Abstract

The stochastic multi-armed bandit model is a simple abstraction that has proven useful in many different contexts in statistics and machine learning. Whereas the achievable limit in terms of regret minimization is now well known, our aim is to contribute to a better understanding of the performance in terms of identifying the m best arms. We introduce generic notions of complexity for the two dominant frameworks considered in the literature: fixed-budget and fixed-confidence settings. In the fixed-confidence setting, we provide the first known distribution-dependent lower bound on the complexity that involves information-theoretic quantities and holds when $m \geq 1$ under general assumptions. In the specific case of two armed-bandits, we derive refined lower bounds in both the fixed-confidence and fixed-budget settings, along with matching algorithms for Gaussian and Bernoulli bandit models. These results show in particular that the complexity of the fixed-budget setting may be smaller than the complexity of the fixed-confidence setting, contradicting the familiar behavior observed when testing fully specified alternatives. In addition, we also provide improved sequential stopping rules that have guaranteed error probabilities and shorter average running times. The proofs rely on two technical results that are of independent interest : a deviation lemma for self-normalized sums (Lemma 7) and a novel change of measure inequality for bandit models (Lemma 1).

Keywords: multi-armed bandit, best-arm identification, pure exploration, information-theoretic divergences, sequential testing

1. Introduction

We investigate in this paper the complexity of finding the m best arms in a stochastic multi-armed bandit model. A bandit model ν is a collection of K arms, where each arm ν_a $(1 \leq a \leq K)$ is a probability distribution on $\mathbb{R}$ with expectation μ_a. At each time $t = 1, 2, \ldots$, an agent chooses an option $A_t \in \{1, \ldots, K\}$ and receives an independent draw Z_t from the corresponding arm ν_{A_t}. We denote by $\mathbb{P}_\nu$ (resp. $\mathbb{E}_\nu$) the probability law (resp. expectation) of the process (Z_t). The agent's goal is to identify the m best arms, that is, the set $\mathcal{S}_m^*$ of indices of the m arms with highest expectation. Letting $(\mu_{[1]}, \ldots, \mu_{[K]})$ be the K-tuple of expectations $(\mu_1, \ldots, \mu_K)$ sorted in decreasing order, we assume that the bandit model ν belongs to a class $\mathcal{M}_m$ such that for every $\nu \in \mathcal{M}_m$, $\mu_{[m]} > \mu_{[m+1]}$, so that $\mathcal{S}_m^*$ is unambiguously defined.

In order to identify $\mathcal{S}_m^*$, the agent must use a strategy defining which arms to sample from, when to stop sampling, and which set $\hat{S}_m$ to choose. More precisely, its strategy consists in a triple $\mathcal{A} = ((A_t), \tau, \hat{S}_m)$ in which :

- the *sampling rule* determines, based on past observations, which arm A_t is chosen at time t; in other words, A_t is $\mathcal{F}_{t-1}$-measurable, with $\mathcal{F}_t = \sigma(A_1, Z_1, \ldots, A_t, Z_t)$;
- the *stopping rule* τ controls the end of the data acquisition phase and is a stopping time with respect to $(\mathcal{F}_t)_{t\in\mathbb{N}}$ satisfying $\mathbb{P}(\tau < +\infty) = 1$;
- the *recommendation rule* provides the arm selection and is a $\mathcal{F}_\tau$-measurable random subset $\hat{S}_m$ of $\{1, \ldots, K\}$ of size m.

In the bandit literature, two different settings have been considered. In the *fixed-confidence setting*, a risk parameter δ is fixed, and a strategy $\mathcal{A}(\delta)$ is called *δ-PAC* if, for every choice of $\nu \in \mathcal{M}_m$, $\mathbb{P}_\nu(\hat{S}_m = \mathcal{S}_m^*) \geq 1 - \delta$. The goal is to obtain δ-PAC strategies that require a number of draws τ_δ that is as small as possible. More precisely, we focus on strategies minimizing the expected number of draws $\mathbb{E}_\nu[\tau_\delta]$, which is also called the *sample complexity*. The subscript δ in τ_δ will be omitted when there is no ambiguity. We call a family of strategies $A = (\mathcal{A}(\delta))_{\delta\in(0,1)}$ *PAC* if for every δ, $\mathcal{A}(\delta)$ is δ-PAC.

Alternatively, in the *fixed-budget setting*, the number of draws τ is fixed in advance to some value $t \in \mathbb{N}$ and for this budget t, the goal is to choose the sampling and recommendation rules of a strategy $\mathcal{A}(t)$ so as to minimize the failure probability $p_t(\nu) := \mathbb{P}_\nu(\hat{S}_m \neq S_m^*)$. In the fixed-budget setting, a family of strategies A$=(\mathcal{A}(t))_{t\in\mathbb{N}^*}$ is called *consistent* if, for every choice of $\nu \in \mathcal{M}_m$, $p_t(\nu)$ tends to zero when t increases to infinity.

In order to unify and compare these approaches, we define the *complexity* $\kappa_C(\nu)$ (resp. $\kappa_B(\nu)$) of best-arm identification in the fixed-confidence (resp. fixed-budget) setting as follows:

$$\kappa_{\mathrm{C}}(\nu) = \inf_{A \text{ PAC}} \limsup_{\delta\to 0} \frac{\mathbb{E}_\nu[\tau_\delta]}{\log \frac{1}{\delta}}, \qquad \kappa_{\mathrm{B}}(\nu) = \inf_{A \text{ consistent}} \left(\limsup_{t\to\infty} -\frac{1}{t}\log p_t(\nu)\right)^{-1}. \quad (1)$$

Heuristically, on the one hand for a given bandit model ν, and a small value of δ, a fixed-confidence optimal strategy needs an average number of samples of order $\kappa_C(\nu)\log\frac{1}{\delta}$ to identify the m best arms with probability at least $1-\delta$. On the other hand, for large values of t the probability of error of a fixed-budget optimal strategy is of order $\exp(-\kappa_B(\nu)t)$, which means that a budget of approximately $t = \kappa_B(\nu)\log\frac{1}{\delta}$ draws is required to ensure a probability of error of order δ. Most of the existing performance bounds for the fixed confidence and fixed budget settings can indeed be expressed using these complexity measures.

In this paper, we aim at evaluating and comparing these two complexities. To achieve this, two ingredients are needed: a lower bound on the sample complexity of any δ-PAC algorithm (resp. on the failure probability of any consistent algorithm) and a δ-PAC (resp.

consistent) strategy whose sample complexity (resp. failure probability) attains the lower bound (often referred to as a 'matching' strategy). We present below new lower bounds on $\kappa_C(\nu)$ and $\kappa_B(\nu)$ that feature information-theoretic quantities as well as strategies that match these lower bounds in two-armed bandit models.

A particular class of algorithms will be considered in the following: those using a *uniform sampling strategy*, that sample the arms in a round-robin fashion. Whereas it is well known that when $K > 2$ uniform sampling is not desirable, it will prove efficient in some examples of two-armed bandits. This specific setting, relevant in practical applications discussed in Section 3, is studied in greater details along the paper. In this case, an algorithm using uniform sampling can be regarded as a statistical test of the hypothesis $H_0 : (\mu_1 \leq \mu_2)$ against $H_1 : (\mu_1 > \mu_2)$ based on paired samples (X_s, Y_s) of ν_1, ν_2; namely a test based on a fixed number of samples in the fixed-budget setting, and, a *sequential test* in the fixed-confidence setting, in which a (random) stopping rule determines when the experiment is to be terminated.

Classical sequential testing theory provides a first element of comparison between the fixed-budget and fixed-confidence settings, in the simpler case of fully specified alternatives. Consider for instance the case where ν_1 and ν_2 are Gaussian laws with the same known variance σ^2, the means μ_1 and μ_2 being known up to a permutation. Denoting by P the joint distribution of the paired samples (X_s, Y_s), one must choose between the hypotheses $H_0 : P = \mathcal{N}\left(\mu_1, \sigma^2\right) \otimes \mathcal{N}\left(\mu_2, \sigma^2\right)$ and $H_1 : P = \mathcal{N}\left(\mu_2, \sigma^2\right) \otimes \mathcal{N}\left(\mu_1, \sigma^2\right)$. It is known since Wald (1945) that among the sequential tests such that type I and type II error probabilities are both smaller than δ, the Sequential Probability Ratio Test (SPRT) minimizes the expected number of required samples, and is such that $\mathbb{E}_\nu[\tau] \simeq 2\sigma^2/(\mu_1 - \mu_2)^2 \log(1/\delta)$. However, the batch test that minimizes both probabilities of error is the Likelihood Ratio test; it can be shown to require a sample size of order $8\sigma^2/(\mu_1 - \mu_2)^2 \log(1/\delta)$ in order to ensure that both type I and type II error probabilities are smaller than δ. Thus, when the sampling strategy is uniform and the parameters are known, there is a clear gain in using randomized stopping strategies. We will show below that this conclusion is not valid anymore when the values of μ_1 and μ_2 are not assumed to be known. Indeed, for two-armed Gaussian bandit models we show that $\kappa_B(\nu) = \kappa_C(\nu)$ and for two-armed Bernoulli bandit models we show that $\kappa_C(\nu) > \kappa_B(\nu)$.

1.1 Related Works

Bandit models have received a considerable interest since their introduction by Thompson (1933) in the context of medical trials. An important focus was set on a different perspective, in which each observation is considered as a reward: the agent aims at maximizing its cumulative rewards. Equivalently, his goal is to minimize the expected *regret* up to horizon $t \geq 1$ defined as $R_t(\nu) = t\mu_{[1]} - \mathbb{E}_\nu\left[\sum_{s=1}^t Z_s\right]$. Regret minimization, which is paradigmatic of the so-called *exploration versus exploitation dilemma*, was introduced by Robbins (1952) and its complexity is well understood for simple families of parametric bandits. In generic one-parameter models, Lai and Robbins (1985) prove that, with a proper notion of consistency adapted to regret minimization,

$$\inf_{A \text{ consistent}} \liminf_{t\to\infty} \frac{R_t(\nu)}{\log t} \geq \sum_{a:\mu_a<\mu_{[1]}} \frac{(\mu_{[1]} - \mu_a)}{\mathrm{KL}(\nu_a, \nu_{[1]})} ,$$

where $\mathrm{KL}(\nu_i, \nu_j)$ denotes the Kullback-Leibler divergence between distributions ν_i and ν_j. This bound was later generalized by Burnetas and Katehakis (1996) to distributions that depend on several parameters. Since then, non-asymptotic analyses of efficient algorithms matching this bound have been proposed. Optimal algorithms include the KL-UCB algorithm of Cappé et al. (2013)—a variant of UCB1 (Auer et al., 2002) using informational upper bounds, Thompson Sampling (Kaufmann et al., 2012b; Agrawal and Goyal, 2013), the DMED algorithm (Honda and Takemura, 2011) and Bayes-UCB (Kaufmann et al., 2012a). This paper is a contribution towards similarly characterizing the complexity of *pure exploration*, where the goal is to determine the best arms without trying to maximize the cumulative observations.

Bubeck et al. (2011) show that in the fixed-budget setting, when $m = 1$, any sampling strategy designed to minimize regret performs poorly with respect to the *simple regret* $r_t := \mu^* - \mu_{\hat{S}_1}$, which is closely related to the probability $p_t(\nu)$ of recommending the wrong arm. Therefore, good strategies for best-arm identification need to be quite different from regret-minimizing strategies. We will show below that the complexities $\kappa_B(\nu)$ and $\kappa_C(\nu)$ of best-arm identification also involve information terms, but these are different from the Kullback-Leibler divergence featured in Lai and Robbins' lower bound on the regret.

The problem of best-arm identification has been studied since the 1950s under the name 'ranking and identification problems'. The first advances on this topic are summarized in the monograph by Bechhofer et al. (1968) who consider the fixed-confidence setting and strategies based on uniform sampling. In the fixed confidence setting, Paulson (1964) first introduces a sampling strategy based on eliminations for single best arm identification: the arms are successively discarded, the remaining arms being sampled uniformly. This idea was later used for example by Jennison et al. (1982); Maron and Moore (1997) and by Even-Dar et al. (2006) in the context of bounded bandit models, in which each arm ν_a is a probability distribution on $[0, 1]$. m best arms identification with $m > 1$ was considered for example by Heidrich-Meisner and Igel (2009), in the context of reinforcement learning. Kalyanakrishnan et al. (2012) later proposed an algorithm that is no longer based on eliminations, called LUCB (for Lower and Upper Confidence Bounds) and still designed for bounded bandit models. Bounded distributions are in fact particular examples of distributions with subgaussian tails, to which the proposed algorithms can be easily generalized. A relevant quantity introduced in the analysis of algorithms for bounded (or subgaussian) bandit models is the 'complexity term'

$$H(\nu) = \sum_{a\in\{1,2,\dots K\}} \frac{1}{\Delta_a^2} \quad \text{with} \quad \Delta_a = \begin{cases} \mu_a - \mu_{[m+1]} & \text{for } a \in \mathcal{S}_m^*, \\ \mu_{[m]} - \mu_a & \text{for } a \in (\mathcal{S}_m^*)^c. \end{cases} \tag{2}$$

The upper bound on the sample complexity of the LUCB algorithm of Kalyanakrishnan et al. (2012) implies in particular that $\kappa_C(\nu) \leq 292H(\nu)$. Some of the existing works on the fixed-confidence setting do not bound τ in expectation but rather show that $\mathbb{P}_\nu(\hat{\mathcal{S}}_m = \mathcal{S}_m^*, \tau = O\left(H(\nu)\right)) \geq 1 - \delta$. These results are not directly comparable with the complexity $\kappa_C(\nu)$, although no significant gap is to be observed yet.

Recent works have focused on obtaining upper bounds on the number of samples whose dependency in terms of the squared-gaps Δ_a (for subgaussian arms) is optimal when the Δ_a's go to zero, and δ remains fixed. Karnin et al. (2013) and Jamieson et al. (2014) exhibit

δ-PAC algorithms for which there exists a constant C such that, with high probability, the number of samples used satisfies

$$\tau \leq C_0 \sum_{a \neq a^*} \frac{1}{\Delta_a^2} \log\left(\frac{1}{\delta} \log \frac{1}{\Delta_a}\right),$$

and Jamieson et al. (2014) show that the dependency in $\Delta_a^{-2} \log(\log(\Delta_a^{-1}))$ is optimal when Δ_a goes to zero. However, the constant C_0 is large and does not lead to improved upper bounds on the complexity term $\kappa_C(\nu)$.

For $m = 1$, the work of Mannor and Tsitsiklis (2004) provides a lower bound on $\kappa_C(\nu)$ in the case of Bernoulli bandit models, under the following ϵ-relaxation sometimes considered in the literature. For some tolerance parameter $\epsilon \geq 0$ the agent has to ensure that $\hat{S}_m$ is included in the set of (ϵ, m) optimal arms $\mathcal{S}^*_{m,\epsilon} = \{a : \mu_a \geq \mu_{[m]} - \epsilon\}$ with probability at least $1 - \delta$. This relaxation has to be considered, for example, when $\mu_{[m]} = \mu_{[m+1]}$, but has never been considered in the literature for the fixed-budget setting. In this paper, we focus on the case $\epsilon = 0$ that allows for a comparison between the fixed-confidence and fixed-budget settings. Mannor and Tsitsiklis (2004) show that if an algorithm is δ-PAC, then in the bandit model $\nu = (\mathcal{B}(\mu_1), \dots, \mathcal{B}(\mu_K))$ such that $\forall a$, $\mu_a \in [0, \alpha]$ for some $\alpha \in (0, 1)$, there exists two sets $\mathcal{G}_\alpha(\nu) \subset \mathcal{S}_1^*$ and $\mathcal{H}_\alpha(\nu) \subset \{1, \dots, K\} \backslash \mathcal{S}_1^*$ and a positive constant C_α such that

$$\mathbb{E}_\nu[\tau] \geq C_\alpha \left(\sum_{a \in \mathcal{G}_\alpha(\nu)} \frac{1}{\epsilon^2} + \sum_{a \in \mathcal{H}_\alpha(\nu)} \frac{1}{(\mu_{[1]} - \mu_a)^2} \right) \log\left(\frac{1}{8\delta}\right).$$

This bound is non asymptotic (as emphasized by the authors), although not completely explicit. In particular, the subset $\mathcal{G}_\alpha$ and $\mathcal{H}_\alpha$ do not always form a partition of the arms (it can happen that $\mathcal{G}_\alpha \cup \mathcal{H}_\alpha \neq \{1, \dots, K\}$), hence the complexity term does not involve a sum over all the arms. For $m > 1$, the only lower bound available in the literature is the worst-case result of Kalyanakrishnan et al. (2012). It states that for every δ-PAC algorithm *there exists* a bandit model ν such that $\mathbb{E}_\nu[\tau] \geq K/(18375\epsilon^2) \log(m/8\delta)$. This result, however, does not provide a lower bound on the complexity $\kappa_C(\nu)$.

The fixed-budget setting has been studied by Audibert et al. (2010); Bubeck et al. (2011) for single best-arm identification in bounded bandit models. For multiple arm identification ($m > 1$), still in bounded bandit models, Bubeck et al. (2013b) introduce the SAR (for Successive Accepts and Rejects) algorithm. An upper bound on the failure probability of the SAR algorithm yields $\kappa_B(\nu) \leq 8 \log(K) H(\nu)$.

For $m = 1$, Audibert et al. (2010) prove an asymptotic lower bound on the probability of error for Bernoulli bandit models. They state that for every algorithm and every bandit problem ν such that $\forall a$, $\mu_1 \in [\alpha, 1 - \alpha]$, there exists a permutation of the arms ν' such that

$$p_t(\nu') \geq \exp(-t/C_\alpha H_2(\nu'))), \quad \text{with} \quad H_2(\nu) = \max_{i; \mu_{[i]} < \mu_{[1]}} \frac{i}{\left(\mu_{[1]} - \mu_{[i]}\right)^2} \quad \text{and} \quad C_\alpha = \frac{\alpha(1-\alpha)}{5 + o(1)}.$$

Gabillon et al. (2012) propose the UGapE algorithm for m best-arm identification for $m > 1$. By changing only one parameter in some confidence regions, this algorithm can be adapted either to the fixed-budget or to the fixed-confidence setting. However, a careful inspection shows that UGapE cannot be used in the fixed-budget setting without the

knowledge of the complexity term $H(\nu)$. This drawback is shared by other algorithms designed for the fixed-budget setting, like the UCB-E algorithm of Audibert et al. (2010) or the KL-LUCB-E algorithm of Kaufmann and Kalyanakrishnan (2013).

1.2 Content of the Paper

The gap between lower and upper bounds known so far does not permit to identify exactly the complexity terms $\kappa_B(\nu)$ and $\kappa_C(\nu)$ defined in (1). Not only do they involve imprecise multiplicative constants but by analogy with the Lai and Robbins' bound for the expected regret, the quantities $H(\nu), H_2(\nu)$ presented above are only expected to be relevant in the Gaussian case.

The improvements of this paper mainly concern the fixed-confidence setting, which will be considered in the next three Sections. We first propose in Section 2 a distribution-dependent lower bound on $\kappa_C(\nu)$ that holds for $m > 1$ and for general classes of bandit models (Theorem 4). This information-theoretic lower bound permits to interpret the quantity $H(\nu)$ defined in (2) as a subgaussian approximation.

Theorem 6 in Section 3 proposes a tighter lower bound on $\kappa_C(\nu)$ for general classes of two-armed bandit models, as well as a lower bound on the sample complexity of δ-PAC algorithms using uniform sampling. In Section 4 we propose, for Gaussian bandits with known—but possibly different—variances, an algorithm exactly matching this bound. We also consider the case of Bernoulli distributed arms, for which we show that uniform sampling is nearly optimal in most cases. We propose a new algorithm using uniform sampling and a non-trivial stopping strategy that is close to matching the lower bound.

Section 5 gathers our contributions to the fixed-budget setting. For two-armed bandits, Theorem 12 provides a lower bound on $\kappa_B(\nu)$ that is in general different from the lower bound obtained for $\kappa_C(\nu)$ in the fixed-confidence setting. Then we propose matching algorithms for the fixed-budget setting that allow for a comparison between the two settings. For Gaussian bandits, we show that $\kappa_C(\nu) = \kappa_B(\nu)$, whereas for Bernoulli bandits $\kappa_C(\nu) > \kappa_B(\nu)$, proving that the two complexities are not necessarily equal. As a first step towards a lower bound on $\kappa_B(\nu)$ when $m > 1$, we also give in Section 5 new lower bounds on the probability of error $p_t(\nu)$ of any consistent algorithm, for Gaussian bandit models.

Section 6 contains numerical experiments that illustrate the performance of matching algorithms for Gaussian and Bernoulli two-armed bandits, comparing the fixed-confidence and fixed-budget settings.

Our contributions follow from two main mathematical results of more general interest. Lemma 1 provides a general relation between the expected number of draws and Kullback-Leibler divergences of the arms' distributions, which is the key element to derive the lower bounds (it also permits, for example, to derive Lai and Robbin's lower bound on the regret in a few lines). Lemma 7 is a tight deviation inequality for martingales with sub-Gaussian increments, in the spirit of the Law of Iterated Logarithm, that permits here to derive efficient matching algorithms for two-armed bandits.

2. Generic Lower Bound in the Fixed-Confidence Setting

Introducing the Kullback-Leibler divergence of any two probability distributions p and q:

$$\mathrm{KL}(p,q) = \begin{cases} \int \log\left[\frac{dp}{dq}(x)\right] dp(x) \text{ if } q \ll p, \\ +\infty \text{ otherwise,} \end{cases}$$

we make the assumption that there exists a set $\mathcal{P}$ of probability measures such that for all $\nu = (\nu_1, \dots, \nu_K) \in \mathcal{M}_m$, for $a \in \{1, \dots, K\}, \nu_a \in \mathcal{P}$ and that $\mathcal{P}$ satisfies

$$\forall p, q \in \mathcal{P},\ p \neq q \ \Rightarrow\ 0 < \mathrm{KL}(p,q) < +\infty.$$

A class $\mathcal{M}_m$ of bandit models satisfying this property is called *identifiable*.

All the distribution-dependent lower bounds derived in the bandit literature (e.g., Lai and Robbins, 1985; Mannor and Tsitsiklis, 2004; Audibert et al., 2010) rely on *changes of distribution*, and so do ours. A change of distribution relates the probabilities of the same event under two different bandit models ν and ν'. The following lemma provides a new, synthetic, inequality from which lower bounds are directly derived. This result, proved in Appendix A, encapsulates the technical aspects of the change of distribution. The main ingredient in its proof is a lower bound on the *expected log-likelihood ratio* of the observations under two different bandit models which is of interest on its own and is stated as Lemma 19 in Appendix A. To illustrate the interest of Lemma 1 even beyond the pure exploration framework, we give in Appendix B a new, simple proof of Burnetas and Katehakis (1996)'s generalization of Lai and Robbins' lower bound in the regret minimization framework based on Lemma 1.

Let $N_a(t) = \sum_{s=1}^{t} \mathbb{1}_{\{A_s = a\}}$ be the number of draws of arm a between the instants 1 and t and $N_a = N_a(\tau)$ be the total number of draws of arm a by some algorithm $\mathcal{A} = ((A_t), \tau, \hat{S}_m)$.

Lemma 1 *Let ν and ν' be two bandit models with K arms such that for all a, the distributions ν_a and ν'_a are mutually absolutely continuous. For any almost-surely finite stopping time σ with respect to $(\mathcal{F}_t)$,*

$$\sum_{a=1}^{K} \mathbb{E}_\nu[N_a(\sigma)]\mathrm{KL}(\nu_a, \nu'_a) \geq \sup_{\mathcal{E} \in \mathcal{F}_\sigma} d(\mathbb{P}_\nu(\mathcal{E}), \mathbb{P}_{\nu'}(\mathcal{E})),$$

where $d(x,y) := x\log(x/y) + (1-x)\log((1-x)/(1-y))$ is the binary relative entropy, with the convention that $d(0,0) = d(1,1) = 0$.

Remark 2 *This result can be considered as a generalization of Pinsker's inequality to bandit models: in combination with the inequality $d(p,q) \geq 2(p-q)^2$, it yields:*

$$\sup_{\mathcal{E} \in \mathcal{F}_\sigma} |\mathbb{P}_\nu(\mathcal{E}) - \mathbb{P}_{\nu'}(\mathcal{E})| \leq \sqrt{\frac{\sum_{a=1}^{K} \mathbb{E}_\nu[N_a(\sigma)]\mathrm{KL}(\nu_a, \nu'_a)}{2}}\ .$$

However, it is important in this paper not to use this weaker form *of the statement, as we will consider events $\mathcal{E}$ of probability very close to 0 or 1. In this regime, we will make use of the following inequality:*

$$\forall\ x \in [0,1], \qquad d(x, 1-x) \geq \log\frac{1}{2.4x}\ , \tag{3}$$

which can be checked easily.

2.1 Lower Bound on the Sample Complexity of a δ-PAC Algorithm

We now propose a non-asymptotic lower bound on the expected number of samples needed to identify the m best arms in the fixed confidence setting, which straightforwardly yields a lower bound on $\kappa_C(\nu)$.

Theorem 4 holds for an identifiable class of bandit models of the form:

$$\mathcal{M}_m = \{\nu = (\nu_1, \dots, \nu_K) : \nu_i \in \mathcal{P}, \mu_{[m]} > \mu_{[m+1]}\} \tag{4}$$

such that the set of probability measures $\mathcal{P}$ satisfies Assumption 3 below.

Assumption 3 *For all $p, q \in \mathcal{P}^2$ such that $p \neq q$, for all $\alpha > 0$,*
there exists $q_1 \in \mathcal{P}$: $\mathrm{KL}(p,q) < \mathrm{KL}(p,q_1) < \mathrm{KL}(p,q) + \alpha$ and $\mathbb{E}_{X\sim q_1}[X] > \mathbb{E}_{X\sim q}[X]$,
there exists $q_2 \in \mathcal{P}$: $\mathrm{KL}(p,q) < \mathrm{KL}(p,q_2) < \mathrm{KL}(p,q) + \alpha$ and $\mathbb{E}_{X\sim q_2}[X] < \mathbb{E}_{X\sim q}[X]$.

These continuity conditions are reminiscent of the assumptions of Lai and Robbins (1985); they include families of parametric bandits continuously parameterized by their means (e.g., Bernoulli, Poisson, exponential distributions).

Theorem 4 *Let $\nu \in \mathcal{M}_m$, where $\mathcal{M}_m$ is defined by (4), and assume that $\mathcal{P}$ satisfies Assumption 3; any algorithm that is δ-PAC on $\mathcal{M}_m$ satisfies, for $\delta \leq 0.15$,*

$$\mathbb{E}_\nu[\tau] \geq \left[\sum_{a \in \mathcal{S}_m^*} \frac{1}{\mathrm{KL}(\nu_a, \nu_{[m+1]})} + \sum_{a \notin \mathcal{S}_m^*} \frac{1}{\mathrm{KL}(\nu_a, \nu_{[m]})}\right] \log\left(\frac{1}{2.4\delta}\right).$$

Proof. Without loss of generality, one may assume that the arms are ordered such that $\mu_1 \geq \cdots \geq \mu_K$. Thus $\mathcal{S}_m^* = \{1, ..., m\}$. Let $\mathcal{A} = ((A_t), \tau, \hat{S}_m)$ be a δ-PAC algorithm and fix $\alpha > 0$. For all $a \in \{1, \dots, K\}$, from Assumption 3 there exists an alternative model

$$\nu' = (\nu_1, \dots, \nu_{a-1}, \nu'_a, \nu_{a+1}, \dots, \nu_K)$$

in which the only arm modified is arm a, and ν'_a is such that:

- $\mathrm{KL}(\nu_a, \nu_{m+1}) < \mathrm{KL}(\nu_a, \nu'_a) < \mathrm{KL}(\nu_a, \nu_{m+1}) + \alpha$ and $\mu'_a < \mu_{m+1}$ if $a \in \{1, \dots, m\}$,
- $\mathrm{KL}(\nu_a, \nu_m) < \mathrm{KL}(\nu_a, \nu'_a) < \mathrm{KL}(\nu_a, \nu_m) + \alpha$ and $\mu'_a > \mu_m$ if $a \in \{m+1, \dots, K\}$.

In particular, on the bandit model ν' the set of optimal arms is no longer $\{1, \dots, m\}$. Thus, introducing the event $\mathcal{E} = (\hat{\mathcal{S}}_m = \{1, \dots, m\}) \in \mathcal{F}_\tau$, any δ-PAC algorithm satisfies $\mathbb{P}_\nu(\mathcal{E}) \geq 1 - \delta$ and $\mathbb{P}_{\nu'}(\mathcal{E}) \leq \delta$. Lemma 1 applied to the stopping time τ (such that $N_a(\tau) = N_a$ is the total number of draws of arm a) and the monotonicity properties of $d(x,y)$ ($x \mapsto d(x,y)$ is increasing when $x > y$ and decreasing when $x < y$) yield

$$\mathrm{KL}(\nu_a, \nu'_a)\mathbb{E}_\nu[N_a] \geq d(1-\delta, \delta) \geq \log(1/2.4\delta),$$

where the last inequality follows from (3). From the definition of the alternative model, one obtains for $a \in \{1, \dots, m\}$ or $b \in \{m+1, \dots, K\}$ respectively, for every $\alpha > 0$,

$$\mathbb{E}_\nu[N_a] \geq \frac{\log(1/2.4\delta)}{\mathrm{KL}(\nu_a, \nu_{m+1}) + \alpha} \quad \text{and} \quad \mathbb{E}_\nu[N_b] \geq \frac{\log(1/2.4\delta)}{\mathrm{KL}(\nu_b, \nu_m) + \alpha}.$$

Letting α tend to zero and summing over the arms yields the bound on $\mathbb{E}_\nu[\tau] = \sum_{a=1}^{K} \mathbb{E}_\nu[N_a]$.

Remark 5 *This inequality can be made tighter for values of δ that are sufficiently close to zero, for which the right-hand-side can then be made arbitrarily close to* $\log(1/\delta)$.

Lemma 1 can also be used to improve the result of Mannor and Tsitsiklis (2004) that holds for $m = 1$ under the ϵ-relaxation described before. Combining the changes of distribution of this paper with Lemma 1 yields, for every $\epsilon > 0$ and $\delta \leq 0.15$,

$$\mathbb{E}_\nu[\tau] \geq \left(\frac{|\{a : \mu_a \geq \mu_{[1]} - \epsilon\}| - 1}{\mathrm{KL}\left(\mathcal{B}(\mu_{[1]}), \mathcal{B}(\mu_{[1]} - \epsilon)\right)} + \sum_{a:\mu_a \leq \mu_{[1]} - \epsilon} \frac{1}{\mathrm{KL}\left(\mathcal{B}(\mu_a), \mathcal{B}(\mu_{[1]} + \epsilon)\right)} \right) \log \frac{1}{2.4\delta},$$

where $|\mathcal{X}|$ denotes the cardinal of the set $\mathcal{X}$ and $\mathcal{B}(\mu)$ the Bernoulli distribution of mean μ.

2.2 Bounds on the Complexity for Exponential Bandit Models

Theorem 4 yields the following lower bound on the complexity term:

$$\kappa_C(\nu) \geq \sum_{a \in \mathcal{S}_m^*} \frac{1}{\mathrm{KL}(\nu_a, \nu_{[m+1]})} + \sum_{a \notin \mathcal{S}_m^*} \frac{1}{\mathrm{KL}(\nu_a, \nu_{[m]})}.$$

Thus, one may want to obtain strategies whose sample complexity can be proved to be of the same magnitude. The only algorithm that has been analyzed so far with an information-theoretic perspective is the KL-LUCB algorithm of Kaufmann and Kalyanakrishnan (2013), designed for *exponential bandit models*: that is

$$\mathcal{M}_m = \left\{ \nu = (\nu_{\theta_1}, \dots, \nu_{\theta_K}) : (\theta_1, \dots, \theta_K) \in \Theta^K, \theta_{[m]} > \theta_{[m+1]} \right\},$$

where ν_θ belongs to a *canonical one-parameter exponential family*. This means that there exists a twice differentiable strictly convex function b such that ν_θ has a density with respect to some reference measure given by

$$f_\theta(x) = \exp(\theta x - b(\theta)), \quad \text{for } \theta \in \Theta \subset \mathbb{R}. \tag{5}$$

Distributions from a canonical one-parameter exponential family can be parameterized either by their natural parameter θ or by their mean. Indeed $\dot{b}(\theta) = \mu(\theta)$, the mean of the distribution ν_θ and $\ddot{b}(\theta) = \mathrm{Var}[\nu_\theta] > 0$. The mapping $\theta \mapsto \mu(\theta)$ is strictly increasing, and the means are ordered in the same way as the natural parameters. Exponential families include in particular Bernoulli distributions, or Gaussian distributions with common variances (see Cappé et al. (2013) for more details about exponential families).

We introduce the following shorthand to denote the Kullback-Leibler divergence in exponential families: $\mathrm{K}(\theta, \theta') = \mathrm{KL}(\nu_\theta, \nu_{\theta'})$ for $(\theta, \theta') \in \Theta^2$. Combining the upper bound on the sample complexity of the KL-LUCB algorithm obtained by Kaufmann and Kalyanakrishnan (2013) and the lower bound of Theorem 4, the complexity $\kappa_C(\nu)$ can be bounded as

$$\sum_{a \in \mathcal{S}_m^*} \frac{1}{\mathrm{K}(\theta_a, \theta_{[m+1]})} + \sum_{a \notin \mathcal{S}_m^*} \frac{1}{\mathrm{K}(\theta_a, \theta_{[m]})} \leq \kappa_C(\nu) \leq 24 \min_{\theta \in [\theta_{[m+1]}, \theta_{[m]}]} \sum_{a=1}^K \frac{1}{\mathrm{K}^*(\theta_a, \theta)}, \tag{6}$$

where $\mathrm{K}^*(\theta, \theta')$ is the Chernoff information between the distributions ν_θ and $\nu_{\theta'}$ (see Cover and Thomas (2006) and Kaufmann and Kalyanakrishnan (2013) for earlier notice of the

relevance of this quantity in the best-arm selection problem). Chernoff information is defined as follows and illustrated in Figure 1:

$$\mathrm{K}^*(\theta, \theta') = \mathrm{K}(\theta^*, \theta), \text{ where } \theta^* \text{ is such that } \mathrm{K}(\theta^*, \theta) = \mathrm{K}(\theta^*, \theta').$$

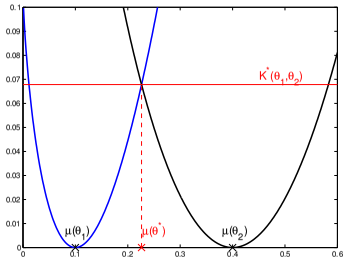

Figure 1: For Bernoulli distributions, the blue and black curves represent respectively $\mathrm{KL}(\mathcal{B}(\mu), \mathcal{B}(\mu_1))$ and $\mathrm{KL}(\mathcal{B}(\mu), \mathcal{B}(\mu_2))$ as a function of μ. Their intersection gives the value of the Chernoff information between $\mathcal{B}(\mu_1)$ and $\mathcal{B}(\mu_2)$, two distributions alternatively parameterized by their natural parameter θ_1 and θ_2.

3. Improved Lower Bounds for Two-Armed Bandits

Two armed-bandits are of particular interest as they offer a theoretical framework for sequential A/B Testing. A/B Testing is a popular procedure used, for instance, for website optimization: two versions of a web page, say A and B, are empirically compared by being presented to users. Each user is shown only one version $A_t \in \{1, 2\}$ and provides a real-valued index of the quality of the page, Z_t, which is modeled as a sample of a probability distribution ν_1 or ν_2. For example, a standard objective is to determine which web page has the highest conversion rate (probability that a user actually becomes a customer) by receiving binary feedback from the users. In standard A/B Testing algorithms, the two versions are presented equally often. It is thus of particular interest to investigate whether uniform sampling is optimal or not.

Even for two-armed bandits, the upper and lower bounds on the complexity $\kappa_C(\nu)$ given in (6) do not match. We propose in this section a refined lower bound on $\kappa_C(\nu)$ based on a different change of distribution. This lower bound features a quantity reminiscent of Chernoff information, and we will exhibit algorithms matching (or approximately matching) this new bound in Section 4. Theorem 6 provides a non-asymptotic lower bound on the sample complexity $\mathbb{E}_\nu[\tau]$ of any δ-PAC algorithm. It also provides a lower bound on the performance of algorithms using a uniform sampling strategy, which will turn out to be efficient in some cases.

Theorem 6 *Let $\mathcal{M}$ be an identifiable class of two-armed bandit models and let $\nu = (\nu_1, \nu_2) \in \mathcal{M}$ be such that $\mu_1 > \mu_2$. Any algorithm that is δ-PAC on $\mathcal{M}$ satisfies, for all $\delta \in]0,1]$,*

$$\mathbb{E}_\nu[\tau] \geq \frac{1}{c_*(\nu)} \log\left(\frac{1}{2.4\delta}\right), \quad \textit{where} \quad c_*(\nu) := \inf_{(\nu_1',\nu_2') \in \mathcal{M}: \mu_1' < \mu_2'} \max\left\{\mathrm{KL}(\nu_1,\nu_1'), \mathrm{KL}(\nu_2,\nu_2')\right\}.$$

Moreover, any δ-PAC algorithm using a uniform sampling strategy satisfies,

$$\mathbb{E}_\nu[\tau] \geq \frac{1}{I_*(\nu)} \log\left(\frac{1}{2.4\delta}\right), \ \textit{where} \ I_*(\nu) := \inf_{(\nu_1',\nu_2') \in \mathcal{M}: \mu_1' < \mu_2'} \frac{\mathrm{KL}\left(\nu_1,\nu_1'\right) + \mathrm{KL}\left(\nu_2,\nu_2'\right)}{2}. \tag{7}$$

Obviously, one has $I_*(\nu) \leq c_*(\nu)$. Theorem 6 implies in particular that $\kappa_C(\nu) \geq 1/c_*(\nu)$. It is possible to give explicit expressions for the quantities $c_*(\nu)$ and $I_*(\nu)$ for important classes of parametric bandit models that will be considered in the next section.

The class of Gaussian bandits with known variances σ_1^2 and σ_2^2, further considered in Section 4.1, is

$$\mathcal{M} = \{\nu = \left(\mathcal{N}\left(\mu_1,\sigma_1^2\right), \mathcal{N}\left(\mu_2,\sigma_2^2\right)\right) : (\mu_1,\mu_2) \in \mathbb{R}^2, \mu_1 \neq \mu_2\}. \tag{8}$$

For this class,

$$\mathrm{KL}(\mathcal{N}\left(\mu_1,\sigma_1\right), \mathcal{N}\left(\mu_2,\sigma_2\right)) = \frac{(\mu_1-\mu_2)^2}{2\sigma_2^2} + \frac{1}{2}\left[\frac{\sigma_1^2}{\sigma_2^2} - 1 - \log\frac{\sigma_1^2}{\sigma_2^2}\right] \tag{9}$$

and direct computations yield

$$c_*(\nu) = \frac{(\mu_1-\mu_2)^2}{2(\sigma_1+\sigma_2)^2} \quad \text{and} \quad I_*(\nu) = \frac{(\mu_1-\mu_2)^2}{4(\sigma_1^2+\sigma_2^2)}.$$

The observation that, when the variances are different $c_*(\nu) > I_*(\nu)$, will be shown to imply that strategies based on uniform sampling are sub-optimal (by a factor $1 \leq 2(\sigma_1^2+\sigma_2^2)/(\sigma_1+\sigma_2)^2 \leq 2$).

The more general class of two-armed exponential bandit models, further considered in Section 4.2, is

$$\mathcal{M} = \{\nu = (\nu_{\theta_1}, \nu_{\theta_2}) : (\theta_1,\theta_2) \in \Theta^2, \theta_1 \neq \theta_2\}$$

where ν_{θ_a} has density f_{θ_a} given by (5). There

$$c_*(\nu) = \inf_{\theta \in \Theta} \max\left(\mathrm{K}(\theta_1,\theta), \mathrm{K}(\theta_2,\theta)\right) = \mathrm{K}_*(\theta_1,\theta_2),$$

where $\mathrm{K}_*(\theta_1,\theta_2) = \mathrm{K}(\theta_1,\theta_*)$, with θ_* is defined by $\mathrm{K}(\theta_1,\theta_*) = \mathrm{K}(\theta_2,\theta_*)$. This quantity is analogous to the Chernoff information $\mathrm{K}^*(\theta_1,\theta_2)$ introduced in Section 2 but with 'reversed' roles for the arguments. $I_*(\nu)$ may also be expressed more explicitly as

$$I_*(\nu) = \frac{\mathrm{K}\left(\theta_1,\overline{\theta}\right) + \mathrm{K}\left(\theta_2,\overline{\theta}\right)}{2}, \quad \text{where} \quad \mu(\overline{\theta}) = \frac{\mu_1+\mu_2}{2}.$$

Appendix C provides further useful properties of these quantities and in particular Figure 7 illustrates the property that for two-armed exponential bandit models, the lower bound on $\kappa_C(\nu)$ provided by Theorem 6,

$$\kappa_C(\nu) \geq \left(\frac{1}{\mathrm{K}_*(\theta_1,\theta_2)}\right), \tag{10}$$

is indeed always tighter than the lower bound of Theorem 4,

$$\kappa_C(\nu) \geq \left(\frac{1}{\mathrm{K}(\theta_1,\theta_2)} + \frac{1}{\mathrm{K}(\theta_2,\theta_1)}\right). \tag{11}$$

Interestingly, the changes of distribution used to derive the two results are not the same. On the one hand, for inequality (11), the changes of distribution involved modify a single arm at a time: one of the arms is moved just below (or just above) the other (see Figure 2, left). This is the idea also used, for example, to obtain the lower bound of Lai and Robbins (1985) on the cumulative regret. On the other hand, for inequality (10), both arms are modified at the same time: they are moved close to the common intermediate value θ_* but with a reversed ordering (see Figure 2, right).

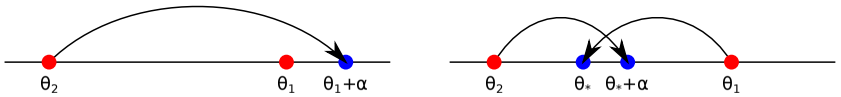

Figure 2: Alternative bandit models considered to obtain the lower bounds of Theorem 4 (left) and Theorem 6 (right).

We now give the proof of Theorem 6, in order to show how easily it follows from Lemma 1.

Proof of Theorem 6. Without loss of generality, one may assume that the bandit model $\nu = (\nu_1,\nu_2)$ is such that the best arm is $a^* = 1$. Consider any alternative bandit model $\nu' = (\nu_1',\nu_2')$ in which $a^* = 2$. Let $\mathcal{E}$ be the event $\mathcal{E} = (\hat{S}_1 = 1)$, which belongs to $\mathcal{F}_\tau$.

Let $\mathcal{A} = ((A_t),\tau,\hat{S}_1)$ be a δ-PAC algorithm: by assumptions, $\mathbb{P}_\nu(\mathcal{E}) \geq 1-\delta$ and $\mathbb{P}_{\nu'}(\mathcal{E}) \leq \delta$. Applying Lemma 1 (with the stopping time τ) and using again the monotonicity properties of $d(x,y)$ and inequality (3)

$$\mathbb{E}_\nu[N_1]\mathrm{KL}(\nu_1,\nu_1') + \mathbb{E}_\nu[N_2]\mathrm{KL}(\nu_2,\nu_2') \geq \log(1/(2.4\delta)). \tag{12}$$

Using moreover that $\tau = N_1 + N_2$, one has

$$\mathbb{E}_\nu[\tau] \geq \frac{\log\left(\frac{1}{2.4\delta}\right)}{\max_{a=1,2}\mathrm{KL}(\nu_a,\nu_a')}. \tag{13}$$

The result follows by optimizing over the possible model ν' satisfying $\mu_1' < \mu_2'$ to make the right hand side of the inequality as large as possible. More precisely, for every $\alpha > 0$, from the definition of $c_*(\nu)$, there exists $\nu_\alpha' = (\nu_1',\nu_2')$ for which

$$\max_{a=1,2}\mathrm{KL}(\nu_a,\nu_a') < c_*(\nu) + \alpha.$$

Inequality (13) for the particular choice $\nu' = \nu_\alpha'$ yields $\mathbb{E}_\nu[\tau] \geq (c_*(\nu)+\alpha)^{-1}\log(1/(2.4\delta))$, and the first statement of Theorem 6 follows by letting α go to zero. In the particular case of exponential bandit models, the alternative model consists in choosing $\nu_1' = \nu_{\theta_*}$ and $\nu_2' = \nu_{\theta_*+\epsilon}$ for some ϵ, as illustrated on Figure 2, so that $\max_{a=1,2}\mathrm{KL}(\nu_a,\nu_a')$ is of order $\mathrm{K}_*(\theta_1,\theta_2)$.

When $\mathcal{A}$ uses uniform sampling, using the fact that $\mathbb{E}_\nu[N_1] = \mathbb{E}[N_2] = \mathbb{E}[\tau]/2$ in Equation (12) similarly gives the second statement of Theorem 6.

4. Matching Algorithms for Two-Armed Bandits

For specific instances of two-armed bandit models, we now present algorithms with performance guarantees that closely match the lower bounds of Theorem 6. For Gaussian bandits with known (and possibly different) variances, we describe in Section 4.1 an algorithm termed α-Elimination that is optimal and thus makes it possible to determine the complexity $\kappa_C(\nu)$. For Bernoulli bandit models, we present in Section 4.2 the SGLRT algorithm that uses uniform sampling and is close to optimal.

4.1 Gaussian Bandit Models

We focus here on the class of two-armed Gaussian bandit models with known variances presented in (8), where σ_1 and σ_2 are fixed. We prove that

$$\kappa_C(\nu) = \frac{2(\sigma_1+\sigma_2)^2}{(\mu_1-\mu_2)^2}$$

by exhibiting a strategy that reaches the performance bound of Theorem 6. This strategy uses non-uniform sampling in case where σ_1 and σ_2 differ. When $\sigma_1 = \sigma_2$, we provide in Theorem 8 an improved stopping rule that is δ-PAC and results in a significant reduction of the expected number of samples used.

The α-Elimination algorithm introduced in this Section can also be used in more general two-armed bandit models, where the distribution ν_a is σ_a^2-subgaussian. This means that the probability distribution ν_a satisfies

$$\forall \lambda \in \mathbb{R}, \quad \mathbb{E}_{X\sim\nu_a}\left[e^{\lambda X}\right] \leq \frac{\lambda^2\sigma_a^2}{2}.$$

This covers in particular the cases of bounded distributions with support in $[0,1]$ (that are 1/4-subgaussian). In these more general cases, the algorithm enjoys the same theoretical properties: it is δ-PAC and its sample complexity is bounded as in Theorem 9 below.

4.1.1 Equal Variances

We start with the simpler case $\sigma_1 = \sigma_2 = \sigma$. Thus, the quantity $I_*(\nu)$ introduced in Theorem 6 coincides with $c_*(\nu)$, which suggests that uniform sampling could be optimal. A uniform sampling strategy equivalently collects paired samples (X_s, Y_s) from both arms. The difference $X_s - Y_s$ is normally distributed with mean $\mu = \mu_1 - \mu_2$ and a δ-PAC algorithm is equivalent to a sequential test of $H_0 : (\mu < 0)$ versus $H_1 : (\mu > 0)$ such that both type I and type II error probabilities are bounded by δ. Robbins (1970) proposes the stopping rule

$$\tau = \inf\left\{ t \in 2\mathbb{N}^* : \Big|\sum_{s=1}^{t/2}(X_s - Y_s)\Big| > \sqrt{2\sigma^2 t\beta(t,\delta)} \right\}, \text{with } \beta(t,\delta) = \frac{t+1}{t}\log\left(\frac{t+1}{2\delta}\right). \quad (14)$$

The recommendation rule chooses the empirically best arm at time τ. This procedure can be seen as an *elimination strategy*, in the sense of Jennison et al. (1982). The authors of this paper derive a lower bound on the sample complexity of any δ-PAC *elimination* strategy

(whereas our lower bound applies to *any* δ-PAC algorithm) which is matched by Robbins' algorithm: the above stopping rule τ satisfies

$$\lim_{\delta\to 0}\frac{\mathbb{E}_\nu[\tau]}{\log(1/\delta)} = \frac{8\sigma^2}{(\mu_1-\mu_2)^2}.$$

This value coincide with the lower bound on $\kappa_C(\nu)$ of Theorem 6 in the case of two-armed Gaussian distributions with similar known variance σ^2. This proves that in this case, Robbins' rule (14) is not only optimal among the class of elimination strategies, but also among the class of δ-PAC algorithm.

Any δ-PAC elimination strategy that uses a threshold function (or *exploration rate*) $\beta(t,\delta)$ smaller than Robbins' also matches our asymptotic lower bound, while stopping earlier than the latter. From a practical point of view, it is therefore interesting to exhibit smaller exploration rates that preserve the δ-PAC property. The failure probability of such an algorithm is upper bounded, for example when $\mu_1 < \mu_2$, by

$$\mathbb{P}_\nu\left(\exists k\in\mathbb{N} : \sum_{s=1}^{k}\frac{X_s - Y_s - (\mu_1-\mu_2)}{\sqrt{2\sigma^2}} > \sqrt{2k\beta(2k,\delta)}\right) = \mathbb{P}\left(\exists k\in\mathbb{N} : S_k > \sqrt{2k\beta(2k,\delta)}\right) \quad (15)$$

where S_k is a sum of k i.i.d. variables of distribution $\mathcal{N}(0,1)$. Robbins (1970) obtains a non-explicit confidence region of risk at most δ by choosing $\beta(2k,\delta) = \log(\log(k)/\delta) + o(\log\log(k))$. The dependency in k is in some sense optimal, because the Law of Iterated Logarithm (LIL) states that $\limsup_{k\to\infty} S_k/\sqrt{2k\log\log(k)} = 1$ almost surely. In this paper, we propose a new deviation inequality for a martingale with sub-Gaussian increments, stated as Lemma 7, that permits to build an explicit confidence region reminiscent of the LIL. A related result was recently derived independently by Jamieson et al. (2014).

Lemma 7 *Let $\zeta(u) = \sum_{k\geq 1} k^{-u}$. Let $X_1, X_2, \ldots$ be independent random variables such that, for all $\lambda \in \mathbb{R}$, $\phi(\lambda) := \log\mathbb{E}[\exp(\lambda X_1)] \leq \lambda^2\sigma^2/2$. For every positive integer t let $S_t = X_1 + \cdots + X_t$. Then, for all $\eta > 1$ and $x \geq \frac{8}{(e-1)^2}$,*

$$\mathbb{P}\left(\exists t\in\mathbb{N}^* : S_t > \sqrt{2\sigma^2 t(x+\eta\log\log(et))}\right) \leq \sqrt{e}\,\zeta\left(\eta\left(1-\frac{1}{2x}\right)\right)\left(\frac{\sqrt{x}}{2\sqrt{2}}+1\right)^\eta \exp(-x).$$

Lemma 7 allows to prove Theorem 8 below, as detailed in Appendix E, where we also provide a proof of Lemma 7.

Theorem 8 *For $\delta \leq 0.1$, with*

$$\beta(t,\delta) = \log(1/\delta) + 3\log\log(1/\delta) + (3/2)\log(\log(et/2)), \quad (16)$$

the elimination strategy is δ-PAC.

We refer to Section 6 for numerical simulations that illustrate the significant savings (in the average number of samples needed to reach a decision) resulting from the use of the less conservative exploration rate allowed by Theorem 8.

4.1.2 Mismatched Variances

In the case where $\sigma_1 \neq \sigma_2$, we rely on the α-Elimination strategy, described in Algorithm 1 below. For $a = 1, 2$, $\hat{\mu}_a(t)$ denotes the empirical mean of the samples gathered from arm a up to time t. The algorithm is based on a non-uniform sampling strategy governed by the parameter $\alpha \in (0, 1)$, that maintains the proportion of draws of arm 1 close to α. At the end of every round t, $N_1(t) = \lceil \alpha t \rceil$, $N_2(t) = t - \lceil \alpha t \rceil$ and $\hat{\mu}_1(t) - \hat{\mu}_2(t) \sim \mathcal{N}\left(\mu_1 - \mu_2, \sigma_t^2(\alpha)\right)$ (where $\sigma_t^2(\alpha)$ is defined at line 6 of Algorithm 1). The sampling schedule used here is thus deterministic.

Algorithm 1 α-Elimination

Require: Exploration function $\beta(t, \delta)$, parameter α.

1: *Initialization*: $\hat{\mu}_1(0) = \hat{\mu}_2(0) = 0$, $\sigma_0^2(\alpha) = 1$, $t = 0$
2: **while** $|\hat{\mu}_1(t) - \hat{\mu}_2(t)| \leq \sqrt{2\sigma_t^2(\alpha)\beta(t, \delta)}$ **do**
3: $t \leftarrow t + 1$.
4: If $\lceil \alpha t \rceil = \lceil \alpha(t-1) \rceil$, $A_t \leftarrow 2$, else $A_t \leftarrow 1$
5: Observe $Z_t \sim \nu_{A_t}$ and compute the empirical means $\hat{\mu}_1(t)$ and $\hat{\mu}_2(t)$
6: Compute $\sigma_t^2(\alpha) = \sigma_1^2/\lceil \alpha t \rceil + \sigma_2^2/(t - \lceil \alpha t \rceil)$
7: **end while**
8: **return** $\underset{a=1,2}{\operatorname{argmax}}\ \hat{\mu}_a(t)$

Theorem 9 shows that an optimal allocation of samples between the two arms consists in maintaining the proportion of draws of arm 1 close to $\sigma_1/(\sigma_1+\sigma_2)$ (which is also the case in the fixed-budget setting, see Section 5.1). Indeed, for $\alpha = \sigma_1/(\sigma_1+\sigma_2)$, the α-elimination algorithm is δ-PAC with a suitable exploration rate and (almost) matches the lower bound on $\mathbb{E}_\nu[\tau]$, at least asymptotically when $\delta \to 0$. Its proof can be found in Appendix D.

Theorem 9 *If $\alpha = \sigma_1/(\sigma_1 + \sigma_2)$, the α-elimination strategy using the exploration rate $\beta(t, \delta) = \log \frac{t}{\delta} + 2 \log\log(6t)$ is δ-PAC on $\mathcal{M}$ and satisfies, for every $\nu \in \mathcal{M}$, for every $\epsilon > 0$,*

$$\mathbb{E}_\nu[\tau] \leq (1+\epsilon)\frac{2(\sigma_1+\sigma_2)^2}{(\mu_1-\mu_2)^2}\log\left(\frac{1}{\delta}\right) + \underset{\delta\to 0}{o_\epsilon}\left(\log\left(\frac{1}{\delta}\right)\right).$$

Remark 10 *When $\sigma_1 = \sigma_2$, 1/2-elimination reduces, up to rounding effects, to the elimination procedure described in Section 4.1.1, for which Theorem 8 suggests an exploration rate of order $\log(\log(t)/\delta)$. As the feasibility of this exploration rate when $\sigma_1 \neq \sigma_2$ is yet to be established, we focus on Gaussian bandits with equal variances in the numerical experiments of Section 6.*

4.2 Bernoulli Bandit Models

We consider in this section the class of Bernoulli bandit models

$$\mathcal{M} = \{\nu = (\mathcal{B}(\mu_1), \mathcal{B}(\mu_2)) : (\mu_1, \mu_2) \in (0; 1)^2, \mu_1 \neq \mu_2\},$$

where each arm can be alternatively parameterized by the natural parameter of the exponential family, $\theta_a = \log(\mu_a/(1-\mu_a))$. Observing that in this particular case little can

be gained by departing from uniform sampling, we consider the SGLRT algorithm (to be defined below) that uses uniform sampling together with a stopping rule that is not based on the mere difference of the empirical means.

For Bernoulli bandit models, the quantities $I_*(\nu)$ and $c_*(\nu)$ introduced in Theorem 6 happen to be practically very close (see Figure 3 in Section 5 below). There is thus a strong incentive to use uniform sampling and in the rest of this section we consider algorithms that aim at matching the bound (7) of Theorem 6—that is, $\mathbb{E}_\nu[\tau] \leq \log(1/\delta)/I_*(\nu)$, at least for small values of δ—, which provides an upper bound on $\kappa_C(\nu)$ that is very close to $1/c_*(\nu)$. For simplicity, as $I_*(\nu)$ is here a function of the means of the arms only, we will denote $I_*(\nu)$ by $I_*(\mu_1, \mu_2)$.

When the arms are sampled uniformly, finding an algorithm that matches the bound of (7) boils down to determining a proper stopping rule. In all the algorithms studied so far, the stopping rule was based on the difference of the empirical means of the arms. For Bernoulli arms the 1/2-Elimination procedure described in Algorithm 1 can be used, as each distribution ν_a is bounded and therefore 1/4-subgaussian. More precisely, with $\beta(t, \delta)$ as in Theorem 8, the algorithm stopping at the first time t such that

$$\hat{\mu}_1(t) - \hat{\mu}_2(t) > \sqrt{2\beta(t,\delta)/t}$$

has its sample complexity bounded by $2/(\mu_1 - \mu_2)^2 \log(1/\delta) + o(\log(1/\delta))$. Yet, Pinsker's inequality implies that $I_*(\mu_1, \mu_2) > (\mu_1 - \mu_2)^2/2$ and this algorithm is thus not optimal with respect to the bound (7) of Theorem 6. The approximation $I_*(\mu_1, \mu_2) = (\mu_1 - \mu_2)^2/(8\mu_1(1-\mu_1)) + o\left((\mu_1 - \mu_2)^2\right)$ suggests that the loss with respect to the optimal error exponent is particularly significant when both means are close to 0 or 1.

To circumvent this drawback, we propose the SGLRT (for Sequential Generalized Likelihood Ratio Test) stopping rule, described in Algorithm 2. The appearance of I_* in the stopping criterion of Algorithm 2 is a consequence of the observation that it is related to the generalized likelihood ratio statistic for testing the equality of two Bernoulli proportions. To test $H_0 : (\mu_1 = \mu_2)$ against $H_1 : (\mu_1 \neq \mu_2)$ based on $t/2$ paired samples of the arms $W_s = (X_s, Y_s)$, the Generalized Likelihood Ratio Test (GLRT) rejects H_0 when

$$\frac{\max_{\mu_1,\mu_2:\mu_1=\mu_2} L(W_1, \ldots, W_{t/2}; \mu_1, \mu_2)}{\max_{\mu_1,\mu_2} L(W_1, \ldots, W_{t/2}; \mu_1, \mu_2)} < z_\delta,$$

where $L(W_1, \ldots, W_{t/2}; \mu_1, \mu_2)$ denotes the likelihood of the observations given parameters μ_1 and μ_2. It can be checked that the ratio that appears in the last display is equal to

Algorithm 2 Sequential Generalized Likelihood Ratio Test (SGLRT)

Require: Exploration function $\beta(t, \delta)$.

1: *Initialization*: $\hat{\mu}_1(0) = \hat{\mu}_2(0) = 0$. $t = 0$.
2: **while** $(tI_*(\hat{\mu}_1(t), \hat{\mu}_2(t)) \leq \beta(t, \delta)) \bigcup (t = 1\ (mod.\ 2))$ **do**
3: $t = t + 1$. $A_t = t\ (mod.\ 2)$.
4: Observe $Z_t \sim \nu_{A_t}$ and compute the empirical means $\hat{\mu}_1(t)$ and $\hat{\mu}_2(t)$.
5: **end while**
6: **return** $a = \underset{a=1,2}{\operatorname{argmax}}\ \hat{\mu}_a(t)$.

$\exp(-tI_*(\hat{\mu}_{1,t/2}, \hat{\mu}_{2,t/2}))$. This equality is a consequence of the rewriting

$$I_*(x,y) \quad = \quad H\left(\frac{x+y}{2}\right) - \frac{1}{2}\left[H(x) + H(y)\right],$$

where $H(x) = -x\log(x) - (1-x)\log(1-x)$ denotes the binary entropy function. Hence, Algorithm (2) can be interpreted as a sequential version of the GLRT with (varying) threshold $z_{t,\delta} = \exp(-\beta(t,\delta))$.

Elements of analysis of the SGLRT. The SGLRT algorithm is also related to the KL-LUCB algorithm of Kaufmann and Kalyanakrishnan (2013). A closer examination of the KL-LUCB stopping criterion reveals that, in the specific case of two-armed bandits, it is equivalent to stopping when $t\mathrm{KL}_*(\mathcal{B}(\hat{\mu}_1(t)), \mathcal{B}(\hat{\mu}_2(t)))$ gets larger than some threshold. We also mentioned the fact that $\mathrm{KL}_*(\mathcal{B}(x), \mathcal{B}(y))$ and $I_*(x,y)$ are very close (see Figure 3). Using results from Kaufmann and Kalyanakrishnan (2013), one can thus prove (see Appendix F) the following lemma.

Lemma 11 *With the exploration rate*

$$\beta(t,\delta) = 2\log\left(\frac{t(\log(3t))^2}{\delta}\right)$$

the SGLRT algorithm is δ-PAC.

For this exploration rate, we were able to obtain the following asymptotic guarantee on the stopping time τ of Algorithm 2:

$$\forall \epsilon > 0, \quad \limsup_{\delta \to 0} \frac{\tau}{\log(1/\delta)} \leq \frac{2(1+\epsilon)}{I_*(\mu_1,\mu_2)} \quad a.s.$$

(see Lemma 26 in Appendix F for the proof of this result). By analogy with the result of Theorem 8 we conjecture that the analysis of Kaufmann and Kalyanakrishnan (2013)—on which the result of Lemma 11 is based—is too conservative and that the use of an exploration rate of order $\log(\log(t)/\delta)$ should also lead to a δ-PAC algorithm. This conjecture is supported by the numerical experiments reported in Section 6 below. Besides, for this choice of exploration rate, Lemma 26 also shows that

$$\forall \epsilon > 0, \quad \limsup_{\delta \to 0} \frac{\tau}{\log(1/\delta)} \leq \frac{(1+\epsilon)}{I_*(\mu_1,\mu_2)} \quad a.s..$$

5. The Fixed-Budget Setting

In this section, we focus on the fixed-budget setting and we provide new upper and lower bounds on the complexity term $\kappa_B(\nu)$.

For two-armed bandits, we obtain in Theorem 12 lower bounds analogous to those of Theorem 6 in the fixed-confidence setting. We present matching algorithms for Gaussian and Bernoulli bandits. This allows for a comparison between the fixed-budget and fixed-confidence setting in these specific cases. More specifically, we show that $\kappa_B(\nu) = \kappa_C(\nu)$ for Gaussian bandit models, whereas $\kappa_C(\nu) > \kappa_B(\nu)$ for Bernoulli bandit models.

When $K > 2$ and $m \geq 1$, we present a first step towards obtaining more general results, by providing lower bounds on the probability of error $p_t(\nu)$ for Gaussian bandits with equal variances.

5.1 Comparison of the Complexities for Two-Armed Bandits

We present here an asymptotic lower bound on $p_t(\nu)$ that directly yields a lower bound on $\kappa_B(\nu)$. Moreover, we provide a lower bound on the failure probability of consistent algorithms using uniform sampling. The proof of Theorem 12 bears similarities with that of Theorem 6, and we provide it in Appendix G.1. However, it is important to note that the informational quantities $c^*(\nu)$ and $I^*(\nu)$ defined in Theorem 12 are in general different from the quantities $c_*(\nu)$ and $I_*(\nu)$ previously defined for the fixed-confidence setting (see Theorem 6). Appendix C contains a few additional elements of comparison between these quantities in the case of one-parameter exponential families of distributions.

Theorem 12 *Let $\nu = (\nu_1, \nu_2)$ be a two-armed bandit model such that $\mu_1 > \mu_2$. In the fixed-budget setting, any consistent algorithm satisfies*

$$\limsup_{t\to\infty} -\frac{1}{t}\log p_t(\nu) \leq c^*(\nu), \quad \textit{where} \quad c^*(\nu) := \inf_{(\nu_1',\nu_2')\in\mathcal{M}:\mu_1'<\mu_2'} \max\left\{\mathrm{KL}(\nu_1',\nu_1), \mathrm{KL}(\nu_2',\nu_2)\right\}.$$

Moreover, any consistent algorithm using a uniform sampling strategy satisfies

$$\limsup_{t\to\infty} -\frac{1}{t}\log p_t(\nu) \leq I^*(\nu), \quad \textit{where} \quad I^*(\nu) := \inf_{(\nu_1',\nu_2')\in\mathcal{M}:\mu_1'<\mu_2'} \frac{\mathrm{KL}(\nu_1',\nu_1) + \mathrm{KL}(\nu_2',\nu_2)}{2}. \tag{17}$$

Gaussian distributions. As the Kullback-Leibler divergence between two Gaussian distributions—(9)—is symmetric with respect to the means when the variances are held fixed, it holds that $c^*(\nu) = c_*(\nu)$. To find a matching algorithm, we introduce the simple family of *static strategies* that draw n_1 samples from arm 1 followed by $n_2 = t - n_1$ samples of arm 2, and then choose arm 1 if $\hat{\mu}_{1,n_1} > \hat{\mu}_{2,n_2}$, where $\hat{\mu}_{i,n_i}$ denotes the empirical mean of the n_i samples from arm i. Assume for instance that $\mu_1 > \mu_2$. Since $\hat{\mu}_{1,n_1} - \hat{\mu}_{2,n_2} - \mu_1 + \mu_2 \sim \mathcal{N}\left(0, \sigma_1^2/n_1 + \sigma_2^2/n_2\right)$, the probability of error of such a strategy is upper bounded by

$$\mathbb{P}\left(\hat{\mu}_{1,n_1} < \hat{\mu}_{2,n_2}\right) \quad \leq \quad \exp\left(-\left(\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}\right)^{-1} \frac{(\mu_1-\mu_2)^2}{2}\right).$$

The right hand side is minimized when $n_1/(n_1+n_2) = \sigma_1/(\sigma_1+\sigma_2)$, and the static strategy drawing $n_1 = \lceil \sigma_1 t/(\sigma_1+\sigma_2)\rceil$ times arm 1 is such that

$$\liminf_{t\to\infty} -\frac{1}{t}\log p_t(\nu) \geq \frac{(\mu_1-\mu_2)^2}{2(\sigma_1+\sigma_2)^2} = c^*(\nu)\,.$$

This shows in particular that for Gaussian distributions the two complexities are equal:

$$\kappa_B(\nu) = \kappa_C(\nu) = \frac{2(\sigma_1+\sigma_2)^2}{(\mu_1-\mu_2)^2}.$$

Exponential families. For exponential family bandit models, it can be observed that

$$c^*(\nu) = \inf_{\theta\in\Theta} \max\left(\mathrm{K}(\theta,\theta_1), \mathrm{K}(\theta,\theta_2)\right) = \mathrm{K}^*(\theta_1,\theta_2),$$

where $\mathrm{K}^*(\theta_1,\theta_2)$ is the Chernoff information between the distributions ν_{θ_1} and ν_{θ_2}. We recall that $\mathrm{K}^*(\theta_1,\theta_2) = \mathrm{K}(\theta^*,\theta_1)$, where θ^* is defined by $\mathrm{K}(\theta^*,\theta_1) = \mathrm{K}(\theta^*,\theta_2)$. Moreover, one has

$$I^*(\nu) = \frac{\mathrm{K}\left(\frac{\theta_1+\theta_2}{2},\theta_1\right) + \mathrm{K}\left(\frac{\theta_1+\theta_2}{2},\theta_2\right)}{2}.$$

In particular, the quantity $c^*(\nu) = \mathrm{K}^*(\theta_1,\theta_2)$ does not always coincide with the quantity $c_*(\nu) = \mathrm{K}_*(\theta_1,\theta_2)$ defined in Theorem 6. More precisely, $c_*(\nu)$ and $c^*(\nu)$ are equal when the log-partition function $b(\theta)$ is (Fenchel) self-conjugate, which is the case for Gaussian and exponential variables (see Appendix C). However, for Bernoulli distributions, it can be checked that $c^*(\nu) > c_*(\nu)$. By exhibiting a matching strategy in the fixed-budget setting (Theorem 13), we show that this implies that $\kappa_C(\nu) > \kappa_B(\nu)$ in the Bernoulli case (Theorem 14). We also show that in this case, only little can be gained by departing from uniform sampling.

Theorem 13 *Consider a two-armed exponential bandit model and $\alpha(\theta_1,\theta_2)$ be defined by*

$$\alpha(\theta_1,\theta_2) = \frac{\theta^*-\theta_1}{\theta_2-\theta_1} \quad \textit{where} \quad \mathrm{K}(\theta^*,\theta_1) = \mathrm{K}(\theta^*,\theta_2).$$

For all t, the static strategy that allocates $\lceil \alpha(\theta_1,\theta_2)t \rceil$ samples to arm 1, and recommends the empirical best arm, satisfies $p_t(\nu) \leq \exp(-tK^*(\theta_1,\theta_2))$.

Theorem 13, whose proof can be found in Appendix G.2, shows in particular that for every exponential family bandit model there exists a consistent static strategy such that

$$\liminf_{t\to\infty} -\frac{1}{t}\log p_t \geq \mathrm{K}^*(\theta_1,\theta_2), \quad \text{and hence that} \quad \kappa_B(\nu) = \frac{1}{\mathrm{K}^*(\theta_1,\theta_2)}.$$

By combining this observation with Theorem 6 and the fact that, $\mathrm{K}_*(\theta_1,\theta_2) < \mathrm{K}^*(\theta_1,\theta_2)$ for Bernoulli distributions, one obtains the following inequality.

Theorem 14 *For two-armed Bernoulli bandit models, $\kappa_C(\nu) > \kappa_B(\nu)$.*

Note that we have determined the complexity of the fixed-budget setting by exhibiting an algorithm (leading to an upper bound on κ_B) that is of limited practical interest for Bernoulli bandit models. Indeed, the optimal static strategy defined in Theorem 13 requires the knowledge of the quantity $\alpha(\theta_1,\theta_2)$, that depends on the unknown means of the arms. So far, it is not known whether there exists a *universal* strategy, that would satisfy $p_t(\nu) \leq \exp(-\mathrm{K}^*(\theta_1,\theta_2)t)$ on *every* Bernoulli bandit model.

However, Lemma 27 shows that the strategy that uses uniform sampling and recommends the empirical best-arm satisfies $p_t(\nu) \leq \exp(-I^*(\nu)t)$, and matches the bound (17) of Theorem 12 (see Remark 28 in Appendix G.2). The fact that, just as in the fixed-confidence setting $I^*(\nu)$ is very close to $c^*(\nu)$ shows that the problem-dependent optimal strategy described above can be approximated by a very simple, universal algorithm that samples the arms uniformly. Figure 3 represents the different informational functions c_*, I_*, c^* and I^* when the mean μ_1 varies, for two fixed values of μ_2. It can be observed that $c^*(\nu)$ and $c_*(\nu)$ are almost indistinguishable from $I^*(\nu)$ and $I_*(\nu)$, respectively, while there is a gap between $c^*(\nu)$ and $c_*(\nu)$.

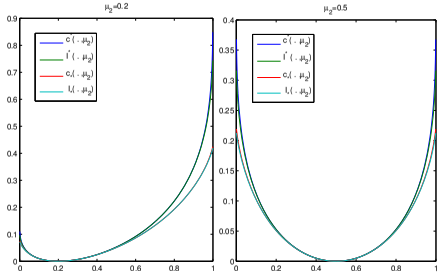

Figure 3: Comparison of different informational quantities for Bernoulli bandit models.

5.2 Lower Bound on $p_t(\nu)$ in More General Cases

Theorem 12 provides a direct counterpart to Theorem 6, allowing for a complete comparison between the fixed confidence and fixed budget settings in the case of two-armed bandits. However, we were not able to obtain a general lower bound for K-armed bandit that would be directly comparable to that of Theorem 4 in the fixed budget setting. Using Lemma 15 stated below (a variant of Lemma 1 proved in Appendix A.2), we were nonetheless able to derive tighter, non-asymptotic, lower bounds on $p_t(\nu)$ in the particular case of Gaussian bandit models with equal known variance, $\mathcal{M}_m = \{\nu = (\nu_1,\dots,\nu_K) : \nu_a = \mathcal{N}\left(\mu_a,\sigma^2\right), \mu_a \in \mathbb{R}, \mu_{[m]} \neq \mu_{[m+1]}\}$.

Lemma 15 *Let ν and ν' be two bandit models such that $\mathcal{S}^*_m(\nu) \neq \mathcal{S}^*_m(\nu')$. Then*

$$\max\left(\mathbb{P}_\nu(\mathcal{S} \neq \mathcal{S}^*_m(\nu)), \mathbb{P}_{\nu'}(\mathcal{S} \neq \mathcal{S}^*_m(\nu'))\right) \geq \frac{1}{4}\exp\left(-\sum_{a=1}^K \mathbb{E}_\nu[N_a]\mathrm{KL}(\nu_a,\nu'_a)\right).$$

Theorem 16 *Let ν be a Gaussian bandit model such that $\mu_1 > \mu_2 \geq \cdots \geq \mu_K$ and let*

$$H'(\nu) = \sum_{a=2}^K \frac{2\sigma^2}{(\mu_1-\mu_a)^2}.$$

There exists a bandit model $\nu^{[a]}$, $a \in \{2,\dots,K\}$, (see Figure 4) which satisfies $H'(\nu^{[a]}) \leq H'(\nu)$ and is such that

$$\max\left(p_t(\nu), p_t(\nu^{[a]})\right) \geq \exp\left(-\frac{4t}{H'(\nu)}\right).$$

This result is to be compared to the lower bound of Audibert et al. (2010). While Theorem 16 does not really provide a lower bound on $\kappa_B(\nu)$, the complexity term $H(\nu)$ is close to the quantity that appears in Theorem 4 for the fixed-confidence setting (in the Gaussian case), which improves over the term $H_2(\nu) = \max_{i:\mu_{[i]}<\mu_{[1]}} i(\mu_{[1]}-\mu_{[i]})^{-2}$ featured in Theorem 4 of Audibert et al. (2010).

For $m > 1$, building on the same ideas, Theorem 17 provides a first lower bound, which we believe leaves room for improvement.

Theorem 17 *Let ν be such that $\mu_1 > \dots \mu_m > \mu_{m+1} > \dots > \mu_K$ and let*

$$H^+(\nu) = \sum_{a=1}^{m} \frac{2\sigma^2}{(\mu_a - \mu_{m+1})^2}, \quad H^-(\nu) = \sum_{a=m+1}^{K} \frac{2\sigma^2}{(\mu_m - \mu_a)^2}, \quad \text{and} \quad H(\nu) = H^+(\nu) + H^-(\nu).$$

There exists $a \in \{1, \dots, m\}$ and $b \in \{m+1, \dots K\}$ such that the bandit model $\nu^{[a,b]}$ described on Figure 4 satisfies $H(\nu^{[a,b]}) < H(\nu)$ and is such that

$$\max\left(p_t(\nu), p_t(\nu^{[a,b]})\right) \geq \frac{1}{4}\exp\left(-\frac{4t}{\tilde{H}(\nu)}\right), \quad \text{where} \quad \tilde{H}(\nu) = \frac{H(\nu)\min(H^+(\nu), H^-(\nu))}{H(\nu) + \min(H^+(\nu), H^-(\nu))}.$$

The proofs of Theorem 16 and Theorem 17 are very similar. For this reason, we provide in Appendix G.3 only the latter. Introducing the gaps Δ_a defined in (2), the precise definition of the modified problems $\nu^{[a]}$ and $\nu^{[a,b]}$ in the statement of the two results is:

$$\nu^{[a]}: \left\{ \begin{array}{rcl} \mu'_k &=& \mu_k \text{ for all } k \neq a \\ \mu'_a &=& \mu_a + 2\Delta_a \end{array} \right. \quad \text{and} \quad \nu^{[a,b]}: \left\{ \begin{array}{rcl} \mu'_k &=& \mu_k \text{ for all } k \notin \{a,b\} \\ \mu'_a &=& \mu_a - 2\Delta_b \\ \mu'_b &=& \mu_b + 2\Delta_a \end{array} \right. .$$

6. Numerical Experiments

In this section, we focus on two-armed models and provide experimental experiments designed to compare the fixed-budget and fixed-confidence settings (in the Gaussian and Bernoulli cases) and to illustrate the improvement resulting from the adoption of the reduced exploration rate of Theorem 8.

In Figure 5, we consider two Gaussian bandit models with known common variance: the 'easy' one is $\{\mathcal{N}(0.5, 0.25), \mathcal{N}(0, 0.25)\}$, corresponding to $\kappa_C = \kappa_B = \kappa = 8$, on the left; and the 'difficult' one is $\{\mathcal{N}(0.01, 0.25), \mathcal{N}(0, 0.25)\}$, that is $\kappa = 2\times 10^4$, on the right. In the fixed-budget setting, stars ('*') report the probability of error $p_n(\nu)$ as a function of n. In the fixed-confidence setting, we plot both the empirical probability of error by circles ('O') and the specified maximal error probability δ by crosses ('X') as a function of the empirical average of the running times. Note the logarithmic scale used for the probabilities on the y-axis. All results are averaged over $N = 10^6$ independent Monte Carlo replications. For comparison purposes, a plain line represents the theoretical rate $t \mapsto \exp(-t(1/\kappa))$ which is a straight line on the log scale.

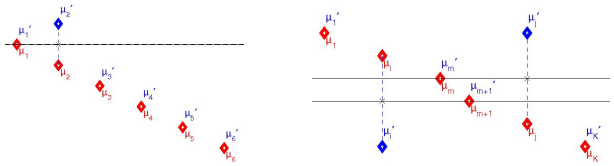

Figure 4: Left: bandit models ν, in red, and $\nu^{[2]}$, in blue (Theorem 16). Right: bandit models ν, in red, and $\nu^{[i,j]}$, in blue (Theorem 17).

In the fixed-confidence setting, we report results for elimination algorithms of the form (14) for three different exploration rates $\beta(t,\delta)$. The exploration rate we consider are: the provably-PAC rate of Robbins' algorithm $\log(t/\delta)$ (large blue symbols), the conjectured optimal exploration rate $\log((\log(t)+1)/\delta)$, almost provably δ-PAC according to Theorem 8 (bold green symbols), and the rate $\log(1/\delta)$, which would be appropriate if we were to perform the stopping test only at a single pre-specified time (orange symbols). For each algorithm, the log probability of error is approximately a linear function of the number of samples, with a slope close to $-1/\kappa$, where κ is the complexity. A first observation is that the 'traditional' rate of $\log(t/\delta)$ is much too conservative, with running times for the difficult problem (right plot) which are about three times longer than those of other methods for comparable error rates. As expected, the rate $\log((\log(t)+1)/\delta)$ significantly reduces the running times while maintaining proper control of the probability of failure, with empirical error rates ('O' symbols) below the corresponding confidence parameters δ (represented by 'X' symbols). Conversely, the use of the non-sequential testing threshold $\log(1/\delta)$ seems too risky, as one can observe that the empirical probability of error may be larger than δ on difficult problems. To illustrate the gain in sample complexity resulting from the knowledge of the means, we also represented in red the performance of the SPRT algorithm mentioned in the introduction of Section 5 along with the theoretical relation between the probability of error and the expected number of samples, materialized as a dashed line. The SPRT stops for t such that $|(\mu_1 - \mu_2)(S_{1,t/2} - S_{2,t/2})| > \log(1/\delta)$.

Robbins' algorithm is δ-PAC and matches the complexity (which is illustrated by the slope of the measures), though in practice the use of the exploration rate $\log((\log(t)+1)/\delta)$ leads to huge gain in terms of number of samples used. It is important to keep in mind that running times play the same role as error exponents and hence the threefold increase of average running times observed on the rightmost plot of Figure 5 when using $\beta(t,\delta) = \log(t/\delta)$ is really prohibitive.

On Figure 6, we compare on two Bernoulli bandit models the performance of the SGLRT algorithm described in Section 4.2 (Algorithm 2) using two different exploration rates, $\log(1/\delta)$ and $\log((\log(t)+1)/\delta)$, to the 1/2-elimination stopping rule (Algorithm 1) that stops when the difference of empirical means exceeds the threshold $\sqrt{2\beta(t,\delta)/t}$ (for the

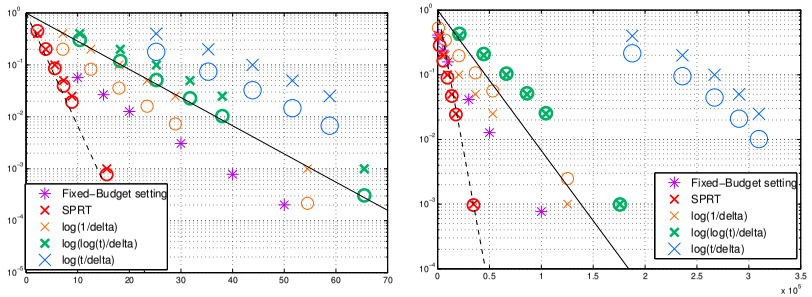

Figure 5: Experimental results for Gaussian bandit models

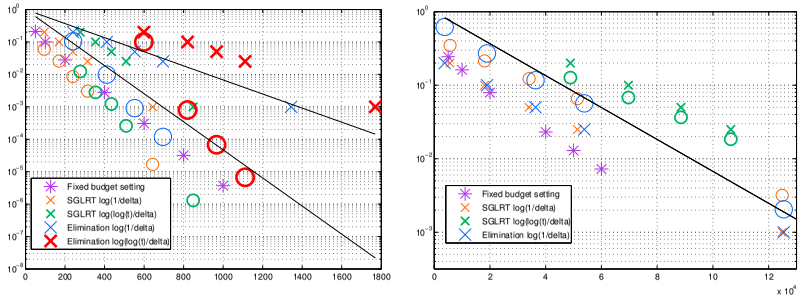

Figure 6: Results for Bernoulli bandit models: $0.2 - 0.1$ (left) and $0.51 - 0.5$ (right).

same exploration rates). Plain lines also materialize the theoretical optimal rate $t \mapsto \exp(-t/\kappa_C(\nu))$ and the rate attained by the 1/2-Elimination algorithm $t \mapsto \exp(-t/\kappa')$, where $\kappa' = 2/(\mu_1 - \mu_2)^2$. On the bandit model $0.51 - 0.5$ (right) these two rates are very close and SGLRT mostly coincides with Elimination, but on the bandit model $0.2 - 0.1$ (left) the practical gain of the use of a more sophisticated stopping strategy is well illustrated. Besides, our experiments show that SGLRT using $\log((\log(t)+1)/\delta)$ is δ-PAC on both the (relatively) easy and difficult problems we consider, unlike the other algorithms considered.

If one compares the results for the fixed-budget setting (in purple) to those for the best δ-PAC algorithm (or conjectured δ-PAC for SGLRT in the Bernoulli case), in green, one can observe that to obtain the same probability of error, the fixed-confidence algorithm usually needs an average number of samples that is about twice larger than the deterministic number of samples required by the fixed-budget setting algorithm. This remark should be related to the fact that a δ-PAC algorithm is designed to be uniformly good across all problems, whereas consistency is a weak requirement in the fixed-budget setting: any strategy that draws both arm infinitely often and recommends the empirical best is consistent. Figure 5 also shows that when the values of μ_1 and μ_2 are unknown, the sequential version of the test is no more preferable to its batch counterpart and can even become much worse if the exploration rate $\beta(t,\delta)$ is chosen too conservatively. This observation should be mitigated by the fact that the sequential (or fixed-confidence) approach is adaptive with respect to the difficulty of the problem whereas it is impossible to predict the efficiency of a batch (or fixed-budget) experiment without some prior knowledge regarding the difficulty of the problem under consideration.

7. Conclusion

Our aim with this paper has been to provide a framework for evaluating, in a principled way, the performance of fixed-confidence and fixed-budget algorithms designed to identify the best arm(s) in stochastic environments.

For two-armed bandits, we obtained rather complete results, identifying the complexity of both settings in important parametric families of distributions. In doing so, we observed that standard testing strategies based on uniform sampling are optimal or close to optimal for Gaussian distributions with matched variance or Bernoulli distributions but can be

improved (by non-uniform sampling) for Gaussian distributions with distinct variances. This latter observation can certainly be generalized to other models, starting with the case of Gaussian distributions whose variances are a priori unknown. In the case of Bernoulli distributions, we have also shown that fixed-confidence algorithms that use the difference of the empirical means as a stopping criterion are bound to be sub-optimal. Finally, we have shown, through the comparison of the complexities $\kappa_C(\nu)$ and $\kappa_B(\nu)$, that the behavior observed when testing fully specified alternatives where fixed confidence (or sequential) algorithms may be 'faster on average' than the fixed budget (or batch) ones is not true anymore when the parameters of the models are unknown.

For models with more than two arms, we obtained the first generic (i.e. not based on the sub-Gaussian tail assumption) distribution-dependent lower bound on the complexity of m best-arms identification in the fixed-confidence setting (Theorem 4). Currently available performance bounds for algorithms performing m best-arms identification—those of Kaufmann and Kalyanakrishnan (2013) notably—show a small gap with this result and it is certainly of interest to investigate whether those analyses and/or the bound of Theorem 4 may be improved to bridge the gap. For the fixed-budget setting we made only a small step towards the understanding of the complexity of m best-arms identification and our results can certainly be greatly improved.

Acknowledgments

We thank Sébastien Bubeck for fruitful discussions during the visit of the first author at Princeton University. This work has been supported by the ANR-2010-COSI-002 and ANR-13-BS01-0005 grants of the French National Research Agency.

Appendix A. Changes of Distributions

Let ν and ν' be two bandit models such that for all $a \in \{1, K\}$ the distributions ν_a and ν'_a are mutually absolutely continuous. For each a, there exists a measure λ_a such that ν_a and ν'_a have a density f_a and f'_a respectively with respect to λ_a. One can introduce the log-likelihood ratio of the observations up to time t under an algorithm $\mathcal{A}$:

$$L_t = L_t(A_1, \ldots, A_t, Z_1, \ldots, Z_t) := \sum_{a=1}^{K} \sum_{s=1}^{t} \mathbb{1}_{(A_s=a)} \log\left(\frac{f_a(Z_s)}{f'_a(Z_s)}\right).$$

The key element in a change of distribution is the following classical lemma that relates the probabilities of an event under $\mathbb{P}_\nu$ and $\mathbb{P}_{\nu'}$ through the log-likelihood ratio of the observations. Such a result has often been used in the bandit literature for ν and ν' that differ just from one arm, for which the expression of the log-likelihood ratio is simpler. In this paper, we consider more general changes of distributions, and we therefore provide a full proof of Lemma 18 in Appendix A.3.

Lemma 18 *Let σ be any stopping time with respect to $\mathcal{F}_t$. For every event $\mathcal{E} \in \mathcal{F}_\sigma$ (i.e., $\mathcal{E}$ such that $\mathcal{E} \cap (\sigma = t) \in \mathcal{F}_t$),*

$$\mathbb{P}_{\nu'}(\mathcal{E}) = \mathbb{E}_\nu[\mathbb{1}_\mathcal{E} \exp(-L_\sigma)]$$

A.1 Proof of Lemma 1

To prove Lemma 1, we state a first inequality on the expected log-likelihood ratio in Lemma 19, which is of independent interest.

Lemma 19 *Let σ be any almost surely finite stopping time with respect to $\mathcal{F}_t$. For every event $\mathcal{E} \in \mathcal{F}_\sigma$,*

$$\mathbb{E}_\nu[L_\sigma] \geq d(\mathbb{P}_\nu(\mathcal{E}), \mathbb{P}_{\nu'}(\mathcal{E})).$$

Lemma 1 easily follows: introducing $(Y_{a,s})$, the sequence of i.i.d. samples successively observed from arm a, the log-likelihood ratio L_t can be rewritten

$$L_t = \sum_{a=1}^{K} \sum_{s=1}^{N_a(t)} \log\left(\frac{f_a(Y_{a,s})}{f'_a(Y_{a,s})}\right); \quad \text{and} \quad \mathbb{E}_\nu\left[\log\left(\frac{f_a(Y_{a,s})}{f'_a(Y_{a,s})}\right)\right] = \mathrm{KL}(\nu_a, \nu'_a).$$

Wald's Lemma (see e.g., Siegmund (1985)) applied to $L_\sigma = \sum_{a=1}^{K} \sum_{s=1}^{N_a(\sigma)} \log\left(\frac{f_a(Y_{a,s})}{f'_a(Y_{a,s})}\right)$ yields

$$\mathbb{E}_\nu[L_\sigma] = \sum_{a=1}^{K} \mathbb{E}_\nu[N_a(\sigma)]\mathrm{KL}(\nu_a, \nu'_a). \tag{18}$$

Combining this equality with the inequality in Lemma 19 completes the proof.

Proof of Lemma 19. Let σ be a stopping time with respect to $(\mathcal{F}_t)$.

We start by showing that for all $\mathcal{E} \in \mathcal{F}_\sigma$, $\mathbb{P}_\nu(\mathcal{E}) = 0 \Leftrightarrow \mathbb{P}_{\nu'}(\mathcal{E}) = 0$. This proves Lemma 19 for events $\mathcal{E}$ such that $\mathbb{P}_\nu(\mathcal{E}) = 0$ or 1, for which the quantity $d(\mathbb{P}_\nu(\mathcal{E}), \mathbb{P}_{\nu'}(\mathcal{E})) = d(0,0)$ or $d(1,1)$ is equal to zero by convention, and the inequality thus holds since the left-hand side is non-negative (which is clear from the rewriting (18)). Let $\mathcal{E} \in \mathcal{F}_\sigma$. Lemma 18 yields $\mathbb{P}_{\nu'}(\mathcal{E}) = \mathbb{E}_\nu[\mathbb{1}_\mathcal{E} \exp(-L_\sigma)]$. Thus $\mathbb{P}_{\nu'}(\mathcal{E}) = 0$ implies $\mathbb{1}_\mathcal{E} \exp(-L_\sigma) = 0$ $\mathbb{P}_\nu - a.s.$ As $\mathbb{P}_\nu(\sigma < +\infty) = 1$, $\mathbb{P}_\nu(\exp(L_\sigma) > 0) = 1$ and $\mathbb{P}_{\nu'}(\mathcal{E}) = 0 \Rightarrow \mathbb{P}_\nu(\mathcal{E}) = 0$. A similar reasoning yields $\mathbb{P}_\nu(\mathcal{E}) = 0 \Rightarrow \mathbb{P}_{\nu'}(\mathcal{E}) = 0$.

Let $\mathcal{E} \in \mathcal{F}_\sigma$ be such that $0 < \mathbb{P}_\nu(\mathcal{E}) < 1$ (then $0 < \mathbb{P}_{\nu'}(\mathcal{E}) < 1$). Lemma 18 and the conditional Jensen inequality lead to

$$\begin{aligned}
\mathbb{P}_{\nu'}(\mathcal{E}) &= \mathbb{E}_\nu[\exp(-L_\sigma)\mathbb{1}_\mathcal{E}] = \mathbb{E}_\nu[\mathbb{E}_\nu[\exp(-L_\sigma)|\mathbb{1}_\mathcal{E}]\mathbb{1}_\mathcal{E}] \\
&\geq \mathbb{E}_\nu[\exp\left(-\mathbb{E}_\nu[L_\sigma|\mathbb{1}_\mathcal{E}]\right)\mathbb{1}_\mathcal{E}] = \mathbb{E}_\nu[\exp\left(-\mathbb{E}_\nu[L_\sigma|\mathbb{1}_\mathcal{E}]\mathbb{1}_\mathcal{E}\right)\mathbb{1}_\mathcal{E}] \\
&= \mathbb{E}_\nu[\exp\left(-\mathbb{E}_\nu[L_\sigma|\mathcal{E}]\mathbb{1}_\mathcal{E}\right)\mathbb{1}_\mathcal{E}] = \mathbb{E}_\nu[\exp\left(-\mathbb{E}_\nu[L_\sigma|\mathcal{E}]\right)\mathbb{1}_\mathcal{E}] \\
&= \exp\left(-\mathbb{E}_\nu[L_\sigma|\mathcal{E}]\right)\mathbb{P}_\nu(\mathcal{E}).
\end{aligned}$$

Writing the same for the event $\overline{\mathcal{E}}$ yields $\mathbb{P}_{\nu'}(\overline{\mathcal{E}}) \geq \exp\left(-\mathbb{E}_\nu[L_\sigma|\overline{\mathcal{E}}]\right)\mathbb{P}_\nu(\overline{\mathcal{E}})$, hence

$$\mathbb{E}_\nu[L_\sigma|\mathcal{E}] \geq \log\frac{\mathbb{P}_\nu(\mathcal{E})}{\mathbb{P}_{\nu'}(\mathcal{E})} \quad \text{and} \quad \mathbb{E}_\nu[L_\sigma|\overline{\mathcal{E}}] \geq \log\frac{\mathbb{P}_\nu(\overline{\mathcal{E}})}{\mathbb{P}_{\nu'}(\overline{\mathcal{E}})}. \tag{19}$$

Therefore one can write

$$\begin{aligned}
\mathbb{E}_\nu[L_\sigma] &= \mathbb{E}_\nu[L_\sigma|\mathcal{E}]\mathbb{P}_\nu(\mathcal{E}) + \mathbb{E}_\nu[L_\sigma|\overline{\mathcal{E}}]\mathbb{P}_\nu(\overline{\mathcal{E}}) \\
&\geq \mathbb{P}_\nu(\mathcal{E})\log\frac{\mathbb{P}_\nu(\mathcal{E})}{\mathbb{P}_{\nu'}(\mathcal{E})} + \mathbb{P}_\nu(\overline{\mathcal{E}})\log\frac{\mathbb{P}_\nu(\overline{\mathcal{E}})}{\mathbb{P}_{\nu'}(\overline{\mathcal{E}})} = d(\mathbb{P}_\nu(\mathcal{E}), \mathbb{P}_{\nu'}(\mathcal{E})),
\end{aligned}$$

which concludes the proof.

A.2 Proof of Lemma 15

The proof bears strong similarities with that of Lemma 1, but an extra ingredient is needed: Lemma 4 of Bubeck et al. (2013a), that provides a lower bound on the sum of type I and type II probabilities of error in a statistical test.

Lemma 20 *Let ρ_0,ρ_1 be two probability distributions supported on some set $\mathcal{X}$, with ρ_1 absolutely continuous with respect to ρ_0. Then for any measurable function $\phi : \mathcal{X} \to \{0,1\}$, one has*

$$\mathbb{P}_{X\sim\rho_0}(\phi(X) = 1) + \mathbb{P}_{X\sim\rho_1}(\phi(X) = 0) \geq \frac{1}{2}\exp(-\mathrm{KL}(\rho_0, \rho_1)).$$

Let ν and ν' be two bandit models that do not have the same set of optimal arms. We denote by $\mathcal{S}_1, \ldots, \mathcal{S}_M$ the $M = \binom{K}{m}$ subsets of m, ordered so that $\mathcal{S}_1$ (resp. $\mathcal{S}_2$) is the set of m best arms in problem ν (resp. ν'). One has

$$\begin{aligned}
\max\left(\mathbb{P}_\nu(\hat{\mathcal{S}}_m \neq \mathcal{S}_1), \mathbb{P}_{\nu'}(\hat{\mathcal{S}}_m \neq \mathcal{S}_2)\right) &\geq \frac{1}{2}\left(\mathbb{P}_\nu(\hat{\mathcal{S}}_m \neq \mathcal{S}_1) + \mathbb{P}_{\nu'}(\hat{\mathcal{S}}_m \neq \mathcal{S}_2)\right) \\
&\geq \frac{1}{2}\left(\mathbb{P}_\nu(\hat{\mathcal{S}}_m \neq \mathcal{S}_1) + \mathbb{P}_{\nu'}(\hat{\mathcal{S}}_m = \mathcal{S}_1)\right).
\end{aligned}$$

Let $\rho_0 = \mathcal{L}(\hat{\mathcal{S}}_m)$ and $\rho_1 = \mathcal{L}'(\hat{\mathcal{S}}_m)$ be the distribution of $\hat{\mathcal{S}}_m$ for algorithm $\mathcal{A}$ under problems ν and ν' respectively. ρ_1 is absolutely continuous with respect to ρ_0, since as mentioned above, for any event in $\mathcal{F}_t$, $\mathbb{P}_\nu(A) = 0 \Leftrightarrow \mathbb{P}_{\nu'}(A) = 0$. Therefore one can apply Lemma 20 with ρ_0,ρ_1 and $\phi(x) = \mathbb{1}_{(x\neq\mathcal{S}_1)}$ and write

$$\max\left(\mathbb{P}_\nu(\hat{\mathcal{S}}_m \neq \mathcal{S}_1), \mathbb{P}_{\nu'}(\hat{\mathcal{S}}_m \neq \mathcal{S}_2)\right) \geq \frac{1}{4}\exp\left(-\mathrm{KL}(\mathcal{L}(\hat{\mathcal{S}}_m), \mathcal{L}'(\hat{\mathcal{S}}_m))\right).$$

To conclude the proof, it remains to show that $\mathrm{KL}(\mathcal{L}(\hat{\mathcal{S}}_m), \mathcal{L}'(\hat{\mathcal{S}}_m))$ is upper bounded by $\sum_{a=1}^{K}\mathbb{E}_\nu[N_a(t)]\mathrm{KL}(\nu_a, \nu'_a)$, which is equal to $\mathbb{E}_\nu[L_t]$, as shown above (equation (18)).

The rest of the proof boils down to prove a lower bound on $\mathbb{E}_\nu[L_t]$ slightly different from the one used to obtain Lemma 1. For $k \in \{1, \ldots, M\}$, applying inequality (19) to $(\hat{\mathcal{S}}_m = \mathcal{S}_k) \in \mathcal{F}_\tau$ yields

$$\mathbb{E}_\nu[L_t|\hat{\mathcal{S}}_m = \mathcal{S}_k] \geq \log\left(\frac{\mathbb{P}_\nu(\hat{\mathcal{S}}_m = \mathcal{S}_k)}{\mathbb{P}_{\nu'}(\hat{\mathcal{S}}_m = \mathcal{S}_k)}\right).$$

Thus one can write, letting $\mathcal{I} = \{k \in \{1, \ldots, M\} : \mathbb{P}_\nu(\hat{\mathcal{S}}_m = \mathcal{S}_k) \neq 0\}$,

$$\begin{aligned}
\mathbb{E}_\nu[L_t] &= \sum_{k\in\mathcal{I}} \mathbb{E}_\nu[L_t|\hat{\mathcal{S}}_m = \mathcal{S}_k]\mathbb{P}(\hat{\mathcal{S}}_m = \mathcal{S}_k) \\
&\geq \sum_{k\in\mathcal{I}} \log\left(\frac{\mathbb{P}_\nu(\hat{\mathcal{S}}_m = \mathcal{S}_k)}{\mathbb{P}_{\nu'}(\hat{\mathcal{S}}_m = \mathcal{S}_k)}\right)\mathbb{P}_\nu(\hat{\mathcal{S}}_m = \mathcal{S}_k) = \mathrm{KL}(\mathcal{L}(\hat{\mathcal{S}}_m), \mathcal{L}'(\hat{\mathcal{S}}_m)),
\end{aligned}$$

which concludes the proof.

A.3 Proof of Lemma 18

Recall that for all $a \in \{1,\dots,K\}$ there exists a measure λ_a such that ν_a (resp. ν'_a) has density f_a (resp. f'_a) with respect to λ_a. For all $a \in \{1,\dots,K\}$, let $(Y_{a,t})_{t\in\mathbb{N}}$ be an i.i.d. sequence such that if $A_t = a$, $Z_t = Y_{a,t}$.

We start by showing by induction that for all $n \in \mathbb{N}$ the following statement is true: for every function $g : \mathbb{R}^n \to \mathbb{R}$ measurable,

$$\mathbb{E}_{\nu'}[g(Z_1,\dots,Z_n)] = \mathbb{E}_{\nu}\left[g(Z_1,\dots,Z_n)\exp(-L_n(Z_1,\dots,Z_n))\right].$$

The result for $n = 1$ follows from the following calculation:

$$\begin{aligned}
\mathbb{E}_{\nu'}[g(Z_1)] &= \mathbb{E}_{\nu'}\left[\sum_{a=1}^K \mathbb{1}_{(A_1=a)} g(Y_{a,1})\right] = \sum_{a=1}^K \mathbb{E}_{\nu'}\left[\mathbb{1}_{(A_1=a)}\mathbb{E}_{\nu'}[g(Y_{a,1})|\mathcal{F}_0]\right] \\
&= \sum_{a=1}^K \mathbb{P}_{\nu'}(A_1=a)\mathbb{E}_{\nu'}[g(Y_{a,1})] = \sum_{a=1}^K \mathbb{P}_{\nu}(A_1=a)\mathbb{E}_{\nu}\left[g(Y_{a,1})\frac{f'_a(Y_{a,1})}{f_a(Y_{a,1})}\right] \\
&= \mathbb{E}_{\nu}\left[\sum_{a=1}^K \mathbb{1}_{(A_1=a)} g(Y_{a,1})\frac{f'_a(Y_{a,1})}{f_a(Y_{a,1})}\right] \\
&= \mathbb{E}_{\nu}\left[g(Z_1)\sum_{a=1}^K \mathbb{1}_{(A_1=a)}\exp\left(-\log\frac{f'_a(Z_1)}{f_a(Z_1)}\right)\right] \\
&= \mathbb{E}_{\nu}\left[g(Z_1)\exp\left(-\sum_{a=1}^K \mathbb{1}_{(A_1=a)}\log\frac{f'_a(Z_1)}{f_a(Z_1)}\right)\right] \\
&= \mathbb{E}_{\nu}\left[g(Z_1)\exp(-L_1(Z_1))\right].
\end{aligned}$$

We use that the initial choice of action satisfies $\mathbb{P}_\nu(A_1 = a) = \mathbb{P}_{\nu'}(A_1 = a)$.

We now assume that the statement holds for some integer n, and show it holds for $n+1$. Let $g : \mathbb{R}^{n+1} \to \mathbb{R}$ be a measurable function.

$$\begin{aligned}
&\mathbb{E}_{\nu'}[g(Z_1,\dots,Z_n,Z_{n+1})] = \mathbb{E}_{\nu'}[\mathbb{E}_{\nu'}[g(Z_1,\dots,Z_n,Z_{n+1})|\mathcal{F}_n]] \\
&\quad\overset{(*)}{=} \mathbb{E}_{\nu}\left[\mathbb{E}_{\nu'}[g(Z_1,\dots,Z_n,Z_{n+1})|\mathcal{F}_n]\exp\left(-L_n(Z_1,\dots,Z_n)\right)\right] \\
&\quad= \mathbb{E}_{\nu}\left[\sum_{a=1}^K \mathbb{1}_{A_{n+1}=a}\mathbb{E}_{\nu'}[g(Z_1,\dots,Z_n,Y_{a,n+1})|\mathcal{F}_n]\exp\left(-L_n(Z_1,\dots,Z_n)\right)\right] \\
&\quad= \mathbb{E}_{\nu}\left[\sum_{a=1}^K \mathbb{1}_{A_{n+1}=a}\int g(Z_1,\dots,Z_n,z)\frac{f'_a(z)}{f_a(z)}f_a(z)d\lambda_a(z)\exp\left(-L_n(Z_1,\dots,Z_n)\right)\right].
\end{aligned}$$

Observing that on the event $(A_{n+1} = a)$, $L_{n+1}(Z_1,\dots,Z_n,z) = L_n(Z_1,\dots,Z_n) + \log\frac{f_a(z)}{f'_a(z)}$ leads to:

$$\begin{aligned}
&\mathbb{E}_{\nu'}[g(Z_1,\dots,Z_n,Z_{n+1})] \\
&\quad= \mathbb{E}_{\nu}\left[\sum_{a=1}^K \mathbb{1}_{A_{n+1}=a}\int g(Z_1,\dots,Z_n,z)\exp(-L_{n+1}(Z_1,\dots,Z_n,z))f_a(z)d\lambda_a(z)\right] \\
&\quad= \mathbb{E}_{\nu}\left[\sum_{a=1}^K \mathbb{1}_{A_{n+1}=a}\mathbb{E}_{\nu}\left[g(Z_1,\dots,Z_n,Y_{a,n+1})\exp(-L_{n+1}(Z_1,\dots,Z_n,Y_{a,n+1}))|\mathcal{F}_n\right]\right] \\
&\quad= \mathbb{E}_{\nu}\left[\mathbb{E}_{\nu}\left[g(Z_1,\dots,Z_n,Z_{n+1})\exp(-L_{n+1}(Z_1,\dots,Z_n,Z_{n+1}))|\mathcal{F}_n\right]\right] \\
&\quad= \mathbb{E}_{\nu}\left[g(Z_1,\dots,Z_n,Z_{n+1})\exp(-L_{n+1}(Z_1,\dots,Z_n,Z_{n+1}))\right].
\end{aligned}$$

Hence, the statement is true for all n, and we have shown that for every $\mathcal{E} \in \mathcal{F}_n$,

$$\mathbb{P}_{\nu'}(\mathcal{E}) = \mathbb{E}_{\nu}[\mathbb{1}_{\mathcal{E}}\exp(-L_n)].$$

Let σ be a stopping time w.r.t. $(\mathcal{F}_n)$ and $\mathcal{E} \in \mathcal{F}_\sigma$.

$$\mathbb{P}_{\nu'}(\mathcal{E}) = \mathbb{E}_{\nu'}[\mathbb{1}_{\mathcal{E}}] = \sum_{n=0}^\infty \mathbb{E}_{\nu'}[\underbrace{\mathbb{1}_{\mathcal{E}}\mathbb{1}_{(\sigma=n)}}_{\in\mathcal{F}_n}] = \sum_{n=0}^\infty \mathbb{E}_{\nu}[\mathbb{1}_{\mathcal{E}}\mathbb{1}_{(\sigma=n)}\exp(-L_n)] = \mathbb{E}_{\nu}[\mathbb{1}_{\mathcal{E}}\exp(-L_\sigma)].$$

Appendix B. A Short Proof of Burnetas and Katehakis' Lower Bound on the Regret

In the regret minimization framework, briefly described in the Introduction, a bandit algorithm only consists in a sampling rule (there is no stopping rule nor recommendation rule). The arms must be chosen sequentially so as to minimize the regret, that is strongly related to the number of draws of the sub-optimal arms (using the notation $\mu^* = \mu_{[1]}$):

$$R_T(\nu) = \mu^* T - \mathbb{E}_\nu\left[\sum_{t=1}^T Z_t\right] = \sum_{a:\mu_a<\mu^*}(\mu^* - \mu_a)\,\mathbb{E}_\nu\big[N_a(T)\big] \tag{20}$$

The lower bound given by Lai and Robbins (1985) on the regret holds for families of distributions parameterized by a (single) real parameter. Their result has been generalized by Burnetas and Katehakis (1996) to larger classes of parametric distributions. The version we give here deals with identifiable classes of the form $\mathcal{M} = (\mathcal{P})^K$, where $\mathcal{P}$ is a set of probability measures satisfying

$$\forall \nu_a,\nu_b \in \mathcal{P},\ \nu_a \neq \nu_b \ \Rightarrow\ 0 < \mathrm{KL}(\nu_a,\nu_b) < +\infty.$$

Theorem 21 *Let $\mathcal{M}$ be an identifiable class of bandit models. Consider a bandit algorithm such that for all $\nu \in \mathcal{M}$ having a unique optimal arm, for all $\alpha \in (0,1]$, $R_T(\nu) = o(T^\alpha)$. Then, for all $\nu \in \mathcal{M}$,*

$$\mu_a < \mu^* \ \Rightarrow\ \liminf_{T\to\infty}\frac{\mathbb{E}_\nu[N_a(T)]}{\log(T)} \geq \frac{1}{\mathcal{K}_{inf}(\nu_a;\mu^*)}, \tag{21}$$

where $\mathcal{K}_{inf}(p;\mu) = \inf\{\mathrm{KL}(p,q) : q \in \mathcal{P} \text{ and } \mathbb{E}_{X\sim q}[X] > \mu\}$.

Proof. Let $\nu = (\nu_1, \dots, \nu_K)$ be a bandit model such that arm 1 is the unique optimal arm. Without loss of generality, we show that inequality (21) holds for the sub-optimal arm $a = 2$. Consider the alternative bandit model ν' such that $\nu'_a = \nu_a$ for all $a \neq 2$ and $\nu'_2 \in \mathcal{P}$ is such that $\mathbb{E}_{X\sim\nu'_2}[X] > \mu_1$. Arm 1 is thus the unique optimal arm under the model ν, whereas arm 2 is the unique optimal arm under the model ν'. For every integer T, let $\mathcal{E}_T$ be the event defined by

$$\mathcal{E}_T = \left(N_1(T) \leq T - \sqrt{T}\right).$$

Clearly, $\mathcal{E}_T \in \mathcal{F}_T$. From Lemma 1, applied to the stopping time $\sigma = T$ a.s.,

$$\mathbb{E}_\nu[N_2(T)]\mathrm{KL}(\nu_2, \nu'_2) \geq d(\mathbb{P}_\nu(\mathcal{E}_T), \mathbb{P}_{\nu'}(\mathcal{E}_T)). \tag{22}$$

The event $\mathcal{E}_T$ is not very likely to hold under the model ν, in which the optimal arm should be drawn of order $T - C\log(T)$ times, whereas it is very likely to happen under ν', in which arm 1 is sub-optimal and thus only drawn little. More precisely, Markov inequality yields

$$\begin{aligned}
\mathbb{P}_\nu(\mathcal{E}_T) &= \mathbb{P}_\nu(T - N_1(T) \geq \sqrt{T}) \leq \frac{\sum_{a\neq 1}\mathbb{E}_\nu[N_a(T)]}{\sqrt{T}} \\
\mathbb{P}_{\nu'}(\mathcal{E}_T^c) &= \mathbb{P}_{\nu'}(N_1(T) \geq T - \sqrt{T}) \leq \frac{\mathbb{E}_{\nu'}[N_1(T)]}{T - \sqrt{T}} \leq \frac{\sum_{a\neq 2}\mathbb{E}_{\nu'}[N_a(T)]}{T - \sqrt{T}}
\end{aligned}$$

From the formulation (20), every algorithm that is uniformly efficient in the above sense satisfies

$$\sum_{a\neq 1}\mathbb{E}_\nu[N_a(T)] = o(T^\alpha) \quad \text{and} \quad \sum_{a\neq 2}\mathbb{E}_{\nu'}[N_a(T)] = o(T^\alpha)$$

for all $\alpha \in (0, 1]$. Hence $\mathbb{P}_\nu(\mathcal{E}_T) \underset{n\to\infty}{\to} 0$ and $\mathbb{P}_{\nu'}(\mathcal{E}_T) \underset{n\to\infty}{\to} 1$. Therefore, we get

$$\frac{d(\mathbb{P}_\nu(\mathcal{E}_T), \mathbb{P}_{\nu'}(\mathcal{E}_T))}{\log(T)} \underset{T\to\infty}{\sim} \frac{1}{\log(T)}\log\left(\frac{1}{\mathbb{P}_{\nu'}(\mathcal{E}_T^c)}\right) \geq \frac{1}{\log(T)}\log\left(\frac{T - \sqrt{T}}{\sum_{a\neq 2}\mathbb{E}_{\nu'}[N_a(T)]}\right).$$

The right hand side rewrites

$$1 + \frac{\log\left(1 - \frac{1}{\sqrt{T}}\right)}{\log(T)} - \frac{\log\left(\sum_{a\neq 2}\mathbb{E}_{\nu'}[N_a(T)]\right)}{\log(T)} \underset{T\to\infty}{\to} 1$$

using the fact that $\sum_{a\neq 2}\mathbb{E}_{\nu'}[N_a(T)] = o(T^\alpha)$ for all $\alpha \in (0, 1]$. Finally, for every $\nu'_2 \in \mathcal{P}$ such that $\mathbb{E}_{X\sim\nu'_2}[X] > \mu_1$ on obtains, using inequality (22)

$$\liminf_{T\to\infty} \frac{\mathbb{E}[N_2(T)]}{\log(T)} \geq \frac{1}{\mathrm{KL}(\nu_2, \nu'_2)}.$$

For all $\epsilon \in (0, 1)$, ν'_2 can then be chosen such that $\mathrm{KL}(\nu_2, \nu'_2) \leq \mathcal{K}_{\inf}(\nu_2, \mu_1)/(1 - \epsilon)$, and the conclusion follows when ϵ goes to zero.

Appendix C. Properties of K_* and K^* in Exponential Families

In this section, we review properties of K_* defined in Section 3 as well as those of K^* defined in Section 5 in the case of one-parameter exponential family distributions. We recall that $\mathrm{K}_*(\theta_1, \theta_2) = \mathrm{K}(\theta_1, \theta_*)$ where θ_* is defined by $\mathrm{K}(\theta_1, \theta_*) = \mathrm{K}(\theta_2, \theta_*)$ and that $\mathrm{K}^*(\theta_1, \theta_2) = \mathrm{K}(\theta^*, \theta_1)$ where θ^* is defined by $\mathrm{K}(\theta^*, \theta_1) = \mathrm{K}(\theta^*, \theta_2)$.

Figure 7 displays the geometric constructions corresponding to the complexity terms of Theorems 4 and 6, respectively. As seen on the picture, the convexity of the function $\theta \mapsto K(\theta_i, \theta)$, for any value of θ_i, implies that

$$\frac{1}{\mathrm{K}_*(\theta_1, \theta_2)} \geq \frac{1}{\mathrm{K}(\theta_1, \theta_2)} + \frac{1}{\mathrm{K}(\theta_2, \theta_1)}.$$

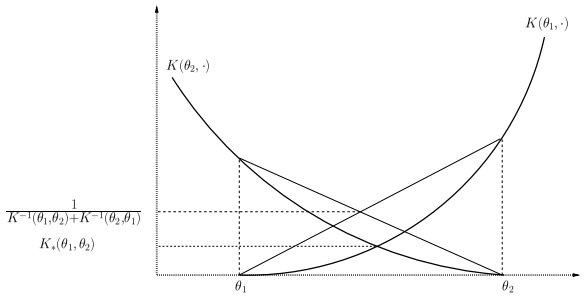

Figure 7: Comparison of the complexity terms featured in Theorems 4 and 6.

It is well known that in exponential families, the Kullback-Leibler divergence between distributions parameterized by their natural parameter, θ, may be related to the Bregman divergence associated with the log-partition function b:

$$\mathrm{K}(\theta_1, \theta_2) = b(\theta_2) - b(\theta_1) - \dot{b}(\theta_1)(\theta_2 - \theta_1) = \mathrm{Bregman}_b(\theta_2, \theta_1).$$

From this representation, its is straightforward to show that

- $\mathrm{K}(\theta_1, \theta_2)$ is a twice differentiable strictly convex function of its second argument,
- θ^* corresponds to the dual parameter $\mu^* := \dot{b}(\theta^*) = (b(\theta_2) - b(\theta_1))/(\theta_2 - \theta_1)$,
- $\mathrm{K}^*(\theta_1, \theta_2)$ admits the following variational representation

$$\mathrm{K}^*(\theta_1, \theta_2) = \max_{\theta\in(\theta_1,\theta_2)} \left\{ b(\theta_1) + \frac{b(\theta_2) - b(\theta_1)}{\theta_2 - \theta_1}(\theta - \theta_1) - b(\theta), \right\},$$

  corresponding to the maximal gap shown on Figure 8 (achieved in θ^* for which $\dot{b}(\theta^*) = \mu^*$). The quantity $I^*(\theta_1, \theta_2)$ related to the use of uniform sampling, is equal to the value of the gap in $\theta = (\theta_1 + \theta_2)/2$, which confirms that it is indeed smaller than $\mathrm{K}^*(\theta_1, \theta_2)$.

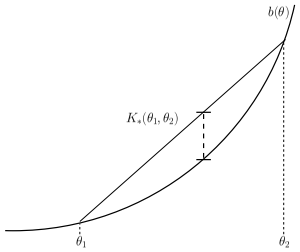

Figure 8: Interpretation of $\mathrm{K}^*(\theta_1,\theta_2)$.

Indexing the distributions in the exponential family by their mean $\mu = \dot{b}(\theta)$ rather than their natural parameter θ and using the dual representation

$$\mathrm{K}(\mu_1,\mu_2) = b^\star(\mu_1) - b^\star(\mu_2) - \dot{b}^\star(\mu_2)(\mu_1-\mu_2) = \mathrm{Bregman}_{b^\star}(\mu_1,\mu_2),$$

where $b^\star(\mu) := \sup_\theta(\theta\mu - b(\theta))$ is the Fenchel conjugate of b, similarly yields

- $\mathrm{K}(\mu_1,\mu_2)$ is a twice differentiable strictly convex function of its first argument,
- $\theta_* = \dot{b}^\star(\mu_*) = (b^\star(\mu_2) - b^\star(\mu_1))/(\mu_2-\mu_1)$;
- $\mathrm{K}_*(\theta_1,\theta_2)$ is defined by

$$\mathrm{K}_*(\theta_1,\theta_2) = \max_{\mu\in(\mu_1,\mu_2)} \left\{ b^\star(\mu_1) + \frac{b^\star(\mu_2)-b^\star(\mu_1)}{\mu_2-\mu_1}(\mu-\mu_1) - b^\star(\mu), \right\}.$$

From what precedes, equality between K_* and K^* for all values of the parameters is only achievable when the log-partition function b is self-conjugate.

Appendix D. Proof of Theorem 9

Let $\alpha = \sigma_1/(\sigma_1+\sigma_2)$. We first prove that with the exploration rate $\beta(t,\delta) = \log(t/\delta) + 2\log\log(6t)$ the algorithm is δ-PAC. Assume that $\mu_1 > \mu_2$ and recall $\tau = \inf\{t\in\mathbb{N} : |d_t| > \sqrt{2\sigma_t^2(\alpha)\beta(t,\delta)}\}$, where $d_t := \hat{\mu}_1(t) - \hat{\mu}_2(t)$. The probability of error of the α-elimination strategy is upper bounded by

$$\begin{aligned}
\mathbb{P}_\nu\left(d_\tau \le -\sqrt{2\sigma_\tau^2(\alpha)\beta(\tau,\delta)}\right) &\le \mathbb{P}_\nu\left(d_\tau - (\mu_1-\mu_2) \le -\sqrt{2\sigma_\tau^2(\alpha)\beta(\tau,\delta)}\right)\\
&\le \mathbb{P}_\nu\left(\exists t\in\mathbb{N}^* : d_t - (\mu_1-\mu_2) < -\sqrt{2\sigma_t^2(\alpha)\beta(t,\delta)}\right)\\
&\le \sum_{t=1}^{\infty} \exp\left(-\beta(t,\delta)\right),
\end{aligned}$$

by an union bound and Chernoff bound applied to $d_t - (\mu_1-\mu_2) \sim \mathcal{N}\left(0,\sigma_t^2(\alpha)\right)$. The choice of $\beta(t,\delta)$ mentioned above ensures that the series in the right hand side is upper bounded

by δ, which shows the algorithm is δ-PAC:

$$\begin{aligned}
\sum_{t=1}^{\infty} e^{-\beta(t,\delta)} &\le \delta\sum_{t=1}^{\infty}\frac{1}{t(\log(6t))^2} \le \delta\left(\frac{1}{(\log 6)^2} + \int_1^\infty \frac{dt}{t(\log(6t))^2}\right)\\
&= \delta\left(\frac{1}{(\log 6)^2} + \frac{1}{\log(6)}\right) \le \delta.
\end{aligned}$$

To upper bound the expected sample complexity, we start by upper bounding the probability that τ exceeds some deterministic time T:

$$\begin{aligned}
\mathbb{P}_\nu(\tau\ge T) &\le \mathbb{P}_\nu\left(\forall t = 1\dots T,\ d_t \le \sqrt{2\sigma_t^2(\alpha)\beta(t,\delta)}\right) \le \mathbb{P}_\nu\left(d_T \le \sqrt{2\sigma_T^2(\alpha)\beta(T,\delta)}\right)\\
&= \mathbb{P}_\nu\left(d_T - (\mu_1-\mu_2) \le -\left[(\mu_1-\mu_2) - \sqrt{2\sigma_T^2(\alpha)\beta(T,\delta)}\right]\right)\\
&\le \exp\left(-\frac{1}{2\sigma_T^2(\alpha)}\left[(\mu_1-\mu_2) - \sqrt{2\sigma_T^2(\alpha)\beta(T,\delta)}\right]^2\right).
\end{aligned}$$

The last inequality follows from Chernoff bound and holds for T such that $(\mu_1-\mu_2) > \sqrt{2\sigma_T^2(\alpha)\beta(T,\delta)}$. Now, for $\gamma\in(0,1)$ we introduce

$$T_\gamma^* := \inf\left\{ t_0\in\mathbb{N} : \forall t\ge t_0, (\mu_1-\mu_2) - \sqrt{2\sigma_t^2(\alpha)\beta(t,\delta)} > \gamma(\mu_1-\mu_2)\right\}.$$

This quantity is well defined as $\sigma_t^2(\alpha)\beta(t,\delta)$ goes to zero when t goes to infinity. Then,

$$\begin{aligned}
\mathbb{E}_\nu[\tau] &\le T_\gamma^* + \sum_{T=T_\gamma^*+1} \mathbb{P}\left(\tau\ge T\right)\\
&\le T_\gamma^* + \sum_{T=T_\gamma^*+1} \exp\left(-\frac{1}{2\sigma_T^2(\alpha)}\left[(\mu_1-\mu_2) - \sqrt{2\sigma_T^2(\alpha)\beta(T,\delta)}\right]^2\right)\\
&\le T_\gamma^* + \sum_{T=T_\gamma^*+1}^{\infty} \exp\left(-\frac{1}{2\sigma_T^2(\alpha)}\gamma^2(\mu_1-\mu_2)^2\right).
\end{aligned}$$

For all $t\in\mathbb{N}^*$, it is easy to show that the following upper bound on $\sigma_t^2(\alpha)$ holds:

$$\forall t\in\mathbb{N},\ \sigma_t^2(\alpha) \le \frac{(\sigma_1+\sigma_2)^2}{t}\times\frac{t-\frac{\sigma_1}{\sigma_2}}{t-\frac{\sigma_1}{\sigma_2}-1}. \tag{23}$$

Using the bound (23), one has

$$\begin{aligned}
\mathbb{E}_\nu[\tau] &\le T_\gamma^* + \int_0^\infty \exp\left(-\frac{t}{2(\sigma_1+\sigma_2)^2}\frac{t-\frac{\sigma_1}{\sigma_2}-1}{t-\frac{\sigma_1}{\sigma_2}}\gamma^2(\mu_1-\mu_2)^2\right)dt\\
&\le T_\gamma^* + \frac{2(\sigma_1+\sigma_2)^2}{\gamma^2(\mu_1-\mu_2)^2}\exp\left(\frac{\gamma^2(\mu_1-\mu_2)^2}{2(\sigma_1+\sigma_2)^2}\right).
\end{aligned}$$

We now give an upper bound on T^*_γ. Let $r \in [0, e/2-1]$. There exists $N_0(r)$ such that for $t \geq N_0(r)$, $\beta(t,\delta) \leq \log(t^{1+r}/\delta)$. Using also (23), one gets $T^*_\gamma = \max(N_0(t), \tilde{T}_\gamma)$, where

$$\tilde{T}_\gamma = \inf\left\{ t_0 \in \mathbb{N} : \forall t \geq t_0, \frac{(\mu_1-\mu_2)^2}{2(\sigma_1+\sigma_2)^2}(1-\gamma)^2 t > \frac{t - \frac{\sigma_1}{\sigma_2} - 1}{t - \frac{\sigma_1}{\sigma_2}} \log \frac{t^{1+r}}{\delta} \right\}.$$

If $t > (1+\gamma\frac{\sigma_1}{\sigma_2})/\gamma$ one has $(t-\frac{\sigma_1}{\sigma_2}-1)/(t-\frac{\sigma_1}{\sigma_2}) \leq (1-\gamma)^{-1}$. Thus $\tilde{T}_\gamma = \max((1+\gamma\frac{\sigma_1}{\sigma_2})/\gamma, T'_\gamma)$, with

$$T'_\gamma = \inf\left\{ t_0 \in \mathbb{N} : \forall t \geq t_0, \exp\left(\frac{(\mu_1-\mu_2)^2}{2(\sigma_1+\sigma_2)^2}(1-\gamma)^3 t\right) \geq \frac{t^{1+r}}{\delta} \right\}.$$

The following Lemma, whose proof can be found below, helps us bound this last quantity.

Lemma 22 *For every $\beta, \eta > 0$ and $s \in [1, e/2]$, the following implication is true:*

$$x_0 = \frac{s}{\beta}\log\left(\frac{e\log\left(1/(\beta^s\eta)\right)}{\beta^s\eta}\right) \quad \Rightarrow \quad \forall x \geq x_0, \quad e^{\beta x} \geq \frac{x^s}{\eta}.$$

Applying Lemma 22 with $\eta = \delta$, $s = 1+r$ and $\beta = (1-\gamma)^3(\mu_1-\mu_2)^2/(2(\sigma_1+\sigma_2)^2)$ leads to

$$T'_\gamma \leq \frac{(1+r)}{(1-\gamma)^3} \times \frac{2(\sigma_1+\sigma_2)^2}{(\mu_1-\mu_2)^2}\left[\log\frac{1}{\delta} + \log\log\frac{1}{\delta}\right] + R(\mu_1,\mu_2,\sigma_1,\sigma_2,\gamma,r),$$

with

$$R(\mu_1,\mu_2,\sigma_1,\sigma_2,\gamma,r) = \frac{1+r}{(1-\gamma)^3}\frac{2(\sigma_1+\sigma_2)^2}{(\mu_1-\mu_2)^2}\left[1 + (1+r)\log\left(\frac{2(\sigma_1+\sigma_2)^2}{(1-\gamma)^3(\mu_1-\mu_2)^2}\right)\right].$$

Now for $\epsilon > 0$ fixed, choosing r and γ small enough leads to

$$\mathbb{E}_\nu[\tau] \leq (1+\epsilon)\frac{2(\sigma_1+\sigma_2)^2}{(\mu_1-\mu_2)^2}\left[\log\frac{1}{\delta} + \log\log\frac{1}{\delta}\right] + \mathcal{C}(\mu_1,\mu_2,\sigma_1,\sigma_2,\epsilon),$$

where $\mathcal{C}$ is a constant independent of δ. It can be noted that $\mathcal{C}(\mu_1,\mu_2,\sigma_1,\sigma_2,\epsilon)$ goes to infinity when ϵ goes to zero, but for a fixed $\epsilon > 0$,

$$(1+\epsilon)\frac{2(\sigma_1+\sigma_2)^2}{(\mu_1-\mu_2)^2}\log\log\frac{1}{\delta} + \mathcal{C}(\mu_1,\mu_2,\sigma_1,\sigma_2,\epsilon) = \underset{\delta\to 0}{o_\epsilon}\left(\log\frac{1}{\delta}\right),$$

which concludes the proof.

Proof of Lemma 22. Lemma 22 easily follows from the fact that for $\eta > 0$ and $s \in [1, e/2]$,

$$x_0 = s\log\left(\frac{e\log\left(\frac{1}{\eta}\right)}{\eta}\right) \quad \Rightarrow \quad \forall x \geq x_0, \quad e^x \geq \frac{x^s}{\eta}$$

Indeed, it suffices to apply this statement to $x = x\beta$ and $\eta = \eta\beta^s$. The mapping $x \mapsto e^x - x^s/\eta$ is increasing when $x \geq s$. As $x_0 \geq s$, it suffices to prove that x_0 defined above

satisfies $e^{x_0} \geq x_0^s/\eta$.

$$\begin{aligned}
\log\left(\frac{x_0^s}{\eta}\right) &= s\log\left(s\log\left(\frac{e\log\frac{1}{\eta}}{\eta}\right)\right) + \log\frac{1}{\eta} \\
&= s\left(\log(s) + \log\left[\log\frac{1}{\eta} + \log\left(e\log\frac{1}{\eta}\right)\right]\right) + \log\frac{1}{\eta} \\
&\leq s\left(\log(s) + \log\left[2\log\frac{1}{\eta}\right]\right) + \log\frac{1}{\eta}
\end{aligned}$$

where we use that for all y, $\log(y) \leq \frac{1}{e}y$. Then, using that $s \geq 1$,

$$\log\left(\frac{x_0^s}{\eta}\right) \leq s\left(\log(s) + \log(2) + \log\log\frac{1}{\eta} + \log\frac{1}{\eta}\right).$$

For $s \leq \frac{e}{2}$, $\log(s) + \log(2) \leq 1$, hence

$$\log\left(\frac{x_0^s}{\eta}\right) \leq s\left(1 + \log\log\frac{1}{\eta} + \log\frac{1}{\eta}\right) = s\log\left(\frac{e\log\left(\frac{1}{\eta}\right)}{\eta}\right) = x_0,$$

which is equivalent to $e^{x_0} \geq \frac{x_0^s}{\eta}$ and concludes the proof.

Appendix E. A Refined Exploration Rate for α-Elimination

E.1 Proof of Theorem 8

According to (15), to prove Theorem 8 it is enough to show that for

$$\beta(t,\delta) = \log(1/\delta) + 3\log\log(1/\delta) + (3/2)\log\log(et),$$

if $S_t = \sum_{s=1}^t X_s$ is a sum of i.i.d $\mathcal{N}(0,1)$ random variables, one has

$$\mathbb{P}(\exists t \in \mathbb{N}^* : S_t > \sqrt{2t\beta(t,\delta)}) \leq \delta. \tag{24}$$

Let $z = \log(1/\delta)$. Using Lemma 7, one can write, choosing $x = z + 3\log z$ and $\beta = 3/2$,

$$\mathbb{P}\Big(\exists t \in \mathbb{N} : S_t > \sqrt{2t\beta(t,\delta)}\Big) \leq \frac{\sqrt{e}}{8}\zeta\Big(\frac{3}{2} - \frac{3}{4(z+3\log z)}\Big)\frac{(\sqrt{z+3\log z}+\sqrt{8})^{3/2}}{z^3}\delta.$$

It can be shown numerically that for $z \geq 2.03$,

$$\frac{\sqrt{e}}{8}\zeta\Big(\frac{3}{2} - \frac{3}{4(z+3\log z)}\Big)\frac{(\sqrt{z+3\log z}+\sqrt{8})^{3/2}}{z^3} \leq 1.$$

Thus for $\delta \leq \exp(-2.03) \leq 0.1$, inequality (24) holds.

E.2 Proof of Lemma 7.

We start by stating three technical lemmas, whose proofs are partly omitted.

Lemma 23 *For every $\eta > 0$, every positive integer k, and every integer t such that $(1+\eta)^{k-1} \leq t \leq (1+\eta)^k$,*

$$\sqrt{\frac{(1+\eta)^{k-1/2}}{t}} + \sqrt{\frac{t}{(1+\eta)^{k-1/2}}} \leq (1+\eta)^{1/4} + (1+\eta)^{-1/4} .$$

Lemma 24 *For every $\eta > 0$,*

$$A(\eta) := \frac{4}{\left((1+\eta)^{1/4} + (1+\eta)^{-1/4}\right)^2} \geq 1 - \frac{\eta^2}{16}.$$

Lemma 25 *Let t be such that $(1+\eta)^{k-1} \leq t \leq (1+\eta)^k$. Then,*

$$\sigma\sqrt{2z} \geq \frac{A(\eta)z}{\lambda\sqrt{t}} + \frac{\lambda\sigma^2\sqrt{t}}{2}, \quad \textit{with} \quad \lambda = \sigma^{-1}\sqrt{2zA(\eta)/(1+\eta)^{k-1/2}}.$$

Proof of Lemma 25.

$$\frac{A(\eta)z}{\lambda\sqrt{t}} + \frac{\lambda\sigma^2\sqrt{t}}{2} = \frac{\sigma\sqrt{2zA(\eta)}}{2}\left(\sqrt{\frac{(1+\eta)^{k-1/2}}{t}} + \sqrt{\frac{t}{(1+\eta)^{k-1/2}}}\right) \leq \sigma\sqrt{2z}$$

according to Lemma 23.

□

An important fact is that for every $\lambda \in \mathbb{R}$, because the X_i are σ-subgaussian, $W_t = \exp(\lambda S_t - t\frac{\lambda^2\sigma^2}{2}))$ is a super-martingale, and thus, for every positive u,

$$\mathbb{P}\left(\bigcup_{t\geq 1}\left\{\lambda S_t - t\frac{\lambda^2\sigma^2}{2} > u\right\}\right) \leq \exp(-u). \tag{25}$$

Let $\eta \in (0, e-1]$ to be defined later, and let $T_k = \mathbb{N} \cap \left[(1+\eta)^{k-1}, (1+\eta)^k\right[$.

$$\mathbb{P}\left(\bigcup_{t\geq 1}\left\{\frac{S_t}{\sigma\sqrt{2t}} > \sqrt{x+\beta\log\log(et)}\right\}\right) \leq \sum_{k=1}^{\infty}\mathbb{P}\left(\bigcup_{t\in T_k}\left\{\frac{S_t}{\sigma\sqrt{2t}} > \sqrt{x+\beta\log\log(et)}\right\}\right)$$
$$\leq \sum_{k=1}^{\infty}\mathbb{P}\left(\bigcup_{t\in T_k}\left\{\frac{S_t}{\sigma\sqrt{2t}} > \sqrt{x+\beta\log\left(k\log(1+\eta)\right)}\right\}\right) .$$

We use that $\eta \leq e-1$ to obtain the last inequality since this condition implies

$$\log(\log(e(1+\eta)^{k-1}) \geq \log(k\log(1+\eta)).$$

For $k \geq 1$, let $z_k = x + \beta\log\left(k\log(1+\eta)\right)$ and $\lambda_k = \sigma^{-1}\sqrt{2z_kA(\eta)/(1+\eta)^{k-1/2}}$. Lemma 25 shows that for every $t \in T_k$,

$$\left\{\frac{S_t}{\sigma\sqrt{2t}} > \sqrt{z_k}\right\} \subset \left\{\frac{S_t}{\sqrt{t}} > \frac{A(\eta)z_k}{\lambda_k\sqrt{t}} + \frac{\sigma^2\lambda_k\sqrt{t}}{2}\right\} .$$

Thus, by inequality (25),

$$\mathbb{P}\left(\bigcup_{t\in T_k}\left\{\frac{S_t}{\sigma\sqrt{2t}} > \sqrt{z_k}\right\}\right) \leq \mathbb{P}\left(\bigcup_{t\in T_k}\left\{\frac{S_t}{\sqrt{t}} > \frac{A(\eta)z_k}{\lambda_k\sqrt{t}} + \frac{\sigma^2\lambda_k\sqrt{t}}{2}\right\}\right)$$
$$= \mathbb{P}\left(\bigcup_{t\in T_k}\left\{\lambda_kS_t - \frac{\sigma^2\lambda_k^2t}{2} > A(\eta)z_k\right\}\right)$$
$$\leq \exp\left(-A(\eta)z_k\right) = \frac{\exp(-A(\eta)x)}{(k\log(1+\eta))^{\beta A(\eta)}} .$$

One chooses $\eta^2 = 8/x$ for x such that $x \geq \frac{8}{(e-1)^2}$ (which ensures $\eta \leq e-1$). Using Lemma 24, one obtains that $\exp(-A(\eta)x) \leq \sqrt{e}\exp(-x)$. Moreover,

$$\frac{1}{\log(1+\eta)} \leq \frac{1+\eta}{\eta} = \frac{\sqrt{x}}{2\sqrt{2}} + 1 .$$

Thus,

$$\mathbb{P}\left(\bigcup_{t\in T_k}\left\{\frac{S_t}{\sigma\sqrt{2t}} > \sqrt{z_k}\right\}\right) \leq \frac{\sqrt{e}}{k^{\beta A(\eta)}}\left(\frac{\sqrt{x}}{2\sqrt{2}} + 1\right)^{\beta A(\eta)}\exp(-x)$$
$$\leq \frac{\sqrt{e}}{k^{\beta A(\eta)}}\left(\frac{\sqrt{x}}{2\sqrt{2}} + 1\right)^{\beta}\exp(-x).$$

Hence,

$$\mathbb{P}\left(\bigcup_{t\geq 1}\left\{\frac{S_t}{\sigma\sqrt{2t}} > \sqrt{x+\beta\log\log(et)}\right\}\right) \leq \sqrt{e}\zeta\left(\beta A(\eta)\right)\left(\frac{\sqrt{x}}{2\sqrt{2}} + 1\right)^{\beta A(\eta)}\exp\left(-x\right)$$
$$\leq \sqrt{e}\zeta\left(\beta\left(1 - \frac{1}{2x}\right)\right)\left(\frac{\sqrt{x}}{2\sqrt{2}} + 1\right)^{\beta}\exp\left(-x\right),$$

using the lower bound on $A(\eta)$ given in Lemma 24 and the fact that $A(\eta)$ is upper bounded by 1.

Appendix F. Bernoulli Bandit Models

F.1 Proof of Lemma 11

Assume that $\mu_1 < \mu_2$. Recall the KL-LUCB algorithm of Kaufmann and Kalyanakrishnan (2013). For two-armed bandit models, this algorithm samples the arms uniformly and builds

for both arms a confidence interval based on KL-divergence $\mathcal{I}_a(t) = [l_{a,t/2}, u_{a,t/2}]$, with

$$\begin{aligned} u_{a,s} &= \sup\{q > \hat{\mu}_{a,s} : sd(\hat{\mu}_{a,s}, q) \leq \tilde{\beta}(s,\delta)\}, \quad \text{where} \quad d(x,y) = \mathrm{KL}(\mathcal{B}(x), \mathcal{B}(y)) \\ l_{a,s} &= \inf\{q < \hat{\mu}_{a,s} : sd(\hat{\mu}_{a,s}, q) \leq \tilde{\beta}(s,\delta)\}, \end{aligned}$$

for some exploration rate that we denote by $\tilde{\beta}(t,\delta)$. The algorithm stops when the confidence intervals are separated; that is either $l_{1,t/2} > u_{2,t/2}$ or $l_{2,t/2} > u_{1,t/2}$, and recommends the empirical best arm. A picture helps to convince oneself that

$$(l_{1,s} > u_{2,s}) \;\Leftrightarrow\; (\hat{\mu}_{1,s} > \hat{\mu}_{2,s}) \cap (sd_*(\hat{\mu}_{1,s}, \hat{\mu}_{2,s}) > \beta(s,\delta)) \tag{26}$$

Additionally, as mentioned before, $I_*(x,y)$ is very close to the quantity $d_*(x,y)$ and one has more precisely $I_*(x,y) < d_*(x,y)$. Using all this, we can upper bound the probability of error of Algorithm 2 in the following way.

$$\begin{aligned} &\mathbb{P}_\nu\left(\exists t \in 2\mathbb{N}^* : \hat{\mu}_{1,t/2} > \hat{\mu}_{2,t/2}, tI_*(\hat{\mu}_{1,t/2}, \hat{\mu}_{2,t/2}) > \beta(t,\delta)\right) \\ &\quad \leq \mathbb{P}_\nu\left(\exists t \in 2\mathbb{N}^* : \hat{\mu}_{1,t/2} > \hat{\mu}_{2,t/2}, (t/2)d_*(\hat{\mu}_{1,t/2}, \hat{\mu}_{2,t/2}) > (\beta(t,\delta)/2)\right) \\ &\quad = \mathbb{P}_\nu\left(\exists s \in \mathbb{N}^* : \hat{\mu}_{1,s} > \hat{\mu}_{2,s}, sd_*(\hat{\mu}_{1,s}, \hat{\mu}_{2,s}) > (\beta(2s,\delta)/2)\right) \\ &\quad = \mathbb{P}_\nu(\exists s \in \mathbb{N}^* : l_{1,s} > u_{2,s}) \leq \mathbb{P}_\nu(\exists s \in \mathbb{N}^* : (\mu_1 < l_{1,s}) \cup (\mu_2 > u_{2,s})) \\ &\quad \leq 2\sum_{s=1}^{\infty} \exp(-\beta(2s,\delta)/2) \end{aligned}$$

where the last inequality follows from an union bound and for example Lemma 4 of Kaufmann and Kalyanakrishnan (2013). Note that the indices $l_{1,s}$ and $u_{2,s}$ involved here use the exploration rate $\tilde{\beta}(s,\delta) = \beta(2s,\delta)/2$. The choice $\beta(t,\delta)$ in the statement of the Lemma shows the last series is upper bounded by δ, which concludes the proofs.

F.2 An Asymptotic Bound for the Stopping Time

Lemma 26 *Consider a strategy that uses uniform sampling and a stopping rule of the form*

$$\tau = \inf\left\{t \in 2\mathbb{N}^* : tf(\hat{\mu}_{1,t/2}, \hat{\mu}_{2,t/2}) \geq \log\left(\frac{g(t)}{\delta}\right)\right\}$$

where f is a continuous function such that $f(\mu_1,\mu_2) \neq 0$ and $g(t) = o(t^r)$ for all $r > 0$. Then for all $\epsilon > 0$,

$$\mathbb{P}_\nu\left(\limsup_{\delta\to 0} \frac{\tau}{\log(1/\delta)} \leq \frac{1+\epsilon}{f(\mu_1,\mu_2)}\right) = 1.$$

Proof. We fix $\epsilon > 0$ and introduce

$$\sigma = \max\left\{t \in 2\mathbb{N}^* : f(\hat{\mu}_{1,t/2}, \hat{\mu}_{2,t/2}) \leq \frac{f(\mu_1,\mu_2)}{1+\epsilon/2}\right\}.$$

By the law of large numbers, $\mathbb{P}(\sigma < +\infty) = 1$. Hence, $\lim_{n\to\infty} \mathbb{P}(\sigma \leq n) = 1$ and for every $\alpha \in (0,1)$ there exists $N(\epsilon,\alpha,\mu_1,\mu_2)$ such that $\mathbb{P}(\sigma \leq N(\epsilon,\alpha,\mu_1,\mu_2)) \geq 1-\alpha$. Therefore, introducing the event

$$E_\alpha = \left(\forall t \geq N(\epsilon,\alpha,\mu_1,\mu_2), f(\hat{\mu}_{1,t/2}, \hat{\mu}_{2,t/2}) > \frac{f(\mu_1,\mu_2)}{1+\epsilon/2}\right), \quad \text{one has} \quad \mathbb{P}(E_\alpha) \geq 1-\alpha.$$

On the event E_α,

$$\begin{aligned} \tau &\leq \max\left(N(\epsilon,\alpha,\mu_1,\mu_2); \inf\left\{t \in \mathbb{N} : t\frac{f(\mu_1,\mu_2)}{1+\epsilon/2} \geq \log\left(\frac{g(t)}{\delta}\right)\right\}\right) \\ \tau &\leq N(\epsilon,\alpha,\mu_1,\mu_2) + \inf\left\{t \in \mathbb{N} : t\frac{f(\mu_1,\mu_2)}{1+\epsilon/2} \geq \log\left(\frac{g(t)}{\delta}\right)\right\} \end{aligned}$$

We can use Lemma 22 to bound the right term in the right hand side, which shows that there exists a constant $C(\epsilon,\mu_1,\mu_2)$ independent of δ such that

$$\tau \leq N(\epsilon,\alpha,\mu_1,\mu_2) + \frac{1+\epsilon}{f(\mu_1,\mu_2)}\left[\log\frac{1}{\delta} + \log\log\frac{1}{\delta}\right] + C(\epsilon,\mu_1,\mu_2)$$

Thus we proved that for all $\alpha > 0$,

$$\mathbb{P}\left(\limsup_{\delta\to 0} \frac{\tau}{\log(1/\delta)} \leq \frac{1+\epsilon}{f(\mu_1,\mu_2)}\right) \geq 1-\alpha.$$

This concludes the proof.

Appendix G. Upper and Lower Bounds in the Fixed-Budget Setting

G.1 Proof of Theorem 12

Without loss of generality, assume that the bandit model $\nu = (\nu_1,\nu_2)$ is such that $a^* = 1$. Consider any alternative bandit model $\nu' = (\nu_1',\nu_2')$ in which $a^* = 2$. Let $\mathcal{A}$ be a consistent algorithm such that $\tau = t$ and consider the event $A = (\hat{\mathcal{S}}_1 = 1)$. Clearly $A \in \mathcal{F}_t = \mathcal{F}_\tau$.

Lemma 1 applied to the stopping time $\sigma = t$ a.s. and the event A gives

$$\mathbb{E}_{\nu'}[N_1(t)]\mathrm{KL}(\nu_1',\nu_1) + \mathbb{E}_{\nu'}[N_2(t)]\mathrm{KL}(\nu_2',\nu_2) \geq d(\mathbb{P}_{\nu'}(A), \mathbb{P}_\nu(A)).$$

Note that $p_t(\nu) = 1 - \mathbb{P}_\nu(A)$ and $p_t(\nu') = \mathbb{P}_{\nu'}(A)$. As algorithm $\mathcal{A}$ is correct on both ν and ν', for every $\epsilon > 0$ there exists $t_0(\epsilon)$ such that for all $t \geq t_0(\epsilon)$, $\mathbb{P}_{\nu'}(A) \leq \epsilon \leq \mathbb{P}_\nu(A)$. For $t \geq t_0(\epsilon)$,

$$\mathbb{E}_{\nu'}[N_1(t)]\mathrm{KL}(\nu_1',\nu_1) + \mathbb{E}_{\nu'}[N_2(t)]\mathrm{KL}(\nu_2',\nu_2) \geq d(\epsilon, 1-p_t(\nu)) \geq (1-\epsilon)\log\frac{1-\epsilon}{p_t(\nu)} + \epsilon\log\epsilon.$$

Taking the limsup and letting ϵ go to zero, one can show that

$$\limsup_{t\to\infty} -\frac{1}{t}\log p_t(\nu) \leq \limsup_{t\to\infty} \sum_{a=1}^{2} \frac{\mathbb{E}_{\nu'}[N_a(t)]}{t}\mathrm{KL}(\nu_a',\nu_a) \leq \max_{a=1,2} \mathrm{KL}(\nu_a',\nu_a).$$

Optimizing over the possible model ν' satisfying $\mu_1' < \mu_2'$ to make the right hand side of the inequality as small as possible gives the result.

For algorithms using uniform sampling, $\limsup -\frac{1}{t}\log p_t(\nu)$ is upper bounded by the quantity $(\mathrm{KL}(\nu_1',\nu_1) + \mathrm{KL}(\nu_2',\nu_2))/2$, which yields the second statement of the Theorem.

G.2 An Optimal Static Strategy for Exponential Families

Bounding the probability of error of a static strategy using n_1 samples from arm 1 and n_2 samples from arm 2 relies on the following lemma.

Lemma 27 *Let $(X_{1,t})_{t\in\mathbb{N}}$ and $(X_{2,t})_{t\in\mathbb{N}}$ be two independent i.i.d sequences, such that $X_{1,1}\sim\nu_{\theta_1}$ and $X_{2,1}\sim\nu_{\theta_2}$ belong to an exponential family. Assume that $\mu(\theta_1)>\mu(\theta_2)$. Then*

$$\mathbb{P}\left(\frac{1}{n_1}\sum_{t=1}^{n_1}X_{1,t}<\frac{1}{n_2}\sum_{t=1}^{n_2}X_{2,t}\right)\leq\exp(-(n_1+n_2)g_\alpha(\theta_1,\theta_2)), \tag{27}$$

where $\alpha=\frac{n_1}{n_1+n_2}$ and $g_\alpha(\theta_1,\theta_2):=\alpha\mathrm{K}(\alpha\theta_1+(1-\alpha)\theta_2,\theta_1)+(1-\alpha)\mathrm{K}(\alpha\theta_1+(1-\alpha)\theta_2,\theta_2)$.

The function $\alpha\mapsto g_\alpha(\theta_1,\theta_2)$, can be maximized analytically, and the value α^* that realizes the maximum is given by

$$\begin{aligned}\mathrm{K}(\alpha^*\theta_1+(1-\alpha^*)\theta_2,\theta_1) &= \mathrm{K}(\alpha^*\theta_1+(1-\alpha^*)\theta_2,\theta_2)\\ \alpha^*\theta_1+(1-\alpha^*)\theta_1 &= \theta^*\\ \alpha^* &= \frac{\theta^*-\theta_2}{\theta_1-\theta_2}\end{aligned}$$

where θ^* is defined by $\mathrm{K}(\theta^*,\theta_1)=\mathrm{K}(\theta^*,\theta_2)=\mathrm{K}^*(\theta_1,\theta_2)$. More interestingly, the associated rate is such that

$$g_{\alpha^*}(\theta_1,\theta_2)=\alpha^*\mathrm{K}(\theta^*,\theta_1)+(1-\alpha^*)\mathrm{K}(\theta^*,\theta_2)=\mathrm{K}^*(\theta_1,\theta_2),$$

which leads to Theorem 13.

Remark 28 *When $\mu_1>\mu_2$, applying Lemma 27 with $n_1=n_2=t/2$ yields*

$$\mathbb{P}\left(\hat{\mu}_{1,t/2}<\mu_{2,t/2}\right)\leq\exp\left(-\frac{\mathrm{K}\left(\theta_1,\frac{\theta_1+\theta_2}{2}\right)+\mathrm{K}\left(\theta_2,\frac{\theta_1+\theta_2}{2}\right)}{2}t\right)=\exp\big(-I_*(\nu)t\big),$$

which shows that the strategy using uniform sampling and recommending the empirical best arm matches the lower bound (17) in Theorem 12.

Proof of Lemma 27. The i.i.d. sequences $(X_{1,t})_{t\in\mathbb{N}}$ and $(X_{2,t})_{t\in\mathbb{N}}$ have respective densities f_{θ_1} and f_{θ_2} where $f_\theta(x)=\exp(\theta x-b(\theta))$ and $\mu(\theta_1)=\mu_1,\mu(\theta_2)=\mu_2$. α is such that $n_1=\alpha n$ and $n_2=(1-\alpha)n$. One can write

$$\mathbb{P}\left(\frac{1}{n_1}\sum_{t=1}^{n_1}X_{1,t}-\frac{1}{n_2}\sum_{t=1}^{n_2}X_{2,t}<0\right)=\mathbb{P}\left(\alpha\sum_{t=1}^{n_2}X_{2,t}-(1-\alpha)\sum_{t=1}^{n_1}X_{1,t}\geq 0\right).$$

For every $\lambda>0$, multiplying by λ, taking the exponential of the two sides and using Markov's inequality (this technique is often referred to as Chernoff's method), one gets

$$\begin{aligned}\mathbb{P}\left(\frac{1}{n_1}\sum_{t=1}^{n_1}X_{1,t}-\frac{1}{n_2}\sum_{t=1}^{n_2}X_{2,t}<0\right) &\leq \left(\mathbb{E}_\nu[e^{\lambda\alpha X_{2,1}}]\right)^{(1-\alpha)n}\left(\mathbb{E}_\nu[e^{\lambda(1-\alpha)X_{1,1}}]\right)^{\alpha n}\\ &= \exp\Bigg(n\underbrace{\left[(1-\alpha)\phi_{X_{2,1}}(\lambda\alpha)+\alpha\phi_{X_{1,1}}(-(1-\alpha)\lambda)\right]}_{G_\alpha(\lambda)}\Bigg)\end{aligned}$$

with $\phi_X(\lambda)=\log\mathbb{E}_\nu[e^{\lambda X}]$ for any random variable X. If $X\sim f_\theta$ a direct computation gives $\phi_X(\lambda)=b(\lambda+\theta)-b(\theta)$. Therefore the function $G_\alpha(\lambda)$ introduced above rewrites

$$G_\alpha(\lambda)=(1-\alpha)(b(\lambda\alpha+\theta_2)-b(\theta_2))+\alpha(b(\theta_1-(1-\alpha)\lambda)-b(\theta_1)).$$

Using that $b'(x)=\mu(x)$, we can compute the derivative of G and see that this function as a unique minimum in λ^* given by

$$\mu(\theta_1-(1-\alpha)\lambda^*)=\mu(\theta_2+\alpha\lambda^*)\quad\Leftrightarrow\quad\theta_1-(1-\alpha)\lambda^*=\theta_2+\alpha\lambda^*\quad\Leftrightarrow\quad\lambda^*=\theta_1-\theta_2,$$

using that $\theta\mapsto\mu(\theta)$ is one-to-one. One can also show that

$$G(\lambda^*) \;=\; (1-\alpha)[b(\alpha\theta_1+(1-\alpha)\theta_2)-b(\theta_2)]+\alpha[b(\alpha\theta_1+(1-\alpha)\theta_2)-b(\theta_1)].$$

Using the expression of the KL-divergence between ν_{θ_1} and ν_{θ_2} as a function of the natural parameters: $\mathrm{K}(\theta_1,\theta_2)=\mu(\theta_1)(\theta_1-\theta_2)-b(\theta_1)+b(\theta_2)$, one can also show that

$$\begin{aligned}&\alpha\mathrm{K}(\alpha\theta_1+(1-\alpha)\theta_2,\theta_1)\\ &\qquad=-\alpha(1-\alpha)\mu(\alpha\theta_1+(1-\alpha)\theta_2)(\theta_1-\theta_2)+\alpha[-b(\alpha\theta_1+(1-\alpha)\theta_2)+b(\theta_1)]\\ &(1-\alpha)\mathrm{K}(\alpha\theta_1+(1-\alpha)\theta_2,\theta_2)\\ &\qquad=\alpha(1-\alpha)\mu(\alpha\theta_1+(1-\alpha)\theta_2)(\theta_1-\theta_2)+(1-\alpha)[-b(\alpha\theta_1+(1-\alpha)\theta_2)+b(\theta_2)]\end{aligned}$$

Summing these two equalities leads to

$$G(\lambda^*)=-\left[\alpha\mathrm{K}(\alpha\theta_1+(1-\alpha)\theta_2,\theta_1)+(1-\alpha)\mathrm{K}(\alpha\theta_1+(1-\alpha)\theta_2,\theta_2)\right]=-g_\alpha(\theta_1,\theta_2).$$

Hence the inequality $\mathbb{P}\left(\frac{1}{n_1}\sum_{t=1}^{n_1}X_{1,t}<\frac{1}{n_2}\sum_{t=1}^{n_2}X_{2,t}\right)\leq\exp(nG(\lambda^*))$ concludes the proof.

G.3 Proof of Theorem 17

First, with Δ_a as defined in the introduction, there exists one arm $a\in\{1,\dots,K\}$ such that $\mathbb{E}_\nu[N_a(t)]\leq 2\sigma^2t/(H(\nu)\Delta_a^2)$. Otherwise, a contradiction is easily obtained.

Case 1 If $a\in\{1,\dots m\}$ there exists $b\in\{m+1,\dots K\}$ such that $\mathbb{E}_\nu[N_b(t)]\leq\frac{2\sigma^2t}{H^-(\nu)\Delta_b^2}$.

Case 2 If $a\in\{m+1,\dots K\}$ there exists $b\in\{1,\dots,m\}$ such that $\mathbb{E}_\nu[N_b(t)]\leq\frac{2\sigma^2t}{H^+(\nu)\Delta_b^2}$.

These two cases are very similar, and the idea is to propose an easier alternative model in which we change only arm a and b, the arms that are less drawn among the set of good and the set of bad arms. Assume that we are in Case 1. We introduce $\nu^{[a,b]}$ a Gaussian bandit model such that:

$$\begin{cases}\mu'_k &= \mu_k \text{ for all } k\notin\{a,b\}\\ \mu'_a &= \mu_a-2\Delta_b\\ \mu'_b &= \mu_b+2\Delta_a\end{cases}$$

In $\nu^{[a,b]}$ good arm a becomes a bad arm and bad arm b becomes a good arm. One can easily check (or convince oneself with Figure 4) that $H(\nu^{[a,b]})\leq H(\nu)$ and as already explained, ν and $\nu^{[a,b]}$ do not share their optimal arms. Thus Lemma 15 yields

$$\begin{aligned}\max\left(p_t(\nu),p_t(\nu^{[a,b]})\right) &\geq \frac{1}{4}\exp\left(-\left[\mathbb{E}_\nu[N_a(t)]\mathrm{KL}(\nu_a,\nu'_a))+\mathbb{E}_\nu[N_b(t)]\mathrm{KL}(\nu_b,\nu'_b)\right]\right)\\ &= \frac{1}{4}\exp\left(-\left[\mathbb{E}_\nu[N_a(t)]\frac{(2\Delta_a)^2}{2\sigma^2}+\mathbb{E}_\nu[N_b(t)]\frac{(2\Delta_b)^2}{2\sigma^2}\right]\right),\end{aligned}$$

thus

$$\begin{aligned}\max\left(p_t(\nu), p_t(\nu^{[a,b]})\right) &\geq \frac{1}{4}\exp\left(-\left[\frac{2\sigma^2 t}{H\Delta_a^2}\frac{4\Delta_a^2}{2\sigma^2}+\frac{2\sigma^2 t}{H^-\Delta_b^2}\frac{4\Delta_b^2}{2\sigma^2}\right]\right)\\ &= \frac{1}{4}\exp\left(-\frac{4t}{\tilde{H}}\right) \quad \text{with} \quad \tilde{H}=\frac{HH^-}{H+H^-}.\end{aligned}$$

Abstract

High-dimensional datasets are well-approximated by low-dimensional structures. Over the past decade, this empirical observation motivated the investigation of detection, measurement, and modeling techniques to exploit these low-dimensional intrinsic structures, yielding numerous implications for high-dimensional statistics, machine learning, and signal processing. Manifold learning (where the low-dimensional structure is a manifold) and dictionary learning (where the low-dimensional structure is the set of sparse linear combinations of vectors from a finite dictionary) are two prominent theoretical and computational frameworks in this area. Despite their ostensible distinction, the recently-introduced Geometric Multi-Resolution Analysis (GMRA) provides a robust, computationally efficient, multiscale procedure for simultaneously learning manifolds and dictionaries.

In this work, we prove non-asymptotic probabilistic bounds on the approximation error of GMRA for a rich class of data-generating statistical models that includes "noisy" manifolds, thereby establishing the theoretical robustness of the procedure and confirming empirical observations. In particular, if a dataset aggregates near a low-dimensional manifold, our results show that the approximation error of the GMRA is completely independent of the ambient dimension. Our work therefore establishes GMRA as a provably fast algorithm for dictionary learning with approximation and sparsity guarantees. We include several numerical experiments confirming these theoretical results, and our theoretical framework provides new tools for assessing the behavior of manifold learning and dictionary learning procedures on a large class of interesting models.

Keywords: dictionary learning, multi-resolution analysis, manifold learning, robustness, sparsity

1. Introduction

In many high-dimensional data analysis problems, existence of *efficient data representations* can dramatically boost the statistical performance and the computational efficiency of learning algorithms. Inversely, in the absence of efficient representations, the curse of dimensionality implies that required sample sizes must grow exponentially with the ambient dimension, which ostensibly renders many statistical learning tasks completely untenable. Parametric statistical modeling seeks to resolve this difficulty by restricting the family of candidate distributions for the data to a collection of probability measures indexed by a finite-dimensional parameter. By contrast, nonparametric statistical models are more flexible and oftentimes more precise, but usually require data samples of large sizes unless the data exhibits some simple latent structure (e.g., some form of sparsity). Such structural considerations are essential for establishing convergence rates, and oftentimes these structural considerations are geometric in nature.

One classical geometric assumption asserts that the data, modeled as a set of points in $\mathbb{R}^D$, in fact lies on (or perhaps very close to) *a single d-dimensional affine subspace* $V \in \mathbb{R}^D$ where $d \ll D$. Tools such as PCA (see Hotelling, 1933, 1936; Pearson, 1901) estimate V in a stable fashion under suitable assumptions. Generalizing this model, one may assert that the data lies on a union of several low-dimensional affine subspaces instead of just one, and in this case the estimation of the *multiple affine subspaces* from data samples already inspired intensive research due to its subtle complexity (e.g., see Chen and Lerman, 2009; Chen and Maggioni, 2011; Elhamifar and Vidal, 2009; Fischler and Bolles, 1981; Ho et al., 2003; Liu et al., 2010; Ma et al., 2007, 2008; Sugaya and Kanatani, 2004; Tipping and Bishop, 1999; Vidal et al., 2005; Yan and Pollefeys, 2006; Zhang et al., 2010). A widely used form of this model is that of k-sparse data, where there exists a dictionary (i.e., a collection of vectors) $\Phi = \{\varphi_i\}_{i=1}^m \subset \mathbb{R}^D$ such that each observed data point $x \in \mathbb{R}^d$ may be expressed as a linear combination of at most $k \ll D$ elements of Φ. These *sparse representations* offer great convenience and expressivity for signal processing tasks (such as in Peyré, 2009; Protter and Elad, 2007), compressive sensing, statistical estimation, and learning (e.g., see Aharon et al., 2006; Candes and Tao, 2007; Chen et al., 1998; Donoho, 2006; Kreutz-Delgado et al., 2003; Lewicki et al., 1998; Maurer and Pontil, 2010, among others), and even exhibits connections with representations in the visual cortex (see Olshausen and Field, 1997). In geometric terminology, such sparse representations are generally attainable when the local *intrinsic dimension* of the observations is small. For these applications, the dictionary is usually assumed to be known a priori, instead of being learned from the data, but it has been recognized in the past decade that data-dependent dictionaries may perform significantly better than generic dictionaries even in classical signal processing tasks.

The k-sparse data model motivates a large amount of research in dictionary learning, where Φ is learned from data rather than being fixed in advance: given n samples $X_1, \ldots, X_n$ from a probability distribution μ in $\mathbb{R}^D$ representing the training data, an algorithm "learns" a dictionary $\widehat{\Phi}$ which provides sparse representations for the observations sampled from μ. This problem and its optimal algorithmic solutions are far from being well-understood, at least compared to the understanding that we have for classical dictionaries such as Fourier, wavelets, curvelets, and shearlets. These dictionaries arise in computational harmonic analysis approaches to image processing, and Donoho (1999) (for example) provides rigorous,

optimal approximation results for simple classes of images. The work of Gribonval et al. (2013) present general bounds for the complexity of learning the dictionaries (see also Maurer and Pontil, 2010; Vainsencher et al., 2011, and references therein). The algorithms used in dictionary learning are often computationally demanding, and many of them are based on high-dimensional non-convex optimization (Mairal et al., 2010). The emphasis of existing work is often made on the generality of the approach, where minimal assumptions are made on geometry of the distribution from which the sample is generated. These "pessimistic" techniques incur bounds dependent upon the ambient dimension D in general (even in the standard case of data lying on one hyperplane).

A different type of geometric assumption on the data gives rise to manifold learning, where the observations aggregate on a *suitably regular manifold* $\mathcal{M}$ of dimension d isometrically embedded in $\mathbb{R}^D$ (notable works include Belkin and Niyogi, 2003; Coifman et al., 2005a,b; Coifman and Maggioni, 2006; Donoho and Grimes, 2002, 2003; Fefferman et al.; Genovese et al., 2012b; Jones et al., 2008, 2010; Little et al., 2012, 2009; Roweis and Saul, 2000; Tenenbaum et al., 2000; Zhang and Zha, 2002, among others). This setting has been recognized as useful in a variety of applications (e.g. Causevic et al., 2006; Coifman et al., 2006; Rahman et al., 2005), influencing work in the applied mathematics and machine learning communities during the past several years. It has also been recognized that in many cases the data does not naturally aggregate on a smooth manifold (as in Little et al., 2012, 2009; Wakin et al., 2005), with examples arising in imaging that contradict the smoothness conditions. While this phenomenon is not as widely recognized as it probably could be, we believe that it is crucial to develop methods (both for dictionary and manifold learning) that are robust not only to noise, but also to modeling error. Such concerns motivated the work on intrinsic dimension estimation of noisy data sets (see Little et al., 2012, 2009), where smoothness of the underlying distribution of the data is not assumed, but only certain natural conditions (possibly varying with the scale of the data) are imposed. The central idea of the aforementioned works is to perform the multiscale singular value decomposition (SVD) of the data, an approach inspired by the works of David and Semmes (1993) and Jones (1990) in classical geometric measure theory. These techniques were further extended in several directions in the papers by Chen and Maggioni (2011); Chen et al. (2011a,b), while Allard et al. (2012); Chen and Maggioni (2010) built upon this work to construct multiscale dictionaries for the data based on the idea of Geometric Multi-Resolution Analysis (GMRA).

Until these recent works introduced the GMRA construction, connections between dictionary learning and manifold learning had not garnered much attention in the literature. These papers showed that, for intrinsically low-dimensional data, one may perform dictionary learning very efficiently by exploiting the underlying geometry, thereby illuminating the relationship between manifold learning and dictionary learning. In these papers, it was demonstrated that, in the infinite sample limit and under a manifold model assumption for the distribution of the data (with mild regularity conditions for the manifold), the GMRA algorithm efficiently learns a dictionary in which the data admits sparse representations. More interestingly, the examples in that paper show that the GMRA construction succeeds on real-world data sets which do not admit a structure consistent with the smooth manifold modeling assumption, suggesting that the GMRA construction exhibits robustness to modeling error. This desirable behavior follows naturally from design decisions; GMRA

combines two elements that add stability: a multiscale decomposition and localized SVD. Similar ideas appeared in work applying dictionary learning to computer vision problems, for example in the paper by Yu et al. (2009), where local linear approximations are used to create dictionaries. These techniques appeared at roughly the same time as GMRA (Chen and Maggioni (2010)), but were not multiscale in nature, and the selection of the local scale is crucial in applications. These techniques also lacked any finite or infinite sample guarantees, nor considered the effect of noise. They were however successfully applied in computer vision problems, most notably in the Pascal 2007 challenge.

In this paper, we analyze the finite sample behavior of (a slightly modified version of) that construction, and prove strong finite-sample guarantees for its behavior under general conditions on the geometry of a probability distribution generating the data. In particular, we show that these conditions are satisfied when the probability distribution is concentrated "near" a manifold, which robustly accounts for noise and modeling errors. In contrast to the pessimistic bounds mentioned above, the bounds that we prove only depend on the "intrinsic dimension" of the data. It should be noted that our method of proof produces non-asymptotic bounds, and requires several explicit geometric arguments not previously available in the literature (at least to the best of our knowledge). Some of our geometric bounds could be of independent interest to the manifold learning community.

The GMRA construction is therefore proven to simultaneously "learn" manifolds (in sense that it outputs a suitably close approximation to points on a manifold) and dictionaries in which data are represented sparsely. Moreover, the construction is guaranteed to be robust with respect to noise and to the "perturbations" of the manifold model. The GMRA construction is fast, linear in the size of the data matrix, inherently online, does not require nonlinear optimization, and is not iterative. Finally, our results may be combined with recent GMRA compressed sensing techniques and algorithms presented in Iwen and Maggioni (2013), yielding both a method to learn a dictionary in a stable way on a finite set of training data, and a way of performing compressive sensing and reconstruction (with guarantees) from a small number of (suitable) linear projections (again without the need for expensive convex optimization).

This paper is organized as follows: Section 2 introduces the main definitions and notation employed throughout the paper. Section 3 explains the main contributions, formally states the results and provides comparison with existing literature. Finally, Sections 4 and 5 are devoted to the proofs of our main results, Theorem 2 and Theorem 7.

2. Geometric Multi-Resolution Analysis (GMRA)

This section describes the main results of the paper, starting in a somewhat informal form. The statements will be made precise in the course of the exposition. In the statements below, "$\gtrsim$" and "$\lesssim$" denote inequalities up to multiplicative constants and logarithmic factors.

Statement of results. *Let $\sigma \geq 0$ be a fixed small constant, and let $\varepsilon \gtrsim \sigma$ be given. Suppose that $n \gtrsim \varepsilon^{-(1+d/2)}$, and let $\mathcal{X}_n = \{X_1, \ldots, X_n\}$ be an i.i.d. sample from Π, a probability distribution with density supported in a tube of radius σ around a smooth closed*

d-dimensional manifold $\mathcal{M} \hookrightarrow \mathbb{R}^D$, with $d > 1$. There exists an algorithm that, given $\mathcal{X}_n$, outputs the following objects:

- *a dictionary $\widehat{\Phi}_\varepsilon = \{\widehat{\varphi}_i\}_{i \in \mathcal{J}_\varepsilon} \subset \mathbb{R}^D$;*
- *a nonlinear "encoding" operator $\widehat{\mathcal{D}}_\varepsilon : \mathbb{R}^D \to \mathbb{R}^{\mathcal{J}_\varepsilon}$ which takes $x \in \mathbb{R}^D$ and returns the coefficients of its approximation by the elements of $\widehat{\Phi}_\varepsilon$;*
- *a "decoding" operator $\widehat{\mathcal{D}}_\varepsilon^{-1} : \mathbb{R}^{\mathcal{J}_\varepsilon} \to \mathbb{R}^D$ which maps a sequence of coefficients to an element of $\mathbb{R}^D$.*

Moreover, the following properties hold with high probability:

i. $\mathrm{Card}(\mathcal{J}_\varepsilon) \lesssim \varepsilon^{-d/2}$;

ii. the image of $\widehat{\mathcal{D}}_\varepsilon$ is contained in the set $S_{d+1} \subset \mathbb{R}^{\mathcal{J}_\varepsilon}$ of all $(d+1)$ - sparse vectors (i.e., vectors with at most $d+1$ nonzero coordinates);

iii. the reconstruction error satisfies

$$\sup_{x \in \mathrm{support}(\Pi)} \|x - \widehat{\mathcal{D}}_\varepsilon^{-1} \widehat{\mathcal{D}}_\varepsilon(x)\| \lesssim \varepsilon;$$

iv. the time complexity for computing

- *$\widehat{\Phi}_\varepsilon$ is $O(C^d(D+d^2)\varepsilon^{-(1+\frac{d}{2})}\log(1/\varepsilon))$, where C is a universal constant;*
- *$\widehat{\mathcal{D}}_\varepsilon(x)$ is $O(d(D + d\log(1/\varepsilon)))$, and for $\widehat{\mathcal{D}}_\varepsilon^{-1}(x)$ is $O(d(D+\log(1/\varepsilon)))$.*

If a new observation X_{n+1} from Π becomes available, $\widehat{\Phi}_\varepsilon$ may be updated in time $O(C^d(D+d^2)\log(1/\varepsilon))$.

In other words, we can construct a data-dependent dictionary $\widehat{\Phi}_\varepsilon$ of cardinality $O(\varepsilon^{-d/2})$ by looking at $O(\varepsilon^{-1-\frac{d}{2}})$ data points drawn from Π, such that $\widehat{\Phi}_\varepsilon$ provides both $(d+1)$-sparse approximations to data and has expected "reconstruction error" of order ε (with high probability). Note that the cost of encoding the $(d+1)$ non-zero coefficients requires $O((d+1)\log(\mathrm{Card}(\mathcal{J}_\varepsilon))) = O(d^2\log(1/\epsilon))$. Moreover, the algorithm producing this dictionary is fast and can be quickly updated if new points become available. We want to emphasize that the complexity of our construction only depends on the desired accuracy ε, and is independent of the total number of samples (for example, it is enough to use only the first $\simeq \varepsilon^{-(1+d/2)}$ data points). Many existing techniques in dictionary learning cannot guarantee a requested accuracy, or a given sparsity, and a certain computational cost as a function of the two. Our results above completely characterize the tradeoffs between desired precision, dictionary size, sparsity, and computational complexity for our dictionary learning procedure.

We also remark that a suitable version of compressed sensing applies to the dictionary representations used in the theorem: we refer the reader to the work by Iwen and Maggioni (2013), and its applications to hyperspectral imaging by Chen et al. (2012).

2.1 Notation

For $v \in \mathbb{R}^D$, $\|v\|$ denotes the standard Euclidean norm in $\mathbb{R}^D$. $B_d(0,r)$ is the Euclidean ball in $\mathbb{R}^d$ of radius r centered at the origin, and we let $B(0,r) := B_D(0,r)$. Proj_V stands for the orthogonal projection onto a linear subspace $V \subseteq \mathbb{R}^D$, $\dim(V)$ for its dimension and $V^\perp$ for its orthogonal complement. For $x \in \mathbb{R}^D$, let Proj_{x+V} be the affine projection onto the affine subspace $x+V$ defined by $\mathrm{Proj}_{x+V}(y) = x + \mathrm{Proj}_V(y-x)$, for $y \in \mathbb{R}^D$.

Given a matrix $A \in \mathbb{R}^{k \times l}$, we write $A = [a_1|\cdots|a_l]$, where a_i stands for the ith column of A. The operator norm is denoted by $\|A\|$, the Frobenius norm by $\|A\|_F$ and the matrix transpose by A^T. If $k = l$, $\mathrm{tr}\,(A)$ denotes the trace. For $v \in \mathbb{R}^k$, let $\mathrm{diag}(v)$ be the $k \times k$ diagonal matrix with $(\mathrm{diag}(v))_{ii} = v_i,\ i = 1, \ldots, k$. Finally, we use $\mathrm{span}\{a_i\}_{i=1}^l$ to denote the linear span of the columns of A.

Given a C^2 function $f : \mathbb{R}^l \to \mathbb{R}^k$, let f_i denote the ith coordinate of the function f for $i = 1, \ldots k$, $Df(v)$ the Jacobian of f at $v \in \mathbb{R}^l$, and $D^2 f_i(v)$ the Hessian of the ith coordinate at v.

We shall use $d\mathrm{Vol}$ to denote Lebesgue measure on $\mathbb{R}^D$, and if $U \subset \mathbb{R}^D$ is Lebesgue measurable, $\mathrm{Vol}(U)$ stands for the Lebesgue measure of U. We will use $\mathrm{Vol}_{\mathcal{M}}$ to denote the volume measure on a d-dimensional manifold $\mathcal{M}$ in $\mathbb{R}^D$ (note that this coincides with the d-dimensional Hausdorff measure for the subset $\mathcal{M}$ of $\mathbb{R}^D$), $U_{\mathcal{M}}$ - the uniform distribution over $\mathcal{M}$, and $d_{\mathcal{M}}(x,y)$ to denote the geodesic distance between two points $x, y \in \mathcal{M}$. For a probability measure Π on $\mathbb{R}^D$, $\mathrm{supp}(\Pi) := \cap_{C \text{ closed}, \Pi(C)=1} C$ stands for its support. Finally, for $x, y \in \mathbb{R}$, $x \vee y := \max(x,y)$.

2.2 Definition of the Geometric Multi-Resolution Analysis (GMRA)

We assume that the data are identically, independently distributed samples from a Borel probability measure Π on $\mathbb{R}^D$. Let $1 \le d \le D$ be an integer. A GMRA with respect to the probability measure Π consists of a collection of (nonlinear) operators $\{P_j : \mathbb{R}^D \to \mathbb{R}^D\}_{j \ge 0}$. For each "resolution level" $j \ge 0$, P_j is uniquely defined by a collection of pairs of subsets and affine projections, $\{(C_{j,k}, P_{j,k})\}_{k=1}^{N(j)}$, where the subsets $\{C_{j,k}\}_{k=1}^{N(j)}$ form a measurable partition of $\mathbb{R}^D$ (that is, members of $\{C_{j,k}\}_{k=1}^{N(j)}$ are pairwise disjoint and the union of all members is $\mathbb{R}^D$). P_j is constructed by piecing together local affine projections. Namely, let

$$P_{j,k}(x) := c_{j,k} + \mathrm{Proj}_{V_{j,k}}(x - c_{j,k}),$$

where $c_{j,k} \in \mathbb{R}^D$ and $V_{j,k}$ are defined as follows. Let $\mathbb{E}_{j,k}$ stand for the expectation with respect to the conditional distribution $d\Pi_{j,k}(x) = d\Pi(x | x \in C_{j,k})$. Then

$$c_{j,k} = \mathbb{E}_{j,k} x, \tag{1}$$

$$V_{j,k} = \operatorname*{argmin}_{\dim(V)=d} \mathbb{E}_{j,k} \|x - c_{j,k} - \mathrm{Proj}_V(x - c_{j,k})\|^2, \tag{2}$$

where the minimum is taken over all linear spaces V of dimension d. In other words, $c_{j,k}$ is the conditional mean and $V_{j,k}$ is the subspace spanned by eigenvectors corresponding to d largest eigenvalues of the conditional covariance matrix

$$\Sigma_{j,k} = \mathbb{E}_{j,k}[(x - c_{j,k})(x - c_{j,k})^T]. \tag{3}$$

Note that we have implicitly assumed that such a subspace $V_{j,k}$ is unique, which will always be the case throughout this paper. Given such a $\{(C_{j,k}, P_{j,k})\}_{k=1}^{N(j)}$, we define

$$P_j(x) := \sum_{k=1}^{N(j)} I\{x \in C_{j,k}\} P_{j,k}(x)$$

where $I\{x \in C_{j,k}\}$ is the indicator function of the set $C_{j,k}$.

It was shown in the paper by Allard et al. (2012) that if Π is supported on a smooth, closed d-dimensional submanifold $\mathcal{M} \hookrightarrow \mathbb{R}^D$, and if the partitions $\{C_{j,k}\}_{j=1}^{N(j)}$ satisfy some regularity conditions for each j, then, for any $x \in \mathcal{M}$, $\|x - P_j(x)\| \leq C(\mathcal{M})2^{-2j}$ for all $j \geq j_0(\mathcal{M})$. This means that the operators P_j provide an efficient "compression scheme" $x \mapsto P_j(x)$ for $x \in \mathcal{M}$, in the sense that every x can be well-approximated by a linear combination of at most $d+1$ vectors from the dictionary $\Phi_{2^{-2j}}$ formed by $\{c_{j,k}\}_{k=1}^{N(j)}$ and the union of the bases of $V_{j,k},\ k = 1 \dots N(j)$. Furthermore, operators efficiently encoding the "difference" between P_j and P_{j+1} were constructed, leading to a multiscale compressible representation of $\mathcal{M}$.

In practice, Π is unknown and we only have access to the *training data* $\mathcal{X}_n = \{X_1, \dots, X_n\}$, which are assumed to be i.i.d. with distribution Π. In this case, operators P_j are replaced by their estimators

$$\widehat{P}_j(x) := \sum_{k=1}^{N(j)} I\{x \in C_{j,k}\} \widehat{P}_{j,k}(x)$$

where $\{C_{j,k}\}_{k=1}^{N(j)}$ is a suitable partition of $\mathbb{R}^D$ *obtained from the data*,

$$\begin{aligned} \widehat{P}_{j,k}(x) &:= \widehat{c}_{j,k} + \mathrm{Proj}_{\widehat{V}_{j,k}}(x - \widehat{c}_{j,k}), \\ \widehat{c}_{j,k} &:= \frac{1}{|\mathcal{X}_{j,k}|} \sum_{x \in \mathcal{X}_{j,k}} x, \\ \widehat{V}_{j,k} &:= \operatorname*{argmin}_{\dim(V)=d} \frac{1}{|\mathcal{X}_{j,k}|} \sum_{x \in \mathcal{X}_{j,k}} \|x - \widehat{c}_{j,k} - \mathrm{Proj}_V(x - \widehat{c}_{j,k})\|^2, \end{aligned} \tag{4}$$

$\mathcal{X}_{j,k} = C_{j,k} \cap \mathcal{X}_n$, and $|\mathcal{X}_{j,k}|$ denotes the number of elements in $\mathcal{X}_{j,k}$. We shall call these $\widehat{P}_j$ the *empirical GMRA*.

Moreover, the dictionary $\widehat{\Phi}_{2^{-2j}}$ is formed by $\{\hat{c}_{j,k}\}_{k=1}^{N(j)}$ and the union of bases of $\hat{V}_{j,k},\ k = 1 \dots N(j)$. The "encoding" and "decoding" operators $\widehat{\mathcal{D}}_{2^{-2j}}$ and $\widehat{\mathcal{D}}^{-1}_{2^{-2j}}$ mentioned above are now defined in the obvious way, so that $\widehat{\mathcal{D}}^{-1}_{2^{-2j}} \widehat{\mathcal{D}}_{2^{-2j}}(x) = \widehat{P}_{j,k}(x)$ for any $x \in C_{j,k}$.

We remark that the "intrinsic dimension" d is assumed to be known throughout this paper. In practice, it can be estimated within the GMRA construction using the "multiscale SVD" ideas of Little et al. (2012, 2009). The estimation technique is based on inspecting (for a given point $x \in C_{j,k}$) the behavior of the singular values of the covariance matrix $\Sigma_{j,k}$ as j varies. For alternative methods, see Camastra and Vinciarelli (2001); Levina and Bickel (2004) and references therein and in the review section of Little et al. (2012).

3. Main Results

Our main goal is to obtain *probabilistic*, non-asymptotic bounds on the performance of the *empirical* GMRA under certain structural assumptions on the underlying distribution of the data. In practice, the data rarely belongs precisely to a smooth low-dimensional submanifold. One way to relax this condition is to assume that it is "sufficiently close" to a reasonably regular set. Here we assume that the underlying distribution is supported in a thin tube around a manifold. We may interpret the displacement from the manifold as noise, in which case we are making no assumption on distribution of the noise besides boundedness. Another way to model this situation is to allow *additive noise*, whence the observations are assumed to be of the form $X = Y + \xi$, where Y belongs to a submanifold of $\mathbb{R}^D$, ξ is independent of Y, and the distribution of ξ is known. This leads to a singular deconvolution problem (see Genovese et al., 2012b; Koltchinskii, 2000). Our assumptions however may also be interpreted as relaxing the "manifold assumption": even in the absence of noise we do allow data to be not exactly supported on a manifold. Our results will elucidate how the error of sparse approximation via GMRA depends on the "thickness" of the tube, which quantifies stability and robustness properties of our algorithm.

As we mentioned before, our GMRA construction is entirely data-dependent: it takes the point cloud of cardinality n as an input and for every $j \in \mathbb{Z}_+$ returns the partition $\{C_{j,k}\}_{k=1}^{N(j)}$ and associated affine projectors $\widehat{P}_{j,k}$. We will measure performance of the empirical GMRA by the $L_2(\Pi)$-error

$$\mathbb{E}\left\|X - \widehat{P}_j(X)\right\|^2 := \int\limits_{\mathrm{supp}(\Pi)} \left\|x - \widehat{P}_j(x)\right\|^2 d\Pi(x) \tag{5}$$

or by the $\|\cdot\|_{\infty,\Pi}$-error defined as

$$\left\|\mathrm{Id} - \widehat{P}_j\right\|_{\infty,\Pi} := \sup_{x \in \mathrm{supp}(\Pi)} \left\|x - \widehat{P}_j(x)\right\|, \tag{6}$$

where $\widehat{P}_j$ is defined by (4). Note, in particular, that these errors are "out-of-sample", i.e. measure the accuracy of the GMRA representations on all possible samples, not just those used to train the GMRA, which would not correspond to a learning problem.

The presentation is structured as follows: we start from the natural decomposition

$$\left\|x - \widehat{P}_j(x)\right\| \leq \underbrace{\|x - P_j(x)\|}_{\text{approximation error}} + \underbrace{\left\|P_j(x) - \widehat{P}_j(x)\right\|}_{\text{random error}}$$

and state the general conditions on the underlying distribution and partition scheme that suffice to guarantee that

1. the distribution-dependent operators P_j yield good approximation, as measured by $\mathbb{E}\|x - P_j(x)\|^2$: this is the bias (squared) term, which is non-random;

2. the empirical version $\widehat{P}_j$ is with high probability close to P_j, so that $\mathbb{E}\left\|\widehat{P}_j(x) - P_j(x)\right\|^2$ is small (with high probability): this is the variance term, which is random.

This leads to our first result, Theorem 2, where the error $\mathbb{E}\left\|x-\widehat{P}_j(x)\right\|^2$ of the empirical GMRA is bounded with high probability.

We will state this first result in a rather general setting (assumptions A1-A4) below), and after developing this general result, we consider the special but important case where the distribution Π generating the data is supported in thin tube around a smooth submanifold, and for a (concrete, efficiently computable, online) partition scheme we show that the conditions of Theorem 2 are satisfied. This is summarized in the statement of Theorem 7, that may be interpreted as proving finite-sample bounds for our GMRA-based dictionary learning scheme for high-dimensional data that suitably concentrates around a manifold. It is important to note that most of the constants in our results are explicit. The only geometric parameters involved in the bounds are the dimension d of the manifold (but not the ambient dimension D), its *reach* (see τ in (9)) and the "tube thickness" σ.

Among the existing literature, the papers Allard et al. (2012); Chen et al. (2012) introduced the idea of using multiscale geometric decomposition of data to estimate the distribution of points sampled in high-dimensions. However in the first paper no finite sample analysis was performed, and in the second the connection with geometric properties of the distribution of the data is not made explicit, with the conditions are expressed in terms of certain approximation spaces within the space of probability distributions in $\mathbb{R}^D$, with Wasserstein metrics used to measure distances and approximation errors.

The recent paper by Canas et al. (2012) is close in scope to our work; its authors present probabilistic guarantees for approximating a manifold with a global solution of the so-called k-flats (Bradley and Mangasarian, 2000) problem in the case of distributions supported on manifolds. It is important to note, however, that our estimator is explicitly and efficiently computable, while exact global solution of k-flats is usually unavailable and certain approximations have to be used in practice, with convergence to a global minimum is conditioned on suitable unknown initializations. In practice it is often reported that there exist many local minima with very different values, and good initializations are not trivial to find. In this work we obtain better convergence rates, with fast algorithms, and we also seamlessly tackle the case of noise and model error, which is beyond what was studied previously. We consider this development extremely relevant in applications, both because real data is corrupted by noise and the assumption that data lies exactly on a smooth manifold is often unrealistic. A more detailed comparison of theoretical guarantees for k-flats and for our approach is given after we state the main results in Subsection 3.2 below.

Another body of literature connected to this work studies the complexity of dictionary learning. For example, Gribonval et al. (2013) present general bounds for the convergence of global minimums of empirical risks in dictionary learning optimization problems (those results build on and generalize the works of Maurer and Pontil (2010); Vainsencher et al. (2011), among several others). While the rates obtained in those works seem to be competitive with our rates in certain regimes, the fact that their bounds must hold over entire families of dictionaries implies that those error rates generally involve a scaling constant of the order $\sqrt{Dk}$, where D is the ambient dimension and k is the number of "atoms" in the dictionary. Our bounds are independent of the ambient dimension D but implicitly include terms which depend upon the number of our "atoms." It should be noted that the number

of atoms in the dictionary learned by GMRA increase so as to approximate the fine structure of a dataset with more precision. As such, our attainment of the minimax lower bounds for manifold estimation in the Hausdorff metric (obtained in (Genovese et al., 2012a)) should be expected. While dictionaries produced from dictionary learning should reveal the fine structure of a dataset through careful examination of the representations they induce, these representations are often ambiguous unless additional structure is imposed on both the dictionaries and the datasets. On the other hand, the GMRA construction induces completely unambiguous sparse representations that can be used in regression and classification tasks with confidence.

In the course of the proof, we obtain several results that should be of independent interest. In particular, Lemma 18 gives upper and lower bounds for the volume of the tube around a manifold in terms of the reach (7) and tube thickness. While the exact tubular volumes are given by Weyl's tube formula (see Gray, 2004), our bound are exceedingly easy to state in terms of simple global geometric parameters.

For the details on numerical implementation of GMRA and its modifications, see the works by Allard et al. (2012); Chen and Maggioni (2010).

3.1 Finite Sample Bounds for Empirical GMRA

In this section, we shall present the finite sample bounds for the empirical GMRA described above. For a fixed resolution level j, we first state sufficient conditions on the distribution Π and the partition $\{C_{j,k}\}_{k=1}^{N(j)}$ for which these $L_2(\Pi)$-error bounds hold (see Theorem 2 below).

Suppose that for all integers $j_{\min} \le j \le j_{\max}$ the following is true:

(A1) There exists an integer $1 \le d \le D$ and a positive constant $\theta_1 = \theta_1(\Pi)$ such that for all $k = 1, \dots, N(j)$,

$$\Pi(C_{j,k}) \ge \theta_1 2^{-jd}\,.$$

(A2) There is a positive constant $\theta_2 = \theta_2(\Pi)$ such that for all $k = 1, \dots, N(j)$, if X is drawn from $\Pi_{j,k}$ then, Π - almost surely,

$$\|X - c_{j,k}\| \le \theta_2 2^{-j}\,.$$

(A3) Let $\lambda_1^{j,k} \ge \ldots \ge \lambda_D^{j,k} \ge 0$ denote the eigenvalues of the covariance matrix $\Sigma_{j,k}$ (defined in (3)). Then there exist $\sigma = \sigma(\Pi) \ge 0$, $\theta_3 = \theta_3(\Pi)$, $\theta_4 = \theta_4(\Pi) > 0$, and some $\alpha > 0$ such that for all $k = 1 \dots N(j)$,

$$\lambda_d^{j,k} \ge \theta_3 \frac{2^{-2j}}{d} \quad \text{and} \quad \sum_{l=d+1}^{D} \lambda_l^{j,k} \le \theta_4(\sigma^2 + 2^{-2(1+\alpha)j}) \le \frac{1}{2}\lambda_d^{j,k}.$$

If in addition

(A4) There exists $\theta_5 = \theta_5(\Pi)$ such that

$$\|\mathrm{Id} - P_j\|_{\infty,\Pi} \le \theta_5 \left(\sigma + 2^{-(1+\alpha)j}\right),$$

then the bounds are also guaranteed to hold for the $\|\cdot\|_{\infty,\Pi}$-error (6).

Remark 1

i. *Assumption* (A1) *entails that the distribution assigns a reasonable amount of probability to each partition element, assumption* (A2) *ensures that samples from partition elements are always within a ball around the centroid, and assumption* (A3) *controls the effective dimensionality of the samples within each partition element. Assumption* (A4) *just assumes a bound on the error for the theoretical GMRA reconstruction.*

ii. *Note that the constants* $\theta_i,\ i = 1 \dots 4$, *are independent of the resolution level* j.

iii. *It is easy to see that Assumption (A3) implies a bound on the "local approximation error": since* P_j *acts on* $C_{j,k}$ *as an affine projection on the first* d *"principal components", we have*

$$\begin{aligned}\mathbb{E}_{j,k}\|x - P_j(x)\|^2 &= \operatorname{tr}\left[\mathbb{E}_{j,k}\left(x - c_{j,k} - \operatorname{Proj}_{V_{j,k}}(x)\right)(x - c_{j,k} - \operatorname{Proj}_{V_{j,k}}(x))^T\right] \\ &= \sum_{l=d+1}^{D} \lambda_l^{j,k} \le \theta_4(\sigma^2 + 2^{-2(1+\alpha)j}).\end{aligned}$$

iv. *The parameter* σ *is introduced to cover "noisy" models, including the situations when* Π *is supported in a thin tube of width* σ *around a low-dimensional manifold* $\mathcal{M}$. *Whenever* Π *is supported on a smooth* d*-dimensional manifold,* σ *can be taken to be* 0.

v. *The stipulation*

$$\theta_4(\sigma^2 + 2^{-2(1+\alpha)j}) \le \frac{1}{2}\lambda_d^{j,k}$$

guarantees that the spectral gap $\lambda_d^{j,k} - \lambda_{d+1}^{j,k}$ *is sufficiently large.*

We are in position to state our main result.

Theorem 2 *Suppose that* ***(A1)-(A3)*** *are satisfied, let* $X, X_1, \dots, X_n$ *be an i.i.d. sample from* Π, *and set* $\bar{d} := 4d^2\theta_2^4/\theta_3^2$. *Then for any* $j_{\min} \le j \le j_{\max}$ *and any* $t \ge 1$ *such that* $t + \log(\bar{d} \vee 8) \le \frac{1}{2}\theta_1 n 2^{-jd}$,

$$\mathbb{E}\|X - \widehat{P}_j(X)\|^2 \le 2\theta_4\left(\sigma^2 + 2^{-2j(1+\alpha)}\right) + c_1 2^{-2j}\frac{(t + \log(\bar{d} \vee 8))d^2}{n2^{-jd}},$$

and if in addition ***(A4)*** *is satisfied,*

$$\left\|\mathrm{Id} - \widehat{P}_j\right\|_{\infty,\Pi} \le \theta_5\left(\sigma + 2^{-(1+\alpha)j}\right) + \sqrt{\frac{c_1}{2}2^{-2j}\frac{(t + \log(\bar{d} \vee 8))d^2}{n2^{-jd}}}$$

with probability $\ge 1 - \frac{2^{jd+1}}{\theta_1}\left(e^{-t} + e^{-\frac{\theta_1}{16}n2^{-jd}}\right)$, *where* $c_1 = 2\left(12\sqrt{2}\frac{\theta_2^3}{\theta_3\sqrt{\theta_1}} + 4\sqrt{2}\frac{\theta_2}{d\sqrt{\theta_1}}\right)^2$.

3.2 Distributions Concentrated near Smooth Manifolds

Of course, the statement of Theorem 2 has little value unless assumptions **(A1)-(A4)** can be verified for a rich class of underlying distributions. We now introduce an important class of models and an algorithm to construct suitable partitions $\{C_{j,k}\}$ which together satisfy these assumptions. Let $\mathcal{M}$ be a smooth (or at least C^2, so changes of coordinate charts admit continuous second-order derivatives), closed d-dimensional submanifold of $\mathbb{R}^D$. We recall the definition of the *reach* (see Federer, 1959), an important global characteristic of $\mathcal{M}$. Let

$$D(\mathcal{M}) = \{y \in \mathbb{R}^D : \exists! x \in \mathcal{M} \text{ s.t. } \|x - y\| = \inf_{z\in\mathcal{M}}\|z - y\|\}, \tag{7}$$

$$\mathcal{M}_r = \{y \in \mathbb{R}^D : \inf_{x\in\mathcal{M}}\|x - y\| < r\}. \tag{8}$$

Then

$$\operatorname{reach}(\mathcal{M}) := \sup\{r \ge 0 :\ \mathcal{M}_r \subseteq D(\mathcal{M})\}, \tag{9}$$

and we shall always use τ to denote the reach of the manifold $\mathcal{M}$.

Definition 3 *Assume that* $0 \le \sigma < \tau$. *We shall say that the distribution* Π *satisfies the* $(\boldsymbol{\tau}, \boldsymbol{\sigma})$**-model assumption** *if there exists a smooth (or at least* C^2*), compact submanifold* $\mathcal{M} \hookrightarrow \mathbb{R}^D$ *with reach* τ *such that* $\operatorname{supp}(\Pi) = \mathcal{M}_\sigma$, Π *and* $\mathcal{U}_{\mathcal{M}_\sigma}$ *(the uniform distribution on* $\mathcal{M}_\sigma$*) are absolutely continuous with respect to each other, and so Radon-Nikodym derivative* $\frac{d\Pi}{dU_{\mathcal{M}_\sigma}}$ *satisfies*

$$0 < \phi_1 \le \frac{d\Pi}{d\mathcal{U}_{\mathcal{M}_\sigma}} \le \phi_2 < \infty \qquad \mathcal{U}_{\mathcal{M}_\sigma}\text{- almost surely.} \tag{10}$$

Example 1 *Consider the unit sphere of radius* R *in* $\mathbb{R}^D$, $\mathcal{S}_R$. *Then* $\tau = R$ *for this manifold, and for any* $\sigma < R$, *the uniform distribution on the set* $B(0, R + \sigma) \setminus B(0, R - \sigma)$ *satisfies the* (σ, τ)*-model assumption. On the other hand, taking the uniform distribution on a* σ*-thickening of the union of two line segments emanating from the origin produces a distribution which does not satisfy the* (σ, τ) *model assumption. In particular,* $\tau = 0$ *for the underlying manifold.*

Remark 4 *We will implicitly assume that constants* ϕ_1 *and* ϕ_2 *do not depend on the ambient dimension* D *(or depend on a slowly growing function of* D, *such as* $\log D$*) - the bound of Theorem 7 shows that this is the "interesting case". On the other hand, we often do not need the full power of* (τ, σ) *- model assumption, see the Remark 9 after Theorem 7.*

Our partitioning scheme is based on the data structure known as the *cover tree* introduced by Beygelzimer et al. (2006) (see also Ciaccia et al., 1997; Karger and Ruhl, 2002; Yianilos, 1993). We briefly recall its definition and basic properties. Given a set of n distinct points $S_n = \{x_1, \dots, x_n\}$ in some metric space (S, ρ), the cover tree T on S_n satisfies the following: let $T_j \subset S_n,\ j = 0, 1, 2, \dots$ be the set of nodes of T at level j. Then

1. $T_j \subset T_{j+1}$;

2. for all $y \in T_{j+1}$, there exists $z \in T_j$ such that $\rho(y,z) < 2^{-j}$;

3. for all $y, z \in T_j$, $\rho(y,z) > 2^{-j}$.

Remark 5 *Note that these properties imply the following: for any $y \in S_n$, there exists $z \in T_j$ such that $\rho(y,z) < 2^{-j+1}$.*

Theorem 3 in (Beygelzimer et al., 2006) shows that the cover tree always exists; for more details, see the aforementioned paper.

We will construct a cover tree for the collection $X_1, \ldots, X_n$ of i.i.d. samples from the distribution Π with respect to the Euclidean distance $\rho(x,y) := \|x-y\|$. Assume that $T_j := T_j(X_1, \ldots, X_n) = \{a_{j,k}\}_{k=1}^{N(j)}$. Define the indexing map

$$k(x) := \operatorname*{argmin}_{1 \le k \le N(j)} \|x - a_{j,k}\|$$

(ties are broken by choosing the smallest value of k), and partition $\mathbb{R}^D$ into the Voronoi regions

$$C_{j,k} = \{x \in \mathbb{R}^D : k_j(x) = k\}. \tag{11}$$

Let $\varepsilon(n,t)$ be the smallest $\varepsilon > 0$ which satisfies

$$n \ge \frac{1}{\phi_1} \left(\frac{\tau+\sigma}{\tau-\sigma}\right)^d \beta_1 \left(\log \beta_2 + t\right), \tag{12}$$

where $\beta_1 = \frac{\mathrm{Vol}_{\mathcal{M}}(\mathcal{M})}{\cos^d(\delta_1)\mathrm{Vol}(B_d(0,\varepsilon/4))}$, $\beta_2 = \frac{\mathrm{Vol}_{\mathcal{M}}(\mathcal{M})}{\cos^d(\delta_2)\mathrm{Vol}(B_d(0,\varepsilon/8))}$, $\delta_1 = \arcsin(\varepsilon/8\tau)$, and $\delta_2 = \arcsin(\varepsilon/16\tau)$.

Remark 6 *For large enough n, this requirement translates into $n \ge C(\mathcal{M}, d, \phi_1)\left(\frac{1}{\varepsilon}\right)^d \left(\log \frac{1}{\varepsilon} + t\right)$ for some constant $C(\mathcal{M}, d, \phi_1)$.*

We are ready to state the main result of this section.

Theorem 7 *Suppose that Π satisfies the (τ,σ)-model assumption. Let $X_1, \ldots, X_n$ be an i.i.d. sample from Π, construct a cover tree T from $\{X_i\}_{i=1}^n$, and define $C_{j,k}$ as in (11). Assume that $\varepsilon(n,t) < \sigma$. Then, for all $j \in \mathbb{Z}_+$ such that $2^{-j} > 8\sigma$ and $3 \cdot 2^{-j} + \sigma < \tau/8$, the partition $\{C_{j,k}\}_{k=1}^{N(j)}$ and Π satisfy **(A1)**, **(A2)**, **(A3)**, and **(A4)** with probability $\ge 1 - e^{-t}$*

for

$$\theta_1 = \frac{\phi_1 \mathrm{Vol}(B_d(0,1))}{2^{4d}\,\mathrm{Vol}_{\mathcal{M}}(\mathcal{M})}\left(\frac{\tau-\sigma}{\tau+\sigma}\right)^d,$$
$$\theta_2 = 12,$$
$$\theta_3 = \frac{\phi_1/\phi_2}{2^{4d+8}\left(1+\frac{\sigma}{\tau}\right)^d},$$
$$\theta_4 = 2 \vee \frac{2^3 3^4}{\tau^2},$$
$$\theta_5 = \left(2 \vee \frac{2^2 3^2}{\tau}\right)\left(1 + 3\cdot 2^5\sqrt{2d}\left(1+\frac{\sigma}{\tau}\right)^{d/2}\left(\frac{1+\left(\frac{25}{71}\right)^2}{1-\frac{1}{9\cdot 2^{12}}}\right)^{d/4}\right),$$
$$\alpha = 1.$$

One may combine the results of Theorem 7 and Theorem 2 as follows: given an i.i.d. sample $X_1, \ldots, X_n$ from Π, use the first $\lceil \frac{n}{2} \rceil$ points $\{X_1, \ldots, X_{\lceil \frac{n}{2} \rceil}\}$ to obtain the partition $\{C_{j,k}\}_{k=1}^{N(j)}$, while the remaining $\{X_{\lceil \frac{n}{2} \rceil + 1}, \ldots, X_n\}$ are used to construct the operator $\hat{P}_j$ (see (4)). This makes our GMRA construction entirely (cover tree, partitions, affine linear projections) data-dependent. We observe that since our approximations are piecewise linear, they are insensitive to regularity of the manifold beyond first order, so the estimates saturate at $\alpha = 1$.

When σ is very small or equal to 0, the bounds resulting from Theorem 2 can be "optimized" over j to get the following statement (we present only the bounds for the $L_2(\Pi)$ error, but the results $\|\cdot\|_{\infty,\Pi}$ are similar).

Corollary 8 *Assume that conditions of Theorem 7 hold, and that n is sufficiently large. Then for all $A \ge 1$ such that $A \log n \le c_4 n$, the following holds:*

(a) *if $d \in \{1,2\}$,*

$$\inf_{j \in \mathbb{Z}: 2^{-j} < \tau/24} \mathbb{E}\|x - \widehat{P}_j(x)\|^2 \le C_1 \left(\frac{\log n}{n}\right)^{\frac{2}{d}};$$

(b) *if $d \ge 3$,*

$$\inf_{j \in \mathbb{Z}: 2^{-j} < \tau/24} \mathbb{E}\|x - \widehat{P}_j(x)\|^2 \le C_2 \left(\frac{\log n}{n}\right)^{\frac{4}{d+2}} \tag{13}$$

with probability $\ge 1 - c_3 n^{-A}$, where C_1 and C_2 depend only on $A, \tau, d, \phi_1/\phi_2, \mathrm{Vol}_{\mathcal{M}}(\mathcal{M})$ and c_3, c_4 depend only on $\tau, d, \phi_1/\phi_2, \mathrm{Vol}_{\mathcal{M}}(\mathcal{M})$.

Proof In case (a), it is enough to set $t := (A+1)\log n$, $2^{-j} := \left(\frac{16t}{\theta_1 n}\right)^{1/d}$, and apply Theorem 2. For case (b), set $t := (A+1)\log n$ and $2^{-j} := \left(\frac{A \log n}{n}\right)^{\frac{1}{d+2}}$. ■

Finally, we note that the claims *ii.* and *iii.* stated in the beginning of Section 2 easily follow

from our general results (it is enough to choose n such that $\varepsilon \simeq n^{-\frac{2}{d+2}}$ and $2^{-j} = \sqrt{\varepsilon}$). Claim *i.* follows from assumption **(A1)** and Theorem 7. Computational complexity bounds *iv.* follow from the associated computational cost estimates for the cover trees algorithm and the randomized singular value decomposition, and are discussed in detail in Sections 3 and 8 of (Allard et al., 2012).

Remark 9 *It follows from our proof that it is sufficient to assume a weaker (but somewhat more technical) form of (τ, σ)-model condition for the conclusion of Theorem 7 to hold. Namely, let $\tilde{\Pi}$ be the pushforward of Π under the projection $\mathrm{Proj}_{\mathcal{M}} : \mathcal{M}_\sigma \to \mathcal{M}$, and assume that there exists $\tilde{\phi}_1 > 0$ such that for any measurable $A \subseteq \mathcal{M}$*

$$\tilde{\Pi}(A) := \Pi\left(\mathrm{Proj}_{\mathcal{M}}^{-1}(A)\right) \geq \tilde{\phi}_1 U_{\mathcal{M}}(A).$$

Moreover, suppose that there exists $\tilde{\phi}_2 > 0$ such that for any $y \in \mathcal{M}$, any set $A \subset \mathcal{M}_\sigma$ and any $\tau > r \geq 2\sigma$ such that $B(y,r) \cap \mathcal{M}_\sigma \subseteq A \subseteq B(y, 12r)$, we have

$$\Pi(A) \leq \tilde{\phi}_2 \mathcal{U}_{\mathcal{M}_\sigma}(A).$$

In some circumstances, checking these two conditions is not hard (e.g., when $\mathcal{M}$ is a sphere, Y is uniformly distributed on $\mathcal{M}$, η is spherically symmetric "noise" independent of Y and such that $\|\eta\| \leq \sigma$, and Π is the distribution of $Y + \eta$), but (τ, σ) - assumption does not need to hold with constants ϕ_1 and ϕ_2 independent of D.

3.3 Connections to Previous Work and Further Remarks

It is useful to compare our rates with results of Theorem 4 in (Canas et al., 2012). In particular, this theorem implies that, given a sample of size n from the Borel probability measure Π on the smooth d-dimensional manifold $\mathcal{M}$, the $L_2(\Pi)$-error of approximation of $\mathcal{M}$ by $k_n = C_1(\mathcal{M}, \Pi) n^{d/(2(d+4))}$ affine subspaces is bounded by $C_2(\mathcal{M}, \Pi) n^{-2/(d+4)}$. Here, the dependence of k_n on n is "optimal" in a sense that it minimizes the upper bound for the risk obtained in (Canas et al., 2012). If we set $\sigma = 0$ in our results, then it easily follows from Theorems 7 and 2 that the $L_2(\Pi)$-error achieved by our GMRA construction for $2^j \simeq n^{\frac{1}{2(d+4)}}$ (so that $N(j) \simeq k_n$ to make the results comparable) is of the same order $n^{-\frac{2}{d+4}}$. However, this choice of j is not optimal in this case - in particular, setting $2^{j_n} \simeq n^{\frac{1}{d+2}}$, we obtain as in (13) a $L_2(\Pi)$-error of order $n^{-\frac{2}{d+2}}$, which is a faster rate. Moreover, we also obtain results in the sup norm, and not only for mean square error. We should note that technically our results require the stronger condition (10) on the underlying measure Π, while theoretical guarantees in (Canas et al., 2012) are obtained assuming only the upper bound $\frac{d\Pi}{dU_{\mathcal{M}}} \leq \phi_2 < \infty$, where $U_{\mathcal{M}} := \frac{d\,\mathrm{Vol}_{\mathcal{M}}}{\mathrm{Vol}_{\mathcal{M}}(\mathcal{M})}$ is the uniform distribution over $\mathcal{M}$.

The rate (13) is the same (up to log-factors) as the minimax rate obtained for the problem considered in (Genovese et al., 2012a) of estimating a manifold from the samples corrupted with the additive noise that is "normal to the manifold". Our theorems are stated under more general conditions, however, we only prove *robustness-type* results and do not address the problem of *denoising*. At the same time, the estimator proposed in (Genovese et al., 2012a) is (unlike our method) not suitable for applications. The paper (Genovese et al., 2012b) considers (among other problems) the noiseless case of manifold estimation

under Hausdorff loss, and obtains the minimax rate of order $n^{-\frac{2}{d}}$. Performed numerical simulation (see Section 6) suggest that our construction also appears to achieve this rate in the noiseless case. However, our main focus is on the case $\sigma > 0$.

The work of Fefferman et al. establishes the sampling complexity of testing the hypothesis if an unknown distribution is close to being on a manifold (with known reach, volume, dimension) in the Mean Squared sense, is also related to the work discussed in this section, and to the present one. While our results do imply that if we have enough points, as prescribed by our main theorems, and the MSE does not decay as prescribed, then the data with high probability does not satisfy the geometric assumptions in the corresponding theorem, this is still different from the hypothesis testing problem. There may distributions not satisfying our assumptions, such that GMRA still yields good approximations: in fact we welcome and do not rule out these situations. Fefferman et al. also present an algorithm for constructing an approximation to the manifold; however such an algorithm does not seem easy to implement in practice. The emphasis in this work is on moving to a more general setting than the manifold setting, focusing on multiscale approaches that are robust (locally, because of SVD, as well as across scales), and fast, easily implementable algorithms.

We remark that we analyze the case of one manifold $\mathcal{M}$, and its "perturbation" in the sense of having a measure supported in a tube around $\mathcal{M}$. Our construction however is multiscale and in particular local. Many extensions are immediate, for example to the case of multiple manifolds (possibly of different dimensions) with non-intersecting tubes around them. The case of unbounded noise is also of interest: if the noise has sub-Gaussian tails then very few points are outside a tube of radius dependent on the sub-Gaussian moment, and these "outliers" are easily disregarded as there are few and far away, so they do not affect the construction and the analysis at fine scales. Another situation is when there are many gross outliers, for example points uniformly distributed in high-dimension in, say, a cube containing $\mathcal{M}$. But then the volume of such cube is so large that unless the number of points is huge (at least exponential in the ambient dimension D), almost all of these points are in fact far from each other and from $\mathcal{M}$ with very high probability, so that again they do affect the analysis and the algorithms. These are some of the advantages of the multiscale approach, which would otherwise have the potential of corrupting the results (or complicating the analysis of) other global algorithms, such as k-flats.

4. Preliminaries

This section contains the remaining definitions and preliminary technical facts that will be used in the proofs of our main results.

Given a point y on the manifold $\mathcal{M}$, let $T_y\mathcal{M}$ be the associated tangent space, and let $T_y^\perp \mathcal{M}$ be the orthogonal complement of $T_y\mathcal{M}$ in $\mathbb{R}^D$. We define the projection from the tube $\mathcal{M}_\sigma$ (see (8)) onto the manifold $\mathrm{Proj}_{\mathcal{M}} : \mathcal{M}_\sigma \to \mathcal{M}$ by

$$\mathrm{Proj}_{\mathcal{M}}(x) = \operatorname*{argmin}_{y \in \mathcal{M}} \|x - y\|$$

and note that $\sigma < \tau$, together with (7), implies that $\mathrm{Proj}_{\mathcal{M}}$ is well-defined on $\mathcal{M}_\sigma$, and

$$\mathrm{Proj}_{\mathcal{M}}(y + \xi) = y$$

whenever $y \in \mathcal{M}$ and $\xi \in T_y^\perp \mathcal{M} \cap B(0,\sigma)$.

Next, we recall some facts about the volumes of parallelotopes that will prove useful in Section 5. For a matrix $A \in \mathbb{R}^{k\times l}$ with $l \leq k$, we shall abuse our previous notation and let $\mathrm{Vol}(A)$ also denote the volume of the parallelotope formed by the columns of A. Let A and B be $k \times l_1$ and $k \times l_2$ matrices respectively with $l_1 + l_2 \leq k$, and note that

$$\mathrm{Vol}([A\,|\,B]) \leq \mathrm{Vol}(A)\mathrm{Vol}(B)$$

where $([A\,|\,B])$ denotes the concatenation of A and B into a $k \times (l_1 + l_2)$ matrix. Moreover, if the columns of A and B are all mutually orthogonal, we clearly have that $\mathrm{Vol}([A\,|\,B]) = \mathrm{Vol}(A)\mathrm{Vol}(B)$. Assuming that I is the $l_1 \times l_1$ identity matrix, we have the bound $\mathrm{Vol}\begin{pmatrix} A \\ I \end{pmatrix} \geq 1$. The following proposition gives volume bounds for specific types of perturbations that we shall encounter.

Proposition 10 *Suppose $Y = [y_1|\cdots|y_d]$ is symmetric d by d matrix such that $\|Y\| \leq q < 1$. Then*

$$\begin{aligned} \mathrm{Vol}\begin{pmatrix} I+Y \\ X \end{pmatrix} &\leq (1+q)^d \,\mathrm{Vol}\begin{pmatrix} I \\ X \end{pmatrix} \\ \mathrm{Vol}\begin{pmatrix} I+Y & X^T \\ X & -I \end{pmatrix} &\geq (1-q)^d \,\mathrm{Vol}\begin{pmatrix} I & X^T \\ X & -I \end{pmatrix}. \end{aligned}$$

This proof (as well as the proofs of our other supporting technical contributions) is given in the Appendix. Finally, let us recall several important geometric consequences involving the reach:

Proposition 11 *The following holds:*

i. For all $x, y \in \mathcal{M}$ such that $\|x - y\| \leq \tau/2$, we have

$$d_{\mathcal{M}}(x,y) \leq \tau - \tau\sqrt{1 - 2\frac{\|x-y\|}{\tau}} \leq 2\|x-y\|.$$

ii. Let $\gamma(t) : [0,1] \mapsto \mathcal{M}$ be the arclength-parameterized geodesic. Then $\|\gamma''(t)\| \leq \frac{1}{\tau}$ for all t.

iii. Let ϕ be the angle between $T_x\mathcal{M}$ and $T_y\mathcal{M}$, in other words,

$$\cos(\phi) := \min_{u\in T_x\mathcal{M}, \|u\|=1} \max_{v\in T_y\mathcal{M}, \|v\|=1} |\langle u, v\rangle|.$$

If $\|x-y\| \leq \frac{\tau}{2}$, then $\cos(\phi) \geq \sqrt{1 - 2\frac{\|x-y\|}{\tau}}$.

iv. If x is such that $\|x-y\| < \tau/2$, then x is a regular point of $\mathrm{Proj}_{y+T_y\mathcal{M}} : \mathcal{B}(y, \tau/2) \cap \mathcal{M} \to y + T_y\mathcal{M}$ (in other words, the Jacobian of $\mathrm{Proj}_{y+T_y\mathcal{M}}$ at x is nonsingular).

v. Let $y \in \mathcal{M}$, $r < \tau$ and $A = \mathcal{M} \cap B(y,r)$. Then

$$B_d(y, r\cos(\theta)) \subseteq \mathrm{Proj}_{y+T_y\mathcal{M}}(A),$$

where $\theta = \arcsin\left(\frac{r}{2\tau}\right)$.

Proof Part *i.* is the statement of Proposition 6.3 and part *ii.* - of Proposition 6.1 in (Niyogi et al., 2008). Part *iii.* is demonstrated in Lemma 5.4 of the same paper, and this lemma coincides with *iv.* Part *v.* is proven in Lemma 5.3 of (Niyogi et al., 2008). ■

5. Proofs of the Main Results

The rest of the paper is devoted to the proofs of our main results.

5.1 Overview of the Proofs

We begin by providing an overview of the main steps of the proofs to aid comprehension. The proof of Theorem 2 begins by invoking the bias-variance decomposition:

$$\|x - \widehat{P}_j(x)\|^2 \leq 2\|x - P_j(x)\|^2 + 2\|P_j(x) - \widehat{P}_j(x)\|^2.$$

Remark 1, part *iii.* and the decomposition

$$\mathbb{E}\|X - P_j(X)\|^2 = \sum_{k=1}^{N(j)} \Pi(C_{j,k})\mathbb{E}_{j,k}\|X - P_j(X)\|^2$$

gives us the first term in the bound of Theorem 2. Note that this contribution is deterministic.

The next step in the proof is to bound the stochastic error $\mathbb{E}\|P_j(x) - \widehat{P}_j(x)\|^2$ with high probability. We start with the bound

$$\begin{aligned} \|P_j(x) - \widehat{P}_j(x)\| &= \|c_{j,k} - \widehat{c}_{j,k} + \mathrm{Proj}_{V_{j,k}}(x - c_{j,k}) - \mathrm{Proj}_{\widehat{V}_{j,k}}(x - c_{j,k} + c_{j,k} - \widehat{c}_{j,k})\| \quad (14) \\ &\leq 2\|c_{j,k} - \widehat{c}_{j,k}\| + \|\mathrm{Proj}_{V_{j,k}} - \mathrm{Proj}_{\widehat{V}_{j,k}}\| \cdot \|x - c_{j,k}\|. \quad (15) \end{aligned}$$

for $x \in C_{j,k}$. We then use concentration of measure results (matrix Bernstein-type inequality) to bound the terms

$$\|c_{j,k} - \widehat{c}_{j,k}\| \text{ and } \left\|\widehat{\Sigma}_{j,k} - \Sigma_{j,k}\right\|$$

with high probability. The latter bound and Assumption **(A3)** allows us to invoke Theorem 14 to obtain a bound of the form

$$\|\mathrm{Proj}_{V_{j,k}} - \mathrm{Proj}_{\widehat{V}_{j,k}}\| \leq C\left\|\widehat{\Sigma}_{j,k} - \Sigma_{j,k}\right\|.$$

Finally, the term $\|x - c_{j,k}\|$ is controlled by Assumption **(A2)**.

The proof of Theorem 7 is primarily supported by a volume comparison theorem that allows for the cancellation of the "noisy" terms that would imply dependency on D. That is, supposing that $\mathrm{Proj}_{\mathcal{M}} : \mathcal{M}_\sigma \to \mathcal{M}$ is the projection from the σ-tubular neighborhood onto the underlying manifold with reach τ, if $U \subset \mathcal{M}$ is $\mathrm{Vol}_{\mathcal{M}}$-measurable with $\mathrm{Vol}_{\mathcal{M}}(U) > 0$, we have that

$$\left(1 - \frac{\sigma}{\tau}\right)^d \leq \frac{\mathrm{Vol}(\mathrm{Proj}_{\mathcal{M}}^{-1}(U))}{\mathrm{Vol}_{\mathcal{M}}(U)\mathrm{Vol}(B_{D-d}(0,\sigma))} \leq \left(1 + \frac{\sigma}{\tau}\right)^d.$$

This is encapsulated in Lemma 18. This allows us to relate probabilities on the tubular neighborhood with probabilities on the manifold itself, which only involve d-dimensional volumes.

The first thing that this allows us to do is to ensure that a sufficiently large sample from $\mathcal{U}_{\mathcal{M}_\sigma}$, $\{X_i\}_{i=1}^N$, has that $\{\mathrm{Proj}_{\mathcal{M}}(X_i)\}_{i=1}^N$ is an ε-net for $\mathcal{M}$. Running the cover tree algorithm at the appropriate scale and invoking the cover tree properties at this scale yields the constant for Assumption **(A2)**. Cover tree properties also ensure that each partition element contains a large enough portion of the tubular neighborhood, which we then relate to a portions of the manifold whose volume is comparable to d-dimensional Euclidean volumes. This approach provides the constant for Assumption **(A1)**. Finally, the constants from Assumption **(A3)** and **(A4)** are obtained from local moment estimates based upon these volume bounds.

Now, the volume comparison bounds themselves are proven by considering coordinate systems that locally invert orthogonal projections onto tangent spaces. The fact that the manifold has reach τ imposes bounds on the Jacobians and second-order terms for these local inversions. These bounds are ultimately used to bound volume distortions, and lead to the volume comparison result above.

5.2 Proof of Theorem 2

Assumption **(A3)** above controls the $L_2(\Pi)$ approximation error of $x \in M$ by $P_j(x)$ (see Remark 1, part *iii.*), hence we will concentrate on the stochastic error $\|\widehat{P}_j(x) - P_j(x)\|$. To this end, we will need to estimate $\|c_{j,k} - \widehat{c}_{j,k}\|$ and $\|\mathrm{Proj}_{V_{j,k}} - \mathrm{Proj}_{\widehat{V}_{j,k}}\|$, $k = 1 \dots N(j)$.

One of the main tools required to obtain this bound is the noncommutative Bernstein's inequality.

Theorem 12 *(Minsker, 2013, Theorem 2.1) Let $Z_1, \dots, Z_n \in \mathbb{R}^{D\times D}$ be a sequence of independent symmetric random matrices such that $\mathbb{E}Z_i = 0$ and $\|Z_i\| \le U$ a.s., $1 \le i \le n$. Let*

$$\sigma^2 := \left\| \sum_{i=1}^n \mathbb{E}Z_i^2 \right\|.$$

Then for any $t \ge 1$

$$\left\| \sum_{i=1}^n Z_i \right\| \le 2\max\left(\sigma\sqrt{t + \log(\bar{D})}, U(t + \log(\bar{D})) \right) \tag{16}$$

with probability $\ge 1 - e^{-t}$, where $\bar{D} := 4\frac{\mathrm{tr}\left(\sum_{i=1}^n \mathbb{E}Z_i^2\right)}{\sigma^2}$.

Note that we always have $\bar{D} \le 4D$. We use this inequality to estimate $\|\widehat{\Sigma}_{j,k} - \Sigma_{j,k}\|$: let $\Pi(dx|A)$ be the conditional distribution of X given that $X \in A$, and set $\Pi_{j,k}(dx) := \Pi(dx|C_{j,k})$. Let $m_{j,k} := \sum_{i=1}^n I\{X_i \in C_{j,k}\}$ to be the number of samples in $C_{j,k}$, $k = 1 \dots N(j)$. Let $I \subset \{1, \dots, n\}$ be such that $|I| = m$. Conditionally on the event $A_I := \{X_i \in C_{j,k} \text{ for } i \in I, \text{ and } X_i \notin C_{j,k} \text{ for } i \notin I\}$, the random variables $\{X_i,\ i \in I\}$ are independent with distribution $\Pi_{j,k}$. Then

$$\begin{aligned}\Pr\left(\left\|\widehat{\Sigma}_{j,k} - \Sigma_{j,k}\right\| \ge s \,|\, m_{j,k} = m \right) &= \sum_{I\subset\{1,\dots,n\}, |I|=m} \Pr\left(\left\|\widehat{\Sigma}_{j,k} - \Sigma_{j,k}\right\| \ge s \,|\, A_I \right) \frac{1}{\binom{n}{m}} \\ &= \Pr\left(\left\|\widehat{\Sigma}_{j,k} - \Sigma_{j,k}\right\| \ge s \,|\, A_{\{1,\dots,m\}} \right).\end{aligned} \tag{17}$$

To estimate $\Pr\left(\left\|\widehat{\Sigma}_{j,k} - \Sigma_{j,k}\right\| \ge s \,|\, A_{\{1,\dots,m\}} \right)$, we use the following inequality. Recall that

$$\bar{d} = 4d^2\frac{\theta_2^4}{\theta_3^2},$$

where θ_2, θ_3 are the constants in Assumptions **(A2)** and **(A3)**.

Lemma 13 *Let $X, X_1, \dots, X_m$ be an i.i.d. sample from $\Pi_{j,k}$. Set*

$$\widehat{c}_{j,k} = \frac{1}{m}\sum_{i=1}^m X_i \quad \text{and} \quad \widehat{\Sigma}_{j,k} := \frac{1}{m}\sum_{i=1}^m (X_i - \widehat{c}_{j,k})(X_i - \widehat{c}_{j,k})^T.$$

Assume that $m \ge t + \log(\bar{d} \vee 8)$. Then with probability $\ge 1 - 2e^{-t}$,

$$\left\|\widehat{\Sigma}_{j,k} - \Sigma_{j,k}\right\| \le 6r^2\sqrt{\frac{t + \log(\bar{d} \vee 8)}{m}}.$$

Proof We want to estimate

$$\begin{aligned}\left\|\widehat{\Sigma}_{j,k} - \Sigma_{j,k}\right\| &= \left\| \frac{1}{m}\sum_{i=1}^m (X_i - c_{j,k})(X_i - c_{j,k})^T - \Sigma_{j,k} + (c_{j,k} - \widehat{c}_{j,k})(c_{j,k} - \widehat{c}_{j,k})^T \right\| \\ &\le \left\| \frac{1}{m}\sum_{i=1}^m (X_i - c_{j,k})(X_i - c_{j,k})^T - \Sigma_{j,k} \right\| + \left\| (c_{j,k} - \widehat{c}_{j,k})(c_{j,k} - \widehat{c}_{j,k})^T \right\|.\end{aligned} \tag{18}$$

Set $r := \theta_2 \cdot 2^{-j}$. Recall that $\|x - c_{j,k}\| \le r$ for all $x, y \in C_{i,j}$ by assumption **(A2)**. It implies that

1. for all $1 \le i \le m$, $\|(X_i - c_{j,k})(X_i - c_{j,k})^T\| \le r^2$ almost surely,
2. $\left\|\mathbb{E}\left[(X_i - c_{j,k})(X_i - c_{j,k})^T\right]^2\right\| = \left\|\mathbb{E}\|X_i - c_{j,k}\|^2(X_i - c_{j,k})(X_i - c_{j,k})^T\right\| \le r^2\|\Sigma_{j,k}\|$.

Therefore, by Theorem 12 applied to $Z_i := \frac{1}{m}(X_i - c_{j,k})(X_i - c_{j,k})^T$, $i = 1 \dots m$,

$$\begin{aligned}\left\| \frac{1}{m}\sum_{i=1}^m (X_i - c_{j,k})(X_i - c_{j,k})^T - \Sigma_{j,k} \right\| &\le 2\left(r\sqrt{\frac{(t + \log(\bar{d}))\|\Sigma_{j,k}\|}{m}} \vee r^2\frac{t + \log(\bar{d})}{m} \right) \\ &= 2r^2\sqrt{\frac{(t + \log(\bar{d}))}{m}}\left(\sqrt{\frac{t + \log(\bar{d})}{m}} \vee \sqrt{\left\|\frac{\Sigma_{j,k}}{r^2}\right\|} \right)\end{aligned}$$

with probability $\geq 1 - e^{-t}$. Note that $\|\Sigma_{j,k}\| \leq \operatorname{tr}(\Sigma_{j,k}) \leq r^2$. Moreover,

$$\bar{D} = 4\frac{\operatorname{tr}(\mathbb{E}Z_1^2)}{\|\mathbb{E}Z_1^2\|} \leq 4\frac{\mathbb{E}(\operatorname{tr} Z_1)^2}{\left(\lambda_d^{j,k}\right)^2} \leq 4d^2\frac{r^4}{\theta_3^2 2^{-4j}} = 4d^2\frac{\theta_2^4}{\theta_3^2} = \bar{d}$$

by assumption **(A3)** and the definition of r. Since $\frac{t+\log(\bar{d})}{m} \leq 1$ by assumption,

$$\left\|\frac{1}{m}\sum_{i=1}^{m}(X_i - c_{j,k})(X_i - c_{j,k}) - \Sigma_{j,k}\right\| \leq 2r^2\sqrt{\frac{t+\log(\bar{d})}{m}}.$$

For the second term in (18), note that $\left\|(c_{j,k} - \widehat{c}_{j,k})(c_{j,k} - \widehat{c}_{j,k})^T\right\| = \|c_{j,k} - \widehat{c}_{j,k}\|^2$. We apply Theorem 12 to the symmetric matrices

$$G_i := \begin{pmatrix} 0 & (X_i - c_{j,k})^T \\ X_i - c_{j,k} & 0 \end{pmatrix}.$$

Noting that $\|G_i\| = \|X_i - c_{j,k}\| \leq r$ almost surely,

$$\|\mathbb{E}G_i^2\| = \mathbb{E}\|X_i - c_{j,k}\|^2 = \operatorname{tr}(\Sigma_{j,k}) \leq r^2,$$

and $\frac{\operatorname{tr}(\mathbb{E}G_i^2)}{\|\mathbb{E}G_i^2\|} = 2$, we get that for all t such that $t + \log 8 \leq m$, with probability $\geq 1 - e^{-t}$

$$\|\widehat{c}_{j,k} - c_{j,k}\| \leq 2\left[r\sqrt{\frac{(t+\log 8)}{m}} \vee r\frac{t+\log 8}{m}\right] \leq 2r\sqrt{\frac{t+\log 8}{m}}, \tag{19}$$

hence with the same probability

$$\left\|(c_{j,k} - \widehat{c}_{j,k})(c_{j,k} - \widehat{c}_{j,k})^T\right\| \leq 4r^2\frac{t+\log 8}{m},$$

and the claim follows. ∎

Given the previous result, we can estimate the angle between the eigenspaces of $\widehat{\Sigma}_{j,k}$ and $\Sigma_{j,k}$:

Theorem 14 *(Davis and Kahan, 1970), or (Zwald and Blanchard, 2006, Theorem 3).*
Let $\delta_d = \delta_d(\Sigma_{j,k}) := \frac{1}{2}(\lambda_d^{j,k} - \lambda_{d+1}^{j,k})$. If $\|\widehat{\Sigma}_{j,k} - \Sigma_{j,k}\| < \delta_d/2$, then

$$\left\|\operatorname{Proj}_{V_{j,k}} - \operatorname{Proj}_{\widehat{V}_{j,k}}\right\| \leq \frac{\|\widehat{\Sigma}_{j,k} - \Sigma_{j,k}\|}{\delta_d},$$

Since $\delta_d \geq \frac{\theta_3}{2\theta_2^2}\frac{r^2}{d}$ by assumption **(A3)**, the previous result implies that, conditionally on the event $\{m_{j,k} = m\}$, with probability $\geq 1 - 2e^{-t}$,

$$\left\|\operatorname{Proj}_{V_{j,k}} - \operatorname{Proj}_{\widehat{V}_{j,k}}\right\| \leq 12d\frac{\theta_2^2}{\theta_3}\sqrt{\frac{t+\log(\bar{d}\vee 8)}{m}}.$$

It remains to obtain the unconditional bound. Set $n_{j,k} := n\Pi(C_{j,k})$ and note that $n_{j,k} \geq \theta_1 n 2^{-jd}$ by assumption **(A1)**. To this end, we have

$$\begin{aligned}
&\Pr\left(\max_{k=1\dots N(j)}\left\|\operatorname{Proj}_{V_{j,k}} - \operatorname{Proj}_{\widehat{V}_{j,k}}\right\| \geq 12\frac{\theta_2^2}{\theta_3}\sqrt{\frac{(t+\log(\bar{d}\vee 8))d^2}{n_{j,k}/2}}\right) \\
&\leq \Pr\left(\max_{k=1\dots N(j)}\left\|\operatorname{Proj}_{V_{j,k}} - \operatorname{Proj}_{\widehat{V}_{j,k}}\right\| \geq 12\frac{\theta_2^2}{\theta_3}\sqrt{\frac{(t+\log(\bar{d}\vee 8))d^2}{n_{j,k}/2}}\,\middle|\, m_{j,k} \geq n_{j,k}/2,\ k = 1\dots N(j)\right) \\
&+ \Pr\left(\bigcup_{k=1}^{N(j)}\{m_{j,k} < n_{j,k}/2\}\right) \leq N(j)e^{-t} + \sum_{k=1}^{N(j)}\Pr\left(m_{j,k} < n_{j,k}/2\right).
\end{aligned}$$

Recall that $m_{j,k} = \sum_{i=1}^{n} I\{X_i \in C_{j,k}\}$, hence $\mathbb{E}m_{j,k} = n_{j,k}$ and $\operatorname{Var}(m_{j,k}) \leq n_{j,k}$. Bernstein's inequality (see Lemma 2.2.9 in van der Vaart and Wellner, 1996) implies that

$$|m_{j,k} - n_{j,k}| \leq \left(2\sqrt{sn_{j,k}} \vee \frac{4}{3}s\right)$$

with probability $\geq 1 - e^{-s}$. Choosing $s = \frac{n_{j,k}}{16}$, we deduce that $\Pr(m_{j,k} < n_{j,k}/2) \leq e^{-\frac{\theta_1}{16}n2^{-jd}}$, and, since $N(j) \leq \frac{1}{\theta_1}2^{jd}$ by assumption **(A1)**,

$$\sum_{k=1}^{N(j)}\Pr\left(m_{j,k} < n_{j,k}/2\right) \leq \frac{1}{\theta_1}2^{jd}e^{-\frac{\theta_1}{16}n2^{-jd}}$$

and

$$\Pr\left(\max_{k=1\dots N(j)}\left\|\operatorname{Proj}_{V_{j,k}} - \operatorname{Proj}_{\widehat{V}_{j,k}}\right\| \geq 12\frac{\theta_2^2}{\theta_3}\sqrt{\frac{(t+\log(\bar{d}\vee 8))d^2}{n_{j,k}/2}}\right) \leq \frac{2^{jd}}{\theta_1}\left(e^{-t} + e^{-\frac{\theta_1}{16}n2^{-jd}}\right) \tag{20}$$

A similar argument implies that

$$\Pr\left(\max_{k=1\dots N(j)}\|c_{j,k} - \widehat{c}_{j,k}\| \geq 2r\sqrt{\frac{t+\log(\bar{d}\vee 8)}{n_{j,k}/2}}\right) \leq \frac{2^{jd}}{\theta_1}\left(e^{-t} + e^{-\frac{\theta_1}{16}n2^{-jd}}\right). \tag{21}$$

We are in position to conclude the proof of Theorem 2. With assumption **(A2)**, (20), and (21), the initial bound (14) implies that, with high probability,

$$\|P_j(x) - \widehat{P}_j(x)\| \leq 4\sqrt{2}\frac{\theta_2}{\sqrt{\theta_1}}2^{-j}\sqrt{\frac{t+\log(\bar{d}\vee 8)}{n2^{-jd}}} + 12\sqrt{2}\frac{\theta_2^3}{\theta_3\sqrt{\theta_1}}2^{-j}\sqrt{\frac{(t+\log(\bar{d}\vee 8))d^2}{n2^{-jd}}}.$$

Combined with assumption **(A3)** (see Remark 1, part *iii.*), this yields the result.

5.3 Proof of Theorem 7

Recall that $\mathcal{M} \hookrightarrow \mathbb{R}^D$ is a smooth (or at least C^2) compact manifold without boundary, with reach τ, and equipped with the volume measure $d\mathrm{Vol}_{\mathcal{M}}$. Our proof is divided into several steps, and each of them is presented in a separate subsection to improve readability.

5.3.1 Local Inversions of the Projection

In this section, we introduce lemmas which ensure that (for $r < \tau/8$) the projection map $\text{Proj}_{y+T_y\mathcal{M}}$ is injective on $B(y,r) \cap \mathcal{M}$, and hence invertible by part *iv.* of Proposition 11. We also demonstrate that the derivatives of this inverse are bounded in a suitable sense. These estimates shall allow us to develop bounds on volumes in $\mathcal{M}_\sigma$.

We begin by proving a bound on the local deviation of the manifold from a tangent plane.

Lemma 15 *Suppose $\eta \in T_y^\perp\mathcal{M}$ with $\|\eta\| = 1$ and $z \in B(y,r) \cap \mathcal{M}$, where $r \leq \tau/2$. Then*

$$|\langle \eta, z - y \rangle| \leq \frac{2r^2}{\tau}$$

Our next lemma quantitatively establishes the local injectivity of the affine projections onto tangent spaces. [1]

Lemma 16 *Suppose $y \in \mathcal{M}$ and $r < \tau/8$. Then $\text{Proj}_{y+T_y\mathcal{M}} : B(y,r) \cap \mathcal{M} \to y + T_y\mathcal{M}$ is injective.*

There are two important conclusions that Lemma 16 provides. First of all, it indicates that, under a certain radius bound, the manifold does not "curve back" into particular regions. This is helpful when we begin to examine upper bounds on local volumes. More importantly, if we let $J_{y,r} = \text{Proj}_{y+T_y\mathcal{M}}(B(y,r) \cap \mathcal{M})$, then there is a well-defined inverse map f of $\text{Proj}_{y+T_y\mathcal{M}}$, $f : J_{y,r} \to B(y,r) \cap \mathcal{M}$, when $r < \tau/8$. Part *iv* of Proposition 11 implies that f is at least a C^2 function, and part *v* of Proposition 11 implies that there is a d-dimensional ball inside of $J_{y,r}$ of radius $\cos(\theta)r$, where $\theta = \arcsin(r/2\tau)$.

Whenever we refer to such an f, we think of $J_{y,r}$ as a subset in the span of the first d canonical directions, and we identify f with the value f takes in the span of the remaining $D - d$ directions. Thus, we identify f with the function whose graph is a small part of the manifold. Such an identification is obtained via an affine transformation, so we may do this without any loss of generality. Using these assumptions, we may prove the following bounds.

Proposition 17 *Let $\varepsilon < \tau/8$, and assume f is defined above so that $v \longmapsto \begin{pmatrix} v \\ f(v) \end{pmatrix}$ is the inverse of $\text{Proj}_{y+T_y\mathcal{M}}$ in $B(y,\varepsilon)$ for some $y \in \mathcal{M}$. Then*

$$\sup_{v \in B_d(0,\varepsilon)} \|Df(v)\| \leq \frac{2\varepsilon}{\tau - 2\varepsilon} \tag{22}$$

and

$$\sup_{v \in B_d(0,\varepsilon)} \sup_{u \in \mathcal{S}^{D-d-1}} \left\| \sum_{i=1}^{D-d-1} u_i D^2 f_i(v) \right\| \leq \frac{\tau^2}{(\tau - 2\varepsilon)^3}. \tag{23}$$

1. In an independent work, Eftekhari and Wakin (2013) prove a slightly stronger result that holds for $r < \tau/4$.

5.3.2 Volume Bounds

The main result of this section is Lemma 18, which allows us to compare volumes in $\mathcal{M}_\sigma$ with volumes in $\mathcal{M}$. It also establishes an upper bound on volumes, which is an essential ingredient when we control the conditional distribution of Π subject to being in a particular $C_{j,k}$. The form of the bounds also allows us to cancel out noisy terms that would make the estimates depend upon the ambient dimension D.

Lemma 18 *Suppose $\sigma < \tau$, suppose $U \subseteq \mathcal{M}$ is measurable, and define $P : \mathcal{M}_\sigma \to \mathcal{M}$ so that $x \mapsto \text{Proj}_{\mathcal{M}}(x)$ under P. Then*

i. $\left(1 - \frac{\sigma}{\tau}\right)^d \text{Vol}_{\mathcal{M}}(U)\text{Vol}(B_{D-d}(0,\sigma)) \leq \text{Vol}(P^{-1}(U)) \leq \left(1 + \frac{\sigma}{\tau}\right)^d \text{Vol}_{\mathcal{M}}(U)\text{Vol}(B_{D-d}(0,\sigma))$

ii. If $r + \sigma \leq \tau/8$, then

$$\text{Vol}(\mathcal{M}_\sigma \cap B(y,r)) \leq \left(1 + \frac{\sigma}{\tau}\right)^d \left(1 + \left(\frac{2(r+\sigma)}{\tau - 2(r+\sigma)}\right)^2\right)^{d/2} \text{Vol}(B_d(0, r+\sigma))\text{Vol}(B_{D-d}(0,\sigma)).$$

5.3.3 Absolute Continuity of the Pushforward of $U_{\mathcal{M}_\sigma}$, and Local Moments

Recall that $U_{\mathcal{M}_\sigma}$ is the uniform distribution over $\mathcal{M}_\sigma$, and let $U_{\mathcal{M}} := \frac{d\,\text{Vol}_{\mathcal{M}}}{\text{Vol}_{\mathcal{M}}(\mathcal{M})}$ be the uniform distribution over $\mathcal{M}$. In this section, we exploit the volume bounds of the previous subsection to obtain control over probabilities and local moments of $U_{\mathcal{M}_\sigma}$. Our first result allows us to get the lower bounds for $U_{\mathcal{M}_\sigma}$ that are independent of the ambient dimension D.

Lemma 19 *Suppose $\sigma < \tau$, and let $\widetilde{U}_{\mathcal{M}_\sigma}$ denote the pushforward of $U_{\mathcal{M}_\sigma}$ under $\text{Proj}_{\mathcal{M}}$. Then $\widetilde{U}_{\mathcal{M}_\sigma}$ and $U_{\mathcal{M}}$ are mutually absolutely continuous with respect to each other, and*

$$\left(\frac{\tau - \sigma}{\tau + \sigma}\right)^d \leq \frac{d\widetilde{U}_{\mathcal{M}_\sigma}}{dU_{\mathcal{M}}} \leq \left(\frac{\tau + \sigma}{\tau - \sigma}\right)^d.$$

Proof This is a straightforward consequence of part *i.* of Lemma 18. ■

The next lemma quantitatively establishes the the decay of the local eigenvalues required in the second part of Assumption **(A3)**.

Lemma 20 *Suppose Π is a distribution supported on $\mathcal{M}_\sigma$, and let $r < \tau/2$. Further assume that Z is the random variable drawn from Π conditioned on the event $Z \in Q$ where $\mathcal{M}_\sigma \cap Q \subset B(y,r)$ for some $y \in \mathcal{M}$. If Σ is the covariance matrix of Z, then*

$$\sum_{i=d+1}^{D} \lambda_i(\Sigma) \leq 2\sigma^2 + \frac{8r^4}{\tau^2},$$

where $\lambda_i(\Sigma)$ are the eigenvalues of Σ arranged in the decreasing order.

Finally, we derive a lower bound on the upper eigenvalues of the local covariance for the uniform distribution (needed to satisfy the first part of assumption **(A3)**). This is done in the following lemma.

Lemma 21 *Suppose that $Q \subseteq \mathbb{R}^D$ is such that*

$$B(y, r_1) \subseteq Q \text{ and } \mathcal{M}_\sigma \cap Q \subset B(y, r_2)$$

for some $y \in \mathcal{M}$ and $\sigma < r_1 < r_2 < \tau/8 - \sigma$. Let Z be drawn from $U_{\mathcal{M}_\sigma}$ conditioned on the event $Z \in Q$, and suppose Σ is the covariance matrix of Z. Then

$$\lambda_d(\Sigma) \geq \frac{1}{4\left(1+\frac{\sigma}{\tau}\right)^d}\left(\frac{r_1-\sigma}{r_2+\sigma}\right)^d \left(\frac{1-\left(\frac{r_1-\sigma}{2\tau}\right)^2}{1+\left(\frac{2(r_2+\sigma)}{\tau-2(r_2+\sigma)}\right)^2}\right)^{d/2} \frac{(r_1-\sigma)^2}{d}.$$

The following statement is key to establishing the error bounds for GMRA measured in sup-norm.

Lemma 22 *Assume that conditions of Lemma 21 hold, and let $V_d := V_d(\Sigma)$ be the subspace corresponding to the first d principal components of Z. Then*

$$\sup_{x\in Q} \|x - \mathbb{E}Z - \mathrm{Proj}_{V_d}(x - \mathbb{E}Z)\| \leq 2\sigma + \frac{4r_2^2}{\tau} + \frac{r_2}{r_1-\sigma}\sqrt{4\sigma^2 + \frac{16r_2^4}{\tau^2}}\,\gamma(\sigma,\tau,d,r_1,r_2),$$

where $\gamma(\sigma,\tau,d,r_1,r_2) = 4\sqrt{2d}\left(1+\frac{\sigma}{\tau}\right)^{d/2}\left(\frac{r_2+\sigma}{r_1-\sigma}\right)^{d/2}\left(\frac{1+\left(\frac{2(r_2+\sigma)}{\tau-2(r_2+\sigma)}\right)^2}{1-\left(\frac{r_1-\sigma}{2\tau}\right)^2}\right)^{d/4}$.

Notice that the term containing $\gamma(\sigma,\tau,d,r_1,r_2)$ is often of smaller order, so that the approximation is essentially controlled by the maximum of σ and $\frac{r_2^2}{\tau}$.

5.3.4 Putting all the Bounds Together

In this final subsection, we prove Theorem 7. We begin by translating Proposition 3.2 in (Niyogi et al., 2008) into our setting. As before, let $\mathcal{X}_n = \{X_1, \ldots, X_n\}$ be an i.i.d. sample from Π, and the ϕ_1 be the constant defined by (10).

Proposition 23 *(Niyogi et al., 2008, Proposition 3.2) Suppose $0 < \varepsilon < \frac{\tau}{2}$, and also that n and t satisfy*

$$n \geq \varepsilon^{-d}\frac{1}{\phi_1}\left(\frac{\tau+\sigma}{\tau-\sigma}\right)^d \beta_1\left(\log(\varepsilon^{-d}\beta_2) + t\right), \tag{24}$$

where $\beta_1 = \frac{\mathrm{Vol}_{\mathcal{M}}(\mathcal{M})}{\cos^d(\delta_1)\mathrm{Vol}(B_d(0,1/4))}$, $\beta_2 = \frac{\mathrm{Vol}_{\mathcal{M}}(\mathcal{M})}{\cos^d(\delta_2)\mathrm{Vol}(B_d(0,1/8))}$, $\delta_1 = \arcsin(\varepsilon/8\tau)$, and $\delta_2 = \arcsin(\varepsilon/16\tau)$. Let $\mathcal{E}_{\varepsilon/2,n}$ be the event that

$$\mathcal{Y} = \{Y_j = \mathrm{Proj}_{\mathcal{M}}(X_j)\}_{j=1}^n$$

is $\varepsilon/2$-dense in $\mathcal{M}$ (that is, $\mathcal{M} \subseteq \bigcup_{i=1}^n B(Y_i, \varepsilon/2)$). Then, $\Pi^n(\mathcal{E}_{\varepsilon,n}) \geq 1 - e^{-t}$, where Π^n is the n-fold product measure of Π.

Proof The proof closely follows the one given in (Niyogi et al., 2008). The only additional observation to make is that, if $\widetilde{\Pi}$ is the pushforward measure of Π under $\mathrm{Proj}_{\mathcal{M}} : \mathcal{M}_\sigma \to \mathcal{M}$, then

$$\begin{aligned}
\widetilde{\Pi}\left(\mathcal{M} \cap B(y, \varepsilon/8)\right) &= \Pi(\mathrm{Proj}_{\mathcal{M}}^{-1}(\mathcal{M} \cap B(y, \varepsilon/8))) \\
&\geq \phi_1 U_{\mathcal{M}_\sigma}(\mathrm{Proj}_{\mathcal{M}}^{-1}(\mathcal{M} \cap B(y, \varepsilon/8))) \\
&= \phi_1 \widetilde{U}_{\mathcal{M}_\sigma}(\mathcal{M} \cap B(y, \varepsilon/8)) \\
&\geq \phi_1 \left(\frac{\tau-\sigma}{\tau+\sigma}\right)^d U_{\mathcal{M}}(\mathcal{M} \cap B(y, \varepsilon/8)).
\end{aligned}$$

by Lemma 18. ∎

If $\varepsilon \ll \tau$, previous proposition implies that we roughly need $n \geq \mathrm{Const}(\mathcal{M}, d)\left(\frac{1}{\varepsilon}\right)^d \log\frac{1}{\varepsilon}$ points to get an ε-net for $\mathcal{M}$. For the remainder of this section, we identify $\varepsilon := \varepsilon(n,t)$ with the smallest $\varepsilon > 0$ satisfying (24) in the statement of Proposition 23, and we also assume that $\varepsilon < \sigma$. Take $j \in \mathbb{Z}_+$ such that

$$\sigma < 2^{-j-2} < \tau. \tag{25}$$

Let $C_{j,k}$ be the partition of $\mathbb{R}^D$ into Voronoi cells defined by (11). Recall that $T_j = \{a_{j,k}\}_{k=1}^{N(j)} \subset \mathcal{X}_n$ is the set of nodes of the cover tree at level j, and set $z_{j,k} = \mathrm{Proj}_{\mathcal{M}}(a_{j,k})$.

Lemma 24 *With probability $\geq 1 - e^{-t}$, for all j satisfying (25) and $k = 1, \ldots, N(j)$,*

$$B\left(z_{j,k}, 2^{-j-2}\right) \subseteq C_{j,k} \text{ and } C_{j,k} \cap \mathcal{M}_\sigma \subseteq B(a_{j,k}, 3\cdot 2^{-j-2} + 2^{-j+1}) \subseteq B(z_{j,k}, 3\cdot 2^{-j}). \tag{26}$$

We now use Lemma 24 to obtain bounds on the constants θ_i for $i = 1, \ldots, 4$ and α. We prove a lemma for each of the assumptions **(A1)**, **(A2)**, and **(A3)** and then collect them as the proof of Theorem 7.

Proof [Proof of Theorem 7] Since the hypotheses of Lemma 24 are satisfied with high probability, we first obtain

$$\begin{aligned}
\Pi(C_{j,k}) &\geq \Pi(B(z_{j,k}, 2^{-j-2})) \\
&\geq \phi_1 U_{\mathcal{M}_\sigma}(B(z_{j,k}, 2^{-j-2})) \\
&= \phi_1 \frac{\mathrm{Vol}(\mathcal{M}_\sigma \cap B(z_{j,k}, 2^{-j-2}))}{\mathrm{Vol}(\mathcal{M}_\sigma)} \\
&\geq \phi_1 \frac{\mathrm{Vol}(\mathrm{Proj}_{\mathcal{M}}^{-1}(\mathcal{M} \cap B(z_{j,k}, 2^{-j-2} - \sigma)))}{\mathrm{Vol}(\mathcal{M}_\sigma)} \\
&\geq \phi_1 \left(\frac{\tau-\sigma}{\tau+\sigma}\right)^d \frac{\cos(\delta)^d \mathrm{Vol}(B_d(0, 2^{-j-2} - \sigma))}{\mathrm{Vol}_{\mathcal{M}}(\mathcal{M})} \\
&\geq \frac{\phi_1 \mathrm{Vol}(B_d(0,1))}{2^{4d}\,\mathrm{Vol}_{\mathcal{M}}(\mathcal{M})}\left(\frac{\tau-\sigma}{\tau+\sigma}\right)^d 2^{-jd}.
\end{aligned}$$

where $\delta = \arcsin((2^{-j-2} - \sigma)/2\tau))$. Thus,

$$\theta_1 \geq \frac{\phi_1 \mathrm{Vol}(B_d(0,1))}{2^{4d}\,\mathrm{Vol}\,_{\mathcal{M}}(\mathcal{M})}\left(\frac{\tau-\sigma}{\tau+\sigma}\right)^d$$

Since the support is contained in a ball of radius $3 \cdot 2^{-j}$, we easily obtain that $\theta_2 \leq 12$. Finally, it is not difficult to deduce from Lemmas 20 and 21 that

$$\theta_3 \geq \frac{\phi_1/\phi_2}{2^{4d+8}\left(1+\frac{\sigma}{\tau}\right)^d},\ \theta_4 \leq \left(2 \vee \frac{2^3 3^4}{\tau^2}\right),\ \text{and } \alpha = 1.$$

Lemma 22 together with Lemma 24 imply that

$$\theta_5 \leq \left(2 \vee \frac{4\cdot 3^2}{\tau}\right)\left(1 + 3\cdot 2^5\sqrt{2d}\left(1+\frac{\sigma}{\tau}\right)^{d/2}\left(\frac{1+\left(\frac{25}{71}\right)^2}{1-\frac{1}{9\cdot 2^{12}}}\right)^{d/4}\right).$$

■

6. Numerical Experiments

In this section, we present some numerical experiments consistent with our results.

6.1 Spheres of Varying Dimension in $\mathbb{R}^D$

We consider n points $X_1, \ldots, X_n$ sampled i.i.d. from the uniform distribution on the unit sphere in $\mathbb{R}^{d+1}$

$$\mathcal{M} = \mathbb{S}^d := \{x \in \mathbb{R}^{d+1} : \|x\| = 1\}.$$

We then embed $\mathbb{S}^d$ into $\mathbb{R}^D$ for $D \in \{10, 100\}$ by applying a random orthogonal transformation $\mathbb{R}^{d+1} \to \mathbb{R}^D$. Of course, the actual realization of this projection is irrelevant since our construction is invariant under orthogonal transformations. After performing this embedding, we add two types of noise. In the first case, we add Gaussian noise ξ with distribution $\mathcal{N}(0, \frac{\sigma^2}{D} I_D)$: the scaling factor $\frac{1}{D}$ is chosen so that $\mathbb{E}\|\xi\|^2 = \sigma^2$. Since the norm of a Gaussian vector is tightly concentrated around its mean, this model is well-approximated by the "truncated Gaussian" model where the distribution of the additive noise is the same as the conditional distribution of ξ given $\|\xi\| \leq C\sigma$, where C is such that $C\sigma < 1$. In this case, the constants in $(1, C\sigma)$-model assumption would be prohibitively large, so instead we can verify the conditions given in Remark 9 directly: due to symmetry, we have that for any $A \subset \mathbb{S}^d$,

$$\Pi\left(\mathrm{Proj}\,_{\mathcal{M}}^{-1}(A)\right) = U_{\mathcal{M}}(A) = U_{\mathcal{M}_\sigma}\left(\mathrm{Proj}\,_{\mathcal{M}}^{-1}(A)\right). \tag{27}$$

On the other hand, it is a simple geometric exercise to show that, for any B such that $B(y,r) \cap \mathcal{M}_\sigma \subseteq B \subseteq B(y, 12r)$ and $\tau/2 = 1/2 > r \geq 2C\sigma$,

$$\mathrm{Proj}\,_{\mathcal{M}}^{-1}\left(\mathcal{M} \cap B(y, \tilde{r}_1)\right) \supseteq B \supseteq \mathrm{Proj}\,_{\mathcal{M}}^{-1}\left(\mathcal{M} \cap B(y, \tilde{r}_2)\right),$$

where $\tilde{r}_1 = \frac{r}{\sqrt{\frac{1+\sqrt{1-r^2}}{2}}}$ and $\tilde{r}_2 = r\sqrt{\frac{3}{4(1+C\sigma)}}$. Lemma 18 and (27) imply that

$$\begin{aligned}\Pi(B) &\leq U_{\mathcal{M}_\sigma}\left(\mathrm{Proj}\,_{\mathcal{M}}^{-1}\left(\mathcal{M} \cap B(y, \tilde{r}_1)\right)\right)\\ &\leq (1+C\sigma)^d\,\mathrm{Vol}\,_{\mathcal{M}}(\mathcal{M} \cap B(y, \tilde{r}_1))\frac{\mathrm{Vol}(B_{D-d}(0, C\sigma))}{\mathrm{Vol}(\mathcal{M}_{C\sigma})}\end{aligned}$$

and

$$\begin{aligned}U_{\mathcal{M}_\sigma}(B) &\geq U_{\mathcal{M}_\sigma}\left(\mathrm{Proj}\,_{\mathcal{M}}^{-1}\left(\mathcal{M} \cap B(y, \tilde{r}_2)\right)\right)\\ &\geq (1-C\sigma)^d\,\mathrm{Vol}\,_{\mathcal{M}}(\mathcal{M} \cap B(y, \tilde{r}_2))\frac{\mathrm{Vol}(B_{D-d}(0, C\sigma))}{\mathrm{Vol}(\mathcal{M}_{C\sigma})},\end{aligned}$$

hence $\Pi(B) \leq \tilde{\phi}_2 U_{\mathcal{M}_\sigma}(B)$ for some $\tilde{\phi}_2$ independent of the ambient dimension D.

We present the behavior of the $L^2(\Pi)$ error in this case in Figure 1, and the rate of approximation at the optimal scale as the number of samples varies in Figure 3, where it is compared to the rates obtained in Corollary 8. From Figure 1, we see that the approximations obtained satisfy our bound, and are typically better even for a modest number of samples in dimensions non-trivially low (e.g. 8000 samples on $\mathbb{S}^8$). In fact, the robustness with respect to sampling is such that the plots barely change from row to row.

The second type of noise is uniform in the radial direction, i.e. we let $\eta \sim \mathrm{Unif}[1-\sigma, 1+\sigma]$ and each noisy point is generated by $\tilde{X}_i = X_i + \eta_i \frac{X_i}{\|X_i\|}$. This is an example where the noise is not independent of X. Once again, it is easy to check directly that conditions of Remark 9 hold (the argument mimics the approach we used for the truncated Gaussian noise). Simulation results for this scenario are summarized in Figure 2, with the rate of approximation at the optimal scale again in Figure 3.

We considered various settings of the parameters, namely all combinations of: $d \in \{1,2,4,6,8\}$, $n \in \{8000, 16000, 32000, 64000, 128000\}$, $D \in \{100, 1000\}$, $\sigma \in \{0, 0.05, 0.1\}$. We only display some of the results for reasons of space constraints. [2]

6.2 Meyer's Staircase

We consider the (d-dimensional generalization of) Y. Meyer's staircase. Consider the cube $Q = [0,1]^d$ and the set of Gaussians $\mathcal{N}(x; \mu, \delta^2 I_d)$ where the mean μ is allowed to vary over Q, and the function is truncated to only accept arguments $x \in Q$. Varying μ in Q in this manner induces a smooth embedding of a d-dimensional manifold into the infinite dimensional Hilbert space $L^2(Q)$. That is, the Gaussian density centered at $\mu \in Q$ and truncated to $x \in Q$ is a point in $L^2(Q)$. By discretizing Q, we may sample this manifold and project it into a finite dimensional space. In particular, a grid $\Gamma_D \subseteq Q$ of D points (obtained by subdividing in $D^{-\frac{1}{d}}$ equal parts along each dimension) may be generated and considering the evaluations of the set of translated Gaussians on this grid produces an embedding of this manifold into $\mathbb{R}^D$. Sampling n points from this manifold by randomly drawing $\mu_1, \ldots, \mu_n$ uniformly from Q, we obtain a set $\{\mathcal{N}(x; \mu_i, \delta^2 I_d)|_{\Gamma_D}\}_{i=1,\ldots,n}$ of n samples from the "discretized" Meyer's staircase in $\mathbb{R}^D$. This is what we call a sample from Meyer's

2. The code provided at `www.math.duke.edu/~mauro/code.html` can generate all the figures, re-create the data sets, and is easily modified to do more experiments.

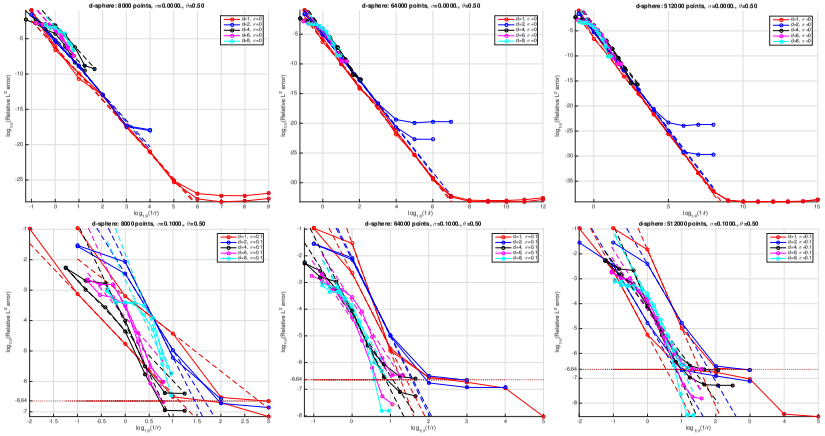

Figure 1: Experiment with $\mathbb{S}^d$, without (top row) and with Gaussian noise (bottom row). The columns correspond to different values of $n \in \{8000, 64000, 512000\}$. In the plots the dots represent the $L^2(\Pi)$ error squared (or MSE) of GMRA approximations (see (5)) as a function of the radius r at scale j; more precisely the abscissa is in terms of $\log_2(1/r_j)$, where r_j is the mean radius of $C_{j,k}$ for a fixed j, and the ordinate is $\log_2 \mathrm{MSE}_j$, where MSE_j is the mean squared error of the GMRA approximation at scale j. Different colors correspond to different intrinsic dimensions d (see legend). The two cases $D = 10, 100$ use the same colors for both the dots and the lines, all of which are essentially superimposed since our results are independent of the ambient dimension D. For each dimension we fit a line to measure the decay, which is $O(r^{-4})$ independently of d, consistently with our analysis. The horizontal dotted line, with corresponding tick mark on the Y axis, represents the noise level σ^2: the approximation error flattens out at roughly that level, as expected.

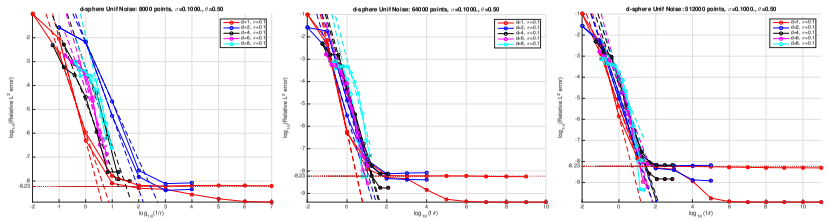

Figure 2: This figure is as the second row of Figure 1, but the noise is radially uniform with width parameter σ. Note that the variance of the noise is $\sigma^2/3$, which is indicated in the figure by horizontal line and an extra tick mark on the Y-axis in the figures. The MSE converges quickly to that level as a function of scale.

staircase, which is illustrated in Figure 4. This example is not artificial: for example, translating a white shape on a black background produces a set of $2 - D$ images with a similar structure to the d-dimensional Meyer's staircase for $d = 2$.

The manifold associated with Meyer's staircase is poorly approximated by subspaces of dimension smaller than $O(D \wedge 1/\delta^D)$, and besides spanning many dimensions in $\mathbb{R}^D$, it has a small reach, depending on d, D, δ. In our examples we considered

$$n = 8000, 16000, 32000, 640000, 128000, \ d = 1, 2, 4, \ D = 2000, \ \text{and } \delta = \frac{5}{100}.$$

We consider the noiseless case, as well as the case where Gaussian noise $\mathcal{N}(0, \frac{1}{D} I_D)$ is added to the data. Since this type of noise does not abide by the (σ, τ)-model assumption and τ is very small for Meyer's staircase, Figure 5 illustrates the behavior of the GMRA approximation outside of the regime where our theory is applicable.

6.3 The MNIST Dataset of Handwritten Digits

We consider the MNIST data set of images of handwritten digits[3], each of size 28×28, grayscale. There are total of $60,000$, from ten classes consisting of digits $0, 1, \ldots, 9$. The intrinsic dimension of this data set is variable across the data, perhaps because different digits have a different number of "degrees of freedom" and across scales, as it is observed in Little et al. (2012). We run GMRA by setting the cover tree scaling parameter θ equal to 0.9 (meaning that we replace $1/2$ with 0.9 in definition of cover trees in section 3.2) in order to slowly "zoom" into the data at multiple scales. As the intrinsic dimension is not well-defined, we set GMRA to pick the dimension of the planes $\mathbb{V}_{j,k}$ adaptively, as the smallest dimension needed to capture half of the "energy" of the data in $C_{j,k}$. The distribution of dimensions of the subspaces $\mathbb{V}_{j,k}$ has median 3 (consistently with the estimates in Little et al. (2012)) and is represented in figure 6. We then compute the L^2 relative approximation error, and compute various quantiles: this is reported in the same figure. The running time on a desktop was few minutes.

3. Available at `http://yann.lecun.com/exdb/mnist/`.

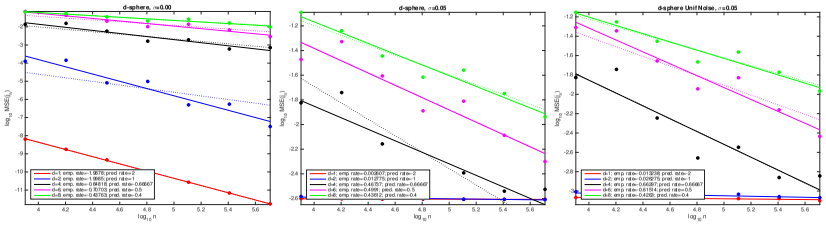

Figure 3: For the example of $\mathbb{S}^d$ considered in this section we consider the MSE error, i.e. $L^2(\Pi)$ squared error (as defined in (5)) at the optimal scale j_n (as in the proof of Corollary 8) as a function of the number of points $n \in \{8000, 16000, 32000, 64000, 128000, 256000, 512000\}$, and compare our empirical rates (solid linear, with the rate reported in the legend under "emp. rate") with the rates predicted by Corollary 8 (dotted lines, with rate reported in the legend under "pred. rate"), for various choices of the intrinsic dimension $d \in \{1, 2, 4, 6, 8\}$ and fixed ambient dimension $D = 10$ (the results are independent of D, so we do note report the - very similar - results obtained for $D = 100$). Left: noiseless case, middle: Gaussian noise, right: radial uniform noise (see text). The rates match our results quite well, except in the case $d = 2$ where we seem to obtain the same convergence rate as in the $d = 1$ case. Here we are choosing the optimal scale to be the finest scale such that, in every cell, we have at least $10d^2$ points. For the noisy cases, the approximation rates for $d = 1, 2$ are not meaningful simply because we have enough points to go the finest scale above the noise level.

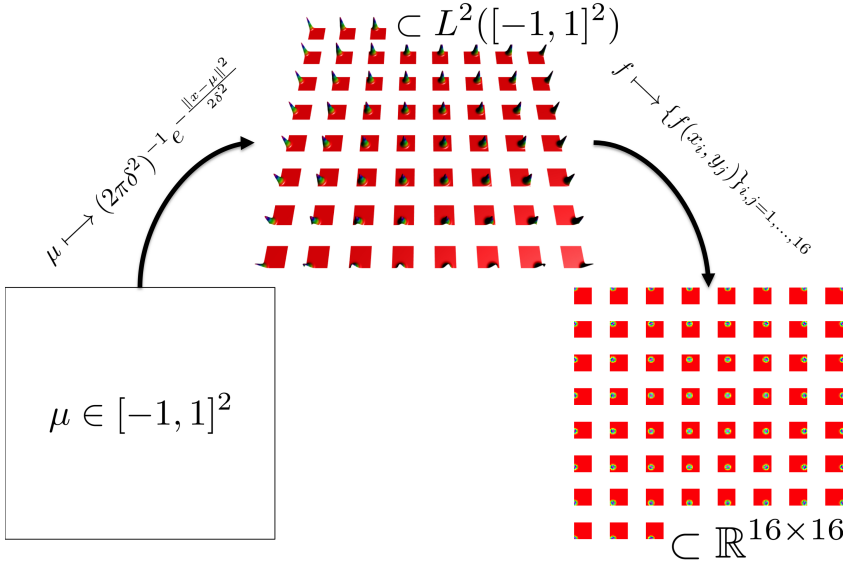

Figure 4: An illustration of Meyer's staircase for $d = 2$. We see that the square is mapped into a subset of $L^2([-1, 1]^2)$ consisting of truncated Gaussians. These are then sampled at points on a uniform, 16 by 16 grid to obtain an embedding of $[0, 1]^2$ into $\mathbb{R}^{16\times 16}$. For small δ, this embedding has a point very close to each coordinate axis in $\mathbb{R}^{16\times 16}$. Thus, it comes as no surprise that this embedding of $[-1, 1]^2$ into $\mathbb{R}^{256}$ has a high degree of curvature.

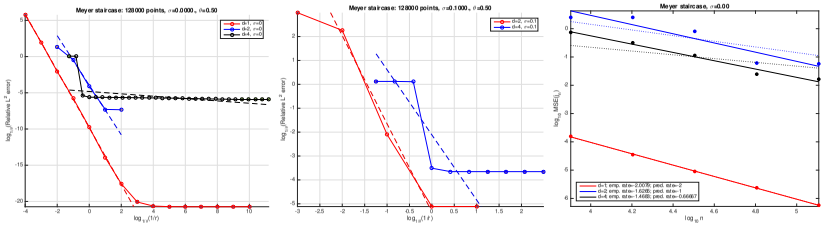

Figure 5: Left and middle: MSE as a function of scale r for the d-dimensional Meyer's staircase, for different values of $n =$, d and σ, standard deviation of Gaussian noise $\mathcal{N}(0, \frac{\sigma^2}{D})$. The small reach of Meyer's staircase makes it harder to approximate, and makes the approximation much more susceptible to noise. Moreover, Gaussian noise is unbounded, so this distribution violates the (σ, τ)-model assumption (albeit only at a small number of points, with high probability). Right: MSE at the optimal scale, chosen so that every cell contains at least $10d^2$ points.

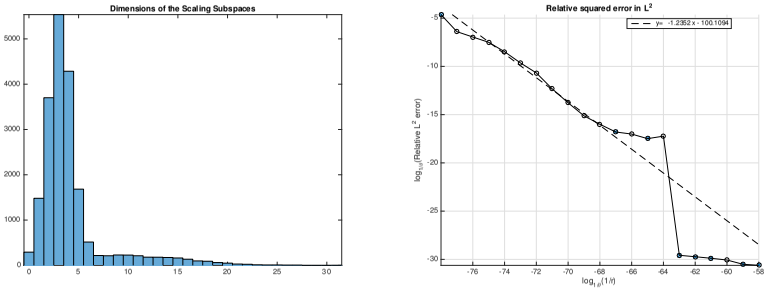

Figure 6: Left: histogram of the dimension of the scaling function subspaces for the MNIST data set. We see that many of the subspaces are very low-dimensional, with dimensions mostly between 2 and 5. Right: L^2 relative approximation error squared as a function of scale. We do not plot the quantiles since many of them are many orders of magnitude smaller (which is a good thing in terms of approximation error), creating artifacts in the plots; they do indicate thought that the structure of the data is highly complex and not heterogeneous. Note that the axis of this plot are in $\log_{1/\theta}$ scale, where $\theta = 0.9$ is the cover tree scaling factor used in this example. Note how the approximation error decreases slowly at the beginning, as there are many classes, rather far from each other, so that it takes a few scales before GMRA starts focusing into each class, at which point the approximation error decreases more rapidly. This phenomenon does not happen uniformly over the data (figure not shown).

6.4 Sonata Kreutzer

We consider a recording of the first movement of the Sonata Kreutzer by L.V. Beethoven, played by Y. Pearlman (violin) and V. Ashkenazy (piano) (EMI recordings). The recording is stereo, sampled at 44.1kHz. We map it to mono by simply summing the two audio channels, and then we generate a high-dimensional dataset as follows. We consider windows of width w seconds, overlapping by δw seconds, and consider the samples in each such time window $[i\delta w, i\delta w + w)$ as a high-dimensional vector X_i', of dimension equal to the sampling rate times w. In our experiment we choose $w = 0.1$ seconds, $\delta w = 0.05$ seconds, and the resulting vectors X_i' are $D' = 551$-dimensional. Since Euclidean distances between the X_i' are far from being perceptually relevant, we transform each X_i' to its cepstrum (see Oppenheim and Schafer (1975)), remove the central low-pass frequency, and discard the symmetric part of the spectrum (the signal is real), obtaining X_i, a vector with $D = 275$ dimensions, and i ranges from 0 to about 130,000. The running time on a desktop was few minutes.

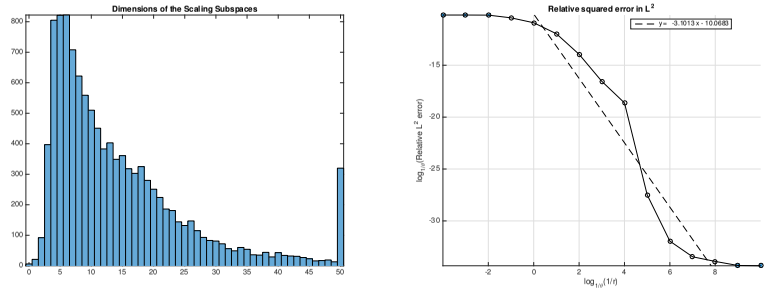

Figure 7: Left: histogram of the dimension of the scaling function subspaces for the Kreutzer sonata dataset. We see that the dimension of the scaling function subspaces is mostly between 4 and 25. Right: mean L^2 relative approximation error squared as a function of scale. We do not plot the quantiles since many of them are many orders of magnitude smaller (which is a good thing in terms of approximation error), creating artifacts in the plots; they do indicate that the structure of the data is highly complex and non-heterogeneous. Note that the axes of this plot are in $\log_{1/\theta}$ scale, where $\theta = 0.9$ is the scaling factor used in this example.

Appendix: Proofs of Geometric Propositions and Lemmas

Proof [Proof of Proposition 10] For the first inequality, let

$$A = \begin{pmatrix} I \\ X \end{pmatrix} \text{ and } B = \begin{pmatrix} Y \\ 0 \end{pmatrix},$$

and for every $T \subset [d]$, we let V_T denote the volume of $\{a_i\}_{i\in T^c} \cup \{b_i\}_{i\in T}$, where a_i and b_i denote the ith columns of A and B respectively. By submultilinearity of the volume we have

$$\mathrm{Vol}(A+B) \leq \sum_{T\in 2^{[d]}} V_T,$$

where $2^{[d]} = \{S : S \subset \{1,\dots,d\}\}$. We now show that $V_T \leq q^{|T|}\mathrm{Vol}(A)$ for every $T \in 2^{[d]}$. The bound $\|Y\| \leq q$ implies $\|y_i\| \leq q$ for all $i = 1,\dots,d$, and so the fact that the volume is a submultiplicative function implies that

$$V_T \leq q^{|T|}\mathrm{Vol}(A_{T^c}).$$

On the other hand, letting $a_1^\perp$ be the orthogonal projection of a_1 onto $\mathrm{span}^\perp\{a_i\}_{i=2}^d$, we note that $\|a_1^\perp\| \geq 1$, and thus

$$\mathrm{Vol}(A_{\{1\}^c}) \leq \|a_1^\perp\|\mathrm{Vol}(A_{\{1\}^c}) = \mathrm{Vol}(A).$$

By induction and invariance of the volume under permutations, we see that $\mathrm{Vol}(A_{T^c}) \leq \mathrm{Vol}(A)$ for all $T \in 2^{[d]}$. Thus,

$$\mathrm{Vol}(A+B) \leq \sum_{T\in 2^{[d]}} q^{|T|}\mathrm{Vol}(A) = (1+q)^d\mathrm{Vol}(A).$$

For the second inequality, since Y is symmetric, we can represent it as $Y = F - G$ where F and G are symmetric positive semidefinite, $FG = GF = 0$, and $\|F\|, \|G\| \leq \|Y\|$. Indeed, if $Y = Q\Lambda Q^T$ is the eigenvalue decomposition of Y with $\Lambda = \mathrm{diag}(\lambda)$, set $\lambda_+ := (\max(0,\lambda_1),\dots,\max(0,\lambda_d))^T$, $\lambda_- := \lambda_+ - \lambda$, and define $F := Q\,\mathrm{diag}(\lambda_+)Q^T$, $G = Q\,\mathrm{diag}(\lambda_-)Q^T$.

Recall the *matrix determinant lemma*: let $T \in \mathbb{R}^{k\times k}$ be invertible, and let $U, V \in \mathbb{R}^{k\times l}$. Then

$$\mathrm{Vol}(T + UV^T) = \mathrm{Vol}(I + V^TT^{-1}U)\mathrm{Vol}(T).$$

Applying it in our case with $U = \begin{pmatrix} \sqrt{F} - \sqrt{G} \\ 0 \end{pmatrix}$, $V = \begin{pmatrix} \sqrt{F} + \sqrt{G} \\ 0 \end{pmatrix}$, and $T = \begin{pmatrix} I & X^T \\ X & -I \end{pmatrix}$, we have that

$$\mathrm{Vol}\begin{pmatrix} I+Y & X^T \\ X & -I \end{pmatrix} = \mathrm{Vol}\left(I + \begin{pmatrix} \sqrt{F} + \sqrt{G} \\ 0 \end{pmatrix}^T \begin{pmatrix} I & X^T \\ X & -I \end{pmatrix}^{-1} \begin{pmatrix} \sqrt{F} - \sqrt{G} \\ 0 \end{pmatrix}\right) \mathrm{Vol}\begin{pmatrix} I & X^T \\ X & -I \end{pmatrix}.$$

By orthogonality of the columns in $\begin{pmatrix} I \\ X \end{pmatrix}$ with the columns in $\begin{pmatrix} X^T \\ -I \end{pmatrix}$, we have that

$$\left\|\begin{pmatrix} I & X^T \\ X & -I \end{pmatrix}\begin{pmatrix} u \\ v \end{pmatrix}\right\| \geq \left\|\begin{pmatrix} u \\ v \end{pmatrix}\right\|,$$

and hence

$$\left\|\begin{pmatrix} \sqrt{F} + \sqrt{G} \\ 0 \end{pmatrix}^T \begin{pmatrix} I & X^T \\ X & -I \end{pmatrix}^{-1} \begin{pmatrix} \sqrt{F} - \sqrt{G} \\ 0 \end{pmatrix}\right\| \leq \sqrt{q}\cdot 1 \cdot \sqrt{q} = q.$$

Therefore, we conclude that

$$\mathrm{Vol}\left(I + \begin{pmatrix} \sqrt{F} + \sqrt{G} \\ 0 \end{pmatrix}^T \begin{pmatrix} I & X^T \\ X & -I \end{pmatrix}^{-1} \begin{pmatrix} \sqrt{F} - \sqrt{G} \\ 0 \end{pmatrix}\right) \geq (1-q)^d,$$

and combining this with the expression from the matrix determinant lemma completes the proof. ■

Proof [Proof of Lemma 15] Let $\gamma : [0, d_{\mathcal{M}}(z,y)] \to \mathcal{M}$ denote the arclength-parameterized geodesic connecting y to z in $\mathcal{M}$. Since γ is a geodesic, there is a $v \in T_y\mathcal{M}$ with $\|v\| = 1$ such that the Taylor expansion

$$z = y + d_{\mathcal{M}}(z,y)v + \int_0^{d_{\mathcal{M}}(z,y)} \gamma''(t)\,(d_{\mathcal{M}}(z,y) - t)\,dt.$$

By Proposition 11, $\|\gamma''(t)\|_2 \leq 1/\tau$ for all t and $d_{\mathcal{M}}(z,y) \leq 2r$, so we have that

$$\begin{aligned} |\langle \eta, z-y\rangle| &= \left|\left\langle \eta, \int_0^{d_{\mathcal{M}}(z,y)} \gamma''(t)\,(d_{\mathcal{M}}(z,y)-t)\,dt\right\rangle\right| \\ &\leq \int_0^{d_{\mathcal{M}}(z,y)} |\langle \eta, \gamma''(t)\rangle|\,(d_{\mathcal{M}}(z,y)-t)\,dt \\ &\leq \frac{1}{\tau}\int_0^{d_{\mathcal{M}}(z,y)} (d_{\mathcal{M}}(z,y)-t)\,dt \\ &\leq \frac{d_{\mathcal{M}}(z,y)^2}{2\tau} \\ &\leq \frac{2r^2}{\tau}. \end{aligned}$$

■

Proof [Proof of Lemma 16] Suppose a and b are distinct in $B(y,r)\cap\mathcal{M}$. Now, $b-a = v+w$ where $v \in T_a\mathcal{M}$ and $w \in T_a^\perp\mathcal{M}$, and note that $\|w\| \leq \frac{2\|b-a\|^2}{\tau} \leq 4\frac{r}{\tau}$ by Lemma 15. This also implies that

$$\|v\| = \sqrt{\|a-b\|^2 - \|w\|^2} \geq \sqrt{\|a-b\|^2 - 4\frac{\|a-b\|^4}{\tau^2}} \geq \|a-b\|\sqrt{1-16\frac{r^2}{\tau^2}} \geq \|a-b\|\sqrt{1-4\frac{r}{\tau}}.$$

By part *iii.* of Proposition 11, there is a $u \in T_y\mathcal{M}$ such that $\langle u, v\rangle \geq \|v\|\cos(\phi)$ where ϕ is the angle between $T_y\mathcal{M}$ and $T_a\mathcal{M}$. Then

$$\begin{aligned}
|\langle u, b-a\rangle| &\geq |\langle u, v\rangle| - |\langle u, w\rangle| \\
&\geq \|v\|\cos(\phi) - \|w\| \\
&\geq \|a-b\|\sqrt{1-4\frac{r}{\tau}}\sqrt{1-2\frac{r}{\tau}} - 2\frac{\|a-b\|^2}{\tau} \\
&\geq \|b-a\|\left(\sqrt{1-4\frac{r}{\tau}}\sqrt{1-4\frac{r}{\tau}} - 4\frac{r}{\tau}\right) \\
&\geq \|b-a\|\left(1-8\frac{r}{\tau}\right).
\end{aligned}$$

It then follows from $r < \tau/8$ that $\text{Proj}_{T_y\mathcal{M}}(b-a) \neq 0$, and hence $\text{Proj}_{y+T_y\mathcal{M}}(a) \neq \text{Proj}_{y+T_y\mathcal{M}}(b)$ and injectivity holds. ■

Proof [Proof of Proposition 17] For $\varepsilon < \tau/8$, we may define the embedding

$$\begin{pmatrix} v \\ \beta \end{pmatrix} \longmapsto \begin{pmatrix} v \\ f(v) \end{pmatrix} + \begin{pmatrix} Df(v)^T \\ -I \end{pmatrix} \beta$$

where we have assumed (without loss of generality) that $y = 0$ and $T_y\mathcal{M}$ coincides with the span of the first d canonical orthonormal basis members. The domain of this map is the set

$$\Omega = \{(v,\beta) \in \mathbb{R}^d \times \mathbb{R}^{D-d} : v \in T_y\mathcal{M} \cap B(0,\varepsilon), \|\beta\|^2 + \|Df(v)^T\beta\|^2 < \tau^2\}$$

and the Jacobian of this map is

$$\begin{pmatrix} I + \sum_{i=1}^{D-d}\beta_i D^2 f_i(v) & Df(v)^T \\ Df(v) & -I \end{pmatrix}.$$

It is clear that the inverse of the above map is given by

$$x \longmapsto (\text{Proj}_{y+T_y\mathcal{M}}(\text{Proj}_{\mathcal{M}}(x)), \text{Proj}_{T_y^\perp\mathcal{M}}(x - \text{Proj}_{\mathcal{M}}(x))),$$

which is at least a C^1 map. Thus, a necessary condition for the τ-radius normal bundle to embed is that the Jacobian exhibited above is invertible, which in turn implies that

$$\begin{pmatrix} I + \sum_{i=1}^{D-d}\beta_i D^2 f_i(v) & Df(v)^T \\ Df(v) & -I \end{pmatrix}\begin{pmatrix} \zeta \\ Df(v)\zeta \end{pmatrix} \neq 0$$

for all $\zeta \neq 0$ when $(v,\beta) \in \Omega$. This reduces to $(I + \sum \beta_i D^2 f_i(v) + Df(v)^T Df(v))\zeta \neq 0$, and so a necessary condition for embedding is then that the norm of $\sum_{i=1}^{D-d}\beta_i D^2 f_i(v)$ does not exceed $1 + \|Df(v)\|^2$ whenever

$$\left\|\begin{pmatrix} Df(v)^T \\ -I \end{pmatrix}\beta\right\|^2 = \|\beta\|^2 + \|Df(v)^T\beta\|^2 < \tau^2.$$

In particular, this must be true if $\|\beta\| < \tau/\sqrt{1+\|Df(v)\|^2}$. This reduces to the condition that the operator norm

$$\sup_{u\in\mathcal{S}^{D-d-1}}\left\|\sum_{i=1}^{D-d} u_i D^2 f_i(v)\right\| < \frac{(1+\|Df(v)\|^2)^{3/2}}{\tau} < \frac{1}{\tau}\left(1+\|Df(v)\|\right)^3. \tag{28}$$

By the fundamental theorem of calculus, we have that

$$Df(v)x = Df(0)x + \int_0^{\|v\|}[u_v^T D^2 f_i(tu_v)x]dt = \int_0^{\|v\|}[u_v^T D^2 f_i(tu_v)x]dt,$$

where $u_v = v/\|v\|$ and $[u_v^T D^2 f_i(tu_v)x]$ indicates a vector with ith component $u_v^T D^2 f_i(tu_v)x$. Consequently, for any $x \in \mathbb{R}^d$, we have that

$$\begin{aligned}
\|Df(v)x\| &\leq \int_0^{\|v\|}\left\|[u_v^T D^2 f_i(tu_v)x]\right\| dt \leq \|v\| \sup_{t\in[0,\|v\|]}\left\|[u_v^T D^2 f_i(tu_v)x]\right\| \\
&\leq \varepsilon \sup_{t\in[0,\varepsilon]}\left\|[u_v^T D^2 f_i(tu_v)x]\right\|.
\end{aligned} \tag{29}$$

Now,

$$\begin{aligned}
\left\|[u_v^T D^2 f_i(tu_v)x]\right\| &= \sup_{u\in\mathcal{S}^{D-d-1}}\langle u, [u_v^T D^2 f_i(tu_v)x]\rangle = \sup_{u\in\mathcal{S}^{D-d-1}}\sum_{i=1}^{D-d} u_i(u_v^T D^2 f_i(tu_v)x) \\
&= \sup_{u\in\mathcal{S}^{D-d-1}} u_v^T\left(\sum_{i=1}^{D-d} u_i D^2 f_i(tu_v)\right)x \\
&\leq \sup_{u\in\mathcal{S}^{D-d-1}}\|u_v\|\left\|\sum_{i=1}^{D-d} u_i D^2 f_i(tu_v)\right\|\|x\| \\
&= \|x\|\sup_{u\in\mathcal{S}^{D-d-1}}\left\|\sum_{i=1}^{D-d} u_i D^2 f_i(tu_v)\right\|,
\end{aligned}$$

which together with (29) and (28) yields the bound

$$\|Df(v)\| < \frac{\varepsilon}{\tau}\left(1 + \sup_{t\in[0,\varepsilon]}\|Df(tu_v)\|\right)^3.$$

Since this inequality also holds for any v' with $\|v\| \leq \varepsilon'$, taking a supremum yields

$$\sup_{\varepsilon'\in[0,\varepsilon]}\|Df(tu_v)\| \leq \sup_{\varepsilon'\in[0,\varepsilon]}\frac{\varepsilon'}{\tau}\left(1+\sup_{t\in[0,\varepsilon']}\|Df(tu_v)\|\right)^3 \leq \frac{\varepsilon}{\tau}\left(1+\sup_{\varepsilon'\in[0,\varepsilon]}\|Df(tu_v)\|\right)^3,$$

and hence

$$\sup_{v\in B_d(0,\varepsilon)}\|Df(v)\| \leq \frac{\varepsilon}{\tau}\left(1+\sup_{v\in B_d(0,\varepsilon)}\|Df(v)\|\right)^3.$$

Setting $a(\varepsilon') = \sup_{v \in B_d(0,\varepsilon')} \|Df(v)\|$, we have that $a(0) = 0$,

$$a(\varepsilon') \leq \frac{\varepsilon'}{\tau}\left(1 + a(\varepsilon')\right)^3,$$

for all $\varepsilon' \geq 0$, and a is continuous by continuity of $\|Df(v)\|$. Setting $b(\varepsilon') = a(\varepsilon')/(1+a(\varepsilon'))$, we get

$$b(\varepsilon')(1 - b(\varepsilon'))^2 \leq \frac{\varepsilon'}{\tau}.$$

Examining the polynomial $x(1-x)^2$, we see that the sublevel set $x(1-x)^2 \leq \omega$ consists of two components when $\omega < 4/27$. Also note that if $\omega < 1/8$, then

$$2(1-2\omega)^2 = 2 - 8\omega + 8\omega^2 > 2 - 1 = 1,$$

and hence

$$2\omega(1-2\omega)^2 > \omega.$$

Consequently, if x is such that $x(1-x)^2 \leq \omega$ and is in the interval containing zero in the sublevel set $x(1-x)^2 \leq \omega < 1/8$, then $x \leq 2\omega$.

By these observations, continuity of $b(\varepsilon')$, and the fact that $b(0) = 0$, we have that $a(\varepsilon') \leq \frac{2\frac{\varepsilon'}{\tau}}{1-2\frac{\varepsilon'}{\tau}}$, and thus

$$\sup_{v \in B_d(0,\varepsilon)} \|Df(v)\| \leq \frac{2\varepsilon}{\tau - 2\varepsilon}.$$

From the bound in (28) we now acquire the bound

$$\sup_{v \in B_d(0,\varepsilon)} \sup_{u \in \mathcal{S}^{D-d-1}} \left\| \sum_{i=1}^{D-d-1} u_i D^2 f_i(v) \right\| \leq \frac{\tau^2}{(\tau - 2\varepsilon)^3}.$$

■

Proof [Proof of Lemma 18] We first prove part *i*. Let $\varepsilon > 0$ satisfy $\varepsilon < \tau/8$. Because of (23) and the fact that $\|\beta\| \leq \sigma$, we have that

$$\left\| \sum_{i=1}^{D-d} \beta_i D^2 f_i(v) \right\| \leq \frac{\sigma\tau^2}{(\tau - 2\varepsilon)^3}.$$

Since this is also a bound for the columns of $\sum \beta_i D^2 f_i(v)$, Proposition 10 implies that

$$\mathrm{Vol}\begin{pmatrix} I + \sum \beta_i D^2 f_i(v) & Df(v)^T \\ Df(v) & -I \end{pmatrix} \leq \left(1 + \frac{\sigma\tau^2}{(\tau - 2\varepsilon)^3}\right)^d \mathrm{Vol}\begin{pmatrix} I & Df(v)^T \\ Df(v) & -I \end{pmatrix}$$

in $T^{\perp}(\mathcal{M} \cap B(y,\varepsilon)) \cap \mathcal{M}_\sigma$.

On the other hand, we have that

$$\mathrm{Vol}\begin{pmatrix} Df^T(v) \\ -I \end{pmatrix} \leq \prod_{i=1}^{D-d} \sqrt{1 + \|\nabla f_i(v)\|^2} \leq \left(1 + \frac{4\varepsilon^2}{(\tau - 2\varepsilon)^2}\right)^{(D-d)/2}$$

since (22) implies the bounds $\|\frac{\partial f(v)}{\partial v_i}\| \leq \frac{2\varepsilon}{\tau - 2\varepsilon}$ for each $i = 1, \ldots, d$, and the above is the largest this quantity may be subject to these bounds.

When these estimates are joined together, we have an inequality

$$\begin{aligned}\mathrm{Vol}\begin{pmatrix} I + \sum_{i=1}^{D-d} \beta_i D^2 f_i(v) & Df(v)^T \\ Df(v) & -I \end{pmatrix} &\leq \left(1 + \frac{\sigma\tau^2}{(\tau - 2\varepsilon)^3}\right)^d \mathrm{Vol}\begin{pmatrix} I & Df(v)^T \\ Df(v) & -I \end{pmatrix} \\ &\leq \left(1 + \frac{\sigma\tau^2}{(\tau - 2\varepsilon)^3}\right)^d \left(1 + \frac{4\varepsilon^2}{(\tau - 2\varepsilon)^2}\right)^{(D-d)/2} \mathrm{Vol}\begin{pmatrix} I \\ Df(v) \end{pmatrix}.\end{aligned}$$

For an arbitrarily small $\varepsilon > 0$, let $\{U_\gamma\}_{\gamma \in \Gamma}$ denote a finite partition of U into measurable sets such that there for each $\gamma \in \Gamma$, there is a y_γ satisfying $U_\gamma \subset \mathcal{M} \cap B(y_\gamma, \varepsilon)$. Let f_γ denote the inverse of $P_\gamma = \mathrm{Proj}_{y_\gamma + T_{y_\gamma}\mathcal{M}}$ in U_γ, and set

$$E_{\gamma,v} = \{\beta \in \mathbb{R}^{D-d} : \|\beta\|^2 + \|Df_\gamma(v)\beta\|^2 \leq \sigma^2\}$$

for all $v \in P_\gamma(U_\gamma)$. Thus,

$$\begin{aligned}\int_{P_\gamma^{-1}(U_\gamma)} d\mathrm{Vol}(x) &= \int_{P_\gamma(U_\gamma)} \int_{E_{\gamma,v}} \mathrm{Vol}\begin{pmatrix} I + \sum_{i=1}^{D-d} \beta_i D^2 f_i(v) & Df(x)^T \\ Df(v) & -I \end{pmatrix} d\beta dv \\ &\leq \int_{P_\gamma(U_\gamma)} \int_{E_{\gamma,v}} \left(1 + \frac{\sigma\tau^2}{(\tau - 2\varepsilon)^3}\right)^d \left(1 + \frac{4\varepsilon^2}{(\tau - 2\varepsilon)^2}\right)^{(D-d)/2} \mathrm{Vol}\begin{pmatrix} I \\ Df(v) \end{pmatrix} d\beta dv \\ &\leq \left(1 + \frac{\sigma\tau^2}{(\tau - 2\varepsilon)^2}\right)^d \left(1 + \frac{4\varepsilon^2}{(\tau - 2\varepsilon)^2}\right)^{(D-d)/2} \mathrm{Vol}_{\mathcal{M}}(U_\gamma)\mathrm{Vol}(B_{D-d}(0,\sigma))\end{aligned}$$

since $E_{\gamma,v} \subset B_{D-d}(0,\sigma)$. Consequently, we have that

$$\begin{aligned}\mathrm{Vol}(P^{-1}(U)) &= \sum_{\gamma \in \Gamma} \mathrm{Vol}(P_\gamma^{-1}(U_\gamma)) \\ &\leq \sum_{\gamma \in \Gamma} \left(1 + \frac{\sigma\tau^2}{(\tau - 2\varepsilon)^3}\right)^d \left(1 + \frac{4\varepsilon^2}{(\tau - 2\varepsilon)^2}\right)^{(D-d)/2} \mathrm{Vol}_{\mathcal{M}}(U_\gamma)\mathrm{Vol}(B_{D-d}(0,\sigma)) \\ &= \left(1 + \frac{\sigma\tau^2}{(\tau - 2\varepsilon)^3}\right)^d \left(1 + \frac{4\varepsilon^2}{(\tau - 2\varepsilon)^2}\right)^{(D-d)/2} \mathrm{Vol}_{\mathcal{M}}(U)\mathrm{Vol}(B_{D-d}(0,\sigma)).\end{aligned}$$

Since $\varepsilon > 0$ was arbitrary, we obtain

$$\mathrm{Vol}(P^{-1}(U)) \cap \mathcal{M}_\sigma) \leq \left(1 + \frac{\sigma}{\tau}\right)^d \mathrm{Vol}_{\mathcal{M}}(U)\mathrm{Vol}(B_{D-d}(0,\sigma)).$$

This completes the proof of upper bound in part *i*. Using a similar partition strategy, we have that

$$\begin{aligned}
\int_{P_\gamma^{-1}(U_\gamma)} d\mathrm{Vol}(x) &= \int_{P_\gamma(U_\gamma)} \int_{E_{\gamma,v}} \mathrm{Vol}\begin{pmatrix} I + \sum_{i=1}^{D-d} \beta_i D^2 f_i(v) & Df(x)^T \\ Df(v) & -I \end{pmatrix} d\beta dv \\
&\geq \int_{P_\gamma(U_\gamma)} \int_{E_{\gamma,v}} \left(1 - \frac{\sigma\tau^2}{(\tau-2\varepsilon)^3}\right)^d \mathrm{Vol}\begin{pmatrix} I & Df(v)^T \\ Df(v) & -I \end{pmatrix} d\beta dv \\
&= \int_{P_\gamma(U_\gamma)} \int_{E_{\gamma,v}} \left(1 - \frac{\sigma\tau^2}{(\tau-2\varepsilon)^3}\right)^d \mathrm{Vol}\begin{pmatrix} I \\ Df(v) \end{pmatrix} \mathrm{Vol}\begin{pmatrix} Df(v)^T \\ -I \end{pmatrix} d\beta dv \\
&\geq \int_{P_\gamma(U_\gamma)} \int_{E_{\gamma,v}} \left(1 - \frac{\sigma\tau^2}{(\tau-2\varepsilon)^3}\right)^d \mathrm{Vol}\begin{pmatrix} I \\ Df(v) \end{pmatrix} d\beta dv \\
&\geq \int_{P_\gamma(U_\gamma)} \int_{B_{D-d}\left(0, \frac{\sigma}{1+\frac{\varepsilon}{\tau-\varepsilon}}\right)} \left(1 - \frac{\sigma\tau^2}{(\tau-2\varepsilon)^3}\right)^d \mathrm{Vol}\begin{pmatrix} I \\ Df(v) \end{pmatrix} d\beta dv \\
&= \left(1 - \frac{\sigma\tau^2}{(\tau-2\varepsilon)^3}\right)^d \mathrm{Vol}_{\mathcal{M}}(U_\gamma) \mathrm{Vol}\left(B_{D-d}\left(0, \left(1-\frac{\varepsilon}{\tau}\right)\sigma\right)\right)
\end{aligned}$$

In the inequalities above, we have used the fact that there is a ball of radius $\left(1-\frac{\varepsilon}{\tau}\right)\sigma$ inside of $E_{\gamma,v}$ for each γ and each v. Aggregating all of the sums and letting $\varepsilon \to 0$ yields the lower bound in part *i*.

We now prove part *ii*. Note that

$$\mathrm{Vol}(\mathcal{M}_\sigma \cap B(y,r)) \leq \mathrm{Vol}(P^{-1}(\mathcal{M} \cap B(y, r+\sigma)))$$

since $\|\operatorname{Proj}_{\mathcal{M}}(x) - y\| \leq \|x-y\| + \|\operatorname{Proj}_{\mathcal{M}}(x) - x\| \leq r + \sigma$. Part *ii*. now follows from part *i*. and the fact that

$$\begin{aligned}
\mathrm{Vol}_{\mathcal{M}}(\mathcal{M} \cap B(y, r+\sigma)) &\leq \int\limits_{P(\mathcal{M}\cap B(y,r+\sigma))} \mathrm{Vol}\begin{pmatrix} I \\ Df(v) \end{pmatrix} dv \\
&\leq \left(1 + \left(\frac{2(r+\sigma)}{\tau - 2(r+\sigma)}\right)^2\right)^{d/2} \mathrm{Vol}(B_d(0, r+\sigma)).
\end{aligned}$$

■

Proof [Proof of Lemma 20] By the variational characterization of eigenvalues, we have that

$$\begin{aligned}
\sum_{i=d+1}^{D} \lambda_i(\Sigma) &= \operatorname*{argmin}_{\dim(V)=D-d} \mathrm{tr}\left(\operatorname{Proj}_V^T \Sigma \operatorname{Proj}_V\right) \\
&= \operatorname*{argmin}_{\dim(V)=D-d} \mathbb{E}\|\operatorname{Proj}_V(Z - \mathbb{E}Z)\|^2 \\
&= \operatorname*{argmin}_{\dim(V)=d} \mathbb{E}\|Z - \mathbb{E}Z - \operatorname{Proj}_V(Z - \mathbb{E}Z)\|^2.
\end{aligned}$$

Thus, we have that $\sum_{i=d+1}^{D} \lambda_i(\Sigma) \leq \mathbb{E}\|Z - \mathbb{E}Z - \operatorname{Proj}_{T_y\mathcal{M}}(Z - \mathbb{E}Z)\|^2$. Observe that

$$\begin{aligned}
\mathbb{E}\|Z - \mathbb{E}Z - \operatorname{Proj}_{T_y\mathcal{M}}(Z - \mathbb{E}Z)\|^2 =& \mathbb{E}\|Z - y + (y - \mathbb{E}Z) - \operatorname{Proj}_{T_y\mathcal{M}}((Z-y) + (y - \mathbb{E}Z))\|^2 \\
=& \mathbb{E}\|Z - y - \operatorname{Proj}_{T_y\mathcal{M}}(Z-y)\|^2 \\
&- \|(y - \mathbb{E}Z) - \operatorname{Proj}_{T_y\mathcal{M}}(y - \mathbb{E}Z)\|^2 \\
&\leq \mathbb{E}\|Z - y - \operatorname{Proj}_{T_y\mathcal{M}}(Z-y)\|^2.
\end{aligned}$$

Now for any $z \in \mathcal{M}_\sigma \cap B(y,r)$, we have that $z = \beta + x$ where $x \in \mathcal{M}$, and $\beta \in T_x^\perp \mathcal{M}$ satisfies $\|\beta\| \leq \sigma$. Moreover, there is a unique decomposition $x = \eta + v + y$ where $\eta \in T_y^\perp \mathcal{M}$ and $v \in T_y\mathcal{M}$. Thus,

$$\|z - y - \operatorname{Proj}_{T_y\mathcal{M}}(z-y)\| = \|\beta + \eta - \operatorname{Proj}_{T_y\mathcal{M}}\beta\| \leq \|\beta - \operatorname{Proj}_{T_y\mathcal{M}}(\beta)\| + \|\eta\| \leq \sigma + \frac{2r^2}{\tau}, \tag{30}$$

by Lemma 15, and we obtain the bound

$$\mathbb{E}\|Z - \mathbb{E}Z - \operatorname{Proj}_{T_y\mathcal{M}}(Z - \mathbb{E}Z)\|^2 \leq 2\sigma^2 + \frac{8r^4}{\tau^2}. \tag{31}$$

This establishes the required estimate. ■

Proof [Proof of Lemma 21] For any unit vector $u \in T_y\mathcal{M}$ we have

$$\begin{aligned}
\mathbb{E}\langle u, Z - \mathbb{E}Z\rangle^2 &= \frac{1}{\mathrm{Vol}(Q \cap \mathcal{M}_\sigma)} \int_{Q \cap \mathcal{M}_\sigma} \langle u, Z - \mathbb{E}Z\rangle^2 d\mathrm{Vol}(Z) \\
&\geq \frac{1}{\mathrm{Vol}(B(y, r_2) \cap \mathcal{M}_\sigma)} \int_{B(y,r_1)\cap\mathcal{M}_\sigma} \langle u, (Z-y) - \mathbb{E}(Z-y)\rangle^2 d\mathrm{Vol}(Z)
\end{aligned}$$

using the inclusion assumptions, and by adding and subtracting the constant vector y.

We now seek to reduce the domain of integration and perform a change of variables. Since $r_1 \leq \tau/8$, the inverse of the affine projection onto $y + T_y\mathcal{M}$ is injective. Without loss of generality, we assume $y = 0$ and $T_y\mathcal{M}$ is the span of the first d standard orthonormal vectors. Letting f denote the inverse of the affine projection onto $y + T_y\mathcal{M}$, we see that the map

$$\begin{pmatrix} v \\ \beta \end{pmatrix} \longmapsto \begin{pmatrix} v \\ f(v) + \beta \end{pmatrix}$$

is well-defined and injective on $\operatorname{Proj}_{T_y\mathcal{M}}(\mathcal{M} \cap B(y, r_1 - \sigma)) \times (T_y^\perp \mathcal{M} \cap B(0, \sigma))$. Let g denote this map, note that

$$\|x + \beta\| \leq \|x\| + \|\beta\| \leq (r - \sigma) + \sigma = r,$$

for $x \in \mathcal{M} \cap B(y, r_1 - \sigma)$, and hence the image of g is contained in $\mathcal{M}_\sigma \cap B(y, r_1)$. Since the absolute value of the determinant of the Jacobian of g is always 1 (it is lower triangular

with ones on the diagonal), employing the change of coordinates in the reduced domain of integration yields

$$\mathbb{E}\langle u, Z-\mathbb{E}Z\rangle^2 \geq \frac{1}{\mathrm{Vol}(B(y,r_2)\cap\mathcal{M}_\sigma)}\int_{\mathcal{A}}\int_{\mathcal{B}}\left\langle \begin{pmatrix} u \\ 0 \end{pmatrix}, \begin{pmatrix} v \\ f(v)+\beta \end{pmatrix} - \mathbb{E}(Z-y)\right\rangle^2 d\beta dv,$$

where

$$\mathcal{A} = \mathrm{Proj}_{T_y\mathcal{M}}(B(y,r_1-\sigma)\cap\mathcal{M}),\ \mathcal{B} = T_y^\perp\mathcal{M}\cap B(0,\sigma).$$

Note that $B(y,\cos(\theta)(r_1-\sigma))\cap(y+T_y\mathcal{M})\subset\mathcal{A}$. Setting $\mathcal{Q}=\mathrm{Proj}_{T_y\mathcal{M}}$, this immediately reduces to

$$\begin{aligned}\mathbb{E}\langle u, Z-\mathbb{E}Z\rangle^2 &\geq \frac{1}{\mathrm{Vol}(B(y,r_2)\cap\mathcal{M}_\sigma)}\int_{\mathcal{A}}\int_{\mathcal{B}}\langle u, v-\mathbb{E}\mathcal{Q}(Z-y)\rangle^2 d\beta dv\\ &= \frac{\mathrm{Vol}(B_{D-d}(0,\sigma))}{\mathrm{Vol}(B(y,r_2)\cap\mathcal{M}_\sigma)}\int_{\mathcal{A}}\langle u, v-\mathbb{E}\mathcal{Q}(Z-y)\rangle^2 dv\\ &\geq \frac{\mathrm{Vol}(B_{D-d}(0,\sigma))}{\mathrm{Vol}(B(y,r_2)\cap\mathcal{M}_\sigma)}\int_{B_d(0,q)}\langle u, v-\mathbb{E}\mathcal{Q}(Z-y)\rangle^2 dv,\end{aligned}$$

where $q=\cos(\delta)(r_1-\sigma)$ and $\delta=\arcsin((r_1-\sigma)/2\tau)$. Noting that $\int_{B_d(0,q)}\langle u,v\rangle dv = 0$ by symmetry, we now use linearity of the inner product to further reduce the integrand:

$$\begin{aligned}\mathbb{E}\langle u, Z-\mathbb{E}Z\rangle^2 &\geq \frac{\mathrm{Vol}(B_{D-d}(0,\sigma))}{\mathrm{Vol}(B(y,r_2)\cap\mathcal{M}_\sigma)}\int_{B_d(0,q)}\left(\langle u,v\rangle^2 - 2\langle u,v\rangle\langle u,\mathbb{E}\mathcal{Q}(Z-y)\rangle + \langle u,\mathbb{E}\mathcal{Q}(Z-y)\rangle^2\right)dv\\ &= \frac{\mathrm{Vol}(B_{D-d}(0,\sigma))}{\mathrm{Vol}(B(y,r_2)\cap\mathcal{M}_\sigma)}\int_{B_d(0,q)}\left(\langle u,v\rangle^2 + \langle u,\mathbb{E}\mathcal{Q}(Z-y)\rangle^2\right)dv\\ &\geq \frac{\mathrm{Vol}(B_{D-d}(0,\sigma))}{\mathrm{Vol}(B(y,r_2)\cap\mathcal{M}_\sigma)}\int_{B_d(0,q)}\langle u,v\rangle^2 dv\\ &= \frac{\mathrm{Vol}(B_{D-d}(0,\sigma))\mathrm{Vol}(B_d(0,q))}{\mathrm{Vol}(B(y,r_2)\cap\mathcal{M}_\sigma)}\frac{q^2}{d}.\end{aligned}$$

By Lemma 18, we then obtain

$$\begin{aligned}\mathbb{E}\langle u, Z-\mathbb{E}Z\rangle^2 &\geq \left(\left(1+\frac{\sigma}{\tau}\right)\sqrt{1+\left(\frac{2(r_2+\sigma)}{\tau-2(r_2+\sigma)}\right)^2}\right)^{-d}\frac{\mathrm{Vol}(B_d(0,q))}{\mathrm{Vol}(B_d(0,r_2+\sigma))}\frac{q^2}{d}\\ &\geq \frac{1}{4\left(1+\frac{\sigma}{\tau}\right)^d}\left(\frac{r_1-\sigma}{r_2+\sigma}\right)^d\left(\frac{1-\left(\frac{r_1-\sigma}{2\tau}\right)^2}{1+\left(\frac{2(r_2+\sigma)}{\tau-2(r_2+\sigma)}\right)^2}\right)^{d/2}\frac{(r_1-\sigma)^2}{d}. \qquad (32)\end{aligned}$$

Let $V_{d-1}(\Sigma)$ be a subspace corresponding to the first $d-1$ principal components of Z:

$$V_{d-1} = \operatorname*{argmin}_{\dim(V)=d-1}\mathbb{E}\|Z-\mathbb{E}Z-\mathrm{Proj}_V(Z-\mathbb{E}Z)\|,$$

and note that $\lambda_d(\Sigma)=\max_{0\neq u\in V_{d-1}^\perp}\mathbb{E}\left\langle\frac{u}{\|u\|}, Z-\mathbb{E}Z\right\rangle^2$. Since $\dim(V_{d-1}^\perp)=D-d+1$ and $\dim(T_y\mathcal{M})=d$, it is easy to see that $V_{d-1}^\perp\cap T_y\mathcal{M}\neq\emptyset$. For any $u_*\in V_{d-1}^\perp\cap T_y\mathcal{M}$ such that

$\|u_*\|=1$ it follows from Courant-Fischer characterization of $\lambda_d(\Sigma)$ that

$$\lambda_d(\Sigma)\geq\mathbb{E}\langle u_*, Z-\mathbb{E}Z\rangle^2,$$

and (32) implies the desired bound. ■

Proof [Proof of Lemma 22] Let $Q\subset\mathbb{R}^D$ be such that $B(y,r_1)\subset Q$ and $\mathcal{M}_\sigma\cap Q\subset B(y,r_2)$ for some $y\in\mathcal{M}$ and $\sigma<r_1<r_2<\tau/8-\sigma$. Assume that Z is drawn from $U_{\mathcal{M}_\sigma\cap Q}$, let Σ be the covariance matrix of Z and $V_d:=V_d(\Sigma)$ - the subspace corresponding to the first d principal components of Z.

Let $\alpha\in[0,1]$ be such that $\cos(\phi):=\min_{u\in V_d,\|u\|=1}\max_{v\in T_y\mathcal{M},\|v\|=1}|\langle u,v\rangle| = \sqrt{1-\alpha^2}$ is the cosine of the angle between $T_y\mathcal{M}$ and V_d. Then there exists a unit vector $u_*\in(V_d)^\perp$ such that

$$\max_{v\in T_y\mathcal{M},\|v\|=1}|\langle u_*, v\rangle|\geq\alpha.$$

Indeed, let $u'\in V_d$, $v'\in T_y\mathcal{M}$ be unit vectors such that $\cos(\phi)=\langle u',v'\rangle$, Note that $\sqrt{1-\alpha^2}$ is equal to the smallest absolute value among the nonzero singular values of the operator $\mathrm{Proj}_{T_y\mathcal{M}}\mathrm{Proj}_{V_d}$. Since the spectra of the operators $\mathrm{Proj}_{T_y\mathcal{M}}\mathrm{Proj}_{V_d}$ and $\mathrm{Proj}_{V_d}\mathrm{Proj}_{T_y\mathcal{M}}$ coincide by well-known facts from linear algebra, we have that

$$\min_{u\in V_d,\|u\|=1}\max_{v\in T_y\mathcal{M},\|v\|=1}|\langle u,v\rangle| = \min_{v\in T_y\mathcal{M},\|v\|=1}\max_{u\in V_d,\|u\|=1}|\langle u,v\rangle|.$$

In other words, $\mathrm{Proj}_{T_y\mathcal{M}}(u')=\langle u',v'\rangle v'$ and $\mathrm{Proj}_{V_d}(v')=\langle u',v'\rangle u'$. This implies that there exists a unit vector $u_*\in(V_d)^\perp$ such that $v'=\langle v',u'\rangle u'+\langle v',u_*\rangle u_*$, hence $\langle u_*,v'\rangle^2 = 1-\langle v',u'\rangle^2=\alpha^2$, so u_* satisfies the requirement.

To simplify the expressions, let

$$\zeta=\frac{1}{\mathrm{Vol}(Q\cap\mathcal{M}_\sigma)}.$$

We shall now construct upper and lower bounds for

$$\zeta\int_{Q\cap\mathcal{M}_\sigma}\langle u_*, x-\mathbb{E}Z-\mathrm{Proj}_{V_d}(x-\mathbb{E}Z)\rangle^2\,d\mathrm{Vol}(x) = \zeta\int_{Q\cap\mathcal{M}_\sigma}\langle u_*, x-\mathbb{E}Z\rangle^2\,d\mathrm{Vol}(x)$$

which together yield an estimate for α. Write $u_*=u_*^{||}+u_*^\perp$, where $u_*^{||}\in T_y\mathcal{M}$ and $u_*^\perp\in T_y^\perp\mathcal{M}$. By our choice of u_*, we clearly have that $\|u_*^{||}\|=\max_{v\in T_y\mathcal{M},\|v\|=1}\langle u_*,v\rangle\geq\alpha$. Using the elementary inequality $(a+b)^2\geq\frac{a^2}{2}-b^2$, we further deduce that

$$\begin{aligned}\zeta\int_{Q\cap\mathcal{M}_\sigma}\langle u_*, x-\mathbb{E}Z\rangle^2\,d\mathrm{Vol}(x) &\geq \zeta\int_{Q\cap\mathcal{M}_\sigma}\frac{1}{2}\left\langle u_*^{||}, x-\mathbb{E}Z\right\rangle^2 d\mathrm{Vol}(x)\\ &\quad-\zeta\int_{Q\cap\mathcal{M}_\sigma}\left\langle u_*^\perp, x-\mathbb{E}Z\right\rangle^2 d\mathrm{Vol}(x). \qquad (33)\end{aligned}$$

It follows from the proof of Lemma 21 that

$$\zeta\int_{Q\cap\mathcal{M}_\sigma}\frac{1}{2}\left\langle u_*^{||}, x-\mathbb{E}Z\right\rangle^2 d\mathrm{Vol}(x)\geq\frac{\alpha^2}{8\left(1+\frac{\sigma}{\tau}\right)^d}\left(\frac{r_1-\sigma}{r_2+\sigma}\right)^d\left(\frac{1-\left(\frac{r_1-\sigma}{2\tau}\right)^2}{1+\left(\frac{2(r_2+\sigma)}{\tau-2(r_2+\sigma)}\right)^2}\right)^{d/2}\frac{(r_1-\sigma)^2}{d}.$$

For the last term in (33), Lemma 20 (see equation (31)) gives

$$\zeta \int_{Q\cap\mathcal{M}_\sigma} \left\langle u_*^\perp, x-\mathbb{E}Z\right\rangle^2 d\mathrm{Vol}(x) \le \zeta \int_{Q\cap\mathcal{M}_\sigma} \|x-\mathbb{E}Z-\mathrm{Proj}_{T_y\mathcal{M}}(x-\mathbb{E}Z)\|^2 d\mathrm{Vol}(x)$$
$$\le 2\sigma^2 + \frac{8r_2^4}{\tau^2},$$

hence (33) yields

$$\zeta \int_{Q\cap\mathcal{M}_\sigma} \langle u_*, x-\mathbb{E}Z\rangle^2 \, d\mathrm{Vol}(x) \ge \frac{\alpha^2}{8\left(1+\frac{\sigma}{\tau}\right)^d}\left(\frac{r_1-\sigma}{r_2+\sigma}\right)^d \left(\frac{1-\left(\frac{r_1-\sigma}{2\tau}\right)^2}{1+\left(\frac{2(r_2+\sigma)}{\tau-2(r_2+\sigma)}\right)^2}\right)^{d/2} \frac{(r_1-\sigma)^2}{d}$$
$$- 2\sigma^2 - \frac{8r_2^4}{\tau^2}. \tag{34}$$

On the other hand, invoking (31) once again, we have

$$\zeta \int_{Q\cap\mathcal{M}_\sigma} \langle u_*, x-\mathbb{E}Z\rangle^2 \, d\mathrm{Vol}(x) \le 2\sigma^2 + \frac{8r_2^4}{\tau^2}.$$

Combined with (34), this gives

$$\frac{\alpha^2}{8\left(1+\frac{\sigma}{\tau}\right)^d}\left(\frac{r_1-\sigma}{r_2+\sigma}\right)^d \left(\frac{1-\left(\frac{r_1-\sigma}{2\tau}\right)^2}{1+\left(\frac{2(r_2+\sigma)}{\tau-2(r_2+\sigma)}\right)^2}\right)^{d/2} \frac{(r_1-\sigma)^2}{d} \le 4\sigma^2 + \frac{16r_2^4}{\tau^2}, \tag{35}$$

and the upper bound for α follows.

Notice that for any $x \in Q\cap\mathcal{M}_\sigma$,

$$x-\mathbb{E}Z-\mathrm{Proj}_{V_d}(x-\mathbb{E}Z) = x-y-\mathrm{Proj}_{T_y\mathcal{M}}(x-y) + \underbrace{y-\mathbb{E}Z-\mathrm{Proj}_{T_y\mathcal{M}}(y-\mathbb{E}Z)}_{\mathrm{Proj}_{(T_y\mathcal{M})^\perp}(y-\mathbb{E}Z)}$$
$$+ (\mathrm{Proj}_{T_y\mathcal{M}} - \mathrm{Proj}_{V_d})(x-\mathbb{E}Z). \tag{36}$$

It follows from (30) that

$$\|x-y-\mathrm{Proj}_{T_y\mathcal{M}}(x-y)\| = \left\|\mathrm{Proj}_{T_y^\perp\mathcal{M}}(x-y)\right\| \le \sigma + \frac{2r_2^2}{\tau}.$$

Next,

$$\|\mathrm{Proj}_{(T_y\mathcal{M})^\perp}(y-\mathbb{E}Z)\| = \frac{1}{\mathrm{Vol}(Q\cap\mathcal{M}_\sigma)}\left\|\int_{Q\cap\mathcal{M}_\sigma} \mathrm{Proj}_{T_y^\perp\mathcal{M}}(y-z)d\mathrm{Vol}(z)\right\|$$
$$\le \frac{1}{\mathrm{Vol}(Q\cap\mathcal{M}_\sigma)}\int_{Q\cap\mathcal{M}_\sigma}\left\|\mathrm{Proj}_{T_y^\perp\mathcal{M}}(z-y)\right\| d\mathrm{Vol}(z)$$
$$\le \sigma + \frac{2r_2^2}{\tau}.$$

Finally, it is easy to see that

$$\|(\mathrm{Proj}_{T_y\mathcal{M}} - \mathrm{Proj}_{V_d})(x-\mathbb{E}Z)\| \le \|\mathrm{Proj}_{T_y\mathcal{M}}(x-\mathbb{E}Z) - \mathrm{Proj}_{V_d}\mathrm{Proj}_{T_y\mathcal{M}}(x-\mathbb{E}Z)\|$$
$$+ \|\mathrm{Proj}_{T_y^\perp\mathcal{M}}(x-y)\| + \|\mathrm{Proj}_{T_y^\perp\mathcal{M}}(\mathbb{E}Z-y)\|.$$

Let $u_x := \frac{\mathrm{Proj}_{T_y\mathcal{M}}(x-\mathbb{E}Z)}{\|\mathrm{Proj}_{T_y\mathcal{M}}(x-\mathbb{E}Z)\|}$ and note that for any $x \in Q\cap\mathcal{M}_\sigma$, $\|\mathrm{Proj}_{T_y\mathcal{M}}(x-\mathbb{E}Z)\| \le 2r_2$, hence

$$\|\mathrm{Proj}_{T_y\mathcal{M}}(x-\mathbb{E}Z) - \mathrm{Proj}_{V_d}\mathrm{Proj}_{T_y\mathcal{M}}(x-\mathbb{E}Z)\|^2 \le (2r_2)^2\left(1-\|\mathrm{Proj}_{V_d}u_x\|^2\right)$$
$$\le 4r_2^2\left(1-\min_{u\in T_y\mathcal{M},\|u\|=1}\max_{v\in V_d,\|v\|=1}\langle u,v\rangle^2\right)$$
$$= 4r_2^2\alpha^2.$$

Combining the previous bounds with (35) and (36), we obtain the result. ∎

Proof [Proof of Lemma 24] Assume the event $\mathcal{E}_{\varepsilon/2,n} = \{\{Y_1,\dots,Y_n\}$ is an $\varepsilon/2$ - net in $\mathcal{M}\}$ occurs. By Proposition 23, $\Pr(\mathcal{E}_{\varepsilon/2,n}) \ge 1-e^{-t}$.

Since the elements of T_j are 2^{-j}-separated, for any $1 \le k \le N(j)$, $B(a_{j,k}, 2^{-j-1}) \subseteq C_{j,k}$. Moreover, since $\sigma \le 2^{-j-2}$ and $\|a_{j,k}-z_{j,k}\| \le \sigma$,

$$B(z_{j,k}, 2^{-j-1}-2^{-j-2}) \subseteq B(z_{j,k}, 2^{-j-1}-\sigma) \subseteq B(a_{j,k}, 2^{-j-1}),$$

hence the inclusion $B\left(z_{j,k}, 2^{-j-2}\right) \subseteq C_{j,k}$ follows.

To show that $C_{j,k}\cap\mathcal{M}_\sigma \subseteq B(a_{j,k}, 3\cdot 2^{-j-2}+2^{-j+1})$, pick an arbitrary $z \in \mathcal{M}_\sigma$. Note that on the event $\mathcal{E}_{\varepsilon/2,n}$, there exists $y \in \{Y_1,\dots,Y_n\}$ satisfying $\|z-y\| \le \varepsilon/2+\sigma$. Let $x(y) \in \mathcal{X}_n$ be such that $y = \mathrm{Proj}_{\mathcal{M}}(x(y))$. By properties of the cover trees (see Remark 5), there exists $x_* \in T_j$ such that $\|x(y)-x_*\| \le 2^{-j+1}$. Then

$$\|z-x_*\| \le \|z-y\| + \|y-x(y)\| + \|x(y)-x_*\| \le \varepsilon/2 + 2\sigma + 2^{-j+1} \le 3\cdot 2^{-j-2} + 2^{-j+1}.$$

Since z was arbitrary, the result follows. Finally, $B(a_{j,k}, 3\cdot 2^{-j-2}+2^{-j+1}) \subset B(z_{j,k}, 3\cdot 2^{-j})$ holds since $\|a_{j,k}-z_{j,k}\| \le 2^{-j-2}$. ∎

Abstract

The problem of clustering is considered for the case where every point is a time series. The time series are either given in one batch (offline setting), or they are allowed to grow with time and new time series can be added along the way (online setting). We propose a natural notion of consistency for this problem, and show that there are simple, computationally efficient algorithms that are asymptotically consistent under extremely weak assumptions on the distributions that generate the data. The notion of consistency is as follows. A clustering algorithm is called consistent if it places two time series into the same cluster if and only if the distribution that generates them is the same. In the considered framework the time series are allowed to be highly dependent, and the dependence can have arbitrary form. If the number of clusters is known, the only assumption we make is that the (marginal) distribution of each time series is stationary ergodic. No parametric, memory or mixing assumptions are made. When the number of clusters is unknown, stronger assumptions are provably necessary, but it is still possible to devise nonparametric algorithms that are consistent under very general conditions. The theoretical findings of this work are illustrated with experiments on both synthetic and real data.

Keywords: clustering, time series, ergodicity, unsupervised learning

1. Introduction

Clustering is a widely studied problem in machine learning, and is key to many applications across different fields of science. The goal is to partition a given data set into a set of non-overlapping *clusters* in some natural way, thus hopefully revealing an underlying structure in the data. In particular, this problem for time series data is motivated by many research problems from a variety of disciplines, such as marketing and finance, biological and medical research, video/audio analysis, etc., with the common feature that the data are abundant while little is known about the nature of the processes that generate them.

The intuitively appealing problem of clustering is notoriously difficult to formalise. An intrinsic part of the problem is a similarity measure: the points in each cluster are supposed to be close to each other in some sense. While it is clear that the problem of finding the appropriate similarity measure is inseparable from the problem of achieving the clustering objectives, in the available formulations of the problem it is usually assumed that the similarity measure is given: it is either some fixed metric, or just a matrix of similarities between the points. Even with this simplification, it is still unclear how to define good clustering. Thus, Kleinberg (2002) presents a set of fairly natural properties that a good clustering function should have, and further demonstrate that there is no clustering function that satisfies these properties. A common approach is therefore to fix not only the similarity measure, but also some specific objective function — typically, along with the number of clusters — and to construct algorithms that maximise this objective. However, even this approach has some fundamental difficulties, albeit of a different, this time computational, nature: already in the case where the number of clusters is known, and the distance between the points is set to be the Euclidean distance, optimising some fairly natural objectives (such as k-means) turns out to be NP hard (Mahajan et al., 2009).

In this paper we consider a subset of the clustering problem, namely, clustering time series. That is, we consider the case where each data point is a sample drawn from some (unknown) time-series distribution. At first glance this does not appear to be a simplification (indeed, any data point can be considered as a time series of length 1). However, note that time series present a different dimension of asymptotic: with respect to their length, rather than with respect to the total number of points to be clustered. "Learning" along this dimension turns out to be easy to define, and allows for the construction of consistent algorithms under most general assumptions. Specifically, the assumption that each time series is generated by a stationary ergodic distribution is already sufficient to estimate any finite-dimensional characteristic of the distribution with arbitrary precision, provided the series is long enough. Thus, in contrast to the general clustering setup, in the time-series case it is possible to "learn" the distribution that generates each given data point. No assumptions on the dependence between time series are necessary for this. The assumption that a given time series is stationary ergodic is one of the most general assumptions used in statistics; in particular, it allows for arbitrary long-range serial dependence, and subsumes most of the nonparametric as well as modelling assumptions used in the literature on clustering time series, such as i.i.d., (hidden) Markov, or mixing time series.

This allows us to define the following clustering objective: *group a pair of time series into the same cluster if and only if the distribution that generates them is the same.*

Note that this intuitive objective is impossible to achieve outside the time-series framework. Even in the simplest case where the underlying distributions are Gaussian and the number of clusters is known, there is always a nontrivial likelihood for each point to be generated by any of the distributions. Thus, the best one can do is to estimate the parameters of the distributions, rather than to actually cluster the data points. The situation becomes hopeless in the nonparametric setting. In contrast, the fully nonparametric case is tractable for time-series data, both in offline and online scenarios, as explained in the next section.

1.1 Problem Setup

We consider two variants of the clustering problem in this setting: offline (batch) and online, defined as follows.

In the *offline (batch)* setting a finite number N of sequences $\mathbf{x}_1 = (X_1^1, \dots, X_{n_1}^1)$, $\dots, \mathbf{x}_N = (X_1^N, \dots, X_{n_N}^N)$ is given. Each sequence is generated by one of κ different *unknown* time-series distributions. The target clustering is the partitioning of $\mathbf{x}_1, \dots, \mathbf{x}_N$ into κ clusters, putting together those and only those sequences that were generated by the same time-series distribution. We call a batch clustering algorithm *asymptotically consistent* if, with probability 1, it stabilises on the target clustering in the limit as the lengths $n_1, \dots, n_N$ of each of the N samples tend to infinity. The number κ of clusters may be either known or unknown. Note that the asymptotic is not with respect to the number of sequences, but with respect to the individual sequence lengths.

In the *online* setting we have a growing body of sequences of data. The number of sequences as well as the sequences themselves grow with time. The manner of this evolution can be arbitrary; we only require that the length of each individual sequence tend to infinity. Similarly to the batch setting, the joint distribution generating the data is unknown. At time step 1 initial segments of some of the first sequences are available to the learner. At each subsequent time step, new data are revealed, either as an extension of a previously observed sequence, or as a new sequence. Thus, at each time step t a total of $N(t)$ sequences $\mathbf{x}_1, \dots, \mathbf{x}_{N(t)}$ are to be clustered, where each sequence $\mathbf{x}_i$ is of length $n_i(t) \in \mathbb{N}$ for $i = 1..N(t)$. The total number of observed sequences $N(t)$ as well as the individual sequence lengths $n_i(t)$ grow with time. In the online setting, a clustering algorithm is called asymptotically consistent, if almost surely for each fixed batch of sequences $\mathbf{x}_1, \dots, \mathbf{x}_N$, the clustering restricted to this sequences coincides with the target clustering from some time on.

At first glance it may seem that one can use the offline algorithm in the online setting by simply applying it to the entire data observed at every time step. However, this naive approach does not result in a consistent algorithm. The main challenge in the online setting can be identified with what we regard as "bad" sequences: sequences for which sufficient information has not yet been collected, and thus cannot be distinguished based on the process distributions that generate them. In this setting, using a batch algorithm at every time step results in not only mis-clustering such "bad" sequences, but also in clustering incorrectly those for which sufficient data are already available. That is, such "bad" sequences can render the entire batch clustering useless, leading the algorithm to incorrectly cluster even the "good" sequences. Since new sequences may arrive in an uncontrollable (even data-dependent, adversarial) fashion, any batch algorithm will fail in this scenario.

1.2 Results

The first result of this work is a formal definition of the problem of time-series clustering which is rather intuitive, and at the same time allows for the construction of efficient algorithms that are provably consistent under the most general assumptions. The second result is the construction of such algorithms.

More specifically, we propose clustering algorithms that, as we further show, are strongly asymptotically consistent, provided that the number κ of clusters is known, and the process

distribution generating each sequence is stationary ergodic. No restrictions are placed on the dependence between the sequences: this dependence may be arbitrary (and can be thought of as adversarial). This consistency result is established in each of the two settings (offline and online) introduced above.

As follows from the theoretical impossibility results of Ryabko (2010c) that are discussed further in Section 1.4, under the only assumption that the distributions generating the sequences are stationary ergodic, it is impossible to find the correct number of clusters κ, that is, the total number of different time-series distributions that generate the data. Moreover, non-asymptotic results (finite-time bounds on the probability of error) are also provably impossible to obtain in this setting, since this is already the case for the problem of estimating the probability of any finite-time event (Shields, 1996).

Finding the number κ of clusters, as well as obtaining non-asymptotic performance guarantees, is possible under additional conditions on the distributions. In particular, we show that if κ is unknown, it is possible to construct consistent algorithms provided that the distributions are mixing and bounds on the mixing rates are available.

However, the main focus of this paper remains on the general framework where no additional assumptions on the unknown process distributions are made (other than that they are stationary ergodic). As such, the main theoretical and experimental results concern the case of known κ.

Finally, we show that our methods can be implemented efficiently: they are at most quadratic in each of their arguments, and are linear (up to log terms) in some formulations. To test the empirical performance of our algorithms we evaluated them on both synthetic and real data. To reflect the generality of the suggested framework in the experimental setup, we had our synthetic data generated by stationary ergodic process distributions that do not belong to any "simpler" class of distributions, and in particular cannot be modelled as hidden Markov processes with countable sets of states. In the batch setting, the error rates of both methods go to zero with sequence length. In the online setting with new samples arriving at every time step, the error rate of the offline algorithm remains consistently high, whereas that of the online algorithm converges to zero. This demonstrates that, unlike the offline algorithm, the online algorithm is robust to "bad" sequences. To demonstrate the applicability of our work to real-world scenarios, we chose the problem of clustering motion-capture sequences of human locomotion. This application area has also been studied in the works (Li and Prakash, 2011) and (Jebara et al., 2007) that (to the best of our knowledge) constitute the state-of-the-art performance[1] on the data sets they consider, and against which we compare the performance of our methods. We obtained consistently better performance on the data sets involving motion that can be considered ergodic (walking, running), and competitive performance on those involving non-ergodic motions (single jumps).

1. After this paper had been accepted for publication and entered the production stage, the work (Tschannen and Bolcskei, 2015) appeared, which uses the data set of Li and Prakash (2011) and reports a better performance on it as compared to both our algorithm and that of Li and Prakash (2011).

1.3 Methodology and Algorithms

A crucial point of any clustering method is the similarity measure. Since the objective in our formulation is to cluster time series based on the distributions that generate them, the similarity measure must reflect the difference between the underlying distributions. As we aim to make as few assumptions as possible on the distributions that generate the data, and since we make no assumptions on the nature of differences between the distributions, the distance should take into account all possible differences between time-series distributions. Moreover, it should be possible to construct estimates of this distance that are consistent for arbitrary stationary ergodic distributions.

It turns out that a suitable distance for this purpose is the so-called distributional distance. The distributional distance $d(\rho_1, \rho_2)$ between a pair of process distributions ρ_1, ρ_2 is defined (Gray, 1988) as $\sum_{j\in\mathbb{N}} w_j|\rho_1(B_j) - \rho_2(B_j)|$ where, w_j are positive summable real weights, e.g. $w_j = 1/j(j+1)$, and B_j range over a countable field that generates the σ-algebra of the underlying probability space. For example, consider finite-alphabet processes with the binary alphabet $\mathcal{X} = \{0, 1\}$. In this case $B_j,\ j \in \mathbb{N}$ would range over the set $\mathcal{X}^* = \cup_{m\in\mathbb{N}}\mathcal{X}^m$; that is, over all tuples $0, 1, 00, 01, 10, 11, 000, 001, \ldots$; therefore, the distributional distance in this case is the weighted sum of the differences of the probability values (calculated with respect to ρ_1 and ρ_2) of all possible tuples. In this case, the distributional distance metrises the topology of weak convergence. In this work we consider real-valued processes so that the sets B_j range over a suitable sequence of intervals, all pairs of such intervals, triples, and so on (see the formal definitions in Section 2). Although this distance involves infinite summations, we show that its empirical approximations can be easily calculated. Asymptotically consistent estimates of this distance can be obtained by replacing unknown probabilities with the corresponding frequencies (Ryabko and Ryabko, 2010); these estimators have proved useful in various statistical problems concerning ergodic processes (Ryabko and Ryabko, 2010; Ryabko, 2012; Khaleghi and Ryabko, 2012).

Armed with an estimator of the distributional distance, it is relatively easy to construct a consistent clustering algorithm for the batch setting. In particular, we show that the following algorithm is asymptotically consistent. First, a set of κ cluster centres are chosen by κ farthest point initialisation (using an empirical estimate of the distributional distance). This means that the first sequence is assigned as the first cluster centre. Iterating over $2..\kappa$, at every iteration a sequence is sought which has the largest minimum distance from the already chosen cluster centres. Next, the remaining sequences are assigned to the closest clusters.

The online algorithm is based on a *weighted combination* of several clusterings, each obtained by running the offline procedure on different portions of data. The partitions are combined with weights that depend on the batch size and on an appropriate performance measure for each individual partition. The performance measure of each clustering is the minimum inter-cluster distance.

1.4 Related Work

Some probabilistic formulations of the time-series clustering problem can be considered related to ours. Perhaps the closest is in terms of mixture models (Bach and Jordan, 2004; Biernacki et al., 2000; Kumar et al., 2002; Smyth, 1997; Zhong and Ghosh, 2003):

it is assumed that the data are generated by a mixture of κ different distributions that have a particular known form (such as Gaussian, Hidden Markov models, or graphical models). Thus, each of the N samples is independently generated according to one of these κ distributions (with some fixed probability). Since the model of the data is specified quite well, one can use likelihood-based distances (and then, for example, the k-means algorithm), or Bayesian inference, to cluster the data. Another typical objective is to estimate the parameters of the distributions in the mixture (e.g., Gaussians), rather than actually clustering the data points. Clearly, the main difference between this setting and ours is in that we do not assume any known model for the data; we do not even require independence between the samples.

Taking a different perspective, the problem of clustering in our formulations generalises two classical problems in mathematical statistics, namely, homogeneity testing (or the two-sample problem) and process classification (or the three-sample problem). In the *two-sample problem*, given two sequences $\mathbf{x}_1 = (X_1^1, \ldots, X_{n_1}^1)$ and $\mathbf{x}_2 = (X_1^2, \ldots, X_{n_2}^2)$ it is required to test whether they are generated by the same or by different process distributions. This corresponds to the special case of clustering only $N = 2$ data points where the number κ of clusters is unknown: it can be either 1 or 2. In the *three-sample problem,* three sequences $\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3$ are given, and it is known that $\mathbf{x}_1$ and $\mathbf{x}_2$ are generated by different distributions, while $\mathbf{x}_3$ is generated either by the same distribution as $\mathbf{x}_1$ or by the same distribution as $\mathbf{x}_2$. It is required to find which one is the case. This can be seen as clustering $N = 3$ data points, with the number of clusters known: $\kappa = 2$. The classical approach is, of course, to consider Gaussian i.i.d. samples, but general nonparametric solutions exist not only for i.i.d. data (Lehmann, 1986), but also for Markov chains (Gutman, 1989), as well as under certain conditions on the mixing rates of the processes. Observe that the two-sample problem is more difficult to solve than the three-sample problem, since the number κ of clusters is unknown in the former while it is given in the latter. Indeed, as shown by Ryabko (2010c), in general for stationary ergodic (binary-valued) processes there is no solution for the two-sample problem, even in the weakest asymptotic sense. A solution to the three-sample problem for (real-valued) stationary ergodic processes was given by (Ryabko and Ryabko, 2010); it is based on estimating the distributional distance.

More generally, the area of nonparametric statistical analysis of stationary ergodic time series to which the main results of this paper belong, is full of both positive and negative results, some of which are related to the problem of clustering in our formulation. Among these we can mention change point problems (Carlstein and Lele, 1994; Khaleghi and Ryabko, 2012, 2014) hypothesis testing (Ryabko, 2012, 2014; Morvai and Weiss, 2005) and prediction (Ryabko, 1988; Morvai and Weiss, 2012).

1.5 Organization

The remainder of the paper is organised as follows. We start by introducing notation and definitions in Section 2. In Section 3 we define the considered clustering protocol. Our main theoretical results are given in Section 4, where we present our methods, prove their consistency, and discuss some extensions (Section 4.4). Section 5 is devoted to computational considerations. In Section 6 we provide some experimental evaluations on both synthetic and real data. Finally, in Section 7 we provide some concluding remarks and open questions.

2. Preliminaries

Let $\mathcal{X}$ be a measurable space (the domain); in this work we let $\mathcal{X} = \mathbb{R}$ but extensions to more general spaces are straightforward. For a sequence $X_1, \dots, X_n$ we use the abbreviation $X_{1..n}$. Consider the Borel σ-algebra $\mathcal{B}$ on $\mathcal{X}^\infty$ generated by the cylinders $\{B \times \mathcal{X}^\infty : B \in B^{m,l}, m, l \in \mathbb{N}\}$ where, the sets $B^{m,l}, m, l \in \mathbb{N}$ are obtained via the partitioning of $\mathcal{X}^m$ into cubes of dimension m and volume 2^{-ml} (starting at the origin). Let also $B^m := \cup_{l \in \mathbb{N}} B^{m,l}$. We may choose any other means to generate the Borel σ-algebra $\mathcal{B}$ on $\mathcal{X}$, but we need to fix a specific choice for computational reasons. Process distributions are probability measures on the space $(\mathcal{X}^\infty, \mathcal{B})$. Similarly, one can define distributions over the space $((\mathcal{X}^\infty)^\infty, \mathcal{B}_2)$ of infinite matrices with the Borel σ-algebra $\mathcal{B}_2$ generated by the cylinders $\{(\mathcal{X}^\infty)^k \times (B \times \mathcal{X}^\infty) \times (\mathcal{X}^\infty)^\infty : \ B \in B^{m,l}, k, m, l \in \{0\} \cup \mathbb{N}\}$. For $\mathbf{x} = X_{1..n} \in \mathcal{X}^n$ and $B \in B^m$ let $\nu(\mathbf{x}, B)$ denote the *frequency* with which $\mathbf{x}$ falls in B, i.e.

$$\nu(\mathbf{x}, B) := \frac{\mathbb{I}\{n \geq m\}}{n - m + 1} \sum_{i=1}^{n-m+1} \mathbb{I}\{X_{i..i+m-1} \in B\} \tag{1}$$

A process ρ is *stationary* if for any $i, j \in 1..n$ and $B \in \mathcal{B}$, we have

$$\rho(X_{1..j} \in B) = \rho(X_{i..i+j-1} \in B).$$

A stationary process ρ is called *ergodic* if for all $B \in \mathcal{B}$ with probability 1 we have

$$\lim_{n \to \infty} \nu(X_{1..n}, B) = \rho(B).$$

By virtue of the ergodic theorem (e.g., Billingsley, 1961), this definition can be shown to be equivalent to the standard definition of stationary ergodic processes (every shift-invariant set has measure 0 or 1; see, e.g., Gray, 1988).

Definition 1 (Distributional Distance) *The distributional distance between a pair of process distributions ρ_1, ρ_2 is defined as follows (Gray, 1988):*

$$d(\rho_1, \rho_2) = \sum_{m,l=1}^{\infty} w_m w_l \sum_{B \in B^{m,l}} |\rho_1(B) - \rho_2(B)|,$$

where we set $w_j := 1/j(j+1)$, but any summable sequence of positive weights may be used.

In words, this involves partitioning the sets $\mathcal{X}^m$, $m \in \mathbb{N}$ into cubes of decreasing volume (indexed by l) and then taking a sum over the absolute differences in probabilities of all of the cubes in these partitions. The differences in probabilities are weighted: smaller weights are given to larger m and finer partitions.

Remark 2 The distributional distance is more generally defined as

$$d'(\rho_1, \rho_2) := \sum_{i \in \mathbb{N}} w_i |\rho_1(A_i) - \rho_2(A_i)|$$

where A_i ranges over a countable field that generates the σ-algebra of the underlying probability space (Gray, 1988). Definition 1 above is more suitable for implementing and testing

algorithms, while the consistency results of this paper hold for either. Note also that the choice of sets B_i may result in a different topology on the space of time-series distributions. The particular choice we made results in the usual topology of weak convergence (Billingsley, 1999).

We use the following empirical estimates of the distributional distance.

Definition 3 (Empirical estimates of d) *Define the empirical estimate of the distributional distance between a sequence $\mathbf{x} = X_{1..n} \in \mathcal{X}^n, n \in \mathbb{N}$ and a process distribution ρ as*

$$\hat{d}(\mathbf{x}, \rho) := \sum_{m=1}^{m_n} \sum_{l=1}^{l_n} w_m w_l \sum_{B \in B^{m,l}} |\nu(\mathbf{x}, B) - \rho(B)|, \tag{2}$$

and that between a pair of sequences $\mathbf{x}_i \in \mathcal{X}^{n_i}$ $n_i \in \mathbb{N}$, $i = 1, 2$ as

$$\hat{d}(\mathbf{x}_1, \mathbf{x}_2) := \sum_{m=1}^{m_n} \sum_{l=1}^{l_n} w_m w_l \sum_{B \in B^{m,l}} |\nu(\mathbf{x}_1, B) - \nu(\mathbf{x}_2, B)|, \tag{3}$$

where m_n and l_n are any sequences that go to infinity with n, and $(w_j)_{j \in \mathbb{N}}$ are as in Definition 1.

Remark 4 (constants m_n, l_n) The sequences of constants $m_n, l_n (n \in \mathbb{N})$ in the definition of $\hat{d}$ are intended to introduce some computational flexibility in the estimate: while already the choice $m_n, l_n \equiv \infty$ is computationally feasible, other choices give better computational complexity without sacrificing the quality of the estimate; see Section 5. For the asymptotic consistency results this choice is irrelevant. Thus, in the proofs we tacitly assume $m_n, l_n \equiv \infty$; extension to the general case is straightforward.

Lemma 5 ($\hat{d}$ is asymptotically consistent: Ryabko and Ryabko, 2010) *For every pair of sequences $\mathbf{x}_1 \in \mathcal{X}^{n_1}$ and $\mathbf{x}_2 \in \mathcal{X}^{n_2}$ with joint distribution ρ whose marginals $\rho_i, i = 1, 2$ are stationary ergodic we have*

$$\lim_{n_1, n_2 \to \infty} \hat{d}(\mathbf{x}_1, \mathbf{x}_2) = d(\rho_1, \rho_2), \ \rho - a.s., \ \text{and} \tag{4}$$

$$\lim_{n_i \to \infty} \hat{d}(\mathbf{x}_i, \rho_j) = d(\rho_i, \rho_j), \ i, j \in 1, 2, \ \rho - a.s. \tag{5}$$

The proof of this lemma can be found in the work (Ryabko and Ryabko, 2010); since it is important for further development but rather short and simple, we reproduce it here.

Proof The idea of the proof is simple: for each set $B \in \mathcal{B}$, the frequency with which the sample $\mathbf{x}_i$, $i = 1, 2$ falls into B converges to the probability $\rho_i(B)$, $i = 1, 2$. When the sample sizes grow, there will be more and more sets $B \in \mathcal{B}$ whose frequencies have already converged to the corresponding probabilities, so that the cumulative weight of those sets whose frequencies have not converged yet will tend to 0.

Fix $\varepsilon > 0$. We can find an index J such that

$$\sum_{m,l=J}^{\infty} w_m w_l \leq \varepsilon/3.$$

Moreover, for each $m, l \in 1..J$ we can find a finite subset $S^{m,l}$ of $B^{m,l}$ such that

$$\rho_i(S^{m,l}) \geq 1 - \frac{\varepsilon}{6Jw_m w_l}.$$

There exists some N (which depends on the realization $X_1^i, \ldots, X_{n_i}^i,\ i = 1, 2$) such that for all $n_i \geq N,\ i = 1, 2$ we have,

$$\sup_{B \in S^{m,l}} |\nu(\mathbf{x}_i, B) - \rho_i(B)| \leq \frac{\varepsilon \rho_i(B)}{6Jw_m w_l},\ i = 1, 2. \tag{6}$$

For all $n_i \geq N,\ i = 1, 2$ we have

$$\begin{aligned}
|\hat{d}(\mathbf{x}_1, \mathbf{x}_2) - d(\rho_1, \rho_2)| &= \left| \sum_{m,l=1}^{\infty} w_m w_l \sum_{B \in B^{m,l}} \big(|\nu(\mathbf{x}_1, B) - \nu(\mathbf{x}_2, B)| - |\rho_1(B) - \rho_2(B)| \big) \right| \\
&\leq \sum_{m,l=1}^{\infty} w_m w_l \sum_{B \in B^{m,l}} |\nu(\mathbf{x}_1, B) - \rho_1(B)| + |\nu(\mathbf{x}_2, B) - \rho_2(B)| \\
&\leq \sum_{m,l=1}^{J} w_m w_l \sum_{B \in S^{m,l}} \big(|\nu(\mathbf{x}_1, B) - \rho_1(B)| + |\nu(\mathbf{x}_2, B) - \rho_2(B)| \big) + 2\varepsilon/3 \\
&\leq \sum_{m,l=1}^{J} w_m w_l \sum_{B \in S^{m,l}} \frac{\rho_1(B)\varepsilon}{6Jw_m w_l} + \frac{\rho_2(B)\varepsilon}{6Jw_m w_l} + 2\varepsilon/3 \leq \varepsilon,
\end{aligned}$$

which proves (4). The statement (5) can be proven analogously. ■

Remark 6 The triangle inequality holds for the distributional distance $d(\cdot, \cdot)$ and its empirical estimates $\hat{d}(\cdot, \cdot)$ so that for all distributions $\rho_i,\ i = 1..3$ and all sequences $\mathbf{x}_i \in \mathcal{X}^{n_i}\ n_i \in \mathbb{N},\ i = 1..3$ we have

$$\begin{aligned}
d(\rho_1, \rho_2) &\leq d(\rho_1, \rho_3) + d(\rho_2, \rho_3), \\
\hat{d}(\mathbf{x}_1, \mathbf{x}_2) &\leq \hat{d}(\mathbf{x}_1, \mathbf{x}_3) + \hat{d}(\mathbf{x}_2, \mathbf{x}_3), \\
\hat{d}(\mathbf{x}_1, \rho_1) &\leq \hat{d}(\mathbf{x}_1, \rho_2) + d(\rho_1, \rho_2).
\end{aligned}$$

3. Clustering Settings: Offline and Online

We start with a common general probabilistic setup for both settings (offline and online), which we use to formulate each of the two settings separately.

Consider the matrix $\mathbf{X} \in (\mathcal{X}^\infty)^\infty$ of random variables

$$\mathbf{X} := \begin{bmatrix} X_1^1 & X_2^1 & X_3^1 & \ldots \\ X_1^2 & X_2^2 & \ldots & \ldots \\ \vdots & \vdots & \ddots & \vdots \end{bmatrix} \in (\mathcal{X}^\infty)^\infty \tag{7}$$

generated by some probability distribution P on $((\mathcal{X}^\infty)^\infty, \mathcal{B}_2)$. Assume that the marginal distribution of P on each row of $\mathbf{X}$ is one of κ *unknown stationary ergodic* process distributions $\rho_1, \rho_2, \ldots, \rho_\kappa$. Thus, the matrix $\mathbf{X}$ corresponds to infinitely many one-way infinite sequences, each of which is generated by a stationary ergodic distribution. Aside from this assumption, we do not make any further assumptions on the distribution P that generates $\mathbf{X}$. This means that the rows of $\mathbf{X}$ (corresponding to different time-series samples) are allowed to be dependent, and the dependence can be arbitrary; one can even think of the dependence between samples as *adversarial*. For notational convenience we assume that the distributions $\rho_k, k = 1..\kappa$ are ordered based on the order of appearance of their first rows (samples) in $\mathbf{X}$.

Among the various ways the rows of $\mathbf{X}$ may be partitioned into κ disjoint subsets, the most natural partitioning in this formulation is to group together those and only those rows for which the marginal distribution is the same. More precisely, we define the ground-truth partitioning of $\mathbf{X}$ as follows.

Definition 7 (Ground-truth $\mathcal{G}$) *Let*

$$\mathcal{G} = \{\mathcal{G}_1, \ldots, \mathcal{G}_\kappa\}$$

be a partitioning of $\mathbb{N}$ into κ disjoint subsets $\mathcal{G}_k,\ k = 1..\kappa$, such that the marginal distribution of $\mathbf{x}_i,\ i \in \mathbb{N}$ is ρ_k for some $k \in 1..\kappa$ if and only if $i \in \mathcal{G}_k$. We call $\mathcal{G}$ the ground-truth clustering. We also introduce the notation $\mathcal{G}|_N$ for the restriction of $\mathcal{G}$ to the first N sequences:

$$\mathcal{G}|_N := \{\mathcal{G}_k \cap \{1..N\} : k = 1..\kappa\}.$$

3.1 Offline Setting

The problem is formulated as follows. We are given a finite set $S := \{\mathbf{x}_1, \ldots, \mathbf{x}_N\}$ of N samples, for some fixed $N \in \mathbb{N}$. Each sample is generated by one of κ unknown stationary ergodic process distributions $\rho_1, \ldots, \rho_\kappa$. More specifically, the set S is obtained from $\mathbf{X}$ as follows. Some (arbitrary) lengths $n_i \in \mathbb{N},\ i \in 1..N$ are fixed, and $\mathbf{x}_i$ for each $i = 1..N$ is defined as $\mathbf{x}_i := X_{1..n_i}^i$.

A clustering function f takes a finite set $S := \{\mathbf{x}_1, \ldots, \mathbf{x}_N\}$ of samples and an optional parameter κ (the number of target clusters) to produce a partition $f(S, \kappa) := \{C_1, \ldots, C_\kappa\}$ of the index set $\{1..N\}$. The goal is to partition $\{1..N\}$ so as to recover the ground-truth clustering $\mathcal{G}|_N$. For consistency of notation, in the offline setting we identify $\mathcal{G}$ with $\mathcal{G}|_N$. We call a clustering algorithm asymptotically consistent if it achieves this goal for long enough sequences $\mathbf{x}_i,\ i = 1..N$ in S:

Definition 8 (Consistency: offline setting) *A clustering function f is consistent for a set of sequences S if $f(S, \kappa) = \mathcal{G}$. Moreover, denoting $n := \min\{n_1, \ldots, n_N\}$, f is called strongly asymptotically consistent in the offline sense if with probability 1 from some n on it is consistent on the set S: $P(\exists n' \forall n > n' f(S, \kappa) = \mathcal{G}) = 1$. It is weakly asymptotically consistent if $\lim_{n \to \infty} P(f(S, \kappa) = \mathcal{G}) = 1$.*

Note that the notion of consistency above is asymptotic with respect to the minimum sample length n, and not with respect to the number N of samples.

When considering the offline setting with a known number of clusters κ we assume that N is such that $\{1..N\} \cap \mathcal{G}_k \neq \varnothing$ for every $k = 1..\kappa$ (that is, all κ clusters are represented); otherwise we could just take a smaller κ.

3.2 Online Setting

The online problem is formulated as follows. Consider the infinite matrix $\mathbf{X}$ given by (7). At every time step $t \in \mathbb{N}$, a part $S(t)$ of $\mathbf{X}$ is observed corresponding to the first $N(t) \in \mathbb{N}$ rows of $\mathbf{X}$, each of length $n_i(t), i \in 1..N(t)$, i.e.

$$S(t) = \{\mathbf{x}_1^t, \cdots \mathbf{x}_{N(t)}^t\} \text{ where } \mathbf{x}_i^t := X_{1..n_i(t)}^i.$$

This setting is depicted in Figure 1. We assume that the number of samples, as well as the individual sample-lengths grow with time. That is, the length $n_i(t)$ of each sequence $\mathbf{x}_i$ is nondecreasing and grows to infinity (as a function of time t). The number of sequences $N(t)$ also grows to infinity. Aside from these assumptions, the functions $N(t)$ and $n_i(t)$ are completely arbitrary.

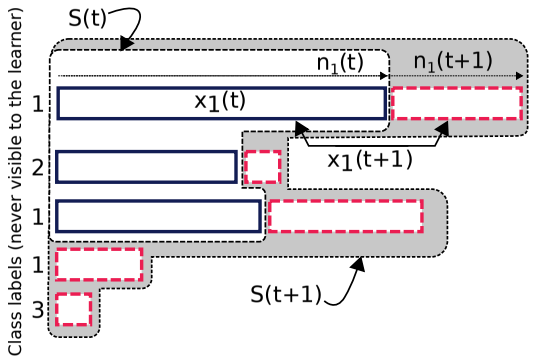

Figure 1: Online Protocol: solid rectangles correspond to sequences available at time t, dashed rectangles correspond to segments arrived at time $t+1$.

An online clustering function is strongly asymptotically consistent if, with probability 1, for each $N \in \mathbb{N}$ from some time on the first N sequences are clustered correctly (with respect to the ground-truth given by Definition 7).

Definition 9 (Consistency: online setting) *A clustering function is strongly (weakly) asymptotically consistent in the online sense, if for every $N \in \mathbb{N}$ the clustering $f(S(t), \kappa)|_N$ is strongly (weakly) asymptotically consistent in the offline sense, where $f(S(t), \kappa)|_N$ is the clustering $f(S(t), \kappa)$ restricted to the first N sequences:*

$$f(S(t), \kappa)|_N := \{f(S(t), \kappa) \cap \{1..N\}, k = 1..\kappa\}.$$

Remark 10 Note that even if the *eventual* number κ of different time-series distributions producing the sequences (that is, the number of clusters in the ground-truth clustering $\mathcal{G}$) is known, the number of observed distributions at each individual time step is unknown. That is, it is possible that at a given time t we have $\left|\mathcal{G}|_{N(t)}\right| < \kappa$.

Known and unknown κ. As mentioned in the introduction, in the general framework described above, consistent clustering (for both the offline and the online problems) with unknown number of clusters is impossible. This follows from the impossibility result of Ryabko (2010c) that states that when we have only two (binary-valued) samples generated (independently) by two stationary ergodic distributions, it is impossible to decide whether they have been generated by the same or by different distributions, even in the sense of weak asymptotic consistency. (This holds even if the distributions come from a smaller class: the set of all B-processes.) Therefore, if the number of clusters is unknown, we are bound to make stronger assumptions. Since our main interest in this paper is to develop consistent clustering algorithms under the general framework described above, for the most part of this paper we assume that the correct number κ of clusters is known. However, in Section 4.3 we also show that under certain mixing conditions on the process distributions that generate the data, it is possible to have consistent algorithms in the case of unknown κ as well.

4. Clustering Algorithms and their Consistency

In this section we present our clustering methods for both the offline and the online settings. The main results, presented in Sections 4.1 (offline) and 4.2 (online), concern the case where the number of clusters κ is known. In Section 4.3 we show that, given the mixing rates of the process distributions that generate the data, it is possible to find the correct number of clusters κ and thus obtain consistent algorithms for the case of unknown κ as well. Finally, Section 4.4 considers some extensions of the proposed settings.

4.1 Offline Setting

Given that we have asymptotically consistent estimates $\hat{d}$ of the distributional distance d, it is relatively simple to construct asymptotically consistent clustering algorithms for the offline setting. This follows from the fact that, since $\hat{d}(\cdot,\cdot)$ converges to $d(\cdot,\cdot)$, for large enough sequence lengths n the points $\mathbf{x}_1, \ldots, \mathbf{x}_N$ have the so-called strict separation property: the points within each target cluster are closer to each other than to points in any other cluster (on strict separation in clustering see, for example, Balcan et al., 2008). This makes many simple algorithms, such as single or average linkage, or the k-means algorithm with certain initialisations, provably consistent.

We present below one specific algorithm that we show to be asymptotically consistent in the general framework introduced. What makes this simple algorithm interesting is that it requires only κN distance calculations (that is, much less than is needed to calculate the distance between each two sequences). In short, Algorithm 1 initialises the clusters using farthest-point initialisation, and then assigns each remaining point to the nearest cluster. More precisely, the sample $\mathbf{x}_1$ is assigned as the first cluster centre. Then a sample is found that is farthest away from $\mathbf{x}_1$ in the empirical distributional distance $\hat{d}$ and is assigned as

the second cluster centre. For each $k = 2..\kappa$ the k^{th} cluster centre is sought as the sequence with the largest minimum distance from the already assigned cluster centres for $1..k-1$. (This initialisation was proposed for use with k-means clustering by Katsavounidis et al., 1994.) By the last iteration we have κ cluster centres. Next, the remaining samples are each assigned to the closest cluster.

Algorithm 1 Offline clustering

INPUT: sequences $S := \{\mathbf{x}_1, \cdots, \mathbf{x}_N\}$**, Number** κ **of clusters**
Initialize κ***-farthest points as cluster-centres:***
$c_1 \leftarrow 1$
$C_1 \leftarrow \{c_1\}$
for $k = 2..\kappa$ **do**
  $c_k \leftarrow \operatorname{argmax}_{i=1..N} \min_{j=1..k-1} \hat{d}(\mathbf{x}_i, \mathbf{x}_{c_j})$***, where ties are broken arbitrarily***
  $C_k \leftarrow \{c_k\}$
end for
Assign the remaining points to closest centres:
for $i = 1..N$ **do**
  $k \leftarrow \operatorname{argmin}_{j \in \bigcup_{k=1}^{\kappa} C_k} \hat{d}(\mathbf{x}_i, \mathbf{x}_j)$
  $C_k \leftarrow C_k \cup \{i\}$
end for
OUTPUT: clusters $C_1, C_2, \cdots, C_\kappa$

Theorem 11 *Algorithm 1 is strongly asymptotically consistent (in the offline sense of Definition 8), provided that the correct number κ of clusters is known, and the marginal distribution of each sequence $\mathbf{x}_i, i = 1..N$ is stationary ergodic.*

Proof To prove the consistency statement we use Lemma 5 to show that if the samples in S are long enough, the samples that are generated by the same process distribution are closer to each other than to the rest of the samples. Therefore, the samples chosen as cluster centres are each generated by a different process distribution, and since the algorithm assigns the rest of the samples to the closest clusters, the statement follows. More formally, let n denote the shortest sample length in S:

$$n_{\min} := \min_{i \in 1..N} n_i.$$

Denote by δ the minimum nonzero distance between the process distributions:

$$\delta := \min_{k \neq k' \in 1..\kappa} \hat{d}(\rho_k, \rho_{k'}).$$

Fix $\varepsilon \in (0, \delta/4)$. Since there are a finite number N of samples, by Lemma 5 for all large enough $n_{\min}$ we have

$$\sup_{\substack{k \in 1..\kappa \\ i \in \mathcal{G}_k \cap \{1..N\}}} \hat{d}(\mathbf{x}_i, \rho_k) \leq \varepsilon. \tag{8}$$

where $\mathcal{G}_k$, $k = 1..\kappa$ denote the ground-truth partitions given by Definition 7. By (8) and applying the triangle inequality we obtain

$$\sup_{\substack{k \in 1..\kappa \\ i,j \in \mathcal{G}_k \cap \{1..N\}}} \hat{d}(\mathbf{x}_i, \mathbf{x}_j) \leq 2\varepsilon. \tag{9}$$

Thus, for all large enough $n_{\min}$ we have

$$\begin{aligned} \inf_{\substack{i \in \mathcal{G}_k \cap \{1..N\} \\ j \in \mathcal{G}_{k'} \cap \{1..N\} \\ k \neq k' \in 1..\kappa}} \hat{d}(\mathbf{x}_i, \mathbf{x}_j) &\geq \inf_{\substack{i \in \mathcal{G}_k \cap \{1..N\} \\ j \in \mathcal{G}_{k'} \cap \{1..N\} \\ k \neq k' \in 1..\kappa}} d(\rho_k, \rho_{k'}) - \hat{d}(\mathbf{x}_i, \rho_k) - \hat{d}(\mathbf{x}_j, \rho_{k'}) \\ &\geq \delta - 2\varepsilon \end{aligned} \tag{10}$$

where the first inequality follows from the triangle inequality, and the second inequality follows from (8) and the definition of δ. In words, (9) and (10) mean that the samples in $\mathcal{S}$ that are generated by the same process distribution are closer to each other than to the rest of the samples. Finally, for all $n_{\min}$ large enough to have (9) and (10) we obtain

$$\max_{i=1..N} \min_{k=1..\kappa-1} \hat{d}(\mathbf{x}_i, \mathbf{x}_{c_k}) \geq \delta - 2\varepsilon > \delta/2$$

where as specified by Algorithm 1, $c_1 := 1$ and $c_k := \operatorname{argmax}_{i=1..N} \min_{j=1..k-1} \hat{d}(\mathbf{x}_i, \mathbf{x}_{c_j})$, $k = 2..\kappa$. Hence, the indices $c_1, \ldots, c_\kappa$ will be chosen to index sequences generated by different process distributions. To derive the consistency statement, it remains to note that, by (9) and (10), each remaining sequence will be assigned to the cluster centre corresponding to the sequence generated by the same distribution. ■

4.2 Online Setting

The online version of the problem turns out to be more complicated than the offline one. The challenge is that, since new sequences arrive (potentially) at every time step, we can never rely on the distance estimates corresponding to all of the observed samples to be correct. Thus, as mentioned in the introduction, the main challenge can be identified with what we regard as "bad" sequences: recently-observed sequences, for which sufficient information has not yet been collected, and for which the estimates of the distance (with respect to any other sequence) are bound to be misleading. Thus, in particular, farthest-point initialisation would not work in this case. More generally, using any batch algorithm on all available data at every time step results in not only mis-clustering "bad" sequences, but also in clustering incorrectly those for which sufficient data are already available.

The solution, realised in Algorithm 2, is based on a *weighted combination* of several clusterings, each obtained by running the offline algorithm (Algorithm 1) on different portions of data. The clusterings are combined with weights that depend on the batch size and on the minimum inter-cluster distance. This last step of combining multiple clusterings with weights may be reminiscent of prediction with expert advice (see Cesa-Bianchi and Lugosi, 2006 for an overview), where experts are combined based on their past performance.

Algorithm 2 Online Clustering

INPUT: Number κ of target clusters
for $t = 1..\infty$ **do**
  Obtain new sequences $S(t) = \{\mathbf{x}_1^t, \cdots, \mathbf{x}_{N(t)}^t\}$
  Initialize the normalization factor: $\eta \leftarrow 0$
  Initialize the final clusters: $C_k(t) \leftarrow \varnothing,\ k = 1..\kappa$
  Generate $N(t) - \kappa + 1$ **candidate cluster centres:**
  for $j = \kappa..N(t)$ **do**
    $\{C_1^j, \ldots, C_\kappa^j\} \leftarrow \mathrm{Alg1}(\{\mathbf{x}_1^t, \cdots, \mathbf{x}_j^t\}, \kappa)$
    $\mu_k \leftarrow \min\{i \in C_k^j\}, k = 1..\kappa$ ▷ Set the smallest index as cluster centre.
    $(c_1^j, \ldots, c_\kappa^j) \leftarrow \mathrm{sort}(\mu_1, \ldots, \mu_\kappa)$ ▷ Sort the cluster centres increasingly.
    $\gamma_j \leftarrow \min_{k \neq k' \in 1..\kappa} \hat{d}(\mathbf{x}^t_{c_k^j}, \mathbf{x}^t_{c_{k'}^j})$ ▷ Calculate performance score.
    $w_j \leftarrow 1/j(j+1)$
    $\eta \leftarrow \eta + w_j \gamma_j$
  end for
  Assign points to clusters:
  for $i = 1..N(t)$ **do**
    $k \leftarrow \mathrm{argmin}_{k' \in 1..\kappa} \frac{1}{\eta} \sum_{j=1}^{N(t)} w_j \gamma_j \hat{d}(\mathbf{x}_i^t, \mathbf{x}^t_{c_{k'}^j})$
    $C_k(t) \leftarrow C_k(t) \cup \{i\}$
  end for
  OUTPUT: $\{C_1(t), \cdots, C_k(t)\}$
end for

However, the difference here is that the performance of each clustering cannot be measured directly.

More precisely, Algorithm 2 works as follows. Given a set $S(t)$ of $N(t)$ samples, the algorithm iterates over $j := \kappa, \ldots, N(t)$ where at each iteration Algorithm 1 is used to cluster the first j sequences $\{\mathbf{x}_1^t, \ldots, \mathbf{x}_j^t\}$ into κ clusters. In each cluster the sequence with the smallest index is assigned as the candidate cluster centre. A performance score γ_j is calculated as the minimum distance $\hat{d}$ between the κ candidate cluster centres obtained at iteration j. Thus, γ_j is an estimate of the minimum inter-cluster distance. At this point we have $N(t) - \kappa + 1$ sets of κ cluster centres $c_1^j, \ldots, c_\kappa^j,\ j = 1..N(t) - \kappa + 1$. Next, every sample $\mathbf{x}_i^t,\ i = 1..N(t)$ is assigned to a cluster, according to the weighted combination of the distances between $\mathbf{x}_i^t$ and the candidate cluster centres obtained at each iteration on j. More precisely, for each $i = 1..N(t)$ the sequence $\mathbf{x}_i^t$ is assigned to the cluster κ, where κ is defined as

$$k := \mathrm{argmin}_{k=1..\kappa} \sum_{j=\kappa}^{N(t)} w_j \gamma_j \hat{d}(\mathbf{x}_i^t, \mathbf{x}^t_{c_k^j}).$$

Theorem 12 *Algorithm 2 is strongly asymptotically consistent (in the online sense of Definition 9), provided the correct number of clusters κ is known, and the marginal distribution of each sequence $\mathbf{x}_i, i \in \mathbb{N}$ is stationary ergodic.*

Before giving the proof of Theorem 12, we provide an intuitive explanation as to how Algorithm 2 works. First, consider the following simple candidate solution. Take some fixed (reference) portion of the samples, run the batch algorithm on it, and then simply assign every remaining sequence to the nearest cluster. Since the offline algorithm is asymptotically consistent, this procedure would be asymptotically consistent as well, but only if we knew that the selected reference of the sequences contains at least one sequence sampled from each and every one of the κ distributions. However, there is no way to find a fixed (not growing with time) portion of data that would be guaranteed to contain a representative of each cluster (that is, of each time-series distribution). Allowing such a reference set of sequences to grow with time would guarantee that eventually it contains representatives of all clusters, but it would break the consistency guarantee for the reference set; since the set grows, this formulation effectively returns us back to the original online clustering problem.

A key observation we make to circumvent this problem is the following. If, for some $j \in \{\kappa, \ldots, N(t)\}$, each sample in the batch $\{\mathbf{x}_1^t, \ldots, \mathbf{x}_j^t\}$ is generated by *at most* $\kappa - 1$ process distributions, any partitioning of this batch into κ sets results in a minimum inter-cluster distance γ_j that, as follows from the asymptotic consistency of $\hat{d}$, converges to 0. On the other hand, if the set of samples $\{\mathbf{x}_1^t, \ldots, \mathbf{x}_j^t\}$ contains sequences generated by all κ process distributions, γ_j converges to a nonzero constant, namely, the minimum distance between the distinct process distributions $\rho_1, \ldots, \rho_\kappa$. In the latter case from some time on the batch $\{\mathbf{x}_1^t, \ldots, \mathbf{x}_j^t\}$ will be clustered correctly. Thus, instead of selecting one reference batch of sequences and constructing a set of clusters based on those, we consider all batches of sequences for $j = \kappa..N(t)$, and combine them with weights. Two sets of weights are involved in this step: γ_j and w_j, where

1. γ_j is used to penalise for small inter-cluster distance, cancelling the clustering results produced based on sets of sequences generated by less than κ distributions;

2. w_j is used to give precedence to chronologically earlier clusterings, protecting the clustering decisions from the presence of the (potentially "bad") newly formed sequences, whose corresponding distance estimates may still be far from accurate.

As time goes on, the batches in which not all clusters are represented will have their weight γ_j converge to 0, while the number of batches that have all clusters represented and are clustered correctly by the offline algorithm will go to infinity, and their total weight will approach 1. Note that, since we are combining different clusterings, it is important to use a consistent ordering of clusters, for otherwise we might sum up clusters generated by different distributions. Therefore, we always order the clusters with respect to the index of the first sequence in each cluster.

Proof [of Theorem 12] First, we show that for every $k \in 1..\kappa$ we have

$$\frac{1}{\eta} \sum_{j=1}^{N(t)} w_j \gamma_j^t \hat{d}(\mathbf{x}^t_{c_k^j}, \rho_k) \to 0 \text{ a.s.} \tag{11}$$

Denote by δ the minimum nonzero distance between the process distributions:

$$\delta := \min_{k \neq k' \in 1..\kappa} \hat{d}(\rho_k, \rho_{k'}). \tag{12}$$

Fix $\varepsilon \in (0, \delta/4)$. We can find an index J such that $\sum_{j=J}^{\infty} w_j \le \varepsilon$. Let $S(t)|_j = \{\mathbf{x}_1^t, \cdots, \mathbf{x}_j^t\}$ denote the subset of $S(t)$ consisting of the first j sequences for $j \in 1..N(t)$. For $k = 1..\kappa$ let

$$s_k := \min\{i \in \mathcal{G}_k \cap 1..N(t)\} \tag{13}$$

index the first sequence in $S(t)$ that is generated by ρ_k where $\mathcal{G}_k,\ k = 1..\kappa$ are the ground-truth partitions given by Definition 7. Define

$$m := \max_{k \in 1..\kappa} s_k. \tag{14}$$

Recall that the sequence lengths $n_i(t)$ grow with time. Therefore, by Lemma 5 (consistency of $\hat{d}$) for every $j \in 1..J$ there exists some $T_1(j)$ such that for all $t \ge T_1(j)$ we have

$$\sup_{\substack{k \in 1..\kappa \\ i \in \mathcal{G}_k \cap \{1..j\}}} \hat{d}(\mathbf{x}_i^t, \rho_k) \le \varepsilon. \tag{15}$$

Moreover, by Theorem 11 for every $j \in m..J$ there exists some $T_2(j)$ such that $\mathrm{Alg1}(S(t)|_j, \kappa)$ is consistent for all $t \ge T_2(j)$. Let

$$T := \max_{\substack{i=1,2 \\ j \in 1..J}} T_i(j).$$

Recall that, by definition (14) of m, $S(t)|_m$ contains samples from all κ distributions. Therefore, for all $t \ge T$ we have

$$\begin{aligned}\inf_{k \ne k' \in 1..\kappa} \hat{d}(\mathbf{x}^t_{c_k^m}, \mathbf{x}^t_{c_{k'}^m}) &\ge \inf_{k \ne k' \in 1..\kappa} d(\rho_k, \rho_{k'}) - \sup_{k \ne k' \in 1..\kappa} (\hat{d}(\mathbf{x}^t_{c_k^m}, \rho_k) + \hat{d}(\mathbf{x}^t_{c_{k'}^m}, \rho_{k'})) \\ &\ge \delta - 2\varepsilon \ge \delta/2,\end{aligned} \tag{16}$$

where the first inequality follows from the triangle inequality and the second inequality follows from the consistency of $\mathrm{Alg1}(S(t)|_m, \kappa)$ for $t \ge T$, the definition of δ given by (12) and the assumption that $\varepsilon \in (0, \delta/4)$. Recall that (as specified in Algorithm 2) we have $\eta := \sum_{j=1}^{N(t)} w_j \gamma_j^t$. Hence, by (16) for all $t \ge T$ we have

$$\eta \ge w_m \delta/2. \tag{17}$$

By (17) and noting that by definition, $\hat{d}(\cdot,\cdot) \le 1$ for all $t \ge T$, for every $k \in 1..\kappa$ we obtain

$$\frac{1}{\eta}\sum_{j=1}^{N(t)} w_j \gamma_j^t \hat{d}(\mathbf{x}^t_{c_k^j}, \rho_k) \le \frac{1}{\eta}\sum_{j=1}^{J} w_j \gamma_j^t \hat{d}(\mathbf{x}^t_{c_k^j}, \rho_k) + \frac{2\varepsilon}{w_m \delta}. \tag{18}$$

On the other hand, by the definition (14) of m, the sequences in $S(t)|_j$ for $j = 1..m-1$ are generated by *at most* $\kappa - 1$ out of the κ process distributions. Therefore, at every iteration on $j \in 1..m-1$ there exists at least one pair of distinct cluster centres that are generated by *the same* process distribution. Therefore, by (15) and (17), for all $t \ge T$ and every $k \in 1..\kappa$ we have,

$$\frac{1}{\eta}\sum_{j=1}^{m-1} w_j \gamma_j^t \hat{d}(\mathbf{x}^t_{c_k^j}, \rho_i) \le \frac{1}{\eta}\sum_{j=1}^{m-1} w_j \gamma_j^t \le \frac{2\varepsilon}{w_m \delta}. \tag{19}$$

Noting that the clusters are ordered in the order of appearance of the distributions, we have $\mathbf{x}^t_{c_k^j} = \mathbf{x}^t_{s_k}$ for all $j = m..J$ and $k = 1..\kappa$, where the index s_k is defined by (13). Therefore, by (15) for all $t \ge T$ and every $k = 1..\kappa$ we have

$$\frac{1}{\eta}\sum_{j=m}^{J} w_j \gamma_j^t \hat{d}(\mathbf{x}^t_{c_k^j}, \rho_k) = \frac{1}{\eta}\hat{d}(\mathbf{x}^t_{s_k}, \rho_k)\sum_{j=m}^{J} w_j \gamma_j^t \le \varepsilon. \tag{20}$$

Combining (18), (19), and (20) we obtain

$$\frac{1}{\eta}\sum_{j=1}^{N(t)} w_j \gamma_j^t \hat{d}(\mathbf{x}^t_{c_k^j}, \rho_k) \le \varepsilon(1 + \frac{4}{w_m \delta}). \tag{21}$$

for all $k = 1..\kappa$ and all $t \ge T$, establishing (11).

To finish the proof of the consistency, consider an index $i \in \mathcal{G}_r$ for some $r \in 1..\kappa$. By Lemma 5, increasing T if necessary, for all $t \ge T$ we have

$$\sup_{\substack{k \in 1..\kappa \\ j \in \mathcal{G}_k \cap 1..N}} \hat{d}(\mathbf{x}_j^t, \rho_k) \le \varepsilon. \tag{22}$$

For all $t \ge T$ and all $k \ne r \in 1..\kappa$ we have,

$$\begin{aligned}\frac{1}{\eta}\sum_{j=1}^{N(t)} w_j \gamma_j^t \hat{d}(\mathbf{x}_i^t, \mathbf{x}^t_{c_k^j}) &\ge \frac{1}{\eta}\sum_{j=1}^{N(t)} w_j \gamma_j^t \hat{d}(\mathbf{x}_i^t, \rho_k) - \frac{1}{\eta}\sum_{j=1}^{N(t)} w_j \gamma_j^t \hat{d}(\mathbf{x}^t_{c_k^j}, \rho_k) \\ &\ge \frac{1}{\eta}\sum_{j=1}^{N(t)} w_j \gamma_j^t (\hat{d}(\rho_k, \rho_r) - \hat{d}(\mathbf{x}_i^t, \rho_r)) - \frac{1}{\eta}\sum_{j=1}^{N(t)} w_j \gamma_j^t \hat{d}(\mathbf{x}^t_{c_k^j}, \rho_k) \\ &\ge \delta - 2\varepsilon(1 + \frac{2}{w_m \delta}),\end{aligned} \tag{23}$$

where the first and second inequalities follow from the triangle inequality, and the last inequality follows from (22), (21) and the definition of δ. Since the choice of ε is arbitrary, from (22) and (23) we obtain

$$\operatorname*{argmin}_{k \in 1..\kappa} \frac{1}{\eta}\sum_{j=1}^{N(t)} w_j \gamma_j^t \hat{d}(\mathbf{x}_i^t, \mathbf{x}^t_{c_k^j}) = r. \tag{24}$$

It remains to note that for any fixed $N \in \mathbb{N}$ from some t on (24) holds for all $i = 1..N$, and the consistency statement follows. ■

4.3 Unknown Number κ of Clusters

So far we have shown that when κ is known in advance, consistent clustering is possible under the only assumption that the samples are generated by unknown stationary ergodic process distributions. However, as follows from the theoretical impossibility results

of Ryabko (2010c) discussed in Section 3, the correct number κ of clusters is not possible to be estimated with no further assumptions or additional constraints. One way to overcome this obstacle is to assume known rates of convergence of frequencies to the corresponding probabilities. Such rates are provided by assumptions on the mixing rates of the process distributions that generate the data.

Here we will show that under some assumptions on the mixing rates (and still without making any modelling or independence assumptions), consistent clustering is possible when the number of clusters is unknown.

The purpose of this section, however, is not to find the weakest assumptions under which consistent clustering (with κ unknown) is possible, nor is it to provide sharp bounds under the assumptions considered; our only purpose here is to demonstrate that asymptotic consistency is achievable in principle when the number of clusters is unknown, under some mild nonparametric assumptions on the time-series distributions. More refined analysis could yield sharper bounds under weaker assumptions, such as those in, for example, (Bosq, 1996; Rio, 1999; Doukhan, 1994; Doukhan et al., 2010).

We introduce *mixing coefficients*, mainly following Rio (1999) in formulations. Informally, mixing coefficients of a stochastic process measure how fast the process forgets about its past. Any one-way infinite stationary process $X_1, X_2, \dots$ can be extended backwards to make a two-way infinite process $\dots, X_{-1}, X_0, X_1, \dots$ with the same distribution. In the definition below we assume such an extension. Define the φ-mixing coefficients of a process μ as

$$\varphi_n(\mu) = \sup_{A\in\sigma(X_{-\infty..k}),B\in\sigma(X_{k+n..\infty}),\mu(A)\neq 0} |\mu(B|A) - \mu(B)|, \tag{25}$$

where $\sigma(..)$ stands for the σ-algebra generated by random variables in brackets. These coefficients are nonincreasing. Define also

$$\theta_n(\mu) := 2 + 8(\varphi_1(\mu) + \dots + \varphi_n(\mu)).$$

A process μ is called uniformly *φ-mixing* if $\varphi_n(\mu) \to 0$. Many important classes of processes satisfy mixing conditions. For example, a stationary irreducible aperiodic Hidden Markov process with finitely many states is uniformly φ-mixing with coefficients decreasing exponentially fast. Other probabilistic assumptions can be used to obtain bounds on the mixing coefficients, see, e.g., (Bradley, 2005) and references therein.

The method that we propose for clustering mixing time series in the offline setting, namely *Algorithm 3*, is very simple. Its inputs are: a set $S := \{\mathbf{x}_1, \dots, \mathbf{x}_N\}$ of samples each of length n_i, $i = 1..N$, the threshold level $\delta \in (0,1)$ and the parameters $m, l \in \mathbb{N}$, $B^{m,l,n}$. The algorithm assigns to the same cluster all samples which are at most δ-far from each other, as measured by $\hat{d}$ with $m_n = m, l_n = l$ and the summation over $B^{m,l}$ restricted to $B^{m,l,n}$. The sets $B^{m,l,n}$ have to be chosen so that in asymptotic they cover the whole space, $\cup_{n\in\mathbb{N}} B^{m,l,n} = B^{m,l}$. For example, $B^{m,l,n}$ may consist of the first b_n cubes around the origin, where $b_n \to \infty$ is a parameter sequence. We do not give a pseudocode implementation of this algorithm, since it is rather clear.

The idea is that the threshold level $\delta = \delta_n$ is selected according to the smallest sample-length $n := \min_{i=1..N} n_i$ and the (known bounds on) mixing rates of the process ρ generating the samples (see Theorem 13). As we show in Theorem 13, if the distribution of the samples satisfies $\varphi_n(\rho) \le \varphi_n \to 0$, where φ_n are known, then one can select (based on φ_n only)

the parameters of Algorithm 3 in such a way that it is weakly asymptotically consistent. Moreover, a bound on the probability of error before asymptotic is provided.

Theorem 13 (Algorithm 3 is consistent for unknown κ) *Fix sequences $m_n, l_n, b_n \in \mathbb{N}$, and let, for each $m, l \in \mathbb{N}$, $B^{m,l,n} \subset B^{m,l}$ be an increasing sequence of finite sets such that $\cup_{n\in\mathbb{N}} B^{m,l,n} = B^{m,l}$. Set $b_n := \max_{l\le l_n, m\le m_n} |B^{m,l,n}|$ and $n := \min_{i=1..N} n_i$. Let also $\delta_n \in (0,1)$. Let $N \in \mathbb{N}$, and suppose that the samples $\mathbf{x}_1, \dots, \mathbf{x}_N$ are generated in such a way that the (unknown marginal) distributions ρ_k, $k = 1..\kappa$ are stationary ergodic and satisfy $\varphi_n(\rho_k) \le \varphi_n$, for all $k = 1..\kappa$, $n \in \mathbb{N}$. Then there exist constants ε_ρ, δ_ρ and n_ρ that depend only on ρ_k, $k = 1..\kappa$, such that for all $\delta_n < \delta_\rho$ and $n > n_\rho$, Algorithm 3 satisfies*

$$P(T \neq \mathcal{G}|_N) \le 2N(N+1)(m_n l_n b_n \gamma_{n/2}(\delta_n) + \gamma_{n/2}(\varepsilon_\rho)) \tag{26}$$

where

$$\gamma_n(\varepsilon) := \sqrt{e}\exp(-n\varepsilon^2/\theta_n),$$

T is the partition output by the algorithm and $\mathcal{G}|_N$ is the ground-truth clustering. In particular, if $\varphi_n = o(1)$, then, selecting the parameters in such a way that $\delta_n = o(1)$, $m_n, l_n, b_n = o(n)$, $m_n, l_n \to \infty$, $\cup_{k\in\mathbb{N}} B^{m,l,k} = B^{m,l}$, $b_n^{m,l} \to \infty$, for all $m, l \in \mathbb{N}$, $\gamma_n(const) = o(1)$, and, finally, $m_n l_n b_n \gamma_n(\delta_n) = o(1)$, as is always possible, Algorithm 3 is weakly asymptotically consistent *(with the number of clusters κ unknown).*

Proof We use the following bound from (Rio, 1999, Corollary 2.1): for any zero-mean $[-1,1]$-valued random process $Y_1, Y_2, \dots$ with distribution P and every $n \in \mathbb{N}$ we have

$$P\left(|\sum_{i=1}^n Y_i| > n\varepsilon\right) \le \gamma_n(\varepsilon). \tag{27}$$

For every $j = 1..N$, every $m < n$, $l \in \mathbb{N}$, and $B \in B^{m,l}$, define the $[-1,1]$-valued processes $\mathbf{Y}^j := Y_1^j, Y_2^j, \dots$ as

$$Y_t^j := \mathbb{I}\{(X_t^j, \dots, X_{t+m-1}^j) \in B\} - \rho_k(X_{1..m}^j \in B),$$

where ρ_k is the marginal distribution of X^j (that is, k is such that $j \in \mathcal{G}_k$). It is easy to see that φ-mixing coefficients for this process satisfy $\varphi_n(\mathbf{Y}^j) \le \varphi_{n-2m}$. Thus, from (27) we have

$$P(|\nu(X_{1..n_j}^j, B) - \rho_k(X_{1..m}^j \in B)| > \varepsilon/2) \le \gamma_{n-2m_n}(\varepsilon/2). \tag{28}$$

Then for every $i, j \in \mathcal{G}_k \cap 1..N$ for some $k \in 1..\kappa$ (that is, $\mathbf{x}_i$ and $\mathbf{x}_j$ are in the same ground-truth cluster) we have

$$P(|\nu(X_{1..n_i}^i, B) - \nu(X_{1..n_j}^j, B)| > \varepsilon) \le 2\gamma_{n-2m_n}(\varepsilon/2).$$

Using the union bound, summing over m, l, and B, we obtain

$$P(\hat{d}(\mathbf{x}_i, \mathbf{x}_j) > \varepsilon) \le 2m_n l_n b_n \gamma_{n-2m_n}(\varepsilon/2). \tag{29}$$

Next, let $i \in \mathcal{G}_k \cap 1..N$ and $j \in \mathcal{G}_{k'} \cap 1..N$ for $k \neq k' \in 1..\kappa$ (i.e., $\mathbf{x}_i, \mathbf{x}_j$ are in two different target clusters). Then, for some $m_{i,j}, l_{i,j} \in \mathbb{N}$ there is $B_{i,j} \in B^{m_{i,j},l_{i,j}}$ such that for some $\tau_{i,j} > 0$ we have

$$|\rho_k(X^i_{1..|B_{i,j}|} \in B_{i,j}) - \rho_{k'}(X^j_{1..|B_{i,j}|} \in B_{i,j})| > 2\tau_{i,j}.$$

Then for every $\varepsilon < \tau_{i,j}/2$ we have

$$P(|\nu(X^i_{1..n_i}, B_{i,j}) - \nu(X^j_{1..n_j}, B_{i,j})| < \varepsilon) \leq 2\gamma_{n-2m_{i,j}}(\tau_{i,j}). \tag{30}$$

Moreover, for $\varepsilon < w_{m_{i,j}} w_{l_{i,j}} \tau_{i,j}/2$ we have

$$P(\hat{d}(\mathbf{x}_i, \mathbf{x}_j) < \varepsilon) \leq 2\gamma_{n-2m_{i,j}}(\tau_{i,j}). \tag{31}$$

Define

$$\delta_\rho := \min_{\substack{k\neq k'\in 1..\kappa \\ i\in\mathcal{G}_k\cap 1..N \\ j\in\mathcal{G}_{k'}\cap 1..N}} w_{m_{i,j}} w_{l_{i,j}} \tau_{i,j}/2, \quad \varepsilon_\rho := \min_{\substack{k\neq k'\in 1..\kappa \\ i\in\mathcal{G}_k\cap 1..N \\ j\in\mathcal{G}_{k'}\cap 1..N}} \tau_{i,j}/2$$

$$n_\rho := 2 \max_{\substack{k\neq k'\in 1..\kappa \\ i\in\mathcal{G}_k\cap 1..N \\ j\in\mathcal{G}_{k'}\cap 1..N}} m_{i,j}.$$

Clearly, from this and (30), for every $\delta < 2\delta_\rho$ and $n > n_\rho$ we obtain

$$P(\hat{d}(\mathbf{x}_i, \mathbf{x}_j) < \delta) \leq 2\gamma_{n/2}(\varepsilon_\rho). \tag{32}$$

Algorithm 3 produces correct results if for every pair i, j we have $\hat{d}(\mathbf{x}_i, \mathbf{x}_j) < \delta_n$ if and only if $i, j \in \mathcal{G}_k \cap 1..N$ for some $k \in 1..\kappa$. Therefore, taking the bounds (29) and (32) together for each of the $N(N+1)/2$ pairs of samples, we obtain (26). ■

For the online setting, consider the following simple extension of Algorithm 3, that we call Algorithm 3'. It applies Algorithm 3 to the first N_t sequences, where the parameters of Algorithm 3 and N_t are chosen in such a way that the bound (26) with $N = N_t$ is $o(1)$ and $N_t \to \infty$ as time t goes to infinity. It then assigns each of the remaining sequences ($\mathbf{x_i}$, $i > N_t$) to the nearest cluster. Note that in this case the bound (26) with $N = N_t$ bounds the error of Algorithm 3' on the first N_t sequences, as long as all of the κ clusters are already represented among the first N_t sequences. Since $N_t \to \infty$, we can formulate the following result.

Theorem 14 *Algorithm 3' is weakly asymptotically consistent in the online setting when the number κ of clusters is unknown, provided that the assumptions of Theorem 13 apply to the first N sequences $\mathbf{x}_1, \ldots, \mathbf{x}_N$ for every $N \in \mathbb{N}$.*

4.4 Extensions

In this section we show that some simple, yet rather general extensions of the main results of this paper are possible, namely allowing for non-stationarity and for slight differences in distributions in the same cluster.

4.4.1 AMS Processes and Gradual Changes

Here we argue that our results can be strengthened to a more general case where the process distributions that generate the data are Asymptotically Mean Stationary (AMS) ergodic. Throughout the paper we have been concerned with stationary ergodic process distributions. Recall from Section 2 that a process ρ is *stationary* if for any $i, j \in 1..n$ and $B \in B^m$, $m \in \mathbb{N}$, we have $\rho(X_{1..j} \in B) = \rho(X_{i..i+j-1} \in B)$. A stationary process is called ergodic if the limiting frequencies converge to their corresponding probabilities, so that for all $B \in \mathcal{B}$ with probability 1 we have $\lim_{n\to\infty} \nu(X_{1..n}, B) = \rho(B)$. This latter convergence of all frequencies is the only property of the process distributions that is used in the proofs (via Lemma 5) which give rise to our consistency results. We observe that this property also holds for a more general class of processes, namely those that are AMS ergodic. Specifically, a process ρ is called *AMS* if for every $j \in 1..n$ and $B \in B^m, m \mathbb{N}$ the series $\lim_{n\to\infty} \sum_{i=1}^{n-j+1} \frac{1}{n} \rho(X_{i..i+j-1} \in B)$ converges to a limit $\bar{\rho}(B)$, which forms a measure, i.e. $\bar{\rho}(X_{1..j} \in B) := \bar{\rho}(B)$, $B \in B^m$, $m \in \mathbb{N}$, called *asymptotic mean* of ρ. Moreover, if ρ is an AMS process, then for every $B \in B^m$, $m \in \mathbb{N}$, the frequency $\nu(X_{1..n}, B)$ converges ρ-a.s. to a random variable with mean $\bar{\rho}(B)$. Similarly to stationary processes, if the random variable to which $\nu(X_{1..n}, B)$ converges is a.s. constant, then ρ is called AMS ergodic. More information on AMS processes can be found in the work (Gray, 1988). However, the main characteristic pertaining to our work is that the class of all processes with AMS properties is composed precisely of those processes for which the almost sure convergence of frequencies to the corresponding probabilities holds. It is thus easy to check that all of the asymptotic results of Sections 4.1, 4.2 carry over to the more general setting where the unknown process distributions that generate the data are AMS ergodic.

4.4.2 Strictly Separated Clusters of Distributions

So far we have defined a cluster as a set of sequences generated by the same distribution. This seems to capture rather well the notion that in the same cluster the objects can be very different (as is the case for stochastically generated sequences), yet are intrinsically of the same nature (they have the same law).

However, one may wish to generalise this further, and allow each sequence to be generated by a different distribution, yet requiring that in the same clusters distributions must be close. Unlike the original formulation, such an extension would require fixing some similarity measure between distributions. The results of the preceding sections suggest using the distributional distance for this purpose.

Specifically, as discussed in Section 4.1, in our formulation, from some time on, the sequences possess the so-called strict separation property in the $\hat{d}$ distance: sequences in the same target cluster are closer to each other than to those in other clusters. One possible way to relax the considered setting is to impose the strict separation property on the distributions that generate the data. Here the separation would be with respect to the distributional distance d. That is, each sequence $\mathbf{x}_i, i = 1..N$, may be generated by its own distribution ρ_i, but the distributions $\{\rho_i : i = 1..N\}$ can be clustered in such a way that the resulting clustering has the strict separation property with respect to d. The goal would then be to recover this clustering based on the given samples. In fact, it can be shown that the offline Algorithm 1 of Section 4.1 is consistent in this setting as well. How this transfers

to the online setting remains open. For the offline case, we can formulate the following result, whose proof is analogous to that of Theorem 11.

Theorem 15 *Assume that each sequence $\mathbf{x}_i$, $i = 1..N$ is generated by a stationary ergodic distribution ρ_i. Assume further that the set of distributions $\{1, \dots, N\}$ admits a partitioning $\mathcal{G} = \{\mathcal{G}_1, \dots, \mathcal{G}_k\}$ that has the strict separation property with respect to d: for all $i, j = 1..k, i \neq j$, for all $\rho_1, \rho_2 \in \mathcal{G}_i$ and all $\rho_3 \in \mathcal{G}_j$ we have $d(\rho_1, \rho_2) < d(\rho_1, \rho_3)$. Then Algorithm 1 is strongly asymptotically consistent, in the sense that almost surely from some $n = \min\{n_1, \dots, n_N\}$ on it outputs the set $\mathcal{G}$.*

5. Computational Considerations

In this section we show that all of the proposed methods are efficiently computable. This claim is further illustrated by the experimental results in the next section. Note, however, that since the results presented are asymptotic, the question of what is the best achievable computational complexity of an algorithm that still has the same asymptotic performance guarantees is meaningless: for example, an algorithm could throw away most of the data and still be asymptotically consistent. This is why we do not attempt to find a resource-optimal way of computing the methods presented.

First, we show that calculating $\hat{d}$ is at most quadratic (up to log terms), and quasilinear if we use $m_n = \log n$. Let us begin by showing that calculating $\hat{d}$ is fully tractable with $m_n, l_n \equiv \infty$. First, observe that for fixed m and l, the sum

$$T^{m,l} := \sum_{B \in B^{m,l}} |\nu(X^1_{1..n_1}, B) - \nu(X^2_{1..n_2}, B)| \tag{33}$$

has not more than $n_1 + n_2 - 2m + 2$ nonzero terms (assuming $m \leq n_1, n_2$; the other case is obvious). Indeed, there are $n_i - m + 1$ tuples of size m in each sequence $\mathbf{x}_i$, $i = 1, 2$ namely, $X^i_{1..m}, X^i_{2..m+1}, \dots, X^i_{n_1-m+1..n_1}$. Therefore, $T^{m,l}$ can be obtained by a finite number of calculations.

Furthermore, let

$$s = \min_{\substack{X^1_i \neq X^2_j \\ i=1..n_1, j=1..n_2}} |X^1_i - X^2_j|, \tag{34}$$

and observe that $T^{m,l} = 0$ for all $m > n$ and for each m, for all $l > \log s^{-1}$ the term $T^{m,l}$ is constant. That is, for each fixed m we have

$$\sum_{l=1}^{\infty} w_m w_l T^{m,l} = w_m w_{\log s^{-1}} T^{m, \log s^{-1}} + \sum_{l=1}^{\log s^{-1}} w_m w_l T^{m,l}$$

so that we simply double the weight of the last nonzero term. (Note also that s is bounded above by the length of the binary precision in representing the random variables X^i_j.) Thus, even with $m_n, l_n \equiv \infty$ one can calculate $\hat{d}$ precisely. Moreover, for a fixed $m \in 1..\log n$ and $l \in 1..\log s^{-1}$ for every sequence $\mathbf{x}_i$, $i = 1, 2$ the frequencies $\nu(\mathbf{x}_i, B)$, $B \in B^{m,l}$ may be calculated using suffix trees or suffix arrays, with $\mathcal{O}(n)$ worst case construction and search complexity (see, e.g., Ukkonen, 1995). Searching all $z := n - m + 1$ occurrences of

subsequences of length m results in $\mathcal{O}(m + z) = \mathcal{O}(n)$ complexity. This brings the overall computational complexity of (3) to $\mathcal{O}(nm_n \log s^{-1})$; this can potentially be improved using specialized structures, e.g., (Grossi and Vitter, 2005).

The following consideration can be used to set m_n. For a fixed l the frequencies $\nu(\mathbf{x}_i, B)$, $i = 1, 2$ of cells in $B \in B^{m,l}$ corresponding to values of m much larger than $\log_n$ (in the asymptotic sense, that is, if $\log_n = o(m)$) are not, in general, consistent estimates of their probabilities, and thus only add to the estimation error. More specifically, for a subsequence $X_{j..j+m}$ with $j = 1..n-m$ of length m the probability $\rho_i(X_{j..j+m} \in B)$, $i = 1, 2$ is of order 2^{-mh_i}, $i = 1, 2$ where h_i denotes the entropy rate of ρ_i, $i = 1, 2$. Moreover, under some (general) conditions (including $h_i > 0$) one can show that, asymptotically, a string of length of order $\log n / h_i$ on average occurs at most once in a string of length n (Kontoyiannis and Suhov, 1994). Therefore, subsequences of length m larger than $\log n$ are typically met 0 or 1 times, and thus are not consistent estimates of probabilities. By the above argument, one can use m_n of order $\log n$. To choose $l_n < \infty$ one can either fix some constant based on the bound on the precision in real computations, or choose it in such a way that each cell B^{m,l_n} contains no more than $\log n$ points for all $m = 1..\log n$ largest values of l_n.

5.1 Complexity of the Algorithms.

The computational complexity of the presented algorithms is dominated by the complexity of calculations of $\hat{d}$ between different pairs of sequences. Thus, it is sufficient to bound the number of pairwise $\hat{d}$ computations.

It is easy to see that the offline algorithm for the case of known κ (Algorithm 1) requires at most κN distance calculations, while for the case of unknown κ all N^2 distance calculations are necessary.

The computational complexity of the updates in the online algorithm can be computed as follows. Assume that the pairwise distance values are stored in a database D, and that for every sequence $\mathbf{x}^{t-1}_i$, $i \in \mathbb{N}$ we have already constructed a suffix tree, using for example, the online algorithm of Ukkonen (1995). At time step t, a new symbol X is received. Let us first calculate the required computations to update D. We have two cases, either X forms a new sequence, so that $N(t) = N(t-1) + 1$, or it is the subsequent element of a previously received segment, say, $\mathbf{x}^t_j$ for some $j \in 1..N(t)$, so that $n_j(t) = n_j(t-1) + 1$. In either case, let $\mathbf{x}^t_j$ denote the updated sequence. Note that for all $i \neq j \in 1..N(t)$ we have $n_i(t) = n_i(t-1)$. Recall the notation $\mathbf{x}^t_i := X^{(i)}_1, \dots X^{(i)}_{n_i(t)}$ for $i \in 1..N(t)$. In order to update D we need to update the distance between $\mathbf{x}^t_j$ and $\mathbf{x}^t_i$ for all $i \neq j \in N(t)$. Thus, we need to search for all m_n new patterns induced by the received symbol X, resulting in complexity at most $\mathcal{O}(N(t) m_n^2 l_n)$. Let $n(t) := \max\{n_1(t), \dots n_{N(t)}(t)\}$, $t \in \mathbb{N}$. As discussed previously, we let $m_n := \log n(t)$; we also define $l_n := \log s(t)^{-1}$ where

$$s(t) := \min_{\substack{i,j \in 1..N(t) \\ u=1..n_i(t), v=1..n_j(t), X^{(i)}_u \neq X^{(j)}_v}} |X^{(i)}_u - X^{(j)}_v|, \ t \in \mathbb{N}.$$

Thus, the per symbol complexity of updating D is at most $\mathcal{O}(N(t) \log^3 n(t))$. However, note that if $s(t)$ decreases from one time step to the next, updating D will have a complexity

of order equivalent to its complete construction, resulting in a computational complexity of order $\mathcal{O}(N(t)n(t)\log^2 n(t))$. Therefore, we avoid calculating $s(t)$ at every time step; instead, we update $s(t)$ at prespecified time steps so that for every $n(t)$ symbols received, D is reconstructed at most $\log n(t)$ times. (This can be done, for example, by recalculating $s(t)$ at time steps where $n(t)$ is a power of 2.) It is easy to see that with the database D of distance values at hand, the rest of the computations are of order at most $\mathcal{O}(N(t)^2)$. Thus, the computational complexity of updates in Algorithm 2 is at most $\mathcal{O}(N(t)^2+N(t)\log^3 n(t))$.

6. Experimental Results

In this section we present empirical evaluations of Algorithms 1 and 2 on both synthetically generated and real data.

6.1 Synthetic Data

We start with synthetic experiments. In order for the experiments to reflect the generality of our approach we have selected time-series distributions that, while being stationary ergodic, cannot be considered as part of any of the usual smaller classes of processes, and are difficult to approximate by finite-state models. Namely, we consider rotation processes used, for example, by Shields (1996) as an example of stationary ergodic processes that are not B-processes. Such time series cannot be modelled by a hidden Markov model with a finite or countably infinite set of states. Moreover, while k-order Markov (or hidden Markov) approximations of this process converge to it in the distributional distance d, they do not converge to it in the $\bar{d}$ distance, a stronger distance than d whose empirical approximations are often used to study general (non-Markovian) processes (e.g., Ornstein and Weiss, 1990).

6.1.1 Time Series Generation

To generate a sequence $\mathbf{x} = X_{1..n}$ we proceed as follows: Fix some parameter $\alpha \in (0,1)$. Select $r_0 \in [0,1]$; then, for each $i = 1..n$ obtain r_i by shifting r_{i-1} by α to the right, and removing the integer part, i.e. $r_i := r_{i-1} + \alpha - \lfloor r_{i-1} + \alpha \rfloor$. The sequence $\mathbf{x} = (X_1, X_2, \cdots)$ is then obtained from r_i by thresholding at 0.5, that is $X_i := \mathbb{I}\{r_i > 0.5\}$. If α is irrational then $\mathbf{x}$ forms a stationary ergodic time series. (We simulate α by a `longdouble` with a long mantissa.)

For the purpose of our experiments, first we fix $\kappa := 5$ difference process distributions specified by $\alpha_1 = 0.31...$, $\alpha_2 = 0.33...$, $\alpha_3 = 0.35...$, $\alpha_4 = 0.37...$, $\alpha_5 = 0.39....$ The parameters α_i are intentionally selected to be close, in order to make the process distributions harder to distinguish. Next we generate an $N \times M$ data matrix $\mathbf{X}$, each row of which is a sequence generated by one of the process distributions. Our task in both the online and the batch setting is to cluster the rows of $\mathbf{X}$ into $\kappa = 5$ clusters.

6.1.2 Batch Setting

In this experiment we demonstrate that in the batch setting, the clustering errors corresponding to both the online and the offline algorithms converge to 0 as the sequence-lengths grow. To this end, at every time step t we take an $N \times n(t)$ submatrix $\mathbf{X}|_{\mathbf{n(t)}}$ of $\mathbf{X}$ composed of the rows of $\mathbf{X}$ terminated at length $n(t)$, where $n(t) = 5t$. Then at each iteration we let

each of the algorithms, (online and offline) cluster the rows of $\mathbf{X}|_{\mathbf{n(t)}}$ into five clusters, and calculate the clustering error rate of each algorithm. As shown in Figure 2 (top) the error rate of each algorithm decreases with sequence length.

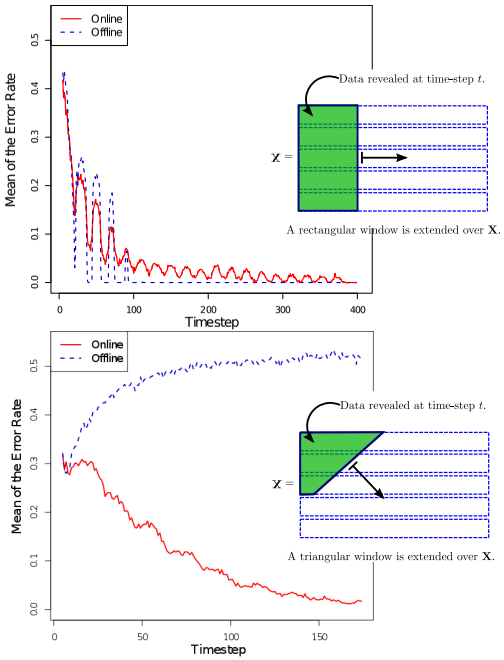

Figure 2: Top: error rate vs. sequence length in batch setting. Bottom: error rate vs. Number of observed samples in online setting. (error rates averaged over 100 runs.)

6.1.3 Online Setting

In this experiment we demonstrate that, unlike the online algorithm, the offline algorithm is consistently confused by the new sequences arriving at each time step in an online setting. To simulate an online setting, we proceed as follows: At every time step t, a triangular window is used to reveal the first $1..n_i(t)$, $i = 1..t$ elements of the first t rows of the data matrix $\mathbf{X}$, with $n_i(t) := 5(t-i)+1$, $i = 1..t$. This gives a total of t sequences, each of length $n_i(t)$, for $i = 1..t$, where the i^{th} sequence for $i = 1..t$ corresponds to the i^{th} row of $\mathbf{X}$ terminated at length $n_i(t)$. At every time step t the online and offline algorithms are each used in turn to cluster the observed t sequences into five clusters. Note that the performance

of both algorithms is measured on all sequences available at a given time, not on a fixed batch of sequences. As shown in Figure 2 (bottom), in this setting the clustering error rate of the offline algorithm remains consistently high, whereas that of the online algorithm converges to zero.

6.2 Real Data

As an application we consider the problem of clustering motion capture sequences, where groups of sequences with similar dynamics are to be identified. Data is taken from the Motion Capture database (MOCAP) which consists of time-series data representing human locomotion. The sequences are composed of marker positions on human body which are tracked spatially through time for various activities.

We compare our results to those obtained with two other methods, namely those of Li and Prakash (2011) and Jebara et al. (2007). Note that we have not implemented these reference methods, rather we have taken the numerical results directly from the corresponding articles. In order to have common grounds for each comparison we use the same sets of sequences[2] and the same means of evaluation as those used by Li and Prakash (2011); Jebara et al. (2007).

In the paper by Li and Prakash (2011) two MOCAP data sets[3] are used, where the sequences in each data set are labelled with either running or walking as annotated in the database. Performance is evaluated via the conditional entropy S of the true labelling with respect to the prediction, i.e., $S := -\sum_{i,j} \frac{\mathcal{M}_{ij}}{\sum_{i',j'} \mathcal{M}_{i'j'}} \log \frac{\mathcal{M}_{ij}}{\sum_{j'} \mathcal{M}_{ij'}}$ where $\mathcal{M}$ denotes the clustering confusion matrix. The motion sequences used by Li and Prakash (2011) are reportedly trimmed to equal duration. However, we use the original sequences as our method is not limited by variation in sequence lengths. Table 1 lists performance of Algorithm 1 as well as that reported for the method of Li and Prakash (2011); Algorithm 1 performs consistently better.

In the paper (Jebara et al., 2007) four MOCAP data sets[4] are used, corresponding to four motions: run, walk, jump and forward jump. Table 2 lists performance in terms of accuracy. The data sets in Table 2 constitute two types of motions:

1. motions that can be considered ergodic: walk, run, run/jog (displayed above the double line), and

2. non-ergodic motions: single jumps (displayed below the double line).

As shown in Table 2, Algorithm 1 achieves consistently better performance on the first group of data sets, while being competitive (better on one and worse on the other) on the non-ergodic motions. The time taken to complete each task is in the order of few minutes on a standard laptop computer.

2. The subject's right foot was used as marker position.
3. The corresponding subject references are #16 and #35.
4. The corresponding subject references are #7, #9, #13, #16 and #35.

	Data set	(Li and Prakash, 2011)	Algorithm 1
1.	Walk vs. Run (#35)	0.1015	**0**
2.	Walk vs. Run (#16)	0.3786	**0.2109**

Table 1: Comparison with the work (Li and Prakash, 2011): Performance in terms of entropy; data sets concern ergodic motion captures.

	Data set	(Jebara et al., 2007)	Algorithm 1
1.	Run(#9) vs. Run/Jog(#35)	**100%**	**100%**
2.	Walk(#7) vs. Run/Jog(#35)	95%	**100%**
3.	Jump vs. Jump fwd.(#13)	87%	**100%**
4.	Jump vs. Jump fwd.(#13, 16)	**66%**	60%

Table 2: Comparison with the work (Jebara et al., 2007): Performance in terms of accuracy; Rows 1 & 2 concern ergodic, Rows 3 & 4 concern non-ergodic motion captures.

7. Discussion

We have proposed a natural notion of consistency for clustering time series in both the online and the offline settings. While in this work we have taken some first steps in investigating the theoretical and algorithmic questions arising in the proposed framework, there are many open problems and exciting directions for future research remaining to be explored. Some of these are discussed in this section.

Rates, optimality. The main focus of this work is on the most general case of highly dependent time series. On the one hand, this captures best the spirit of the unsupervised learning problem in question: the nature of the data is completely unknown, and one tries to find some structure in it. On the other hand, as discussed above, in this generality rates of convergence and finite-sample performance guarantees are provably impossible to obtain, and thus one cannot argue about optimality. While we have provided some results on a more restrictive setting (time series with mixing, Section 4.3), the question of what the optimal performance guarantees are for different classes of time series remains open. In fact, the first interesting question in this direction is not about time series with mixing, but about i.i.d. series. What is the minimal achievable probability of clustering error in this setting, for finite sample sizes, and what algorithms attain it?

Online setting: bad points. In the online setting of Section 4.2, we have assumed that the length of each sequence grows to infinity with time. While this is a good first approximation, this assumption may not be practical. It is interesting to consider the situation in which some sequences stop growing at some point; moreover, it can be assumed that such sequences are not representative of the corresponding distribution. While this clearly makes the problem much more difficult, already in the setting considered in this work we have dealt with "bad" sequences at each time step: these are those sequences which are as yet too short to be informative. This hints at the possibility of obtaining consistent algorithms in the extended setting outlined.

Other metrics and non-metric-based methods. All of the methods presented in this paper are based on the distributional distance d. The main property of this distance that we

exploit is that it can be estimated consistently. In principle, one can use other distances with this property, in order to obtain consistent clustering algorithms. While there are not many known distances that can be consistently estimated for arbitrary stationary ergodic distributions, there is at least one, namely the telescope distance recently introduced by Ryabko and Mary (2013). Moreover, the definition of consistency proposed does not entail the need to use a distance between time-series distributions. As an alternative, the use of compression-based methods can be considered. Such methods have been used to solve various statistical problems concerning stationary ergodic time series (Ryabko and Astola, 2006; Ryabko, 2010a). Compression-based methods have also been used for clustering time-series data before, albeit without consistency analysis, by Cilibrasi and Vitanyi (2005). Combining our consistency framework with these compression-based methods is another promising direction for further research.

Acknowledgments

This paper is an extended version of two conference papers: (Ryabko, 2010b) and (Khaleghi et al., 2012). Most of the work by Azadeh Khaleghi has been done during her PhD at INRIA Lille - Nord Europe. This work is supported by the French Ministry of Higher Education and Research, by FP7/2007-2013 under grant agreements 270327 (CompLACS), by the Nord-Pas-de-Calais Regional Council and FEDER, and by the European Research Council (SMAC-ERC-280032). Jérémie Mary and Philippe Preux acknowledge the support of INRIA. Jérémie Mary further acknowledges INRIA for the support through partial secondments.

Abstract

In machine learning, ensemble methods combine the predictions of multiple base learners to construct more accurate aggregate predictions. Established supervised learning algorithms inject randomness into the construction of the individual base learners in an effort to promote diversity within the resulting ensembles. An undesirable side effect of this approach is that it generally also reduces the accuracy of the base learners. In this paper, we introduce a method that is simple to implement yet general and effective in improving ensemble diversity with only modest impact on the accuracy of the individual base learners. By randomly rotating the feature space prior to inducing the base learners, we achieve favorable aggregate predictions on standard data sets compared to state of the art ensemble methods, most notably for tree-based ensembles, which are particularly sensitive to rotation.

Keywords: feature rotation, ensemble diversity, smooth decision boundary

1. Introduction

Modern statistical learning algorithms combine the predictions of multiple base learners to form ensembles, which typically achieve better aggregate predictive performance than the individual base learners (Rokach, 2010). This approach has proven to be effective in practice and some ensemble methods rank among the most accurate general-purpose supervised learning algorithms currently available. For example, a large-scale empirical study (Caruana and Niculescu-Mizil, 2006) of supervised learning algorithms found that decision tree ensembles consistently outperformed traditional single-predictor models on a representative set of binary classification tasks. Data mining competitions also frequently feature ensemble learning algorithms among the top ranked competitors (Abbott, 2012).

Achieving a good balance between the accuracy of the individual predictors and the diversity of the full ensemble is of critical importance: if the individual predictors are accurate but highly correlated, the benefits of combining them are modest; injecting randomness into the predictors reduces the correlation and promotes diversity but often does so at the expense of reduced accuracy for the individual predictors (Elghazel et al., 2011). A number of techniques have been devised to manage this trade-off and to promote diversity in learning ensembles in a constructive fashion; some methods merely perturb the training data, while others modify the internal structure of the predictors themselves. We now mention

some key examples. In bootstrap aggregation (Breiman, 1996), bootstrap replicates are used to construct multiple versions of a base predictor, which are subsequently aggregated via averaging or majority vote. This approach was found to be particularly effective for predictor classes that are unstable, in the sense that small variations of the input data lead to the construction of vastly different predictors (Hastie et al., 2009). Output smearing or flipping (Breiman, 2000) adds a different noise component to the dependent variable of each base predictor, which has a smoothing effect on the resulting decision boundary, leading to improved generalization performance. Boosting (Freund and Schapire, 1996) is an iterative procedure, where base learners are added sequentially in a forward stagewise fashion. By reweighting the data set at each iteration, later base learners are specialized to focus on the learning instances that proved the most challenging to the existing ensemble. In contrast to bootstrap aggregation, where each bootstrap sample is generated independently, boosting therefore does not lend itself naturally to parallel processing. Random decision forests (Ho, 1995, 1998) randomly select a feature subspace a priori and train a base learner in the chosen subspace using all available data. Instead of randomizing the training data, the structure of each predictor is altered by only including the chosen subset of predictors. Random forests (Breiman, 1999, 2001) combine bootstrap aggregation with the random projection method. At each tree node, a subset of the available predictors is randomly selected and the most favorable split point is found among these candidate predictors. This approach differs from random decision forests, where the selection of predictors is only performed once per tree. More generally, the framework also offers the possibility of using random linear combinations of two or more predictors. A summary of recent enhancements and applications of random forests can be found in Fawagreh et al. (2014). Perfect random tree ensembles (Cutler and Zhao, 2001), extremely random trees / extra trees (Geurts et al., 2006), and completely random decision trees (Liu et al., 2005; Fan et al., 2006) take randomization even further by not only selecting random predictor(s), as in random forests, but by also selecting a random split point, sometimes deterministically chosen from a small set of random candidate split points.

Some of the ensemble methods described specifically require the base learners to be decision trees. This is because decision trees are efficient to create (by recursive binary splitting), the models are straightforward to aggregate, and the individual trees can easily be turned into weak learners (which perform only slightly better than random) by restricting their depth (Kuhn and Johnson, 2013). Furthermore, decision trees exhibit a high variance and this inherent instability is beneficial to the diversity of the ensemble. In addition, decision trees contain a number of desirable features for general purpose data mining, including robustness to outliers and an ability to handle input variables of mixed type and scale, such as continuous and categorical variables, and even missing values (Hastie et al., 2009). However, a decision tree is merely an efficient representation for a set of hyper-rectangles that partition the decision space. For ordinary decision trees, each hyper-rectangle is aligned with at least one of the axes of the chosen coordinate system, resulting in axis parallel decision boundaries. This results in very characteristic piecewise constant stair shapes, even when the number of trees in the ensemble is large, as can be observed visually in low dimensional graphical examples. As a consequence, a much greater number of trees is needed to accurately approximate an oblique decision boundary than a decision boundary that is axis aligned with standard tree ensembles. In order to overcome this limitation, nonlinear

boosting projections (Garca-Pedrajas et al., 2007) provide a different, nonlinear view of the data to each base learner and oblique random forests (Menze et al., 2011) use linear discriminative models or ridge regression to select optimal oblique split directions at each tree node. Another approach that is related to but different from the method proposed in the present paper is embodied by rotation forests (Rodriguez et al., 2006; Kuncheva and Rodriguez, 2007), which take a subset of features and a bootstrap sample of the data and perform a principal component analysis (PCA), rotating the entire feature space before building the next base predictor. In addition to PCA, Kuncheva and Rodriguez (2007) experimented with nonparametric discriminate analysis (NDA) and sparse random projections and in De Bock and Poel (2011), independent component analysis (ICA) is found to yield the best performance.

The premise of the present paper is that it makes sense to rotate the feature space in ensemble learning, particularly for decision tree ensembles, but that it is neither necessary nor desirable to do so in a structured way. This is because structured rotations reduce diversity. Instead, we propose to rotate the feature space randomly before constructing the individual base learners. The random rotation effectively generates a unique coordinate system for each base learner, which we show increases diversity in the ensemble without a significant loss in accuracy. In addition to rotation, affine transformations also include translation, scaling, and shearing (non-uniform scaling combined with rotation). However, only transformations involving rotation have an impact on base learners that are insensitive to monotone transformations of the input variables, such as decision trees. Furthermore, a key difference between random rotation and random projection is that rotations are reversible, implying that there is no loss of information.

The remainder of this paper is structured as follows. Section 2 provides a motivational example for the use of random rotations using a well-known data set. In Section 3 we formally introduce random rotations and provide guidance as to their construction. Section 4 evaluates different application contexts for the technique and performs experiments to assesses its effectiveness. Conclusions and future research are discussed in Section 5. It is our premise that random rotations provide an intuitive, optional enhancement to a number of existing machine learning techniques. For this reason, we provide random rotation code in C/C++ and R in Appendix A, which can be used as a basis for enhancing existing software packages.

2. Motivation

Figure 1 motivates the use of random rotations on the binary classification problem from chapter 2 of Hastie et al. (2009). The goal is to learn the decision boundary, which separates the two classes, from a set of training points. In this example, the training data for each class came from a mixture of ten low-variance Gaussian distributions, with individual means themselves distributed as Gaussian. Since the data is artificially generated, the optimal decision boundary is known by construction.

In this motivational example, we compare two approaches: (1) a standard random forest classifier and (2) a random forest classifier in which each tree is generated on a randomly rotated feature space. It is evident that the random feature rotation has a significant impact on the resulting data partition: despite using the same sequence of random numbers

in the tree induction phase of the random forest algorithm – resulting in the same bootstrap samples and related feature subset selections at each decision branch for the two trees – the resulting tree is not merely a rotated version of the unrotated tree but is, in fact, a very different tree altogether, with a different orientation and a vastly different data partition. This demonstrates the power of the method; diversity is achieved with only a modest loss of information. However, the real benefit is illustrated on the bottom row of Figure 1 and arises from the aggregation of multiple randomly rotated trees. The rotated ensemble exhibits a visibly smoother decision boundary and one that is very close to optimal for this problem. The decision boundary is uncharacteristically smooth for a tree ensemble and is reminiscent of a kernel method, such as a k-nearest neighbor method or a support vector machine. In contrast, even with 10000 trees, the decision boundary for the standard random forest is still notably rectangular shaped. Another striking feature of the random rotation ensemble is the existence of a nearly straight diagonal piece of the decision boundary on the far left. This would be difficult to achieve with an axis-parallel base learner without rotation and it agrees well with the true decision boundary in this example.

3. Random Rotations

In this section, we formally introduce random rotations and describe two practical methods for their construction.

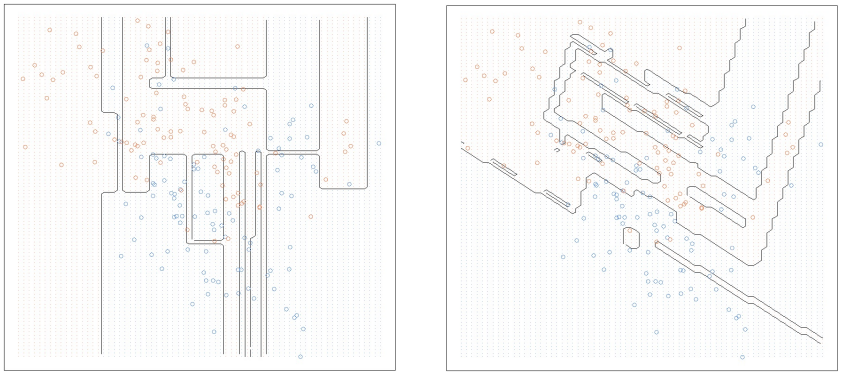
A (proper) rotation matrix R is a real-valued $n \times n$ orthogonal square matrix with unit determinant, that is

$$R^T = R^{-1} \text{ and } |R| = 1. \tag{1}$$

Using the notation from Diaconis and Shahshahani (1987), the set of all such matrices forms the special orthogonal group $SO(n)$, a subgroup of the orthogonal group $O(n)$ that also includes so-called improper rotations involving reflections (with determinant -1). More explicitly, matrices in $SO(n)$ have determinant $|R| = 1$, whereas matrices in $O(n)$ may have determinant $|R| = d$, with $d \in \{-1, 1\}$. Unless otherwise stated, the notation $O(n)$ always refers to the orthogonal group in this paper and is not related to the Bachman-Landau asymptotic notation found in complexity theory.

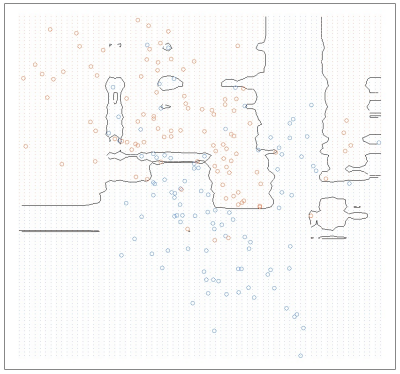
In order to perform a random rotation, we uniformly sample over all feasible rotations. Randomly rotating each angle in spherical coordinates does not lead to a uniform distribution across all rotations for $n > 2$, meaning that some rotations are more likely to be generated than others. It is easiest to see this is in 3 dimensions: suppose we take a unit sphere, denoting the longitude and latitude by the two angles $\lambda \in [\text{-}\pi, \pi]$ and $\phi \in [\text{-}\pi/2, \pi/2]$. If we divide the surface of this sphere into regions by dividing the two angles into equal sized intervals, then the regions closer to the equator ($\phi = 0$) are larger than the regions close to the poles ($\phi = \pm\pi/2$). By selecting random angles, we are equally likely to arrive in each region but due to the different sizes of these regions, points tend to cluster together at the poles. This is illustrated for $n = 3$ in Figure 2, where the undesirable concentration of rotation points near the two poles is clearly visible for the naive method. In this illustration, the spheres are tilted to better visualize the areas near the poles.

The group $O(n)$ does have a natural uniform distribution called the Haar measure, which offers the distribution we need. Using the probabilistic notation from Diaconis and Shahshahani (1987), the random matrix R is said to be uniformly distributed if $P(R \in U) =$

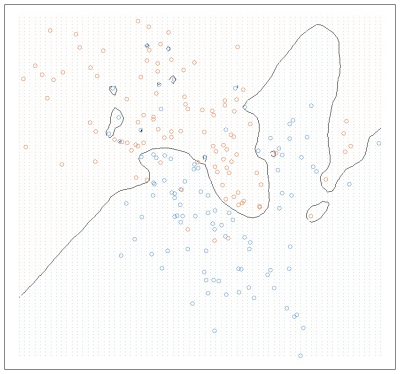


(a) **RF** (ntree=1, mtry=1)

(b) **RR-RF** (ntree=1, mtry=1)

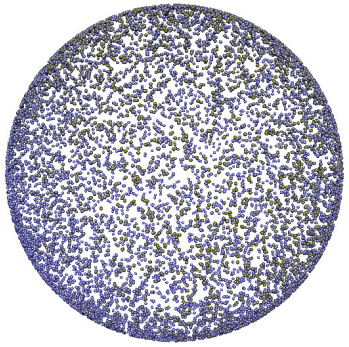


(c) **RF** (ntree=10000, mtry=1)

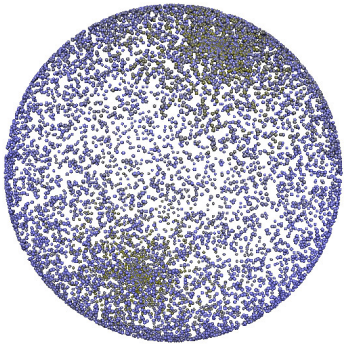


(d) **RR-RF** (ntree=10000, mtry=1)

Figure 1: Comparison of the decision boundary for the standard random forest algorithm (RF, left column) and the modified version with randomly rotated feature space for each tree (RR-RF, right column) on the binary classification task of chapter 2 of Hastie et al. (2009). The top row illustrates a typical decision boundary for a single tree, while the bottom row depicts a fully grown ensemble comprised of 10000 trees in each case. Ntree is the total number of trees in the forest, mtry the number of randomly selected features considered at each decision node.



(a) Uniformly random rotations



(b) Naive random rotations

Figure 2: Comparison of correctly executed uniformly random rotation (left) in three dimensions versus naive method of selecting two random angles in spherical coordinates (right). 10000 random rotations of the same starting vector were generated for each method and distances were computed between each pair of rotations to produce a rank-based gradient, with green dots representing those vectors with the lowest sums of distances.

$P(R \in \Gamma U)$ for every $U \subset O(n)$ and $\Gamma \in O(n)$. Several algorithms exist to generate random orthogonal matrices distributed according to the Haar measure over $O(n)$, some of which are documented in Anderson et al. (1987); Diaconis and Shahshahani (1987); Mezzadri (2007); Ledermann and Alexander (2011). We will focus on two basic approaches to illustrate the concept.

1. (*Indirect Method*) Starting with an $n \times n$ square matrix A, consisting of n^2 independent univariate standard normal random variates, a Householder QR decomposition (Householder, 1958) is applied to obtain a factorization of the form $A = QR$, with orthogonal matrix Q and upper triangular matrix R with positive diagonal elements. The resulting matrix Q is orthogonal by construction and can be shown to be uniformly distributed. In other words, it necessarily belongs to $O(n)$. Unfortunately, if Q does not feature a positive determinant then it is not a proper rotation matrix according to definition (1) above and hence does not belong to $SO(n)$. However, if this is the case then we can flip the sign on one of the (random) column vectors of A to obtain A^+ and then repeat the Householder decomposition. The resulting matrix Q^+ is identical to the one obtained earlier but with a change in sign in the corresponding column and $|Q^+| = 1$, as required for a proper rotation matrix.

2. (*Direct Method*) A second method of obtaining random rotations involves selecting random points on the unit n-sphere directly (Knuth, 1997). This can be accom-

plished by drawing n independent random normal $N(0,1)$ variates $\{v_1, v_2, ..., v_n\}$ and normalizing each by the square root of the sum of squares of all n variates, that is, $x_i = v_i/\sqrt{v_1^2 + v_2^2 + \ldots + v_n^2}$ for $i \in \{1, 2, \ldots, n\}$. In other words, x is a unit vector pointing to a random point on the n-sphere. This construction takes advantage of spherical symmetry in the multivariate Normal distribution. The method is asymptotically faster than the QR approach and an implementation is available in the GNU Scientific Library (Galassi, 2009) as function gsl_ran_dir_nd. It should also be noted that it is straightforward to obtain the individual rotation angles from the random vector x, which makes it possible to move from the (more compact) random vector notation to the random rotation matrix used in the indirect method.

Generating random rotations in software for problems involving fewer than 1000 dimensions is straightforward and fast, even using the simple algorithm described above. Listings 2 and 3 in Appendix A provide examples of the indirect method in C++ and R respectively, both presented without error checking or optimizations. The C++ code takes less than 0.5 seconds on a single core of an Intel Xeon E5-2690 CPU to generate a 1000x1000 random rotation matrix. It uses the Eigen template library (Guennebaud et al., 2010) and a Mersenne Twister (Matsumoto and Nishimura, 1998) pseudorandom number generator. Larger rotation matrices can be computed with GPU assistance (Kerr et al., 2009) and may be pre-computed for use in multiple applications. In addition, for problems exceeding 1000 dimensions it is practical to only rotate a random subset of axes in order to reduce the computational overhead. We recommend that a different random subset is selected for each rotation in this case.

For categorical variables, rotation is unnecessary and ill defined. Intuitively, if a category is simply mapped to a new rotated category, there is no benefit in performing such a rotation.

4. Experiments

Random rotations complement standard learning techniques and are easily incorporated into existing algorithms. In order to examine the benefit of random rotations to ensemble performance, we modified three standard tree ensemble algorithms to incorporate random rotations before the tree induction phase. The necessary modifications are illustrated in pseudo code in Listing 1 below.

All methods tested use classification or regression trees that divide the predictor space into disjoint regions G_j, where $1 \leq j \leq J$, with J denoting the total number of terminal nodes of the tree. Extending the notation in Hastie et al. (2009), we represent a tree as

$$T(x; \theta, \Omega) = \sum_{j=1}^{J} c_j I(R(x) \in G_j), \tag{2}$$

with optimization parameters $\Omega = \{G_j, c_j\}_1^J$, random parameters $\theta = \{R, \omega\}$, where R is the random rotation associated with the tree and ω represents the random sample of (x, y) pairs used for tree induction; $I(\cdot)$ is an indicator function. Each randomly rotated input $R(x)$ is thus mapped to a constant c_j, depending on which region G_j the input belongs to.

For regression, c_j is typically just the average or median of all y_j in region G_j. If we let $|G_j|$ denote the cardinality of G_j, this can be written as

$$c_j = \frac{1}{|G_j|} \sum_{R(x_k) \in G_j} y_k. \tag{3}$$

For classification trees, one of the modes is typically used instead.

Given a loss function $L(y_i, f(x_i))$, for example exponential loss for classification or squared loss for regression, a tree-induction algorithm attempts to approximate the optimization parameters for which the overall loss is minimized, that is

$$\hat{\Omega} = \arg\min_{\Omega} \sum_{j=1}^{J} \sum_{R(x_i) \in G_j} L(y_i, f(R(x_i))) = \arg\min_{\Omega} \sum_{j=1}^{J} \sum_{R(x_i) \in G_j} L(y_i, c_i). \tag{4}$$

This optimization is performed across all parameters Ω but the rotation is explicitly excluded from the search space ($R \in \theta$, but $R \notin \Omega$) because we are advocating a random rotation in this paper. However, conceptually it would be possible to include the rotation in the optimization in an attempt to focus on the most helpful rotations.

Listing 1: Testing Random Rotations (Pseudo Code)

```
Inputs: - training feature matrix X
        - testing feature matrix S
        - total number of classifiers M
        - standard base learner B
        - aggregation weights w

(A) Scale or rank numeric predictors x (Sect. 4.2):
    e.g. x' := (x - Q_k(x))/(Q_{1-k}(x) - Q_k(x))

(B) For m ∈ {1,2,...,M} do
  (1) generate random parameters: θ_m := {R_m, ω_m}
  (2) train standard learner B on R_m(x):
        Ω̂_m = arg min_Ω Σ_{j=1}^{J} Σ_{R(x_i)∈G_j} L(y_i, f(R_m(x_i)))
  (3) compute test or out-of-bag predictions
        T(x, θ_m, Ω_m), x ∈ R_m(S)

(C) Aggregate predictions (vote or average)
      f_M(x) = Σ_{m=1}^{M} w_m T(x; θ_m, Ω_m)
```

In all algorithms considered in this paper, the tree-induction is performed using standard greedy, top-down recursive binary partitioning. This approach will generally not arrive at the globally optimal solution to (4) but constructs a reasonable approximation quickly (Hastie et al., 2009).

The (regression) tree ensemble $f_M(x)$ can then be written as a weighted sum of the individual trees, that is

$$f_M(x) = \sum_{m=1}^{M} w_m T(x; \theta_m, \Omega_m), \tag{5}$$

where M denotes the total number of trees in the ensemble. For classification ensembles, a vote is typically taken instead. It should be noted that a separate rotation is associated with each tree in this notation but the same rotation could theoretically be associated with an entire group of trees. In particular, we can recover the standard setting without random rotation by setting R_m to the identity rotation for all m.

The difference between non-additive ensemble methods like random forests (Breiman, 2001) or extra trees (Geurts et al., 2006) and additive ensembles like boosted trees (Freund and Schapire, 1996) arises in the formulation of the joint model for multiple trees. As we will see, this difference makes testing random rotation with existing additive ensemble libraries much more difficult than with non-additive ensemble libraries. Specifically, random forests and extra trees place an equal weight of $w_m = 1/M$ on each tree, and trees are constructed independently of each other, effectively producing an average of M independent predictions:

$$\hat{\Omega}_m = \arg\min_{\Omega_m} \sum_{j=1}^{J} \sum_{R(x_i) \in G_j} L(y_i, T(x_i; \theta_m, \Omega_m)). \tag{6}$$

In contrast, boosted trees use $w_m = 1$ and each new tree in the sequence is constructed to reduce the residual error of the full existing ensemble $f_{m-1}(x)$, that is

$$\hat{\Omega}_m = \arg\min_{\Omega_m} \sum_{j=1}^{J} \sum_{R(x_i) \in G_j} L(y_i, f_{m-1}(x_i) + T(x_i; \theta_m, \Omega_m)). \tag{7}$$

There are other differences between the two approaches: for example, J, the number of leaf nodes in each tree is often kept small for boosting methods in order to explicitly construct weak learners, while non-additive methods tend to use large, unpruned trees in an effort to reduce bias, since future trees are not able to assist in bias reduction in this case.

We mainly focus on random forest and extra tree ensembles in this paper because both of these algorithms rely on trees that are constructed independently of each other. This provides the advantage that the original tree induction algorithm can be utilized unmodified as a black box in the rotated ensemble, ensuring that any performance differences are purely due to the proposed random rotation and are not the result of any subtle differences (or dependencies) in the construction of the underlying trees.

4.1 Data Sets & Preprocessing

For our comparative study of random rotation, we selected UCI data sets (Bache and Lichman, 2013) that are commonly used in the machine learning literature in order to make the results easier to interpret and compare. Table 5 in Appendix C summarizes the data sets, including relevant dimensional information.

Some algorithms tested were not able to handle categorical input variables or missing values and we performed the following automatic preprocessing steps for each data column:

1. Any column (predictors or response) with at least 10 distinct numeric values was treated as numeric and missing values were imputed using the column median.

2. Any column with fewer than 10 distinct values (numeric or otherwise) or with mostly non-numeric values was treated as categorical, and a separate category was explicitly created for missing values.

3. Categorical predictors with C categories were converted into $(C-1)$ 0/1 dummy variables, with the final dummy variable implied from the others to avoid adding multicollinearity.

Note that after evaluating these three rules, all predictors were either numeric without missing values or categorical dummy variables, with a separate category for missing values.

4.2 Variable Scaling

Rotation can be sensitive to scale in general and outliers in particular. In order to avoid biasing the results, we tested three different scaling methods, all of which only use in-sample information to calibrate the necessary parameters for out-of-sample scaling:

1. (*Basic Scaling*) Numeric values were scaled to $[0, 1]$ using the in-sample min and max values, that is $x' = \min(1, \max(0, (x - \min(x_{is}))/(\max(x_{is}) - \min(x_{is}))))$. This scaling method deals with scale but only avoids out-of-sample outliers. Outliers are dealt with in a relatively crude fashion by applying a fixed cutoff.

2. (*Quantile Scaling*) Numeric values were linearly scaled in such a way that the 5th and 95th percentile of the in-sample data map to 0 and 1 respectively, that is $x' = (x - Q_5(x_{is}))/(Q_{95}(x_{is}) - Q_5(x_{is}))$. In addition, any values that exceed these thresholds were nonlinearly winsorized by adding/subtracting $0.01 \times \log(1 + \log(1 + \Delta))$, where Δ is the absolute difference to the in-sample bounds $Q_5(x_{is})$ or $Q_{95}(x_{is})$. This robust scaling has a breakdown point of 5% and maintains the order of inputs that exceed the thresholds.

3. (*Relative Ranking*) In-sample numeric values v_i were augmented with $\{-\infty, +\infty\}$ and ranked as $R(v_i)$, such that $R(-\infty)$ maps to 0 and $R(+\infty)$ maps to 1. Out-of-sample data was ranked relative to this in-sample map. To accomplish this, the largest v_i is found that is smaller or equal to the out-of-sample data v_o (call it v_i^{max}) and the smallest v_i is found that is greater or equal to the out-of-sample data v_o (v_i^{min}). The out-of-sample rank is then $0.5 \times R(v_i^{min}) + 0.5 \times R(v_i^{max})$. In this way, test elements that match in-sample elements obtain the same rank, test elements that fall in between two elements obtain a rank in between, and because the in-sample values are augmented with infinity, it is never possible to encounter test elements that cannot be mapped. This is the most robust approach to outliers that was tested.

4.3 Method & Evaluation

In order to collect quantitative evidence of the effect of random rotations, we built upon the tree induction algorithms implemented in the widely used R packages *randomForest* (Liaw and Wiener, 2002) and *extraTrees* (Simm and de Abril, 2013). For comparison, we also used the following implementation of rotation forests: https://github.com/ajverster/RotationForest.

Prior to the tests, all data sets were preprocessed and scaled using each of the three techniques described in the previous section (basic scaling, quantile scaling, and ranking).

Random forest and extra trees were tested with and without random rotation (for each scaling), while rotation forests included their own deterministic PCA rotation (Rodriguez et al., 2006) but were also run for each scaling method. Random rotations were tested with and without flip rotations. The combination of tree induction algorithms, scalings, and rotation options resulted in a total of 21 distinct experiments per data set.

For each experiment we performed a random 70-30 split of the data; 70% training data and the remaining 30% served as testing data. The split was performed uniformly at random but enforcing the constraint that at least one observation of each category level had to be present in the training data for categorical variables. This constraint was necessary to avoid situations, where the testing data contained category levels that were absent in the training set. Experiments were repeated 100 times (with different random splits) and the average performance was recorded.

In all cases we used default parameters for the tree induction algorithms, except that we built 5000 trees for each ensemble in the hope of achieving full convergence.

To evaluate the performance of random rotations, we ranked each method for each data set and computed the average rank across all data sets. This allowed us to compare performance of each method across scaling methods and tree induction algorithms in a consistent, nonparametric fashion. In addition, we determined the number of data sets for which each method performed within one cross-sectional standard deviation of the best predictor in order to obtain a measurement of significance. This approach is advocated in (Kuhn and Johnson, 2013) and it can be more informative when there is a cluster of strong predictors that is distinct from the weaker predictors and which would not get detected by simple ranking.

4.4 Results

Table 6 in Appendix C displays the raw results of the detailed testing. As indicated in the previous section, we opted to compare ranks – with low ranks indicating better performance – in order to avoid the problem of comparing problems of different difficulty or comparing regression with classification problems. This is illustrated in Table 1.

Table 1: Ranked performance comparison between random forest with and without random rotation (rf, rrrf), extra trees with and without random rotation (et, rret), and rotation trees (rot). For all data sets (left-hand side), the comparison is performed over the three scaling methods described in the text as basic scaling (b-scale), quantile scaling (q-scale), and ranking (ranked). The values represent ranks of the classification errors for classification problems and the ranks of the RMSE for regression problems. Values that are within one cross-sectional standard deviation of the minimum error are in bold.

In this table, we have omitted flip rotations because their performance was comparable to the simple random rotation, with flip rotations outperforming in 36% of cases, simple rotations outperforming in 45% of cases and ties in the remaining 19% of cases.

The best overall average rank of 6.10 (of 15) was achieved by the random rotation random forest algorithm with simple scaling, followed by the same algorithm with complex scaling (6.48) and ranking (6.55). This algorithm outperformed regardless of scaling. The next lowest rank of 6.72 was achieved by random rotation extra trees using quantile scaling.

It is interesting to note that the average ranks for each scaling type were 7.50 for the complex scaling, 7.65 for the simple scaling and 7.81 for ranking. This indicates that the scaling method was less influential than the selection of the algorithm. In particular, the new method often improved on the original method even when only the ranks of the data were considered. We believe this to be an interesting result because it indicates that even rotating ranks can improve performance. Obviously, ranked data is completely robust to scaling effects and outliers.

The best average rank across scalings was achieved by random rotation random forests with 6.38, followed by extra trees (7.06), random forests (7.20), random rotation extra trees (7.26), and rotation forests (10.38).

In our tests, rotation forests underperformed overall but showed strong performance in some particular cases. The problem here was that when rotation forests did not excel at a problem, they often were the worst performer by a large margin, which had an impact on the average rank. In contrast, random rotation random forests rarely displayed the very best performance but often were among the top predictors. This insight led us to consider predictors that were within one cross-sectional standard deviation of the best predictor for each data set.

Random rotation random forests were within one standard deviation of the best result (highlighted in bold in Table 1) in 67.8% of cases, random forests without rotation in 64.3% of cases, extra trees (with and without rotation) in 49.4% of cases, and rotation forests in 27.6%. It appears to be clear that random rotation can improve performance for a variety of problems and should be included as a user option for standard machine learning packages.

Random rotation appears to work best when numerical predictors outnumber categorical predictors, which are not rotated, and when these numerical predictors exhibit a relatively smooth distribution (rather than a few pronounced clusters). An example of a suitable dataset is Cleveland, with more than half of the variables continuous and spread out evenly. In contrast, Balance is an example of a dataset for which we cannot expect random rotation to perform well. However, in general it is difficult to judge the utility of rotation in advance and we recommend running a small test version of the problem with and without rotation to decide which to use: when the approach is successful, this tends to be apparent early.

Constructing a random rotation matrix using the indirect method described above requires of the order of p^3 operations, where p is the number of predictors to be rotated (time complexity of QR factorization). Multiplying the resulting random rotation matrix with an input vector requires of the order of p^2 operations. During training, this step needs to be performed k times, where k is the number of instances in the training data, for a total of $k \times p^2$ operations. All but one of the UCI datasets contained fewer than 100 predictors, and it takes less than a millisecond to compute a 100x100 random rotation matrix. Hence, with 5000 trees in each ensemble, the additional computational overhead was at most a few

seconds. However, as indicated above, for larger problems it does make sense to restrict the number of rotated predictors to maintain adequate performance.

Next, we consider the question of robustness.

4.5 Parameter Sensitivity and Extensions

In addition to the full tests described above, we also ran a few smaller examples to examine the sensitivity of random rotation to the choice of parameters in the underlying base learners. For this, we used the well known UCI *iris* data set (4 numeric predictors, 3 classes, 150 rows). Table 2 compares the performance of the standard random forest algorithm (RF) and a modified version including random feature rotation (RR-RF) on this data set.

Random Forest Comparison (iris)

parameters		% error		% wins per method

Table 2: Performance comparison of the standard random forest algorithm (RF) and a modified version with randomly rotated feature space for each tree (RR-RF) on the *iris* data set. Ntree is the total number of trees in the forest, mtry the number of randomly selected features considered at each decision node. Statistically significant differences in mean error percentage and win percentage at the 1% level are denoted in bold.

As in the detailed tests, both classifiers made use of the same tree induction algorithm, implemented in the *randomForest* R package, but the feature space was randomly rotated prior to the construction of each tree for the RR-RF algorithm. Since the iris data set only includes 4 predictors, the number of randomly selected features at each decision node (mtry) only has feasible values in 1-4, allowing for an exhaustive comparison. For each parameter setting, we selected 50% of the data (75 cases) at random as the learning data set, while the other half served as the test data set. The experiment was repeated 10000 times for each parameter setting and we kept track of the average error percentage of each method, as well as the percentage of times each method outperformed the other. Once

completed, a Wilcoxon signed-rank test was performed to compare the classification error percentage and win percentage of the original method with that of the modified classifier and to ascertain statistical significance at the 1% level. The modified ensemble featuring random rotation appears to universally outperform the original classifiers on this data set, regardless of parameter settings and in a statistically significant manner. However, it should be noted that the goal of this experiment was not to demonstrate the general usefulness of random rotations – this is achieved by the detailed experiments in the previous section – but rather to show the robustness to parameter changes for a specific data set.

Table 3 shows the analogous results for extra trees, which select both the split feature and the split point at random. Here we used the tree induction algorithm implemented in the *extraTrees* R package. In theory, there exist an infinite number of feasible split points (ncut) that could be chosen but for simplicity, we have only attempted ncut values in the range 1-4, meaning that at most 4 random split points were considered in the tests. The improvement due to rotation is again universal and statistically significant. For reasonable parameters (e.g. ntree ≥ 50), the new method matches or outperforms the original method in over 94% of the randomly generated cases and the performance improvement is 21.7% on average. This is again a very encouraging result, as it demonstrates that the results above are robust, even if non-default parameters are used for the base learners. It is also interesting to note that randomly rotated extra tree ensembles outperform randomly rotated random forests here and they tend to do best with lower ncut values, indicating that more randomness (via rotation, feature selection, and split selection) is helpful for this particular problem.

Table 4 shows comparable results with a gradient boosting machine from the *gbm* R package (Ridgeway, 2013). Since boosting is an additive procedure, where later trees have an explicit dependence on earlier trees in the ensemble, the comparison of the two methods is not as straightforward. More specifically, step (B).(2) in Listing 1 cannot be performed without knowing (and being able to reuse) f_{m-1} in the case of boosting. Unfortunately, the most common software packages for boosting (and *gbm* in particular) do not provide an interface for this. Of course, we could have implemented our own boosting library but then it would not be obvious that the improvement in predictive performance was entirely due to the rotation. For this reason, we opted to demonstrate boosting with a widely used package but on groups of trees, with one rotation per group of 50 trees. The rationale for this choice of group size was that the first few boosting iterations often lead to rapid improvements. In this case, we compared the original method, consisting of 5000 trees in a single ensemble, to a modified version with 100 sub-forests of 50 trees each, whereby each sub-forest was created on a randomly rotated feature space. In other words, the 50 trees in each sub-forest had a dependency, whereas the sub-forests themselves were independent of each other. The final classification was achieved through voting. As is evident from Table 4, randomly rotated gradient boosting machines even outperformed random forests and extra trees on this data set in terms of percentage error. Even when we handicapped the new method by only providing it with relative ranks of the data it outperformed the original (unrotated) method, although not by the same margin.

Extra Tree Ensemble Comparison (iris)

parameters		% error		% wins per method

Table 3: Performance comparison of the standard extra trees algorithm (ET) and a modified version with randomly rotated feature space for each tree (RR-ET) on the *iris* data set. Ntree is the total number of trees in the ensemble, ncut the number of randomly selected split points considered at each decision node. Statistically significant differences in mean error percentage and win percentage at the 1% level are denoted in bold.

Gradient Boosting Comparison (iris)

parameters				performance	
rank only	type	ntree	shrinkage	%error	%wins
no	GBM	1x5000	0.0005	5.063	9.62
no	RR-GBM	100x50	0.0500	**3.831**	**57.26**
yes	GBM	1x5000	0.0005	5.063	22.97
yes	RR-GBM	100x50	0.0500	**4.385**	**46.17**

Table 4: Performance comparison of the standard gradient boosting machine (GBM) and a modified version with randomly rotated feature space for each sub-forest of 50 trees (RR-GBM) on the *iris* data set. A classifier was trained for each parameter setting on a random half of the data and tested on the remaining half. Ntree is the total number of trees in the ensemble, expressed as the product of the number of generated sub-forests (each on a randomly rotated feature space) times the number of trees in each sub-forest. The procedure was repeated 10000 times. Statistically significant differences in mean error percentage and win percentage at the 1% level are denoted in bold. For the robust rank only version, a ranking of each predictive variable was performed using the train data, while the test vectors received an interpolated ranking based solely on relative order information with respect to the train data.

4.6 A Note on Diversity

In Appendix B we closely follow Breiman (2001) to derive an ensemble diversity measure that is applicable to the case of random rotation ensembles. In particular, we show that just like for random forests we can express the average correlation of the raw margin functions across all classifiers in the ensemble in terms of quantities we can easily estimate, specifically

$$\bar{\rho}(\cdot) = \frac{V_{x,y}[\Psi(x,y)]}{E_{\theta_1,\theta_2}[\sigma(\psi(x,y,\theta))]^2}. \tag{8}$$

That is, average correlation $\bar{\rho}$ is the variance of the margin across instances $V_{x,y}[\Psi(x,y)]$, divided by the expectation of the standard deviation σ of the raw margin across (randomized) classifiers squared. Full definitions of these quantities can be found in Appendix B.

As an example of the usefulness of this correlation measure, we estimated $\bar{\rho}$ with $m_{try} = \{1, 4\}$ on the iris example and achieved a correlation of 0.32 and 0.61, respectively. Clearly, the random split selection decorrelates the base learners. We then performed the same calculation including random rotation and achieved 0.22 and 0.39, respectively. In both cases, the correlation decreased by approximately one third. In contrast, the expected margin only decreased by 3.5%, meaning that the accuracy of the individual base learners was only very modestly affected.

5. Conclusion

Random rotations provide a natural way to enhance the diversity of an ensemble with minimal or no impact on the performance of the individual base learners. Rotations are particularly effective for base learners that exhibit axis parallel decision boundaries, as is the case for all of the most common tree-based learning algorithms. The application of random rotation is most effective for continuous variables and is equally applicable to higher dimensional problems.

A generalization of random rotations only uses a subset of rotations for out of sample predictions. This subset is chosen by observing the out-of-bag performance of each rotation in sample. Initial tests revealed that dropping the least effective decile of all random rotations generally improved out of sample performance but more research is needed because the procedure potentially introduces model bias.

Random rotations may also prove to be useful for image analysis. For example, axis-aligned methods for image processing, such as wavelet smoothing, may benefit from repeated random rotations to ensure that the methods become axis-independent.

While random rotations are certainly not a panacea, they are helpful frequently enough that we contend standard data mining packages should provide users the option to randomly rotate the feature space prior to inducing each base learner.

Appendix A

The following listings provide illustrations in two commonly used programming languages for the generation of a random rotation matrix using the indirect method described in section 3 above. The code is kept simple for illustrative purposes and does not contain error checking or performance optimizations.

Listing 2: Random Rotation in C++ using Eigen

```
#include "MersenneTwister.h"
#include <Eigen/Dense>
#include <Eigen/QR>

using namespace Eigen;

// C++: generate random n x n rotation matrix
void random_rotation_matrix(MatrixXd& M, int n)
{
  MTRand mtrand; // twister with random seed

  MatrixXd A(n,n);
  const VectorXd ones(VectorXd::Ones(n));

  for(int i=0; i<n; ++i)
    for(int j=0; j<n; ++j)
      A(i,j) = mtrand.randNorm(0,1);

  const HouseholderQR<MatrixXd> qr(A);
  const MatrixXd Q = qr.householderQ();
  M = Q * (qr.matrixQR().diagonal().array()
           < 0).select(-ones,ones).asDiagonal();

  if(M.determinant() < 0)
    for(int i=0; i<n; ++i)
      M(i,0) = -M(i,0);
}
```

Listing 3: Random Rotation in R

```
# generate random member of orthogonal group O(n)
random_rotation_matrix_incl_flip <- function(n)
{
  QR <- qr(matrix(rnorm(n^2), ncol=n))          # A = QR
  M <- qr.Q(QR) %*% diag(sign(diag(qr.R(QR)))) # diag(R) > 0
  return(M)
}

# generate random member of special orthogonal group SO(n)
random_rotation_matrix <- function(n)
{
  M <- random_rotation_matrix_incl_flip(n)
  if(det(M)<0) M[,1] <- -M[,1]                  # det(M) = +1
  return(M)
}
```

Appendix B

In this appendix, we closely follow Breiman (2001) to derive an ensemble diversity measure that is applicable to random rotation ensembles.

For a given input vector x, we define the label of the class to which classifier $f_M(x)$ assigns the highest probability, save for the correct label y, to be j^M_{max}, that is

$$j^M_{max} := \arg\max_{j \neq y} P(f_M(x) = j). \tag{9}$$

Using this definition, we denote the raw margin function $\psi(x, y)$ for a classification tree ensemble $f_M(x)$ as

$$\psi(x, y, \theta) = I(f_M(x) = y) - I(f_M(x) = j^M_{max}), \tag{10}$$

with indicator function $I(\cdot)$. This expression evaluates to +1 if the classification is correct, -1 if the most probable incorrect class is selected, and 0 otherwise. The margin function $\Psi(x, y)$ is its expectation, that is

$$\begin{aligned} \Psi(x, y) &= E_\theta[\psi(x, y, \theta)] \\ &= P(f_M(x) = y) - P(f_M(x) = j^M_{max}). \end{aligned} \tag{11}$$

The margin function $\Psi(x, y)$ represents the probability of classifying an input x correctly minus the probability of selecting the most probable incorrect class.

If we denote the out-of-bag instances for classification tree $T(x; \theta_m, \Omega_m)$ as O_m, then these probabilities can be estimated as

$$\hat{P}(f_M(x) = k) = \frac{\sum^M_{m=1} I(T(x; \theta_m, \Omega_m) = k \wedge (x, y) \in O_m)}{\sum^M_{m=1} I((x, y) \in O_m)}, \tag{12}$$

where the denominator counts the number of base learners for which (x, y) is out-of-bag. If we were to use a separate testing data set S, as we do in our examples, this can be further simplified to

$$\hat{P}(f_M(x) = k) = \frac{1}{M} \sum_{m=1}^{M} I(T(x; \theta_m, \Omega_m) = k), \tag{13}$$

where any instance (x, y) must be selected from S. From this, the expected margin can be estimated as

$$\hat{E}_{x,y}[\Psi(x, y)] = \hat{E}_{x,y}[\hat{P}(f_M(x) = y) - \hat{P}(f_M(x) = j^M_{max})] \tag{14}$$

and its variance as

$$\hat{V}_{x,y}[\Psi(x, y)] = \hat{E}_{x,y}[(\hat{P}(f_M(x) = y) - \hat{P}(f_M(x) = j^M_{max}))^2] - \hat{E}_{x,y}[\Psi(x, y)]^2. \tag{15}$$

The expectations are computed over the training set for the out-of-bag estimator or the testing data set respectively, depending on which approach is used.

Using Chebyshev's inequality, we can derive a bound for the probability of achieving a negative margin, a measure of the generalization error:

$$\begin{aligned} P(\Psi(x, y) < 0) &\leq P(|E_{x,y}[\Psi(x, y)] - \Psi(x, y)| \geq E_{x,y}[\Psi(x, y)]) \\ &\leq \frac{V_{x,y}[\Psi(x, y)]}{E_{x,y}[\Psi(x, y)]^2}, \end{aligned} \tag{16}$$

which can be estimated from equations (14) and (15). Clearly, this inequality is only useful if the expected margin is positive because otherwise the classification is no better than random.

We now follow Breiman's argument for obtaining a measure of ensemble diversity in terms of the random classifier parameters θ, which in our case include the random rotation in addition to the bootstrap samples. First, we note that for independent and identically distributed (i.i.d.) random parameters θ_1 and θ_2, we have

$$\begin{aligned} E_{\theta_1,\theta_2}[\psi(x, y, \theta_1) \times \psi(x, y, \theta_2)] &= E_{\theta_1}[\psi(x, y, \theta_1)] \times E_{\theta_2}[\psi(x, y, \theta_2)] \\ &= \Psi(x, y) \times \Psi(x, y) \\ &= \Psi(x, y)^2. \end{aligned} \tag{17}$$

Therefore, the variance of $\Psi(x, y)$ can be reformulated as

$$\begin{aligned} V_{x,y}[\Psi(x, y)] &= E_{x,y}[\Psi(x, y)^2] - E_{x,y}[\Psi(x, y)]^2 \\ &= E_{x,y}[E_{\theta_1,\theta_2}[\psi(x, y, \theta_1) \times \psi(x, y, \theta_2)]] - E_{x,y}[E_{\theta_1}[\psi(x, y, \theta_1)]] \times E_{x,y}[E_{\theta_2}[\psi(x, y, \theta_2)]] \\ &= E_{\theta_1,\theta_2}[E_{x,y}[\psi(x, y, \theta_1) \times \psi(x, y, \theta_2)] - E_{x,y}[\psi(x, y, \theta_1)] \times E_{x,y}[\psi(x, y, \theta_2)]] \\ &= E_{\theta_1,\theta_2}[Cov_{x,y}[\psi(x, y, \theta_1), \psi(x, y, \theta_2)]] \\ &= E_{\theta_1,\theta_2}[\rho(\psi(x, y, \theta_1), \psi(x, y, \theta_2))] \times E_{\theta_1,\theta_2}[\sigma(\psi(x, y, \theta_1)) \times \sigma(\psi(x, y, \theta_2))] \\ &= E_{\theta_1,\theta_2}[\rho(\psi(x, y, \theta_1), \psi(x, y, \theta_2))] \times E_{\theta_1,\theta_2}[\sigma(\psi(x, y, \theta))]^2. \end{aligned} \tag{18}$$

This result allows us to express the average correlation of the raw margin functions across all classifiers in the ensemble in terms of quantities we can easily estimate, specifically

$$\bar{\rho}(\cdot) = \frac{V_{x,y}[\Psi(x, y)]}{E_{\theta_1,\theta_2}[\sigma(\psi(x, y, \theta))]^2}, \tag{19}$$

where we can use (15) as an estimate of the numerator. In other words, correlation represents the variance of the margin across instances, divided by the expectation of the standard deviation of the raw margin across (randomized) classifiers squared.

To estimate the denominator across all random parameters θ – i.e. the individual base learners and rotations – we can use

$$\begin{aligned} E_{\theta_1,\theta_2}[\sigma(x, y, \theta)] = \frac{1}{M} \sum_{m=1}^{M} &\sqrt{P(f_m(x) = y) + P(f_m(x) = j^m_{max}) -} \\ &\overline{(P(f_m(x) = y) - P(f_m(x) = j^m_{max}))^2}, \end{aligned} \tag{20}$$

where the probabilities are calculated for each individual classifier across all instances (x, y) in the out-of-bag or test set respectively, i.e. in the case of a test set S we would use

$$\hat{P}(f_m(x) = k) = \frac{1}{|S|} \sum_{(x_i,y)\in S} I(T(x_i; \theta_m, \Omega_m) = k), \tag{21}$$

with $|S|$ denoting the cardinality of S.

Table 6: Raw performance comparison between random forest with and without random rotation (rf, rrrf), extra trees with and without random rotation (et, rret), and rotation trees (rot). For all data sets (left-hand side), the comparison is performed over the three scaling methods described in the text as basic scaling (b-scale), quantile scaling (q-scale), and ranking (ranked). The values represent classification errors for classification problems and RMSE for regression problems ($\times$10000).

Abstract

The statistical comparison of multiple algorithms over multiple data sets is fundamental in machine learning. This is typically carried out by the Friedman test. When the Friedman test rejects the null hypothesis, multiple comparisons are carried out to establish which are the significant differences among algorithms. The multiple comparisons are usually performed using the mean-ranks test. The aim of this technical note is to discuss the inconsistencies of the mean-ranks post-hoc test with the goal of discouraging its use in machine learning as well as in medicine, psychology, etc.. We show that the outcome of the mean-ranks test depends on the pool of algorithms originally included in the experiment. In other words, the outcome of the comparison between algorithms A and B depends also on the performance of the other algorithms included in the original experiment. This can lead to paradoxical situations. For instance the difference between A and B could be declared significant if the pool comprises algorithms C, D, E and not significant if the pool comprises algorithms F, G, H. To overcome these issues, we suggest instead to perform the multiple comparison using a test whose outcome only depends on the two algorithms being compared, such as the sign-test or the Wilcoxon signed-rank test.

Keywords: statistical comparison, Friedman test, post-hoc test

1. Introduction

The statistical comparison of multiple algorithms over multiple data sets is fundamental in machine learning; it is typically carried out by means of a statistical test. The recommended approach is the Friedman test (Demšar, 2006). Being non-parametric, it does *not* require commensurability of the measures across different data sets, it does *not* assume normality of the sample means and it is *robust* to outliers.

When the Friedman test rejects the null hypothesis of no difference among the algorithms, post-hoc analysis is carried out to assess which differences are significant. A series of pairwise comparison is performed adjusting the significance level via Bonferroni correction or other more powerful approaches (Demšar, 2006; Garcia and Herrera, 2008) to control the family-wise Type I error.

The mean-ranks post-hoc test (McDonald and Thompson, 1967; Nemenyi, 1963), is recommended as pairwise test for multiple comparisons in most books of nonparametric statistics: see for instance Gibbons and Chakraborti (2011, Sec. 12.2.1), Kvam and Vidakovic (2007, Sec. 8.2) and Sheskin (2003, Sec. 25.2). It is also commonly used in machine learning (Demšar, 2006; Garcia and Herrera, 2008). The mean-ranks test is based on the statistic:

$$z = |\bar{R}_A - \bar{R}_B| / \sqrt{\frac{m(m+1)}{6n}},$$

where $\bar{R}_A, \bar{R}_B$ are the mean ranks (as computed by the Friedman test) of algorithms A and B, m is the number of algorithms to be compared and n the number of datasets. The mean-ranks $\bar{R}_A, \bar{R}_B$ are computed considering the performance of all the m algorithms. Thus the outcome of the comparison between A and B depends also on the performance of the other (m-2) algorithms included in the original experiment. This can lead to paradoxical situations. For instance the difference between A and B could be declared *significant* if the pool comprises algorithms C, D, E and *not significant* if the pool comprises algorithms F, G, H. The performance of the remaining algorithms should instead be irrelevant when comparing algorithms A and B. This problem has been pointed out several times in the past by Miller (1966); Gabriel (1969); Fligner (1984) and also by Hollander et al. (2013, Sec. 7.3). Yet it is ignored by most literature on nonparametric statistics. However this issue should not be ignored, as it can increase the type I error when comparing two equivalent algorithms and conversely decrease the power when comparing algorithms whose performance is truly different. In this technical note, all these inconsistencies of the mean-ranks test will be discussed in details and illustrated by means of highlighting examples with the goal of discouraging its use in machine learning as well as in medicine, psychology, etc..

To avoid theses issues, we instead recommend to perform the pairwise comparisons of the post-hoc analysis using the *Wilcoxon signed-rank test* or the *sign test*. The decisions of such tests do not depend on the pool of algorithms included in the initial experiment. It is understood that, regardless the specific test adopted for the pairwise comparisons, it is necessary to control the family-wise type I error. This can be obtained through Bonferroni correction or through more powerful approaches (Demšar, 2006; Garcia and Herrera, 2008).

Even better would be the adoption of the Bayesian methods for hypothesis testing. They overcome the many drawbacks (Demšar, 2008; Goodman, 1999; Kruschke, 2010) of the null-hypothesis significance tests. For instance, Bayesian counterparts of the Wilcoxon and of the sign test have been presented in Benavoli et al. (2014); Benavoli et al. (2014); a Bayesian approach for comparing cross-validated algorithms on multiple data sets is discussed by Corani and Benavoli (2015).

2. Friedman Test

The performance of multiple algorithms tested on multiple datasets can be organized in a matrix:

$$\begin{array}{c} \\ Algorithms \end{array} \begin{array}{c} Datasets \\ \begin{bmatrix} X_{11} & X_{12} & \dots & X_{1n} \\ X_{21} & X_{22} & \dots & X_{2n} \\ \vdots & \vdots & \vdots & \vdots \\ X_{m1} & X_{m2} & \dots & X_{mn} \end{bmatrix} \end{array} \tag{1}$$

where X_{ij} denotes the performance of the i-th algorithm on the j-th dataset (for $i = 1, \dots, m$ and $j = 1, \dots, n$). The observations (performances) in different columns are assumed to be independent. The algorithms are ranked column-by-column and each entry X_{ij} is replaced by its rank relative to the other observations in the j-th column:

$$\mathbf{R} = \begin{bmatrix} R_{11} & R_{12} & \dots & R_{1n} \\ R_{21} & R_{22} & \dots & R_{2n} \\ \vdots & \vdots & \vdots & \vdots \\ R_{m1} & R_{m2} & \dots & R_{mn} \end{bmatrix}, \tag{2}$$

where R_{ij} is the rank of the algorithm i in the j-th dataset. The sum of the i-th row $R_i = \sum_{j=1}^{n} R_{ij}$, $\forall\ i = 1, \dots, m$, depends on how the i-th algorithm performs w.r.t. the other $(m-1)$ algorithms. Under the null hypothesis of the Friedman test (no difference between the algorithms) the average value of R_i is $n(m+1)/2$. The statistic of the Friedman test is

$$S = \frac{12}{nm(m+1)} \sum_{j=1}^{n} \left[R_j - \frac{n(m+1)}{2} \right]^2, \tag{3}$$

which under the null hypothesis has a chi-squared distribution with $m-1$ degrees of freedom. For $m = 2$, the Friedman test corresponds to the sign test.

3. Mean Ranks Post-Hoc Test

If the Friedman test rejects the null hypothesis one has to establish which are the significant differences among the algorithms. If all classifiers are compared to each other, one has to perform $m(m-1)/2$ pairwise comparisons.

When performing multiple comparisons, one has to control the family-wise error rate, namely the probability of at least one erroneous rejection of the null hypothesis among the $m(m-1)/2$ pairwise comparisons. In the following example we control the family-wise error (FWER) rate through the Bonferroni correction, even though more powerful techniques are also available (Demšar, 2006; Garcia and Herrera, 2008). However our discussion of the shortcomings of the mean-ranks test is valid regardless the specific approach adopted to control the FWER.

The mean-rank test claims that the i-th and the j-th algorithm are significantly different if:

$$|\bar{R}_i - \bar{R}_j| \geq z^* \sqrt{\frac{m(m+1)}{6n}}. \tag{4}$$

where $\bar{R}_i = \frac{1}{n} R_i$ is the mean rank of the i-th algorithm and z^* is the Bonferroni corrected $\alpha/m(m-1)$ upper standard normal quantile (Gibbons and Chakraborti, 2011, Sec. 12.2.1). Equation (4) is based on the large sample ($n > 10$) approximation of the distribution of the statistic. The actual distribution of the statistic $|\bar{R}_i - \bar{R}_j|$ is derived assuming all the $(m!)^n$ ranks in (2) to be equally probable. Under this assumption the variance of $|\bar{R}_i - \bar{R}_j|$ is $m(m+1)/6n$, which originates the term under the square root in (4).

The sampling distribution of the statistic $|\bar{R}_i - \bar{R}_j|$ assumes all ranks configurations in (2) to be equally probable. Yet this assumption is not tenable: the post-hoc analysis is performed *because* the null hypothesis of the Friedman test has been rejected.

4. Inconsistencies of the Mean-Ranks Test

We illustrate the inconsistencies the mean-ranks test by presenting three examples. All examples refer to the analysis of the accuracy of different classifiers on multiple data sets. We show that the outcome of the test depends both on the actual difference of accuracy between algorithm A and B *and* on the accuracy of the remaining algorithms.

4.1 Example 1: Artificially Increasing Power

Assume we have tested five algorithms A, B, C, D, E on 20 datasets obtaining the accuracies:

	Datasets																			
A	50	50	50	50	50	50	50	50	50	50	80	80	80	80	80	80	80	80	80	80
B	80	80	80	80	80	80	80	80	80	80	50	50	50	50	50	50	50	50	50	50
C	55	55	55	55	55	55	55	55	55	55	45	45	45	45	45	45	45	45	45	45
D	60	60	60	60	60	60	60	60	60	60	85	85	85	85	85	85	85	85	85	85
E	65	65	65	65	65	65	65	65	65	65	90	90	90	90	90	90	90	90	90	90

The corresponding ranks are:

	Datasets																			
A	1	1	1	1	1	1	1	1	1	1	3	3	3	3	3	3	3	3	3	3
B	5	5	5	5	5	5	5	5	5	5	2	2	2	2	2	2	2	2	2	2
C	2	2	2	2	2	2	2	2	2	2	1	1	1	1	1	1	1	1	1	1
D	3	3	3	3	3	3	3	3	3	3	4	4	4	4	4	4	4	4	4	4
E	4	4	4	4	4	4	4	4	4	4	5	5	5	5	5	5	5	5	5	5

where better algorithms are given higher ranks. We aim at comparing A and B. Algorithm B is better than A in the first ten datasets, while A is better than B in the remaining ten. The two algorithms have the same mean performance and their differences are symmetrically distributed. Each algorithms wins on half the data sets. Different types of two-sided tests (t-test, Wilcoxon signed-rank test, sign-test) return the same p-value, $p = 1$. The mean-ranks test correspond in this case to the sign-test and thus also its p-value is 1. This is most extreme result in favor of the null hypothesis.

Now assume that we compare A, B together with C, D, E. In the first ten datasets, algorithm A is worse than C, D, E, which in turn are worse than B. In the remaining ten datasets, C is worse than A, B, which in turn are worse than D, E. The p-value of the

Friedman test is $p \approx 10^{-10}$ and, thus, it rejects the null hypothesis. We can thus perform the post-hoc test (4) with $z^* = 2.807$ (the Bonferroni corrected $\alpha/m(m-1)$ upper standard normal quantile for $\alpha = 0.05$ and $m = 5$). The significance level has been adjusted to $\alpha/m(m-1)$, since we are performing $m(m-1)/2$ two-sided comparisons. The mean ranks of A, B are respectively 2 and 3.5 and, thus, since $|\bar{R}_A - \bar{R}_B| = 1.5$ and $z^*\sqrt{\frac{m(m+1)}{6n}} \approx 1.4$ we can reject the null hypothesis. The result of the post-hoc test is that the algorithms A, B have significantly different performance.

The decisions of the mean-ranks test are not consistent:

- if it compares A, B alone, it does not reject the null hypothesis;
- if it compares A, B together with C, D, E, it rejects the null hypothesis concluding that A, B have significantly different performance.

The presence of C, D, E artificially introduces a difference between A, B by changing the mean ranks of A, B. For instance, D and E rank always better than A, while they never outperform B when it works well (i.e., datasets from one to ten); in a real case study, a similar result would probably indicate that while B is well suited for the first ten datasets, D, E and A are better suited for the last ten. The difference (in rank) between A and B is artificially amplified by the presence of D and E only when B is better than A. The point is that a large differences in the global ranks of two classifiers does not necessarily correspond to large differences in their accuracies (and vice versa, as we will see in the next example).

This issue can happen in practice.[1] Assume that a researcher presents a new algorithm A_0 and some of its weaker variations A_1, A_2,...,A_k and compares the new algorithms with an existing algorithm B. When B is better, the rank is $B \succ A_0 \succ \ldots \succ A_k$. When A_0 is better, the rank is $A_0 \succ A_1 \succ \ldots \succ A_k \succ B$. Therefore, the presence of A_1, A_2,...,A_k artificially increases the difference between A_0 and B.

4.2 Example 2: Low Power Due to the Remaining Algorithms

Assume the performance of algorithms A and B on different data sets to be normally distributed as follows:

$$A \sim N(0,1), \quad B \sim N(1.5,1).$$

The pool of algorithms comprises also C, D, E, whose performance is distributed as follows:

$$C \sim N(5,1), \quad D \sim N(6,1), \quad E \sim N(7,1).$$

A collection of 20 data sets is considered.

For the sake of simplicity, assume we want to compare only A and B. There is thus no need of correction for multiple comparisons.

When comparing A and B, the power of the two-sided sign test with $\alpha = 0.05$ is *very* high: 0.94 (we have evaluated the power numerically by Monte Carlo simulation). The power of the mean-ranks test is instead only 0.046. We can explain the large difference

1. We thank the anonymous reviewer for suggesting this example.

of power as follows. The sign test (under normal approximation of the distribution of the statistic) claims significance when:

$$|\bar{R}_A - \bar{R}_B| \geq z^*\sqrt{\frac{1}{n}}$$

while the mean-ranks test (4) claims significance when:

$$|\bar{R}_A - \bar{R}_B| \geq z^*\sqrt{\frac{m(m+1)}{6n}} = z^*\sqrt{\frac{5}{n}},$$

with $m = 5$. Since the algorithms C, D, E have mean performances that are much larger than those of A, B, the mean-ranks difference $|\bar{R}_A - \bar{R}_B|$ is equal for the two test. However the mean-ranks estimates the variance of the statistic $|\bar{R}_A - \bar{R}_B|$ to be five times larger compared to the sign test. The critical value of the mean-ranks test is inflated by $\sqrt{5}$, largely decreasing the power of the test. In fact for the mean-ranks test the variance of $|\bar{R}_A - \bar{R}_B|$ increases with the number of algorithms included in the initial experiment.

4.3 Example 3: Real Classifiers on UCI Data Sets

Finally, we compare the accuracies of seven classifiers on 54 datasets. The classifiers are: J48 decision tree (C_1); hidden naive Bayes (C_2); averaged one-dependence estimator (AODE) (C_3); naive-Bayes (C_4); J48 graft (C_5), locally weighted naive-Bayes (C_6), random forest (C_7). The whole set of results is given in Appendix. Each classifier has been assessed via 10 runs of 10-folds cross-validation. We performed all the experiments using WEKA.[2] All these classifiers are described in Witten and Frank (2005).

The accuracies are reported in Table 2. Assume that our aim is to compare C_1, C_2, C_3, C_4 alone. Therefore, we consider just the first 4 columns in Table 2. The mean ranks are:

$$C_2 = 2.676, \quad C_4 = 1.917, \quad C_1 = 2.518, \quad C_3 = 2.888.$$

The Friedman test rejects the null hypothesis. The pairwise comparisons for the pair C_2, C_4 gives the statistic

$$z = |\bar{R}_2 - \bar{R}_4|/\sqrt{m(m+1)/6n} = 3.06.$$

Since 3.06 is greater than $z^* = 2.64$ (the Bonferroni corrected $\alpha/m(m-1)$ upper standard normal quantile for $\alpha = 0.05$ and $m = 4$), the mean-ranks procedure finds the algorithms C_2, C_4 to be significantly different.

If we compare C_2, C_4 together with C_1, C_5, the mean ranks are:

$$C_2 = 2.713, \quad C_4 = 2.102, \quad C_1 = 2.528, \quad C_5 = 2.657.$$

Again, Friedman test rejects the null hypothesis. The pairwise comparisons for the pair C_2, C_4 gives the statistic

$$z = |\bar{R}_2 - \bar{R}_4|/\sqrt{m(m+1)/6n} = 2.46,$$

2. `http://www.cs.waikato.ac.nz/ml/weka/`

	Card=2	Card=3	Card=4
C_2 vs. C_4	7/10	9/10	3/5
C_2 vs. C_7	1/10	-	-
C_3 vs. C_7	2/10	-	-
C_4 vs. C_6	9/10	5/10	-

Table 1: Pairwise comparisons that are affected (numbers of decisions that are significantly different/number of subsets) by the performance of the other algorithms. Here Card=2 means that, for each pair C_a, C_b on the left column, we are considering the subsets $\{C_a, C_b, C_x, C_y\}$, Card=3 $\{C_a, C_b, C_x, C_y, C_z\}$ and Card=4 $\{C_a, C_b, C_x, C_y, C_z, C_w\}$. The symbol "-" means that the comparison does not depend on the subset of algorithms.

which is smaller than z^*. Thus the difference between algorithms C_2 and C_4 is *not* significant.

The accuracies of C_2 and C_4 are the same in the two cases but again the decisions of the mean-ranks are conditional to the group of classifiers we are considering.

Consider building a set of four classifiers $\{C_2, C_4, C_x, C_y\}$. By differently choosing C_x and C_y we can build ten different such sets. For each subset we run the mean-ranks test to check whether the difference between C_2 and C_4 is significantly different. The difference is claimed to be *significant* in 7 cases and *not significant* in 3 cases.

Now consider a set of five classifiers $\{C_2, C_4, C_x, C_y, C_z\}$. By differently choosing C_x, C_y and C_z we can build ten different such sets. This yields 10 further cases in which we compare again C_2 and C_4. Their difference is claimed to be significant in 9/10 cases.

Table 1 reports the pairwise comparisons for which the statistical decision changes with the pool of classifiers that are considered. The outcome of the mean-ranks test when comparing the same pair of classifiers clearly depends on the pool of alternative classifiers $\{C_x, C_y, \ldots\}$ which is assumed.

4.4 Maximum Type I Error

A further drawback of the mean-ranks test which has not been discussed in the previous examples is that it cannot control the maximum type I error, that is, the probability of falsely declaring any pair of algorithms to be different regardless of the other $m-2$ algorithms. If the accuracies of all algorithms but one are equal, it does not guarantee the family-wise Type I error to be smaller than α when comparing the $m-1$ equivalent algorithms. We point the reader to Fligner (1984) for a detailed discussion on this aspect.

5. A Suggested Procedure

Given the above issues, we recommend to avoid the mean-ranks test for the post-hoc analysis. One should instead perform the multiple comparison using tests whose decision depend only on the two algorithms being compared, such as the sign test or the Wilcoxon signed-rank test. The sign test is more robust, as it only assumes the observations to be identically distributed. Its drawback is low power. The Wilcoxon signed-rank test is more powerful

and thus it is generally recommended (Demšar, 2006). Compared to the sign test, the Wilcoxon signed-rank test makes the additional assumption of a symmetric distribution of the differences between the two algorithms being compared. The decision between sign test and signed-rank test thus depends on whether the symmetry assumption is tenable on to the analyzed data.

Regardless the adopted test, the multiple comparisons should be performed adjusting the significance level to control the family-wise Type-I error. This can be done using the correction for multiple comparison discussed by Demšar (2006); Garcia and Herrera (2008). If we adopt the Wilcoxon signed-rank test in Example 3 for comparing C_2, C_4, we obtain the p-value 0.0002, independently from the performance of the other algorithms. Thus, for any pool of algorithms C_2, C_4, C_x, C_y, we always report the same decision: C_2, C_4 are significantly different because the p-value is less than the Bonferroni corrected significance level $\alpha/m(m-1)$ (in the case $m=4$, $\alpha/m(m-1) = 0.0042$).

6. Software

The MATLAB scripts of the above examples can be downloaded from `ipg.idsia.ch/software/meanRanks/matlab.zip`

7. Conclusions

The mean-ranks post-hoc test is widely used test for multiple pairwise comparison. We discuss a number of drawbacks of this test, which we recommend to avoid. We instead recommend to adopt the sign-test or the Wilcoxon signed-rank, whose decision does not depend on the pool of classifiers included in the original experiment.

We moreover bring to the attention of the reader the Bayesian counterparts of these tests, which overcome the many drawbacks (Kruschke, 2010, Chap.11) of null-hypothesis significance testing.

Abstract

The problem of matching two sets of features appears in various tasks of computer vision and can be often formalized as a problem of permutation estimation. We address this problem from a statistical point of view and provide a theoretical analysis of the accuracy of several natural estimators. To this end, the minimax rate of separation is investigated and its expression is obtained as a function of the sample size, noise level and dimension of the features. We consider the cases of homoscedastic and heteroscedastic noise and establish, in each case, tight upper bounds on the separation distance of several estimators. These upper bounds are shown to be unimprovable both in the homoscedastic and heteroscedastic settings. Interestingly, these bounds demonstrate that a phase transition occurs when the dimension d of the features is of the order of the logarithm of the number of features n. For $d = O(\log n)$, the rate is dimension free and equals $\sigma(\log n)^{1/2}$, where σ is the noise level. In contrast, when d is larger than $c \log n$ for some constant $c > 0$, the minimax rate increases with d and is of the order of $\sigma(d \log n)^{1/4}$. We also discuss the computational aspects of the estimators and provide empirical evidence of their consistency on synthetic data. Finally, we show that our results extend to more general matching criteria.

Keywords: permutation estimation, minimax rate of separation, feature matching

1. Introduction

In this paper, we present a rigorous statistical analysis of the problem of permutation estimation and multiple feature matching from noisy observations. More precisely, let $\{X_1, \dots, X_n\}$ and $\{X_1^\sharp, \dots, X_m^\sharp\}$ be two sets of vectors from $\mathbb{R}^d$, hereafter referred to as noisy features, containing many matching elements. That is, for many X_i's there is a $X_j^\sharp$ such that X_i and $X_j^\sharp$ coincide up to an observation noise (or measurement error). Our goal is to estimate an application $\pi^* : \{1, \dots, n\} \to \{1, \dots, m\}$ for which each X_i matches with $X^\sharp_{\pi^*(i)}$ and to provide tight conditions which make it possible to accurately recover π^* from data.

In order to define a statistical framework allowing us to compare different estimators of π^*, we confine[1] our attention to the case $n = m$, that is when the two sets of noisy features have equal sizes. Furthermore, we assume that there exists a unique permutation of $\{1, \dots, n\}$, denoted π^*, leading to pairs of features $(X_i, X^\sharp_{\pi^*(i)})$ that match up to a measurement error. In such a situation, it is clearly impossible to recover the true permutation π^* if some features within the set $\{X_1, \dots, X_n\}$ are too close. Based on this observation, we propose to measure the quality of a procedure of permutation estimation by the minimal distance between pairs of different features for which the given procedure is still consistent. This quantity will be called *separation distance* and will be the main concept of interest in the present study. In this respect, the approach we adopted is close in spirit to the minimax theory of hypotheses testing (see, for instance, Spokoiny (1996); Ingster and Suslina (2003)).

1.1 A Motivating Example: Feature Matching in Computer Vision

Many tasks of computer vision, such as object recognition, motion tracking or structure from motion, are currently carried out using algorithms that contain a step of feature matching, cf. Szeliski (2010); Hartley and Zisserman (2003). The features are usually local descriptors that serve to summarize the images. The most famous examples of such features are perhaps SIFT (Lowe, 2004) and SURF (Bay et al., 2008). Once the features have been computed for each image, an algorithm is applied to match features of one image to those of another one. The matching pairs are then used for estimating the deformation of the object, for detecting the new position of the followed object, for creating a panorama, etc. In this paper, we are interested in simultaneous matching of a large number of features. The main focus is on the case when the two sets of features are extracted from the images that represent the same scene with a large overlap, and therefore the sets of features are (nearly) of the same size and every feature in the first image is also present in the second one. This problem is made more difficult by the presence of noise in the images, and thus in the features as well. Typically, due to the high resolution of most images, the number of features is large and their dimension is relatively large as well (128 for SIFT and 64 for SURF). It is therefore important to characterize the behavior of various matching procedures as a function of the number of features, the dimension and the noise level.

1.2 Main Contributions

We consider four procedures of permutation estimation that naturally arise in this context. The first one is a greedy procedure that sequentially assigns to each feature X_i the closest feature $X_j^\sharp$ among those features that have not been assigned at an earlier step. The three other estimators are defined as minimizers of the (profiled-)log-likelihood under three different modeling assumptions. These three modeling assumptions are that the noise level is constant across all the features (homoscedastic noise), that the noise level is variable (heteroscedastic noise) but known and that the noise level is variable and unknown. The corresponding estimators are respectively called least sum of squares (LSS) estimator, least sum of normalized squares (LSNS) estimator and least sum of logarithms (LSL) estimator.

1. These assumptions are imposed for the purpose of getting transparent theoretical results and are in no way necessary for the validity of the considered estimation procedures, as discussed later in the paper.

We first consider the homoscedastic setting and show that all the considered estimators are consistent under similar conditions on the minimal distance between distinct features κ. These conditions state that κ is larger than some function of the noise level σ, the sample size n and the dimension d. This function is the same for the four aforementioned procedures and is given, up to a multiplicative factor, by

$$\kappa^*(\sigma, n, d) = \sigma \max((\log n)^{1/2}, (d \log n)^{1/4}). \tag{1}$$

Then, we prove that this expression provides the optimal rate of the separation distance in the sense that for some absolute constant c if $\kappa \leq c\kappa^*(\sigma, n, d)$ then there is no procedure capable of consistently estimating π^*.

In the heteroscedastic case, we provide an upper bound on the identifiability threshold ensuring the consistency of the LSNS and LSL estimators. Up to a proper normalization by the noise level, this bound is of the same form as (1) and, therefore, the ignorance of the noise level does not seriously affect the quality of estimation. Furthermore, the LSL estimator is easy to adapt to the case $n \neq m$ and is robust to the presence of outliers in the features. We carried out a small experimental evaluation that confirms that in the heteroscedastic setting the LSL estimator is as good as the LSNS (pseudo-) estimator and that they outperform the two other estimators: the greedy estimator and the least sum of squares. We also argue that the three estimators stemming from the maximum likelihood methodology are efficiently computable either by linear programming or by the Hungarian algorithm.

Note that different loss functions may be used for measuring the distance between an estimated permutation and the true one. Most results of this paper are established for the 0-1 loss, which equals one if the estimator and the true permutation differ at least at one location and equals 0 otherwise. However, it is of interest to analyze the situation with the Hamming distance as well, since it amounts to controlling the proportion of the mismatched features and, hence, offers a more graduated evaluation of the quality of estimation. We show that in the case of the Hamming distance, in the regime of moderately large dimension (*i.e.,* $d \geq c \log n$ for some constant $c > 0$) the rate of separation is exactly the same as in the case of the 0-1 distance. The picture is more complex in the regime of small dimensionality $d = o(\log(n))$, in which we get the same upper bound as for the 0-1 loss but the lower bound is expressed in terms of the logarithm of the packing number of an ℓ_2 ball of the symmetric group. We conjecture that this quantity is of the order of $n \log(n)$ and check this conjecture for relatively small values of n. If this conjecture is correct, our lower bound coincides up to a multiplicative factor with the upper bound.

Finally, let us mention that some of the results of the present work have been presented in the AI-STATS 2013 conference and published in the proceedings (Collier and Dalalyan, 2013).

1.3 Plan of the Paper

We introduce in Section 2 a model for the problem of matching two sets of features and of estimation of a permutation. The estimating procedures analyzed in this work are presented in Section 3, whereas their performances in terms of rates of separation distance are described in Section 4. In Section 5, computational aspects of the estimating procedures are discussed

while Section 6 is devoted to the statement of some extensions of our results. We report in Section 7 the results of some numerical experiments. The proofs of the theorems and of the lemmas are postponed to Sections 9 and 10, respectively.

2. Notation and Problem Formulation

We begin with formalizing the problem of matching two sets of features $\{X_1, \dots, X_n\}$ and $\{X_1^\sharp, \dots, X_m^\sharp\}$ with $n, m \geq 2$. In what follows we assume that the observed features are randomly generated from the model

$$\begin{cases} X_i = \theta_i + \sigma_i \xi_i \ , \\ X_j^\sharp = \theta_j^\sharp + \sigma_j^\sharp \xi_j^\sharp, \end{cases} \qquad i = 1, \dots, n \text{ and } j = 1, \dots, m \tag{2}$$

where

- $\boldsymbol{\theta} = \{\theta_1, \dots, \theta_n\}$ and $\boldsymbol{\theta}^\sharp = \{\theta_1^\sharp, \dots, \theta_m^\sharp\}$ are two collections of vectors from $\mathbb{R}^d$, corresponding to the original features, which are unavailable,
- $\sigma_1, \dots, \sigma_n, \sigma_1^\sharp, \dots, \sigma_m^\sharp$ are positive real numbers corresponding to the levels of noise contaminating each feature,
- $\xi_1, \dots, \xi_n$ and $\xi_1^\sharp, \dots, \xi_m^\sharp$ are two independent sets of i.i.d. random vectors drawn from the Gaussian distribution with zero mean and identity covariance matrix.

The task of feature matching consists in finding a bijection π^* between the largest possible subsets S_1 and S_2 of $\{1, \dots, n\}$ and $\{1, \dots, m\}$ respectively, such that

$$\forall\, i \in S_2, \quad \theta_i^\sharp \equiv \theta_{\pi^*(i)}, \tag{3}$$

where $\equiv$ is an equivalence relation that we call *matching criterion*. The features that do not belong to S_1 or S_2 are called *outliers*. To ease presentation, we mainly focus on the case where the matching criterion is the equality of two vectors. However, as discussed in Section 6.2, most results carry over the equivalence corresponding to equality of two vectors transformed by a given linear transformation. Furthermore, it turns out that statistical inference for the matching problem is already quite involved when no outlier is present in the data. Therefore, we make the following assumption

$$m = n \qquad \text{and} \qquad S_1 = S_2 = \{1, \dots, n\}. \tag{4}$$

Note however that the procedures we consider below admit natural counterparts in the setting with outliers. We will also restrict ourselves to noise levels satisfying some constraints. The two types of constraints we consider, referred to as homoscedastic and heteroscedastic setting, correspond to the relations $\sigma_i = \sigma_i^\sharp = \sigma$, $\forall i = 1, \dots, n$, and $\sigma_{\pi^*(i)} = \sigma_i^\sharp$, $\forall i = 1, \dots, n$.

In this formulation, the data generating distribution is defined by the (unknown) parameters $\boldsymbol{\theta}$, $\boldsymbol{\sigma} = (\sigma_i, \dots, \sigma_n)$ and π^*. In the problem of matching, we focus our attention on the problem of estimating the parameter π^* only, considering $\boldsymbol{\theta}$ and $\boldsymbol{\sigma}$ as nuisance parameters. In what follows, we denote by $\mathbf{P}_{\boldsymbol{\theta},\boldsymbol{\sigma},\pi^*}$ the probability distribution of the vector $(X_1, \dots, X_n, X_1^\sharp, \dots, X_n^\sharp)$ defined by (2) under the conditions (3) and (4). We write $\mathbf{E}_{\boldsymbol{\theta},\boldsymbol{\sigma},\pi^*}$

for the expectation with respect to $\mathbf{P}_{\boldsymbol{\theta},\boldsymbol{\sigma},\pi^*}$. The symmetric group, *i.e.,* the set of all permutations of $\{1,\dots,n\}$, will be denoted by $\mathfrak{S}_n$.

We will use two measures of quality for quantifying the error of an estimator $\hat{\pi}$ of the permutation π^*. These errors are defined as the 0-1 distance and the normalized Hamming distance between $\hat{\pi}$ and π^*, given by

$$\delta_{0\text{-}1}(\hat{\pi},\pi^*) \triangleq \mathbb{1}_{\{\hat{\pi}\neq\pi^*\}}, \qquad \delta_H(\hat{\pi},\pi^*) \triangleq \frac{1}{n}\sum_{k=1}^{n}\mathbb{1}_{\{\hat{\pi}(k)\neq\pi^*(k)\}}. \tag{5}$$

Our ultimate goal is to design estimators that have an expected error smaller than a prescribed level α under the weakest possible conditions on the nuisance parameter $\boldsymbol{\theta}$. The estimation of the permutation or, equivalently, the problem of matching is more difficult when the features are hardly distinguishable. To quantify this phenomenon, we introduce the separation distance $\kappa(\boldsymbol{\theta})$ and the relative separation distance $\bar{\kappa}(\boldsymbol{\theta},\boldsymbol{\sigma})$, which measure the minimal distance between distinct features and the minimal distance-to-noise ratio, respectively. The precise definitions are

$$\kappa(\boldsymbol{\theta}) \triangleq \min_{i\neq j}\|\theta_i-\theta_j\|, \qquad \bar{\kappa}(\boldsymbol{\theta},\boldsymbol{\sigma}) \triangleq \min_{i\neq j}\frac{\|\theta_i-\theta_j\|}{(\sigma_i^2+\sigma_j^2)^{1/2}}. \tag{6}$$

We will see that in the heteroscedastic case the last quantity is more suitable for characterizing the behavior of the estimators than the first one.

Clearly, if $\bar{\kappa}(\boldsymbol{\theta},\boldsymbol{\sigma})=0$ and σ_i's are all equal, then the parameter π^* is nonidentifiable, in the sense that there exist two different permutations π_1^* and π_2^* such that the distributions $\mathbf{P}_{\boldsymbol{\theta},\boldsymbol{\sigma},\pi_1^*}$ and $\mathbf{P}_{\boldsymbol{\theta},\boldsymbol{\sigma},\pi_2^*}$ coincide. Therefore, the condition $\bar{\kappa}(\boldsymbol{\theta},\boldsymbol{\sigma})>0$ is necessary for the existence of consistent estimators of π^*. Furthermore, good estimators are those consistently estimating π^* even if $\bar{\kappa}(\boldsymbol{\theta},\boldsymbol{\sigma})$ is small. To give a precise sense to these considerations, let $\alpha\in(0,1)$ be a prescribed tolerance level and let us call *perceivable separation distance* of a given estimation procedure $\hat{\pi}$ the quantity

$$\bar{\kappa}_\alpha(\hat{\pi}) \triangleq \inf\Big\{\kappa>0 \,\Big|\, \max_{\pi\in\mathfrak{S}_n}\sup_{\bar{\kappa}(\boldsymbol{\theta},\boldsymbol{\sigma})>\kappa}\mathbf{P}_{\boldsymbol{\theta},\boldsymbol{\sigma},\pi}(\hat{\pi}\neq\pi)\le\alpha\Big\},$$

where we skip the dependence on n, d and $\boldsymbol{\sigma}$. Here, the perceivable separation distance is defined with respect to the 0-1 distance, the corresponding definition for the Hamming distance is obtained by replacing $\mathbf{P}_{\boldsymbol{\theta},\boldsymbol{\sigma},\pi}(\hat{\pi}\neq\pi)$ by $\mathbf{E}_{\boldsymbol{\theta},\boldsymbol{\sigma},\pi}[\delta_H(\hat{\pi},\pi)]$. Finally, we call *minimax separation distance* the smallest possible perceivable separation distance achieved by an estimator $\hat{\pi}$, *i.e.,*

$$\bar{\kappa}_\alpha \triangleq \inf_{\hat{\pi}}\ \bar{\kappa}_\alpha(\hat{\pi}), \tag{7}$$

where the infimum is taken over all possible estimators of π^*. In the following sections, we establish nonasymptotic upper and lower bounds on the minimax separation distance which coincide up to a multiplicative constant independent of n, d and $\boldsymbol{\sigma}$. We also show that a suitable version of the maximum profiled likelihood estimator is minimax-separation-rate-optimal both in the homoscedastic and heteroscedastic settings.

3. Estimation Procedures

As already mentioned, we will consider four estimators. The simplest one, called greedy algorithm and denoted by π^{gr} is defined as follows: $\pi^{\mathrm{gr}}(1)=\arg\min_{j\in\{1,\dots,n\}}\|X_j-X_1^\sharp\|$ and, for every $i\in\{2,\dots,n\}$, recursively define

$$\pi^{\mathrm{gr}}(i) \triangleq \arg\min_{j\notin\{\pi^{\mathrm{gr}}(1),\dots,\pi^{\mathrm{gr}}(i-1)\}}\|X_j-X_i^\sharp\|. \tag{8}$$

A drawback of this estimator is that it is not symmetric: the resulting permutation depends on the initial numbering of the features. However, we will show that this estimator is minimax-separation-rate-optimal in the homoscedastic setting.

A common approach for avoiding incremental estimation and taking into consideration all the observations at the same time consists in defining the estimator $\hat{\pi}$ as a maximizer of the profiled likelihood. In the homoscedastic case, which is the first setting we studied, the computations lead to the estimator

$$\pi^{\mathrm{LSS}} \triangleq \arg\min_{\pi\in\mathfrak{S}_n}\sum_{i=1}^{n}\|X_{\pi(i)}-X_i^\sharp\|^2. \tag{9}$$

which will be referred to as the *Least Sum of Squares* (LSS) estimator.

The LSS estimator takes into account the distance between the observations irrespectively of the noise levels. The fact of neglecting the noise levels, while harmless in the homoscedastic setting, turns out to cause serious loss of efficiency in terms of the perceivable distance of separation in the setting of heteroscedastic noise. Yet, in the latter setting, the distance between the observations is not as relevant as the signal-to-noise ratio $\|\theta_i-\theta_j\|^2/(\sigma_i^2+\sigma_j^2)$. Indeed, when the noise levels are small, two noisy but distinct vectors are easier to distinguish than when the noise levels are large.

The computation of the maximum likelihood estimator in the heteroscedastic case with known noise levels also suggests that the signal-to-noise ratio should be taken into account. In this setting, the likelihood maximization leads to the *Least Sum of Normalized Squares* (LSNS) estimator

$$\pi^{\mathrm{LSNS}} \triangleq \arg\min_{\pi\in\mathfrak{S}_n}\sum_{i=1}^{n}\frac{\|X_{\pi(i)}-X_i^\sharp\|^2}{\sigma_{\pi(i)}^2+\sigma_i^{\sharp\,2}}. \tag{10}$$

We will often call the LSNS a pseudo-estimator, to underline the fact that it requires the knowledge of the noise levels σ_i which are generally unavailable.

In the general setting, when no information on the noise levels is available, the likelihood is maximized over all nuisance parameters (features and noise levels). But this problem is underconstrained, and the result of this maximization is $+\infty$. This can be circumvented by assuming a proper relation between the noise levels. As mentioned earlier, we chose the assumption

$$\forall\, i\in\{1,\dots,n\}, \quad \sigma_i^\sharp=\sigma_{\pi^*(i)}. \tag{11}$$

The maximum likelihood estimator under this constraint is the *Least Sum of Logarithms* (LSL) defined as

$$\pi^{\mathrm{LSL}} \triangleq \arg\min_{\pi\in\mathfrak{S}_n}\sum_{i=1}^{n}\log\|X_{\pi(i)}-X_i^\sharp\|^2. \tag{12}$$

We will prove that this estimator is minimax-rate-optimal both in the homoscedastic and the heteroscedastic cases.

4. Performance of the Estimators

The purpose of this section is to assess the quality of the aforementioned procedures. To this end, we present conditions for the consistency of these estimators in the form of upper bounds on their perceivable separation distance. Furthermore, to compare this bounds with the minimax separation distance, we establish lower bounds on the latter and prove that it coincides up to a constant factor with the perceivable separation distance of the LSL estimator.

4.1 Homoscedastic Setup

We start by considering the homoscedastic case, in which upper and lower bounds matching up to a constant are obtained for all the estimators introduced in the previous section.

Theorem 1 *Let $\alpha \in (0,1)$ be a tolerance level and $\sigma_j = \sigma_j^\sharp = \sigma$ for all $j \in \{1,\dots,n\}$. If $\hat\pi$ denotes any one of the estimators (8)-(12), then*

$$\bar\kappa_\alpha(\hat\pi) \le 4\max\Big\{\Big(2\log\frac{8n^2}{\alpha}\Big)^{1/2}, \Big(d\log\frac{4n^2}{\alpha}\Big)^{1/4}\Big\}.$$

An equivalent way of stating this result is that if

$$\kappa = 4\sigma\max\Big\{\Big(4\log\frac{8n^2}{\alpha}\Big)^{1/2}, \Big(4d\log\frac{4n^2}{\alpha}\Big)^{1/4}\Big\}$$

and Θ_κ is the set of all $\boldsymbol{\theta} \in \mathbb{R}^{n\times d}$ such that $\kappa(\boldsymbol{\theta}) \ge \kappa$, then

$$\max_{\pi^*\in\mathfrak{S}_n}\sup_{\boldsymbol{\theta}\in\Theta_\kappa} \mathbf{P}_{\boldsymbol{\theta},\boldsymbol{\sigma},\pi^*}(\hat\pi \ne \pi^*) \le \alpha$$

for all the estimators defined in Section 3. Note that this result is nonasymptotic. Furthermore, it tells us that the perceivable separation distance of the procedures under consideration is at most of the order of

$$\max\Big\{(\log n)^{1/2}, (d\log n)^{1/4}\Big\}. \tag{13}$$

It is interesting to observe that there are two regimes in this rate, the boundary of which corresponds to the case where d is of the order of $\log n$. For dimensions that are significantly smaller than $\log n$, the perceivable distance of separation is dimension free. On the other hand, when d is larger than $c\log n$ for some absolute constant $c > 0$, the perceivable distance of separation deteriorates with increasing d at the polynomial rate $d^{1/4}$. However, this result does not allow us to deduce any hierarchy between the four estimators, since it provides the same upper bound for all of them. Moreover, as stated in the next theorem, this bound is optimal up to a multiplicative constant.

Theorem 2 *Assume that $n \ge 6$, Θ_κ is the set of all $\boldsymbol{\theta} \in \mathbb{R}^{n\times d}$ such that $\kappa(\boldsymbol{\theta}) \ge \kappa$. Then there exist two absolute constants $c, C > 0$ such that for*

$$\kappa = 2^{-5/2}\sigma\max\Big\{(\log n)^{1/2}, (cd\log n)^{1/4}\Big\},$$

the following lower bound holds

$$\inf_{\hat\pi}\max_{\pi^*\in\mathfrak{S}_n}\sup_{\boldsymbol{\theta}\in\Theta_\kappa} \mathbf{P}_{\boldsymbol{\theta},\boldsymbol{\sigma},\pi^*}(\hat\pi \ne \pi^*) > C,$$

where the infimum is taken over all permutation estimators.

An equivalent way of stating this result is to say that, for any $\alpha \le C$, the minimax distance of separation satisfies the inequality

$$\bar\kappa_\alpha \ge \frac{1}{8}\max\big\{(\log n)^{1/2}, (cd\log n)^{1/4}\big\}.$$

Combined with Theorem 1, this implies that the minimax rate of separation is given by the expression $\max\big\{(\log n)^{1/2}, (d\log n)^{1/4}\big\}$.

In order to avoid any possible confusion, we emphasize that the rate obtained in this and subsequent sections concerns the speed of decay of the separation distance and not the estimation risk measured by $\mathbf{P}_{\boldsymbol{\theta},\boldsymbol{\sigma},\pi^*}(\hat\pi \ne \pi^*)$. For the latter, considering κ as fixed, one readily derives from Theorem 1 that

$$\max_{\pi^*\in\mathfrak{S}_n}\sup_{\boldsymbol{\theta}\in\Theta_\kappa} \mathbf{P}_{\boldsymbol{\theta},\boldsymbol{\sigma},\pi^*}(\hat\pi \ne \pi^*) \le \max\Big\{8n^2\exp\Big(-\frac{\kappa^2}{2^6\sigma^2}\Big), 4n^2\exp\Big(-\frac{\kappa^4}{2^{10}d\sigma^4}\Big)\Big\} \tag{14}$$

for the four estimators $\hat\pi$ defined in the previous section by equations (8)-(12). We do not know whether the right-hand side of this inequality is the correct rate for the minimax risk $R^{\mathrm{mmx}} = \inf_{\hat\pi}\sup_{(\boldsymbol{\theta},\pi^*)\in\Theta_\kappa\times\mathfrak{S}_n} \mathbf{P}_{\boldsymbol{\theta},\boldsymbol{\sigma},\pi^*}(\hat\pi \ne \pi^*)$. In fact, one can adapt the proof of Theorem 2 to get a lower bound on R^{mmx} which is of the same form as the right-hand side in (14), but with constants 2^6 and 2^{10} replaced by smaller ones. The ratio of such a lower bound and the upper bound in (14) tends to 0 and, therefore, does not provide the minimax rate of estimation, in the most common sense of the term. However, one may note that the minimax rate of separation established in this work is the analogue of the minimax rate of estimation of the Bahadur risk, see Bahadur (1960); Korostelev (1996); Korostelev and Spokoiny (1996).

4.2 Heteroscedastic Setup

We switch now to the heteroscedastic setting, which allows us to discriminate between the four procedures. Note that the greedy algorithm, the LSS and the LSL have a serious advantage over the LSNS since they can be computed without knowing the noise levels $\boldsymbol{\sigma}$.

Theorem 3 *Let $\alpha \in (0,1)$ and condition (11) be fulfilled. If $\hat\pi$ is either π^{LSNS} (if the noise levels σ_i are known) or π^{LSL} (when the noise levels are unknown), then*

$$\bar\kappa_\alpha(\hat\pi) \le 4\max\Big\{\Big(2\log\frac{8n^2}{\alpha}\Big)^{1/2}, \Big(d\log\frac{4n^2}{\alpha}\Big)^{1/4}\Big\}.$$

This result tells us that the performance of the LSNS and LSL estimators, measured in terms of the order of magnitude of the separation distance, is not affected by the heteroscedasticity of the noise levels. Two natural questions arise: 1) is this performance the best possible over all the estimators of π^* and 2) is the performance of the LSS and the greedy estimator as good as that of the LSNS and LSL?

To answer the first question, we start by discarding the degenerate situations where faster rates can be achieved by estimators that are heavily based on the knowledge of the noise levels $\boldsymbol{\sigma}$. In fact, although considering $\boldsymbol{\sigma}$ as known limits considerably the scope of applications of the methods, the definition (7) involves a minimum over all possible estimators $\hat{\pi}$ which are allowed to depend on $\boldsymbol{\sigma}$. For some specific noise levels $\boldsymbol{\sigma}$, from a purely theoretical point of view, knowing $\boldsymbol{\sigma}$ may lead to a substantially better minimax rate and even to a separation equal to zero, which corresponds to an estimator that has no real practical interest. Indeed, under condition (11), it is possible to estimate the permutation π^* by fitting the noise levels. For instance, we can define an estimator $\hat{\pi}$ as follows: $\hat{\pi}(1) = \arg\min_{i=1,\dots,n} \left|\frac{1}{2d}\|X_i - X_1^\#\|^2 - \sigma_i^2\right|$ and, recursively, for every $j \in \{2,\dots,n\}$,

$$\hat{\pi}(j) = \arg \min_{i \notin \{\hat{\pi}(1),\dots,\hat{\pi}(j-1)\}} \left|\frac{1}{2d}\|X_i - X_j^\#\|^2 - \sigma_i^2\right|.$$

This provides an accurate estimator of π^*—for vectors $\{\theta_j\}$ that are very close—as soon as the noise levels are different enough from each other. In particular, the estimated permutation $\hat{\pi}$ coincides with the true permutation π^* on the event

$$\forall i \in \{1,\dots,n\}, \qquad \left|\frac{1}{2d}\|X_{\pi^*(i)} - X_i^\#\|^2 - \sigma_{\pi^*(i)}^2\right| < \min_{j \neq \pi^*(i)} \left|\frac{\|X_j - X_i^\#\|^2}{2d} - \sigma_j^2\right|,$$

which includes the event:

$$\left|\frac{1}{2d}\|X_{\pi^*(i)} - X_i^\#\|^2 - \sigma_{\pi^*(i)}^2\right| + \left|\frac{\|X_j - X_i^\#\|^2}{2d} - \frac{\sigma_j^2 + \sigma_{\pi^*(i)}^2}{2}\right| < \frac{|\sigma_j^2 - \sigma_{\pi^*(i)}^2|}{2} \qquad (15)$$

for all $(i,j) \in \{1,\dots,n\}^2$ such that $j \neq \pi^*(i)$. Using standard bounds on the tails of the χ^2 distribution recalled in Lemma 10 of Section 9, in the case when all the vectors θ_j are equal, one can check that the left-hand side in (15) is of the order of $(\sigma_{\pi^*(i)}^2 + \sigma_j^2)\max\left\{\sqrt{(\log n)/d}, (\log n)/d\right\}$. This implies that we can consistently identify the permutation when

$$\forall (i,j) \in \{1,\dots,n\}^2, \quad i \neq j, \qquad \left|\frac{\sigma_j^2}{\sigma_i^2} - 1\right| \gg \max\left\{\sqrt{\frac{\log n}{d}}, \frac{\log n}{d}\right\},$$

even if the separation distance is equal to zero. In order to discard such kind of estimators from the competition in the procedure of determining the minimax rates, we restrict our attention to the noise levels for which the values $|\frac{\sigma_j^2}{\sigma_i^2} - 1|$ are not larger than $C\max\left\{\sqrt{(\log n)/d}, (\log n)/d\right\}$ for $j \neq i$.

Theorem 4 *Assume that $n \geq 6$, $\bar{\Theta}_\kappa$ is the set of all $\boldsymbol{\theta} \in \mathbb{R}^{n\times d}$ such that $\bar{\kappa}(\boldsymbol{\theta}, \boldsymbol{\sigma}) \geq \kappa$ and*

$$\frac{\max_i \sigma_i^2}{\min_i \sigma_i^2} - 1 \leq \max\left\{\sqrt{\frac{\log n}{16d}}, \frac{\log n}{16d}\right\}.$$

Then there exist two constants $c, C > 0$ such that $\kappa < (1/8)\max\{(\log n)^{1/2}, (cd\log n)^{1/4}\}$, implies that

$$\inf_{\hat{\pi}} \max_{\pi^* \in \mathfrak{S}_n} \sup_{\boldsymbol{\theta} \in \bar{\Theta}_\kappa} \mathbf{P}_{\boldsymbol{\theta},\boldsymbol{\sigma},\pi^*}(\hat{\pi} \neq \pi^*) > C,$$

where the infimum is taken over all permutation estimators.

It is clear that the constants c and C of the previous theorem are closely related. The inspection of the proof shows that, for instance, if $c \leq 1/20$ then C is larger than 17%.

Let us discuss now the second question raised earlier in this section and concerning the theoretical properties of the greedy algorithm and the LSS under heteroscedasticity. In fact, the perceivable distances of separation of these two procedures are significantly worse than those of the LSNS and the LSL especially for large dimensions d. We state the corresponding result for the greedy algorithm, a similar conclusion being true for the LSS as well. The superiority of the LSNS and LSL is also confirmed by the numerical simulations presented in Section 7 below. In the next theorem and in the sequel of the paper, we denote by id the identity permutation defined by $id(i) = i$ for all $i \in \{1,\dots,n\}$.

Theorem 5 *Assume that $d \geq 225\log 6$, $n = 2$, $\sigma_1^2 = 3$ and $\sigma_2^2 = 1$. Then the condition $\kappa < 0.1(2d)^{1/2}$ implies that*

$$\sup_{\boldsymbol{\theta} \in \bar{\Theta}_\kappa} \mathbf{P}_{\boldsymbol{\theta},\boldsymbol{\sigma},id}(\pi^{gr} \neq id) \geq 1/2.$$

This theorem shows that if d is large, the necessary condition for π^{gr} to be consistent is much stronger than the one obtained for π^{LSL} in Theorem 3. Indeed, for the consistency of π^{gr}, κ needs to be at least of the order of $d^{1/2}$, whereas $d^{1/4}$ is sufficient for the consistency of π^{LSL}. Hence, the maximum likelihood estimators LSNS and LSL that take into account noise heteroscedasticity are, as expected, more interesting than the simple greedy estimator[2].

5. Computational Aspects

At first sight, the computation of the estimators (9)-(12) requires to perform an exhaustive search over the set of all possible permutations, the number of which, $n!$, is prohibitively large. This is in practice impossible to do on a standard PC as soon as $n \geq 20$. In this section, we show how to compute these (maximum likelihood) estimators in polynomial time using, for instance, algorithms of linear programming[3].

To explain the argument, let us consider the LSS estimator

$$\pi^{\mathrm{LSS}} = \arg\min_{\pi \in \mathfrak{S}_n} \sum_{i=1}^n \|X_{\pi(i)} - X_i^\#\|^2.$$

2. It should be noted that the conditions of Theorem 5 are not compatible with those of Theorem 4. Hence, strictly speaking, the former does not imply that the greedy estimator is not minimax under the conditions of the latter.
3. The idea of reducing the problem of permutation estimation to a linear program has been already used in the literature, however, without sufficient theoretical justification: see, for instance, Jebara (2003).

For every permutation π, we denote by P^π the $n \times n$ permutation matrix with coefficients $P^\pi_{ij} = \mathbb{1}_{\{j=\pi(i)\}}$. Then we can give the equivalent formulation

$$\pi^{\mathrm{LSS}} = \arg\min_{\pi \in \mathfrak{S}_n} \mathbf{tr}\big(MP^\pi\big), \tag{16}$$

where M is the matrix with coefficient $\|X_i - X_j^\sharp\|^2$ at the i^{th} row and j^{th} column. The cornerstone of our next argument is the Birkhoff-von Neumann theorem stated below, which can be found for example in (Budish et al., 2013).

Theorem 6 (Birkhoff-von Neumann Theorem) *Assume that $\mathcal{P}$ is the set of all doubly stochastic matrices of size n, i.e., the matrices whose entries are nonnegative and sum up to 1 in every row and every column. Then every matrix in $\mathcal{P}$ is a convex combination of matrices $\{P^\pi : \pi \in \mathfrak{S}_n\}$. Furthermore, permutation matrices are the vertices of the simplex $\mathcal{P}$.*

In view of this result, the combinatorial optimization problem (16) is equivalent to the following problem of continuous optimization:

$$P^{\mathrm{LSS}} = \arg\min_{P \in \mathcal{P}} \mathbf{tr}\big(MP\big), \tag{17}$$

in the sense that π is a solution to (16) if and only if P^π is a solution to (17). To prove this claim, let us remark that for every $P \in \mathcal{P}$, there exist coefficients $\alpha_1, \dots, \alpha_{n!} \in [0,1]$ such that $P = \sum_{i=1}^{n!} \alpha_i P^{\pi_i}$ and $\sum_{i=1}^{n!} \alpha_i = 1$. Therefore, we have $\mathbf{tr}\big(MP\big) = \sum_{i=1}^{n!} \alpha_i \mathbf{tr}\big(MP^{\pi_i}\big) \geq \min_{\pi \in \mathfrak{S}_n} \mathbf{tr}\big(MP^\pi\big)$ and $\mathbf{tr}\big(MP^{\mathrm{LSS}}\big) \geq \mathbf{tr}\big(MP^{\pi^{\mathrm{LSS}}}\big)$.

The great advantage of (17) is that it concerns the minimization of a linear function under linear constraints and, therefore, is a problem of linear programming that can be efficiently solved even for large values of n. The same arguments apply to the estimators π^{LSNS} and π^{LSL}, only the matrix M needs to be changed.

There is a second way to compute the estimators LSS, LSNS and LSL efficiently. Indeed, the computation of the aforementioned maximum likelihood estimators is a particular case of the assignment problem, which consists in finding a minimum weight matching in a weighted bipartite graph, where the matrix of the costs is the matrix M from above. This means that the cost of assigning the i^{th} feature of the first image to the j^{th} feature of the second image is either

- the squared distance $\|X_i - X_j^\sharp\|^2$,
- or the normalized squared distance $\|X_i - X_j^\sharp\|^2/(\sigma_i^2 + (\sigma_j^\sharp)^2)$,
- or the logarithm of the squared distance $\log \|X_i - X_j^\sharp\|^2$.

The so-called Hungarian algorithm presented in Kuhn (1955) solves the assignment problem in time $O(n^3)$.

6. Extensions

In this section, we briefly discuss possible extensions of the foregoing results to other distances, more general matching criteria and to the estimation of an arrangement.

$n =$	4	5	6	7	8	9	10	11	12
$M_n \geq$	19	57	179	594	1939	3441	11680	39520	86575
$\frac{\log M_n}{n \log n} \geq$	0.53	0.50	0.48	0.47	0.455	0.412	0.407	0.401	0.381
$\frac{\log M_n}{n \log n} \leq$	0.53	0.50	0.48	0.47	0.455	0.445	0.436	0.427	0.420

Table 1: The values of $M_n = \mathcal{M}(1/4, B_{2,n}(2), \delta_H)$ for $n \in \{4, \dots, 12\}$. The lower bound is just the cardinality of one ϵ-packing, not necessarily the largest one. The upper bound is merely the cardinality of the ℓ_2-ball.

6.1 Minimax Rates for the Hamming Distance

In the previous sections, the minimax rates were obtained for the error of estimation measured by the risk $\mathbf{P}_{\boldsymbol{\theta},\boldsymbol{\sigma},\pi^*}(\hat{\pi} \neq \pi^*) = \mathbf{E}_{\boldsymbol{\theta},\boldsymbol{\sigma},\pi^*}[\delta_{0\text{-}1}(\hat{\pi}, \pi^*)]$, which may be considered as too restrictive. Indeed, one could find acceptable an estimate having a small number of mismatches, if it makes it possible to significantly reduce the perceivable distance of separation. These considerations lead to investigating the behavior of the estimators in terms of the Hamming loss, *i.e.*, to studying the risk

$$\mathbf{E}_{\boldsymbol{\theta},\boldsymbol{\sigma},\pi^*}[\delta_H(\hat{\pi}, \pi^*)] = \mathbf{E}_{\boldsymbol{\theta},\boldsymbol{\sigma},\pi^*}\Big[\frac{1}{n}\sum_{i=1}^{n} \mathbb{1}_{\{\hat{\pi}(i) \neq \pi^*(i)\}}\Big]$$

corresponding to the expected average number of mismatched features. Another advantage of studying the Hamming loss instead of the 0-1 loss is that the former sharpens the difference between the performances of various estimators. Note, however, that thanks to the inequality $\delta_H(\hat{\pi}, \pi^*) \leq \delta_{0\text{-}1}(\hat{\pi}, \pi^*)$, all the upper bounds established for the minimax rate of separation under the 0-1 loss directly carry over to the case of the Hamming loss. This translates into the following theorem.

Theorem 7 *Let $\alpha \in (0,1)$ and condition (11) be fulfilled. If $\hat{\pi}$ is either π^{LSNS} or π^{LSL}, then $\bar{\kappa}_\alpha(\hat{\pi}) \leq 4 \max\big\{\big(2\log\frac{8n^2}{\alpha}\big)^{1/2}, \big(d\log\frac{4n^2}{\alpha}\big)^{1/4}\big\}$. That is, if*

$$\kappa = 4\max\Big\{\Big(2\log\frac{8n^2}{\alpha}\Big)^{1/2}, \Big(d\log\frac{4n^2}{\alpha}\Big)^{1/4}\Big\}$$

and $\bar{\Theta}_\kappa$ is the set of all $\boldsymbol{\theta} \in \mathbb{R}^{n\times d}$ such that $\bar{\kappa}(\boldsymbol{\theta}, \sigma) \geq \kappa$, then

$$\max_{\pi^* \in \mathfrak{S}_n} \sup_{\boldsymbol{\theta} \in \bar{\Theta}_\kappa} \mathbf{E}_{\boldsymbol{\theta},\boldsymbol{\sigma},\pi^*}[\delta_H(\hat{\pi}, \pi^*)] \leq \alpha.$$

While this upper bound is an immediate consequence of Theorem 3, getting lower bounds for the Hamming loss appears to be more difficult. To state the corresponding result, let is consider the case of homoscedastic noise and introduce some notation. We denote by $\delta_2(\cdot,\cdot)$ the normalized ℓ^2-distance on the space of permutations $\mathfrak{S}_n$: $\delta_2(\pi,\pi')^2 = \frac{1}{n}\sum_{k=1}^n \big(\pi(k) - \pi'(k)\big)^2$. Let $B_{2,n}(R)$ be the ball of $(\mathfrak{S}_n, \delta_2)$ with radius R centered at *id*. As usual, we denote by $\mathcal{M}(\epsilon, B_{2,n}(R), \delta_H)$ the ϵ-packing number of the ℓ_2-ball $B_{2,n}(R)$ in the metric δ_H. This

means that $\mathcal{M}(\epsilon, B_{2,n}(R), \delta_H)$ is the largest integer M such that there exist permutations $\pi_1, \dots, \pi_M \in B_{2,n}(R)$ satisfying $\delta_H(\pi_i, \pi_j) \geq \epsilon$ for every $i \neq j$. One can easily check that replacing $B_{2,n}(R)$ by any other ball of radius R leaves the packing number $\mathcal{M}(\epsilon, B_{2,n}(R), \delta_H)$ unchanged. We set $M_n = \mathcal{M}(1/4, B_{2,n}(2), \delta_H)$.

Theorem 8 *Let $\sigma_k = \sigma$ for all $k \in \{1, \dots, n\}$ and $\bar{\Theta}_\kappa$ is the set of all $\boldsymbol{\theta} \in \mathbb{R}^{n \times d}$ such that $\bar{\kappa}(\boldsymbol{\theta}, \boldsymbol{\sigma}) \geq \kappa$. Furthermore, assume that one of the following two conditions is fulfilled:*

- *$n \geq 3$ and $\kappa = (1/4)\big(\frac{\log M_n}{n}\big)^{1/2}$,*
- *$n \geq 26$, $d \geq 24 \log n$ and $\kappa \leq (1/8)(d \log n)^{1/4}$.*

Then $\inf_{\hat{\pi}} \max_{\pi^* \in \mathfrak{S}_n} \sup_{\boldsymbol{\theta} \in \bar{\Theta}_\kappa} \mathbf{E}_{\boldsymbol{\theta}, \boldsymbol{\sigma}, \pi^*}[\delta_H(\hat{\pi}, \pi^*)] > 2.15\%$.

This result implies that in the regime of moderately large dimension, $d \geq 24 \log n$, the minimax rate of the separation is the same as the one under the 0-1 loss and it is achieved by the LSL estimator. The picture is less clear in the regime of small dimensions, $d = o(\log n)$. If one proves that for some $c > 0$, the inequality $\log M_n \geq cn \log n$ holds for every $n \geq 3$, then the lower bound of the last theorem matches the upper bound of Theorem 7 up to constant factors and leads to the minimax rate of separation $\max\{(\log n)^{1/2}, (d \log n)^{1/4}\}$. Unfortunately, we were unable to find any result on the order of magnitude of $\log M_n$, therefore, we cannot claim that there is no gap between our lower bound and the upper one. However, we did a small experiment for evaluating M_n for small values of n. The result is reported in Table 1.

6.2 More General Matching Criteria

In the previous sections, we were considering two vectors θ_i and $\theta_j^\sharp$ as matching if $\theta_i \equiv \theta_j^\sharp$, and $\equiv$ was the usual equality. In this part, we show that our results can be extended to more general matching criteria, defined as follows. Let A, $A^\sharp$ be two known $p \times d$ matrices with some $p \in \mathbb{N}$ and b, $b^\sharp$ be two known vectors from $\mathbb{R}^d$. We write $\theta \equiv_{A,b} \theta^\sharp$, if

$$A(\theta - b) = A^\sharp(\theta^\sharp - b^\sharp). \tag{18}$$

Note that the case of equality studied in previous sections is obtained for $A = A^\sharp = \mathbf{I}_d$ and $b = b^\sharp = 0$, where $\mathbf{I}_d$ is the identity matrix of size d. Let us first note that without loss of generality, by a simple transformation of the features, one can replace (18) by the simpler relation

$$\bar{\theta} = B\bar{\theta}^\sharp, \tag{19}$$

where $\bar{\theta} \in \mathbb{R}^{d_1}$ for $d_1 = \operatorname{rank}(A)$, $\bar{\theta}^\sharp \in \mathbb{R}^{d_2}$ for $d_2 = \operatorname{rank}(A^\sharp)$ and B is a $d_1 \times d_2$ known matrix. Indeed, let $A = U^\top \Lambda V$ (resp. $A^\sharp = \tilde{U}^\top \tilde{\Lambda} \tilde{V}$) be the singular value decomposition of A (resp. $A^\sharp$), with orthogonal matrices $U \in \mathbb{R}^{d_1 \times p}$, $V \in \mathbb{R}^{d_1 \times d}$ and a diagonal matrix $\Lambda \in \mathbb{R}^{d_1 \times d_1}$ with positive entries. Then, one can deduce (19) from (18) by setting $\bar{\theta} = V(\theta - b)$, $\bar{\theta}^\sharp = \tilde{V}(\theta^\sharp - b^\sharp)$ and $B = \Lambda^{-1} U \tilde{U}^\top \tilde{\Lambda}$. Of course, the same transformation should be applied to the observed noisy features, which leads to $\bar{X}_i = V(X_i - b)$ and $\bar{X}_i^\sharp = \tilde{V}(X^\sharp - b^\sharp)$. Since V and $\tilde{V}$ are orthogonal matrices, *i.e.*, satisfy the relations $VV^\top = \mathbf{I}_{d_1}$ and $\tilde{V}\tilde{V}^\top = \mathbf{I}_{d_2}$, the noise component in the transformed noisy features is still white Gaussian.

All the four estimators introduced in Section 3 can be adapted to deal with such type of criterion. For example, denoting by M the matrix $B(B^\top B)^+ B^\top + BB^\top$ where M^+ is the Moore-Penrose pseudoinverse of the matrix M, the LSL estimator should be modified as follows

$$\pi^{\mathrm{LSL}} \triangleq \arg\min_{\pi \in \mathfrak{S}_n} \sum_{i=1}^n \log \|M^+(\bar{X}_{\pi(i)} - B\bar{X}_i^\sharp)\|^2. \tag{20}$$

All the results presented before can be readily extended to this case. In particular, if we assume that all the nonzero singular values of B are bounded and bounded away from 0 and $\operatorname{rank}(B) = q$, then the minimax rate of separation is given by $\max\big\{(\log n)^{1/2}, (q \log n)^{1/4}\big\}$. This rate is achieved, for instance, by the LSL estimator.

Let us briefly mention two situations in which this kind of general affine criterion may be useful. First, if each feature θ (resp. $\theta^\sharp$) corresponds to a patch in an image I (resp. $I^\sharp$), then for detecting pairs of patches that match each other it is often useful to neglect the changes in illumination. This may be achieved by means of the criterion $A\theta = A\theta^\sharp$ with $A = \mathbf{I}_d - \frac{1}{d}\mathbf{1}_d\mathbf{1}_d^\top$. Indeed, the multiplication of the vector θ by A corresponds to removing from pixel intensities the mean pixel intensity of the patch. This makes the feature invariant by change of illumination. The method described above applies to this case and the corresponding rate is $\max\big\{(\log n)^{1/2}, ((d-1)\log n)^{1/4}\big\}$ since the matrix A is of rank $d-1$. Second, consider the case when each feature combines the local descriptor of an image and the location in the image at which this descriptor is computed. If we have at our disposal an estimator of the transformation that links the two images and if this transformation is linear, then we are in the aforementioned framework. For instance, let each θ be composed of a local descriptor $\mathbf{d} \in \mathbb{R}^{d-2}$ and its location $\mathbf{x} \in \mathbb{R}^2$. Assume that the first image I from which the features $\theta_i = [\mathbf{d}_i, \mathbf{x}_i]$ are extracted is obtained from the image $I^\sharp$ by a rotation of the plane. Let R be an estimator of this rotation and $\theta_i^\sharp = [\mathbf{d}_i^\sharp, \mathbf{x}_i^\sharp]$ be the features extracted from the image $I^\sharp$. Then, the aim is to find the permutation π such that $\mathbf{d}_i^\sharp = \mathbf{d}_{\pi(i)}$ and $\mathbf{x}_i^\sharp = R\mathbf{x}_{\pi(i)}$ for every $i = 1, \dots, n$. This corresponds to taking in (19) the matrix B given by

$$B = \begin{pmatrix} \mathbf{I}_{d-2} & 0 \\ 0 & R \end{pmatrix}.$$

This matrix B being orthogonal, the resulting minimax rate of separation is exactly the same as when $B = \mathbf{I}_d$.

Remark 9 *An interesting avenue for future research concerns the determination of the minimax rates in the case when the equivalence of two features is understood under some transformation A which is not completely determined. For instance, one may consider that the features θ and θ' match if there is a matrix A in a given parametric family $\{A_\tau : \tau \in \mathbb{R}\} \subset \mathbb{R}^{d \times d}$ for which $\theta = A\theta'$. In other terms, $\theta \equiv \theta'$ is understood as $\inf_\tau \|\theta - A_\tau \theta'\| = 0$. Such a criterion of matching may be useful for handling various types of invariance (see Collier and Dalalyan (2015); Collier (2012) for invariance by translation).*

6.3 Estimation of an Arrangement

An interesting extension concerns the case of the estimation of a general arrangement, *i.e.*, the case when m and n are not necessarily identical. In such a situation, without loss of

generality, one can assume that $n \leq m$ and look for an injective function

$$\pi^* : \{1, \dots, n\} \to \{1, \dots, m\}.$$

All the estimators presented in Section 3 admit natural counterparts in this rectangular setting. Furthermore, the computational method using the Birkhoff-von Neumann theorem is still valid in this setting, and is justified by the extension of the Birkhoff-von Neumann theorem recently proved by Budish et al. (2013). In this case, the minimization should be carried out over the set of all matrices P of size (n, m) such that $P_{i,j} \geq 0$, and

$$\begin{cases} \sum_{i=1}^{n} P_{i,j} \leq 1 \\ \sum_{j=1}^{m} P_{i,j} = 1 \end{cases}, \quad (i,j) \in \{1, \dots, n\} \times \{1, \dots, m\}.$$

From a practical point of view, it is also important to consider the issue of robustness with respect to the presence of outliers, *i.e.,* when for some i there is no $X_j^\#$ matching with X_i. The detailed exploration of this problem being out of scope of the present paper, let us just underline that the LSL-estimator seems to be well suited for such a situation because of the robustness of the logarithmic function. Indeed, the correct matches are strongly rewarded because $\log(0) = -\infty$ and the outliers do not interfere too much with the estimation of the arrangement thanks to the slow growth of log in $+\infty$.

7. Experimental Results

We have implemented all the procedures in Matlab and carried out numerical experiments on synthetic data. To simplify, we have used the general-purpose solver SeDuMi (Sturm, 1999) for solving linear programs. We believe that it is possible to speed-up the computations by using more adapted first-order optimization algorithms, such as coordinate gradient descent. However, even with this simple implementation, the running times are reasonable: for a problem with $n = 500$ features, it takes about six seconds to compute a solution to (17) on a standard PC.

7.1 Homoscedastic noise

We chose $n = d = 200$ and randomly generated a $n \times d$ matrix $\boldsymbol{\theta}$ with i.i.d. entries uniformly distributed on $[0, \tau]$, with several values of τ varying between 1.4 and 3.5. Then, we randomly chose a permutation π^* (uniformly from $\mathfrak{S}_n$) and generated the sets $\{X_i\}$ and $\{X_i^\#\}$ according to (2) with $\sigma_i = \sigma_i^\# = 1$. Using these sets as data, we computed the four estimators of π^* and evaluated the average error rate $\frac{1}{n}\sum_{i=1}^{n} \mathbb{1}_{\{\hat{\pi}(i) \neq \pi^*(i)\}}$. The result, averaged over 500 independent trials, is plotted in Fig. 1.

Note that the three estimators originating from the maximum likelihood methodology lead to the same estimators, while the greedy algorithm provides an estimator which is much worse than the others when the parameter κ is small.

7.2 Heteroscedastic noise

This experiment is similar to the previous one, but the noise level is not constant. We still chose $n = d = 200$ and defined $\boldsymbol{\theta} = \tau I_d$, where I_d is the identity matrix and τ varies between

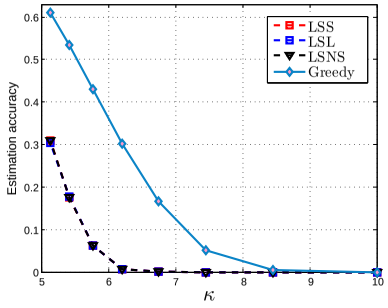

Figure 1: Average error rate of the four estimating procedures in the experiment with homoscedastic noise as a function of the minimal distance κ between distinct features. One can observe that the LSS, LSNS and LSL procedures are indistinguishable and perform much better than the greedy algorithm.

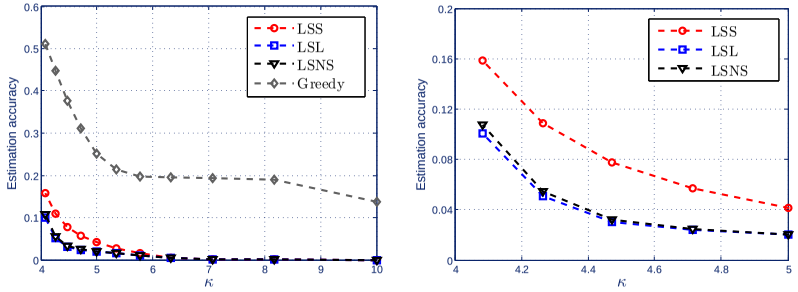

Figure 2: Left: Average error rate of the four estimating procedures in the experiment with heteroscedastic noise as a function of the minimal distance κ between distinct features. Right: zoom on the same plots. One can observe that the LSNS and LSL are almost indistinguishable and, as predicted by the theory, perform better than the LSS and the greedy algorithm.

4 and 10. Then, we randomly chose a permutation π^* (uniformly from $\mathfrak{S}_n$) and generated the sets $\{X_i\}$ and $\{X_i^\#\}$ according to (2) with $\sigma_{\pi^*(i)} = \sigma_i^\# = 1$ for 10 randomly chosen values of i and $\sigma_{\pi^*(i)} = \sigma_i^\# = 0.5$ for the others. Using these sets as data, we computed the four estimators of π^* and evaluated the average error rate $\frac{1}{n}\sum_{i=1}^{n} \mathbb{1}_{\{\hat{\pi}(i) \neq \pi^*(i)\}}$. The result, averaged over 500 independent trials, is plotted in Fig. 2.

Note that among the noise-level-adaptive estimators, LSL outperforms the two others and is as accurate as, and even slightly better than the LSNS pseudo-estimator. This confirms the theoretical findings presented in foregoing sections.

8. Conclusion and Future Work

Motivated by the problem of feature matching, we proposed a rigorous framework for studying the problem of permutation estimation from a minimax point of view. The key notion in our framework is the minimax rate of separation, which plays the same role as in the statistical hypotheses testing theory (Ingster and Suslina, 2003). We established theoretical guarantees for several natural estimators and proved the optimality of some of them. The results appeared to be quite different in the homoscedastic and in the heteroscedastic cases. However, we have shown that the least sum of logarithms estimator outperforms the other procedures both theoretically and empirically.

Several avenues of future work have been already mentioned in previous sections. In particular, investigating the statistical properties of the arrangement estimation problem described in Section 6.3 and considering the case of unspecified transformation relating the features may have a significant impact on the practice of feature matching.

Another interesting question is to extend the statistical inference developed here for the problem of feature matching to the more general assignment problem. The latter aims at assigning m tasks to n agents such that the cost of assignment is as small as possible. Various settings of this problem have been considered in the literature (Pentico, 2007) and many algorithms for solving the problem have been proposed (Romeijn and Morales, 2000). However, to the best of our knowledge, the statistical aspects of the problem in the case where the cost matrix is corrupted by noise have not been studied so far.

9. Proofs of the Theorems

In this section we collect the proofs of the theorems. We start with the proof of Theorem 3, since it concerns the more general setting and the proof of Theorem 1 can be deduced from that of Theorem 3 by simple arguments. We then prove the other theorems in the usual order and postpone the proofs of some technical lemmas to the next section.

Proof of Theorem 3 To ease notation and without loss of generality, we assume that π^* is the identity permutation denoted by id. Furthermore, since there is no risk of confusion, we write $\mathbf{P}$ instead of $\mathbf{P}_{\boldsymbol{\theta},\boldsymbol{\sigma},\pi^*}$. We wish to bound the probability of the event $\Omega = \{\hat{\pi} \neq id\}$.

Let us first denote by $\hat{\pi}$ the maximum likelihood estimator π^{LSL} defined by (12). We have

$$\Omega \subset \bigcup_{\pi \neq id} \Omega_\pi,$$

where

$$\Omega_\pi = \Big\{ \sum_{i=1}^n \log \frac{\|X_i - X_i^\#\|^2}{\|X_{\pi(i)} - X_i^\#\|^2} \geq 0 \Big\} = \Big\{ \sum_{i:\pi(i)\neq i} \log \frac{\|X_i - X_i^\#\|^2}{\|X_{\pi(i)} - X_i^\#\|^2} \geq 0 \Big\}.$$

On the one hand, for every permutation π,

$$\begin{aligned}\sum_{\pi(i)\neq i} \log\Big(\tfrac{2\sigma_i^2}{\sigma_i^2+\sigma_{\pi(i)}^2}\Big) &= \sum_{i=1}^n \big(\log(2\sigma_i^2) - \log(\sigma_i^2+\sigma_{\pi(i)}^2)\big)\\ &= \sum_{i=1}^n \frac{\log(2\sigma_i^2)+\log(2\sigma_{\pi(i)}^2)}{2} - \log(\sigma_i^2+\sigma_{\pi(i)}^2)\end{aligned}$$

so, using the concavity of the logarithm, this quantity is nonpositive. Therefore,

$$\begin{aligned}\Omega_\pi &\subset \Big\{ \sum_{i:\pi(i)\neq i} \log \tfrac{\|X_i - X_i^\#\|^2/(2\sigma_i^2)}{\|X_{\pi(i)} - X_i^\#\|^2/(\sigma_i^2+\sigma_{\pi(i)}^2)} \geq 0 \Big\}\\ &\subset \bigcup_{i=1}^n \bigcup_{j\neq i} \Big\{ \frac{\|X_i - X_i^\#\|^2}{2\sigma_i^2} \geq \frac{\|X_j - X_i^\#\|^2}{\sigma_j^2+\sigma_i^2} \Big\}.\end{aligned}$$

This readily yields $\Omega \subset \bar{\Omega}$, where

$$\bar{\Omega} = \bigcup_{i=1}^n \bigcup_{j\neq i} \Big\{ \frac{\|X_i - X_i^\#\|^2}{2\sigma_i^2} \geq \frac{\|X_j - X_i^\#\|^2}{\sigma_j^2+\sigma_i^2} \Big\}. \tag{21}$$

Furthermore, the same inclusion is true for the LSNS estimator as well. Therefore, the rest of the proof is common for the estimators LSNS and LSL.

We set $\sigma_{i,j} = (\sigma_i^2+\sigma_j^2)^{1/2}$ and

$$\zeta_1 = \max_{i\neq j} \Big| \frac{(\theta_i-\theta_j)^\top(\sigma_i\xi_i - \sigma_j\xi_j^\#)}{\|\theta_i-\theta_j\|\sigma_{i,j}} \Big|, \quad \zeta_2 = d^{-1/2} \max_{i,j} \Big| \Big\| \frac{\sigma_i\xi_i - \sigma_j\xi_j^\#}{\sigma_{i,j}} \Big\|^2 - d \Big|.$$

Since $\pi^* = id$, it holds that for every $i \in \{1,\dots,n\}$,

$$\|X_i - X_i^\#\|^2 = \sigma_i^2\|\xi_i - \xi_i^\#\|^2 \leq 2\sigma_i^2(d + \sqrt{d}\zeta_2).$$

Similarly, for every $j \neq i$,

$$\|X_j - X_i^\#\|^2 = \|\theta_j-\theta_i\|^2 + \|\sigma_j\xi_j - \sigma_i\xi_i^\#\|^2 + 2(\theta_j-\theta_i)^\top(\sigma_j\xi_j - \sigma_i\xi_i^\#).$$

Therefore,

$$\|X_j - X_i^\#\|^2 \geq \|\theta_j-\theta_i\|^2 + \sigma_{i,j}^2(d - \sqrt{d}\zeta_2) - 2\|\theta_j-\theta_i\|\sigma_{i,j}\zeta_1.$$

This implies that on the event $\Omega_1 = \{\bar{\kappa}(\boldsymbol{\theta},\boldsymbol{\sigma}) \geq \zeta_1\}$ it holds that

$$\frac{\|X_j - X_i^\#\|^2}{\sigma_{i,j}^2} \geq \bar{\kappa}(\boldsymbol{\theta},\boldsymbol{\sigma})^2 - 2\bar{\kappa}(\boldsymbol{\theta},\boldsymbol{\sigma})\zeta_1 + d - \sqrt{d}\zeta_2.$$

Combining these bounds, we get that

$$\Omega \cap \Omega_1 \subset \Big\{ d + \sqrt{d}\zeta_2 \geq \bar{\kappa}(\boldsymbol{\theta},\boldsymbol{\sigma})^2 - 2\bar{\kappa}(\boldsymbol{\theta},\boldsymbol{\sigma})\zeta_1 + d - \sqrt{d}\zeta_2 \Big\},$$

which implies that

$$\begin{aligned}\mathbf{P}(\Omega) &\le \mathbf{P}(\Omega_1^{\complement}) + \mathbf{P}\big(\Omega \cap \Omega_1\big)\\ &\le \mathbf{P}\big(\zeta_1 \ge \bar\kappa(\boldsymbol{\theta},\boldsymbol{\sigma})\big) + \mathbf{P}(2\sqrt{d}\zeta_2 + 2\bar\kappa(\boldsymbol{\theta},\boldsymbol{\sigma})\zeta_1 \ge \bar\kappa(\boldsymbol{\theta},\boldsymbol{\sigma})^2)\\ &\le 2\mathbf{P}\big(\zeta_1 \ge \tfrac{\bar\kappa(\boldsymbol{\theta},\boldsymbol{\sigma})}{4}\big) + \mathbf{P}\big(\zeta_2 \ge \tfrac{\bar\kappa(\boldsymbol{\theta},\boldsymbol{\sigma})^2}{4\sqrt{d}}\big). \end{aligned} \tag{22}$$

Finally, one easily checks that for suitably chosen random variables $\zeta_{i,j}$ drawn from the standard Gaussian distribution, it holds that $\zeta_1 = \max_{i\neq j}|\zeta_{i,j}|$. Therefore, using the well-known tail bound for the standard Gaussian distribution in conjunction with the union bound, we get

$$\mathbf{P}\big(\zeta_1 \ge \tfrac{1}{4}\bar\kappa(\boldsymbol{\theta},\boldsymbol{\sigma})\big) \le \sum\nolimits_{i\neq j} \mathbf{P}\big(|\zeta_{i,j}| \ge \tfrac{1}{4}\bar\kappa(\boldsymbol{\theta},\boldsymbol{\sigma})\big) \le 2n^2 e^{-\frac{1}{32}\bar\kappa(\boldsymbol{\theta},\boldsymbol{\sigma})^2}. \tag{23}$$

To bound the large deviations of the random variable ζ_2, we rely on the following result.

Lemma 10 (Laurent and Massart (2000), Eq. (4.3) and (4.4)) *If Y is drawn from the chi-squared distribution $\chi^2(D)$, where $D \in \mathbb{N}^*$, then, for every $x > 0$,*

$$\begin{cases} \mathbf{P}\big(Y - D \le -2\sqrt{Dx}\big) \le e^{-x},\\ \mathbf{P}\big(Y - D \ge 2\sqrt{Dx} + 2x\big) \le e^{-x}. \end{cases}$$

As a consequence, $\forall y > 0$, $\mathbf{P}\big(D^{-1/2}|Y - D| \ge y\big) \le 2\exp\big\{-\frac{1}{8}y(y \wedge \sqrt{D})\big\}$.

This inequality, combined with the union bound, yields

$$\mathbf{P}\Big(\zeta_2 \ge \tfrac{\bar\kappa(\boldsymbol{\theta},\boldsymbol{\sigma})^2}{4\sqrt{d}}\Big) \le 2n^2 \exp\Big\{-\frac{(\bar\kappa(\boldsymbol{\theta},\boldsymbol{\sigma})/16)^2}{d}(\bar\kappa^2(\boldsymbol{\theta},\boldsymbol{\sigma}) \wedge 8d)\Big\}. \tag{24}$$

Combining inequalities (22)-(24), we obtain that as soon as

$$\bar\kappa(\boldsymbol{\theta},\boldsymbol{\sigma}) \ge 4\Big(\sqrt{2\log(8n^2/\alpha)} \vee \big(d\log(4n^2/\alpha)\big)^{1/4}\Big),$$

we have $\mathbf{P}(\hat\pi \neq \pi^*) = \mathbf{P}(\Omega) \le \alpha$.

Proof of Theorem 1 Without loss of generality, we assume $\pi^* = id$. It holds that, on the event

$$\mathcal{A} = \bigcap_{i=1}^n \bigcap_{j\neq i} \Big\{\|X_i - X_i^\#\| < \|X_j - X_i^\#\|\Big\},$$

all the four estimators coincide with the true permutation id. Therefore, we have

$$\{\hat\pi \neq id\} \subseteq \bigcup_{i=1}^n \bigcup_{j\neq i} \Big\{\|X_i - X_i^\#\| \ge \|X_j - X_i^\#\|\Big\}.$$

The latter event is included in $\bar\Omega$ at the right-hand side of (21), the probability of which has been already shown to be small in the previous proof.

Proof of Theorem 2 We refer the reader to the proof of Theorem 4 below, which concerns the more general situation. Indeed, when all the variances σ_j are equal, Theorem 4 boils down to Theorem 2.

Proof of Theorem 4 To establish lower bounds for various types of risks we will use the following lemma:

Lemma 11 (Tsybakov (2009), Theorem 2.5) *Assume that for some integer $M \ge 2$ there exist distinct permutations $\pi_0, \dots, \pi_M \in \mathfrak{S}_n$ and mutually absolutely continuous probability measures $\mathbf{Q}_0, \dots, \mathbf{Q}_M$ defined on a common probability space $(\mathcal{Z}, \mathscr{Z})$ such that*

$$\frac{1}{M}\sum_{j=1}^M K(\mathbf{Q}_j, \mathbf{Q}_0) \le \frac{1}{8}\log M.$$

Then, for every measurable mapping $\tilde\pi : \mathcal{Z} \to \mathfrak{S}_n$,

$$\max_{j=0,\dots,M} \mathbf{Q}_j(\tilde\pi \neq \pi_j) \ge \frac{\sqrt{M}}{\sqrt{M}+1}\Big(\frac{3}{4} - \frac{1}{2\sqrt{\log M}}\Big).$$

To prove Theorem 4, we split the inequality $8\kappa \le \max\{(\log n)^{1/2}, (cd\log n)^{1/4}\}$ into two cases

$$\begin{aligned} &\textbf{Case 1:} && 8\kappa \le (\log n)^{1/2},\\ &\textbf{Case 2:} && (\log n)^{1/2} \le 8\kappa \le (cd\log n)^{1/4}. \end{aligned}$$

Case 1: We assume that $8\kappa \le (\log n)^{1/2}$.
Denote by m the largest integer such that $2m \le n$. We assume without loss of generality that the noise levels are ranked in increasing order: $\sigma_1 \le \ldots \le \sigma_n$. Then, we construct a least favorable set of vectors for the estimation of the permutation. To ease notation, we set $\sigma_{i,j} = (\sigma_i^2 + \sigma_j^2)^{1/2}$.

Lemma 12 *Assume that m is the largest integer such that $2m \le n$. Then there is a set of vectors $\boldsymbol{\theta}$ such that*

$$\frac{\|\theta_1 - \theta_2\|}{\sigma_{1,2}} = \ldots = \frac{\|\theta_{2m-1} - \theta_{2m}\|}{\sigma_{2m-1,2m}} = \kappa,$$

and for every pair $\{i,j\}$ different from the pairs $\{1,2\}, \dots, \{2m-1, 2m\}$ we have

$$\frac{\|\theta_i - \theta_j\|}{\sigma_{i,j}} > \kappa\Big(1 + \frac{\max_{1\le\ell\le n}\sigma_\ell}{\min_{1\le\ell\le n}\sigma_\ell}\Big).$$

Let $\boldsymbol{\theta}^0$ be the set constructed in Lemma 12. The latter implies that $\boldsymbol{\theta}^0$ belongs to $\bar\Theta_\kappa$, so that, denoting for every $k \in \{1, \dots, m\}, \pi_k = (2k-1\ 2k)$ the transposition of $\mathfrak{S}_n$ that only permutes $2k-1$ and $2k$, and $\pi_0 = id$, we get the following lower bound for the risk:

$$\inf_{\hat\pi} \sup_{(\pi,\boldsymbol{\theta})\in\mathfrak{S}_n\times\bar\Theta_\kappa} \mathbf{P}_{\boldsymbol{\theta},\pi}(\hat\pi \neq \pi) \ge \inf_{\hat\pi} \max_{k=0,\dots,m} \mathbf{P}_{\boldsymbol{\theta}^0,\pi_k}(\hat\pi \neq \pi_k).$$

In order to use Lemma 11 with $\mathbf{Q}_j = \mathbf{P}_{\boldsymbol{\theta}^0,\pi_j}$, we compute for every $k \in \{1,\dots,m\}$

$$K(\mathbf{P}_{\boldsymbol{\theta}^0,\pi_k}, \mathbf{P}_{\boldsymbol{\theta}^0,\pi_0}) = \|\theta^0_{2k-1} - \theta^0_{2k}\|^2 \Big(\frac{1}{2\sigma^2_{2k}} + \frac{1}{2\sigma^2_{2k-1}}\Big) + \frac{d}{2}\Big(\frac{\sigma^2_{2k-1}}{\sigma^2_{2k}} + \frac{\sigma^2_{2k}}{\sigma^2_{2k-1}} - 2\Big).$$

Using the fact that $\|\theta^0_{2k-1} - \theta^0_{2k}\|^2 = \kappa^2(\sigma^2_{2k-1} + \sigma^2_{2k})$, we get

$$K(\mathbf{P}_{\boldsymbol{\theta}^k,\pi_k}, \mathbf{P}_{\boldsymbol{\theta}^0,\pi_0}) = \frac{\kappa^2}{2}\big(2 + \sigma^2_{2k-1}\sigma^{-2}_{2k} + \sigma^2_{2k}\sigma^{-2}_{2k-1}\big) + \frac{d}{2}\Big(\frac{\sigma^2_{2k-1}}{\sigma^2_{2k}} + \frac{\sigma^2_{2k}}{\sigma^2_{2k-1}} - 2\Big).$$

The inequality $\sigma^2_{2k-1} \le \sigma^2_{2k}$ implies the following two relations:

$$\frac{\sigma^2_{2k-1}}{\sigma^2_{2k}} + \frac{\sigma^2_{2k}}{\sigma^2_{2k-1}} - 2 \le \frac{\sigma^2_{2k}}{\sigma^2_{2k-1}} - 1$$
$$\frac{\sigma^2_{2k-1}}{\sigma^2_{2k}} + \frac{\sigma^2_{2k}}{\sigma^2_{2k-1}} - 2 = \frac{\sigma^2_{2k-1}}{\sigma^2_{2k}}\Big(\frac{\sigma^2_{2k}}{\sigma^2_{2k-1}} - 1\Big)^2 \le \Big(\frac{\sigma^2_{2k}}{\sigma^2_{2k-1}} - 1\Big)^2.$$

This readily yields $\frac{\sigma^2_{2k-1}}{\sigma^2_{2k}} + \frac{\sigma^2_{2k}}{\sigma^2_{2k-1}} - 2 \le \frac{\log n}{16d}$ and, therefore,

$$K(\mathbf{P}_{\boldsymbol{\theta}^k,\pi_k}, \mathbf{P}_{\boldsymbol{\theta}^0,\pi_0}) \le \kappa^2\Big(\frac{3}{2} + \frac{\sigma^2_{2k}}{2\sigma^2_{2k-1}}\Big) + \frac{\log n}{32}.$$

Next, we apply the following result.

Lemma 13 *Let $a_1, a_2, \dots, a_m$ be real numbers larger than one such that $\prod_{k=1}^m a_k \le A$. Then, $\sum_{k=1}^m a_k \le m + \log A \max_k a_k$.*

Proof We use the simple inequality $e^x \le 1 + xe^x$ for all $x \ge 0$. Replacing x by $\log a_k$ and summing over $k = 1,\dots,m$ we get

$$\sum_{k=1}^m a_k \le \sum_{k=1}^m 1 + a_k \log a_k \le m + \max_{k=1,\dots,m} a_k \log \prod_{k=1}^m a_k \le m + \max_{k=1,\dots,m} a_k \log A.$$

This completes the proof of the lemma. ■

We apply this lemma to $a_k = \sigma^2_{2k}/\sigma^2_{2k-1}$. Since the variances are sorted in increasing order, we have $\prod_{k=1}^m a_k \le \prod_{i=1}^{n-1} \sigma^2_{i+1}/\sigma^2_i = \sigma^2_n/\sigma^2_1 \le 1 + \gamma_{n,d}$ with $\gamma_{n,d} = \max\big((\frac{\log n}{16d})^{1/2}, \frac{\log n}{16d}\big)$. In conjunction with the inequality $\log(1+x) \le x$, this entails that $\sum_{k=1}^m \sigma^2_{2k}/\sigma^2_{2k-1} \le m + \gamma_{n,d}(1+\gamma_{n,d})$. Then, since $\log n \le 1.8 \log m$ for $n \ge 6$ and $\gamma_{n,d} \le 0.2 \log n \le 0.36 \log m$, we get

$$\begin{aligned}\frac{1}{m}\sum_{k=1}^m K(\mathbf{P}_{\boldsymbol{\theta}^k,\pi_k}, \mathbf{P}_{\boldsymbol{\theta}^0,\pi_0}) &\le \kappa^2\Big(\frac{3}{2} + \frac{1}{2m}\sum_{k=1}^m \frac{\sigma^2_{2k}}{\sigma^2_{2k-1}}\Big) + \frac{9\log m}{160}\\ &\le \kappa^2\Big(2 + \frac{\gamma_{n,d}}{2m}\big\{1 + \gamma_{n,d}\big\}\Big) + \frac{9\log m}{160}\\ &\le \kappa^2\Big(2 + \frac{0.18\log m}{m}\big\{1 + 0.36\log m\big\}\Big) + \frac{9\log m}{160}.\end{aligned}$$

Finally, using the fact that $m \ge 3$, we get $\frac{1}{m}\sum_{k=1}^m K(\mathbf{P}_{\boldsymbol{\theta}^k,\pi_k}, \mathbf{P}_{\boldsymbol{\theta}^0,\pi_0}) \le 2.1\kappa^2 + \frac{9\log m}{160} \le \frac{\log m}{8}$ since $\kappa^2 \le \frac{1}{64}\log n \le \frac{9}{320}\log m$.

We conclude by Lemma 11 and by the monotonicity of the function $m \mapsto \frac{\sqrt{m}}{1+\sqrt{m}}\big(\frac{3}{4} - \frac{1}{2\sqrt{\log m}}\big)$ that

$$\inf_{\hat\pi} \sup_{(\pi,\boldsymbol{\theta}) \in \mathfrak{S}_n \times \bar\Theta_\kappa} \mathbf{P}_{\boldsymbol{\theta},\pi}(\hat\pi \ne \pi) \ge \frac{\sqrt{3}}{\sqrt{3}+1}\Big(\frac{3}{4} - \frac{1}{2\sqrt{\log 3}}\Big) \ge 0.17.$$

Case 2: We assume that $(\log n)^{1/2} \le 8\kappa \le (cd\log n)^{1/4}$ with $c \le 1/20$. In this case, we have $d \ge \frac{1}{c}\log n$. To get the desired result, we use Lemma 11 for a properly chosen family of probability measures described below.

Lemma 14 *Let $\epsilon_1, \dots, \epsilon_n$ be real numbers defined by*

$$\epsilon_k = \sqrt{2/d}\,\kappa\sigma_k, \qquad \forall k \in \{1,\dots,n\},$$

and let μ be the uniform distribution on $\mathcal{E} = \{\pm\epsilon_1\}^d \times \ldots \times \{\pm\epsilon_n\}^d$. We denote by $\mathbf{P}_{\mu,\pi}$ the probability measure on $\mathbb{R}^{d\times n}$ defined by $\mathbf{P}_{\mu,\pi}(A) = \int_{\mathcal{E}} \mathbf{P}_{\boldsymbol{\theta},\pi}(A)\,\mu(d\boldsymbol{\theta})$. Assume that $\sigma_1 \le \ldots \le \sigma_n$. For two positive integers $k < k' \le n$, set $\gamma = \frac{\sigma^2_{k'}}{\sigma^2_k}$ and let $\pi = (k\ k')$ be the transposition that only permutes k and k'. Then

$$K(\mathbf{P}_{\mu,\pi}, \mathbf{P}_{\mu,id}) \le 4\kappa^2\big(1 - \gamma^{-1}\big) + \frac{8\kappa^4}{d}\big(2 + \big(1 + (2/d)\kappa^2\big)^2\gamma^2\big) + \frac{1}{2}\big(d + 2\kappa^2\big)(\gamma - 1)^2$$

and $\mu(\mathcal{E}\backslash\bar\Theta_\kappa) \le (n(n-1)/2)\ e^{-d/8}$.

The assumption on the noise levels entails that, for any integer $k \in \{1,\dots,k'\}$, $1 \le \frac{\sigma^2_{k'}}{\sigma^2_k} \le 1 + \frac{1}{4}(\frac{\log n}{d})^{1/2}$, and consequently, $(\gamma-1)^2 = \big(\frac{\sigma^2_{k'}}{\sigma^2_k} - 1\big)^2 \le 4^{-2}\big(\frac{\log n}{d}\big)$. Furthermore, $\frac{\kappa^2}{d} \le \frac{c}{64} \le \frac{1}{64}$ provided that $c \le 1$. Finally, for the Kullback-Leibler divergence between $\mathbf{P}_{\mu,\pi_{k,k'}}$ and $\mathbf{P}_{\mu,id}$, where $\pi_{k,k'} = (k\ k')$ is the transposition from $\mathfrak{S}_n$ permuting only k and k', it holds

$$\begin{aligned}K(\mathbf{P}_{\mu,\pi_{k,k'}}, \mathbf{P}_{\mu,id}) &\le \kappa^2\sqrt{\frac{\log n}{d}} + \frac{8\kappa^4}{d}\Big(2 + \frac{33^2}{32^2}\big(1 + 0.25\big)^2\Big) + \frac{33d}{64} \times \frac{\log n}{16d}\\ &\le \frac{\log n}{8} \le \frac{\log n(n-1)/2}{8},\end{aligned}$$

where we have used once again the facts that $c \le 1$ and $n \ge 3$. Applying Lemma 11 with $M = n(n-1)/2$, $\mathbf{Q}_0 = \mathbf{P}_{\mu,id}$ and $\{\mathbf{Q}_j\}_{j=1,\dots,M} = \{\mathbf{P}_{\mu,\pi_{k,k'}}\}_{k\ne k'}$, we obtain

$$\begin{aligned}\max_{\pi^*\in\mathfrak{S}_n} \sup_{\boldsymbol{\theta}\in\bar\Theta_\kappa} \mathbf{P}_{\boldsymbol{\theta},\pi^*}\big(\hat\pi \ne \pi^*\big) &\ge \max_{\pi^*\in\{id\}\cup\{\pi_{k,k'}\}} \int_{\bar\Theta_\kappa} \mathbf{P}_{\boldsymbol{\theta},\pi^*}\big(\hat\pi \ne \pi^*\big)\frac{\mu(d\boldsymbol{\theta})}{\mu(\bar\Theta_\kappa)}\\ &\ge \max_{\pi^*\in\{id\}\cup\{\pi_{k,k'}\}} \mathbf{P}_{\mu,\pi^*}\big(\hat\pi \ne \pi^*\big) - \mu(\mathcal{E}\backslash\bar\Theta_\kappa)\\ &\ge \frac{\sqrt{15}}{\sqrt{15}+1}\Big(\frac{3}{4} - \frac{1}{2\sqrt{\log 15}}\Big) - \frac{n(n-1)}{2}e^{-d/8}.\end{aligned}$$

In view of the inequalities $d \ge (1/c)\log n$, $c \le 1/20$ and $n \ge 6$, we get the inequality $\max_{\pi^*\in\mathfrak{S}_n} \sup_{\boldsymbol{\theta}\in\bar\Theta_\kappa} \mathbf{P}_{\boldsymbol{\theta},\pi^*}\big(\hat\pi \ne \pi^*\big) \ge 22.4\%$.

Proof of Theorem 5 Since the event $\{\pi^{\rm gr} \neq id\}$ includes the event

$$\Omega_2 = \{\|X_1 - X_1^\sharp\|^2 > \|X_2 - X_1^\sharp\|^2\},$$

it is sufficient to bound from below the probability of Ω_2. To this end, we choose any $\boldsymbol{\theta} \in \mathbb{R}^{n\times d}$ satisfying $\|\theta_1 - \theta_2\| = 2\kappa$. This readily implies that $\boldsymbol{\theta}$ belongs to $\bar\Theta_\kappa$. Furthermore, for suitably chosen random variables $\eta_1 \sim \chi^2_d$, $\eta_2 \sim \chi^2_d$ and $\eta_3 \sim \mathcal{N}(0,1)$, it holds that $\|X_1 - X_1^\sharp\|^2 - \|X_2 - X_1^\sharp\|^2 = 6\eta_1 - 4\kappa^2 - 8\kappa\eta_3 - 4\eta_2$. The random terms in the last sum can be controlled using Lemma 10. More precisely, for every $x > 0$, each one of the following three inequalities holds true with probability at least $1 - e^{-x^2}$:

$$\eta_1 \geq d - 2\sqrt{d}x, \quad \eta_2 \leq d + 2\sqrt{d}x + 2x^2, \quad \eta_3 \leq \sqrt{2}x.$$

This implies that with probability at least $1 - 3e^{-x^2}$, we have

$$\|X_1 - X_1^\sharp\|^2 - \|X_2 - X_1^\sharp\|^2 \geq 2d - 20\sqrt{d}x - 4(\kappa + \sqrt{2}x)^2.$$

If $x = \sqrt{\log 6}$, then the conditions imposed on κ and d ensure that the right-hand side of the last inequality is positive. Therefore, $\mathbf{P}(\Omega_2) \geq 1 - 3e^{-x^2} = 1/2$.

Proof of Theorem 8 The proof is split into two parts. In the first part, we consider the case $\kappa \leq \frac{1}{4}\sqrt{\frac{\log M_n}{n}}$, while in the second part the case $\kappa \leq \frac{1}{8}\big(\frac{\log n}{d}\big)^{1/4}$ with $d \geq 24\log n$ and is analyzed. In both cases, the main tool we use is the following result.

Lemma 15 (Tsybakov (2009), Theorem 2.5) *Assume that for some integer $M \geq 2$ there exist distinct permutations $\pi_0, \dots, \pi_M \in \mathfrak{S}_n$ and mutually absolutely continuous probability measures $\mathbf{Q}_0, \dots, \mathbf{Q}_M$ defined on a common probability space $(\mathcal{Z}, \mathscr{Z})$ such that*

$$\begin{cases} \exists\ s > 0,\ \forall\ i \neq j,\ \delta(\pi_i, \pi_j) \geq 2s, \\ \frac{1}{M}\sum_{j=1}^M K(\mathbf{Q}_j, \mathbf{Q}_0) \leq \frac{1}{8}\log M. \end{cases}$$

Then, for every measurable mapping $\tilde\pi : \mathcal{Z} \to \mathfrak{S}_n$,

$$\max_{j=0,\dots,M} \mathbf{Q}_j\big(\delta(\hat\pi, \pi_j) \geq s\big) \geq \frac{\sqrt{M}}{\sqrt{M}+1}\Big(\frac{3}{4} - \frac{1}{2\sqrt{\log M}}\Big).$$

We now have to choose M and $\pi_0, \dots, \pi_M$ in a suitable manner, which will be done differently according to the relationship between n and d.

Case 1: We assume that $\kappa \leq \frac{1}{4}\sqrt{\frac{\log M_n}{n}}$.
Let $M = M_n$ with $M_n = \mathcal{M}(1/4, B_{2,n}(2), \delta_H)$ and let $\boldsymbol{\theta} = (\theta_1, \dots, \theta_n)$ be the set of vectors $\theta_k = k\kappa\sigma(1, 0, \dots, 0) \in \mathbb{R}^d$. Clearly, $\boldsymbol{\theta}$ belongs to $\bar\Theta_\kappa$. By definition of the packing number, there exist $\pi_1, \dots, \pi_{M_n}$, permutations from $\mathfrak{S}_n$, such that

$$\delta_2(\pi_j, id) \leq 2, \qquad \delta_H(\pi_i, \pi_j) \geq \frac{1}{4}; \qquad \forall i, j \in \{1, \dots, M_n\},\ i \neq j.$$

Defining $\mathbf{Q}_j = \mathbf{P}_{\boldsymbol{\theta},\pi_j}$ for $j = 1, \dots, M_n$ and $\mathbf{Q}_0 = \mathbf{P}_{\boldsymbol{\theta},id}$ we get

$$\begin{aligned} K(\mathbf{Q}_j, \mathbf{Q}_0) &= \frac{1}{2\sigma^2}\sum_{k=1}^n \|\theta_{\pi_j(k)} - \theta_k\|^2 = \frac{\kappa^2}{2}\sum_{k=1}^n (\pi_j(k) - k)^2 \\ &= \frac{n\kappa^2}{2}\,\delta_2(\pi_j, id)^2 \leq 2n\kappa^2. \end{aligned}$$

Therefore, using Lemma 15 with $s = 1/8$ we infer from $\kappa \leq \frac{1}{4}\big(\frac{\log M_n}{n}\big)^{1/2}$ that

$$\min_{\hat\pi} \max_{j=0,\dots,M_n} \mathbf{P}_{\boldsymbol{\theta},\pi_j}(\delta_H(\hat\pi, \pi_j) \geq 1/8) \geq \frac{\sqrt{3}}{\sqrt{3}+1}\Big(\frac{3}{4} - \frac{1}{2\sqrt{\log 3}}\Big) \approx 17.31\%.$$

As a consequence, we obtain that

$$\begin{aligned} \min_{\hat\pi} \max_{(\pi,\boldsymbol{\theta})\in\mathfrak{S}_n\times\bar\Theta_\kappa} \mathbf{E}_{\boldsymbol{\theta},\pi}[\delta_H(\hat\pi, \pi)] &\geq \min_{\hat\pi} \max_{j=0,\dots,M} \mathbf{E}_{\boldsymbol{\theta},\pi}[\delta_H(\hat\pi, \pi)\mathbb{1}_{\{\delta_H(\hat\pi,\pi)\geq 1/8\}}] \\ &\geq \frac{1}{8}\min_{\hat\pi} \max_{j=0,\dots,M} \mathbf{E}_{\boldsymbol{\theta},\pi}[\mathbb{1}_{\{\delta_H(\hat\pi,\pi)\geq 1/8\}}] \\ &\geq 2.15\%. \end{aligned}$$

This completes the proof of the first case.

Case 2: We assume that $d \geq 24\log n$ and $\kappa \leq \frac{1}{8}(d\log n)^{1/4}$. Let μ be the uniform distribution on $\{\pm\epsilon\}^{m\times d}$ with $\epsilon = \sqrt{2/d}\,\sigma\kappa$, as in Lemma 14. For any set of permutations $\{\pi_0, \dots, \pi_M\} \subset \mathfrak{S}_n$, in view of Markov's inequality,

$$\sup_{(\pi,\boldsymbol{\theta})\in\mathfrak{S}_n\times\bar\Theta_\kappa} \mathbf{E}_{\boldsymbol{\theta},\pi}\big[\delta_H(\hat\pi, \pi)\big] \geq \frac{3}{16}\Big(\max_{i=0,\dots,M} \mathbf{P}_{\mu,\pi_i}\Big(\delta_H(\hat\pi, \pi_i) \geq \frac{3}{16}\Big) - \mu(\bar\Theta_\kappa^{\complement})\Big).$$

We choose M and $\pi_0, \dots, \pi_M$ as in the following lemma.

Lemma 16 *For any integer $n \geq 4$ there exist permutations $\pi_0, \dots, \pi_M \in \mathfrak{S}_n$ such that*

$$\pi_0 = id, \qquad M \geq (n/24)^{n/6},$$

each π_i is a composition of at most $n/2$ transpositions with disjoint supports, and for every distinct pair of indices $i, j \in \{0, \dots, M\}$ we have

$$\delta_H(\pi_i, \pi_j) \geq 3/8.$$

As π_i is a product of transpositions, the Kullback-Leibler divergence between $\mathbf{P}_{\mu,\pi_i}$ and $\mathbf{P}_{\mu,\pi_0}$ can be computed by independence thanks to Lemma 14:

$$\frac{1}{M}\sum_{i=1}^M K(\mathbf{P}_{\mu,\pi_i}, \mathbf{P}_{\mu,\pi_0}) \leq \frac{n}{2} \times \frac{8\kappa^4}{d}\Big(2 + \Big[1 + \frac{2\kappa^2}{d}\Big]^2\Big) = \frac{16n\kappa^4}{d},$$

where the last inequality follows from the bound $\kappa \leq 0.45 d^{1/2}$. For $n \geq 26$, it holds that $M \geq 2$ and

$$\log M \geq \frac{n(\log n - \log 24)}{6} \geq \frac{\log n}{512}.$$

Consequently, $\frac{16n\kappa^4}{d} \le \frac{1}{8}\log M$ which allows us to apply Lemma 15. This yields

$$\begin{aligned}\inf_{\hat\pi}\sup_{(\pi,\boldsymbol{\theta})\in\mathfrak{S}_n\times\bar\Theta_\kappa}\mathbf{E}_{\boldsymbol{\theta},\pi}[\delta_H(\hat\pi,\pi)] &\ge \frac{3}{16}\Big[\frac{\sqrt{2}}{\sqrt{2}+1}\Big(\frac{3}{4}-\frac{1}{2\sqrt{\log 2}}\Big)-\frac{n^2}{2}e^{-d/8}\Big]\\ &\ge \frac{3}{16}\Big[0.077-\frac{n^2}{2}e^{-24\log(n)/8}\Big]\\ &\ge \frac{3}{16}\Big[0.077-\frac{1}{2n}\Big]\ge 5.81\%.\end{aligned}$$

10. Proofs of the Lemmas

Proof of Lemma 12 Let us denote $r_\sigma = \max_{1\le\ell\le n}\sigma_\ell/\min_{1\le\ell\le n}\sigma_\ell$. It suffices to set $\theta_1 = 0\in\mathbb{R}^d$,

$$\begin{aligned}\theta_{2k+1} &= \kappa\Big(\sigma_{1,2}+\ldots+\sigma_{2k-1,2k}+k\big(1+r_\sigma\big),0,\ldots,0\Big)\in\mathbb{R}^d,\\ \theta_{2k} &= \kappa\Big(\sigma_{1,2}+\ldots+\sigma_{2k-1,2k}+(k-1)\big(1+r_\sigma\big),0,\ldots,0\Big)\in\mathbb{R}^d\end{aligned}$$

for all $k=1,\ldots,m-1$. If n is impair, one can set $\theta_n=\theta_{n-1}+\kappa\big(1+r_\sigma\big)(1,0,\ldots,0)$. One readily checks that these vectors satisfy the desired conditions.

Proof of Lemma 14 Without loss of generality, we assume hereafter that $\pi\in\mathfrak{S}_n$ is the transposition permuting 1 and 2. Recall that the uniform distribution on $\{\pm\epsilon_1\}^d\times\ldots\times\{\pm\epsilon_n\}^d$ can also be written as the product $\mu=\bigotimes_{\ell=1}^n\mu_\ell$, where μ_ℓ is the uniform distribution on $\{\pm\epsilon_\ell\}^d$. Let us introduce an auxiliary probability distribution $\tilde\mu$ on $\mathbb{R}^{n\times d}$ defined as $\tilde\mu=\delta_{\mathbf{0}}\otimes\delta_{\mathbf{0}}\otimes\mu_2\otimes\ldots\otimes\mu_m$ with $\delta_{\mathbf{0}}$ being the Dirac delta measure at $\mathbf{0}\in\mathbb{R}^d$. We set $\mathbf{P}_{\tilde\mu,id}(\cdot)=\int_\Theta\mathbf{P}_{\boldsymbol{\theta},id}(\cdot)\tilde\mu(d\boldsymbol{\theta})$.

We first compute the density of $\mathbf{P}_{\mu,\pi}$ w.r.t. $\mathbf{P}_{\mu,id}$, which can be written as

$$\frac{d\mathbf{P}_{\mu,\pi}}{d\mathbf{P}_{\mu,id}}(\boldsymbol{X},\boldsymbol{X}^\sharp)=\frac{d\mathbf{P}_{\mu,\pi}}{d\mathbf{P}_{\tilde\mu,id}}(\boldsymbol{X},\boldsymbol{X}^\sharp)\bigg/\Big(\frac{d\mathbf{P}_{\mu,id}}{d\mathbf{P}_{\tilde\mu,id}}(\boldsymbol{X},\boldsymbol{X}^\sharp)\Big),\quad \boldsymbol{X},\boldsymbol{X}^\sharp\in\mathbb{R}^{n\times d}.$$

For every $\theta_i\in\mathbb{R}^d$ we denote by $\mathbf{P}_{\theta_i,\sigma_i}$ the probability distribution of X_i from (2), given by

$$\frac{d\mathbf{P}_{\theta_i,\sigma_i}}{d\mathbf{P}_{0,\sigma_j}}(x)=\exp\Big\{-\frac{\|\theta_i\|^2}{2\sigma_i^2}+\frac{1}{\sigma_i^2}(x,\theta_i)-\frac{\|x\|^2}{2}(\sigma_i^{-2}-\sigma_j^{-2})\Big\},\quad\forall x\in\mathbb{R}^d.$$

With this notation, we have

$$\begin{aligned}\frac{d\mathbf{P}_{\mu,\pi}}{d\mathbf{P}_{\tilde\mu,id}}(\boldsymbol{X},\boldsymbol{X}^\sharp)&=\mathbf{E}_\mu\bigg[\frac{d\mathbf{P}_{\theta_1,\sigma_1}}{d\mathbf{P}_{0,\sigma_1}}(X_1)\frac{d\mathbf{P}_{\theta_2,\sigma_2}}{d\mathbf{P}_{0,\sigma_2}}(X_2)\frac{d\mathbf{P}_{\theta_2,\sigma_2}}{d\mathbf{P}_{0,\sigma_1}}(X_1^\sharp)\frac{d\mathbf{P}_{\theta_1,\sigma_1}}{d\mathbf{P}_{0,\sigma_2}}(X_2^\sharp)\bigg]\\ &=\mathbf{E}_\mu\bigg[\frac{d\mathbf{P}_{\theta_1,\sigma_1}}{d\mathbf{P}_{0,\sigma_1}}(X_1)\frac{d\mathbf{P}_{\theta_1,\sigma_1}}{d\mathbf{P}_{0,\sigma_2}}(X_2^\sharp)\bigg]\times\mathbf{E}_\mu\bigg[\frac{d\mathbf{P}_{\theta_2,\sigma_2}}{d\mathbf{P}_{0,\sigma_2}}(X_2)\frac{d\mathbf{P}_{\theta_2,\sigma_2}}{d\mathbf{P}_{0,\sigma_1}}(X_1^\sharp)\bigg]\\ &=\prod_{k=1}^d\cosh\Big(\frac{\epsilon_1}{\sigma_1^2}(X_{1,k}+X_{2,k}^\sharp)\Big)\cosh\Big(\frac{\epsilon_2}{\sigma_2^2}(X_{2,k}+X_{1,k}^\sharp)\Big)\\ &\quad\times\exp\Big\{-\frac{1}{2}(\|X_1^\sharp\|^2-\|X_2^\sharp\|^2)(\sigma_2^{-2}-\sigma_1^{-2})\Big\}.\end{aligned}$$

Similarly,

$$\begin{aligned}\frac{d\mathbf{P}_{\mu,id}}{d\mathbf{P}_{\tilde\mu,id}}(\boldsymbol{X},\boldsymbol{X}^\sharp)&=\mathbf{E}_\mu\bigg[\frac{d\mathbf{P}_{\theta_1,\sigma_1}}{d\mathbf{P}_{0,\sigma_1}}(X_1)\frac{d\mathbf{P}_{\theta_2,\sigma_2}}{d\mathbf{P}_{0,\sigma_2}}(X_2)\frac{d\mathbf{P}_{\theta_1,\sigma_1}}{d\mathbf{P}_{0,\sigma_1}}(X_1^\sharp)\frac{d\mathbf{P}_{\theta_2,\sigma_2}}{d\mathbf{P}_{0,\sigma_2}}(X_2^\sharp)\bigg]\\ &=\mathbf{E}_\mu\bigg[\frac{d\mathbf{P}_{\theta_1,\sigma_1}}{d\mathbf{P}_{0,\sigma_1}}(X_1)\frac{d\mathbf{P}_{\theta_1,\sigma_1}}{d\mathbf{P}_{0,\sigma_1}}(X_1^\sharp)\bigg]\times\mathbf{E}_\mu\bigg[\frac{d\mathbf{P}_{\theta_2,\sigma_2}}{d\mathbf{P}_{0,\sigma_2}}(X_2)\frac{d\mathbf{P}_{\theta_2,\sigma_2}}{d\mathbf{P}_{0,\sigma_2}}(X_2^\sharp)\bigg]\\ &=\prod_{k=1}^d\cosh\Big(\frac{\epsilon_1}{\sigma_1^2}(X_{1,k}+X_{1,k}^\sharp)\Big)\cosh\Big(\frac{\epsilon_2}{\sigma_2^2}(X_{2,k}+X_{2,k}^\sharp)\Big).\end{aligned}$$

Thus, we get that

$$\begin{aligned}\frac{d\mathbf{P}_{\mu,\pi}}{d\mathbf{P}_{\mu,id}}(\boldsymbol{X},\boldsymbol{X}^\sharp)&=\prod_{k=1}^d\frac{\cosh\big(\frac{\epsilon_1}{\sigma_1^2}(X_{1,k}+X_{2,k}^\sharp)\big)}{\cosh\big(\frac{\epsilon_1}{\sigma_1^2}(X_{1,k}+X_{1,k}^\sharp)\big)}\times\prod_{k=1}^d\frac{\cosh\big(\frac{\epsilon_2}{\sigma_2^2}(X_{2,k}+X_{1,k}^\sharp)\big)}{\cosh\big(\frac{\epsilon_2}{\sigma_2^2}(X_{2,k}+X_{2,k}^\sharp)\big)}\\ &\quad\times\exp\Big\{-\frac{1}{2}(\|X_1^\sharp\|^2-\|X_2^\sharp\|^2)(\sigma_2^{-2}-\sigma_1^{-2})\Big\}.\end{aligned}$$

Then, we compute the Kullback-Leibler divergence,

$$\begin{aligned}K(\mathbf{P}_{\mu,\pi},\mathbf{P}_{\mu,id})&=\int\log\Big(\frac{d\mathbf{P}_{\mu,\pi}}{d\mathbf{P}_{\mu,id}}(\boldsymbol{X},\boldsymbol{X}^\sharp)\Big)d\mathbf{P}_{\mu,\pi}(\boldsymbol{X},\boldsymbol{X}^\sharp)\\ &=\sum_{k=1}^d\sum_{j=1}^2\bigg\{\mathbf{E}_\mu\Big[\int\log\cosh\Big[\frac{\epsilon_j}{\sigma_j^2}(2\theta_{j,k}+\sigma_j\sqrt{2}x)\Big]\varphi(x)dx\Big]\\ &\quad-\mathbf{E}_\mu\Big[\int\log\cosh\Big[\frac{\epsilon_j}{\sigma_j^2}(\theta_{1,k}+\theta_{2,k}+\sigma_{12}x)\Big]\varphi(x)dx\Big]\bigg\}\\ &\quad+\frac{d}{2}\mathbf{E}_\mu\Big[\int_{\mathbb{R}}((\theta_{1,1}+\sigma_1x)^2-(\theta_{2,1}+\sigma_2x)^2)\varphi(x)\,dx\Big](\sigma_2^{-2}-\sigma_1^{-2}),\end{aligned}$$

where φ is the density function of the standard Gaussian distribution. We evaluate the first two terms of the last display using the following inequalities:

$$\forall u\in\mathbb{R},\qquad\frac{u^2}{2}-\frac{u^4}{12}\le\log\cosh(u)\le\frac{u^2}{2},\tag{25}$$

while for the third term the exact computation yields:

$$\begin{aligned}\mathbf{E}_\mu\Big[\int_{\mathbb{R}}((\theta_{1,1}+\sigma_1x)^2-(\theta_{2,1}+\sigma_2x)^2)\varphi(x)\,dx\Big]&=\epsilon_1^2+\sigma_1^2-\epsilon_2^2-\sigma_2^2\\ &=(\sigma_1^2-\sigma_2^2)(1+(2/d)\kappa^2).\end{aligned}$$

In conjunction with the facts that $\epsilon_1/\sigma_1 = \epsilon_2/\sigma_2$, $\sigma_1 \le \sigma_2$ and $\epsilon_1 \le \epsilon_2$, this leads to

$$\begin{aligned}
&\mathbf{E}_\mu\biggl[\int \log\cosh\Bigl[\frac{\epsilon_j}{\sigma_j^2}(2\theta_{j,k}+\sigma_j\sqrt{2}x)\Bigr]\varphi(x)dx \le \frac{\epsilon_j^2}{\sigma_j^2}+2\frac{\epsilon_j^4}{\sigma_j^4} = \frac{\epsilon_2^2}{\sigma_2^2}+2\frac{\epsilon_2^4}{\sigma_2^4},\\
&\mathbf{E}_\mu\biggl[\int \log\cosh\Bigl[\frac{\epsilon_j}{\sigma_j^2}(\theta_{1,k}+\theta_{2,k}+\sigma_{1,2}x)\Bigr]\varphi(x)dx\biggr]\\
&\quad\ge \frac{\epsilon_j^2}{2\sigma_j^4}\Bigl(\epsilon_1^2+\epsilon_2^2+\sigma_1^2+\sigma_2^2\Bigr)\\
&\qquad -\frac{\epsilon_j^4}{12\sigma_j^8}\Bigl(\epsilon_1^4+\epsilon_2^4+3(\sigma_1^2+\sigma_2^2)^2+6\epsilon_1^2\epsilon_2^2+6(\sigma_1^2+\sigma_2^2)(\epsilon_1^2+\epsilon_2^2)\Bigr)\\
&\quad\ge \frac{\epsilon_2^2(\epsilon_1^2+\sigma_1^2)}{\sigma_2^4}-\frac{\epsilon_1^4(\epsilon_2^2+\sigma_2^2)^2}{\sigma_1^8}.
\end{aligned}$$

Thus, we get that

$$\begin{aligned}
(1/d)K(\mathbf{P}_{\mu,\pi},\mathbf{P}_{\mu,id}) &\le \frac{2\epsilon_2^2}{\sigma_2^2}+\frac{4\epsilon_2^4}{\sigma_2^4}-\frac{2\epsilon_2^2(\epsilon_1^2+\sigma_1^2)}{\sigma_2^4}+\frac{2\epsilon_1^4(\epsilon_2^2+\sigma_2^2)^2}{\sigma_1^8}\\
&\quad+\frac{1}{2}\bigl(1+(2/d)\kappa^2\bigr)(\sigma_1^2-\sigma_2^2)(\sigma_2^{-2}-\sigma_1^{-2})\\
&\le \frac{4\kappa^2}{d}\Bigl(1-\frac{\sigma_1^2}{\sigma_2^2}\Bigr)+\frac{16\kappa^4}{d^2}+\frac{8\kappa^4}{d^2}\bigl(1+(2/d)\kappa^2\bigr)^2\frac{\sigma_2^4}{\sigma_1^4}\\
&\quad+\frac{1}{2}\bigl(1+(2/d)\kappa^2\bigr)\Bigl(\frac{\sigma_2^2}{\sigma_1^2}-1\Bigr)^2.
\end{aligned}$$

To complete the proof, we need to evaluate $\mu(\mathcal{E}\setminus\bar\Theta_\kappa)$. We note that in view of the union bound,

$$\begin{aligned}
\mu(\mathcal{E}\setminus\bar\Theta_\kappa) &= \mu\Bigl(\bigcup_{k=1}^n\bigcup_{k'\ne k}\{\boldsymbol{\theta}:\|\theta_k-\theta_{k'}\|<\kappa\sigma_{k,k'}\}\Bigr)\\
&\le \frac{n(n-1)}{2}\max_{k\ne k'}\mu\bigl(\{\boldsymbol{\theta}:\|\theta_k-\theta_{k'}\|^2<\kappa^2\sigma_{k,k'}\}\bigr)\\
&= \frac{n(n-1)}{2}\max_{k\ne k'}\mathbf{P}\bigl(d\epsilon_k^2+d\epsilon_{k'}^2-2d\epsilon_k\epsilon_{k'}\bar\zeta<\kappa^2\sigma_{k,k'}^2\bigr),
\end{aligned}$$

where $\bar\zeta=\frac{1}{d}\sum_{j=1}^d\zeta_j$ with $\zeta_1,\dots,\zeta_d$ being i.i.d. Rademacher random variables (*i.e.*, random variables taking the values $+1$ and -1 with probability $1/2$). One easily checks that

$$\frac{d\epsilon_k^2+d\epsilon_{k'}^2-\kappa^2\sigma_{k,k'}^2}{2d\epsilon_k\epsilon_{k'}} = \frac{2\sigma_k^2+2\sigma_{k'}^2-(\sigma_k^2+\sigma_{k'}^2)}{4\sigma_k\sigma_{k'}} \ge \frac{1}{2}.$$

Therefore, using the Hoeffding inequality, we get $\mu(\mathcal{E}\setminus\bar\Theta_\kappa)\le\frac{1}{2}n(n-1)\mathbf{P}\bigl(\bar\zeta>1/2\bigr)\le\frac{1}{2}n(n-1)e^{-d/8}$.

Proof of Lemma 16 We first prove an auxiliary result.

Lemma 17 *For any integer $n\ge 2$ there exist permutations $\pi_0,\pi_1,\dots,\pi_M$ in $\mathfrak{S}_n$ such that*

$$\pi_0 = id, \qquad M\ge (n/8)^{n/2}$$

and for any pair $i,j\in\{0,\dots,M\}$ of distinct indices we have $\delta_H(\pi_i,\pi_j)\ge\frac{1}{2}$.

Proof When $n\le 8$, the claim of this lemma is trivial since one can always find at least one permutation that differs from the identity at all the positions and thus $M\ge 1\ge(n/8)^{n/2}$. Let us consider the case $n>8$. For every $\pi\in\mathfrak{S}_n$, denote

$$E_\pi \triangleq \Bigl\{\pi'\in\mathfrak{S}_n\,\Big|\,\frac{1}{n}\sum_{i=1}^n\mathbb{1}_{\{\pi(i)\ne\pi'(i)\}}\ge 1/2\Bigr\}.$$

We first notice that for every $\pi\in\mathfrak{S}_n$, there is a one-to-one correspondence between E_{id} and E_π through the bijection

$$\phi:\left|\begin{array}{ccc} E_{id} & \longrightarrow & E_\pi\\ \pi' & \longmapsto & \pi\circ\pi'\end{array}\right.,$$

so that $\#E_\pi=\#E_{id}$. The following lemma, proved later on in this section, gives a bound for this number.

Lemma 18 *Let $n\ge 2$ be an integer and m be the smallest integer such that $2m\ge n$. Then*

$$\#E_{id}^{\complement}\le\frac{4n!}{m!}.$$

Now we denote $\pi_0=id$ and choose π_1 in E_{id}. Then, it is sufficient to choose π_2 as any element from $E_{id}\cap E_{\pi_1}$, the latter set being nonempty since

$$\begin{aligned}
\#\bigl(E_{\pi_0}\cap E_{\pi_1}\bigr) &\ge \#\mathfrak{S}_n-\#E_{\pi_0}^{\complement}-\#E_{\pi_1}^{\complement}\\
&\ge n!\times\Bigl(1-\frac{8}{m!}\Bigr)>0.
\end{aligned}$$

We can continue the construction until π_i if

$$1-\frac{4i}{m!}>0 \qquad\Longleftrightarrow\qquad i<\frac{m!}{4}.$$

To conclude, we observe that

$$\frac{m!}{4}>\frac{1}{4}\Bigl(\frac{n}{2e}\Bigr)^{n/2}\ge\Bigl(\frac{n}{8}\Bigr)^{n/2}.$$

■

Let us denote by m the largest integer such that $2m\le n$, and choose

$$\tilde\pi_0,\tilde\pi_1,\dots,\tilde\pi_M\in\mathfrak{S}_m \quad\text{with}\quad M\ge(m/8)^{m/2}$$

as in Lemma 17, so that for every $i\ne j\in\{0,\dots,M\}$, $\delta_H(\tilde\pi_i,\tilde\pi_j)\ge\frac{1}{2}$. We use each permutation $\tilde\pi_i\in\mathfrak{S}_m$ to construct a permutation $\pi_i\in\mathfrak{S}_n$. The idea of the construction

is as follows: the permutation π_i is a product of m transpositions of distinct supports, and each transposition permutes an even integer with an odd one. We set $\pi_0 = id$ and for every i in $\{1, \dots, M\}$,

$$\pi_i = \big(1\ 2\tilde{\pi}_i(1)\big) \circ \big(3\ 2\tilde{\pi}_i(2)\big) \circ \ldots \circ \big(2m-1\ 2\tilde{\pi}_i(m)\big) \in \mathfrak{S}_n.$$

With these choices, the number of differences between π_i and π_j is exactly twice as much as the number of differences between $\tilde{\pi}_i$ and $\tilde{\pi}_j$. To sum up, for every pair of distinct indices $i, j \in \{0, \dots, M\}$,

$$\frac{1}{n}\sum_{k=1}^{n} \mathbb{1}_{\{\pi_i(k)\neq\pi_j(k)\}} = \frac{2m}{n} \times \frac{1}{m}\sum_{k=1}^{m} \mathbb{1}_{\{\tilde{\pi}_i(k)\neq\tilde{\pi}_j(k)\}} \geq \frac{m}{n} \geq \frac{3}{8}, \qquad \forall n \geq 4.$$

To complete the proof, we note that $m \geq n/3$.

Proof of Lemma 18 For every $\ell \in \{m, \dots, n\}$, counting all the permutations π such that $\sum_{k=1}^{n} \mathbb{1}_{\{\pi(k)\neq k\}} = \ell$, we get

$$\#E_{id} = !n + !(n-1)\binom{n}{1} + \ldots + !(n-m)\binom{n}{m},$$

where $!\ell$ is the number of derangements, the permutations such that none of the elements appear in their original position, in $\mathfrak{S}_\ell$ for $\ell \geq 1$. We know that

$$\forall\ \ell \geq 1, \qquad !\ell = \ell! \times \sum_{j=0}^{\ell} \frac{(-1)^j}{j!},$$

which, using the alternating series test, yields

$$\forall\ \ell \geq 1, \qquad !\ell \geq \ell! \times \Big(e^{-1} - \frac{1}{(\ell+1)!}\Big).$$

It follows that

$$\begin{aligned}
\#E_{id} &\geq n! \times \Big(e^{-1} - \frac{1}{(n-m+1)!}\Big) \times \Big(1 + \frac{1}{1!} + \ldots + \frac{1}{m!}\Big) \\
&\geq n! \times \Big(e^{-1} - \frac{1}{(n-m+1)!}\Big) \times \Big(e - \frac{e}{(m+1)!}\Big) \\
&\geq n! \times \Big(1 - \frac{e}{(n-m+1)!} - \frac{1}{(m+1)!}\Big).
\end{aligned}$$

Therefore,

$$\#E_{id}^{\complement} \leq n! \times \Big(\frac{e}{(n-m+1)!} + \frac{1}{(m+1)!}\Big) \leq \frac{4n!}{m!}.$$

Abstract

Applying standard Markov chain Monte Carlo (MCMC) algorithms to large data sets is computationally expensive. Both the calculation of the acceptance probability and the creation of informed proposals usually require an iteration through the whole data set. The recently proposed stochastic gradient Langevin dynamics (SGLD) method circumvents this problem by generating proposals which are only based on a subset of the data, by skipping the accept-reject step and by using decreasing step-sizes sequence $(\delta_m)_{m\geq 0}$.

We provide in this article a rigorous mathematical framework for analysing this algorithm. We prove that, under verifiable assumptions, the algorithm is consistent, satisfies a central limit theorem (CLT) and its asymptotic bias-variance decomposition can be characterized by an explicit functional of the step-sizes sequence $(\delta_m)_{m\geq 0}$. We leverage this analysis to give practical recommendations for the notoriously difficult tuning of this algorithm: it is asymptotically optimal to use a step-size sequence of the type $\delta_m \asymp m^{-1/3}$, leading to an algorithm whose mean squared error (MSE) decreases at rate $\mathcal{O}(m^{-1/3})$.

Keywords: Markov chain Monte Carlo, Langevin dynamics, big data

1. Introduction

We are entering the age of Big Data, where significant advances across a range of scientific, engineering and societal pursuits hinge upon the gain in understanding derived from the analyses of large scale data sets. Examples include recent advances in genome-wide association studies (Hirschhorn and Daly, 2005; McCarthy et al., 2008; Wang et al., 2005), speech recognition (Hinton et al., 2012), object recognition (Krizhevsky et al., 2012), and self-driving cars (Thrun, 2010). As the quantity of data available has been outpacing the computational resources available in recent years, there is an increasing demand for new scalable learning methods, for example methods based on stochastic optimization (Robbins and Monro, 1951a; Srebro and Tewari, 2010; Sato, 2001; Hoffman et al., 2010), distributed computational architectures (Ahmed et al., 2012; Neiswanger et al., 2013; Minsker et al., 2014), greedy optimization (Harchaoui and Jaggi, 2014), as well as the development of specialized computing systems supporting large scale machine learning applications (Gonzalez, 2014).

Recently, there has also been increasing interest in methods for Bayesian inference scalable to Big Data settings. Rather than attempting a single point estimate of parameters typical in optimization-based or maximum likelihood settings, Bayesian methods attempt to obtain characterizations of the full posterior distribution over the unknown parameters and latent variables in the model, hence providing better characterizations of the uncertainties inherent in the learning process, as well as providing protection against overfitting. Scalable Bayesian methods proposed in the recent literature include stochastic variational inference (Sato, 2001; Hoffman et al., 2010), which applies stochastic approximation techniques to optimizing a variational approximation to the posterior, parallelized Monte Carlo (Neiswanger et al., 2013; Minsker et al., 2014), which distributes the computations needed for Monte Carlo sampling across a large compute cluster, as well as subsampling-based Monte Carlo (Welling and Teh, 2011; Ahn et al., 2012; Korattikara et al., 2014), which attempt to reduce the computational complexity of Markov chain Monte Carlo (MCMC) methods by applying updates to small subsets of data.

In this paper we study the asymptotic properties of the stochastic gradient Langevin dynamics (SGLD) algorithm first proposed by Welling and Teh (2011). SGLD is a subsampling-based MCMC algorithm based on combining ideas from stochastic optimization, specifically using small subsets of data to estimate gradients, with Langevin dynamics, a MCMC method making use of gradient information to produce better parameter updates. Welling and Teh (2011) demonstrated that SGLD works well on a variety of models and this has since been extended by Ahn et al. (2012, 2014) and Patterson and Teh (2013b).

The stochastic gradients in SGLD introduce approximations into the Markov chain, whose effect has to be controlled by using a slowly decreasing sequence of step sizes. Welling and Teh (2011) provided an intuitive argument that as the step-size decreases the variations introduced by the stochastic gradients gets dominated by the natural stochasticity of Langevin dynamics, the result being that the stochastic gradient approximation should wash out asymptotically and that the Markov chain should converge to the true posterior distribution.

In this paper, we make this intuitive argument more precise by providing conditions under which SGLD converges to the targeted posterior distribution; we describe a number of characterizations of this convergence. Specifically, we show that estimators derived from SGLD are consistent (Theorem 7) and satisfy a central limit theorem (CLT) (Theorem 8); the bias-variance trade-off of the algorithm is discussed in details in Section 5. In Section 6 we prove that, when observed on the right (inhomogeneous) time scale, the sample path of the algorithm converges to a Langevin diffusion (Theorem 9).

Our analysis reveals that for a sequence of step-sizes with algebraic decay $\delta_m \asymp m^{-\alpha}$ the optimal choice, when measured in terms of rate of decay of the mean squared error (MSE), is given for $\alpha_\star = 1/3$; the choice $\delta_m \asymp m^{-\alpha_\star}$ leads to an algorithm that converges at rate $\mathcal{O}(m^{-1/3})$. This rate of convergence is worse than the standard Monte-Carlo $m^{-1/2}$-rate of convergence. This is not due to the stochastic gradients used in SGLD, but rather to the decreasing step-sizes.

These results are asymptotic in the sense that they characterise the behaviour of the algorithm as the number of steps approaches infinity. Therefore they do not necessarily translate into any insight into the behaviour for finite computational budgets which is the regime in which the SGLD might provide computational gains over alternatives. The mathematical framework described in this article show that the SGLD is a sound algorithm, an important result that has been missing in the literature.

In the remainder of this article, the notation $\mathrm{N}(\mu, \sigma^2)$ denotes a Gaussian distribution with mean μ and variance σ^2. For two positive functions $f, g : \mathbb{R} \to [0, \infty)$, one writes $f \lesssim g$ to indicate that there exists a positive constant $C > 0$ such that $f(\theta) \leq C\, g(\theta)$; we write $f \asymp g$ if $f \lesssim g \lesssim f$. For a probability measure π on a measured space $\mathcal{X}$, a measurable function $\varphi : \mathcal{X} \to \mathbb{R}$ and a measurable set $A \subset \mathcal{X}$, we define $\pi(\varphi; A) = \int_{\theta \in A} \varphi(\theta)\, \pi(d\theta)$ and $\pi(\varphi) = \pi(\varphi; \mathcal{X})$. Finally, densities of probability distributions on $\mathbb{R}^d$ are implicitly assumed to be defined with respect to the usual d-dimensional Lebesgue measure.

2. Stochastic Gradient Langevin Dynamics

Many MCMC algorithms evolving in a continuous state space, say $\mathbb{R}^d$, can be realised as discretizations of a continuous time Markov process $(\theta_t)_{t \geq 0}$. An example of such a continuous time process, which is central to SGLD as well as many other algorithms, is the Langevin diffusion, which is given by the stochastic differential equation

$$d\theta_t = \frac{1}{2} \nabla \log \pi(\theta_t)\, dt + dW_t, \tag{1}$$

where $\pi : \mathbb{R}^d \to (0, \infty)$ is a probability density and $(W_t)_{t \geq 0}$ is a standard Brownian motion in $\mathbb{R}^d$. The linear operator $\mathcal{A}$ denotes the generator of the Langevin diffusion (1): for a twice continuously differentiable test function $\varphi : \mathbb{R}^d \to \mathbb{R}$,

$$\mathcal{A}\varphi(\theta) = \frac{1}{2} \langle \nabla \log \pi(\theta), \nabla \varphi(\theta) \rangle + \frac{1}{2} \Delta \varphi(\theta), \tag{2}$$

where $\Delta\varphi \stackrel{\text{def}}{=} \sum_{i=1}^d \nabla_i^2 \varphi$ denotes the standard Laplacian operator. The motivation behind the choice of Langevin diffusions is that, under certain conditions, they are ergodic with respect to the distribution π; for example, (Roberts and Tweedie, 1996; Stramer and Tweedie, 1999a,b; Mattingly et al., 2002) describe drift conditions of the type described in Section 3.2 that ensure that the total variation distance from stationarity of the law at time t of the Langevin diffusion (1) decreases to zero exponentially quickly as $t \to \infty$.

Given a time-step $\delta > 0$ and a current position θ_t, it is often straightforward to simulate a random variable $\theta_\star$ that is approximately distributed as the law of $\theta_{t+\delta}$ given θ_t. For

stochastic differential equations, the Euler-Maruyama scheme (Maruyama, 1955) might be the simplest approach for approximating the law of $\theta_{t+\delta}$. For a Langevin diffusion this reads

$$\theta_\star = \theta_t + \frac{1}{2} \delta \nabla \log \pi(\theta_t) + \delta^{1/2}\, \eta \tag{3}$$

for a standard d-dimensional centred Gaussian random variable η. To fully correct the discretization error, one can adopt a Metropolis-Hastings accept-reject mechanism. The resulting algorithm is usually referred to as the Metropolis-Adjusted-Langevin algorithm (MALA) (Roberts and Tweedie, 1996). Other discretizations can be used as proposals. For example, the random walk Metropolis-Hastings algorithm uses the discretization of a standard Brownian motion as the proposal, while the Hamiltonian Monte Carlo (HMC) algorithm (Duane et al., 1987) is based on discretizations of an Hamiltonian system of differential equations. See the excellent review of Neal (2010) for further information.

In this paper, we shall consider the situation where the target π is the density of the posterior distribution under a Bayesian model where there are $N \gg 1$ i.i.d. observations, the so called Big Data regime,

$$\pi(\theta) \propto \mathrm{p}_0(\theta) \prod_{i=1}^N \mathrm{p}\left(y_i \,|\, \theta\right). \tag{4}$$

Here, both computing the gradient term $\nabla \log \pi(\theta_t)$ and evaluating the Metropolis-Hastings acceptance ratio require a computational budget that scales unfeasibly as $\mathcal{O}(N)$. One approach is to use a standard random walk proposal instead of Langevin dynamics, and to efficiently approximating the Metropolis-Hastings accept-reject mechanism using only a subset of the data (Korattikara et al., 2014; Bardenet et al., 2014).

This paper is concerned with stochastic gradient Langevin dynamics (SGLD), an alternative approach proposed by Welling and Teh (2011). This follows the opposite route and chooses to completely avoid the computation of the Metropolis-Hastings ratio. By choosing a discretization of the Langevin diffusion (1) with a sufficiently small step-size $\delta \ll 1$, because the Langevin diffusion is ergodic with respect to π, the hope is that even if the Metropolis-Hastings accept-reject mechanism is completely avoided, the resulting Markov chain still has an invariant distribution that is close to π. Choosing a decreasing sequence of step-sizes $\delta_m \to 0$ should even allow us to converge to the exact posterior distribution. To further make this approach viable in large N settings, the gradient term $\nabla \log \pi(\theta)$ can be further approximated using a subsampling strategy. For an integer $1 \leq n \leq N$ and a random subset $\tau \stackrel{\text{def}}{=} (\tau_1, \ldots, \tau_n)$ of $[N] \equiv \{1, \ldots, N\}$ generated by sampling with or without replacement from $[N]$, the quantity

$$\nabla \log \mathrm{p}_0(\theta) + \frac{N}{n} \sum_{i=1}^n \nabla \log \mathrm{p}(x_{\tau_i} \mid \theta) \tag{5}$$

is an unbiased estimator of $\nabla \log \pi(\theta)$. Most importantly, this stochastic estimate can be computed with a computational budget that scales as $\mathcal{O}(n)$ with n potentially much smaller than N. Indeed, the larger the quotient n/N, the smaller the variance of this estimate.

Stochastic gradient methods have a long history in optimisation and machine learning and are especially relevant in the large dataset regime considered in this article (Robbins

and Monro, 1951b; Bottou, 2010; Hoffman et al., 2013). In this paper we will adopt a slightly more general framework and assume that one can compute an unbiased estimate $\widehat{\nabla \log \pi}(\theta, \mathcal{U})$ to the gradient $\nabla \log \pi(\theta)$, where $\mathcal{U}$ is an auxiliary random variable which contains all the randomness involved in constructing the estimate. Without loss of generality we may assume (although this is unnecessary) that $\mathcal{U}$ is uniform on $(0,1)$. The unbiasedness of the estimator $\widehat{\nabla \log \pi}(\theta, \mathcal{U})$ means that

$$\mathbf{E}\left[H(\theta, \mathcal{U})\right] = 0 \qquad \text{with} \qquad H(\theta, \mathcal{U}) \stackrel{\text{def}}{=} \widehat{\nabla \log \pi}(\theta, \mathcal{U}) - \nabla \log \pi(\theta). \tag{6}$$

In summary, the SGLD algorithm can be described as follows. For a sequence of asymptotically vanishing time-steps $(\delta_m)_{m \geq 0}$ and an initial parameter $\theta_0 \in \mathbb{R}^d$, if the current position is θ_{m-1}, the next position θ_m is defined though the recursion

$$\theta_m = \theta_{m-1} + \frac{1}{2} \delta_m \widehat{\nabla \log \pi}(\theta_{m-1}, \mathcal{U}_m) + \delta_m^{1/2} \eta_m \tag{7}$$

for an i.i.d. sequence $\eta_m \sim \mathrm{N}(0, I_d)$, and an independent and i.i.d. sequence $\mathcal{U}_m$ of auxiliary random variables. This is the equivalent of the Euler-Maruyama discretization (3) of the Langevin diffusion (1) with a decreasing sequence of step-sizes and a stochastic estimate to the gradient term. The analysis presented in this article assumes for simplicity that the initial position θ_0 of the algorithm is deterministic; in the simulation study of Section 7, the algorithms are started at the MAP estimator. Indeed, more general situations could be analysed with similar arguments at the cost of slightly less transparent proofs. Note that the process $(\theta_m)_{m \geq 0}$ is a non-homogeneous Markov chain, and many standard analysis techniques for homogeneous Markov chains do not apply.

For a test function $\varphi : \mathbb{R}^d \to \mathbb{R}$, the expectation of φ with respect to the posterior distribution π can be approximated by the weighted sum

$$\pi_m(\varphi) \stackrel{\text{def}}{=} \frac{\delta_1 \varphi(\theta_0) + \ldots + \delta_m \varphi(\theta_{m-1})}{T_m} \tag{8}$$

with $T_m = \delta_1 + \ldots + \delta_m$. The quantity $\pi_m(\varphi)$ thus approximates the ergodic average $T_m^{-1} \int_0^{T_m} \varphi(\theta_t)\, dt$ between time zero and $t = T_m$. During the course of the proof of our fluctuation Theorem 8, we will need to consider more general averaging schemes than the one above. Instead, for a general positive sequence of weights $\omega = (\omega_m)_{m \geq 1}$, we define the ω-weighted sum

$$\pi_m^{\omega}(\varphi) \stackrel{\text{def}}{=} \frac{\omega_1 \varphi(\theta_0) + \ldots + \omega_m \varphi(\theta_{m-1})}{\Omega_m} \tag{9}$$

with $\Omega_m \stackrel{\text{def}}{=} \omega_1 + \ldots + \omega_m$. Indeed, $\pi_m^{\omega}(\varphi) = \pi_m(\varphi)$ in the particular case $(\omega_m)_{m \geq 1} = (\delta_m)_{m \geq 1}$; we will consider the weight sequence $\omega = \{\delta_m^2\}_{m \geq 1}$ in the proof of Theorem 8.

Let us mention several directions that can be explored to improve upon the basic SGLD algorithm explored in this paper. Langevin diffusions of the type $d\theta_t = \mathrm{drift}(\theta_t)\, dt + M(\theta_t)\, dW_t$, reversible with respect to the posterior distribution π, can be constructed for various choices of positive definite volatility matrix function $M : \mathbb{R}^d \to \mathbb{R}^{d,d}$. Note nonetheless that, for a non-constant volatility matrix function $\theta \mapsto M(\theta)$, the drift term typically

involves derivatives of M. Concepts of information geometry (Amari and Nagaoka, 2007) give principled ways (Livingstone and Girolami, 2014) of choosing the volatility matrix function M; when the Fisher information matrix is used, this leads to the Riemannian manifold MALA algorithm (Girolami and Calderhead, 2011). This approach has recently been applied to the Latent Dirichlet Allocation model for topic modelling (Patterson and Teh, 2013a). For high-dimensional state spaces $d \gg 1$, one can use a constant volatility function M, also known in this case as the preconditioning matrix, for taking into account the information contained in the prior distribution p_0 in the hope of obtaining better mixing properties (Beskos et al., 2008; Cotter et al., 2013); infinite dimensional limits are obtained in (Pillai et al., 2012; Hairer et al., 2014). Under an uniform-ellipticity condition and a growth assumption on the volatility matrix function $M : \mathbb{R}^d \to \mathbb{R}^{d,d}$, we believe that our framework could, at the cost of increasing complexity in the proofs, be extended to this setting. To avoid the slow random walk behaviour of Markov chains based on discretization of reversible diffusion processes, one can use instead discretizations of an Hamiltonian system of ordinary differential equations (Duane et al., 1987; Neal, 2010); when coupled with the stochastic estimates to the gradient above described, this leads to the stochastic gradient Hamiltonian Monte Carlo algorithm of (Chen et al., 2014).

In the rest of this paper, we will build a rigorous framework for understanding the properties of this SGLD algorithm, demonstrating that the heuristics and numerical evidences presented in Welling and Teh (2011) were indeed correct.

3. Assumptions and Stability Analysis

This section starts with the basics assumptions we will need for the asymptotic results to follow, and illustrates some of the potential stability issues that may occur, would the SGLD algorithm be applied without care.

3.1 Basic Assumptions

Throughout this text, we assume that the sequence of step-sizes $\delta = (\delta_m)_{m \geq 1}$ satisfies the following usual assumption.

Assumption 1 *The step-sizes $\delta = (\delta_m)_{m \geq 1}$ form a decreasing sequence with*

$$\lim_{m \to \infty} \delta_m = 0 \qquad \textit{and} \qquad \lim_{m \to \infty} T_m = \infty.$$

Indeed, this assumption is easily seen to also be necessary for the Law of Large Numbers of Section 4 to hold. Furthermore, we will need at several occasions to assume the following assumption on the oscillations of a sequence of step-sizes $(\omega_m)_{m \geq 1}$.

Assumption 2 *The step-sizes sequence $(\omega_m)_{m \geq 1}$ is such that $\omega_m \to 0$ and $\Omega_m \to \infty$ and*

$$\lim_{m \to \infty} \sum_{m \geq 1} \left| \Delta(\omega_m / \delta_m) \right| / \Omega_m < \infty \qquad \textit{and} \qquad \sum_{m \geq 1} \omega_m^2 / [\delta_m \Omega_m^2] < \infty.$$

where $\Delta(\omega_m/\delta_m) \stackrel{\text{def}}{=} \omega_{m+1}/\delta_{m+1} - \omega_m/\delta_m$.

Remark 3 *Assumption 2 holds if $\delta = (\delta_m)_{m\geq 1}$ satisfies Assumption (1) and the weights are defined as $\omega_m = \delta_m^p$, for some some exponent $p \geq 1$ small enough for $\Omega_m \to \infty$. This is because the first sum is less than $\sum_{m\geq 1} \left|\Delta(\omega_m/\delta_m)\right|/\Omega_1 = \delta_1^{p-1}/\Omega_1$, while the finiteness of the second sum can be seen as follows:*

$$\begin{aligned}\sum_{m\geq 1} \omega_m^2/\left(\delta_m \Omega_m^2\right) &\lesssim 1 + \sum_{m\geq 2} \left(\omega_m/\delta_m\right)^2 \left(1/\Omega_{m-1} - 1/\Omega_m\right) \\ &\lesssim 1 + \sum_{m\geq 2} \left(1/\Omega_{m-1} - 1/\Omega_m\right) = 1 + 1/\Omega_1.\end{aligned}$$

For any exponents $0 < \alpha < 1$ and $0 < p < 1/\alpha$ the sequences $\delta_m = (m_0 + m)^{-\alpha}$ and $\omega_m = \delta_m^p$ satisfy both Assumption 1 and Assumption 2.

3.2 Stability

Under assumptions on the tails of the posterior density π, the Langevin diffusion (1) is non-explosive and for any starting position $\theta_0 \in \mathbb{R}^d$ the total-variation distance $d_{\mathrm{TV}}\big(\mathbf{P}(\theta_t \in \cdot), \pi\big)$ converges to zero as $t \to \infty$. For instance, Theorem 2.1 of (Roberts and Tweedie, 1996) shows that it is sufficient to assume that the drift term satisfies the condition $(1/2)\left\langle \nabla \log \pi(\theta), \theta \right\rangle \leq \alpha\|\theta\|^2 + \beta$ for some constants $\alpha, \beta > 0$. We refer the interested reader to (Roberts and Tweedie, 1996; Stramer and Tweedie, 1999a,b; Roberts and Stramer, 2002; Mattingly et al., 2002) for a detailed study of the convergence properties of the Langevin diffusion (1).

Unfortunately, stability of the continuous time Langevin diffusion does not always translate into good behaviour for its Euler-Maruyama discretization. For example, even if the drift term points towards the right direction in the sense that $\langle \nabla \log \pi(\theta), \theta \rangle < 0$ for every parameter θ, it might happen that the magnitude of the drift term is too large so that the Euler-Maruyama discretization *overshoots* and becomes unstable. In a one dimensional setting, this would lead to a Markov chain that diverges in the sense that the sequence $(\theta_m)_{m\geq 0}$ alternates between taking arbitrarily large positive and negative values. Lemma 6.3 of (Mattingly et al., 2002) gives such an example with a target density $\pi(\theta) \propto \exp\{-\theta^4\}$. See also Theorem 3.2 of (Roberts and Tweedie, 1996) for examples of the same flavours.

Guaranteeing stability of the Euler-Maruyama discretization requires stronger Lyapunov type conditions. At a heuristic level, one must ensure that the drift term $\nabla \log \pi(\theta)$ points towards the centre of the state space. In addition, the previous discussion indicates that one must also ensure that the magnitude of this drift term is not too large. The following assumptions satisfy both heuristics, and we will show are enough to guarantee that the SGLD algorithm is consistent, with asymptotically Gaussian fluctuations.

Assumption 4 *The drift term $\theta \mapsto \frac{1}{2}\nabla \log \pi(\theta)$ is continuous. There exists a Lyapunov function $V : \mathbb{R}^d \to [1, \infty)$ that tends to infinity as $\|\theta\| \to \infty$, is twice differentiable with bounded second derivatives, and satisfies the following conditions.*

1. *There exists an exponent $p_H \geq 2$ such that*

$$\mathbf{E}\left[\left\|H(\theta, \mathcal{U})\right\|^{2p_H}\right] \lesssim V^{p_H}(\theta). \tag{10}$$

This implies that $\mathbf{E}\left[\left\|H(\theta,\mathcal{U})\right\|^{2p}\right] \lesssim V^p(\theta)$ for any exponent $0 \leq p \leq p_H$.

2. *For every $\theta \in \mathbb{R}^d$ we have*

$$\left\|\nabla V(\theta)\right\|^2 + \left\|\nabla \log \pi(\theta)\right\|^2 \lesssim V(\theta). \tag{11}$$

3. *There are constants $\alpha, \beta > 0$ such that for every $\theta \in \mathbb{R}^d$ we have*

$$\frac{1}{2}\left\langle \nabla V(\theta), \nabla \log \pi(\theta) \right\rangle \leq -\alpha V(\theta) + \beta. \tag{12}$$

Equation (12) ensures that on average the drift term $\widehat{\nabla \log \pi}(\theta)$ points towards the centre of the state space, while equations (10) and (11) provide control on the magnitude of the (stochastic) drift term. The drift condition (12) implies in particular that the Langevin diffusion (1) converges exponentially quickly towards the equilibrium distribution π (Mattingly et al., 2002; Roberts and Tweedie, 1996). The proof of the Law of Large Numbers (LLN) and the Central Limit Theorem (CLT) both exploit the following Lemma.

Lemma 5 (Stability) *Let the step-sizes $(\delta_m)_{m\geq 1}$ satisfy Assumption 1 and suppose that the stability Assumptions 4 hold. For any exponent $0 \leq p \leq p_H$ the following bounds hold almost surely,*

$$\sup_{m\geq 1} \pi_m(V^{p/2}) < \infty \qquad \text{and} \qquad \sup_{m\geq 1} \mathbf{E}\left[V^p(\theta_m)\right] < \infty. \tag{13}$$

Moreover, for any exponent $0 \leq p \leq p_H$ we have $\pi(V^p) < \infty$. If the sequence of weights $(\omega_m)_{m\geq 1}$ satisfies Assumption 2 the following holds almost surely,

$$\sup_{m\geq 1} \pi_m^{\omega}(V^{p/2}) < \infty \tag{14}$$

The technical proof can be found in Section B. The idea is to leverage condition (12) in order to establish that the function V^p satisfies both discrete and continuous drift conditions.

3.3 Scope of the Analysis

For a posterior density π of the form (4) and the usual unbiased estimate to $\nabla \log \pi$ described in Equation (5), to establish that Equations (10) and (11) hold it suffices to verify that the prior density p_0 is such that $\left\|\nabla \log \mathrm{p}_0(\theta)\right\|^2 \lesssim V(\theta)$ and that for any index $1 \leq i \leq N$ the likelihood term $\mathrm{p}(\, y_i \,|\, \theta)$ is such that

$$\left\|\nabla \log \mathrm{p}\left(\, y_i \,|\, \theta\right)\right\|^{2p_H} \lesssim V^{p_H}(\theta).$$

Indeed, in these circumstances, we have $\left\|H(\theta,\mathcal{U})\right\|^{2p_H} \lesssim \sum_{i=1}^N \left\|\nabla \log \mathrm{p}(y_i \mid \theta)\right\|^{2p_H}$. Several such examples are described in Section 7.

It is important to note that the drift Condition (12) typically does not hold for distributions with heavy tails such that $\nabla \log \pi(x) \to 0$ as $\|x\| \to \infty$ (Roberts and Tweedie, 1996). For example, the standard MALA algorithm is not geometrically ergodic when $\nabla \log \pi(x)$ converges to zero as $\|x\| \to \infty$ (Theorem 4.3 of (Roberts and Tweedie, 1996)); indeed, the analysis of standard local-move MCMC algorithms when applied to target densities with heavy tails is delicate and typically necessitate other tools Stramer and Tweedie (1999b);

Jarner and Roberts (2007); Kamatani (2014) than the approach based on drift conditions of the type (12). The analysis of the properties of the SGLD algorithm when applied to such heavy tail densities is out of the scope of this article. It is important to note that many more complex scenarios involving high-dimensionality, multi-modality, non-parametric settings where the complexity of the target distribution increases with the size of the data, or combination thereof, are examples of interesting and relevant situations where our analysis typically does not apply; analysing the SGLD algorithm when applied to these challenging target distributions is well out of the scope of this article.

4. Consistency

The problem of estimating the invariant distribution of a stochastic differential equation by using a diminishing step-size Euler discretization has been well explored in the literature (Lamberton and Pages, 2002, 2003; Lemaire, 2007; Panloup, 2008; Pages and Panloup, 2012), while (Mattingly et al., 2002) studied the bias and variance of similar algorithms when fixed step-sizes are used instead. We leverage some of these techniques and adapt it to our setting where the drift term can only be unbiasedly estimated, and establish in this section that the SGLD algorithm is consistent under Assumptions 1 and 4. More precisely, we prove that almost surely the sequence $(\pi_m)_{m\geq 1}$ defined in Equation (8) converges weakly towards π. Specifically, under growth assumptions on a test function $\varphi : \mathbb{R}^d \to \mathbb{R}$, the following strong law of large numbers holds almost surely,

$$\lim_{m\to\infty} \frac{\delta_1 \varphi(\theta_0) + \ldots + \delta_m \varphi(\theta_m)}{T_m} = \int_{\mathbb{R}^d} \varphi(\theta)\, \pi(d\theta),$$

with a similar result for ω-weighted empirical averages, under assumptions on the weight sequence ω. The proofs of several results of this paper make use of the following elementary lemma.

Lemma 6 *Let $(\Delta M_k)_{k\geq 0}$ and $(R_k)_{k\geq 0}$ be two sequences of random variables adapted to a filtration $(\mathcal{F}_k)_{k\geq 0}$ and let $(\Gamma_k)_{k\geq 0}$ be an increasing sequence of positive real numbers. The limit*

$$\lim_{m\to\infty} \frac{\sum_{k=0}^{m} \Delta M_k + R_k}{T_m} = 0 \tag{15}$$

holds almost surely if the following two conditions are satisfied.

1. *The process $M_m = \sum_{k\leq m} \Delta M_k$ is a martingale, i.e. $\mathbf{E}[\,\Delta M_k \,|\, \mathcal{F}_k] = 0$ and*

$$\lim_{k\to\infty} \sum_{k\geq 0} \frac{\mathbf{E}\left[|\Delta M_k|\right]^2}{T_k^2} < \infty. \tag{16}$$

2. *The sequence $(R_k)_{k\geq 0}$ is such that*

$$\lim_{k\to\infty} \sum_{k\geq 0} \frac{\mathbf{E}\left[|R_k|\right]}{T_k} < \infty. \tag{17}$$

The above lemma, whose proof can be found in the appendix A, is standard; Lamberton and Pages (2002) also follows this route to prove several of their results.

Theorem 7 *(Consistency) Let the step-sizes satisfy Assumption* (1) *and suppose that the stability Assumptions 4 hold for a Lyapunov function $V : \mathbb{R}^d \to [1,\infty)$. Let $0 \leq p < p_H/2$ and $\varphi : \mathbb{R}^d \to \mathbb{R}$ be a test function such that $|\varphi(\theta)|/V^p(\theta)$ is globally bounded. Then the following limit holds almost surely:*

$$\lim_{m\to\infty} \pi_m(\varphi) = \pi(\varphi). \tag{18}$$

If in addition the sequence of weights $\{\omega_m\}_{m\geq 1}$ satisfies Assumption (2)*, a similar result holds almost surely for the ω-weighted ergodic average:*

$$\lim_{m\to\infty} \pi_m^{\omega}(\varphi) = \pi(\varphi). \tag{19}$$

Proof In the following, we write $\mathbf{E}_k[\,\cdot\,]$ and $\mathbf{P}_k(\,\cdot\,)$ to denote the conditional expectation $\mathbf{E}[\,\cdot\,|\,\theta_k]$ and conditional probability $\mathbf{P}(\,\cdot\,|\,\theta_k)$ respectively. We use the notation $\Delta\theta_k \stackrel{\text{def}}{=} (\theta_{k+1} - \theta_k)$. Finally, for notational convenience, we only present the proof in the scalar case $d = 1$, the multidimensional case being entirely similar. We will give a detailed proof of Equation (18) and then briefly describe how the more general Equation (19) can be proven using similar arguments. To prove Equation (18), we first show that the sequence $(\pi_m)_{m\geq 1}$ almost surely converges weakly to π. Equation (18) is then proved in a second stage.

Weak convergence of $(\pi_m)_{m\geq 1}$. To prove that almost surely the sequence $(\pi_m)_{m\geq 1}$ converges weakly towards π it suffices to prove that the sequence is almost surely weakly pre-compact and that any weakly convergent subsequence of $(\pi_m)_{m\geq 0}$ necessarily (weakly) converges towards π. By Prokhorov's Theorem (Billingsley, 1995) and Equation (13), because the Lyapunov function V goes to infinity as $\|\theta\| \to \infty$, the sequence $(\pi_m)_{m\geq 1}$ is almost surely weakly pre-compact. It thus remains to show that if a subsequence converges weakly to a probability measure π_∞ then $\pi_\infty = \pi$.

Since the Langevin diffusion (1) has a unique strong solution and its generator $\mathcal{A}$ is uniformly elliptic, Theorem 9.17 of Chapter 4 of (Ethier and Kurtz, 1986) yields that it suffices to verify that for any smooth and compactly supported test function $\varphi : \mathbb{R} \to \mathbb{R}$ and any limiting distribution π_∞ of the sequence $(\pi_m)_{m\geq 1}$ the following holds,

$$\pi_\infty(\mathcal{A}\varphi) = 0. \tag{20}$$

To prove Equation (20) we use the following decomposition of $\pi_m(\mathcal{A}\varphi)$,

$$\left\{\frac{\sum_{k=1}^{m} \mathbf{E}_{k-1}[\varphi(\theta_k) - \varphi(\theta_{k-1})]}{T_m}\right\} - \left\{\frac{\sum_{k=1}^{m} \mathbf{E}_{k-1}[\varphi(\theta_k) - \varphi(\theta_{k-1})]}{T_m} - \pi_m(\mathcal{A}\varphi)\right\}. \tag{21}$$

- Let us prove that the first term of (21) converges almost surely to zero. The numerator is equal to the sum of $\sum_{k=1}^{m} \mathbf{E}_{k-1}[\varphi(\theta_k)] - \varphi(\theta_k)$ and $\varphi(\theta_m) - \varphi(\theta_0)$. By boundedness of φ, the term $\{\varphi(\theta_m) - \varphi(\theta_0)\}/T_m$ converges almost surely to zero. By Lemma 6, to

conclude is suffices to show that the martingale difference terms $\mathbf{E}_{k-1}\left[\varphi(\theta_k)\right] - \varphi(\theta_k)$ are such that

$$\sum_{k\geq 1} \frac{\mathbf{E}\left[\left|\mathbf{E}_{k-1}\left[\varphi(\theta_k)\right] - \varphi(\theta_k)\right|^2\right]}{T_k^2} \; < \; \infty.$$

Because φ is Lipschitz, it suffices to prove that $\sum_{k\geq 1} \mathbf{E}\left(\|\theta_{k+1} - \theta_k\|^2\right)/T_k^2$ is finite. The stability Assumption 4 and Lemma 5 imply that the supremum $\sup_m \mathbf{E}\left[V(\theta_m)\right]$ is finite. Since $\mathbf{E}_k\left[\|\theta_{k+1} - \theta_k\|^2\right] \lesssim \delta_{k+1}^2\, V(\theta) + \delta_{k+1}$, it follows that $\mathbf{E}\left(\|\theta_{k+1} - \theta_k\|^2\right)$ is less than a constant multiple of δ_{k+1}. Under Assumption 1, because the telescoping sum $\sum_{k\geq 1} T^{-1}(k) - T^{-1}(k+1)$ is finite, the sum $\sum_{k\geq 1} \delta_k/T_k^2$ is finite. This concludes the proof that the first term in (21) converges almost surely to zero.

- The second term of (21) equals $\big(R_0 + \ldots + R_{m-1}\big)/T_m$ with

$$R_k \stackrel{\text{def}}{=} \mathbf{E}_k\left[\varphi(\theta_{k+1}) - \varphi(\theta_k)\right] - \mathcal{A}\varphi(\theta_k)\,\delta_{k+1}. \tag{22}$$

We now show that there exists a constant C such that the bound $|R_k| \leq C\,\delta_{k+1}^{3/2}$ holds for any $k \geq 0$. To do so, let $K > 0$ be such that the support of the test function φ is included in the compact set $\Omega = [-K, K]$. We examine two cases separately.

– If $|\theta_k| > K+1$ then $\varphi(\theta_k) = \mathcal{A}\varphi(\theta_k) = 0$ so that $|R_k| \leq \|\varphi\|_\infty \times \mathbf{P}_k(\theta_{k+1} \in \Omega)$. Since $\theta_{k+1} - \theta_k = \left\{\frac{1}{2}\nabla \log \pi(\theta_k) + H(\theta_k, \mathcal{U})\right\}\delta_{k+1} + \sqrt{\delta_{k+1}}\,\eta$ we have

$$\begin{aligned}\mathbf{P}_k(\theta_{k+1} \in \Omega) \leq\; & \mathbb{I}\left(\left|\frac{1}{2}\nabla \log \pi(\theta_k)\right| \geq \frac{\mathrm{dist}(\theta_k, \Omega)}{3\,\delta_{k+1}}\right) \\ & + \mathbf{P}_k\left(|H(\theta_k, \mathcal{U})| \geq \frac{\mathrm{dist}(\theta_k, \Omega)}{3\,\delta_{k+1}}\right) + \mathbf{P}_k\left(|\eta| \geq \frac{\mathrm{dist}(\theta_k, \Omega)}{3\,\sqrt{\delta_{k+1}}}\right).\end{aligned}$$

We have used the notation $\mathbb{I}(A)$ for denoting the indicator function of the event A. Under Assumption 4 we have $|\nabla \log \pi(\theta)| \lesssim V(\theta)^{1/2} \lesssim 1 + \|\theta\|$ so that the quotient $|\nabla \log \pi(\theta)|/\mathrm{dist}(\theta, \Omega)$ is bounded on the set $\{\theta : |\theta| > K\}$; this shows that the first term equals zero for δ_k small enough. To prove that the second term is bounded by a constant multiple of δ_{k+1}^2, it suffices to use Markov's inequality and the fact that $\mathbf{E}[H(\theta_k, \mathcal{U})^2]/\mathrm{dist}^2(\theta, \Omega)$ is bounded on $\{\theta : |\theta| > K\}$; this is because $\mathbf{E}[H(\theta_k, \mathcal{U})^2]$ is less than a constant multiple of $V(\theta)$ and $V(\theta) \lesssim 1 + \|\theta\|^2$ by Assumption 4. The third term is less than a constant multiple of δ_{k+1}^2 by Markov's inequality and the fact that η has a finite moment of order four.

– If $|\theta_k| \leq K+1$, we decompose R_k into two terms. A second order Taylor formula yields

$$\begin{aligned}R_k &= \frac{1}{2}\,\delta_{k+1}^2\,\varphi''(\theta_k)\left\{\left[\nabla \log \pi(\theta_k)\right]^2 + \mathbf{E}_k\left[H^2(\theta_k, \mathcal{U})\right]\right\} \\ &\quad + (1/2)\;\mathbf{E}_k\left[(\Delta\theta_k)^3 \int_0^1 \varphi'''(\theta_k + u\,\Delta\theta_k)\,(1-u)^2\,du\right] \\ &= R_{k,1} + R_{k,2}.\end{aligned}$$

Under Assumption 4, the quantities $\left[\nabla \log \pi(\theta_k)\right]^2$ and $\mathbf{E}[H^2(\theta_k, \mathcal{U})]$ are upper bounded by a constant multiple of $V(\theta_k)$. Since the function $\theta \mapsto \varphi''(\theta)\,V(\theta)$ is globally bounded (because continuous with compact support) this shows that $R_{k,1}$ is less than a constant multiple of δ_{k+1}^2. Since $|\theta_k| \leq K+1$, the bounds $\mathbf{E}[H^3(\theta, \mathcal{U})] \lesssim V^{3/2}(\theta)$ and $\sup_{k\geq 0} \mathbf{E}[V^{3/2}(\theta_k)] < \infty$ (see Lemma 5) yield that $\mathbf{E}_k\left|\Delta\theta_k\right|^3 \leq 9\,\overline{C}\,(\delta_{k+1}^3 + \delta_{k+1}^{3/2}) \lesssim \delta_{k+1}^{3/2}$ with

$$\overline{C} = 1 + \sup_{\theta:|\theta|<K+1} |\nabla \log \pi(\theta)|^3 + \mathbf{E}\left[|H(\theta, \mathcal{U})|^3\right].$$

Note that $\overline{C}$ is finite by Assumption 4 and Lemma 5.

We have thus proved that there is a constant C such $|R_k| \leq C\,\delta_{k+1}^{3/2}$ for $k \geq 0$; it follows that the sum $(R_0 + \ldots + R_{m-1})/T_m$ is less than a constant multiple of $\left(\delta_1^{3/2} + \ldots + \delta_m^{3/2}\right)/T_m$. Under Assumption 1, this upper bound converges to zero as $m \to \infty$, hence the conclusion.

This ends the proof of the almost sure weak convergence of π_m towards π.

Proof of Equation (18). By assumption we have $|\varphi(\theta)| \leq C_p\,V^p(\theta)$ for some constant $C_p > 0$ and exponent $p < p_H/2$. To show that $\pi_m(\varphi) \to \pi(\varphi)$ almost surely, we will use Lemma 5 and the almost sure weak convergence, which guarantees that $\pi_m(\widetilde{\varphi}) \to \pi(\widetilde{\varphi})$ for a continuous and bounded test function $\widetilde{\varphi}$.

For any $t > 0$, the set $\Omega_t \stackrel{\text{def}}{=} \{\theta : V(\theta) \leq t\}$ is compact and Tietze's extension theorem (Rudin, 1986, Theorem 20.4) yields that there exists a continuous function $\widetilde{\varphi}_t$ with compact support that agrees with φ on Ω_t and such that $\|\widetilde{\varphi}_t\|_\infty = \sup\{|\varphi(\theta)| : \theta \in \Omega_t\}$. We can indeed also assume that $|\widetilde{\varphi}_t(\theta)| \leq C_p\,V^p(\theta)$. Since Lemma 5 states that $\sup_m \pi_m(V^{p_H/2})$ is almost surely finite, it follows that

$$|\pi_m(\varphi) - \pi_m(\widetilde{\varphi}_t)| \leq 2\,C_p\,\pi_m(V^p\,\mathbb{1}_{V\geq t}) \leq 2\,C_p\,\frac{\sup_m \pi_m(V^{p_H/2})}{t^{p_H/2-p}},$$

where the last inequality follows from the fact that for any probability measure μ, exponents $0 < p < q$ and scalar $t > 0$ we have $\mu(V^p\,\mathbb{1}_{V\geq t}) \leq \mu(V^q\,\mathbb{1}_{V\geq t})/t^{q-p}$. Similarly

$$|\pi(\varphi) - \pi(\widetilde{\varphi}_t)| \leq 2\,C_p\,\pi(V^{p_H/2})/t^{p_H/2-p}.$$

By the triangle inequality, we thus have,

$$|\pi_m(\varphi) - \pi(\varphi)| \leq 2\,C_p\,\frac{\sup_m \pi_m(V^{p_H/2})}{t^{p_H/2-p}} + \left|\pi_m(\widetilde{\varphi}_t) - \pi(\widetilde{\varphi}_t)\right| + 2\,C_p\,\frac{\pi(V^{p_H/2})}{t^{p_H/2-p}}.$$

On the right-hand-side, the term in the middle can be made arbitrarily small as $m \to \infty$ since π_m converges weakly towards π, while the other two terms converges to zero as $t \to \infty$. This concludes the proof of Equation (18).

Proof of Equation (19). The approach is very similar to the proof of Equation (18) and for this reason we only highlight the main differences. The same argument shows that the

sequence π_m^ω is tight and it suffices to show that $\pi_\infty^\omega(\mathcal{A}\varphi) = 0$ for any weak limit π_∞^ω of the sequence $(\pi_m^\omega)_{m\geq 0}$ for obtaining the almost sure weak convergences of $(\pi_m^\omega)_{m\geq 0}$ towards π. One can then upgrade this almost sure weak convergence to a Law of Large Numbers. To prove (19), we thus concentrate on proving that $\pi_\infty^\omega(\mathcal{A}\varphi) = 0$. For a smooth and compactly supported test function φ we use the decomposition $\pi_m^\omega(\mathcal{A}\varphi) = S_1(m) + S_2(m) + S_3(m)$ with

$$\left\{\begin{array}{ll} S_1(m) & = \frac{1}{\Omega_m}\sum_{k=1}^m \frac{\omega_k}{\delta_k}\big(\mathbf{E}_{k-1}[\varphi(\theta_k)] - \varphi(\theta_k)\big) \\ S_2(m) & = \frac{1}{\Omega_m}\sum_{k=1}^m \frac{\omega_k}{\delta_k}\big(\varphi(\theta_k) - \varphi(\theta_{k-1})\big) \\ S_3(m) & = \pi_m^\omega(\mathcal{A}\varphi) - \frac{1}{\Omega_m}\sum_{k=1}^m \frac{\omega_k}{\delta_k}\mathbf{E}_{k-1}[\varphi(\theta_k) - \varphi(\theta_{k-1})] \end{array}\right.$$

and prove that each term converges to zero almost surely. For $S_1(m)$, by Lemma 6 it suffices to show that $\sum_{k\geq 1}(\omega_k/\delta_k)^2\,\mathbf{E}\left[\{\mathbf{E}_{k-1}[\varphi(\theta_k)] - \varphi(\theta_k)\}^2\right]/\Omega_k^2$ is finite. This follows from the bound $\mathbf{E}\left[\big(\mathbf{E}_{k-1}[\varphi(\theta_k)] - \varphi(\theta_k)\big)^2\right] \lesssim \delta_k$ and the fact that $\sum_{m\geq 0}\omega_m^2/(\Omega_m^2\,\delta_m)$ is finite. For $S_2(m)$, we can write it as

$$S_2(m) = \frac{-\frac{\omega_1}{\delta_1}\varphi(\theta_0) + \frac{\omega_{m+1}}{\delta_{m+1}}\varphi(\theta_m) - \sum_{k=1}^m \varphi(\theta_k)\,\Delta(\omega_k/\delta_k)}{\Omega_m}.$$

Because $\Omega_m \to \infty$, $(\omega_{m+1}/\delta_{m+1})/\Omega_m \to 0$ and φ is bounded, one can concentrate on proving that $\Omega_m^{-1}\sum_{k=1}^m \varphi(\theta_k)\,\Delta(\omega_k/\delta_k)$ converges almost surely to zero. By Lemma 6, it suffices to verify that $\sum_{k\geq 1}\mathbf{E}\left[|\varphi(\theta_k)\,\Delta(\omega_k/\delta_k)|\right]/\Omega_k$ is finite; this directly follows from the boundedness of φ and Assumption 2. Finally, algebra shows that $S_3(m) = \Omega_m^{-1}\sum_1^m(\omega_k/\delta_k)\,R_{k-1}$ with the quantity R_k defined in Equation (22). It has been proved that there is a constant C such that, almost surely, $|R_k| \leq C\,\delta_{k+1}^{3/2}$ for all $k \geq 0$. Since $\delta_m \to 0$, the rescaled sum $\Omega_m^{-1}\sum_{k\leq m}\omega_k\delta_k^{1/2}$ converges to zero as $m \to \infty$. It follows that $S_3(m)$ converges almost surely to zero. ■

5. Fluctuations, Bias-Variance Analysis, and Central Limit Theorem

The previous section shows that, under suitable conditions, for a test function $\varphi : \mathbb{R}^d \to \mathbb{R}$ the quantity $\pi_m(\varphi)$ converges almost surely to $\pi(\varphi)$ as $m \to \infty$. In this section, we investigate the fluctuations of $\pi_m(\varphi)$ around its asymptotic value $\pi(\varphi)$. We establish that the asymptotic bias-variance decomposition of the SGLD algorithm is dictated by the behaviour of the sequence

$$\mathbb{B}_m \stackrel{\text{def}}{=} T_m^{-1/2}\sum_{k=0}^{m-1}\delta_{k+1}^2. \tag{23}$$

Indeed, the proof of Theorem 8 reveals that the fluctuations of $\pi_m(\varphi)$ are of order $\mathcal{O}\left(T_m^{-1/2}\right)$ and its bias is of order $\mathcal{O}\left(T_m^{-1}\sum_{k=0}^{m-1}\delta_{k+1}^2\right)$; the quantity $\mathbb{B}_m$ is thus the ratio of the typical scales of the bias and fluctuations. In the case where $\mathbb{B}_m \to 0$, the fluctuations dominate

the bias and the rescaled difference $T_m^{1/2} \times (\pi_m(\varphi) - \pi(\varphi))$ converges weakly to a centred Gaussian distribution. In the case where $\mathbb{B}_m \to \mathbb{B}_\infty \in (0,\infty)$, there is an exact balance between the scale of the bias and the scale of the fluctuations; the rescaled quantity $T_m^{1/2} \times (\pi_m(\varphi) - \pi(\varphi))$ converges to a non-centred Gaussian distribution. Finally, in the case where $\mathbb{B}_m \to \infty$, the bias dominates and the rescaled quantity $\left(T_m^{-1}\sum_{k=1}^m \delta_k^2\right)^{-1} \times (\pi_m(\varphi) - \pi(\varphi))$ converges in probability to a quantity $\mu(\varphi) \in \mathbb{R}$ whose exact value is described in the sequel. The strategy of the proof is standard; the solution h of the Poisson equation

$$\varphi - \pi(\varphi) = \mathcal{A}h \tag{24}$$

is introduced so that the additive functional $\pi_m(\varphi)$ of the trajectory of the Markov process $\{\theta_k\}_{k\geq 0}$ can be expressed as the sum of a martingale and a remainder term. A central limit for martingales can then be invoked to describe the asymptotic behaviour of the fluctuations

Theorem 8 *(Fluctuations) Let the step-sizes $(\delta_m)_{m\geq 1}$ satisfy Assumption 1 and assume that Assumption 4 holds for an exponent $p_H \geq 5$. Let $\varphi : \mathbb{R}^d \to \mathbb{R}$ be a test function and assume that the unique solution $h : \mathbb{R}^d \to \mathbb{R}$ to the Poisson Equation (24) satisfies $\|\nabla^n h(\theta)\| \lesssim V^{p_H}(\theta)$ for $n \leq 4$ and has a bounded fifth derivative. Define $\sigma^2(\varphi) = \pi\Big(\|\nabla h\|^2\Big)$.*

- *In case the fluctuations dominate, i.e. $\mathbb{B}_m \to 0$, the following convergence in distribution holds,*
$$\lim_{m\to\infty} T_m^{1/2}\left\{\pi_m(\varphi) - \pi(\varphi)\right\} \;=\; \mathrm{N}\left(0, \sigma^2(\varphi)\right). \tag{25}$$
- *In case the fluctuations and the bias are on the same scale, i.e. $\mathbb{B}_m \to \mathbb{B}_\infty \in (0,\infty)$, the following convergence in distribution holds,*
$$\lim_{m\to\infty} T_m^{1/2}\left\{\pi_m(\varphi) - \pi(\varphi)\right\} \;=\; \mathrm{N}\left(\mu(\varphi), \sigma^2(\varphi)\right), \tag{26}$$
with the asymptotic bias
$$\mu(\varphi) = -\mathbb{B}_\infty\,\mathbf{E}\left[\frac{1}{8}\nabla^2 h(\Theta)\widehat{\nabla\log\pi}(\Theta,\mathcal{U})^2 + \frac{1}{4}\nabla^3 h(\Theta)\nabla\log\pi(\Theta) + \frac{1}{24}\nabla^4 h(\Theta)\right]$$
where the random variables $\Theta \overset{\mathcal{D}}{\sim} \pi$ and $\mathcal{U}$ are independent.
- *In case the bias dominates, i.e. $\mathbb{B}_m \to \infty$, the following limit holds in probability,*
$$\lim_{m\to\infty} \frac{\pi_m(\varphi) - \pi(\varphi)}{T_m^{-1}\sum_{k=1}^m \delta_k^2} \;=\; \mu(\varphi). \tag{27}$$

Proof The proof follows the strategy described in Lamberton and Pages (2002), with the additional difficulty that only unbiased estimates of the drift term of the Langevin diffusion are available. We use the decomposition

$$\pi_m(\varphi) - \pi(\varphi) = \left\{\frac{\sum_{k=0}^{m-1}\delta_{k+1}\,\mathcal{A}h(\theta_k) - (h(\theta_{k+1}) - h(\theta_k))}{T_m}\right\} + \left\{\frac{h(\theta_m) - h(\theta_0)}{T_m}\right\}. \tag{28}$$

A fifth order Taylor expansion and Equation (7) yields that

$$h(\theta_{k+1}) - h(\theta_k) = \sum_{n=1}^{4} \left\{ \sum_{i=0}^{n} \mathcal{C}_{n,i}^{(k)} \, \delta_{k+1}^{(n+i)/2} \right\} + \nabla^5 h(\xi_k) \, (\theta_{k+1} - \theta_k)^5 / 5!. \tag{29}$$

In the above, we have defined $\mathcal{C}_{n,i}^{(k)} \equiv \left(2^i \, i! \, (n-i)!\right)^{-1} \nabla^n h(\theta_k) \widehat{\nabla \log \pi}(\theta_k, \mathcal{U}_{k+1})^i \eta_{k+1}^{n-i}$; the quantity ξ_k lies between θ_k and θ_{k+1}. It follows from the expression (2) of the generator of the $\mathcal{A}$ of the Langevin diffusion (1) and decomposition (28) that $\pi_m(\varphi) - \pi(\varphi) = \mathscr{F}_m + \mathscr{B}_m + \mathscr{R}_m$ where the fluctuation and bias terms are given by

$$\mathscr{F}_m \equiv -\frac{1}{T_m} \sum_{k=0}^{m-1} \mathcal{C}_{1,0}^{(k)} \delta_{k+1}^{1/2} \quad \text{and} \quad \mathscr{B}_m \equiv -\frac{1}{T_m} \sum_{k=0}^{m-1} \left\{ \mathcal{C}_{2,2}^{(k)} + \mathcal{C}_{3,1}^{(k)} + \mathcal{C}_{4,0}^{(k)} \right\} \delta_{k+1}^2$$

while the remainder term reads

$$\begin{aligned} \mathscr{R}_m \equiv & -\frac{1}{T_m} \sum_{k=0}^{m-1} \left\{ \frac{1}{2} H(\theta_k, \mathcal{U}_{k+1}) \, \nabla h(\theta_k) + \frac{1}{2} \left(\eta_{k+1}^2 - 1 \right) \nabla^2 h(\theta_k) \right\} \delta_{k+1} \\ & - \frac{1}{T_m} \sum_{k=0}^{m-1} \left\{ \sum_{(n,i) \in \mathcal{I}_{\mathscr{R}}} \mathcal{C}_{n,i}^{(k)} \, \delta_{k+1}^{(n+i)/2} \right\} - \frac{1}{T_m} \sum_{k=0}^{m-1} \nabla^5 h(\xi_k) \, (\theta_{k+1} - \theta_k)^5 / 5! \\ & + \left\{ \frac{h(\theta_m) - h(\theta_0)}{T_m} \right\} \end{aligned} \tag{30}$$

for $\mathcal{I}_{\mathscr{R}} = \bigcup_{p \in \{3,5,6,7,8\}} \mathcal{I}_{\mathscr{R},p}$ and $\mathcal{I}_{\mathscr{R},p} \equiv \{(n,i) \in [1:4] \times [0:4] \, : \, i \leq n, \, i+n = p\}$. We will show that the remainder term is negligible in the sense that each term on the R.H.S of Equation (30), when multiplied by either $T_m^{1/2}$ or $T_m(\sum_{k=0}^{m-1} \delta_{k+1}^2)^{-1}$, converges in probability to zero; in other words, each one of these terms is dominated asymptotically by either the fluctuations or the bias and is thus negligible. We then show that when multiplied by $T_m^{1/2}$, the fluctuation term converges in distribution to $\mathrm{N}(0, \sigma^2(\varphi))$. Finally, we show that the bias term converge to $\mu(\varphi)$ when rescaled by its typical scale, $T_m(\sum_{k=0}^{m-1} \delta_{k+1}^2)^{-1}$. Putting these results together under the three cases of $\mathbb{B}_m \to 0$, $\mathbb{B}_m \to \mathbb{B}_\infty \in (0, \infty)$ and $\mathbb{B}_m \to \infty$ leads to the results of the Theorem.

Remainder Term

we start by proving that the term $\mathscr{R}_m$ is negligible. The term $\{h(\theta_m) - h(\theta_0)\}/T_m^{1/2}$ converges to zero in probability because $|h(\theta)| \lesssim V^{p_H}(\theta)$ and Lemma 5 shows that

$$\sup_{m \geq 0} \mathbf{E}[V^{p_H}(\theta_m)] < \infty a.s..$$

Similarly, Assumptions 1 and 4 and Lemma 5 yield that

$$\mathbf{E}\left[\nabla^5 h(\xi_k) \, (\theta_{k+1} - \theta_k)^5 \right] \lesssim \mathbf{E}\left[|\eta_{k+1}|^5 \right] \delta_{k+1}^{5/2} + \mathbf{E}\left[\left| \widehat{\nabla \log \pi}(\theta_k, \mathcal{U}_{k+1}) \right|^5 \right] \delta_{k+1}^5 \lesssim \delta_{k+1}^{5/2}$$

from which it follows that $\left\{ \sum_{k=0}^{m-1} \nabla^5 h(\xi_k) \, (\theta_{k+1} - \theta_k)^5 \right\} / \left\{ \sum_{k=0}^{m-1} \delta_{k+1}^2 \right\}$ converges to zero in probability; we have exploited the fact that $\nabla^5 h$ is assumed to be globally bounded. Essentially the same argument yield that the high-order terms are asymptotically negligible: for $(n,i) \in \mathcal{I}_{\mathscr{R},p}$ and $p \in \{5,6,7,8\}$ the limit

$$\lim_{m \to \infty} \frac{\sum_{k=0}^{m-1} \mathcal{C}_{n,i}^{(k)} \, \delta_{k+1}^{(n+i)/2}}{\sum_{k=0}^{m-1} \delta_{k+1}^2} = 0$$

holds in probability because the coefficients $\mathcal{C}_{n,i}^{(k)}$ are uniformly bounded in expectation and the quantity $\left(\sum_{k=0}^{m-1} \delta_{k+1}^{(n+i)/2} \right) / \left(\sum_{k=0}^{m-1} \delta_{k+1}^2 \right)$ converges to zero since $(n+i)/2 \geq 5/2$ and $\delta_k \to 0$. To conclude, one needs to verify that the low order terms are also negligible in the sense that the limit

$$\lim_{m \to \infty} \frac{\sum_{k=0}^{m-1} X_{n,i}^{(k)} \delta_{k+1}^{(n+i)/2}}{T_m^{1/2}} = 0$$

holds in probability with $X_{1,1}^{(k)} = \nabla h(\theta_k) \, H(\theta_k, \mathcal{U}_{k+1})$ and $X_{2,0}^{(k)} = \nabla^2 h(\theta_k)(\eta_{k+1}^2 - 1)$ and $X_{2,1}^{(k)} = -\mathcal{C}_{2,1}^{(k)}$ and $X_{3,0}^{(k)} = -\mathcal{C}_{3,0}^{(k)}$. Since $\mathbf{E}\left[X_{n,i}^{(k)} \middle| \mathcal{F}_k \right] = 0$ where $\mathcal{F}_k = \sigma(\theta_0, \ldots, \theta_k)$ is the natural filtration associated to the process $(\theta_k)_{k \geq 0}$ it follows that

$$\mathbf{E}\left[\left(\frac{\sum_{k=0}^{m-1} X_{n,i}^{(k)} \delta_{k+1}^{(n+i)/2}}{T_m^{1/2}} \right)^2 \right] = \frac{\sum_{k=0}^{m-1} \mathbf{E}\left[(X_{n,i}^{(k)})^2 \right] \delta_{k+1}^{n+i}}{T_m} \lesssim \frac{\sum_{k=0}^{m-1} \delta_{k+1}^{n+i}}{T_m} \to 0.$$

We made use of the fact that the expectations $\mathbf{E}\left[(X_{n,i}^{(k)})^2 \right]$ are uniformly bounded for all $k \geq 0$ by the same arguments as above, and that the final expression converges to 0 since $n+i \geq 2$, $\delta_m \to 0$ and $T_m \to \infty$. This concludes the proof that the remainder term $\mathscr{R}_m$ is asymptotically negligible.

Fluctuation Term

we now prove that the fluctuations term converges in distribution at Monte-Carlo rate towards a Gaussian distribution,

$$T_m^{1/2} \, \mathscr{F}_m \equiv -\frac{\sum_{k=0}^{m-1} \nabla h(\theta_k) \, \delta_{k+1}^{1/2} \, \eta_{k+1}}{T_m^{1/2}} \to \mathrm{N}\left(0, \sigma^2(\varphi)\right).$$

Using the standard martingale central limit theorem (e.g. Theorem 3.2, Chapter 3 of (Hall and Heyde, 1980)), it suffices to verify that for any $\varepsilon > 0$ the following limits hold in probability,

$$\lim_{m \to \infty} \sum_{k=0}^{m-1} \frac{\mathbf{E}_k\left[Z_k^2 \mathbb{I}\left(Z_k^2 > T_m \varepsilon \right) \right]}{T_m} = 0 \quad \text{and} \quad \lim_{m \to \infty} \frac{\sum_{k=0}^{m-1} \mathbf{E}_k\left[Z_k^2 \right]}{T_m} = \sigma^2(\varphi)$$

with $Z_k \stackrel{\text{def}}{=} \nabla h(\theta_k)\,\delta_{k+1}^{1/2}\,\eta_{k+1}$. Since $\mathbf{E}_k\left[Z_k^2\right] = \nabla h(\theta_k)^2\,\delta_{k+1}$ and the function $\theta \mapsto \nabla h(\theta)^2$ satisfies the assumptions of Theorem 7, the second limit directly follows from Theorem 7. For proving the first limit, note that the Cauchy-Schwarz's inequality and the boundedness of ∇h imply that $\mathbf{E}_k\left[Z_k^2\,\mathbb{I}\big(Z_k^2 > T_m\varepsilon\big)\right] \lesssim \delta_{k+1} \times \mathbf{P}\left[\delta_{k+1}\,\|\nabla h\|_\infty^2\,\eta_{k+1}^2 > T_m\,\varepsilon\right]^{1/2}$; the Markov's inequality thus yields that

$$\sum_{k=0}^{m-1} \mathbf{E}_k\left[Z_k^2\,I\big(Z_k^2 > T_m\varepsilon\big)\right]/T_m \lesssim \frac{\sum_{k=0}^{m-1}\delta_{k+1}^2}{T_m^2\,\varepsilon}.$$

Since $T_m^{-2}\sum_{k=0}^{m-1}\delta_{k+1}^2 \to 0$, the conclusion follows.

Bias term: we conclude by proving that the bias term is such that the limit

$$\lim_{m\to\infty} \frac{\mathscr{B}_m}{\sum_{k=1}^m \delta_k^2/T_m} \;=\; \mu(\varphi)$$

holds in probability. The quantity $\mathscr{B}_m/\big(\sum_{k=1}^m \delta_k^2/T_m\big)^{-1}$ can also be expressed as

$$\frac{\sum_{k=0}^{m-1}\Psi(\theta_k)\,\delta_{k+1}^2}{\sum_{k=0}^{m-1}\delta_{k+1}^2} + \frac{\sum_{k=0}^{m-1}\Delta M_k\,\delta_{k+1}^2}{\sum_{k=0}^{m-1}\delta_{k+1}^2} \tag{31}$$

for a martingale difference term $\Delta M_k \equiv \left(\mathcal{C}_{2,2}^{(k)} + \mathcal{C}_{3,1}^{(k)} + \mathcal{C}_{4,0}^{(k)}\right) - \Psi(\theta_k)$ where $\Psi(\theta_k) \equiv \mathbf{E}\left[\mathcal{C}_{2,2}^{(k)} + \mathcal{C}_{3,1}^{(k)} + \mathcal{C}_{4,0}^{(k)}\,\middle|\,\mathcal{F}_k\right]$ and $\left(\mathcal{C}_{2,2}^{(k)} + \mathcal{C}_{3,1}^{(k)} + \mathcal{C}_{4,0}^{(k)}\right)$ equals

$$\frac{1}{8}\nabla^2 h(\theta_k)\widehat{\nabla\log\pi}(\theta_k,\mathcal{U}_{k+1})^2 + \frac{1}{4}\nabla^3 h(\theta_k)\widehat{\nabla\log\pi}(\theta_k,\mathcal{U}_{k+1})\eta_{k+1}^2 \quad + \frac{1}{24}\nabla^4 h(\theta_k)\eta_{k+1}^4.$$

Under the assumptions of Theorem 8, the function Ψ satisfies the hypothesis of Theorem 7 applied to the weight sequence $\{\delta_k^2\}_{k\geq 0}$; it follows that the first term in Equation (31) converge almost surely to $\mu(\varphi)$. It remains to prove that the second term in Equation (31) also converges almost surely to zero. By Lemma 6, it suffices to prove that the martingale

$$m \mapsto \sum_{k=0}^{m} \frac{\Delta M_k\,\delta_{k+1}^2}{\sum_{j=1}^{k+1}\delta_{j+1}^2}$$

is bounded in L^2. Under the Assumption of Theorem 8, Lemma 5 yields that the martingale difference term ΔM_k is uniformly bounded in L^2 from which the conclusion readily follows. ■

For the standard choice of step-sizes $\delta_m = (m_0+m)^{-\alpha}$ the statistical fluctuations dominate in the range $1/3 < \alpha \leq 1$, there is an exact balance between bias and fluctuations for $\alpha = 1/3$, and the bias dominates for $0 < \alpha < 1/3$. The optimal rate of convergence is obtained for $\alpha = 1/3$ and leads to an algorithm that converges at rate $m^{-1/3}$.

6. Diffusion Limit

In this section we show that, when observed on the right (inhomogeneous) time scale, the sample path of the SGLD algorithm converges to the continuous time Langevin diffusion of Equation (1), confirming the heuristic discussion in Welling and Teh (2011).

The result is based on the continuity properties of the Itô's map $\mathcal{I} : \mathcal{C}([0,T],\mathbb{R}^d) \to \mathcal{C}([0,T],\mathbb{R}^d)$, which sends a continuous path $w \in \mathcal{C}([0,T],\mathbb{R}^d)$ to the unique solution $v = \mathcal{I}(w)$ of the integral equation,

$$v_t = \theta_0 + \frac{1}{2}\int_{s=0}^t \nabla\log\pi(v_s)\,ds + w_t \qquad \text{for all} \quad t\in[0,T].$$

If the drift function $\theta \mapsto \frac{1}{2}\nabla\log\pi(\theta)$ is globally Lipschitz, then the Itô's map $\mathcal{I}$ is well defined and continuous. Further, the image $\mathcal{I}(W)$ under the Itô map of a standard Brownian motion W on $[0,T]$ can be seen to be described by Langevin diffusion (1).

The approach, inspired by ideas in Mattingly et al. (2012); Pillai et al. (2012), is to construct a sequence of coupled Markov chains $(\theta^{(r)})_{r\geq 1}$, each started at the same initial state $\theta_0 \in \mathbb{R}^d$ and evolved according to the SGLD algorithm with step-sizes $\delta^{(r)} \stackrel{\text{def}}{=} (\delta_k^{(r)})_{k=1}^{m(r)}$ such that

$$\sum_{k=1}^{m(r)} \delta_k^{(r)} = T$$

and with increasingly fine mesh sizes $\text{mesh}(\delta^{(r)}) \to 0$ with

$$\text{mesh}(\delta^{(r)}) \stackrel{\text{def}}{=} \max\left\{\delta_k^{(r)} \;:\; 1\leq k\leq m(r)\right\}.$$

Define $T_0^{(r)} = 0$ and $T_k^{(r)} = \delta_1^{(r)} + \cdots + \delta_k^{(r)}$ for each $k \geq 1$. The Markov chains are coupled to W as follows:

$$\left\{\begin{array}{ll} \eta_k^{(r)} & = (\delta_k^{(r)})^{-1/2}\Big(W(T_k^{(r)}) - W(T_{k-1}^{(r)})\Big) \\ \theta_k^{(r)} & = \theta_{k-1}^{(r)} + \frac{1}{2}\,\delta_k^{(r)}\Big\{\nabla\log\pi(\theta_{k-1}^{(r)}) + H(\theta_{k-1}^{(r)},\mathcal{U}_k^{(r)})\Big\} \;+\; (\delta_k^{(r)})^{1/2}\,\eta_k^{(r)}, \end{array}\right. \tag{32}$$

for an i.i.d. collection of auxiliary random variables $(\mathcal{U}_k^{(r)})_{r\geq 1,k\geq 1}$. Note that $(\eta_k^{(r)})_{k\geq 1}$ form an i.i.d. sequence of $\mathrm{N}(0,1)$ variables for each r. We can construct piecewise affine continuous time sample paths $(S^{(r)})_{r\geq 1}$ by linearly interpolating the Markov chains,

$$S^{(r)}\Big(xT_{k-1}^{(r)} + (1-x)T_k^{(r)}\Big) = x\,\theta_{k-1}^{(r)} + (1-x)\,\theta_k^{(r)}, \tag{33}$$

for $x \in [0,1]$. The approach then amounts to showing that each $S^{(r)}$ can be expressed as $\mathcal{I}(\widetilde{W}^{(r)}) + e^{(r)}$, where $\widetilde{W}^{(r)}$ is a sequence of stochastic processes converging to W and $e^{(r)}$ is asymptotically negligible, and making use of the continuity properties of the Itô map $\mathcal{I}$.

Theorem 9 *Let Assumption 4 holds and suppose that the drift function $\theta \mapsto (1/2)\nabla\,\log\pi(\theta)$ is globally Lipschitz on $\mathbb{R}^d$. If $\text{mesh}(\delta^{(r)}) \to 0$ as $r\to\infty$, then the sequence of continuous time processes $(S^{(r)})_{r\geq 1}$ defined in Equation (33) converges weakly on $\big(\mathcal{C}([0,T],\mathbb{R}^d),\|\cdot\|_\infty\big)$ to the Langevin diffusion (1) started at $S_0 = \theta_0$.*

Proof Since the drift term $s \mapsto (1/2)\nabla \log \pi(s)$ is globally Lipschitz on $\mathbb{R}^d$, Lemma 3.7 of (Mattingly et al., 2012) shows that the Itô's map $\mathcal{I} : \mathcal{C}([0,T],\mathbb{R}^d) \to \mathcal{C}([0,T],\mathbb{R}^d)$ is well-defined and continuous, under the topology over the space $\mathcal{C}([0,T],\mathbb{R}^d)$ induced by the supremum norm $\|w\|_\infty \equiv \sup\{|w_t| : 0 \leq t \leq T\}$. By the Continuous Mapping Theorem, because the Langevin diffusion (1) can be seen as the image under the Itô's map $\mathcal{I}$ of a standard Brownian motion on $[0,T]$ evolving in $\mathbb{R}^d$, it suffices to verify that the process $S^{(r)}$ can be expressed as $\mathcal{I}(\widetilde{W}^{(r)}) + e^{(r)}$ where $\widetilde{W}^{(k)}$ is a sequence of stochastic processes that converge weakly in $\mathcal{C}([0,T],\mathbb{R}^d)$ to a standard Brownian motion W and $e^{(r)}$ is an error term that is asymptotically negligible in the sense that $\|e^{(r)}\|_\infty$ converges to zero in probability.

For convenience, we define $\widetilde{W}^{(r)}$ as the continuous piecewise affine processes that satisfies $\widetilde{W}^{(r)}(T_k^{(r)}) = W(T_k^{(r)})$ for all $0 \leq k \leq m(r)$ and that is affine in between. It follows that for any time $T_{k-1}^{(r)} \leq t \leq T_k^{(r)}$ we have

$$
\begin{aligned}
S^{(r)}(t) &= S^{(r)}(T_{k-1}^{(r)}) + \left(\int_{T_{k-1}^{(r)}}^{t} \frac{1}{2} \nabla \log \pi\big(S^{(r)}(T_{k-1}^{(r)})\big) du + \widetilde{W}^{(r)}(t) - \widetilde{W}(T_{k-1}^{(r)}) \right) \\
&\quad + \frac{1}{2} \int_{T_{k-1}^{(r)}}^{t} H\big(S^{(r)}(T_{k-1}^{(r)}), \mathcal{U}_k^{(r)}\big) du \\
&= \underbrace{\theta_0 + \left(\int_0^t \frac{1}{2} \nabla \log \pi\big(S^{(r)}(u)\big) du + \widetilde{W}^{(r)}(t) \right)}_{\mathcal{I}(\widetilde{W})(t)} \\
&\quad + \underbrace{\int_0^t \frac{1}{2} \left(\nabla \log \pi\big(\widehat{S}^{(r)}(u)\big) - \nabla \log \pi\big(S^{(r)}(u)\big) \right) du}_{e_1^{(r)}(t)} \\
&\quad + \frac{1}{2} \underbrace{\int_0^t H\big(\widehat{S}^{(r)}(u), \mathcal{U}_k^{(r)}\big) du}_{e_2^{(r)}(t)},
\end{aligned}
$$

where $\widehat{S}^{(r)}$ is a piecewise constant (non-continuous) process, $\widehat{S}^{(r)}(t) = S^{(r)}(T_{k-1}^{(r)}) = \theta_{k-1}^{(r)}$ for $t \in [T_{k-1}^{(r)}, T_k^{(r)})$. The process $S^{(r)}$ can thus be expressed as the sum $\mathcal{I}(W^{(r)}) + e_1^{(r)} + e_2^{(r)}$. Since the mesh-size of the partition $\delta^{(r)}$ converges to zero as $r \to \infty$, standard properties of Brownian motions yield that $\widetilde{W}^{(r)}$ converges weakly in $\big(\mathcal{C}([0,t],\mathbb{R}^d), \|\cdot\|_{\infty,[0,T]}\big)$ to W, a standard Brownian motion in $\mathbb{R}^d$. To conclude the proof, we need to check that the quantities $\|e_1^{(r)}\|_\infty$ and $\|e_2^{(r)}\|_\infty$ converge to zero in probability. To prove $\mathbf{E}\left[\|e_2^{(r)}\|_\infty^2\right] \to 0$ in probability, we have,

$$
\begin{aligned}
\mathbf{E}\left[\|e_2^{(r)}\|_\infty^2\right] &\leq 4\, \mathbf{E}\left[\|e_2^{(r)}(T)\|^2\right] = 4 \sum_{k=1}^{m(r)} \big(\delta_k^{(r)}\big)^2\, \mathbf{E}\left[H\Big(\theta_{k-1}^{(r)}, \mathcal{U}_k^{(r)}\Big)^2\right] \\
&\lesssim \sum_{k=1}^{m(r)} \big(\delta_k^{(r)}\big)^2\, \mathbf{E}\left[V(\theta_{k-1}^{(r)})\right] \leq \mathrm{mesh}(\delta^{(r)}) \sum_{k=1}^{m(r)} \delta_k^{(r)}\, \mathbf{E}\left[V(\theta_{k-1}^{(r)})\right] \\
&\leq \mathrm{mesh}(\delta^{(r)}) \times T \times \sup\left\{ \mathbf{E}\left[V(\theta_{k-1}^{(r)})\right] : r \geq 1, 1 \leq k \leq m(r) \right\} \lesssim \mathrm{mesh}(\delta^{(r)}).
\end{aligned}
$$

We have used Doob's martingale inequality, Assumption 4 and Lemma 5. Since $\mathrm{mesh}(\delta^{(r)})$ converges to zero, the conclusion follows. To prove $\mathbf{E}\left[\|e_1^{(r)}\|_\infty\right] \to 0$ in probability, we use Equation (32) and note that since the drift function $\theta \mapsto \frac{1}{2}\nabla \log \pi(\theta)$ is globally Lipschitz, for each $T_{k-1}^{(r)} \leq u \leq T_k^{(r)}$ we have,

$$
\begin{aligned}
\left\| \nabla \log\big(\widehat{S}^{(r)}(u)\big) - \nabla \log\big(S^{(r)}(u)\big) \right\| &\lesssim \left\| \theta_k^{(r)} - \theta_{k-1}^{(r)} \right\| \\
&\lesssim \|\nabla \log \pi(\theta_{k-1}^{(r)})\|\, \delta_k^{(r)} + \|H(\theta_{k-1}^{(r)}, \mathcal{U}_k^{(r)})\|\, \delta_k^{(r)} + \sqrt{\delta_k^{(r)}}\, \|\eta_k^{(r)}\|.
\end{aligned}
$$

It follows that

$$
\mathbf{E}\left[\|e_1^{(r)}\|_\infty\right] \lesssim \sum_{k=1}^{m(r)} \delta_k^{(r)} \left(\|\nabla \log \pi(\theta_k^{(r)})\|\, \delta_k^{(r)} + \|H(\theta_k^{(r)}, \mathcal{U}_k)\|\, \delta_k^{(r)} + \sqrt{\delta_k^{(r)}}\, \|\eta_k^{(r)}\| \right).
$$

Since $\mathrm{mesh}(\delta^{(r)})$ converges to zero and by Assumption 4 and Lemma 5 the suprema

$$
\begin{cases}
\sup & \left\{ \mathbf{E}\left[\|\nabla \log \pi(\theta_k^{(r)})\|\right] : r \geq 1, 1 \leq k \leq m(r) \right\}, \\
\sup & \left\{ \mathbf{E}\left[\|H(\theta_k^{(r)}, \mathcal{U}_k)\|\right] : r \geq 1, 1 \leq k \leq m(r) \right\}
\end{cases}
$$

are finite, it readily follows that $\|e_1^{(r)}\|_\infty$ converges to zero in expectation. ■

7. Numerical Illustrations

In this section we illustrate the use of the SGLD method to a simple Gaussian toy model and to a Bayesian logistic regression problem. We verify that both models satisfy Assumption 4, the main assumption needed for our asymptotic results to hold. Simulations are then performed to empirically confirm our theory; for step-sizes sequences of the type $\delta_m = (m_0 + m)^{-\alpha}$, both the rate of decay of the MSE and the impact of the sub-sampling scheme are investigated. The main purpose of this article is to establish the missing theoretical foundation of stochastic gradient methods for the approximation of expectations. For more exhaustive simulation studies we refer to Welling and Teh (2011); S. Ahn and Welling (2012); Patterson and Teh (2013a); Chen et al. (2014). By considering a logistic regression model, we demonstrate that the SGLD can be advantageous over the Metropolis-Adjusted-Langevin (MALA) algorithm if the available computational budget only allows a few iterations through the whole data set, see Section 7.2.2.

7.1 Linear Gaussian model

Consider N independent and identically distributed observations $(x_i)_{i=1}^N$ from the two parameters location model given by

$$x_i \mid \theta \sim \mathrm{N}(\theta, \sigma_x^2).$$

We use a Gaussian prior $\theta \sim \mathrm{N}(0, \sigma_\theta^2)$ and assume that the variance hyper-parameters σ_θ^2 and σ_x^2 are both known. The posterior density $\pi(\theta)$ is normally distributed with mean μ_p and variance σ_p^2 given by

$$\mu_p = \bar{x}\left(1 + \frac{\sigma_x^2}{N\sigma_\theta^2}\right)^{-1} \qquad \text{and} \qquad \sigma_p^2 = \frac{\sigma_x^2}{N}\left(1 + \frac{\sigma_x^2}{N\sigma_\theta^2}\right)^{-1}$$

where $\bar{x} = (x_1 + \ldots + x_N)/N$ is the sample average of the observations. In this case, we have

$$\nabla \log \pi(\theta) = -\frac{\theta - \mu_p}{\sigma_p^2} \quad \text{and} \quad H(\theta, \mathcal{U}) = \Big\{(N/n) \sum_{j \in \mathcal{I}_n(\mathcal{U})} x_j - \sum_{1 \le i \le N} x_i\Big\}/\sigma_x^2$$

for a random subset $\mathcal{I}_n(\mathcal{U}) \subset [N]$ of cardinal n.

7.1.1 Verification of Assumption 4

We verify in this section that Assumption (4) is satisfied for the following choice of Lyapunov function,

$$V(\theta) = 1 + \frac{(\theta - \mu_p)^2}{2\,\sigma_p^2}.$$

Since the error term $H(\theta,\mathcal{U})$ is globally bounded, the drift $(1/2)\nabla \log \pi$ and the Lyapunov function V are linear, Assumptions (4).1 and (4).2 are satisfied. Finally, to verify Assumption (4).3, it suffices to note that since $\nabla \log \pi(\theta) = -(\theta - \mu_p)/\sigma_p^2$ we have

$$\left\langle \nabla V(\theta), \frac{1}{2}\nabla \log \pi(\theta) \right\rangle = -\frac{(\theta - \mu_p)^2}{2\,\sigma_p^4} = \frac{1 - V(\theta)}{\sigma_p^2}.$$

In other words, Assumption (4).3 holds with $\alpha = \beta = 1/\sigma_p^2$.

7.1.2 Simulations

We chose $\sigma_\theta = 1$, $\sigma_x = 5$ and created a data set consisting of $N = 100$ data points simulated from the model. We used $n = 10$ as the size of subsets used to estimate the gradients. We evaluated the convergence behaviour of SGLD using the test function $\mathcal{A}\varphi$ where $\varphi = \sin(x - \mu_p - 0.5\sigma_p)$.

We are interested in confirming the asymptotic convergence regimes of Theorem 8 by running SGLD with a range of step sizes, and plotting the mean squared error (MSE) achieved by the estimate $\pi_m(\mathcal{A}\varphi)$ against the number of steps m of the algorithm to determine the rates of convergence. We used step sizes $\delta_m = (m + m_0(\alpha))^{-\alpha}$, for $\alpha \in \{0.1, 0.2, 0.3, 0.33, 0.4, 0.5\}$ where $m_0(\alpha)$ is chosen such that δ_1 is less than the posterior

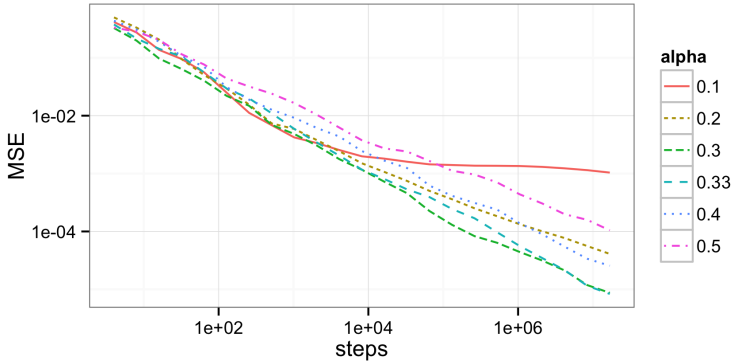

Figure 1: Decay of the MSE for step sizes $\delta_m \asymp m^{-\alpha}$, $\alpha \in \{0.1, 0.2, 0.3, 0.33, 0.4, 0.5\}$. The MSE decays algebraically for all step sizes, with fastest decay at approximately $\alpha = 0.33$.

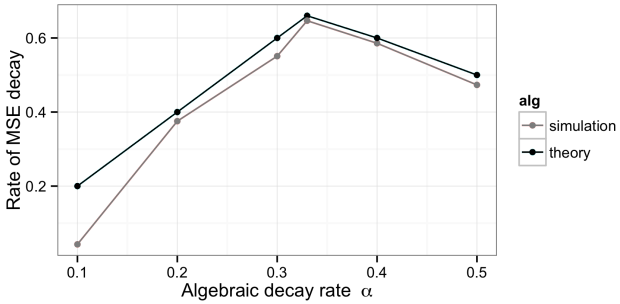

Figure 2: Rates of decay of the MSE obtained from estimating the asymptotic slopes of the plots in Figure 1, compared to theoretical findings of Theorem 8. The fastest convergence rate is achieved at $\alpha = 1/3$.

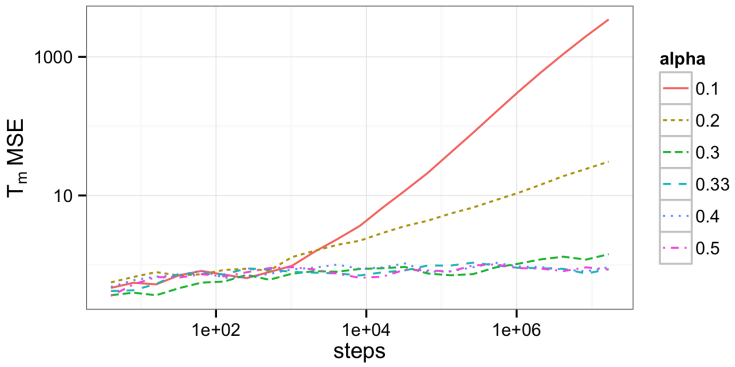

Figure 3: Plots of the MSE multiplied by T_m against the number of steps m. The plots are flat for $\alpha \geq 0.33$, demonstrating that the MSE scales as T_m^{-1} in this regime, while the plots diverge for $\alpha < 0.33$, demonstrating that it decays at a slower rate here.

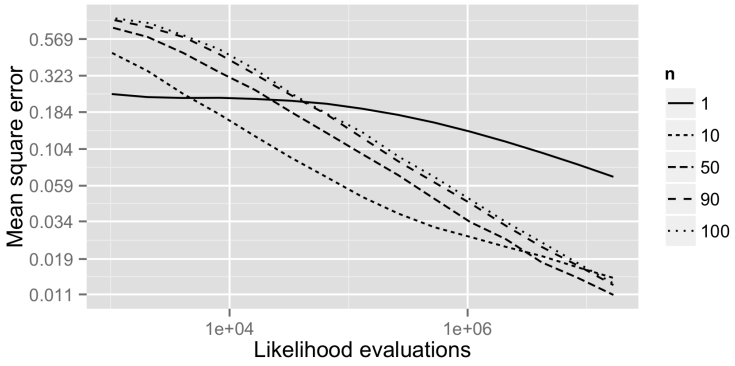

Figure 4: Behaviour of the mean squared error for different subsample sizes n.

standard deviation. According to the Theorem, the MSE should scale as T_m^{-1} for $\alpha > 1/3$, and $\sum_{k=1}^m \delta_k^2/T_m$ for $\alpha \leq 1/3$.

The observed MSE is plotted against m on a log-log plot in Figure 1. As predicted by the theory, the optimal rate of decay is around $\alpha_\star = 1/3$. To be more precise, we estimate the rates of decay by estimating the slopes on the log-log plots. This is plotted in Figure 2, which also shows a good match to the theoretical rates given in Theorem 8, where the best rate of decay is 2/3 achieved at $\alpha = 1/3$. Finally, to demonstrate that there are indeed two distinct regimes of convergence, in Figure 3 we have plotted the MSE multiplied by T_m. For $\alpha > 1/3$, the plots remain flat, showing that the MSE does indeed decay as T_m^{-1}. For $\alpha < 1/3$, the plots diverge, showing that the MSE decays at a slower rate than T_m^{-1}.

For $\alpha = 0.33$, Figure 4 depicts how the MSE decreases as a function of the number of likelihood evaluations for subsample sizes $n = 1, 5, 10, 50, 100$.

7.2 Logistic Regression

We verify in this section that Assumption (4) is satisfied for the following logistic regression model. Consider N independent and identically observations $(y_i)_{i=1}^N$ distributed as

$$\mathbb{P}(y_i = 1 \mid x_i, \theta) \;=\; 1 - \mathbb{P}(y_i = -1 \mid x_i, \theta) \;=\; \mathrm{logit}\big(\langle \theta, x_i \rangle\big) \tag{34}$$

for covariate $x_i \in \mathbb{R}^d$, unknown parameter $\theta \in \mathbb{R}^d$ and function $\mathrm{logit}(z) = e^z/(1+e^z)$. We assume a centred Gaussian prior on $\theta \in \mathbb{R}^d$ with positive definite symmetric covariance matrix $C \in \mathbb{R}^{d \times d}$. It follows that

$$\nabla \log \pi(\theta) = -C^{-1}\theta + \sum_{i=1}^N \mathrm{logit}\big(-y_i \langle \theta, x_i \rangle\big)\, y_i\, x_i$$

$$H(\theta, \mathcal{U}) = (N/n) \sum_{j \in \mathcal{I}_n(U)} \mathrm{logit}\big(-y_j \langle \theta, x_j \rangle\big)\, y_j\, x_j - \sum_{1 \leq i \leq N} \mathrm{logit}\big(-y_i \langle \theta, x_i \rangle\big)\, y_i\, x_i$$

for a random subset $\mathcal{I}_n(\mathcal{U}) \subset [N]$ of cardinal n.

7.2.1 Verification of Assumption 4

We verify in this section that Assumption (4) is satisfied for the Lyapunov function $V(\theta) = 1 + \|\theta\|^2$. Since $H(\theta, \mathcal{U})$ is globally bounded and $\|\nabla V(\theta)\|^2 = \|\theta\|^2$ and

$$\|\nabla \log \pi(\theta)\|^2 \lesssim 1 + \|C^{-1}\theta\|^2 \lesssim 1 + \|\theta\|^2 = V(\theta),$$

it is straightforward to see that Assumption (4).1 and (4).2 are satisfied. Finally,

$$\begin{aligned}\left\langle \nabla V(\theta), \frac{1}{2} \nabla \log \pi(\theta) \right\rangle &= -\frac{1}{2} \langle \theta, C^{-1}\theta \rangle + \frac{1}{2} \sum_{i=1}^N \mathrm{logit}\big(-y_i \langle \theta, x_i \rangle\big)\, y_i \, \langle \theta, x_i \rangle \\ &\leq -\frac{\lambda_{\min}}{2} \|\theta\|^2 + \frac{\sum_{i=1}^N \|x_i\|}{2} \|\theta\| \leq -\frac{\lambda_{\min}}{4} V(\theta) + \beta\end{aligned}$$

with $\lambda_{\min} > 0$ the smallest eigenvalue of C^{-1} and $\beta \in (0, \infty)$ the global maximum over $\theta \in \mathbb{R}^d$ of the function $\theta \mapsto -\frac{\lambda_{\min}}{4}\|\theta\|^2 + \frac{\sum_{i=1}^N \|x_i\|}{2}\|\theta\|$.

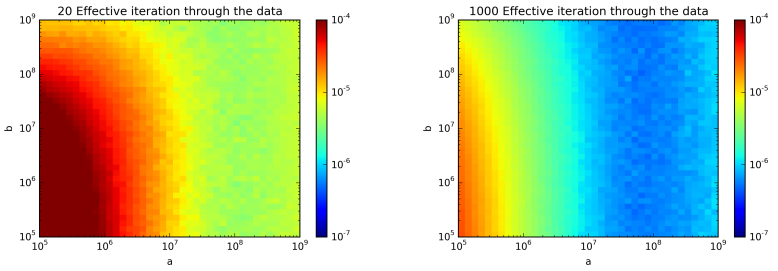

Figure 5: Expected MSE of the SGLD-based estimate variance estimate of the first component for $n = 30$ and step sizes $\delta_m = (a \cdot m + b)^{-0.38}$ after 20 and 1000 iterations through the data set

7.2.2 Comparison of the SGLD and the MALA for Logistic Regression

We consider a simulated dataset where $d = 3$ and $N = 1000$. We set the input covariates $x_i = (x_{i,1}, x_{i,2}, 1)$ with $x_{i,1}, x_{i,2} \overset{\text{i.i.d.}}{\sim} \mathrm{N}(0,1)$ for $i = 1 \dots N$, and use a Gaussian prior $\theta \sim \mathrm{N}(0, I)$. We draw a $\theta_0 \sim \mathrm{N}(0, I)$ and based on it we generate y_i according to the model probabilities (34). In the following we compare MALA in SGLD by comparing their estimate for the variance of the first component.

The findings of this article show that SGLD-based expectation estimates converge at a slower rate of at most $n^{-\frac{1}{3}}$ compared to the standard rate of $n^{-\frac{1}{2}}$ for standard MCMC algorithms such as the MALA algorithm. In the following we demonstrate that in the non-asymptotic regime (allowing only a few passes through the data set) the SGLD can be advantageous. We start both algorithms at the MAP estimator and we ensure that this study is not biased due to different speeds in finding the mode of the posterior. For a fair comparison we tune the MALA to an acceptance rate of approximately 0.564 following the findings of Roberts and Rosenthal (1998). For the SGLD-based variance estimate of the first component for $n = 30$ we choose $\delta_m = (a \cdot m + b)^{-0.38}$ as step sizes and optimise over the choices of a and b. This is achieved by estimating the MSE for choices of a and b on a log-scale grid based on 512 independent runs. The estimates based on 20 and 1000 effective iterations through the data set the averages are visualised in the heat maps in Figure 5. That means we limit the algorithm to 200 and 1000000 likelihood evaluations, respectively. The figures indicate that the range of the good parameter choices seems to be the same in both cases. Using the heat map for the estimated MSE after 20 iterations through the data set, we pick $a = 5.89 \cdot 10^7$ and $b = 7.90 \cdot 10^8$ and compare the time behaviour of the SGLD and the MALA algorithm in Figure 6. The figure is a simulation evidence that the SGLD algorithm can be advantageous in the initial phase for the first few iterations through the data set. This recommends further investigation as the initial phase can be quite different from the asymptotic phase.

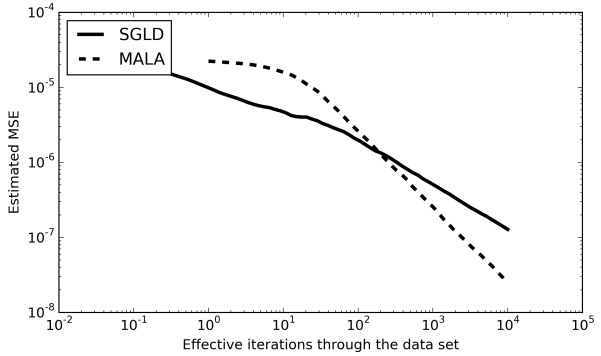

Figure 6: Behaviour of the MSE of estimating the posterior variance of the first component for 3-dimensional logistic regression of MALA and SGLD with tuned parameters

8. Conclusion

So far, the research on the SGLD algorithm has mainly been focused on extending the methodology. In particular, a parallel version has been introduced in Ahn et al. (2014) and it has been adapted to natural gradients in Patterson and Teh (2013b). This research has been accompanied by promising simulations. In contrast, we have focused in this article on providing rigorous mathematical foundations for the SGLD algorithm by showing that the step-size weighted estimator $\pi_m(f)$ is consistent, satisfies a central limit theorem and its asymptotic bias-variance decomposition can be characterised by an explicit functional $\mathbb{B}_m$ of the step-sizes sequence $(\delta_m)_{m \geq 0}$. The consistency of the algorithm is mainly due to the decreasing step-sizes procedure that asymptotically removes the bias from the discretization and ultimately mitigates the use of an unbiased estimate of the gradient instead of the exact value. Additionally, we have proved a diffusion limit result that establishes that, when observed on the right (inhomogeneous) time scale, the sample paths of the SGLD can be approximated by a Langevin diffusion.

The CLT and bias-variance decomposition can be leveraged to show that it is optimal to choose a step-sizes sequences $(\delta_m)_{m \geq 0}$ that scales as $\delta_m \asymp m^{-1/3}$; the resulting algorithm converges at rate $m^{-1/3}$. Note that this recommendation is different from the previously suggested Welling and Teh (2011) choice of $\delta_m \asymp m^{-1/2}$.

Our theory suggests that an optimally tuned SGLD method converges at rate $\mathcal{O}(m^{-1/3})$, and is thus asymptotically less efficient than a standard MCMC procedure. We believe that this result does not necessarily preclude SGLD to be more efficient in the initial transient phase, a result hinted at in Figure 4; the detailed study of this (non-asymptotic) phenomenon is an interesting venue of research. The asymptotic convergence rate of SGLD depends crucially on the decreasing step sizes, which is required to reduce the effect of the discretization bias due to the lack of a Metropolis-Hastings correction. Another avenue of exploration is to determine more precisely the bias resulting from the discretization of the

Langevin diffusion, and to study the effect of the choice of step sizes in terms of the trade-off between bias, variance, and computation.

Appendix A. Proof of Lemma 6

Recall Kronecker's Lemma (Shiryaev, 1996, Lemma IV.3.2) that states that for a non-decreasing and positive sequence $b_m \to \infty$ and another real valued sequence $(a_m)_{m\geq 0}$ such that the series $\sum_{m\geq 0} a_m/b_m$ converges the following limit holds,

$$\lim_{m\to\infty} \frac{\sum_{k=0}^{m} a_k}{b_m} \;=\; 0.$$

For proving Equation (15) it thus suffices to show that the sums $\sum_{k\geq 0} |\Delta M_k|/T_k$ and $\sum_{k\geq 0} |X_k|/T_k$ are almost surely finite. This follows from Condition (16) (L^2 martingale convergence theorem) and Condition (17).

Appendix B. Proof of Lemma 5

For clarity, the proof is only presented in the scalar case $d = 1$; the multidimensional setting is entirely similar. Before embarking on the proof, let us first mention some consequences of Assumptions 4 that will be repeatedly used in the sequel. Since the second derivative V'' is globally bounded and $(V')^2$ is upper bounded by a multiple of V, we have that

$$\left|(V^p)''(\theta)\right| \lesssim V^{p-1}(\theta) \tag{35}$$

and that the function $V^{1/2}$ is globally Lipschitz. By expressing the quantity $V^p(\theta+\varepsilon)$ as $\big(V^{1/2}(\theta) + [V^{1/2}(\theta+\varepsilon) - V^{1/2}(\theta)]\big)^{2p}$, it then follows that

$$V^p(\theta+\varepsilon) \lesssim V^p(\theta) + |\varepsilon|^{2p}. \tag{36}$$

Similarly, Definition (7), the bound $\|\nabla \log \mathrm{p}(\theta)\|^2 \lesssim V(\theta)$ and Equation (10) yield that for any exponent $0 \leq p \leq p_H$ the following holds,

$$\mathbf{E}_m[\,|\theta_{m+1} - \theta_m|^{2p}\,] \lesssim \delta_{m+1}^{2p}\, V^p(\theta) + \delta_{m+1}^p. \tag{37}$$

For clarity, the proof of Lemma (5) is separated into several steps. First, we establish that the process $m \mapsto V^p(\theta_m)$ satisfies a Lyapunov type condition; see Equation (38) below. We then describe how Equation (13) follows from this Lyapunov condition. The fact that $\pi(V^p)$ is finite can be seen as a consequence of Theorem 2.2 of (Roberts and Tweedie, 1996).

- *Discrete Lyapunov condition.*
  Let us prove that there exists an index $m_0 \geq 0$ and constants $\alpha_p, \beta_p > 0$ such that for any $m \geq m_0$ we have

$$\mathbf{E}_m\left[V^p(\theta_{m+1}) - V^p(\theta_m)\right]/\delta_{m+1} \;\leq\; -\alpha_p\, V^p(\theta_m) + \beta_p. \tag{38}$$

Since for any ε there exists C_ε such that $V^{p-1}(\theta) \leq C_\varepsilon + \varepsilon V^p(\theta)$, for proving (38) it actually suffices to verify that we have

$$\mathbf{E}_m\left[V^p(\theta_{m+1}) - V^p(\theta_m)\right]/\delta_{m+1} \;\leq\; -\widetilde{\alpha}_p\, V^p(\theta_m) + \widetilde{\beta}_p\, V^{p-1}(\theta_m) \tag{39}$$

for some constants $\widetilde{\alpha_p}, \widetilde{\beta_p} > 0$ and index $m \geq 1$ large enough. A second order Taylor expansion yields that the left hand side of (39) is less than

$$\mathbf{E}_m\left[(V^p)'(\theta_m)\,(\theta_{m+1} - \theta_m)\right]/\delta_{m+1} + \frac{1}{2}\,\mathbf{E}_m\left[(V^p)''(\xi)\,(\theta_{m+1} - \theta_m)^2\right]/\delta_{m+1} \tag{40}$$

for a random quantity ξ lying between θ_m and θ_{m+1}. Since $\mathbf{E}_m[\theta_{m+1} - \theta_m] = \frac{1}{2}\nabla \log \mathrm{p}(\theta_m)$, the drift condition (12) yields that the first term of (40) is less than

$$p\, V^{p-1}(\theta_m)\,(-\alpha\, V(\theta_m) + \beta) \tag{41}$$

for $\alpha, \beta > 0$ given by Equation (12). Consequently, for proving Equation (38), it remains to bound the second term of (40). Equation (35) shows that $|(V^p)''(\xi)|$ is upper bounded by a multiple of $|V^{p-1}(\xi)|$; the bound (36) then yields that $|V^{p-1}(\xi)|$ is less than a constant multiple of $|V^{p-1}(\theta_m)| + |\theta_{m+1} - \theta_m|^{2(p-1)}$. It follows from the bound (37) on the difference $(\theta_{m+1} - \theta_m)$ and the assumption $\mathbf{E}[\,\|H(\theta, \mathcal{U})\|^{2p_H}\,] \lesssim V^{p_H}(\theta)$ that for any $\varepsilon > 0$ one can find an index $m_0 \geq 1$ large enough such that for any index $m \geq m_0$ the second term of (39) is less than a constant multiple of

$$\varepsilon\, V^p(\theta_m) + \beta_{p,\varepsilon}\, V^{p-1}(\theta) \tag{42}$$

for a constant $\beta_{p,\varepsilon} > 0$. Equations (41) and (42) directly yield to Equation (39), which in turn implies to Equation (38).

- *Proof that* $\sup_{m\geq 1}\, \mathbf{E}[V^p(\theta_m)] \,<\, \infty$ *for any* $p \leq p_H$.
  Equations (36) and (37) show that if $\mathbf{E}[V^p(\theta_m)]$ is finite then so is $\mathbf{E}[V^p(\theta_{m+1})]$. Under the conditions of Lemma 5, this shows that $\mathbf{E}[V^p(\theta_m)]$ is finite for any $m \geq 0$. An inductive argument based on the discrete Lyapunov Equation (38) then yields that for any index $m \geq m_0$ the expectation $\mathbf{E}[V^p(\theta_m)]$ is less than

$$\max\Big(\beta_p/\alpha_p, \max\big\{\,\mathbf{E}[V^p(\theta_m)] :\;\; 0 \leq m \leq m_0\big\}\Big). \tag{43}$$

  It follows that $\sup_{m\geq 1}\, \mathbf{E}[V^p(\theta_m)]$ is finite.

- *Proof that* $\sup_{m\geq 1}\, \pi_m(V^p) \,<\, \infty$ *for any* $p \leq p_H/2$.
  One needs to prove that the sequence $(1/T_m)\sum_{k=m_0}^{m} \delta_{k+1} V^p(\theta_k)$ is almost surely bounded. The discrete Lyapunov Equation (38) yields that $\delta_{k+1} V^p(\theta_k)$ is less than $\delta_{k+1}\,\beta_p/\alpha_p - \mathbf{E}_k[V^p(\theta_{k+1}) - V^p(\theta_k)]/\alpha_p$; this yields that $(1/T_m)\sum_{k=m_0}^{m} \delta_{k+1} V^p(\theta_k)$ is less than a constant multiple of

$$1 + \frac{V^p(\theta_{m_0})}{T_m} + \frac{1}{T_m}\sum_{k=m_0}^{m} \Big\{V^p(\theta_{k+1}) - \mathbf{E}_k[V^p(\theta_{k+1})]\Big\}.$$

To conclude the proof, we prove that the last term in the above displayed Equation almost surely converges to zero; by Lemma 6, it suffices to prove that the quantity

$$\sum_{k\geq m_0} \mathbf{E}\left[\left|\frac{V^p(\theta_{k+1}) - \mathbf{E}_k[V^p(\theta_{k+1})]}{T_k}\right|^2\right] \tag{44}$$

is almost surely finite. We have $\mathbf{E}\left[|V^p(\theta_{k+1}) - \mathbf{E}_k[V^p(\theta_{k+1})]|^2\right] \leq 2 \times \mathbf{E}[|\,V^p(\theta_{k+1}) - V^p(\theta_k)\,|^2]$ and the mean value theorem yields that

$$|V^p(\theta_{k+1}) - V^p(\theta_k)| \lesssim V^{p-1}(\xi)\, V'(\xi)\, (\theta_{k+1} - \theta_k)$$

for some ξ lying between θ_k and θ_{k+1}. The bound $|V'(\theta)| \lesssim V^{1/2}(\theta)$ and Equation (36) then yield that $|V^p(\theta_{k+1}) - V^p(\theta_k)| \lesssim V^{p-1/2}(\theta_k)\left|\theta_{k+1} - \theta_k\right| + \left|\theta_{k+1} - \theta_k\right|^{2p}$. From the bound (37) and the assumption that $\mathbf{E}[H(\theta, \mathcal{U})^{2p_H}] \lesssim V^{p_H}(\theta)$ it follows that the quantity in Equation (44) is less than a constant multiple of

$$\sum_{k\geq m_0} \frac{\mathbf{E}\left[\,V^{2p}(\theta_k)\,\right] \times \delta_k}{T^2(k)}.$$

Since $\mathbf{E}\left[V^{2p}(\theta_k)\right]$ is uniformly bounded for any $p \leq p_H/2$ and $\sum_{m\geq m_0} \delta_m / T^2(m) < \infty$ (because the sum $\sum_m T^{-1}(m+1) - T^{-1}(m)$ is finite), the conclusion follows.

- *Proof of* $\pi(V^p) < \infty$ *for any* $p \geq 0$.
  Since $V(\theta) \lesssim 1 + \|\theta\|^2$, the drift condition (12) yields that Theorem 2.1 of (Roberts and Tweedie, 1996) holds. Moreover, the bound $V^{p-1}(\theta) \leq C_\varepsilon + \varepsilon\, V^p(\theta)$ implies that there are constants $\alpha_{p,*}.\beta_{p,*} > 0$ such that

$$\mathcal{A}V^p(\theta) \leq -\alpha_{p,*}\, V^p(\theta) + \beta_{p,*} \tag{45}$$

  where $\mathcal{A}$ is the generator of the Langevin diffusion (1). Theorem 2.2 of (Roberts and Tweedie, 1996) gives the conclusion.

Proof that $\sup_{m\geq 1}\ \pi_m^\omega(V^p) < \infty$ *for any* $p \leq p_H/2$.
One needs to prove that the sequence $[1/\Omega_m] \times \sum_{k=m_0}^m \omega_{k+1} V^p(\theta_k)$ is almost surely bounded. The bound $\delta_{k+1} V^p(\theta_k) \lesssim \delta_{k+1}\, \beta_p/\alpha_p - \mathbf{E}_k[V^p(\theta_{k+1}) - V^p(\theta_k)]/\alpha_p$ yields that $\pi_m^\omega(V^p)$ is less than a constant multiple of

$$1 + \frac{(\omega_{m_0}/\delta_{m_0})\, V^p(\theta_{m_0})}{T_m} \quad +\Omega^{-1}(m)\ \sum_{k=m_0+1}^m (\omega_k/\delta_k)\left\{V^p(\theta_{k+1}) - \mathbf{E}_k[V^p(\theta_{k+1})]\right\}$$
$$+\Omega^{-1}(m)\ \sum_{k=m_0}^{m-1} \Delta(\omega_k/\delta_k)\, V^p(\theta_k).$$

To conclude the proof, we establish that the following limits hold almost surely,

$$\lim_{m\to\infty}\ \Omega^{-1}(m)\ \sum_{k=m_0+1}^m (\omega_k/\delta_k)\left\{V^p(\theta_{k+1}) - \mathbf{E}_k[V^p(\theta_{k+1})]\right\} = 0 \tag{46}$$
$$\lim_{m\to\infty}\ \Omega^{-1}(m)\ \sum_{k=m_0}^{m-1} \Delta(\omega_k/\delta_k)\, V^p(\theta_k) = 0. \tag{47}$$

To prove Equation (46) it suffices to use the assumption that $\sum_{m\geq 0} \omega_m^2/[\delta_m \Omega_m^2] < \infty$ and then follow the same approach used to establish that the quantity (44) is finite. Lemma 6 shows that to prove Equation (47) it suffices to verify that

$$\mathbf{E}\Big[\sum_{m\geq 0} \left|\Delta(\omega_m/\delta_m)\right| V^p(\theta_m)/\Omega_m\Big] < \infty.$$

This directly follows from the assumption that $\sum_{m\geq 0} \left|\Delta(\omega_m/\delta_m)\right|/\Omega_m < \infty$ and the fact that $\sup_{m\geq 0} \mathbf{E}[V^p(\theta_m)]$ is finite.

Abstract

We explored the effect of introducing prior knowledge into the intermediate level of deep supervised neural networks on two tasks. On a task we designed, all black-box state-of-the-art machine learning algorithms which we tested, failed to generalize well. We motivate our work from the hypothesis that, there is a training barrier involved in the nature of such tasks, and that humans learn useful intermediate concepts from other individuals by using a form of supervision or guidance using a curriculum. Our results provide a positive evidence in favor of this hypothesis. In our experiments, we trained a two-tiered MLP architecture on a dataset for which each input image contains three sprites, and the binary target class is 1 if all of three shapes belong to the same category and otherwise the class is 0. In terms of generalization, black-box machine learning algorithms could not perform better than chance on this task. Standard deep supervised neural networks also failed to generalize. However, using a particular structure and guiding the learner by providing intermediate targets in the form of intermediate concepts (the presence of each object) allowed us to solve the task efficiently. We obtained much better than chance, but imperfect results by exploring different architectures and optimization variants. This observation might be an indication of optimization difficulty when the neural network trained without hints on this task. We hypothesize that the learning difficulty is due to the *composition* of two highly non-linear tasks. Our findings are also consistent with the hypotheses on cultural learning inspired by the observations of training of neural networks sometimes getting stuck, even though good solutions exist, both in terms of training and generalization error.

Keywords: deep learning, neural networks, optimization, evolution of culture, curriculum learning, training with hints

1. Introduction

There is a recent emerging interest in different fields of science for *cultural learning* (Henrich and McElreath, 2003) and how groups of individuals that communicates within each other can learn in ways superior to solely individual learning. This is further witnessed by the emergence of new research fields such as "Social Neuroscience". Learning from other agents in an environment by the means of cultural transmission of knowledge with a peer-to-peer communication is an efficient and natural way of acquiring or propagating common knowledge. A popular belief on how the information is transmitted between individuals is that bits of information are transmitted by small units, called memes, which share some characteristics of genes, such as self-replication, mutation and response to selective pressures (Dawkins, 1976).

This paper investigates an aspect of the hypothesis (which is further elaborated in Bengio (2013a)) that human culture and the evolution of ideas have been crucial to counter an optimization issue: this difficulty would otherwise make it harder for human brains to capture high level knowledge of the world without the help of other educated humans. In this paper, machine learning experiments are used to explore some elements of this hypothesis by seeking answers for the following questions: are there machine learning tasks which are intrinsically hard for a lone learning agent, but those tasks may become easier when intermediate concepts are provided by another agent as an additional intermediate learning cues, in the spirit of curriculum learning (Bengio et al., 2009)? What makes learning such tasks more difficult? Can specific initial values of the neural-network parameters yield success when random initialization yield complete failure? Is it possible to verify that the problem being faced is an optimization problem or a regularization problem or does it influence both training and test behavior? These are the questions discussed (if not completely addressed) here, which relate to the following broader question: how can humans (and potentially one day, machines) learn complex concepts?

In the focus of this paper, results of different machine learning algorithms on an artificial learning task involving binary 64×64 images are presented. In that task, each image in the dataset contains 3 Pentomino tetris sprites (simple shapes). The task is to figure out if all the sprites in the image are the same or not. Several black-box state-of-the-art machine learning algorithms have been tested and none of them was able to perform better than a random predictor on the test set. Nevertheless, by providing hints about the intermediate concepts (the presence and location of particular sprite classes), can help a neural network to solve the task easily and fast. But the same model without the hints either fails to learn the task or learns it much more slowly and with substantially worse generalization accuracy. Surprisingly, our attempts at solving this problem with unsupervised pre-training algorithms also failed. For showing the impact of intermediate level guidance, we experimented with a two-tiered neural network, with supervised pre-training of the first part to recognize the category of sprites independently of their orientation and scale, at different locations, while the second part learns from the output of the first part and predicts the binary task of interest.

The objective of this paper is not to propose a novel learning algorithm or architecture, but rather to refine our understanding of the learning difficulties involved with composed tasks. Our results also bring empirical evidence in favor of some of the hypotheses from Bengio (2013a), as well as to introduce particular form of curriculum learning (Bengio et al., 2009) based on hints.

Building difficult AI problems has a long history in computer science. Hard AI problems are being studied to create CAPTCHAs that are easy to solve for humans, but hard to solve for machines (Von Ahn et al., 2003). In this paper we are investigating a difficult problem for the off-the-shelf black-box machine learning algorithms. The source code of some experiments presented in that paper is available at `https://github.com/caglar/kmatters`.

1.1 Curriculum Learning and Cultural Evolution for Effective Local Minima

What Bengio (2013a) calls an **effective local minimum**, is a point where iterative training stalls, either because of an actual local minimum or due to optimization algorithm is unable (in reasonable time) to find a descent path to a substantially better solution that exists. It is not yet clear why neural network training sometimes stalls in this way, although recent

work suggests that it would generally not be because of local minima (Dauphin et al., 2014; Choromanska et al., 2015). In this paper, we hypothesize that some more abstract learning tasks such as those obtained by composing simpler tasks are more likely to yield such effective local minima for neural networks, and are generally hard for general-purpose machine learning algorithms.

The idea that learning can be enhanced by guiding the learner through intermediate easier tasks is old, starting with animal training by *shaping* (Skinner, 1958; Peterson, 2004; Krueger and Dayan, 2009). Bengio et al. (2009) introduce a computational hypothesis related to a presumed issue with effective local minima when directly learning the target task: good solutions correspond to hard-to-find-by-chance effective local minima, and intermediate tasks prepare the learner's internal configuration (parameters) in a way that is similar to continuation methods in global optimization. A continuation method would go through a sequence of intermediate optimization problems, starting with a convex one where local minima are no issue, and gradually morphing into the target task of interest.

In a related vein, Bengio (2013a) makes the following inferences based on experimental observations about training of deep neural networks:

Point 1: Training deep architectures is easier when some hints are given about the function that the intermediate levels should compute (Hinton et al., 2006; Weston et al., 2008; Salakhutdinov and Hinton, 2009; Bengio, 2009). *The experiments performed here expand in particular on this point.*

Point 2: It is much easier to train a neural network with supervision (where examples are provided to it when a concept is present and not present in a variety of examples) than to expect unsupervised learning to discover the concept (which may also happen but usually leads to poorer renditions of the concept). *The poor results obtained here with unsupervised pre-training reinforce that hypothesis.*

Point 3: Directly training all layers of a deep network together does not only makes it more difficult to exploit all the extra modeling power of a deeper architecture but in some cases it can yield worse results as the number of *required layers* is increased (Larochelle et al., 2009; Erhan et al., 2010). *The experiments performed here also reinforce that hypothesis.*

Point 4: Erhan et al. (2010) observed that no two training trajectories ended up in the same effective local minimum, out of hundreds of runs, even when comparing solutions as functions from input to output, rather than in parameter space (thus eliminating from the picture the presence of symmetries and multiple local minima due to relabeling and other reparametrizations). This suggests that the number of different effective local minima (even when considering them only in function space) must be huge.

Point 5: Unsupervised pre-training changes the initial conditions of the descent procedure and it can allow to reach substantially better effective local minima (in terms of generalization error). But as empirically observed by (Erhan et al., 2010), better local minima do not appear to be reachable by chance alone on the same architectures. *The experiments performed here provide another piece of evidence in favor of the hypothesis that random initialization can yield rather poor results while specifically targeted initialization can have a drastic impact, that is, the effective local minima are not just numerous but that some small subset of them are much better and hard to reach by chance.* Nevertheless, recent work showed that rather deep feed-forward networks can be very successfully trained when large quantities of labeled data is available (Ciresan et al., 2010; Glorot et al., 2011; Krizhevsky et al., 2012). Nonetheless, the experiments reported here suggest that it all depends on the task and architecture being considered, since even with very large quantities of labeled examples, most the deep networks trained here were unsuccessful.

Based on the above points, Bengio (2013a) then proposed the following hypotheses regarding learning of high-level abstractions.

- **Deeper Networks are Harder Hypothesis:** Although solutions may exist, effective local minima are generally more likely to hamper learning as the required depth of the architecture increases.
- **Abstractions are Harder Hypothesis:** High-level abstractions are unlikely to be discovered by a single human learner by chance, because these abstractions are represented by a deep subnetwork of the brain, which learns by local descent, thus being sensitive to the issue associated with the above hypothesis.
- **Guided Learning Hypothesis:** A human brain can learn high level abstractions if guided by the signals produced by other agents that act as hints or indirect supervision for these high-level abstractions.
- **Memes Divide-and-Conquer Hypothesis:** Linguistic exchange, individual learning and the recombination of memes constitute an efficient evolutionary recombination operator in the meme-space. This helps human learners to *collectively* build better internal representations of their environment, including fairly high-level abstractions.

This paper particularly focuses on "*Point 1*" above and testing the "*Guided Learning Hypothesis*", using machine learning algorithms to provide experimental evidence. The experiments performed also provide evidence in favor of the "*Deeper Harder Hypothesis*" and are related to the "*Abstractions Harder Hypothesis*". Performance of machine learning algorithms are far from the current capabilities of humans on several tasks, and it is important to tackle the remaining obstacles to approach AI. For this purpose, the question to be answered is why on some tasks humans learn effortlessly from very few labeled examples, while machine learning algorithms fail miserably?

2. Optimization Difficulty of Learning High-level Concepts

As hypothesized in the "*Local Descent Hypothesis*", human brains would rely on a local approximate descent, just like a Multi-Layer Perceptron trained by a gradient-based iterative optimization. The main argument in favor of this hypothesis relies on the biologically-grounded assumption that although firing patterns in the brain change rapidly, synaptic strengths underlying these neural activities change only gradually, making sure that behaviors are generally consistent across time. If a learning algorithm is based on a form of local (for example gradient-based) descent, it can be sensitive to effective local minima (Bengio, 2013a).

When one trains a neural network, at some point in the training phase the evaluation of error seems to saturate, even if new examples are introduced. In particular Erhan et al. (2010) find that early examples have a much larger weight in the final solution. It looks like the learner

is stuck in or near a local minimum. But since it is difficult to verify if this is near a true local minimum or simply an effect of strong ill-conditioning or a saddle-point, we call such a "stuck" configuration an *effective local minimum*, whose definition depends not just on the optimization objective but also on the limitations of the optimization algorithm.

Erhan et al. (2010) highlighted both the issue of effective local minima and a regularization effect when initializing a deep network with unsupervised pre-training. Interestingly, as the network gets deeper the difficulty due to effective local minima seemed to be get more pronounced in these experiments. That might be because the number of effective local minima increases (more like an actual local minima issue), or maybe because the good ones are harder to reach (more like an ill-conditioning issue) and more work will be needed to clarify this question.

As a result of Point 4 we hypothesize that it is very difficult for an individual's brain to discover some higher level abstractions by chance only. As mentioned in the "*Guided Learning Hypothesis*" humans get hints from other humans and learn high-level concepts with the guidance of other humans. But some high-level concepts may also be hardwired in the brain, as assumed in the universal grammar hypothesis (Montague, 1970), or in nature vs nurture discussions in cognitive science. Curriculum learning (Bengio et al., 2009) and incremental learning (Solomonoff, 1989), are specific examples of this phenomena. Curriculum learning is done by properly choosing the sequence of examples seen by the learner, where simpler examples are introduced first and more complex examples shown when the learner is ready for them. One of the hypotheses on why a curriculum works states that curriculum learning acts as a continuation method that allows one to discover a good minimum: continuation methods first find a good minimum of a smoother objective function and then gradually change the objective function towards the desired one, while tracking local minima along the way. Recent experiments on human subjects also suggest that humans *teach* by using a curriculum strategy (Khan et al., 2011).

Some parts of the human brain are known to have a hierarchical organization (for example, the visual cortex) consistent with the deep architecture studied in the machine learning literature. As a stimulus is transmitted from the sensory level to higher levels of the visual cortex, higher level areas tend to respond to stimuli in a way corresponding to the detection of more concepts. This is consistent with the *Deep Abstractions Hypothesis*.

Training neural networks and machine learning algorithms by decomposing the learning task into sub-tasks and exploiting prior information about the task is well-established and in fact constitutes the main approach to solving industrial problems with machine learning. The contribution of this paper is rather on rendering explicitly, the effective local minima issue and providing evidence on the type of problems for which this difficulty arises. This prior information and hints given to the learner can be viewed as an inductive bias for a particular task, an important ingredient to obtain a good generalization error (Mitchell, 1980). An interesting earlier finding in that line of research was done with Explanation Based Neural Networks (EBNN) in which a neural network transfers knowledge across multiple learning tasks. An EBNN uses previously learned domain knowledge as an initialization or search bias (that is to constrain the learner in the parameter space) (O'Sullivan, 1996; Mitchell and Thrun, 1993).

Another related work in machine learning is mainly focused on reinforcement learning algorithms, based on incorporating prior knowledge in terms of logical rules to the learning algorithm as a prior knowledge to speed up and bias learning (Kunapuli et al., 2010; Towell and Shavlik, 1994). Also defining sub-tasks and sub-goals to guide the agent is a well-established principle in hierarchical reinforcement learning (Barto and Mahadevan, 2003).

3. Experimental Setup

Some tasks, which seem reasonably easy for humans to learn (keeping in mind that humans can exploit prior knowledge, either from previous learning or innate knowledge), are nonetheless appearing almost impossible to learn for current generic state-of-art machine learning algorithms.

Here we study more closely such a task, which becomes learnable if one provides hints to the learner about appropriate intermediate concepts. Interestingly, the task we used in our experiments is not only hard for deep neural networks but also for non-parametric machine learning algorithms such as SVMs, boosting and decision trees.

The result of the experiments for varying size of dataset with several off-the-shelf black box machine learning algorithms and some popular deep learning algorithms are provided in Table 4. The detailed explanations about the algorithms and the hyperparameters used for those algorithms are given in the Appendix Section B. We also provide some explanations about the methodologies conducted for the experiments at Section 3.3.

3.1 Pentomino Dataset

In order to test our hypothesis, we designed an artificial dataset for object recognition using 64×64 binary images. The source code for the script that generates the artificial Pentomino datasets (Arcade-Universe) is available at: `https://github.com/caglar/Arcade-Universe`. This implementation is based on Olivier Breuleux's bugland dataset generator. If the task is two tiered (i.e., with guidance provided), the task in the first part is to recognize and locate each Pentomino object class[1] in the image. The second part/final binary classification task is to figure out if all the Pentominoes in the image are of the same shape class or not. If a neural network learned to detect the categories of each object at each location in an image, the remaining task becomes an XOR-like operation over the detected object categories. The types of Pentomino objects that is used for generating the dataset are illustrated in Figure 1 and correspond to Pentomino sprites N, P, F, Y, J, and Q, along with the Pentomino N2 sprite (mirror of "Pentomino N" sprite), the Pentomino F2 sprite (mirror of "Pentomino F" sprite), and the Pentomino Y2 sprite (mirror of "Pentomino Y" sprite).

Figure 1: Different classes of Pentomino shapes used in our dataset.

As shown in Figures 2(a) and 2(b), the synthesized images are fairly simple and do not have any texture. Foreground pixels are "1" and background pixels are "0". Images of the training and test sets are generated iid. For notational convenience, we assume that the domain of raw input images is X, the set of sprites is S, the set of intermediate object categories for each possible location in the image is denoted as Y and the set of possible final binary task outcomes is $Z = \{0, 1\}$. Two different types of rigid body transformation is performed: sprite rotation, $rot(X, \gamma)$,where the set of all rotations is $\Gamma = \{\gamma\text{: } (\gamma = 90 \times \phi) \wedge [(\phi \in \mathbb{N}), (0 \leq \phi \leq 3)]\}$ and sprite scaling, $scale(X, \alpha)$, where $\alpha \in \{1, 2\}$ is the scaling factor. The data generating procedure is summarized below.

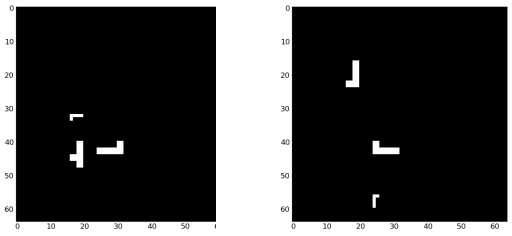
1. A human learner does not seem to need to be taught the shape categories of each Pentomino sprite in order to solve the task. On the other hand, humans have lots of previously learned knowledge about the notion of shape and how central it is in defining categories.

Sprite transformations: Before placing the sprites in an empty image, for each image $x \in X$, a value for $z \in Z$ is randomly sampled whether to have (or not) the same three Pentomino sprite shapes in the image. Conditioned on the constraint given by z, three sprites s_{ij} at location $(i,\ j)$ are randomly selected from the set S without replacement. Using a uniform probability distribution over all possible scales, a scale is chosen and accordingly each sprite in the image is scaled. Then each sprite is randomly rotated by a multiple of 90 degrees.

Sprite placement: Upon completion of sprite transformations, a 64×64 uniform grid is generated which is divided into 8×8 blocks, each block being of size 8×8 pixels, three different blocks are randomly selected from the $64 = 8 \times 8$ on the grid and the transformed objects are each placed into one of the three selected blocks. Consequently, the objects cannot overlap, by construction.

Each sprite is centered in the block in which it is located. Thus there is no object translation inside the blocks. The translation invariance can be achieved by being invariant to the location of the block inside the image.

A Pentomino sprite is guaranteed to not overflow the block in which it is located, and there are no collisions or overlaps between sprites, making the task simpler. The largest possible Pentomino sprite can actually be fit into an 8×4 mask.



(a) sprites, not all same type (b) sprites, all same type

Figure 2: Left (a): An example image from the dataset which has *a different sprite type* in it. Right (b): An example image from the dataset that has only one type of Pentomino object in it, but with different orientations and scales.

3.2 Control Experiments

To explore the effect of changing the complexity of the input representation on the difficulty of the task, a set of experiments have been designed with symbolic representations of the information in each patch. In all cases an empty patch is represented with a vector of all elements 0. In this section we are considering alternative representations to raw image representation for an abstract task similar to Pentomino. Basically we are seeking for an ideal representation that can be fed as an input to a regular feedforward MLP or another black-box classifier to perform well.

The following four experiments have been conducted, each one of them using a different input representation for each patch.

Experiment 1: One-hot representation without transformations: In this experiment several trials is done with a 10-input one-hot vector per patch. Each input corresponds to an object category given explicitly (corresponding to one input bit).

Experiment 2: Disentangled representations: In this experiment, we did trials with 16 binary inputs per patch, 10 one-hot bits for representing each object category, 4 for rotations and 2 for scaling, that is, the whole information about the input is given, but it is perfectly disentangled. This would ideally be reproduced by an unsupervised learning algorithm over each patch, if it was able to perfectly disentangle the image representation.

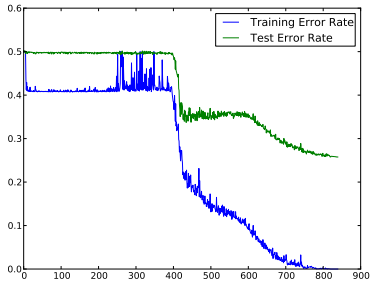
Experiment 3: One-hot representation with transformations: For each of the ten object types there are $8 = 4 \times 2$ possible transformations. Two objects in two different patches are the considered "the same" (for the final task) if their category is the same regardless of the transformations. The one-hot representation of a patch corresponds to the cross-product between the 10 object shape classes and the 4×2 transformations, that is, one out of $80 = 10 \times 4 \times 2$ possibilities represented in an 80-bit one-hot vector. This also contains all the information about the input image patch, but spread out in a kind of non-parametric and non-informative (not disentangled) way, like a perfect memory-based unsupervised learner (like clustering) could produce. Nevertheless, the shape class would be easier to read out from this representation than the image representation (it could be obtained by forming an OR over 8 of the bits).

Experiment 4: One-hot representation with 80 choices: This representation has the same 1 of 80 one-hot representation per patch but the target task is defined differently. Two objects in two different patches are considered the same iff they have exactly the same 80-bit one-hot representation (that are of the same object category with the same transformation applied).

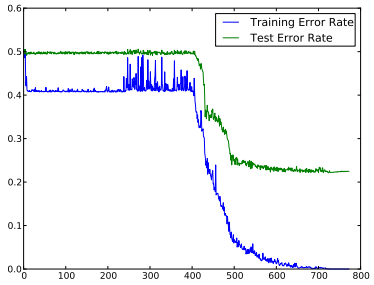
The first experiment is a sanity check. It was conducted with single hidden-layered MLPs using rectifier and tanh nonlinearity, and the task was learned perfectly (0 error on both training and test dataset) with very few training epochs.

The results of Experiment 2 are given in Table 1. To improve our results, we experimented with the Maxout non-linearity in a feedforward MLP (Goodfellow et al., 2013) with two hidden layers. Unlike the typical Maxout network mentioned in the original paper, regularizers have been deliberately avoided in order to focus on the optimization issue, i.e: no weight decay, norm constraint on the weights, or dropout. Although learning from a disentangled representation is more difficult than learning from perfect object detectors, it is feasible with some architectures such as the Maxout network. Note that this representation is the kind of representation that one could hope an unsupervised learning algorithm could discover, at best, as argued in Bengio et al. (2012).

The only results obtained on the validation set for Experiment 3 and Experiment 4 are shown respectively in Table 2 and Table 3. In these experiments a tanh MLP with two hidden layers have been tested with the same hyperparameters. In experiment 3 the complexity of the problem comes from the transformations ($8 = 4 \times 2$) and the number of object types.



(a) Training and Test Errors for Experiment 4



(b) Training and Test Errors for Experiment 3

Figure 3: tanh MLP training curves. Left (a): The training and test errors of Experiment 3 over 800 training epochs with 100k training examples using tanh MLP. Right (b):The training and test errors of Experiment 4 over 700 training epochs with 100k training examples using tanh MLP.

But in experiment 4, the only source of complexity of the task comes from the number of different object types. These results are in between the complete failure and complete success observed with other experiments, suggesting that the task could become solvable with better training or more training examples. Figure 3 illustrates the progress of training a tanh MLP, on both the training and test error, for Experiments 3 and 4. Clearly, MLPs were able to make significant progress on the task, but the task is far from being solved completely. On experiment 3 for both maxout and tanh, there was a long plateau where the training error and objective stays almost same. Maxout did just chance on the experiment for about 120 iterations on the training and the test set. But after 120^{th} iteration, the training and test error started to decline and eventually it was able to solve the task. Moreover as seen from the curves in Figure 3(a) and 3(b), the training and test error curves are almost the same for both tasks. This implies that for one-hot inputs, whether you increase the number of possible transformations for each object or the number of object categories, as soon as the number of possible configurations is same, the complexity of the problem is almost the same for the MLP.

Learning Algorithm	**Training Error**	**Test Error**
SVM	0.0	35.6
Random Forests	1.29	40.475

3.3 Learning Algorithms Evaluated

Initially the models are cross-validated by using 5-fold cross-validation. With $40,000$ examples, this gives $32,000$ examples for training and $8,000$ examples for testing. For training neural networks, we used stochastic gradient descent (SGD). The following standard learning algorithms were first evaluated: decision trees, SVMs with Gaussian kernel, ordinary fully-connected Multi-Layer Perceptrons, Random Forests, k-Nearest Neighbors, Convolutional Neural Networks, and Stacked Denoising Auto-Encoders with supervised fine-tuning. More details of the configurations and hyper-parameters for each of them are given in Appendix Section B. We obtained significantly better than chance results with only variations of the Structured Multi-Layer Perceptron that is described in this paper.

3.3.1 Structured Multi-Layer Perceptron (SMLP)

The neural network architecture that is used to solve this task is called the SMLP (Structured Multi-Layer Perceptron), a deep neural network with two parts as illustrated in Figure 4 and 6.

The bottom part, P1NN (*Part 1 Neural Network*, as it is called in the rest of the paper), has shared weights and local connectivity, with one identical MLP instance of the P1NN for each patch of the image, and typically an 11-element output vector per patch (unless otherwise noted). The idea is that these 11 outputs per patch could represent the detection of the sprite shape category (or the absence of sprite in the patch). The upper part, P2NN (*Part 2 Neural Network*) is a fully connected one hidden layer MLP that takes as input the concatenation of the outputs of the patch-wise P1NNs over all the patches. Note that the first layer of P1NN is similar to a convolutional layer but where the stride equals the kernel size, such that windows do not overlap, that is, P1NN can be decomposed into separate networks sharing the same parameters but applied on different patches of the input image, so that each network can

actually be trained patch-wise in the case where a target is provided for the P1NN outputs. The P1NN output for patch $\mathbf{p_i}$ which is extracted from the image $\mathbf{x}$ is computed as follows:

$$\mathrm{f}_\theta(\mathbf{p_i}) = \mathrm{g}_2(\mathbf{V}\mathrm{g}_1(\mathbf{U}\mathbf{p_i} + \mathbf{b}) + \mathbf{c}) \tag{1}$$

where $\mathbf{p_i} \in \mathcal{R}^d$ is the input patch/receptive field extracted from location i of a single image. $\mathbf{U} \in \mathcal{R}^{d_h \times d}$ is the weight matrix for the first layer of P1NN and $\mathbf{b} \in \mathcal{R}^d_h$ is the vector of biases for the first layer of P1NN. $\mathrm{g}_1(\cdot)$ is the activation function of the first layer and $\mathrm{g}_2(\cdot)$ is the activation function of the second layer. In many of the experiments, best results were obtained with $\mathrm{g}_1(\cdot)$ a rectified linear unit as non-linearity (a.k.a. as ReLU), which is $max(0,\ X)$ (Jarrett et al., 2009; Nair and Hinton, 2010; Glorot et al., 2011). $\mathbf{V} \in \mathcal{R}^{d_h \times d_o}$ is the second layer's weights matrix and $\mathbf{c} \in \mathcal{R}_{d_o}$ are the biases of the second layer of the P1NN, with d_o expected to be smaller than d_h.

In this way, $\mathrm{g}_1(\mathbf{U}\mathbf{p_i} + \mathbf{b})$ is an overcomplete representation of the input patch that can potentially represent all the possible Pentomino shapes for all factors of variations in the patch (rotation, scaling and Pentomino shape type). On the other hand, when trained with hints, $\mathrm{f}_\theta(\mathbf{p_i})$ is expected to be the lower dimensional representation of a Pentomino shape category invariant to scaling and rotation in the given patch.

In the experiments with SMLP trained with hints the P1NN is applied to each 8×8 patch and expected to predict it shape category (or the absence of a Pentomino object in the patch). The input representation of P2NN is obtained from the concatenated output of P1NN across all the 64 patch locations:

$\mathbf{h_o} = [\mathrm{f}_\theta(\mathbf{p_0}), \cdots, \mathrm{f}_\theta(\mathbf{p_i}), \cdots, \mathrm{f}_\theta(\mathbf{p_N}))]$ where N is the number of patches and the $\mathrm{h}_o \in \mathcal{R}^{d_i}, d_i = d_o \times N$. $\mathbf{h_o}$ is the concatenated output of the P1NN at each patch.

$\mathbf{h_o}$ is standardized for each training and test sample separately, so that the per-feature mean and variance across examples are respectively 0 and 1. That standardization layer seems to be crucial for successfully training the SMLP. Details of the standardization layer are given in Section A.

The concatenated output of P1NN is fed as an input to the P2NN. P2NN is a feedforward MLP with a sigmoid output layer using a single rectifier hidden layer. The task of P2NN is to perform a nonlinear logical operation on the representation provided at the output of P1NN.

3.3.2 Structured Multi Layer Perceptron Trained with Hints (SMLP-hints)

The SMLP-hints architecture exploits a hint about the presence and category of Pentomino objects, specifying a semantics for the P1NN outputs. P1NN is trained with the intermediate target Y, specifying the type of Pentomino sprite shape present (if any) at each of the 64 patches (8×8 non-overlapping blocks) of the image. Because a possible answer at a given location can be "none of the object types" that is, an empty patch, y_p (for patch p) can take one of the 11 possible values, 1 for rejection and the rest for the Pentomino shape classes, illustrated in Figure 1:

$$y_p = \begin{cases} 0 & \text{if patch } p \text{ is empty} \\ s \in S & \text{if the patch } p \text{ contains a Pentomino sprite .} \end{cases}$$

A similar task has been studied by Fleuret et al. (2011) (at SI appendix Problem 17), who compared the performance of humans vs computers.

The SMLP-hints architecture takes advantage of dividing the task into two subtasks during training with prior information about intermediate-level relevant factors. Because the sum of the training losses decomposes into the loss on each patch, the P1NN can be pre-trained patch-wise. Each patch-specific component of the P1NN is a fully connected MLP with 8×8 inputs and 11 outputs with a softmax output layer. SMLP-hints uses the standardization given in Equation 8 but with $\epsilon = 0$.

In general, standardization layer for SMLP seems to make the training much easier and the distribution of activations of P1NN becomes much more peaky.

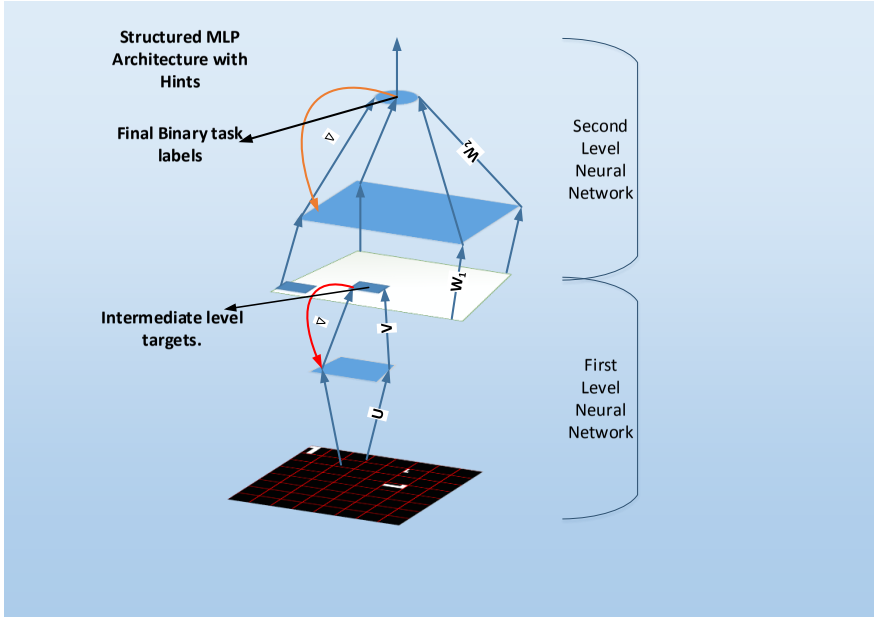

Figure 4: Structured MLP architecture, used with hints (trained in two phases, first P1NN, bottom two layers, then P2NN, top two layers). In SMLP-hints, P1NN is trained on each $8x8$ patch extracted from the image and the softmax output probabilities of all 64 patches are concatenated into a 64×11 vector that forms the input of P2NN. Only $\mathbf{U}$ and $\mathbf{V}$ parameters are learned in the P1NN and its output on each patch is fed into P2NN. The first level and the second level neural networks are trained separately, not jointly.

By default, the SMLP uses rectifier hidden units as activation function: we found a significant boost by using rectifier compared to hyperbolic tangent and sigmoid activation functions. The P1NN has a highly overcomplete architecture with 1024 hidden units per patch, and L1 and L2 weight decay regularization coefficients on the weights (not the biases) are respectively $1e-6$ and $1e-5$. The learning rate for the P1NN is 0.75. 1 training epoch was enough for the P1NN to learn the features of Pentomino shapes perfectly on the 40000 training examples. The

P2NN has 2048 hidden units. L1 and L2 penalty coefficients for the P2NN are 1e-6, and the learning rate is 0.1. These were selected by trial and error based on validation set error. Both P1NN (for each patch) and P2NN are fully-connected neural networks, even though P1NN globally is a special kind of convolutional neural network.

Filters of the first layer of SMLP are shown in Figure 5. These are the examples of the filters obtained with the SLMP-hints trained with 40k examples, whose results are given in Table 4. Those filters look very noisy but they work perfectly on the Pentomino task.

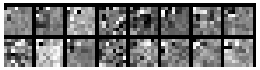

Figure 5: Filters of Structured MLP architecture, trained with hints on 40k examples.

3.3.3 Deep and Structured Supervised MLP without Hints (SMLP-nohints)

SMLP-nohints uses the same connectivity pattern (and deep architecture) that is also used in the SMLP-hints architecture, but without using the intermediate targets (Y). It directly predicts the final outcome of the task (Z), using the same number of hidden units, the same connectivity and the same activation function for the hidden units as SMLP-hints. 120 hyperparameter values have been evaluated by randomly selecting the number of hidden units from $[64, 128, 256, 512, 1024, 1200, 2048]$ and randomly sampling 20 learning rates uniformly in the log-domain within the interval of $[0.008, 0.8]$. Two fully connected hidden layers with 1024 hidden units (same as P1NN) per patch is used and 2048 (same as P2NN) for the last hidden layer, with twenty training epochs. For this network the best results are obtained with a learning rate of 0.05. The source code of the structured MLP is available at the GitHub repository: `https://github.com/caglar/structured_mlp`.

We decided to experiment with various SMLP-nohint architectures and optimization procedures, trying unsuccessfully to achieve as good results with SMLP-nohint as with SMLP-hints.

Rectifier Non-Linearity A rectifier nonlinearity is used for the activations of MLP hidden layers. We observed that using piecewise linear nonlinearity activation function such as the rectifier can make the optimization more tractable.

Intermediate Layer

The output of the P1NN is considered as an intermediate layer of the SMLP. For the SMLP-hints, only softmax output activations have been tried at the intermediate layer, and that sufficed to learn the task. Since things did not work nearly as well with the SMLP-nohints, several different activation functions have been tried: softmax$(\cdot)$, tanh$(\cdot)$, sigmoid$(\cdot)$ and linear activation functions.

Adaptive Learning Rates We have experimented with several different adaptive learning rate algorithms. We tried RMSprop (Tieleman and Hinton, 2012), Adadelta (Zeiler, 2012), Adagrad (Duchi et al., 2011) and a linearly $(\frac{1}{t})$ decaying learning rate (Bengio, 2013b). For the SMLP-nohints with sigmoid activation function we have found Adadelta(Zeiler, 2012) converging faster to an effective local minimum and usually yielding better generalization error compared to the others.

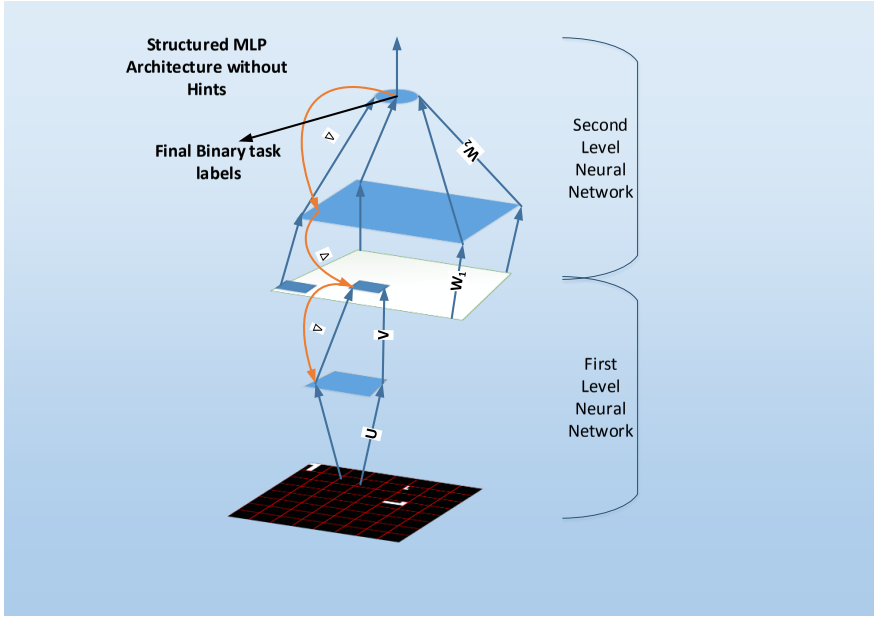

Figure 6: Structured MLP architecture, used without hints (SMLP-nohints). It is the same architecture as SMLP-hints (Figure 4) but with both parts (P1NN and P2NN) trained jointly with respect to the final binary classification task.

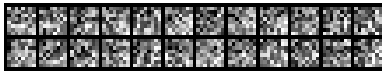

Figure 7: First layer filters learned by the Structured MLP architecture, trained without using hints on 447600 examples with online SGD and a sigmoid intermediate layer activation.

3.3.4 Deep and Structured MLP with Unsupervised Pre-Training

Several experiments have been conducted using an architecture similar to the SMLP-nohints, but by using unsupervised pre-training of P1NN, with Denoising Auto-Encoders (DAE) and/or Contractive Auto-Encoders (CAE). Supervised fine-tuning proceeds as in the deep and structured MLP without hints. Because an unsupervised learner may not focus the representation just on the shapes, a larger number of intermediate-level units at the output of P1NN has been explored: previous work on unsupervised pre-training generally found that larger hidden layers were optimal when using unsupervised pre-training, because not all unsupervised features will be relevant to the task at hand. Instead of limiting to 11 units per patch, we experimented with networks with up to 20 hidden (i.e., code) units per patch in the second-layer patch-wise auto-encoder.

In Appendix B we also provided the result of some experiments with binary-binary RBMs trained on 8×8 patches from the 40k training dataset.

For the second P1NN layer, a DAE with rectifier hidden units was trained with L1 sparsity and weight decay on the weights of the auto-encoder. The greedy layerwise unsupervised pre-training procedure is used to train the deep auto-encoder architecture (Bengio et al., 2007). In unsupervised pretraining experiments, tied weights have been used. Different combinations of CAE and DAE for unsupervised pretraining have been tested, but none of the configurations tested managed to learn the Pentomino task, as shown in Table 4. In terms of generalization, without hints for the permutation-invariant Pentomino dataset, an MLP using L_p units introduced in (Gulcehre et al., 2013) is the best performing model in Table 4.

3.4 Does the Effect Persist with Larger Training Set Sizes?

The results shown in this section indicate that the problem in the Pentomino task clearly is not just a regularization problem, but also involves an optimization difficulty. This is suggested by the experiments in which the training set size is increased (eventually to the point of doing online learning and never repeating the same example twice), without solving the problem. In the online mini-batch setting, parameter updates are performed as follows:

$$\theta_{t+1} = \theta_t - \Delta_{\theta_t}, \tag{2}$$

$$\Delta_{\theta_t} = \epsilon \frac{\sum_i^N \nabla_{\theta_t} \mathcal{L}(x_i, \theta_t)}{N}. \tag{3}$$

where $L(x_i, \theta_t)$ is the loss incurred on the i-th example x_i of the minibatch, with parameters θ_t, $t \in \mathcal{Z}^+$, N is the number of examples in the mini-batch, and ϵ is the learning rate.

Ordinary batch learning algorithms converge linearly to the optimum θ^*, however the noisy gradient estimates in the online SGD will cause parameter θ to fluctuate near the local optima. On the other hand, online SGD directly optimizes the expected risk, because the examples are drawn iid from the ground-truth distribution (Bottou, 2010). Thus:

$$\mathcal{L}_\infty = \mathrm{E}[\mathcal{L}(\mathbf{x}, \theta)] = \int_{\mathbf{x}} \mathcal{L}(\mathbf{x}, \theta) p(\mathbf{x}) d\mathbf{x}, \tag{4}$$

where $\mathcal{L}_\infty$ is the generalization error. Therefore online SGD is trying to minimize the expected risk with noisy updates. Those noisy updates can have regularization effect:

$$\Delta_{\theta_t} = \epsilon \frac{\sum_t^N \nabla_{\theta_t} \mathcal{L}(x_t, \theta_t)}{N} = \epsilon \nabla_{\theta_t} \mathcal{L}(\mathbf{X}, \theta_t) + \epsilon \xi_t. \tag{5}$$

where $\nabla_{\theta_t} \mathcal{L}(\mathbf{X}, \theta_t)$ is the true gradient and ξ_t is the zero-mean stochastic gradient "noise" due to computing the gradient over a finite-size mini-batch sample.

An SMLP-nohints model was trained by online SGD with a randomly generated online Pentomino data stream. We used Adadelta (Zeiler, 2012) on mini-batches of 100 examples. In the online SGD experiments, two SMLP-nohints that are trained with and without standardization at the intermediate layer have the same hyperparameters. The SMLP-nohints P1NN patch-wise submodel has 2048 hidden units and the SMLP intermediate layer has $1152 = 64 \times 18$ units. The intermediate layer nonlinearity is sigmoid. P2NN has 2048 hidden units.

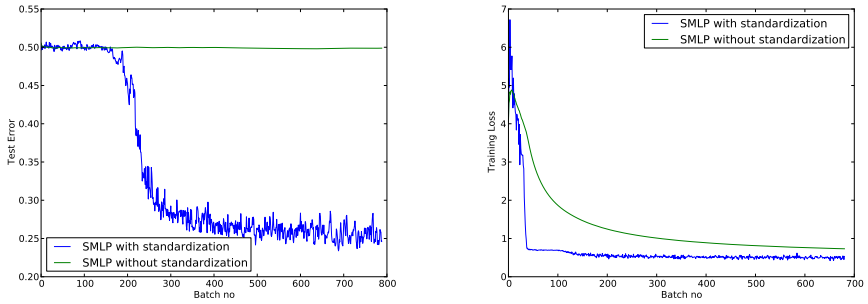
We trained SMLP-nohints both with and without standardization at the intermediate layer. The experiments illustrated in Figures 8(a) and 8(b) are using the same architecture as in the SMLP experiments reported in Table 4. The figures show the training and test results when training on the stream of 545400 randomly generated Pentomino samples.

Training of SMLP-nohints is done with mini-batch Adadelta and standardization in the intermediate layer, on 1046000 training examples from a randomly generated Pentomino data stream. At the end of the training, test error went down to 27.5%.

In SMLP-nohints experiment *without standardization*, the model is trained with the 1580000 Pentomino examples using online mini-batch SGD. P1NN has 2048 hidden units and 16 sigmoid output units per patch. P2NN has 1024 hidden units for the hidden layer. We used Adadelta to automatically adapt the learning rate. At the end of training this SMLP, the test error remained stuck, at 50.1%.

3.4.1 Experiments with Larger Training Sets

We consider the effect of training different learners with different numbers of training examples. For the experimental results shown in Table 4, we used 3 training set sizes of 20k, 40k and 80k examples. We generated each dataset with different random seeds (so they do not overlap). Figure 9 also shows the error bars for an ordinary MLP with three hidden layers, for a larger range of training set sizes, between 40k and 320k examples. The number of training epochs is 8 (more did not help), and there are 3 hidden layers with 2048 feature detectors. Learning rate



(a) (i) Test Error of SMLP-nohints (b) (ii) Training Error of SMLP-nohints

Figure 8: Online training and test errors of SMLP-nohints with and without standardization in the intermediate layer. Sigmoid nonlinearity has been used as an intermediate layer activation function. The x-axis is in units of blocks of 400 examples in the training set.

is 0.01 with tanh activation function. We used both L1, L2 penalty on weights and they are both $1e-6$.

Decision trees and SVMs can overfit the training set but they could not generalize on the test set. Note that the results reported in Table 4 are with hyper-parameters selected based on validation set error, and with early-stopping. Lower training errors are possible by avoiding regularizations and using large enough models. On the training set, an MLP with two large hidden layers (several thousands) could reach to almost 0% training error, but still it did not manage to achieve a good test error.

In the experimental results shown in Figure 9, we evaluated the impact of adding more training data for the fully-connected MLP. In those experiments, we used an MLP with three hidden layers where each layer has 2048 hidden units. The tanh$(\cdot)$ activation function is used with 0.05 learning rate and mini-batches of size 200.

As seen on Figure 9, adding more training examples did not help for both training and test error. This is reinforcing the hypothesis that the difficulty encountered is one of optimization, not of regularization.

3.5 Experiments on Effect of Initializing with Hints

Initialization of the parameters in a neural network can have a big impact on the learning and generalization (Glorot and Bengio, 2010). Previously Erhan et al. (2010) showed that initializing the parameters of a neural network with unsupervised pretraining guides the learning towards basins of attraction of effective local minima that provide better generalization. In this section we analyze the effect of hints to initialize the SMLP, continuing training without hints. The SMLP is pretrained for 1 epoch using the hints and then for 60 epochs without hints on the 40k examples of training set. We also compared the same architecture with the same hyperparameters, against the SMLP-nohints trained for 61 iterations on the same dataset. After one iteration of hint-based training SMLP obtained 9% training error and 39% test error.

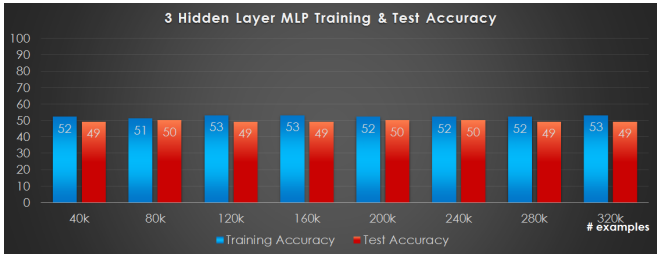


Figure 9: Training and test error bar charts for a regular MLP with 3 hidden layers. There is no significant improvement on the generalization error of the MLP as the new training examples are introduced.

Following the hint based training, SMLP is trained without hints for 60 epochs, but at epoch 18, it already got 0% training and 0% test error. The hyperparameters for this experiment and the experiment that the results shown for the SMLP-hints in Table 4 are the same. Figure 10 suggests that initializing with hints can give the same generalization performance but training takes longer.

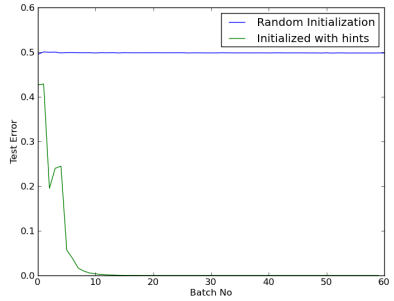

Figure 10: Plots showing the test error of SMLP with random initialization vs initializing with hint based training.

3.6 Experiments on Optimization for Pentomino Dataset

With extensive hyperparameter optimization and using standardization in the intermediate level of the SMLP with softmax nonlinearity, SMLP-nohints was able to get 5.3% training and 6.7% test error on the $80k$ Pentomino training dataset. The key ingredient was the use of a larger hidden layer. We used 2050 hidden units in the P1NN, 11 softmax outputs per patch, and 1024 hidden units in the P2NN. The network was trained with a learning rate 0.1 without using any adaptive learning rate. The SMLP uses a rectifier nonlinearity for hidden layers of both P1NN and P2NN. We also applied a small amount of L_1 and L_2 regularization on the weights of the network.

An MLP with 2 hidden layers, each 1024 rectifier units, was trained using **LBFGS** (the implementation from the scipy.optimize library) on $40k$ training examples, with gradients computed on batches of 10000 examples at each iteration. However, after convergence of training, the MLP was still doing chance on the test dataset.

In order to observe the effect of introducing the intermediate level hints into the SMLP for optimization, we compared the learning curves of the same SMLP model trained with and without hints. To train the SMLP with hints, we jointly optimize the loss for hints $\mathcal{L}_{\text{hints}}(\mathbf{X}; \{\boldsymbol{\theta}_1, \boldsymbol{\theta}_2\})$, and for the Pentomino task $\mathcal{L}_{\text{pentomino}}(\mathbf{X}; \{\boldsymbol{\theta}_1, \boldsymbol{\theta}_2, \boldsymbol{\theta}_3\})$ together as a joint loss $\mathcal{L}_{\text{joint}}(\mathbf{X}; \{\boldsymbol{\theta}_1, \boldsymbol{\theta}_2, \boldsymbol{\theta}_3\})$ as in Eqn 6:

$$\mathcal{L}_{\text{joint}}(\mathbf{X}; \{\boldsymbol{\theta}_1, \boldsymbol{\theta}_2, \boldsymbol{\theta}_3\}) = \lambda \mathcal{L}_{\text{hints}}(\mathbf{X}; \{\boldsymbol{\theta}_1, \boldsymbol{\theta}_2\}) + \ (1 - \lambda)\mathcal{L}_{\text{pentomino}}(\mathbf{X}; \{\boldsymbol{\theta}_1, \boldsymbol{\theta}_3\}). \tag{6}$$

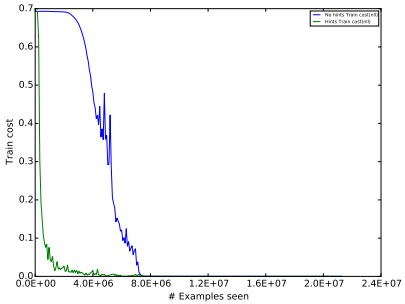

Figure 11: Plot showing the training learning curve of SMLP from random initialization when training with hints and without hints. SMLP training with hints converges faster than the training without hints. This means that the optimizing the training objective with hints is easier than optimizing without hints.

As seen on Figure 11 and 12, hint based training converges faster and the training of SMLP without hints overfits. This aligns with the hypothesis that hints make the optimization easier. But in the mean time, hints cost, puts the model into a basin of attraction to where a solution on the test set can easily be found. For the experiments in these plots, we cross-validated momentum, learning rate, standard deviation of the initialization and minibatch size. We trained the models with rectifier activation function using 512 hidden units at each layer. We trained the first level MLP on patches. It outputs 11 features for each such patch, with a softmax$(\cdot)$ activation function over the 11 units. We ran 64 different trials for the hyperparameters of the SMLP-hints. The learning rate is randomly sampled in log-space from the range $[5e-5, 1e-2]$, momentum is sampled from uniform distribution in the range $[0.25, 0.99]$, batch sizes and standard deviations of the weights are sampled from the grids $\{100, 200, 300, 400\}$ and $\{0.01, 0.025, 0.05\}$. We ran 150 different trials to explore hyperparameters for the SMLP-nohints. The learning rate is randomly sampled in log-space from the range $[6e-5, 8e-2]$, momentum is chosen randomly from the range $[0.25, 0.99]$, batch sizes and standard deviations of the weights are sampled from the grids $\{100, 200, 300, 400\}$ and $\{0.01, 0.025, 0.038, 0.05\}$ respectively for the without hints training. At the end of the hyper-parameter search, we chose the

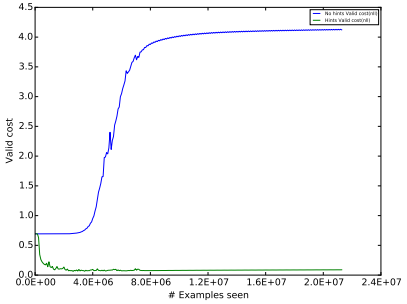

Figure 12: Plot showing validation learning curve of SMLP from random initialization when training with and without hints. Training of SMLP without hints overfits.

best hyper-parameters based on the training cost after 20000 updates. The codes to reproduce these experiments are available at `https://github.com/caglar/PentominoExps`.

We used a soft-curriculum strategy, for training our models. We started the training by only optimizing the easy hint objective function, namely setting λ to 1 in the beginning of the training and linearly annealing it towards to 0.1 in 10000 updates.

4. Conclusion and Discussion

In this paper we have shown an example of a toy task which seems to be quiet difficult to solve by standard black-box machine learning algorithms, but it can be solved almost perfectly when one encourages a particular semantics on the intermediate-level representation which is guided by the prior knowledge about the task. Both tasks have the particularity that they are defined by the composition of two non-linear sub-tasks (for example, object detection on one hand, and a non-linear logical operation similar to XOR on the other hand).

What is interesting is that for neural networks, we can compare two networks with exactly the same architecture but a different pre-training, one of which uses the known intermediate concepts to teach an intermediate representation to the network. With enough capacity and training time they can overfit. But they failed solve the task, as seen by test set performances.

We know that a structured deep network can learn the task, if it is initialized in the right place, and it can do that from a relatively small number of examples. Furthermore we have shown that if one pre-trains the SMLP with hints for only one epoch, eventually it is able to solve the task. But the same architecture trained from random initialization failed to generalize as well as the pretrained network.

Considering the fact that even SMLP-nohints with standardization after being trained using online SGD over 1046000 generated examples and still gets 27.5% test error. This suggests that in addition to the optimization effect of hints, there is also a regularization effect, since a much larger training set allowed to reduce test error, albeit not as much as using hints and a much smaller training set.

We also investigated the effect of introducing hints on the convergence of the optimization of SMLP in Figure 11. After hyperparameter optimization, we observed that SMLP trained with hints converges on training set faster and achieves lower validation error as well. This supports our claims that the optimizing with hints cost is easier.

What we hypothesize is that for most initializations and architectures (in particular the fully-connected ones), although it is possible to find a *good effective local minimum of training error* when enough capacity is provided, it is difficult (without the proper initialization) to find a good local minimum of generalization error. On the other hand, when the network architecture is constrained enough, even though a good solution exists (e.g. with the SMLP architecture), it seems that the optimization problem can still be difficult and even training error remains stuck high without the standardization layer. Standardization makes the training objective of the SMLP easier to optimize and helps it to find at least a *better effective local minimum of training error*. This finding suggests that by using specific architectural constraints and sometimes domain specific knowledge about the problem, one can alleviate the optimization difficulty that generic neural network architectures face.

It could be that the combination of the network architecture and training procedure produces a training dynamics that tends to yield into these minima that are poor from the point of view of generalization error, even when they manage to slowly nail training error by providing enough capacity. Of course, as the number of examples increases, we would expect this discrepancy to decrease, but then the optimization problem could still make the task unfeasible in practice. Note however that our preliminary experiments with increasing the training set size (8-fold) for MLPs did not reveal signs of potential improvements in test error yet, as shown in Figure 9. Even using online training on 545400 Pentomino examples, the SMLP-nohints architecture was still doing far from perfect in terms of generalization error (Figure 8(a)).

These findings bring supporting evidence to the "Guided Learning Hypothesis" and "Deeper Harder Hypothesis" from Bengio (2013a): higher level abstractions, which are expressed by composing simpler concepts are more difficult to learn (with the learner often getting in an effective local minimum), but that difficulty can be overcome if another agent provides hints about intermediate-level abstractions which are relevant to the task.

Many interesting questions remain open. Would a network without any guiding hint eventually find the 0% error solution provided enough training time and/or with alternate parameterizations? To what extent is ill-conditioning a core issue? The results with LBFGS were disappointing but changes in the architectures (such as standardization of the intermediate level) seem to make training much easier. Clearly, one can reach good solutions from an appropriate initialization, pointing in the direction of an issue with local minima, but it may be that good solutions are also reachable from other initializations, albeit going through a ill-conditioned path in parameter space. Why did our attempts at learning the intermediate concepts in an unsupervised way fail? Are these results specific to the task we are testing or a limitation of the unsupervised feature learning algorithm tested? Trying with many more unsupervised variants and exploring explanatory hypotheses for the observed failures could help us answer that. Finally, and most ambitious, can we solve these kinds of problems if we allow a community of learners to collaborate and collectively discover and combine partial solutions in order to obtain solutions to more abstract tasks like the one presented here? Indeed, we would like to discover learning algorithms that can solve such tasks without the use of prior knowledge as specific and strong as the one used in the SMLP here. These experiments could be

inspired by and inform us about potential mechanisms for collective learning through cultural evolutions in human societies.

Appendix A. Standardization Layer

Normalization has been used occasionally in convolutional neural network to encourage the competition between the hidden units. (Jarrett et al., 2009) used a local contrast normalization layer in their architecture which performs subtractive and divisive normalization. A local contrast normalization layer enforces a local competition between adjacent features in the feature map and between features at the same spatial location in different feature maps. Similarly, (Krizhevsky et al., 2012) observed that using a local response layer that enjoys the benefit of using local normalization scheme aids generalization.

Standardization has been observed to be crucial for SMLP trained either with or without hints. In both SMLP-hints and SMLP-nohints experiments, the neural network was not able to generalize or even learn the training set without using standardization in the SMLP intermediate layer, doing just chance performance. More specifically, in the SMLP-nohints architecture, standardization is part of the computational graph, hence the gradients are being backpropagated through it. The mean and the standard deviation is computed for each hidden unit separately at the intermediate layer as in Equation 9. But in order to prevent numerical underflows during the backpropagation, we used $\epsilon = 1e - 8$ (Equation 8).

The benefit of having sparse activations may be specifically important for the ill-conditioned problems, for the following reasons. When a hidden unit is "off", its gradient (the derivative of the loss with respect to its activation before the non-linearity is applied) is usually close to 0 as well. That means that all off-diagonal second derivatives involving that hidden unit (for example, its input weights) are also near 0. This is basically like removing some columns and rows from the Hessian matrix associated with a particular example. It has been observed that the condition number of the Hessian matrix (specifically, its largest eigenvalue) increases as the size of the network increases (Dauphin and Bengio, 2013), making training considerably slower and inefficient. Hence one would expect that as sparsity of the gradients (obtained because of sparsity of the activations) increases, training would become more efficient, as if we were training a smaller sub-network for each example, with shared weights across examples, as in dropouts (Hinton et al., 2012).

Standardization layer is on top of the output of P1NN which centers the activations and performs divisive normalization by dividing by the standard deviation over a mini-batch of the activations of that layer. We denote the standardization function $z(\cdot)$. Standardization makes use of the mean and standard deviation computed for each hidden unit such that each hidden unit of $\mathbf{h_o}$ will have 0 activation and unit standard deviation on average over the mini-batch. X is the set of pentomino images in the mini-batch, where $X \in R^{d_{in} \times N}$ is a matrix with N images. $h_o^{(i)}(\mathbf{x_j})$ is the vector of activations of the i-th hidden unit of hidden layer $h_o(\mathbf{x_j})$ for the j-th example, with $x_j \in X$.

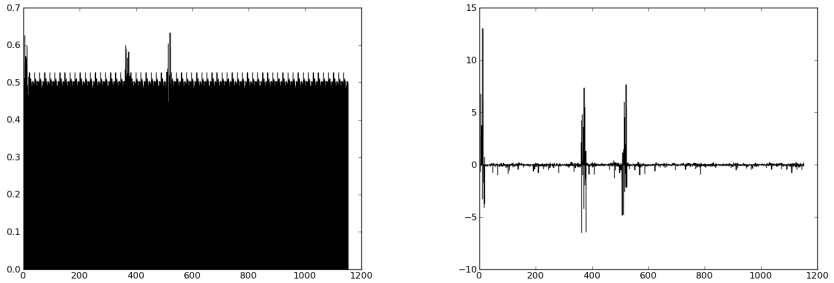
$$\mu_{h_o^{(i)}} = \frac{1}{N} \sum_{\mathbf{x_j} \in X} h_o^{(i)}(\mathbf{x_j}), \tag{7}$$

$$\sigma_{h_o^{(i)}} = \sqrt{\frac{\sum_j^N (h_o^{(i)}(\mathbf{x_j}) - \mu_{h_o^{(i)}})^2}{N} + \epsilon}, \tag{8}$$

$$z(h_o^{(i)}(\mathbf{x_j})) = \frac{h_o^{(i)}(\mathbf{x_j}) - \mu_{h_o^{(i)}}}{\max(\sigma_{h_o^{(i)}}, \epsilon)}. \tag{9}$$

where ϵ is a very small constant, that is used to prevent numerical underflows in the standard deviation. P1NN is trained on each 8×8 patches extracted from the image.

In Figure 13, the activation of each hidden unit in a bar chart is shown: the effect of standardization is significant, making the activations sparser.



(a) Before standardization.

(b) After standardization.

Figure 13: Activations of the intermediate-level hidden units of an SLMP-nohints for a particular examples (x-axis: hidden unit number, y-axis: activation value). Left (a): before standardization. Right (b): after standardization.

In Figure 15, one can see the activation histogram of the SMLP-nohints intermediate layer, showing the distribution of activation values, before and after standardization. Again the sparsifying effect of standardization is very apparent.

In Figures 15 and 13, the intermediate level activations of SMLP-nohints are shown before and after standardization. These are for the same SMLP-nohints architecture whose results are presented on Table 4. For that same SMLP, the Adadelta (Zeiler, 2012) adaptive learning rate scheme has been used, with 512 hidden units for the hidden layer of P1NN and rectifier activation function. For the output of the P1NN, 11 sigmoid units have been used while P2NN had 1200 hidden units with a rectifier activation function. The output nonlinearity of the P2NN is a sigmoid and the training objective is the binary cross-entropy.

Appendix B. Binary-Binary RBMs on Pentomino Dataset

We trained binary-binary RBMs (both visible and hidden are binary) on 8×8 patches extracted from the Pentomino Dataset using PCD (stochastic maximum likelihood), a weight decay of .0001 and a sparsity penalty[2]. We used 256 hidden units and trained by SGD with a batch size of 32 and an annealing learning rate (Bengio, 2013b) starting from 1e-3 with annealing rate 1.000015. The RBM is trained with momentum starting from 0.5 to 0.9. The biases are initialized to -2 in order to get a sparse representation. The RBM is trained for 120 epochs (approximately 50 million updates).

After pretraining the RBM, its parameters are used to initialize the first layer of an SMLP-nohints network. As in the usual architecture of the SMLP-nohints on top of P1NN, there is an intermediate layer. Both P1NN and the intermediate layer have a sigmoid nonlinearity, and the intermediate layer has 11 units per location. This SMLP-nohints is trained with Adadelta and standardization at the intermediate layer [3].

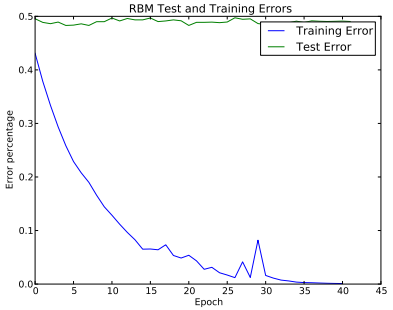


Figure 14: Training and test errors of an SMLP-nohints network whose first layer is pre-trained as an RBM. Training error reduces to 0% at epoch 42, but test error is still chance.

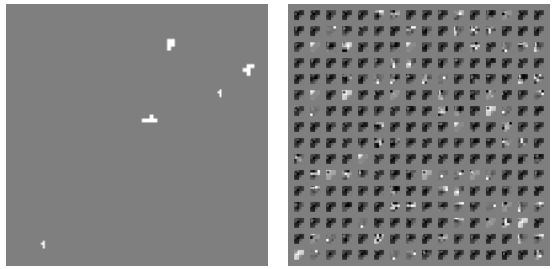
Experimental Setup and Hyper-parameters

B.1 Decision Trees

We used the decision tree implementation in the scikit-learn (Fabian Pedregosa, 2011) python package which is an implementation of the CART (Regression Trees) algorithm. The CART algorithm constructs the decision tree recursively and partitions the input space such that the samples belonging to the same category are grouped together (Breiman et al., 1984). We used The Gini index as the impurity criteria. We evaluated the hyper-parameter configurations with a grid-search. We cross-validated the maximum depth (max_depth) of the tree (for preventing the algorithm to severely overfit the training set) and minimum number of samples required to create a split (min_split). 20 different configurations of hyper-parameter values were evaluated. We obtained the best validation error with $max\_depth = 300$ and $min\_split = 8$.

2. implemented as TorontoSparsity in pylearn2, see the yaml file in the repository for more details
3. In our auto-encoder experiments we directly fed features to P2NN without standardization and Adadelta.



(a) Samples of RBM (b) Filters learned by RBM

Figure 15: Inspecting the representation learned by RBM. Left (a): 100 samples generated from trained RBM. All the generated samples are valid Pentomino shapes. Right (b): 100 Binary-Binary RBM Pentomino negative samples.

B.2 Support Vector Machines

We used the "Support Vector Classifier (SVC)" implementation from the scikit-learn package which in turn uses the libsvm's Support Vector Machine (SVM) implementation. Kernel-based SVMs are non-parametric models that map the data into a high dimensional space and separate different classes with hyperplane(s) such that the support vectors for each category will be separated by a large margin. We cross-validated three hyper-parameters of the model using grid-search: C, γ and the type of kernel($kernel\_type$). C is the penalty term (weight decay) for the SVM and γ is a hyper-parameter that controls the width of the Gaussian for the RBF kernel. For the polynomial kernel, γ controls the flexibility of the classifier (degree of the polynomial) as the number of parameters increases (Hsu et al., 2003; Ben-Hur and Weston, 2010). We evaluated forty-two hyper-parameter configurations. That includes, two kernel types: $\{RBF,\ Polynomial\}$; three gammas: $\{1e-2,\ 1e-3,\ 1e-4\}$ for the RBF kernel, $\{1, 2, 5\}$ for the polynomial kernel, and seven C values among: $\{0.1, 1, 2, 4, 8, 10, 16\}$. As a result of the grid search and cross-validation, we have obtained the best test error by using the RBF kernel, with $C = 2$ and $\gamma = 1$.

B.3 Multi Layer Perceptron

We have our own implementation of Multi Layer Perceptron based on the Theano (Bergstra et al., 2010) machine learning libraries. We have selected 2 hidden layers, the rectifier activation function, and 2048 hidden units per layer. We cross-validated three hyper-parameters of the model using random-search, sampling the learning rates ϵ in log-domain, and selecting $L1$ and $L2$ regularization penalty coefficients in sets of fixed values, evaluating 64 hyperparameter values. The range of the hyperparameter values are $\epsilon \in [0.0001, 1]$, $L1 \in \{0., 1e-6, 1e-5, 1e-4\}$ and $L2 \in \{0, 1e-6, 1e-5\}$. As a result, the following were selected: $L1 = 1e-6$, $L2 = 1e-5$ and $\epsilon = 0.05$.

B.4 Random Forests

We used scikit-learn's implementation of "Random Forests" decision tree learning. The Random Forests algorithm creates an ensemble of decision trees by randomly selecting for each tree a subset of features and applying bagging to combine the individual decision trees (Breiman, 2001). We have used grid-search and cross-validated the max_depth, min_split, and number of trees ($n\_estimators$). We have done the grid-search on the following hyperparameter values, $n\_estimators \in \{5, 10, 15, 25, 50\}$, $max\_depth \in \{100, 300, 600, 900\}$, and $min\_splits \in \{1, 4, 16\}$. We obtained the best validation error with $max\_depth = 300$, $min\_split = 4$ and $n\_estimators = 10$.

B.5 k-Nearest Neighbors

We used scikit-learn's implementation of k-Nearest Neighbors (k-NN). k-NN is an instance-based, lazy learning algorithm that selects the training examples closest in Euclidean distance to the input query. It assigns a class label to the test example based on the categories of the k closest neighbors. The hyper-parameters we have evaluated in the cross-validation are the number of neighbors (k) and $weights$. The $weights$ hyper-parameter can be either "uniform" or "distance". With "uniform", the value assigned to the query point is computed by the majority vote of the nearest neighbors. With "distance", each value assigned to the query point is computed by weighted majority votes where the weights are computed with the inverse distance between the query point and the neighbors. We have used $n\_neighbours \in \{1, 2, 4, 6, 8, 12\}$ and $weights \in \{"uniform", "distance"\}$ for hyper-parameter search. As a result of cross-validation and grid search, we obtained the best validation error with $k = 2$ and $weights$="uniform".

B.6 Convolutional Neural Nets

We used a Theano (Bergstra et al., 2010) implementation of Convolutional Neural Networks (CNN) from the deep learning tutorial at `deeplearning.net`, which is based on a vanilla version of a CNN LeCun et al. (1998). Our CNN has two convolutional layers. Following each convolutional layer, we have a max-pooling layer. On top of the convolution-pooling-convolution-pooling layers there is an MLP with one hidden layer. In the cross-validation we have sampled 36 learning rates in log-domain in the range $[0.0001, 1]$ and the number of filters from the range $[10, 20, 30, 40, 50, 60]$ uniformly. For the first convolutional layer we used 9×9 receptive fields in order to guarantee that each object fits inside the receptive field. As a result of random hyperparameter search and doing manual hyperparameter search on the validation dataset, the following values were selected:

- The number of features used for the first layer is 30 and the second layer is 60.
- For the second convolutional layer, 7×7 receptive fields. The stride for both convolutional layers is 1.
- Convolved images are downsampled by a factor of 2×2 at each pooling operation.
- The learning rate for CNN is 0.01 and it was trained for 8 epochs.

B.7 Maxout Convolutional Neural Nets

We used the pylearn2 (`https://github.com/lisa-lab/pylearn2`) implementation of maxout convolutional networks (Goodfellow et al., 2013). There are two convolutional layers in the selected architecture, without any pooling. In the last convolutional layer, there is a maxout non-linearity. The following were selected by cross-validation: learning rate, number of channels for the both convolution layers, number of kernels for the second layer and number of units and pieces per maxout unit in the last layer, a linearly decaying learning rate, momentum starting from 0.5 and saturating to 0.8 at the 200'th epoch. Random search for the hyperparameters was used to evaluate 48 different hyperparameter configurations on the validation dataset. For the first convolutional layer, 8×8 kernels were selected to make sure that each Pentomino shape fits into the kernel. Early stopping was used and test error on the model that has the best validation error is reported. Using norm constraint on the fan-in of the final softmax units yields slightly better result on the validation dataset.

As a result of cross-validation and manually tuning the hyperparameters we used the following hyperparameters:

- 16 channels per convolutional layer. 600 hidden units for the maxout layer.
- 6x6 kernels for the second convolutional layer.
- 5 pieces for the convolution layers and 4 pieces for the maxout layer per maxout units.
- We decayed the learning rate by the factor of 0.001 and the initial learning rate is 0.026367. But we scaled the learning rate of the second convolutional layer by a constant factor of 0.6.
- The norm constraint (on the incoming weights of each unit) is 1.9365.

Figure 16 shows the first layer filters of the maxout convolutional net, after being trained on the 80k training set for 85 epochs.

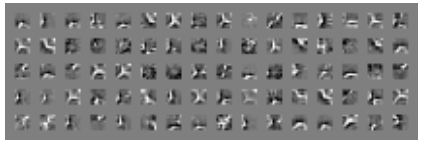


Figure 16: Maxout convolutional net first layer filters. Most of the filters were able to learn the basic edge structure of the Pentomino shapes.

B.8 Stacked Denoising Auto-Encoders

Denoising Auto-Encoders (DAE) are a form of regularized auto-encoder (Bengio et al., 2013). The DAE forces the hidden layer to discover more robust features and prevents it from simply learning the identity by reconstructing the input from a corrupted version of it (Vincent et al., 2010). Two DAEs were stacked, resulting in an unsupervised transformation with two hidden layers of 1024 units each. Parameters of all layers are then fine-tuned with supervised fine-tuning using logistic regression as the classifier and SGD as the gradient-based optimization

algorithm. The stochastic corruption process is binomial (0 or 1 replacing each input value, with probability 0.2). The selected learning rate is $\epsilon_0 = 0.01$ for the DAe and $\epsilon_1 = 0.1$ for supervised fine-tuning. Both L1 and L2 penalty for the DAEs and for the logistic regression layer are set to 1e-6.

B.8.1 CAE+MLP with Supervised Finetuning:

A regularized auto-encoder which sometimes outperforms the DAE is the Contractive Auto-Encoder (CAE), (Rifai et al., 2012), which penalizes the Frobenius norm of the Jacobian matrix of derivatives of the hidden units with respect to the CAE inputs. The CAE serves as pre-training for an MLP, and in the supervised fine-tuning state, the Adagrad method was used to automatically tune the learning rate (Duchi et al., 2011).

After training a CAE with 100 sigmoidal units patch-wise, the features extracted on each patch are concatenated and fed as input to an MLP. The selected Jacobian penalty coefficient is 2, the learning rate for pre-training is 0.082 with batch size of 200 and 200 epochs of unsupervised learning are performed on the training set. For supervised finetuning, the learning rate is 0.12 over 100 epochs, L1 and L2 regularization penalty terms respectively are 1e-4 and 1e-6, and the top-level MLP has 6400 hidden units.

B.8.2 Greedy Layerwise CAE+DAE Supervised Finetuning:

For this experiment we stack a CAE with sigmoid non-linearities and then a DAE with rectifier non-linearities during the pre-training phase. As recommended by Glorot et al. (2011) we have used a softplus nonlinearity for reconstruction, $softplus(x) = log(1 + e^x)$. We used an L1 penalty on the rectifier outputs to obtain a sparser representation with rectifier non-linearity and L2 regularization to keep the non-zero weights small.

The main difference between the DAE and CAE is that the DAE yields more robust reconstruction whereas the CAE obtains more robust features (Rifai et al., 2011).

As seen on Figure 6 the weights U and V are shared on each patch and we concatenate the outputs of the last auto-encoder on each patch to feed it as an input to an MLP with a large hidden layer.

We used 400 hidden units for the CAE and 100 hidden units for DAE. The learning rate used for the CAE is 0.82 and for DAE it is 9*1e-3. The corruption level for the DAE (binomial noise) is 0.25 and the contraction level for the CAE is 2.0. The L1 regularization penalty for the DAE is 2.25*1e-4 and the L2 penalty is 9.5*1e-5. For the supervised finetuning phase the learning rate used is 4*1e-4 with L1 and L2 penalties respectively 1e-5 and 1e-6. The top-level MLP has 6400 hidden units. The auto-encoders are each trained for 150 epochs while the whole MLP is fine-tuned for 50 epochs.

B.8.3 Greedy Layerwise DAE+DAE Supervised Finetuning:

For this architecture, we have trained two layers of denoising auto-encoders greedily and performed supervised finetuning after unsupervised pre-training. The motivation for using two denoising auto-encoders is the fact that rectifier nonlinearities work well with the deep networks but it is difficult to train CAEs with the rectifier non-linearity. We have used the same type of denoising auto-encoder that is used for the greedy layerwise CAE+DAE supervised finetuning experiment.

In this experiment we have used 400 hidden units for the first layer DAE and 100 hidden units for the second layer DAE. The other hyperparameters for DAE and supervised finetuning are the same as with the *CAE+DAE MLP Supervised Finetuning* experiment.

Abstract

Comparing strings and assessing their similarity is a basic operation in many application domains of machine learning, such as in information retrieval, natural language processing and bioinformatics. The practitioner can choose from a large variety of available similarity measures for this task, each emphasizing different aspects of the string data. In this article, we present Harry, a small tool specifically designed for measuring the similarity of strings. Harry implements over 20 similarity measures, including common string distances and string kernels, such as the Levenshtein distance and the Subsequence kernel. The tool has been designed with efficiency in mind and allows for multi-threaded as well as distributed computing, enabling the analysis of large data sets of strings. Harry supports common data formats and thus can interface with analysis environments, such as Matlab, Pylab and Weka.

Keywords: string kernels, string distances, similarity measures for strings

1. Introduction

The comparison of strings is a basic operation in many applications of machine learning. Several problems of information retrieval and natural language processing center on comparing strings (see Salton and McGill, 1986). Similarly, several tasks in bioinformatics revolve around assessing the similarity of sequences (see Borgwardt, 2011). The problem underlying these tasks—*measuring the similarity or dissimilarity of two strings*—has been a vivid topic of research for over five decades, ranging from early telecommunication to modern machine learning and data analysis. As a result, the practitioner can choose from a large variety of available methods for assessing the similarity of strings[1], each emphasizing different aspects and characteristics of the data.

In this article we present Harry, a small tool specifically designed for measuring the similarity of strings and making various comparison methods available for analysis of string data. Harry implements over 20 common similarity measures, including classic string distances, such as the Damerau (1964) and Levenshtein (1966) distance, as well as modern string kernels, such as the Spectrum and Subsequence kernel (Lodhi et al., 2002). As the pairwise comparison of strings usually induces a quadratic run-time, Harry has been designed with efficiency in mind and allows for multi-threaded as well as distributed computing, which enables calculating large distance and kernel matrices. Harry supports common data formats and thus can interface with analysis tools and environments, such as Matlab, Pylab, Weka and LibSVM.

1. For ease of presentation, we use the term *similarity* synonymously with *dissimilarity* in this article.

While there also exist other tools implementing similarity measures for strings, such as the popular module python-Levenshtein, the generic toolbox Shogun (Sonnenburg et al., 2010) and the R package KeBABS for biological sequences (Palme et al., 2015), none of these tools provides a similarly broad range of similarity measures in comparison with Harry. Moreover, Harry complements the tool Sally (Rieck et al., 2012) which maps strings to vectors and allows for applying vectorial comparison functions to strings, such as the Euclidean and Manhattan distance. In combination, Harry & Sally provide a versatile basis for analyzing string data.

2. A Brief Overview of Harry

Harry implements a generic framework for the comparison of strings and assessing their similarity. In the following, we briefly discuss the main features of this framework.

2.1 Supported Similarity Measures

The current version of Harry supports the similarity measures listed in Table 1. Included are classic string distances by Damerau (1964) and Levenshtein (1966) as well as more recent methods, such as distances by Jaro (1989) and Bennett et al. (1998). Furthermore, the tool implements string kernels as described by Shawe-Taylor and Cristianini (2004) and allows for mapping kernels to distances and vice versa. In addition to distances and kernels, Harry also implements so-called similarity coefficients, such as the Jaccard index, which assess similarity in terms of matching sets of characters or words (Sokal and Sneath, 1963).

String Distances (10)			
Bag distance	Hamming distance	Kernel-substitution distance	String alignment distance
Compression distance	Jaro distance	Lee distance	
Damerau-Levenshtein distance	Jaro-Winkler distance	Levenshtein distance	
String Kernels (4)			
Distance-substitution kernel	Spectrum kernel	Subsequence kernel	Weighted-degree kernel
Similarity Coefficients (7)			
Braun-Blanquet coefficient	Kulczynski coefficient	Simpson coefficient	Sokal-Sneath coefficient
Jaccard coefficient	Otsuka coefficient	Soerensen-Dice coefficient	

Table 1: Similarity measures for strings supported by Harry (version 0.4.1).

2.2 Scalable Computation

For the efficient processing of large sets of strings, Harry makes use of multi-threading and distributes the workload over multiple CPU cores (see option `-n`). The run-time performance of Harry thus scales linearly with the number of cores and enables computing large distance and kernel matrices. Furthermore, Harry can split the calculation of large matrices into smaller chunks, where these chunks are either defined manually as sub-matrices (see options `-x` and `-y`) or automatically from the number of requested splits (option `-s`). Using this splitting the computation of similarity measures can be easily distributed over multiple hosts and carried out with systems for high performance computing, such as the LSF or SGE platform.

The run-time performance of Harry is further improved by caching recurrent computations (option `-a`), such as during the normalization of string kernels and distances. The underlying cache builds on a lightweight synchronization that ensures little overhead, even if several threads concurrently access the data. The caching can also be applied directly to the computed similarity values (option `-G`) and speed up the comparison of data sets with duplicate strings.

2.3 Interfaces and Preprocessing

To interface with other analysis tools and environments, Harry implements support for common input and output formats. The tool can read string data from text files, directories and compressed archives (option `-i`). Moreover, it is able to store computed similarity matrices in output formats suitable for Matlab, Pylab, Weka and LibSVM (option `-o`). Additionally, Harry is bundled with a Python module that enables efficiently comparing strings in Python without storing data on disk.

Harry supports several preprocessing functions that improve string comparison in particular fields of application. For example, the tool enables the user to change the granularity of the comparison to either bytes, bits or tokens (option `-g`). In the latter setting the input strings are partitioned into tokens using a set of delimiter characters, thereby enabling the analysis of structured data, such as text and log entries. Moreover, Harry supports removing stop tokens from strings, transforming tokens to Soundex codes and encoding non-printable characters in texts.

The data format, preprocessing functions and the selected similarity measure can be specified on the command line as well as in a configuration file (option `-c`). As a result, experiments with Harry can be easily reproduced using stored configurations.

3. Experiments with Harry

We demonstrate the efficiency of Harry in an empirical evaluation, where we first study its scalability (Section 3.1) and then compare its performance to related tools (Section 3.2). In all experiments we consider the data sets listed in Table 2 which contain strings of DNA snippets, protein sequences, Twitter messages and network traces, respectively.

Data set	**ARTS**	**SPROT**	**TWEETS**	**WEBFP**
Type of strings	DNA snippets	Protein sequences	Twitter messages	Network traces
Average length of strings	2,400 bases	457 proteins	126 characters	1,312 packets
Size of alphabet	4 bases	22 proteins	69 characters	6 packet sizes

Table 2: Data sets for evaluation. Each data set consists of 1,000 strings randomly drawn from the original source: ARTS (Sonnenburg et al., 2006); SPROT (O'Donovan et al., 2002); TWEETS (Twitter.com); WEBFP (Cai et al., 2012).

3.1 Scalability of Harry

In our first experiment, we compute the Levenshtein (1966) distance, the normalized compression distance (Bennett et al., 1998) and the Subsequence kernel (Lodhi et al., 2002) on all four data sets using Harry. We repeat the computation with a different number of available CPU cores and measure the run-time in terms of comparisons per second.

Figure 1 shows the results of this experiment. The Levenshtein distance and the Subsequence kernel scale perfectly linear with the number of CPU cores, reaching peak performances of 10^5 and 10^4 comparisons per second, respectively. The compression distance scales almost linearly, as the caching used for normalization induces a slight overhead when more than 8 cores are used.

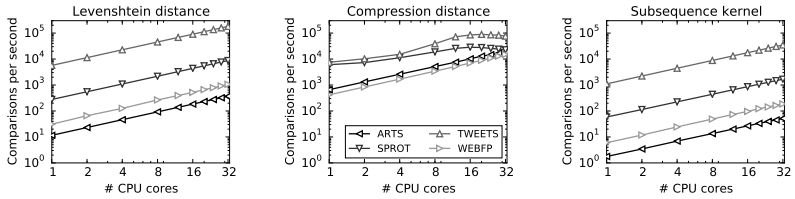

Figure 1: Run-time performance of Harry with varying number of CPU cores.

3.2 Comparative Evaluation

In the second experiment, we compare Harry with other tools for measuring string similarity. We consider the Python modules *python-Levenshtein* (0.11.2) and *python-jellyfish* (0.5.0) that implement the Levenshtein distance and its variants, the library *CompLearn* (1.1.7) that focuses on compression distances, and the machine learning toolbox *Shogun* (4.0.0) that provides several string kernels. For each of the four data sets, we randomly draw 100 strings, compute a full similarity matrix with each tool and measure the run-time over 10 runs.

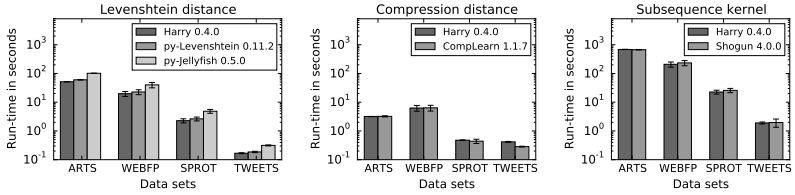

Figure 2: Comparative evaluation of Harry and related software tools.

The averaged results for the comparative evaluation are shown in Figure 2. In all settings, Harry is on par with the other tools and provides a similar and often even better performance. Given that each of the related tools focuses only on a subset of similarity measures, this experiment demonstrates the versatile yet efficient implementation of Harry.

4. Conclusions

Harry provides access to a wide range of similarity measures and enables their efficient computation on string data. In combination with Sally (Rieck et al., 2012), the tool is a perfect fit for analyzing and learning with strings. The source code of Harry along with documentation and a tutorial is available at *http://www.mlsec.org/harry*.

Abstract

The Gibbs sampler is one of the most popular algorithms for inference in statistical models. In this paper, we introduce a herding variant of this algorithm, called herded Gibbs, that is entirely deterministic. We prove that herded Gibbs has an $O(1/T)$ convergence rate for models with independent variables and for fully connected probabilistic graphical models. Herded Gibbs is shown to outperform Gibbs in the tasks of image denoising with MRFs and named entity recognition with CRFs. However, the convergence for herded Gibbs for sparsely connected probabilistic graphical models is still an open problem.

Keywords: Gibbs sampling, herding, deterministic sampling

1. Introduction

Over the last 60 years, we have witnessed great progress in the design of randomized sampling algorithms; see for example Liu (2001); Doucet et al. (2001); Andrieu et al. (2003); Robert and Casella (2004) and the references therein. In contrast, the design of deterministic algorithms for "sampling" from distributions is still in its inception (Chen et al., 2010; Holroyd and Propp, 2010; Chen et al., 2011; Murray and Elliott, 2012). There are, however, many important reasons for pursuing this line of attack on the problem. From a theoretical perspective, this is a well defined mathematical challenge whose solution might have important consequences. It also brings us closer to reconciling the fact that we typically use pseudo-random number generators to run Monte Carlo algorithms on classical, Von Neumann architecture, computers. Moreover, the theory for some of the recently proposed deterministic sampling algorithms has taught us that they can achieve $O(1/T)$ convergence rates (Chen et al., 2010; Holroyd and Propp, 2010), which are much faster than the standard Monte Carlo rates of $O(1/\sqrt{T})$ for computing ergodic averages. From a practical perspective, the design of deterministic sampling algorithms creates an opportunity for researchers to apply a great body of knowledge on optimization to the problem of sampling; see for example Bach et al. (2012) for an early example of this.

The domain of application of currently existing deterministic sampling algorithms is still very narrow. Importantly, the only available deterministic tool for sampling from unnormalized multivariate probability distributions is the Markov Chain Quasi-Monte Carlo method (Chen et al., 2011), but there is no theoretical result to show a better convergence rate than a standard MCMC method yet. This is very limiting because the problem of sampling from unnormalized distributions is at the heart of the field of Bayesian inference and the probabilistic programming approach to artificial intelligence (Lunn et al., 2000; Carbonetto et al., 2005; Milch and Russell, 2006; Goodman et al., 2008). At the same time, despite great progress in Monte Carlo simulation, the celebrated Gibbs sampler continues to be one of the most widely-used algorithms. For example, it is the inference engine behind popular statistics packages (Lunn et al., 2000), several tools for text analysis (Porteous et al., 2008), and Boltzmann machines (Ackley et al., 1985; Hinton and Salakhutdinov, 2006). The popularity of Gibbs stems from its generality and simplicity of implementation.

Without any doubt, it would be remarkable if we could design generic deterministic Gibbs samplers with fast (theoretical and empirical) rates of convergence. In this paper, we take steps toward achieving this goal by capitalizing on a recent idea for deterministic simulation known as herding. Herding (Welling, 2009a,b; Gelfand et al., 2010) is a deterministic procedure for generating samples $\mathbf{x} \in \mathcal{X} \subseteq \mathbb{R}^n$, such that the empirical moments $\boldsymbol{\mu}$ of the data are matched. The herding procedure, at iteration t, is as follows:

$$\begin{aligned} \mathbf{x}^{(t)} &= \arg\max_{\mathbf{x}\in\mathcal{X}} \langle \mathbf{w}^{(t-1)}, \boldsymbol{\phi}(\mathbf{x}) \rangle, \\ \mathbf{w}^{(t)} &= \mathbf{w}^{(t-1)} + \boldsymbol{\mu} - \boldsymbol{\phi}(\mathbf{x}^{(t)}), \end{aligned} \tag{1}$$

where $\boldsymbol{\phi} : \mathcal{X} \to \mathcal{H}$ is a feature map (statistic) from $\mathcal{X}$ to a Hilbert space $\mathcal{H}$ with inner product $\langle \cdot, \cdot \rangle$, $\mathbf{w} \in \mathcal{H}$ is the vector of parameters, and $\boldsymbol{\mu} \in \mathcal{H}$ is the moment vector (expected value of $\boldsymbol{\phi}$ over the data) that we want to match. If we choose normalized features by making $\|\boldsymbol{\phi}(\mathbf{x})\|$ constant for all $\mathbf{x}$, then the update to generate samples $\mathbf{x}^{(t)}$ for $t = 1, 2, \ldots, T$ in Equation 1 is equivalent to minimizing the objective

$$J(\mathbf{x}_1, \ldots, \mathbf{x}_T) = \left\| \boldsymbol{\mu} - \frac{1}{T} \sum_{t=1}^{T} \boldsymbol{\phi}(\mathbf{x}^{(t)}) \right\|^2, \tag{2}$$

where T may have no prior known value and $\|\cdot\| = \sqrt{\langle \cdot, \cdot \rangle}$ is the naturally defined norm based upon the inner product of the space $\mathcal{H}$ (Chen et al., 2010; Bach et al., 2012).

Herding can be used to produce samples from *normalized* probability distributions. This is done as follows. Let $\boldsymbol{\mu}$ denote a discrete, normalized probability distribution, with $\mu_i \in [0, 1]$ and $\sum_{i=1}^{n} \mu_i = 1$. A natural feature in this case is the vector $\boldsymbol{\phi}(x)$ that has all entries equal to zero, except for the entry at the position indicated by x. For instance, if $x = 2$ and $n = 5$, we have $\boldsymbol{\phi}(x) = (0, 1, 0, 0, 0)^T$. Hence, $\widehat{\boldsymbol{\mu}} = T^{-1} \sum_{t=1}^{T} \boldsymbol{\phi}(x^{(t)})$ is an empirical estimate of the distribution. In this case, one step of the herding algorithm

involves finding the largest component of the weight vector ($i^\star = \arg\max_{i\in\{1,2,..,n\}} \mathbf{w}_i^{(t-1)}$), setting $x^{(t)} = i^\star$, fixing the $i^\star$-entry of $\boldsymbol{\phi}(x^{(t)})$ to one and all other entries to zero, and updating the weight vector: $\mathbf{w}^{(t)} = \mathbf{w}^{(t-1)} + (\boldsymbol{\mu} - \boldsymbol{\phi}(x^{(t)}))$. The output is a set of samples $\{x^{(1)}, \ldots, x^{(T)}\}$ for which the empirical estimate $\widehat{\boldsymbol{\mu}}$ converges on the target distribution $\boldsymbol{\mu}$ as $O(1/T)$.

The herding method, as described thus far, only applies to normalized distributions or to problems where the objective is not to guarantee that the samples come from the right target, but to ensure that some moments are matched. An interpretation of herding in terms of Bayesian quadrature has been put forward recently by Huszar and Duvenaud (2012).

In this paper, we will show that it is possible to use herding to generate samples from more complex *unnormalized* probability distributions. In particular, we introduce a deterministic variant of the popular Gibbs sampling algorithm, which we refer to as *herded Gibbs*. While Gibbs relies on drawing samples from the *full-conditionals* at random, herded Gibbs generates the samples by matching the full-conditionals. That is, one simply applies herding to all the full-conditional distributions.

The experiments will demonstrate that the new algorithm outperforms Gibbs sampling and mean field methods in the domain of sampling from sparsely connected probabilistic graphical models, such as grid-lattice Markov random fields (MRFs) for image denoising and conditional random fields (CRFs) for natural language processing.

We advance the theory by proving that the deterministic Gibbs algorithm converges for distributions of independent variables and fully-connected probabilistic graphical models. However, a proof establishing suitable conditions that ensure convergence of herded Gibbs sampling for sparsely connected probabilistic graphical models is still unavailable.

2. Herded Gibbs Sampling

For a graph of discrete nodes $\mathcal{G} = (V, E)$, where the set of nodes are the random variables $V = \{X_i\}_{i=1}^N$, $X_i \in \mathcal{X}$, let π denote the *target distribution* defined on $\mathcal{G}$.

Gibbs sampling is one of the most popular methods to draw samples from π. Gibbs alternates (either systematically or randomly) the sampling of each variable X_i given $\mathbf{X}_{\mathcal{N}(i)} = \mathbf{x}_{\mathcal{N}(i)}$, where i is the index of the node, and $\mathcal{N}(i)$ denotes the neighbors of node i. That is, Gibbs generates each sample from its full-conditional distribution $p(X_i|\mathbf{x}_{\mathcal{N}(i)})$.

Herded Gibbs replaces the sampling from full-conditionals with herding at the level of the full-conditionals. That is, it alternates a process of matching the full-conditional distributions $p(X_i = x_i|\mathbf{X}_{\mathcal{N}(i)})$. To do this, herded Gibbs defines a set of auxiliary weights $\{w_{i,\mathbf{x}_{\mathcal{N}(i)}}\}$ for any value of $X_i = x_i$ and $\mathbf{X}_{\mathcal{N}(i)} = \mathbf{x}_{\mathcal{N}(i)}$. For ease of presentation, we assume the domain of X_i is binary, $\mathcal{X} = \{0, 1\}$, and we use one weight for every i and assignment to the neighbors $\mathbf{x}_{\mathcal{N}(i)}$. Herded Gibbs can be trivially generalized to the discrete setting by employing weight vectors in $\mathbb{R}^{|\mathcal{X}|}$ instead of scalars.

If the binary variable X_i has four binary neighbors $\mathbf{X}_{\mathcal{N}(i)}$, we must maintain $2^4 = 16$ weight vectors. Only the weight vector corresponding to the current instantiation of the neighbors is updated, as illustrated in Algorithm 1[1]. The memory complexity of herded Gibbs is exponential in the maximum node degree. Note the algorithm is a deterministic Markov process with state $(\mathbf{X}, \mathbf{W})$.

1. Code is available at `http://www.mareija.ca/research/code/`

Algorithm 1 Herded Gibbs Sampling

Input: T.

Step 1: Set $t = 0$. Initialize $\mathbf{X}^{(0)}$ in the support of π and $w^{(0)}_{i,\mathbf{x}_{\mathcal{N}(i)}}$ in $(\pi(X_i = 1|\mathbf{x}_{\mathcal{N}(i)}) - 1, \pi(X_i = 1|\mathbf{x}_{\mathcal{N}(i)}))$.

for $t = 1 \to T$ **do**

Step 2: Pick a node i according to some policy. Denote $w = w^{(t-1)}_{i,\mathbf{x}^{(t-1)}_{\mathcal{N}(i)}}$.

Step 3: If $w > 0$, set $x_i^{(t)} = 1$, otherwise set $x_i^{(t)} = 0$.

Step 4: Update weight $w^{(t)}_{i,\mathbf{x}^{(t)}_{\mathcal{N}(i)}} = w^{(t-1)}_{i,\mathbf{x}^{(t-1)}_{\mathcal{N}(i)}} + \pi(X_i = 1|\mathbf{x}^{(t-1)}_{\mathcal{N}(i)}) - x_i^{(t)}$.

Step 5: Keep the values of all the other nodes $x_j^{(t)} = x_j^{(t-1)}, \forall j \neq i$ and all the other weights $w^{(t)}_{j,\mathbf{x}_{\mathcal{N}(j)}} = w^{(t-1)}_{j,\mathbf{x}_{\mathcal{N}(j)}}, \forall j \neq i$ or $\mathbf{x}_{\mathcal{N}(j)} \neq \mathbf{x}^{(t-1)}_{\mathcal{N}(i)}$.

end for

Output: $\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(T)}$

The initialization in the first step of Algorithm 1 guarantees that $\mathbf{X}^{(t)}$ always remains in the support of π with the reason to be explained in Section 3.1. For a deterministic scan policy in step 2, we take the value of variables $\mathbf{x}^{(tN)}, t \in \mathbb{N}$ as a sample sequence. Throughout the paper all experiments employ a fixed variable traversal for sample generation. We call one such traversal of the variables a *sweep*.

3. Analysis

As herded Gibbs sampling is a deterministic algorithm, the probability distribution of the sample at any step t is a single point mass and there is no stationary distribution of states. Instead, we examine the average of the sample states over time and hypothesize that it converges to the joint distribution, our target distribution, π. To make the treatment precise, we need the following definition:

Definition 1 *For a graph of discrete nodes $\mathcal{G} = (V, E)$, where the set of nodes $V = \{X_i\}_{i=1}^N$, $X_i \in \mathcal{X}$, $P_T^{(\tau)}$ is the empirical estimate of the joint distribution obtained by averaging over T samples acquired from $\mathcal{G}$. $P_T^{(\tau)}$ is derived from T samples, collected at the end of every sweep over N variables, starting from the τ^{th} sweep:*

$$P_T^{(\tau)}(\mathbf{X} = \mathbf{x}) = \frac{1}{T} \sum_{k=\tau}^{\tau+T-1} \mathbb{I}(\mathbf{X}^{(kN)} = \mathbf{x}). \tag{3}$$

The definition of $P_T^{(\tau)}$ is illustrated in Figure 1. Our goal is to prove that the limiting average sample distribution over time converges to the target distribution π. Specifically, we want to show the following:

$$\lim_{T\to\infty} P_T^{(\tau)}(\mathbf{x}) = \pi(\mathbf{x}), \forall \tau \geq 0. \tag{4}$$

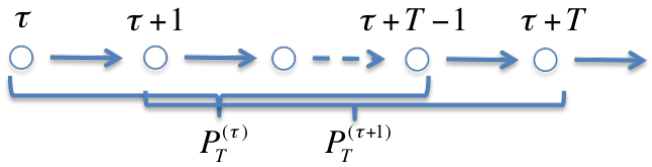

Figure 1: Sample distribution over T sweeps. Each node refers to the joint state at the end of one sweep.

If this holds, we also want to know what the convergence rate is.

3.1 Single Variable Models

We begin the theoretical analysis with a graph of one binary variable. For this graph, there is only one weight w and herded Gibbs is equivalent to the standard herding algorithm. Denote $\pi(X=1)$ as π for notational simplicity. The sequence of X is determined by the dynamics of w (shown in Figure 2a):

$$w^{(t)} = w^{(t-1)} + \pi - \mathbb{I}(w^{(t-1)} > 0), \quad X^{(t)} = \begin{cases} 1 & \text{if } w^{(t-1)} > 0 \\ 0 & \text{otherwise} \end{cases}. \tag{5}$$

The following lemma shows that $(\pi-1, \pi]$ is the invariant interval of the dynamics.

Lemma 1 *If w is the weight of the herding dynamics of a single binary variable X with probability $P(X=1)=\pi$, and $w^{(s)} \in (\pi-1, \pi]$ at some step $s \geq 0$, then $w^{(t)} \in (\pi-1, \pi], \forall t \geq s$. Moreover, for $T \in \mathbb{N}$, we have:*

$$\sum_{t=s+1}^{s+T} \mathbb{I}[X^{(t)}=1] \in [T\pi - 1, T\pi + 1], \tag{6}$$

$$\sum_{t=s+1}^{s+T} \mathbb{I}[X^{(t)}=0] \in [T(1-\pi) - 1, T(1-\pi) + 1]. \tag{7}$$

See the proof in Appendix A. It follows immediately that the state $X=1$ is visited at a frequency close to π with an error:

$$|P_T^{(\tau)}(X=1) - \pi| \leq \frac{1}{T}. \tag{8}$$

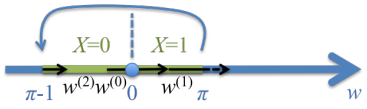
This is known as the fast moment matching property in Welling (2009a,b); Gelfand et al. (2010). When w is outside the invariant interval, it is easy to observe that w will move into it monotonically at a linear speed in a transient period. So we will always consider an initialization of $w \in (\pi-1, \pi]$ from now on.

Another immediate consequence of Lemma 1 is that the initialization in Algorithm 1 ensures that $\mathbf{X}^{(t)}$ always remain in the support of π. That is because when we consider

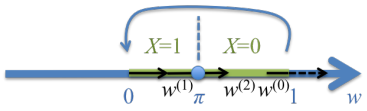
the set of iterations that involves a particular weight $w_{i,\mathbf{x}_{\mathcal{N}(i)}}$, the dynamics of that weight is equivalent to that of a single variable model with a probability $\pi(X_i = 1|\mathbf{x}_{\mathcal{N}(i)})$. If a joint state $\mathbf{X}$ is going to move outside the support at some iteration t, from e. g. $\mathbf{x}^{(t-1)} = (x_i = 0, \mathbf{x}_{-i})$ to $\mathbf{x}^{(t)} = (x_i = 1, \mathbf{x}_{-i})$ where $\mathbf{x}_{-i}$ denotes all the other variables but x_i, then the corresponding weight $w_{i,\mathbf{x}_{\mathcal{N}(i)}}^{(t-1)}$ must be positive according to the algorithm. However, the conditional probability $\pi(X_i = 1|\mathbf{x}_{\mathcal{N}(i)}) = 0$ because $\pi(\mathbf{x}^{(t-1)}) > 0$ and $\pi(\mathbf{x}^{(t)}) = 0$. Following Lemma 1 the weight $w_{i,\mathbf{x}_{\mathcal{N}(i)}}^{(t-1)} \in (-1, 0]$, leading to a contradiction. The same argument applies when $\mathbf{X}$ tries to move from $\mathbf{x}^{(t-1)} = (x_i = 1, \mathbf{x}_{-i})$ to $\mathbf{x}^{(t)} = (x_i = 0, \mathbf{x}_{-i})$. Therefore, once initialized inside the support, the samples of Algorithm 1 will remain in the support for any $t > 0$.

It will be useful for the next section to introduce an equivalent representation of the weight dynamics by taking a one-to-one mapping $w \leftarrow w \mod 1$ (we define $1 \mod 1 = 1$) with a little abuse of the symbol w. We think of the new variable w as updated by a constant translation vector in a circular unit interval $(0, 1]$ as shown in Figure 2b. That is,

$$w^{(t)} = (w^{(t-1)} + \pi) \mod 1, \quad X^{(t)} = \begin{cases} 1 & \text{if } w^{(t-1)} < \pi \\ 0 & \text{otherwise} \end{cases}. \tag{9}$$



(a) Representation in Equation 5.



(b) Equivalent representation.

Figure 2: Herding dynamics for a single variable. Black arrows show the trajectory of $w^{(t)}$ for 2 iterations.

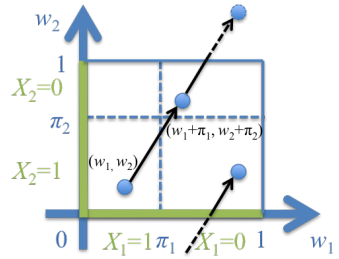


Figure 3: Herding dynamics for two independent variables in the equivalent representation.

3.2 Empty Graphs

The analysis of herded Gibbs for empty graphs is a natural extension of that for single variables. In an empty graph, all the variables are independent of each other and herded Gibbs reduces to running N one-variable chains in parallel. Denote the marginal distribution $\pi_i := \pi(X_i = 1)$.

Examples of failing convergence in the presence of rational ratios between the π_is were observed in Bach et al. (2012). There the need for further theoretical research on this matter

was pointed out. The following theorem provides a sufficient condition for convergence in the restricted domain of empty graphs.

Theorem 2 *For an empty graph, when herded Gibbs has a fixed scanning order, and* $\{1, \pi_1, \ldots, \pi_N\}$ *are rationally independent, the empirical distribution* $P_T^{(\tau)}$ *converges to the target distribution* π *as* $T \to \infty$ *for any* $\tau \geq 0$.

A set of n real numbers, $x_1, x_2, \ldots, x_n$, is said to be rationally independent if for any set of rational numbers, $a_1, a_2, \ldots, a_n$, we have $\sum_{i=1}^n a_i x_i = 0 \Leftrightarrow a_i = 0, \forall 1 \leq i \leq n$.

Proof For an empty graph of N independent vertices, the dynamics of the weight vector $\mathbf{w}$ after one sweep over all variables are equivalent to a constant translation mapping in an N-dimensional circular unit space $(0,1]^N$, as shown in Figure 3:

$$\begin{aligned} \mathbf{w}^{(t)} &= (\mathbf{w}^{(t-1)} + \boldsymbol{\pi}) \mod 1 \\ &= (\mathbf{w}^{(0)} + t\boldsymbol{\pi}) \mod 1, \quad x_i^{(t)} = \begin{cases} 1 & \text{if } w_i^{(t-1)} < \pi_i \\ 0 & \text{otherwise} \end{cases}, \forall 1 \leq i \leq N. \end{aligned} \tag{10}$$

The Kronecker-Weyl theorem (Weyl, 1916) states that the sequence $\tilde{\mathbf{w}}^{(t)} = t\pi \mod 1, t \in \mathbb{Z}^+$ is equidistributed (or uniformly distributed) on $(0,1]^N$ if and only if $(1, \pi_1, \ldots, \pi_N)$ is rationally independent. Intuitively, when $(1, \pi_1, \ldots, \pi_N)$ is rationally independent, the trajectory of $\tilde{\mathbf{w}}^{(t)}$ can not form a closed loop in the circular unit space and will thereby cover the entire space uniformly.

Since we can define a one-to-one volume preserving transformation between $\tilde{\mathbf{w}}^{(t)}$ and $\mathbf{w}^{(t)}$ as $(\tilde{\mathbf{w}}^{(t)} + \mathbf{w}^{(0)}) \mod 1 = \mathbf{w}^{(t)}$, the sequence of weights $\{\mathbf{w}^{(t)}\}$ is also uniformly distributed in $(0,1]^N$.

Now define the mapping from a state value x_i to an interval of w_i as

$$A_i(x) = \begin{cases} (0, \pi_i] & \text{if } x = 1 \\ (\pi_i, 1] & \text{if } x = 0 \end{cases} \tag{11}$$

and let $|A_i|$ be its measure. We obtain the limiting distribution of the joint state as

$$\begin{aligned} \lim_{T\to\infty} P_T^{(\tau)}(\mathbf{X} = \mathbf{x}) &= \lim_{T\to\infty} \frac{1}{T} \sum_{t=1}^{T} \mathbb{I}\left[\mathbf{w}^{(t-1)} \in \prod_{i=1}^{N} A_i(x_i)\right] \\ &= \prod_{i=1}^{N} |A_i(x_i)| = \prod_{i=1}^{N} \pi(X_i = x_i) = \pi(\mathbf{X} = \mathbf{x}). \end{aligned} \tag{12}$$

■

The rational independence condition in the application of the Kronecker-Weyl theorem ensures that the probabilistic independence between different variables will be respected by the herding dynamics. When the condition fails, the convergence of joint distribution is not guaranteed but the marginal distribution of each variables will still converge to their target distribution because the N one-variable chains run independently from each other.

3.3 Fully-Connected Graphs

When herded Gibbs is applied to fully-connected (complete) graphs, convergence is guaranteed even with rationally dependent conditional probabilities. In fact, herded Gibbs converges to the target joint distribution at a rate of $O(1/T)$ with a $O(\log(T))$ burn-in period. This statement is formalized in Theorem 3 and a corollary when we ignore the burn-in period, with proofs provided respectively in Appendix B.4 and B.5.

Theorem 3 *For a fully-connected graph, when herded Gibbs has a fixed scanning order and a Dobrushin coefficient of the corresponding Gibbs sampler* $\eta < 1$*, there exist constants* $l > 0$*, and* $B > 0$ *such that*

$$d_v(P_T^{(\tau)} - \pi) \leq \frac{\lambda}{T}, \forall T \geq T^*, \tau > \tau^*(T), \tag{13}$$

where $\lambda = \frac{2N(1+\eta)}{l(1-\eta)}$, $T^* = \frac{2B}{l}$, $\tau^*(T) = \log_{\frac{2}{1+\eta}}\left(\frac{(1-\eta)lT}{4N}\right)$*, and* $d_v(\delta\pi) := \frac{1}{2}||\delta\pi||_1$.

Corollary 4 *When the conditions of Theorem 3 hold, and we start collecting samples at the end of every sweep from the beginning, that is setting* $\tau = 0$*, the error of the sample distribution is bounded by:*

$$d_v(P_T^{(\tau=0)} - \pi) \leq \frac{\lambda + \tau^*(T)}{T} = O(\frac{\log(T)}{T}), \quad \forall T \geq T^* + \tau^*(T^*). \tag{14}$$

The Dobrushin ergodic coefficient (Brémaud, 1999) measures the geometric convergence rate of a Markov chain. The constant l in the convergence rate can be interpreted as a lower bound of the transition probability between any pair of states in the support of the target distribution. For a strictly positive distribution, the constants l and B are

$$l = \pi_{\min}^N, \quad B = \pi_{\min}^N + \frac{1 - (2\pi_{\min})^N}{1 - 2\pi_{\min}}. \tag{15}$$

where $\pi_{\min}$ is the minimal conditional probability $\pi_{\min} = \min_{1\leq i\leq N, \mathbf{x}_{-i}} \pi(x_i|\mathbf{x}_{-i})$. We refer the readers to Equation 34 in Proposition 5 in the appendix for a general distribution. Notice that l has an exponential term, with N in the exponent, leading to an exponentially large constant. This is unavoidable for any sampling algorithm when considering the convergence to a joint distribution with 2^N states. As for the marginal distributions, it is obvious that the convergence rate of herded Gibbs is also $O(1/T)$ because marginal probabilities are linear functions of the joint distribution. In fact, we observe very rapid convergence results for the marginals in practice, so stronger theoretical results about the convergence of the marginal distributions seem plausible.

The proof proceeds by first bounding the discrepancy between the chain of empirical estimates of the joint obtained by averaging over T herded Gibbs samples, $\{P_T^{(s)}\}, s \geq \tau$, and a Gibbs chain initialized at $P_T^{(\tau)}$. After one sweep over N variables, this discrepancy is bounded above by $2N/lT$.

The Gibbs chain has geometric convergence to π and the distance between the Gibbs and herded Gibbs chains decreases as $O(1/T)$. When the distance between $P_T^{(\tau)}$ and π is

sufficiently large, the geometric convergence rate to π dominates the discrepancy of herded Gibbs and thus we infer that $P_T^{(\tau)}$ converges to a neighborhood of π geometrically in time τ for a fixed T. To round-off the proof, we must find a limiting value for τ. The proof concludes with an $O(\log(T))$ burn-in for τ.

When there exist conditional independencies in a distribution, we can still apply herded Gibbs with a fully connected graph and treat all the other variables as the Markov blanket of the variable to be sampled. Theorem 3 and its corollary still apply. Alternatively, we can apply herded Gibbs on a more compact representation with an incomplete graph. It requires less memory to run herded Gibbs because the number of weights depends exponentially on the neighborhood size. However, for a generic graph we have no mathematical guarantees for the convergence rate of herded Gibbs. In fact, one can easily construct synthetic examples for which herded Gibbs does not seem to converge to the true marginals and joint distribution. For the examples covered by our theorems and for examples with real data, herded Gibbs demonstrates good behaviour. The exact conditions under which herded Gibbs converges for sparsely connected graphs are still unknown.

4. Experiments

We illustrate the performance of herded Gibbs with two synthetic examples and two real experiments for image denoising and natural language processing respectively.

4.1 Simple Complete Graph

We begin with an illustration of how herded Gibbs substantially outperforms Gibbs and a deterministic Gibbs sampler based on MCQMC on a simple complete graph. The MCQMC algorithm replaces the random number generator of the regular Gibbs sampler with a completely uniformly distributed (CUD) sequence (Chen et al., 2011). We consider a fully-connected model of two variables, X_1 and X_2, as shown in Figure 4; the joint distribution of these variables is shown in Table 1. We run each sampler for 2.6×10^5 iterations. We use a small linear feedback shift registers (LFSR) described in (Chen et al., 2012) to generate the CUD sequence and choose the size of the LFSR so that the entire period of the sequence will be used for one run of the Markov chain. Both Gibbs and MCQMC-based Gibbs are run 100 times with different random seeds to assess their average performance. Herded Gibbs is run only once because different initialization does not show noticeable difference in its performance. Figure 5 shows the marginal distribution $P(X_1 = 1)$ and the joint distribution approximated by all the algorithms for different ϵ. As ϵ decreases, all the approaches require more iterations to converge, but herded Gibbs clearly outperforms the other two algorithms. Figure 5c also shows that herding does indeed exhibit a linear convergence rate. MCQMC-based Gibbs does not show any improvement on the error of the sample distribution compared to the standard Gibbs.

4.2 Simple Incomplete Graph

We also illustrate a simple counterexample where the sample distribution of herded Gibbs does not converge to the target distribution when the graph is incomplete. Figure 7 shows a four-variable graphical model with two missing edges, $X_1 - X_4$, $X_2 - X_3$. The unary

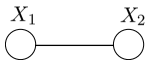

Figure 4: Two-variable model.

	$\mathbf{X_1 = 0}$	$\mathbf{X_1 = 1}$	$\mathbf{P(X_2)}$
$\mathbf{X_2 = 0}$	$1/4 - \epsilon$	ϵ	$1/4$
$\mathbf{X_2 = 1}$	ϵ	$3/4 - \epsilon$	$3/4$
$\mathbf{P(X_1)}$	$1/4$	$3/4$	1

Table 1: Joint distribution of the two-variable model.

and pairwise energies of existing edges are random sampled from a standard Gaussian distribution $\mathcal{N}(0, 1)$. We apply herded Gibbs for 10^8 iterations and compare the joint sample distribution with the true distribution. While the discrepancy is marginal as depicted in Figure 6b, the L_1 error plot in 6b does not show a tendency to converging to zero.

4.3 MRF for Image Denoising

Next, we consider the standard setting of a grid-lattice MRF for image denoising. Let us assume that we have a binary image corrupted by noise, and that we want to infer the original clean image. Let $X_i \in \{-1, +1\}$ denote the unknown true value of pixel i, and y_i the observed, noise-corrupted value of this pixel. We take advantage of the fact that neighboring pixels are likely to have the same label by defining an MRF with an Ising prior. That is, we specify a rectangular 2D lattice with the following pair-wise clique potentials:

$$\psi_{ij}(x_i, x_j) = \begin{pmatrix} e^{J_{ij}} & e^{-J_{ij}} \\ e^{-J_{ij}} & e^{J_{ij}} \end{pmatrix} \tag{16}$$

and joint distribution:

$$p(\mathbf{x}|\mathbf{J}) = \frac{1}{Z(\mathbf{J})} \prod_{i \sim j} \psi_{ij}(x_i, x_j) = \frac{1}{Z(\mathbf{J})} \exp\left(\frac{1}{2} \sum_{i \sim j} J_{ij} x_i x_j \right), \tag{17}$$

where $i \sim j$ is used to indicate that nodes i and j are connected. The known parameters J_{ij} establish the coupling strength between nodes i and j. Note that the matrix $\mathbf{J}$ is symmetric. If all the $J_{ij} > 0$, then neighboring pixels are likely to be in the same state.

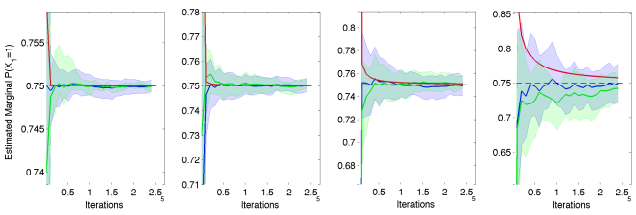
The MRF model combines the Ising prior with a likelihood model as follows:

$$p(\mathbf{x}, \mathbf{y}) \quad = \quad p(\mathbf{x}) p(\mathbf{y}|\mathbf{x}) = \left[\frac{1}{Z} \prod_{i \sim j} \psi_{ij}(x_i, x_j) \right] \cdot \left[\prod_i p(y_i|x_i) \right]. \tag{18}$$

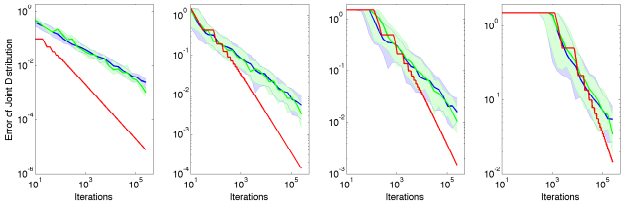
The potentials ψ_{ij} encourage label smoothness. The likelihood terms $p(y_i|x_i)$ are conditionally independent (e.g. Gaussians with known variance σ^2 and mean $\boldsymbol{\mu}$ centered at each value of x_i, denoted μ_{x_i}). In more precise terms,

$$p(\mathbf{x}, \mathbf{y}|\mathbf{J}, \boldsymbol{\mu}, \sigma) = \frac{1}{Z(\mathbf{J}, \boldsymbol{\mu}, \sigma)} \exp\left(\frac{1}{2} \sum_{i \sim j} J_{ij} x_i x_j - \frac{1}{2\sigma^2} \sum_i (y_i - \mu_{x_i})^2 \right). \tag{19}$$

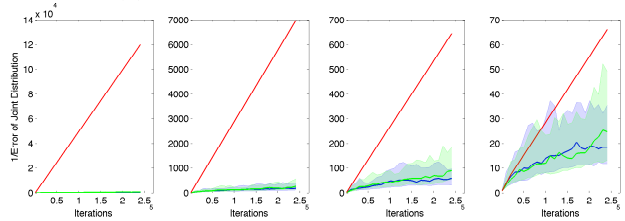
When the coupling parameters J_{ij} are identical, say $J_{ij} = J$, we have $\sum_{ij} J_{ij} f(x_i, x_j) = J \sum_{ij} f(x_i, x_j)$. Hence, different neighbor configurations result in the same value of $J \sum_{ij} f(x_i, x_j)$.



(a) Approximate marginals.

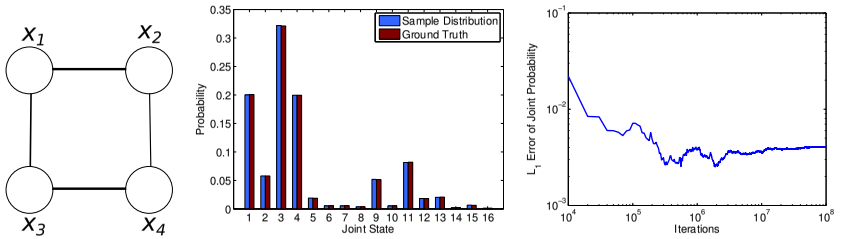


(b) Log-log plot of the L_1 error of the joint distribution.



(c) Inverse of the L_1 error of the joint distribution.

Figure 5: Approximating a marginal (a) and joint (b, c) distribution with Gibbs (blue), MCQMC-based Gibbs (green) and herded Gibbs (red) for an MRF of two variables, constructed so as to make the move from state $(0, 0)$ to $(1, 1)$ progressively more difficult as ϵ decreases. The four columns, from left to right, are for $\epsilon = 0.1$, $\epsilon = 0.01$, $\epsilon = 0.001$ and $\epsilon = 0.0001$. Table 1 provides the joint distribution for these variables. The shaded areas for Gibbs and MCQMC-based Gibbs correspond to 25%-75% quantile of 100 runs. Rows (b) and (c) illustrate that the empirical convergence rate of herded Gibbs matches the expected theoretical rate. As the error of herded Gibbs in (b) and (c) frequently drops to extremely small values for some iterations and jumps back, we plot the upper-bound (envelope) of the error for herded Gibbs defined as $\tilde{e}_t = \max_{\tau \geq t} e_\tau$ to remove the oscillating behavior for a better visualization.



(a) **(b)** **(c)**

Figure 7: Four-variable model represented as an incomplete graph. (a): Graphical Model. (b): Joint distribution of samples from herded Gibbs vs. the ground truth. (c): Log-log plot of the L_1 error of the joint sample distribution.

If we store the conditionals for configurations with the same sum together, we only need to store as many conditionals as different possible values that the sum could take. This enables us to develop a shared version of herded Gibbs that is more memory efficient where we only maintain and update weights for *distinct states* of the Markov blanket of each variable. The shared version of herded Gibbs also exhibits a different dynamics as the standard version as shown in the following result, and the convergence property of this algorithm remains an open problem.

In this exemplary image denoising experiment, noisy versions of the binary image, depicted in Figure 8 (left), were created through the addition of Gaussian noise, with varying σ. Figure 8 (right) shows a corrupted image with $\sigma = 4$. The L_2 reconstruction errors as a function of the number of iterations, for this example, are shown in Figure 9. The plot compares the herded Gibbs method against Gibbs and two versions of mean field with different damping factors (Murphy, 2012). The results demonstrate that the herded Gibbs techniques are among the best methods for solving this task.

A comparison for different values σ is presented in Table 2. As expected mean field does well in the low-noise scenario, but the performance of the shared version of herded Gibbs as the noise increases is significantly better.

4.4 CRF for Named Entity Recognition

Named entity recognition (NER) involves the identification of entities, such as people and locations, within a text sample. A conditional random field (CRF) for NER models the relationship between entity labels and sentences with a conditional probability distribution: $P(X|Y, \theta)$, where X is a labeling, Y is a sentence, and θ is a vector of coupling parameters. The parameters, θ, are feature weights and model relationships between variables X_i and Y_j or X_i and X_j. A chain CRF only employs relationships between adjacent variables, whereas a skip-chain CRF can employ relationships between variables where subscripts i and j differ dramatically. Skip-chain CRFs are important in language tasks, such as NER

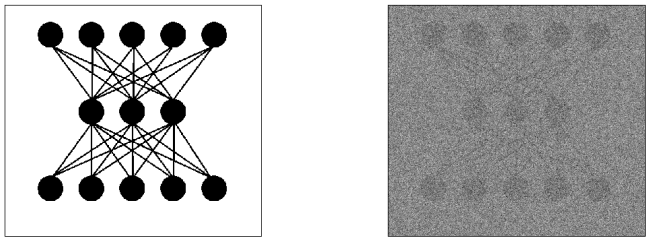


Figure 8: Original image (left) and its corrupted version (right), with noise parameter $\sigma = 4$.

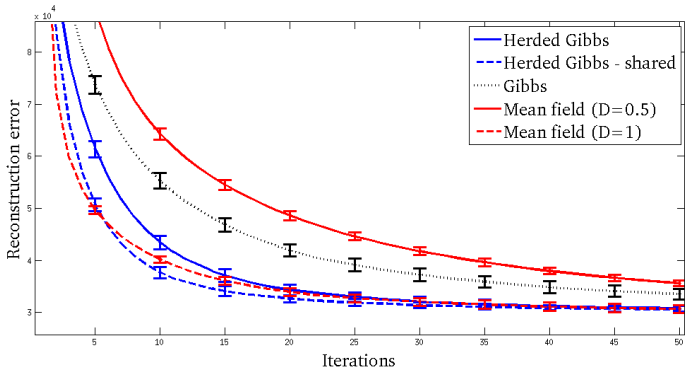

Figure 9: Reconstruction errors for the image denoising task. The results are averaged across 10 corrupted images with Gaussian noise $\mathcal{N}(0, 16)$. The error bars correspond to one standard deviation. Mean field requires the specification of the damping factor D.

and semantic role labeling, because they allow us to model long dependencies in a stream of words, see Figure 10.

Once the parameters have been learned, the CRF can be used for inference; a labeling for some sentence Y is found by maximizing the above probability. Inference for CRF models in the NER domain is typically carried out with the Viterbi algorithm. However, if we want to accommodate long term dependencies, thus resulting in the so called skip-chain CRFs,

Method \ σ	2	4	6	8
Herded Gibbs	21.58(0.26)	32.07(0.98)	47.52(1.64)	67.93(2.78)
Herded Gibbs - shared	22.24(0.29)	**31.40**(0.59)	**42.62**(1.98)	**58.49**(2.86)
Gibbs	21.63(0.28)	37.20(1.23)	63.78(2.41)	90.27(3.48)
Mean field (D=0.5)	**15.52**(0.30)	41.76(0.71)	76.24(1.65)	104.08(1.93)
Mean field (D=1)	17.67(0.40)	32.04(0.76)	51.19(1.44)	74.74(2.21)

Table 2: Errors of image denoising example after 30 iterations (all measurements have been scaled by $\times 10^{-3}$). We use an Ising prior with $J_{ij} = 1$ and four Gaussian noise models with different σ's. For each σ, we generated 10 corrupted images by adding Gaussian noise. The final results shown here are averages and standard deviations (in parentheses) across the 10 corrupted images. D denotes the damping factor in mean field.

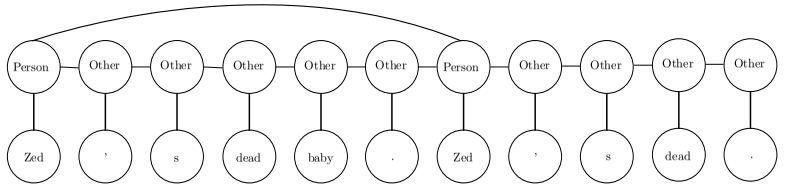

Figure 10: Typical skip-chain CRF model for named entity recognition.

Viterbi becomes prohibitively expensive. To surmount this problem, the Stanford named entity recognizer (J. R. Finkel and Manning, 2005) makes use of annealed Gibbs sampling.

To demonstrate herded Gibbs on a practical application of great interest in text mining, we modify the standard inference procedure of the Stanford named entity recognizer by replacing the annealed Gibbs sampler with the herded Gibbs sampler. The herded Gibbs sampler is not annealed. Notice that the label of a word X_i is a discrete variable with possibly multiple values. As discussed in Section 2 we generalize herded Gibbs for binary variables to discrete variables by assigning a different weight $w_{i,\mathbf{x}_{\mathcal{N}(i)}}$ for each value of X_i. To find the maximum a posteriori sequence X, we compute the joint discrete probability of every sample and choose the one with the highest probability as the prediction. The faster a sampler mixes in the state space, the more likely that a sample with high probability will be generated given a the same amount of time. In order to be able to compare against Viterbi, we have purposely chosen to use single-chain CRFs. We remind the reader, however, that the herded Gibbs algorithm could be used in cases where Viterbi inference is not possible.

We used the pre-trained 3-class CRF model in the Stanford NER package (J. R. Finkel and Manning, 2005). This model is a linear chain CRF with pre-defined features and pre-trained feature weights, θ. For the test set, we used the corpus for the NIST 1999 IE-ER Evaluation. Performance is measured in per-entity F_1 $\left(F_1 = 2 \cdot \frac{\text{precision} \cdot \text{recall}}{\text{precision} + \text{recall}}\right)$. For all the

"Pumpkin" (*Tim Roth*) and "Honey Bunny" (*Amanda Plummer*) are having breakfast in a diner. They decide to rob it after realizing they could make money off the customers as well as the business, as they did during their previous heist. Moments after they initiate the hold-up, the scene breaks off and the title credits roll. As *Jules Winnfield* (*Samuel L. Jackson*) drives, *Vincent Vega* (*John Travolta*) talks about his experiences in **Europe**, from where he has just returned: the hash bars in **Amsterdam**, the French McDonald's and its "Royale with Cheese".

Figure 11: Results for the application of the NER CRF to a random Wikipedia sample (Wik, 2013). Entities are automatically classified as person (red italic), location (green boldfaced) and organization (orange underlined).

methods, except Viterbi, we show F_1 scores after 100, 400 and 800 iterations in Table 3. For Gibbs, the results shown are the averages and standard deviations over 5 random runs. We used a linear annealing schedule for Gibbs. As the results illustrate, herded Gibbs attains the same accuracy as Viterbi and it is faster than annealed Gibbs. Unlike Viterbi, herded Gibbs can be easily applied to skip-chain CRFs. After only 400 iterations (90.5 seconds), herded Gibbs already achieves an F_1 score of 84.75, while Gibbs, even after 800 iterations (115.9 seconds) only achieves an F_1 score of 84.61. The experiment thus clearly demonstrates that (i) herded Gibbs does no worse than the optimal solution, Viterbi, and (ii) herded Gibbs yields more accurate results for the same amount of computation than Gibbs sampling. Figure 11 provides a representative NER example of the performance of Gibbs, herded Gibbs and Viterbi (all methods produced the same annotation for this short example).

Method \ Iterations	100	400	800
Annealed Gibbs	84.36(0.16) [55.73s]	84.51(0.10) [83.49s]	84.61(0.05) [115.92s]
Herded Gibbs	84.70 [59.08s]	84.75 [90.48s]	84.81 [132.00s]
Viterbi			84.81[46.74s]

Table 3: F_1 scores for Gibbs, herded Gibbs and Viterbi on the NER task. The average computational time each approach took to do inference for the entire test set is listed (in square brackets). After only 400 iterations (90.48 seconds), herded Gibbs already achieves an F_1 score of 84.75, while Gibbs, even after 800 iterations (115.92 seconds) only achieves an F_1 score of 84.61. For the same computation, herded Gibbs is more accurate than Gibbs.

5. Conclusions and Future Work

In this paper, we introduced herded Gibbs, a deterministic variant of the popular Gibbs sampling algorithm. While Gibbs relies on drawing samples from the full-conditionals at random, herded Gibbs generates the samples by matching the full-conditionals. Importantly, the herded Gibbs algorithm is very close to the Gibbs algorithm and hence retains its simplicity of implementation.

The synthetic, denoising and named entity recognition experiments provided evidence that herded Gibbs outperforms Gibbs sampling. However, as discussed, herded Gibbs requires storage of the conditional distributions for all instantiations of the neighbors in the worst case. This storage requirement indicates that it is more suitable for sparse probabilistic graphical models, such as the CRFs used in information extraction. At the other extreme, the paper advanced the theory of deterministic sampling by showing that herded Gibbs converges with rate $O(1/T)$ for models with independent variables and fully-connected models. Thus, there is gap between theory and practice that needs to be narrowed. We do not anticipate that this will be an easy task, but it is certainly a key direction for future work.

We should mention that it is also possible to design parallel versions of herded Gibbs in an asynchronous Jacobi fashion. Preliminary study shows that these are less efficient than the synchronous Gauss-Seidel version of herded Gibbs discussed in this paper. However, if many cores are available, we strongly recommend the parallel implementation as it will likely outperform the current sequential implementation.

The design of efficient herding algorithms for densely connected probabilistic graphical models remains an important area for future research. Such algorithms, in conjunction with Rao Blackwellization, would enable us to attack many statistical inference tasks, including Bayesian variable selection and Dirichlet processes.

There are also interesting connections with other algorithms to explore. First, herding has ties to multicanonical sampling algorithms (Bornn et al., 2013), which while not deterministic, employ similar biasing/reweighting schemes. Second, if for a fully connected graphical model we build a new graph where every state is a node and directed connections exist between nodes that can be reached with a single herded Gibbs update, then herded Gibbs is very similar to the Rotor-Router model of Holroyd and Propp (2010)[2]. This deterministic analogue of a random walk has provably superior concentration rates for quantities such as normalized hitting frequencies, hitting times and occupation frequencies. In line with our own convergence results, it is shown that discrepancies in these quantities decrease as $O(1/T)$ instead of the usual $O(1/\sqrt{T})$. We expect that many of the results from this literature apply to herded Gibbs as well. The connection with the work of Art Owen and colleagues, see for example Chen et al. (2011), also needs to be explored further. Their work uses *completely uniformly distributed (CUD) sequences* to drive Markov chain Monte Carlo schemes. It is not clear, following discussions with Art Owen, that CUD sequences can be constructed in a greedy way as in herding.

2. We thank Art Owen for pointing out this connection.

Appendix A. Proof of Lemma 1

Proof We first show that $w \in (\pi - 1, \pi], \forall t \geq s$. This is easy to observe by induction as $w^{(s)} \in (\pi - 1, \pi]$ and if $w^{(t)} \in (\pi - 1, \pi]$ for some $t \geq s$, then, following Equation 5, we have:

$$w^{(t+1)} = \begin{cases} w^{(t)} + \pi - 1 \in (\pi - 1, 2\pi - 1] \subseteq (\pi - 1, \pi], & \text{if } w^{(t)} > 0, \\ w^{(t)} + \pi \in (2\pi - 1, \pi] \subseteq (\pi - 1, \pi], & \text{otherwise.} \end{cases} \tag{20}$$

Summing up both sides of Equation 5 over t immediately gives us the result of Equation 6 since:

$$T\pi - \sum_{t=s+1}^{s+T} \mathbb{I}[X^{(t)} = 1] = w^{(s+T)} - w^{(s)} \in [-1, 1]. \tag{21}$$

In addition, Equation 7 follows by observing that $\mathbb{I}[X^{(t)} = 0] = 1 - \mathbb{I}[X^{(t)} = 1]$. ■

Appendix B. Proof of Theorem 3

In this appendix, we give an upper bound for the convergence rate of the sampling distribution in fully connected graphs. As herded Gibbs sampling is deterministic, the distribution of a variable's state at every iteration degenerates to a single state. As such, we study here the empirical distribution of a collection of samples.

The structure of the proof is as follows (with notation defined in the next subsection): We study the distribution distance between the invariant distribution π and the empirical distribution of T samples collected starting from sweep τ, $P_T^{(\tau)}$. We show that the distance decreases as $\tau \Rightarrow \tau + 1$ with the help of an auxiliary regular Gibbs sampling Markov chain initialized at $\pi^{(0)} = P_T^{(\tau)}$, as shown in Figure 12. On the one hand, the distance between the regular Gibbs chain after one iteration, $\pi^{(1)}$, and π decreases according to the geometric convergence property of MCMC algorithms on compact state spaces. On the other hand, we show that in one step the distance between $P_T^{(\tau+1)}$ and $\pi^{(1)}$ increases by at most $O(1/T)$. Since the $O(1/T)$ distance term dominates the exponentially small distance term, the distance between $P_T^{(\tau+1)}$ and π is bounded by $O(1/T)$. Moreover, after a short burn-in period, $L = O(\log(T))$, the empirical distribution $P_T^{(\tau+L)}$ will have an approximation error in the order of $O(1/T)$.

B.1 Notation

Assume without loss of generality that in the systematic scanning policy, the variables are sampled in the order $1, 2, \cdots, N$.

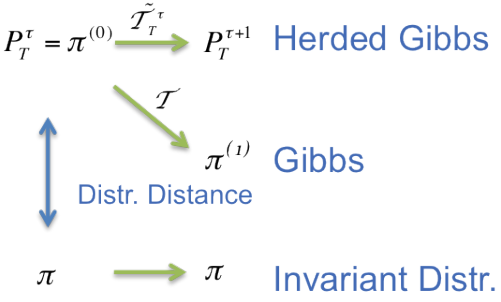

Figure 12: Transition kernels and relevant distances for the proof of Theorem 3.

B.1.1 State Distribution

- Denote by $\mathcal{X}_+$ the support of the distribution π, that is, the set of states with positive probability.
- We use τ to denote the time in terms of sweeps over all of the N variables, and t to denote the time in terms of steps where one step constitutes the updating of one variable. For example, at the end of τ sweeps, we have $t = \tau N$.
- Recall the sample/empirical distribution, $P_T^{(\tau)}$, presented in Definition 1.
- Denote the sample/empirical distribution at the i^{th} step within a sweep as $P_{T,i}^{(\tau)}, \tau \geq 0, T > 0, 0 \leq i \leq N$, as shown in Figure 13:

$$P_{T,i}^{(\tau)}(\mathbf{X} = \mathbf{x}) = \frac{1}{T} \sum_{k=\tau}^{\tau+T-1} \mathbb{I}(\mathbf{X}^{(kN+i)} = \mathbf{x}).$$

This is the distribution of T samples collected at the i^{th} step of every sweep, starting from the τ^{th} sweep. Clearly, $P_T^{(\tau)} = P_{T,0}^{(\tau)} = P_{T,N}^{(\tau-1)}$.

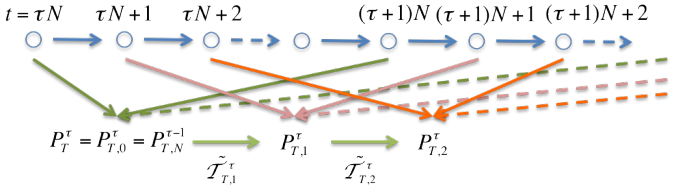

Figure 13: Distribution over time within a sweep.

- Denote the distribution of a regular Gibbs sampling Markov chain after L sweeps of updates over the N variables with $\pi^{(L)}, L \geq 0$.

  For a given time τ, we construct a Gibbs Markov chain with initial distribution $\pi^0 = P_T^{(\tau)}$ and the same scanning order of herded Gibbs, as shown in Figure 12.

B.1.2 Transition Kernel

- Denote the transition kernel of regular Gibbs for the step of updating a variable X_i with $\mathcal{T}_i$, and for a whole sweep with $\mathcal{T}$.

  By definition, $\pi^0\mathcal{T} = \pi^1$. The transition kernel for a single step can be represented as a $2^N \times 2^N$ matrix:

$$\mathcal{T}_i(\mathbf{x}, \mathbf{y}) = \begin{cases} 0, & \text{if } \mathbf{x}_{-i} \neq \mathbf{y}_{-i} \\ \pi(X_i = y_i | \mathbf{x}_{-i}), & \text{otherwise} \end{cases}, 1 \leq i \leq N, \mathbf{x}, \mathbf{y} \in \{0,1\}^N, \tag{22}$$

  where $\mathbf{x}$ is the current state vector of N variables, $\mathbf{y}$ is the state of the next step, and $\mathbf{x}_{-i}$ denotes all the components of $\mathbf{x}$ excluding the i^{th} component. If $\pi(\mathbf{x}_{-i}) = 0$, the conditional probability is undefined and we set it with an arbitrary distribution. Consequently, $\mathcal{T}$ can also be represented as:

$$\mathcal{T} = \mathcal{T}_1 \mathcal{T}_2 \cdots \mathcal{T}_N.$$

- Denote the Dobrushin ergodic coefficient (Brémaud, 1999) of the regular Gibbs kernel with $\eta \in [0,1]$. When $\eta < 1$, the regular Gibbs sampler has a geometric rate of convergence of

$$d_v(\pi^{(1)} - \pi) = d_v(\mathcal{T}\pi^{(0)} - \pi) \leq \eta d_v(\pi^{(0)} - \pi), \forall \pi^{(0)}. \tag{23}$$

  A common sufficient condition for $\eta < 1$ is that $\pi(\mathbf{X})$ is strictly positive.

- Consider the sequence of sample distributions $P_T^{(\tau)}, \tau = 0, 1, \cdots$ in Figures 1 and 13. We define the transition kernel of herded Gibbs for the step of updating variable X_i from $P_{T,i-1}^{(\tau)}$ to $P_{T,i}^{(\tau)}$ with $\tilde{\mathcal{T}}_{T,i}^{(\tau)}$, and for a whole sweep from $P_T^{(\tau)}$ to $P_T^{(\tau+1)}$ with $\tilde{\mathcal{T}}_T^{(\tau)}$. Unlike regular Gibbs, the transition kernel is not homogeneous. It depends on both the time τ and the sample size T. Nevertheless, we can still represent the single step transition kernel as a matrix:

$$\tilde{\mathcal{T}}_{T,i}^{(\tau)}(\mathbf{x}, \mathbf{y}) = \begin{cases} 0, & \text{if } \mathbf{x}_{-i} \neq \mathbf{y}_{-i} \\ P_{T,i}^{(\tau)}(X_i = y_i | \mathbf{x}_{-i}), & \text{if } \mathbf{x}_{-i} = \mathbf{y}_{-i} \end{cases}, 1 \leq i \leq N, \mathbf{x}, \mathbf{y} \in \{0,1\}^N, \tag{24}$$

  where $P_{T,i}^{(\tau)}(X_i = y_i | \mathbf{x}_{-i})$ is defined as:

$$P_{T,i}^{(\tau)}(X_i = y_i | \mathbf{x}_{-i}) = \frac{N_{\text{num}}}{N_{\text{den}}},$$

$$N_{\text{num}} = T P_{T,i}^{(\tau)}(\mathbf{X}_{-i} = \mathbf{x}_{-i}, X_i = y_i) = \sum_{k=\tau}^{\tau+T-1} \mathbb{I}(\mathbf{X}_{-i}^{(kN+i)} = \mathbf{x}_{-i}, X_i^{(kN+i)} = y_i),$$

$$N_{\text{den}} = T P_{T,i-1}^{(\tau)}(\mathbf{X}_{-i} = \mathbf{x}_{-i}) = \sum_{k=\tau}^{\tau+T-1} \mathbb{I}(\mathbf{X}_{-i}^{(kN+i-1)} = \mathbf{x}_{-i}), \tag{25}$$

where N_{num} is the number of occurrences of a joint state, and N_{den} is the number of occurrences of a conditioning state in the previous step. When $\pi(\mathbf{x}_{-i}) = 0$, we know that $N_{\text{den}} = 0$ with a proper initialization of herded Gibbs, and we simply set $\tilde{\mathcal{T}}_{T,i}^{(\tau)} = \mathcal{T}_i$ for these entries. It is not hard to verify the following identity by expanding every term with its definition

$$P_{T,i}^{(\tau)} = P_{T,i-1}^{(\tau)} \tilde{\mathcal{T}}_{T,i}^{(\tau)},$$

and consequently,

$$P_T^{(\tau+1)} = P_T^{(\tau)} \tilde{\mathcal{T}}_T^{(\tau)},$$

with

$$\tilde{\mathcal{T}}_T^{(\tau)} = \tilde{\mathcal{T}}_{T,1}^{(\tau)} \tilde{\mathcal{T}}_{T,2}^{(\tau)} \cdots \tilde{\mathcal{T}}_{T,N}^{(\tau)}.$$

B.2 Linear Visiting Rate

We prove in this section that every joint state in the support of the target distribution is visited, at least, at a linear rate. This result will be used to measure the distance between the Gibbs and herded Gibbs transition kernels.

Proposition 5 *If a graph is fully connected, herded Gibbs sampling scans variables in a fixed order, and the corresponding Gibbs sampling Markov chain is irreducible, then for any state $\mathbf{x} \in \mathcal{X}_+$ and any index $i \in [1, N]$, the state is visited at least at a linear rate. Specifically,*

$$\exists l > 0, B > 0, s.t., \forall i \in [1, N], \mathbf{x} \in \mathcal{X}_+, T \in \mathbb{N}, s \in \mathbb{N},$$
$$\sum_{k=s}^{s+T-1} \mathbb{I}\left[\mathbf{X}^{(t=Nk+i)} = \mathbf{x}\right] \geq lT - B. \tag{26}$$

Denote the minimum nonzero conditional probability as

$$\pi_{\min} = \min_{1 \leq i \leq N, \pi(x_i | \mathbf{x}_{-i}) > 0} \pi(x_i | \mathbf{x}_{-i}).$$

The following lemma, which is needed to prove Proposition 5, gives an inequality between the number of visits of two sets of states in consecutive steps. Please refer to Figure 14 for an illustration of the two sets of states and the mapping defined in the lemma.

Lemma 6 *Given any integer $i \in [1, N]$, a set of states $\mathbb{X} \subseteq \mathcal{X}_+$, and a mapping $F : \mathbb{X} \to \mathcal{X}_+$ that corresponds to any possible state transition for a Gibbs step at variable X_i, that is, F is any mapping satisfying*

$$\mathbf{F}(\mathbf{x})_{-i} = \mathbf{x}_{-i} \text{ and } \pi(\mathbf{F}(\mathbf{x})_i | \mathbf{x}) > 0, \forall \mathbf{x} \in \mathbb{X}, \tag{27}$$

let $\mathbb{Y} = \cup_{\mathbf{x} \in \mathbb{X}} F(\mathbf{x})$. We have that, if the graph is fully connected, for any $s \geq 0$ and $T > 0$, the number of times any state in $\mathbb{Y}$ is visited in the set of all i'th step in sweeps $s, s+1, \ldots, s+T-1$, denoted as $C_i = \{t = kN + i : s \leq k \leq s+T-1\}$, is lower

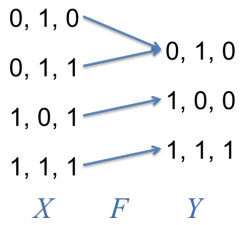

Figure 14: Example of the mapping defined in Lemma 6 with $i = 3$.

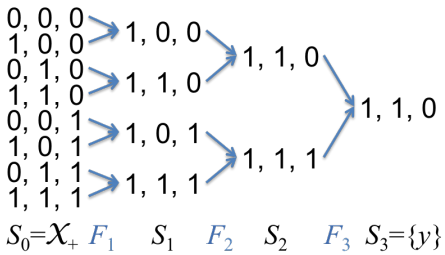

Figure 15: Example of the set of all paths from $\mathbf{x} \in \mathbb{X}_+$ to $\mathbf{y} = (1, 1, 0)$. Variables are updated in the order of $i = 1, 2, 3$. In this example, all the conditional distributions are positive and $\mathbf{y}$ can be reached from any state in $N = 3$ steps. Therefore, $t^* = 3$.

bounded by a function of the number of times any state in $\mathbb{X}$ is visited in the previous steps $C_{i-1} = \{t = kN + i - 1 : s \le k \le s + T - 1\}$ as:

$$\sum_{t \in C_i} \mathbb{I}\left[\mathbf{X}^{(t)} \in \mathbb{Y}\right] \ge \pi_{min} \sum_{t \in C_{i-1}} \mathbb{I}\left[\mathbf{X}^{(t)} \in \mathbb{X}\right] - |\mathbb{Y}|. \tag{28}$$

Proof As a complement to Condition 27, we can define F^{-1} as the inverse mapping from $\mathbb{Y}$ to subsets of $\mathbb{X}$ so that for any $\mathbf{y} \in \mathbb{Y}$, $\mathbf{x} \in F^{-1}(\mathbf{y})$, we have $\mathbf{x}_{-i} = \mathbf{y}_{-i}$, and $\cup_{\mathbf{y} \in \mathbb{Y}} F^{-1}(\mathbf{y}) = \mathbb{X}$. It's easy to observe that

$$\mathbb{I}\left[\mathbf{X}_{-i}^{(t)} = \mathbf{y}_{-i}\right] \ge \mathbb{I}\left[\mathbf{X}^{(t)} \in F^{-1}(\mathbf{y})\right], \forall t, \mathbf{y} \in \mathbb{Y}. \tag{29}$$

At every step of the herded Gibbs algorithm, only one weight is updated. Consider the sequence of steps when a weight $w_{i,\mathbf{x}_{N(i)}}$ is updated, we denote the segment of that sequence in sweeps $[s, s+T-1]$ as $C_i(\mathbf{x}_{N(i)})$. By definition of the herded Gibbs algorithm, $C_i(\mathbf{x}_{N(i)}) = \{t : t \in C_i, \mathbf{X}_{N(i)}^{(t-1)} = \mathbf{x}_{N(i)}\} = \{t : t \in C_i, \mathbf{X}_{N(i)}^{(t)} = \mathbf{x}_{N(i)}\} \subseteq C_i$.

Because the graph is fully connected, $N(i) = -i$, the full conditional state $\mathbf{X}_{-i}^{(t)}$ with $t \in C_i(\mathbf{x}_{N(i)})$ is uniquely determined. Since the value $X_i^{(t)}$ is determined by $w_{i,\mathbf{x}_{-i}}$ for any $t \in C_i(\mathbf{x}_{-i})$, we can apply Lemma 1 and get that for any $\mathbf{y} \in \mathbb{Y}$,

$$\sum_{t \in C_i} \mathbb{I}\left[\mathbf{X}^{(t)} = \mathbf{y}\right] = \sum_{t \in C_i(\mathbf{y}_{-i})} \mathbb{I}\left[X_i^{(t)} = y_i\right] \ge \pi(y_i|\mathbf{y}_{-i})|C_i(\mathbf{y}_{-i})| - 1 \ge \pi_{\min}|C_i(\mathbf{y}_{-i})| - 1. \tag{30}$$

Since the variables $\mathbf{X}_{-i}$ are not changed at steps in C_i, combining with Equation 29 we can show

$$|C_i(\mathbf{y}_{-i})| = \sum_{t \in C_i} \mathbb{I}\left[\mathbf{X}_{-i}^{(t)} = \mathbf{y}_{-i}\right] = \sum_{t \in C_{i-1}} \mathbb{I}\left[\mathbf{X}_{-i}^{(t)} = \mathbf{y}_{-i}\right] \ge \sum_{t \in C_{i-1}} \mathbb{I}\left[\mathbf{X}^{(t)} \in F^{-1}(\mathbf{y})\right]. \tag{31}$$

Combining the fact that $\cup_{\mathbf{y} \in \mathbb{Y}} F^{-1}(\mathbf{y}) = \mathbb{X}$ and summing up both sides of Equation 30 over $\mathbb{Y}$ proves the lemma:

$$\sum_{t \in C_i} \mathbb{I}\left[\mathbf{X}^{(t)} \in \mathbb{Y}\right] \ge \sum_{\mathbf{y} \in \mathbb{Y}} \left(\pi_{\min} \sum_{t \in C_{i-1}} \mathbb{I}\left[\mathbf{X}^{(t)} \in F^{-1}(\mathbf{y})\right] - 1\right) \ge \pi_{\min} \sum_{t \in C_{i-1}} \mathbb{I}\left[\mathbf{X}^{(t)} \in \mathbb{X}\right] - |\mathbb{Y}|. \tag{32}$$

■

Remark 7 *A fully connected graph is a necessary condition for the application of Lemma 1 in Equation 30. If a graph is not fully connected ($N(i) \neq -i$), a weight $w_{i,\mathbf{x}_{N(i)}}$ is associated with a partial conditional state and may be shared by multiple full conditional states. In that case $C_i(\mathbf{x}_{N(i)}) = \{t : t \in C_i, \mathbf{X}_{N(i)}^{(t)} = \mathbf{x}_{N(i)}\}$, and we can no longer use Lemma 1 to get a lower bound for the number of visits to a particular **joint** state, not to mention a linear visiting rate in Proposition 5.*

Now let us prove Proposition 5 by iteratively applying Lemma 6.

Proof [Proof of Proposition 5] Because the corresponding Gibbs sampler is irreducible and any Gibbs sampler is aperiodic, there exists a constant $t^* > 0$ such that for any state $\mathbf{y} \in \mathcal{X}_+$, and any step i in a sweep, we can find a path of length t^* from any state $\mathbf{x} \in \mathcal{X}_+$ with a positive transition probability, $Path(\mathbf{x}) = (\mathbf{x} = \mathbf{x}(0), \mathbf{x}(1), \ldots, \mathbf{x}(t^*) = \mathbf{y})$, where each step of the path follows the Gibbs updating scheme. For a strictly positive distribution, the minimum value of t^* is N. We show an example of the paths in a graph with 3 variables and a strictly positive distribution in Figure 15.

Denote $\tau^* = \lceil t^*/N \rceil$ and the j^{th} element of the path $Path(\mathbf{x})$ as $Path(\mathbf{x}, j)$. We can define $t^* + 1$ subsets $S_j \subseteq \mathcal{X}_+, 0 \le j \le t^*$ as the union of all the j^{th} states in the path from any state in $\mathcal{X}_+$:

$$S_j = \cup_{\mathbf{x} \in \mathcal{X}_+} Path(\mathbf{x}, j).$$

By definition of these paths, we know $S_0 = \mathcal{X}_+$ and $S_{t^*} = \{\mathbf{y}\}$, and there exits an integer $i(j)$ and a mapping $F_j : S_{j-1} \to S_j, \forall j$ that satisfy the condition in Lemma 6 ($i(j)$ is the index of the variable to be updated, and the mapping is defined by the transition paths). Also notice that any state in S_j can be different from $\mathbf{y}$ by at most $\min\{N, t^* - j\}$ variables, and therefore $|S_j| \le 2^{\min\{N, t^*-j\}}$.

Let us apply Lemma 6 recursively from $j = t^*$ to 1 as

$$\begin{aligned}
&\sum_{k=s}^{s+T-1} \mathbb{I}\left[\mathbf{X}^{(Nk+i)} = \mathbf{y}\right] \geq \sum_{k=s+\tau^*}^{s+T-1} \mathbb{I}\left[\mathbf{X}^{(Nk+i)} = \mathbf{y}\right] \\
&= \sum_{k=s+\tau^*}^{s+T-1} \mathbb{I}\left[\mathbf{X}^{(Nk+i)} \in S_{t^*}\right] && \text{(b.c. } S_{t^*} = \{\mathbf{y}\}) \\
&\geq \pi_{\min} \sum_{k=s+\tau^*}^{s+T-1} \mathbb{I}\left[\mathbf{X}^{(Nk+i-1)} \in S_{t^*-1}\right] - |S_{t^*}| && \text{(Lemma 6, } \mathbb{X} = S_{t^*-1}, \mathbb{Y} = S_{t^*}) \\
&\geq \pi_{\min}^2 \sum_{k=s+\tau^*}^{s+T-1} \mathbb{I}\left[\mathbf{X}^{(Nk+i-2)} \in S_{t^*-2}\right] - \pi_{\min}|S_{t^*-1}| - |S_{t^*}| && \text{(Lemma 6, } \mathbb{X} = S_{t^*-2}, \mathbb{Y} = S_{t^*-1}) \\
&\geq \cdots \\
&\geq \pi_{\min}^{t^*} \sum_{k=s+\tau^*}^{s+T-1} \mathbb{I}\left[\mathbf{X}^{(Nk+i-t^*)} \in S_0 = \mathcal{X}_+\right] - \sum_{j=0}^{t^*-1} \pi_{\min}^j |S_{t^*-j}| && \text{(Lemma 6, } \mathbb{X} = S_0, \mathbb{Y} = S_1) \\
&\geq \pi_{\min}^{t^*}(T - \tau^*) - \sum_{j=0}^{t^*-1} \pi_{\min}^j 2^{\min\{N,j\}}. && \text{(b.c. } \mathbb{I}\left[\mathbf{X}^{(t)} \in \mathcal{X}_+\right] = 1)
\end{aligned} \tag{33}$$

The proof is concluded by choosing the constants

$$l = \pi_{\min}^{t^*}, \quad B = \tau^* \pi_{\min}^{t^*} + \sum_{j=0}^{t^*-1} \pi_{\min}^j 2^{\min\{N,j\}}. \tag{34}$$

■

Remark 8 *For a strictly positive distribution, the constants reduce to*

$$l = \pi_{min}^N, \quad B = \pi_{min}^N + \sum_{j=0}^{N-1} (2\pi_{min})^j = \pi_{min}^N + \frac{1 - (2\pi_{min})^N}{1 - 2\pi_{min}}.$$

B.3 Herded Gibbs's Transition Kernel $\tilde{\mathcal{T}}_T^{(\tau)}$ is an Approximation to $\mathcal{T}$

The following proposition shows that $\tilde{\mathcal{T}}_T^{(\tau)}$ is an approximation to the regular Gibbs sampler's transition kernel $\mathcal{T}$ with an error of $O(1/T)$.

Proposition 9 *For a fully connected graph, if the herded Gibbs has a fixed scanning order and the corresponding Gibbs sampling Markov chain is irreducible, then for any $\tau \geq 0$, $T \geq T^* := \frac{2B}{l}$ where l and B are the constants in Proposition 5, the following inequality holds:*

$$\|\tilde{\mathcal{T}}_T^{(\tau)} - \mathcal{T}\|_\infty \leq \frac{4N}{lT}. \tag{35}$$

Proof

When $\mathbf{x} \notin \mathcal{X}_+$, we have the equality $\tilde{\mathcal{T}}_{T,i}^{(\tau)}(\mathbf{x}, \mathbf{y}) = \mathcal{T}_i(\mathbf{x}, \mathbf{y})$ by definition. When $\mathbf{x} \in \mathcal{X}_+$ but $\mathbf{y} \notin \mathcal{X}_+$, then $N_{\text{den}} = 0$ (see the notation of $\tilde{\mathcal{T}}_T^{(\tau)}$ for definition of N_{den}) as $\mathbf{y}$ will never be visited and thus $\tilde{\mathcal{T}}_{T,i}^{(\tau)}(\mathbf{x}, \mathbf{y}) = 0 = \mathcal{T}_i(\mathbf{x}, \mathbf{y})$ also holds. Let us consider the entries in $\tilde{\mathcal{T}}_{T,i}^{(\tau)}(\mathbf{x}, \mathbf{y})$ with $\mathbf{x}, \mathbf{y} \in \mathcal{X}_+$ in the following.

Because $\mathbf{X}_{-i}$ is not updated at i^{th} step of every sweep, we can replace $i - 1$ in the definition of N_{den} by i and get

$$N_{\text{den}} = \sum_{k=\tau}^{\tau+T-1} \mathbb{I}(\mathbf{X}_{-i}^{(kN+i)} = \mathbf{x}_{-i}).$$

Notice that the set of times $\{t = kN + i : \tau \leq k \leq \tau + T - 1, \mathbf{X}_{-i}^t = \mathbf{x}_{-i})\}$, whose size is N_{den}, is a consecutive set of times when $w_{i,\mathbf{x}_{-i}}$ is updated. By Lemma 1, we obtain a bound for the numerator

$$\begin{aligned}
&N_{\text{num}} \in [N_{\text{den}}\pi(X_i = y_i|\mathbf{x}_{-i}) - 1, N_{\text{den}}\pi(X_i = y_i|\mathbf{x}_{-i}) + 1] \Leftrightarrow \\
&|P_{T,i}^{(\tau)}(X_i = y_i|\mathbf{x}_{-i}) - \pi(X_i = y_i|\mathbf{x}_{-i})| = |\frac{N_{\text{num}}}{N_{\text{den}}} - \pi(X_i = y_i|\mathbf{x}_{-i})| \leq \frac{1}{N_{\text{den}}}.
\end{aligned} \tag{36}$$

Also by Proposition 5, we know every state in $\mathcal{X}_+$ is visited at a linear rate, there hence exist constants $l > 0$ and $B > 0$, such that the number of occurrence of any conditioning state $\mathbf{x}_{-i}$, N_{den}, is bounded by

$$N_{\text{den}} \geq \sum_{k=\tau}^{\tau+T-1} \mathbb{I}(\mathbf{X}^{(kN+i)} = \mathbf{x}) \geq lT - B \geq \frac{l}{2}T, \quad \forall T \geq \frac{2B}{l}. \tag{37}$$

Combining equations (36) and (37), we obtain

$$|P_{T,i}^{(\tau)}(X_i = y_i|\mathbf{x}_{-i}) - \pi(X_i = y_i|\mathbf{x}_{-i})| \leq \frac{2}{lT}, \quad \forall T \geq \frac{2B}{l}. \tag{38}$$

Since the matrix $\tilde{\mathcal{T}}_{T,i}^{(\tau)}$ and $\mathcal{T}_i$ differ only at those elements where $\mathbf{x}_{-i} = \mathbf{y}_{-i}$, we can bound the L_1 induced norm of the transposed matrix of their difference by

$$\begin{aligned}
\|(\tilde{\mathcal{T}}_{T,i}^{(\tau)} - \mathcal{T}_i)^T\|_1 &= \max_{\mathbf{x}} \sum_{\mathbf{y}} |\tilde{\mathcal{T}}_{T,i}^{(\tau)}(\mathbf{x}, \mathbf{y}) - \mathcal{T}_i(\mathbf{x}, \mathbf{y})| \\
&= \max_{\mathbf{x}} \sum_{y_i} |P_{T,i}^{(\tau)}(X_i = y_i|\mathbf{x}_{-i}) - \pi(X_i = y_i|\mathbf{x}_{-i})| \\
&\leq \frac{4}{lT}, \quad \forall T \geq \frac{2B}{l}.
\end{aligned} \tag{39}$$

Observing that both $\tilde{\mathcal{T}}_T^{(\tau)}$ and $\mathcal{T}$ are multiplications of N component transition matrices, and the transition matrices, $\tilde{\mathcal{T}}_T^{(\tau)}$ and $\mathcal{T}_i$, have a unit L_1 induced norm as:

$$\|(\tilde{\mathcal{T}}_{T,i}^{(\tau)})^T\|_1 = \max_{\mathbf{x}} \sum_{\mathbf{y}} |\tilde{\mathcal{T}}_{T,i}^{(\tau)}(\mathbf{x}, \mathbf{y})| = \max_{\mathbf{x}} \sum_{\mathbf{y}} P_{T,i}^{(\tau)}(X_i = y_i|\mathbf{x}_{-i}) = 1, \tag{40}$$

$$\|(\mathcal{T}_i)^T\|_1 = \max_{\mathbf{x}} \sum_{\mathbf{y}} |\mathcal{T}_i(\mathbf{x}, \mathbf{y})| = \max_{\mathbf{x}} \sum_{\mathbf{y}} P(X_i = y_i|\mathbf{x}_{-i}) = 1, \tag{41}$$

we can further bound the L_1 norm of the difference, $(\tilde{\mathcal{T}}_T^{(\tau)} - \mathcal{T})^T$. Let $P \in \mathbb{R}^N$ be any vector with nonzero norm. Using the triangular inequality, the difference of the resulting vectors after applying $\tilde{\mathcal{T}}_T^{(\tau)}$ and $\mathcal{T}$ is bounded by

$$\begin{aligned}\|P(\tilde{\mathcal{T}}_T^{(\tau)} - \mathcal{T})\|_1 =& \|P\tilde{\mathcal{T}}_{T,1}^{(\tau)} \dots \tilde{\mathcal{T}}_{T,N}^{(\tau)} - P\mathcal{T} \dots \mathcal{T}_N\|_1 \\ \leq& \|P(\tilde{\mathcal{T}}_{T,1}^{(\tau)} - \mathcal{T}_1)\tilde{\mathcal{T}}_{T,2}^{(\tau)} \dots \tilde{\mathcal{T}}_{T,N}^{(\tau)}\|_1 + \\ & \|P\mathcal{T}_1(\tilde{\mathcal{T}}_{T,2}^{(\tau)} - \mathcal{T}_2)\tilde{\mathcal{T}}_{T,3}^{(\tau)} \dots \tilde{\mathcal{T}}_{T,N}^{(\tau)}\|_1 + \\ & \dots \\ & \|P\mathcal{T}_1 \dots \mathcal{T}_{N-1}(\tilde{\mathcal{T}}_{T,N}^{(\tau)} - \mathcal{T}_N)\|_1, \end{aligned} \tag{42}$$

where the i'th term is

$$\begin{aligned}\|P\mathcal{T}_1 \dots \mathcal{T}_{i-1}(\tilde{\mathcal{T}}_{T,i}^{(\tau)} - \mathcal{T}_i)\tilde{\mathcal{T}}_{T,i+1}^{(\tau)} \dots \tilde{\mathcal{T}}_{T,N}^{(\tau)}\|_1 &\leq \|P\mathcal{T}_1 \dots \mathcal{T}_{i-1}(\tilde{\mathcal{T}}_{T,i}^{(\tau)} - \mathcal{T}_i)\|_1 && \text{(Unit } L_1 \text{ norm, Eqn. 40)} \\ &\leq \|P\mathcal{T}_1 \dots \mathcal{T}_{i-1}\|_1 \frac{4}{lT} && \text{(Eqn. 39)} \\ &\leq \|P\|_1 \frac{4}{lT}. && \text{(Unit } L_1 \text{ norm, Eqn. 41)} \end{aligned} \tag{43}$$

Consequently, we get the L_1 induced norm of $(\tilde{\mathcal{T}}_T^{(\tau)} - \mathcal{T})^T$ as

$$\|(\tilde{\mathcal{T}}_T^{(\tau)} - \mathcal{T})^T\| = \max_P \frac{\|P(\tilde{\mathcal{T}}_T^{(\tau)} - \mathcal{T})\|_1}{\|P\|_1} \leq \frac{4N}{lT}, \quad \forall T \geq \frac{2B}{l}. \tag{44}$$

■

B.4 Proof of Theorem 3

When we initialize the herded Gibbs and regular Gibbs with the same distribution (see Figure 12), since the transition kernel of herded Gibbs is an approximation to regular Gibbs and the distribution of regular Gibbs converges to the invariant distribution, we expect that herded Gibbs also approaches the invariant distribution.

Proof [Proof of Theorem 3] Construct an auxiliary regular Gibbs sampling Markov chain initialized with $\pi^{(0)}(\mathbf{X}) = P_T^{(\tau)}(\mathbf{X})$ and the same scanning order as herded Gibbs. As $\eta < 1$, the Gibbs Markov chain has uniform geometric convergence rate as shown in Equation (23).

Also, the Gibbs Markov chain must be irreducible due to $\eta < 1$ and therefore Proposition 9 applies here. We can bound the distance between the distributions of herded Gibbs after one sweep of all variables, $P_T^{(\tau+1)}$, and the distribution after one sweep of regular Gibbs sampling, $\pi^{(1)}$ by

$$\begin{aligned} & d_v(P_T^{(\tau+1)} - \pi^{(1)}) = d_v(\pi^{(0)}(\tilde{\mathcal{T}}_T^{(\tau)} - \mathcal{T})) = \frac{1}{2}\|\pi^{(0)}(\tilde{\mathcal{T}}_T^{(\tau)} - \mathcal{T})\|_1 \\ & \leq \frac{2N}{lT}\|\pi^{(0)}\|_1 = \frac{2N}{lT}, \quad \forall T \geq T^*, \tau \geq 0. \end{aligned} \tag{45}$$

Now we study the change of discrepancy between $P_T^{(\tau)}$ and π as a function as τ. Applying the triangle inequality of d_v:

$$\begin{aligned} & d_v(P_T^{(\tau+1)} - \pi) = d_v(P_T^{(\tau+1)} - \pi^{(1)} + \pi^{(1)} - \pi) \leq d_v(P_T^{(\tau+1)} - \pi^{(1)}) + d_v(\pi^{(1)} - \pi) \\ & \leq \frac{2N}{lT} + \eta d_v(P_T^{(\tau)} - \pi), \quad \forall T \geq T^*, \tau \geq 0. \end{aligned} \tag{46}$$

The last inequality follows Equations (23) and (45). When the sample distribution is outside a neighborhood of π, $\mathcal{B}_{\epsilon_1}(\pi)$, with $\epsilon_1 = \frac{4N}{(1-\eta)lT}$, i.e.

$$d_v(P_T^{(\tau)} - \pi) \geq \frac{4N}{(1-\eta)lT}, \tag{47}$$

we get a geometric convergence rate toward the invariant distribution by combining the two equations above:

$$d_v(P_T^{(\tau+1)} - \pi) \leq \frac{1-\eta}{2} d_v(P_T^{(\tau)} - \pi) + \eta d_v(P_T^{(\tau)} - \pi) = \frac{1+\eta}{2} d_v(P_T^{(\tau)} - \pi). \tag{48}$$

So starting from $\tau = 0$, we have a burn-in period for herded Gibbs to enter $\mathcal{B}_{\epsilon_1}(\pi)$ in a finite number of rounds. Denote the first time it enters the neighborhood by τ'. According to the geometric convergence rate in Equations 48 and $d_v(P_T^{(0)} - \pi) \leq 1$

$$\tau' \leq \left\lceil \log_{\frac{1+\eta}{2}}\left(\frac{\epsilon_1}{d_v(P_T^{(0)} - \pi)}\right) \right\rceil \leq \left\lceil \log_{\frac{1+\eta}{2}}(\epsilon_1) \right\rceil = \lceil \tau^*(T) \rceil. \tag{49}$$

After that burn-in period, the herded Gibbs sampler will stay within a smaller neighborhood, $\mathcal{B}_{\epsilon_2}(\pi)$, with $\epsilon_2 = \frac{1+\eta}{1-\eta}\frac{2N}{lT}$, i.e.

$$d_v(P_T^{(\tau)} - \pi) \leq \frac{1+\eta}{1-\eta}\frac{2N}{lT}, \quad \forall \tau > \tau'. \tag{50}$$

This is proved by induction:

1. Equation (50) holds at $\tau = \tau' + 1$. This is because $P_T^{(\tau')} \in \mathcal{B}_{\epsilon_1}(\pi)$ and following Eqn. 46 we get
$$d_v(P_T^{(\tau'+1)} - \pi) \leq \frac{2N}{lT} + \eta\epsilon_1 = \epsilon_2. \tag{51}$$
2. For any $\tau \geq \tau' + 2$, assume $P_T^{(\tau-1)} \in \mathcal{B}_{\epsilon_2}(\pi)$. Since $\epsilon_2 < \epsilon_1$, $P_T^{(\tau-1)}$ is also in the ball $\mathcal{B}_{\epsilon_1}(\pi)$. We can apply the same computation as when $\tau = \tau' + 1$ to prove $d_v(P_T^{(\tau)} - \pi) \leq \epsilon_2$. So inequality (50) is always satisfied by induction.

Consequently, Theorem 3 is proved when combining (50) with the inequality $\tau' \leq \lceil \tau^*(T) \rceil$ in Equation(49). ■

Remark 10 *Similarly to the regular Gibbs sampler, the herded Gibbs sampler also has a burn-in period with geometric convergence rate. After that, the distribution discrepancy is in the order of* $O(1/T)$*, which is faster than the regular Gibbs sampler. Notice that the length of the burn-in period depends on* T*, specifically as a function of* $\log(T)$*.*

Remark 11 *Irrationality is not required to prove the convergence on a fully-connected graph.*

B.5 Proof of Corollary 4

Proof Since $\tau^*(T)$ is a monotonically increasing function of T, for any $T \geq T^* + \tau^*(T^*)$, we can find a number t so that

$$T = t + \tau^*(t), t \geq T^*.$$

Partition the sample sequence $S_{0,T} = \{\mathbf{X}^{(kN)} : 0 \leq k < T\}$ into two parts: the burn-in period $S_{0,\tau^*(t)}$ and the stable period $S_{\tau^*(t),T}$. The discrepancy in the burn-in period is bounded by 1 and according to Theorem 3, the discrepancy in the stable period is bounded by

$$d_v(\tilde{P}(S_{t,T}) - \pi) \leq \frac{\lambda}{t}.$$

Hence, the discrepancy of the whole set $S_{0,T}$ is bounded by

$$\begin{aligned}
&d_v(\tilde{P}(S_{0,T}) - \pi) = d_v\left(\frac{\tau^*(t)}{T}\tilde{P}(S_{0,\tau^*(t)}) + \frac{t}{T}\tilde{P}(S_{\tau^*(t),T}) - \pi\right) \\
&\leq d_v\left(\frac{\tau^*(t)}{T}(\tilde{P}(S_{0,\tau^*(t)}) - \pi\right) + d_v\left(\frac{t}{T}(\tilde{P}(S_{\tau^*(t),T}) - \pi\right) \\
&\leq \frac{\tau^*(t)}{T}d_v(\tilde{P}(S_{0,\tau^*(t)}) - \pi) + \frac{t}{T}d_v(\tilde{P}(S_{\tau^*(t),T}) - \pi) \\
&\leq \frac{\tau^*(t)}{T} \cdot 1 + \frac{t}{T}\frac{\lambda}{t} \leq \frac{\tau^*(T) + \lambda}{T}. \qquad (52)
\end{aligned}$$

Abstract

This paper performs a complexity analysis of a class of serial and parallel compositional models of multiple objects and shows that they enable efficient representation and rapid inference. Compositional models are generative and represent objects in a hierarchically distributed manner in terms of parts and subparts, which are constructed recursively by part-subpart compositions. Parts are represented more coarsely at higher level of the hierarchy, so that the upper levels give coarse summary descriptions (e.g., there is a horse in the image) while the lower levels represents the details (e.g., the positions of the legs of the horse). This hierarchically distributed representation obeys the *executive summary* principle, meaning that a high level executive only requires a coarse summary description and can, if necessary, get more details by consulting lower level executives. The parts and subparts are organized in terms of hierarchical dictionaries which enables *part sharing* between different objects allowing efficient representation of many objects. The first main contribution of this paper is to show that compositional models can be mapped onto a parallel visual architecture similar to that used by bio-inspired visual models such as deep convolutional networks but more explicit in terms of representation, hence enabling part detection as well as object detection, and suitable for complexity analysis. Inference algorithms can be run on this architecture to exploit the gains caused by part sharing and executive summary. Effectively, this compositional architecture enables us to perform exact inference simultaneously over a large class of generative models of objects. The second contribution is an analysis of the complexity of compositional models in terms of computation time (for serial computers) and numbers of nodes (e.g., "neurons") for parallel computers. In particular, we compute the complexity gains by part sharing and executive summary and their dependence on how the dictionary scales with the level of the hierarchy. We explore three regimes of scaling behavior where the dictionary size (i) increases exponentially with the level of the hierarchy, (ii) is determined by an unsupervised compositional learning algorithm applied to real data, (iii) decreases exponentially with scale. This analysis shows that in some regimes the use of shared parts enables algorithms which can perform inference in time linear in the number of levels for an exponential number of objects. In other regimes part sharing has little advantage for serial computers but can enable linear processing on parallel computers.

Keywords: compositional models, object detection, hierarchical architectures, part sharing

1. Introduction

A fundamental problem of vision is how to deal with the enormous complexity of images and visual scenes. The total number of possible images is astronomically large Kersten (1987). The number of objects is also huge and has been estimated at around 30,000 Biederman (1987). We observe also that humans do not simply detect objects but also *parse* them into their parts and subparts, which adds another level of complexity. How can a biological, or artificial, vision system deal with this complexity? For example, considering the enormous input space of images and output space of objects, how can humans interpret images in less than 150 msec Thorpe et al. (1996)?

There are three main issues involved. Firstly, how can a visual system be designed so that it can efficiently *represent* large numbers of objects, including their parts and subparts? Secondly, how can a visual system rapidly *infer* which object, or objects, are present in an input image and perform related tasks such as estimating the positions of their parts and subparts? And, thirdly, how can this representation be *learnt* in an unsupervised, or weakly supervised fashion? In summary, what visual *architectures* enable us to overcome these three issues?

Studies of mammalian visual systems offer some suggestions for how these complexity issues can be addressed. These visual systems are organized hierarchically with the lower levels (e.g., in areas V1 and V2) tuned to small image features while the higher levels (i.e. in area IT) are tuned to objects. This leads to a class of bio-inspired visual architectures, of varying degrees of biological plausibility, which represent the visual world in terms of hierarchies of features which are shared between multiple objects Fukushima (1988); Riesenhuber and Poggio (1999); Hinton et al. (2006); Serre et al. (2007); Adams and Williams (2003); Poon and Domingos (2010); Zeiler et al. (2010); LeCun and Bengio (1995); Borenstein and Ullman (2002); Kokkinos and Yuille (2011); Krizhevsky et al. (2012). This sharing of hierarchical features suggest ways to deal with the complexity issues but, to the best of our knowledge, there have been no complexity studies of these classes of architectures. We note that the purpose of this paper is not to attempt to model the known structure of mammalian visual systems. Instead, own goal of this work is to see whether it is possible to derive properties of mammalian visual systems from first principles by developing a visual architecture that addresses the complexity problems of vision.

In this paper, we address the complexity issues from the perspective of compositional models Geman et al. (2002) by extending and analyzing a specific class of models Zhu et al. (2008, 2010). Compositional models are cousins of the bio-inspired hierarchical models and we briefly discuss their similarities and differences in section (6). The key idea of compositionality is to represent objects by recursive composition from parts and subparts which enables: (i) part sharing between different objects, and (ii) hierarchically distributed representations of objects where the positions of parts are represented more coarsely than the position of subparts, which we call the executive-summary principle. This gives rise to natural learning and inference algorithms which proceed from sub-parts to parts to objects (e.g., inference is efficient because a leg detector can be used for detecting the legs of cows,

horses, and yaks). The explicitness of the object representations helps quantify the efficiency of part-sharing, and executive summary, and make mathematical analysis possible. They also enable us to parse the objects into their parts and subparts, instead of only detecting objects. The compositional models we study are based on prior work Zhu et al. (2008, 2010) but we make several technical modifications. These include re-formulating the models so that the positions of the parts are restricted to lie on a set of discrete lattices (coarser lattices for high-level parts). This enables a parallel implementation of compositional models which helps clarify the similarities, and differences, to bio-inspired models. For completeness, we briefly summarize how compositional models can be learnt in an unsupervised manner Zhu et al. (2008, 2010) and discuss how this relates to the memorization algorithms of Valiant (2000). But we emphasize that this paper does not directly address learning but instead explores the consequence of the representations which were learnt. We note that previous work has addressed the complexity of visual search and attention Blanchard and Geman (2005), Tsotsos (2011).

Our analysis assumes that objects are represented by hierarchical graphical probability models which are composed from more elementary models by *part-subpart compositions*. An object – a graphical model with $\mathcal{H}$ levels – is defined as a composition of r parts which are graphical models with $\mathcal{H}-1$ levels. These parts are defined recursively in terms of subparts which are represented by graphical models of increasingly lower levels. It is convenient to specify these compositional models in terms of a set of dictionaries $\{\mathcal{M}_h : h = 0, ..., \mathcal{H}\}$ where the level-h parts in dictionary $\mathcal{M}_h$ are composed in terms of r level-$(h-1)$ parts in dictionary $\mathcal{M}_{h-1}$. The highest level dictionaries $\mathcal{M}_{\mathcal{H}}$ represent the set of all objects. The lowest level dictionaries $\mathcal{M}_0$ represent the elementary features that can be measured from the input image. Part-subpart composition enables us to construct a very large number of objects by different compositions of elements from the lowest-level dictionary (like building an object from a lego kit). It enables us to perform *part-sharing* during learning and inference, which can lead to enormous reductions in complexity, as our mathematical analysis will show. We stress that the parts and subparts are deformable (i.e. non-rigid).

There are three factors which enable computational efficiency. The first is *part-sharing*, as described above, which means that we only need to perform inference on the dictionary elements. The second is the *executive-summary principle*. This principle allows us to represent the state of a part coarsely because we are also representing the state of its subparts (e.g., a top level executive of a business company will only want to know that "there is a horse in the field" and will not care about the exact positions of its legs, which will be known by the lower level executives). For example, consider a letter T which is composed of a horizontal and vertical bar. If the positions of these two bars are specified precisely, then we only need to represent the position of the letter T more crudely (it is sufficient for it to be "bound" to the two bars, and for their positions to be represented separately). The third factor is *parallelism* which arises because the part dictionaries can be implemented in parallel. This is roughly similar to having a set of non-linear receptive fields for each dictionary element. This enables extremely rapid inference at the cost of a larger, but parallel, graphical model. The inference proceeds in a single bottom-up and top-down pass, where the bottom-up pass rapidly estimates an executive summary which enables the the top-down pass to estimate the lower-level details.

The compositional section (2) introduces the key ideas of compositional models and section (3) describes how they are used to generate images. Section (4) describes the compositional architecture and the inference algorithms for serial and parallel implementations. Section (5) performs a complexity analysis and shows potential exponential gains by using compositional models. Section (6) discusses the relations between compositional models and bio-inspired hierarchical models, briefly discusses how compositional models can be learnt in an unsupervised manner, discusses robust variants of compositional models and summaries an analysis of robustness (which is presented in the appendix).

2. Compositional Models

Compositional models are based on the idea that objects are built by compositions of parts which, in turn, are compositions of more elementary parts. Section (2.1) describes part-subparts compositions which are the basic building block of our approach. In section (2.2) we discuss how to build objects by recursively making part-subpart compositions. Section (2.3) describes the state variables and how they take values on a hierarchy of lattices. In section (2.4) we discuss hierarchical dictionaries and part sharing. In section (2.5) we specify the probability distributions for objects.

2.1 Compositional Part-Subparts

We formulate part-subpart compositions by probabilistic graphical models which specify how a part is composed of its subparts. This consists of a parent node ν with a *type* τ_ν and a *state variable* x_ν. The parent node represents the part and has r child nodes $Ch(\nu) = (\nu_1, ..., \nu_r)$, representing the subparts, which have types $\tau_{Ch(\nu)} = (\tau_{\nu_1}, ..., \tau_{\nu_r})$ and state variables $x_{Ch(\nu)} = (x_{\nu_1}, ..., x_{\nu_r})$ (r is fixed for all part-subpart compositions in this paper). For concreteness the state variables represent the position of the parts, or subparts in the image (unless otherwise specified, our analysis is directly extended to other cases where they represent other image properties, such as mini-epitomes or active patches Papandreou et al. (2014); Mao et al. (2014)). Similarly, the types represent geometric entities (e.g., the letters T, L or vertical/horizontal bars indicted by V, H). The type τ_ν of the parent node is specified by the types τ_{ν_i} of the child nodes and by the *spatial relations* λ_ν between the child nodes. Hence we express $\tau_\nu = (\tau_{\nu_1}, ..., \tau_{\nu_r}, \lambda_\nu)$. For example, in Figure (1) we represent the letters T and L by part-subparts where the parent has type "T" or "L". In both cases, there are two child nodes (i.e. $r = 2$) with types "vertical bar" and "horizontal bar" and the spatial relations are represented by λ_T and λ_L respectively. This is illustrated in Figure (1).

The spatial configuration of the part-subpart is represented by the state of the parent x_ν and the states of the children $x_{Ch(\nu)}$. The state of the parent x_ν provides an *executive summary* description of the part (e.g., there is a cow in the right side of the image) while the states of the children $x_{Ch(\nu)}$ gives the details (e.g., the positions of the head, torso, and legs of the cow). In this paper, we restrict the spatial position x_ν to take a discrete set of values, see section (2.3), which differs from earlier work where they were allowed to be continuous Zhu et al. (2008, 2010).

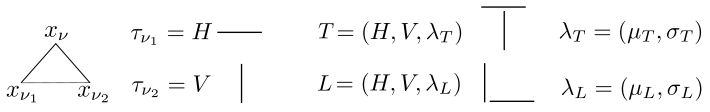

Figure 1: Compositional part-subpart models $T = (H, V, \lambda_T)$ and $L = (H, V, \lambda_L)$ for letters T and L are constructed from the same elementary components τ_H, τ_V, horizontal and vertical bar using different spatial relations $\lambda_T = (\mu_T, \sigma_T)$ and $\lambda_L = (\mu_L, \sigma_L)$, where μ denotes average displacement between the bars and σ^2 is the variance. The state x_ν of the parent node gives the summary position of the object, the *executive summary*, while the positions x_{ν_1} and x_{ν_2} of the components give the detailed positions of its components.

The probability distribution for the part-subpart model relates the states of the part and the subparts by:

$$P(x_{Ch(\nu)}|x_\nu; \tau_\nu) = \delta(x_\nu - f(x_{Ch(\nu)}))h(x_{Ch(\nu)}; \lambda_\nu). \quad (1)$$

Here $f(.)$ is a deterministic function, so the state of the parent node is determined uniquely by the state of the child nodes ($\delta(.)$ is a Dirac delta function if x_ν takes continuous values, and a Kronecker delta if x_ν takes discrete values). The function $h(.)$, which is parameterized by λ, specifies a distribution on the relative states of the child nodes. The distribution $P(x_{Ch(\nu)}|x_\nu; \tau_\nu)$ is local in the sense that $P(x_{Ch(\nu)}|x_\nu; \tau_\nu) = 0$, unless $|x_{\nu_i} - x_\nu|$ is smaller than a threshold for all $i = 1, .., r$. This requirement captures the intuition that subparts of a part are typically close together.

For example, in the simple example shown in Figure (1), the function $f(x_{\nu_1}, x_{\nu_2})$ specifies the average positions x_{ν_1} and x_{ν_2} of the horizontal and vertical bars, rounded off to the nearest position on the lattice. We set $h(.; \lambda)$ to be a discretized variant of the Gaussian distribution on the relative positions of the two bars, so $\lambda = (\mu, \sigma)$ where μ is the mean relative positions and σ is the covariance. Observe that the parts T and L have the same subparts – horizontal and vertical bars – but they have different spatial relations λ_T and λ_L (because the mean relative positions of the bars are different for T's and L's). Hence the two compositional models for the T and L have types $T = (H, V, \lambda_T)$ and $L = (H, V, \lambda_L)$.

2.2 Representing an Object Using a Hierarchical Graph

We model an object recursively from parts and subparts using part-subpart compositions. This is illustrated in Figure (2) where we combine T's and L's with other parts to form more complex objects. The basic idea is to build increasingly complex shapes by treating the parts as subparts of higher order parts.

More formally, an object is represented by a graph with nodes $\mathcal{V}$. State variables x_ν and types τ_ν are defined at the nodes $\nu \in \mathcal{V}$. The graph has a hierarchical structure with levels $h \in \{0, ..., \mathcal{H}\}$, where $\mathcal{V} = \bigcup_{h=0}^{\mathcal{H}} \mathcal{V}_h$. The edges in the graph specify the part-subpart compositions by connecting each node at level-h to r nodes at level-$h-1$. Each object has a single, root node, at level-$\mathcal{H}$. Any node $\nu \in \mathcal{V}_h$ (for $h > 0$) has r children nodes $Ch(\nu)$

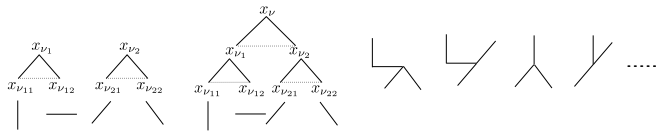

Figure 2: Object models are built recursively by part-subpart relations, Each object is represented by a hierarchical graph whose edges specify the part-subpart relationships. Each node ν has a type τ_ν and a state variable x_ν. Left Panel: Two part-subpart models, where the subparts are bars at four different angles (horizontal, vertical, forty-five degrees up, and forty-five degrees down). Center Panel: Combining two part-subpart models by composition to make a higher level model. Right Panel: Some examples of the higher-level models that can be obtained by different compositions.

in $\mathcal{V}_{h-1}$ indexed by $(\nu_1, ..., \nu_r)$ (corresponding to the subparts of the part). Hence there are $r^{\mathcal{H}-h}$ nodes at level-h (i.e. $|\mathcal{V}_h| = r^{\mathcal{H}-h}$).

The type of object is specified by the type $\tau_\mathcal{H}$ of the root node. Hence we use $\mathcal{V}^{\tau_\mathcal{H}}$ to refer to the nodes of the graph for object $\tau_\mathcal{H}$. The types of its descendant nodes are specified recursively by $\tau_{Ch(\nu)} = (\tau_{\nu_1}, ..., \tau_{\nu_r})$. The types of the lowest-level nodes, at $h = 0$ specify elementary features (e.g., horizontal and vertical bars). Hence we can think of an object as being constructed recursively by combining elementary structures with spatial relations (e.g., like building an object from a lego kit).

2.3 State Variables and Hierarchical Lattices

We require the state variables $\{x_\nu : \nu \in \mathcal{V}\}$ to satisfy the executive summary principle. To enforce this, we require that the positions of the subparts are specified at greater resolution than the positions of the parts. This is done by requiring that the state variables take values on a hierarchical lattice which we describe in this section. More precisely, the positions of the parts and subparts are specified by state variables x_ν which take values in a *set of lattices* $\{\mathcal{D}_h : h = 0, ..., \mathcal{H}\}$, so that a level-$h$ node, $\nu \in \mathcal{V}_h$, takes position $x_\nu \in \mathcal{D}_h$. The state variable of the root node gives the top-level executive summary of the object and lies on the lattice $\mathcal{D}_\mathcal{H}$. The state variables of the leaf nodes $\mathcal{V}_0$ of the graph take values on the image lattice $\mathcal{D}_0$.

The lattices are regularly spaced and the number of lattice points decreases by a factor of $q < 1$ for each level, so $|\mathcal{D}_h| = q^h|\mathcal{D}_0|$, see Figure (3)(left panel). This decrease in number of lattice points imposes the *executive summary principle*. The lattice spacing is designed so that parts do not overlap. At higher levels of the hierarchy the parts cover larger regions of the image and so the lattice spacing must be larger, and hence the number of lattice points smaller, to prevent overlapping. Note that previous work Zhu et al. (2008, 2010) was not formulated on lattices and used non-maximal suppression to achieve a similar effect.

We use the notation $\vec{x}_\nu$ to denote the state of node ν and all its descendants. This can be defined recursively by $\vec{x}_\nu = (x_\nu, x_{Ch(\nu)}, ...)$. Figure (3)(right panel) shows the object

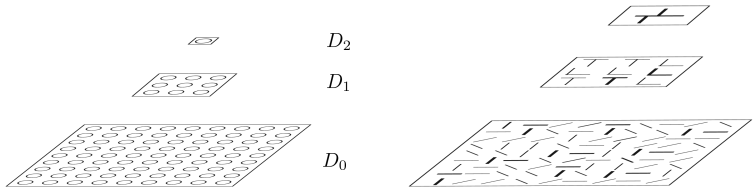

Figure 3: The hierarchical lattices. Left Panel: the size of the lattices decrease with scale by a factor $q = 1/9$ which helps enforce executive summary and prevent having multiple hypotheses which overlap too much. Right Panel: How an object is represented by a hierarchically distributed representation with coarse summary of position at the top level and more details at the lower levels.

represented hierarchically where the upper level encodes the summary and the lower-levels encode the details. By a slight abuse of notation, we specify the state vector of an object $\tau_{\mathcal{H}}$ by $\vec{x}_{\tau_{\mathcal{H}}}$. *In summary*, an object $\tau_{\mathcal{H}}$ is represented by a graph with nodes $\mathcal{V}^{\tau_{\mathcal{H}}}$ and state variables $\vec{x}_{\tau_{\mathcal{H}}}$.

2.4 Multiple Types of Objects, Shared Parts, and Hierarchical Dictionaries

Now suppose we have a large set of objects (each with $\mathcal{H}$ levels). We can represent each object separately by a hierarchical graph, as discussed in the last two subsections, but this is wasteful and cumbersome because it does not exploit the sharing of parts between different objects.

Instead, we represent objects and their parts by hierarchical dictionaries $\{\mathcal{M}_h : h = 0, ..., \mathcal{H}\}$. The top-level dictionary specifies the object types $\tau_{\mathcal{H}} \in \mathcal{M}_{\mathcal{H}}$. The level-$h$ dictionary specifies the types $\mathcal{M}_h$ of the parts at level h. The dictionary elements in $\mathcal{M}_h$ are built by compositions of r elements from the dictionary $\mathcal{M}_{h-1}$ at the previous level using part-subpart composition as described in section (2.1). An object is specified by the type of its root node $\tau_{\mathcal{H}} \in \mathcal{M}_{\mathcal{H}}$. It is composed of a set $Ch(\tau_{\mathcal{H}})$ of r parts from level-$\mathcal{H}-1$ with types plus spatial relations $\lambda_{\tau_{\mathcal{H}}}$ between them. Hence we express $\tau_{\mathcal{H}} = (\tau_{\mathcal{H},1}, ..., \tau_{\mathcal{H},r}; \lambda_{\tau_{\mathcal{H}}})$. In turn, these parts can be expressed in terms of lower-level subparts so that we can recursively specify the types of all parts of the object and the spatial relationships between them. More formally, any level-h part $\tau_h \in \mathcal{M}_h$ can be expressed as a composition of r level-$h-1$ parts $Ch(\tau_h) = \{\tau_{h,i} : i = 1, ..., r\}$, where $\tau_{h,i} \in \mathcal{M}_{h-1}$, and by spatial relations λ_{τ_h}. For example, in Figure (1) we have $\mathcal{M}_1 = \{T, L\}$ and $\mathcal{M}_0 = \{H, V\}$, where the compositions are given by $T = (H, V, \lambda_T)$ and $L = (H, V, \lambda_L)$ (here $r = 2$).

The hierarchical dictionaries enable us to make part-sharing explicit, which will enable us to analyze its effectiveness in section (5). Part-sharing is illustrated in Figure (4) by two models A and B which share level-1 part b. Hierarchical dictionaries are shown in Figure (5) where the dictionaries are $\mathcal{M}_2 = \{A, B\}, \mathcal{M}_1 = \{a, b, c\}$ and $\mathcal{M}_0 = \{\gamma, \epsilon, \delta, \}$. For example, the level-2 part A is composed from level-1 parts a and b (plus spatial relations, which are

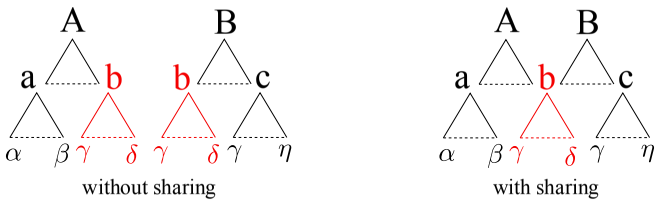

Figure 4: Part sharing. Two Level-2 parts A and B are composed from Lavel-1 parts a, b and c which, in turn, are composed from Level-0 parts $(\alpha, \beta), (\gamma, \delta)$ and (γ, ζ) respectively. Left Panel: the Level-2 parts are modeled separately and the fact that they share a Level-1 part is not exploited. Right Panel: In this paper we represent the part sharing explicitly and exploit it for efficient representation and inference.

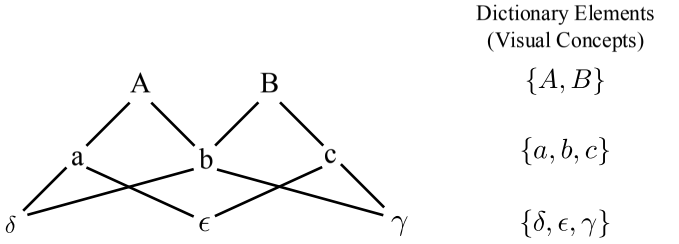

Figure 5: Representing objects in terms of hierarchical dictionaries with shared parts. There are two object models A, B at the top level, three parts a, b and c at the middle level, and three subparts γ, δ and ϵ at the bottom level. The Level-2 models A and B are composed from Level-1 parts a, b and c, which are composed from Level-0 parts. Here a is composed from δ and ϵ, b is composed from δ and γ, and c is composed from ϵ and γ. This illustrates part sharing, for example ϵ is shared between parts a and c, part b is shared between A and B.

not shown here for simplicity), while the level-1 part a is composed from level-0 parts δ and ϵ (also ignoring their spatial relations).

In summary, we represent an object $\tau_{\mathcal{H}} \in \mathcal{M}_{\mathcal{H}}$ by a graph $\mathcal{V}^{\tau_{\mathcal{H}}} = \bigcup_{h=0}^{\mathcal{H}} \mathcal{V}_h^{\tau_{\mathcal{H}}}$. There is a single node at level $\mathcal{H}$, r nodes at level $\mathcal{H}-1$, and $r^{\mathcal{H}-h}$ nodes at level h. The state $\vec{x}_{\tau_{\mathcal{H}}}$ is specified by the state $x_{\tau_{\mathcal{H}}}$ of the root node and its descendants.

We note that the unsupervised learning algorithm in Zhu et al. (2010) automatically generates this hierarchical dictionary, as reviewed in section (6.2).

2.5 Probability Distributions for Objects

We specify the probability model for an object of type $\tau_{\mathcal{H}} \in \mathcal{M}_{\mathcal{H}}$ in terms of the probabilities of its part-subpart relations:

$$P(\vec{x}_{\tau_{\mathcal{H}}}|\tau_{\mathcal{H}}) = U(x_{\tau_{\mathcal{H}}}) \prod_{\nu \in \mathcal{V}^{\tau_{\mathcal{H}}}/\mathcal{V}_0^{\tau_{\mathcal{H}}}} P(x_{Ch(\nu)}|x_\nu; \tau_\nu). \tag{2}$$

Here $\mathcal{V}^{\tau_{\mathcal{H}}}/\mathcal{V}_0^{\tau_{\mathcal{H}}}$ denotes all the nodes of the graph $\mathcal{V}^{\tau_{\mathcal{H}}}$ except the leaf nodes $\mathcal{V}_0^{\tau_{\mathcal{H}}}$. $U(x_{\tau_{\mathcal{H}}})$ is the uniform distribution, which means that the object is equally likely to be anywhere in the image.

This model can be used to generate the positions of parts and subparts by sampling. This is performed by sampling the position $x_{\tau_{\mathcal{H}}}$ of the root node from $U(x_{\tau_{\mathcal{H}}})$, then sampling recursively from $P(x_{Ch(\nu)}|x_\nu; \tau_\nu)$ to get the positions of the parts and subparts until we obtain samples $\{x_\nu : \nu \in \mathcal{V}_0^{\tau_{\mathcal{H}}}\}$ for the leaf nodes.

3. Generative Models of Images

The models in the previous section specify distributions for the positions $\vec{x}_{\tau_{\mathcal{H}}}$ of an object $\tau_{\mathcal{H}}$, its parts and, in particular, for the positions $\{x_\nu : \nu \in \mathcal{V}_0^{\tau_{\mathcal{H}}}\}$ of the leaf nodes. In this section we describe how we can use these models to generate an image $\mathbf{I} = \{I(x) : x \in \mathcal{D}_0\}$.

This is done by introducing distributions for local image properties depending on the types and positions of the leaf nodes of the objects (e.g., the horizontal and vertical bars). We also specify a default, or background, distribution for the image properties at places where no low-level parts are present (i.e. no leaf nodes take these states).

More formally, we specify distributions $P(I(x)|\tau)$ for image property $I(x)$ at position $x \in \mathcal{D}_0$ if there is a leaf-level part $\tau \in \mathcal{M}_0$ at x. In addition, we specify a default *background distribution* $P(I(x)|\tau_0)$ for the image property at x if no part is present, which we denote by τ_0. For example, we could use the distributions for the properties of features on, or off, edges as described in Konishi et al. (2003). Note, we only allow the leaf-level parts $\mathcal{M}_0$ to directly generate image properties.

This gives a generative model for images. We first select an object at random from $\mathcal{M}_{\mathcal{H}}$ and sample from equation (2) to get a configuration of the object and its parts including, in particular, the leaf nodes. Then for each leaf node we sample from the appropriate $P(I(x)|\tau)$ depending on the type of the leaf node. At places where no leaf node is present we sample from $P(I(x)|\tau_0)$.

Observe that we can extend this generative model in two ways. Firstly, we can sample a background image if no object is present at all, by sampling from $P(I(x)|\tau_0)$, at every

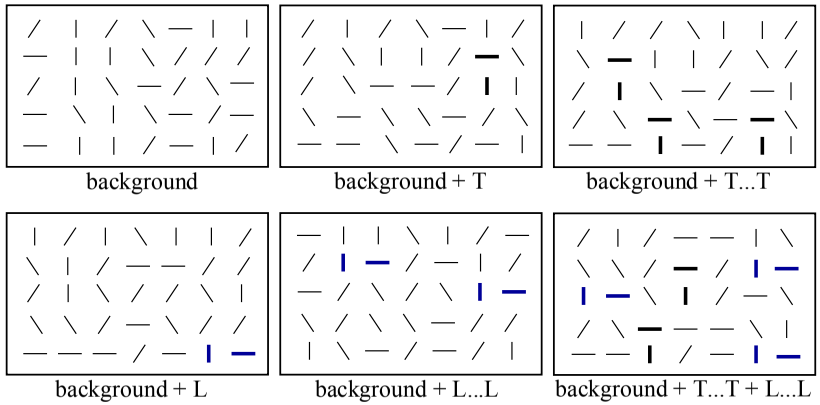

Figure 6: The generative model allows there to be several different objects in the image together with background clutter. This figure illustrates images generated by different models: (i) purely background, (ii) background with one T, (iii) background with several T's, (iv) background with an L, (v) background with several L's, and (vi) background with T's and L's.

position x. Secondly, we can sample for many objects being in the image provided they do not overlap, again by sampling from the models to find the positions of their leaf nodes and then sampling from $P(I(x)|\tau)$ or $P(I(x)|\tau_0)$ as appropriate. This can also be extended to sampling from objects and parts of objects. In this paper we mainly concentrate on the case where there is either a single object or no object in the image, although our analysis can be extended to these other more complex situations. We illustrate images sampled from different generative models in Figure (6).

3.1 The Generative Model for Objects and Backgrounds

We now specify the distributions more precisely. If there is no object in the image, then we generate it by sampling from the *background distribution*:

$$P_B(\mathbf{I}) = \prod_{x \in \mathcal{D}_0} P(I(x)|\tau_0). \tag{3}$$

This assumes that each image position x is background and so is sampled independently from $P(I(x)|\tau_0)$.

If there is a single object $\tau_{\mathcal{H}}$ present, then the prior $P(\vec{x}_{\tau_{\mathcal{H}}}|\tau_{\mathcal{H}})$, see equation (2), gives a distribution over a set of points $\mathcal{L}(\vec{x}_{\tau_{\mathcal{H}}}) = \{x_\nu : \nu \in \mathcal{V}_0^{\tau_{\mathcal{H}}}\}$ (the leaf nodes of the graph), which are a subset of the image lattice (i.e., $x_\nu \in \mathcal{D}_0$ if $\nu \in \mathcal{V}_0^{\tau_{\mathcal{H}}}$) and specifies their types $\{\tau_\nu : \nu \in \mathcal{V}_0^{\tau_{\mathcal{H}}}\}$. We denote these leaf nodes by $\{(x, \tau(x)) : x \in \mathcal{L}(\vec{x}_{\tau_{\mathcal{H}}})\}$ where $\tau(x)$ is specified in the natural manner (i.e. if $x = x_\nu$ for $\nu \in \mathcal{V}_0^{\tau_{\mathcal{H}}}$ then $\tau(x) = \tau_\nu$). Then we

sample from the distributions $P(I(x)|\tau(x))$ for the probability of the image $I(x)$ at positions $x \in \mathcal{L}(\vec{x}_{\tau_\mathcal{H}})$ conditioned on the type of the leaf node. We sample from the default $P(I(x)|\tau_0)$ at positions $x \in \mathcal{D}_0/\mathcal{L}(\vec{x}_{\tau_\mathcal{H}})$ where there is no leaf node of the object.

This specifies a likelihood function for the states $\vec{x}_{\tau_\mathcal{H}}$ of the object model $\tau_\mathcal{H}$. This likelihood function depends only on the leaf nodes $\nu \in \mathcal{V}_0^{\tau_\mathcal{H}}$:

$$P(\mathbf{I}|\vec{x}_{\tau_\mathcal{H}}) = \prod_{x \in \mathcal{L}(\vec{x}_{\tau_\mathcal{H}})} P(I(x)|\tau(x)) \times \prod_{x \in \mathcal{D}_0/\mathcal{L}(\vec{x}_{\tau_\mathcal{H}})} P(I(x)|\tau_0). \quad (4)$$

Combining this likelihood with the prior, specified in equation (2), gives the generative model for the image of an object:

$$P(\mathbf{I}|\vec{x}_{\tau_\mathcal{H}})P(\vec{x}_{\tau_\mathcal{H}}|\tau_\mathcal{H}) \quad (5)$$

, where the prior $P(\vec{x}_{\tau_\mathcal{H}}|\tau_\mathcal{H})$ is given by equation (2).

An important quality in our analysis is the *log-likelihood ratio* of the probability of an image $\mathbf{I}$ conditioned on whether there is an object in the image of type $\tau_\mathcal{H}$ and configuration $\vec{x}_{\tau_\mathcal{H}}$ or if no object is present, $P_B(\mathbf{I})$ from equation (3). This gives a log-likelihood ratio:

$$\log \frac{P(\mathbf{I}|\vec{x}_{\tau_\mathcal{H}})P(\vec{x}_{\tau_\mathcal{H}}|\tau_\mathcal{H})}{P_B(\mathbf{I})} = \sum_{x \in \mathcal{L}(\vec{x}_{\tau_\mathcal{H}})} \log \frac{P(I(x)|\tau(x))}{P(I(x)|\tau_0)} + \sum_{\nu \in \mathcal{V}^{\tau_\mathcal{H}}/\mathcal{V}_0^{\tau_\mathcal{H}}} \log P(x_{Ch(\nu)}|x_\nu;\tau_\nu) + \log U(x_{\tau_\mathcal{H}}), \quad (6)$$

where the $\sum_\nu$ is performed over all part-subpart relations for object type $\tau_\mathcal{H}$.

All the visual tasks we study in this paper can be reduced to computing the log-likelihood ratios for different objects and different configurations of their state variables. For example, if the log-likelihood ratios are small for all object configurations then we can decide that no object is present. Alternatively, the configuration which maximizes the log-likelihood ratio determines the most probable object in the image and the most likely positions of its parts, The next section shows how we can perform all these visual tasks exactly and efficiently using a visual architecture which exploits compositionality.

4. The Compositional Architecture and Exact Inference

We now discuss the inference algorithms required to perform the visual tasks of determining which objects, if any, are present in the image, and estimate their positions including the positions of their subparts. These visual tasks can be decomposed into two subtasks: (i) state estimation, to determine the optimal states for each model and hence the most probable positions of the objects and their parts, and (ii) model selection, to determine whether objects are present or not and which objects are most likely. As we will show, both tasks can be reduced to calculating and comparing log-likelihood ratios which can be performed efficiently using dynamic programming methods.

Firstly we describe, in section (4.1), how to do state estimation for each object separately and then discuss how we can perform model selection to decide which objects, if any, are

present in the image. Secondly, in section (4.2) we discuss how these inference tasks can be made more efficient for multiple object categories by exploiting part sharing using the hierarchical dictionaries. Thirdly, in section (4.3) we describe a parallel formulation for inference exploiting part sharing. We stress that we are performing *exact inference* and no approximations are made.

4.1 Inference for Single Objects: State Estimation and Model Selection

We first describe a standard dynamic programming algorithm for finding the optimal state of a single object model. Then we describe how the same computations can be used to perform model selection and hence applied to the detection and state estimation if the object appears multiple times in the image (provided it is non-overlapping).

Consider performing inference for a single object model $\tau_\mathcal{H}$ defined by equations (2) and (4). Calculating the MAP estimate of the state variables $\vec{x}_{\nu_\mathcal{H}}$ requires computing its most probable state $\vec{x}^*_{\tau_\mathcal{H}} = \arg\max_{\vec{x}_{\tau_\mathcal{H}}} \{\log P(\mathbf{I}|\vec{x}_{\tau_\mathcal{H}}) + \log P(\vec{x}_{\tau_\mathcal{H}}|\tau_\mathcal{H})\}$. This is equivalent to finding the state variables which maximize the log-likelihood ratio of $P(\mathbf{I}|\vec{x}_{\tau_\mathcal{H}})P(\vec{x}_{\tau_\mathcal{H}}|\tau_\mathcal{H})$ and the background distribution $P_B(\mathbf{I})$, which we specified in equation (6) (because $P_B(\mathbf{I})$ depends only on the image and is independent of the state variables). This requires estimating:

$$\vec{x}^*_{\tau_\mathcal{H}} = \arg\max_{\vec{x}_{\tau_\mathcal{H}}} \{ \sum_{x \in \mathcal{L}(\vec{x}_{\tau_\mathcal{H}})} \log \frac{P(I(x)|\tau(x))}{P(I(x)|\tau_0)} + \sum_{\nu \in \mathcal{V}^{\tau_\mathcal{H}}/\mathcal{V}_0^{\tau_\mathcal{H}}} \log P(x_{Ch(\nu)}|x_\nu;\tau_\nu) + \log U(x_{\tau_\mathcal{H}}) \}. \quad (7)$$

Here $\mathcal{L}$ denotes the positions of the leaf nodes of the graph, which must be determined during inference.

The optimal state $\vec{x}^*_{\tau_\mathcal{H}}$ can be estimated efficiently by dynamic programming. This involves a bottom-up pass which recursively computes the *local evidence* $\phi(x_\nu, \tau_\nu)$ for the *hypothesis* that there is a part τ_ν with state variable x_ν (i.e. with executive level summary x_ν). This is specified by $\phi(x_\nu, \tau_\nu) = \max_{\vec{x}_\nu/x_\nu} \{\log \frac{P(\mathbf{I}|\vec{x}_\nu)}{P_B(\mathbf{I})} + \log P(\vec{x}_\nu|\tau_\nu)\}$, where $\max_{\vec{x}_\nu/x_\nu}$ specifies that we fix the state of the position x_ν of the part τ_ν while maximizing over the states of its descendants (recall that $\vec{x}_\nu = (x_\nu, x_{Ch(\nu)}, ...)$). The local evidence can be interpreted as the log-ratio of the hypothesis test that there is a part τ_ν present at x_ν compared to the probability that it is not (i.e. the image properties are generated instead by the background model). The local evidences for the part hypotheses are computed bottom-up and we call it "local" because it ignores the context evidence for the part which will be provided during top-down processing (i.e. that evidence for other parts of the object, in consistent positions, will strengthen the evidence for this part). The local evidences for the part hypotheses are computed recursively by the formula:

$$\phi(x_\nu, \tau_\nu) = \max_{x_{Ch(\nu)}} \{ \sum_{i=1}^{r} \phi(x_{\nu_i}, \tau_{\nu_i}) + \log P(x_{Ch(\nu)}|x_\nu, \tau_\nu) \}. \quad (8)$$

At level-$\mathcal{H}$ the *bottom-up pass* outputs the *global evidence* $\phi(x_{\tau_\mathcal{H}}, \tau_\mathcal{H})$ for the hypothesis that object $\tau_\mathcal{H}$ occurs at position $x_{\tau_\mathcal{H}}$. This enables us to determine the best executive summary position for the object together with the log-likelihood ratio of the best state

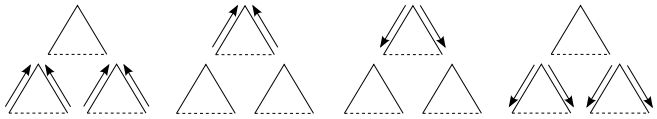

Figure 7: The feedforward (bottom-up) pass propagates hypotheses from the lowest level to the middle level (far left panel) and then from the middle level to the top level (left panel). The best top-level state is selected. The feedback (top-down) pass propagates information from the top node disambiguating the middle level nodes (right panel) and then from the middle level nodes to the lowest levels (far right panel). The bottom-up pass enables the algorithm to rapidly estimate the top-level executive summary description. The top-down pass enables high-level context to eliminate false hypotheses at the lower levels– informally, "high-level tells low-level to stop gossiping".

configuration:

$$x^*_{\tau_\mathcal{H}} = \arg\max_{x \in \mathcal{D}_\mathcal{H}} \phi(x, \tau_\mathcal{H}), \qquad \text{with evidence} \quad \phi(x^*_{\tau_\mathcal{H}}, \tau_\mathcal{H}). \tag{9}$$

We can compare the log-likelihood ratio of the best state configuration to perform *model selection* either by determining whether it is above a fixed threshold $T_\mathcal{H}$, to determine whether the object is present or not, or to compare its value for different objects to determine which object is most likely to be in the image.

Then we can perform a *top-down pass* of dynamic programming to estimate the most probable states $\vec{x}^*_{\tau_\mathcal{H}}$ of the entire model by recursively performing:

$$x^*_{Ch(\nu)} = \arg\max_{x_{Ch(\nu)}} \{\sum_{i=1}^{r} \phi(x_{\nu_i}, \tau_{\nu_i}) + \log P(x_{Ch(\nu)} | x^*_\nu, \tau_\nu)\}. \tag{10}$$

This outputs the most probable configuration of this object $\tau_\mathcal{H}$ in the image:

$$\vec{x}^*_{\tau_\mathcal{H}} = x^*_{\tau_\mathcal{H}}, ... \tag{11}$$

It should be emphasized that the algorithm first computes the best "executive summary" description $x_{\tau_\mathcal{H}}$ of the object as the output of the feedforward pass, together with the log-likelihood ratio for the optimal configuration, and only later determines the optimal estimates of the lower-level states of the object in the top-down pass. Hence, the algorithm is faster at detecting that there is a cow in the right side image (estimated in the bottom-up pass) and is slower at determining the position of the feet of the cow (estimated in the top-down pass). The algorithm is also quicker at determining whether there is a cow or a horse in the image, at the end of the bottom-up pass, than it is at estimating the most likely positions of the parts of the cow or the horse. This is illustrated in Figure (7).

The algorithm also has an intuitive interpretation. The bottom up pass propagates local hypotheses for parts up the hierarchy, see Figures (7,8). These hypotheses may be

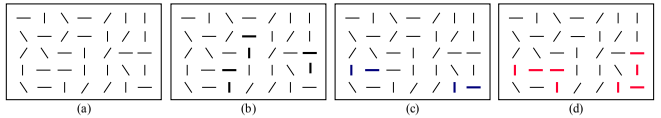

Figure 8: An alternative perspective on inference. Input image (far left panel), hypotheses for T's and L's (left and right panels), detections of the composite object (far right panel).

extremely ambiguous at the lower levels of the hierarchy due to the local ambiguity of images. But as we ascend the hierarchy the hypotheses become increasingly unambiguous because the parts become larger and more structured. This could be analyzed by using the techniques developed in Yuille et al. (2001). From another perspective, the top-down process "binds" the parts to the subparts and hence relates to the standard binding problem of neural networks Valiant (2000).

So far we have described how to use dynamic programming, with a bottom-up and top-down pass, to compute the MAP estimate of the configuration $\vec{x}_{\tau_\mathcal{H}}$ of an object $\tau_\mathcal{H}$ in the image. But this approach allows us to do more. For example, instead of detecting objects we can use the algorithm to detect parts again by using the evidence $\phi(x_\nu, \tau_\nu)$ as a log-likelihood ratio test to determine if the part is present or not. The log-likelihood test will tend to have a large error rate for low level parts (because of their ambiguity) but will increasingly have fewer errors for larger parts since these are less ambiguous. Intuitively, it is possible for a human to confuse the leg of a cow with the leg of a horse but it is extremely unlikely that an entire horse and cow cannot be distinguished. Using this strategy it may be possible to decide that an object part is present or not without waiting for the context provided by the top-down processing. Making premature decisions like this may cause problems, however, which we analyze in section (6.3).

In addition, we can compute the probability that the object occurs several times in the image, by computing the set $\{x_{\tau_\mathcal{H}} : \phi(x^*_{\tau_\mathcal{H}}, \tau_\mathcal{H}) > T_\mathcal{H}\}$, to compute the "executive summary" descriptions for each object (e.g., the coarse positions of each object). We then perform the top-down pass initialized at each coarse position (i.e. at each point of the set described above) to determine the optimal configuration for the states of the objects. Hence, we can reuse the computations required to detect a single object in order to detect multiple instances of the object (provided there are no overlaps). The number of objects in the image is determined by the log-likelihood ratio test with respect to the background model. It can be shown that this is equivalent to performing optimal inference simultaneously over a set of different generative models of the image, where one model assumes that there is one instance of the object in the image, another model assumes there are two (non-overlapping), and so on.

4.2 Compositional Architecture: Inference on Multiple Objects by Part Sharing using the Hierarchical Dictionaries

The previous section performed MAP estimation, and computed log-likelihood ratios, for each object separately. But this is wasteful since if the objects share parts because it computes the same quantities multiple times. This section describes how we can exploit part sharing to perform these computations more efficiently for many objects simultaneously.

The main idea is that we only need to compute the local evidence $\phi(x_\nu, \tau_\nu)$ for each part $\tau_\nu \in \mathcal{M}_h$ *once* independently of how many objects the part occurs in (or how many times it occurs within each object). This means that we can compute the evidence for all objects at all positions $\{\phi(\vec{x}_{\tau_\mathcal{H}}, \tau_\mathcal{H}) : \vec{x}_{\tau_\mathcal{H}} \in \mathcal{D}_\mathcal{H},\ \tau_\mathcal{H} \in \mathcal{M}_\mathcal{H}\}$ by recursively computing the evidences $\{\phi(x_\nu, \tau_\nu) : x_\nu \in \mathcal{D}_h,\ \tau_\nu \in \mathcal{M}_h\}$ using equation (8) for all $x_\nu \in \mathcal{D}_h,\ \tau_\nu \in \mathcal{M}_h$.

We then perform model selection at the top-level by thresholding the evidence for each object at each position. More precisely, for each object $\tau_\mathcal{H} \in \mathcal{M}_\mathcal{H}$ we determine the set of positions $\mathcal{S}_{\tau_\mathcal{H}} = \{x_{\tau_\mathcal{H}} \in \mathcal{D}_\mathcal{H} : s.t.\ \phi(x_{\tau_\mathcal{H}}, \tau_\mathcal{H}) > T_\mathcal{H}\}$ where the evidence for that object is above threshold. Then we perform the top-down pass, equation (10), starting at all positions $\mathcal{S}_{\tau_\mathcal{H}}$ for all $\tau_\mathcal{H} \in \mathcal{M}_\mathcal{H}$. In short, we perform bottom-up inference to detect which objects are present and the positions of the executive summaries. Then we perform top-down processing to estimate the positions of the parts, the full configurations, of the detected objects. Note, if this process detects two or more objects in the same position then we will need to compare their evidences to select which one is most likely, but our framework assumes that this is unlikely to occur because there is little ambiguity for complete objects.

Note that we are performing exact inference over multiple object models at the same time. This may be un-intuitive to some readers because this corresponds to doing exact inference over a probability model which can be expressed as a graph with a large number of closed loops, see Figure (4). We note that this applies only to a subclass of compositional models including Zhu et al. (2008, 2010). The main point is that part-sharing enables us perform inference efficiently for many models at the same time.

4.3 Parallel Formulation of the Compositional Architecture

Finally, we observe that all the computations required for performing inference on multiple objects can be parallelized.

Parallelization is possible for both the bottom-up and the top-down passes. Firstly, the bottom-up pass requires calculating the $\phi(x_\nu, \tau_\nu)$'s at each layer-h using equation (8). These calculations are done separately for each type $\tau_\nu \in \mathcal{M}_h$ and at each spatial position $x_\nu \in \mathcal{D}_h$, see equation (8). They depend only on input from local subregions of layer-$(h-1)$. Hence they can be computed in parallel. This enables us to compute the global evidence for objects at the top level: $\phi(x_{\tau_\mathcal{H}}, \tau_\mathcal{H})$ for all $x_{\tau_\mathcal{H}} \in \mathcal{D}_\mathcal{H}$ and $\tau_\mathcal{H} \in \mathcal{M}_\mathcal{H}$. We threshold at each node $x_{\tau_\mathcal{H}} \in \mathcal{D}_\mathcal{H}$ to determine if the object is detected, which is also a local operation. Secondly, the top-down pass is also parallelizable because its operation, see equation (10), is also local. Note that top-down processing is only done starting from nodes at level-$\mathcal{H}$ where objects have been detected.

This leads to a graphical architecture which contains $|\mathcal{M}_h| \times |\mathcal{D}_h|$ nodes at level h, and hence a total of $\sum_{h=0}^{\mathcal{H}} |\mathcal{M}_h| \times |\mathcal{D}_h|$ nodes. There are a total of $r \sum_{h=1}^{\mathcal{H}} |\mathcal{M}_h| \times |\mathcal{D}_h|$ connections. These connections are local and "convolutional" in the sense that they are

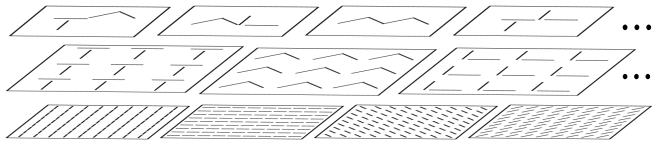

Figure 9: Parallel Hierarchical Implementation. Bottom Row: Four Level-0 parts are placed at each point in the image lattice $\mathcal{D}_0$. Middle Row: Level-1 parts are placed at each point on the coarser lattice $\mathcal{D}_1$ (we show three Level-1 models). Top Row: object models are placed at the nodes of the top level lattice ($\mathcal{H} = 2$ in this figure). This can be thought of as non-linear receptive fields analogous to bio-inspired hierarchical models.

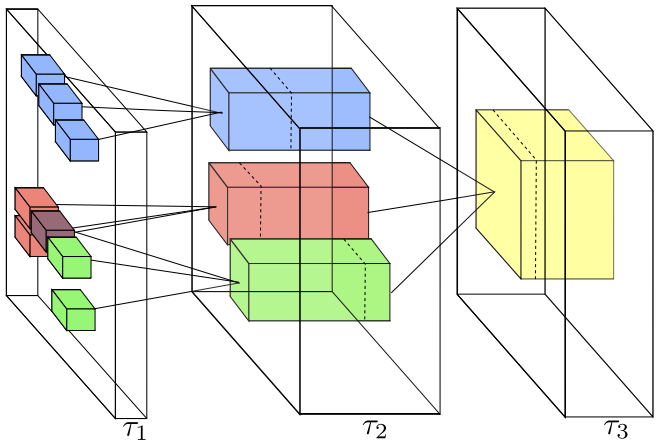

Figure 10: This figure illustrates the parallel hierarchical architecture. At each level there are nodes tuned to different types of parts (similar to the different features occurring in bio-inspired models).

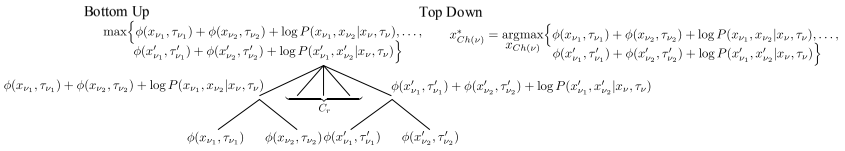

Figure 11: Parallel implementation of Dynamic Programming. The left part of the figure shows the bottom-up pass of dynamic programming. The local evidence for the parent node is obtained by taking the maximum of the scores of the C_r possible states of the child nodes. This can be computed by a two-layer network where the first level computes the scores for all C_r child node states, which can be done in parallel, and the second level compute the maximum score. This is like an AND operation followed by an OR. The top-down pass requires the parent node to select which of the C_r child configurations gave the maximum score, and suppressing the other configurations.

the same at different places in the image. Nodes at level-h can be represented by (τ_ν, x_ν) and so they represent a part of type $\tau_\nu \in \mathcal{M}_h$ at position $x_\nu \in \mathcal{D}_h$. This is illustrated in Figures (9) and (10).

We can think of the nodes at different levels of the hierarchy as being non-linear "receptive fields". At level-0, these receptive fields are tuned to specific image properties (e.g., horizontal or vertical bars). Note that the receptive fields are highly non-linear (i.e. they do not obey the superposition principle). Nevertheless they are broadly speaking, tuned to image stimuli which have the mean shape of the corresponding part τ_ν. In agreement, with findings about mammalian cortex, the receptive fields become more sensitive to image structure (e.g., from bars, to more complex shapes) at increasing levels. Moreover, their sensitivity to spatial position decreases because at higher levels the models only encode the executive summary descriptions, on coarser lattices, while the finer details of the object are represented more precisely at the lower levels. Moreover, they are influenced both by bottom-up processing (during the bottom-up pass) and by top-down processing (during the top-down pass). The bottom-up processing computes the local evidence while the top-down pass modifies it by the high-level context.

The computations required by this parallel implementation are illustrated in Figure (11). Each step of the bottom-up pass is performed by a two-layer network, see Figure (11), where the first layer performs an AND operation (to compute the local evidence for a specific configuration of the child nodes) and the second layer performs an OR, or max operation, to determine the local evidence (by max-ing over the possible child configurations). The top-down pass only has to perform an arg max computation to determine which child configuration gave the best local evidence.

5. Complexity Analysis

We now analyze the complexity of the inference algorithms for performing the tasks of object detection and object parsing. Firstly, we analyze complexity for a single object (without part-sharing). Secondly, we study the complexity for multiple objects with shared parts. Thirdly, we consider the complexity of the parallel implementation.

The complexity is expressed in terms of the following quantities: (I) The size $|\mathcal{D}_0|$ of the image. (II) The scale decrease factor q (enabling executive summary). (III) The number $\mathcal{H}$ of levels of the hierarchy. (IV) The sizes $\{|\mathcal{M}_h| : h = 0, ..., \mathcal{H}\}$ of the hierarchical dictionaries. (V) The number r of subparts of each part. (VI) The number C_r of possible part-subpart configurations.

5.1 Complexity for Single Objects and Ignoring Part Sharing

This section estimates the complexity of inference N_{s_o} for a single object and the complexity N_{m_o} for multiple objects when part sharing is not used. These results are for comparison to the complexities derived in the following section which use part sharing.

The inference complexity for a single object requires computing: (i) the number N_{bu} of computations required by the bottom-up pass, (ii) the number N_{m_s} of computations required by model selection at the top-level of the hierarchy, and (iii) the number N_{td} of computations required by the top-down pass.

The complexity N_{bu} of the bottom-up pass can be computed from equation (8). This requires a total of C_r computations for each position x_ν for each level-h node. There are $r^{\mathcal{H}-h}$ nodes at level-h and each can take $|\mathcal{D}_0|q^h$ positions. This gives a total of $|\mathcal{D}_0|C_r q^h r^{\mathcal{H}-h}$ computations at level h. This can be summed over all levels to yield:

$$N_{bu} = \sum_{h=1}^{\mathcal{H}} |\mathcal{D}_0|C_r r^{\mathcal{H}}(q/r)^h = |\mathcal{D}_0|C_r r^{\mathcal{H}} \sum_{h=1}^{\mathcal{H}} (q/r)^h = |\mathcal{D}_0|C_r \frac{qr^{\mathcal{H}-1}}{1-q/r}\{1-(q/r)^{\mathcal{H}}\}. \quad (12)$$

Observe that the main contributions to N_{bu} come from the first few levels of the hierarchy because the factors $(q/r)^h$ decrease rapidly with h. This calculation uses $\sum_{h=1}^{\mathcal{H}} x^h = \frac{x(1-x^{\mathcal{H}})}{1-x}$. For large $\mathcal{H}$ we can approximate N_{bu} by $|\mathcal{D}_0|C_r \frac{qr^{\mathcal{H}-1}}{1-q/r}$ (because $(q/r)^{\mathcal{H}}$ will be small).

We calculate $N_{m_s} = q^{\mathcal{H}}|\mathcal{D}_0|$ for the complexity of model selection (which only requires thresholding at every point on the top-level lattice).

The complexity N_{td} of the top-down pass is computed from equation (10). At each level there are $r^{\mathcal{H}-h}$ nodes and we must compute C_r computations for each. This yields complexity of $\sum_{h=1}^{\mathcal{H}} C_r r^{\mathcal{H}-h}$ for each possible root node. There are at most $q^{\mathcal{H}}|\mathcal{D}_0|$ possible root nodes (depending on the results of the model selection stage). This yields an upper bound:

$$N_{td} \leq |\mathcal{D}_0|C_r q^{\mathcal{H}} \frac{r^{\mathcal{H}-1}}{1-1/r}\{1-\frac{1}{r^{\mathcal{H}-1}}\}. \quad (13)$$

Clearly the complexity is dominated by the complexity N_{bu} of the bottom-up pass. For simplicity, we will bound/approximate this by:

$$N_{s_o} = |\mathcal{D}_0|C_r \frac{qr^{\mathcal{H}-1}}{1-q/r}. \quad (14)$$

Now suppose we perform inference for multiple objects simultaneously without exploiting shared parts. In this case the complexity will scale linearly with the number $|\mathcal{M}_{\mathcal{H}}|$ of objects. This gives us complexity:

$$N_{m_o} = |\mathcal{M}_{\mathcal{H}}||\mathcal{D}_0|C_r\frac{qr^{\mathcal{H}-1}}{1-q/r}. \tag{15}$$

5.2 Computation with Shared Parts in Series and in Parallel

This section computes the complexity using part sharing. We first study complexity for the standard serial implementation of part sharing and then for the parallel implementation.

Now suppose we perform inference on many objects with part sharing using a serial computer. This requires performing computations over the part-subpart compositions between elements of the dictionaries. At level h there are $|\mathcal{M}_h|$ dictionary elements. Each can take $|\mathcal{D}_h| = q^h|\mathcal{D}_0|$ possible states. The bottom-up pass requires performing C_r computations for each of them. This gives a total of $\sum_{h=1}^{\mathcal{H}}|\mathcal{M}_h|C_r|\mathcal{D}_0|q^h = |\mathcal{D}_0|C_r\sum_{h=1}^{\mathcal{H}}|\mathcal{M}_h|q^h$ computations for the bottom-up process. The complexity of model selection is $|\mathcal{D}_0|q^{\mathcal{H}} \times (|\mathcal{M}_{\mathcal{H}}|+1)$ (this is between all the objects, and the background model, at all points on the top lattice). As in the previous section, the complexity of the top-down process is less than the complexity of the bottom-up process. Hence the complexity for multiple objects using part sharing is given by:

$$N_{ps} = |\mathcal{D}_0|C_r\sum_{h=1}^{\mathcal{H}}|\mathcal{M}_h|q^h. \tag{16}$$

Next consider the parallel implementation. In this case almost all of the computations are performed in parallel and so the complexity is now expressed in terms of the number of "neurons" required to encode the dictionaries, see Figure (9). This is specified by the total number of dictionary elements multiplied by the number of spatial copies of them:

$$N_n = \sum_{h=1}^{\mathcal{H}}|\mathcal{M}_h|q^h|\mathcal{D}_0|. \tag{17}$$

The computation, both the forward and backward passes of dynamic programming, are linear in the number $\mathcal{H}$ of levels. We only need to perform the computations illustrated in Figure (11) between all adjacent levels.

Hence the parallel implementation gives speed which is linear in $\mathcal{H}$ at the cost of a possibly large number N_n of "neurons" and connections between them.

5.3 Advantages of Part Sharing in Different Regimes

The advantages of part-sharing depend on how the number of parts $|\mathcal{M}_h|$ scales with the level h of the hierarchy. In this section we consider three different regimes: (I) The *exponential growth regime* where the size of the dictionaries increases exponentially with the level h. (II) The *empirical growth regime* where we use the size of the dictionaries found experimentally by compositional learning Zhu et al. (2010). (III) The *exponential decrease regime* where the size of the dictionaries decreases exponentially with level h. For all these

regimes we compare the advantages of the serial and parallel implementations using part sharing by comparison to the complexity results obtained without sharing.

Exponential growth of dictionaries is a natural regime to consider. It occurs when subparts are allowed to combine with all other subparts (or a large fraction of them) which means that the number of part-subpart compositions is polynomial in the number of subparts. This gives exponential growth in the size of the dictionaries if it occurs at different levels (e.g., consider the enormous number of objects that can be built using lego).

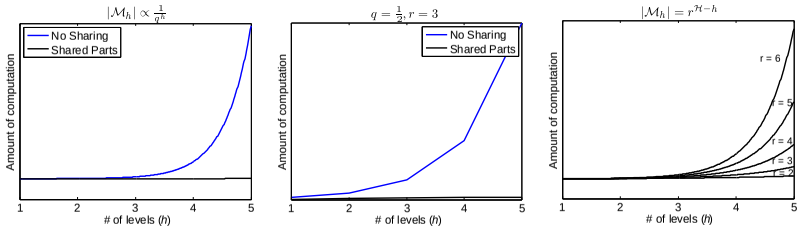
An interesting special case of the exponential growth regime is when $|\mathcal{M}_h|$ scales like $1/q^h$ (recall $q < 1$), see Figure (12) (left panel). In this case the complexity of computation for serial part-sharing, and the number of neurons required for parallel implementation, scales only with the number of levels $\mathcal{H}$. This follows from equations (16) and (17). But nevertheless the number of objects that can be detected scales exponentially with $\mathcal{H}$, as $(1/q)^{\mathcal{H}}$. By contrast, the complexity of inference without part-sharing also scales exponentially as $(1/q)^{\mathcal{H}}$, see equation (15), because we have to perform a fixed number of computations, given by equation (14), for each of an exponential number of objects. This is summarized by the following result.

Result 1: If the number of shared parts scales exponentially by $|\mathcal{M}_h| \propto \frac{1}{q^h}$ then we can perform inference for order $(1/q)^{\mathcal{H}}$ objects using part sharing in time linear in $\mathcal{H}$, or with a number of neurons linear in $\mathcal{H}$ for parallel implementation. By contrast, inference without part-sharing requires exponential complexity.

To what extent is exponential growth a reasonable assumption for real world objects? This motivates us to study the empirical growth regime using the dictionaries obtained by the compositional learning experiments reported in Zhu et al. (2010). In these experiments, the size of the dictionaries increased rapidly at the lower levels (i.e. small h) and then decreased at higher levels (roughly consistent with the findings of psychophysical studies – Biederman, personal communication). For these "empirical dictionaries" we plot the growth, and the number of computations at each level of the hierarchy, in Figure (12)(center panel). This shows complexity which roughly agrees with the exponential growth model. This can be summarized by the following result:

Result 2: If $|\mathcal{M}_h|$ grows slower than $1/q^h$ and if $|\mathcal{M}_h| < r^{\mathcal{H}-h}$ then there are gains due to part sharing using serial and parallel computers. This is illustrated in Figure (12)(center panel) based on the dictionaries found by unsupervised computational learning Zhu et al. (2010). In parallel implementations, computation is linear in $\mathcal{H}$ while requiring a limited number of nodes ("neurons").

Finally we consider the exponential decrease regime. To motivate this regime, suppose that the dictionaries are used to model image appearance, by contrast to the dictionaries based on geometrical features such as bars and oriented edges (as used in Zhu et al. (2010)). It is reasonable to assume that there are a large number of low-level dictionaries used to model the enormous variety of local intensity patterns. The number of higher-level dictionaries can decrease because they can be used to capture a cruder summary description of a larger image region, which is another instance of the executive summary principle. For example, the low-level dictionaries could be used to provide detailed modeling of the local appearance of a cat, or some other animal, while the higher-level dictionaries could give simpler descriptions like "cat-fur" or "dog-fur" or simply "fur". In this case, it is plausible



(a) (b) (c)

Figure 12: The curves are plotted as a function of h. Left panel: The first plot is the case where $M_h = a/(q^h)$. So we have a constant cost for the computations, when we have shared parts. Center panel: This plot is based on the experiment of Zhu et al. (2010). Right panel: The third plot is the case where M_h decreases exponentially. The amount of computation is the same for the shared and non-shared cases.

that the size of the dictionaries decreases exponentially with the level h. The results for this case emphasize the advantages of parallel computing.

Result 3: If $|\mathcal{M}_h| = r^{\mathcal{H}-h}$ then there is no gain for part sharing if serial computers are used, see Figure (12)(right panel). Parallel implementations can do inference in time which is linear in $\mathcal{H}$ but require an exponential number of nodes ("neurons").

Result 3 may appear negative at first glance even for the parallel version since it requires an exponentially large number of neurons to encode the lower level dictionaries. But it may relate to one of the more surprising facts about the visual cortex in monkeys and humans, if we identify the nodes of the compositional models with neurons in the visual cortex, namely that the first two visual areas, V1 and V2, where low-level dictionaries would be implemented are enormous compared to the higher levels such as IT where object detection takes places. Current models of V1 and V2 mostly relegate them to being a large filter bank which seems paradoxical considering their size. For example, Lennie (1998) has stated when reviewing the functions of V1 and V2 "perhaps the most troublesome objection to the picture I have delivered is that an enormous amount of cortex is used to achieve remarkably little". Perhaps the size of these visual areas is because they are encoding dictionaries of visual appearance.

6. Discussion

This section discusses three important topics. Section (6.1) discusses the relation of compositional models to the more traditional bio-inspired hierarchical models, such as deep convolutional networks. In section (6.2) we briefly describe how compositional models can be learnt in an unsupervised manner. Section (6.3) describes how to extend compositional models to make them more robust, and describes an analysis of robustness which is presented in detail in Appendix A.

6.1 Compositional Models and Bio-inspired Hierarchical Architectures

The parallel compositional architecture described in the last two sections has several similarities to bio-inspired models and in particular to deep convolutional networks Krizhevsky et al. (2012). The graphical structures of the models are similar and the nodes at each level of the hierarchy are indexed by position in the image lattice and by the type of the part, or correspondingly, the index of the feature detector (i.e. the class of feature detectors in a convolutional network corresponds to the set of part types for compositional models).

But there are also several differences which we now discuss. Compositional models were developed from the literature on deformable template models of objects where the representation of objects parts and spatial relations is fundamental. These deformable template models are designed to detect the parts of objects and not simply to detect which objects are present in an image. Compositional models, and the closely related grammar models, enable parts to be shared between multiple objects while, by contrast, bio-inspired models share features.

In particular, compositional models have explicit part-subpart relationships which enable them to represent spatial relations explicitly and to perform tasks like parsing in addition to detection. These part-subpart relations are learnt by hierarchical clustering algorithms Zhu et al. (2008, 2010) so that a part is composed from r subparts and the spatial relations between the subparts are explicitly modeled. This differs from the way that features are related in convolutional networks. The difference is most apparent at the final layers where convolutional networks are fully connected (i.e. all features at the top-level can be used for all objects) while compositional models still restrict the objects to be composed of r subparts. In other words, the final level of a compositional model is exactly the same as all the previous levels (i.e. it does not extract hierarchical features using one learning algorithm and then learn a classifier on top).

In addition, the compositional models are generative. This has several advantages including the possibility of dealing robustly with occlusion and missing parts, as we discuss in the next section, and the ability (in principle) to synthesize images of the object by activating top-level object nodes. These abilities suggest models for visual attention and other top-down processing.

Using this compositional architecture, the inference is performed by a bottom-up process which propagates hypotheses (for the states of nodes at the low-levels of the hierarchy) up the hierarchy. As they ascend the hierarchy they have access to more information about the image (i.e. the higher level nodes represent larger parts of the image) and hence become less ambiguous. A top-down process is used to disambiguate the lower level hypotheses using the context provided by the higher level nodes – "high-level tells low-level to stop gossiping". We stress that this is exact inference – similar (and sometimes identical) to dynamic programming on probabilistic context free grammars. Hence, as implemented in the compositional architecture, we see that we can have generative models of many objects but we can nevertheless perform inference rapidly by bottom-up processing followed by top-down stage which determines the positions of the object parts/subparts by eliminating false hypotheses.

More technically, we now specify a rough translation between compositional models and deep convolutional neural networks (DCNNs). The types τ in compositional models

translate into the feature channels of DCNNs. The local evidence $\phi(x_\nu, \tau_\nu)$ for type τ at position x_ν corresponds to the activation $z_{i,k}$ of the k^{th} channel at position i in a DCNN. If we ignore max-pooling, for simplicity, the DCNN will have update rule:

$$\phi(x_\nu, \tau_\nu) = \sum_{i, x_{\nu_i}} \omega_{i, x_{\nu_i}} \max\{0, \phi(x_{\nu_i}, \tau_{\nu_i})\},$$

with weights $\omega_{i,x_{\nu_i}}$ and where the summation is over the child nodes ν_i and over their positions x_{ν_i}. The max-pooling replaces $\phi(x_{\nu_i}, \tau_{\nu_i})$ by $\max_{y \in Nbh(x_{\nu_i})} \phi(y, \tau_{\nu_i})$, where $Nbh(x_{\nu_i})$ is a spatial neighbourhood centered on x_{ν_i}. Hence both update rules involve maximization steps but for DCNNs they are independent for each feature channel and for compositional models they depend on the states of all the children. DCNN includes weights $\omega_{i,x_{\nu_i}}$, which are trained discriminatively by backpropagation, while compositional models use probabilities $P(x_{Ch(\nu)}|x_\nu, \tau_\nu)$. The learning for compositional models is unsupervised and is discussed in section (6.2).

6.2 Unsupervised Learning

This section briefly sketches the unsupervised learning algorithm. We refer to Zhu et al. (2008, 2010); Yuille (2011) for more details. The strategy is hierarchical clustering which proceeds by recursively learning the dictionaries.

We start with a level-0 dictionary of parts $\tau \in \mathcal{M}_0$ with associated models $P(I(x)|\tau)$ and a default distribution $P(I(x)|\tau_0)$. These are assumed as inputs to the learning process. But they could be learnt by unsupervised learning as in Papandreou et al. (2014); Mao et al. (2014).

Then we select a threshold T_0 and for each level-0 type $\tau \in \mathcal{M}_0$ we detect a set of image positions $\{x_i^\tau : i = 1, ..., N\}$ where the log-likelihood test for τ is above threshold, i.e. $\log \frac{P(I(x_i^\tau)|\tau)}{P(I(x)|\tau_0)} > T_0$. This corresponds to the set of places where the part has been detected. This process depends on the threshold T_0 which will be discussed later.

Next we seek compositions of parts that occur frequently together with regular spatial arrangements. This is performed by clustering the detected parts using a set of probabilistic models of form $h(x_{\tau_1}, ..., x_{\tau_r}; \lambda)$, see equation (1), to estimate the λ's (the clustering is done separately for different combinations of level-0 types). This yields the level-1 dictionary $\mathcal{M}_1$, where each level-1 part is described by a probability distribution specified by the types of its children $\tau_1, ..., \tau_r$ and the spatial relations given by $h(.,.,...;\lambda)$. We then repeat the process. More specifically, we detect level-1 parts using the log-likelihood ratio test with a threshold T_1 and perform clustering to create the level-2 dictionary $\mathcal{M}_2$. We continue recursively using detected parts as inputs to another spatial clustering stage. The process terminates automatically when we fail to detect any new clusters. This will depend on our choice of clusters, the detection thresholds, and a threshold on the number of instances needed to constitute a cluster. For more details see Zhu et al. (2008, 2010). The whole process can be interpreted as a breadth first search through the space of possible generative models of the image, see Yuille (2011).

6.3 Robust Compositional Models

It is also important to study the robustness of compositional models when some parts are undetected. This is an important issue because objects can often be partially occluded in which case some parts are not observed directly. Also some forms of inference require thresholding the log-likelihood ratios of objects to determine if they have been detected (i.e. without waiting to detect the complete object) and we need to understand what happens for the false negatives when we threshold the log-likelihoods. As described above, thresholding is also used during learning, which gives more motivation for understanding the errors it causes and how to minimize them. Finally, we note that any realistic neural implementation of compositional models must be robust to failures of neural elements.

These issues were addressed in previous work Zhu et al. (2008, 2010) which showed empirically that compositional models could be made robust to some errors of this type. This section briefly describes some of these extensions. In addition to the motivations given above, we also want ways to extend compositional models to allow for parts to have variable numbers of subparts or to be partially invariant to image transformations. Firstly, the part-subpart distributions $P(\vec{x}_{Ch(\nu)}|x_\nu, \tau_\nu)$ were made insensitive to rotations and expansions in the image plane. Secondly, the 2-out-of-3 rule (described below) made the model robust to failure to detect parts or to malfunctioning neurons. Thirdly, the imaging terms could be extended so that the model generates image features (instead of the image values directly) and could include direct image input to higher levels. All these extensions were successfully tested on natural images Zhu et al. (2008, 2010).

The 2-out-of-3 rule is described as follows. In our implementations Zhu et al. (2008, 2010) a part-subpart composition has three subparts. The 2-out-of-3 rule allowed the parent node to be activated if only two subparts were detected, even if the image response at the third part is inconsistent with the object (e.g., if the object is partially occluded). The intuition is that if two parts are detected then the spatial relations between the parts, embedded in the term $h(\vec{x}; \lambda_\nu)$ of $P(\vec{x}_{Ch(\nu)}|x_\nu, \tau_\nu)$, is sufficient to predict the position of the third part. This can be used during inference while paying a penalty for not detecting the part. From another perspective, this is equivalent to having a mixture of different part-subparts compositions where the part could correspond to three subparts or two subparts. This can be extended to allow a larger range of possible subpart combinations thereby increasing the flexibility. Note that this would not affect the computational time for a parallel model.

We analyzed the robustness of the 2-out-of-3 rule when parts are missing. This analysis is presented in appendix A. It shows that provided the probability of detecting each part is above a threshold value (assuming the part is present) then the probability of detecting the entire object correctly tends to 1 as the number of levels of the hierarchy increases.

7. Summary

This paper provides a complexity analysis of what is arguably one of the most fundamental problem of visions – how, a biological or artificial vision system could rapidly detect and recognize an enormous number of different objects. We focus on a class of hierarchical compositional models Zhu et al. (2008, 2010) whose formulation makes it possible to perform this analysis. We conjecture that similar results, exploiting the sharing of parts and hierarchical distributed representations, will apply to the more sophisticated models needed

to address the full complexity of object detection and parsing. Similar results may apply to related bio-inspired hierarchical models of vision (e.g., those cited in the introduction). We argue that understanding complexity is a key issue in the design of artificial intelligent systems and understanding the biological nature of intelligence. Indeed perhaps the major scientific advances this century will involve the study of complexity Hawking (2000). We note that complexity results have been obtained for other visual tasks Blanchard and Geman (2005),Tsotsos (2011).

Technically this paper has required us to re-formulate compositional models to define a compositional architecture which facilitates the sharing of parts. It is noteworthy that we can effectively perform exact inference on a large number of generative image models (of this class) simultaneously using a single architecture. It is interesting to see if this ability can be extended to other classes of graphical models and be related to the literature on rapid ways to do exact inference, see Chavira et al. (2004).

Finally, we note that the parallel inference algorithms used by this class of compositional models have an interesting interpretation in terms of the bottom-up versus top-down debate concerning processing in the visual cortex DiCarlo et al. (2012). The algorithms have rapid parallel inference, in time which is linear in the number of layers, and which rapidly estimates a coarse "executive summary" interpretation of the image. The full interpretation of the image takes longer and requires a top-down pass where the high-level context is able to resolve ambiguities which occur at the lower levels. Of course, for some simple images the local evidence for the low level parts is sufficient to detect the parts in the bottom-up pass and so the top-down pass is not needed. But more generally, in the bottom-up pass the neurons are very active and represent a large number of possible hypotheses which are pruned out during the top-down pass using context, when "high-level tells low-level to stop gossiping".

Acknowledgments

Many of the ideas in this paper were obtained by analyzing models developed by L. Zhu and Y. Chen in collaboration with the first author. G. Papandreou and C. Coryell gave very useful feedback on drafts of this work. D. Kersten gave patient feedback on speculations about how these ideas might relate to the brain. The WCU program at Korea University, under the supervision of S-W Lee, gave peace and time to develop these ideas. We gratefully acknowledge support from the ARO 62250-CS and and the Center for Minds, Brains and Machines (CBMM), funded by NSF STC award CCF-1231216.

Appendix A

We analyze the 2-out-of-3 rule to show its robustness to missing parts. Consider two layers of part-subpart compositions with a parent part, three subparts, and nine sub-subparts. The 2-out-of-3 rule enables us to detect the part even in cases where only four of the nine sub-subparts are detected (provided that one subpart has no sub-subparts detected and the remaining two subparts have two sub-subparts detected each). To study this in more detail, let ρ be the probability of detecting a subpart and $f(\rho)$ be the probability of detecting the

part. Using the 2-out-of-3 rule, we obtain the update rule:

$$\rho_{h+1} = f(\rho_h), \quad \text{with } f(\rho) = \rho^3 + 3\rho^2(1-\rho). \tag{18}$$

We can analyze the robustness of the rule by studying the behavior of the iterative map $\rho_{t+1} = f(\rho_t)$. It can be calculated that there are fixed points at $\rho = 0, 0.5, 1$. Observe that $f(\rho) > \rho$ for $0.5 < \rho < 1$ and $f(\rho) < \rho$ for $0 < \rho < 0.5$, see Figure (13). Hence if the initial value of $\rho < 0.5$ (i.e. the detectors at the leaf nodes miss the object more than half the time) then the iterative map converges to zero and we cannot detect the object. Conversely, if $\rho > 0.5$ (the initial detectors miss parts less than half the time) then the iterative map converges to 1 and we always detect the object if there are a sufficient number of levels.

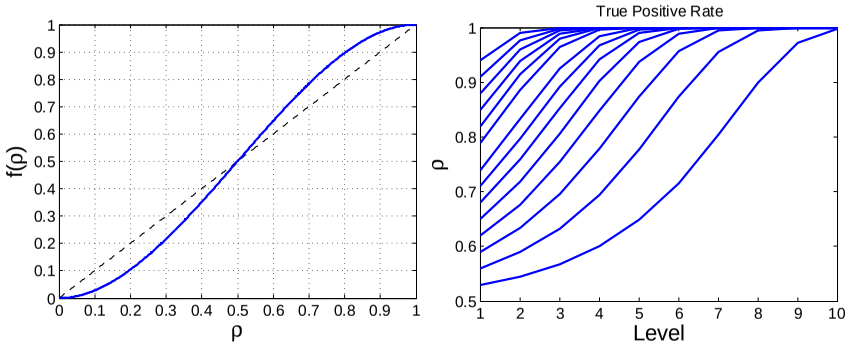


Figure 13: Left Panel: we plot $f(\rho)$ as a function of ρ, showing fixed points at $\rho = 0, 0.5, 1$, and that $f(\rho) > \rho$ for $0.5 < \rho < 1$, but $f(\rho) < \rho$ for $0 < \rho < 0.5$. Right Panel: we show the true positive rate (the detection rate) as a function of the number of levels and in terms of the ρ parameter.

We performed simulations to verify this result and to estimate how many levels are needed to obtain almost perfect detection as a function of ρ. These are shown in Figure (13)(right panel). Observe that if $\rho > 0.6$ then only a small number of levels are needed to get almost perfect performance.

Abstract

This paper considers the problem of subspace clustering under noise. Specifically, we study the behavior of Sparse Subspace Clustering (SSC) when either adversarial or random noise is added to the unlabeled input data points, which are assumed to be in a union of low-dimensional subspaces. We show that a modified version of SSC is *provably effective* in correctly identifying the underlying subspaces, even with noisy data. This extends theoretical guarantee of this algorithm to more practical settings and provides justification to the success of SSC in a class of real applications.

Keywords: Subspace clustering, robustness, stability, compressive sensing, sparse

1. Introduction

Subspace clustering is a problem motivated by many real applications. It is now widely known that many high dimensional data including motion trajectories (Costeira and Kanade, 1998), face images (Basri and Jacobs, 2003), network hop counts (Eriksson et al., 2012), movie ratings (Zhang et al., 2012) and social graphs (Chen et al., 2014) can be modeled as samples drawn from the *union* of multiple low-dimensional linear subspaces (illustrated in Figure 1). Subspace clustering, arguably the most crucial step to understand such data, refers to the task of clustering the data into their original subspaces and uncovering the underlying structure of the data. The partitions correspond to different rigid objects for motion trajectories, different people for face data, subnets for network data, like-minded users in movie database and latent communities for social graph.

Subspace clustering has drawn significant attention in the last decade and a great number of algorithms have been proposed, including Expectation-Maximization-like local optimization algorithms, e.g., K-plane (Bradley and Mangasarian, 2000) and Q-flat (Tseng, 2000), algebraic methods, e.g., Generalized Principal Component Analysis (GPCA) (Vidal et al., 2005), matrix factorization methods (Costeira and Kanade, 1998, 1995), spectral clustering-based methods (Lauer and Schnorr, 2009; Chen and Lerman, 2009), bottom-up local sampling and affinity-based methods (e.g., Yan and Pollefeys, 2006; Rao et al., 2008), and the convex optimization-based methods: namely, Low Rank Representation (LRR) (Liu et al., 2010, 2013) and Sparse Subspace Clustering (SSC) (Elhamifar and Vidal, 2009, 2013). For a comprehensive survey and comparisons, we refer the readers to the tutorial (Vidal, 2010). Among these algorithms, SSC is known to enjoy superb empirical performance, *even for noisy data*. For example, it is the state-of-the-art algorithm for motion segmentation on Hopkins155 benchmark (Tron and Vidal, 2007; Elhamifar and Vidal, 2009), and has been shown to be more robust than LRR as the number of clusters increase (Elhamifar and Vidal, 2013).

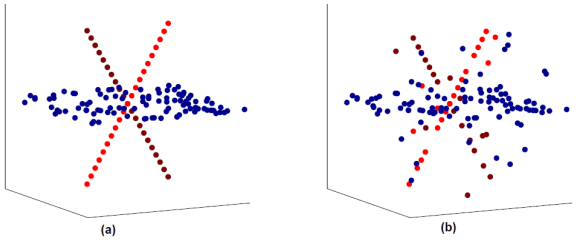

Figure 1: Exact (a) and noisy (b) data in union-of-subspace

The key idea of SSC is to represent each data point by a sparse linear combination of the remaining data points using ℓ_1 minimization. Without introducing the notations (which is deferred in Section 3), the noiseless and noisy versions of SSC solve respectively

$$\min_{c_i} \|c_i\|_1 \quad s.t. \quad x_i = X_{-i}c_i, \qquad \text{and} \qquad \min_{c_i} \|c_i\|_1 + \frac{\lambda}{2}\|x_i - X_{-i}c_i\|^2,$$

for each data column x_i, and the hope is that c_i will be supported only on indices of the data points from the same subspace as x_i. While this formulation is for linear subspaces, affine subspaces can also be dealt with by augmenting data points with an offset variable 1.

Effort has been made to explain the practical success of SSC by analyzing the noiseless version. Elhamifar and Vidal (2010) show that under certain conditions, *disjoint* subspaces (i.e., they are not overlapping) can be exactly recovered. A recent geometric analysis of SSC (Soltanolkotabi et al., 2012) broadens the scope of the results significantly to the case when subspaces can be overlapping. However, while these analyses advanced our understanding of SSC, one common drawback is that data points are assumed to be lying *exactly* on the subspaces. This assumption can hardly be satisfied in practice. For example, motion trajectories data are only *approximately* of rank-4 due to perspective distortion of camera, tracking errors and pixel quantization (Costeira and Kanade, 1998); similarly, face images are not precisely of rank-9 since human faces are at best *approximated* by a convex body (Basri and Jacobs, 2003).

In this paper, we address this problem and provide a theoretical analysis of SSC with noisy or corrupted data. Our main result shows that a modified version of SSC (see Eq. (3.2)) succeeds when the magnitude of noise does not exceed a threshold determined by a geometric gap between the *inradius* and the *subspace incoherence* (see below for precise definitions). This complements the result of Soltanolkotabi et al. (2012) that shows the

same geometric gap determines whether SSC succeeds for the noiseless case. Indeed, when the noise vanishes, our results reduce to the noiseless case results of Soltanolkotabi et al..

While our analysis is based upon the geometric analysis of Soltanolkotabi et al. (2012), the analysis is more involved: In SSC, sample points are used as the dictionary for sparse recovery, and therefore noisy SSC requires analyzing a noisy dictionary. We also remark that our results on noisy SSC are *exact*, i.e., as long as the noise magnitude is smaller than a threshold, the recovered subspace clusters are *correct*. This is in sharp contrast to the majority of previous work on structure recovery for noisy data where stability/perturbation bounds are given—i.e., the obtained solution is *approximately* correct, and the approximation gap goes to zero only when the noise diminishes.

Lastly, we remark that an independently developed work (Soltanolkotabi et al., 2014) analyzed the same algorithm *under a statistical model* that generates the data. In contrast, our main results focus on the cases when the data are deterministic. Moreover, when we specialize our general result to the same statistical model, we show that we can handle a significantly larger amount of noise under certain regimes.

The paper is organized as follows. In Section 2, we review previous and ongoing works related to this paper. In Section 3, we formally define the notations, explain our method and the models of our analysis. Then we present our main theoretical results in Section 4 with examples and remarks to explain the practical implications of each theorem. In Section 5 and 6, proofs of the deterministic and randomized results are provided. We then evaluate our method experimentally in Section 7 with both synthetic data and real-life data, which confirms the prediction of the theoretical results. Lastly, Section 8 summarizes the paper and discuss some open problems for future research in the task of subspace clustering.

2. Related works

In this section, we review previous and ongoing theoretical studies on the problem of subspace clustering.

2.1 Nominal performance guarantee for noiseless data

Most previous analyses concern about the nominal performance of a particular subspace clustering algorithm with noiseless data. The focus is to relax the assumptions on the underlying subspaces and data generation.

A number of methods have been shown working under the *independent subspace* assumption including the early factorization-based methods (Costeira and Kanade, 1998; Kanatani, 2001), LRR (Liu et al., 2010) and the initial guarantee of SSC (Elhamifar and Vidal, 2009). Recall that the data points are drawn from a union of subspaces, the *independent subspace* assumption requires each subspace to be linearly independent to the *span* of all other subspaces. Equivalently, this assumption requires the sum of each subspace's dimension to be equal to the dimension of the span of all subspaces. For example, in a two dimensional plane, one can only have 2 independent lines. If there are three lines intersecting at the origin, even if each pair of the lines are independent, they are not considered independent as a whole.

Independent Subspaces	$\dim[\mathcal{S}_1 \otimes ... \otimes \mathcal{S}_L] = \sum_{\ell=1}^{L} \dim[\mathcal{S}_\ell]$.
Disjoint Subspaces	$\mathcal{S}_\ell \cap \mathcal{S}_k = \mathbf{0}$ for all $\{(\ell, k) \vert \ell \neq k\}$.
Overlapping Subspaces	$\mathcal{S}_\ell \neq \mathcal{S}_k$ for all $\{(\ell, k) \vert \ell \neq k\}$ [1].

Table 1: Comparison of conditions on the underlying subspaces.

Disjoint subspace assumption only requires pairwise linear independence, and hence is more meaningful in practice. To the best of our knowledge, only GPCA (Vidal et al., 2005) and SSC (Elhamifar and Vidal, 2010, 2013) have been shown to provably handle the data under *disjoint subspace* assumption. GPCA however is not a polynomial time algorithm. Its computational complexity increases exponentially with respect to the number and dimension of the subspaces.

Soltanolkotabi et al. (2012) developed a geometric analysis that further extends the performance guarantee of SSC, and in particular it covers some cases when the underlying subspaces are *overlapping*, meaning that two subspaces can even share a basis. The analysis reveals that the success of SSC relies on the difference of two geometric quantities (inradius r and incoherence μ) to be greater than 0, which leads to by far the most general and strongest theoretical guarantee for noiseless SSC. A summary of these assumptions on the subspaces and their formal definition are given in Table 1.

We remark that our robust analysis extends from Soltanolkotabi et al. (2012) and therefore is inherently capable of handling the same range of problems, namely disjoint and overlapping subspaces. This is formalized later in Section 4.

2.2 Robust performance guarantee

Previous studies of the subspace clustering under noise have been mostly empirical. For instance, factorization, spectral clustering and local affinity based approaches, which we mentioned above, are able to produce a (sometimes good) solution even for noisy real data. Convex optimization based approaches like LRR and SSC can be naturally reformulated as a robust method by relaxing the hard equality constraints to a penalty term in the objective function. In fact, the superior results of SSC and LRR on motion segmentation and face clustering data are produced using the robust extension in Elhamifar and Vidal (2009) and Liu et al. (2010) instead of the well-studied noiseless version.

As of writing, there have been very few subspace clustering methods that is guaranteed to work when data are noisy. Besides the conference version of the current paper (Wang and Xu, 2013), an independent work (Soltanolkotabi et al., 2014) also analyzed SSC under noise. Subsequently, there has been noisy guarantees for other algorithms, e.g., thresholding based approach (Heckel and Bölcskei, 2013) and orthogonal matching pursuit (Dyer et al., 2013). The main difference between our work and Soltanolkotabi et al. (2014) is that our guarantee works for a more general set of problems when the data and noise may not be

1. "Overlapping subspace model" does not need any additional assumptions on subspaces, as long as the subspace membership for every data point is properly defined to resolve the identifiability issues. For instance, if data point $x \in \mathcal{S}_\ell \cap \mathcal{S}_k$, it is reasonable to assume x is from either $\mathcal{S}_\ell$ or $\mathcal{S}_k$; and SSC might be successful in clustering x to either $\mathcal{S}_\ell$ or $\mathcal{S}_k$, when their corresponding separation conditions hold. In fact, the separation conditions in Soltanolkotabi et al. (2012) could hold even if one subspace is completely contained in another.

	This paper	(Wang and Xu, 2013)	Soltanolkotabi et al. (2014)
Fully deterministic	$O(r(r-\mu))$	$O(r(r-\mu))$	N.A.
Deterministic + random noise	$O((n/d)^{\frac{1}{4}}(r-\mu))$	$O(r-\mu)$	N.A.
Semi-random data + random noise	$O\left(\frac{n^{\frac{1}{4}}}{\sqrt{d}}(1-\frac{\text{aff}}{\sqrt{d}})\right)$	$O\left(\frac{1}{\sqrt{d}}(1-\frac{\text{aff}}{\sqrt{d}})\right)$	$O\left(1-\frac{\text{aff}}{\sqrt{d}}\right)$
Fully-random data + random noise	$O\left(\frac{n^{\frac{1}{4}}}{\sqrt{d}}(1-\frac{\sqrt{d}}{\sqrt{n}})\right)$	$O\left(\frac{1}{\sqrt{d}}(1-\frac{\sqrt{d}}{\sqrt{n}})\right)$	$O\left(1-\frac{\sqrt{d}}{\sqrt{n}}\right)$

Table 2: Comparison of the level of noise tolerable for noisy subspace clustering methods. Note that "aff" is the *unnormalized* affinity defined in Soltanolkotabi et al. (2012)

.

random, whereas the key arguments in the proof in Soltanolkotabi et al. (2014) rely on the assumption that data points are uniformly distributed on the unit sphere within each subspace, which corresponds to the "semi-random model" in our paper. As illustrated in Elhamifar and Vidal (2013, Figure 9 and 10), the semi-random model is not a good fit for either the motion segmentation and the face clustering data sets, as in these data sets there is a fast decay in the singular values of each subspace. The uniform distribution assumption becomes even harder to justify as the dimension d of each subspace gets larger—a regime where the analysis in Soltanolkotabi et al. (2014) focuses on.

Moreover, with a minor modification in our analysis that sharpens the bound of the tuning parameter that ensures the solution is non-trivial, we are able to get a result that is stronger than Soltanolkotabi et al. (2014) in cases when the dimension of each subspace $d \leq O(\sqrt{n})$ [2]. This result extends the provably guarantee of SSC to a setting where the signal to noise ratio (SnR) is allowed to go to 0 as the ambient dimension gets large. In summary, we compare our results in terms of the level of noise that can be provably tolerated in Table 2. These comparisons are in the same setting modulo some slight differences in the noise model and successful criteria. It is worth noting that when $d > O(\sqrt{n})$, Soltanolkotabi et al. (2014)'s bound is sharper. We will provide more details in the Appendix.

Lastly, we note that the notion of robustness in this paper is confined to the noise/arbitrary corruptions added to the legitimate data. It is not the robustness against outliers in the data, unless otherwise specified. Handling outliers is a completely different problem. Solutions have been proposed for LRR in Liu et al. (2012) by decomposing a $\ell_{2,1}$ norm column-wise sparse components and for SSC in Soltanolkotabi et al. (2012) by objective value thresholding. However these results require non-outlier data points to be free of noise, therefore are not comparable to the study in this paper.

3. Problem setup

In this section, we specify the notations that will be use throughout the paper and explain the formal problem setup.

2. Admittedly, Soltanolkotabi et al. (2014) obtained better noise-tolerance than the comparable result in our conference version (Wang and Xu, 2013).

3.1 Notations

We denote the uncorrupted data matrix by $Y \in \mathbb{R}^{n\times N}$, where each column of Y (normalized to unit vector [3]) belongs to a union of L subspaces

$$\mathcal{S}_1 \cup \mathcal{S}_2 \cup ... \cup \mathcal{S}_L.$$

Each subspace $\mathcal{S}_\ell$ is of dimension d_ℓ and contains N_ℓ data samples with $N_1 + N_2 + ... + N_L = N$. We observe the noisy data matrix $X = Y + Z$, where Z is some arbitrary noise matrix. Let $Y^{(\ell)} \in \mathbb{R}^{n\times N_\ell}$ denote the selection of columns in Y that belongs to $\mathcal{S}_\ell$, and denote the corresponding columns in X and Z by $X^{(\ell)}$ and $Z^{(\ell)}$ respectively. Without loss of generality, let $X = [X^{(1)}, X^{(2)}, ..., X^{(L)}]$ be ordered. In addition, we use subscript "$-i$" to represent a matrix that excludes column i, e.g., $X^{(\ell)}_{-i} = [x^{(\ell)}_1, ..., x^{(\ell)}_{i-1}, x^{(\ell)}_{i+1}, ..., x^{(\ell)}_{N_\ell}]$. Calligraphic letters such as $\mathcal{X}, \mathcal{Y}_\ell$ represent the set containing all columns of the corresponding matrix (e.g., X and $Y^{(\ell)}$).

For any matrix X, $\mathcal{P}(X)$ represents the symmetrized convex hull of its columns, i.e., $\mathcal{P}(X) = \text{conv}(\pm\mathcal{X})$. Also let $\mathcal{P}^{(\ell)}_{-i} := \mathcal{P}(X^{(\ell)}_{-i})$ and $\mathcal{Q}^{(\ell)}_{-i} := \mathcal{P}(Y^{(\ell)}_{-i})$ for short. $\mathbb{P}_{\mathcal{S}}$ and $\text{Proj}_{\mathcal{S}}$ denote respectively the projection matrix and projection operator (acting on a set) to subspace $\mathcal{S}$. Throughout the paper, $\|\cdot\|$ represents 2-norm for vectors and operator norm for matrices; other norms will be explicitly specified (e.g., $\|\cdot\|_1, \|\cdot\|_\infty$).

3.2 Method and the criterion of success

Original SSC solves the linear program

$$\min_{c_i} \|c_i\|_1 \quad s.t. \quad x_i = X_{-i}c_i, \tag{3.1}$$

for each data point x_i. Solutions are arranged into matrix $C = [c_1, ..., c_N]$, then spectral clustering techniques such as Ng et al. (2002) are applied on the affinity matrix $W = |C| + |C|^T$ ($|\cdot|$ represents entrywise absolute value). Note that when $Z \neq 0$, this method breaks down: indeed (3.1) may even be infeasible.

To handle noisy X, a natural extension is to relax the equality constraint in (3.1) and solve the following unconstrained minimization problem instead (Elhamifar and Vidal, 2013):

$$\min_{c_i} \|c_i\|_1 + \frac{\lambda}{2}\|x_i - X_{-i}c_i\|^2. \tag{3.2}$$

We will focus on Formulation (3.2) in this paper. Notice that (3.2) coincides with standard LASSO. Yet, since our task is subspace clustering, the analysis of LASSO (mainly for the task of support recovery) does not extend to SSC. In particular, existing literature for LASSO to succeed requires the dictionary X_{-i} to satisfy the Restricted Isometry Property (RIP for short; Candès, 2008) or the Null-space property (Donoho et al., 2006), but neither of them is satisfied in the subspace clustering setup.[4]

3. We assume the normalization condition for ease of presentation. Our results can be extended to the case when each column of the noisy data points $X = Y + Z$ is normalized, as well as the case where no normalizing is performed at all, under simple modifications to the conditions.

4. As a simple illustrative example, suppose X obeys RIP and x be the first column of X, matrix $[X, x]$ violates RIP for 2-sparse signal $(1, 0, ..., 0, -1)$. On the contrary, the inradius of X and $[X, x]$ will be exactly the same.

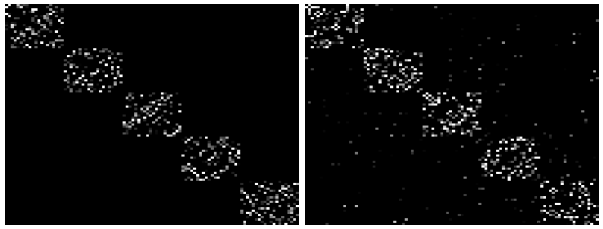

Figure 2: Illustration of LASSO-Subspace Detection Property/Self-Expressiveness Property. **Left:** SEP holds. **Right:** SEP is violated even though spectral clustering is likely to cluster this affinity graph perfectly into 5 blocks.

In the subspace clustering task, there is no single "ground-truth" C to compare the solution against. Instead, the algorithm succeeds if each sample is expressed as a linear combination of samples belonging to the same subspace, as the following definition states.

Definition 1 (LASSO Subspace Detection Property) *We say the subspaces $\{\mathcal{S}_\ell\}_{\ell=1}^k$ and noisy sample points X from these subspaces obey LASSO subspace detection property with parameter λ, if and only if it holds that for all i, the optimal solution c_i to* (3.2) *with parameter λ satisfies:*

(1) c_i is not a zero vector, i.e., the solution is non-trivial, (2) Nonzero entries of c_i correspond to only columns of X sampled from the same subspace as x_i.

This property ensures that the output matrix C and (naturally) the affinity matrix W are exactly block diagonal with each subspace cluster represented by a disjoint block. The property is illustrated in Figure 2. For convenience, we will refer to the second requirement alone as "*Self-Expressiveness Property*" (SEP), as defined in Elhamifar and Vidal (2013).

Note that the LASSO Subspace Detection Property is a strong condition. In practice, spectral clustering does not require the exact block diagonal structure for perfect segmentation (check Figure 8b in our simulation section for details). A caveat is that it is also not sufficient for perfect segmentation, since it does not guarantee each diagonal block forms a connected component. This is a known problem for SSC (Nasihatkon and Hartley, 2011), although we observe that in practice graph connectivity is usually not a big issue. Proving the high-confidence connectivity (even under probabilistic models) remains an open problem, except for the almost trivial cases when the subspaces are independent (Liu et al., 2013; Wang et al., 2013).

3.3 Models of analysis:

Our objective here is to provide sufficient conditions upon which the LASSO subspace detection properties hold in the four models given in Table 2, ranging from fully deterministic to fully random. Precise definitions of these models will be given in Section 4.

4. Main results

In this section, we present our theoretical guarantee for LASSO-SSC under the four aforementioned models. We will start by describing subspace clustering for a fixed dataset where each data point can be perturbed by an arbitrary noise of bounded size. Then we will incrementally add stochastic assumptions and state the corresponding results with conditions that reveal explicit dependence on parameters of the model.

4.1 Deterministic model

We start by defining two concepts adapted from the original proposal of Soltanolkotabi et al. (2012).

Definition 2 (Projected Dual Direction) *Let ν be the optimal solution to the dual optimization program*[5]

$$\max_{\nu} \langle x, \nu \rangle - \frac{1}{2\lambda}\nu^T\nu, \quad \textit{subject to:} \quad \|X^T\nu\|_\infty \leq 1;$$

and $\mathcal{S}$ is a low-dimensional subspace. The projected dual direction *v is defined as*

$$v(x, X, \mathcal{S}, \lambda) \triangleq \frac{\mathbb{P}_{\mathcal{S}}\nu}{\|\mathbb{P}_{\mathcal{S}}\nu\|}.$$

Definition 3 (Projected Subspace Incoherence Property) *Compactly denote projected dual direction $v_i^{(\ell)} = v(x_i^{(\ell)}, X_{-i}^{(\ell)}, \mathcal{S}_\ell, \lambda)$ and $V^{(\ell)} = [v_1^{(\ell)}, ..., v_{N_\ell}^{(\ell)}]$. We say that vector set $\mathcal{X}_\ell$ is μ-incoherent to other points if*

$$\mu \geq \mu(\mathcal{X}_\ell) := \max_{y \in \mathcal{Y}\setminus\mathcal{Y}_\ell} \|{V^{(\ell)}}^T y\|_\infty.$$

Here, μ measures the incoherence between corrupted subspace samples $\mathcal{X}_\ell$ and clean data points in other subspaces (illustrated in Figure 4). As $\|y\| = 1$ by the normalization assumption, the range of μ is $[0, 1]$. In case of random subspaces in high dimension, μ is close to zero. Moreover, as we will see later, for deterministic subspaces and random data points, μ is proportional to their expected angular distance (measured by cosine of canonical angles).

Definition 2 and 3 differ from the *dual direction* and *subspace incoherence property* of Soltanolkotabi et al. (2012) in that we require a projection to a particular subspace to cater to the analysis of the noise case. Also, since they reduce to the original definitions when data are noiseless and $\lambda \to \infty$, these definitions can be considered as a generalization of their original version.

Definition 4 (inradius) *The inradius of a convex body $\mathcal{P}$, denoted by $r(\mathcal{P})$, is defined as the radius of the largest Euclidean ball inscribed in $\mathcal{P}$.*

The inradius of a $\mathcal{Q}_{-i}^{(\ell)}$ describes the dispersion of the data points. Well-dispersed data lead to larger inradius and skewed/concentrated distribution of data have small inradius. An illustration is given in Figure 3.

5. This definition is related to (5.3), the dual problem of (3.2), which we will define in the proof.

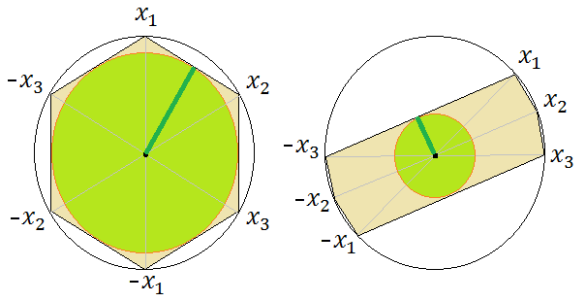

Figure 3: Illustration of inradius and data distribution. The inradius measures how well data points represent a subspace.

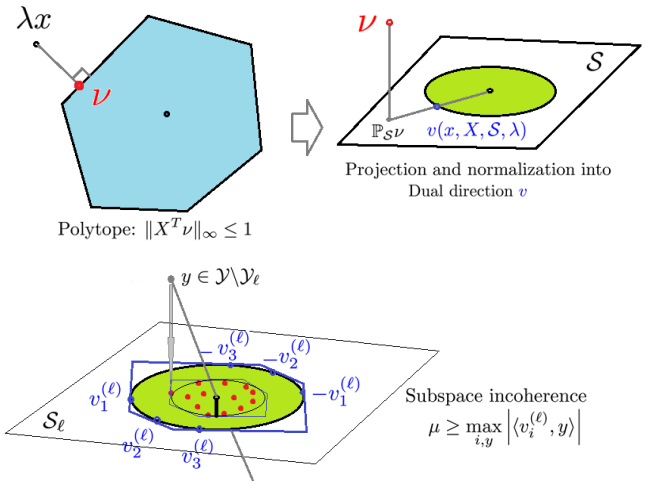

Figure 4: Illustrations of the projected dual direction and subspace incoherence property. The projected dual direction in Definition 2 is essentially an Euclidean projection to the polytope, followed by a projection to the subspace and normalization. There is a dual direction associated with each data point in the subspace. Jointly, $\left\{x \middle| \max_i \left|\langle v_i^{(\ell)}, x\rangle\right| \leq \mu\right\}$ defines a polygon in the subspace $\mathcal{S}_\ell$, and subspace incoherence μ is given by the smallest such polytope that contains the projections of all external point y into the this subspace.

Definition 5 (Deterministic noise model) *Consider arbitrary additive noise Z to Y, each column z_i is bounded by the two quantities below:*

$$\delta := \max_i \|z_i\|, \qquad \delta_1 := \max_{i,\ell} \|\mathbb{P}_{\mathcal{S}_\ell} z_i\|,$$

As we assume the uncorrupted data point y has unit norm, δ essentially describes the amount of allowable relative error.

Theorem 6 *Under the deterministic noise model, compactly denote*

$$\mu_\ell := \mu(\mathcal{X}_\ell), \qquad r_\ell := \min_{\{i:x_i\in\mathcal{X}_\ell\}} r(\mathcal{Q}_{-i}^{(\ell)}), \qquad r := \min_{\ell=1,\ldots,L} r_\ell.$$

If $\mu_\ell < r_\ell$ for each $\ell = 1, ..., L$, furthermore

$$\delta \leq \min_{\ell=1,\ldots,L} \frac{r(r_\ell - \mu_\ell)}{2 + 7r_\ell}$$

then LASSO subspace detection property holds for all weighting parameter λ in the range

$$\frac{1}{r - 2\delta - \delta^2} < \lambda < \min_{\ell=1,\ldots,L} \left\{ \frac{r_\ell - \mu_\ell - 2\delta_1}{\delta(1+\delta)(2 + r_\ell - \delta_1)} \right\}$$

which is guaranteed to be non-empty.

We now offer some discussions of the theorem and the proof will be given in Section 5.

Noiseless case. When $\delta = 0$, i.e., there is no noise, the condition reduces to $\mu_\ell < r_\ell$, which coincides with the result in Soltanolkotabi et al. (2012). The exact LP formulation (3.1) is equivalent to $\lambda \to \infty$. Our result implies that unconstrained LASSO formulation (3.2) works for any $\lambda > \frac{1}{r}$.

Signal-to-Noise Ratio. Condition $\delta \leq \frac{r(r-\mu)}{2+7r}$ can be interpreted as the breaking point under increasing magnitude of attack. This suggests that SSC by (3.2) is provably robust to arbitrary noise having signal-to-noise ratio (SnR) greater than $\Theta\left(\frac{1}{r(r-\mu)}\right)$. (Notice that $0 < r < 1$, and hence $7r + 2 = \Theta(1)$.)

Tuning parameter λ. The range of the parameter λ in the theorem depends on unknown parameters μ, r and δ, and therefore cannot be used in practice to choose the parameter in practice. It does however justify that when δ is small, the range of λ that LASSO-SSC works is large, therefore not hard to tune. In practice, we do not need to know λ in prior. One approach is to trace the Lasso path (Tibshirani et al., 2013) until we have about k non-zero entries in the coefficient vector. If we would like to use a single λ for all columns, a good point to start is to take λ to be in the order of $O\left(\frac{1}{\min_j \max_{i\neq j} |x_i^T x_j|}\right)$, this ensures the solution to be at least non-trivial.

Agnostic subspace clustering. The robustness to deterministic error is important, since in practice the union-of-subspace structures are usually only good approximations.

If each subspace has decaying singular values (e.g., motion segmentation, face clustering (Elhamifar and Vidal, 2013) and hybrid system identification(Vidal et al., 2003)), the deterministic guarantee allows for the flexibility in choosing the cut-off points, e.g., take 90% of the energy as signal and treat the remaining spectrum as noise. If one keeps a smaller number of singular values (a smaller subspace dimension), the inradius will likely to be larger [6], although the noise level also increases. It is possible that the conditions in Theorem 6 are satisfied for some decomposition (e.g., those with a large spectral gap) but not others. The nice thing is that this is not a tuning parameter, but rather a theoretical property that remains agnostic to the users. In fact, the algorithm will be provably effective as long as the conditions are satisfied for any signal noise decomposition (not restricted to rank-projection). None of these is possible if distributional assumptions are made to either the data or the noise.

4.2 Randomized models

We further analyze three randomized models with increasing level of randomness.

- **Deterministic+Random Noise.** Subspaces and samples in subspace are arbitrary; the noise obeys the Random Noise model (Definition 7).
- **Semi-random+Random Noise.** Subspace is deterministic, but samples in each subspace are drawn iid uniformly from the intersection of the unit sphere and the subspace; the noise obeys the Random Noise model.
- **Fully random.** Both subspace and samples are drawn uniformly at random from their respective domains; the noise is iid Gaussian.

In each of these models, we improve the performance guarantee over our conference version (Wang and Xu, 2013). In the most well-studied semi-random model, we are able to handle cases where the noise level is much larger than the signal, and hence improves upon the best known result for SSC Soltanolkotabi et al. (2014). A detailed comparison of the noise tolerance of these methods is given in Table 2.

Definition 7 (Random noise model) *Our random noise model is defined to be any additive Z that is (1) column wise iid; (2) spherical symmetric; and (3) $\|z_i\| \leq \delta$ for all $i = 1, ..., N$ with probability at least $1 - 1/N$.*

A good example of our random noise model is iid Gaussian noise. Let each entry $Z_{ij} \sim N(0, \sigma^2/n)$. It is known that (see Lemma 18) for some constant C

$$\mathbb{P}\left(\delta := \max_i \|z_i\| > \sqrt{1 + \frac{6\log N}{n}}\sigma\right) \leq C/N^2.$$

Theorem 8 (Deterministic+Random Noise) *Under random noise model, compactly denote r_ℓ, r and μ_ℓ as in Theorem 6, furthermore let*

$$\epsilon := \sqrt{\frac{6\log N}{n - \max_\ell d_\ell}} \leq \sqrt{\frac{C\log(N)}{n}}.$$

6. A formal relationship between inradius and smallest singular value is described in Wang et al. (2013).

If $\mu_\ell < r_\ell$ for all $\ell = 1, ..., k$,

$$\epsilon\delta < \min_{\ell=1,..,L} \frac{r_\ell - \mu_\ell}{2\sqrt{d_\ell} + 2}, \qquad \text{and} \qquad \epsilon\delta(1+\delta) < \min_{\ell=1,..,L} \frac{r(r_\ell - \mu_\ell)}{4r_\ell + 6},$$

then with probability at least $1 - 9/N$, LASSO subspace detection property holds for all weighting parameter λ in the range

$$\frac{1}{r - 2\epsilon\delta - \epsilon\delta^2} < \lambda < \min_{\ell=1,..,L} \left\{ \frac{r_\ell - \mu_\ell - \delta\epsilon - \delta\sqrt{d_\ell}\epsilon}{\epsilon\delta(1+\delta)(3 + r_\ell - \delta\sqrt{d_\ell}\epsilon)} \right\} \tag{4.1}$$

which is guaranteed to be non-empty.

Low SnR paradigm. Compared to Theorem 6, Theorem 8 considers a more benign noise which leads to a stronger result. In particular, without assuming any statistical model on how data are generated, we show that LASSO-SSC is able to tolerate noise of level $O\left((\frac{n}{\log N})^{1/4}(r(r_\ell - \mu_\ell))^{1/2}\right)$ or $O\left((\frac{n}{d\log N})^{1/2}(r_\ell - \mu_\ell)\right)$ (whichever is smaller). This extends SSC's guarantee with deterministic data to cases where the noise can be significantly larger than the signal. In fact, the SnR can go to 0 as the ambient dimension gets large.

On the other hand, Theorem 8 shows that LASSO-SSC is able to tolerate a constant level of noise when the geometric gap $r_\ell - \mu_\ell$ is as small as $O(\sqrt{d/n})$. This is arguably near-optimal (when d is small) as the projection of a constant-level random noise into a d-dimensional subspace has an expected magnitude of the same order, which could easily close up the small geometric gap for some non-trivial probability if the noise is much larger.

Margin of error. Since the bound depends critically on $(r_\ell - \mu_\ell)$—the difference of inradius and incoherence—which is the geometric gap that appears in the noiseless guarantee of Soltanolkotabi et al. (2012). We will henceforth call this gap the *margin of error*.

We now analyze this margin of error under different generative models. We start from the semi-random model, where the distance between two subspaces is measured as follows.

Definition 9 *The* affinity *between two subspaces is defined by:*

$$\text{aff}(\mathcal{S}_k, \mathcal{S}_\ell) = \sqrt{\cos^2\theta_{k\ell}^{(1)} + ... + \cos^2\theta_{k\ell}^{(\min(d_k,d_\ell))}},$$

where $\theta_{k\ell}^{(i)}$ is the i^{th} canonical angle between the two subspaces. Let U_k and U_ℓ be a set of orthonormal bases of each subspace, then $\text{aff}(\mathcal{S}_k, \mathcal{S}_\ell) = \|U_k^T U_\ell\|_F$.

When data points are randomly sampled from each subspace, the geometric entity $\mu(\mathcal{X}_\ell)$ can be expressed using this (more intuitive) subspace affinity, which leads to the following theorem.

Theorem 10 (Semi-random model+random noise) *Under the semi-random model with random noise, there exists a non-empty range of λ such that LASSO subspace detection property holds with probability $1 - \frac{9}{N} - \frac{1}{L^2}\sum_{\ell\neq\ell'}\frac{1}{(N_\ell+1)N_{\ell'}}e^{-\frac{t}{4}} - 6\sum_{\ell=1}^{L}(e^{\gamma_1(n-d_\ell)} + e^{\gamma_2 d_\ell} + e^{-\sqrt{N_\ell d_\ell}})$*

as long as the noise level obeys

$$\delta(1+\delta) \le \max_{\ell,\ell'} \sqrt{\frac{n-d}{6\log N}} \frac{\sqrt{\log\kappa}}{40K_2\sqrt{dd_\ell}} \left(1 - \frac{K_1K_2\mathrm{aff}(\mathcal{S}_\ell,\mathcal{S}_{\ell'})}{\sqrt{d_{\ell'}}}\right),$$

where $K_1 := (t\log[(N_\ell+1)N_{\ell'}] + \log L)$, $K_2 := 4\sqrt{\frac{1}{\log\kappa_\ell}}$, $\kappa_\ell := N_\ell/d_\ell$, $\frac{\log\kappa}{d} := \min_\ell \frac{\log\kappa_\ell}{d_\ell}$, *and* γ_1, γ_2 *are absolute constants.*

The proof is essentially substituting the incoherence and inradius parameters in Theorem 8 with meaningful bounds, so Theorem 10 can be regarded as a corollary of Theorem 8.

Overlapping subspaces. Similar to the results in Soltanolkotabi et al. (2012), Theorem 10 demonstrates that LASSO-SSC can handle overlapping subspaces with noisy samples. By Definition 9, $\mathrm{aff}(\mathcal{S}_k, \mathcal{S}_\ell)$ can be small even if $\mathcal{S}_k$ and $\mathcal{S}_\ell$ share a basis.

Comparison to Soltanolkotabi et al. (2014). In the high dimensional setting when $n \gg d$, our result is able to handle the low SnR regime when $\delta = \Theta(n^{1/4}/d^{1/2})$, while Soltanolkotabi et al. (2014) needs δ to be bounded by a small constant.

In the case when d is a constant fraction of n, however, our bound is worse by a factor of $\sqrt{d}$. Soltanolkotabi et al. (2014) is still able to handle a small constant noise while we needs $\delta < O(\frac{1}{\sqrt{d}})$. The suboptimal bound might be due to the fact that we are simply developing the theorem for the semi-random model as a corollary of Theorem 8 and haven not fully exploit the structure of the semi-random model in the proof.

We now turn to the fully random case.

Theorem 11 (Fully random model) *Suppose there are L subspaces each with dimension d, chosen independently and uniformly at random. For each subspace, $\kappa d + 1$ points are chosen independently and uniformly from the unit sphere inside each subspace. Each measurement is corrupted by iid Gaussian noise $\sim N(0, \sigma^2/n)$. Furthermore, if*

$$d < \frac{c(\kappa)^2\log\kappa}{24\log N} n, \qquad \text{and} \qquad \sigma(1+\sigma) < \frac{c(\kappa)^2\log\kappa}{20}\frac{\sqrt{n}}{d},$$

then with probability at least $1 - \frac{10}{N} - Ne^{-\sqrt{\kappa}d}$, the LASSO subspace detection property holds for any λ in the range

$$\frac{C_1\sqrt{d}}{c(\kappa)\sqrt{\log\kappa}} < \lambda < \frac{C_2 c(\kappa)\sqrt{n\log\kappa}}{\sigma\sqrt{d\log N}}, \tag{4.2}$$

which is guaranteed to be non-empty. Here, C_1, C_2 are absolute constants.

The results under this simple model are very interpretable. It provides intuitive guideline in how robustness of LASSO-SSC change with respect to the various parameters of the data. One one hand, it is sensitive to the dimension of each subspace d, since the $\sigma \le \tilde{\Theta}(\frac{n^{1/4}}{\sqrt{d}})$. This dependence on subspace dimension d is not a critical limitation as most interesting applications indeed have very low subspace-dimension, as summarized in Table 3. On the other hand, the dependence on the number of subspaces L (in both $\log\kappa$ and $\log N$ since $N = L(\kappa d + 1)$) is only logarithmic. This suggests that SSC is robust even when there are many clusters, and $Ld \gg n$.

Application	Cluster rank
3D motion segmentation (Costeira and Kanade, 1998)	rank = 4
Face clustering (with shadow) (Basri and Jacobs, 2003)	rank = 9
Diffuse photometric face (Zhou et al., 2007)	rank = 3
Network topology discovery (Eriksson et al., 2012)	rank = 2
Hand writing digits (Hastie and Simard, 1998)	rank = 12
Social graph clustering (Chen et al., 2014)	rank = 1

4.3 Geometric interpretations

A geometric illustration of the condition in Theorem 6 is given in Figure 5 in comparison to the geometric separation condition in the noiseless case.

The left pane depicts the separation condition $\mu_\ell \le r_\ell$ in Theorem 2.5 of Soltanolkotabi et al. (2012). The blue polygon represents the the intersection of halfspaces defined with dual directions that are also the tangent to the red inscribing sphere. More precisely, this is $\left\{x \in \mathcal{S}_\ell \middle| \middle|\langle v_i^\ell, x\rangle\right| \le r_\ell\}$. From our illustration of μ in Figure 4, we can easily tell that $\mu_\ell \le r_\ell$ if and only if the projection of external data points fall inside this solid blue polygon. We call this solid blue polygon the successful region.

The right pane illustrates our guarantee of Theorem 6 under bounded deterministic noise. The successful condition requires that the whole red ball (analogous to uncertainty set in Robust Optimization (Ben-Tal and Nemirovski, 1998; Bertsimas and Sim, 2004)) around each external data point to fall inside the dashed red polygon, which is smaller than the blue polygon by a factor related to the noise level and the inradius.

The successful region is affected by the noise because the design matrix is also arbitrarily perturbed and the dual solution is no longer within each subspace $\mathcal{S}_\ell$. Specifically, as will

become clear in the proof, the key of showing SEP boils down to proving $\langle \nu_i^{(\ell)}, x_j \rangle < 1$ for all pairs of $(\nu_i^{(\ell)}, x_j)$ where

$$\nu_i^{(\ell)} = \arg\max_{\nu} \langle \nu, x_i^{(\ell)} \rangle - \frac{1}{2\lambda}\|\nu\|^2 \text{ s.t. } \|\nu^T X_{-i}^{(\ell)}\|_\infty \le 1,$$

and x_j is any point from another subspace. In the noiseless case we can always take $\nu_i^{(\ell)} \in \mathcal{S}_\ell$ and $\langle \nu_i^{(\ell)}, x_j \rangle \le \frac{\mu_\ell}{r_\ell}$. For noisy data and LASSO-SSC, we can no longer do that. In fact, for any fixed λ, the dual solution will be uniquely determined by a projection of $\lambda x_i^{(\ell)}$ on to the feasible region $\|\nu^T X_{-i}^{(\ell)}\|_\infty \le 1$ (see the first pane of Figure 4). The absolute value of the inner product $\langle \nu_i^{(\ell)}, x_j \rangle$ will depend on the magnitude of the dual solution, especially its component perpendicular to the current subspace. Indeed by carefully choosing the error, we can make $\mathbb{P}_{\mathcal{S}_\ell^\perp}\nu$ very correlated with some external data point x_j.

To illustrate this further, we plot the shape of this feasible region in 3D (see Figure 6(b)). From the feasible region alone, it seems that the magnitude of dual variable can potentially be quite large. Luckily, the quadratic penalty in the objective function allows us to exploit the optimality of the solution ν and bound the "out-of-subspace" component of ν, which results in a much smaller region where the solution can potentially be (given in Figure 6(c)). The region for the "in-subspace" component is also smaller as is shown in Figure 7. A more detailed argument of this is given in Section 5.3 of the proof.

Admittedly, the geometric interpretation under noise is slightly messier than the noiseless case, but it is clear that the largest deterministic noise LASSO-SSC can tolerate must be smaller than geometric gap $r_\ell - \mu_\ell$. Theorem 6 show that a sufficient condition is $\delta \le O(r(r_\ell - \mu_\ell))$. It remains unclear whether this gap can be closed without additional assumptions.

Finally, we note that for the random noise model in Theorem 8, the geometric interpretation is similar, except that the impact of the noise is weakened. Thanks to the randomness and the corresponding concentration of measure, we may bound the reduction of the successful region with a much smaller value comparing to the adversarial noise case.

5. Proof of the Deterministic Result

In this section, we provide the proof for Theorem 6.

Instead of analyzing (3.2) directly, we consider an equivalent constrained version by introducing slack variable e_i:

$$\mathbf{P}_0: \quad \min_{c_i, e_i} \|c_i\|_1 + \frac{\lambda}{2}\|e_i\|^2 \quad s.t. \quad x_i^{(\ell)} = X_{-i}c_i + e_i. \tag{5.1}$$

The constraint can be rewritten as

$$y_i^{(\ell)} + z_i^{(\ell)} = (Y_{-i} + Z_{-i})c_i + e_i. \tag{5.2}$$

The dual program of (5.1) is:

$$\mathbf{D}_0: \quad \max_{\nu} \langle x_i, \nu \rangle - \frac{1}{2\lambda}\nu^T\nu \quad s.t. \quad \|(X_{-i})^T\nu\|_\infty \le 1. \tag{5.3}$$

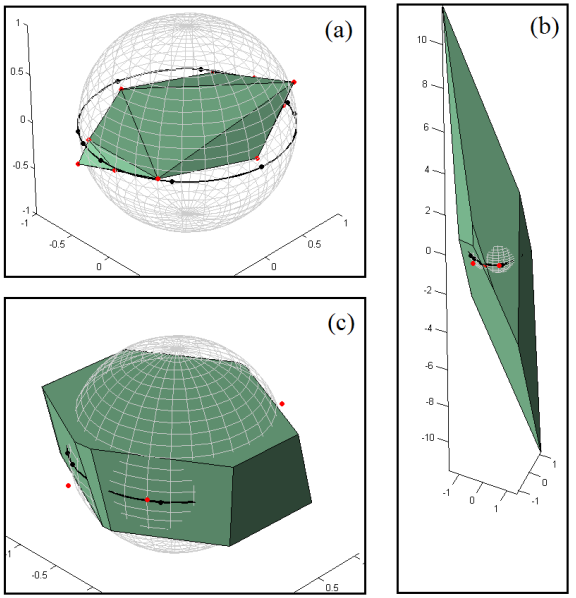

Figure 6: Illustration of **(a)** the convex hull of noisy data points, **(b)** its polar set and **(c)** the intersection of polar set and $\|\nu_2\|$ bound. The polar set (b) defines the feasible region of (5.7). It is clear that ν_2 can take very large value in (b) if we only consider feasibility. By considering optimality, we know the optimal ν must be inside the region in (c).

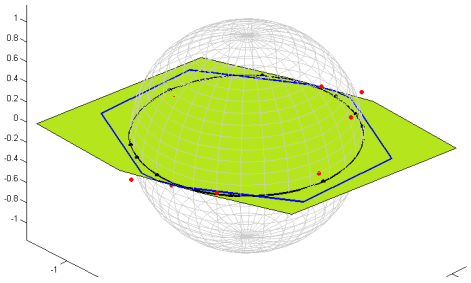

Figure 7: The projection of the polar set (the green area) in comparison to the projection of the polar set with $\|\nu_2\|$ bound (the blue polygon). It is clear that the latter is much smaller.

Recall that we want to establish the conditions on noise magnitude δ, structure of the data (μ and r in the deterministic model and affinity in the semi-random model), and ranges of valid λ such that by Definition 1, the solution c_i is *non-trivial* and has support indices inside the column set $X_{-i}^{(\ell)}$ (i.e., satisfies SEP).

The proof is hence organized into three main steps:

(1) Proving SEP by duality. First we establish a set of conditions on the optimal dual variable of D_0 corresponding to all primal solutions satisfying SEP. Then we construct such a dual variable ν as a certificate of proof. This is presented in Section 5.1, 5.2 and 5.3.

(2) Proving non-trivialness by showing that the optimal value is smaller than the value of the trivial solution (i.e., $c^* = 0$ and $e^* = x_i^{(\ell)}$). This step is given in Section 5.4.

(3) Showing the existence of a proper λ. As it will be made clear later, conditions for (1) include $\lambda < A$ and (2) requires $\lambda > B$ for some expression A and B. Then it is natural to request $B < A$, so that a valid λ exists. It turns out that this condition boils down to $\delta < C$ for some expression C. This argument is carried over in Section 5.5.

5.1 Optimality Condition

Consider a general convex optimization problem:

$$\min_{c,e} \|c\|_1 + \frac{\lambda}{2}\|e\|^2 \qquad s.t. \quad x = Ac + e. \tag{5.4}$$

We state Lemma 12, which extends Lemma 7.1 in Soltanolkotabi et al. (2012).

Lemma 12 *Consider a vector $y \in \mathbb{R}^d$ and a matrix $A \in \mathbb{R}^{d\times N}$. If there exists a triplet (c, e, ν) obeying $y = Ac + e$ and c has support $S \subseteq T$, furthermore the dual certificate vector ν satisfies*

$$A_s^T\nu = \mathrm{sgn}(c_S), \quad \nu = \lambda e, \quad \|A_{T\cap S^c}^T\nu\|_\infty \le 1, \quad \|A_{T^c}^T\nu\|_\infty < 1,$$

then any optimal solution (c^*, e^*) to (5.4) obeys $c^*_{T^c} = 0$.

Proof For optimal solution (c^*, e^*), we have:

$$\begin{aligned}
&\|c^*\|_1 + \frac{\lambda}{2}\|e^*\|^2 \\
=&\|c^*_S\|_1 + \|c^*_{T\cap S^c}\|_1 + \|c^*_{T^c}\|_1 + \frac{\lambda}{2}\|e^*\|^2 \\
\ge&\|c_S\|_1 + \langle \mathrm{sgn}(c_S), c^*_S - c_S\rangle + \|c^*_{T\cap S^c}\|_1 + \|c^*_{T^c}\|_1 + \frac{\lambda}{2}\|e\|^2 + \langle \lambda e, e^* - e\rangle \\
=&\|c_S\|_1 + \langle \nu, A_S(c^*_S - c_S)\rangle + \|c^*_{T\cap S^c}\|_1 + \|c^*_{T^c}\|_1 + \frac{\lambda}{2}\|e\|^2 + \langle \nu, e^* - e\rangle \\
=&\|c_S\|_1 + \frac{\lambda}{2}\|e\|^2 + \|c^*_{T\cap S^c}\|_1 - \langle \nu, A_{T\cap S^c}(c^*_{T\cap S^c})\rangle + \|c^*_{T^c}\|_1 - \langle \nu, A_{T^c}(c^*_{T^c})\rangle.
\end{aligned} \tag{5.5}$$

To see $\frac{\lambda}{2}\|e^*\|^2 \ge \frac{\lambda}{2}\|e\|^2 + \langle \lambda e, e^* - e\rangle$, note that the right hand side equals to $\lambda\left(-\frac{1}{2}e^Te + (e^*)^Te\right)$, which takes a maximal value of $\frac{\lambda}{2}\|e^*\|^2$ when $e = e^*$. The last equation holds because both

(c, e) and (c^*, e^*) are feasible solution, such that $\langle \nu, A(c^* - c)\rangle + \langle \nu, e^* - e\rangle = \langle \nu, Ac^* + e^* - (Ac + e)\rangle = 0$. Also, note that $\|c_S\|_1 + \frac{\lambda}{2}\|e\|^2 = \|c\|_1 + \frac{\lambda}{2}\|e\|^2$.

With the inequality constraints of ν given in the lemma statement, we have

$$\langle \nu, A_{T\cap S^c}(c^*_{T\cap S^c})\rangle = \langle A^T_{T\cap S^c}\nu, (c^*_{T\cap S^c})\rangle \le \|A^T_{T\cap S^c}\nu\|_\infty \|c^*_{T\cap S^c}\|_1 \le \|c^*_{T\cap S^c}\|_1.$$

Substitute into (5.5), we get:

$$\|c^*\|_1 + \frac{\lambda}{2}\|e^*\|^2 \ge \|c\|_1 + \frac{\lambda}{2}\|e\|^2 + (1 - \|A^T_{T^c}\nu\|_\infty)\|c^*_{T^c}\|_1,$$

where $(1 - \|A^T_{T^c}\nu\|_\infty)$ is strictly greater than 0.

Using the fact that (c^*, e^*) is an optimal solution, $\|c^*\|_1 + \frac{\lambda}{2}\|e^*\|^2 \le \|c\|_1 + \frac{\lambda}{2}\|e\|^2$. Therefore, $\|c^*_{T^c}\|_1 = 0$ and (c, e) is also an optimal solution. This concludes the proof. ■

The next step is to apply Lemma 12 with $x = x_i^{(\ell)}$ and $A = X_{-i}$ and then construct a triplet (c, e, ν) such that dual certificate ν satisfying all conditions and c satisfies SEP. Then we can conclude that all optimal solutions of (5.1) satisfy SEP.

5.2 Construction of Dual Certificate

To construct the dual certificate, we consider the following *fictitious* optimization problem (and its dual) that explicitly requires that all feasible solutions satisfy SEP[7] (note that one can not solve such problem in practice without knowing the subspace clusters, and hence the name "fictitious").

$$\mathbf{P}_1: \quad \min_{c_i^{(\ell)}, e_i} \|c_i^{(\ell)}\|_1 + \frac{\lambda}{2}\|e_i\|^2 \quad s.t. \quad y_i^{(\ell)} + z_i = (Y_{-i}^{(\ell)} + Z_{-i}^{(\ell)})c_i^{(\ell)} + e_i; \tag{5.6}$$

$$\mathbf{D}_1: \quad \max_{\nu} \langle x_i^{(\ell)}, \nu\rangle - \frac{1}{2\lambda}\nu^T\nu \quad s.t. \quad \|(X_{-i}^{(\ell)})^T\nu\|_\infty \le 1. \tag{5.7}$$

This optimization problem is feasible because $y_i^{(\ell)} \in span(Y_{-i}^{(\ell)}) = \mathcal{S}_\ell$ so any $c_i^{(\ell)}$ obeying $y_i^{(\ell)} = Y_{-i}^{(\ell)}c_i^{(\ell)}$ and corresponding $e_i = z_i - Z_{-i}^{(\ell)}c_i^{(\ell)}$ is a pair of feasible solution. Then by strong duality, the dual program is also feasible, which implies that for every optimal solution (c, e) of (5.6) with c supported on S, there exist ν satisfying:

$$\left\{\begin{array}{c} \|((Y_{-i}^{(\ell)})^T_{S^c} + (Z_{-i}^{(\ell)})^T_{S^c})\nu\|_\infty \le 1, \quad \nu = \lambda e, \\ ((Y_{-i}^{(\ell)})^T_S + (Z_{-i}^{(\ell)})^T_S)\nu = \mathrm{sgn}(c_S). \end{array}\right\}$$

This construction of ν satisfies all conditions in Lemma 12 with respect to

$$\begin{cases} c_i = [0, ..., 0, c_i^{(\ell)}, 0, ..., 0] \text{ with } c_i^{(\ell)} = c, \\ e_i = e, \end{cases} \tag{5.8}$$

except

$$\left\|[X_1, ..., X_{\ell-1}, X_{\ell+1}, ..., X_L]^T\nu\right\|_\infty < 1,$$

7. To be precise, it is the corresponding $c_i = [0, ..., 0, (c_i^{(\ell)})^T, 0, ..., 0]^T$ that satisfies SEP.

i.e., we must check for all data point $x \in \mathcal{X} \setminus \mathcal{X}^\ell$,

$$|\langle x, \nu \rangle| < 1. \tag{5.9}$$

Thus, if we show that the solution of (5.7) ν also satisfies (5.9), we can conclude that ν is a dual certificate required in Lemma 12, which implies that the candidate solution (5.8) associated with optimal (c, e) of (5.6) is indeed the optimal solution of (5.1) and therefore SEP holds.

5.3 Dual separation condition

Our strategy to show (5.9) is to provide an upper bound of $|\langle x, \nu \rangle|$ then impose the inequality on the upper bound.

First, we find it appropriate to project ν to the subspace $\mathcal{S}_\ell$ and its orthogonal complement subspace then analyze separately. For convenience, denote $\nu_1 := \mathbb{P}_{S_\ell}(\nu)$, $\nu_2 := \mathbb{P}_{\mathcal{S}_\ell^\perp}(\nu)$. Then

$$\begin{aligned} |\langle x, \nu \rangle| =& |\langle y + z, \nu \rangle| \leq |\langle y, \nu_1 \rangle| + |\langle y, \nu_2 \rangle| + |\langle z, \nu \rangle| \\ \leq& \mu(\mathcal{X}_\ell)\|\nu_1\| + \|y\|\|\nu_2\| |\cos(\angle(y, \nu_2))| + \|z\|\|\nu\| |\cos(\angle(z, \nu))|. \end{aligned} \tag{5.10}$$

To see the last inequality, check that by Definition 3, $|\langle y, \frac{\nu_1}{\|\nu_1\|} \rangle| \leq \mu(\mathcal{X}_\ell)$.

Since we are considering general (possibly adversarial) noise, we will use the relaxation $|\cos(\theta)| \leq 1$ for all cosine terms (a better bound under random noise will be given later). Thus, what left is to bound $\|\nu_1\|$ and $\|\nu_2\|$ (note $\|\nu\| = \sqrt{\|\nu_1\|^2 + \|\nu_2\|^2} \leq \|\nu_1\| + \|\nu_2\|$).

5.3.1 Bounding $\|\nu_1\|$

We first bound $\|\nu_1\|$ by exploiting the feasible region of ν_1 in (5.7):

$$\left\{ \nu \middle| \|(X_{-i}^{(\ell)})^T \nu\|_\infty \leq 1 \right\},$$

which is equivalent to

$$\left\{ \nu \middle| x_j^T \nu \leq 1 \quad \text{for every column } x_j \text{ of } X_{-i}^{(\ell)} \right\}.$$

Decompose the condition into

$$y_j^T \nu_1 + (\mathbb{P}_{\mathcal{S}_\ell} z_j)^T \nu_1 + z_j^T \nu_2 \leq 1.$$

and relax the expression into

$$y_j^T \nu_1 + (\mathbb{P}_{\mathcal{S}_\ell} z_j)^T \nu_1 \leq 1 - z_j^T \nu_2 \leq 1 + \delta \|\nu_2\|. \tag{5.11}$$

The relaxed condition contains the feasible region of ν_1 in (5.7). It turns out that the geometric properties of this relaxed feasible region provides an upper bound of $\|\nu_1\|$.

Definition 13 (polar set) *The polar set $\mathcal{K}^o$ of set $\mathcal{K} \in \mathbb{R}^d$ is defined as*

$$\mathcal{K}^o = \left\{ y \in \mathbb{R}^d : \langle x, y \rangle \leq 1 \text{ for all } x \in \mathcal{K} \right\}.$$

By the polytope geometry, we have

$$\|(Y_{-i}^{(\ell)} + \mathbb{P}_{\mathcal{S}_\ell}(Z_{-i}^{(\ell)}))^T \nu_1\|_\infty \leq 1 + \delta\|\nu_2\| \;\Leftrightarrow\; \nu_1 \in \left[\mathcal{P}\left(\frac{Y_{-i}^{(\ell)} + \mathbb{P}_{\mathcal{S}_\ell}(Z_{-i}^{(\ell)})}{1 + \delta\|\nu_2\|} \right) \right]^o := \mathcal{T}^o. \tag{5.12}$$

Now we introduce the concept of circumradius.

Definition 14 (circumradius) *The circumradius of a convex body $\mathcal{P}$, denoted by $R(\mathcal{P})$, is defined as the radius of the smallest Euclidean ball containing $\mathcal{P}$.*

The magnitude $\|\nu_1\|$ is bounded by $R(\mathcal{T}^o)$. Moreover, by the the following lemma we may find the circumradius by analyzing the polar set of $\mathcal{T}^o$ instead. By the property of polar operator, polar of a polar set gives the tightest convex envelope of the original set, i.e., $(\mathcal{K}^o)^o = conv(\mathcal{K})$. Since $\mathcal{T} = \text{conv}\left(\pm \frac{Y_{-i}^{(\ell)} + \mathbb{P}_{\mathcal{S}_\ell}(Z_{-i}^{(\ell)})}{1 + \delta\|\nu_2\|} \right)$ is convex in the first place, the polar set of $\mathcal{T}^o$ is $\mathcal{T}$.

Lemma 15 (Page 448 in Brandenberg et al. (2004)) *For a symmetric convex body $\mathcal{P}$, i.e. $\mathcal{P} = -\mathcal{P}$, inradius of $\mathcal{P}$ and circumradius of polar set of $\mathcal{P}$ satisfy:*

$$r(\mathcal{P}) R(\mathcal{P}^o) = 1.$$

Lemma 16 *Given $X = Y + Z$, denote $\rho := \max_i \|\mathbb{P}_{\mathcal{S}} z_i\|$, furthermore $Y \in \mathcal{S}$ where $\mathcal{S}$ is a linear subspace, then we have:*

$$r(\text{Proj}_{\mathcal{S}}(\mathcal{P}(X))) \geq r(\mathcal{P}(Y)) - \rho$$

Proof First note that projection to a subspace is a linear operator. Hence $\text{Proj}_{\mathcal{S}}(\mathcal{P}(X)) = \mathcal{P}(\mathbb{P}_{\mathcal{S}} X)$. Then by definition, the boundary set of $\mathcal{P}(\mathbb{P}_{\mathcal{S}} X)$ is $\mathcal{B} := \{y \mid y = \mathbb{P}_{\mathcal{S}} X c; \|c\|_1 = 1\}$. Inradius by definition is the largest ball containing in the convex body, hence $r(\mathcal{P}(\mathbb{P}_{\mathcal{S}} X)) = \min_{y \in \mathcal{B}} \|y\|$. Now we provide a lower bound of it:

$$\|y\| \geq \|Yc\| - \|\mathbb{P}_{\mathcal{S}} Z c\| \geq r(\mathcal{P}(Y)) - \sum\nolimits_j \|\mathbb{P}_{\mathcal{S}} z_j\| |c_j| \geq r(\mathcal{P}(Y)) - \rho \|c\|_1.$$

This concludes the proof. ■

A bound of $\|\nu_1\|$ follows directly from Lemma 15 and Lemma 16:

$$\begin{aligned} \|\nu_1\| \leq& (1 + \delta\|\nu_2\|) R(\mathcal{P}(Y_{-i}^{(\ell)} + \mathbb{P}_{\mathcal{S}_\ell}(Z_{-i}^{(\ell)}))) \\ =& \frac{1 + \delta\|\nu_2\|}{r(\mathcal{P}(Y_{-i}^{(\ell)} + \mathbb{P}_{\mathcal{S}_\ell}(Z_{-i}^{(\ell)}))} = \frac{1 + \delta\|\nu_2\|}{r(\text{Proj}_{\mathcal{S}_\ell}(\mathcal{P}(X_{-i}^{(\ell)})))} \leq \frac{1 + \delta\|\nu_2\|}{r(\mathcal{Q}_{-i}^\ell) - \delta_1}. \end{aligned} \tag{5.13}$$

This bound depends on $\|\nu_2\|$, which we analyze below.

5.3.2 Bounding $\|\nu_2\|$

Since ν is the optimal solution to $\mathbf{D}_1$, it obeys the second optimality condition in Lemma 12:

$$\nu = \lambda e_i = \lambda(x_i - X_{-i}^{(\ell)} c).$$

By projecting ν to $\mathcal{S}_\ell^\perp$, we get $\nu_2 = \lambda \mathbb{P}_{\mathcal{S}_\ell^\perp}(x_i - X_{-i}^{(\ell)} c) = \lambda \mathbb{P}_{\mathcal{S}_\ell^\perp}(z_i - Z_{-i}^{(\ell)} c)$. It follows that

$$\begin{aligned}\|\nu_2\| &\le \lambda \left(\|\mathbb{P}_{\mathcal{S}_\ell^\perp} z_i\| + \|\mathbb{P}_{\mathcal{S}_\ell^\perp} Z_{-i}^{(\ell)} c\| \right) \\ &\le \lambda \left(\|\mathbb{P}_{\mathcal{S}_\ell^\perp} z_i\| + \sum_j |c_j| \|\mathbb{P}_{\mathcal{S}_\ell^\perp} z_j\| \right) \\ &\le \lambda(\|c\|_1 + 1)\delta_2 \le \lambda(\|c\|_1 + 1)\delta. \end{aligned} \tag{5.14}$$

Now we bound $\|c\|_1$. Since (c, e) is the optimal solution, $\|c\|_1 + \frac{\lambda}{2}\|e\|^2 \le \|\tilde{c}\|_1 + \frac{\lambda}{2}\|\tilde{e}\|^2$ for any feasible solution $(\tilde{c}, \tilde{e})$. Let $\tilde{c}$ be the solution of

$$\min_c \ \|c\|_1 \quad s.t. \quad y_i^{(\ell)} = Y_{-i}^{(\ell)} c, \tag{5.15}$$

then by strong duality,

$$\|\tilde{c}\|_1 = \max_\nu \left\{ \langle \nu, y_i^{(\ell)} \rangle \mid \|[Y_{-i}^{(\ell)}]^T \nu\|_\infty \le 1 \right\}.$$

By Lemma 15, the optimal dual solution $\tilde{\nu}$ satisfies $\|\tilde{\nu}\| \le \frac{1}{r(\mathcal{Q}_{-i}^\ell)}$. It follows that

$$\|\tilde{c}\|_1 = \langle \tilde{\nu}, y_i^{(\ell)} \rangle = \|\tilde{\nu}\| \|y_i^{(\ell)}\| \le \frac{1}{r(\mathcal{Q}_{-i}^\ell)}.$$

On the other hand, $\tilde{e} = z_i - Z_{-i}^{(\ell)} \tilde{c}$, so $\|\tilde{e}\|^2 \le (\|z_i\| + \sum_j \|z_j\| |\tilde{c}_j|)^2 \le (\delta + \|\tilde{c}\|_1 \delta)^2$, thus

$$\|c\|_1 \le \|\tilde{c}\|_1 + \frac{\lambda}{2}\|\tilde{e}\|^2 - \frac{\lambda}{2}\|e\|^2 \le \frac{1}{r(\mathcal{Q}_{-i}^\ell)} + \frac{\lambda}{2}\delta^2 \left[1 + \frac{1}{r(\mathcal{Q}_{-i}^\ell)}\right]^2 - \frac{1}{2\lambda}\|\nu_2\|^2.$$

Note that we used the property $\frac{\lambda}{2}\|e\|^2 = \frac{1}{2\lambda}\|\nu\|^2 \ge \frac{1}{2\lambda}\|\nu_2\|^2$. Substitute the bound of $\|c_1\|_1$ into (5.14) we get

$$\begin{aligned} & \|\nu_2\| \le \lambda \left(\frac{1}{r(\mathcal{Q}_{-i}^\ell)} + \frac{\lambda}{2}\delta^2 \left[1 + \frac{1}{r(\mathcal{Q}_{-i}^\ell)}\right]^2 + 1 \right) \delta - \frac{\delta}{2}\|\nu_2\|^2 \\ \Leftrightarrow \quad & \|\nu_2\| + \frac{\delta}{2}\|\nu_2\|^2 \le \lambda\delta \left(\frac{1}{r(\mathcal{Q}_{-i}^\ell)} + 1 \right) + \frac{\delta}{2} \left[\lambda\delta \left(\frac{1}{r(\mathcal{Q}_{-i}^\ell)} + 1 \right) \right]^2. \end{aligned}$$

Since function $f(\alpha) = \alpha + \frac{\delta}{2}\alpha^2$ monotonically increases when $\alpha > 0$, the above inequality implies

$$\|\nu_2\| \le \lambda\delta \left(\frac{1}{r(\mathcal{Q}_{-i}^\ell)} + 1 \right), \tag{5.16}$$

which gives the desired bound for $\|\nu_2\|$.

5.3.3 Conditions for $|\langle x, \nu \rangle| < 1$

Putting together (5.10), (5.13) and (5.16), we have the upper bound of $|\langle x, \nu \rangle|$:

$$\begin{aligned} & |\langle x, \nu \rangle| \le (\mu(\mathcal{X}_\ell) + \|\mathbb{P}_{\mathcal{S}_\ell} z\|)\|\nu_1\| + (\|y\| + \|\mathbb{P}_{\mathcal{S}_\ell^\perp} z\|)\|\nu_2\| \\ \le & \frac{\mu(\mathcal{X}_\ell) + \delta_1}{r(\mathcal{Q}_{-i}^\ell) - \delta_1} + \left(\frac{(\mu(\mathcal{X}_\ell) + \delta_1)\delta}{r(\mathcal{Q}_{-i}^\ell) - \delta_1} + 1 + \delta \right) \|\nu_2\| \\ \le & \frac{\mu(\mathcal{X}_\ell) + \delta_1}{r(\mathcal{Q}_{-i}^\ell) - \delta_1} + \lambda\delta(1+\delta) \left(\frac{1}{r(\mathcal{Q}_{-i}^\ell)} + 1 \right) + \frac{\lambda\delta^2(\mu(\mathcal{X}_\ell) + \delta_1)}{r(\mathcal{Q}_{-i}^\ell) - \delta_1} \left(\frac{1}{r(\mathcal{Q}_{-i}^\ell)} + 1 \right). \end{aligned}$$

For convenience, we further relax the second $r(\mathcal{Q}_{-i}^\ell)$ into $r(\mathcal{Q}_{-i}^\ell) - \delta_1$. The dual separation condition is thus guaranteed with

$$\frac{\mu(\mathcal{X}_\ell) + \delta_1 + \lambda\delta(1+\delta) + \lambda\delta^2(\mu(\mathcal{X}_\ell) + \delta_1)}{r(\mathcal{Q}_{-i}^\ell) - \delta_1} + \lambda\delta(1+\delta) + \frac{\lambda\delta^2(\mu(\mathcal{X}_\ell) + \delta_1)}{r(\mathcal{Q}_{-i}^\ell)(r(\mathcal{Q}_{-i}^\ell) - \delta_1)} < 1.$$

Denote $\rho := \lambda\delta(1+\delta)$, assume $\delta < r(\mathcal{Q}_{-i}^\ell)$, $(\mu(\mathcal{X}_\ell) + \delta_1) < 1$ and simplify the form with

$$\frac{\lambda\delta^2(\mu(\mathcal{X}_\ell) + \delta_1)}{r(\mathcal{Q}_{-i}^\ell) - \delta_1} + \frac{\lambda\delta^2(\mu(\mathcal{X}_\ell) + \delta_1)}{r(\mathcal{Q}_{-i}^\ell)(r(\mathcal{Q}_{-i}^\ell) - \delta_1)} < \frac{\rho}{r(\mathcal{Q}_{-i}^\ell) - \delta_1},$$

we get a sufficient condition

$$\mu(\mathcal{X}_\ell) + 2\rho + \delta_1 < (1 - \rho)\left(r(\mathcal{Q}_{-i}^\ell) - \delta_1\right). \tag{5.17}$$

To generalize (5.17) to all data of all subspaces, the following must hold for each $\ell = 1, ..., k$:

$$\mu(\mathcal{X}_\ell) + 2\rho + \delta_1 < (1 - \rho)\left(\min_{\{i : x_i \in X^{(\ell)}\}} r(\mathcal{Q}_{-i}^{(\ell)}) - \delta_1 \right). \tag{5.18}$$

This gives a first condition on δ and λ (within ρ), which we call it "**dual separation condition**" under noise. Note that this reduces to exactly the geometric condition in Soltanolkotabi et al. (2012)'s Theorem 2.5 when $\delta = 0$.

5.4 Avoid trivial solutions

Besides SEP, we also need to show the solution is non-trivial. The idea is that when λ is large enough, the trivial solution $c^* = 0$, $e^* = x_i^{(\ell)}$ can never be optimal.

As we trace along the regularization path by increasing λ from 0, one column of the design matrix X_{-i} will enter the support set. This column will be the one that attains $\|X_{-i}^T x_i\|_\infty$, and $\lambda = \frac{1}{\|X_{-i}^T x_i\|_\infty}$ when it happens. Therefore, as long as $\lambda > \frac{1}{\|X_{-i}^T x_i\|_\infty}$, the solution will not be trivial.

Note that under the dual separation condition, we only need to consider points in the same subspace. So $\|X_{-i}^T x_i\|_\infty = \left\| [X_{-i}^{(\ell)}]^T x_i \right\|_\infty$. Let $x_j \in X_{-i}^{(\ell)}$ be the column that attains

the maximum in $\left\|[X_{-i}^{(\ell)}]^T x_i\right\|_\infty$ and $y_k \in Y_{-i}^{(\ell)}$ be the column that attains the maximum in $\left\|[Y_{-i}^{(\ell)}]^T y_i\right\|_\infty$ (if there are more than one maximizers, pick any one), we can write

$$\begin{aligned}\left\|[X_{-i}^{(\ell)}]^T x_i\right\|_\infty &= |\langle x_j, x_i\rangle| \geq |\langle x_k, x_i\rangle| \\ &= |\langle y_k, y_i\rangle + \langle y_k, z_i\rangle + \langle z_k, y_i\rangle + \langle z_k, z_i\rangle| \\ &\geq |\langle y_k, y_i\rangle| - |\langle y_k, z_i\rangle + \langle z_k, y_i\rangle + \langle z_k, z_i\rangle| \\ &= \left\|[Y_{-i}^{(\ell)}]^T y_i\right\|_\infty - |\langle y_k, z_i\rangle + \langle z_k, y_i\rangle + \langle z_k, z_i\rangle| \\ &\geq r(\mathcal{Q}_{-i}^{(\ell)}) - 2\delta - \delta^2. \end{aligned} \tag{5.19}$$

The last inequality follows from the upper bound of noise magnitude and the observation that the inradius of $\mathcal{Q}_{-i}^{(\ell)}$ defines a uniform lower bound of $\left\|[Y_{-i}^{(\ell)}]^T w\right\|_\infty$ for any unit vector $w \in \mathcal{S}_\ell$. Therefore, as long as

$$\lambda \geq \frac{1}{r(\mathcal{Q}_{-i}^{(\ell)}) - 2\delta - \delta^2}, \tag{5.20}$$

the solution c_i for ith column is not trivial. This bound is strictly better than what we obtain in the conference version (Wang and Xu, 2013) and is the key for improving the rate for noise tolerance over the previous version. Also, check that

$$\delta < \frac{r(r_\ell - \mu_\ell)}{2 + 7r_\ell} \tag{5.21}$$

under bound of δ in the theorem statement, $r(\mathcal{Q}_{-i}^{(\ell)}) - 2\delta - \delta^2 > 0$ for any i, ℓ.

A side remark is that the Lasso regularization path is formally described in Tibshirani et al. (2013) and it is unique whenever the data points are in general position. As a result, we can potentially calculate the entry point of kth non-zero coefficient for any $0 < k < d$, any x_i and X_{-i}. This would however complicate the results unnecessarily, as Lasso path is not monotone (some coefficient may leave the support set as λ increases). We therefore stick to the simpler requirement of c_i being non-trivial.

5.5 Existence of a proper λ

Basically, (5.18) and (5.20) must be satisfied simultaneously for all $\ell = 1, ..., L$. Essentially (5.20) gives a condition of λ from below, and (5.18) gives a condition from above. Recall that the denotations $r_\ell := \min_{\{i: x_i \in X^{(\ell)}\}} r(\mathcal{Q}_{-i}^{(\ell)})$, $\mu_\ell := \mu(\mathcal{X}_\ell)$ and $r = \min_\ell r_\ell$, the condition on λ is:

$$\max_\ell \frac{1}{r_\ell - 2\delta - \delta^2} < \lambda < \min_\ell \frac{r_\ell - \mu_\ell - 2\delta_1}{\delta(1+\delta)(2 + r_\ell - \delta_1)}.$$

With the observation that

$$\max_\ell \frac{1}{r_\ell - 2\delta - \delta^2} = \frac{1}{\min r_\ell - 2\delta - \delta^2},$$

it suffices to require λ to obey for each ℓ:

$$\frac{1}{r - 2\delta - \delta^2} < \lambda < \frac{r_\ell - \mu_\ell - 2\delta_1}{\delta(1+\delta)(2 + r_\ell - \delta_1)}. \tag{5.22}$$

We will now show that under condition (5.21), the range (5.22) is not an empty set. Again, we relax δ_1 to δ in (5.22) and get

$$\frac{1}{r - 2\delta - \delta^2} < \frac{r_\ell - \mu_\ell - 2\delta}{\delta(1+\delta)(2 + r_\ell - \delta)}. \tag{5.23}$$

Since all denominators are positive, we obtain the standard form of the inequality

$$A\delta^3 + B\delta^2 + C\delta + D < 0$$

with

$$\begin{cases} A = -3 \leq 0 \\ B = -3 + 2(r_\ell - \mu_\ell) + r_\ell \leq 0 \\ C = 2 + 4(r_\ell - \mu_\ell) + r_\ell + 2r \leq 2 + 7r_\ell \\ D = -r(r_\ell - \mu_\ell) \end{cases}$$

Check that (5.21) is sufficient for the above 3rd order inequality to hold. Therefore,

$$(5.21) \Rightarrow A\delta^3 + B\delta^2 + C\delta + D < 0 \Leftrightarrow (5.23) \Rightarrow (5.22) \text{ is not an empty set.}$$

This completes the proof of Theorem 6.

6. Proof of Results for Randomized Cases

In this section, we provide proofs to the theorems of the three randomized models:

- **Deterministic data+random noise;**
- **Semi-random data+random noise;**
- **Fully random.**

To do this, we need to bound δ_1, $\cos(\angle(z, \nu))$ and $\cos(\angle(y, \nu_2))$ when Z follows the *Random Noise Model*, such that a better dual separation condition can be obtained. Moreover, for the *Semi-random* and the *Random data model*, we need to bound $r(\mathcal{Q}_{-i}^{(\ell)})$ when data samples from each subspace are drawn uniformly and bound $\mu(\mathcal{X}_\ell)$ when subspaces are randomly generated. These require the following lemmas.

Lemma 17 (Upper bound on the area of spherical cap) *Let $a \in \mathbb{R}^n$ be a random vector sampled from a unit sphere and z is a fixed vector. Then we have:*

$$Pr\left(|a^T z| > \epsilon \|z\|\right) \leq 2e^{\frac{-n\epsilon^2}{2}}$$

This Lemma is extracted from an equation in page 29 of Soltanolkotabi et al. (2012), which is in turn adapted from the upper bound on the area of spherical cap in Ball (1997). By definition of the Random Noise Model, z_i is spherical symmetric, which implies that the direction of z_i is distributed uniformly on the n-dimensional unit sphere. Hence Lemma 17 applies whenever an inner product involves z. As an example, we write the following lemma.

Lemma 18 (Properties of Gaussian noise) *For Gaussian random matrix $Z \in \mathbb{R}^{n\times N}$, if each entry $Z_{i,j} \sim N(0, \frac{\sigma}{\sqrt{n}})$, then each column z_i satisfies:*

1. $Pr(\|z_i\|^2 > (1+t)\sigma^2) \le e^{\frac{n}{2}(\log(t+1)-t)}$
2. $Pr(|\langle z_i, z\rangle| > \epsilon\|z_i\|\|z\|) \le 2e^{\frac{-n\epsilon^2}{2}}$

where z is any fixed vector, or a random vector that is independent to z_i.

Proof The second property follows directly from Lemma 17 as Gaussian vector has a uniformly random direction.

To show the first property, we observe that the sum of n independent square Gaussian random variables follows χ^2 distribution with degree of freedom n. In other words, we have

$$\|z_i\|^2 = |Z_{1i}|^2 + ... + |Z_{ni}|^2 \sim \frac{\sigma^2}{n}\chi^2(n).$$

By Hoeffding's inequality, we have an approximation of its CDF (Dasgupta and Gupta, 2003), which gives us

$$Pr(\|z_i\|^2 > \alpha\sigma^2) = 1 - \mathrm{CDF}_{\chi^2_n}(\alpha) \le (\alpha e^{1-\alpha})^{\frac{n}{2}}.$$

Substitute $\alpha = 1+t$, we obtain the concentration statement in the lemma. ■

By Lemma 18, $\delta = \max_i \|z_i\|$ is bounded with high probability. δ_1 can be bounded even more tightly because each $\mathcal{S}_\ell$ is low-rank. Likewise, $\cos(\angle(z,\nu))$ is bounded by a small value with high probability. Moreover, since $\nu = \lambda e = \lambda(x_i - X_{-i}c)$, $\nu_2 = \lambda\mathbb{P}_{\mathcal{S}_\ell^\perp}(z_i - Z_{-i}c)$. Thus ν_2 is indeed a weighted sum of random noise in a $(n-d_\ell)$-dimensional subspace. Consider y a fixed vector, $\cos(\angle(y,\nu_2))$ is also bounded with high probability.

Replace these observations into (5.9) and the corresponding bound of $\|\nu_1\|$ and $\|\nu_2\|$, we obtain the equivalent *dual separation condition* under the random noise model (equivalent to (5.17) in the proof of the deterministic case). This is formalized in the following lemma.

Lemma 19 (Dual separation condition under random noise) *Let $\rho := \lambda\delta(1+\delta)$ and*

$$\epsilon := \sqrt{\frac{6\log N}{n - \max_\ell d_\ell}} \le \sqrt{\frac{C\log(N)}{n}}$$

for some constant C. Under random noise model, if for each $\ell = 1, ..., L$

$$\mu(\mathcal{X}_\ell) + \delta\epsilon + 3\rho\epsilon \le (1-\rho\epsilon)(\max_i r(\mathcal{Q}^{(\ell)}_{-i}) - \delta\sqrt{d_\ell}\epsilon), \tag{6.1}$$

then dual separation condition (5.9) *holds for all data points with probability at least $1-8/N$.*

Proof Recall that we want to find an upper bound of $|\langle x, \nu\rangle|$.

$$|\langle x,\nu\rangle| \le \mu\|\nu_1\| + \|y\|\|\nu_2\||\cos(\angle(y,\nu_2))| + \|z\|\|\nu\||\cos(\angle(z,\nu))| \tag{6.2}$$

Here we will bound the two cosine terms and δ_1 under the random noise model.

As discussed above, directions of z and ν_2 are independently and uniformly distributed on the n-dimension unit sphere. Then by Lemma 17,

$$\begin{cases} Pr\left(\cos(\angle(z,\nu)) > \sqrt{\frac{6\log N}{n}}\right) \le \frac{2}{N^3}; \\ Pr\left(\cos(\angle(y,\nu_2)) > \sqrt{\frac{6\log N}{n-d_\ell}}\right) \le \frac{2}{N^3}; \\ Pr\left(\cos(\angle(z,\nu_2)) > \sqrt{\frac{6\log N}{n}}\right) \le \frac{2}{N^3}. \end{cases}$$

Using the same technique, we derive a bound for δ_1. Given an orthonormal basis U of S_ℓ, $\mathbb{P}_{S_\ell}z = UU^Tz$, then

$$\|UU^Tz\| = \|U^Tz\| = \sqrt{\sum_{i=1,...,d_\ell} |U^T_{:,i}z|^2}.$$

Apply Lemma 17 for each i, then by union bound, we get:

$$Pr\left(\|\mathbb{P}_{S_\ell}z\| > \sqrt{\frac{6d_\ell\log N}{n}}\delta\right) \le \frac{2d_\ell}{N^3}.$$

Since δ_1 is the worse case bound for all L subspace and all N noise vector, then a union bound gives:

$$Pr\left(\delta_1 > \sqrt{\frac{6d_\ell\log N}{n}}\delta\right) \le \frac{2\sum_\ell d_\ell}{N^2}$$

Moreover, we can find a probabilistic bound for $\|\nu_1\|$ too by a variation of (5.11) for the random case, which now becomes

$$y_i^T\nu_1 + (\mathbb{P}_{\mathcal{S}_\ell}z_i)^T\nu_1 \le 1 - z_i^T\nu_2 \le 1 + \delta_2\|\nu_2\||\cos\angle(z_i,\nu_2)|. \tag{6.3}$$

Substituting the upper bound of the cosines to (6.2) and (6.3), we get respectively

$$|\langle x,\nu\rangle| \le \mu\|\nu_1\| + \|y\|\|\nu_2\|\sqrt{\frac{6\log N}{n-d_\ell}} + \|z\|\|\nu\|\sqrt{\frac{6\log N}{n}},$$

and

$$\|\nu_1\| \le \frac{1 + \delta\|\nu_2\|\sqrt{\frac{6\log N}{n}}}{r(\mathcal{Q}^\ell_{-i}) - \delta_1}.$$

This new bound of $\|\nu_1\|$ follows from (6.3), Lemma 15 and 16. For the bound of $\|\nu_2\|$ we simply use (5.16):

$$\|\nu_2\| \le \lambda\delta\left(\frac{1}{r(\mathcal{Q}^\ell_{-i})} + 1\right).$$

To lighten notations in this proof, denote

$$r := r(\mathcal{Q}^{\ell}_{-i}), \quad \epsilon := \sqrt{\frac{6\log N}{n - \max_\ell d_\ell}}, \quad \mu := \mu(\mathcal{X}_\ell).$$

Substitute them in the bound, we get

$$\begin{aligned}
|\langle x, \nu\rangle| \leq & \frac{\mu+\delta\epsilon}{r-\epsilon\sqrt{d_\ell}\delta} + \frac{\lambda\delta^2(\mu+\delta\epsilon)\epsilon}{r-\epsilon\sqrt{d_\ell}\delta}\left(\frac{1}{r}+1\right) + \lambda\delta\epsilon\left(\frac{1}{r}+1\right) + \lambda\delta^2\epsilon\left(\frac{1}{r}+1\right) \\
= & \frac{\mu+\delta\epsilon}{r-\epsilon\sqrt{d_\ell}\delta} + \frac{\lambda\epsilon\delta^2(\frac{\mu+\delta\epsilon}{r}) + \lambda\epsilon\delta^2(\mu+\delta\epsilon)}{r-\epsilon\sqrt{d_\ell}\delta} + \frac{\lambda\delta(\delta+1)\epsilon}{r} + \lambda\delta(\delta+1)\epsilon \\
\underset{*}{\leq} & \frac{\mu+\delta\epsilon}{r-\epsilon\sqrt{d_\ell}\delta} + \frac{\lambda\epsilon\delta^2}{r-\epsilon\sqrt{d_\ell}\delta} + \frac{\lambda\epsilon\delta^2}{r-\epsilon\sqrt{d_\ell}\delta} + \frac{\lambda\epsilon(\delta+\delta^2)}{r-\epsilon\sqrt{d_\ell}\delta} + \lambda\epsilon(\delta+\delta^2) \\
= & \frac{\mu+\delta\epsilon+\lambda\epsilon(\delta+3\delta^2)}{r-\epsilon\sqrt{d_\ell}\delta} + \lambda\epsilon(\delta+\delta^2) \underset{**}{\leq} \frac{\mu+\delta\epsilon+3\rho\epsilon}{r-\epsilon\sqrt{d_\ell}\delta} + \rho\epsilon. \qquad (6.4)
\end{aligned}$$

In the inequality "$*$", we used $(\mu+\epsilon\delta)/r < 1$ and $\mu+\epsilon\delta < 1$; and in the inequality "$**$", we used $\lambda\delta^2 \leq \lambda\epsilon(\delta+\delta^2)$ and replaced all such expression with $\rho\epsilon$ that we defined earlier.

Now impose the dual detection constraint on the upper bound, we get:

$$\rho\epsilon + \frac{\mu+\delta\epsilon+3\rho\epsilon}{r-\delta\sqrt{d_\ell}\epsilon} < 1.$$

Reorganized the inequality, we reach the desired condition:

$$\mu+\delta\epsilon < (1-\rho\epsilon)(r-\delta\sqrt{d_\ell}\epsilon) - 3\rho\epsilon.$$

There are N^2 instances for each of the three events related to the cosine value, apply union bound we get the failure probability $\frac{6}{N} + \frac{2\sum_\ell d_\ell}{N^2} \leq \frac{8}{N}$. Note $\sum_\ell d_\ell \leq N$ because one needs at least d_ℓ data points to span an d_ℓ dimensional subspace. This concludes the proof. ■

Lemma 20 (Avoid trivial solution under random noises) *Let* $\epsilon = \sqrt{\frac{6\log N}{n}}$ *and assume* $\min_\ell r_\ell - 2\epsilon\delta - \epsilon\delta^2 > 0$. *If we take*

$$\lambda > (r_\ell - 2\epsilon\delta - \epsilon\delta^2)^{-1} \qquad (6.5)$$

for every $\ell = 1, ..., n$, *then the solution* $c_i \neq 0$ *for all* i *with probability at least* $1 - 6/N^2$.

Proof We use the same argument as in Section 5.4, except that we now have a tighter probabilistic bound for (5.19). For any i, k in the equation, z_i and z_k are independent to each other and to y_k, y_i respectively. Therefore, we can invoke Lemma 17 and obtain

$$|\langle y_k, z_i\rangle + \langle z_k, y_i\rangle + \langle z_k, z_i\rangle| \leq 2\epsilon\delta + \epsilon\delta^2,$$

with probability greater than $2/N^3$. The proof is complete by taking the union bound over all $3\sum_i N_\ell = 3N$ instances. ■

6.1 Proof of Theorem 8 for Deterministic Data and Random Noise

We now prove Theorem 8. Lemma 19 has already provided the separation condition. The things left are to find the range of λ and update the condition of δ.

The range of λ: The range of valid λ for the random noise case can be obtained by substituting $\delta_1 < \delta\sqrt{d_\ell}\epsilon$ in (6.5) and rewriting (6.1) with respect to λ. This gives us

$$\frac{1}{r-2\epsilon\delta-\epsilon\delta^2} < \lambda < \frac{r_\ell - \mu_\ell - \delta\epsilon - \delta\sqrt{d_\ell}\epsilon}{\epsilon\delta(1+\delta)(3+r_\ell-\delta\sqrt{d_\ell}\epsilon)}. \qquad (6.6)$$

We remark that a critical difference from the deterministic noise model is that now there is a small ϵ in the denominator of the upper endpoint of the interval. Assume small μ, the valid range of λ expands to an order of $\Theta(1/r) \leq \lambda \leq \Theta(r/(\epsilon\max\{\delta^2, \delta\}))$.

The condition of δ: Now we will show that the two conditions

$$\epsilon\delta < \min_\ell \frac{r_\ell - \mu_\ell}{2\sqrt{d_\ell}+2}, \qquad \text{and} \qquad \epsilon\delta(1+\delta) < \min_\ell \frac{r(r_\ell-\mu_\ell)}{4r_\ell+6},$$

stated in the Theorem 8 are sufficient for the three inequalities

$$\begin{cases}
r_\ell - \mu_\ell - \delta\epsilon > 0; & (6.7)\\
r - 2\delta\epsilon - \epsilon\delta^2 > 0; & (6.8)\\
\dfrac{1}{r-2\epsilon\delta-\epsilon\delta^2} < \dfrac{r_\ell-\mu_\ell-\delta\epsilon-\delta\sqrt{d_\ell}\epsilon}{\epsilon\delta(1+\delta)(3+r_\ell-\delta\sqrt{d_\ell}\epsilon)}; & (6.9)
\end{cases}$$

to hold for $\ell = 1, ..., L$. Note that we used (6.7) in (6.4) when we derive the dual separation condition and (6.8) is assumed in Lemma 20, lastly (6.9) ensures a valid λ to exist in (6.6). Inequality (6.7) and (6.8) hold trivially given the two conditions, it remains to show (6.9):

$$\begin{aligned}
\delta(1+\delta) < \frac{r(r_\ell-\mu_\ell)}{\epsilon(4r_\ell+6)} & \Leftrightarrow \epsilon\delta(1+\delta)(2r_\ell+3) < \frac{r(r_\ell-\mu_\ell)}{2} \\
& \Rightarrow \epsilon\delta(1+\delta)(r_\ell-\mu_\ell+r_\ell+3) < \frac{r(r_\ell-\mu_\ell)}{2} \\
& \Leftrightarrow \epsilon\delta(1+\delta)(r_\ell+3) + 2\epsilon\delta(1+\delta)\frac{r_\ell-\mu_\ell}{2} < \frac{r(r_\ell-\mu_\ell)}{2} \\
& \Leftrightarrow \frac{1}{r-2\epsilon\delta-2\epsilon\delta^2} < \frac{r_\ell-\mu_\ell}{2\epsilon\delta(1+\delta)(r_\ell+3)} \\
& \Rightarrow \frac{1}{r-2\epsilon\delta-\epsilon\delta^2} < \frac{r_\ell-\mu_\ell}{2\epsilon\delta(1+\delta)(r_\ell+3-\delta\sqrt{d_\ell}\epsilon)} \overset{(a)}{\Rightarrow} (6.9),
\end{aligned}$$

where (a) holds by applying the first condition. This concludes the proof for Theorem 8.

6.2 Proof of Theorem 10 for the Semi-random Model with Random Noise

To prove Theorem 10, we only need to bound the inradius r and the incoherence parameter μ under the new assumptions, then plug them into Theorem 8.

Lemma 21 (Inradius bound of random samples) *In random sampling setting, when each subspace is sampled $N_\ell = \kappa_\ell d_\ell$ data points randomly, we have:*

$$Pr\left\{ c(\kappa_\ell)\sqrt{\frac{\beta \log(\kappa_\ell)}{d_\ell}} \le r(\mathcal{Q}_{-i}^{(\ell)}) \text{ for all pairs } (\ell, i) \right\} \ge 1 - \sum_{\ell=1}^{L} N_\ell e^{-d_\ell^\beta N_\ell^{1-\beta}}$$

This is extracted from Section-7.2.1 of Soltanolkotabi et al. (2012). $\kappa_\ell = (N_\ell - 1)/d_\ell$ is the relative number of iid samples. $c(\kappa)$ is some positive value for all $\kappa > 1$ and for a numerical value κ_0, if $\kappa > \kappa_0$, we can take $c(\kappa) = \frac{1}{\sqrt{8}}$. Take $\beta = 0.5$, we get the required bound of r in Theorem 10.

Now, we provide a probabilistic upper bound of the projected subspace incoherence condition under the semi-random model by adapting Lemma 7.5 of Soltanolkotabi et al. (2012) into our new setup.

Lemma 22 (Incoherence bound) *In deterministic subspaces/random sampling setting, the subspace incoherence is bounded from above:*

$$Pr\Big\{ \mu(\mathcal{X}_\ell) \le t\left(\log[(N_\ell+1)N_{\ell'}] + \log L\right) \frac{\text{aff}(S_\ell, S_{\ell'})}{\sqrt{d_\ell}\sqrt{d_{\ell'}}} \\ \text{for all pairs}(\ell, \ell') \text{ with } \ell \ne \ell' \Big\} \ge 1 - \frac{1}{L^2} \sum_{\ell \ne \ell'} \frac{1}{(N_\ell+1)N_{\ell'}} e^{-\frac{t}{4}}.$$

Proof The proof is an extension of a similar proof in Soltanolkotabi et al. (2012). First we will show that when noise $z_i^{(\ell)}$ is spherical symmetric, and clean data points $y_i^{(\ell)}$ has iid uniform random direction, projected dual directions $v_i^{(\ell)}$ also follows a uniform random distribution.

Now we prove the claim. First by definition,

$$v_i^{(\ell)} = v(x_i^{(\ell)}, X_{-i}^{(\ell)}, \mathcal{S}_\ell, \lambda) = \frac{\mathbb{P}_{S_\ell}\nu}{\|\mathbb{P}_{S_\ell}\nu\|} = \frac{\nu_1}{\|\nu_1\|}.$$

Recall that ν is the unique optimal solution of $\mathbf{D}_1$ (5.7). Fix λ, $\mathbf{D}_1$ depends on two inputs, so we denote $\nu(x, X)$ and consider ν a function. Moreover, $\nu_1 = \mathbb{P}_{\mathcal{S}}\nu$ and $\nu_2 = \mathbb{P}_{\mathcal{S}^\perp}\nu$. Let $U \in n \times d$ be a set of orthonormal basis of d-dimensional subspace $\mathcal{S}$ and a rotation matrix $R \in \mathbb{R}^{d\times d}$. Then rotation matrix within subspace is hence URU^T. Let

$$x_1 := \mathbb{P}_{\mathcal{S}} x = y + z_1 \sim URU^T y + URU^T z_1,$$
$$x_2 := \mathbb{P}_{\mathcal{S}^\perp} x = z_2.$$

As y is distributed uniformly on the unit sphere of $\mathcal{S}$, and z is a spherical symmetric noise (hence z_1 and z_2 are also spherical symmetric in subspace), for any fixed $\|x_1\|$, the distribution is uniform on the sphere, namely the conditional distribution $Pr(x_1 | \|x_1\| = \alpha)$ is uniform on the sphere with radius α. It suffices to show that with fixed $\|x_1\|$, v (the unit direction of projected dual variable ν_1) also follows a uniform distribution on a unit sphere of the subspace.

Since inner product $\langle x, \nu\rangle = \langle x_1, \nu_1\rangle + \langle x_2, \nu_2\rangle$, we argue that if ν is the optimal solution of

$$\max_\nu \langle x, \nu\rangle - \frac{1}{2\lambda}\nu^T\nu, \quad \text{subject to:} \quad \|X^T\nu\|_\infty \le 1,$$

then the optimal solution of the following optimization

$$\max_\nu \langle URU^T x_1 + x_2, \nu\rangle - \frac{1}{2\lambda}\nu^T\nu,$$
$$\text{subject to:} \quad \|(URU^T X_1 + X_2)^T\nu\|_\infty \le 1,$$

is indeed the transformed ν under the same R, i.e.,

$$\begin{aligned}\nu(R) &= \nu(URU^T x_1 + x_2, URU^T X_1 + X_2) \\ &= URU^T \nu_1(x, X) + \nu_2(x, X) = URU^T\nu_1 + \nu_2. \end{aligned} \tag{6.10}$$

To verify the argument, check that $\nu^T\nu = \nu(R)^T\nu(R)$ and

$$\langle URU^T x_1 + x_2, \nu(R)\rangle = \langle URU^T x_1, URU^T\nu_1\rangle + \langle x_1, \nu_2\rangle = \langle x, \nu\rangle$$

for all inner products in both objective function and constraints, preserving the optimality.

By projecting (6.10) to subspace, we show that operator $v(x, X, S)$ is linear *vis a vis* subspace rotation URU^T, i.e.,

$$v(R) = \frac{\mathbb{P}_{S_\ell}\nu(R)}{\|\mathbb{P}_{S_\ell}\nu(R)\|} = \frac{URU^T\nu_1}{\|URU^T\nu_1\|} = URU^T v. \tag{6.11}$$

On the other hand, we know that

$$URU^T x_1 + x_2 \sim x_1 + x_2, \qquad URU^T X_1 + X_2 \sim X_1 + X_2,$$

where $A \sim B$ means that the random variables A and B follows the same distribution. This is because when $\|x_1\|$ is fixed and each columns in X_1 has fixed magnitudes, $URU^T x_1 \sim x_1$ and $URU^T X_1 \sim X_1$. Also, adding additional random variables x_2 and X_2 changes the distribution the same way on both sides. Therefore,

$$v(R) = v(URU^T x_1 + x_2, URU^T X_1 + X_2, \mathcal{S}) \sim v(x, X, \mathcal{S}). \tag{6.12}$$

Combining (6.11) and (6.12), we conclude that for any rotation R

$$v_i^{(\ell)}(R) \sim URU^T v_i^{(\ell)}.$$

In other words, the distribution of $v_i^{(\ell)}$ is uniform on the unit sphere of $\mathcal{S}_\ell$.

After this key step, the rest is identical to the proof of Lemma 7.5 of Soltanolkotabi et al. (2012). The idea is to use Lemma 17 (upper bound of area of spherical caps) to provide a probabilistic bound of the pairwise inner product and Borell's inequality to show the concentration around the expected cosine canonical angles, namely, $\|U^{(k)^T}U^{(\ell)}\|_F/\sqrt{d_\ell}$. The proof is standard so we omit it in this paper. ■

6.3 Proof of Theorem 11 for the Fully Random Model with Gaussian Noises

The proof of Theorem 11 essentially applies Theorem 8 with specific inradius bound and incoherence bound. The bound for inradius is given in Lemma 21 and we use the following Lemma extracted from Step 2 of Section 7.3 in Soltanolkotabi et al. (2012) to bound the subspace incoherence.

Lemma 23 (Incoherence bound of random subspaces) *In random subspaces setting, the projected subspace incoherence is bounded from above:*

$$Pr\left\{\mu(\mathcal{X}_\ell) \le \sqrt{\frac{6\log N}{n}} \text{ for all } \ell\right\} \ge 1 - \frac{2}{N}.$$

Now that we have shown that the projected dual directions are randomly distributed in their respective subspace, together with the fact that the subspaces themselves are randomly generated, we conclude that all clean data points y and projected dual direction v from different subspaces can be considered iid generated from the ambient space. The proof of Lemma 23 follows by simply applying Lemma 17 and a union bound across all N^2 events.

7. Experiments

To demonstrate the practical implications of our robustness guarantees for LASSO-SSC, we conduct four numerical experiments including three with synthetic generated data and one with real data. For fast computation, we use ADMM implementation of LASSO solver[8] with default numerical parameters. Its complexity is proportional to the problem size and the convergence guarantee (Boyd et al., 2011). We also implement a simple ADMM solver for the matrix version SSC

$$\min_C \ \|C\|_1 + \frac{\lambda}{2}\|X - XC\|_F^2 \quad \text{s.t.} \quad \text{diag}(C) = 0,$$

which is consistently faster than the column-by-column LASSO version. This algorithm is first described in Elhamifar and Vidal (2013). To be self-contained, we provide the pseudocode and some numerical simulation in the appendix.

7.1 Numerical simulation

Our three numerical simulations test the effects of noise magnitude δ, subspace rank d and number of subspace L respectively.

7.1.1 Methods

To test our methods for all parameters, we scan through an exponential grid of λ ranging from $\sqrt{n}\times 10^{-2}$ to $\sqrt{n}\times 10^{3}$. In all experiments, ambient dimension $n = 100$, relative sampling $\kappa = 5$, subspace and data are drawn uniformly at random from unit sphere

8. Freely available at: http://www.stanford.edu/~boyd/papers/admm/

and then corrupted by Gaussian noise $Z_{ij} \sim N(0, \sigma/\sqrt{n})$. We measure the success of the algorithm by the relative violation of Self-Expressiveness Property defined below.

$$\text{RelViolation}\,(C, \mathcal{M}) = \frac{\sum_{(i,j)\notin\mathcal{M}} |C|_{i,j}}{\sum_{(i,j)\in\mathcal{M}} |C|_{i,j}}$$

where $\mathcal{M}$ is the ground truth mask containing all (i,j) such that $x_i, x_j \in \mathcal{X}^{(\ell)}$ for some ℓ. Note that $\text{RelViolation}\,(C,\mathcal{M}) = 0$ implies that SEP is satisfied. We also check that there is no all-zero columns in C, and the solution is considered trivial otherwise.

7.1.2 Results

The simulation results confirm our theoretical findings. In particular, Figure 8a shows that LASSO subspace detection property is possible for a very large range of λ and the dependence on noise magnitude is roughly $1/\sigma$ as predicted in (4.1). Comparing the Figure 8a and 8b, it is clear that exact subspace detection property is not necessary for perfect classification. In addition, the sharp contrast of Figure 9a and 9b demonstrates our observations on the sensitivity of d and L. Observe that in Figure 9a beyond a point, subspace detection property is not possible for any λ. Whereas in Figure 9b even at the point when $dL = 200$ (subspaces are highly dependent), subspace detection property still holds for a large range of λ.

7.2 Face Clustering Experiments

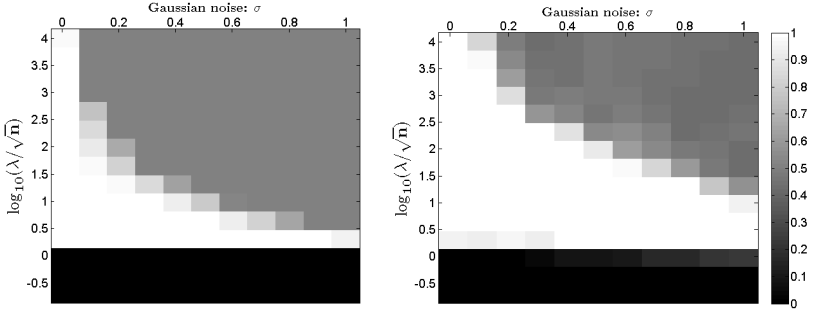
In this section, we evaluate the noise robustness of with LASSO-SSC on Extended YaleB (Lee et al., 2005), a real life face data set of 38 subjects. For each subject, 64 face images are taken under different illuminations.

7.2.1 Subspace Modeling of Face Images

According to Basri and Jacobs (2003), face images under different illuminations can be well-approximated by a 9-dimensional linear subspace. In addition, Zhou et al. (2007) reveals the underlying 3-dimensional subspace structure by assuming Lambert's reflectance and ignoring the shadow pixels. For the physics of this subspace model, we refer the readers to Basri and Jacobs (2003) and Zhou et al. (2007) for detailed explanations.

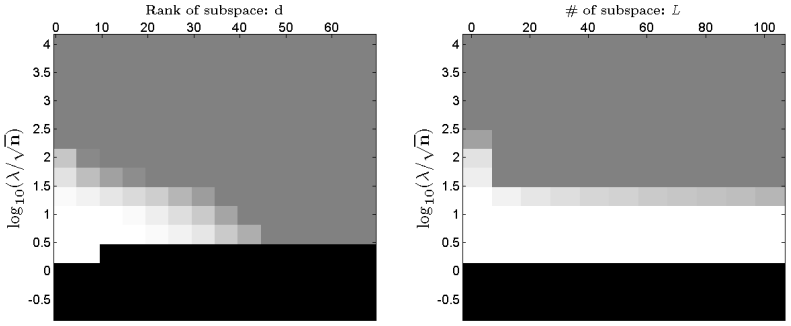
Method: We conduct face clustering experiments on Extended YaleB data set with both 9D and 3D representations of face images and compare them under varying number of subspaces L and different level of injected noise. Specifically, the 9D subspaces are generated by projecting the data matrix corresponding to each subject to a 9D subspace via PCA and the 3D subspaces are generated by a factorization-based robust matrix completion method (Wang et al., 2015). Then we scan through a random selection of $[2, 4, 6, 10, 12, 18, 38]$ subjects and for each experiment we inject additive Gaussian noise $N(0, \sigma/\sqrt{n})$ with $\sigma = [0, 0.01, ..., 0.99, 1]$[9]. Each photo is resized to 48×42 so we have ambient dimension $n = 2016$ and there are 64 sample points for each subspace, hence $N = 64L$.

9. In order to compare the effect of varying level of noise, we choose to inject artificial noise in this experiment. The performance of LASSO-SSC on real noise/data corruptions is well-documented in the motion segmentation experiments of Elhamifar and Vidal (2009, 2013)



(a) Effect of noise level on SEP. (b) Effect of noise level on clustering accuracy.

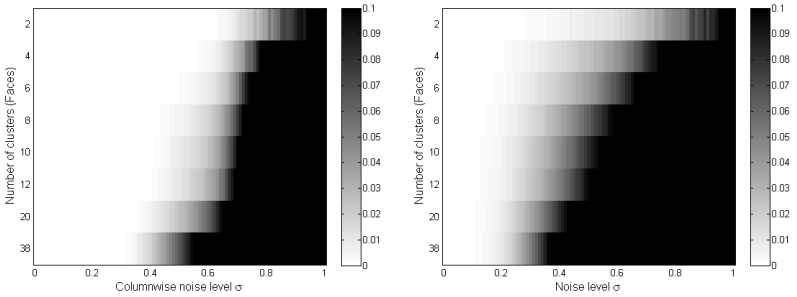
Figure 8: Effects of noise level on LASSO-SSC performance. Simulated under the fully random model with $n = 100, d = 4, L = 3, \kappa = 5$ against increasing Gaussian noise $N(0, \sigma/\sqrt{n})$. For each setting, results are plotted in grayscale across an exponential grid of tuning parameters λ along the vertical axis. **(a)** shows the effect of noise on subspace detection property (Definition 1). In particular, **Black** means trivial solution ($C = 0$); **Gray** means RelViolation > 0.1, and **White** denotes RelViolation $= 0$. **(b)** shows the corresponding clustering accuracy on the same experiment. The rate of accurate classification is represented in grayscale, where white region means perfect classification.



(a) Effect of cluster rank d. (b) Effect of number of subspaces L.

Black: trivial solution ($C = 0$); **Gray:** RelViolation > 0.1; **White:** RelViolation $= 0$.

Figure 9: Effects of other model parameters on LASSO-SSC performance. Simulated under the fully random model with default parameter $n = 100, d = 2, L = 3, \kappa = 5, \sigma = 0.2$. In **(a)** varies subspace dimension d **(b)** varies the number of subspaces L. For each setting, results are plotted in grayscale across an exponential grid of tuning parameters λ along the vertical axis.



(a) Rank 3 photometric face. (b) Rank 9 faces (after projection).

Figure 10: RelViolation of the two face clustering experiments.

The parameter λ is not carefully tuned, but simply chosen to be $\sqrt{n}$, which is order-wise correct for small σ according to (4.1).

7.2.2 Results

As we can see in Figure 10a and 10b, the range where LASSO-Subspace Detection Property holds is much larger for the rank-3 experiments than the rank-9 experiments. Also, the recovery is not sensitive to the number of faces we want to cluster. Indeed, LASSO-SSC is able to succeed for both rank-9 and rank-3 data with a considerable range of noise even for the full 38 subjects clustering task.

These observations confirm our theoretical and simulation results—on deterministic subspace data from a real-life problem—that noise robustness of LASSO-SSC is sensitive to the subspace dimension d but not the number of subspaces L.

8. Conclusion and Future Directions

We presented a theoretical analysis for noisy subspace segmentation problem that is of great practical interests. We showed that the popular SSC algorithm *exactly* (not approximately) detects the subspaces in the noisy case, which justified its empirical success on real problems. Our results are the first in showing LASSO-SSC to work under deterministic data and noise. For stochastic noise, we show that LASSO-SSC works even when noise is much larger than the signal. In addition, we discovered the orderwise relationship between LASSO-SSC's robustness to the level of noise and the subspace dimension, and we found that robustness is insensitive to the number of subspaces. These results lead to new theoretical understanding of SSC, and provide guidelines for practitioners and application-level researchers to judge whether SSC could possibly work well for their respective applications.

Open problems for subspace clustering include the graph connectivity problem (Nasihatkon and Hartley, 2011), missing data problem (a first attempt in Eriksson et al. (2012), which unfortunately requires an unrealistic number of data), sparse corruptions on data and

others. One direction closely related to this paper is to introduce a more practical metric of success. As we illustrated in the paper, subspace detection property is not necessary for perfect clustering. In fact from a pragmatic point of view, even perfect clustering is not necessary. Typical applications allow for a small number of misclassifications. It would be interesting to see whether stronger robustness results can be obtained for a more practical metric of success.

Appendix A. Differences to Soltanolkotabi et al. (2014)

As we reviewed above, Soltanolkotabi et al. (2014) analyzed almost the same algorithm under the semi-random model. Besides the comparisons we made in Section 2 regarding the model of analysis and allowable noise level, there are a few other minor differences which we list here.

"Non-trivial" v.s. "Many true discoveries". In LASSO-Subspace Detection Property, we only require the resulting regression coefficient to be non-zero, while Soltanolkotabi et al. (2014, Theorem 3.2) has a result showing the conditions under which the number of non-zero coefficient is a constant fraction of subspace dimension d. Our results are weaker but more general (works without the semi-random assumption).

In fact, the conditions are more similar than different. We both pick regression coefficient of the same order in the semi-random model. In addition, when d becomes smaller than $\log \rho(i)/c_0$, these two conditions are essentially the same.

Choosing parameter λ. Soltanolkotabi et al. (2014) provides a two-pass mechanism to adaptively tune the parameter λ for each LASSO-SSC and the results are proven for this particular λ. On the other hand, our results are stated for any λ in a specified range. The choice of λ can also be independently tuned for each LASSO-SSC.

In practice, it is advisable to choose λ slightly larger than what is required for it to be non-trivial. We described two strategies in the discussion underneath Theorem 6.

Proof techniques. The proofs are admittedly similar in many ways (since we solve the same problem!), but the key technical components in controlling the magnitude of dual variables ν_1 and ν_2 are different. Soltanolkotabi et al. (2014, Lemma 8.5) relies on the semi-random model, and the resulting restricted isometry property (of the block of data points corresponding to each subspace). In contrast, our bound for $\|\nu_2\|$ does not require any probabilistic assumptions, therefore more general. It is however looser than Soltanolkotabi et al. (2014, Lemma 8.5) by a factor of $\sqrt{d}$ when we specialized in the semi-random model. This is probably what led to our worse dependence on the subspace dimension d in the bound we described in the discussion of Theorem 10.

In conclusion, we find that our results are complementary to that in Soltanolkotabi et al. (2014) and provide a novel point of view to the theoretical analysis for subspace clustering problems.

Appendix B. Numerical algorithm to solve Matrix-LASSO-SSC

In this section we outline the steps of solving the matrix version of LASSO-SSC below. Note that Elhamifar and Vidal (2013) derived a more general version of Matrix-LASSO-SSC to account for not only noisy but also sparse corruptions. We include this appendix merely for the convenience of the readers. Consider

$$\min_C \|C\|_1 + \frac{\lambda}{2}\|X - XC\|_F^2 \quad \text{s.t.} \quad \operatorname{diag}(C) = 0. \tag{B.1}$$

While this convex optimization problem can be solved by some off-the-shelf general purpose solvers such as SeDuMi (Sturm, 1999) or SDPT3 (Toh et al., 1999), such approaches are usually slow and non-scalable. An ADMM (Boyd et al., 2011) version of the problem is described here for fast computation. It solves an equivalent optimization program

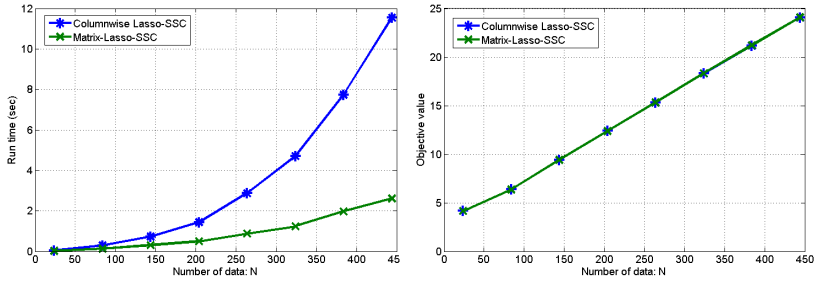
$$\min_C \|C\|_1 + \frac{\lambda}{2}\|X - XJ\|_F^2 \quad \text{s.t.} \quad J = C - \operatorname{diag}(C). \tag{B.2}$$

We add to the Lagrangian with an additional quadratic penalty term for the equality constraint and get the augmented Lagrangian

$$\mathcal{L} = \|C\|_1 + \frac{\lambda}{2}\|X - XJ\|_F^2 + \frac{\mu}{2}\|J - C + \operatorname{diag}(C)\|_F^2 + tr(\Lambda^T(J - C + \operatorname{diag}(C))),$$

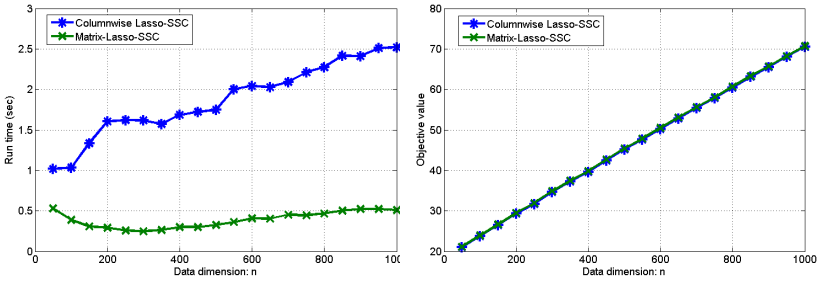
where Λ is the dual variable and μ is a parameter. Optimization is done by alternatingly optimizing over J, C and Λ until convergence. The update steps are derived by solving $\partial\mathcal{L}/\partial J = 0$ and $\partial\mathcal{L}/\partial C = 0$. Notice that the objective function is non-differentiable for C at origin so we use the now standard soft-thresholding operator (Donoho, 1995). For both variables, the solution is given in closed-forms. For the update of Λ, we simply use the gradient descent method. For details of the ADMM algorithm and its guarantee, please refer to Boyd et al. (2011). To accelerate the convergence, it is possible to introduce a parameter ρ and increase μ by $\mu = \rho\mu$ at every iteration. The full algorithm is summarized in Algorithm 1.

Note that for the special case when $\rho = 1$, the inverse of $(\lambda Y^T Y + \mu I)$ can be precomputed, and hence each iteration can be computed in linear time. Empirically, we found it good to set $\mu = \lambda$ and it takes roughly 50-100 iterations to converge to a sufficiently good points. We remark that the matrix version of the algorithm is much faster than the column-by-column ADMM-Lasso and achieves almost the same numerical accuracy; see our experiments in Figure 11a,11b,12a and 12b.



(a) Running time comparison. (b) Objective value comparison.

Figure 11: Comparisons of the two optimization procedures with an increasing number of data. Simulated under fully random model with $n = 100, d = 4, L = 3, \sigma = 0.2$, κ increases from 2 to 40 such that the number of data goes from 24 to 480. From Figure **(a)**, it appears that the matrix version scales better with increasing number of data compared to columnwise LASSO. Figure **(b)** shows that the objective value obtained at stop points of two algorithms are nearly the same.



(a) Running time comparison. (b) Objective value comparison.

Figure 12: Comparisons of the two optimization procedures with an increasing ambient dimension. Simulated with $\kappa = 5, d = 4, L = 3, \sigma = 0.2$, ambient dimension n increases from 50 to 1000. Note that the dependence on dimension is weak for both algorithm at this small scale due to the fast vectorized computation. Nevertheless, it is clear from Figure 12a that the matrix version of SSC runs faster. Figure **(b)** shows that the objective value obtained at stop points of two algorithms are nearly the same.

Algorithm 1 Matrix-LASSO-SSC

Input: Data points as columns in $X \in \mathbb{R}^{n \times N}$, tradeoff parameter λ, numerical parameters μ_0 and ρ.
Initialize $C = 0$, $J = 0$, $\Lambda = 0$, $k = 0$.
while not converged **do**

1. Update J by
$$J = (\lambda X^T X + \mu_k I)^{-1}(\lambda X^T X + \mu_k C - \Lambda).$$
2. Update C by
$$C' = \text{SoftThresh}_{\frac{1}{\mu_k}}\left(J + \Lambda/\mu_k\right),$$
$$C = C' - \text{diag}(C').$$
3. Update Λ by
$$\Lambda = \Lambda + \mu_k(J - C)$$
4. Update parameter $\mu_{k+1} = \rho\mu_k$.
5. Iterate $k = k + 1$;

end while
Output: Affinity matrix $W = |C| + |C|^T$

Abstract

In Markov decision processes (MDPs), the variance of the reward-to-go is a natural measure of uncertainty about the long term performance of a policy, and is important in domains such as finance, resource allocation, and process control. Currently however, there is no tractable procedure for calculating it in large scale MDPs. This is in contrast to the case of the expected reward-to-go, also known as the value function, for which effective simulation-based algorithms are known, and have been used successfully in various domains. In this paper[1] we extend temporal difference (TD) learning algorithms to estimating the variance of the reward-to-go for a fixed policy. We propose variants of both TD(0) and LSTD(λ) with linear function approximation, prove their convergence, and demonstrate their utility in an option pricing problem. Our results show a dramatic improvement in terms of sample efficiency over standard Monte-Carlo methods, which are currently the state-of-the-art.

Keywords: Reinforcement learning, Markov decision processes, variance estimation, simulation, temporal differences

1. Introduction

In sequential decision making within the Markov Decision Process (MDP) framework, whether in a planning setting (Puterman, 1994; Powell, 2011) or a reinforcement learning setting (RL; Bertsekas and Tsitsiklis, 1996, Sutton and Barto, 1998), the decision maker ultimately obtains a policy π, often with some guarantees on its expected long-term performance. This typical conclusion of the policy optimization process is the starting point of our work.

We consider the policy π to be fixed[2], and we are interested in understanding how π performs in practice, with the natural quantity of interest being the reward-to-go from each state of the system. The *expected* reward-to-go J, also known as the *value function*, is often a part of an optimization process, and efficient methods for learning it are well known. In many applications, however, looking at expectations is not enough, and it seems only reasonable to estimate other statistics of the reward-to-go, such as its *variance*, denoted by V. Quite surprisingly, this topic has received very little attention; at the current state-of-the-art, the only solution for large-scale MDPs is a naive Monte-Carlo approach, demanding extensive simulations of the long-term outcomes *from each system state*. In this paper we explore much more efficient alternatives.

We further motivate policy evaluation with respect to the variance of the reward-to-go. The variance is an intuitive measure of uncertainty, and common practice in many domains such as finance, process control, and clinical decision making (Sharpe, 1966; Shortreed et al., 2011). As we show in the paper, in an option pricing domain, the uncertainty captured by the variance of the reward-to-go highlights important properties of the policy, that are not visible by looking at the value function alone.

The variance may also be used for policy selection. In some practical situations, a full policy-optimization procedure is not an option, and the agent can only select between several predefined policies. For example, it may be that each policy is designed by an expert (e.g., a private equity or investment fund), and the agent can simply select between several policies, given the current features of the system (e.g., current economic indicators). A related financial experiment in a non-sequential setting was reported by Moody and Saffell (2001), which selected between several investment types, and which emphasized the importance of incorporating variance-based objectives in the policy selection.

Finally, the value function has proved to be a fundamental ingredient in many policy optimization algorithms. The variance of the reward-to-go may thus prove valuable for *risk aware* optimization algorithms, a topic that has gained significant interest recently (Filar et al., 1995; Mihatsch and Neuneier, 2002; Geibel and Wysotzki, 2005; Mannor and Tsitsiklis, 2013). Therefore, the policy evaluation methods in this work may be used as a sub-procedure in policy optimization. Since the conference publication of this work, this idea has already been explored by Tamar and Mannor (2013) and Prashanth and Ghavamzadeh (2013). Both Tamar and Mannor (2013) and Prashanth and Ghavamzadeh (2013) suggested actor-critic algorithms, in which the critic uses the policy evaluation ideas introduced in this paper. We are certain that risk-aware policy evaluation would play a major role in future risk-aware optimization algorithms as well.

The principal challenge in policy evaluation arises when the state space is large, or continuous. Then, solving Bellman's equation for the value or its extension (Sobel, 1982) for the variance becomes intractable. This difficulty is even more pronounced in the learning setting, when a model of the process is not available, and the evaluation has to be *estimated* from a limited amount of samples. Fortunately, for the case of the value function, effective learning approaches are known.

Temporal Difference methods (TD; Sutton, 1988) typically employ *function approximation* to represent the value function in a lower dimensional subspace, and *learn* the approximation parameters efficiently, by fitting the spatiotemporal relations in Bellman's equation to the observed (or simulated) data. TD methods have been studied extensively, both theoretically (Bertsekas, 2012, Lazaric et al., 2010) and empirically (e.g., Tesauro, 1995, Powell, 2011, Section 14.5), and are considered to be the state-of-the-art in policy evaluation.

1. This paper extends an earlier work by the authors (Tamar et al., 2013).
2. This setting is also known as a Markov reward process.

However, when it comes to evaluating additional statistics of the reward-to-go, such as its variance, little is known. This may be due to the fact that the linearity of the expectation in Bellman's equation plays a key role in TD algorithms.

In this paper we present a TD framework for learning the variance of the reward-to-go, using function approximation, in problems where a model is not available, or too large to solve. To our knowledge, this is the first work that addresses the challenge of large state spaces, by considering an approximation scheme for the variance. Our approach is based on the following observation: the second moment of the reward-to-go, denoted by M, together with the value function J, satisfies a linear 'Bellman-like' equation. By extending TD methods to jointly estimate J and M with linear function approximation, we obtain a solution for estimating the variance, using the relation $V = M - J^2$.

We propose both a variant of Least Squares Temporal Difference (LSTD; Boyan 2002) and of TD(0) (Sutton and Barto, 1998) for jointly estimating J and M with linear function approximation. For these algorithms, we provide convergence guarantees and error bounds. In addition, we introduce novel methods for enforcing the approximate variance to be positive, through a constrained TD equation or through an appropriate choice of features. An empirical evaluation of our approach on an American-style option pricing problem demonstrates a dramatic improvement in terms of sample efficiency compared to Monte Carlo techniques—the current state of the art.

A previous study by Sato et al. (2001) suggested TD equations for J and V, without function approximation. Their approach relied on a non-linear equation for V, and it is not clear how it may be extended to handle large state spaces. More recently, Morimura et al. (2010) proposed TD learning rules for a parametric distribution of the return, albeit without function approximation nor formal guarantees. In the Bayesian Gaussian process temporal difference framework of Engel et al. (2005), the reward-to-go is assumed to have a Gaussian posterior distribution, and its mean and variance are estimated. However, the resulting variance is a product of both stochastic transitions and model uncertainty, and is thus different than the variance considered here. For average reward MDPs, several studies (e.g., Filar et al., 1989) considered the variation of the reward from its average. This measure of variability is not suitable for the discounted and episodic settings considered here. A different line of work considers MDPs with a *dynamic-risk* measure (Ruszczyński, 2010). In dynamic risk, instead of considering the reward-to-go as the random variable of interest, the risk is defined iteratively over the possible future trajectories. In an optimization setting, dynamic-risk has some favorable properties such as time-consistency, and a dynamic programming formulation (Ruszczyński, 2010). However, the variance of the reward-to-go considered here is considerably more intuitive, and leads to a much simpler approach.

This paper is organized as follows. In Section 2 we present our formal MDP setup. In Section 3 we derive the fundamental equations for jointly approximating J and M, and discuss their properties. A solution to these equations may be obtained by sampling, through the use of TD algorithms, as presented in Section 4. As it turns out, our approximation scheme may result in cases where the approximate variance is negative. We discuss this in Section 5, and propose methods for avoiding it. Section 6 presents an empirical evaluation on an option pricing problem, and Section 7 concludes, and discusses future directions.

2. Framework and Background

We consider an episodic MDP[3] (also known as a stochastic shortest path problem; Bertsekas 2012) in discrete time with a finite state space $X \triangleq \{1, \ldots, n\}$ and a terminal state x^*. A *fixed* policy π determines, for each $x \in X$, a stochastic transition to a subsequent state $x' \in \{X \cup x^*\}$ with probability $P(x'|x)$. We consider a deterministic and bounded reward function $r : X \to \mathbb{R}$, and assume zero reward at the terminal state. We denote by x_k the state at time k, where $k = 0, 1, 2, \ldots$.

A policy is said to be *proper* (Bertsekas, 2012) if there is a positive probability that the terminal state x^* will be reached after at most n transitions, from any initial state. Throughout this paper we make the following assumption:

Assumption 1 *The policy π is proper.*

Let $\gamma \in (0, 1]$ denote a discount factor. We emphasize that the case $\gamma = 1$, corresponding to a non-discounted setting, is allowed, and much of our effort in the sequel is to handle this special and important case. Let $\tau \triangleq \min\{k > 0 | x_k = x^*\}$ denote the first visit time to the terminal state, and let the random variable B denote the accumulated (and possibly discounted) reward along the trajectory until that time

$$B \triangleq \sum_{k=0}^{\tau-1} \gamma^k r(x_k).$$

In this work, we are interested in the mean-variance tradeoff in B, represented by the *value function*

$$J(x) \triangleq \mathbb{E}\left[B | x_0 = x\right], \quad x \in X,$$

and the *variance of the reward-to-go*

$$V(x) \triangleq \mathrm{Var}\left[B | x_0 = x\right], \quad x \in X.$$

We will find it convenient to define also the *second moment of the reward-to-go*

$$M(x) \triangleq \mathbb{E}\left[B^2 | x_0 = x\right], \quad x \in X.$$

Our goal is to estimate the functions $J(x)$ and $V(x)$ from trajectories obtained by simulating the MDP with policy π.

3. Approximation of the Variance of the Reward-To-Go

In this section we derive a projected equation method for approximating $J(x)$ and $M(x)$ using linear function approximation. The approximation of $V(x)$ will then follow from the relation $V(x) = M(x) - J(x)^2$.

Our starting point is a system of equations for $J(x)$ and $M(x)$, first derived by Sobel (1982) for a discounted infinite horizon case, and extended here to the episodic case. The equation for J is the well known Bellman equation for a fixed policy, and independent of the equation for M.

3. In particular, any finite horizon MDP is an episodic MDP, for which our results apply. Extending these results to the infinite horizon discounted setting is straightforward.

Proposition 2 *The following equations hold for $x \in X$*

$$\begin{aligned} J(x) &= r(x) + \gamma \sum_{x' \in X} P(x'|x) J(x'), \\ M(x) &= r(x)^2 + 2\gamma r(x) \sum_{x' \in X} P(x'|x) J(x') + \gamma^2 \sum_{x' \in X} P(x'|x) M(x'). \end{aligned} \tag{1}$$

Furthermore, under Assumption 1 a unique solution to Eq. (1) *exists.*

A straightforward proof is given in Appendix A.

At this point the reader may wonder why an equation for V is not presented. While such an equation may be derived (see, e.g., Sobel 1982, Tamar et al. 2012), it is not linear. The linearity of (1) in J and M is the key to our approach. As we show in the next subsection, the solution to (1) may be expressed as the fixed point of a linear mapping in the joint space of J and M. We will then show that a projection of this mapping onto a linear feature space is contracting, thus allowing us to use the TD methodology to estimate J and M.

3.1 A Projected Fixed Point Equation in the Joint Space of J and M

For the sequel, we introduce the following vector notations. We denote by $P \in \mathbb{R}^{n \times n}$ and $r \in \mathbb{R}^n$ the episodic MDP transition matrix and reward vector, i.e., $P_{x,x'} = P(x'|x)$ and $r_x = r(x)$, where $x, x' \in X$. Also, we define the diagonal matrix $R \triangleq diag(r)$.

For a vector $z \in \mathbb{R}^{2n}$ we let $z_J \in \mathbb{R}^n$ and $z_M \in \mathbb{R}^n$ denote its leading and ending n components, respectively. Thus, such a vector belongs to the joint space of J and M.

We define the mapping $T : \mathbb{R}^{2n} \to \mathbb{R}^{2n}$ by

$$\begin{aligned} [Tz]_J &= r + \gamma P z_J, \\ [Tz]_M &= Rr + 2\gamma RP z_J + \gamma^2 P z_M. \end{aligned} \tag{2}$$

It may easily be verified that a fixed point of T is a solution to (1), and by Proposition 2 such a fixed point exists and is unique.

When the state space X is large, however, a direct solution of (1) is not feasible. A popular approach in this case is to approximate $J(x)$ by restricting it to a lower dimensional subspace, and use simulation based TD algorithms to *learn* the approximation parameters (Bertsekas, 2012). In this paper we extend this approach to the approximation of $M(x)$ as well.

We consider a linear approximation architecture of the form

$$\tilde{J}(x) = \phi_J(x)^\top w_J, \quad \tilde{M}(x) = \phi_M(x)^\top w_M,$$

where $w_J \in \mathbb{R}^l$ and $w_M \in \mathbb{R}^m$ are the approximation parameter vectors, $\phi_J(x) \in \mathbb{R}^l$ and $\phi_M(x) \in \mathbb{R}^m$ are state dependent features, and $(\cdot)^\top$ denotes the transpose of a vector. The low dimensional subspaces are therefore

$$S_J = \{\Phi_J w | w \in \mathbb{R}^l\}, \quad S_M = \{\Phi_M w | w \in \mathbb{R}^m\},$$

where Φ_J and Φ_M are matrices whose rows are $\phi_J(x)^\top$ and $\phi_M(x)^\top$, respectively. We make the following standard independence assumption on the features.

Assumption 3 *The matrix Φ_J has rank l and the matrix Φ_M has rank m.*

We now discuss how the approximation parameters w_J and w_M are chosen. The idea behind TD methods is to fit the approximate $\tilde{J}$ and $\tilde{M}$ to obey Eq. (1) in some sense. Specifically, this is done by considering a *projection* of T onto the approximation subspaces S_J and S_M, and choosing $\tilde{J}$ and $\tilde{M}$ as the unique fixed point of this projected operator. As outlined earlier, our ultimate goal is to learn w_J and w_M from simulated trajectories of the MDP. Thus, it is constructive to consider projections onto S_J and S_M with respect to a norm that is weighted according to the state occupancy in these trajectories. We now define this projection.

For a trajectory $x_0, \ldots, x_{\tau-1}$, where x_0 is drawn from a fixed distribution $\zeta_0(x)$, and the states evolve according to the MDP with policy π, define the state occupancy probabilities

$$q_t(x) = P(x_t = x), \quad x \in X, \quad t = 0, 1, \ldots,$$

and let

$$\begin{aligned} q(x) &= \sum_{t=0}^{\infty} q_t(x), \quad x \in X, \\ Q &\triangleq diag(q). \end{aligned}$$

We make the following assumption on the policy π and initial distribution ζ_0

Assumption 4 *Each state has a positive probability of being visited, namely, $q(x) > 0$ for all $x \in X$.*

Note that if ζ_0 may be controlled (for example, if we have access to a simulator), Assumption 4 may be trivially satisfied by choosing a positive ζ_0 for all states. Alternatively, if some state has a zero probability of being visited under π, then it is irrelevant for policy evaluation, and we can remove it from the state space. In this case, so long as Assumption 3 still holds (i.e., the linear features remain identifiable) all our subsequent derivations remain valid.

For vectors in $\mathbb{R}^n$, we recall the weighted Euclidean norm

$$\|y\|_q = \sqrt{\sum_{i=1}^{n} q(i) \left(y(i)\right)^2}, \quad y \in \mathbb{R}^n,$$

and we denote by Π_J and Π_M the projections from $\mathbb{R}^n$ onto the subspaces S_J and S_M, respectively, with respect to this norm. Note that the projection operators Π_J and Π_M are linear, and may be written explicitly as $\Pi_J = \Phi_J(\Phi_J^\top Q \Phi_J)^{-1} \Phi_J^\top Q$, and similarly for Π_M.

For some $z \in \mathbb{R}^{2n}$ we denote by Π the projection of z_J onto S_J and z_M onto S_M, namely

$$\Pi = \begin{pmatrix} \Pi_J & 0 \\ 0 & \Pi_M \end{pmatrix}. \tag{3}$$

We are now ready to fully describe our approximation scheme. We consider the *projected* fixed point equation

$$z = \Pi T z, \tag{4}$$

and, letting z^* denote its solution (which we will show to be unique), propose the approximate value function $\tilde{J} = z_J^* \in S_J$ and second moment function $\tilde{M} = z_M^* \in S_M$.

We shall now derive an important property of the projected operator ΠT, namely, that it is a contraction. This leads to the uniqueness of z^*, and to a simple bound on the approximation error. As in regular TD algorithms, this contraction property also underlies the convergence of several sampling-based algorithms, to be presented in the next section.

We begin by stating a well known result (Proposition 7.1.1 of Bertsekas, 2012) regarding the contraction properties of the *projected Bellman operator* $\Pi_J T_J$, where $T_J y = r + \gamma P y$.

Lemma 5 *(Proposition 7.1.1 of Bertsekas, 2012) Let Assumptions 1, 3, and 4 hold. The linear operator P and the projected linear operator $\Pi_J P$ are non-expansions in the $\|\cdot\|_q$ norm, and satisfy*

$$\|\Pi_J P y\|_q \leq \|P y\|_q \leq \|y\|_q \quad \forall y \in \mathbb{R}^n.$$

In addition, $\Pi_J P$ is a contraction in some norm, i.e., there exists some norm $\|\cdot\|_J$ and some $\beta_J < 1$ such that

$$\|\Pi_J P y\|_J \leq \beta_J \|y\|_J, \quad \forall y \in \mathbb{R}^n.$$

Lemma 5 immediately leads to the following result:

Lemma 6 *Let Assumptions 1, 3, and 4 hold. Then, there exists some norm $\|\cdot\|_J$ and some $\beta_J < 1$ such that*

$$\|\gamma \Pi_J P y\|_J \leq \beta_J \|y\|_J, \quad \forall y \in \mathbb{R}^n.$$

Similarly, there exists some norm $\|\cdot\|_M$ and some $\beta_M < 1$ such that

$$\|\gamma \Pi_M P y\|_M \leq \beta_M \|y\|_M, \quad \forall y \in \mathbb{R}^n.$$

Note that for $\gamma < 1$, Lemma 6 holds with the norm $\|\cdot\|_q$ and contraction modulus γ, by the non-expansiveness property of $\Pi_J P$ in Lemma 5. The more difficult case $\gamma = 1$, however, requires the expressions in Lemma 6.

Next, we define a weighted-norm on $\mathbb{R}^{2n}$, in which a parameter α balances between the weight of the J components' norm, and the weight of the M components' norm, as defined in Lemma 6. The intuition behind this weighted-norm, is that by carefully selecting the balance α, we shall show that the contraction properties in Lemma 6 guarantee a contraction property for the projected operator ΠT, in this norm.

Definition 7 *For a vector $z \in \mathbb{R}^{2n}$ and a scalar $0 < \alpha < 1$, the α-weighted norm is*

$$\|z\|_\alpha = \alpha \|z_J\|_J + (1-\alpha)\|z_M\|_M, \tag{5}$$

where $\|\cdot\|_J$ and $\|\cdot\|_M$ are defined in Lemma 6.

Our main result of this section is given in the following proposition, where we show that the projected operator ΠT is a contraction with respect to a suitable α-weighted norm.

Proposition 8 *Let Assumptions 1, 3, and 4 hold. Then, there exists some $0 < \alpha < 1$ and some $\beta < 1$ such that ΠT is a β-contraction with respect to the α-weighted norm, i.e.,*

$$\|\Pi T z_1 - \Pi T z_2\|_\alpha \leq \beta \|z_1 - z_2\|_\alpha, \quad \forall z_1, z_2 \in \mathbb{R}^{2n}.$$

Proof From the definition of ΠT in (2) and (3), we have that for any $z_1, z_2 \in \mathbb{R}^{2n}$ we have $\|\Pi T z_1 - \Pi T z_2\|_\alpha = \|\Pi \mathcal{P}(z_1 - z_2)\|_\alpha$, where

$$\Pi \mathcal{P} = \begin{pmatrix} \gamma \Pi_J P & 0 \\ 2\gamma \Pi_M R P & \gamma^2 \Pi_M P \end{pmatrix}.$$

Thus, it suffices to show that for all $z \in \mathbb{R}^{2n}$

$$\|\Pi \mathcal{P} z\|_\alpha \leq \beta \|z\|_\alpha.$$

We will now show that $\|\Pi \mathcal{P} z\|_\alpha$ may be separated into two terms which may be bounded by Lemma 6, and an additional cross term. By balancing α and β, this term may be contained to yield the required contraction.

We have

$$\begin{aligned} \|\Pi \mathcal{P} z\|_\alpha =& \alpha \|\gamma \Pi_J P z_J\|_J \\ &+ (1-\alpha)\|2\gamma \Pi_M R P z_J + \gamma^2 \Pi_M P z_M\|_M \\ \leq& \alpha \|\gamma \Pi_J P z_J\|_J + (1-\alpha)\|\gamma^2 \Pi_M P z_M\|_M \\ &+ (1-\alpha)\|2\gamma \Pi_M R P z_J\|_M \\ \leq& \alpha \beta_J \|z_J\|_J + (1-\alpha)\gamma \beta_M \|z_M\|_M \\ &+ (1-\alpha)\|2\gamma \Pi_M R P z_J\|_M, \end{aligned} \tag{6}$$

where the equality is by definition of the α weighted norm (5), the first inequality is from the triangle inequality, and the second inequality is by Lemma 6. Now, we claim that there exists some finite C such that

$$\|2\gamma \Pi_M R P y\|_M \leq C \|y\|_J, \quad \forall y \in \mathbb{R}^n. \tag{7}$$

To see this, note that since $\mathbb{R}^n$ is a finite dimensional real vector space, all vector norms are equivalent (Horn and Johnson, 2012, Corollary 5.4.5) therefore there exist finite C_1 and C_2 such that for all $y \in \mathbb{R}^n$

$$C_1 \|2\gamma \Pi_M R P y\|_2 \leq \|2\gamma \Pi_M R P y\|_M \leq C_2 \|2\gamma \Pi_M R P y\|_2,$$

where $\|\cdot\|_2$ denotes the Euclidean norm. Let λ denote the spectral norm of the matrix $2\gamma \Pi_M R P$, which is finite since all the matrix elements are finite. We have that

$$\|2\gamma \Pi_M R P y\|_2 \leq \lambda \|y\|_2, \quad \forall y \in \mathbb{R}^n.$$

Using again the fact that all vector norms are equivalent, there exists a finite C_3 such that

$$\|y\|_2 \leq C_3 \|y\|_J, \quad \forall y \in \mathbb{R}^n.$$

Setting $C = C_2 \lambda C_3$ we get the desired bound. Let $\tilde{\beta} = \max\{\beta_J, \gamma \beta_M\} < 1$, and choose $\epsilon > 0$ such that

$$\tilde{\beta} + \epsilon < 1.$$

Now, choose α such that $\alpha = \frac{C}{\epsilon+C}$. We have that

$$(1-\alpha)C = \alpha\epsilon,$$

and plugging this into (7) yields

$$(1-\alpha)\|2\gamma\Pi_M RPy\|_M \leq \alpha\epsilon\|y\|_J. \tag{8}$$

We now return to (6), where we have

$$\begin{aligned}
&\alpha\beta_J\|z_J\|_J + (1-\alpha)\gamma\beta_M\|z_M\|_M + (1-\alpha)\|2\gamma\Pi_M RPz_J\|_M \\
\leq&\alpha\beta_J\|z_J\|_J + (1-\alpha)\gamma\beta_M\|z_M\|_M + \alpha\epsilon\|z_J\|_J \\
\leq&(\tilde{\beta}+\epsilon)\left(\alpha\|z_J\|_J + (1-\alpha)\|z_M\|_M\right),
\end{aligned}$$

where the first inequality is by (8), and the second is by the definition of $\tilde{\beta}$. We have thus shown that

$$\|\Pi\mathcal{P}z\|_\alpha \leq (\tilde{\beta}+\epsilon)\|z\|_\alpha.$$

Finally, choose $\beta = \tilde{\beta}+\epsilon$. ■

Proposition 8 guarantees that the projected operator ΠT has a unique fixed point. Let us denote this fixed point by z^*, and let w_J^*, w_M^* denote the corresponding weights, which are unique due to Assumption 3

$$\begin{aligned}
\Pi T z^* &= z^*, \\
z_J^* &= \Phi_J w_J^*, \\
z_M^* &= \Phi_M w_M^*.
\end{aligned} \tag{9}$$

In the next proposition, using a standard result of Bertsekas and Tsitsiklis (1996), we provide a bound on the approximation error.

Proposition 9 *Let Assumptions 1, 3, and 4 hold. Denote by $z_{true} \in \mathbb{R}^{2n}$ the true value and second moment functions, i.e., $[z_{true}]_J = J$, and $[z_{true}]_M = M$. Then,*

$$\|z_{true} - z^*\|_\alpha \leq \frac{1}{1-\beta}\|z_{true} - \Pi z_{true}\|_\alpha,$$

with α and β defined in Proposition 8.

Proof This result is similar to Lemma 6.9 in Bertsekas and Tsitsiklis (1996). We have

$$\begin{aligned}
\|z_{true} - z^*\|_\alpha \leq& \|z_{true} - \Pi z_{true}\|_\alpha + \|\Pi z_{true} - z^*\|_\alpha \\
=& \|z_{true} - \Pi z_{true}\|_\alpha + \|\Pi T z_{true} - \Pi T z^*\|_\alpha \\
\leq& \|z_{true} - \Pi z_{true}\|_\alpha + \beta\|z_{true} - z^*\|_\alpha.
\end{aligned}$$

Rearranging gives the stated result. ■

Note that by definition, Πz_{true} is the best approximation we can hope for (in terms of the α-weighted squared error) in our approximation subspace. Thus, the approximation error $\|z_{true} - z^*\|_\alpha$ is ultimately bounded by the choice of features, which in practice should be chosen wisely.

At this point, the reader may question the usefulness of the projected fixed-point approximation over simpler approximation schemes, such as the direct projection Πz_{true}. As we show in the next section, the projected fixed-point architecture supports a family of sampling-based TD estimation algorithms, with efficient batch and online implementations. Furthermore, as we show empirically in Section 6, these TD algorithms perform well in practice, especially in the regime of a small sample size. For conventional TD algorithms, these benefits are well-established (Bertsekas, 2012), and gave rise to their popularity. Here we extend this to the variance of the reward-to-go.

4. Simulation Based Estimation Algorithms

In this section we propose algorithms that estimate $\tilde{J}$ and $\tilde{M}$ from sampled trajectories of the MDP, based on the approximation architecture of the previous section.

We begin by writing the projected equation (9) in matrix form. First, let us write the equation explicitly as

$$\begin{aligned}
\Pi_J\left(r + \gamma P\Phi_J w_J^*\right) &= \Phi_J w_J^*, \\
\Pi_M\left(Rr + 2\gamma RP\Phi_J w_J^* + \gamma^2 P\Phi_M w_M^*\right) &= \Phi_M w_M^*.
\end{aligned} \tag{10}$$

Recalling the definition of Q, projecting a vector y onto Φw satisfies the following orthogonality condition

$$\Phi^\top Q(y - \Phi w) = 0.$$

We therefore have

$$\begin{aligned}
\Phi_J^\top Q\left(\Phi_J w_J^* - \left(r + \gamma P\Phi_J w_J^*\right)\right) &= 0, \\
\Phi_M^\top Q\left(\Phi_M w_M^* - \left(Rr + 2\gamma RP\Phi_J w_J^* + \gamma^2 P\Phi_M w_M^*\right)\right) &= 0,
\end{aligned}$$

which can be written as

$$Aw_J^* = b, \quad Cw_M^* = d, \tag{11}$$

with

$$\begin{aligned}
A &= \Phi_J^\top Q\left(I - \gamma P\right)\Phi_J, \quad b = \Phi_J^\top Q r, \\
C &= \Phi_M^\top Q\left(I - \gamma^2 P\right)\Phi_M, \quad d = \Phi_M^\top Q R\left(r + 2\gamma P\Phi_J A^{-1} b\right),
\end{aligned} \tag{12}$$

and the matrices A and C are invertible since Proposition 8 guarantees a unique solution to (9) and Assumption 3 guarantees the unique weights of its projection.

Let us now outline our proposed algorithms. The first algorithm is a variant of the Least Squares Temporal Difference algorithm (LSTD; Boyan 2002), and aims to solve Eq. (11) directly, by forming sample based estimates of the terms A, b, C, and d. This is a batch algorithm that is known to make efficient use of data in its nominal version, and as we show empirically, demonstrates efficient performance in our case as well. The second algorithm

is a variant of online TD(0) (Sutton and Barto, 1998). In its nominal form, TD(0) has been successfully used as the critic in actor-critic algorithms (Konda and Tsitsiklis, 2003). Our extended TD(0) variant may be used similarly in a *risk-adjusted* actor-critic algorithm (Tamar and Mannor, 2013; Prashanth and Ghavamzadeh, 2013). The third algorithm is a variant of LSTD(λ), in which, similarly to standard LSTD(λ), Eq. (11) is extended to its multi-step counterpart. The fourth algorithm is not based on the TD equation (11), but uses least squares regression to estimate the direct projection Πz_{true}. We compare this algorithm with the LSTD variants in Section 6.

4.1 A Least Squares TD Algorithm

Our first simulation-based algorithm is an extension of the LSTD algorithm (Boyan, 2002). We simulate N trajectories of the MDP with the policy π and initial state distribution ζ_0. Let $x_0^k, x_1^k, \ldots, x_{\tau^k-1}^k$ and τ^k, where $k = 0, 1, \ldots, N$, denote the state sequence and visit times to the terminal state within these trajectories, respectively. We now use these trajectories to form the following estimates of the terms in (12)

$$\begin{aligned}
A_N &= \mathbb{E}_N\left[\sum_{t=0}^{\tau-1}\phi_J(x_t)(\phi_J(x_t)-\gamma\phi_J(x_{t+1}))^\top\right],\\
b_N &= \mathbb{E}_N\left[\sum_{t=0}^{\tau-1}\phi_J(x_t)r(x_t)\right],\\
C_N &= \mathbb{E}_N\left[\sum_{t=0}^{\tau-1}\phi_M(x_t)(\phi_M(x_t)-\gamma^2\phi_M(x_{t+1}))^\top\right],\\
d_N &= \mathbb{E}_N\left[\sum_{t=0}^{\tau-1}\phi_M(x_t)r(x_t)\left(r(x_t)+2\gamma\phi_J(x_{t+1})^\top A_N^{-1}b_N\right)\right],
\end{aligned} \tag{13}$$

where $\mathbb{E}_N$ denotes an empirical average over trajectories, i.e., $\mathbb{E}_N[f(x,\tau)] = \frac{1}{N}\sum_{k=1}^N f(x^k,\tau^k)$. The LSTD approximation is given by

$$\hat{w}_J^* = A_N^{-1}b_N, \quad \hat{w}_M^* = C_N^{-1}d_N.$$

The next theorem shows that LSTD converges.

Theorem 10 *Let Assumptions 1, 3, and 4 hold. Then $\hat{w}_J^* \to w_J^*$ and $\hat{w}_M^* \to w_M^*$ as $N \to \infty$ with probability 1.*

The proof involves a straightforward application of the law of large numbers and is described in Appendix B. For regular LSTD, $\mathcal{O}(1/\sqrt{n})$ convergence rates were derived under certain mixing conditions of the MDP by Konda (2002, based on a central limit theorem argument) and Lazaric et al. (2010, based on a finite time analysis), and may be extended to the algorithm presented here.

4.2 An Online TD(0) Algorithm

Our second estimation algorithm is an extension of the well known TD(0) algorithm (Sutton and Barto, 1998). Again, we simulate trajectories of the MDP corresponding to the policy

π and initial state distribution ζ_0, and we iteratively update our estimates at every visit to the terminal state. An extension to an algorithm that updates at every state transition is also possible, but we do not pursue such here.

For some $0 \le t < \tau^k$ and weights w_J, w_M, we introduce the TD terms

$$\begin{aligned}
\delta_J^k(t,w_J,w_M) =& r(x_t^k) + \left(\gamma\phi_J(x_{t+1}^k)^\top - \phi_J(x_t^k)^\top\right)w_J,\\
\delta_M^k(t,w_J,w_M) =& r^2(x_t^k) + 2\gamma r(x_t^k)\phi_J(x_{t+1}^k)^\top w_J\\
&+ \left(\gamma^2\phi_M(x_{t+1}^k)^\top - \phi_M(x_t^k)^\top\right)w_M.
\end{aligned}$$

Note that δ_J^k is the standard TD error (Sutton and Barto, 1998). For the intuition behind δ_M^k, observe that M in (1) is equivalent to the value function of an MDP with stochastic reward $r(x)^2 + 2\gamma r(x)J(x')$, where $x' \sim P(x'|x)$. The TD term δ_M^k is the equivalent TD error, with $\phi_J(x')^\top w_J$ substituting $J(x')$. The TD(0) algorithm is given by

$$\begin{aligned}
\hat{w}_{J;k+1} &= \hat{w}_{J;k} + \xi_k\sum_{t=0}^{\tau^k-1}\phi_J(x_t)\delta_J^k(t,\hat{w}_{J;k},\hat{w}_{M;k}),\\
\hat{w}_{M;k+1} &= \hat{w}_{M;k} + \xi_k\sum_{t=0}^{\tau^k-1}\phi_M(x_t)\delta_M^k(t,\hat{w}_{J;k},\hat{w}_{M;k}),
\end{aligned}$$

where $\{\xi_k\}$ are positive step sizes.

The next theorem shows that TD(0) converges.

Theorem 11 *Let Assumptions 1, 3, and 4 hold, and let the step sizes satisfy*

$$\sum_{k=0}^\infty \xi_k = \infty, \quad \sum_{k=0}^\infty \xi_k^2 < \infty.$$

Then $\hat{w}_{J;k} \to w_J^*$ and $\hat{w}_{M;k} \to w_M^*$ as $k \to \infty$ with probability 1.

Proof The proof is based on representing the algorithm as a stochastic approximation, and uses a result of Borkar (2008) to show that the iterates asymptotically track a certain ordinary differential equation (ODE). This ODE will then be shown to have a unique asymptotically stable equilibrium exactly at w_J^*, w_M^*.

A straightforward expectation calculation (see (22) and (23) in Appendix B for the derivation) shows that for all k we have

$$\begin{aligned}
\mathbb{E}\left[\sum_{t=0}^{\tau^k-1}\phi_J(x_t)\delta_J^k(t,w_J,w_M)\right] &= \Phi_J^\top Q r - \Phi_J^\top Q\left(I-\gamma P\right)\Phi_J w_J,\\
\mathbb{E}\left[\sum_{t=0}^{\tau^k-1}\phi_M(x_t)\delta_M^k(t,w_J,w_M)\right] &= \Phi_M^\top Q R\left(r+2\gamma P\Phi_J w_J\right) - \Phi_M^\top Q\left(I-\gamma^2 P\right)\Phi_M w_M.
\end{aligned}$$

Letting $\hat{w}_k = (\hat{w}_{J;k}, \hat{w}_{M;k})$ denote a concatenated weight vector in the joint space $\mathbb{R}^l \times \mathbb{R}^m$ we can write the TD algorithm in a stochastic approximation form as

$$\hat{w}_{k+1} = \hat{w}_k + \xi_k\left(z + M\hat{w}_k + \delta M_{k+1}\right), \tag{14}$$

where

$$M = \begin{pmatrix} \Phi_J^\top Q\left(\gamma P - I\right)\Phi_J & 0 \\ 2\gamma\Phi_M^\top QRP\Phi_J & \Phi_M^\top Q\left(\gamma^2 P - I\right)\Phi_M \end{pmatrix},$$

$$z = \begin{pmatrix} \Phi_J^\top Qr \\ \Phi_M^\top QRr \end{pmatrix},$$

and the noise terms δM_{k+1} satisfy

$$\mathbb{E}\left[\delta M_{k+1}|F_n\right] = 0,$$

where F_n is the filtration $F_n = \sigma(\hat{w}_m, \delta M_m, m \leq n)$, since different trajectories are independent.

We first claim that the eigenvalues of M have a negative real part. To see this, observe that M is block triangular, and its eigenvalues are just the eigenvalues of $M_1 \triangleq \Phi_J^\top Q\left(\gamma P - I\right)\Phi_J$ and $M_2 \triangleq \Phi_M^\top Q\left(\gamma^2 P - I\right)\Phi_M$. Lemma 6.10 of Bertsekas and Tsitsiklis (1996), shows that under Assumptions 1 and 4, the matrix $Q(\gamma P - I)$ is negative definite in the sense that $x^\top(\gamma P - I)x < 0 \quad \forall x \neq 0$ (Lemma 6.10 of Bertsekas and Tsitsiklis, 1996 is stated for the case $\gamma = 1$, but an extension to the simpler discounted case is trivial). By Assumption 3, this implies that the matrices M_1 and M_2 are negative definite in the sense that $x^\top M_1 x < 0 \quad \forall x \neq 0$, and $x^\top M_2 x < 0 \quad \forall x \neq 0$. Example 6.6 of Bertsekas, 2012 shows that the eigenvalues of a negative definite matrix have a negative real part. It therefore follows that the eigenvalues of M_1 and M_2 have a negative real part. Thus, the eigenvalues of M have a negative real part.

Next, let $h(w) = Mw + z$, and observe that the following conditions hold.

Condition 1 *The map h is Lipschitz.*

Condition 2 *The step sizes satisfy*

$$\sum_{k=0}^{\infty}\xi_k = \infty, \quad \sum_{k=0}^{\infty}\xi_k^2 < \infty.$$

Condition 3 *$\{\delta M_n\}$ is a martingale difference sequence, i.e., $\mathbb{E}\left[\delta M_{n+1}|F_n\right] = 0$.*

The next condition also holds

Condition 4 *The functions $h_c(w) \triangleq h(cw)/c, c \geq 1$ satisfy $h_c(w) \to h_\infty(w)$ as $c \to \infty$, uniformly on compacts, and $h_\infty(w)$ is continuous. Furthermore, the ODE*

$$\dot{w}(t) = h_\infty(w(t))$$

has the origin as its unique globally asymptotically stable equilibrium.

This is easily verified by noting that $h(cw)/c = Mw + c^{-1}z$, and since z is finite, $h_c(w)$ converges uniformly as $c \to \infty$ to $h_\infty(w) = Mw$. The stability of the origin is guaranteed since the eigenvalues of M have a negative real part (Khalil and Grizzle, 1996).

Theorem 7 in Chapter 3 of Borkar (2008) states that if Conditions 1-4 hold, the following condition holds

Condition 5 *The iterates of (14) remain bounded almost surely, i.e., $\sup_k \|\hat{w}_k\| < \infty$, a.s.*

Finally, we use a standard stochastic approximation result that, given that the above conditions hold, relates the convergence of the iterates of (14) with the asymptotic behavior of the ODE

$$\dot{w}(t) = h(w(t)). \tag{15}$$

Since the eigenvalues of M have a negative real part, (15) has a unique globally asymptotically stable equilibrium point (Khalil and Grizzle, 1996), which by (11) is exactly $\hat{w}* = (\hat{w}_J^*, \hat{w}_M^*)$. Formally, by Theorem 2 in Chapter 2 of Borkar (2008) we have that if Conditions 1, 2, 3 and 5 hold, then $\hat{w}_k \to \hat{w}*$ as $k \to \infty$ with probability 1. ■

It is interesting to note that despite the fact that the update of w_M depends on w_J, the algorithm converges using a single time scale, i.e., the same step-size schedule, for both w_J and w_M. This is in contrast with, for example, actor critic algorithms, that also have dependent updates but require multiple time-scales for convergence (Konda and Tsitsiklis, 2003). An intuitive reason for this is that the update for w_J is independent of w_M, therefore w_J will converge regardless, and w_M will 'track' it until convergence. Asymptotic convergence rates for TD(0) may also be derived along the lines of Konda (2002).

4.3 Multistep LSTD(λ) Algorithms

A common method in value function approximation (Bertsekas, 2012) is to replace the single-step mapping T_J with a multistep version, that takes into account multi-step transitions. For some $0 < \lambda < 1$, the multistep Bellman operator $T_J^{(\lambda)}$ is given by

$$T_J^{(\lambda)}(y) \triangleq (1-\lambda)\sum_{l=0}^{\infty}\lambda^l T_J^{l+1}(y) = (I - \lambda\gamma P)^{-1}r + \gamma P^{(\lambda,\gamma)}y,$$

where $P^{(\lambda,\gamma)} = (1-\lambda)\sum_{l=0}^{\infty}\lambda^l\gamma^l P^{l+1}$. The projected equation (10) then becomes

$$\Pi_J T_J^{(\lambda)}\left(\Phi_J w_J^{*(\lambda)}\right) = \Phi_J w_J^{*(\lambda)}.$$

Similarly, we may write a multistep equation for M

$$\Pi_M T_M^{(\lambda)}\left(\Phi_M w_M^{*(\lambda)}\right) = \Phi_M w_M^{*(\lambda)}, \tag{16}$$

where

$$T_M^{(\lambda)} \triangleq (1-\lambda)\sum_{l=0}^{\infty}\lambda^l T_{M^*}^{l+1},$$

and

$$T_{M^*}(y) \triangleq Rr + 2\gamma RP\Phi_J w_J^{*(\lambda)} + \gamma^2 Py.$$

Note the difference between T_{M^*} and $[T]_M$ defined earlier: we are no longer working on the joint space of J and M but instead we have an independent equation for approximating J,

and its solution $w_J^{*(\lambda)}$ is part of Equation (16) for approximating M. We can also write $T_M^{(\lambda)}$ explicitly as:

$$T_M^{(\lambda)}(y) = (I - \lambda\gamma^2 P)^{-1}\left(Rr + 2\gamma RP\Phi_J w_J^{*(\lambda)}\right) + \gamma^2 P^{(\lambda,\gamma^2)} y,$$

where $P^{(\lambda,\gamma^2)} = (1-\lambda)\sum_{l=0}^{\infty}\lambda^l\gamma^{2l}P^{l+1}$.

Proposition 7.1.1 of Bertsekas (2012) shows that for any $0 < \lambda < 1$ and $0 < \gamma \leq 1$ the projected operator $\Pi_J P^{(\lambda,\gamma)}$ is a contraction in the $\|\cdot\|_q$ norm. Therefore, both $\Pi_J T_J^{(\lambda)}$ and $\Pi_M T_M^{(\lambda)}$ are contractions with respect to the $\|\cdot\|_q$ norm, and both multistep projected equations have a unique solution. In a similar manner to the single step version, the projected equations may be written in matrix form

$$A^{(\lambda)} w_J^{*(\lambda)} = b^{(\lambda)}, \quad C^{(\lambda)} w_M^{*(\lambda)} = d^{(\lambda)}, \tag{17}$$

where

$$\begin{aligned}
A^{(\lambda)} &= \Phi_J^\top Q\left(I - \gamma P^{(\lambda,\gamma)}\right)\Phi_J, \quad b^{(\lambda)} = \Phi_J^\top Q(I - \lambda\gamma P)^{-1} r,\\
C^{(\lambda)} &= \Phi_M^\top Q\left(I - \gamma^2 P^{(\lambda,\gamma^2)}\right)\Phi_M,\\
d^{(\lambda)} &= \Phi_M^\top Q(I - \lambda\gamma^2 P)^{-1} R\left(r + 2\gamma P\Phi_J w_J^{*(\lambda)}\right).
\end{aligned}$$

Simulation based estimates $A_N^{(\lambda)}$ and $b_N^{(\lambda)}$ of the expressions above may be obtained by using eligibility traces, as described in Section 6.3.6 of Bertsekas (2012), and the LSTD(λ) approximation is then given by $\hat{w}_J^{*(\lambda)} = (A_N^{(\lambda)})^{-1} b_N^{(\lambda)}$. By substituting $w_J^{*(\lambda)}$ with $\hat{w}_J^{*(\lambda)}$ in the expression for $d^{(\lambda)}$, a similar procedure may be used to derive estimates $C_N^{(\lambda)}$ and $d_N^{(\lambda)}$, and to obtain the LSTD(λ) approximation $\hat{w}_M^{*(\lambda)} = (C_N^{(\lambda)})^{-1} d_N^{(\lambda)}$. A convergence result similar to Theorem 10 may also be obtained. Due to the similarity to the LSTD procedure in (13), the details are omitted. Finally, we note that a straightforward modification of the TD(0) algorithm to a multistep TD(λ) variant is also possible, using eligibility traces and following the procedure described in Section 6.3.6 of Bertsekas (2012).

4.4 A Direct Least Squares Regression Algorithm

We conclude this section with a simple regression style algorithm, which is not based on the TD approximation architecture of Section 3, but to our knowledge has not been proposed before.

As before, we let $x_0^k, x_1^k, \ldots, x_{\tau^k-1}^k$ denote the state sequence of the k'th simulated trajectory, and define the regression targets as

$$\hat{B}_t^k = \sum_{i=t}^{\tau^k-1} \gamma^{i-t} r(x_t^k).$$

Our approximation weights are now given by the solutions to the least squares problems

$$\hat{w}_J^* = \arg\min_{w_J} \sum_{k=1}^{N}\sum_{t=0}^{\tau^k-1}\left(\phi_J(x_t^k)^\top w_J - \hat{B}_t^k\right)^2,$$

and

$$\hat{w}_M^* = \arg\min_{w_M} \sum_{k=1}^{N}\sum_{t=0}^{\tau^k-1}\left(\phi_M(x_t^k)^\top w_M - \left(\hat{B}_t^k\right)^2\right)^2.$$

It may easily be verified that the approximate value $\tilde{J}$ and second moment $\tilde{M}$ of such a procedure converge, as $N \to \infty$, to the *direct* approximations $\Pi_J J$ and $\Pi_M M$, respectively. We further explore this algorithm and its relation to TD based algorithms in the empirical evaluation of Section 6.

5. Non Negative Approximate Variance

The TD algorithms of the preceding section approximate J and M by the solution to the fixed point equation (9). While Proposition 9 shows that the approximation errors of $\tilde{J}$ and $\tilde{M}$ are bounded, it does not guarantee that the approximated variance $\tilde{V}$, given by $\tilde{M} - \tilde{J}^2$, is non-negative for all states. A trivial remedy is to set all negative values of $\tilde{V}$ to zero; however, by such we lose information in these states. In this section we propose two alternative approaches to this problem. The first is through the choice of features, where we show that for the direct approximation $\Pi_J J$ and $\Pi_M M$, we can choose features that guarantee non-negative variance.

The second approach is based on the observation that non-negativeness of the variance may be written as a linear constraint in the weights for M. By adding such constraints to the projection in the fixed point equation (9), we obtain a different approximation architecture, in which non-negative variance is inherent. We show that this approximation scheme may be computed efficiently.

5.1 A Suitable Features Approach

For this section consider the direct approximation of J and M, as in Section 4.4, where we have $\tilde{J} = \Pi_J J$ and $\tilde{M} = \Pi_M M$. We investigate conditions under which $\tilde{M}(x) - \tilde{J}(x)^2 \geq 0$ for all $x \in X$.

Consider the following assumptions on the features:

Assumption 12 *The same features are used for J and M, i.e., $\Phi_J = \Phi_M$.*

Assumption 13 *The features are able to exactly represent a constant function, i.e., there exists w such that $\phi_J(x)^\top w = 1$ for all $x \in X$.*

We claim that Assumptions 12 and 13 suffice for guaranteeing non-negative approximate variance.

Proposition 14 *Let Assumptions 12 and 13 hold. Then $\tilde{M}(x) - \tilde{J}(x)^2 \geq 0$ for all $x \in X$.*

Proof First, by definition we have

$$V(x) = M(x) - J(x)^2 \geq 0. \tag{18}$$

Next, observe that Assumption 12 implies $\Pi_J = \Pi_M$.

Let $x \in X$, and recall that the projection operator is linear, thus we can write

$$\tilde{J}(x) = \sum_{i \in X} J(i)\omega_x(i), \quad \tilde{M}(x) = \sum_{i \in X} M(i)\omega_x(i), \tag{19}$$

where $\omega_x(i)$ are the projection weights for state x. Let $\bar{\omega}_x = \sum_{i \in X} \omega_x(i)$. We have

$$\tilde{J}(x)^2 = \bar{\omega}_x^2 \left(\sum_{i \in X} J(i) \frac{\omega_x(i)}{\bar{\omega}_x} \right)^2 \leq \bar{\omega}_x^2 \sum_{i \in X} J(i)^2 \frac{\omega_x(i)}{\bar{\omega}_x} \leq \bar{\omega}_x \sum_{i \in X} M(i)\omega_x(i) = \bar{\omega}_x \tilde{M}(x),$$

where the first inequality is by Jensen's inequality, the second inequality is by (18), and the equalities are by (19). Thus, $\bar{\omega}_x \leq 1$ guarantees $\tilde{V}(x) \geq 0$. We now claim that Assumption 13 guarantees $\bar{\omega}_x = 1$ for all x. To see this, consider a constant value function $J = 1$ for all states; clearly we have $\tilde{J} = 1$, as the weighted Euclidean error for this approximation is zero. Plugging in (19) gives $\sum_{i \in X} \omega_x(i) = 1$ for all x. ■

Proposition 14 concerns the approximation architecture itself, and not the estimation procedure. Therefore, it applies to the algorithms discussed above only asymptotically.

Many popular linear function approximation features such as grid tiles and CMAC's (Sutton and Barto, 1998) are able to represent a constant function. For these schemes, $\tilde{V}(x) \geq 0$ is guaranteed. For other schemes, we can guarantee $\tilde{V}(x) \geq 0$ by simply adding a constant feature to the feature set. Thus, at least for the direct approximation, it appears that a non-negative approximate variance is easily obtained. Whether a similar procedure may be applied to the fixed-point approximation is currently not known. However, Proposition 9 suggests that at least when the contraction modulus is small, the fixed-point approximation should behave similarly to the direct approximation. In the next section we propose a different approach, which *modifies* the fixed-point approximation to guarantee non-negative variance, regardless of the choice of features.

5.2 A Linearly Constrained Projection Approach

In this section we show that by adding linear constraints to the projected fixed point equation, we can guarantee a non-negative approximate variance. This modified approximation architecture admits a computationally efficient solution by a modification of the LSTD algorithm of Section 4.

First, let us write the equation for the second moment weights (10) with the projection operator as an explicit minimization

$$w_M^* = \arg\min_w \|\Phi_M w - \left(Rr + 2\gamma RP\Phi_J w_J^* + \gamma^2 P\Phi_M w_M^*\right)\|_q.$$

Observe that a non-negative approximate variance in some state x may be written as a *linear* inequality in w_M^* (but non-linear in w_J^*)

$$\phi_M(x)^\top w_M^* - (\phi_J(x)^\top w_J^*)^2 \geq 0.$$

We propose to add such inequality constraints to the projection operator. Let $\{x_1, \ldots, x_s\}$ denote a set of states in which we demand that the variance be non-negative. Let $H \in \mathbb{R}^{s \times m}$

denote a matrix with the features $-\phi_M^\top(x_i)$ as its rows, and let $g \in \mathbb{R}^s$ denote a vector with elements $-(\phi_J(x_i)^\top w_J^*)^2$. We write the non-negative-variance projected equation for the second moment as

$$w_M^+ = \begin{cases} \arg\min_w & \|\Phi_M w - \left(Rr + 2\gamma RP\Phi_J w_J^* + \gamma^2 P\Phi_M w_M^+\right)\|_q \\ \text{s.t.} & Hw \leq g \end{cases}. \tag{20}$$

Here, w_M^+ denotes the weights of $\tilde{M}$ in the *modified* approximation architecture. We now discuss whether a solution to (20) exists, and how it may be obtained.

Let us assume that the constraints in (20) admit a feasible solution:

Assumption 15 *There exists w such that $Hw < g$.*

Note that a trivial way to satisfy Assumption 15 is to have some feature vector that is positive for all states. To see this, let i^+ denote the index of the positive feature vector, and choose w to be all zeros, except for the i^+ element, which should satisfy $w_{i^+} < -\left(\max_{1 \leq i \leq s} |g_i|\right) / \left(\max_{1 \leq i \leq s} H_{i,i^+}\right)$.

Equation (20) is a form of projected equation studied by Bertsekas (2011), the solution of which exists, and may be obtained by the following iterative procedure

$$w_{k+1} = \Pi_{\Xi, \hat{W}_M}[w_k - \eta \Xi^{-1}(Cw_k - d)], \tag{21}$$

where C and d are defined in (12), Ξ is an arbitrary positive definite symmetric matrix, $\eta \in \mathbb{R}$ is a positive step size, and $\Pi_{\Xi, \hat{W}_M}$ denotes a projection onto the convex set $\hat{W}_M = \{w | Hw \leq g\}$ with respect to the Ξ weighted Euclidean norm.

The following lemma, which is based on a convergence result of Bertsekas (2011), guarantees that for $\gamma < 1$, the iteration (21) converges. For the non-discounted setting a similar result may be obtained by using the multi-step approach with $\lambda > 0$, as detailed in Tamar et al. (2013).

Lemma 16 *Assume $\gamma < 1$, and let Assumptions 1, 3, 4, and 15 hold. Then (20) admits a unique solution w_M^+, and there exists $\bar{\eta} > 0$ such that $\forall \eta \in (0, \bar{\eta})$ and $\forall w_0 \in \mathbb{R}^m$ the iteration (21) converges at a linear rate to w_M^+ (i.e., $\|w_k - w_M^+\|$ converges to 0 at least as fast as a geometric progression).*

Proof Bertsekas (2011) shows that projected fixed-point equations of the form

$$w^* = \begin{cases} \arg\min_w & \|\Phi w - T_{\text{lin}}(\Phi w^*)\|_q \\ \text{s.t.} & w \in \Omega \end{cases},$$

where $T_{\text{lin}}(y) = A_{\text{lin}} y + b_{\text{lin}}$ is a contracting linear operator, and Ω is a polyhedral set, may be solved iteratively by

$$w_{k+1} = \Pi_{\Xi, \Omega}[w_k - \eta \Xi^{-1}(C_{\text{lin}} w_k - d_{\text{lin}})],$$

where $\Pi_{\Xi, \Omega}$ projects onto Ω w.r.t. the norm $\|y\|_\Xi = \sqrt{y^\top \Xi y}$ for an arbitrary symmetric and positive-definite matrix Ξ, $C_{\text{lin}} = \Phi^\top Q(I - A_{\text{lin}})\Phi$ and $d_{\text{lin}} = \Phi' Q b_{\text{lin}}$. Specifically, the convergence result of Bertsekas (2011) shows that when T_{lin} is a contraction in the $\|\cdot\|_q$

norm, Ω is polyhedral, and Φ is full rank, there exists $\bar{\eta} > 0$ such that for all $\eta \in (0, \bar{\eta})$, and for all $w_0 \in \mathbb{R}^m$, the preceding iteration converges at a linear rate to the unique solution of the projected fixed point equation described above.

Substituting $T_{\text{lin}}(y)$ with $T_M(y) = Rr + 2\gamma RP\Phi_J w_J^* + \gamma^2 Py$, and Ω with the set defined by $Hw \leq g$, we obtain the projected fixed point equation (20), and the corresponding iteration (21). To apply the convergence result, the full-rank of Φ_M is guaranteed by Assumption 3, and the contraction of T_M in the $\|\cdot\|_q$ norm is guaranteed by Lemma 5, since P is a non-expansion and $\gamma < 1$. ■

Generally, C, d, and w_J^* are not known in advance, and should be replaced in (21) with their simulation based estimates, C_N, d_N, and $\hat{w}_J^*$, proposed in the previous section. The convergence of these estimates, together with the result of Lemma 16, lead to the following result; the proof is detailed in Appendix C.

Theorem 17 *Consider the algorithm in* (21) *with C, d, and w_J^* replaced by C_N, d_N, and $\hat{w}_J^*$, respectively, and with $k(N)$ replacing k for a specific N. Also, let the assumptions in Lemma 16 hold, and let $\eta \in (0, \bar{\eta})$, with $\bar{\eta}$ defined in Lemma 16. Then $w_{k(N)} \to w_M^+$ as $N \to \infty$ and $k(N) \to \infty$ almost surely. Namely, for any $\bar{\epsilon} > 0$ w.p. 1 there is a $\bar{N}(\bar{\epsilon})$ such that for any $N > \bar{N}(\bar{\epsilon})$ there is a $k(N, \bar{\epsilon})$, such that for all $k > k(N, \bar{\epsilon})$ we have $\|w_{k;N} - w_M^+\| \leq \bar{\epsilon}$.*

We remark that we do not know how to quantify how the linear constraints affect the approximation error. While intuitively our constraints add prior information that is 'correct' in some sense (since we know that the true variance is positive), it is not hard to construct examples where the constraints actually increase the error. In the following, we provide an illustration of the linearly constrained projection approach on a toy problem. We qualitatively show that the method effectively produces a non-negative solution, without significantly affecting the approximation error.

Consider the Markov chain depicted in Figure 1, which consists of n states with reward -1 and a terminal state x^* with zero reward. Assume no discounting, i.e., $\gamma = 1$. The transitions from each state is either to a subsequent state (with probability p) or to a preceding state (with probability $1-p$), with the exception of the first state which transitions to itself instead. We chose to approximate J and M with polynomials of degree 1 and 2, respectively, i.e., $\Phi_J(x) = [1, x]^\top$ and $\Phi_M(x) = [1, x, x^2]^\top$. For such a small problem, the fixed point equation (17) may be solved exactly, yielding the approximation depicted in Figure 2 (dotted line), for $p = 0.7$, $N = 30$, and $\lambda = 0.95$. Note that the variance, in Figure 2C, is negative for the last two states. Using algorithm (21) we obtained a positive variance constrained approximation, which is depicted in Figure 2 (dashed line). Note how the approximate variance has been adjusted to be positive for all states.

6. Experiments

In this section we present numerical simulations of policy evaluation for an option pricing domain. We show that in terms of sample efficiency, our LSTD(λ) algorithm significantly outperforms the current state-of-the-art. We begin by describing the domain and its modeling as an MDP, and then present our policy evaluation results. We emphasize that our

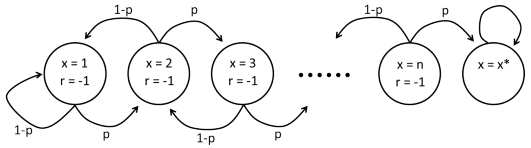

Figure 1: An example Markov chain.

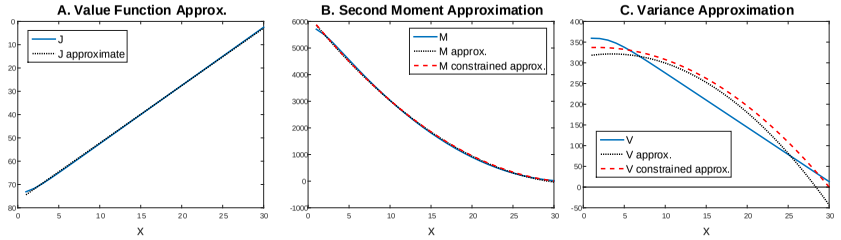

Figure 2: Value, second moment and variance approximation.

results only concern policy evaluation, and not policy optimization. The following MDP description is given for the purpose of presentation completeness.

6.1 Option Pricing

An American-style put option (Hull, 2006) is a contract which gives the owner the right, but not the obligation, to sell an asset at a specified strike price K on or before some maturity time t^*. Letting x_t denote the price (state) of the asset at time $t \leq t^*$, the immediate payoff of executing the option at that time is therefore $\max(0, K - x_t)$. Assuming Markov state transitions, an optimal execution policy may be found by solving a finite horizon MDP, and the expected profit under that policy is termed the 'fair' price of the option. Since the state space is typically continuous, an exact solution is infeasible, calling for approximate, sampling based techniques (Longstaff and Schwartz, 2001; Tsitsiklis and Van Roy, 2001; Li et al., 2009).

The option pricing problem may be formulated as an MDP as follows. To account for the finite horizon, we include time explicitly in the state, thus, the state at time t is $\{x_t; t\}$. The action set is binary, where 1 stands for executing the option and 0 for continuing to hold it. Once an option is executed, or when $t = t^*$, a transition to a terminal state takes place. Otherwise, the state transitions to $\{x_{t+1}; t+1\}$ where x_{t+1} is determined by a stochastic kernel $P(x_{t+1}|x_t, t)$. In our experiments we used a Bernoulli price fluctuation model (Cox

et al., 1979),

$$x_{t+1} = \begin{cases} f_u x_t, & \text{w.p. } p \\ f_d x_t, & \text{w.p. } 1-p \end{cases},$$

where the up and down factors, f_u and f_d, are constant. The reward for executing $u = 1$ at state x is $r(x) \triangleq \max(0, K - x)$ and zero otherwise. Note that by definition, for any state x in which the policy decides to execute, the reward-to-go is deterministic and equal to $r(x)$. Thus, we only need to estimate J and V for states in which the policy decides to hold. We focus on 'in-the-money' options, in which K is equal to the initial price x_0, and set $T = 20$.

A policy π was obtained using the LSPI algorithm (Lagoudakis and Parr, 2003; Li et al., 2009) with 2-dimensional (for x and t) radial basis function (RBF) features, as detailed in Tamar et al. (2014). It is well-known (Duffie, 2010), and intuitive, that the optimal policy (in terms of expected return) for the put option has a threshold structure—the policy executes if the price is below some boundary $\bar{x}_t$, and holds otherwise. It is also known, that $\bar{x}_t$ is monotonically increasing in t. Our policy π has such a structure as well. We emphasize, however, that the specific method of generating the policy π is not the focus of this work, as we are only interested in *evaluating* π. Thus, any policy generation method could have been used, and LSPI was chosen for convenience. In the following, we evaluate the value functions J and V for π.

6.2 Results

We now present our policy evaluation results for the put option domain. MATLAB® code for reproducing these results is available on the web-site `https://sites.google.com/site/variancetdcode/`.

We first calculate the 'true' value function J and standard deviation of reward-to-go $\sqrt{V}$, as shown in Figure 3. These plots were obtained using Monte Carlo (MC), by taking the empirical average and standard deviation of the reward of 10,000 trajectories starting from 323 equally spaced points in the state space for which the policy π decides to hold, a total of $N = 3,230,000$ trajectories. To our knowledge, an MC approach is the current state-of-the-art for obtaining an estimate of V.

Note the exercise boundary $\bar{x}_t$, emphasized with a dashed line in the value function plot. For x smaller than $\bar{x}_t$, the policy decides to exercise, therefore the value is linear in x and the variance is zero. Also note the discontinuous ridges on the J and $\sqrt{V}$ plots. These ridges are due to the discrete transition model, and occur when a transition to the next state (or the state following the next state) crosses the exercise boundary. To the risk-sensitive decision maker, these ridges are important, as they separate states with roughly the same expected return but with very different variance.

In Figure 4 we show the RMS error of the approximation $\sqrt{\tilde{V}}$ (compared to the 'true' $\sqrt{V}$) computed using the LSTD(0) algorithm of Section 4, for different budgets of sample trajectories N. We tested two popular feature sets: RBF features with 77 equally spaced centers, and tile features with 600 uniform non-overlapping tiles. In both cases the same features were used for both J and M. The sample trajectories were simulated independently, starting from uniformly distributed initial states. We compare our results to MC estimates obtained with the same trajectories.

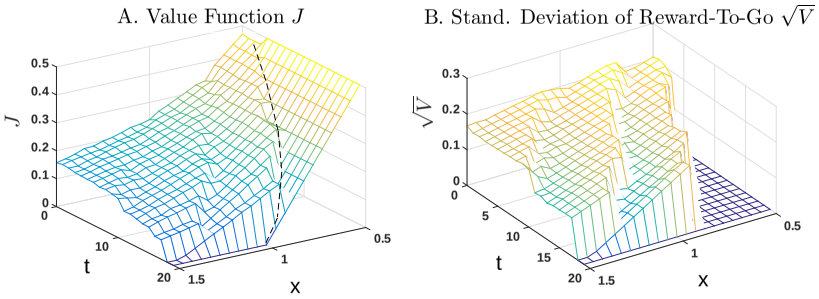

Figure 3: True value function J and standard deviation of the reward-to-go $\sqrt{V}$.

As can be seen, by exploiting relations *between* states and using the generalization capabilities of the function approximation, LSTD is able to fully exploit the data, and performs significantly better than MC for relatively small sample sizes. On the other hand, LSTD is limited by the expressiveness of its function approximation, and its error is therefore bounded.

Note that for $N \leq 323$ the MC estimate is meaningless, as the empirical standard deviation cannot be calculated from only one sample. LSTD however, is able to provide a reasonable result. Also note that the LSTD estimate is defined over the whole state-space, whereas the MC estimate is only defined for the discrete set of evaluation points.

To further appreciate the advantage of function approximation, we provide a visual comparison of the approximated standard deviation of reward-to-go $\sqrt{\tilde{V}}$. In Figure 5 we plot $\sqrt{\tilde{V}}$ obtained using a budget of $N = 2000$ sample trajectories starting from uniformly distributed states. In the left plot, we show the results of LSTD(λ) with RBF features (with 77 equally spaced centers in x and t). The variance in states where the policy decides to execute was set to zero manually, as there is no need to estimate it. In comparison, on the right plot we present the results of a Monte Carlo algorithm, with the same amount of data trajectories $N = 2000$. Clearly, LSTD(λ) makes better use of the limited data, with a plot that is much more similar to the true standard deviation (Figure 3; right). More importantly, the relevant structure in $\sqrt{V}$ outlined above is clear in the LSTD(λ) result (up to a smoothness limitation of the RBFs), yielding important information for the decision maker.

In Figure 6 we consider the LSTD(λ) algorithm with the tile features discussed above, and explore the effect of λ on the RMS error in $\sqrt{\tilde{V}}$. As in regular LSTD, λ can be seen to trade off estimation bias and variance (Bertsekas, 2012). In addition, we compare LSTD(λ) to the direct least squares algorithm of Section 4.4. For the case of the value function J, it is well-known (Bertsekas, 2012) that the direct approximation is equivalent to the limit $\lambda \to 1$. Our results suggest that a similar relation holds for the variance V as well. Furthermore, these results highlight the superior performance of the TD approach in the small sample size regime.

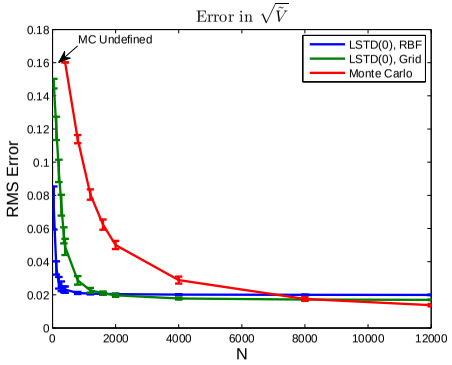

Figure 4: LSTD(0) vs. Monte Carlo. The RMS error of $\sqrt{\tilde{V}}$ on a set of evaluation points (see text) is shown vs. the budget of sample trajectories N, for LSTD(0) with two types of features and for Monte Carlo. Standard deviation error-bars from 20 runs are shown.

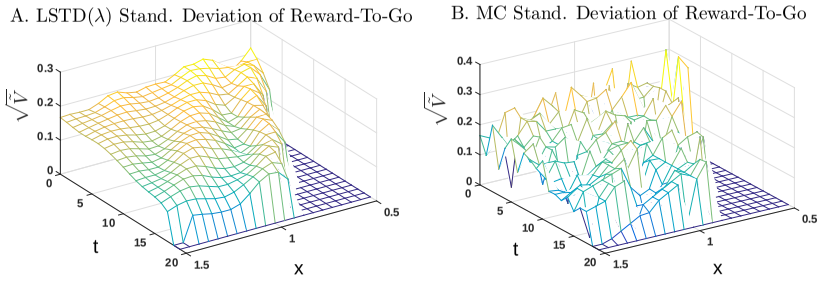

Figure 5: Approximate standard deviation of the reward-to-go $\sqrt{\tilde{V}}$. Left plot was obtained by LSTD(λ) with RBF features, using 2000 trajectories and $\lambda = 0.3$. Right plot was obtained using Monte Carlo, also with 2000 trajectories.

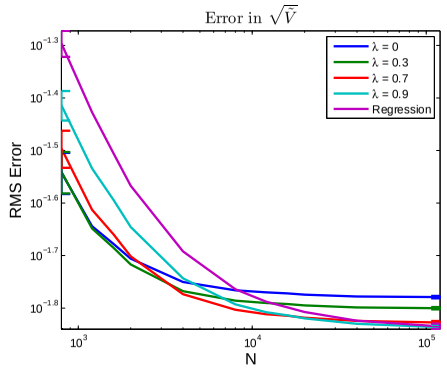

Figure 6: LSTD(λ) Results. The RMS error of $\sqrt{\tilde{V}}$ on a set of evaluation points (see text) is shown vs. the budget of sample trajectories N for different λ, and also for the least squares regression algorithm. For clarity, a log scale is used, and the error-bars (standard deviation from 20 runs) are shown only for marginal points.

7. Conclusion

We presented an extension of the TD framework for policy evaluation in MDPs with respect to the variance of the reward-to-go. Our framework deals with the curse of dimensionality by using function approximation, and uses a bootstrapping technique, based on an extension of the Bellman equation to the second moment, to achieve good performance even for a small sample size. We presented both formal guarantees and empirical evidence that this approach is useful in problems with a large state space, and limited sample budget.

A natural extension of this work is to consider higher moments, and statistical properties such as skewness and kurtosis of the reward-to-go. An extension of Bellman's equation to higher moments was proposed by Sobel (1982), and it may be used to derive TD equations similarly to the work presented here. This may also be useful for optimizing the expectation of a general function f of the accumulated reward $\mathbb{E}[f(B)]$, by looking at the first few terms in the Taylor expansion of f. It would be interesting to see whether a TD approach may be developed for other risk measures such as the value at risk or semi-deviation.

Another interesting direction is to use the variance of the reward-to-go to *guide feature selection*, or feature modification. For example, consider tile features. A large variance-to-go for states that belong to a particular tile may indicate that the value function in that tile varies greatly, and therefore it may be beneficial to split the tile into smaller segments. Of course, another explanation for the variance may be the inherent stochasticity of the system. Thus, a thoughtful feature-selection method should take that also into account. In a related topic, the variance of the reward-to-go may also be used to *guide exploration*, since intuitively, states with higher variance should be allocated more exploration resources, to potentially decrease the variance, if possible.

We conclude with a discussion on policy optimization with respect to a mean-variance tradeoff. While a naive variance-penalized policy iteration algorithm may be easily conceived, its usefulness should be questioned, as it was shown to be problematic for the standard deviation adjusted reward (Sobel, 1982) and the variance constrained reward (Mannor and Tsitsiklis, 2013). An alternative approach is to pursue *locally* optimal policies by using a gradient based method. Tamar et al. (2012) proposed policy gradient algorithms for a class of variance related criteria, and showed their convergence to local optima. These algorithms may be extended to use the variance function in an actor-critic type scheme (Sato et al., 2001), and recent work has extended these ideas to large-scale MDPs by employing function approximation, and using the TD policy evaluation algorithms presented here (Tamar and Mannor, 2013; Prashanth and Ghavamzadeh, 2013).

Acknowledgments

We would like to thank our anonymous reviewers for helpful comments and suggestions. The research leading to these results has received funding from the European Research Council under the European Union's Seventh Framework Program (FP/2007-2013) / ERC Grant Agreement n. 306638. Aviv Tamar is also partially funded by the Viterbi Scholarship, Technion.

Appendix A. Proof of Proposition 2

Proof The equation for $J(x)$ is well-known, and its proof is given here only for completeness. Choose $x \in X$. Then,

$$\begin{aligned}
J(x) &= \mathbb{E}\left[B|x_0 = x\right] \\
&= \mathbb{E}\left[\sum_{k=0}^{\tau-1} \gamma^k r(x_k) \middle| x_0 = x\right] \\
&= r(x) + \mathbb{E}\left[\sum_{k=1}^{\tau-1} \gamma^k r(x_k) \middle| x_0 = x\right] \\
&= r(x) + \gamma \mathbb{E}\left[\mathbb{E}\left[\sum_{k=1}^{\tau-1} \gamma^{k-1} r(x_k) \middle| x_0 = x, x_1 = x'\right]\right] \\
&= r(x) + \gamma \sum_{x' \in X} P(x'|x) J(x'),
\end{aligned}$$

where we excluded the terminal state from the last sum since reaching it ends the trajectory.

Similarly,

$$\begin{aligned}
M(x) &= \mathbb{E}\left[B^2|x_0 = x\right] \\
&= \mathbb{E}\left[\left(\sum_{k=0}^{\tau-1} \gamma^k r(x_k)\right)^2 \middle| x_0 = x\right] \\
&= \mathbb{E}\left[\left(r(x_0) + \sum_{k=1}^{\tau-1} \gamma^k r(x_k)\right)^2 \middle| x_0 = x\right] \\
&= r(x)^2 + 2r(x)\mathbb{E}\left[\sum_{k=1}^{\tau-1} \gamma^k r(x_k) \middle| x_0 = x\right] + \mathbb{E}\left[\left(\sum_{k=1}^{\tau-1} \gamma^k r(x_k)\right)^2 \middle| x_0 = x\right] \\
&= r(x)^2 + 2\gamma r(x) \sum_{x' \in X} P(x'|x) J(x') + \gamma^2 \sum_{x' \in X} P(x'|x) M(x').
\end{aligned}$$

The uniqueness of the value function J for a proper policy is well known, cf. Proposition 3.2.1 in Bertsekas (2012). The uniqueness of M follows by observing that in the equation for M, M may be seen as the value function of an MDP with the same transitions but with reward $r(x)^2 + 2\gamma r(x) \sum_{x' \in X} P(x'|x) J(x')$. Since only the rewards change, the policy remains proper and Proposition 3.2.1 in Bertsekas (2012) applies. ■

Appendix B. Proof of Theorem 10

Proof Let $\phi_1(x)$, $\phi_2(x)$ be some vector functions of the state. We claim that

$$\mathbb{E}\left[\sum_{t=0}^{\tau-1} \phi_1(x_t)\phi_2(x_t)^\top\right] = \sum_x q(x)\phi_1(x)\phi_2(x)^\top \equiv \Phi_1^\top Q \Phi_2, \tag{22}$$

where Φ_1 and Φ_2 are matrices with rows $\phi_1(x)$ and $\phi_2(x)$, respectively. To see this, let $\mathbb{1}(\cdot)$ denote the indicator function and write

$$\begin{aligned}
\mathbb{E}\left[\sum_{t=0}^{\tau-1} \phi_1(x_t)\phi_2(x_t)^\top\right] &= \mathbb{E}\left[\sum_{t=0}^{\tau-1} \sum_x \phi_1(x)\phi_2(x)^\top \mathbb{1}(x_t = x)\right] \\
&= \mathbb{E}\left[\sum_x \phi_1(x)\phi_2(x)^\top \sum_{t=0}^{\tau-1} \mathbb{1}(x_t = x)\right] \\
&= \sum_x \phi_1(x)\phi_2(x)^\top \mathbb{E}\left[\sum_{t=0}^{\tau-1} \mathbb{1}(x_t = x)\right].
\end{aligned}$$

Now, note that the last term on the right hand side is an expectation (over all possible trajectories) of the number of visits to a state x until reaching the terminal state, which is

exactly $q(x)$ since

$$\begin{aligned} q(x) &= \sum_{t=0}^{\infty} P(x_t = x) \\ &= \sum_{t=0}^{\infty} \mathbb{E}[\mathbb{1}(x_t = x)] \\ &= \mathbb{E}\left[\sum_{t=0}^{\infty} \mathbb{1}(x_t = x)\right] \\ &= \mathbb{E}\left[\sum_{t=0}^{\tau-1} \mathbb{1}(x_t = x)\right], \end{aligned}$$

where the third equality is by the dominated convergence theorem (Grimmett and Stirzaker, 2001, Sec. 5.6), and last equality follows from the absorbing property of the terminal state. Similarly, we have

$$\mathbb{E}\left[\sum_{t=0}^{\tau-1} \phi_1(x_t)\phi_2(x_{t+1})^\top\right] = \sum_x \sum_{x'} q(x)P(x'|x)\phi_1(x)\phi_2(x')^\top \equiv \Phi_1^\top Q P \Phi_2, \qquad (23)$$

since

$$\begin{aligned} \mathbb{E}\left[\sum_{t=0}^{\tau-1} \phi_1(x_t)\phi_2(x_{t+1})^\top\right] &= \mathbb{E}\left[\sum_{t=0}^{\tau-1} \sum_x \sum_{x'} \phi_1(x)\phi_2(x')^\top \mathbb{1}(x_t = x, x_{t+1} = x')\right] \\ &= \mathbb{E}\left[\sum_x \sum_{x'} \phi_1(x)\phi_2(x')^\top \sum_{t=0}^{\tau-1} \mathbb{1}(x_t = x, x_{t+1} = x')\right] \\ &= \sum_x \sum_{x'} \phi_1(x)\phi_2(x')^\top \mathbb{E}\left[\sum_{t=0}^{\tau-1} \mathbb{1}(x_t = x, x_{t+1} = x')\right], \end{aligned}$$

and

$$\begin{aligned} q(x)P(x'|x) &= \sum_{t=0}^{\infty} P(x_t = x)P(x'|x) \\ &= \sum_{t=0}^{\infty} P(x_t = x, x_{t+1} = x') \\ &= \sum_{t=0}^{\infty} \mathbb{E}[\mathbb{1}(x_t = x, x_{t+1} = x')] \\ &= \mathbb{E}\left[\sum_{t=0}^{\infty} \mathbb{1}(x_t = x, x_{t+1} = x')\right] \\ &= \mathbb{E}\left[\sum_{t=0}^{\tau-1} \mathbb{1}(x_t = x, x_{t+1} = x')\right]. \end{aligned}$$

Since trajectories between visits to the recurrent state are statistically independent, the law of large numbers together with the expressions in (22) and (23) suggest that the approximate expressions in (13) converge to their expected values with probability 1, therefore we have

$$\begin{aligned} A_N &\to A, \quad b_N \to b, \\ C_N &\to C, \quad d_N \to D, \end{aligned}$$

and

$$\begin{aligned} \hat{w}^*_{J;N} &= A_N^{-1} b_N \to A^{-1} b = w^*_J, \\ \hat{w}^*_{M;N} &= C_N^{-1} d_N \to C^{-1} d = w^*_M. \end{aligned}$$

■

Appendix C. Proof of Theorem 17

To show the convergence of the simulation-based version of (21) to a solution of (20), we need to bound the effect of simulation noise on the fixed point of (21). The difficulty, is that simulation noise affects both the terms in the update, C and d, and terms in the projection step—the set $\hat{W}_M$ onto which we project. In addition, the noise in C and d effectively adds noise to the weights q of the norm in (20), which should also be bounded.

We begin by proving several intermediate results. The first concerns the continuity of fixed points of contraction operators.

Lemma 18 *Let T_1 be a γ-contraction in the q_1 norm, and T_2 be a γ-contraction in the q_2 norm. Assume that there exists some δ' such that*

$$\|T_1 x - T_2 x\|_{q_1} \le \delta + \delta' \|x\|_{q_1}, \quad \forall x.$$

Let x_1^* and x_2^* denote the fixed points of T_1 and T_2, respectively. Then the following holds:

$$\|x_2^* - x_1^*\|_{q_1} \le \frac{\delta + \delta' \|x_2^*\|_{q_1}}{1 - \gamma}.$$

Proof We have

$$\begin{aligned} \|x_2^* - x_1^*\|_{q_1} &= \|T_2 x_2^* - x_1^*\|_{q_1} \\ &= \|T_2 x_2^* + T_1 x_2^* - T_1 x_2^* - x_1^*\|_{q_1} \\ &\le \|T_1 x_2^* - x_1^*\|_{q_1} + \|T_2 x_2^* - T_1 x_2^*\|_{q_1} \\ &\le \|T_1 x_2^* - T_1 x_1^*\|_{q_1} + \delta + \delta' \|x_2^*\|_{q_1} \\ &\le \gamma \|x_2^* - x_1^*\|_{q_1} + \delta + \delta' \|x_2^*\|_{q_1}. \end{aligned}$$

Rearranging, gives:

$$\|x_2^* - x_1^*\|_{q_1} \le \frac{\delta + \delta' \|x_2^*\|_{q_1}}{1 - \gamma}.$$

■

The following results concerns the sensitivity of weighted Euclidean-norm projections.

Lemma 19 *Let $\|\cdot\|_q$ and $\|\cdot\|_{q'}$ denote weighted Euclidean-norms on $\mathbb{R}^n$ with weights $q > 0$ and $q' > 0$, respectively. Let Π and Π' denote projections onto a closed and convex set $S \subset \mathbb{R}^n$, w.r.t. the norms $\|\cdot\|_q$ and $\|\cdot\|_{q'}$, respectively. For any $x \in \mathbb{R}^n$ we have:*

$$\|\Pi x - \Pi' x\|_q^2 \leq 2\|q - q'\|_\infty \left(\|\Pi x - x\|_2^2 + \|\Pi' x - x\|_2^2\right).$$

Proof If $x \in S$ the result is trivial. We assume in the following $x \notin S$. Let $Q = diag(q)$ and $Q' = diag(q')$. For any $x, y \in \mathbb{R}^n$ we have

$$\begin{aligned}
\left|\|x-y\|_q^2 - \|x-y\|_{q'}^2\right| &= \left|(x-y)^\top Q(x-y) - (x-y)^\top Q'(x-y)\right| \\
&= \left|(x-y)^\top (Q-Q')(x-y)\right| \\
&\leq \sum_{i=1}^n |q_i - q_i'|(x_i - y_i)^2 \\
&\leq \|q-q'\|_\infty \|x-y\|_2^2.
\end{aligned} \tag{24}$$

Therefore, we have that

$$\|\Pi' x - x\|_{q'}^2 \geq \|\Pi' x - x\|_q^2 - \|q-q'\|_\infty \|\Pi' x - x\|_2^2. \tag{25}$$

Now, let H denote the hyper-plane that is orthogonal to the projection error $\Pi x - x$, and passes through Πx:

$$H \doteq \left\{y \in \mathbb{R}^n : (y - \Pi x)^\top Q(x - \Pi x) = 0\right\},$$

and let L denote a line that passes through x and $\Pi' x$:

$$L \doteq \left\{y \in \mathbb{R}^n : y = x + z(\Pi' x - x), \quad z \in \mathbb{R}\right\}.$$

By properties of the projection Πx (Hiriart-Urruty and Lemaréchal, 2013) we have $(y - \Pi x)^\top Q(x - \Pi x) \leq 0 \quad \forall y \in S$. Since $(x - \Pi x)^\top Q(x - \Pi x) > 0$, it follows that H separates x from S. Since $\Pi' x \in S$, H also separates x from $\Pi' x$. Let p^* denote the intersection of L and H. By the previous arguments, p^* exists, and

$$\Pi' x - x = \alpha(p^* - x), \tag{26}$$

with $\alpha \geq 1$. Now, we have

$$\begin{aligned}
\|\Pi' x - x\|_q^2 &= \|\alpha(p^* - x)\|_q^2 \\
&= \alpha^2 \|p^* - x\|_q^2 \\
&= \alpha^2 \|p^* - \Pi x\|_q^2 + \alpha^2 \|\Pi x - x\|_q^2 \\
&\geq \alpha^2 \|p^* - \Pi x\|_q^2 + \|\Pi x - x\|_{q'}^2 - \|q - q'\|_\infty \|\Pi x - x\|_2^2,
\end{aligned}$$

where the last equality is by the Pythagorean theorem, which holds due to the orthogonality of H to the error $\Pi x - x$, and the inequality is since $\alpha \geq 1$, and (24). Plugging in (25), we obtain:

$$\|\Pi' x - x\|_{q'}^2 - \|\Pi x - x\|_{q'}^2 \geq \alpha^2 \|p^* - \Pi x\|_q^2 - \|q - q'\|_\infty \left(\|\Pi x - x\|_2^2 + \|\Pi' x - x\|_2^2\right). \tag{27}$$

However, by definition of the projection $\Pi' x$, we must have $\|\Pi' x - x\|_{q'}^2 - \|\Pi x - x\|_{q'}^2 \leq 0$, therefore rearranging (27) leads to:

$$\alpha^2 \|p^* - \Pi x\|_q^2 \leq \|q - q'\|_\infty \left(\|\Pi x - x\|_2^2 + \|\Pi' x - x\|_2^2\right). \tag{28}$$

Now, let H' denote a parallel hyper-plane to H that passes through $\Pi' x$:

$$H' \doteq \left\{y \in \mathbb{R}^n : (y - \Pi' x)^\top Q(x - \Pi x) = 0\right\}.$$

Also, let L' denote the line between x and Πx:

$$L' \doteq \left\{y \in \mathbb{R}^n : y = x + z(\Pi x - x), \quad z \in \mathbb{R}\right\}.$$

By definition, H' is orthogonal to L'; denote by p^{**} their intersection. By triangle similarity (the triangles $\{x, \Pi x, p^*\}$ and $\{x, p^{**}, \Pi' x\}$), and (26) we have

$$\frac{\|\Pi' x - p^{**}\|_q^2}{\|\Pi x - p^*\|_q^2} = \frac{\|\Pi' x - x\|_q^2}{\|p^* - x\|_q^2} = \alpha^2, \tag{29}$$

therefore, using (28)

$$\|\Pi' x - p^{**}\|_q^2 = \alpha^2 \|p^* - \Pi x\|_q^2 \leq \|q - q'\|_\infty \left(\|\Pi x - x\|_2^2 + \|\Pi' x - x\|_2^2\right). \tag{30}$$

From the Pythagorean theorem (by the orthogonality of H' to L') we have:

$$\|\Pi' x - \Pi x\|_q^2 = \|\Pi x - p^{**}\|_q^2 + \|\Pi' x - p^{**}\|_q^2, \tag{31}$$

and

$$\|\Pi' x - x\|_q^2 = \|\Pi' x - p^{**}\|_q^2 + \|p^{**} - x\|_q^2,$$

and from the last equation we also have

$$\|\Pi' x - x\|_q^2 \geq \|p^{**} - x\|_q^2.$$

Now, from the last inequality:

$$\begin{aligned}
\|\Pi' x - x\|_q^2 &\geq \|p^{**} - x\|_q^2 \\
&\geq \|p^{**} - \Pi x\|_q^2 + \|\Pi x - x\|_q^2 \\
&\geq \|p^{**} - \Pi x\|_q^2 + \|\Pi x - x\|_{q'}^2 - \|q - q'\|_\infty \|\Pi x - x\|_2^2,
\end{aligned}$$

where the second inequality is since x, Πx, and p^{**} are on L', therefore $\|p^{**} - x\|_q = \|p^{**} - \Pi x\|_q + \|\Pi x - x\|_q$, and the last inequality is by (24). Proceeding similarly as in (27), we plug in (25) to obtain:

$$\|\Pi' x - x\|_{q'}^2 - \|\Pi x - x\|_{q'}^2 \geq \|p^{**} - \Pi x\|_q^2 - \|q - q'\|_\infty \left(\|\Pi x - x\|_2^2 + \|\Pi' x - x\|_2^2\right), \tag{32}$$

and similarly to (28), by definition of the projection $\Pi' x$, we must have $\|\Pi' x - x\|_{q'}^2 - \|\Pi x - x\|_{q'}^2 \leq 0$, therefore rearranging (32) leads to:

$$\|p^{**} - \Pi x\|_q^2 \leq \|q - q'\|_\infty \left(\|\Pi x - x\|_2^2 + \|\Pi' x - x\|_2^2\right). \tag{33}$$

Finally, plugging in (30), and (33) in (31) we obtain

$$\|\Pi' x - \Pi x\|_q^2 \leq 2\|q - q'\|_\infty \left(\|\Pi x - x\|_2^2 + \|\Pi' x - x\|_2^2\right).$$

■

We now proceed with the proof of Theorem 17. To simplify the presentation, we break the proof into several parts.
In part 1, we show show that the sampled version of algorithm (21) with N samples corresponds to solving (20) with P_N, a sampled version of the transition matrix, replacing P.
In part 2, we show that for each N, algorithm (21) would converge (in k) by Lemma 16 to a fixed point of the *sampled* projected equation.
In part 3, we show that the solution of the sampled projected equation converges (in N) to the the solution of the original projected equation. We do this by showing a continuity of the solution w.r.t. P and its derived quantities, q and w_J^*, from which convergence then follows by the law of large numbers.
In part 4, we collect our convergence results in k and N and complete the proof.

C.1 A Sampled Version of Eq. (21)

Let $S^+ = \{\Phi_M w | w \in \mathbb{R}^m, Hw \leq g\}$ denote the set onto which we project in the modified projection (20), and let Π_q^+ denote a projection onto S^+ w.r.t. the q-weighted Euclidean norm. Note that S^+ is a convex set, therefore Π_q^+ is a non-expansion in the $\|\cdot\|_q$ norm (Hiriart-Urruty and Lemaréchal, 2013). Furthermore, we can write Eq. (20) as follows:

$$w_M^+ = \Pi_q^+ T^+ w_M^+,$$

where $T^+(w) = Rr + 2\gamma RP\Phi_J w_J^* + \gamma^2 P\Phi_M w$.

After we have observed N trajectories, let P_N denote the corresponding empirical transition matrix, given by:

$$P_N(x'|x) = \left(\frac{1}{\sum_{k=1}^N \tau_k}\right) \sum_{k=1}^N \sum_{t=0}^{\tau_k - 1} \mathbb{1}(x_t^k = x, x_{t+1}^k = x'),$$

and let $\zeta_{0;N}$ denote the empirical initial state distribution, i.e.,

$$\zeta_{0;N}(x) = \left(\frac{1}{N}\right) \sum_{k=1}^N \mathbb{1}(x_0^k = x).$$

Also, let q_N denote the state occupancy probabilities in an MDP with P and ζ_0 replaced by P_N and $\zeta_{0;N}$ (cf. the definition of q in Section 3). For large enough N, q_N satisfies Assumption 4.

Let $\hat{w}_J^* = A_N^{-1} b_N$, with A_N and b_N defined in (13); for large enough N, $\hat{w}_J^*$ is well defined (Boyan, 2002).

Furthermore, let g_N denote a vector with elements $-(\phi_J(x_i)^\top \hat{w}_J^*)^2$.

We define the set $S_N^+ = \{\Phi_M w | w \in \mathbb{R}^m, Hw \leq g_N\}$, and denote by $\Pi_{q_N}^+$ a projection onto S_N^+ w.r.t. the q_N-weighted Euclidean norm. We also define the operator

$$T_N^+(w) \doteq Rr + 2\gamma RP_N\Phi_J \hat{w}_J^* + \gamma^2 P_N \Phi_M w,$$

which is the sampled version of T^+. Note that T_N^+ is a γ^2-contraction.

Consider now the following projected fixed point equation:

$$w_{M;N}^+ = \Pi_{q_N}^+ T_N^+ w_{M;N}^+, \tag{34}$$

and the iterative procedure

$$w_{k+1;N} = \Pi_{\Xi, \hat{W}_{M;N}}[w_{k;N} - \eta \Xi^{-1}(C_N w_{k;N} - d_N)], \tag{35}$$

where C_N and d_N are defined in (13), Ξ is an arbitrary positive definite matrix, $\eta \in \mathbb{R}$ is a positive step size, and $\Pi_{\Xi, \hat{W}_{M;N}}$ denotes a projection onto the convex set $\hat{W}_{M;N} = \{w | Hw \leq g_N\}$ with respect to the Ξ weighted Euclidean norm.

C.2 Convergence in k

By definition, the sampled C_N, d_N, q_N and $\hat{w}_J^*$ correspond to their non-sampled counterparts C, d, q and w_J^*, respectively, on an MDP with the empirical probabilities P_N and $\zeta_{0;N}$ replacing P and ζ_0. As a result, applying Lemma 16 to Eq. 35, we have that $w_{k;N}$ converges to $w_{M;N}^+$. Therefore, for each N and $\delta > 0$ there exists some $k(N, \delta)$ such that for all $k > k(N, \delta)$

$$\|w_{k;N} - w_{M;N}^+\| \leq \delta. \tag{36}$$

C.3 Convergence in N

We will now show that as $N \to \infty$, $w_{M;N}^+ \to w_M^+$.

Let $\epsilon, \tilde{\epsilon} > 0$. We claim that w.p. 1, there exists $N(\epsilon, \tilde{\epsilon})$, such that for all $N > N(\epsilon, \tilde{\epsilon})$ we have

$$\|\Pi_q^+ T^+ w - \Pi_{q_N}^+ T_N^+ w\|_q \leq \epsilon + \tilde{\epsilon}\|w\|_q, \quad \forall w. \tag{37}$$

We now prove (37). First, we have:

$$\begin{aligned}\|\Pi_q^+ T^+ w - \Pi_{q_N}^+ T_N^+ w\|_q &= \|\Pi_q^+ T^+ w + \Pi_q^+ T_N^+ w - \Pi_q^+ T_N^+ w - \Pi_{q_N}^+ T_N^+ w\|_q \\ &\leq \underbrace{\|\Pi_q^+ T^+ w - \Pi_q^+ T_N^+ w\|_q}_{A} + \underbrace{\|\Pi_q^+ T_N^+ w - \Pi_{q_N}^+ T_N^+ w\|_q}_{B}.\end{aligned} \tag{38}$$

C.3.1 A Bound on (A):

We have:

$$\begin{aligned}\|\Pi_q^+ T^+ w - \Pi_q^+ T_N^+ w\|_q &\leq \|T^+ w - T_N^+ w\|_q \\ &= \|2\gamma RP\Phi_J w_J^* - 2\gamma RP_N\Phi_J \hat{w}_J^* + \gamma^2(P - P_N)\Phi_M w\|_q \\ &\leq \|2\gamma RP\Phi_J w_J^* - 2\gamma RP_N\Phi_J \hat{w}_J^*\|_q + \|\gamma^2(P - P_N)\Phi_M w\|_q \\ &\triangleq \eta_1(N) + \|\gamma^2(P - P_N)\Phi_M w\|_q \\ &\leq \eta_1(N) + \eta_2(N)\|w\|_q,\end{aligned} \tag{39}$$

where the first inequality is by the non-expansion property of the projection, and the third inequality is by defining $\eta_2(N)$ as the $\|\cdot\|_q$ induced matrix norm of $\gamma^2(P-P_N)\Phi_M$ (Horn and Johnson, 2012, Definition 5.6.1).

C.3.2 A Bound on (B):

Denote by $\hat{\Pi}_q^+$ a projection onto S_N^+ w.r.t. the q-weighted Euclidean norm. We have

$$\begin{aligned}\|\Pi_q^+ T_N^+ w - \Pi_{q_N}^+ T_N^+ w\|_q &= \|\Pi_q^+ T_N^+ w + \hat{\Pi}_q^+ T_N^+ w - \hat{\Pi}_q^+ T_N^+ w - \Pi_{q_N}^+ T_N^+ w\|_q \\ &\le \underbrace{\|\Pi_q^+ T_N^+ w - \hat{\Pi}_q^+ T_N^+ w\|_q}_{B_1} + \underbrace{\|\hat{\Pi}_q^+ T_N^+ w - \Pi_{q_N}^+ T_N^+ w\|_q}_{B_2}.\end{aligned}$$

C.3.3 A Bound on (B_1):

We bound B_1 using a result of Yen (1995), which gives a general Lipschitz bound for perturbations of projections onto convex polyhedra (S_N^+ by definition is a convex polyhedron). By theorem 2.1 of Yen (1995), for all w, there exists a constant K such that

$$\|\Pi_q^+ T_N^+ w - \hat{\Pi}_q^+ T_N^+ w\|_q \le K\|g - g_N\|_2 \triangleq \eta_3(N). \tag{40}$$

C.3.4 A Bound on (B_2):

We bound B_2 using Lemma 19, which yields:

$$\|\hat{\Pi}_q^+ T_N^+ w - \Pi_{q_N}^+ T_N^+ w\|_q^2 \le 2\|q - q_N\|_\infty \left(\|\hat{\Pi}_q^+ T_N^+ w - T_N^+ w\|_2^2 + \|\Pi_{q_N}^+ T_N^+ w - T_N^+ w\|_2^2\right).$$

By norm equivalence on finite-dimensional spaces, there exists λ such that $\|x\|_2 \le \lambda\|x\|_q$ and $\|x\|_2 \le \lambda\|x\|_{q_N}$ for all x. Therefore

$$\|\hat{\Pi}_q^+ T_N^+ w - \Pi_{q_N}^+ T_N^+ w\|_q^2 \le 2\|q - q_N\|_\infty \lambda^2 \left(\|\hat{\Pi}_q^+ T_N^+ w - T_N^+ w\|_q^2 + \|\Pi_{q_N}^+ T_N^+ w - T_N^+ w\|_{q_N}^2\right).$$

For any $\hat{s} \in S_N^+$ we now have, by definition of the projections $\hat{\Pi}_q^+$ and $\Pi_{q_N}^+$:

$$\|\hat{\Pi}_q^+ T_N^+ w - \Pi_{q_N}^+ T_N^+ w\|_q^2 \le 2\|q - q_N\|_\infty \lambda^2 \left(\|\hat{s} - T_N^+ w\|_q^2 + \|\hat{s} - T_N^+ w\|_{q_N}^2\right).$$

As before, by norm equivalence on finite-dimensional spaces, there exists $\tilde{\lambda}$ such that $\|x\|_{q_N} \le \lambda\|x\|_q$ for all x, therefore

$$\|\hat{\Pi}_q^+ T_N^+ w - \Pi_{q_N}^+ T_N^+ w\|_q^2 \le 2\|q - q_N\|_\infty \lambda^2 (1+\tilde{\lambda}^2)\|\hat{s} - T_N^+ w\|_q^2,$$

and setting $\bar{\lambda} = \sqrt{\lambda^2(1+\tilde{\lambda}^2)}$ we have

$$\begin{aligned}\|\hat{\Pi}_q^+ T_N^+ w - \Pi_{q_N}^+ T_N^+ w\|_q &\le \sqrt{2\|q - q_N\|_\infty}\bar{\lambda}\|\hat{s} - T_N^+ w\|_q \\ &\le \sqrt{2\|q - q_N\|_\infty}\bar{\lambda}\left(\|\hat{s}\|_q + \|T_N^+ w\|_q\right) \\ &\le \sqrt{2\|q - q_N\|_\infty}\bar{\lambda}\left(\|\hat{s}\|_q + C + \|w\|_q\right),\end{aligned}$$

where the constant C exists since T_N^+ is linear and a contraction. Therefore, setting $\eta_4(N) = \sqrt{2\|q - q_N\|_\infty}\bar{\lambda}\left(\|\hat{s}\|_q + C\right)$ and $\eta_5(N) = \sqrt{2\|q - q_N\|_\infty}\bar{\lambda}$ we have

$$\|\hat{\Pi}_q^+ T_N^+ w - \Pi_{q_N}^+ T_N^+ w\|_q \le \eta_4(N) + \eta_5(N)\|w\|_q. \tag{41}$$

C.3.5 Proof of (37):

We now return to (38), where, using (39), (40), and (41) we have

$$\|\Pi_q^+ T^+ w - \Pi_{q_N}^+ T_N^+ w\|_q \le \eta_1(N) + \eta_2(N)\|w\|_q + \eta_3(N) + \eta_4(N) + \eta_5(N)\|w\|_q.$$

The uniform convergence of empirical distributions (Van der Vaart, 2000, Theorem 19.1) guarantees that P_N and $\zeta_{0;N}$ uniformly converge to P and ζ_0 w.p. 1, respectively, and therefore $q_N \to q$ and $\hat{w}_J^* \to w_J^*$ w.p. 1. Therefore, for every $\epsilon, \tilde{\epsilon} > 0$, w.p. 1 there is some $N(\epsilon, \tilde{\epsilon})$ such that for $N > N(\epsilon, \tilde{\epsilon})$ we have $\eta_1(N)+\eta_3(N)+\eta_4(N) \le \epsilon$, and $\eta_2(N)+\eta_5(N) \le \tilde{\epsilon}$, therefore Eq. (37) holds.

Using Lemma 18 and Eq. (37) we have that for $N > N(\epsilon, \tilde{\epsilon})$

$$\|w_{M;N}^+ - w_M^+\|_q \le \frac{\epsilon + \tilde{\epsilon}\|w_M^+\|_q}{1-\gamma}. \tag{42}$$

C.4 Convergence in k and N

Finally, using (42) and (36) we have that for any $\bar{\epsilon} > 0$, w.p. 1 there is a $N(\bar{\epsilon})$ such that for any $N > N(\bar{\epsilon})$ there is a $k(N, \bar{\epsilon})$, such that for all $k > k(N, \bar{\epsilon})$

$$\|w_{k;N} - w_M^+\| \le \bar{\epsilon}.$$

Abstract

We study consistency properties of surrogate loss functions for general multiclass learning problems, defined by a general multiclass loss matrix. We extend the notion of classification calibration, which has been studied for binary and multiclass 0-1 classification problems (and for certain other specific learning problems), to the general multiclass setting, and derive necessary and sufficient conditions for a surrogate loss to be calibrated with respect to a loss matrix in this setting. We then introduce the notion of *convex calibration dimension* of a multiclass loss matrix, which measures the smallest 'size' of a prediction space in which it is possible to design a convex surrogate that is calibrated with respect to the loss matrix. We derive both upper and lower bounds on this quantity, and use these results to analyze various loss matrices. In particular, we apply our framework to study various subset ranking losses, and use the convex calibration dimension as a tool to show both the existence and non-existence of various types of convex calibrated surrogates for these losses. Our results strengthen recent results of Duchi et al. (2010) and Calauzènes et al. (2012) on the non-existence of certain types of convex calibrated surrogates in subset ranking. We anticipate the convex calibration dimension may prove to be a useful tool in the study and design of surrogate losses for general multiclass learning problems.

Keywords: Statistical consistency, multiclass loss, loss matrix, surrogate loss, convex surrogates, calibrated surrogates, classification calibration, subset ranking.

1. Introduction

There has been significant interest and progress in recent years in understanding consistency properties of surrogate risk minimization algorithms for various learning problems, such as binary classification, multiclass 0-1 classification, and various forms of ranking and multi-label prediction problems (Lugosi and Vayatis, 2004; Jiang, 2004; Zhang, 2004a; Steinwart, 2005; Bartlett et al., 2006; Zhang, 2004b; Tewari and Bartlett, 2007; Steinwart, 2007; Cossock and Zhang, 2008; Xia et al., 2008; Duchi et al., 2010; Ravikumar et al., 2011; Buffoni et al., 2011; Gao and Zhou, 2011; Kotlowski et al., 2011). Any such problem that involves a finite number of class labels and predictions can be viewed as an instance of a general multiclass learning problem, whose structure is defined by a suitable loss matrix. While the above studies have enabled an understanding of learning problems corresponding to certain forms of loss matrices, a framework for analyzing consistency properties for a general multiclass problem, defined by a general loss matrix, has remained elusive.

In this paper, we develop a unified framework for studying consistency properties of surrogate losses for such general multiclass learning problems, defined by a general multiclass loss matrix. For algorithms minimizing a surrogate loss, the question of consistency with respect to the target loss matrix reduces to the question of *calibration* of the surrogate loss with respect to the target loss.[1] We start by giving both necessary and sufficient conditions for a surrogate loss function to be calibrated with respect to any given target loss matrix. These conditions generalize previous conditions for the multiclass 0-1 loss studied for example by Tewari and Bartlett (2007). We then introduce the notion of *convex calibration dimension* of a loss matrix, a fundamental quantity that measures the smallest 'size' of a prediction space in which it is possible to design a convex surrogate that is calibrated with respect to the given loss matrix. This quantity can be viewed as representing one measure of the intrinsic 'difficulty' of the loss, and has a non-trivial behavior in the sense that one can give examples of loss matrices defined on the same number of class labels that have very different values of the convex calibration dimension, ranging from one (in which case one can achieve consistency by learning a single real-valued function) to practically the number of classes (in which case one must learn as many real-valued functions as the number of classes). We give upper and lower bounds on this quantity in terms of various algebraic and geometric properties of the loss matrix, and apply these results to analyze various loss matrices.

As concrete applications of our framework, we use the convex calibration dimension as a tool to study various loss matrices that arise in subset ranking problems, including the normalized discounted cumulative gain (NDCG), pairwise disagreement (PD), and mean average precision (MAP) losses. A popular practice in subset ranking, where one needs to rank a set of r documents by relevance to a query, has been to learn r real-valued scoring functions by minimizing a convex surrogate loss in r dimensions, and to then sort the r documents based on these scores. As discussed recently by Duchi et al. (2010) and Calauzènes et al. (2012), such an approach cannot be consistent for the PD and MAP losses, since these losses do not admit convex calibrated surrogates in r dimensions that can be used together with the sorting operation. We obtain a stronger result; in particular, we show that the convex calibration dimension of these losses is lower bounded by a quadratic function of r, which means that if minimizing a convex surrogate loss, one necessarily needs to learn $\Omega(r^2)$ real-valued functions to achieve consistency for these losses.

1.1 Related Work

There has been much work in recent years on consistency and calibration of surrogate losses for various learning problems. We give a brief overview of this body of work here.

Initial work on consistency of surrogate risk minimization algorithms focused largely on binary classification. For example, Steinwart (2005) showed the consistency of support vector machines with universal kernels for the problem of binary classification; Jiang (2004)

1. Assuming the surrogate risk minimization procedure is itself consistent (with respect to the surrogate loss); in most cases, this can be achieved by minimizing the surrogate risk over a function class that approaches a universal function class as the training sample size increases, e.g. see Bartlett et al. (2006).

and Lugosi and Vayatis (2004) showed similar results for boosting methods. Bartlett et al. (2006) and Zhang (2004a) studied the calibration of margin-based surrogates for binary classification. In particular, in their seminal work, Bartlett et al. (2006) established that the property of 'classification calibration' of a surrogate loss is equivalent to its minimization yielding 0-1 consistency, and gave a simple necessary and sufficient condition for convex margin-based surrogates to be calibrated w.r.t. the binary 0-1 loss. More recently, Reid and Williamson (2010) analyzed the calibration of a general family of surrogates termed proper composite surrogates for binary classification. Variants of standard 0-1 binary classification have also been studied; for example, Yuan and Wegkamp (2010) studied consistency for the problem of binary classification with a reject option, and Scott (2012) studied calibrated surrogates for cost-sensitive binary classification.

Over the years, there has been significant interest in extending the understanding of consistency and calibrated surrogates to various multiclass learning problems. Early work in this direction, pioneered by Zhang (2004b) and Tewari and Bartlett (2007), considered mainly the multiclass 0-1 classification problem. This work generalized the framework of Bartlett et al. (2006) to the multiclass 0-1 setting and used these results to study calibration of various surrogates proposed for multiclass 0-1 classification, such as the surrogates of Weston and Watkins (1999), Crammer and Singer (2001), and Lee et al. (2004). In particular, while the multiclass surrogate of Lee et al. (2004) was shown to calibrated for multiclass 0-1 classification, it was shown that several other widely used multiclass surrogates are in fact not calibrated for multiclass 0-1 classification.

More recently, there has been much work on studying consistency and calibration for various other learning problems that also involve finite label and prediction spaces. For example, Gao and Zhou (2011) studied consistency and calibration for multi-label prediction with the Hamming loss. Another prominent class of learning problems for which consistency and calibration have been studied recently is that of subset ranking, where instances contain queries together with sets of documents, and the goal is to learn a prediction model that given such an instance ranks the documents by relevance to the query. Various subset ranking losses have been investigated in recent years. Cossock and Zhang (2008) studied subset ranking with the discounted cumulative gain (DCG) ranking loss, and gave a simple surrogate calibrated w.r.t. this loss; Ravikumar et al. (2011) further studied subset ranking with the normalized DCG (NDCG) loss. Xia et al. (2008) considered the 0-1 loss applied to permutations. Duchi et al. (2010) focused on subset ranking with the pairwise disagreement (PD) loss, and showed that several popular convex score-based surrogates used for this problem are in fact not calibrated w.r.t. this loss; they also conjectured that such surrogates may not exist. Calauzènes et al. (2012) showed conclusively that there do not exist any convex score-based surrogates that are calibrated w.r.t. the PD loss, or w.r.t. the mean average precision (MAP) or expected reciprocal rank (ERR) losses. Finally, in a more general study of subset ranking losses, Buffoni et al. (2011) introduced the notion of 'standardization' for subset ranking losses, and gave a way to construct convex calibrated score-based surrogates for subset ranking losses that can be 'standardized'; they showed that while the DCG and NDCG losses can be standardized, the MAP and ERR losses cannot be standardized.

We also point out that in a related but different context, consistency of ranking has also been studied in the instance ranking setting (Clémençon and Vayatis, 2007; Clémençon et al., 2008; Kotlowski et al., 2011; Agarwal, 2014).

Finally, Steinwart (2007) considered consistency and calibration in a very general setting. More recently, Pires et al. (2013) used Steinwart's techniques to obtain surrogate regret bounds for certain surrogates w.r.t. general multiclass losses, and Ramaswamy et al. (2013) showed how to design explicit convex calibrated surrogates for any low-rank loss matrix.

1.2 Contributions of this Paper

As noted above, we develop a unified framework for studying consistency and calibration for general multiclass (finite-output) learning problems, described by a general loss matrix. We give both necessary conditions and sufficient conditions for a surrogate loss to be calibrated w.r.t. a given multiclass loss matrix, and introduce the notion of *convex calibration dimension* of a loss matrix, which measures the smallest 'size' of a prediction space in which it is possible to design a convex surrogate that is calibrated with respect to the loss matrix. We derive both upper and lower bounds on this quantity in terms of certain algebraic and geometric properties of the loss matrix, and apply these results to study various subset ranking losses. In particular, we obtain stronger results on the non-existence of convex calibrated surrogates for certain types of subset ranking losses than previous results in the literature (and also positive results on the existence of convex calibrated surrogates for these losses in higher dimensions). The following is a summary of the main differences from the conference version of this paper (Ramaswamy and Agarwal, 2012):

- Enhanced definition of positive normal sets of a surrogate loss at a sequence of points (Definition 5; this is required for proofs of stronger versions of our earlier results).
- Stronger necessary condition for calibration (Theorem 7).
- Stronger versions of upper and lower bounds on the convex calibration dimension, with full proofs (Theorems 12, 16).
- Conditions under which the upper and lower bounds are tight (Section 4.3).
- Application to a more general setting of the PD loss (Section 5.2).
- Additional applications to the NDCG and MAP losses (Sections 5.1, 5.3).
- Additional examples and illustrations throughout (Examples 5, 6, 7, 9; Figures 3, 4).
- Minor improvements and changes in emphasis in notation and terminology.

1.3 Organization

We start in Section 2 with some preliminaries and examples that will be used as running examples to illustrate concepts throughout the paper, and formalize the notion of calibration with respect to a general multiclass loss matrix. In Section 3, we derive both necessary conditions and sufficient conditions for calibration with respect to general loss matrices; these are both of independent interest and useful in our later results. Section 4 introduces the notion of convex calibration dimension of a loss matrix and derives both upper and lower bounds on this quantity. In Section 5, we apply our results to study the convex calibration dimension of various subset ranking losses. We conclude with a brief discussion in Section 6. Shorter proofs are included in the main text; all longer proofs are collected in Section 7 so as to maintain easy readability of the main text. The only exception to

this is proofs of Lemma 2 and Theorem 3, which closely follow earlier proofs of Tewari and Bartlett (2007) and are included for completeness in Appendix A. Some calculations are given in Appendices B and C.

2. Preliminaries, Examples, and Background

In this section we set up basic notation (Section 2.1), give background on multiclass loss matrices and risks (Section 2.2) and on multiclass surrogates and calibration (Section 2.3), and then define certain properties associated with multiclass losses and surrogates that will be useful in our study (Section 2.4).

2.1 Notation

Throughout the paper, we denote $\mathbb{R} = (-\infty, \infty)$, $\mathbb{R}_+ = [0, \infty)$, $\overline{\mathbb{R}} = [-\infty, \infty]$, $\overline{\mathbb{R}}_+ = [0, \infty]$. Similarly, $\mathbb{Z}$ and $\mathbb{Z}_+$ denote the sets of all integers and non-negative integers, respectively. For $n \in \mathbb{Z}_+$, we denote $[n] = \{1, \ldots, n\}$. For a predicate ϕ, we denote by $\mathbf{1}(\phi)$ the indicator of ϕ, which takes the value 1 if ϕ is true and 0 otherwise. For $z \in \mathbb{R}$, we denote $z_+ = \max(0, z)$. For a vector $\mathbf{v} \in \mathbb{R}^n$, we denote $\|\mathbf{v}\|_0 = \sum_{i=1}^n \mathbf{1}(v_i \neq 0)$ and $\|\mathbf{v}\|_1 = \sum_{i=1}^n |v_i|$. For a set $\mathcal{A} \subseteq \mathbb{R}^n$, we denote by relint($\mathcal{A}$) the relative interior of $\mathcal{A}$, by cl($\mathcal{A}$) the closure of $\mathcal{A}$, by span($\mathcal{A}$) the linear span (or linear hull) of $\mathcal{A}$, by aff($\mathcal{A}$) the affine hull of $\mathcal{A}$, and by conv($\mathcal{A}$) the convex hull of $\mathcal{A}$. For a vector space $\mathcal{V}$, we denote by dim($\mathcal{V}$) the dimension of $\mathcal{V}$. For a matrix $\mathbf{M} \in \mathbb{R}^{m \times n}$, we denote by rank($\mathbf{M}$) the rank of $\mathbf{M}$, by affdim($\mathbf{M}$) the affine dimension of the set of columns of $\mathbf{M}$ (i.e. the dimension of the subspace parallel to the affine hull of the columns of $\mathbf{M}$), by null($\mathbf{M}$) the null space of $\mathbf{M}$, and by nullity($\mathbf{M}$) the nullity of $\mathbf{M}$ (i.e. the dimension of the null space of $\mathbf{M}$). We denote by Δ_n the probability simplex in $\mathbb{R}^n$: $\Delta_n = \{\mathbf{p} \in \mathbb{R}^n_+ : \sum_{i=1}^n p_i = 1\}$. Finally, we denote by Π_n the set of all permutations of $[n]$, i.e. the set of all bijective mappings $\sigma : [n] \to [n]$; for a permutation $\sigma \in \Pi_n$ and element $i \in [n]$, $\sigma(i)$ therefore represents the position of element i under σ.

2.2 Multiclass Losses and Risks

The general multiclass learning problem we consider can be described as follows: There is a finite set of *class labels* $\mathcal{Y}$ and a finite set of possible *predictions* $\widehat{\mathcal{Y}}$, which we take without loss of generality to be $\mathcal{Y} = [n]$ and $\widehat{\mathcal{Y}} = [k]$ for some $n, k \in \mathbb{Z}_+$. We are given training examples $(X_1, Y_1), \ldots, (X_m, Y_m)$ drawn i.i.d. from a distribution D on $\mathcal{X} \times \mathcal{Y}$, where $\mathcal{X}$ is an instance space, and the goal is to learn from these examples a prediction model $h : \mathcal{X} \to \widehat{\mathcal{Y}}$ which given a new instance $x \in \mathcal{X}$, makes a prediction $\widehat{y} = h(x) \in \widehat{\mathcal{Y}}$. In many common learning problems, the label and prediction spaces are the same, i.e. $\widehat{\mathcal{Y}} = \mathcal{Y}$, but in general, these could be different (e.g. when there is an 'abstain' option available to a classifier, in which case $k = n + 1$).

The performance of a prediction model is measured via a *loss function* $\ell : \mathcal{Y} \times \widehat{\mathcal{Y}} \to \mathbb{R}_+$, or equivalently, by a *loss matrix* $\mathbf{L} \in \mathbb{R}_+^{n \times k}$, with (y, t)-th element given by $\ell_{yt} = \ell(y, t)$; here $\ell_{yt} = \ell(y, t)$ defines the penalty incurred on predicting $t \in [k]$ when the true label is $y \in [n]$. We will use the notions of loss matrix and loss function interchangeably. Some examples of common multiclass loss functions and corresponding loss matrices are given below:

Example 1 (0-1 loss) *Here $\mathcal{Y} = \widehat{\mathcal{Y}} = [n]$, and the loss incurred is 1 if the predicted label t is different from the actual class label y, and 0 otherwise:*

$$\ell^{0\text{-}1}(y, t) \;=\; \mathbf{1}\big(t \neq y\big) \qquad \forall y, t \in [n]\,.$$

The loss matrix $\mathbf{L}^{0\text{-}1}$ for $n = 3$ is shown in Figure 1(a). This is one of the most commonly used multiclass losses, and is suitable when all prediction errors are considered equal.

Example 2 (Ordinal regression loss) *Here $\mathcal{Y} = \widehat{\mathcal{Y}} = [n]$, and predictions t farther away from the actual class label y are penalized more heavily, e.g. using absolute distance:*

$$\ell^{\text{ord}}(y, t) \;=\; |t - y| \qquad \forall y, t \in [n]\,.$$

The loss matrix $\mathbf{L}^{\text{ord}}$ for $n = 3$ is shown in Figure 1(b). This loss is often used when the class labels satisfy a natural ordinal property, for example in evaluating recommender systems that predict the number of stars (say out of 5) assigned to a product by user.

Example 3 (Hamming loss) *Here $\mathcal{Y} = \widehat{\mathcal{Y}} = [2^r]$ for some $r \in \mathbb{Z}_+$, and the loss incurred on predicting t when the actual class label is y is the number of bit-positions in which the r-bit binary representations of $t - 1$ and $y - 1$ differ:*

$$\ell^{\text{Ham}}(y, t) \;=\; \sum_{i=1}^{r} \mathbf{1}\big((t-1)_i \neq (y-1)_i\big) \qquad \forall y, t \in [2^r]\,,$$

where for each $z \in \{0, \ldots, 2^r - 1\}$, $z_i \in \{0, 1\}$ denotes the i-th bit in the r-bit binary representation of z. The loss matrix $\mathbf{L}^{\text{Ham}}$ for $r = 2$ is shown in Figure 1(c). This loss is frequently used in sequence learning applications, where each element in $\mathcal{Y} = \widehat{\mathcal{Y}}$ is a binary sequence of length r, and the loss in predicting a sequence $\mathbf{t} \in \{0, 1\}^r$ when the true label sequence is $\mathbf{y} \in \{0, 1\}^r$ is simply the Hamming distance between the two sequences.

Example 4 ('Abstain' loss) *Here $\mathcal{Y} = [n]$ and $\widehat{\mathcal{Y}} = [n + 1]$, where $t = n + 1$ denotes a prediction of 'abstain' (or 'reject'). One possible loss function in this setting assigns a loss of 1 to incorrect predictions in $[n]$, 0 to correct predictions, and $\frac{1}{2}$ for abstaining:*

$$\ell^{(?)}(y, t) \;=\; \mathbf{1}\big(t \in [n]\big) \cdot \mathbf{1}\big(t \neq y\big) + \frac{1}{2} \cdot \mathbf{1}\big(t = n + 1\big) \qquad \forall y \in [n], t \in [n + 1]\,.$$

The loss matrix $\mathbf{L}^{(?)}$ for $n = 3$ is shown in Figure 1(d). This type of loss is suitable in applications where making an erroneous prediction is more costly than simply abstaining. For example, in medical diagnosis applications, when uncertain about the correct prediction, it may be better to abstain and request human intervention rather than make a misdiagnosis.

As noted above, given examples $(X_1, Y_1), \ldots, (X_m, Y_m)$ drawn i.i.d. from a distribution D on $\mathcal{X} \times [n]$, the goal is to learn a prediction model $h : \mathcal{X} \to [k]$. More specifically, given a target loss matrix $\mathbf{L} \in \mathbb{R}_+^{n \times k}$ with (y, t)-th element ℓ_{yt}, the goal is to learn a model $h : \mathcal{X} \to [k]$ with small expected loss on a new example drawn randomly from D, which we will refer to as the $\mathbf{L}$-*risk* or $\mathbf{L}$-*error* of h:

$$\text{er}_D^{\mathbf{L}}[h] \;\triangleq\; \mathbf{E}_{(X,Y)\sim D}\big[\ell_{Y,h(X)}\big]\,. \tag{1}$$

$$\underset{\text{(a)}}{\begin{bmatrix} 0 & 1 & 1 \\ 1 & 0 & 1 \\ 1 & 1 & 0 \end{bmatrix}} \quad \underset{\text{(b)}}{\begin{bmatrix} 0 & 1 & 2 \\ 1 & 0 & 1 \\ 2 & 1 & 0 \end{bmatrix}} \quad \underset{\text{(c)}}{\begin{bmatrix} 0 & 1 & 1 & 2 \\ 1 & 0 & 2 & 1 \\ 1 & 2 & 0 & 1 \\ 2 & 1 & 1 & 0 \end{bmatrix}} \quad \underset{\text{(d)}}{\begin{bmatrix} 0 & 1 & 1 & \frac{1}{2} \\ 1 & 0 & 1 & \frac{1}{2} \\ 1 & 1 & 0 & \frac{1}{2} \end{bmatrix}}$$

Figure 1: Loss matrices corresponding to Examples 1-4: (a) $\mathbf{L}^{0\text{-}1}$ for $n = 3$; (b) $\mathbf{L}^{\text{ord}}$ for $n = 3$; (c) $\mathbf{L}^{\text{Ham}}$ for $r = 2$ ($n = 4$); (d) $\mathbf{L}^{(?)}$ for $n = 3$.

Clearly, denoting the t-th column of $\mathbf{L}$ as $\boldsymbol{\ell}_t = (\ell_{1t}, \ldots, \ell_{nt})^\top \in \mathbb{R}^n_+$, and the class probability vector at an instance $x \in \mathcal{X}$ under D as $\mathbf{p}(x) = (p_1(x), \ldots, p_n(x))^\top \in \Delta_n$, where $p_y(x) = \mathbf{P}(Y = y \mid X = x)$ under D, the $\mathbf{L}$-risk of h can be written as

$$\text{er}^{\mathbf{L}}_D[h] \;=\; \mathbf{E}_X\left[\sum_{y=1}^{n} p_y(X)\, \ell_{y,h(X)}\right] \;=\; \mathbf{E}_X\left[\mathbf{p}(X)^\top \boldsymbol{\ell}_{h(X)}\right]. \tag{2}$$

The *optimal* $\mathbf{L}$*-risk* or *optimal* $\mathbf{L}$*-error* for a distribution D is then simply the smallest $\mathbf{L}$-risk or $\mathbf{L}$-error that can be achieved by any model h:

$$\text{er}^{\mathbf{L},*}_D \;\triangleq\; \inf_{h:\mathcal{X}\to[k]} \text{er}^{\mathbf{L}}_D[h] \;=\; \inf_{h:\mathcal{X}\to[k]} \mathbf{E}_X\left[\mathbf{p}(X)^\top \boldsymbol{\ell}_{h(X)}\right] \;=\; \mathbf{E}_X\left[\min_{t\in[k]} \mathbf{p}(X)^\top \boldsymbol{\ell}_t\right]. \tag{3}$$

Ideally, one would like to minimize (approximately) the $\mathbf{L}$-risk, e.g. by selecting a model that minimizes the average $\mathbf{L}$-loss on the training examples among some suitable class of models. However, minimizing the discrete $\mathbf{L}$-risk directly is typically computationally difficult. Consequently, one usually minimizes a (convex) *surrogate* risk instead.

2.3 Multiclass Surrogates and Calibration

Let $d \in \mathbb{Z}_+$, and let $\mathcal{C} \subseteq \mathbb{R}^d$ be a convex set. A *surrogate loss function* $\psi : \mathcal{Y} \times \mathcal{C} \to \mathbb{R}_+$ acting on the *surrogate prediction space* $\mathcal{C}$ assigns a penalty $\psi(y, \mathbf{u})$ on making a surrogate prediction $\mathbf{u} \in \mathcal{C}$ when the true label is $y \in [n]$. The ψ*-risk* or ψ*-error* of a surrogate prediction model $\mathbf{f} : \mathcal{X} \to \mathcal{C}$ w.r.t. a distribution D on $\mathcal{X} \times [n]$ is then defined as

$$\text{er}^{\psi}_D[\mathbf{f}] \;\triangleq\; \mathbf{E}_{(X,Y)\sim D}\Big[\psi\big(Y, \mathbf{f}(X)\big)\Big]. \tag{4}$$

The surrogate ψ can be represented via n real-valued functions $\psi_y : \mathcal{C} \to \mathbb{R}_+$ for $y \in [n]$, defined as $\psi_y(\mathbf{u}) = \psi(y, \mathbf{u})$; equivalently, we can also represent the surrogate ψ as a vector-valued function $\boldsymbol{\psi} : \mathcal{C} \to \mathbb{R}^n_+$, defined as $\boldsymbol{\psi}(\mathbf{u}) = \big(\psi_1(\mathbf{u}), \ldots, \psi_n(\mathbf{u})\big)^\top$. Clearly, the ψ-risk of $\mathbf{f}$ can then be written as

$$\text{er}^{\psi}_D[\mathbf{f}] \;=\; \mathbf{E}_X\left[\sum_{y=1}^{n} p_y(X)\, \psi_y(\mathbf{f}(X))\right] \;=\; \mathbf{E}_X\Big[\mathbf{p}(X)^\top \boldsymbol{\psi}(\mathbf{f}(X))\Big]. \tag{5}$$

The *optimal* ψ*-risk* or *optimal* ψ*-error* for a distribution D is then simply the smallest ψ-risk or ψ-error that can be achieved by any model $\mathbf{f}$:

$$\text{er}^{\psi,*}_D \;\triangleq\; \inf_{\mathbf{f}:\mathcal{X}\to\mathcal{C}} \text{er}^{\psi}_D[\mathbf{f}] \;=\; \inf_{\mathbf{f}:\mathcal{X}\to\mathcal{C}} \mathbf{E}_X\Big[\mathbf{p}(X)^\top \boldsymbol{\psi}(\mathbf{f}(X))\Big] \;=\; \mathbf{E}_X\left[\inf_{\mathbf{u}\in\mathcal{C}} \mathbf{p}(X)^\top \boldsymbol{\psi}(\mathbf{u})\right]. \tag{6}$$

We will find it convenient to define the sets

$$\mathcal{R}_\psi \;\triangleq\; \boldsymbol{\psi}(\mathcal{C}) \;\subseteq\; \mathbb{R}^n_+ \tag{7}$$

$$\mathcal{S}_\psi \;\triangleq\; \text{conv}(\mathcal{R}_\psi) \;\subseteq\; \mathbb{R}^n_+. \tag{8}$$

Clearly, the optimal ψ-risk can then also be written as

$$\text{er}^{\psi,*}_D \;=\; \mathbf{E}_X\left[\inf_{\mathbf{z}\in\mathcal{R}_\psi} \mathbf{p}(X)^\top \mathbf{z}\right] \;=\; \mathbf{E}_X\left[\inf_{\mathbf{z}\in\mathcal{S}_\psi} \mathbf{p}(X)^\top \mathbf{z}\right]. \tag{9}$$

Example 5 (Crammer-Singer surrogate) *The Crammer-Singer surrogate was proposed as a hinge-like surrogate loss for 0-1 multiclass classification (Crammer and Singer, 2001). For $\mathcal{Y} = [n]$, the Crammer-Singer surrogate $\boldsymbol{\psi}^{\text{CS}}$ acts on the surrogate prediction space $\mathcal{C} = \mathbb{R}^n$ and is defined as follows:*

$$\psi^{\text{CS}}_y(\mathbf{u}) \;=\; \max_{y'\in[n], y'\neq y} \big(1 - (u_y - u_{y'})\big)_+ \qquad \forall y \in [n], \mathbf{u} \in \mathbb{R}^n.$$

A surrogate $\boldsymbol{\psi}$ is convex if ψ_y is convex $\forall y \in [n]$. As an example, the Crammer-Singer surrogate defined above is clearly convex. Given training examples $(X_1, Y_1), \ldots, (X_m, Y_m)$ drawn i.i.d. from a distribution D on $\mathcal{X} \times [n]$, a (convex) surrogate risk minimization algorithm using a (convex) surrogate loss $\boldsymbol{\psi} : \mathcal{C} \to \mathbb{R}^n_+$ learns a surrogate prediction model by minimizing (approximately, based on the training sample) the ψ-risk; the learned model $\mathbf{f} : \mathcal{X} \to \mathcal{C}$ is then used to make predictions in the original space $[k]$ via some transformation $\text{pred} : \mathcal{C} \to [k]$. This yields a prediction model $h : \mathcal{X} \to [k]$ for the original multiclass problem given by $h = (\text{pred} \circ \mathbf{f})$: the prediction on a new instance $x \in \mathcal{X}$ is given by $\text{pred}(\mathbf{f}(x))$, and the $\mathbf{L}$-risk incurred is $\text{er}^{\mathbf{L}}_D[\text{pred} \circ \mathbf{f}]$. As an example, several surrogate risk minimizing algorithms for multiclass classification with respect to 0-1 loss (including that based on the Crammer-Singer surrogate) use a surrogate space $\mathcal{C} = \mathbb{R}^n$, learn a function of the form $\mathbf{f} : \mathcal{X} \to \mathbb{R}^n$, and predict according to $\text{pred}(\mathbf{f}(x)) = \text{argmax}_{t\in[n]}\, f_t(x)$.

Under suitable conditions, surrogate risk minimization algorithms that approximately minimize the ψ-risk based on a training sample are known to be consistent with respect to the ψ-risk, i.e. to converge (in probability) to the optimal ψ-risk as the number of training examples m increases. This raises the natural question of whether, for a given loss matrix $\mathbf{L}$, there are surrogate losses ψ for which consistency with respect to the ψ-risk also guarantees consistency with respect to the $\mathbf{L}$-risk, i.e. guarantees convergence (in probability) to the optimal $\mathbf{L}$-risk (defined in Eq. (3)). As we shall see below, this amounts to the question of *calibration* of surrogate losses ψ w.r.t. a given target loss matrix $\mathbf{L}$, and has been studied in detail for the 0-1 loss and for square losses of the form $\ell(y, t) = a_y \mathbf{1}(t \neq y)$, which can be analyzed similarly to the 0-1 loss (Zhang, 2004b; Tewari and Bartlett, 2007). In this paper, we consider this question for general multiclass loss matrices $\mathbf{L} \in \mathbb{R}^{n\times k}_+$, including rectangular loss matrices with $k \neq n$. The only assumption we make on $\mathbf{L}$ is that for each $t \in [k]$, $\exists \mathbf{p} \in \Delta_n$ such that $\text{argmin}_{t'\in[k]}\, \mathbf{p}^\top \boldsymbol{\ell}_{t'} = \{t\}$ (otherwise the element $t \in [k]$ never needs to be predicted and can simply be ignored).

We will need the following definitions and basic results, generalizing those of Zhang (2004b), Bartlett et al. (2006), and Tewari and Bartlett (2007). The notion of calibration will be central to our study; as Theorem 3 below shows, calibration of a surrogate loss ψ

w.r.t. $\mathbf{L}$ corresponds to the property that consistency w.r.t. ψ-risk implies consistency w.r.t. $\mathbf{L}$-risk. Proofs of Lemma 2 and Theorem 3 can be found in Appendix A.

Definition 1 ($(\mathbf{L},\mathcal{P})$-calibration) *Let $\mathbf{L} \in \mathbb{R}_+^{n\times k}$ and $\mathcal{P} \subseteq \Delta_n$. A surrogate loss function $\boldsymbol{\psi} : \mathcal{C} \to \mathbb{R}_+^n$ is said to be* $(\mathbf{L},\mathcal{P})$-calibrated *if there exists a function* $\text{pred} : \mathcal{C} \to [k]$ *such that*

$$\forall \mathbf{p} \in \mathcal{P} : \quad \inf_{\mathbf{u}\in\mathcal{C}:\text{pred}(\mathbf{u})\notin \text{argmin}_t \mathbf{p}^\top \boldsymbol{\ell}_t} \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}) \;>\; \inf_{\mathbf{u}\in\mathcal{C}} \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}) \,.$$

If $\boldsymbol{\psi}$ is $(\mathbf{L},\Delta_n)$-calibrated, we simply say $\boldsymbol{\psi}$ is $\mathbf{L}$-calibrated.

The above definition of calibration clearly generalizes that used in the binary case. For example, in the case of binary 0-1 classification, with $n = k = 2$ and $\mathbf{L}^{0\text{-}1} = \left[\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right]$, the probability simplex Δ_2 is equivalent to the interval $[0, 1]$, and it can be shown that one only need consider surrogates on the real line, $\mathcal{C} = \mathbb{R}$, and the predictor 'sign'; in this case one recovers the familiar definition of binary classification calibration of Bartlett et al. (2006), namely that a surrogate $\psi : \mathbb{R} \to \mathbb{R}_+^2$ is $(\mathbf{L}^{0\text{-}1}, \Delta_2)$-calibrated if

$$\forall p \in [0, 1], p \neq \frac{1}{2} : \quad \inf_{u\in\mathbb{R}:\text{sign}(u)\neq\text{sign}(p-\frac{1}{2})} p\,\psi_1(u)+(1-p)\psi_2(u) \;>\; \inf_{u\in\mathbb{R}} p\,\psi_1(u)+(1-p)\psi_2(u) \,.$$

Similarly, in the case of binary cost-sensitive classification, with $n = k = 2$ and $\mathbf{L}^c = \left[\begin{smallmatrix} 0 & 1-c \\ c & 0 \end{smallmatrix}\right]$ where $c \in (0, 1)$ is the cost of a false positive and $(1-c)$ that of a false negative, one recovers the corresponding definition of Scott (2012), namely that a surrogate $\psi : \mathbb{R} \to \mathbb{R}_+^2$ is $(\mathbf{L}^c, \Delta_2)$-calibrated if

$$\forall p \in [0, 1], p \neq c : \quad \inf_{u\in\mathbb{R}:\text{sign}(u)\neq\text{sign}(p-c)} p\,\psi_1(u)+(1-p)\psi_2(u) \;>\; \inf_{u\in\mathbb{R}} p\,\psi_1(u)+(1-p)\psi_2(u) \,.$$

The following lemma gives a characterization of calibration similar to that used by Tewari and Bartlett (2007):

Lemma 2 *Let $\mathbf{L} \in \mathbb{R}_+^{n\times k}$ and $\mathcal{P} \subseteq \Delta_n$. Then a surrogate loss $\boldsymbol{\psi} : \mathcal{C} \to \mathbb{R}_+^n$ is $(\mathbf{L},\mathcal{P})$-calibrated iff there exists a function* $\text{pred}' : \mathcal{S}_\psi \to [k]$ *such that*

$$\forall \mathbf{p} \in \mathcal{P} : \quad \inf_{\mathbf{z}\in\mathcal{S}_\psi:\text{pred}'(\mathbf{z})\notin \text{argmin}_t \mathbf{p}^\top \boldsymbol{\ell}_t} \mathbf{p}^\top \mathbf{z} \;>\; \inf_{\mathbf{z}\in\mathcal{S}_\psi} \mathbf{p}^\top \mathbf{z} \,.$$

In this paper, we will mostly be concerned with $(\mathbf{L},\Delta_n)$-calibration, which as noted above, we refer to as simply $\mathbf{L}$-calibration. The following result, whose proof is a straightforward generalization of that of a similar result for the 0-1 loss given by Tewari and Bartlett (2007), explains why $\mathbf{L}$-calibration is useful:

Theorem 3 *Let $\mathbf{L} \in \mathbb{R}_+^{n\times k}$. A surrogate loss $\boldsymbol{\psi} : \mathcal{C} \to \mathbb{R}_+^n$ is $\mathbf{L}$-calibrated iff there exists a function* $\text{pred} : \mathcal{C} \to [k]$ *such that for all distributions D on $\mathcal{X} \times [n]$ and all sequences of (vector) functions $\mathbf{f}_m : \mathcal{X} \to \mathcal{C}$,*

$$\text{er}_D^{\boldsymbol{\psi}}[\mathbf{f}_m] \longrightarrow \text{er}_D^{\boldsymbol{\psi},*} \qquad \textit{implies} \qquad \text{er}_D^{\mathbf{L}}[\text{pred} \circ \mathbf{f}_m] \longrightarrow \text{er}_D^{\mathbf{L},*} \,.$$

In particular, Theorem 3 implies that a surrogate $\boldsymbol{\psi}$ is $\mathbf{L}$-calibrated if and only if $\exists$ a mapping $\text{pred} : \mathcal{C} \to [k]$ such that any ψ-consistent algorithm learning models of the form $\mathbf{f}_m : \mathcal{X} \to \mathcal{C}$ (from i.i.d. examples $(X_1, Y_1), \ldots, (X_m, Y_m)$) yields an $\mathbf{L}$-consistent algorithm learning models of the form $(\text{pred} \circ \mathbf{f}_m) : \mathcal{X} \to [k]$.

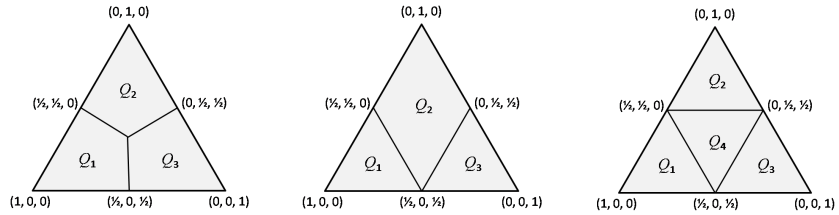

Figure 2: Trigger probability sets for (a) 0-1 loss $\mathbf{L}^{0\text{-}1}$; (b) ordinal regression loss $\mathbf{L}^{\text{ord}}$; and (c) 'abstain' loss $\mathbf{L}^{(?)}$; all for $n = 3$, for which the probability simplex can be visualized easily. Calculations of these sets can be found in Appendix B.

2.4 Trigger Probabilities and Positive Normals

Our goal is to study conditions under which a surrogate loss $\boldsymbol{\psi} : \mathcal{C} \to \mathbb{R}_+^n$ is $\mathbf{L}$-calibrated for a target loss matrix $\mathbf{L} \in \mathbb{R}_+^{n\times k}$. To this end, we will now define certain properties of both multiclass loss matrices $\mathbf{L}$ and multiclass surrogates $\boldsymbol{\psi}$ that will be useful in relating the two. Specifically, we will define *trigger probability sets* associated with a multiclass loss matrix $\mathbf{L}$, and *positive normal sets* associated with a multiclass surrogate $\boldsymbol{\psi}$; in Section 3 we will use these to obtain both necessary and sufficient conditions for calibration.

Definition 4 (Trigger probability sets) *Let $\mathbf{L} \in \mathbb{R}_+^{n\times k}$. For each $t \in [k]$, the* trigger probability set of $\mathbf{L}$ at t *is defined as*

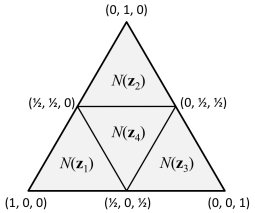
$$\mathcal{Q}_t^{\mathbf{L}} \;\triangleq\; \left\{\mathbf{p} \in \Delta_n : \mathbf{p}^\top(\boldsymbol{\ell}_t - \boldsymbol{\ell}_{t'}) \leq 0 \;\forall t' \in [k]\right\} \;=\; \left\{\mathbf{p} \in \Delta_n : t \in \text{argmin}_{t'\in[k]} \mathbf{p}^\top \boldsymbol{\ell}_{t'}\right\}.$$

In words, the trigger probability set $\mathcal{Q}_t^{\mathbf{L}}$ is the set of class probability vectors for which predicting t is optimal in terms of minimizing $\mathbf{L}$-risk. Such sets have also been studied by Lambert and Shoham (2009) and O'Brien et al. (2008) in a different context. Lambert and Shoham (2009) show that these sets form what is called a power diagram, which is a generalization of the Voronoi diagram. Trigger probability sets for the 0-1, ordinal regression, and 'abstain' loss matrices (described in Examples 1, 2 and 4) are illustrated in Figure 2; the corresponding calculations can be found in Appendix B.

Definition 5 (Positive normal sets) *Let $\boldsymbol{\psi} : \mathcal{C} \to \mathbb{R}_+^n$. For each point $\mathbf{z} \in \mathcal{S}_\psi$, the* positive normal set of $\boldsymbol{\psi}$ at $\mathbf{z}$ *is defined as*[2]

$$\mathcal{N}^\psi(\mathbf{z}) \;\triangleq\; \left\{\mathbf{p} \in \Delta_n : \mathbf{p}^\top(\mathbf{z} - \mathbf{z}') \leq 0 \;\forall \mathbf{z}' \in \mathcal{S}_\psi\right\} \;=\; \left\{\mathbf{p} \in \Delta_n : \mathbf{p}^\top \mathbf{z} = \inf_{\mathbf{z}'\in\mathcal{S}_\psi} \mathbf{p}^\top \mathbf{z}'\right\}.$$

2. For points $\mathbf{z}$ in the interior of $\mathcal{S}_\psi$, $\mathcal{N}^\psi(\mathbf{z})$ is empty.



$$\mathcal{N}^{\mathrm{CS}}(\mathbf{z}_1) = \{\mathbf{p} \in \Delta_3 : p_1 \geq \tfrac{1}{2}\}$$
$$\mathcal{N}^{\mathrm{CS}}(\mathbf{z}_2) = \{\mathbf{p} \in \Delta_3 : p_2 \geq \tfrac{1}{2}\}$$
$$\mathcal{N}^{\mathrm{CS}}(\mathbf{z}_3) = \{\mathbf{p} \in \Delta_3 : p_3 \geq \tfrac{1}{2}\}$$
$$\mathcal{N}^{\mathrm{CS}}(\mathbf{z}_4) = \{\mathbf{p} \in \Delta_3 : \max(p_1, p_2, p_3) \leq \tfrac{1}{2}\}$$

Figure 3: Positive normal sets for the Crammer-Singer surrogate $\boldsymbol{\psi}^{\mathrm{CS}}$ for $n = 3$, at 4 points $\mathbf{z}_i = \boldsymbol{\psi}^{\mathrm{CS}}(\mathbf{u}_i) \in \mathbb{R}^3_+$ $(i \in [4])$ for $\mathbf{u}_1 = (1,0,0)^\top$, $\mathbf{u}_2 = (0,1,0)^\top$, $\mathbf{u}_3 = (0,0,1)^\top$, and $\mathbf{u}_4 = (0,0,0)^\top$. Calculations of these sets are based on Lemma 9 and can be found in Appendix C.

For any sequence of points $\{\mathbf{z}_m\}$ *in* $\mathcal{S}_\psi$*, the* positive normal set of $\boldsymbol{\psi}$ at $\{\mathbf{z}_m\}$ *is defined as*[3]

$$\mathcal{N}^{\psi}(\{\mathbf{z}_m\}) \triangleq \left\{\mathbf{p} \in \Delta_n : \lim_{m\to\infty} \mathbf{p}^\top \mathbf{z}_m = \inf_{\mathbf{z}' \in \mathcal{S}_\psi} \mathbf{p}^\top \mathbf{z}'\right\}.$$

In words, the positive normal set $\mathcal{N}^{\psi}(\mathbf{z})$ at a point $\mathbf{z} = \boldsymbol{\psi}(\mathbf{u}) \in \mathcal{R}_\psi$ is the set of class probability vectors for which predicting $\mathbf{u}$ is optimal in terms of minimizing ψ-risk. Such sets were also studied by Tewari and Bartlett (2007). The extension to sequences of points in $\mathcal{S}_\psi$ is needed for technical reasons in some of our proofs. Note that for $\mathcal{N}^{\psi}(\{\mathbf{z}_m\})$ to be well-defined, the sequence $\{\mathbf{z}_m\}$ need not converge itself; however if the sequence $\{\mathbf{z}_m\}$ does converge to some point $\mathbf{z} \in \mathcal{S}_\psi$, then $\mathcal{N}^{\psi}(\{\mathbf{z}_m\}) = \mathcal{N}^{\psi}(\mathbf{z})$. Positive normal sets for the Crammer-Singer surrogate (described in Example 5) at 4 points are illustrated in Figure 3; the corresponding calculations can be found in Appendix C.

3. Conditions for Calibration

In this section we give both necessary conditions (Section 3.1) and sufficient conditions (Section 3.2) for a surrogate $\boldsymbol{\psi}$ to be calibrated w.r.t. an arbitrary target loss matrix $\mathbf{L}$. Both sets of conditions involve the trigger probability sets of $\mathbf{L}$ and the positive normal sets of $\boldsymbol{\psi}$; in Section 3.3 we give a result that facilitates computation of positive normal sets for certain classes of surrogates $\boldsymbol{\psi}$.

3.1 Necessary Conditions for Calibration

We start by deriving necessary conditions for $\mathbf{L}$-calibration of a surrogate loss $\boldsymbol{\psi}$. Consider what happens if for some point $\mathbf{z} \in \mathcal{S}_\psi$, the positive normal set of $\boldsymbol{\psi}$ at $\mathbf{z}$, $\mathcal{N}^{\psi}(\mathbf{z})$, has a non-empty intersection with the interiors of two trigger probability sets of $\mathbf{L}$, say $\mathcal{Q}^{\mathbf{L}}_1$ and $\mathcal{Q}^{\mathbf{L}}_2$ (see Figure 4 for an illustration), which means $\exists \mathbf{q}_1, \mathbf{q}_2 \in \mathcal{N}^{\psi}(\mathbf{z})$ with $\operatorname{argmin}_{t\in[k]} \mathbf{q}_1^\top \boldsymbol{\ell}_t = \{1\}$ and $\operatorname{argmin}_{t\in[k]} \mathbf{q}_2^\top \boldsymbol{\ell}_t = \{2\}$. If $\boldsymbol{\psi}$ is $\mathbf{L}$-calibrated, then by Lemma 2, we have $\exists \mathrm{pred}' : \mathcal{S}_\psi \to [k]$

3. For sequences $\{\mathbf{z}_m\}$ for which $\lim_{m\to\infty} \mathbf{p}^\top \mathbf{z}_m$ does not exist for any $\mathbf{p}$, $\mathcal{N}^{\psi}(\mathbf{z})$ is empty.

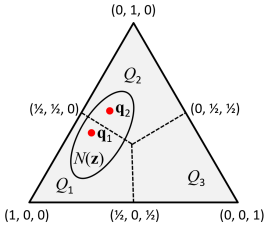


Figure 4: Visual proof of Theorem 6. If a surrogate $\boldsymbol{\psi}$ is such that its positive normal set $\mathcal{N}^{\psi}(\mathbf{z})$ at some point $\mathbf{z}$ has non-empty intersection with the interiors of two trigger probability sets (say $\mathcal{Q}^{\mathbf{L}}_1$ and $\mathcal{Q}^{\mathbf{L}}_2$) of $\mathbf{L}$, then $\boldsymbol{\psi}$ cannot be $\mathbf{L}$-calibrated.

such that

$$\inf_{\mathbf{z}' \in \mathcal{S}_\psi : \mathrm{pred}'(\mathbf{z}') \neq 1} \mathbf{q}_1^\top \mathbf{z}' = \inf_{\mathbf{z}' \in \mathcal{S}_\psi : \mathrm{pred}'(\mathbf{z}') \notin \operatorname{argmin}_t \mathbf{q}_1^\top \boldsymbol{\ell}_t} \mathbf{q}_1^\top \mathbf{z}' > \inf_{\mathbf{z}' \in \mathcal{S}_\psi} \mathbf{q}_1^\top \mathbf{z}' = \mathbf{q}_1^\top \mathbf{z}$$
$$\inf_{\mathbf{z}' \in \mathcal{S}_\psi : \mathrm{pred}'(\mathbf{z}') \neq 2} \mathbf{q}_2^\top \mathbf{z}' = \inf_{\mathbf{z}' \in \mathcal{S}_\psi : \mathrm{pred}'(\mathbf{z}') \notin \operatorname{argmin}_t \mathbf{q}_2^\top \boldsymbol{\ell}_t} \mathbf{q}_2^\top \mathbf{z}' > \inf_{\mathbf{z}' \in \mathcal{S}_\psi} \mathbf{q}_2^\top \mathbf{z}' = \mathbf{q}_2^\top \mathbf{z}.$$

The first inequality above implies $\mathrm{pred}'(\mathbf{z}) = 1$; the second inequality implies $\mathrm{pred}'(\mathbf{z}) = 2$, leading to a contradiction. This gives us the following necessary condition for $\mathbf{L}$-calibration of $\boldsymbol{\psi}$, which requires the positive normal sets of $\boldsymbol{\psi}$ at all points $\mathbf{z} \in \mathcal{S}_\psi$ to be 'well-behaved' w.r.t. $\mathbf{L}$ in the sense of being contained within individual trigger probability sets of $\mathbf{L}$ and generalizes the 'admissibility' condition used for 0-1 loss by Tewari and Bartlett (2007):

Theorem 6 *Let* $\mathbf{L} \in \mathbb{R}^{n\times k}_+$*, and let* $\boldsymbol{\psi} : \mathcal{C} \to \mathbb{R}^n_+$ *be* $\mathbf{L}$*-calibrated. Then for all points* $\mathbf{z} \in \mathcal{S}_\psi$*, there exists some* $t \in [k]$ *such that* $\mathcal{N}^{\psi}(\mathbf{z}) \subseteq \mathcal{Q}^{\mathbf{L}}_t$*.*

Proof See above discussion. ■

In fact, we have the following stronger necessary condition, which requires the positive normal sets of $\boldsymbol{\psi}$ not only at all points $\mathbf{z} \in \mathcal{S}_\psi$ but also at all sequences $\{\mathbf{z}_m\}$ in $\mathcal{S}_\psi$ to be contained within individual trigger probability sets of $\mathbf{L}$:

Theorem 7 *Let* $\mathbf{L} \in \mathbb{R}^{n\times k}_+$*, and let* $\boldsymbol{\psi} : \mathcal{C} \to \mathbb{R}^n_+$ *be* $\mathbf{L}$*-calibrated. Then for all sequences* $\{\mathbf{z}_m\}$ *in* $\mathcal{S}_\psi$*, there exists some* $t \in [k]$ *such that* $\mathcal{N}^{\psi}(\{\mathbf{z}_m\}) \subseteq \mathcal{Q}^{\mathbf{L}}_t$*.*

Proof Assume for the sake of contradiction that there is some sequence $\{\mathbf{z}_m\}$ in $\mathcal{S}_\psi$ for which $\mathcal{N}^{\psi}(\{\mathbf{z}_m\})$ is not contained in $\mathcal{Q}^{\mathbf{L}}_t$ for any $t \in [k]$. Then $\forall t \in [k]$, $\exists \mathbf{q}_t \in \mathcal{N}^{\psi}(\{\mathbf{z}_m\})$ such that $\mathbf{q}_t \notin \mathcal{Q}^{\mathbf{L}}_t$, i.e. such that $t \notin \operatorname{argmin}_{t'} \mathbf{q}_t^\top \boldsymbol{\ell}_{t'}$. Now, since $\boldsymbol{\psi}$ is $\mathbf{L}$-calibrated, by Lemma 25, there exists a function $\mathrm{pred}' : \mathcal{S}_\psi \to [k]$ such that for all $\mathbf{p} \in \mathcal{N}^{\psi}(\{\mathbf{z}_m\})$, we have $\mathrm{pred}'(\mathbf{z}_m) \in \arg\min_{t'} \mathbf{p}^\top \boldsymbol{\ell}_{t'}$ for all large enough m. In particular, for $\mathbf{p} = \mathbf{q}_t$, we get $\mathrm{pred}'(\mathbf{z}_m) \in \operatorname{argmin}_{t'} \mathbf{q}_t^\top \boldsymbol{\ell}_{t'}$ ultimately. Since this is true for each $t \in [k]$, we get $\mathrm{pred}'(\mathbf{z}_m) \in \cap_{t\in[k]} \operatorname{argmin}_{t'} \mathbf{q}_t^\top \boldsymbol{\ell}_{t'}$ ultimately. However by choice of $\mathbf{q}_t$, this intersection

is empty, thus yielding a contradiction. This completes the proof. ■

Note that Theorem 7 includes Theorem 6 as a special case, since $\mathcal{N}^{\psi}(\mathbf{z}) = \mathcal{N}^{\psi}(\{\mathbf{z}_m\})$ for the constant sequence $\mathbf{z}_m = \mathbf{z}\ \forall m$. We stated Theorem 6 separately above since it had a simple, direct proof that helps build intuition.

Example 6 (Crammer-Singer surrogate is not calibrated for 0-1 loss) *Looking at the positive normal sets of the Crammer-Singer surrogate $\boldsymbol{\psi}^{\mathrm{CS}}$ (for $n = 3$) shown in Figure 3 and the trigger probability sets of the 0-1 loss $\mathbf{L}^{0\text{-}1}$ shown in Figure 2(a), we see that $\mathcal{N}^{\mathrm{CS}}(\mathbf{z}_4)$ is not contained in any single trigger probability set of $\mathbf{L}^{0\text{-}1}$, and therefore applying Theorem 6, it is immediately clear that $\boldsymbol{\psi}^{\mathrm{CS}}$ is not $\mathbf{L}^{0\text{-}1}$-calibrated (this was also established by Tewari and Bartlett (2007) and Zhang (2004b)).*

3.2 Sufficient Condition for Calibration

We now give a sufficient condition for $\mathbf{L}$-calibration of a surrogate loss $\boldsymbol{\psi}$ that will be helpful in showing calibration of various surrogates. In particular, we show that for a surrogate loss $\boldsymbol{\psi}$ to be $\mathbf{L}$-calibrated, it is sufficient for the above property of positive normal sets of $\boldsymbol{\psi}$ being contained in trigger probability sets of $\mathbf{L}$ to hold for only a finite number of points in $\mathcal{S}_{\psi}$, as long as the corresponding positive normal sets jointly cover Δ_n:

Theorem 8 *Let $\mathbf{L} \in \mathbb{R}_+^{n \times k}$ and $\boldsymbol{\psi} : \mathcal{C} \to \mathbb{R}_+^n$. Suppose there exist $r \in \mathbb{Z}_+$ and $\mathbf{z}_1, \ldots, \mathbf{z}_r \in \mathcal{S}_{\psi}$ such that $\bigcup_{j=1}^{r} \mathcal{N}^{\psi}(\mathbf{z}_j) = \Delta_n$ and for each $j \in [r]$, $\exists t \in [k]$ such that $\mathcal{N}^{\psi}(\mathbf{z}_j) \subseteq \mathcal{Q}_t^{\mathbf{L}}$. Then $\boldsymbol{\psi}$ is $\mathbf{L}$-calibrated.*

Example 7 (Crammer-Singer surrogate is calibrated for $\mathbf{L}^{(?)}$ and $\mathbf{L}^{\mathrm{ord}}$ for $n = 3$) *Inspecting the positive normal sets of the Crammer-Singer surrogate $\boldsymbol{\psi}^{\mathrm{CS}}$ (for $n = 3$) in Figure 3 and the trigger probability sets of the 'abstain' loss matrix $\mathbf{L}^{(?)}$ in Figure 2(c), we see that $\mathcal{N}^{\mathrm{CS}}(\mathbf{z}_i) = \mathcal{Q}_i^{(?)}\ \forall i \in [4]$, and therefore by Theorem 8, the Crammer-Singer surrogate $\boldsymbol{\psi}^{\mathrm{CS}}$ is $\mathbf{L}^{(?)}$-calibrated. Similarly, looking at the trigger probability sets of the ordinal regression loss matrix $\mathbf{L}^{\mathrm{ord}}$ in Figure 2(b) and again applying Theorem 8, we see that the Crammer-Singer surrogate $\boldsymbol{\psi}^{\mathrm{CS}}$ is also $\mathbf{L}^{\mathrm{ord}}$-calibrated!*

Some additional examples of applications of Theorems 6 and 8 are provided in Section 3.3 below. Both the necessary and sufficient conditions above will also be used when we study the convex calibration dimension of a loss matrix $\mathbf{L}$ in Section 4.

3.3 Computation of Positive Normal Sets

Both the necessary and sufficient conditions for calibration above involve the positive normal sets $\mathcal{N}^{\psi}(\mathbf{z})$ at various points $\mathbf{z} \in \mathcal{S}_{\psi}$. Thus in order to use the above results to show that a surrogate $\boldsymbol{\psi}$ is (or is not) $\mathbf{L}$-calibrated, one needs to be able to compute or characterize the sets $\mathcal{N}^{\psi}(\mathbf{z})$. Here we give a method for computing these sets for certain surrogates $\boldsymbol{\psi}$ at certain points $\mathbf{z} \in \mathcal{S}_{\psi}$. Specifically, the following result gives an explicit method for computing $\mathcal{N}^{\psi}(\mathbf{z})$ for convex surrogate losses $\boldsymbol{\psi}$ operating on a convex surrogate space $\mathcal{C} \subseteq \mathbb{R}^d$, at points $\mathbf{z} = \boldsymbol{\psi}(\mathbf{u}) \in \mathcal{R}_{\psi}$ for which the subdifferential $\partial\psi_y(\mathbf{u})$ for each $y \in [n]$

can be described as the convex hull of a finite number of points in $\mathbb{R}^d$; this is particularly applicable for piecewise linear surrogates.[4,5]

Lemma 9 *Let $\mathcal{C} \subseteq \mathbb{R}^d$ be a convex set and let $\boldsymbol{\psi} : \mathcal{C} \to \mathbb{R}_+^n$ be convex. Let $\mathbf{z} = \boldsymbol{\psi}(\mathbf{u})$ for some $\mathbf{u} \in \mathcal{C}$ such that $\forall y \in [n]$, the subdifferential of ψ_y at $\mathbf{u}$ can be written as*

$$\partial\psi_y(\mathbf{u}) = \mathrm{conv}\left(\{\mathbf{w}_1^y, \ldots, \mathbf{w}_{s_y}^y\}\right)$$

for some $s_y \in \mathbb{Z}_+$ and $\mathbf{w}_1^y, \ldots, \mathbf{w}_{s_y}^y \in \mathbb{R}^d$. Let $s = \sum_{y=1}^n s_y$, and let

$$\mathbf{A} = \left[\mathbf{w}_1^1 \ldots \mathbf{w}_{s_1}^1 \mathbf{w}_1^2 \ldots \mathbf{w}_{s_2}^2 \ldots\ldots \mathbf{w}_1^n \ldots \mathbf{w}_{s_n}^n\right] \in \mathbb{R}^{d \times s}; \qquad \mathbf{B} = [b_{yj}] \in \mathbb{R}^{n \times s},$$

where b_{yj} is 1 if the j-th column of $\mathbf{A}$ came from $\{\mathbf{w}_1^y, \ldots, \mathbf{w}_{s_y}^y\}$ and 0 otherwise. Then

$$\mathcal{N}^{\psi}(\mathbf{z}) = \left\{\mathbf{p} \in \Delta_n : \mathbf{p} = \mathbf{B}\mathbf{q} \text{ for some } \mathbf{q} \in \mathrm{null}(\mathbf{A}) \cap \Delta_s\right\},$$

where $\mathrm{null}(\mathbf{A}) \subseteq \mathbb{R}^s$ denotes the null space of the matrix $\mathbf{A}$.

The proof makes use of the fact that a convex function $\phi : \mathbb{R}^d \to \mathbb{R}$ attains its minimum at $\mathbf{u}_0 \in \mathbb{R}^d$ iff the subdifferential $\partial\phi(\mathbf{u}_0)$ contains $\mathbf{0} \in \mathbb{R}^d$ (e.g. see Bertsekas et al. (2003)). We will also make use of the fact that if $\phi_1, \phi_2 : \mathbb{R}^d \to \mathbb{R}$ are convex functions, then the subdifferential of their sum $\phi_1 + \phi_2$ at $\mathbf{u}_0$ is is equal to the Minkowski sum of the subdifferentials of ϕ_1 and ϕ_2 at $\mathbf{u}_0$:

$$\partial(\phi_1 + \phi_2)(\mathbf{u}_0) \;=\; \left\{\mathbf{w}_1 + \mathbf{w}_2 : \mathbf{w}_1 \in \partial\phi_1(\mathbf{u}_0), \mathbf{w}_2 \in \partial\phi_2(\mathbf{u}_0)\right\}.$$

Proof (Proof of Lemma 9)

We have for all $\mathbf{p} \in \mathbb{R}^n$,

$$\begin{aligned}
\mathbf{p} \in \mathcal{N}^{\psi}(\boldsymbol{\psi}(\mathbf{u})) &\iff \mathbf{p} \in \Delta_n,\ \mathbf{p}^{\top}\boldsymbol{\psi}(\mathbf{u}) \leq \mathbf{p}^{\top}\mathbf{z}'\ \forall \mathbf{z}' \in \mathcal{S}_{\psi} \\
&\iff \mathbf{p} \in \Delta_n,\ \mathbf{p}^{\top}\boldsymbol{\psi}(\mathbf{u}) \leq \mathbf{p}^{\top}\mathbf{z}'\ \forall \mathbf{z}' \in \mathcal{R}_{\psi} \\
&\iff \mathbf{p} \in \Delta_n,\ \text{and the convex function } \phi(\mathbf{u}') = \mathbf{p}^{\top}\boldsymbol{\psi}(\mathbf{u}') = \textstyle\sum_{y=1}^n p_y \psi_y(\mathbf{u}') \\
&\qquad \text{achieves its minimum at } \mathbf{u}' = \mathbf{u} \\
&\iff \mathbf{p} \in \Delta_n,\ \mathbf{0} \in \sum_{y=1}^{n} p_y \partial\psi_y(\mathbf{u}) \\
&\iff \mathbf{p} \in \Delta_n,\ \mathbf{0} = \sum_{y=1}^{n} p_y \sum_{j=1}^{s_y} v_j^y \mathbf{w}_j^y \text{ for some } \mathbf{v}^y \in \Delta_{s_y} \\
&\iff \mathbf{p} \in \Delta_n,\ \mathbf{0} = \sum_{y=1}^{n} \sum_{j=1}^{s_y} q_j^y \mathbf{w}_j^y \text{ for some } \mathbf{q}^y = p_y \mathbf{v}^y, \quad \mathbf{v}^y \in \Delta_{s_y} \\
&\iff \mathbf{p} \in \Delta_n, \mathbf{A}\mathbf{q} = \mathbf{0} \text{ for some } \mathbf{q} = (p_1\mathbf{v}^1, \ldots, p_n\mathbf{v}^n)^{\top} \in \Delta_s, \quad \mathbf{v}^y \in \Delta_{s_y} \\
&\iff \mathbf{p} = \mathbf{B}\mathbf{q} \text{ for some } \mathbf{q} \in \mathrm{null}(\mathbf{A}) \cap \Delta_s\,.
\end{aligned}$$

4. Recall that a vector function is convex if all its component functions are convex.
5. Recall that the subdifferential of a convex function $\phi : \mathbb{R}^d \to \overline{\mathbb{R}}$ at a point $\mathbf{u}_0 \in \mathbb{R}^d$ is defined as $\partial\phi(\mathbf{u}_0) = \left\{\mathbf{w} \in \mathbb{R}^d : \phi(\mathbf{u}) - \phi(\mathbf{u}_0) \geq \mathbf{w}^{\top}(\mathbf{u} - \mathbf{u}_0)\ \forall \mathbf{u} \in \mathbb{R}^d\right\}$ and is a convex set in $\mathbb{R}^d$ (e.g. see Bertsekas et al. (2003)).

■

We now give examples of computation of positive normal sets using Lemma 9 for two convex surrogates, both of which operate on the one-dimensional surrogate space $\mathcal{C} = \mathbb{R}$, and as we shall see, turn out to be calibrated w.r.t. the ordinal regression loss $\mathbf{L}^{\text{ord}}$ but not w.r.t. the 0-1 loss $\mathbf{L}^{\text{0-1}}$ or the 'abstain' loss $\mathbf{L}^{(?)}$. As another example of an application of Lemma 9, calculations showing computation of positive normal sets of the Crammer-Singer surrogate (as shown in Figure 3) are given in the appendix.

Example 8 (Positive normal sets of 'absolute' surrogate) *Let $n = 3$, and let $\mathcal{C} = \mathbb{R}$. Consider the 'absolute' surrogate $\boldsymbol{\psi}^{\text{abs}} : \mathbb{R} \to \mathbb{R}^3_+$ defined as follows:*

$$\psi^{\text{abs}}_y(u) = |u - y| \qquad \forall y \in [3],\, u \in \mathbb{R}\,. \tag{10}$$

Clearly, $\boldsymbol{\psi}^{\text{abs}}$ is a convex function (see Figure 5). Moreover, we have

$$\mathcal{R}_{\text{abs}} \;=\; \boldsymbol{\psi}^{\text{abs}}(\mathbb{R}) \;=\; \left\{(|u-1|, |u-2|, |u-3|)^\top : u \in \mathbb{R}\right\} \subset \mathbb{R}^3_+\,.$$

Now let $u_1 = 1$, $u_2 = 2$, and $u_3 = 3$, and let

$$\begin{array}{rcccl}
\mathbf{z}_1 &=& \boldsymbol{\psi}^{\text{abs}}(u_1) &=& \boldsymbol{\psi}^{\text{abs}}(1) \;=\; (0,1,2)^\top \in \mathcal{R}_{\text{abs}} \\
\mathbf{z}_2 &=& \boldsymbol{\psi}^{\text{abs}}(u_2) &=& \boldsymbol{\psi}^{\text{abs}}(2) \;=\; (1,0,1)^\top \in \mathcal{R}_{\text{abs}} \\
\mathbf{z}_3 &=& \boldsymbol{\psi}^{\text{abs}}(u_3) &=& \boldsymbol{\psi}^{\text{abs}}(3) \;=\; (2,1,0)^\top \in \mathcal{R}_{\text{abs}}\,.
\end{array}$$

Let us consider computing the positive normal sets of $\boldsymbol{\psi}^{\text{abs}}$ at the 3 points $\mathbf{z}_1, \mathbf{z}_2, \mathbf{z}_3$ above. To see that $\mathbf{z}_1$ satisfies the conditions of Lemma 9, note that

$$\begin{array}{rcccl}
\partial\psi^{\text{abs}}_1(u_1) &=& \partial\psi^{\text{abs}}_1(1) &=& [-1,1] = \text{conv}(\{+1,-1\})\,; \\
\partial\psi^{\text{abs}}_2(u_1) &=& \partial\psi^{\text{abs}}_2(1) &=& \{-1\} = \text{conv}(\{-1\})\,; \\
\partial\psi^{\text{abs}}_3(u_1) &=& \partial\psi^{\text{abs}}_3(1) &=& \{-1\} = \text{conv}(\{-1\})\,.
\end{array}$$

Therefore, we can use Lemma 9 to compute $\mathcal{N}^{\text{abs}}(\mathbf{z}_1)$. Here $s = 4$, and

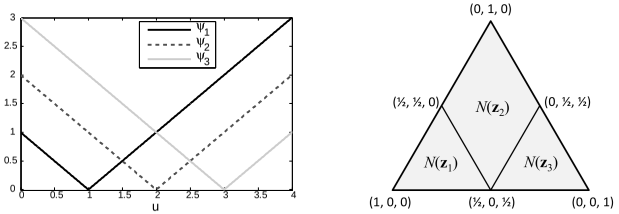
$$\mathbf{A} = \begin{bmatrix} +1 & -1 & -1 & -1 \end{bmatrix}; \quad \mathbf{B} = \begin{bmatrix} 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}.$$

This gives

$$\begin{array}{rcl}
\mathcal{N}^{\text{abs}}(\mathbf{z}_1) &=& \left\{\mathbf{p} \in \Delta_3 : \mathbf{p} = (q_1 + q_2, q_3, q_4) \text{ for some } \mathbf{q} \in \Delta_4,\; q_1 - q_2 - q_3 - q_4 = 0\right\} \\
&=& \left\{\mathbf{p} \in \Delta_3 : \mathbf{p} = (q_1 + q_2, q_3, q_4) \text{ for some } \mathbf{q} \in \Delta_4,\; q_1 = \tfrac{1}{2}\right\} \\
&=& \left\{\mathbf{p} \in \Delta_3 : p_1 \geq \tfrac{1}{2}\right\}.
\end{array}$$

It is easy to see that $\mathbf{z}_2$ and $\mathbf{z}_3$ also satisfy the conditions of Lemma 9; similar computations then yield

$$\begin{array}{rcl}
\mathcal{N}^{\text{abs}}(\mathbf{z}_2) &=& \left\{\mathbf{p} \in \Delta_3 : p_1 \leq \tfrac{1}{2}, p_3 \leq \tfrac{1}{2}\right\} \\
\mathcal{N}^{\text{abs}}(\mathbf{z}_3) &=& \left\{\mathbf{p} \in \Delta_3 : p_3 \geq \tfrac{1}{2}\right\}.
\end{array}$$



(a) (b)

Figure 5: (a) The 'absolute' surrogate $\boldsymbol{\psi}^{\text{abs}} : \mathbb{R} \to \mathbb{R}^3_+$ (for $n = 3$), and (b) its positive normal sets at 3 points $\mathbf{z}_i = \boldsymbol{\psi}^{\text{abs}}(u_i) \in \mathbb{R}^3_+$ ($i \in [3]$) for $u_1 = 1, u_2 = 2, u_3 = 3$. See Example 8 for details.

The positive normal sets above are shown in Figure 5. Comparing these with the trigger probability sets in Figure 2, we have by Theorem 8 that $\boldsymbol{\psi}^{\text{abs}}$ is $\mathbf{L}^{\text{ord}}$-calibrated, and by Theorem 6 that $\boldsymbol{\psi}^{\text{abs}}$ is not calibrated w.r.t. $\mathbf{L}^{\text{0-1}}$ or $\mathbf{L}^{(?)}$.

Example 9 (Positive normal sets of 'ϵ-insensitive' surrogate) *Let $n = 3$, and let $\mathcal{C} = \mathbb{R}$. Let $\epsilon \in [0, 0.5)$, and consider the 'ϵ-insensitive' surrogate $\boldsymbol{\psi}^{\epsilon} : \mathbb{R} \to \mathbb{R}^3_+$ defined as follows:*

$$\psi^{\epsilon}_y(u) = \left(|u - y| - \epsilon\right)_+ \qquad \forall y \in [3],\, u \in \mathbb{R}\,. \tag{11}$$

For $\epsilon = 0$, we have $\boldsymbol{\psi}^{\epsilon} = \boldsymbol{\psi}^{\text{abs}}$. Clearly, $\boldsymbol{\psi}^{\epsilon}$ is a convex function (see Figure 6). Moreover, we have

$$\mathcal{R}_{\epsilon} \;=\; \boldsymbol{\psi}^{\epsilon}(\mathbb{R}) \;=\; \left\{\left((|u-1| - \epsilon)_+, (|u-2| - \epsilon)_+, (|u-3| - \epsilon)_+\right)^\top : u \in \mathbb{R}\right\} \subset \mathbb{R}^3_+\,.$$

For concreteness, we will take $\epsilon = 0.25$ below, but similar computations hold $\forall \epsilon \in (0, 0.5)$. Let $u_1 = 1 + \epsilon = 1.25$, $u_2 = 2 - \epsilon = 1.75$, $u_3 = 2 + \epsilon = 2.25$, and $u_4 = 3 - \epsilon = 2.75$, and let

$$\begin{array}{rcccl}
\mathbf{z}_1 &=& \boldsymbol{\psi}^{0.25}(u_1) &=& \boldsymbol{\psi}^{0.25}(1.25) \;=\; (0, 0.5, 1.5)^\top \in \mathcal{R}_{0.25} \\
\mathbf{z}_2 &=& \boldsymbol{\psi}^{0.25}(u_2) &=& \boldsymbol{\psi}^{0.25}(1.75) \;=\; (0.5, 0, 1)^\top \in \mathcal{R}_{0.25} \\
\mathbf{z}_3 &=& \boldsymbol{\psi}^{0.25}(u_3) &=& \boldsymbol{\psi}^{0.25}(2.25) \;=\; (1, 0, 0.5)^\top \in \mathcal{R}_{0.25} \\
\mathbf{z}_4 &=& \boldsymbol{\psi}^{0.25}(u_4) &=& \boldsymbol{\psi}^{0.25}(2.75) \;=\; (1.5, 0.5, 0)^\top \in \mathcal{R}_{0.25}\,.
\end{array}$$

Let us consider computing the positive normal sets of $\boldsymbol{\psi}^{0.25}$ at the 4 points $\mathbf{z}_i$ ($i \in [4]$) above. To see that $\mathbf{z}_1$ satisfies the conditions of Lemma 9, note that

$$\begin{array}{rcccl}
\partial\psi^{0.25}_1(u_1) &=& \partial\psi^{0.25}_1(1.25) &=& [0,1] = \text{conv}(\{0,1\})\,; \\
\partial\psi^{0.25}_2(u_1) &=& \partial\psi^{0.25}_2(1.25) &=& \{-1\} = \text{conv}(\{-1\})\,; \\
\partial\psi^{0.25}_3(u_1) &=& \partial\psi^{0.25}_3(1.25) &=& \{-1\} = \text{conv}(\{-1\})\,.
\end{array}$$

Therefore, we can use Lemma 9 to compute $\mathcal{N}^{0.25}(\mathbf{z}_1)$. *Here* $s = 4$, *and*

$$\mathbf{A} = \begin{bmatrix} 0 & 1 & -1 & -1 \end{bmatrix}; \quad \mathbf{B} = \begin{bmatrix} 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}.$$

This gives

$$\begin{aligned} \mathcal{N}^{0.25}(\mathbf{z}_1) &= \left\{\mathbf{p} \in \Delta_3 : \mathbf{p} = (q_1 + q_2, q_3, q_4) \text{ for some } \mathbf{q} \in \Delta_4,\ q_2 - q_3 - q_4 = 0\right\} \\ &= \left\{\mathbf{p} \in \Delta_3 : \mathbf{p} = (q_1 + q_2, q_3, q_4) \text{ for some } \mathbf{q} \in \Delta_4,\ q_1 + q_2 \geq q_3 + q_4\right\} \\ &= \left\{\mathbf{p} \in \Delta_3 : p_1 \geq \tfrac{1}{2}\right\}. \end{aligned}$$

Similarly, to see that $\mathbf{z}_2$ *satisfies the conditions of Lemma 9, note that*

$$\begin{aligned} \partial\psi_1^{0.25}(u_2) &= \partial\psi_1^{0.25}(1.75) = \{1\} = \text{conv}(\{1\}); \\ \partial\psi_2^{0.25}(u_2) &= \partial\psi_2^{0.25}(1.75) = [-1, 0] = \text{conv}(\{-1, 0\}); \\ \partial\psi_3^{0.25}(u_2) &= \partial\psi_3^{0.25}(1.75) = \{-1\} = \text{conv}(\{-1\}). \end{aligned}$$

Again, we can use Lemma 9 to compute $\mathcal{N}^{0.25}(\mathbf{z}_2)$*; here* $s = 4$, *and*

$$\mathbf{A} = \begin{bmatrix} 1 & -1 & 0 & -1 \end{bmatrix}; \quad \mathbf{B} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}.$$

This gives

$$\begin{aligned} \mathcal{N}^{0.25}(\mathbf{z}_2) &= \left\{\mathbf{p} \in \Delta_3 : \mathbf{p} = (q_1, q_2 + q_3, q_4) \text{ for some } \mathbf{q} \in \Delta_4,\ q_1 - q_2 - q_4 = 0\right\} \\ &= \left\{\mathbf{p} \in \Delta_3 : p_1 \geq p_3,\ p_1 \leq \tfrac{1}{2}\right\}. \end{aligned}$$

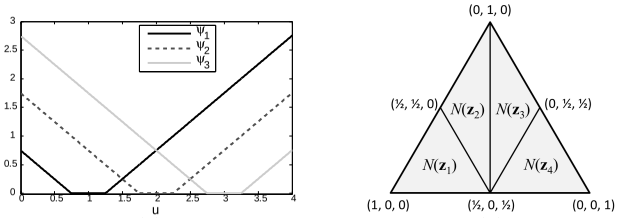
It is easy to see that $\mathbf{z}_3$ *and* $\mathbf{z}_4$ *also satisfy the conditions of Lemma 9; similar computations then yield*

$$\begin{aligned} \mathcal{N}^{0.25}(\mathbf{z}_3) &= \left\{\mathbf{p} \in \Delta_3 : p_1 \leq p_3,\ p_3 \leq \tfrac{1}{2}\right\} \\ \mathcal{N}^{0.25}(\mathbf{z}_4) &= \left\{\mathbf{p} \in \Delta_3 : p_3 \geq \tfrac{1}{2}\right\}. \end{aligned}$$

The positive normal sets above are shown in Figure 6. Comparing these with the trigger probability sets in Figure 2, we have by Theorem 8 that $\boldsymbol{\psi}^{0.25}$ *is* $\mathbf{L}^{\text{ord}}$*-calibrated, and by Theorem 6 that* $\boldsymbol{\psi}^{0.25}$ *is not calibrated w.r.t.* $\mathbf{L}^{0\text{-}1}$ *or* $\mathbf{L}^{(?)}$.

4. Convex Calibration Dimension

We now turn to the study of a fundamental quantity associated with the property of $\mathbf{L}$-calibration. Specifically, in Examples 6 and 7 above, we saw that to develop a surrogate calibrated w.r.t. to the ordinal regression loss $\mathbf{L}^{\text{ord}}$ for $n = 3$, it was sufficient to consider a surrogate prediction space $\mathcal{C} = \mathbb{R}$, with dimension $d = 1$; in addition, the surrogates we considered were convex, and can therefore be used in developing computationally efficient



(a) (b)

Figure 6: (a) The 'ϵ-insensitive' surrogate $\boldsymbol{\psi}^{\epsilon} : \mathbb{R} \to \mathbb{R}^3_+$ for $\epsilon = 0.25$ (and $n = 3$), and (b) its positive normal sets at 4 points $\mathbf{z}_i = \boldsymbol{\psi}^{\epsilon}(u_i) \in \mathbb{R}^3_+$ $(i \in [4])$ for $u_1 = 1.25, u_2 = 1.75, u_3 = 2.25, u_4 = 2.75$. See Example 9 for details.

algorithms. In fact the same surrogate prediction space with $d = 1$ can be used to develop similar convex surrogate losses calibrated w.r.t. the $\mathbf{L}^{\text{ord}}$ for *any* $n \in \mathbb{Z}_+$. However not all multiclass loss matrices $\mathbf{L}$ have such 'low-dimensional' convex surrogates. This raises the natural question of what is the smallest dimension d that supports a convex $\mathbf{L}$-calibrated surrogate for a given multiclass loss $\mathbf{L}$, and leads us to the following definition:

Definition 10 (Convex calibration dimension) *Let* $\mathbf{L} \in \mathbb{R}^{n \times k}_+$. *Define the* convex calibration dimension (CC dimension) *of* $\mathbf{L}$ *as*

$$\text{CCdim}(\mathbf{L}) \triangleq \min\left\{d \in \mathbb{Z}_+ : \exists \text{ a convex set } \mathcal{C} \subseteq \mathbb{R}^d \text{ and a convex surrogate } \boldsymbol{\psi} : \mathcal{C} \to \mathbb{R}^n_+ \text{ that is } \mathbf{L}\text{-calibrated}\right\},$$

if the above set is non-empty, and $\text{CCdim}(\mathbf{L}) = \infty$ *otherwise.*

The CC-dimension of a loss matrix $\mathbf{L}$ provides an important measure of the 'complexity' of designing convex calibrated surrogates for $\mathbf{L}$. Indeed, while the computational complexity of minimizing a surrogate loss, as well as that of converting surrogate predictions into target predictions, can depend on factors other than the dimension d of the surrogate space $\mathcal{C} \subseteq \mathbb{R}^d$, in the absence of other guiding factors, one would in general prefer to use a surrogate in a lower dimension d since this involves learning a smaller number of real-valued functions.

From the above discussion, $\text{CCdim}(\mathbf{L}^{\text{ord}}) = 1$ for all n. In the following, we will be interested in developing an understanding of the CC dimension for general loss matrices $\mathbf{L}$, and in particular in deriving upper and lower bounds on this quantity.

4.1 Upper Bounds on the Convex Calibration Dimension

We start with a simple result that establishes that the CC dimension of any multiclass loss matrix $\mathbf{L}$ is finite, and in fact is strictly smaller than the number of class labels n.

Lemma 11 *Let $\mathbf{L} \in \mathbb{R}_+^{n \times k}$. Let $\mathcal{C} = \left\{\mathbf{u} \in \mathbb{R}_+^{n-1} : \sum_{j=1}^{n-1} u_j \leq 1\right\}$, and for each $y \in [n]$, let $\psi_y : \mathcal{C} \to \mathbb{R}_+$ be given by*

$$\psi_y(\mathbf{u}) \;=\; \mathbf{1}(y \neq n)\,(u_y - 1)^2 + \sum_{j \in [n-1], j \neq y} {u_j}^2 \,.$$

Then $\boldsymbol{\psi}$ is $\mathbf{L}$-calibrated. In particular, since $\boldsymbol{\psi}$ is convex, $\text{CCdim}(\mathbf{L}) \leq n-1$.

It may appear surprising that the convex surrogate $\boldsymbol{\psi}$ in the above lemma, operating on a surrogate space $\mathcal{C} \subset \mathbb{R}^{n-1}$, is $\mathbf{L}$-calibrated for *all* multiclass losses $\mathbf{L}$ on n classes. However this makes intuitive sense, since in principle, for any multiclass problem, if one can estimate the conditional probabilities of the n classes accurately (which requires estimating $n-1$ real-valued functions on $\mathcal{X}$), then one can predict a target label that minimizes the expected loss according to these probabilities. Minimizing the above surrogate effectively corresponds to such class probability estimation. Indeed, the above lemma can be shown to hold for any surrogate that is a strictly proper composite multiclass loss (Vernet et al., 2011).

In practice, when the number of class labels n is large (such as in a sequence labeling task, where n is exponential in the length of the input sequence), the above result is not very helpful; in such cases, it is of interest to develop algorithms operating on a surrogate prediction space in a lower-dimensional space. Next we give a different upper bound on the CC dimension that depends on the loss $\mathbf{L}$, and for certain losses, can be significantly tighter than the general bound above.

Theorem 12 *Let $\mathbf{L} \in \mathbb{R}_+^{n \times k}$. Then* $\text{CCdim}(\mathbf{L}) \leq \text{affdim}(\mathbf{L})$.

Proof Let $\text{affdim}(\mathbf{L}) = d$. We will construct a convex $\mathbf{L}$-calibrated surrogate loss $\boldsymbol{\psi}$ with surrogate prediction space $\mathcal{C} \subseteq \mathbb{R}^d$.

Let $\mathcal{V} \subseteq \mathbb{R}^n$ denote the (d-dimensional) subspace parallel to the affine hull of the column vectors of $\mathbf{L}$, and let $\mathbf{r} \in \mathbb{R}^n$ be the corresponding translation vector, so that $\mathcal{V} = \text{aff}(\{\boldsymbol{\ell}_1, \ldots, \boldsymbol{\ell}_k\}) + \mathbf{r}$. Let $\mathbf{v}_1, \ldots, \mathbf{v}_d \in \mathcal{V}$ be d linearly independent vectors in $\mathcal{V}$. Let $\{\mathbf{e}_1, \ldots, \mathbf{e}_d\}$ denote the standard basis in $\mathbb{R}^d$, and define a linear function $\widetilde{\boldsymbol{\psi}} : \mathbb{R}^d \to \mathbb{R}^n$ by

$$\widetilde{\boldsymbol{\psi}}(\mathbf{e}_j) = \mathbf{v}_j \quad \forall j \in [d] \,.$$

Then for each $\mathbf{v} \in \mathcal{V}$, there exists a unique vector $\mathbf{u} \in \mathbb{R}^d$ such that $\widetilde{\boldsymbol{\psi}}(\mathbf{u}) = \mathbf{v}$. In particular, since $\boldsymbol{\ell}_t + \mathbf{r} \in \mathcal{V}\ \forall t \in [k]$, there exist unique vectors $\mathbf{u}_1, \ldots, \mathbf{u}_k \in \mathbb{R}^d$ such that for each $t \in [k]$, $\widetilde{\boldsymbol{\psi}}(\mathbf{u}_t) = \boldsymbol{\ell}_t + \mathbf{r}$. Let $\mathcal{C} = \text{conv}(\{\mathbf{u}_1, \ldots, \mathbf{u}_k\}) \subseteq \mathbb{R}^d$, and define $\boldsymbol{\psi} : \mathcal{C} \to \mathbb{R}_+^n$ as

$$\boldsymbol{\psi}(\mathbf{u}) = \widetilde{\boldsymbol{\psi}}(\mathbf{u}) - \mathbf{r} \quad \forall \mathbf{u} \in \mathcal{C} \,.$$

To see that $\boldsymbol{\psi}(\mathbf{u}) \in \mathbb{R}_+^n\ \forall \mathbf{u} \in \mathcal{C}$, note that for any $\mathbf{u} \in \mathcal{C}$, $\exists \boldsymbol{\alpha} \in \Delta_k$ such that $\mathbf{u} = \sum_{t=1}^k \alpha_t \mathbf{u}_t$, which gives $\boldsymbol{\psi}(\mathbf{u}) = \widetilde{\boldsymbol{\psi}}(\mathbf{u}) - \mathbf{r} = \left(\sum_{t=1}^k \alpha_t \widetilde{\boldsymbol{\psi}}(\mathbf{u}_t)\right) - \mathbf{r} = \left(\sum_{t=1}^k \alpha_t (\boldsymbol{\ell}_t + \mathbf{r})\right) - \mathbf{r} = \sum_{t=1}^k \alpha_t \boldsymbol{\ell}_t$ (and $\boldsymbol{\ell}_t \in \mathbb{R}_+^n\ \forall t \in [k]$). The function $\boldsymbol{\psi}$ is clearly convex. To show $\boldsymbol{\psi}$ is $\mathbf{L}$-calibrated, we will use Theorem 8. Specifically, consider the k points $\mathbf{z}_t = \boldsymbol{\psi}(\mathbf{u}_t) = \boldsymbol{\ell}_t \in \mathcal{R}_\psi$ for $t \in [k]$. By definition of $\boldsymbol{\psi}$, we have $\mathcal{S}_\psi = \text{conv}(\boldsymbol{\psi}(\mathcal{C})) = \text{conv}(\{\boldsymbol{\ell}_1, \ldots, \boldsymbol{\ell}_k\})$; from the definitions of positive normals and trigger probabilities, it then follows that $\mathcal{N}^\psi(\mathbf{z}_t) = \mathcal{N}^\psi(\boldsymbol{\ell}_t) = \mathcal{Q}_t^{\mathbf{L}}$ for all $t \in [k]$. Thus by Theorem 8, $\boldsymbol{\psi}$ is $\mathbf{L}$-calibrated. ■

Since $\text{affdim}(\mathbf{L})$ is equal to either $\text{rank}(\mathbf{L})$ or $\text{rank}(\mathbf{L}) - 1$, this immediately gives us the following corollary:

Corollary 13 *Let $\mathbf{L} \in \mathbb{R}_+^{n \times k}$. Then* $\text{CCdim}(\mathbf{L}) \leq \text{rank}(\mathbf{L})$.

Proof Follows immediately from Theorem 12 and the fact that $\text{affdim}(\mathbf{L}) \leq \text{rank}(\mathbf{L})$. ■

Example 10 (CC dimension of Hamming loss) *Let $n = 2^r$ for some $r \in \mathbb{Z}_+$, and consider the Hamming loss $\mathbf{L}^{\text{Ham}} \in \mathbb{R}_+^{n \times n}$ defined in Example 3. As in Example 3, for each $z \in \{0, \ldots, 2^r - 1\}$, let $z_i \in \{0, 1\}$ denote the i-th bit in the r-bit binary representation of z. For each $y \in [n]$, define $\boldsymbol{\sigma}_y \in \{\pm 1\}^r$ as*

$$\sigma_{yi} \;=\; 2\,(y-1)_i - 1 \;=\; \begin{cases} +1 & \text{if } (y-1)_i = 1 \\ -1 & \text{otherwise.} \end{cases}$$

Then we have

$$\begin{aligned} \ell_{yt}^{\text{Ham}} &= \sum_{i=1}^{r} \mathbf{1}\big((y-1)_i \neq (t-1)_i\big) \\ &= \sum_{i=1}^{r} \left(\frac{1 - \sigma_{yi}\sigma_{ti}}{2}\right) \\ &= \frac{r}{2} - \sum_{i=1}^{r} \frac{\sigma_{yi}\sigma_{ti}}{2} \qquad \forall y, t \in [n] \,. \end{aligned}$$

Thus $\text{affdim}(\mathbf{L}^{\text{Ham}}) \leq r$, and therefore by Theorem 12, we have $\text{CCdim}(\mathbf{L}^{\text{Ham}}) \leq r$. This is a significantly tighter upper bound than the bound of $2^r - 1$ given by Lemma 11.

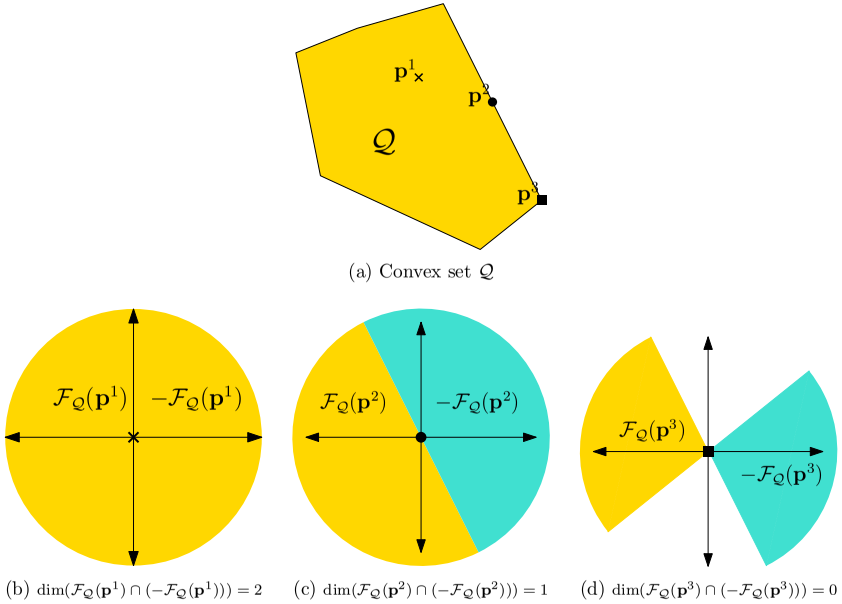
4.2 Lower Bound on the Convex Calibration Dimension

In this section we give a lower bound on the CC dimension of a loss matrix $\mathbf{L}$ and illustrate it by using it to calculate the CC dimension of the 0-1 loss. In Section 5 we will explore applications of the lower bound to obtaining impossibility results on the existence of convex calibrated surrogates in low-dimensional surrogate spaces for certain types of subset ranking losses. We will need the following definition:

Definition 14 (Feasible subspace dimension) *The* feasible subspace dimension *of a convex set $\mathcal{Q} \subseteq \mathbb{R}^n$ at a point $\mathbf{p} \in \mathcal{Q}$, denoted by $\mu_{\mathcal{Q}}(\mathbf{p})$, is defined as the dimension of the subspace $\mathcal{F}_{\mathcal{Q}}(\mathbf{p}) \cap (-\mathcal{F}_{\mathcal{Q}}(\mathbf{p}))$, where $\mathcal{F}_{\mathcal{Q}}(\mathbf{p})$ is the cone of feasible directions of $\mathcal{Q}$ at $\mathbf{p}$.*[6]

In essence, the feasible subspace dimension of a convex set Q at a point $\mathbf{p} \in \mathcal{Q}$ is simply the dimension of the smallest face of $\mathcal{Q}$ containing $\mathbf{p}$; see Figure 7 for an illustration.

6. For a set $\mathcal{Q} \subseteq \mathbb{R}^n$ and point $\mathbf{p} \in \mathcal{Q}$, the cone of feasible directions of $\mathcal{Q}$ at $\mathbf{p}$ is defined as $\mathcal{F}_{\mathcal{Q}}(\mathbf{p}) = \{\mathbf{v} \in \mathbb{R}^n :\ \exists \epsilon_0 > 0 \text{ such that } \mathbf{p} + \epsilon\mathbf{v} \in \mathcal{Q}\ \forall \epsilon \in (0, \epsilon_0)\}$.



(a) Convex set $\mathcal{Q}$

(b) $\dim(\mathcal{F}_{\mathcal{Q}}(\mathbf{p}^1) \cap (-\mathcal{F}_{\mathcal{Q}}(\mathbf{p}^1))) = 2$ (c) $\dim(\mathcal{F}_{\mathcal{Q}}(\mathbf{p}^2) \cap (-\mathcal{F}_{\mathcal{Q}}(\mathbf{p}^2))) = 1$ (d) $\dim(\mathcal{F}_{\mathcal{Q}}(\mathbf{p}^3) \cap (-\mathcal{F}_{\mathcal{Q}}(\mathbf{p}^3))) = 0$

Figure 7: Illustration of feasible subspace dimension $\mu_{\mathcal{Q}}(\mathbf{p})$ of a 2-dimensional convex set $\mathcal{Q}$ at three points $\mathbf{p} = \mathbf{p}^1, \mathbf{p}^2, \mathbf{p}^3$. Here $\mu_{\mathcal{Q}}(\mathbf{p}^1) = 2$, $\mu_{\mathcal{Q}}(\mathbf{p}^2) = 1$, and $\mu_{\mathcal{Q}}(\mathbf{p}^3) = 0$.

Both the proof of the lower bound we will provide below and its applications make use of the following lemma, which gives a method to calculate the feasible subspace dimension for certain convex sets $\mathcal{Q}$ and points $\mathbf{p} \in \mathcal{Q}$:

Lemma 15 *Let* $\mathcal{Q} = \left\{\mathbf{q} \in \mathbb{R}^n : \mathbf{A}^1\mathbf{q} \leq \mathbf{b}^1, \mathbf{A}^2\mathbf{q} \leq \mathbf{b}^2, \mathbf{A}^3\mathbf{q} = \mathbf{b}^3\right\}$. *Let* $\mathbf{p} \in \mathcal{Q}$ *be such that* $\mathbf{A}^1\mathbf{p} = \mathbf{b}^1$, $\mathbf{A}^2\mathbf{p} < \mathbf{b}^2$. *Then* $\mu_{\mathcal{Q}}(\mathbf{p}) = \text{nullity}\left(\begin{bmatrix}\mathbf{A}^1\\ \mathbf{A}^3\end{bmatrix}\right)$.

Proof We will show that $\mathcal{F}_{\mathcal{Q}}(\mathbf{p}) \cap (-\mathcal{F}_{\mathcal{Q}}(\mathbf{p})) = \text{null}\left(\begin{bmatrix}\mathbf{A}^1\\ \mathbf{A}^3\end{bmatrix}\right)$, from which the lemma follows.

First, let $\mathbf{v} \in \text{null}\left(\begin{bmatrix}\mathbf{A}^1\\ \mathbf{A}^3\end{bmatrix}\right)$. Then for $\epsilon > 0$, we have

$$\begin{aligned}
\mathbf{A}^1(\mathbf{p} + \epsilon\mathbf{v}) &= \mathbf{A}^1\mathbf{p} + \epsilon\mathbf{A}^1\mathbf{v} = \mathbf{A}^1\mathbf{p} + \mathbf{0} = \mathbf{b}^1\\
\mathbf{A}^2(\mathbf{p} + \epsilon\mathbf{v}) &< \mathbf{b}^2 \quad \text{for small enough } \epsilon, \text{ since } \mathbf{A}^2\mathbf{p} < \mathbf{b}^2\\
\mathbf{A}^3(\mathbf{p} + \epsilon\mathbf{v}) &= \mathbf{A}^3\mathbf{p} + \epsilon\mathbf{A}^3\mathbf{v} = \mathbf{A}^3\mathbf{p} + \mathbf{0} = \mathbf{b}^3\,.
\end{aligned}$$

Thus $\mathbf{v} \in \mathcal{F}_{\mathcal{Q}}(\mathbf{p})$. Similarly, we can show $-\mathbf{v} \in \mathcal{F}_{\mathcal{Q}}(\mathbf{p})$. Thus $\mathbf{v} \in \mathcal{F}_{\mathcal{Q}}(\mathbf{p}) \cap (-\mathcal{F}_{\mathcal{Q}}(\mathbf{p}))$, giving $\text{null}\left(\begin{bmatrix}\mathbf{A}^1\\ \mathbf{A}^3\end{bmatrix}\right) \subseteq \mathcal{F}_{\mathcal{Q}}(\mathbf{p}) \cap (-\mathcal{F}_{\mathcal{Q}}(\mathbf{p}))$. Now let $\mathbf{v} \in \mathcal{F}_{\mathcal{Q}}(\mathbf{p}) \cap (-\mathcal{F}_{\mathcal{Q}}(\mathbf{p}))$. Then for small enough $\epsilon > 0$, we have both $\mathbf{A}^1(\mathbf{p} + \epsilon\mathbf{v}) \leq \mathbf{b}^1$ and $\mathbf{A}^1(\mathbf{p} - \epsilon\mathbf{v}) \leq \mathbf{b}^1$. Since $\mathbf{A}^1\mathbf{p} = \mathbf{b}^1$, this gives $\mathbf{A}^1\mathbf{v} = \mathbf{0}$. Similarly, for small enough $\epsilon > 0$, we have $\mathbf{A}^3(\mathbf{p} + \epsilon\mathbf{v}) = \mathbf{b}^3$; since $\mathbf{A}^3\mathbf{p} = \mathbf{b}^3$, this gives $\mathbf{A}^3\mathbf{v} = \mathbf{0}$. Thus $\begin{bmatrix}\mathbf{A}^1\\ \mathbf{A}^3\end{bmatrix}\mathbf{v} = \mathbf{0}$, giving $\mathcal{F}_{\mathcal{Q}}(\mathbf{p}) \cap (-\mathcal{F}_{\mathcal{Q}}(\mathbf{p})) \subseteq \text{null}\left(\begin{bmatrix}\mathbf{A}^1\\ \mathbf{A}^3\end{bmatrix}\right)$. ■

The following gives a lower bound on the CC dimension of a loss matrix $\mathbf{L}$ in terms of the feasible subspace dimension of the trigger probability sets $\mathcal{Q}_t^{\mathbf{L}}$ at points $\mathbf{p} \in \mathcal{Q}_t^{\mathbf{L}}$:

Theorem 16 *Let* $\mathbf{L} \in \mathbb{R}_+^{n\times k}$. *Let* $\mathbf{p} \in \Delta_n$ *and* $t \in \arg\min_{t'} \mathbf{p}^\top \boldsymbol{\ell}_{t'}$ *(equivalently, let* $\mathbf{p} \in \mathcal{Q}_t^{\mathbf{L}}$*). Then*

$$\text{CCdim}(\mathbf{L}) \geq \|\mathbf{p}\|_0 - \mu_{\mathcal{Q}_t^{\mathbf{L}}}(\mathbf{p}) - 1\,.$$

The above lower bound allows us to calculate precisely the CC dimension of the 0-1 loss:

Example 11 (CC dimension of 0-1 loss) *Let* $n \in \mathbb{Z}_+$, *and consider the 0-1 loss* $\mathbf{L}^{0\text{-}1} \in \mathbb{R}_+^{n\times n}$ *defined in Example 1. Take* $\mathbf{p} = (\frac{1}{n}, \ldots, \frac{1}{n})^\top \in \Delta_n$. *Then* $\mathbf{p} \in \mathcal{Q}_t^{0\text{-}1}$ *for all* $t \in [k] = [n]$ *(see Figure 2); in particular, we have* $\mathbf{p} \in \mathcal{Q}_1^{0\text{-}1}$. *Now* $\mathcal{Q}_1^{0\text{-}1}$ *can be written as*

$$\begin{aligned}
\mathcal{Q}_1^{0\text{-}1} &= \left\{\mathbf{q} \in \Delta_n : q_1 \geq q_y \;\forall y \in \{2, \ldots, n\}\right\}\\
&= \left\{\mathbf{q} \in \mathbb{R}^n : \begin{bmatrix}-\mathbf{e}_{n-1} & \mathbf{I}_{n-1}\end{bmatrix}\mathbf{q} \leq \mathbf{0}, -\mathbf{q} \leq \mathbf{0}, \mathbf{e}_n^\top\mathbf{q} = 1\right\},
\end{aligned}$$

where $\mathbf{e}_{n-1}$, $\mathbf{e}_n$ *denote the* $(n-1) \times 1$ *and* $n \times 1$ *all ones vectors, respectively, and* $\mathbf{I}_{n-1}$ *denotes the* $(n-1) \times (n-1)$ *identity matrix. Moreover, we have* $\begin{bmatrix}-\mathbf{e}_{n-1} & \mathbf{I}_{n-1}\end{bmatrix}\mathbf{p} = 0$, $-\mathbf{p} < \mathbf{0}$. *Therefore, by Lemma 15, we have*

$$\mu_{\mathcal{Q}_1^{0\text{-}1}}(\mathbf{p}) = \text{nullity}\left(\begin{bmatrix}-\mathbf{e}_{n-1} & \mathbf{I}_{n-1}\\ & \mathbf{e}_n^\top\end{bmatrix}\right) = \text{nullity}\left(\begin{bmatrix}-1 & 1 & 0 & \ldots & 0\\ -1 & 0 & 1 & \ldots & 0\\ & & \vdots & & \\ -1 & 0 & 0 & \ldots & 1\\ 1 & 1 & 1 & \ldots & 1\end{bmatrix}\right) = 0\,.$$

Moreover, $\|\mathbf{p}\|_0 = n$. *Thus by Theorem 16, we have* $\text{CCdim}(\mathbf{L}^{0\text{-}1}) \geq n - 1$. *Combined with the upper bound of Lemma 11, this gives* $\text{CCdim}(\mathbf{L}^{0\text{-}1}) = n - 1$.

4.3 Tightness of Bounds

The upper and lower bounds above are not necessarily tight in general. For example, for the n-class ordinal regression loss of Example 2, we know that $\text{CCdim}(\mathbf{L}^{\text{ord}}) = 1$; however the upper bound of Theorem 12 only gives $\text{CCdim}(\mathbf{L}^{\text{ord}}) \leq n - 1$. Similarly, for the n-class abstain loss of Example 4, it can be shown that $\text{CCdim}(\mathbf{L}^{(?)}) = O(\ln n)$ (in fact we conjecture it to be $\Theta(\ln n)$) (Ramaswamy et al., 2015), whereas the upper bound of Theorem 12 gives $\text{CCdim}(\mathbf{L}^{(?)}) \leq n$, and the lower bound of Theorem 16 yields only $\text{CCdim}(\mathbf{L}^{(?)}) \geq 1$. However, as we show below, for certain losses $\mathbf{L}$, the bounds of Theorems 12 and 16 are in fact tight (upto an additive constant of 1).

Lemma 17 *Let $\mathbf{L} \in \mathbb{R}_+^{n\times k}$. Let $\mathbf{p} \in \text{relint}(\Delta_n)$ and $c \in \mathbb{R}_+$ be such that $\mathbf{p}^\top \boldsymbol{\ell}_t = c \ \forall t \in [k]$. Then $\forall t \in [k]$,*

$$\mu_{\mathcal{Q}_t^{\mathbf{L}}}(\mathbf{p}) \leq n - \text{affdim}(\mathbf{L})\,.$$

Proof Since $\mathbf{p}^\top \boldsymbol{\ell}_t = c \ \forall t \in [k]$, we have $\mathbf{p} \in \mathcal{Q}_t^{\mathbf{L}} \ \forall t \in [k]$. In particular, we have $\mathbf{p} \in \mathcal{Q}_1^{\mathbf{L}}$. Now

$$\mathcal{Q}_1^{\mathbf{L}} \;=\; \left\{ \mathbf{q} \in \mathbb{R}^n : \begin{bmatrix} (\boldsymbol{\ell}_2 - \boldsymbol{\ell}_1)^\top \\ \vdots \\ (\boldsymbol{\ell}_k - \boldsymbol{\ell}_1)^\top \end{bmatrix} \mathbf{q} \geq \mathbf{0}, -\mathbf{q} \leq \mathbf{0}, \mathbf{e}_n^\top \mathbf{q} = 1 \right\}.$$

Moreover, $\begin{bmatrix} (\boldsymbol{\ell}_2 - \boldsymbol{\ell}_1)^\top \\ \vdots \\ (\boldsymbol{\ell}_k - \boldsymbol{\ell}_1)^\top \end{bmatrix} \mathbf{p} = \mathbf{0}$ and $-\mathbf{p} < \mathbf{0}$. Therefore, by Lemma 15, we have

$$\mu_{\mathcal{Q}_1^{\mathbf{L}}}(\mathbf{p}) \;=\; \text{nullity}\left(\begin{bmatrix} (\boldsymbol{\ell}_2 - \boldsymbol{\ell}_1)^\top \\ \vdots \\ (\boldsymbol{\ell}_k - \boldsymbol{\ell}_1)^\top \\ \mathbf{e}_n^\top \end{bmatrix} \right) \;=\; n - \text{rank}\left(\begin{bmatrix} (\boldsymbol{\ell}_2 - \boldsymbol{\ell}_1)^\top \\ \vdots \\ (\boldsymbol{\ell}_k - \boldsymbol{\ell}_1)^\top \\ \mathbf{e}_n^\top \end{bmatrix} \right) \;\leq\; n - \text{affdim}(\mathbf{L})\,.$$

A similar proof holds for $\mu_{\mathcal{Q}_t^{\mathbf{L}}}(\mathbf{p})$ for all other $t \in [k]$. ■

Combining the above result with Theorem 16 immediately gives the following:

Theorem 18 *Let $\mathbf{L} \in \mathbb{R}_+^{n\times k}$. If $\exists \mathbf{p} \in \text{relint}(\Delta_n), c \in \mathbb{R}_+$ such that $\mathbf{p}^\top \boldsymbol{\ell}_t = c \ \forall t \in [k]$, then*

$$\text{CCdim}(\mathbf{L}) \geq \text{affdim}(\mathbf{L}) - 1\,.$$

Proof Follows immediately from Theorem 16 and Lemma 17. ■

Intuitively, the condition that $\exists \mathbf{p} \in \text{relint}(\Delta_n), c \in \mathbb{R}_+$ such that $\mathbf{p}^\top \boldsymbol{\ell}_t = c \ \forall t \in [k]$ in Lemma 17 and Theorem 18 above captures the essence of a hard problem: in this case, if the underlying label probability distribution $\mathbf{p}'$ is very close to $\mathbf{p}$, then it becomes hard to decide which element $t \in [k]$ is an optimal prediction. This is essentially what leads the lower bound on the CC-dimension to become tight in this case.

A particularly useful application of Theorem 18 is to losses $\mathbf{L}$ whose columns $\boldsymbol{\ell}_t$ can be obtained from one another by permuting entries:

Corollary 19 *Let $\mathbf{L} \in \mathbb{R}_+^{n\times k}$ be such that all columns of $\mathbf{L}$ can be obtained from one another by permuting entries, i.e. $\forall t_1, t_2 \in [k], \ \exists \sigma \in \Pi_n$ such that $\ell_{y,t_2} = \ell_{\sigma(y),t_1} \ \forall y \in [n]$. Then*

$$\text{CCdim}(\mathbf{L}) \geq \text{affdim}(\mathbf{L}) - 1\,.$$

Proof Let $\mathbf{p} = \left(\frac{1}{n}, \ldots, \frac{1}{n}\right)^\top \in \text{relint}(\Delta_n)$. Let $c = \frac{\|\boldsymbol{\ell}_1\|_1}{n}$. Then under the given condition, $\mathbf{p}^\top \boldsymbol{\ell}_t = c \ \forall t \in [k]$. The result then follows from Theorem 18. ■

We will use the above corollary in establishing lower bounds on the CC dimension of certain subset ranking losses below.

5. Applications to Subset Ranking

We now consider applications of the above framework to analyzing various subset ranking problems, where each instance $x \in \mathcal{X}$ consists of a query together with a set of r documents (for simplicity, $r \in \mathbb{Z}_+$ here is fixed), and the goal is to learn a prediction model which given such an instance predicts a ranking (permutation) of the r documents (Cossock and Zhang, 2008).[7] We consider three popular losses used for subset ranking: the normalized discounted cumulative gain (NDCG) loss, the pairwise disagreement (PD) loss, and the mean average precision (MAP) loss.[8] Each of these subset ranking losses can be viewed as a specific type of multiclass loss acting on a certain label space $\mathcal{Y}$ and prediction space $\widehat{\mathcal{Y}}$. In particular, for the NDCG loss, the label space $\mathcal{Y}$ contains r-dimensional multi-valued relevance vectors; for PD loss, $\mathcal{Y}$ contains directed acyclic graphs on r nodes; and for MAP loss, $\mathcal{Y}$ contains r-dimensional binary relevance vectors. In each case, the prediction space $\widehat{\mathcal{Y}}$ is the set of permutations of r objects: $\widehat{\mathcal{Y}} = \Pi_r$. We study the convex calibration dimension of these losses below. Specifically, we show that the CC dimension of the NDCG loss is upper bounded by r (Section 5.1), and that of both the PD and MAP losses is lower bounded by a quadratic function of r (Sections 5.2 and 5.3). Our result on the CC dimension of the NDCG loss is consistent with previous results in the literature showing the existence of r-dimensional convex calibrated surrogates for NDCG (Ravikumar et al., 2011; Buffoni et al., 2011); our results on the CC dimension of the PD and MAP losses strengthen previous results of Calauzènes et al. (2012), who showed non-existence of r-dimensional convex calibrated surrogates (with a fixed argsort predictor) for PD and MAP.

5.1 Normalized Discounted Cumulative Gain (NDCG)

The NDCG loss is widely used in information retrieval applications (Järvelin and Kekäläinen, 2000). Here $\mathcal{Y}$ is the set of r-dimensional relevance vectors with say s relevance levels, $\mathcal{Y} = \{0, 1, \ldots, s-1\}^r$, and $\widehat{\mathcal{Y}}$ is the set of permutations of r objects, $\widehat{\mathcal{Y}} = \Pi_r$ (thus here $n = |\mathcal{Y}| = s^r$ and $k = |\widehat{\mathcal{Y}}| = r!$). The loss on predicting a permutation $\sigma \in \Pi_r$ when the true label is $\mathbf{y} \in \{0, 1, \ldots, s-1\}^r$ is given by

$$\ell^{\text{NDCG}}(\mathbf{y}, \sigma) \;=\; 1 - \frac{1}{z(\mathbf{y})} \sum_{i=1}^{r} \frac{2^{y_i} - 1}{\log_2(\sigma(i) + 1)}\,,$$

where $z(\mathbf{y})$ is a normalizer that ensures the loss is non-negative and depends only on $\mathbf{y}$. The NDCG loss can therefore be viewed as a multiclass loss matrix $\mathbf{L}^{\text{NDCG}} \in \mathbb{R}_+^{s^r \times r!}$. Clearly, $\text{affdim}(\mathbf{L}^{\text{NDCG}}) \leq r$, and therefore by Theorem 12, we have

$$\text{CCdim}(\mathbf{L}^{\text{NDCG}}) \;\leq\; r\,.$$

Indeed, previous results in the literature have shown the existence of r-dimensional convex calibrated surrogates for NDCG (Ravikumar et al., 2011; Buffoni et al., 2011).

7. The term 'subset ranking' here refers to the fact that in a query-based setting, each instance involves a different 'subset' of documents to be ranked; see (Cossock and Zhang, 2008).
8. Note that NDCG and MAP are generally expressed as gains, where a higher value corresponds to better performance; we can express them as non-negative losses by subtracting them from a suitable constant.

5.2 Pairwise Disagreement (PD)

Here the label space $\mathcal{Y}$ is the set of all directed acyclic graphs (DAGs) on r vertices, which we shall denote as $\mathcal{G}_r$; for each directed edge (i,j) in a graph $G \in \mathcal{G}_r$ associated with an instance $x \in \mathcal{X}$, the i-th document in the document set in x is preferred over the j-th document. The prediction space $\widehat{\mathcal{Y}}$ is again the set of permutations of r objects, $\widehat{\mathcal{Y}} = \Pi_r$. The loss on predicting a permutation $\sigma \in \Pi_r$ when the true label is $G \in \mathcal{G}_r$ is given by

$$\begin{aligned}
\ell^{\mathrm{PD}}(G,\sigma) &= \sum_{(i,j)\in G} \mathbf{1}\big(\sigma(i) > \sigma(j)\big) \\
&= \sum_{i=1}^{r}\sum_{j=1}^{r} \mathbf{1}\big((i,j)\in G\big)\cdot \mathbf{1}\big(\sigma(i) > \sigma(j)\big) \\
&= \sum_{i=1}^{r}\sum_{j=1}^{i-1} \mathbf{1}\big((i,j)\in G\big)\cdot \mathbf{1}\big(\sigma(i) > \sigma(j)\big) + \mathbf{1}\big((j,i)\in G\big)\cdot\Big(1 - \mathbf{1}\big(\sigma(i) > \sigma(j)\big)\Big) \\
&= \sum_{i=1}^{r}\sum_{j=1}^{i-1} \Big(\mathbf{1}\big((i,j)\in G\big) - \mathbf{1}\big((j,i)\in G\big)\Big)\cdot \mathbf{1}\big(\sigma(i) > \sigma(j)\big) + \sum_{i=1}^{r}\sum_{j=1}^{i-1} \mathbf{1}\big((j,i)\in G\big)\,.
\end{aligned}$$

The PD loss can be viewed as a multiclass loss matrix $\mathbf{L}^{\mathrm{PD}} \in \mathbb{R}_+^{|\mathcal{G}_r|\times r!}$. Note that the second term in the sum above depends only the label G; removing this term amounts to simply subtracting a fixed vector from each column of the loss matrix, which does not change the properties of the minimizer of the loss or its CC dimension. We can therefore consider the following loss instead:

$$\widetilde{\ell}^{\mathrm{PD}}(G,\sigma) \;=\; \sum_{i=1}^{r}\sum_{j=1}^{i-1} \Big(\mathbf{1}\big((i,j)\in G\big) - \mathbf{1}\big((j,i)\in G\big)\Big)\cdot \mathbf{1}\big(\sigma(i) > \sigma(j)\big)\,.$$

The resulting loss matrix $\widetilde{\mathbf{L}}^{\mathrm{PD}}$ clearly has rank at most $\frac{r(r-1)}{2}$. Therefore, by Corollary 13, we have

$$\mathrm{CCdim}(\mathbf{L}^{\mathrm{PD}}) \;=\; \mathrm{CCdim}(\widetilde{\mathbf{L}}^{\mathrm{PD}}) \;\leq\; \frac{r(r-1)}{2}\,.$$

In fact one can show that the rank of $\widetilde{\mathbf{L}}^{\mathrm{PD}}$ is exactly $\frac{r(r-1)}{2}$:

Proposition 20 $\mathrm{rank}(\widetilde{\mathbf{L}}^{\mathrm{PD}}) = \frac{r(r-1)}{2}$.

Moreover, it is easy to see that the columns of $\widetilde{\mathbf{L}}^{\mathrm{PD}}$ can all be obtained from one another by permuting entries. Therefore, by Corollary 19, we also have

$$\mathrm{CCdim}(\mathbf{L}^{\mathrm{PD}}) \;=\; \mathrm{CCdim}(\widetilde{\mathbf{L}}^{\mathrm{PD}}) \;\geq\; \frac{r(r-1)}{2} - 2\,.$$

Informally, this implies that a convex surrogate that achieves calibration w.r.t. $\mathbf{L}^{\mathrm{PD}}$ over the full probability simplex must effectively 'estimate' all edge weights. Formally, this strengthens previous results of Duchi et al. (2010) and Calauzènes et al. (2012). In particular, Duchi et al. (2010) showed that certain popular r-dimensional convex surrogates are not

calibrated for the PD loss, and conjectured that such convex calibrated surrogates (in r dimensions) do not exist; Calauzènes et al. (2012) showed that indeed there do not exist any r-dimensional convex surrogates that use argsort as the predictor and are calibrated for the PD loss. The above result allows us to go further and conclude that in fact, one cannot design convex calibrated surrogates for the PD loss in any prediction space of less than $\frac{r(r-1)}{2} - 2$ dimensions (regardless of the predictor used).

5.3 Mean Average Precision (MAP)

Here the label space $\mathcal{Y}$ is the set of all (non-zero) r-dimensional binary relevance vectors, $\mathcal{Y} = \{0,1\}^r \setminus \{\mathbf{0}\}$, and the prediction space $\widehat{\mathcal{Y}}$ is again the set of permutations of r objects, $\widehat{\mathcal{Y}} = \Pi_r$. The loss on predicting a permutation $\sigma \in \Pi_r$ when the true label is $\mathbf{y} \in \{0,1\}^r \setminus \{\mathbf{0}\}$ is given by

$$\begin{aligned}
\ell^{\mathrm{MAP}}(\mathbf{y},\sigma) &= 1 - \frac{1}{\|\mathbf{y}\|_1}\sum_{i:y_i=1}\frac{1}{\sigma(i)}\sum_{j=1}^{\sigma(i)} y_{\sigma^{-1}(j)} \\
&= 1 - \frac{1}{\|\mathbf{y}\|_1}\sum_{i=1}^{r}\frac{y_i}{\sigma(i)}\sum_{j=1}^{\sigma(i)} y_{\sigma^{-1}(j)} \\
&= 1 - \frac{1}{\|\mathbf{y}\|_1}\sum_{i=1}^{r}\sum_{j=1}^{i}\frac{y_{\sigma^{-1}(i)}\,y_{\sigma^{-1}(j)}}{i} \\
&= 1 - \frac{1}{\|\mathbf{y}\|_1}\sum_{i=1}^{r}\sum_{j=1}^{i}\frac{y_i\,y_j}{\max(\sigma(i),\sigma(j))} \qquad (12)
\end{aligned}$$

Thus the MAP loss can be viewed as a multiclass loss matrix $\mathbf{L}^{\mathrm{MAP}} \in \mathbb{R}_+^{(2^r-1)\times r!}$. Clearly, $\mathrm{affdim}(\mathbf{L}^{\mathrm{MAP}}) \leq \frac{r(r+1)}{2}$, and therefore by Theorem 12, we have

$$\mathrm{CCdim}(\mathbf{L}^{\mathrm{MAP}}) \;\leq\; \frac{r(r+1)}{2}\,.$$

One can also show the following lower bound on the rank of $\mathbf{L}^{\mathrm{MAP}}$:

Proposition 21 $\mathrm{rank}(\mathbf{L}^{\mathrm{MAP}}) \geq \frac{r(r-1)}{2} - 2$.

Again, it is easy to see that the columns of $\mathbf{L}^{\mathrm{MAP}}$ can all be obtained from one another by permuting entries, and therefore by Corollary 19, we have

$$\mathrm{CCdim}(\mathbf{L}^{\mathrm{MAP}}) \;\geq\; \frac{r(r-1)}{2} - 4\,.$$

This again strengthens a previous result of Calauzènes et al. (2012), who showed that there do not exist any r-dimensional convex surrogates that use argsort as the predictor and are calibrated for the MAP loss. As with the PD loss, the above result allows us to go further and conclude that in fact, one cannot design convex calibrated surrogates for the MAP loss in any prediction space of less than $\frac{r(r-1)}{2} - 4$ dimensions (regardless of the predictor used).

6. Conclusion

We have developed a unified framework for studying consistency properties of surrogate risk minimization algorithms for general multiclass learning problems, defined by a general multiclass loss matrix. In particular, we have introduced the notion of *convex calibration dimension* (CC dimension) of a multiclass loss matrix, a fundamental quantity that measures the smallest 'size' of a prediction space in which it is possible to design a convex surrogate that is calibrated with respect to the given loss matrix, and have used this to analyze consistency properties of surrogate losses for various multiclass learning problems.

Our study both generalizes previous results and sheds new light on various multiclass losses. For example, our analysis shows that for the n-class 0-1 loss, any convex calibrated surrogate must necessarily entail learning at least $n-1$ real-valued functions, thus showing that the calibrated multiclass surrogate of Lee et al. (2004), whose minimization entails learning n real-valued functions, is essentially not improvable (in the sense of the number of real-valued functions that need to be learned). Another implication of our study is to the pairwise disagreement (PD) and mean average precision (MAP) losses for subset ranking: while previous results have shown that for subset ranking problems with r documents per query, there do not exist r-dimensional convex calibrated surrogates for the PD and MAP losses, our analysis shows that (a) these losses do admit convex calibrated surrogates in higher dimensions, and (b) to obtain such convex calibrated surrogates for these losses, one needs to operate in an $\Omega(r^2)$-dimensional surrogate prediction space (i.e. one needs to learn $\Omega(r^2)$ real-valued functions, rather than just r real-valued 'scoring' functions).

As discussed in Section 4.3, while the upper and lower bounds we have obtained on the CC dimension are tight (up to an additive constant of 1) for certain classes of loss matrices, they can be quite loose in general. An important open direction is to obtain a characterization of the CC dimension in more general settings. It would also be useful to develop methods for deriving explicit surrogate regret bounds for general calibrated surrogates, through which one can relate the excess target risk to the excess surrogate risk for any multiclass loss and corresponding calibrated surrogate. Finally, another interesting direction would be to develop a generic procedure for designing convex calibrated surrogates operating on a 'minimal' space according to the CC dimension of a given loss matrix. There has been some recent progress in this direction in (Ramaswamy et al., 2013), where a general method is described for designing convex calibrated surrogates in a surrogate space with dimension at most the rank of the given loss matrix. However, while the rank forms an upper bound on the CC dimension of the loss matrix, as discussed above, this bound is not always tight, giving rise to the possibility of designing convex calibrated surrogates in lower-dimensional spaces for certain losses. Resolving these issues will contribute significantly to our understanding of the conditions under which convex calibrated surrogates can be designed for a given multiclass learning problem.

7. Proofs

7.1 Proof of Theorem 8

The proof uses the following technical lemma:

Lemma 22 *Let $\mathbf{L} \in \mathbb{R}_+^{n \times k}$ and $\boldsymbol{\psi} : \mathcal{C} \to \mathbb{R}_+^n$. Suppose there exist $r \in \mathbb{N}$ and $\mathbf{z}_1, \ldots, \mathbf{z}_r \in \mathcal{R}_\psi$ such that $\bigcup_{j=1}^r \mathcal{N}^\psi(\mathbf{z}_j) = \Delta_n$ and for each $j \in [r]$, $\exists t \in [k]$ such that $\mathcal{N}^\psi(\mathbf{z}_j) \subseteq \mathcal{Q}_t^{\mathbf{L}}$. Then any element $\mathbf{z} \in \mathcal{S}_\psi$ can be written as $\mathbf{z} = \mathbf{z}' + \mathbf{z}''$ for some $\mathbf{z}' \in \text{conv}(\{\mathbf{z}_1, \ldots, \mathbf{z}_r\})$ and $\mathbf{z}'' \in \mathbb{R}_+^n$.*

Proof (Proof of Lemma 22)

Let $\mathcal{S}' = \{\mathbf{z}' + \mathbf{z}'' : \mathbf{z}' \in \text{conv}(\{\mathbf{z}_1, \ldots, \mathbf{z}_r\}), \mathbf{z}'' \in \mathbb{R}_+^n\}$, and suppose there exists a point $\mathbf{z} \in \mathcal{S}_\psi$ which cannot be decomposed as claimed, i.e. such that $\mathbf{z} \notin \mathcal{S}'$. Then by the Hahn-Banach theorem (e.g. see Gallier (2009), corollary 3.10), there exists a hyperplane that strictly separates $\mathbf{z}$ from $\mathcal{S}'$, i.e. $\exists \mathbf{w} \in \mathbb{R}^n$ such that $\mathbf{w}^\top \mathbf{z} < \mathbf{w}^\top \mathbf{a}\ \forall \mathbf{a} \in \mathcal{S}'$. It is easy to see that $\mathbf{w} \in \mathbb{R}_+^n$ (since a negative component in $\mathbf{w}$ would allow us to choose an element $\mathbf{a}$ from $\mathcal{S}'$ with arbitrarily small $\mathbf{w}^\top \mathbf{a}$).

Now consider the vector $\mathbf{q} = \mathbf{w} / \sum_{i=1}^n w_i \in \Delta_n$. Since $\bigcup_{j=1}^r \mathcal{N}^\psi(\mathbf{z}_j) = \Delta_n$, $\exists j \in [r]$ such that $\mathbf{q} \in \mathcal{N}^\psi(\mathbf{z}_j)$. By definition of positive normals, this gives $\mathbf{q}^\top \mathbf{z}_j \leq \mathbf{q}^\top \mathbf{z}$, and therefore $\mathbf{w}^\top \mathbf{z}_j \leq \mathbf{w}^\top \mathbf{z}$. But this contradicts our construction of $\mathbf{w}$ (since $\mathbf{z}_j \in \mathcal{S}'$). Thus it must be the case that every $\mathbf{z} \in \mathcal{S}_\psi$ is also an element of $\mathcal{S}'$. ■

Proof (Proof of Theorem 8)

We will show $\mathbf{L}$-calibration of $\boldsymbol{\psi}$ via Lemma 2. For each $j \in [r]$, let

$$T_j = \left\{ t \in [k] : \mathcal{N}^\psi(\mathbf{z}_j) \subseteq \mathcal{Q}_t^{\mathbf{L}} \right\};$$

by assumption, $T_j \neq \emptyset\ \forall j \in [r]$. By Lemma 22, for every $\mathbf{z} \in \mathcal{S}_\psi$, $\exists \boldsymbol{\alpha} \in \Delta_r, \mathbf{u} \in \mathbb{R}_+^n$ such that $\mathbf{z} = \sum_{j=1}^r \alpha_j \mathbf{z}_j + \mathbf{u}$. For each $\mathbf{z} \in \mathcal{S}_\psi$, arbitrarily fix a unique $\boldsymbol{\alpha}^{\mathbf{z}} \in \Delta_r$ and $\mathbf{u}^{\mathbf{z}} \in \mathbb{R}_+^n$ satisfying the above, i.e. such that

$$\mathbf{z} = \sum_{j=1}^r \alpha_j^{\mathbf{z}} \mathbf{z}_j + \mathbf{u}^{\mathbf{z}}.$$

Now define $\text{pred}' : \mathcal{S}_\psi \to [k]$ as

$$\text{pred}'(\mathbf{z}) = \min \left\{ t \in [k] : \exists j \in [r] \text{ such that } \alpha_j^{\mathbf{z}} \geq \tfrac{1}{r} \text{ and } t \in T_j \right\}.$$

We will show pred' satisfies the condition for ℓ-calibration.

Fix any $\mathbf{p} \in \Delta_n$. Let

$$J_{\mathbf{p}} = \left\{ j \in [r] : \mathbf{p} \in \mathcal{N}^\psi(\mathbf{z}_j) \right\};$$

since $\Delta_n = \bigcup_{j=1}^r \mathcal{N}^\psi(\mathbf{z}_j)$, we have $J_{\mathbf{p}} \neq \emptyset$. Clearly,

$$\forall j \in J_{\mathbf{p}} : \mathbf{p}^\top \mathbf{z}_j = \inf_{\mathbf{z} \in \mathcal{S}_\psi} \mathbf{p}^\top \mathbf{z} \tag{13}$$

$$\forall j \notin J_{\mathbf{p}} : \mathbf{p}^\top \mathbf{z}_j > \inf_{\mathbf{z} \in \mathcal{S}_\psi} \mathbf{p}^\top \mathbf{z} \tag{14}$$

Moreover, from definition of T_j, we have

$$\forall j \in J_{\mathbf{p}} : \quad t \in T_j \implies \mathbf{p} \in \mathcal{Q}_t^{\mathbf{L}} \implies t \in \text{argmin}_{t'} \mathbf{p}^\top \boldsymbol{\ell}_{t'}.$$

Thus we get

$$\forall j \in J_{\mathbf{p}} : \quad T_j \subseteq \operatorname{argmin}_{t'} \mathbf{p}^\top \boldsymbol{\ell}_{t'} . \tag{15}$$

Now, for any $\mathbf{z} \in \mathcal{S}_\psi$ for which $\text{pred}'(\mathbf{z}) \notin \arg\min_{t'} \mathbf{p}^\top \boldsymbol{\ell}_{t'}$, we must have $\alpha_j^{\mathbf{z}} \geq \frac{1}{r}$ for at least one $j \notin J_{\mathbf{p}}$ (otherwise, we would have $\text{pred}'(\mathbf{z}) \in T_j$ for some $j \in J_{\mathbf{p}}$, giving $\text{pred}'(\mathbf{z}) \in \arg\min_{t'} \mathbf{p}^\top \boldsymbol{\ell}_{t'}$, a contradiction). Thus we have

$$\begin{aligned}
\inf_{\mathbf{z} \in \mathcal{S}_\psi : \text{pred}'(\mathbf{z}) \notin \operatorname{argmin}_{t'} \mathbf{p}^\top \boldsymbol{\ell}_{t'}} \mathbf{p}^\top \mathbf{z} &= \inf_{\mathbf{z} \in \mathcal{S}_\psi : \text{pred}'(\mathbf{z}) \notin \operatorname{argmin}_{t'} \mathbf{p}^\top \boldsymbol{\ell}_{t'}} \sum_{j=1}^{r} \alpha_j^{\mathbf{z}} \mathbf{p}^\top \mathbf{z}_j + \mathbf{p}^\top \mathbf{u}^{\mathbf{z}} && (16) \\
&\geq \inf_{\boldsymbol{\alpha} \in \Delta_r : \alpha_j \geq \frac{1}{r} \text{ for some } j \notin J_{\mathbf{p}}} \sum_{j=1}^{r} \alpha_j \mathbf{p}^\top \mathbf{z}_j && (17) \\
&\geq \min_{j \notin J_{\mathbf{p}}} \inf_{\alpha_j \in [\frac{1}{r}, 1]} \alpha_j \mathbf{p}^\top \mathbf{z}_j + (1 - \alpha_j) \inf_{\mathbf{z} \in \mathcal{S}_\psi} \mathbf{p}^\top \mathbf{z} && (18) \\
&> \inf_{\mathbf{z} \in \mathcal{S}_\psi} \mathbf{p}^\top \mathbf{z} , && (19)
\end{aligned}$$

where the last inequality follows from Eq. (14). Since the above holds for all $\mathbf{p} \in \Delta_n$, by Lemma 2, we have that $\boldsymbol{\psi}$ is $\mathbf{L}$-calibrated. ■

7.2 Proof of Lemma 11

Proof For each $\mathbf{u} \in \mathcal{C}$, define $\mathbf{p}^{\mathbf{u}} = \begin{pmatrix} \mathbf{u} \\ 1 - \sum_{j=1}^{n-1} u_j \end{pmatrix} \in \Delta_n$. Define $\text{pred} : \mathcal{C} \to [k]$ as

$$\text{pred}(\mathbf{u}) \;=\; \min \left\{ t \in [k] : \mathbf{p}^{\mathbf{u}} \in Q_t^{\mathbf{L}} \right\} .$$

We will show that pred satisfies the condition of Definition 1.

Fix $\mathbf{p} \in \Delta_n$. It can be seen that

$$\mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}) \;=\; \sum_{j=1}^{n-1} \left(p_j (u_j - 1)^2 + (1 - p_j) \, {u_j}^2 \right) .$$

Minimizing the above over $\mathbf{u}$ yields the unique minimizer $\mathbf{u}^* = (p_1, \ldots, p_{n-1})^\top \in \mathcal{C}$, which after some calculation gives

$$\inf_{\mathbf{u} \in \mathcal{C}} \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}) \;=\; \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}^*) \;=\; \sum_{j=1}^{n-1} p_j (1 - p_j) .$$

Now, for each $t \in [k]$, define

$$\text{regret}_{\mathbf{p}}^{\mathbf{L}}(t) \;\triangleq\; \mathbf{p}^\top \boldsymbol{\ell}_t - \min_{t' \in [k]} \mathbf{p}^\top \boldsymbol{\ell}_{t'} .$$

Clearly, $\text{regret}_{\mathbf{p}}^{\mathbf{L}}(t) = 0 \iff \mathbf{p} \in \mathcal{Q}_t^{\mathbf{L}}$. Note also that $\mathbf{p}^{\mathbf{u}^*} = \mathbf{p}$, and therefore $\text{regret}_{\mathbf{p}}^{\mathbf{L}}(\text{pred}(\mathbf{u}^*)) = 0$. Let

$$\epsilon \;=\; \min_{t \in [k] : \mathbf{p} \notin \mathcal{Q}_t^{\mathbf{L}}} \text{regret}_{\mathbf{p}}^{\mathbf{L}}(t) \;>\; 0 .$$

Then we have

$$\begin{aligned}
\inf_{\mathbf{u} \in \mathcal{C} : \text{pred}(\mathbf{u}) \notin \operatorname{argmin}_t \mathbf{p}^\top \boldsymbol{\ell}_t} \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}) &= \inf_{\mathbf{u} \in \mathcal{C} : \text{regret}_{\mathbf{p}}^{\mathbf{L}}(\text{pred}(\mathbf{u})) \geq \epsilon} \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}) && (20) \\
&= \inf_{\mathbf{u} \in \mathcal{C} : \text{regret}_{\mathbf{p}}^{\mathbf{L}}(\text{pred}(\mathbf{u})) \geq \text{regret}_{\mathbf{p}}^{\mathbf{L}}(\text{pred}(\mathbf{u}^*)) + \epsilon} \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}) . && (21)
\end{aligned}$$

Now, we claim that the mapping $\mathbf{u} \mapsto \text{regret}_{\mathbf{p}}^{\mathbf{L}}(\text{pred}(\mathbf{u}))$ is continuous at $\mathbf{u} = \mathbf{u}^*$. To see this, suppose the sequence $\mathbf{u}_m$ converges to $\mathbf{u}^*$. Then it is easy to see that $\mathbf{p}^{\mathbf{u}_m}$ converges to $\mathbf{p}^{\mathbf{u}^*} = \mathbf{p}$, and therefore for each $t \in [k]$, $(\mathbf{p}^{\mathbf{u}_m})^\top \boldsymbol{\ell}_t$ converges to $\mathbf{p}^\top \boldsymbol{\ell}_t$. Since by definition of pred we have that for all m, $\text{pred}(\mathbf{u}_m) \in \operatorname{argmin}_t (\mathbf{p}^{\mathbf{u}_m})^\top \boldsymbol{\ell}_t$, this implies that for all large enough m, $\text{pred}(\mathbf{u}_m) \in \operatorname{argmin}_t \mathbf{p}^\top \boldsymbol{\ell}_t$. Thus for all large enough m, $\text{regret}_{\mathbf{p}}^{\mathbf{L}}(\text{pred}(\mathbf{u}_m)) = 0$; i.e. the sequence $\text{regret}_{\mathbf{p}}^{\mathbf{L}}(\text{pred}(\mathbf{u}_m))$ converges to $\text{regret}_{\mathbf{p}}^{\mathbf{L}}(\text{pred}(\mathbf{u}^*))$, yielding continuity at $\mathbf{u}^*$. In particular, this implies $\exists \delta > 0$ such that

$$\|\mathbf{u} - \mathbf{u}^*\| < \delta \implies \text{regret}_{\mathbf{p}}^{\mathbf{L}}(\text{pred}(\mathbf{u})) - \text{regret}_{\mathbf{p}}^{\mathbf{L}}(\text{pred}(\mathbf{u}^*)) < \epsilon .$$

This gives

$$\begin{aligned}
\inf_{\mathbf{u} \in \mathcal{C} : \text{regret}_{\mathbf{p}}^{\mathbf{L}}(\text{pred}(\mathbf{u})) \geq \text{regret}_{\mathbf{p}}^{\mathbf{L}}(\text{pred}(\mathbf{u}^*)) + \epsilon} \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}) &\geq \inf_{\mathbf{u} \in \mathcal{C} : \|\mathbf{u} - \mathbf{u}^*\| \geq \delta} \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}) && (22) \\
&> \inf_{\mathbf{u} \in \mathcal{C}} \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}) , && (23)
\end{aligned}$$

where the last inequality holds since $\mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u})$ is a strictly convex function of $\mathbf{u}$ and $\mathbf{u}^*$ is its unique minimizer. The above sequence of inequalities give us that

$$\inf_{\mathbf{u} \in \mathcal{C} : \text{pred}(\mathbf{u}) \notin \operatorname{argmin}_t \mathbf{p}^\top \boldsymbol{\ell}_t} \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}) \;>\; \inf_{\mathbf{u} \in \mathcal{C}} \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}) . \tag{24}$$

Since this holds for all $\mathbf{p} \in \Delta_n$, we have that $\boldsymbol{\psi}$ is $\mathbf{L}$-calibrated. ■

7.3 Proof of Theorem 16

The proof will require the lemma below, which relates the feasible subspace dimensions of different trigger probability sets at points in their intersection; we will also make critical use of the notion of ϵ-subdifferentials of convex functions (Bertsekas et al., 2003), the main properties of which are also recalled below.

Lemma 23 *Let $\ell : [n] \times [k] \to \mathbb{R}_+^n$. Let $\mathbf{p} \in \text{relint}(\Delta_n)$. Then for any $t_1, t_2 \in \arg\min_{t'} \mathbf{p}^\top \boldsymbol{\ell}_{t'}$ (i.e. such that $\mathbf{p} \in \mathcal{Q}_{t_1}^{\mathbf{L}} \cap \mathcal{Q}_{t_2}^{\mathbf{L}}$),*

$$\mu_{\mathcal{Q}_{t_1}^{\mathbf{L}}}(\mathbf{p}) = \mu_{\mathcal{Q}_{t_2}^{\mathbf{L}}}(\mathbf{p}) .$$

Proof (Proof of Lemma 23)

Let $t_1, t_2 \in \arg\min_{t'} \mathbf{p}^\top \boldsymbol{\ell}_{t'}$ (i.e. $\mathbf{p} \in \mathcal{Q}_{t_1}^{\mathbf{L}} \cap \mathcal{Q}_{t_2}^{\mathbf{L}}$). Now

$$\mathcal{Q}_{t_1}^{\mathbf{L}} = \left\{ \mathbf{q} \in \mathbb{R}^n : -\mathbf{q} \leq \mathbf{0}, \mathbf{e}_n^\top \mathbf{q} = 1, (\boldsymbol{\ell}_{t_1} - \boldsymbol{\ell}_t)^\top \mathbf{q} \leq 0 \;\forall t \in [k] \right\} ,$$

where $\mathbf{e}_n$ denotes the $n \times 1$ all ones vector. Moreover, we have $-\mathbf{p} < \mathbf{0}$, and $(\boldsymbol{\ell}_{t_1} - \boldsymbol{\ell}_t)^\top \mathbf{p} = 0$ iff $\mathbf{p} \in \mathcal{Q}_t^{\mathbf{L}}$. Let $\left\{t \in [k] : \mathbf{p} \in \mathcal{Q}_t^{\mathbf{L}}\right\} = \left\{\widetilde{t}_1, \ldots, \widetilde{t}_r\right\}$ for some $r \in [k]$. Then by Lemma 15, we have

$$\mu_{Q_{t_1}^{\mathbf{L}}} = \text{nullity}(\mathbf{A}_1)\,,$$

where $\mathbf{A}_1 \in \mathbb{R}^{(r+1)\times n}$ is a matrix containing r rows of the form $(\boldsymbol{\ell}_{t_1} - \boldsymbol{\ell}_{\widetilde{t}_j})^\top, j \in [r]$ and the all ones row. Similarly, we get

$$\mu_{Q_{t_2}^{\mathbf{L}}} = \text{nullity}(\mathbf{A}_2)\,,$$

where $\mathbf{A}_2 \in \mathbb{R}^{(r+1)\times n}$ is a matrix containing r rows of the form $(\boldsymbol{\ell}_{t_2} - \boldsymbol{\ell}_{\widetilde{t}_j})^\top, j \in [r]$ and the all ones row. It can be seen that the subspaces spanned by the first r rows of $\mathbf{A}_1$ and $\mathbf{A}_2$ are both equal to the subspace parallel to the affine space containing $\boldsymbol{\ell}_{\widetilde{t}_1}, \ldots, \boldsymbol{\ell}_{\widetilde{t}_r}$. Thus both $\mathbf{A}_1$ and $\mathbf{A}_2$ have the same row space and hence the same null space and nullity, and therefore $\mu_{\mathcal{Q}_{t_1}^{\mathbf{L}}}(\mathbf{p}) = \mu_{\mathcal{Q}_{t_2}^{\mathbf{L}}}(\mathbf{p})$. ■

ϵ-Subdifferentials of a Convex Function. For any $\epsilon > 0$, the ϵ-subdifferential of a convex function $\phi : \mathbb{R}^d \to \overline{\mathbb{R}}$ at a point $\mathbf{u}_0 \in \mathbb{R}^d$ is defined as follows (Bertsekas et al., 2003):

$$\partial_\epsilon \phi(\mathbf{u}_0) = \left\{\mathbf{w} \in \mathbb{R}^d : \phi(\mathbf{u}) - \phi(\mathbf{u}_0) \geq \mathbf{w}^\top(\mathbf{u} - \mathbf{u}_0) - \epsilon \;\; \forall \mathbf{u} \in \mathbb{R}^d\right\}.$$

We recall some important properties of ϵ-subdifferentials below:

- $\mathbf{0} \in \partial_\epsilon \phi(\mathbf{u}_0) \iff \phi(\mathbf{u}_0) \leq \inf_{\mathbf{u}\in\mathbb{R}^d} \phi(\mathbf{u}) + \epsilon\,.$
- For any $\lambda > 0$, $\partial_\epsilon(\lambda\phi(\mathbf{u}_0)) = \lambda\, \partial_{(\epsilon/\lambda)}\phi(\mathbf{u}_0)\,.$
- If $\phi = \phi_1 + \ldots + \phi_n$ for some convex functions $\phi_i : \mathbb{R}^d \to \overline{\mathbb{R}}$, then

$$\partial_\epsilon \phi(\mathbf{u}_0) \;\subseteq\; \partial_\epsilon \phi_1(\mathbf{u}_0) + \ldots + \partial_\epsilon \phi_n(\mathbf{u}_0) \;\subseteq\; \partial_{n\epsilon}\phi(\mathbf{u}_0)\,.$$

- $\epsilon_1 \leq \epsilon_2 \implies \partial_{\epsilon_1}\phi(\mathbf{u}_0) \subseteq \partial_{\epsilon_2}\phi(\mathbf{u}_0)\,.$

We are now ready to give the proof of the lower bound on the CC dimension.

Proof (Proof of Theorem 16)

Let $d \in \mathbb{Z}_+$ be such that there exists a convex set $\mathcal{C} \subseteq \mathbb{R}^d$ and surrogate loss $\boldsymbol{\psi} : \mathcal{C} \to \mathbb{R}_+^n$ such that $\boldsymbol{\psi}$ is $\mathbf{L}$-calibrated. We will show that $d \geq \|\mathbf{p}\|_0 - \mu_{\mathcal{Q}_t^{\mathbf{L}}}(\mathbf{p}) - 1$. We consider two cases:

Case 1: $\mathbf{p} \in \text{relint}(\Delta_n)$.

In this case $\|\mathbf{p}\|_0 = n$. We will show that there exist $\mathcal{H} \subseteq \Delta_n$ and $t_0 \in [k]$ satisfying the following three conditions:

(a) $\mathbf{p} \in \mathcal{H}$;
(b) $\mu_{\mathcal{H}}(\mathbf{p}) = n - d - 1$; and
(c) $\mathcal{H} \subseteq \mathcal{Q}_{t_0}^{\mathbf{L}}$.

Clearly, conditions (a) and (c) above imply $\mathbf{p} \in \mathcal{Q}_{t_0}^{\mathbf{L}}$. Conditions (b) and (c) will then give

$$\mu_{\mathcal{Q}_{t_0}^{\mathbf{L}}}(\mathbf{p}) \;\geq\; \mu_{\mathcal{H}}(\mathbf{p}) \;=\; n - d - 1\,.$$

Further, by Lemma 23, we will then have that

$$\mu_{\mathcal{Q}_t^{\mathbf{L}}}(\mathbf{p}) \;=\; \mu_{\mathcal{Q}_{t_0}^{\mathbf{L}}}(\mathbf{p}) \;\geq\; n - d - 1\,,$$

thus proving the claim.

We now show how to construct $\mathcal{H}$ and t_0 satisfying the above conditions. Let $\{\mathbf{u}_m\}$ be a sequence in $\mathcal{C}$ such that

$$\mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}_m) \longrightarrow \inf_{\mathbf{z}\in\mathcal{S}_\psi} \mathbf{p}^\top \mathbf{z} = \inf_{\mathbf{u}\in\mathcal{C}} \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u})\,.$$

Let

$$\epsilon_m = \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}_m) - \inf_{\mathbf{u}\in\mathcal{C}} \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u})\,.$$

Then clearly $\epsilon_m \to 0$. Now, for each m, we have

$$\begin{aligned}
\mathbf{0} \;&\in\; \partial_{\epsilon_m}(\mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}_m)) \\
&\subseteq\; \partial_{\epsilon_m}(p_1\psi_1(\mathbf{u}_m)) + \ldots + \partial_{\epsilon_m}(p_n\psi_n(\mathbf{u}_m)) \\
&=\; p_1\, \partial_{(\epsilon_m/p_1)}(\psi_1(\mathbf{u}_m)) + \ldots + p_n\, \partial_{(\epsilon_m/p_n)}(\psi_n(\mathbf{u}_m))\,.
\end{aligned}$$

Therefore $\exists \mathbf{w}_y^m \in \partial_{(\epsilon_m/p_y)}(\psi_y(\mathbf{u}_m))\;\forall y \in [n]$ such that

$$\sum_{y=1}^n p_y \mathbf{w}_y^m = \mathbf{0}\,.$$

Let

$$\mathbf{A}^m = \left[\mathbf{w}_1^m \ldots \mathbf{w}_n^m\right] \in \mathbb{R}^{d\times n}\,,$$

and define

$$\begin{aligned}
\mathcal{H}_m \;&=\; \left\{\mathbf{q} \in \Delta_n : \mathbf{A}^m\mathbf{q} = \mathbf{0}\right\} \\
&=\; \left\{\mathbf{q} \in \mathbb{R}^n : \mathbf{A}^m\mathbf{q} = \mathbf{0}\,, \mathbf{e}_n^\top\mathbf{q} = 1\,, -\mathbf{q} \leq \mathbf{0}\right\},
\end{aligned}$$

where $\mathbf{e}_n$ denotes the $n \times 1$ all ones vector. Clearly, $\mathbf{p} \in \mathcal{H}_m$ and $-\mathbf{p} < \mathbf{0}$; therefore by Lemma 15, we have

$$\mu_{\mathcal{H}_m}(\mathbf{p}) \;=\; \text{nullity}\left(\begin{bmatrix}\mathbf{A}^m \\ \mathbf{e}_n^\top\end{bmatrix}\right) \;\geq\; n - (d+1)\,.$$

This means that there exist $(n-d-1)$ orthonormal vectors $\mathbf{v}_1^m, \ldots, \mathbf{v}_{n-d-1}^m \in \mathbb{R}^n$ whose span $\mathcal{V}^m = \text{span}(\{\mathbf{v}_1^m, \ldots, \mathbf{v}_{n-d-1}^m\})$ is contained in $\mathcal{F}_{\mathcal{H}_m}(\mathbf{p}) \cap (-\mathcal{F}_{\mathcal{H}_m}(\mathbf{p}))$. It can be verified that this in turn implies

$$\{\mathbf{p} + \mathbf{v} : \mathbf{v} \in \mathcal{V}^m\} \cap \Delta_n \;\subseteq\; \mathcal{H}_m\,.$$

Now, $\{(\mathbf{v}_1^m, \ldots, \mathbf{v}_{n-d-1}^m)\}$ is a bounded sequence in $(\mathbb{R}^n)^{n-d-1}$ and must therefore have a convergent subsequence, say with indices $r_1, r_2, \ldots$, converging to some limit point $(\mathbf{v}_1, \ldots, \mathbf{v}_{n-d-1}) \in (\mathbb{R}^n)^{n-d-1}$. It can be verified that $\mathbf{v}_1, \ldots, \mathbf{v}_{n-d-1}$ must also form an orthonormal set of vectors. Let $\mathcal{V} = \text{span}(\{\mathbf{v}_1, \ldots, \mathbf{v}_{n-d-1}\})$, and define

$$\mathcal{H} \;=\; \{\mathbf{p} + \mathbf{v} : \mathbf{v} \in \mathcal{V}\} \cap \Delta_n \,.$$

Clearly $\mathbf{p} \in \mathcal{H}$, and moreover, since $\mathbf{p} \in \text{relint}(\Delta_n)$, we have $\mu_{\mathcal{H}}(\mathbf{p}) = n - d - 1$, thus satisfying conditions (a) and (b) above.

For condition (c), we will show that $\mathcal{H} \subseteq \mathcal{N}^{\psi}(\{\mathbf{z}_m\})$, where $\mathbf{z}_m = \boldsymbol{\psi}(\mathbf{u}_{r_m})$; the claim will then follow from Theorem 7. Consider any point $\mathbf{q} \in \mathcal{H}$. By construction of $\mathcal{H}$, we must have that $\mathbf{q}$ is the limit point of some convergent sequence $\{\mathbf{q}_m\}$ in Δ_n satisfying $\mathbf{q}_m \in \mathcal{H}_{r_m}\ \forall m$, i.e. $\mathbf{A}^{r_m}\mathbf{q}_m = \mathbf{0}\ \forall m$. Therefore for each m, we have

$$\begin{aligned}
\mathbf{0} \;=\; \sum_{y=1}^{n} q_{m,y}\mathbf{w}_y^{r_m} \;&\in\; \sum_{y=1}^{n} q_{m,y}\,\partial_{(\epsilon_{r_m}/p_y)}(\psi_y(\mathbf{u}_{r_m})) \\
&=\; \sum_{y=1}^{n} \partial_{(\epsilon_{r_m} q_{m,y}/p_y)}(q_y^m\,\psi_y(\mathbf{u}_{r_m})) \\
&\subseteq\; \sum_{y=1}^{n} \partial_{(\epsilon_{r_m}/p_{\min})}(q_{m,y}\,\psi_y(\mathbf{u}_{r_m})) \\
&\subseteq\; \partial_{(n\epsilon_{r_m}/p_{\min})}(\mathbf{q}_m{}^{\top}\boldsymbol{\psi}(\mathbf{u}_{r_m}))\,,
\end{aligned}$$

where $p_{\min} = \min_{y\in[n]} p_y > 0$ (since $\mathbf{p} \in \text{relint}(\Delta_n)$). This gives for each m:

$$\mathbf{q}_m{}^{\top}\mathbf{z}_m \;=\; \mathbf{q}_m{}^{\top}\boldsymbol{\psi}(\mathbf{u}_{r_m}) \;\leq\; \inf_{\mathbf{u}\in\mathbb{R}^d} \mathbf{q}_m{}^{\top}\boldsymbol{\psi}(\mathbf{u}) + \frac{n\epsilon_{r_m}}{p_{\min}} \;=\; \inf_{\mathbf{z}\in\mathcal{S}_{\psi}} \mathbf{q}_m{}^{\top}\mathbf{z} + \frac{n\epsilon_{r_m}}{p_{\min}}\,.$$

Taking limits as $m \to \infty$, we thus get

$$\lim_{m\to\infty} \mathbf{q}_m{}^{\top}\mathbf{z}_m \leq \lim_{m\to\infty} \inf_{\mathbf{z}\in\mathcal{S}_{\psi}} \mathbf{q}_m{}^{\top}\mathbf{z}\,. \tag{25}$$

Now, since $\{\mathbf{z}_m\}$ is bounded, we have

$$\lim_{m\to\infty} \mathbf{q}_m{}^{\top}\mathbf{z}_m = \lim_{m\to\infty} (\mathbf{q}_m - \mathbf{q})^{\top}\mathbf{z}_m + \lim_{m\to\infty} \mathbf{q}^{\top}\mathbf{z}_m = \lim_{m\to\infty} \mathbf{q}^{\top}\mathbf{z}_m\,. \tag{26}$$

Moreover, since the mapping $\mathbf{p} \mapsto \inf_{\mathbf{z}\in\mathcal{S}_{\psi}} \mathbf{p}^{\top}\mathbf{z}$ is continuous over its domain Δ_n (see Lemma 24), we have

$$\lim_{m\to\infty} \inf_{\mathbf{z}\in\mathcal{S}_{\psi}} \mathbf{q}_m{}^{\top}\mathbf{z} = \inf_{\mathbf{z}\in\mathcal{S}_{\psi}} \mathbf{q}^{\top}\mathbf{z}\,. \tag{27}$$

Putting together Equations (25), (26) and (27), we therefore get

$$\lim_{m\to\infty} \mathbf{q}^{\top}\mathbf{z}_m = \inf_{\mathbf{z}\in\mathcal{S}_{\psi}} \mathbf{q}^{\top}\mathbf{z}\,. \tag{28}$$

Thus $\mathbf{q} \in \mathcal{N}^{\psi}(\{\mathbf{z}_m\})$. Since $\mathbf{q}$ was an arbitrary point in $\mathcal{H}$, this gives $\mathcal{H} \subseteq \mathcal{N}^{\psi}(\{\mathbf{z}_m\})$. The claim follows.

Case 2: $\mathbf{p} \notin \text{relint}(\Delta_n)$.

For each $\mathbf{b} \in \{0,1\}^n \setminus \{\mathbf{0}\}$, define

$$\mathcal{P}^{\mathbf{b}} = \left\{\mathbf{q} \in \Delta_n : q_y > 0 \iff b_y = 1\right\}.$$

Clearly, the set $\{\mathcal{P}^{\mathbf{b}} : \mathbf{b} \in \{0,1\}^n \setminus \{\mathbf{0}\}\}$ forms a partition of Δ_n. Moreover, for $\mathbf{b} = \mathbf{e}_n$ (the $n \times 1$ all ones vector), we have

$$\mathcal{P}^{\mathbf{e}_n} \;=\; \left\{\mathbf{q} \in \Delta_n : q_y > 0\ \forall y \in [n]\right\} \;=\; \text{relint}(\Delta_n)\,.$$

Therefore we have $\mathbf{p} \in \mathcal{P}^{\mathbf{b}}$ for some $\mathbf{b} \in \{0,1\}^n \setminus \{\mathbf{0}, \mathbf{e}_n\}$, with $\|\mathbf{p}\|_0 = \|\mathbf{b}\|_0$. Now, define $\boldsymbol{\psi}^{\mathbf{b}} : \mathcal{C} \to \mathbb{R}_+^{\|\mathbf{b}\|_0}$, $\mathbf{L}^{\mathbf{b}} \in \mathbb{R}_+^{\|\mathbf{b}\|_0 \times k}$, and $\mathbf{p}^{\mathbf{b}} \in \Delta_{\|\mathbf{b}\|_0}$ as projections of $\boldsymbol{\psi}$, $\mathbf{L}$ and $\mathbf{p}$ onto the $\|\mathbf{b}\|_0$ coordinates $y : b_y = 1$, so that $\boldsymbol{\psi}^{\mathbf{b}}(\mathbf{u})$ contains the elements of $\boldsymbol{\psi}(\mathbf{u})$ corresponding to coordinates $y : b_y = 1$, the columns $\boldsymbol{\ell}_t^{\mathbf{b}}$ of $\mathbf{L}^{\mathbf{b}}$ contain the elements of the columns $\boldsymbol{\ell}_t$ of $\mathbf{L}$ corresponding to the same coordinates $y : b_y = 1$, and similarly, $\mathbf{p}^{\mathbf{b}}$ contains the strictly positive elements of $\mathbf{p}$. Since $\boldsymbol{\psi}$ is $\mathbf{L}$-calibrated, and therefore in particular is calibrated w.r.t. $\mathbf{L}$ over $\{\mathbf{q} \in \Delta_n : q_y = 0\ \forall y : b_y = 0\}$, we have that $\boldsymbol{\psi}^{\mathbf{b}}$ is $\mathbf{L}^{\mathbf{b}}$-calibrated (over $\Delta_{\|\mathbf{b}\|_0}$). Moreover, by construction, we have $\mathbf{p}^{\mathbf{b}} \in \text{relint}(\Delta_{\|\mathbf{b}\|_0})$. Therefore by Case 1 above, we have

$$d \;\geq\; \|\mathbf{b}\|_0 - \mu_{\mathcal{Q}_t^{\mathbf{L}^{\mathbf{b}}}}(\mathbf{p}^{\mathbf{b}}) - 1\,.$$

The claim follows since $\mu_{\mathcal{Q}_t^{\mathbf{L}^{\mathbf{b}}}}(\mathbf{p}^{\mathbf{b}}) \leq \mu_{\mathcal{Q}_t^{\mathbf{L}}}(\mathbf{p})$.

■

7.4 Proof of Proposition 20

Proof We will establish $\text{rank}(\widetilde{\mathbf{L}}^{\text{PD}}) \geq \frac{r(r-1)}{2}$ by showing the existence of $\frac{r(r-1)}{2}$ linearly independent rows in $\widetilde{\mathbf{L}}^{\text{PD}}$; the claim will then follow by combining this with the previously stated upper bound $\text{rank}(\widetilde{\mathbf{L}}^{\text{PD}}) \leq \frac{r(r-1)}{2}$.

Consider the $\frac{r(r-1)}{2}$ rows of $\widetilde{\mathbf{L}}^{\text{PD}}$ corresponding to graphs consisting of single directed edges (i,j) with $i < j$. We claim these rows are linearly independent. To see this, suppose for the sake of contradiction that this is not the case. Then one of these rows, say the row corresponding to the graph with directed edge (a,b) for some $a, b \in [r]$, $a < b$, can be written as a linear combination of the other rows:

$$\widetilde{\ell}^{\text{PD}}((a,b),\sigma) \;=\; \sum_{1\leq i<j\leq r\,,\,(i,j)\neq(a,b)} c_{ij}\,\widetilde{\ell}^{\text{PD}}((i,j),\sigma) \qquad \forall \sigma \in \Pi_r\,, \tag{29}$$

for some coefficients $c_{ij} \in \mathbb{R}$. Now consider two permutations $\sigma, \sigma' \in \Pi_r$ such that

$$\begin{aligned}
\sigma(a) &= \sigma'(b) \\
\sigma(b) &= \sigma'(a) \\
\sigma(i) &= \sigma'(i)\ \forall i \neq a, b\,.
\end{aligned}$$

Then applying Eq. (29) to these two permutations gives

$$\widetilde{\ell}^{\mathrm{PD}}((a,b),\sigma) \;=\; \widetilde{\ell}^{\mathrm{PD}}((a,b),\sigma')\,.$$

However from the definition of $\widetilde{\mathbf{L}}^{\mathrm{PD}}$ it is easy to verify that the columns corresponding to these two permutations have identical entries in all rows except for the row corresponding to the graph (a,b), giving

$$\begin{aligned}\widetilde{\ell}^{\mathrm{PD}}((i,j),\sigma) &= \widetilde{\ell}^{\mathrm{PD}}((i,j),\sigma') \qquad \forall i<j, (i,j)\neq(a,b)\,;\\ \widetilde{\ell}^{\mathrm{PD}}((a,b),\sigma) &\neq \widetilde{\ell}^{\mathrm{PD}}((a,b),\sigma')\,.\end{aligned}$$

This yields a contradiction, and therefore we must have that the $\frac{r(r-1)}{2}$ rows above are linearly independent, giving

$$\mathrm{rank}(\widetilde{\mathbf{L}}^{\mathrm{PD}}) \geq \frac{r(r-1)}{2}\,.$$

The claim follows. ■

7.5 Proof of Proposition 21

Proof From Eq. (12), we have that $\mathbf{L}^{\mathrm{MAP}} \in \mathbb{R}^{(2^r-1)\times r!}$ can be written as

$$\mathbf{L}^{\mathrm{MAP}} = \mathbf{e}_{(2^r-1)}\mathbf{e}_{r!}^\top - \mathbf{A}\mathbf{B}\,,$$

where $\mathbf{e}_{(2^r-1)}$ and $\mathbf{e}_{r!}$ denote the $(2^r-1)\times 1$ and $r!\times 1$ all ones vectors, respectively, and where $\mathbf{A}\in\mathbb{R}^{(2^r-1)\times\frac{r(r+1)}{2}}$ and $\mathbf{B}\in\mathbb{R}^{\frac{r(r+1)}{2}\times r!}$ are given by

$$\begin{aligned}A_{\mathbf{y},(i,j)} &= \frac{1}{\|\mathbf{y}\|_1}y_i y_j \qquad \forall \mathbf{y}\in\{0,1\}^r\setminus\{\mathbf{0}\},\; i,j\in[r]: i\leq j\,,\\ B_{(i,j),\sigma} &= \frac{1}{\max(\sigma(i),\sigma(j))} \qquad \forall i,j\in[r]: i\leq j,\; \sigma\in\Pi_r\,.\end{aligned}$$

We will show that

$$\mathrm{rank}(\mathbf{A}) \;\geq\; \frac{r(r+1)}{2}-1 \tag{30}$$

and

$$\mathrm{rank}(\mathbf{B}) \;\geq\; \frac{r(r-1)}{2}\,. \tag{31}$$

The result will then follow, since we will then have

$$\begin{aligned}\mathrm{rank}(\mathbf{L}^{\mathrm{MAP}}) &= \mathrm{rank}\left(\mathbf{e}_{(2^r-1)}\mathbf{e}_{r!}^\top - \mathbf{A}\mathbf{B}\right)\\ &\geq \mathrm{rank}(\mathbf{A}\mathbf{B}) - 1\\ &\geq \mathrm{rank}(\mathbf{B}) - 2\,, \quad \text{since } \mathbf{A} \text{ is away from full (column) rank by at most 1}\\ &\geq \frac{r(r-1)}{2} - 2\,.\end{aligned}$$

To see why Eq. (30) is true, consider the 2^r vectors $\mathbf{v}^\alpha\in\mathbb{R}^{2^r}$ defined as

$$v^\alpha_{\mathbf{y}} = \prod_{i\in\alpha} y_i \quad \forall \alpha\subseteq[r]\,, \mathbf{y}\in\{0,1\}^r\,.$$

It is easy to see that these vectors form a basis in $\mathbb{R}^{2^r}$. The columns of $\mathbf{A}$ can be obtained from the $\frac{r(r+1)}{2}$ vectors $\mathbf{v}^\alpha$ corresponding to subsets $\alpha\subseteq[r]$ of sizes 1 and 2, by removing the element corresponding to $\mathbf{y}=\mathbf{0}$ and dividing all other rows corresponding to $\mathbf{y}\in\{0,1\}^r\setminus\{\mathbf{0}\}$ by $\|\mathbf{y}\|_1$. This establishes the lower bound on $\mathrm{rank}(\mathbf{A})$ in Eq. (30).

To see why Eq. (31) is true, let us make the dependence of $\mathbf{B}$ on r explicit by denoting $\mathbf{B}_r=\mathbf{B}$, and observe that $\mathbf{B}_r$ can be decomposed as

$$\mathbf{B}_r = \begin{bmatrix}\mathbf{B}_{r-1} & \mathbf{D}\\ \mathbf{C} & \mathbf{E}\end{bmatrix}\,,$$

where the sub-matrix $\mathbf{B}_{r-1}\in\mathbb{R}^{\frac{r(r-1)}{2}\times(r-1)!}$ is obtained by taking the $\frac{r(r-1)}{2}$ rows (i,j) in $\mathbf{B}_r$ with $i\leq j<r$ and the $(r-1)!$ columns σ in $\mathbf{B}_r$ with $\sigma(r)=r$:

	$\Upsilon=\{\sigma\in\Pi_r:\sigma(r)=r\}$	$\Omega=\{\sigma\in\Pi_r:\sigma(r)\neq r\}$
$\Gamma=\{(i,j)\in[r]\times[r]: i\leq j<r\}$	$\mathbf{B}_{r-1}$	$\mathbf{D}$
$\Lambda=\{(i,j)\in[r]\times[r]: i\leq j=r\}$	$\mathbf{C}$	$\mathbf{E}$

Consider the matrix $\mathbf{C}\in\mathbb{R}^{r\times(r-1)!}$. Each entry in this matrix has the form $\frac{1}{\max(\sigma(i),\sigma(j))}$ with $i\leq j=r$ and $\sigma(r)=r$. Thus all entries in $\mathbf{C}$ are equal to $\frac{1}{r}$ and $\mathrm{rank}(\mathbf{C})=1$.

Next, consider the matrix $\mathbf{E}\in\mathbb{R}^{r\times(r!-(r-1)!)}$. We will show that there are $r-1$ linearly independent columns in $\mathbf{E}$. In particular, consider any permutations $\sigma^1,\sigma^2,\ldots,\sigma^{r-1}$ in the set Ω such that $\sigma^j(j)=r$ and $\sigma^j(r)=r-1$ (such permutations clearly exist). The sub-matrix of $\mathbf{E}$ corresponding to these columns is given by

	$\sigma^1(1)=r$ $\sigma^1(r)=r-1$	$\sigma^2(2)=r$ $\sigma^2(r)=r-1$	$\ldots$ $\ldots$	$\sigma^{r-1}(r-1)=r$ $\sigma^{r-1}(r)=r-1$
$(1,r)$	$\frac{1}{r}$	$\frac{1}{r-1}$	$\cdots$	$\frac{1}{r-1}$
$(2,r)$	$\frac{1}{r-1}$	$\frac{1}{r}$	$\cdots$	$\frac{1}{r-1}$
$\vdots$	$\vdots$	$\vdots$	$\ddots$	$\vdots$
$(r-1,r)$	$\frac{1}{r-1}$	$\frac{1}{r-1}$	$\cdots$	$\frac{1}{r}$
(r,r)	$\frac{1}{r-1}$	$\frac{1}{r-1}$	$\cdots$	$\frac{1}{r-1}$

Thus excluding the last row of $\mathbf{E}$, one gets a square $(r-1)\times(r-1)$ matrix with diagonal entries equal to $\frac{1}{r}$ and off-diagonal entries equal to $\frac{1}{r-1}$. The last row of $\mathbf{E}$ has all entries equal to $\frac{1}{r-1}$. Clearly, this gives $\mathrm{rank}(\mathbf{E})=r-1$. Moreover, the span of the $r-1$ column vectors of $\mathbf{E}$ does not intersect with column space of $\mathbf{C}$ non-trivially, since it does not contain the all ones vector. This implies that the $r-1$ columns of $\mathbf{B}_r$ corresponding to the permutations $\sigma^1,\sigma^2,\ldots,\sigma^{r-1}\in\Omega$ (which yield the linearly independent columns of $\mathbf{E}$),

together with the columns of $\mathbf{B}_r$ corresponding to permutations $\sigma \in \Upsilon$ that yield linearly independent columns of $\mathbf{B}_{r-1}$, are all linearly independent. Therefore, we have

$$\text{rank}(\mathbf{B}_r) \;\geq\; \text{rank}(\mathbf{B}_{r-1}) + r - 1\,.$$

Trivially, $\text{rank}(\mathbf{B}_1) \geq 0$. Expanding the above recursion therefore gives

$$\text{rank}(\mathbf{B}_r) \;\geq\; \frac{r(r-1)}{2}\,.$$

This establishes the lower bound on $\text{rank}(\mathbf{B})$ in Eq. (31). ■

Appendix A. Proofs of Lemma 2 and Theorem 3

A.1 Proof of Lemma 2

Proof Let $\boldsymbol{\psi} : \mathcal{C} \to \mathbb{R}^n_+$. We will show that $\exists$ pred : $\mathcal{C} \to [k]$ satisfying the condition in Definition 1 if and only if $\exists$ pred$' : \mathcal{S}_\psi \to [k]$ satisfying the stated condition.

('if' direction) First, suppose $\exists$ pred$' : \mathcal{S}_\psi \to [k]$ such that

$$\forall \mathbf{p} \in \mathcal{P} : \quad \inf_{\mathbf{z} \in \mathcal{S}_\psi : \text{pred}'(\mathbf{z}) \notin \text{argmin}_t \, \mathbf{p}^\top \boldsymbol{\ell}_t} \mathbf{p}^\top \mathbf{z} \;>\; \inf_{\mathbf{z} \in \mathcal{S}_\psi} \mathbf{p}^\top \mathbf{z}\,.$$

Define pred : $\mathcal{C} \to [k]$ as follows:

$$\text{pred}(\mathbf{u}) = \text{pred}'(\boldsymbol{\psi}(\mathbf{u})) \quad \forall \mathbf{u} \in \mathcal{C}\,.$$

Then for all $\mathbf{p} \in \mathcal{P}$, we have

$$\begin{aligned}
\inf_{\mathbf{u} \in \mathcal{C} : \text{pred}(\mathbf{u}) \notin \text{argmin}_t \, \mathbf{p}^\top \boldsymbol{\ell}_t} \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}) &= \inf_{\mathbf{z} \in \mathcal{R}_\psi : \text{pred}'(\mathbf{z}) \notin \text{argmin}_t \, \mathbf{p}^\top \boldsymbol{\ell}_t} \mathbf{p}^\top \mathbf{z} \\
&\geq \inf_{\mathbf{z} \in \mathcal{S}_\psi : \text{pred}'(\mathbf{z}) \notin \text{argmin}_t \, \mathbf{p}^\top \boldsymbol{\ell}_t} \mathbf{p}^\top \mathbf{z} \\
&> \inf_{\mathbf{z} \in \mathcal{S}_\psi} \mathbf{p}^\top \mathbf{z} \\
&= \inf_{\mathbf{u} \in \mathcal{C}} \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u})\,.
\end{aligned}$$

Thus $\boldsymbol{\psi}$ is $(\mathbf{L}, \mathcal{P})$-calibrated.

('only if' direction) Conversely, suppose $\boldsymbol{\psi}$ is $(\mathbf{L}, \mathcal{P})$-calibrated, so that $\exists$ pred : $\mathcal{C} \to [k]$ such that

$$\forall \mathbf{p} \in \mathcal{P} : \quad \inf_{\mathbf{u} \in \mathcal{C} : \text{pred}(\mathbf{u}) \notin \text{argmin}_t \, \mathbf{p}^\top \boldsymbol{\ell}_t} \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}) \;>\; \inf_{\mathbf{u} \in \mathcal{C}} \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u})\,.$$

By Caratheodory's Theorem (e.g. see Bertsekas et al. (2003)), we have that every $\mathbf{z} \in \mathcal{S}_\psi$ can be expressed as a convex combination of at most $n+1$ points in $\mathcal{R}_\psi$, i.e. for every $\mathbf{z} \in \mathcal{S}_\psi$, $\exists \boldsymbol{\alpha} \in \Delta_{n+1}, \mathbf{u}_1, \ldots, \mathbf{u}_{n+1} \in \mathcal{C}$ such that $\mathbf{z} = \sum_{j=1}^{n+1} \alpha_j \boldsymbol{\psi}(\mathbf{u}_j)$; w.l.o.g., we can assume $\alpha_1 \geq \frac{1}{n+1}$. For each $\mathbf{z} \in \mathcal{S}_\psi$, arbitrarily fix a unique such convex combination, i.e. fix $\boldsymbol{\alpha}^{\mathbf{z}} \in \Delta_{n+1}, \mathbf{u}^{\mathbf{z}}_1, \ldots, \mathbf{u}^{\mathbf{z}}_{n+1} \in \mathcal{C}$ with $\alpha^{\mathbf{z}}_1 \geq \frac{1}{n+1}$ such that

$$\mathbf{z} = \sum_{j=1}^{n+1} \alpha^{\mathbf{z}}_j \boldsymbol{\psi}(\mathbf{u}^{\mathbf{z}}_j)\,.$$

Now, define pred$' : \mathcal{S}_\psi \to [k]$ as follows:

$$\text{pred}'(\mathbf{z}) = \text{pred}(\mathbf{u}^{\mathbf{z}}_1) \quad \forall \mathbf{z} \in \mathcal{S}_\psi\,.$$

Then for any $\mathbf{p} \in \mathcal{P}$, we have

$$\begin{aligned}
\inf_{\mathbf{z} \in \mathcal{S}_\psi : \text{pred}'(\mathbf{z}) \notin \text{argmin}_t \, \mathbf{p}^\top \boldsymbol{\ell}_t} \mathbf{p}^\top \mathbf{z} &= \inf_{\mathbf{z} \in \mathcal{S}_\psi : \text{pred}(\mathbf{u}^{\mathbf{z}}_1) \notin \text{argmin}_t \, \mathbf{p}^\top \boldsymbol{\ell}_t} \sum_{j=1}^{n+1} \alpha^{\mathbf{z}}_j \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}^{\mathbf{z}}_j) \\
&\geq \inf_{\boldsymbol{\alpha} \in \Delta_{n+1}, \mathbf{u}_1, \ldots, \mathbf{u}_{n+1} \in \mathcal{C} : \alpha_1 \geq \frac{1}{n+1}, \text{pred}(\mathbf{u}_1) \notin \text{argmin}_t \, \mathbf{p}^\top \boldsymbol{\ell}_t} \sum_{j=1}^{n+1} \alpha_j \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}_j) \\
&\geq \inf_{\boldsymbol{\alpha} \in \Delta_{n+1} : \alpha_1 \geq \frac{1}{n+1}} \sum_{j=1}^{n+1} \inf_{\mathbf{u}_j \in \mathcal{C} : \text{pred}(\mathbf{u}_1) \notin \text{argmin}_t \, \mathbf{p}^\top \boldsymbol{\ell}_t} \alpha_j \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}_j) \\
&\geq \inf_{\alpha_1 \in [\frac{1}{n+1}, 1]} \alpha_1 \inf_{\mathbf{u} \in \mathcal{C} : \text{pred}(\mathbf{u}) \notin \text{argmin}_t \, \mathbf{p}^\top \boldsymbol{\ell}_t} \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}) + (1 - \alpha_1) \sum_{j=2}^{n+1} \inf_{\mathbf{u} \in \mathcal{C}} \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}) \\
&> \inf_{\mathbf{u} \in \mathcal{C}} \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}) \\
&= \inf_{\mathbf{z} \in \mathcal{S}_\psi} \mathbf{p}^\top \mathbf{z}\,.
\end{aligned}$$

Thus pred$'$ satisfies the stated condition. ■

A.2 Proof of Theorem 3

The proof is similar to that for the multiclass 0-1 loss given by Tewari and Bartlett (2007). We will make use of the following two lemmas; the first is a straightforward generalization of a similar lemma in (Tewari and Bartlett, 2007), and the second follows directly from Lemma 2.

Lemma 24 *The map* $\mathbf{p} \mapsto \inf_{\mathbf{z} \in \mathcal{S}_\psi} \mathbf{p}^\top \mathbf{z}$ *is continuous over* Δ_n.

Lemma 25 *Let* $\mathbf{L} \in \mathbb{R}^{n \times k}_+$. *A surrogate* $\boldsymbol{\psi} : \mathcal{C} \to \mathbb{R}^n$ *is* $\mathbf{L}$*-calibrated if and only if there exists a function* pred$' : \mathcal{S}_\psi \to [k]$ *such that the following holds: for all* $\mathbf{p} \in \Delta_n$ *and all sequences* $\{\mathbf{z}_m\}$ *in* $\mathcal{S}_\psi$ *such that* $\lim_{m \to \infty} \mathbf{p}^\top \mathbf{z}_m = \inf_{\mathbf{z} \in \mathcal{S}_\psi} \mathbf{p}^\top \mathbf{z}$, *we have* $\mathbf{p}^\top \boldsymbol{\ell}_{\text{pred}'(\mathbf{z}_m)} = \min_{t \in [k]} \mathbf{p}^\top \boldsymbol{\ell}_t$ *for all large enough* m.

Proof (Proof of Theorem 3)

Let $\boldsymbol{\psi} : \mathcal{C} \to \mathbb{R}^n_+$.

('only if' direction) First, suppose $\boldsymbol{\psi}$ is $\mathbf{L}$-calibrated. Then by Lemma 2, $\exists\ \text{pred}' : \mathcal{S}_\psi \to [k]$ such that

$$\forall \mathbf{p} \in \mathcal{P} : \quad \inf_{\mathbf{z} \in \mathcal{S}_\psi : \text{pred}'(\mathbf{z}) \notin \text{argmin}_t\, \mathbf{p}^\top \boldsymbol{\ell}_t} \mathbf{p}^\top \mathbf{z} \;>\; \inf_{\mathbf{z} \in \mathcal{S}_\psi} \mathbf{p}^\top \mathbf{z}\,.$$

Now, for each $\epsilon > 0$, define

$$H(\epsilon) = \inf_{\mathbf{p} \in \Delta_n, \mathbf{z} \in \mathcal{S}_\psi : \mathbf{p}^\top \boldsymbol{\ell}_{\text{pred}'(\mathbf{z})} - \min_{t \in [k]} \mathbf{p}^\top \boldsymbol{\ell}_t \geq \epsilon} \left\{ \mathbf{p}^\top \mathbf{z} - \inf_{\mathbf{z} \in \mathcal{S}_\psi} \mathbf{p}^\top \mathbf{z} \right\}.$$

We claim that $H(\epsilon) > 0\ \forall \epsilon > 0$. Assume for the sake of contradiction that $\exists \epsilon > 0$ for which $H(\epsilon) = 0$. Then there must exist a sequence $(\mathbf{p}_m, \mathbf{z}_m)$ in $\Delta_n \times \mathcal{S}_\psi$ such that

$$\mathbf{p}_m{}^\top \boldsymbol{\ell}_{\text{pred}'(\mathbf{z}_m)} - \min_{t \in [k]} \mathbf{p}_m{}^\top \boldsymbol{\ell}_t \geq \epsilon \quad \forall m \tag{32}$$

and

$$\mathbf{p}_m{}^\top \mathbf{z}_m - \inf_{\mathbf{z} \in \mathcal{S}_\psi} \mathbf{p}_m{}^\top \mathbf{z} \to 0\,. \tag{33}$$

Since $\mathbf{p}_m$ come from a compact set, we can choose a convergent subsequence (which we still call $\{\mathbf{p}_m\}$), say with limit $\mathbf{p}$. Then by Lemma 24, we have $\inf_{\mathbf{z} \in \mathcal{S}_\psi} \mathbf{p}_m{}^\top \mathbf{z} \longrightarrow \inf_{\mathbf{z} \in \mathcal{S}_\psi} \mathbf{p}^\top \mathbf{z}$, and therefore by Eq. (33), we get

$$\mathbf{p}_m{}^\top \mathbf{z}_m \;\longrightarrow\; \inf_{\mathbf{z} \in \mathcal{S}_\psi} \mathbf{p}^\top \mathbf{z}\,.$$

Now we show that $\mathbf{z}_m$ is a sequence such that $\mathbf{p}^\top \mathbf{z}_m \longrightarrow \inf_{\mathbf{z} \in \mathcal{S}_\psi} \mathbf{p}^\top \mathbf{z}$. Without loss of generality, we assume that the first a coordinates of $\mathbf{p}$ are non-zero and the rest are zero. Hence the first a coordinates of $\mathbf{z}_m$ are bounded for sufficiently large m, and we have

$$\limsup_m \mathbf{p}^\top \mathbf{z}_m = \limsup_m \sum_{y=1}^{a} p_{m,y} z_{m,y} \leq \lim_{m \to \infty} \mathbf{p}_m{}^\top \mathbf{z}_m = \inf_{\mathbf{z} \in \mathcal{S}_\psi} \mathbf{p}^\top \mathbf{z}\,.$$

By Lemma 25, we therefore have $\mathbf{p}^\top \boldsymbol{\ell}_{\text{pred}'(\mathbf{z}_m)} = \min_{t \in [k]} \mathbf{p}^\top \boldsymbol{\ell}_t$ for all large enough m, which contradicts Eq. (32) as $\mathbf{p}_m$ converges to $\mathbf{p}$. Thus we must have $H(\epsilon) > 0\ \forall \epsilon > 0$; the rest of the proof then follows from (Zhang, 2004a).

('if' direction)

Conversely, suppose $\boldsymbol{\psi}$ is not $\mathbf{L}$-calibrated. Consider any $\text{pred} : \mathcal{C} \to [k]$. Then $\exists \mathbf{p} \in \Delta_n$ such that

$$\inf_{\mathbf{u} \in \mathcal{C} : \text{pred}(\mathbf{u}) \notin \text{argmin}_t\, \mathbf{p}^\top \boldsymbol{\ell}_t} \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}) \;=\; \inf_{\mathbf{u} \in \mathcal{C}} \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u})\,.$$

In particular, this means there exists a sequence of points $\{\mathbf{u}_m\}$ in $\mathcal{C}$ such that

$$\text{pred}(\mathbf{u}_m) \notin \text{argmin}_t\, \mathbf{p}^\top \boldsymbol{\ell}_t \quad \forall m$$

and

$$\mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}_m) \;\longrightarrow\; \inf_{\mathbf{u} \in \mathcal{C}} \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u})\,.$$

Now consider a data distribution $D = D_X \times D_{Y|X}$ on $\mathcal{X} \times [n]$, with D_X being a point mass at some $x \in \mathcal{X}$ and $D_{Y|X=x} = \mathbf{p}$. Let $\mathbf{f}_m : \mathcal{X} \to \mathcal{C}$ be any sequence of functions satisfying $\mathbf{f}_m(x) = \mathbf{u}_m\ \forall m$. Then we have

$$\text{er}^{\boldsymbol{\psi}}_D[\mathbf{f}_m] = \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u}_m)\,; \quad \text{er}^{\boldsymbol{\psi},*}_D = \inf_{\mathbf{u} \in \mathcal{C}} \mathbf{p}^\top \boldsymbol{\psi}(\mathbf{u})$$

and

$$\text{er}^{\mathbf{L}}_D[\text{pred} \circ \mathbf{f}_m] = \mathbf{p}^\top \boldsymbol{\ell}_{\text{pred}(\mathbf{u}_m)}\,; \quad \text{er}^{\mathbf{L},*}_D = \min_t \mathbf{p}^\top \boldsymbol{\ell}_t\,.$$

This gives

$$\text{er}^{\boldsymbol{\psi}}_D[\mathbf{f}_m] \;\longrightarrow\; \text{er}^{\boldsymbol{\psi},*}_D$$

but

$$\text{er}^{\mathbf{L}}_D[\text{pred} \circ \mathbf{f}_m] \;\not\longrightarrow\; \text{er}^{\mathbf{L},*}_D\,.$$

This completes the proof. ■

Appendix B. Calculation of Trigger Probability Sets for Figure 2

(a) 0-1 loss $\ell^{\text{0-1}}$ $(n = 3)$.

$$\boldsymbol{\ell}_1 = \begin{pmatrix} 0 \\ 1 \\ 1 \end{pmatrix}\,; \quad \boldsymbol{\ell}_2 = \begin{pmatrix} 1 \\ 0 \\ 1 \end{pmatrix}\,; \quad \boldsymbol{\ell}_3 = \begin{pmatrix} 1 \\ 1 \\ 0 \end{pmatrix}\,.$$

$$\begin{aligned} \mathcal{Q}^{\text{0-1}}_1 &= \{\mathbf{p} \in \Delta_3 : \mathbf{p}^\top \boldsymbol{\ell}_1 \leq \mathbf{p}^\top \boldsymbol{\ell}_2,\ \mathbf{p}^\top \boldsymbol{\ell}_1 \leq \mathbf{p}^\top \boldsymbol{\ell}_3\} \\ &= \{\mathbf{p} \in \Delta_3 : p_2 + p_3 \leq p_1 + p_3,\ p_2 + p_3 \leq p_1 + p_2\} \\ &= \{\mathbf{p} \in \Delta_3 : p_2 \leq p_1,\ p_3 \leq p_1\} \\ &= \{\mathbf{p} \in \Delta_3 : p_1 \geq \max(p_2, p_3)\} \end{aligned}$$

By symmetry,

$$\begin{aligned} \mathcal{Q}^{\text{0-1}}_2 &= \{\mathbf{p} \in \Delta_3 : p_2 \geq \max(p_1, p_3)\} \\ \mathcal{Q}^{\text{0-1}}_3 &= \{\mathbf{p} \in \Delta_3 : p_3 \geq \max(p_1, p_2)\} \end{aligned}$$

(b) Ordinal regression loss ℓ^{ord} $(n = 3)$.

$$\boldsymbol{\ell}_1 = \begin{pmatrix} 0 \\ 1 \\ 2 \end{pmatrix}\,; \quad \boldsymbol{\ell}_2 = \begin{pmatrix} 1 \\ 0 \\ 1 \end{pmatrix}\,; \quad \boldsymbol{\ell}_3 = \begin{pmatrix} 2 \\ 1 \\ 0 \end{pmatrix}\,.$$

$$\begin{aligned}
\mathcal{Q}_1^{\text{ord}} &= \{\mathbf{p} \in \Delta_3 : \mathbf{p}^\top \boldsymbol{\ell}_1 \leq \mathbf{p}^\top \boldsymbol{\ell}_2,\ \mathbf{p}^\top \boldsymbol{\ell}_1 \leq \mathbf{p}^\top \boldsymbol{\ell}_3\} \\
&= \{\mathbf{p} \in \Delta_3 : p_2 + 2p_3 \leq p_1 + p_3,\ p_2 + 2p_3 \leq 2p_1 + p_2\} \\
&= \{\mathbf{p} \in \Delta_3 : p_2 + p_3 \leq p_1,\ p_3 \leq p_1\} \\
&= \{\mathbf{p} \in \Delta_3 : 1 - p_1 \leq p_1\} \\
&= \{\mathbf{p} \in \Delta_3 : p_1 \geq \tfrac{1}{2}\}
\end{aligned}$$

By symmetry,

$$\mathcal{Q}_3^{\text{ord}} = \{\mathbf{p} \in \Delta_3 : p_3 \geq \tfrac{1}{2}\}$$

Finally,

$$\begin{aligned}
\mathcal{Q}_2^{\text{ord}} &= \{\mathbf{p} \in \Delta_3 : \mathbf{p}^\top \boldsymbol{\ell}_2 \leq \mathbf{p}^\top \boldsymbol{\ell}_1,\ \mathbf{p}^\top \boldsymbol{\ell}_2 \leq \mathbf{p}^\top \boldsymbol{\ell}_3\} \\
&= \{\mathbf{p} \in \Delta_3 : p_1 + p_3 \leq p_2 + 2p_3,\ p_1 + p_3 \leq 2p_1 + p_2\} \\
&= \{\mathbf{p} \in \Delta_3 : p_1 \leq p_2 + p_3,\ p_3 \leq p_1 + p_2\} \\
&= \{\mathbf{p} \in \Delta_3 : p_1 \leq 1 - p_1,\ p_3 \leq 1 - p_3\} \\
&= \{\mathbf{p} \in \Delta_3 : p_1 \leq \tfrac{1}{2},\ p_3 \leq \tfrac{1}{2}\}
\end{aligned}$$

(c) 'Abstain' loss $\ell^{(?)}$ ($n = 3$).

$$\boldsymbol{\ell}_1 = \begin{pmatrix} 0 \\ 1 \\ 1 \end{pmatrix};\ \ \boldsymbol{\ell}_2 = \begin{pmatrix} 1 \\ 0 \\ 1 \end{pmatrix};\ \ \boldsymbol{\ell}_3 = \begin{pmatrix} 1 \\ 1 \\ 0 \end{pmatrix};\ \ \boldsymbol{\ell}_4 = \begin{pmatrix} \frac{1}{2} \\ \frac{1}{2} \\ \frac{1}{2} \end{pmatrix}.$$

$$\begin{aligned}
\mathcal{Q}_1^{(?)} &= \{\mathbf{p} \in \Delta_3 : \mathbf{p}^\top \boldsymbol{\ell}_1 \leq \mathbf{p}^\top \boldsymbol{\ell}_2,\ \mathbf{p}^\top \boldsymbol{\ell}_1 \leq \mathbf{p}^\top \boldsymbol{\ell}_3,\ \mathbf{p}^\top \boldsymbol{\ell}_1 \leq \mathbf{p}^\top \boldsymbol{\ell}_4\} \\
&= \{\mathbf{p} \in \Delta_3 : p_2 + p_3 \leq p_1 + p_3,\ p_2 + p_3 \leq p_1 + p_2,\ p_2 + p_3 \leq \tfrac{1}{2}(p_1 + p_2 + p_3)\} \\
&= \{\mathbf{p} \in \Delta_3 : p_2 \leq p_1,\ p_3 \leq p_1,\ p_2 + p_3 \leq \tfrac{1}{2}\} \\
&= \{\mathbf{p} \in \Delta_3 : p_1 \geq \tfrac{1}{2}\}
\end{aligned}$$

By symmetry,

$$\begin{aligned}
\mathcal{Q}_2^{(?)} &= \{\mathbf{p} \in \Delta_3 : p_2 \geq \tfrac{1}{2}\} \\
\mathcal{Q}_3^{(?)} &= \{\mathbf{p} \in \Delta_3 : p_3 \geq \tfrac{1}{2}\}
\end{aligned}$$

Finally,

$$\begin{aligned}
\mathcal{Q}_4^{(?)} &= \{\mathbf{p} \in \Delta_3 : \mathbf{p}^\top \boldsymbol{\ell}_4 \leq \mathbf{p}^\top \boldsymbol{\ell}_1,\ \mathbf{p}^\top \boldsymbol{\ell}_4 \leq \mathbf{p}^\top \boldsymbol{\ell}_2,\ \mathbf{p}^\top \boldsymbol{\ell}_4 \leq \mathbf{p}^\top \boldsymbol{\ell}_2\} \\
&= \{\mathbf{p} \in \Delta_3 : \tfrac{1}{2}(p_1 + p_2 + p_3) \leq \min(p_2 + p_3, p_1 + p_3, p_1 + p_2)\} \\
&= \{\mathbf{p} \in \Delta_3 : \tfrac{1}{2} \leq 1 - \max(p_1, p_2, p_3)\} \\
&= \{\mathbf{p} \in \Delta_3 : \max(p_1, p_2, p_3) \leq \tfrac{1}{2}\}
\end{aligned}$$

Appendix C. Calculation of Positive Normal Sets for Figure 3

For $n = 3$, the Crammer-Singer surrogate $\boldsymbol{\psi}^{\text{CS}} : \mathbb{R}^3 \to \mathbb{R}^3_+$ is given by

$$\begin{aligned}
\psi_1^{\text{CS}}(\mathbf{u}) &= \max(1 + u_2 - u_1, 1 + u_3 - u_1, 0) \\
\psi_2^{\text{CS}}(\mathbf{u}) &= \max(1 + u_1 - u_2, 1 + u_3 - u_2, 0) \\
\psi_3^{\text{CS}}(\mathbf{u}) &= \max(1 + u_1 - u_3, 1 + u_2 - u_3, 0) \quad \forall \mathbf{u} \in \mathbb{R}^3.
\end{aligned}$$

Clearly, $\boldsymbol{\psi}^{\text{CS}}$ is a convex function. Let $\mathbf{u}_1 = (1,0,0)^\top$, $\mathbf{u}_2 = (0,1,0)^\top$, $\mathbf{u}_3 = (0,0,1)^\top$, $\mathbf{u}_4 = (0,0,0)^\top$, and let

$$\begin{aligned}
\mathbf{z}_1 &= \boldsymbol{\psi}^{\text{CS}}(\mathbf{u}_1) = (0,2,2)^\top \\
\mathbf{z}_2 &= \boldsymbol{\psi}^{\text{CS}}(\mathbf{u}_2) = (2,0,2)^\top \\
\mathbf{z}_3 &= \boldsymbol{\psi}^{\text{CS}}(\mathbf{u}_3) = (2,2,0)^\top \\
\mathbf{z}_4 &= \boldsymbol{\psi}^{\text{CS}}(\mathbf{u}_4) = (1,1,1)^\top.
\end{aligned}$$

We apply Lemma 9 to compute the positive normal sets of $\boldsymbol{\psi}^{\text{CS}}$ at the 4 points $\mathbf{z}_1, \mathbf{z}_2, \mathbf{z}_3, \mathbf{z}_4$ above. In particular, to see that $\mathbf{z}_4$ satisfies the conditions of Lemma 9, note that by Danskin's Theorem (Bertsekas et al., 2003), we have that

$$\partial \psi_1^{\text{CS}}(\mathbf{u}_4) = \text{conv}\left(\begin{bmatrix}-1\\+1\\0\end{bmatrix}, \begin{bmatrix}-1\\0\\+1\end{bmatrix}\right);$$

$$\partial \psi_2^{\text{CS}}(\mathbf{u}_4) = \text{conv}\left(\begin{bmatrix}+1\\-1\\0\end{bmatrix}, \begin{bmatrix}0\\-1\\+1\end{bmatrix}\right);$$

$$\partial \psi_3^{\text{CS}}(\mathbf{u}_4) = \text{conv}\left(\begin{bmatrix}+1\\0\\-1\end{bmatrix}, \begin{bmatrix}0\\+1\\-1\end{bmatrix}\right).$$

We can therefore use Lemma 9 to compute $\mathcal{N}^{\text{CS}}(\mathbf{z}_4)$. Here $s = 6$, and

$$\mathbf{A} = \begin{bmatrix} -1 & -1 & 1 & 0 & 1 & 0 \\ 1 & 0 & -1 & -1 & 0 & 1 \\ 0 & 1 & 0 & 1 & -1 & -1 \end{bmatrix};\quad \mathbf{B} = \begin{bmatrix} 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 \end{bmatrix}.$$

By Lemma 9 (and some algebra), this gives

$$\begin{aligned}
\mathcal{N}^{\text{CS}}(\mathbf{z}_4) &= \big\{\mathbf{p} \in \Delta_3 : \mathbf{p} = (q_1 + q_2, q_3 + q_4, q_5 + q_6) \text{ for some } \mathbf{q} \in \Delta_6, \\
&\qquad q_1 + q_2 = q_3 + q_5,\ q_3 + q_4 = q_1 + q_6,\ q_5 + q_6 = q_2 + q_4\big\} \\
&= \big\{\mathbf{p} \in \Delta_3 : p_1 \leq \tfrac{1}{2}, p_2 \leq \tfrac{1}{2}, p_3 \leq \tfrac{1}{2}\big\}.
\end{aligned}$$

It is easy to see that $\mathbf{z}_1, \mathbf{z}_2, \mathbf{z}_3$ also satisfy the conditions of Lemma 9; similar computations then yield

$$\begin{aligned}
\mathcal{N}^{\text{CS}}(\mathbf{z}_1) &= \big\{\mathbf{p} \in \Delta_3 : p_1 \geq \tfrac{1}{2}\big\} \\
\mathcal{N}^{\text{CS}}(\mathbf{z}_2) &= \big\{\mathbf{p} \in \Delta_3 : p_2 \geq \tfrac{1}{2}\big\} \\
\mathcal{N}^{\text{CS}}(\mathbf{z}_3) &= \big\{\mathbf{p} \in \Delta_3 : p_3 \geq \tfrac{1}{2}\big\}.
\end{aligned}$$

Editor: Jeff Bilmes

Abstract

Matrix approximation is a common tool in recommendation systems, text mining, and computer vision. A prevalent assumption in constructing matrix approximations is that the partially observed matrix is low-rank. In this paper, we propose, analyze, and experiment with two procedures, one parallel and the other global, for constructing *local* matrix approximations. The two approaches approximate the observed matrix as a weighted sum of low-rank matrices. These matrices are limited to a local region of the observed matrix. We analyze the accuracy of the proposed local low-rank modeling. Our experiments show improvements in prediction accuracy over classical approaches for recommendation tasks.

Keywords: Matrix approximation, non-parametric methods, kernel smoothing, collaborative Filtering, recommender systems.

1. Introduction

Matrix approximation and completion are prevalent tasks in machine learning. Given few observed matrix entries $\{M_{a_1,b_1}, \ldots, M_{a_m,b_m}\}$, matrix completion constructs a matrix $\hat{M}$ that approximates M at its unobserved entries. Matrix approximation is used heavily in recommendation systems, text processing, computer vision, and bioinformatics. In recommendation systems, for example, the matrix M corresponds to ratings of items (columns) by users (rows). Matrix approximation in this case corresponds to predicting the ratings of all users on all items based on a few observed ratings. In many cases, matrix approximation leads to state-of-the-art models that are used in industrial settings.

In general, the problem of completing a matrix M based on a few observed entries is ill-posed. There are uncountably infinite number of matrices that perfectly agree with the observed entries of M. Therefore, without additional assumptions, selecting or constructing the completion matrix $\hat{M}$ is under-specified and thus ill-defined. A popular assumption is that M is a low-rank matrix, which suggests that it is reasonable to assume that the completed matrix $\hat{M}$ has low-rank. More formally, we approximate a matrix $M \in \mathbb{R}^{n_1 \times n_2}$ by a rank r matrix $\hat{M} = UV^\top$, where $U \in \mathbb{R}^{n_1 \times r}$, $V \in \mathbb{R}^{n_2 \times r}$, and $r \ll \min(n_1, n_2)$. In many real datasets, the low-rank assumption is realistic. Further, low-rank approximations often yield matrices that generalize well to the unobserved entries.

In this paper, we extend low-rank matrix approximation in a way that significantly relaxes the low-rank assumption. Instead of assuming that M can be globally approximated by a low-rank matrix, we assume that M behaves as a low-rank matrix in the vicinity of certain row-column combinations. We therefore construct several low-rank approximations of M, each being accurate in a particular region of the matrix. We express our estimator as a smoothed convex combination of low-rank matrices each of which approximates M in a local region.

The local low-rank assumption can also be motivated as follows. In numerous settings there are a few key latent factors which determine whether a user would like an item or not. In the movie domain such factors may include the main actress, director, released year, genre, and more. However, the number of latent variable is typically limited to no more than twenty. These factors are tacitly learned and automatically constructed as we do not assume that information such as genre or actors are available. For example, if the rank is 5 the ratings given to an item by a user is the inner product of a vector of length 5 which describes the user preferences with a vector of length 5 that describes the item characteristics (these two vectors are the rows of U, V). The same assumption holds in the local low-rank case with the exception that the linear basis underlying the latent factors may change across different groups of users and different types of items.

We use techniques from non-parametric kernel smoothing to achieve two goals. The first goal is to formally develop a notion of local low-rank approximation, and the second is the aggregation of several local models into unified matrix approximation. Standard low-rank matrix approximation techniques achieve consistency in the limit of large data (convergence to the data generating process) assuming that M is low-rank. Our local method achieves consistency without the low-rank assumption. Instead, we require that sufficient number of samples is available in increasingly small neighborhoods. Our analysis mirrors the theory of non-parametric kernel smoothing that was primarily developed for continuous spaces. We also adapt and generalize well-known compressed sensing results to our setting. Our experiments show that local low-rank modeling is significantly more accurate than global low-rank modeling in the context of recommendation systems.

The rest of the paper is organized as follows. We introduce notations and briefly review low-rank matrix approximation in Section 2. In Section 3 we describe our proposed methods. Section 4 provides formal analysis of the proposed approach. Sections 5 and 6 describe in details the two low-rank approximation algorithms. These sections are followed by experimental evaluations described in Sections 7. We then discuss our contribution in the context of related work in Section 8 and conclude with a summary in Section 9.

2. Background: Low-rank matrix approximation

We describe in this section two standard approaches for low-rank matrix approximation (LRMA). We start by establishing the notation used throughout the paper. We denote matrices using upper case letters. The original (partially observed) matrix is denoted by $M \in \mathbb{R}^{n_1 \times n_2}$. A low-rank approximation of M is denoted by $\hat{M} = UV^\top$, where $U \in \mathbb{R}^{n_1 \times r}$, $V \in \mathbb{R}^{n_2 \times r}$, and $r \ll \min(n_1, n_2)$. The set of integers $\{1, \ldots, n\}$ is abbreviated as $[n]$. The

Notation	Explanation
n_1	Number of users.
n_2	Number of items.
m	Number of available ratings.
r	Rank of approximation matrix.
M	Rating matrix, $M \in \mathbb{R}^{n_1 \times n_2}$
U	"Users" profile matrix, $U \in \mathbb{R}^{n_1 \times r}$
V	"Items" profile matrix, $V \in \mathbb{R}^{n_2 \times r}$
Ω	Observed entries of M.
$\mathcal{P}_\Omega(M)$	Projection operator onto observed entries of Ω.
$\hat{\mathcal{T}}(a,b)$	Local approximation of M centered at (a,b).
$\hat{\bar{\mathcal{T}}}(a,b)$	Global approximation of M centered at (a,b).
$A \odot B$	Hadamard product of matrices A and B.
$\|X\|_F$	Frobenius norm of matrix X.
$\|X\|_*$	Nuclear (trace) norm of matrix X.
$\|X\|_\infty$	Sup-norm of matrix X.
$[n]$	Set of natural numbers $\{1, \ldots, n\}$.

Table 1: Summary of Notations and Matrix Operators.

set of indices of the observed entries of M is denoted by $\Omega \stackrel{\text{def}}{=} \{(a_1, b_1), \ldots, (a_m, b_m)\} \subseteq [n_1] \times [n_2]$. The training set is therefore $\{M_{a,b} : (a,b) \in \Omega\}$. Mappings from matrix indices to a matrix space are denoted in calligraphic letters, e.g. $\mathcal{T}$, and are operators of the form $\mathcal{T} : [n_1] \times [n_2] \to \mathbb{R}^{n_1 \times n_2}$. We denote the entry (i,j) of the matrix $\mathcal{T}(a,b)$ as $\mathcal{T}_{i,j}(a,b)$. A projection $\mathcal{P}_\mathtt{A}$ with respect to a set of matrix indices $\mathtt{A}$ is the function $\mathcal{P}_\mathtt{A} : \mathbb{R}^{n_1 \times n_2} \to \mathbb{R}^{n_1 \times n_2}$ defined by

$$[\mathcal{P}_\Omega(M)]_{a,b} \stackrel{\text{def}}{=} \begin{cases} M_{a,b} & (a,b) \in \Omega \\ 0 & \text{otherwise.} \end{cases}$$

We denote by $\odot$ the entry-wise product (also known as the Hadamard or Schur products) of two matrices $[A \odot B]_{i,j} = A_{i,j} B_{i,j}$. We use in this paper three matrix norms:

Frobenius norm $\|X\|_F \stackrel{\text{def}}{=} \sqrt{\sum_i \sum_j X_{i,j}^2}$

Sup-norm $\|X\|_\infty \stackrel{\text{def}}{=} \sup_{i,j} |X_{i,j}|$

Nuclear (trace) norm $\|X\|_* \stackrel{\text{def}}{=} \sum_{i=1}^{r} \sigma_i(X)$

For the nuclear norm $\sigma_i(X)$ is the i'th singular value of X where for symmetric matrices $\|X\|_* = \text{trace}(X)$. Table 1 summarizes notations and matrix operators used throughout the paper.

We describe below two popular approaches for constructing a low-rank approximation $\hat{M}$ of M. The first one, incomplete SVD, is based on minimizing the Frobenius norm of $\mathcal{P}_\mathtt{A}(M - \hat{M})$, while the second one is based on minimizing the nuclear norm of a matrix satisfying constraints constructed from the training set.

A1: Incomplete SVD. The incomplete SVD method constructs a low-rank approximation $\hat{M} = UV^\top$ by solving the problem

$$(U, V) = \arg\min_{U,V} \sum_{(a,b) \in \Omega} ([UV^\top]_{a,b} - M_{a,b})^2 \ , \tag{1}$$

or equivalently

$$\hat{M} = \arg\min_X \|\mathcal{P}_\Omega(X - M)\|_F \ \text{ s.t. } \text{rank}(X) = r. \tag{2}$$

A2: Nuclear norm minimization. An alternative to (2) that originated from the compressed sensing community (Candès and Tao, 2010) is to minimize the nuclear norm of a matrix subject to constraints constructed from the observed entries:

$$\hat{M} = \arg\min_X \|X\|_* \quad \text{s.t.} \quad \|\mathcal{P}_\Omega(X - M)\|_F < \delta \ . \tag{3}$$

Minimizing the nuclear norm $\|X\|_*$ is an effective surrogate for minimizing the rank of X, and solving (3) results in a low-rank matrix $\hat{M} = UV^\top$ that approximates the matrix M. One advantage of *A2* over *A1* is that we do not need to constrain the rank of $\hat{M}$ in advance. Note also that the problem defined by (3), while being convex, may not necessarily scale up easily to large matrices.

3. Local low-rank matrix approximation

In order to facilitate a local low-rank matrix approximation, we need to assume that there exists a metric structure over $[n_1] \times [n_2]$. The distance $d((a,b),(a',b'))$ reflects the similarity between the rows a and a' and columns b and b'. In the case of recommendation systems, for example, $d((a,b),(a',b'))$ expresses the relationship between users a, a' and items b, b'. The distance function may be constructed using the observed ratings $\mathcal{P}_\Omega(M)$ or additional information such as item-item similarity or side information on the users when available. We note that distance between two rows (users) or between two columns (items) is independent of the indices of those rows or columns. As we exchange the order of two rows or columns, the similarity still remains the same. See Section 5 for further details.

In the global matrix factorization setting in Section 2, we assume that the matrix $M \in \mathbb{R}^{n_1 \times n_2}$ has a low-rank structure. In the local setting, however, we assume that the model is characterized by multiple low-rank $n_1 \times n_2$ matrices. Specifically, we assume a mapping $\mathcal{T} : [n_1] \times [n_2] \to \mathbb{R}^{n_1 \times n_2}$ that associates with each row-column combination $[n_1] \times [n_2]$ a low rank matrix that describes the entries of M in its neighborhood (in particular this applies to the observed entries Ω):

$$\mathcal{T} : [n_1] \times [n_2] \to \mathbb{R}^{n_1 \times n_2} \quad \text{where} \quad \mathcal{T}_{a,b}(a,b) = M_{a,b} \ .$$

Without additional assumptions, it is impossible to estimate the mapping $\mathcal{T}$ from a set of $m < n_1 n_2$ observations. We assume, as is often done in non-parametric statistics, that the mapping $\mathcal{T}$ is slowly varying. Since the domain of $\mathcal{T}$ is discrete, the classical definitions of continuity or differentiability are not applicable in our setting. We assume instead that $\mathcal{T}$ is Hölder continuous (see Definition 1 in Section 4).

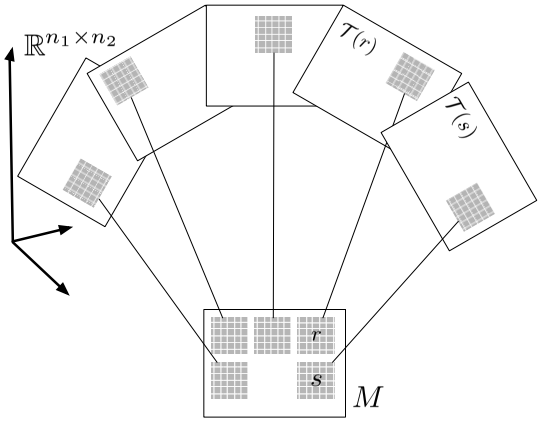

Figure 1: The locally low-rank linear assumption assumes an operator that maps matrix entries to matrices whose image is (a) low-rank, (b) slowly changing, and (c) agrees locally with the original matrix. We emphasize that we draw the figure as if adjacent rows (or columns) are semantically similar just for illustration purpose. In real data, similar users (or items) are usually scattered over the entire space. See text for more details.

Figures 1 shows a graphic illustration of the locally low-rank linear assumption: the operator $\mathcal{T}$ maps matrix entries to matrices whose image is (a) low-rank, (b) slowly changing, and (c) agrees locally with the original matrix. Assumption (b) implies that if $d(s,r)$ is small $\mathcal{T}(s)$ is similar to $\mathcal{T}(r)$, as shown by their spatial closeness in the embedding $\mathbb{R}^{n_1 \times n_2}$. Assumption (c) implies that for all $s \in [n_1] \times [n_2]$, the neighborhood $\{s' : d(s,s') < h\}$ in the original matrix M is approximately described by the corresponding entries of the low-rank matrix $\mathcal{T}(s)$ (shaded regions of M are matched by lines to the corresponding regions in $\mathcal{T}(s)$ that approximate them).

We would like to emphasize that for illustrative purposes, we assume in Figure 1 that there exists a distance function d whose neighborhood structure coincides with the natural order on indices. That is, $s = (a,b)$ is similar to $r = (c,d)$ if $|a-c|$ and $|b-d|$ are small.

Figure 2 shows the relationship between the neighboring entries of the original matrix and the operator image in more detail. The original matrix M (bottom) is described locally by two low-rank matrices $\mathcal{T}(t)$ (near t) and $\mathcal{T}(r)$ (near r). The lines connecting the three matrices identify identical entries: $M_t = \mathcal{T}_t(t)$ and $M_r = \mathcal{T}_r(r)$. The equation at the top right shows a relation tying the three patterned entries. Assuming the distance $d(t,r)$ is small, $\delta = \mathcal{T}_r(t) - \mathcal{T}_r(r) = \mathcal{T}_r(t) - M_r(r)$ is small as well.

Following common approaches in non-parametric statistics, we define a smoothing kernel $K_h(s_1, s_2),\ s_1, s_2 \in [n_1] \times [n_2]$, as a non-negative symmetric unimodal function that is

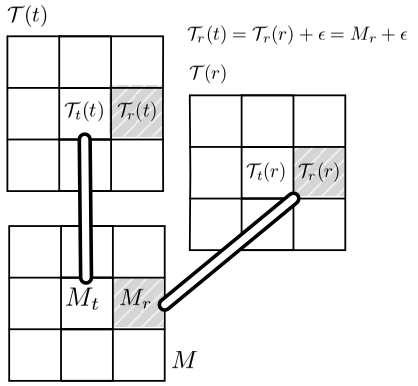

Figure 2: The relationship between the neighboring entries of the original matrix and the operator image. See text for more details.

parameterized by a bandwidth parameter $h > 0$. A large value of h implies that $K_h(s,\cdot)$ has a wide spread, while a small h corresponds to narrow spread of $K_h(s,\cdot)$. Often, it is further assumed that $K_h(x) = K_1(x/h)/h$ and that the kernel integrates to 1: $\int K_h(x)\,dx = 1$. In our case, however, we have a discrete domain rather than a continuous domain. See for instance (Wand and Jones, 1995) for more information on smoothing kernels. Three popular smoothing kernels are the uniform kernel, the triangular kernel, and the Epanechnikov kernel, defined respectively as

$$K_h(s_1,s_2) \propto \mathbf{1}[d(s_1,s_2) < h] \tag{4}$$

$$K_h(s_1,s_2) \propto (1 - h^{-1} d(s_1,s_2))\,\mathbf{1}[d(s_1,s_2) < h] \tag{5}$$

$$K_h(s_1,s_2) \propto (1 - d(s_1,s_2)^2)\,\mathbf{1}[d(s_1,s_2) < h]\ . \tag{6}$$

We denote by $K_h^{(a,b)}$ the matrix whose (i,j)-entry is $K_h((a,b),(i,j))$.

We describe below the local modifications of incomplete SVD (*A1*) and nuclear norm minimization (*A2*) matrix approximations. Both extensions estimate $\mathcal{T}(a,b)$ in the vicinity of $(a,b) \in [n_1] \times [n_2]$ given the samples $\mathcal{P}_\Omega(M)$.

Local-A1: Incomplete SVD

$$\hat{\mathcal{T}}(a,b) = \arg\min_X \|K_h^{(a,b)} \odot \mathcal{P}_\Omega(X - M)\|_F \quad \text{s.t.} \quad \text{rank}(X) = r\ . \tag{7}$$

Local-A2: Nuclear norm minimization

$$\hat{\mathcal{T}}(a,b) = \arg\min_X \|X\|_* \quad \text{s.t.} \quad \|K_h^{(a,b)} \odot \mathcal{P}_\Omega(X - M)\|_F < \delta\ . \tag{8}$$

The two optimization problems above describe how to estimate $\hat{\mathcal{T}}(a,b)$ for a particular choice of $(a,b) \in [n_1] \times [n_2]$. Conceptually, this technique can be applied at each test entry (a,b), resulting in the matrix approximation $\hat{M} \approx M$ where

$$\hat{M}_{a,b} = \hat{\mathcal{T}}_{a,b}(a,b), \quad (a,b) \in [n_1] \times [n_2] \ .$$

However, such a construction would require solving an optimization problem for each matrix entry (a,b) and is thus computationally prohibitive. Instead, we describe in the next subsection how to use a set of q local models $\hat{\mathcal{T}}(s_1), \ldots, \hat{\mathcal{T}}(s_q)$, $s_1, \ldots, s_q \in [n_1] \times [n_2]$ to obtain a computationally efficient estimate $\hat{\hat{\mathcal{T}}}(s)$ for all $s \in [n_1] \times [n_2]$.

3.1 Global Approximation

The problem of recovering a mapping $\mathcal{T}$ from q values without imposing a strong parametric form is known as non-parametric regression. We propose using a variation of locally constant kernel regression (Wand and Jones, 1995), also known as Nadaraya-Watson regression

$$\hat{\hat{\mathcal{T}}}(s) = \sum_{i=1}^{q} \frac{K_h(s_i, s)}{\sum_{j=1}^{q} K_h(s_j, s)} \hat{\mathcal{T}}(s_i) \ . \tag{9}$$

Equation (9) is simply a weighted average of $\hat{\mathcal{T}}(s_1), \ldots, \hat{\mathcal{T}}(s_q)$, where the weights ensure that values of $\hat{\mathcal{T}}$ at indices close to s contribute more than those further away from s. Note that both the left-hand side and the right-hand side of (9) denote matrices. The denominator in (9) ensures that the weights sum to one.

In contrast to $\hat{\mathcal{T}}$, the estimate $\hat{\hat{\mathcal{T}}}$ can be computed for all $s \in [n_1] \times [n_2]$ efficiently since computing $\hat{\hat{\mathcal{T}}}(s)$ simply requires evaluating and averaging $\hat{\mathcal{T}}(s_i)$, $i = 1, \ldots, q$. The resulting matrix approximation is $\hat{\hat{M}}_{a,b} = \hat{\hat{\mathcal{T}}}_{a,b}(a,b)$ and $(a,b) \in [n_1] \times [n_2]$.

The accuracy of $\hat{\hat{\mathcal{T}}}$ as an estimator of $\hat{\mathcal{T}}$ improves with the number of local models q and the degree of continuity of $\hat{\mathcal{T}}$. The accuracy of $\hat{\hat{\mathcal{T}}}$ as an estimator of $\mathcal{T}$ is limited by the quality of the local estimators $\hat{\mathcal{T}}(s_1), \ldots, \hat{\mathcal{T}}(s_q)$. However, assuming that $\hat{\mathcal{T}}(s_1), \ldots, \hat{\mathcal{T}}(s_q)$ are accurate in the neighborhoods of $s_1, \ldots, s_q$, and q is sufficiently large, the estimation error $\hat{\hat{\mathcal{T}}}_{a,b}(a,b) - \mathcal{T}_{a,b}(a,b)$ is likely to be small as we analyze in the next section. We term the resulting approach LLORMA standing for Local LOw Rank Matrix Approximation.

4. Estimation accuracy

In this section we analyze the estimation accuracy of LLORMA. Our analysis consists of two parts. In the first we analyze the large deviation of $\hat{\mathcal{T}}$ from $\mathcal{T}$. Then, based on this analysis, we derive a deviation bound on the global approximation $\hat{\hat{\mathcal{T}}}$. Our analysis technique is based on the seminal paper of Candès and Tao (2010). The goal of this section is to underscore the characteristics of estimation error in terms of parameters such as the train set size, matrix dimensions, and kernel bandwidth.

4.1 Analysis of $\hat{\mathcal{T}} - \mathcal{T}$

Candès and Tao (2010) established that it is possible to estimate an $n_1 \times n_2$ matrix M of rank r if the number of observations $m \geq C\mu r n \log^6 n$, where $n = \min(n_1, n_2)$, C is a

constant, and μ is the strong incoherence property parameter described in Candès and Tao (2010). This bound is tight in the sense that it is close to the information theoretic limit of $\Omega(r\, n \log n)$. As in Candès and Tao (2010), we assume that the observed entries are sampled at random without replacement, avoiding trivial situations in which a row or a column is unsampled.

The aforementioned result is not applicable in our case since the matrix M is not necessarily of low-rank. Concretely, when $r = O(n)$ the bound above degenerates into a sample complexity of $O(n^2 \log n)$ which is clearly larger than the number of entries in the matrix M. We develop below a variation on the results in Candès and Tao (2010) and Candès and Plan (2010) that applies to the *local-A2* compressed-sensing estimator $\hat{\mathcal{T}}$.

Definition 1. Let X be a metric space. A function $f : X \to \mathbb{R}^{n_1 \times n_2}$ is *Hölder continuous* with parameters $\alpha, \beta > 0$ if

$$\forall x, x' \in X : \ \|f(x) - f(x')\|_F \ \leq \ \alpha\, d^\beta(x, x') \ . \tag{10}$$

In our analysis we make the following assumptions: (i) $\mathcal{T}$ is Hölder continuous, (ii) $\mathcal{T}(s)$ is a rank r matrix that satisfies the strong incoherence property, and (iii) the kernel K_h is a uniform kernel based on a product distance function. The Hölder continuity assumption on $\mathcal{T}$ can be replaced by the following weaker condition without affecting the results

$$\|K_h^s \odot (\mathcal{T}(s) - \mathcal{T}(s'))\|_F \ \leq \ \alpha d^\beta(s, s'). \tag{11}$$

We denote by $B_h(s)$ the neighborhood of indices near s, $B_h(s) \stackrel{\text{def}}{=} \{s' \in [n_1] \times [n_2] : d(s,s') < h\}$ and we use $n_1(h,s)$ and $n_2(h,s)$ to denote the number of unique row and column indices, respectively, in $B_h(s)$. Finally, we denote $\gamma = \min(n_1(h,s), n_2(h,s))$.

The proposition below provides a bound on the average squared-error within a neighborhood of s

$$\mathcal{E}(\hat{\mathcal{T}})(s,h) = \sqrt{\frac{1}{|B_h(s)|} \sum_{s' \in B_h(s)} \left(\hat{\mathcal{T}}_{s'}(s) - \mathcal{T}_{s'}(s)\right)^2} \ .$$

Proposition 1. *If $|\Omega \cap B_h(s)| \geq C\mu^2 \gamma r \log^6 \gamma$, then with probability of at least $1 - \delta$,*

$$\mathcal{E}(\hat{\mathcal{T}})(s,h) \leq \frac{\alpha h^\beta}{\sqrt{|B_h(s)|}} \left(4\sqrt{\frac{\gamma(2+p)}{p}} + 2\right) \ ,$$

where $\gamma = \sqrt[3]{1/\delta}$ and $p = |\Omega \cap B_h(s)|/|B_h(s)|$.

Proof Assumptions (i) and (iii) above imply that if $K_h(s,s') > 0$ then

$$\|K_h^s \odot (\mathcal{T}(s) - \mathcal{T}(s'))\|_\infty < \alpha h^\beta \ .$$

We can thus assume that if $d(s,s') < h$, an observation $M_{s'} = \mathcal{T}_{s'}(s')$ is equal to $\mathcal{T}_{s'}(s) + Z$ where Z is a random variable whose absolute value is bounded by αh^β. This means that we can use observations $M_{s'} = \mathcal{T}_{s'}(s')$ for estimating the local model $\mathcal{T}(s)$ as long as we admit a noisy measurement process.

Since K is a uniform kernel based on a product distance by assumption (iii), the set $B_h(s)$ is a Cartesian product set. We view this product set as a matrix of dimensions $n_1(h,s) \times n_2(h,s)$ that we approximate. (Note that $n_1(h,s)$ and $n_2(h,s)$ are monotonically increasing with h, and as $h \to \infty$, $n_1(h,s) = n_1$, $n_2(h,s) = n_2$.) The number of observed entries in this matrix approximation problem is $|\Omega \cap B_h(s)|$.

Applying Theorem 7 in Candès and Plan (2010) to the matrix completion problem described above, we get that if $|\Omega \cap B_h(s)| \geq C\mu^2 \gamma r \log^6 \gamma$, then with probability greater than $1 - \gamma^{-3}$,

$$\|K_h^s \odot (\mathcal{T}(s) - \hat{\mathcal{T}}(s))\|_F \leq \alpha h^\beta \left(4\sqrt{\frac{\gamma(2+p)}{p}} + 2\right),$$

where $p = \frac{|\Omega \cap B_h(s)|}{|B_h(s)|}$ is the density of observed samples. Dividing by $\sqrt{|B_h(s)|}$ concludes the proof. ■

When the observed samples are uniformly spread over the matrix, we get $p = m/(n_1 n_2)$, so

$$\begin{aligned} 4\sqrt{\gamma\frac{2+p}{p}} + 2 &= 4\sqrt{\gamma\frac{2+m/(n_1n_2)}{m/(n_1n_2)}} + 2 \\ &= 4\sqrt{\frac{\gamma(2n_1n_2+m)}{m}} + 2. \end{aligned}$$

Multiplying $\alpha h^\beta / \sqrt{|B_h(s)|}$ yields Corollary 1.

Corollary 1. Assume that the conditions of Proposition 1 hold and in addition the observed samples are spread uniformly with respect to d. Then, the following inequality holds

$$\mathcal{E}(\hat{\mathcal{T}})(s,h) \leq \frac{4\alpha h^\beta}{\sqrt{|B_h(s)|}}\sqrt{\frac{\gamma(2n_1n_2 + m)}{m}} + \frac{2\alpha h^\beta}{\sqrt{|B_h(s)|}}.$$

If in addition the matrix M is squared ($n_1 = n_2 = n$) and the distribution of distances d is uniform, then $n_1(h,s) = n_2(h,s) = n/h$, $|B_h(s)| = (n/h)^2$, and $\gamma = n/h$. In this case, the bound on $\mathcal{E}(\hat{\mathcal{T}})(s,h)$ becomes

$$4\alpha h^{\beta+1/2}\sqrt{\frac{2n}{m} + \frac{1}{n}} + \frac{2\alpha h^{\beta+1}}{n}. \tag{12}$$

In the case of a square matrix with uniformly spread samples, it is instructive to view n, m, h as monotonically increasing sequences, indexed by $k \in \mathbb{N}$ and assume that $\lim_{k\to\infty} n_{[k]} = \lim_{k\to\infty} m_{[k]} = \infty$. In other words, we consider the limit of matrices of increasing sizes with an increasing number of samples. In the case of uniformly distributed distances, the bound (12) will converge to zero if

$$\lim_{k\to\infty} \frac{h_{[k]}^{\beta+1}}{n_{[k]}} = \lim_{k\to\infty} \frac{h_{[k]}^{2\beta+1}}{n_{[k]}} = \lim_{k\to\infty} \frac{h_{[k]}^{2\beta+1} n_{[k]}}{m_{[k]}} = 0.$$

4.2 Analysis of $\hat{\hat{\mathcal{T}}} - \mathcal{T}$

We start by showing that $\hat{\mathcal{T}}$ is Hölder continuous with high probability, and then proceed to analyze the estimation error of $\hat{\hat{\mathcal{T}}}$.

Proposition 2. *If $d(s,s') < h$ and Proposition 1 holds at s, s', then with probability at least $1 - \delta$,*

$$\|K_h^s \odot (\hat{\mathcal{T}}(s) - \hat{\mathcal{T}}(s'))\|_F \leq \alpha h^\beta \left(8\sqrt{\frac{\gamma(2+p)}{p}} + 5\right).$$

where $\gamma = \sqrt[3]{2/\delta}$.

Proof Using the triangle inequality for $\|\cdot\|_F$,

$$\begin{aligned} \|K_h^s \odot (\hat{\mathcal{T}}(s) - \hat{\mathcal{T}}(s'))\|_F &\leq \|K_h^s \odot (\hat{\mathcal{T}}(s) - \mathcal{T}(s))\|_F \\ &+ \|K_h^s \odot (\hat{\mathcal{T}}(s') - \mathcal{T}(s'))\|_F \\ &+ \|K_h^s \odot (\mathcal{T}(s) - \mathcal{T}(s'))\|_F. \end{aligned}$$

We apply the bound from Proposition 1 to the first two terms and use the assumption that $\mathcal{T}$ is Hölder continuous to bound the third term. The adjustment to the confidence level $2\gamma^{-3}$ is obtained using the union bound. ■

Proposition 3. *Assume that Proposition 1 holds. Then, with probability of at least $1 - \delta$,*

$$\mathcal{E}(\hat{\hat{\mathcal{T}}})(s,h) \leq \frac{\alpha h^\beta}{\sqrt{|B_h(s)|}}\left(12\sqrt{\frac{\gamma(2+p)}{p}} + 7\right).$$

where $\gamma = \sqrt[3]{(2|\Omega \cap B_h(s)| + 1)/\delta}$.

Proof Using the triangle inequality we get

$$\begin{aligned} &\|K_h^s \odot (\hat{\hat{\mathcal{T}}}(s) - \mathcal{T}(s))\|_F \leq \\ &\quad \|K_h^s \odot (\hat{\mathcal{T}}(s) - \mathcal{T}(s))\|_F + \|K_h^s \odot (\hat{\hat{\mathcal{T}}}(s) - \hat{\mathcal{T}}(s))\|_F. \end{aligned} \tag{13}$$

We bound the first term using Proposition 1. Since $\hat{\hat{\mathcal{T}}}(s)$ is a weighted average of $\hat{\mathcal{T}}(s_i)$, $i = 1, \ldots, q$ with $s_i \in B_h(s)$, the second term is bounded by

$$\begin{aligned} &\|K_h^s \odot (\hat{\hat{\mathcal{T}}}(s) - \hat{\mathcal{T}}(s))\|_F \\ &\quad = \left\|K_h^s \odot \left(\sum_i \frac{w_i}{\sum_j w_j}\hat{\mathcal{T}}(s_i) - \hat{\mathcal{T}}(s)\right)\right\|_F \\ &\quad = \left\|K_h^s \odot \sum_i \frac{w_i}{\sum_j w_j}(\hat{\mathcal{T}}(s_i) - \hat{\mathcal{T}}(s))\right\|_F \\ &\quad \leq \sum_i \left\|\frac{w_i}{\sum_j w_j} K_h^s \odot (\hat{\mathcal{T}}(s_i) - \hat{\mathcal{T}}(s))\right\|_F \\ &\quad \leq \sum_i \frac{w_i}{\sum_j w_j}\|K_h^s \odot (\hat{\mathcal{T}}(s_i) - \hat{\mathcal{T}}(s))\|_F \ . \end{aligned}$$

There are $|\Omega \cap B_h(s)|$ summands in the above term. We bound each of them using Proposition 2. Together with the bound (13) this gives the desired result (after dividing by $\sqrt{|B_h(s)|}$). The adjustment to the confidence level $(2|\Omega \cap B_h(s)| + 1)\gamma^{-3}$ is obtained using the union bound. ■

5. The Parallel LLORMA Algorithm

In the previous sections, we assumed a general kernel function $K_h(s_1, s_2)$, where $s_1, s_2 \in [n_1] \times [n_2]$. This kernel function may be defined in several ways. For simplicity, we assume a product form $K_h((a,b),(c,d)) = K_{h_1}(a,c)K'_{h_2}(b,d)$ where K and K' are kernels on the spaces $[n_1]$ and $[n_2]$, respectively. We used the Epanechnikov kernel (6) for both K, K' as it achieves the lowest integrated squared error (Wand and Jones, 1995), but other choices are possible as well.

The distance d in (6) can be defined using additional information from an outside source describing row (user) similarity or column (item) similarity. If there is no such information available (as is the case in our experiments), d can be computed solely based on the partially observed matrix M. In that case, we may use any distance measure between two row vectors (for K) or two column vectors (for K'). Empirically, we found that standard distance measures such as the 2-norm or cosine similarity do not perform well when M is sparse.

We therefore instead factorize M using standard incomplete SVD (1) $M \approx UV^\top$. Then, we proceed to compute d based on the distances between the rows of factor matrices U (and V). Concretely, we used arc-cosine between users a and c (and items b and d):

$$d(a,c) = \arccos\left(\frac{\langle U_a, U_c\rangle}{\|U_a\| \cdot \|U_c\|}\right) \quad d(b,d) = \arccos\left(\frac{\langle V_a, V_d\rangle}{\|V_b\| \cdot \|V_d\|}\right) \tag{14}$$

where U_i, V_i are the ith row of the matrix U and V. We tried numerous other distances and similarity scores such as the Euclidean distance and cosine similarity. The arc-cosine score empirically performed better than the other scores we experimented with.

Besides of the distance metric, the anchor points $(s_1, \ldots, s_q)$ that define $\hat{\hat{\mathcal{T}}}$ also play a significant role. There are several ways of choosing the anchor points. We randomly choose among training data points unless stated otherwise. Detailed discussion is on Section 7.3.

Algorithm 1 describes the learning algorithm for estimating the local models at the anchor points $\hat{\mathcal{T}}(s_i)$, with $i = 1, \ldots, q$. In line 14, we solve a weighted (by K_{h_1} and K_{h_2}) SVD problem with L_2 regularization. This minimization problem can be computed with gradient-based methods. After these models are estimated, they are combined using (9) to create the estimate $\hat{\hat{\mathcal{T}}}(s)$ for all $s \in [n_1] \times [n_2]$.

Algorithm 1 can actually run faster than vanilla SVD since (a) the q loops may be computed in parallel, and (b) the rank of the our local models can be significantly lower than the rank of global SVD for similar performance (see Section 7). Also, as the kernel K_h has limited support, (c) $K_h(s, s')$ will have few non-zero entries. The weighted SVD problem at line 14 should be sparser than the global SVD, which should result in an additional speedup.

Algorithm 1 The Parallel LLORMA Algorithm

1: **input:** $M \in \mathbb{R}^{n_1 \times n_2}$ whose entries are defined over Ω
2: **parameters:** kernel function $K(\cdot)$ of widths h_1 and h_2
3: rank r and number of local models q
4: regularization values λ_U, λ_V
5: **for all** $t = 1, \ldots, q$ **parallel do**
6: select (a_t, b_t) at random from Ω
7: **for all** $i = 1, \ldots, n_1$ **do**
8: construct entry i: $[K^{a_t}]_i := K_{h_1}(a_t, i)$
9: **end for**
10: **for all** $j = 1, = \ldots, n_2$ **do**
11: construct entry j: $[K^{b_t}]_j := K_{h_2}(b_t, j)$
12: **end for**
13: set $(U^{(t)}, V^{(t)})$ to be the minimizer of:
14: $$\sum_{(i,j)\in\Omega} [K^{(a_t)}]_i\,[K^{(b_t)}]_j \left([U\,V^\top]_{i,j} - M_{i,j}\right)^2 + \lambda_U \sum_{i,k} U_{i,k}^2 + \lambda_V \sum_{j,k} V_{j,k}^2$$
15: **end for**
16: **output:** $\left\{a_t,\, b_t,\, U^{(t)}, V^{(t)}\right\}_{t=1}^{q}$

6. Global LLORMA

Recall that the parallel LLORMA algorithm from Section 5 constructs q local models based on q different anchor points. It then combines the models via kernel regression to produce $\hat{M}$ using (9) which yields the following approximation,

$$\hat{M}_{u,i} = \sum_{t=1}^{q} \frac{K(u_t,u)K(i_t,i)}{\sum_s K(u_s,u)K(i_s,i)} [U^{(t)}{V^{(t)}}^\top]_{u,i}. \tag{15}$$

That is, the algorithm learns each local model independently based on different subsets of the matrix (with some potential overlap). Alternatively, we can directly optimize a joint loss using all local models while bearing in mind the form of the final model as given by (15). In this section we describe an algorithmic alternative that minimizes the following loss with respect to $\{U^{(t)}, V^{(t)}\}_{t=1}^{q}$,

$$\sum_{(u,i)\in\Omega} (\hat{M}_{u,i} - M_{u,i})^2 = \sum_{(u,i)\in\Omega} \left(\sum_{t=1}^{q} \frac{K(u_t,u)K(i_t,i)}{\sum_s K(u_s,u)K(i_s,i)} [(U^{(t)}{V^{(t)}}^\top]_{u,i} - M_{u,i}\right)^2 . \tag{16}$$

This optimization problem can be solved using gradient-based methods, as we use for the global incomplete SVD. Hence, we solve jointly multiple SVD problems with different weights $(K(u_t,u)K(i_t,i))$ multiplying the original matrix. Since we can decompose M into weighted sums,

$$M_{u,i} = \frac{\sum_t K(u_t,u)K(i_t,i)}{\sum_s K(u_s,u)K(i_s,i)} M_{u,i} \ ,$$

the objective function given by (16) can be rewritten as follows,

$$\sum_{(u,i)\in\Omega}\left(\sum_{t=1}^{q}\frac{K(u_t,u)K(i_t,i)}{\sum_s K(u_s,u)K(i_s,i)}[(U^{(t)}V^{(t)\top}]_{u,i}\;-\;\sum_{t=1}^{q}\frac{K(u_t,u)K(i_t,i)}{\sum_s K(u_s,u)K(i_s,i)}M_{u,i}\right)^2$$
$$=\sum_{(u,i)\in\Omega}\left(\sum_{t=1}^{q}\frac{K(u_t,u)K(i_t,i)}{\sum_s K(u_s,u)K(i_s,i)}\left([(U^{(t)}V^{(t)\top}]_{u,i}-M_{u,i}\right)\right)^2. \quad (17)$$

Let us now examine the difference between the above objective with the one tacitly employed by parallel LLORMA algorithm, which amounts to,

$$\sum_{(u,i)\in\Omega}\sum_{t=1}^{q}K(u_t,u)K(i_t,i)\left([(U^{(t)}V^{(t)\top}]_{u,i}-M_{u,i}\right)^2. \quad (18)$$

By construction, both objectives are minimized with respect to $\{U^{(t)},V^{(t)}\}_{t=1}^{q}$ using the squared deviation from M. The difference between the two models is that (17) has a square that encompasses a sum over anchor points. When expanded the term includes the individual squared terms that appear in (18) as well as additional interaction terms. Namely, parallel LLORMA minimizes the sum of square deviations while global LLORMA minimizes the square deviation of sums. In Algorithm 2 we provide the pseudocode of global LLORMA.

A priori we should expect the global version of LLORMA to result in more accurate estimates of M than parallel LLORMA described in Section 5. However, since the objective can no longer be decoupled, the run time global LLORMA is likely to be longer than its parallel counterpart. We provide experimental results which compare the two versions in terms of performance and running time in Section 7.2.

7. Experiments

We conducted several experiments with recommendation data. In Section 7.1, we compare LLORMA to SVD and other state-of-the-art techniques. We also examine in the section dependency of LLORMA on the rank r, the number of anchor points q, and the training set size. In Section 7.2, we compare the parallel and global versions of LLORMA. Section 7.3 introduces several anchor point selection schemes and compare them experimentally.

We used four popular recommendation systems datasets. The MovieLens[1] dataset is one of the most popular datasets in the literature. We used all versions of MovieLens dataset, namely: 100K ($1K\times 2K$ with 10^5 observations), 1M ($6K\times 4K$ with 10^6 observations), and 10M ($70K\times 10K$ with 10^7 observations). We also tested LLORMA on the Netflix dataset which is of size $480K\times 18K$ with 10^8 observations and the Bookcrossing dataset ($100K\times 300K$ with 10^6 observations). These two datasets are much larger than the MovieLens dataset. We also report results on the Yelp dataset ($40K\times 10K$ with 10^5 observations), which is a recent dataset that is part of the ACM RecSys 2013 challenge[2]. The Bookcrossing

minimize with respect to $\{(U^{(t)},V^{(t)})\}_{t=1}^{q}$:

$$\sum_{(i,j)\in\Omega}\left(\sum_{t=1}^{q}\frac{[K^{(a_t)}]_i\,[K^{(b_t)}]_j\,[U^{(t)}V^{(t)\top}]_{i,j}}{\sum_s[K^{(a_s)}]_i\,[K^{(b_s)}]_j}-M_{i,j}\right)^2+\lambda_U\sum_{i,k}\left[U_{i,k}^{(t)}\right]^2+\lambda_V\sum_{j,k}\left[V_{j,k}^{(t)}\right]^2$$

Output: $\left\{a_t,\,b_t,\,U^{(t)},V^{(t)}\right\}_{t=1}^{q}$

and Yelp datasets reflect a recent trend of very high sparsity, often exhibited in real-world recommendation systems.

Unless stated otherwise, we randomly divided the available data into training and test sets such that the ratio of training set size to test set size was 9:1. We created five random partitions and report the average performance over the five partitions. We used a default rating of $(max+min)/2$ for test users or items which lack any rating, where max and min indicate respectively the maximum and minimum possible rating in the dataset.

In our experiments, we used the Epanechnikov kernel with $h_1=h_2=0.8$, a fixed step-size for gradient descent of $\mu=0.01$, and a 2-norm regularization value of $\lambda_U=\lambda_V=0.001$. These values were selected using cross-validation. We set and did not attempt to optimize the parameters $T=100$ (maximum number of iterations), $\epsilon=0.0001$ (gradient descent convergence threshold), and $q=50$ (number of anchor points). We selected anchor points by sampling uniformly users and items from the training points without replacement. We examine more complex anchor point selection scheme in Section 7.3.

7.1 Performance of Parallel LLORMA

Table 2 lists the performance of LLORMA with 50 anchor points, SVD, and two recent state-of-the-art methods based on results published in (Mackey et al., 2011). For a fixed rank r, LLORMA always outperforms SVD. Both LLORMA and SVD perform better as r increases. Both SVD and LLORMA exhibit diminishing returns as the rank increases. LLORMA with a modest rank $r=5$ outperforms SVD of any rank. We can see that LLORMA also outperforms the Accelerated Proximal Gradient (APG) and Divide-and-Conquer Matrix Factorization (DFC) algorithms. For a reference, the Root Mean Square

Table 2: RMSE achieved by different algorithms on five datasets: MovieLens 1M, MovieLens 10M, Netflix, Bookcrossing, and Yelp. Results for APG (Toh and Yun, 2010) and DFC were taken from (Mackey et al., 2011).

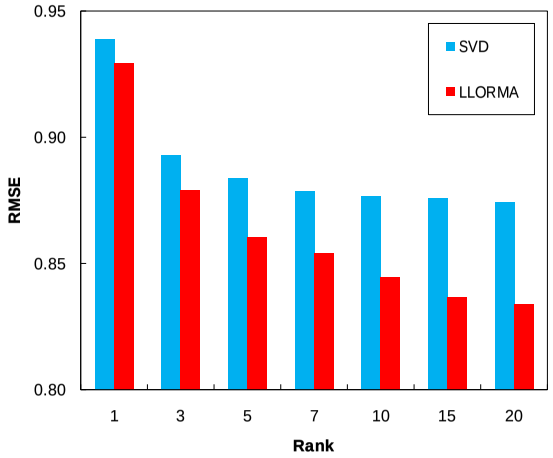

Figure 3: RMSE of LLORMA and SVD as a function of the rank on the Netflix dataset.

Error (RMSE) we achieved (0.8337) is a better score than the goal of Netflix competition (0.8567).[3]

As we can see from Figure 3, the improvement in the performance of SVD is rather minor beyond a rank of 7 while LLORMA's improvement is still evident until a rank of about 20. Both approaches cease to make substantial improvements beyond the aforementioned ranks and exhibit diminishing returns for high ranks. As discussed in earlier sections, the diminishing returns of SVD for high ranks can be interpreted in two ways: (i) The

3. We provide this number merely as reference since we measured our performance on a test set different from original Netflix test set, which is no longer available. Our result are based on a random sub-sampling of the Netflix training data as described above. See also the discussion in (Mackey et al., 2011).

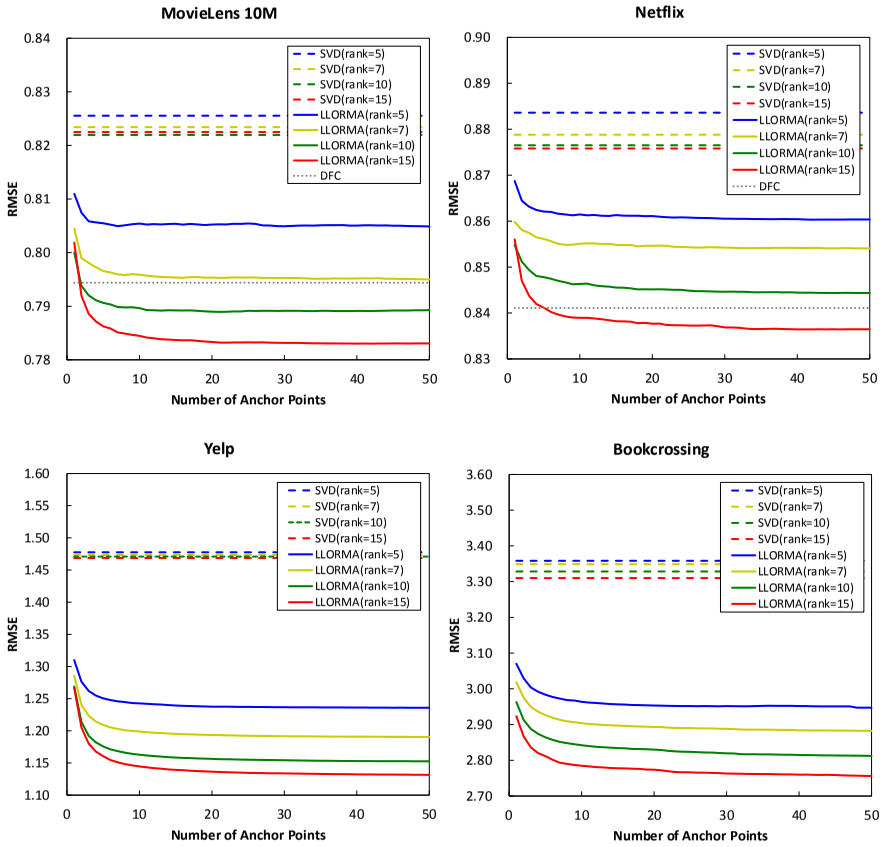

Figure 4: RMSE of LLORMA, SVD, and two baselines on MovieLens 10M (top-left), Netflix (top-right), Yelp (bottom-left), and Bookcrossing (bottom-right) datasets. The results for LLORMA are depicted by thick solid lines, while for SVD with dotted lines. Models of the same rank are have identical colors.

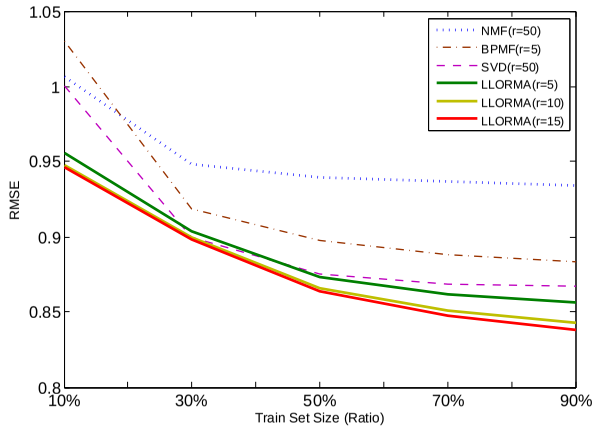

Figure 5: RMSE of SVD, LLORMA, NMF, and BPMF methods as a function of training set size for the MovieLens 1M dataset.

global low-rank assumption is correct and the SVD approximates the rating matrix almost optimally. (ii) The global low-rank assumption is incorrect and the diminishing returns are due to various deficiencies such as overfitting or reaching an inferior local minimum. Since LLORMA improves beyond SVD's best performance, it deems that the second hypothesis is more plausible. The fact that LLORMA's performance asymptotes at higher ranks than SVD may indicate the first hypothesis is to a large extent correct at a local region yet not globally.

Figure 4 compares the RMSE of LLORMA, SVD, and the DFC method of Mackey et al. (2011). We plot the RMSE of LLORMA as a function of the number of anchor points. As in the case of Table 2, both LLORMA and SVD improve as r increases. Here again LLORMA with local rank of at least 5 outperforms SVD of any rank. Moreover, LLORMA outperforms SVD even with only a few anchor points. Figure 5 shows the RMSE of LLORMA as a function of the training set size, and compares it with global SVD of 50. We also plot results for a few other methods that have shown to achieve very good approximation accuracy: non-negative matrix factorization (NMF) with rank 50 (Lee and Seung, 2001) and Bayesian probabilistic matrix factorization (BPMF) with rank 5 (Salakhutdinov and Mnih, 2008b). The test set size was fixed to 10% of the MovieLens 1M and the RMSE was averaged over five random train-test splits. The graph shows that all methods improve as the training set size increases while LLORMA consistently outperforms SVD and the other baselines.

To recap, the experimental results presented thus far indicate that LLORMA outperforms SVD and other state-of-the-art methods even when using relatively lower-rank approximation. Moreover, LLORMA is capable of achieving good accuracy with rather small number of anchor points and seems to perform well across a variety of training set sizes.

7.2 Comparison of Global and Parallel LLORMA

We proposed two implementations of LLORMA in this paper: a decoupled parallel approach (Section 5) and a global approximation version (Section 6). In earlier sections, we conjectured that the global version is likely to be more accurate in terms of RMSE as it directly optimizes the objective function. In terms of computational efficiency, however, we naturally expected the parallel version to be faster as it can take advantage of multicore and distributed computing architectures. In this subsection, we experimentally verify the two conjectures.

We compared the two versions of LLORMA on MovieLens 100K dataset. We tested local rank values in $\{1, 3, 5, 7, 10\}$. The experiment was conducted on a quad-core machine with 4 threads while suspending any other process. For both versions, we constructed 50 local models and repeated the experiment 5 times with different anchor points. Table 3 reports the average test RMSE and average elapsed time for training. As conjectured, global LLORMA results in more accurate estimations on unseen data than parallel LLORMA. However, the performance gap between the two approaches reduces as the rank increases. The parallel version LLORMA runs about 3 times faster than global LLORMA indicating that a fairly high utilization of the multicore architecture.

Method	Global LLORMA		Parallel LLORMA	
Rank	Test RMSE	Time	Test RMSE	Time
1	0.9072	6:04	0.9426	1:09
3	0.9020	10:27	0.9117	3:20
5	0.8990	14:40	0.9041	5:26
7	0.8986	19:43	0.9010	7:50
10	0.8975	28:59	0.8985	11:49

Table 3: RMSE and training time for Global and Parallel LLORMA on MovieLens 100K.

7.3 Anchor Points Selection

The method for selecting anchor points in LLORMA is important as it may affect the prediction time as well as generalization performance. If the row and column indices of the test data are provided in advance, we may choose anchor points from the test set distribution. However, in most applications the test set is not known apriori, and in fact is likely to increase and change in time. We therefore confined ourselves to three sampling methods and one clustering methods based on low-rank representation of the data. In the rest of the section we use q to denote the number of anchor points. The following are anchor point selection methods we tried.

Complete: Sample anchor points uniformly from the entire set of indices $[n_1] \times [n_2]$.

Trainset: Sample anchor points uniformly from the observed entries, Ω.

Coverage: Select anchor points such that no entry in $[n_1] \times [n_2]$ is too distant from the rest of the anchor points.

k-means: Run k-means clustering on the entries in Ω each represented using the induced d-dimensional space obtained by SVD with $k = q$.

The first two sampling methods are straightforward. The third method, termed "Coverage" was implemented by sampling aq with $a > 1$ user-item pairs and then adding an anchor point whose minimum distance to existing anchor points is the largest. The fourth selection methods that we tested is based on clustering the observed entries. It is based on the observation that an anchor point need not be an entry in the observation matrix but may rather consist of a combination of matrix entries. Recall that we weigh each local model based on user and item similarity. As explained in Section 5, each a user (item) is represented as a row of a low-rank matrices U (respectively, V) attained by the global SVD, namely, $M \approx UV^\top$. Denoting the intrinsic dimension of U and V by d, each user and item can be represented as a d-dimensional vector. Instead of each row of U and V, we can generalize the space of anchor points to any point in this d-dimensional vector space. A good set of anchor points may be the q cluster centers of the d-dimensional representations of the entries of M which is computed using the k-means algorithm.

Table 4 provides performance results of *Global* LLORMA using different anchor point selection methods. In the experiments we used the MovieLens 100K datasets with 5 random train-test partitions. The results we report are based on averages over the 5 random splits. As one may anticipate, the different selection schemes perform similarly when q is large. For small values of q (10 or 20), we would like to underscore the following observations. The first two methods (Complete and Trainset) perform similarly. The clustering-based anchor point construction generally performs slightly better than the three other methods. Somewhat surprisingly, the Coverage method performs the worst for small values of q. Nonetheless, when q is sufficiently large all methods achieve about the same results.

7.4 Comparison to Ensemble of Independent Models

The algebraic form of the parallel estimator $\hat{\hat{\mathcal{T}}}$ as given by (9) is a linear combination of local models, each of which focuses on a subset of user-item pairs. This algebraic form is reminiscent of ensemble methods (Jacobs et al., 1991) such as Bagging (Breiman, 1996), where the final model is a linear combination of simple models, each weighed by a predefined coefficient. Ensemble methods such as boosting and Bagging have been shown to be effective tools for combining models primarily for classification tasks. In this section we examine the

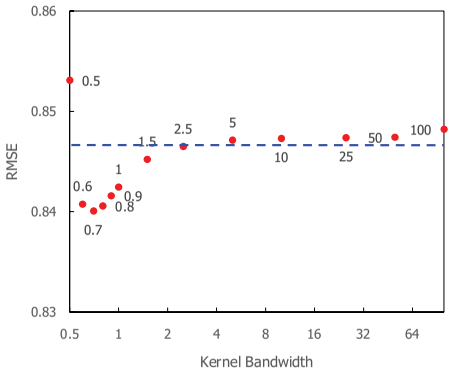

Figure 6: Performance of LLORMA as a function of the kernel width. The vertical axis indicates the approximations' root mean squared error (RMSE) and the horizontal axis the kernel width ($h_1 = h_2$) in log scale. The dotted blue line shows the average RMSE of Bagging for reference.

connection between LLORMA and an ensemble method based on Bagging for low rank matrix approximation.

There are two main differences between Bagging and LLORMA. In Bagging, the dataset constructed for training each sub-model is uniformly sampled with replacements. In contrast, LLORMA's sampling is based on a non-uniform distribution respecting locality as defined by the distance metric over user-item pairs. The second difference is that Bagging assigns equal weights to each base-model. In LLORMA, each *local* model is associated with a weight that is proportional to the proximity of the anchor point to the test point. That is, the weights of the local models vary and are determined at inference time.

We conducted two set of experiments comparing LLORMA with Bagging. In the first experiment, we varied the kernel widths gradually increasing the widths to the matrix dimensions, thus ending with a uniform kernel over Ω. We normalized the kernel width so that a value of 1 corresponds to the full dimension. As the width increases, the overlap between local models becomes more and more substantial. In addition, the bias of each local model increases due to the decrease in locality. Analogously, the variance of each model decreases due to the increase in the actual training set size.

Figure 6 shows performance of LLORMA on MovieLens 100K dataset for various kernel widths. The best performance is obtained for kernel width between 0.7 and 0.8. The performance rapidly deteriorates as the width decreases and slowly degrades as the width increases with an optimal width close to the middle of the range.

In our second experiment, we compared LLORMA with Bagging by taking $|\Omega|$ samples with replacements, which in expectation covers two thirds of the observed entries. Table 5 compares the performance of global SVD of rank 10 and 15, LLORMA with 100 local

models, and Bagging with 100 models. Each result is the average of 5 random splits of the dataset. It is apparent from the table that both LLORMA and Bagging outperform global SVD. Further, LLORMA achieves lower RMSE than Bagging. The improvement of LLORMA over Bagging is statistically significant based on a paired t-test with p-values of 0.0022 for MovieLens 100K and 0.0014 for MovieLens 1M. These p-values correspond to a confidence level over 99%. LLORMA also outperforms Bagging with respect to the median average error (MAE).

Dataset	MovieLens 100K		MovieLens 1M	
Method	MAE	RMSE	MAE	RMSE
SVD rank=10	0.7189	0.9108	0.6922	0.8683
SVD rank=15	0.7170	0.9094	0.6913	0.8676
Bagging	0.6985	0.8930	0.6620	0.8481
LLORMA	0.6936	0.8881	0.6577	0.8423

8. Related work

Matrix factorization for recommender systems have been the focus of voluminous amount of research especially since the Netflix Prize competition. It is clearly impossible to review all of the existing approaches. We review here a few of the notable approaches. Billsus and Pazzani (1998) initially proposed applying SVD for collaborative filtering problems. Salakhutdinov and Mnih (2008a) presented probabilistic matrix factorization (PMF) and later Salakhutdinov and Mnih (2008b) extended matrix factorization to fully Bayesian approach. Lawrence and Urtasun (2009) proposed a non-linear version of PMF. Rennie and Srebro (2005) proposed a maximum-margin approach. Lee et al. (2012b) conducted a comprehensive experimental study comparing a number of state-of-the-art and traditional recommendation system methods using the PREA toolkit (Lee et al., 2012c). Further algorithmic improvements in matrix completion were demonstrated in Toh and Yun (2010); Keshavan et al. (2010). The work that is perhaps the most similar in to LLORMA is Divide-and-Conquer Matrix Factorization (DFC) (Mackey et al., 2011). DFC also divides the completion problems into a set of smaller matrix factorization problems. Our approach differs DFC in that we use a metric structure on $[n_1] \times [n_2]$ and use overlapping partitions. Another matrix approximation by sub-division based on clustering was reported in Mirbakhsh and Ling (2013) for the task of seeking user and item communities. In addition to monolithic matrix factorization scheme, several ensemble methods have also been proposed. DeCoste (2006) suggested ensembles of maximum margin matrix factorization (MMMF). The Netflix Prize winner (Bell et al., 2007; Koren, 2008) used combination of memory-based and matrix factorization methods. The Netflix Prize runner-up (Sill et al., 2009) devised Feature-Weighted Least Square (FWLS) solver, using a linear ensemble of learners with dynamic weights. Lee et al. (2012a) extended FWLS by introducing automatic stage-wise feature induction. Kumar et al. (2009) and Mackey et al. (2011) applied ensembles to Nystrom method and DFC, respectively. Other local learning paradigms were suggested in the context dimensionality such as local principal component analysis (Kambhatla and Leen, 1997) and local linear embedding (LLE) (Roweis and Saul, 2000). A relatively recent paper on matrix completion (Wang et al., 2013) applies low-rank factorization to clusters of points. Last, we would like to point to the formal work on low-rank matrix Completion that is closest to the analysis presented in this paper. Candès and Tao (2010) derived a bound on the performance of low-rank matrix completion. As mentioned in previous section our analysis is based on (Candès and Plan, 2010) who adapted the analysis of Candès and Tao (2010) to noisy settings. Some more remote related results were presented in (Shalev-Shwartz et al., 2011; Foygel and Srebro, 2011; Foygel et al., 2012).

9. Summary

We presented a new approach for low-rank matrix approximation based on the assumption that the matrix is locally low-rank. Our proposed algorithm, called LLORMA, is highly parallelizable and thus scales well with the number of observations and the dimension of the problem. Our experiments indicate that LLORMA outperforms several state-of-the-art methods without a significant computational overhead. We also presented a formal analysis of LLORMA by deriving bounds that generalize standard compressed sensing results and express the dependency of the modeling accuracy on the matrix size, training set size, and locality (kernel bandwidth parameter). Our method is applicable beyond recommendation systems so long as the locality assumption holds and a reasonable metric space can be identified.

Abstract

Information criteria have been popularly used in model selection and proved to possess nice theoretical properties. For classification, Claeskens et al. (2008) proposed support vector machine information criterion for feature selection and provided encouraging numerical evidence. Yet no theoretical justification was given there. This work aims to fill the gap and to provide some theoretical justifications for support vector machine information criterion in both fixed and diverging model spaces. We first derive a uniform convergence rate for the support vector machine solution and then show that a modification of the support vector machine information criterion achieves model selection consistency even when the number of features diverges at an exponential rate of the sample size. This consistency result can be further applied to selecting the optimal tuning parameter for various penalized support vector machine methods. Finite-sample performance of the proposed information criterion is investigated using Monte Carlo studies and one real-world gene selection problem.

Keywords: Bayesian Information Criterion, Diverging Model Spaces, Feature Selection, Support Vector Machines

1. Introduction

We consider binary classification using linear support vector machines (SVMs). It is well known that the standard SVM uses all features while constructing the classification rule. In the extreme case of regression that the number of features is much larger than the sample size, if the true model is non-sparse, no method can identify the truth correctly due to the limited information from the data. This is the so-called *curse of dimensionality*. In many important applications, however, it is reasonable to simplify the problem by assuming the true model to be sparse. For example, in cancer classification using genomic data where the number of probes (or genes) can be tens of thousands and the number of patient samples is typically only a few dozens, biologists find it plausible to assume that only a small subset of genes are relevant. In this case, it is more desirable to build a classifier based only on those relevant genes. Yet in practice, it is largely unknown which genes are relevant and this calls for feature selection methods. The potential benefits of feature selection include reduced computational burden, improved prediction performance and simple model interpretation. See Guyon and Elisseeff (2003) for more discussions. Our goal in this paper is consistent feature selection for the SVM.

There has been a rich literature on feature selection for the SVM. Weston et al. (2000) proposed a scaling method to select important features. Guyon et al. (2002) suggested the SVM recursive feature elimination (SVM RFE) procedure. It has been shown that the SVM can be fitted in the regularization framework using the hinge loss and the L_2 penalty (Wahba et al., 1999). Thereafter various forms of penalized SVMs have been developed for simultaneous parameter estimation and feature selection. Bradley and Mangasarian (1998), Zhu et al. (2004) and Wegkamp and Yuan (2011) studied properties of the L_1 penalized SVM. Wang et al. (2006) proposed SVM with a combination of L_1 and L_2 penalties. Zou and Yuan (2008) considered the L_∞ penalized SVM when there is prior knowledge about the grouping information of features. Zhang et al. (2006) and Becker et al. (2011) suggested SVM with a non-convex penalty in the application of gene selection. Though all these methods target selecting the best subset of features, theoretical justification about how well the selected subset is estimating the true model is still largely underdeveloped. Recently Zhang et al. (2014) showed that the SVM penalized with a class of non-convex penalties enjoys the oracle property (Fan and Li, 2001), that is, the estimated classifier behaves as if the subset of all relevant features is known *a priori*. Yet this model selection consistency result relies heavily on the proper choice of the involved tuning parameter which is often selected by cross-validation in practice. However, Wang et al. (2007) showed that the generalized cross-validation criterion can lead to overfitting even with a very large sample size.

Information criteria such as AIC (Akaike, 1973) and BIC (Schwarz, 1978) have been used for model selection and their theoretical properties have been well studied, see Shao (1997), Shi and Tsai (2002) and references therein. It is well understood that the BIC can identify the true model consistently when the dimensionality is fixed. The idea of combining information criterion with support vector machine to select relevant features was first proposed in Claeskens et al. (2008). They proposed the SVM information criterion (SVMIC$_L$) and provided some encouraging numerical evidence. Yet its theoretical properties, such as model selection consistency, have not been investigated.

In this paper, we propose a consistent SVM information criterion for model selection in the diverging model spaces. We first fill the gap by providing theoretical justification for the criterion SVMIC$_L$ proposed in Claeskens et al. (2008). Our results show that this information criterion is model selection consistent in the fixed dimensional model space, but it can be too liberal when the candidate model space is diverging. To remedy this problem, a modified information criterion for high dimensional case (SVMIC$_H$) is introduced. The extension of model selection consistency from SVMIC$_L$ to SVMIC$_H$ is a challenging problem. The point-wise consistency of SVM solution is enough to justify the model selection consistency if the number of candidate models is fixed. Nevertheless, in the diverging model

spaces the probabilities for favoring an underfitted or overfitted model by the information criterion can accumulate at a very fast speed and alternative techniques are required. We develop the uniform consistency of SVM solution which has not been carefully studied in the literatures. Based on the uniform convergence rate, we prove that the new information criterion possesses model selection consistency even when the number of features diverges at an exponential rate of the sample size. That is, with probability arbitrarily close to one, we can identify the true model from all the underfitted or overfitted models in the diverging model spaces. To the best of our knowledge, this is the first result of model selection consistency for the SVM. We further apply this information criterion to the problem of tuning parameter selection in penalized SVMs. The proposed support vector machine information criterion can be computed easily after fitting the SVM with computation cost much lower than resampling methods like cross-validation. Simulation studies and real data examples confirm the superior performance of the proposed method in terms of model selection consistency and computational scalability.

In Section 2 we define the support vector machine information criterion. Its theoretical properties are studied in Section 3. Sections 4 and 5 present numerical results on simulation examples and real-world gene selection datasets, respectively. We conclude with some discussions in Section 6.

2. Support vector machine information criterion

In this paper we use normal font for scalars and bold font for vectors or matrices. Consider a random pair $(\mathbf{X}, Y)$ with $\mathbf{X}^T = (1, X_1, \ldots, X_p) = (1, (\mathbf{X}^+)^T) \in \mathbf{R}^{(p+1)}$ and $Y \in \{1, -1\}$. Let $\{(\mathbf{X}_i, Y_i)\}_{i=1}^n$ be a set of training data independently drawn from the distribution of $(\mathbf{X}, Y)$. Denote $\boldsymbol{\beta}$ to be a $(p+1)$-dimensional vector of interest with $\boldsymbol{\beta}^T = (\beta_0, \beta_1, \ldots, \beta_p) = (\beta_0, (\boldsymbol{\beta}^+)^T) \in \mathbf{R}^{(p+1)}$. Let $||\cdot||$ be the Euclidean norm operator of a vector. The goal of linear SVM is to estimate a hyperplane defined by $\mathbf{X}^T\boldsymbol{\beta} = 0$ via solving the optimization problem

$$\min_{\boldsymbol{\beta}} \{C \sum_{i=1}^n \xi_i + \frac{1}{2}||\boldsymbol{\beta}^+||^2\} \tag{1}$$

subject to the constraints that $\xi_i \geq 0$ and $Y_i\mathbf{X}_i^T\boldsymbol{\beta} \geq 1 - \xi_i$ for all $i = 1, \ldots, n$, where $C > 0$ is a tuning parameter. This can be written equivalently into an unconstrained regularized empirical loss minimization problem:

$$\min_{\boldsymbol{\beta}} \{\frac{1}{n}\sum_{i=1}^n H(Y_i\mathbf{X}_i^T\boldsymbol{\beta}) + \frac{\lambda_n}{2}||\boldsymbol{\beta}^+||^2\}, \tag{2}$$

where $H(t) = (1-t)_+$ is the hinge loss function, $(z)_+ = \max(z, 0)$ and $\lambda_n > 0$ is a tuning parameter with $C = (n\lambda_n)^{-1}$.

Following the definition in Koo et al. (2008), we denote $(\boldsymbol{\beta}^*)^T = (\beta_0^*, \beta_1^*, \ldots, \beta_p^*) = (\beta_0^*, (\boldsymbol{\beta}^{*+})^T) \in \mathbf{R}^{(p+1)}$ to be the true parameter value that minimizes the population hinge loss. That is,

$$\boldsymbol{\beta}^* = \arg\min_{\boldsymbol{\beta}} \mathbb{E}(1 - Y\mathbf{X}^T\boldsymbol{\beta})_+.$$

Note that $\boldsymbol{\beta}^*$ is not necessarily always the same as the Bayes rule. However, it gives the optimal upper bound of the risk of the 0-1 loss through convex relaxation and its sparsity structure is exactly the same as the one of Bayes rule in special cases such as linear discriminant analysis. For more discussions see Zhang et al. (2014). Denote $S = \{j_1, \ldots, j_d\} \subset \{1, \ldots, p\}$ to be a candidate model, $\mathbf{X}_{i,S}^T = (1, X_{i,j1}, \ldots, X_{i,jd})$, $\boldsymbol{\beta}_S^T = (\beta_0, \beta_{j1}, \ldots, \beta_{jd})$ and $|S|$ the cardinality of S. The subset of all relevant features is defined by $S^* = \{j : 1 \leq j \leq p, \beta_j^* \neq 0\}$. We assume that the truth $\boldsymbol{\beta}^*$ is sparse (i.e., most of its components are exactly zero). Denote $q = |S^*|$ which characterizes the sparsity level. We assume that q is fixed and does not depend on n. In this paper, we consider the diverging model spaces in which the dimensionality $p = p_n$ is allowed to increase with n and can be potentially much larger than n. We also assume that $\lambda_n \to 0$ as $n \to \infty$ and only consider the non-separable case in the limit to ensure the uniqueness of the truth $\boldsymbol{\beta}^*$. Here by non-separable, we mean that the two classes cannot be linearly separated from each other.

To identify the true model S^*, Claeskens et al. (2008) proposed an information criterion for SVM (denoted by SVMIC_L) based on the slack variables $\{\xi_i\}_{i=1}^n$. That is,

$$\text{SVMIC}_L(S) = \sum_{i=1}^n \xi_i + |S|\log(n),$$

where $\{\xi_i\}_{i=1}^n$ are obtained from (1) only using the variables in S. This information criterion is equivalent to

$$\text{SVMIC}_L(S) = \sum_{i=1}^n (1 - Y_i\mathbf{X}_{i,S}^T\widehat{\boldsymbol{\beta}}_S)_+ + |S|\log(n), \tag{3}$$

where $\widehat{\boldsymbol{\beta}}_S = \arg\min\{1/n\sum_{i=1}^n(1 - Y_i\mathbf{X}_{i,S}^T\boldsymbol{\beta}_S)_+ + \lambda_n/2||\boldsymbol{\beta}_S^+||^2\}$. It is evident that the SVMIC_L directly follows the spirit of BIC. Claeskens et al. (2008) fixed $C = 1$ in (1) and found minor difference for different choices of C, which is equivalent to $\lambda_n = 1/n$ in (2). To be consistent with the work in Claeskens et al. (2008), we also consider this choice of λ_n in this paper. There are two potential drawbacks of this information criterion. First, though supported with numerical findings, theoretical properties of SVMIC_L, such as model selection consistency, are largely unknown even under the assumption of a fixed p. Second, in many real world datasets where the dimension can be much larger than the sample size, it would be more appropriate to consider the model selection problem in the framework of diverging model spaces. This extension from low dimensions to high dimensions can greatly change the theoretical properties of the information criterion. Chen and Chen (2008) showed that the ordinary BIC for linear regression cannot identify the true model consistently in the diverging p case. Wang et al. (2009) showed that the ordinary BIC fails to select a consistent shrinkage level in penalized least squares regression with a diverging p. Such results in the literature suggest that SVMIC_L may also suffer from inconsistency in high dimensions and alternative criterion is needed.

To overcome these issues, we propose a modified support vector machine information criterion for model selection in a high dimensional model space (denote by SVMIC_H). This criterion is adpated from SVMIC_L and defined as

$$\text{SVMIC}_H(S) = \sum_{i=1}^n (1 - Y_i\mathbf{X}_{i,S}^T\widehat{\boldsymbol{\beta}}_S)_+ + L_n|S|\log(n), \tag{4}$$

where $\widehat{\boldsymbol{\beta}}_S = \arg\min\{1/n\sum_{i=1}^n(1-Y_i\mathbf{X}_{i,S}^T\boldsymbol{\beta}_S)_+ + \lambda_n/2||\boldsymbol{\beta}_S^+||^2\}$ and L_n is a constant sequence that diverges to infinity. Note that if L_n is a non-diverging constant then this reduces to SVMIC$_L$ in the limit. We will show that SVMIC$_H$ possesses the nice property of model selection consistency even when p increases at an exponential rate of n. Compared to SVMIC$_L$ in Claeskens et al. (2008), our information criterion SVMIC$_H$ adds larger penalty to the size of the selected subset and behaves more conservatively. As we will see, this additional preference for simpler models plays an important role in consistent model selection when we are searching over diverging model spaces.

We make two remarks about SVMIC$_H$. First, the choice of L_n in (4) is flexible. It is *not* a tuning parameter and does not need to be chosen by computationally intensive methods such as cross-validation. We will show that a wide spectrum of L_n can lead to a consistent information criterion. This is further confirmed in our simulations and real data analysis where we examine different choices of L_n. Therefore the computation cost of SVMIC$_H$ is the same as SVMIC$_L$ and much lower than cross-validation. Second, it is possible to define the information criterion as the log-transformed version, that is

$$\log(\sum_{i=1}^n(1-Y_i\mathbf{X}_{i,S}^T\widehat{\boldsymbol{\beta}}_S)_+) + L_n|S|\log(n)/n$$

which is scalar invariant. It can be shown the model selection consistency still holds for this definition. However, we follow the advice from Guyon et al. (2002) to standardize variables before training SVM and as a consequence we automatically have scalar invariance of the sum of slack variables. To be consistent with SVMIC$_L$ defined in Claeskens et al. (2008), we take definition (4) in our paper.

3. Theoretical results

3.1 Notations and conditions

To facilitate technical proofs, we introduce some additional notation. Denote $L(\boldsymbol{\beta}) = \mathbb{E}(1-Y\mathbf{X}^T\boldsymbol{\beta})_+$. Recall that $\boldsymbol{\beta}^* = \arg\min_{\boldsymbol{\beta}} L(\boldsymbol{\beta})$. Let $\mathbf{S}(\boldsymbol{\beta}) = -\mathbb{E}[\mathbf{1}(1-Y\mathbf{X}^T\boldsymbol{\beta}\geq 0)Y\mathbf{X}]$, where $\mathbf{1}(\cdot)$ is the indicator function. Also define $\mathbf{H}(\boldsymbol{\beta}) = \mathbb{E}[\delta(1-Y\mathbf{X}^T\boldsymbol{\beta})\mathbf{X}\mathbf{X}^T]$, where $\delta(\cdot)$ is the Dirac delta function. Koo et al. (2008) showed that under some regularity conditions, $\mathbf{S}(\boldsymbol{\beta})$ and $\mathbf{H}(\boldsymbol{\beta})$ behave like the gradient and Hessian matrix of $L(\boldsymbol{\beta})$, respectively. Furthermore we denote f_+ and f_- to be the densities of $\mathbf{X}^+ \in \mathbf{R}^p$ conditioning on $Y=1$ and $Y=-1$, respectively.

Given the dimension p, the number of candidate models is 2^p-1. When p is very large, we cannot afford to calculate SVMIC$_H(S)$ for all possible subsets. Instead, we only search for the best model in a restricted model space. To be more specific, we denote $\widehat{S}$ the model chosen by SVMIC$_H$ such that

$$\widehat{S} = \arg\min_{S:|S|\leq M_n}\text{SVMIC}_H(S), \tag{5}$$

where M_n is a sequence of positive integers that bounds the size of the restricted model space from above. In this paper, we consider $M_n = O(n^\kappa)$ for some constant $0<\kappa<1/2$, that is, we only consider the candidate model with the size diverges slower than $\sqrt{n}$. One motivation for this choice of M_n is the "bet on sparsity" principle (Hastie et al., 2001).

Note that by Lemma 1 of Zhang et al. (2014), if the number of relevant features diverges faster than $\sqrt{n}$, the true parameter $\boldsymbol{\beta}^*$ cannot be estimated consistently even with the oracle information of the true model S^*. Therefore, there is no need to consider those models with sizes increasing faster than $\sqrt{n}$ as in general no method would work for them even when the true underlying model is known. Notice also that it is possible to prove the model selection consistency without the restricted model space. However, this would requires $p_n = o(\sqrt{n})$, which cannot diverge very fast with the sample size.

We now present the technical conditions that are needed for studying the theoretical properties of SVMIC$_H$.

(A1) f_+ and f_- are continuous and have some common support in $\mathbf{R}^p$.

(A2) $|X_j| \leq M < \infty$ for some positive constant M and $1\leq j\leq p$.

(A3) For all $S\in\{S:|S|\leq M_n, S\supseteq S^*\}$, $\lambda_{\max}(\mathbb{E}(\mathbf{X}_{i,S}\mathbf{X}_{i,S}^T))\leq c_1$, where $\lambda_{\max}(\cdot)$ is the largest eigenvalue of a matrix and $c_1>0$ is a constant.

(A4) The densities of $\mathbf{X}_{i,S^*}^T\boldsymbol{\beta}_{S^*}^*$ conditioning on $Y=1$ and $Y=-1$ are uniformly bounded away from zero and infinity at the neighborhood of $\mathbf{X}_{i,S^*}^T\boldsymbol{\beta}_{S^*}^*=1$ and $\mathbf{X}_{i,S^*}^T\boldsymbol{\beta}_{S^*}^* = -1$, respectively.

(A5) $M_n = O(n^\kappa)$ for some constant $0<\kappa<1/2$.

(A6) $p_n = O(\exp(n^\gamma))$ for some constant $0<\gamma<(1-2\kappa)/5$.

(A7) For all $S\in\{S:|S|\leq M_n, S\supseteq S^*\}$, there exist some positive constants c_2 and c_3 such that $\lambda_{\min}(\mathbf{H}(\boldsymbol{\beta}_S))\geq c_2$ and $\lambda_{\max}(\mathbf{H}(\boldsymbol{\beta}_S)) = O(|S|)$ over the set $\{\boldsymbol{\beta}:||\boldsymbol{\beta}-\boldsymbol{\beta}^*||\leq c_3\}$, where $\lambda_{\min}(\cdot)$ is the smallest eigenvalue of a matrix.

(A8) For all $S\in\{S:|S|\leq M_n, S\supseteq S^*\}$, $\lambda_{\max}(\mathbf{H}(\boldsymbol{\beta}_S^*))\log(p_n) = o(L_n\log(n))$, $L_n\log(n) = o(n)$.

Conditions (A1) is required so that $\mathbf{S}(\boldsymbol{\beta})$ and $\mathbf{H}(\boldsymbol{\beta})$ are well-defined, see Koo et al. (2008) for more details. Condition (A2) is assumed in the literature of high dimensional model selection consistency as in Wang et al. (2012) and Lee et al. (2014). Condition (A3) on the largest eigenvalue is similar to the sparse Riesz condition (Zhang and Huang, 2008) and is often assumed for model selection consistency in the diverging p scenario (Chen and Chen, 2008; Yuan, 2010; Zhang, 2010). Note that the lower bound on the eigenvalue of the covariance matrix of $\mathbf{X}_S$ is not specified. Condition (A4) assumes that as the sample size increases, there is enough information around the non-differentiable point of the hinge loss function. This condition is also required for model selection consistency of non-convex penalized SVM in high dimensions (Zhang et al., 2014). Condition (A6) specifies that p is allowed to diverge at an exponential rate of n. Conditions (A7) requires that the Hessian matrix is well-behaved. More specifically, (A7) requires a lower bound on the smallest eigenvalue of the Hessian matrix in the neighborhood of the true value. Koo et al. (2008) gave sufficient conditions for the positive-definiteness of the Hessian matrix at the true value and showed these conditions hold under the setting of Fisher's linear discriminant analysis with a fixed model size. Condition (A8) specifies the rate requirement of L_n in (4).

3.2 Consistency of SVMIC$_L$ for a fixed p

In this section we assume that the dimension p is fixed and study the theoretical properties of SVMIC$_L$. Let $\Omega = \{S:|S|\leq M\}$ be the candidate model space where M is a positive number. Furthermore, when p is fixed, the total number of candidate models is also fixed.

Note that, to prove the model selection consistency of SVMIC_L, we need to show that

$$\Pr(\inf_{S\in\Omega, S\neq S^*} \text{SVMIC}_L(S) > \text{SVMIC}_L(S^*)) \to 1$$

as $n \to \infty$. By the fact that Ω is a fixed model space, it is sufficient to show the result point-wisely in the model space, that is,

$$\Pr(\text{SVMIC}_L(S) > \text{SVMIC}_L(S^*)) \to 1 \tag{6}$$

for every $S \in \{S : S \in \Omega, S \neq S^*\}$. This point-wise version greatly simplifies the proof. Recall that $\widehat{\boldsymbol{\beta}}_S = \arg\min\{1/n \sum_{i=1}^n (1 - Y_i \mathbf{X}_{i,S}^T \boldsymbol{\beta}_S)_+ + \lambda_n/2 ||\boldsymbol{\beta}_S^+||^2\}$. As we will show in the appendix, it suffices to conclude (6) with the condition that $\widehat{\boldsymbol{\beta}}_S$ is a consistent estimator of $\boldsymbol{\beta}_S^*$ whenever the candidate subset S includes the true subset S^*. By Theorem 1 of Koo et al. (2008), we have $||\widehat{\boldsymbol{\beta}}_S - \boldsymbol{\beta}_S^*|| = O_p(n^{-1/2})$ for every fixed $S \supset S^*$ under the assumption of fixed p. Therefore the point-wise consistency holds. The result is summarized in Lemma 1.

Lemma 1 *Assuming p is a fixed number and $\lambda_n = 1/n$. Under conditions (A1)-(A4) and (A6)-(A7), we have*

$$\Pr(\widehat{S} = S^*) \to 1$$

as $n \to \infty$, where $\widehat{S} = \arg\min_{S:|S|\leq M} SVMIC_L(S)$.

3.3 Consistency of SVMIC_H for a diverging p

The proof becomes much more involved when p is diverging, especially when p diverges much faster than $O(\sqrt{n})$. Let $\Omega = \{S : |S| \leq M_n\}$, $\Omega_+ = \{S : |S| \leq M_n, S \supset S^*, S \neq S^*\}$ and $\Omega_- = \{S : |S| \leq M_n, S \not\supset S^*\}$, where Ω_+ and Ω_- are spaces of overfitted and underfitted models, respectively. Though the information criterion for the fixed model space can differentiate the true model from an arbitrary candidate model, this point-wise result is not sufficient for the overall consistency if the problem requires searching uniformly over a diverging model space. That is, even if (6) holds for every $S \in \Omega$, we still cannot conclude model selection consistency, as the probability of favoring an overfitted or underfitted candidate model rather than the true model can accumulate at very fast speed if the number of candidate models is diverging and hence lead to inconsistent model selection. To control the overall failing probability, we need a uniform convergence rate of SVM solution $\widehat{\boldsymbol{\beta}}_S$ over the diverging model space Ω. Note that $\Omega = \Omega_+ \cup \{S^*\} \cup \Omega_-$. It turns out that the uniform convergence rate of $\widehat{\boldsymbol{\beta}}_S$ over $S \in \Omega_+$ is sufficient for the technical proof. We summarize the uniform rate in Lemma 2 below.

Lemma 2 *Under conditions (A1)-(A7) and $\lambda_n = 1/n$, we have*

$$\sup_{S:|S|<M_n, S\supset S^*} ||\widehat{\boldsymbol{\beta}}_S - \boldsymbol{\beta}_S^*|| = O_p(\sqrt{|S| \log(p)/n}).$$

This uniform convergence rate of SVM solution is far from being a trivial result. Recently Zhang et al. (2014) showed that $||\widehat{\boldsymbol{\beta}}_S - \boldsymbol{\beta}_S^*|| = O_p(\sqrt{|S|/n})$ for a specific diverging model S which satisfies $S \supset S^*$ and $|S| = o(\sqrt{n})$. Although it is an extension of Theorem 1 in Koo et al. (2008) to the diverging p case, it is still only a point-wise result and cannot be applied directly to bound the overall failing probability. Not surprisingly, the uniform convergence rate in Lemma 2 is slower by a factor $\sqrt{\log(p)}$, which is the price we pay to search over the candidate model space uniformly. In fact, this additional term is the main reason for adding the extra penalty L_n in SVMIC_H.

We now give an intuitive explanation why SVMIC_L can fail in the diverging model space. Consider all the overfitted models in Ω_+. We have the following decomposition

$$\begin{aligned}
&\inf_{S\in\Omega_+} \text{SVMIC}_L(S) - \text{SVMIC}_L(S^*) \\
&= \inf_{S\in\Omega_+} \Big\{ \sum_{i=1}^n (1 - Y_i \mathbf{X}_{i,S}^T \widehat{\boldsymbol{\beta}}_S)_+ - \sum_{i=1}^n (1 - Y_i \mathbf{X}_{i,S^*}^T \boldsymbol{\beta}_S^*)_+ + (|S| - |S^*|) \log(n) \Big\}.
\end{aligned} \tag{7}$$

Note that the difference of the sum of hinge loss can be negative and the difference of model size is always positive. We will show in the appendix that the difference of the sum of hinge loss is of order $O_p(n||\widehat{\boldsymbol{\beta}}_S - \boldsymbol{\beta}_S^*||^2)$ under some regularity conditions. For fixed p, it implies that the difference of model size dominates for large n and the sign of (7) is always positive in the limit. For diverging p, however, this is not always the case. By Lemma 2, the difference of hinge loss in (7) is of order $O(|S| \log(p))$ and the difference of model size is of order $O(|S| \log(n))$, thus the sign of (7) can be negative in the limit. Therefore even if we have a very large sample size, SVMIC_L may still favoring the models that are overfitted due to the slower uniform convergence rate of SVM solution. Because SVMIC_L can be viewed as directly following the spirit of ordinary BIC, this result agrees with the findings reported in Chen and Chen (2008) that BIC can be too liberal in high dimensional model selection. Here by liberal, we mean that there is a positive probability that an overfitted model is more favored than the true model by the information criterion even with an infinite sample size.

For SVMIC_H, we can do a similar decomposition as in (7) for all the overfitted models

$$\begin{aligned}
&\inf_{S\in\Omega_+} \text{SVMIC}_H(S) - \text{SVMIC}_H(S^*) \\
&= \inf_{S\in\Omega_+} \Big\{ \sum_{i=1}^n (1 - Y_i \mathbf{X}_{i,S}^T \widehat{\boldsymbol{\beta}}_S)_+ - \sum_{i=1}^n (1 - Y_i \mathbf{X}_{i,S^*}^T \boldsymbol{\beta}_S^*)_+ + L_n(|S| - |S^*|) \log(n) \Big\}.
\end{aligned} \tag{8}$$

Note that the extra term L_n diverges to infinity and the sign of (8) in the limit is determined by the difference of model size, which is always positive. That is, SVMIC_H can identify the true model from all the overfitted models for sufficiently large n. This result is summarized in Lemma 3.

Lemma 3 *Under conditions (A1)-(A8) and $\lambda_n = 1/n$, we have*

$$\Pr(\inf_{S:S\in\Omega_+} SVMIC_H(S) > SVMIC_H(S^*)) \to 1.$$

as $n \to \infty$.

To conclude the model selection consistency, we also need to consider all the underfitted models. This requires a different analysis because for every underfitted model $S \in \Omega_-$, the

difference of the model size $|S| - |S^*|$ can be negative and thus the decomposition in (7) is not helpful. However, one can always add relevant features to the underfitted model and study the enlarged model instead. To be more specific, for every $S \in \Omega_-$, one can always create the enlarged model $\tilde{S}$ such that $\tilde{S} = S \cup S^*$. Note that $\tilde{S}$ is either an overfitted model or the true model. The model $\tilde{S}$ which includes all the signals bridges the underfitted and overfitted model space through the simple fact

$$\begin{aligned}&\inf_{S:S\in\Omega_-} \mathrm{SVMIC}_H(S) - \mathrm{SVMIC}_H(S^*)\\ =&\inf_{S:S\in\Omega_-} \{[\mathrm{SVMIC}_H(S) - \mathrm{SVMIC}_H(\tilde{S})] + [\mathrm{SVMIC}_H(\tilde{S}) - \mathrm{SVMIC}_H(S^*)]\}.\end{aligned}$$

By Lemma 3, in the limit the difference $\mathrm{SVMIC}_H(\tilde{S}) - \mathrm{SVMIC}_H(S^*)$ is non-negative for every $S \in \Omega_-$ (could be exactly 0). Note also that the difference between S and $\tilde{S}$ is at least one missing relevant feature. According to the assumption that the signals do not diminish to 0 as sample size increases, one can show the model with more signals always produces a strictly smaller sum of hinge loss in the limit. That is, for sufficiently large n, we always have

$$\sum_{i=1}^{n}(1 - Y_i\mathbf{X}_{i,S}^T\widehat{\boldsymbol{\beta}}_S)_+ - \sum_{i=1}^{n}(1 - Y_i\mathbf{X}_{i,\tilde{S}}^T\widehat{\boldsymbol{\beta}}_{\tilde{S}})_+ \geq C > 0$$

for every $S \in \Omega_-$ and some constant C does not depend on S. Then we arrive at the following result for the underfitted model space.

Lemma 4 *Under conditions (A1)-(A8) and $\lambda_n = 1/n$, we have*

$$\Pr(\inf_{S:S\in\Omega_-} SVMIC_H(S) > SVMIC_H(S^*)) \to 1.$$

as $n \to \infty$.

By combing Lemma 3 and Lemma 4, we can conclude the model selection consistency of SVMIC_H in the diverging model space.

Theorem 5 *Under conditions (A1)-(A8) and $\lambda_n = 1/n$, we have*

$$\Pr(\hat{S} = S^*) \to 1.$$

as n, $p \to \infty$, where $\widehat{S} = \arg\min_{S:|S|\leq M_n} SVMIC_H(S)$.

3.4 Application to tuning parameter selection in penalized SVMs

Theorem 1 states that SVMIC_H can identify the true model from Ω. However, in practice it can be very time-consuming and even infeasible to calculate $\mathrm{SVMIC}_H(S)$ for every $S \in \Omega$. One possible approach is to form a solution path via penalized SVM and only consider the candidate models on the path. The idea of using solution path has been shown to greatly reduce the computation burden, see Mazumder et al. (2011). For the solution path of penalized SVM, Hastie et al. (2004) studied the L_1 penalized SVM and showed that the solution path is piece-wise linear in C which is the regularization parameter in (1).

Model selection on the solution path is essentially a tuning parameter selection problem. Recently, several methods have been proposed for choosing the tuning parameter based on the BIC-type information criterion, including Wang et al. (2009) for penalized linear regression, Kawano (2012) for bridge regression, Lee et al. (2014) for penalized quantile regression and Fan and Tang (2013) for penalized generalized linear model. Following the ideas therein, we propose to choose the shrinkage level of penalized SVMs based on the modified support vector machine information criterion. Let $\widehat{\boldsymbol{\beta}}_{\lambda_n}^T = (\hat{\beta}_{\lambda_n,0}, \hat{\beta}_{\lambda_n,1}, \ldots, \hat{\beta}_{\lambda_n,p})$ be the solution to some penalized SVM with a tuning parameter λ_n. That is,

$$\widehat{\boldsymbol{\beta}}_{\lambda_n} = \arg\min_{\boldsymbol{\beta}} \{\frac{1}{n}\sum_{i=1}^{n}(1 - Y_i\mathbf{X}_i^T\boldsymbol{\beta})_+ + \sum_{j=1}^{p} p_{\lambda_n}(\beta_j)\}, \tag{9}$$

where $p_{\lambda_n}(\cdot)$ is some penalty function with a tuning parameter λ_n. Denote $\widehat{S}_{\lambda_n} = \{j : 1 \leq j \leq p, \hat{\beta}_{\lambda_n,j} \neq 0\}$. We define the information criterion for choosing tuning parameter λ_n as

$$\mathrm{SVMIC}_H(\lambda_n) = \sum_{i=1}^{n}(1 - Y_i\mathbf{X}_i^T\widehat{\boldsymbol{\beta}}_{\lambda_n})_+ + L_n|\widehat{S}_{\lambda_n}|\log(n),$$

where L_n is defined in $\mathrm{SVMIC}_H(S)$. The selected tuning parameter is the one that minimizes the information criterion and results in the model size within the restricted model space, that is,

$$\widehat{\lambda}_n = \arg\min_{\lambda:|\widehat{S}_\lambda|\leq M_n} \mathrm{SVMIC}_H(\lambda).$$

This information criterion for selecting tuning parameter can be applied to various penalized approaches for sparse SVMs. Note that the feature selection consistency of the SCAD penalized SVM is shown to rely on the proper choice of the tuning parameter (Zhang et al., 2014), where resampling procedure such as five-fold cross-validation is commonly used in practice. As we will also show in our numerical findings in Section 4.2, the proposed information criterion $\mathrm{SVMIC}_H(\lambda_n)$ usually select the shrinkage level that leads to the correct model size. The tuning parameter selected by cross-validation, however, is more likely to be under-penalized and lead to an overfitted model. Furthermore, the cross-validation is more computationally intensive than information criterion and hence less desirable when the number of features is large.

4. Simulations

In this section we study the finite-sample performance of SVMIC_H. We are interested in the model selection ability of $\mathrm{SVMIC}_H(S)$ and the tuning parameter selection ability of $\mathrm{SVMIC}_H(\lambda_n)$. We also examine the effect of different choices of L_n in the definition of SVMIC_H. For all simulations, we consider the rates $\log(\log(n))$, $\sqrt{\log(n)}$, $\log(n)$ and $n^{-1/3}$ for L_n. We compare with SVMIC_L in Claeskens et al. (2008) and the extended Bayesian information criterion (EBIC) proposed in Chen and Chen (2008). Note that EBIC is originally proposed for model selection in the diverging model space in the framework of regression and it has not been applied into classification problem. However, the main strategy therein is to add an additional term $\log(\binom{p}{|S|})\log(n)$ in the BIC penalty, where $\binom{p}{|S|}$ is the number of $|S|$ combinations chosen from p items. We modify EBIC for model

selection of SVM by selecting the model S that minimizes the criterion

$$\sum_{i=1}^{n}(1-Y_i\mathbf{X}_{i,S}^T\widehat{\boldsymbol{\beta}}_S)_+ + |S|\log(n) + \log\left(\binom{p}{|S|}\right)\log(n).$$

This modification essentially follows the idea in Chen and Chen (2008) and we are interested in its finite-sample performance compared with SVMIC$_H$.

To investigate these issues, we conduct the SCAD penalized SVM, which has been shown to enjoy the model selection consistency for a properly chosen tuning parameter (Zhang et al., 2014). That is, given a specific λ_n, we solve (9) with $p_{\lambda_n}(\cdot)$ being the SCAD penalty defined in Fan and Li (2001). The corresponding optimization problem is a non-convex one, for which the local linear approximation (LLA) algorithm (Zou and Li, 2008) is implemented in all our numerical studies. To be more specific, for step $t \geq 1$, given the solution $\widehat{\boldsymbol{\beta}}^{(t-1)} = (\hat{\beta}_0^{(t-1)}, \ldots, \hat{\beta}_p^{(t-1)})^T$ at the previous step, we update by solving

$$\widehat{\boldsymbol{\beta}}^{(t)} = \arg\min_{\boldsymbol{\beta}}\{\frac{1}{n}\sum_{i=1}^{n}(1-Y_i\mathbf{X}_i^T\boldsymbol{\beta})_+ + \sum_{j=1}^{p}p'_{\lambda_n}(|\hat{\beta}_j^{(t-1)}|)|\beta_j|\},$$

where $p'_{\lambda_n}(\cdot)$ denotes the derivative of $p_{\lambda_n}(\cdot)$. Note that each update step can be easily recast as a linear programming (LP) problem and efficiently solved by many popular solvers. In this paper we take the initial value $\{\widehat{\boldsymbol{\beta}}^{(0)} : \hat{\beta}_j^{(0)} = 0, 0 \leq j \leq p\}$ and claim convergence if the value $||\widehat{\boldsymbol{\beta}}^{(t-1)} - \widehat{\boldsymbol{\beta}}^{(t)}||$ is small enough.

4.1 Model selection of SVMIC$_H(S)$

In this subsection we study the model selection ability of SVMIC$_H(S)$. The data are generated from two models. The first model is adapted from Fisher's linear discriminant analysis (LDA) and the second model is related to probit regression.

- Model 1: $\Pr(Y=1) = \Pr(Y=-1) = 0.5$, $\mathbf{X}|(Y=1) \sim MN(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, $\mathbf{X}|(Y=-1) \sim MN(-\boldsymbol{\mu}, \boldsymbol{\Sigma})$, $q=4$, $\boldsymbol{\mu} = (0.25, 0.25, 0.25, 0.25, 0, \ldots, 0)^T \in \mathbf{R}^p$, $\boldsymbol{\Sigma} = (\sigma_{ij})$ with nonzero elements $\sigma_{ii} = 1$ for $i = 1, 2, \cdots, p$ and $\sigma_{ij} = \rho = -0.2$ for $1 \leq i \neq j \leq q$. The Bayes rule is given by sign$(X_1+X_2+X_3+X_4)$ with Bayes error 21.4%.

- Model 2: $\mathbf{X} \sim MN(\mathbf{0}_p, \boldsymbol{\Sigma})$, $\boldsymbol{\Sigma} = (\sigma_{ij})$ with nonzero elements $\sigma_{ii} = 1$ for $i = 1, 2, \cdots, p$ and $\sigma_{ij} = \rho = 0.4^{|i-j|}$ for $1 \leq i \neq j \leq q$, $\Pr(Y=1) = \Phi(\mathbf{X}^T\boldsymbol{\beta})$ where $\Phi(\cdot)$ is the CDF of the standard normal distribution, $q=4$, $\boldsymbol{\beta} = (0.8, 0.8, 0.8, 0.8, 0, \ldots, 0)^T$. The Bayes rule is sign$(0.57X_1+0.34X_2+0.34X_3+0.57X_4)$ with Bayes error 11.5%.

For both models, we construct the solution path using SCAD penalized SVM for candidate models with $|S| \leq M_n = 50$. Our goal is to check how different information criteria evaluate and select the optimal model from all the candidate models on the solution path. We consider three different (n, p) combinations with p ranging from 2000 to 4000 and n is only one tenth of p. Note that Model 1 is a very noisy model with high Bayes error and Model 2 is less noisy but with moderate correlation between the relevant features. We use 200 replications to see the variations of the results. The columns "Correct", "Underfit" and "Overfit" summarize the percentages over 200 replications for correct model selection, overfitting and underfitting, respectively. The numbers under columns "Signal" and "Noise" are the average numbers of selected relevant and irrelevant features, respectively. We also generate an independent dataset with sample size 10000 to evaluate the test error. Numbers in parentheses are the corresponding standard errors.

Table 1 summarizes the model selection results of SVMIC$_L$, SVMIC$_H$ and the criterion proposed in Chen and Chen (2008) for Model 1. For all (n, p) combinations, SVMIC$_H$ shows uniformly higher percentages to identify the correct model than SVMIC$_L$ regardless of the choices of L_n. It can be seen that in the cases p is much larger than n, SVMIC$_L$ behaves too liberal and tends to select an overfitted model. Note that SVMIC$_H$ also has a significantly lower testing error than SVMIC$_L$ in all settings even when SVMIC$_L$ includes slightly more signals in the model. This agrees with the findings in Fan and Fan (2008) that the accumulation of the noises can greatly blur the prediction power. Though the SVMIC$_H$ with different L_n all performs better than SVMIC$_L$, their performances are not exactly the same. For the criteria with a more aggressive penalty on the model size such as $\log(n)$ and $n^{-1/3}$, there are considerable underfitting when the sample size is small ($n = 200$). As the sample size increases, the difference of L_n decreases. This suggests that although asymptotically the choice of L_n can lie in a wide range of spectrums, for small sample sizes some choices of L_n can be too conservative and may not be much better than SVMIC$_L$ which is too liberal. In general, we find $L_n = \sqrt{\log(n)}$ seems to be a reasonable choice for many scenarios.

Another interesting finding is the comparison to the criterion following the spirit in Chen and Chen (2008). Though its theoretical property has not been investigated, the empirical results suggest that it performs similar to SVMIC$_H$ with $L_n = \sqrt{\log(n)}$ in finite samples. In fact, by using the approximation that $\binom{p}{|S|} \approx p^{|S|}$ when p is much larger than $|S|$, one can easily show that

$$\log(n)|S|\log(\log(n)) < \log(n)|S| + \log(n)\log\left(\binom{p}{|S|}\right) < \log(n)|S|\log(n)$$

for $n < p < 10^3 n$ and a very wide range of n. This provides some evidence that the criterion directly adapted from Chen and Chen (2008) behaves more libearal than SVMIC$_H$ with $L_n = \log(n)$ but is more aggressive than SVMIC$_H$ with $L_n = \log(\log(n))$.

Table 2 summarizes the model selection results for Model 2. The SVMIC$_H$ with $\log(\log(n))$ and $\sqrt{\log(n)}$ as L_n perform uniformly better than SVMIC$_L$ and the criterion in Chen and Chen (2008) for all scenarios. Due to the correlations among the signals, the more aggressive choices of L_n suffer from considerable underfitting. Again our empirical results suggest that $L_n = \sqrt{\log(n)}$ seems to be an appropriate choice for a wide range of problems.

4.2 Tuning parameter selection of SVMIC$_H(\lambda)$

In this subsection we examine the tuning parameter selection ability of SVMIC$_H(\lambda)$. The data is generated from the following model.

- $\Pr(Y=1) = \Pr(Y=-1) = 0.5$, $\mathbf{X}|(Y=+1) \sim MN(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, $X|(Y=-1) \sim MN(-\boldsymbol{\mu}, \boldsymbol{\Sigma})$, $q=5$, $\boldsymbol{\mu} = (0.1, 0.2, 0.3, 0.4, 0.5, 0\ldots, 0) \in \mathbf{R}^p$, $\boldsymbol{\Sigma} = (\sigma_{ij}) = \mathbf{1}_p$ nonzero

Table 1: Simulation results for Model 1 over 200 replications

Method	C(%)	O(%)	U(%)	Signal	Noise	Test Error(%)
		$n = 200,\ p = 2000$

elements $\sigma_{ii} = 1$ for $i = 1, 2, \cdots, p$ and $\sigma_{ij} = \rho = -0.2$ for $1 \le i \ne j \le q$. The Bayes rule is $\text{sign}(2.67X_1+2.83X_2+3X_3+3.17X_4+3.33X_5)$ with Bayes error: 6.3%.

We consider $p = 2000$ and 3000 and $n = 10^{-1}p$. Once the data is generated, we construct the solution path of SCAD penalized SVM on a fine grid of λ for candidate models with $|S| \le M_n = 50$. We then choose the best λ based on the definition of $\text{SVMIC}_H(\lambda)$. Similarly as the simulations for model selection, we compare with $\text{SVMIC}_L(\lambda)$ and the criterion in Chen and Chen (2008). We also implement five-fold cross-validation (denoted by 5-CV) and an adjusted version of five-fold cross-validation version (denoted by 5-CV Adj.). The adjusted 5-CV selects the most parsimonious model with MSE less than one standard error above the regular 5-CV. It is known that the adjusted 5-CV performs better than regular 5-CV in terms of selection consistency. An independent dataset with sample size 10000 is generated to evaluate the test error. This procedure is repeated for 100 replications to study the variations of the results.

Table 3 summarizes the tuning parameter selection results. It can be seen that the tuning parameter selected by SVMIC_L often leads to seriously overfitted models. As the sample size increases, SVMIC_H with all choices of L_n have a much higher chance to identify the correct model than SVMIC_L. The tuning parameter selected by SVMIC_H with $L_n = \sqrt{\log(n)}$ seems to give the most appropriate level of regularization to the model. It is not surprising that this SVMIC_H leads to great prediction power in these high dimensional cases. The

performances of five-fold cross-validation and its adjusted version are slightly worse than those of SVMIC_H with L_n fixed at $\log(\log(n))$ and $\sqrt{\log(n)}$. Notice that the computation burden of selecting tuning parameter via information criterion is much lower than cross-validation. This makes our proposed information criteria desirable especially in the case with very large p.

5. Real data examples

5.1 MAQC-II breast cancer data

In this section we consider a real-world example from the breast cancer dataset which is part of the MicroArray Quality Control (MAQC)-II project. The preprocessed data can be downloaded from GEO databases with accession number GSE20194. There are 278 patient samples in the data and each is described by 22283 genes. Among the 278 samples, 164 patients have positive estrogen receptor (ER) status and 114 have negative ER status. Our goal is to predict the biological endpoint labeled by ER status and pick up the relevant genes.

We randomly choose 50 samples from positive ER status and 50 samples from negative ER status as the training data. The remaining 114 positive and 64 negatives are used for evaluating the prediction error, resulting in a test data of 178 patients. The data are

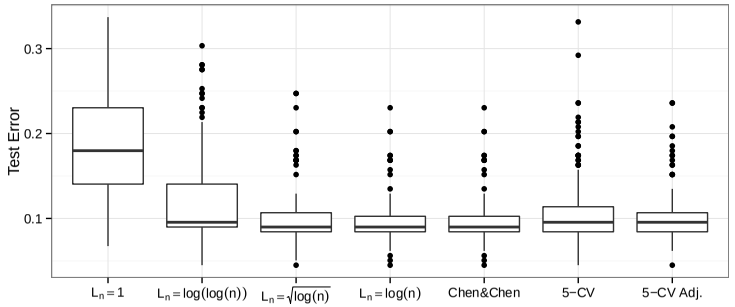
standardized before fitting the classifier. To reduce the computation burden, only 3000 genes with largest absolute values of the two sample t-statistics are used. Such simplification has been considered in Cai and Liu (2011). Though only 3000 genes are used, the classification result is satisfactory. We implement the SCAD penalized SVM to construct the solution path and set the range of λ as $\{2^{-15}, 2^{-14}, \ldots, 2^3\}$. The models on the solution path are selected by SVMIC_L (equivalent to $L_n = 1$), SVMIC_H with L_n at $\log(\log(n))$, $\sqrt{\log(n)}$ and $\log(n)$, the criterion adapted from Chen and Chen (2008), five-fold cross-validations and its adjusted version. This procedure is repeated for 200 replications. The corresponding standard errors are summarized in parentheses. Notice that the 3000 genes with the largest absolute values of t-statistics are pre-selected only using the training data to avoid overfitting so they may be different across the 200 random partitions of the data.

Table 4 summarizes the averages and standard errors for MAQC-II breast cancer data. The criterion $\text{SVMIC}_H(\lambda)$ performs uniformly better than $\text{SVMIC}_L(\lambda)$ regardless of the choice of L_n. It can be easily seen that $\text{SVMIC}_L(\lambda)$ leads to overfitted models in this dataset and has a significant higher misclassification rate. This is in accordance with the theoretical findings in Section 3 that SVMIC_L can be too liberal when the sample size is not comparable to the number of features, while SVMIC_H is a consistent model selection criterion. For this dataset, SVMIC_H with L_n at $\sqrt{\log(n)}$ and $\log(n)$ and the criterion from Chen and Chen (2008) perform the best and are slightly better than cross-validation methods. As in previous arguments, the criterion adapted from the EBIC in Chen and Chen (2008) performs similarly as SVMIC_H with L_n between $\log(\log(n))$ and $\log(n)$ for a wide range of combinations of n and p. Figure 1 summarizes the distributions of test errors over the 200 random partitions of the data for different methods. Note that SVMIC_H is a more

Figure 1: Test error for MAQC-II breast cancer datasets over 200 random partitions



stable method than cross-validations across the partitions of the data. Furthermore, cross-validation based on data resampling is more computationally intensive and this discrepancy is expected to increase dramatically if we take all the genes into consideration, which makes the cross-validation less feasible than information criterion method.

Table 4: Results for MAQC-II breast cancer datasets over 200 random partitions

6. Discussion

In this paper we consider model selection information criterion for support vector machines in the diverging model space. We show that the information criterion proposed in Claeskens et al. (2008) is consistent when the number of features is fixed but can be too liberal if the dimensionality is diverging. A new support vector machine information criterion is proposed for model selection in high dimensions. Based on the uniform convergence rate, we prove that the new information criterion enjoys the model selection consistency even when the number of variables diverges exponentially fast with the sample size. We also link this information criterion to tuning parameter selection for penalized support vector machines. The proposed information criterion is more scalable and easier to compute than resampling techniques such as cross-validation. Simulations and real data examples confirm the model

selection consistency and the ability of selecting tuning parameter when the number of features is much larger than the sample size.

There are several issues yet to be investigated. In this paper we assume that the size of the true model is fixed and the smallest signal does not diminish to zero as the sample size increases. Minimum signal condition has been used in many papers including Fan and Peng (2004) and Fan and Lv (2011). It seems that our condition is stronger than theirs. It is possible to relax this condition. We could possibly assume that $q = q_n$ diverges with n such that $q_n = O(n^{a_1})$ for some $0 \le a_1 < 1/2$. Then we can allow the minimum magnitude of the nonzero-signal to diminish to zero at an appropriate rate such as $\min_{1\le j\le q_n} |\beta_j^*| > an^{-(1-a_2)/2}$ for some constant $a > 0$ and $2a_1 < a_2 \le 1$. In general, the condition we impose on $\min_{1\le j\le q_n} |\beta_j^*|$ is intertwined with the conditions on q and the matrix $\mathbf{X}$, which would be the same for any other high-dimensional regression problem. For a detailed discussion on the beta-min condition in the setting of Lasso regression, we refer to Section 7.4 of Bühlmann et al. (2011). Another direction of interest is to extend the information criterion to nonlinear support vector machine. It is well known that the linear support vector machine can be easily extended to nonlinear feature space using the "kernel trick". Note that it is possible to extend the results in this paper to reproducing kernel Hilbert space with polynomial kernels. For Gaussian radial basis kernels, however, the direct generalization can be problematic as the corresponding reproducing kernel Hilbert space is infinite dimensional. A refined definition of the size of model will be needed in that case and will lead to a more comprehensive study of support vector machine information criterion.

Appendix A.

In this appendix we prove the following results from Section 3.2:

Lemma 1 *Assuming p is a fixed number and $\lambda_n = 1/n$. Under conditions (A1)-(A4) and (A6)-(A7), we have*

$$\Pr(\widehat{S} = S^*) \to 1$$

as $n \to \infty$, where $\widehat{S} = \arg\min_{S:|S|\le M} SVMIC_L(S)$. ■

Proof. Under regularity conditions, Koo et al. (2008) showed $\widehat{\boldsymbol{\beta}}_S$ is root-n consistent in fixed p case for every $S \in \{S : |S| \le M_n\}$. This pointwise result is enough for Lemma 1 since the model space is fixed. The proof is then similar to Lemma 3 and Lemma 4 for diverging p with the uniform convergence rate $\sqrt{|S|\log(p)/n}$ substituted by $\sqrt{n}^{-1}$ and thus is omitted here.

Lemma 2 *Under conditions (A1)-(A7) and $\lambda_n = 1/n$, we have*

$$\sup_{S:|S|<M_n, S\supset S^*} ||\widehat{\boldsymbol{\beta}}_S - \boldsymbol{\beta}_S^*|| = O_p(\sqrt{|S|\log(p)/n}).$$

■

Proof. Recall that $\widehat{\boldsymbol{\beta}}_S = \arg\min_{\boldsymbol{\beta}_S}\{1/n\sum_{i=1}^n(1 - Y_i\mathbf{X}_{i,S}^T\boldsymbol{\beta}_S)_+ + \lambda_n/2||\boldsymbol{\beta}_S^+||^2\}$. We will show that for any $0 < \eta < 1$, there exists a large constant $\triangle$ such that for sufficient large n,

$$\Pr(\inf_{|S|\le M_n, S\supset S^*}\inf_{||\mathbf{u}||=\triangle} l_S(\boldsymbol{\beta}_S^* + \sqrt{|S|\log(p)/n}\mathbf{u}) > l_S(\boldsymbol{\beta}_S^*)) > 1 - \eta$$

where $l_S(\boldsymbol{\beta}_S) = 1/n\sum_{i=1}^n(1 - Y_i\mathbf{X}_{i,S}^T\boldsymbol{\beta}_S)_+ + \lambda_n/2||\boldsymbol{\beta}_S^+||^2$. By the convexity of the hinge loss, this implies that with probability $1-\eta$, we have $\sup_{S:|S|\le M_n, S\supset S^*} ||\widehat{\boldsymbol{\beta}}_S - \boldsymbol{\beta}_S^*|| \le \triangle\sqrt{|S|\log(p)/n}$ and thus Lemma 2 holds.

Notice that we can decompose $l_S(\boldsymbol{\beta}_S^* + \sqrt{|S|\log(p)/n}\mathbf{u}) - l_S(\boldsymbol{\beta}_S^*)$ as

$$\begin{aligned}
&l_S(\boldsymbol{\beta}_S^* + \sqrt{|S|\log(p)/n}\mathbf{u}) - l_S(\boldsymbol{\beta}_S^*)\\
=&1/n\sum_{i=1}^n\{(1 - Y_i\mathbf{X}_{i,S}^T(\boldsymbol{\beta}_S^* + \sqrt{|S|\log(p)/n}\mathbf{u}))_+ - (1 - Y_i\mathbf{X}_{i,S}^T\boldsymbol{\beta}_S^*)_+\}\\
&+ \lambda_n/2||\boldsymbol{\beta}_S^{*+} + \sqrt{|S|\log(p)/n}\mathbf{u}^+||^2 - \lambda_n/2||\boldsymbol{\beta}_S^{*+}||^2. \qquad (10)
\end{aligned}$$

By the fact $||\boldsymbol{\beta}_S^{*+} + \sqrt{|S|\log(p)/n}\mathbf{u}^+||^2 - ||\boldsymbol{\beta}_S^{*+}||^2 \le \triangle|S|\sqrt{\log(p)|S|/n}$ and $\lambda_n = 1/n$, the difference of penalty terms in (10) is $n^{-1}|S|o(1)$. Denote

$$\begin{aligned}
g_{i,S}(\mathbf{u}) =&(1 - Y_i\mathbf{X}_{i,S}^T(\boldsymbol{\beta}_S^* + \sqrt{|S|\log(p)/n}\mathbf{u}))_+ - (1 - Y_i\mathbf{X}_{i,S}^T\boldsymbol{\beta}_S^*)_+\\
&+\sqrt{|S|\log(p)/n}Y_i\mathbf{X}_{i,S}^T\mathbf{u}\mathbf{1}(1 - Y_i\mathbf{X}_{i,S}^T\boldsymbol{\beta}_S^* \ge 0)\\
&+\mathbb{E}[(1 - Y_i\mathbf{X}_{i,S}^T(\boldsymbol{\beta}_S^* + \sqrt{|S|\log(p)/n}\mathbf{u}))_+] - \mathbb{E}[(1 - Y_i\mathbf{X}_{i,S}^T\boldsymbol{\beta}_S^*)_+].
\end{aligned}$$

It can easily checked that $\mathbb{E}[g_{i,S}(\mathbf{u})] = 0$ for $\{S : |S| \le M_n, S \supset S^*\}$ by the definition of $\boldsymbol{\beta}_S^*$ and $\mathbf{S}(\boldsymbol{\beta}^*) = \mathbf{0}$. Next we consider the difference of hinge loss in (10), which can be further composed as

$$1/n\sum_{i=1}^n\{(1 - Y_i\mathbf{X}_{i,S}^T(\boldsymbol{\beta}_S^* + \sqrt{|S|\log(p)/n}\mathbf{u}))_+ - (1 - Y_i\mathbf{X}_{i,S}^T\boldsymbol{\beta}_S^*)_+\} = 1/n(A_n + B_n),$$

where

$$A_n = \sum_{i=1}^{n} g_{i,S}(\mathbf{u})$$

and

$$B_n = \sum_{i=1}^{n} \big\{ -\sqrt{|S|\log(p)/n} Y_i \mathbf{X}_{i,S}^T \mathbf{u}\mathbf{1}(1 - Y_i \mathbf{X}_{i,S}^T \boldsymbol{\beta}_S^* \geq 0) + \mathbb{E}[(1 - Y_i \mathbf{X}_{i,S}^T (\boldsymbol{\beta}_S^* + \sqrt{|S|\log(p)/n}\mathbf{u}))_+] - \mathbb{E}[(1 - Y_i \mathbf{X}_{i,S}^T \boldsymbol{\beta}_S^*)_+] \big\}.$$

The rest of the proof consists of three steps. Step 1 will show

$$\sup_{|S| \leq M_n, S \supset S^*} \sup_{||\mathbf{u}||=\triangle} |A_n| = |S| o_p(1).$$

Step 2 will show $\inf_{|S| \leq M_n, S \supset S^*} \inf_{||\mathbf{u}||=\triangle} B_n$ dominates the terms of order $|S|o_p(1)$. Step 3 will complete the proof by showing $\inf_{|S| \leq M_n, S \supset S^*} \inf_{||\mathbf{u}||=\triangle} B_n > 0$ for sufficient large n and $\triangle$.

Step 1: The main tool to prove this uniform rate is the covering number introduced in Van Der Vaart and Wellner (1996). It suffices to show that

$$\Pr(\sup_{|S| \leq M_n, S \supset S^*} \sup_{||\mathbf{u}||=\triangle} |S|^{-1} |\sum_{i=1}^{n} g_{i,S}(\mathbf{u}|) > \epsilon) \to 0$$

for any $\epsilon > 0$. Notice that the hinge loss satisfies Lipschitz condition and by condition (A3) $\max_i ||\mathbf{X}_{i,S}|| = O_p(\sqrt{|S|}\log(n))$. It can be easily shown that

$$|S|^{-1} g_{i,S}(\mathbf{u}) \leq 3\triangle |S|^{-1} \sqrt{|S|\log(p)/n} \max_i ||\mathbf{X}_{i,S}||$$

and thus $\sup_{|S| \leq M_n, S \supset S^*} \sup_{||\mathbf{u}||=\triangle} |S|^{-1} g_{i,S}(\mathbf{u}) = o_p(1)$. By Lemma 2.5 of van de Geer (2000), the ball $\{\mathbf{u} : ||\mathbf{u}|| \leq \triangle\}$ in $\mathbf{R}^{|S|+1}$ can be covered by N balls with radius δ where $N \leq ((4\triangle + \delta)/\delta)^{|S|+1}$. Denote $\mathbf{u}^1, \ldots, \mathbf{u}^N$ the centers of the N balls. By the fact that $\sup_{|S| \leq M_n, S \supset S^*} \sqrt{|S|\log(p)/n} \max_i ||\mathbf{X}_{i,S}|| = O_p(1)$, we can take $\delta = (nC)^{-1}|S|$ for some large constant C such that

$$\begin{aligned} &\min_{1 \leq k \leq N} \sup_{|S| \leq M_n, S \supset S^*} \sup_{||\mathbf{u}||=\triangle} |S|^{-1} |\sum_{i=1}^{n} g_{i,S}(\mathbf{u}) - \sum_{i=1}^{n} g_{i,S}(\mathbf{u}^k)| \\ \leq &\sup_{|S| \leq M_n, S \supset S^*} 3\triangle n |S|^{-1} \sqrt{|S|\log(p)/n} \max_i ||\mathbf{X}_{i,S}|| \delta \ \leq \ \epsilon/3 \end{aligned} \tag{11}$$

with probability tending to one. Based on (11), it can be easily shown

$$\begin{aligned} &\Pr(\sup_{|S| \leq M_n, S \supset S^*} \sup_{||\mathbf{u}||=\triangle} |S|^{-1} |\sum_{i=1}^{n} g_{i,S}(\mathbf{u})| > \epsilon) \\ \leq &\sum_{|S| \leq M_n, S \supset S^*} \sum_{k=1}^{N} \Pr(|S|^{-1} |\sum_{i=1}^{n} g_{i,S}(\mathbf{u}^k)| > \epsilon/2) \end{aligned}$$

and $\sum_{i=1}^{n} g_{i,S}(\mathbf{u}^k)$ is sum of independent zero-mean random variables. Notice that

$$\begin{aligned} &(1 - Y_i \mathbf{X}_{i,S}^T (\boldsymbol{\beta}_S^* + \sqrt{|S|\log(p)/n}\mathbf{u}))_+ - (1 - Y_i \mathbf{X}_{i,S}^T \boldsymbol{\beta}_S^*)_+ \\ &+\sqrt{|S|\log(p)/n} Y_i \mathbf{X}_{i,S}^T \mathbf{u}\mathbf{1}(1 - Y_i \mathbf{X}_{i,S}^T \boldsymbol{\beta}_S^* \geq 0) = 0 \end{aligned}$$

when we have $|1 - Y_i \mathbf{X}_{i,S}^T \boldsymbol{\beta}_S^*| > \sqrt{|S|\log(p)/n} \max_i ||\mathbf{X}_{i,S}|| \triangle$. Thus we have

$$\begin{aligned} &\sum_{i=1}^{n} \mathbb{E}[g_{i,S}(\mathbf{u}^k)]^2 = \sum_{i=1}^{n} \mathrm{Var}(g_{i,S}(\mathbf{u}^k)) \\ \leq &\sum_{i=1}^{n} \mathbb{E}[(2\sqrt{|S|\log(p)/n} Y_i \mathbf{X}_{i,S}^T \mathbf{u}^k)^2 \mathbf{1}(|1 - Y_i \mathbf{X}_{i,S}^T \boldsymbol{\beta}_S^*| \leq \sqrt{|S|\log(p)/n} \max_i ||\mathbf{X}_{i,S}|| \triangle)]. \end{aligned} \tag{12}$$

By the bounded largest eigenvalue condition in (A3), we have

$$\sum_{i=1}^{n} \mathbb{E}\{[2\sqrt{|S|\log(p)/n} Y_i \mathbf{X}_{i,S}^T \mathbf{u}^k)]^2 \leq C|S|\log(p).$$

By the bounded conditional density condition (A4), we have

$$\Pr(|1 - Y_i \mathbf{X}_{i,S}^T \boldsymbol{\beta}_S^*| \leq \sqrt{|S|\log(p)/n} \max_i ||\mathbf{X}_{i,S}|| \triangle) \leq C|S| \log n \sqrt{\log(p)/n}.$$

Then based on (12) and Cauchy inequality, we have

$$\sum_{i=1}^{n} \mathbb{E}[g_{i,S}(\mathbf{u}^k)]^2 \leq C|S|^2 \log n (\log(p))^{3/2} n^{-1/2}.$$

Then applying Bernstein inequality and condition (A6), we arrive

$$\begin{aligned} &\sum_{|S| \leq M_n, S \supset S^*} \sum_{k=1}^{N} \Pr(|S|^{-1} |\sum_{i=1}^{n} g_{i,S}(\mathbf{u}^k)| > \epsilon/2) \\ \leq &\exp\{M_n \log(p)\} \exp(N) \exp\{-C(\log(n))^{-1} (\log(p))^{-3/2} n^{1/2}\} \to 0 \end{aligned}$$

as $n \to \infty$. This completes the proof of Step 1.

Step 2: First notice that

$$|\sum_{i=1}^{n} Y_i \mathbf{X}_{i,S}^T \mathbf{u}\mathbf{1}(1 - Y_i \mathbf{X}_{i,S}^T \boldsymbol{\beta}_S^* \geq 0)| \leq (|S|+1)^{1/2} \triangle \max_{0 \leq j \leq p} |\sum_{i=1}^{n} Y_i X_{ij,S} \mathbf{1}(1 - Y_i \mathbf{X}_{i,S}^T \boldsymbol{\beta}_S^* \geq 0)|. \tag{13}$$

Note that $\mathbb{E}[Y_i X_{ij,S} \mathbf{1}(1 - Y_i \mathbf{X}_{i,S}^T \boldsymbol{\beta}_S^* \geq 0)] = 0$ for $0 \leq j \leq p$ by the definition of $\mathbf{S}(\boldsymbol{\beta}^*)$. By Lemma 14.24 of Bühlmann et al. (2011), we also have

$$\max_{0 \leq j \leq p} |\sum_{i=1}^{n} Y_i X_{ij,S} \mathbf{1}(1 - Y_i \mathbf{X}_{i,S}^T \boldsymbol{\beta}_S^* \geq 0)| = O_p(\sqrt{n\log(p)}). \tag{14}$$

By Taylor expansion of hinge loss function at $\boldsymbol{\beta}_S^*$, we have

$$\begin{aligned}&\sum_{i=1}^{n}\{\mathbb{E}[(1-Y_i\mathbf{X}_{i,S}^T(\boldsymbol{\beta}_S^*+\sqrt{|S|\log(p)/n}\mathbf{u}))_+]-\mathbb{E}[(1-Y_i\mathbf{X}_{i,S}^T\boldsymbol{\beta}_S^*)_+]\}\\ =&0.5|S|\log(p)\mathbf{u}^T\mathbf{H}(\boldsymbol{\beta}_S^*+t\sqrt{|S|\log(p)/n}\mathbf{u})\mathbf{u}\end{aligned}\tag{15}$$

for some $0<t<1$. As shown by Koo et al. (2008), under condition (A1) and (A2), $\mathbf{H}(\boldsymbol{\beta})$ is element-wise continuous at $\boldsymbol{\beta}_S^*$, thus

$$\mathbf{H}(\boldsymbol{\beta}_S^*+t\sqrt{|S|\log p/n}\mathbf{u})=\mathbf{H}(\boldsymbol{\beta}_S^*)+o_p(1).$$

It can be easily shown by (13), (14), (15) and condition (A7), $0.5|S|\log(p)\mathbf{u}^T\mathbf{H}(\boldsymbol{\beta}_S^*)\mathbf{u}$ dominates other terms in B_n for sufficient large $\triangle$. This completes the proof of Step 2.

Step 3: Notice that $0.5|S|\log(p)\mathbf{u}^T\mathbf{H}(\boldsymbol{\beta}_S^*)\mathbf{u}>0$ by condition (A7). Recall that the difference of penalty terms in (10) is $n^{-1}|S|o(1)$. Therefore $0.5|S|\log p\mathbf{u}^T\mathbf{H}(\boldsymbol{\beta}_S^*)\mathbf{u}$ dominates all the other terms in (10) for sufficient large n and $\triangle$, which completes the proof.

Lemma 3 *Under conditions (A1)-(A8) and $\lambda_n=1/n$, we have*

$$\Pr(\inf_{S:S\in\Omega_+}SVMIC_H(S)>SVMIC_H(S^*))\to 1.$$

as $n\to\infty$. ■

Proof. By definition we have

$$\begin{aligned}&\inf_{S\in\Omega_+}\mathrm{SVMIC}_H(S)-\mathrm{SVMIC}_H(S^*)\\ =&\inf_{S\in\Omega_+}\{\sum_{i=1}^{n}(1-Y_i\mathbf{X}_{i,S}^T\widehat{\boldsymbol{\beta}}_S)_+-\sum_{i=1}^{n}(1-Y_i\mathbf{X}_{i,S^*}^T\widehat{\boldsymbol{\beta}}_{S^*})_++(|S|-|S^*|)\log(n)L_n\}.\end{aligned}$$

Similar to the proof of Lemma 2, it can be shown that $|\sum_{i=1}^n(1-Y_i\mathbf{X}_{i,S}^T\widehat{\boldsymbol{\beta}}_S)_+-\sum_{i=1}^n(1-Y_i\mathbf{X}_{i,S^*}^T\widehat{\boldsymbol{\beta}}_{S^*})_+|$ is dominated by $|S|\log(p)\mathbf{u}^T\mathbf{H}(\boldsymbol{\beta}_S^*)\mathbf{u}$ with probability tending to one. By conditions (A6)-(A8), we have

$$|\sum_{i=1}^{n}(1-Y_i\mathbf{X}_{i,S}^T\widehat{\boldsymbol{\beta}}_S)_+-\sum_{i=1}^{n}(1-Y_i\mathbf{X}_{i,S^*}^T\widehat{\boldsymbol{\beta}}_{S^*})_+|<(|S|-|S^*|)\log(n)L_n$$

for sufficient large n. Notice that $\inf_{S\in\Omega_+}|S|-|S^*|>0$, which completes the proof.

Lemma 4 *Under Conditions (A1)-(A8) and $\lambda_n=1/n$, we have*

$$\Pr(\inf_{S:S\in\Omega_-}SVMIC_H(S)>SVMIC_H(S^*))\to 1.$$

as $n\to\infty$. ■

Proof. For $S\in\Omega_-$, consider the set $\tilde{S}$ with additional signals such that $\tilde{S}=S\cup S^*$. Notice

$$\mathrm{SVMIC}_H(S)-\mathrm{SVMIC}_H(S^*)=\mathrm{SVMIC}_H(S)-\mathrm{SVMIC}_H(\tilde{S})+\mathrm{SVMIC}_H(\tilde{S})-\mathrm{SVMIC}_H(S^*)$$

for $S\in\Omega_-$. Since $|S^*|$ does not diverge with n, we have $|\tilde{S}|<2M_n$ for sufficiently large n and it can easily seen that Lemma 3 still holds for $\tilde{S}$ with any $S\in\Omega_-$. Therefore with high probability we have $\mathrm{SVMIC}_H(\tilde{S})-\mathrm{SVMIC}_H(S^*)\geq 0$. Thus it suffices to show

$$\Pr(\inf_{S\in\Omega_-}\{\mathrm{SVMIC}_H(S)-\mathrm{SVMIC}_H(\tilde{S})\}>0)\to 1$$

as $n\to\infty$. Notice that

$$\begin{aligned}&1/n\{\mathrm{SVMIC}_H(S)-\mathrm{SVMIC}_H(\tilde{S})\}\\ =&1/n\sum_{i=1}^{n}(1-Y_i\mathbf{X}_{i,S}^T\widehat{\boldsymbol{\beta}}_S)_+-1/n\sum_{i=1}^{n}(1-Y_i\mathbf{X}_{i,\tilde{S}}^T\widehat{\boldsymbol{\beta}}_{\tilde{S}})_++1/n(|S|-|\tilde{S}|)\log(n)L_n\end{aligned}$$

and by condition (A8) $1/n(|S|-|\tilde{S}|)\log(n)L_n\to 0$, it suffices to show

$$\inf_{S\in\Omega_-}\{1/n\sum_{i=1}^{n}(1-Y_i\mathbf{X}_{i,S}^T\widehat{\boldsymbol{\beta}}_S)_+-1/n\sum_{i=1}^{n}(1-Y_i\mathbf{X}_{i,\tilde{S}}^T\widehat{\boldsymbol{\beta}}_{\tilde{S}})_+\}\geq C$$

for some constant $C>0$ that does not depend on S.

Recall that $\widehat{\boldsymbol{\beta}}_S=(\beta_{0,S},\beta_{1,S},\ldots,\beta_{|S|,S})^T\in\mathbf{R}^{|S|+1}$. Denote $\widehat{\boldsymbol{\beta}}_{S,\tilde{S}}\in\mathbf{R}^{|\tilde{S}|+1}$ such that the intercept equals to $\beta_{0,S}$, the j-th element equals to $\beta_{j,S}$ if $j\in S$ and 0 if $j\notin S$ for all $j\in\tilde{S}$. Denote also $\delta=\min_{j\in S^*}|\beta_j^*|$ the smallest signal. Then it can be easily seen that $||\widehat{\boldsymbol{\beta}}_{S,\tilde{S}}-\boldsymbol{\beta}_{\tilde{S}}^*||>\delta$. By Lemma 2 we also have $||\widehat{\boldsymbol{\beta}}_{\tilde{S}}-\boldsymbol{\beta}_{\tilde{S}}^*||<\epsilon$ for arbitrary ϵ and sufficient large n. Therefore there exists $\bar{\boldsymbol{\beta}}_{\tilde{S}}=a\widehat{\boldsymbol{\beta}}_{\tilde{S}}+(1-a)\widehat{\boldsymbol{\beta}}_{S,\tilde{S}}$ for some $0<a<1$ such that

$$||\bar{\boldsymbol{\beta}}_{\tilde{S}}-\boldsymbol{\beta}_{\tilde{S}}^*||=\Delta,$$

where Δ is a positive constant such that $\Delta<c_3$ where c_3 is defined in condition (A7). By the definition of $\widehat{\boldsymbol{\beta}}_{\tilde{S}}$ and the convexity of hinge loss function we have

$$\begin{aligned}&1/n\sum_{i=1}^{n}(1-Y_i\mathbf{X}_{i,\tilde{S}}^T\bar{\boldsymbol{\beta}}_{\tilde{S}})_++\lambda_n/2||\bar{\boldsymbol{\beta}}_{\tilde{S}}^+||^2\\ <&a\{1/n\sum_{i=1}^{n}(1-Y_i\mathbf{X}_{i,\tilde{S}}^T\widehat{\boldsymbol{\beta}}_{\tilde{S}})_++\lambda_n/2||\widehat{\boldsymbol{\beta}}_{\tilde{S}}^+||^2\}\\ &+(1-a)\{1/n\sum_{i=1}^{n}(1-Y_i\mathbf{X}_{i,S}^T\widehat{\boldsymbol{\beta}}_{S,\tilde{S}})_++\lambda_n/2||\widehat{\boldsymbol{\beta}}_{S,\tilde{S}}^+||^2\}\\ <&1/n\sum_{i=1}^{n}(1-Y_i\mathbf{X}_{i,\tilde{S}}^T\widehat{\boldsymbol{\beta}}_{S,\tilde{S}})_++\lambda_n/2||\widehat{\boldsymbol{\beta}}_{S,\tilde{S}}^+||^2\\ =&1/n\sum_{i=1}^{n}(1-Y_i\mathbf{X}_{i,S}^T\widehat{\boldsymbol{\beta}}_S)_++\lambda_n/2||\widehat{\boldsymbol{\beta}}_S^+||^2.\end{aligned}\tag{16}$$

By $\lambda_n=n^{-1}$ we have

$$\lambda_n/2||\bar{\boldsymbol{\beta}}_{\tilde{S}}^+||^2-\lambda_n/2||\widehat{\boldsymbol{\beta}}_S^+||^2\leq C\lambda_n(||\widehat{\boldsymbol{\beta}}_{\tilde{S}}^+||^2+||\widehat{\boldsymbol{\beta}}_S^+||^2)\to 0\tag{17}$$

as $n \to \infty$. Similar to the proof of Lemma 2, under condition (A6) and (A8), it can be shown

$$1/n\sum_{i=1}^{n}(1-Y_i\mathbf{X}_{i,\tilde{S}}^T\widehat{\boldsymbol{\beta}}_{\tilde{S}})_+ - 1/n\sum_{i=1}^{n}(1-Y_i\mathbf{X}_{i,\tilde{S}}^T\boldsymbol{\beta}_{\tilde{S}}^*)_+ \le 1/nC|\tilde{S}|\log(p)\lambda_{\max}(\mathbf{H}(\boldsymbol{\beta}_{\tilde{S}}^*)) \to 0 \quad (18)$$

as $n \to \infty$. Notice that

$$\begin{aligned}
&\inf_{S\in\Omega_-}\{1/n\sum_{i=1}^{n}(1-Y_i\mathbf{X}_{i,\tilde{S}}^T\bar{\boldsymbol{\beta}}_{\tilde{S}})_+ - 1/n\sum_{i=1}^{n}(1-Y_i\mathbf{X}_{i,\tilde{S}}^T\boldsymbol{\beta}_{\tilde{S}}^*)_+\}\\
\ge& 1/n\Big\{\inf_{S\in\Omega_-} n\mathbb{E}[(1-Y_i\mathbf{X}_{i,\tilde{S}}^T\bar{\boldsymbol{\beta}}_{\tilde{S}})_+ - (1-Y_i\mathbf{X}_{i,\tilde{S}}^T\boldsymbol{\beta}_{\tilde{S}}^*)_+]\\
&-\sup_{S\in\Omega_-}\{|\sum_{i=1}^{n}(1-Y_i\mathbf{X}_{i,\tilde{S}}^T\bar{\boldsymbol{\beta}}_{\tilde{S}})_+ - \sum_{i=1}^{n}(1-Y_i\mathbf{X}_{i,\tilde{S}}^T\boldsymbol{\beta}_{\tilde{S}}^*)_+ - n\mathbb{E}[(1-Y_i\mathbf{X}_{i,\tilde{S}}^T\bar{\boldsymbol{\beta}}_{\tilde{S}})_+ - (1-Y_i\mathbf{X}_{i,\tilde{S}}^T\boldsymbol{\beta}_{\tilde{S}}^*)_+]|\}\Big\}.
\end{aligned}$$

Similar to the proof of Lemma 2, it can be shown

$$\begin{aligned}
&\sup_{S\in\Omega_-}\{|\sum_{i=1}^{n}(1-Y_i\mathbf{X}_{i,\tilde{S}}^T\bar{\boldsymbol{\beta}}_{\tilde{S}})_+ - \sum_{i=1}^{n}(1-Y_i\mathbf{X}_{i,\tilde{S}}^T\boldsymbol{\beta}_{\tilde{S}}^*)_+ - n\mathbb{E}[(1-Y_i\mathbf{X}_{i,\tilde{S}}^T\bar{\boldsymbol{\beta}}_{\tilde{S}})_+ - (1-Y_i\mathbf{X}_{i,\tilde{S}}^T\boldsymbol{\beta}_{\tilde{S}}^*)_+]|\}\\
=&O_p(|\sum_{i=1}^{n}Y_i\mathbf{X}_{i,\tilde{S}}^T(\bar{\boldsymbol{\beta}}_{\tilde{S}}-\boldsymbol{\beta}_{\tilde{S}}^*)\mathbf{1}(1-Y_i\mathbf{X}_{i,S}^T\boldsymbol{\beta}_{\tilde{S}}^*\ge 0)|) = O_p(\sqrt{n|\tilde{S}|\log(p)}). \qquad (19)
\end{aligned}$$

By Taylor expansion of hinge loss function, we have

$$\mathbb{E}[(1-Y_i\mathbf{X}_{i,\tilde{S}}^T\bar{\boldsymbol{\beta}}_{\tilde{S}})_+ - (1-Y_i\mathbf{X}_{i,\tilde{S}}^T\boldsymbol{\beta}_{\tilde{S}}^*)_+] \ge 0.5\lambda_{\min}(\mathbf{H}(\tilde{\boldsymbol{\beta}}_{\tilde{S}}^*))\Delta^2 > 0, \qquad (20)$$

where $\tilde{\boldsymbol{\beta}}_{\tilde{S}}^*$ lies in the set defined in condition (A7). By (16)-(20), we have

$$\inf_{S\in\Omega_-}\{1/n\sum_{i=1}^{n}(1-Y_i\mathbf{X}_{i,S}^T\widehat{\boldsymbol{\beta}}_S)_+ - 1/n\sum_{i=1}^{n}(1-Y_i\mathbf{X}_{i,\tilde{S}}^T\widehat{\boldsymbol{\beta}}_{\tilde{S}})_+\} \ge 0.5\lambda_{\min}(\mathbf{H}(\boldsymbol{\beta}_{\tilde{S}}^*))\Delta^2 > 0$$

for sufficient large n, which completes the proof.

Theorem 5 *Under conditions (A1)-(A8) and $\lambda_n = 1/n$, we have*

$$\Pr(\hat{S} = S^*) \to 1.$$

as n, $p \to \infty$, where $\widehat{S} = \arg\min_{S:|S|\le M_n} SVMIC_H(S)$. ■

Proof. The proof can be easily checked by combing the results from Lemma 3 and Lemma 4 and thus is omitted here.

Abstract

Local differential privacy has recently surfaced as a strong measure of privacy in contexts where personal information remains private even from data analysts. Working in a setting where both the data providers and data analysts want to maximize the utility of statistical analyses performed on the released data, we study the fundamental trade-off between local differential privacy and utility. This trade-off is formulated as a constrained optimization problem: maximize utility subject to local differential privacy constraints. We introduce a combinatorial family of extremal privatization mechanisms, which we call staircase mechanisms, and show that it contains the optimal privatization mechanisms for a broad class of information theoretic utilities such as mutual information and f-divergences. We further prove that for any utility function and any privacy level, solving the privacy-utility maximization problem is equivalent to solving a finite-dimensional linear program, the outcome of which is the optimal staircase mechanism. However, solving this linear program can be computationally expensive since it has a number of variables that is exponential in the size of the alphabet the data lives in. To account for this, we show that two simple privatization mechanisms, the binary and randomized response mechanisms, are universally optimal in the low and high privacy regimes, and well approximate the intermediate regime.

Keywords: local differential privacy, privacy-preserving machine learning algorithms, information theoretic utilities, f-divergences, mutual information, statistical inference, hypothesis testing, estimation

1. Introduction

In statistical analyses involving data from individuals, there is an increasing tension between the need to share data and the need to protect sensitive information about the individuals. For example, users of social networking sites are increasingly cautious about their privacy, but still find it inevitable to agree to share their personal information in order to benefit from customized services such as recommendations and personalized search (Acquisti, 2004; Acquisti and Grossklags, 2007). There is a certain utility in sharing data for both data providers and data analysts, but at the same time, individuals want *plausible deniability* when it comes to sensitive information.

For such applications, there is a natural core optimization problem to be solved. Assuming both the data providers and analysts want to maximize the utility of the released data, how can they do so while preserving the privacy of participating individuals? The formulation and study of a framework that addresses the fundamental tradeoff between utility and privacy is the focus of this paper.

1.1 Local differential privacy

The need for data privacy appears in two different contexts: the *local privacy* context, as in when individuals disclose their personal information (e.g., voluntarily on social network sites), and the *global privacy* context, as in when institutions release databases of information of several people or answer queries on such databases (e.g., US Government releases census data, companies like Netflix release proprietary data for others to test state of the art machine learning algorithms). In both contexts, privacy is achieved by *randomizing* the data before releasing it. We study the setting of local privacy, in which data providers do not trust the data collector (analyst). Local privacy dates back to Warner (1965), who proposed the *randomized response* method to provide plausible deniability for individuals responding to sensitive surveys.

A natural notion of privacy protection is making inference of information beyond what is released hard. *Differential privacy* has been proposed in the global privacy context to formally capture this notion of privacy (Dwork, 2006; Dwork et al., 2006b; Dwork and Lei, 2009). In a nutshell, differential privacy ensures that an adversary should not be able to reliably infer an individual's record in a database, even with unbounded computational power and access to every other record in the database. Recently, Duchi et al. (2013) extended the notion of differential privacy to the local privacy context. Formally, consider a setting where there are n data providers each owning a data X_i defined on an input alphabet $\mathcal{X}$. The X_i's are independently sampled from some distribution P_ν parameterized by ν. A statistical privatization mechanism Q is a conditional distribution that maps $X_i \in \mathcal{X}$ stochastically to $Y_i \in \mathcal{Y}$, where $\mathcal{Y}$ is an output alphabet possibly larger than $\mathcal{X}$. The Y_i's are referred to as the privatized (sanitized) views of X_i's. In a non-interactive setting, the same privatization mechanism Q is used locally by all individuals. This setting is shown in Figure 1 for the special case of $n = 2$. For some non-negative ε, we follow the definition of Duchi et al. (2013) and say that a mechanism Q is *ε-locally differentially private* if

$$\sup_{S\subset\mathcal{Y},x,x'\in\mathcal{X}} \frac{Q(S|x)}{Q(S|x')} \leq e^{\varepsilon}, \tag{1}$$

where $Q(S|x) = \mathbb{P}(Y_i \in S|X_i = x)$ represents the privatization mechanism. This ensures that for small values of ε, given a privatized data Y_i, it is (almost) equally likely to have come from any data, i.e. x or x'. A small value of ε means that we require a high level of privacy and a large value corresponds to a low level of privacy. At one extreme, for $\varepsilon = 0$, the privatized output must be independent of the private data, and on the other extreme, for $\varepsilon = \infty$, the privatized output can be made equal to the private data.

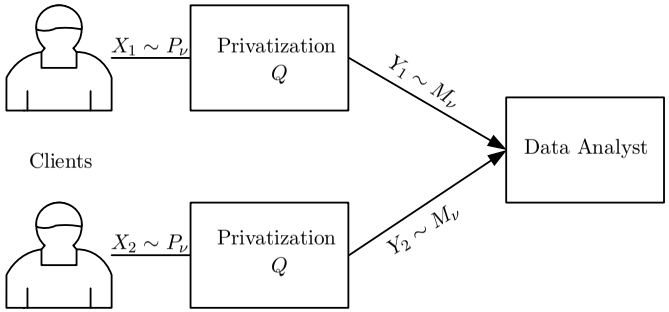

Figure 1: Client i owns X_i sampled from P_ν. Each X_i is privatized by the same ε-locally differentially private mechanism Q. The data analyst only observes the privatized data (Y_i's) and makes an inference on the statistics of the original distribution of the data.

1.2 Information theoretic utilities for statistical analysis

In analyses of statistical databases, the analyst is interested in the *statistics* of the data as opposed to individual records. Naturally, the utility should also be measured in terms of the distribution rather than sample quantities. Concretely, consider a client-server setting where each client with data X_i releases Y_i, a privatized version of the data, via a non-interactive ε-locally differentially private privatization mechanism Q. Assume all the clients use the same privatization mechanism Q, and each client's data is an i.i.d. sample from a distribution P_ν for some parameter ν. Given the privatized views $\{Y_i\}_{i=1}^n$, the data analyst would like to make inferences based on the induced marginal distribution

$$M_\nu(S) \quad \equiv \quad \sum_{x\in\mathcal{X}} Q(S|x)P_\nu(x)\,, \tag{2}$$

for $S \subseteq \mathcal{Y}$. We consider a broad class of convex utility functions, and identify the class of optimal mechanisms, which we call *staircase mechanisms*, in Section 2. We apply this framework to two specific applications: (a) hypothesis testing where the utility is measured in Kullback-Leibler divergence (Section 3) and (b) information preservation where the utility is measured in mutual information (Section 4).

In the binary hypothesis testing setting, $\nu \in \{0,1\}$; therefore, X can be generated by one of two possible distributions P_0 and P_1. The power to discriminate data generated from P_0 to data generated from P_1 depends on the 'distance' between the marginals M_0 and M_1. To measure the ability of such statistical discrimination, our choice of utility of a particular privatization mechanism Q is an information theoretic quantity called Csiszár's f-divergence defined as

$$D_f(M_0||M_1) = \sum_{x\in\mathcal{X}} f\Big(\frac{M_0(x)}{M_1(x)}\Big)\, M_1(x)\,, \tag{3}$$

for some convex function f such that $f(1) = 0$. The Kullback-Leibler (KL) divergence $D_{\mathrm{kl}}(M_0||M_1)$ is a special case with $f(x) = x\log x$, and so is the total variation distance $\|M_0 - M_1\|_{\mathrm{TV}}$ with $f(x) = (1/2)|x-1|$. Such f-divergences capture the quality of statistical inference, such as minimax rates of statistical estimation or error exponents in hypothesis testing (Tsybakov and Zaiats, 2009; Cover and Thomas, 2012). As a motivating example, suppose a data analyst wants to test whether the data is generated from P_0 or P_1 based on privatized views $Y_1, \ldots, Y_n$. According to Chernoff-Stein's lemma, for a bounded type I error probability, the best type II error probability scales as $e^{-n\, D_{\mathrm{kl}}(M_0||M_1)}$. Naturally, we are interested in finding a privatization mechanism Q that minimizes the probability of error by solving the following constraint maximization problem

$$\begin{array}{ll} \underset{Q}{\text{maximize}} & D_{\mathrm{kl}}(M_0\|M_1) \\ \text{subject to} & Q \in \mathcal{D}_\varepsilon \end{array}\,, \tag{4}$$

where $\mathcal{D}_\varepsilon$ is the set of all ε-locally differentially private mechanisms satisfying (1).

In the information preservation setting, X is generated from an underlying distribution P. We are interested in quantifying how much information can be preserved when releasing a private view of the data. In other words, the data provider would like to release an ε-locally differentially private view Y of X that preserves the amount of information in X as much as possible. The utility in this case is measured by the mutual information between X and Y

$$I\left(X;Y\right) = \sum_{\mathcal{X}}\sum_{\mathcal{Y}} P\left(x\right) Q\left(y|x\right) \log\left(\frac{Q\left(y|x\right)}{\sum_{l\in\mathcal{X}} P\left(l\right) Q\left(y|l\right)}\right). \tag{5}$$

Mutual information, as the name suggests, measures the mutual dependence between two random variables. It has been used as a criterion for feature selection and as a measure of similarity between two different clusterings of a data set, in addition to many other applications in signal processing and machine learning. To characterize the fundamental tradeoff between privacy and mutual information, we solve the following constrained maximization problem

$$\begin{array}{ll} \underset{Q}{\text{maximize}} & I(X;Y) \\ \text{subject to} & Q \in \mathcal{D}_\varepsilon \end{array}\,, \tag{6}$$

where $\mathcal{D}_\varepsilon$ is the set of all ε-locally differentially private mechanisms satisfying (1).

Motivated by such applications in statistical analysis, our goal is to provide a general framework for finding optimal privatization mechanisms that maximize information theoretic utilities under local differential privacy. We demonstrate the power of our techniques in a very general setting that includes both hypothesis testing and information preservation.

1.3 Our contributions

We study the fundamental tradeoff between local differential privacy and a rich class of convex utility functions. This class of utilities includes several information theoretic quantities such as mutual information and f-divergences. The privacy-utility tradeoff is posed as a constrained maximization problem: maximize utility subject to local differential privacy constraints. This maximization problem is (a) nonlinear: the utility functions we consider

are convex in Q; (b) non-standard: we are maximizing instead of minimizing a convex function; and (c) infinite dimensional: the space of all differentially private mechanisms is infinite dimensional. We show, in Theorem 2, that for all utility functions considered and any privacy level ε, a *finite* family of *extremal* mechanisms (a finite subset of the corner points of the space of differentially private mechanisms), which we call *staircase* mechanisms, contains the optimal privatization mechanism. We further prove, in Theorem 4, that solving the original privacy-utility problem is equivalent to solving a finite dimensional linear program, the outcome of which is the optimal mechanism. However, solving this linear program can be computationally expensive because it has $2^{|\mathcal{X}|}$ variables. To account for this, we show that two simple staircase mechanisms (the binary and randomized response mechanisms) are optimal in the high and low privacy regimes, respectively, and well approximate the intermediate regime. This contributes an important progress in the differential privacy area, where the privatization mechanisms have been few and almost no exact optimality results are known. As an application, we show that the effective sample size reduces from n to $\varepsilon^2 n$ under local differential privacy in the context of hypothesis testing.

We also study the fundamental tradeoff between utility and approximate differential privacy, a generalized notion of privacy that was first introduced in Dwork et al. (2006a). The techniques we develop for differential privacy do not generalize to approximate differential privacy. To account for this, we use an operational interpretation of approximate differential privacy (developed in Kairouz et al. (2014a)) to prove that a simple mechanism maximizes utility for all levels of privacy when the data is binary.

1.4 Related work

Our work is closely related to the recent work of Duchi et al. (2013) where an upper bound on $D_{\text{kl}}(M_0||M_1)$ was derived under the same local differential privacy setting. Precisely, Duchi et. al. proved that the KL-divergence maximization problem in (4) is at most $4(e^{\varepsilon}-1)^2\|P_1-P_2\|_{TV}^2$. This bound was further used to provide a minimax bound on statistical estimation using information theoretic converse techniques such as Fano's and Le Cam's inequalities. Such tradeoffs also provide tools for comparing various notions of privacy (Barber and Duchi, 2014).

In a similar spirit, we are also interested in maximizing information theoretic quantities under local differential privacy. We generalize the results of Duchi et al. (2013), and provide stronger results in the sense that we (a) consider a broader class of information theoretic utilities; (b) provide explicit constructions for the optimal mechanisms; and (c) recover the existing result of (Duchi et al., 2013, Theorem 1) (with a stronger condition on ε).

Our work also provides a formal connection to an information theoretic notion of privacy called information leakage (Chatzikokolakis et al., 2010; Sankar et al., 2013). Given a privatization mechanism Q, the information leakage is measured by the mutual information between the private data X and the released output Y, i.e. $I(X;Y)$. Information leakage has been widely studied as a practical notion of privacy. However, connections to differential privacy have been studied only indirectly through comparisons to how much distortion is incurred under the two notions of privacy (Sarwate and Sankar, 2014; Wang et al., 2014a). We show that under ε-local differential privacy, $I(X;Y)$ is upper bounded by

$0.5\varepsilon^2 \max_{A\subseteq\mathcal{X}} P(A)P(A^c)+O(\varepsilon^3)$ for small ε. Moreover, we provide an explicit privatization mechanism that achieves this bound.

While there is a vast literature on differential privacy, exact optimality results are only known for a few cases. The typical recipe is to propose a differentially private mechanism inspired by the work of Dwork (2006); Dwork et al. (2006b); McSherry and Talwar (2007) and Hardt and Rothblum (2010), and then establish its near-optimality by comparing the achievable utility to a converse, for example in linear dynamical systems (Wang et al., 2014b), principal component analysis (Chaudhuri et al., 2012; Blocki et al., 2012; Hardt and Roth, 2012; Kapralov and Talwar, 2013), linear queries (Hardt and Talwar, 2010; Hardt et al., 2012), logistic regression (Chaudhuri and Monteleoni, 2008) and histogram release (Lei, 2011). In this paper, we take a different route and solve the utility maximization problem *exactly*.

Optimal differentially private mechanisms are known only in a few cases. Ghosh et al. (2012) showed that the geometric noise adding mechanism is optimal (under a Bayesian setting) for monotone utility functions under count queries (sensitivity one). This was generalized by Geng et. al. (for a worst-case input setting) who proposed a family of mechanisms and proved its optimality for monotone utility functions under queries with arbitrary sensitivity (Geng and Viswanath, 2012, 2013a,b). The family of optimal mechanisms was called *staircase mechanisms* because for any y and any neighboring x and x', the ratio of $Q(y|x)$ to $Q(y|x')$ takes one of three possible values e^{ε}, $e^{-\varepsilon}$, or 1. Since the optimal mechanisms we develop also have an identical property, we retain the same nomenclature.

1.5 Organization

The remainder of the paper is organized as follows. In Section 2, we introduce the family of staircase mechanisms, prove its optimality for a broad class of convex utility functions, and study its combinatorial structure. In Section 3, we study the problem of private hypothesis testing and prove that two staircase mechanisms, the binary and randomized response mechanisms, are optimal for KL-divergence in the high and low privacy regimes, respectively, and (nearly) optimal the intermediate regime. We show, in Section 4, similar results for mutual information. In Section 5, we study approximate local differential privacy, a more general notion of local privacy. Finally, we conclude this paper in Section 6 with a few interesting and nontrivial extensions.

2. Main Results

In this section, we first present a formal definition for staircase mechanisms and prove that they are the optimal solutions to optimization problems of the form (8). We then provide a combinatorial representation for staircase mechanisms that allows us to reduce the infinite dimensional nonlinear program of (8) to a finite dimensional linear program with $2^{|\mathcal{X}|}$ variables. For any given privacy level ε and utility function $U(\cdot)$, one can solve this linear program to obtain the optimal privatization mechanism, albeit with significant computational challenges since the number of variables scales exponentially in the alphabet size. To address this issue, we prove, in Sections 3 and 4, that two simple staircase mechanisms, which we call the binary mechanism and the randomized response mechanism, are optimal

in the high and low privacy regimes, respectively, and well approximate the intermediate regime.

2.1 Optimality of staircase mechanisms

For an input alphabet $\mathcal{X}$ with $|\mathcal{X}| = k$, we represent the set of ε-locally differentially private mechanisms that lead to output alphabets $\mathcal{Y}$ with $|\mathcal{Y}| = \ell$ by

$$\mathcal{D}_{\varepsilon,\ell} = \mathcal{Q}_{k\times\ell} \cap \left\{ Q \ : \ \forall\, x, x' \in \mathcal{X}, S \subseteq \mathcal{Y}, \ \left| \ln \frac{Q\left(S|x\right)}{Q\left(S|x'\right)} \right| \leq \varepsilon \right\},$$

where $\mathcal{Q}_{k\times\ell}$ denotes the set of all $k \times \ell$ dimensional conditional distributions. The set of all ε-locally differentially private mechanisms is given by

$$\mathcal{D}_{\varepsilon} = \cup_{\ell\in\mathbb{N}} \mathcal{D}_{\varepsilon,\ell}. \tag{7}$$

The set of all conditional distributions acting on $\mathcal{X}$ is given by $\mathcal{Q} = \cup_{\ell\in\mathbb{N}} \mathcal{Q}_{k,\ell}$.

We consider two types of utility functions, one for the hypothesis testing setup and another for the information preservation setup. In the hypothesis testing setup, the utility is a function of the privatization mechanism and two priors defined on the input alphabet. Namely, $U\left(P_0, P_1, Q\right) : \mathbb{S}^k \times \mathbb{S}^k \times \mathcal{Q} \to \mathbb{R}_+$, where P_0 and P_1 are positive priors defined on $\mathcal{X}$, and $\mathbb{S}^k$ is the $(k-1)$-dimensional probability simplex. P_ν is said to be positive if $P_\nu\left(x\right) > 0$ for all $x \in \mathcal{X}$. In the information preservation setup, the utility is a function of the privatization mechanism and a prior defined on the input alphabet. Namely, $U\left(P, Q\right) : \mathbb{S}^k \times \mathcal{Q} \to \mathbb{R}_+$, where P is a positive prior defined on $\mathcal{X}$. For notational convenience, we will use $U\left(Q\right)$ to refer to both $U\left(P, Q\right)$ and $U\left(P_0, P_1, Q\right)$.

Definition 1 (Sublinear Functions) *A function $\mu\left(z\right) : \mathbb{R}^k \to \mathbb{R}$ is said to be sublinear if the following two conditions are met*

1. *$\mu\left(\gamma z\right) = \gamma\mu\left(z\right)$ for all $\gamma \in \mathbb{R}_+$.*
2. *$\mu\left(z_1 + z_2\right) \leq \mu\left(z_1\right) + \mu\left(z_2\right)$ for all $z_1, z_2 \in \mathbb{R}^k$.*

Let Q_y be the column of Q corresponding to $Q(y|\cdot)$ and μ be any sublinear function. We are interested in utilities that can be decomposed into a sum of sublinear functions. We study the *fundamental tradeoff between privacy and utility* by solving the following constrained maximization problem

$$\begin{aligned} \underset{Q}{\text{maximize}} \quad & U\left(Q\right) = \sum_{y\in\mathcal{Y}} \mu(Q_y) \\ \text{subject to} \quad & Q \in \mathcal{D}_{\varepsilon} \end{aligned} . \tag{8}$$

This includes maximization over information theoretic quantities of interest in statistical estimation and hypothesis testing such as mutual information, total variation, KL-divergence, and χ^2-divergence (Tsybakov and Zaiats, 2009). Since sub-linearity implies convexity, (8) is in general a complicated nonlinear program: we are maximizing (instead of minimizing) a convex function in Q; further, the dimension of Q might be unbounded: the optimal

privatization mechanism Q^* might produce an infinite output alphabet $\mathcal{Y}$. The following theorem proves that one never needs an output alphabet larger than the input alphabet in order to achieve the maximum utility, and provides a combinatorial representation for the optimal solution.

Theorem 2 *For any sublinear function μ and any $\varepsilon \geq 0$, there exists an optimal mechanism Q^* maximizing the utility in (8) over all ε-locally differentially private mechanisms, such that*

(a) the output alphabet size is at most the input alphabet size, i.e. $|\mathcal{Y}| \leq |\mathcal{X}|$; and

(b) for all $y \in \mathcal{Y}$, and $x, x' \in \mathcal{X}$

$$\left| \ln \frac{Q^*(y|x)}{Q^*(y|x')} \right| \in \{0, \varepsilon\} \ . \tag{9}$$

The first claim of bounded alphabet size is more generally true for any general utility $U\left(Q\right)$ that is convex in Q (not necessarily decomposing into a sum of sublinear functions as in (8)). The second claim establishes that there is an optimal mechanism with an extremal structure; the absolute value of the log-likelihood ratios can only take one of the two extremal values: 0 or e^ε (see Figure 2 for example). We refer to such a mechanism as a staircase mechanism, and define the *family of staircase mechanisms* formally as

$$\mathcal{S}_{\varepsilon} \ \equiv \ \{Q \,|\, \text{ satisfying (9)}\} \ .$$

For all choices of $U\left(Q\right) = \sum_{\mathcal{Y}} \mu(Q_y)$ and any $\varepsilon \geq 0$, Theorem 2 implies that the family of staircase mechanisms includes the optimal solutions to maximization problems of the form (8). Notice that staircase mechanisms are ε-locally differentially private, since any Q satisfying (9) implies that $Q(y|x)/Q(y|x') \leq e^\varepsilon$.

For global differential privacy, we can generalize the definition of staircase mechanisms to hold for all neighboring database queries x, x' (or equivalently within some sensitivity), and recover all known existing optimal mechanisms. Precisely, the geometric mechanism shown to be optimal in Ghosh et al. (2012), and the mechanisms shown to be optimal in Geng and Viswanath (2012, 2013a) (also called staircase mechanisms) are special cases of the staircase mechanisms defined above. We believe that the characterization of these extremal mechanisms and the analysis techniques developed in this paper can be of independent interest to researchers interested in optimal mechanisms for global privacy and more general utilities.

2.2 Combinatorial representation of the staircase mechanisms

Now that we know that staircase mechanisms are optimal, we can try to combinatorially search for the best staircase mechanism for an instance of the function μ and a fixed ε. To this end, we give a simple representation for all staircase mechanisms, exploiting the fact that they are scaled copies of a finite number of patterns.

Let $Q \in \mathbb{R}^{|\mathcal{X}|\times|\mathcal{Y}|}$ be a staircase mechanism, and $k = |\mathcal{X}|$ denote the size of the input alphabet. Then, from the definition of staircase mechanisms, $Q(y|x)/Q(y|x') \in \{e^{-\varepsilon}, 1, e^\varepsilon\}$ and each column $Q(y|\cdot)$ must be proportional to one of the canonical staircase patterns we define next.

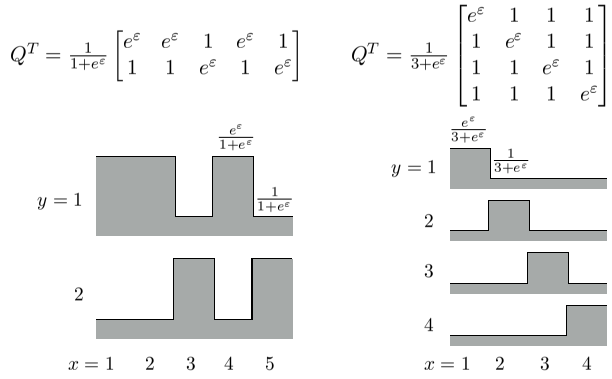

Figure 2: Examples of staircase mechanisms: the binary (left) and the randomized response (right) mechanisms.

Definition 3 (Staircase Pattern Matrix) *Let b_j be the k-dimensional binary vector corresponding to the binary representation of j for $j \leq 2^k - 1$. A matrix $S^{(k)} \in \{1, e^\varepsilon\}^{k \times 2^k}$ is called a staircase pattern matrix if the j-th column of $S^{(k)}$ is $S_j^{(k)} = (e^\varepsilon - 1)\, b_{j-1} + \mathbb{1}$, for $j \in \{1, \ldots, 2^k\}$. Each column of $S^{(k)}$ is a staircase pattern.*

When $k = 3$, there are $2^k = 8$ staircase patterns and the staircase pattern matrix is given by

$$S^{(3)} = \begin{bmatrix} 1 & 1 & 1 & 1 & e^\varepsilon & e^\varepsilon & e^\varepsilon & e^\varepsilon \\ 1 & 1 & e^\varepsilon & e^\varepsilon & 1 & 1 & e^\varepsilon & e^\varepsilon \\ 1 & e^\varepsilon & 1 & e^\varepsilon & 1 & e^\varepsilon & 1 & e^\varepsilon \end{bmatrix} .$$

For all values of k, there are exactly 2^k such patterns, and any column $Q(y|\cdot)$ of Q, a staircase mechanism, is a scaled version of one of the columns of $S^{(k)}$. Using this pattern matrix, we can show that any staircase mechanism Q can be represented as

$$Q \;=\; S^{(k)}\Theta \,, \tag{10}$$

where $\Theta = \mathrm{diag}(\theta)$ is a $2^k \times 2^k$ diagonal matrix and θ is a 2^k-dimensional vector representing the scaling of the columns of $S^{(k)}$. We can now formulate the problem of maximizing the utility as a linear program and prove their equivalence.

Theorem 4 *For any sublinear function μ and any $\varepsilon \geq 0$, the nonlinear program of (8) and the following linear program have the same optimal value*

$$\begin{aligned} \underset{\theta \in \mathbb{R}^{2^k}}{\text{maximize}} \quad & \sum_{j=1}^{2^k} \mu(S_j^{(k)})\theta_j = \mu^T\theta \\ \text{subject to} \quad & S^{(k)}\theta \;=\; \mathbb{1} \\ & \theta \geq 0 \,, \end{aligned} \tag{11}$$

and the optimal solutions are related by (10).

Thus, the infinite dimensional nonlinear program of (8) is now reduced to a finite dimensional linear program. The constraints in (11) ensure that we get a valid probability matrix $Q = S^{(k)}\Theta$ with rows that sum to one. One could potentially solve this LP with 2^k variables but its computational complexity scales exponentially in the alphabet size $k = |\mathcal{X}|$. For practical values of k this might not always be possible. However, in the following sections, we prove that in the high privacy regime ($\varepsilon \leq \varepsilon^*$ for some positive ε^*), there is a single optimal mechanism, which we call the *binary mechanism*, which dominates over all other mechanisms in a very strong sense for all utility functions of practical interest.

In order to understand the above theorem, observe that both the objective function and differential privacy constraints are invariant under *permutations* (or relabelling) of the columns of a privatization mechanism Q. In other words, shuffling the columns of an ε-locally differentially private mechanism Q results in a new ε-locally differentially private mechanism Q' that achieves the same utility. Similarly, both the objective function and differential privacy constraints are invariant under *merging/splitting* of outputs with the same pattern. To be specific, consider a privatization mechanism Q and suppose that there exist two outputs y and y' that have the same pattern, i.e. $Q(y|\cdot) = C\,Q(y'|\cdot)$ for some positive constant C. Then, we can consider a new mechanism Q' by merging the two columns corresponding to y and y'. Let y'' denote this new output. It follows that Q' satisfies the differential privacy constraints and the resulting utility is also preserved. Precisely, using the fact that $Q(y|\cdot) = C\,Q(y'|\cdot)$, it follows that

$$\mu(Q_y) + \mu(Q_{y'}) \;=\; \mu((1+C)Q_y) \;=\; \mu(Q'_{y''}) \,,$$

by the homogeneity property of μ. Therefore, we can naturally define equivalence classes for staircase mechanisms that are equivalent up to a permutation of columns and merging/splitting of columns with the same pattern:

$$[Q] = \{Q' \in \mathcal{S}_\varepsilon \,|\, \exists \text{ a sequence of permutations and merge/split of columns from } Q' \text{ to } Q\} \,.$$

To represent an equivalence class, we use a mechanism in $[Q]$ that is ordered and merged to match the patterns of the pattern matrix $S^{(k)}$. For any staircase mechanism Q, there exists a possibly different staircase mechanism $Q' \in [Q]$ such that $Q' = S^{(k)}\Theta$ for some diagonal matrix Θ with nonnegative entries. Therefore, to solve optimization problems of the form (8), we can restrict our attention to such representatives of equivalent classes. Further, for privatization mechanisms of the form $Q = S^{(k)}\Theta$, the objective function takes the form $\sum_j \mu(S_j^{(k)})\theta_j$, a simple linear function of Θ.

3. Hypothesis Testing

In this section, we study the fundamental tradeoff between local differential privacy and hypothesis testing. In this setting, there are n individuals each with data X_i sampled from a distribution P_ν for a fixed $\nu \in \{0,1\}$. Let Q be a non-interactive privatization mechanism guaranteeing ε-local differential privacy. The output of the privatization mechanism Y_i is distributed according to the induced marginal M_ν defined in (2). With a slight abuse of notation, we will use M_ν and P_ν to represent both probability distributions and probability mass functions. The power to discriminate data sampled from P_0 to data sampled from P_1 depends on the 'distance' between the marginals M_0 and M_1. To measure the ability of such statistical discrimination, our choice of utility of a privatization mechanism Q is an information theoretic quantity called Csiszár's f-divergence defined as

$$D_f(M_0||M_1) = \sum_{\mathcal{Y}} M_1(y) f\Big(\frac{M_0(y)}{M_1(y)}\Big) = U\left(P_0, P_1, Q\right) = U\left(Q\right) \ , \tag{12}$$

for some convex function f such that $f(1) = 0$. The Kullback-Leibler (KL) divergence $D_{\mathrm{kl}}(M_0||M_1)$ is a special case of f-divergence with $f(x) = x\log x$. The total variation distance $\|M_0 - M_1\|_{\mathrm{TV}}$ is also special case with $f(x) = (1/2)|x-1|$. Note that in general, the f-divergence is not necessarily a distance metric since it need not be symmetric or satisfy triangular inequality. We are interested in characterizing the optimal solution to

$$\begin{array}{ll} \underset{Q}{\text{maximize}} & D_f(M_0||M_1) \\ \text{subject to} & Q \in \mathcal{D}_\varepsilon \end{array} \ , \tag{13}$$

where $\mathcal{D}_\varepsilon$ is the set of all ε-locally differentially private mechanisms defined in (7).

A motivating example for this choice of utility is the Neyman-Pearson hypothesis testing framework (Cover and Thomas, 2012). Given the privatized views $\{Y_i\}_{i=1}^n$, the data analyst wants to test whether they are generated from M_0 or M_1. Let the null hypothesis be H_0 : Y_i's are generated from M_0, and the alternative hypothesis $H_1 : Y_i$'s are generated from M_1. For a choice of rejection region $R \subseteq \mathcal{Y}^n$, the probability of false alarm (type I error) is $\alpha = M_0^n(R)$ and the probability of miss detection (type II error) is $\beta = M_1^n(\mathcal{Y}^n \setminus R)$. Let $\beta^{\alpha^*} = \min_{R\subseteq\mathcal{Y}^n, \alpha<\alpha^*} \beta$ denote the minimum type II error achievable while keeping the type I error rate at most α^*. According to Chernoff-Stein lemma (Cover and Thomas, 2012), we know that

$$\lim_{n\to\infty} \frac{1}{n} \log \beta^{\alpha^*} = -D_{\mathrm{kl}}(M_0||M_1) \ .$$

Suppose the analyst knows P_0, P_1, and Q. Then in order to achieve optimal asymptotic error rate, one would want to maximize the KL divergence of the induced marginals, over all ε-locally differentially private mechanisms Q. The results we present in this section (Theorems 5 and 8 to be precise) provide an explicit construction of optimal mechanisms in high and low privacy regimes. Using these optimality results, we prove a fundamental limit on the achievable error rates under differential privacy. Precisely, with data collected from an ε-locally differentially privatization mechanism, one cannot achieve an asymptotic

type II error smaller than

$$\lim_{n\to\infty} \frac{1}{n} \log \beta^{\alpha^*} \geq -\frac{(1+\delta)(e^\varepsilon-1)^2}{(e^\varepsilon+1)} \|P_0 - P_1\|_{\mathrm{TV}}^2 \ \geq -\frac{(1+\delta)(e^\varepsilon-1)^2}{2(e^\varepsilon+1)} D_{\mathrm{kl}}(P_0||P_1) \ ,$$

whenever $\varepsilon \leq \varepsilon^*$, where ε^* is dictated by Theorem 5 and $\delta > 0$ is some arbitrarily small but positive constant. In the equation above, the second inequality follows from Pinsker's inequality. Since $(e^\varepsilon - 1)^2 = O(\varepsilon^2)$ for small ε, the effective sample size is now reduced from n to $\varepsilon^2 n$. This is the price of privacy. In the low privacy regime where $\varepsilon \geq \varepsilon^*$, for ε^* dictated by Theorem 8, one cannot achieve an asymptotic type II error smaller than

$$\lim_{n\to\infty} \frac{1}{n} \log \beta^{\alpha^*} \geq -D_{\mathrm{kl}}(P_0||P_1) + (1-\delta) G(P_0, P_1) e^{-\varepsilon} \ .$$

3.1 Optimality of staircase mechanisms

From the definition of $D_f(M_0||M_1)$, we have that

$$D_f(M_0||M_1) = \sum_{\mathcal{Y}} (P_1^T Q_y) f(P_0^T Q_y / P_1^T Q_y) = \sum_{\mathcal{Y}} \mu\left(Q_y\right) ,$$

where $P_\nu^T Q_y = \sum_{\mathcal{X}} P_\nu(x) Q(y|x)$ and $\mu\left(Q_y\right) = (P_1^T Q_y) f(P_0^T Q_y / P_1^T Q_y)$. For any $\gamma > 0$,

$$\begin{aligned} \mu\left(\gamma Q_y\right) &= \left(P_1^T(\gamma Q_y)\right) f\left(P_0^T\left(\gamma Q_y\right) / P_1^T\left(\gamma Q_y\right)\right) \\ &= \gamma \left(P_1^T Q_y\right) f\left(P_0^T Q_y / P_1^T Q_y\right) \\ &= \gamma \mu\left(Q_y\right) . \end{aligned}$$

Moreover, since the function $\phi(z,t) = tf\left(\frac{z}{t}\right)$ is convex in (z,t) for $0 \leq z,t \leq 1$, then μ is convex in Q_y. Convexity and homogeniety together imply sublinearlity. Therefore, Theorems 2 and 4 apply to $D_f(M_0||M_1)$ and we have that staircases are optimal.

3.2 Optimality of the binary mechanism

For a given P_0 and P_1, the *binary mechanism* is defined as a staircase mechanism with only two outputs $y \in \{0,1\}$ satisfying (see Figure 2)

$$Q(0|x) = \begin{cases} \dfrac{e^\varepsilon}{1+e^\varepsilon} & \text{if } P_0(x) \geq P_1(x) \ , \\ \dfrac{1}{1+e^\varepsilon} & \text{if } P_0(x) < P_1(x) \ . \end{cases} \quad Q(1|x) = \begin{cases} \dfrac{e^\varepsilon}{1+e^\varepsilon} & \text{if } P_0(x) < P_1(x) \ , \\ \dfrac{1}{1+e^\varepsilon} & \text{if } P_0(x) \geq P_1(x) \ . \end{cases} \tag{14}$$

Although this mechanism is extremely simple, perhaps surprisingly, we will establish that it is the optimal mechanism when a high level of privacy is required. Intuitively, the output should be very noisy in the high privacy regime, and we are better off sending just one bit of information that tells you whether your data is more likely to have come from P_0 or P_1.

Theorem 5 *For any pair of distributions P_0 and P_1, there exists a positive ε^* that depends on P_0 and P_1 such that for any f-divergences and any positive $\varepsilon \leq \varepsilon^*$, the binary mechanism maximizes the f-divergence between the induced marginals over all ε-locally differentially private mechanisms.*

This implies that in the high privacy regime, which is a typical setting studied in much of the differential privacy literature, the binary mechanism is universally optimal for all f-divergences. In particular this threshold ε^* is *universal*, in that it does not depend on the particular choice of which f-divergence we are maximizing. It is only a function of P_0 and P_1. This is established by proving a very strong statistical dominance using Blackwell's celebrated result on comparisons of statistical experiments Blackwell (1953). In a nutshell, we prove that any ε-locally differentially private mechanism can be simulated from the output of the binary mechanism for sufficiently small ε. Hence, the binary mechanism dominates over all other mechanisms and at the same time achieves the maximum divergence. A similar idea has been used previously in (Kairouz et al., 2013) to exactly characterize how much privacy degrades under composition attacks.

The optimality of binary mechanisms is not just for high privacy regimes. The next theorem shows that it is *the* optimal solution of (13) for all ε, when the objective function is the total variation distance: $D_f(M_0||M_1) = \|M_0 - M_1\|_{\text{TV}}$.

Theorem 6 *For any pair of distributions P_0 and P_1, and any $\varepsilon \geq 0$, the binary mechanism maximizes the total variation distance between the induced marginals M_0 and M_1 among all ε-locally differentially private mechanisms.*

When maximizing the KL divergence between the induced marginals, we show that the binary mechanism still achieves good performance for $\varepsilon \leq C$ where C is a constant that does not depend on P_0 and P_1. For the special case of KL divergence, let OPT denote the maximum value of (13) and BIN denote the KL divergence when the binary mechanism is used. The next theorem shows that

$$\text{BIN} \quad \geq \quad \frac{1}{2(e^\varepsilon + 1)^2}\text{OPT} \ .$$

Theorem 7 *For any ε and any pair of distributions P_0 and P_1, the binary mechanism is an $1/(2(e^\varepsilon+1)^2)$ approximation of the maximum KL divergence between the induced marginals M_0 and M_1 among all ε-locally differentially private mechanisms.*

Observe that $2(e^\varepsilon + 1)^2 \leq 32$ for $\varepsilon \leq 1$. Therefore, for any $\varepsilon \leq 1$, the simple binary mechanism is at most a constant factor away from the optimal mechanism.

3.3 Optimality of the randomized response mechanism

The *randomized response mechanism* (see Figure 2) is a staircase mechanism with $\mathcal{Y} = \mathcal{X}$ satisfying

$$Q(y|x) = \begin{cases} \dfrac{e^\varepsilon}{|\mathcal{X}| - 1 + e^\varepsilon} & \text{if } y = x \ , \\ \dfrac{1}{|\mathcal{X}| - 1 + e^\varepsilon} & \text{if } y \neq x \ . \end{cases} \tag{15}$$

In other words, the randomized response is a simple randomization over the same alphabet where the true data is released with probability $e^\varepsilon/\left(|\mathcal{X}| - 1 + e^\varepsilon\right)$. We view it as a multiple

choice generalization to the randomized response method proposed by Warner (1965). We now establish that for the special case of optimizing the KL divergence between the induced marginals, the randomized response mechanism is the optimal solution of (13) in the low privacy regime (i.e., $\varepsilon \geq \varepsilon^*$ for some threshold ε^* that depends on P_0 and P_1).

Theorem 8 *There exists a positive ε^* that depends on P_0 and P_1 such that for all P_0 and P_1, and all $\varepsilon \geq \varepsilon^*$, the randomized response mechanism maximizes the KL divergence between the induced marginals among all ε-locally differentially private mechanisms.*

The randomized response mechanism is particularly important because it does not depend on P_0 or P_1. Thus, even if the data providers and analysts do not have access to the priors, they can still use the randomized response mechanism to achieve the optimal (or near-optimal) utility in the moderate to low privacy regimes.

3.4 Numerical Experiments

A typical approach for achieving ε-local differential privacy is to add geometric noise with appropriately chosen variance. For an input with alphabet size $|\mathcal{X}| = k$, this amounts to relabelling the inputs as integers $\{1, \ldots, k\}$ and adding geometric noise, i.e., $Q(y|x) = ((1 - \varepsilon^{1/(k-1)})/(1 + \varepsilon^{1/(k-1)}))\varepsilon^{|y-x|/(k-1)}$ for $y \in \mathbb{Z}$. The output is then truncated at 1 and k to preserve the support.

For 100 instances of randomly chosen P_0 and P_1 defined over an input alphabet of size $|\mathcal{X}| = 6$, we compare the average performance of the binary, randomized response, and geometric mechanisms to the average performance of the optimal staircase mechanism for various values of ε. The optimal staircase mechanism is computed by solving the linear program in Equation (11) for each fixed pair (P_0, P_1) and ε. The left panel of Figure 3 shows the average performance measured by the normalized divergence $D_{\text{kl}}(M_0||M_1)/D_{\text{kl}}(P_0||P_1)$ for all 4 mechanisms. The average is taken over the 100 instances of P_0 and P_1. In the low privacy (large ε) regime, the randomized response achieves optimal performance (which converges exponentially in ε to 1) as predicted. In the high privacy regime (small ε), the binary mechanism achieves optimal performance (which converges quadratically in ε to 0) as predicted. In all regimes, both the binary and randomized response mechanisms provide significant gains over the geometric mechanism.

To illustrate how much worse the binary and the randomized response mechanisms can be relative to the optimal staircase mechanism, we plot in the right panel of Figure 3 the divergence under each mechanism normalized by the divergence under the optimal mechanism. This is done for all 100 instances of P_0 and P_1. In all instances, the binary mechanism is optimal for small ε and the randomized response mechanism is optimal for large ε. However, $D_{\text{kl}}(M_0||M_1)$ under the randomized response mechanism can be as bad as 10% of the optimal one (for small ε). Similarly, $D_{\text{kl}}(M_0||M_1))$ under the binary mechanism can be as bad as 25% of the optimal one (for large ε). To overcome this issue, we propose the following simple strategy: use the better among these two mechanisms. The performance of this strategy is illustrated in Figure 4. For various input alphabet size $|\mathcal{X}| \in \{3, 4, 6, 12\}$, we plot the performance of this mixed strategy for each value of ε and each of the 100 randomly generated instances of P_0 and P_1. This mixed strategy achieves at least 70% for $|\mathcal{X}| = 6$ (and 55% for $|\mathcal{X}| = 12$) of the optimal divergence for all instances. Figure 4 shows

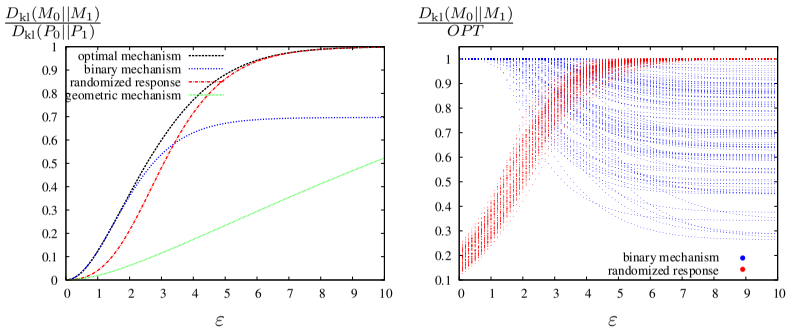

Figure 3: The binary and randomized response mechanisms are optimal in the high-privacy (small ε) and low-privacy (large ε) regimes, respectively, and improve over the geometric mechanism significantly (left). When the regimes are mismatched, $D_{\mathrm{kl}}(M_0||M_1)$ under these mechanisms can be as bad as 10% of the optimal one (right).

that this mixed strategy is not too sensitive to the size of the alphabet k. Therefore, this strategy provides a good mechanism that can be readily used in practice for any value of ε.

3.5 Lower bounds

In this section, we provide converse results on the fundamental limit of differentially private mechanisms; these results follow from our main theorems and are of independent interest in other applications where lower bounds in statistical analysis are studied (Beimel et al., 2008; Hardt and Talwar, 2010; Chaudhuri and Hsu, 2012; De, 2012). For example, a bound similar to (16) was used to provide converse results on the sample complexity for statistical estimation with differentially private data in Duchi et al. (2013).

Corollary 9 *For any $\varepsilon \geq 0$, let Q be any conditional distribution that guarantees ε-local differential privacy. Then, for any pair of distributions P_0, P_1 and any positive $\delta > 0$, there exists a positive ε^* that depends on P_0, P_1 and δ such that for any $\varepsilon \leq \varepsilon^*$ the induced marginals M_0 and M_1 satisfy the bound*

$$D_{\mathrm{kl}}\big(M_0||M_1\big) + D_{\mathrm{kl}}\big(M_1||M_0\big) \quad \leq \quad \frac{2(1+\delta)(e^\varepsilon-1)^2}{(e^\varepsilon+1)} \left\|P_0 - P_1\right\|_{\mathrm{TV}}^2 . \tag{16}$$

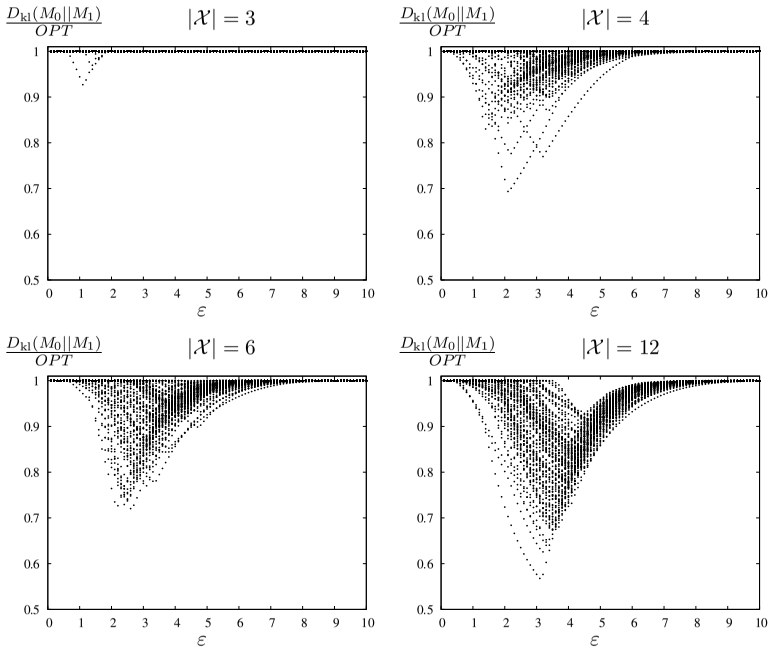

Figure 4: For varying input alphabet size $|\mathcal{X}| \in \{3, 4, 6, 12\}$, at least 55% of the optimal divergence can be achieved by taking the better one between the binary and the randomized response mechanisms.

This follows from Theorem 5 and observing that the binary mechanism achieves

$$\begin{aligned} & D_{\mathrm{kl}}\big(M_0||M_1\big) \\ &= \frac{(e^\varepsilon-1)P_0(T)+1}{e^\varepsilon+1} \log\Big(\frac{1+(e^\varepsilon-1)P_0(T)}{1+(e^\varepsilon-1)P_1(T)}\Big) \\ &\qquad + \frac{(e^\varepsilon-1)P_0(T^c)+1}{e^\varepsilon+1} \log\Big(\frac{1+(e^\varepsilon-1)P_0(T^c)}{1+(e^\varepsilon-1)P_1(T^c)}\Big) \\ &= \frac{(e^\varepsilon-1)^2}{e^\varepsilon+1}(P_0(T)-P_1(T)) + O(\varepsilon^3) \\ &= \frac{(e^\varepsilon-1)^2}{e^\varepsilon+1} \left\|P_0 - P_1\right\|_{\mathrm{TV}}^2 + O(\varepsilon^3) , \end{aligned}$$

where $T \subseteq \mathcal{X}$ is the set of x such that $P_0(x) \geq P_1(x)$. Compared to (Duchi et al., 2013, Theorem 1), we recover their bound of $4(e^\varepsilon-1)^2\|P_0 - P_1\|_{\mathrm{TV}}^2$ with a smaller constant.

We want to note that Duchi et al.'s bound holds for all values of ε and uses a different technique of bounding the KL divergence directly, however no achievable mechanism has been provided. We instead provide an explicit mechanism, that is optimal in high privacy regime.

Similarly, in the low privacy regime, we can show the following converse result.

Corollary 10 *For any $\varepsilon \geq 0$, let Q be any conditional distribution that guarantees ε-local differential privacy. Then, for any pair of distributions P_0 and P_1 and any positive $\delta > 0$, there exists a positive ε^* that depends on P_0 and P_1 and δ such that for any $\varepsilon \geq \varepsilon^*$ the induced marginals M_0 and M_1 satisfy the bound*

$$D_{\mathrm{kl}}\big(M_0||M_1\big) + D_{\mathrm{kl}}\big(M_1||M_0\big) \quad \leq \quad D_{\mathrm{kl}}(P_0||P_1) - (1-\delta)G(P_0,P_1)e^{-\varepsilon}\,. \tag{17}$$

where $G(P_0,P_1) = \sum_{\mathcal{X}}(1-P_0(x))\log(P_1(x)/P_0(x))$.

This follows directly from Theorem 8 and observing that the randomized response mechanism achieves $D_{\mathrm{kl}}(M_0||M_1) = D_{\mathrm{kl}}(P_0||P_1) - G(P_0,P_1)e^{-\varepsilon} + O(e^{-2\varepsilon})$.

Figure 5 illustrates the gap between the divergence achieved by the geometric mechanism described in the previous section and the optimal mechanisms (the binary mechanism for the high privacy regime and the randomized response mechanism for the low privacy regime). For each instance of the 100 randomly generated P_0 and P_1 defined over input alphabets of size $k = 6$, we plot the resulting divergence $D_{\mathrm{kl}}(M_0||M_1)$ as a function of $\|P_0 - P_1\|_{\mathrm{TV}}$ for $\varepsilon = 0.1$, and as a function of $D_{\mathrm{kl}}(P_0||P_1)$ for $\varepsilon = 10$. The binary and the randomized response mechanisms exhibit the scaling predicted by Equation (16) and (17), respectively. Similarly, for total variation, we can get the following converse result.

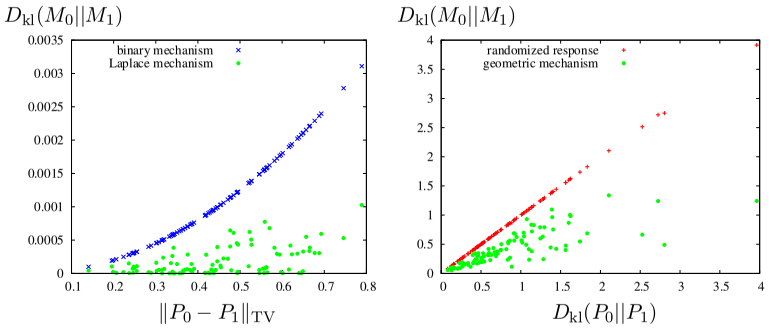

Figure 5: For small $\varepsilon = 0.1$ (left) the binary mechanism achieves the optimal KL divergence, which scales as Equation (16). For large $\varepsilon = 10$ (right) the randomized response achieves the optimal KL divergence, which scales as Equation (17). Both mechanisms improve significantly over the geometric mechanism.

Corollary 11 *For any $\varepsilon \geq 0$, let Q be any conditional distribution that guarantees ε-local differential privacy. Then, for any pair of distributions P_0 and P_1, the induced marginals M_0 and M_1 satisfy the bound $\big\|M_0 - M_1\big\|_{\mathrm{TV}} \leq ((e^{\varepsilon}-1)/(e^{\varepsilon}+1))\,\big\|P_0 - P_1\big\|_{\mathrm{TV}}$, and equality is achieved by the binary mechanism.*

This follows from Theorem 6 and explicitly computing the total variation achieved by the binary mechanism.

4. Information Preservation

In this section, we study the fundamental tradeoff between local privacy and mutual information. Consider a random variable X distributed according to P. The information content in X is captured by entropy

$$H\left(X\right) = -\sum_{\mathcal{X}} P\left(x\right)\log P\left(x\right).$$

We are interested in releasing a differentially private version of X represented by Y. The random variable Y should preserve the information content of X as much as possible while meeting the local differential privacy constraints. Similar to the hypothesis testing setting, we will show that a variant of the binary mechanism is optimal in the high privacy regime and the randomized response mechanism is optimal in the low privacy regime.

Let Q be a non-interactive privatization mechanism guaranteeing ε-local differential privacy. The output of the privatization mechanism Y is distributed according to the induced marginal M given by

$$M(S) \quad = \quad \sum_{x\in\mathcal{X}} Q(S|x)P(x)\,,$$

for $S \subseteq \mathcal{Y}$. With a slight abuse of notation, we will use M and P to represent both probability distributions and probability mass functions. The information content in Y about X is captured by the well celebrated information theoretic quantity called mutual information. The mutual information between X and Y is given by

$$I\left(X;Y\right) = \sum_{\mathcal{X}}\sum_{\mathcal{Y}} P\left(x\right)Q\left(y|x\right)\log\left(\frac{Q\left(y|x\right)}{\sum_{l\in\mathcal{X}}P\left(l\right)Q\left(y|l\right)}\right) = U\left(P,Q\right) = U\left(Q\right).$$

Notice that $I\left(X;Y\right) \leq H\left(X\right)$ and $I\left(X;Y\right)$ is convex in Q (Cover and Thomas, 2012). To preserve the information context in X, we wish to choose a privatization mechanism Q such that the mutual information between X and Y is maximized subject to differential privacy constraints. In other words, we are interested in characterizing the optimal solution to

$$\begin{array}{ll}\underset{Q}{\text{maximize}} & I\left(X;Y\right)\\ \text{subject to} & Q\in\mathcal{D}_{\varepsilon}\end{array}\,, \tag{18}$$

where $\mathcal{D}_{\varepsilon}$ is the set of all ε-locally differentially private mechanisms defined in (7). The above mutual information maximization problem can be thought of as a conditional entropy minimization problem since $I\left(X;Y\right) = H\left(X\right) - H\left(X|Y\right)$.

4.1 Optimal staircase mechanisms

From the definition of $I(X;Y)$, we have that

$$I(X;Y) = \sum_{\mathcal{Y}} \sum_{\mathcal{X}} P(x) Q(y|x) \log \left(\frac{Q(y|x)}{P^T Q_y} \right) = \sum_{\mathcal{Y}} \mu(Q_y),$$

where $P^T Q_y = \sum_{\mathcal{X}} P(x) Q(y|x)$ and $\mu(Q_y) = \sum_{\mathcal{X}} P(x) Q(y|x) \log \left(Q(y|x) / P^T Q_y \right)$. Notice that $\mu(\gamma Q_y) = \gamma \mu(Q_y)$, and by the log-sum inequality, μ is convex. Convexity and homogeneity together imply sublinearity. Therefore, Theorems 2 and 4 apply to $I(X;Y)$ and we have that staircase mechanisms are optimal.

For a given P, the *binary mechanism for mutual information* is defined as a staircase mechanism with only two outputs $y \in \{0,1\}$ (see Figure 2). Let $T \subseteq \mathcal{X}$ be the set that partitions $\mathcal{X}$ into two partitions, T and T^c, such that $|P(T) - P(T^c)|$ is minimized. Precisely,

$$T \in \arg\min_{A \subseteq \mathcal{X}} \left| P(A) - \frac{1}{2} \right|. \tag{19}$$

Observe that there are always multiple choices for T. Indeed, for any minimizing set T, T^c is also a minimizing set since $|P(T) - 1/2| = |P(T^c) - 1/2|$. When there is only one such pair, the binary mechanism is uniquely defined as

$$Q(0|x) = \begin{cases} \dfrac{e^\varepsilon}{1+e^\varepsilon} & \text{if } x \in T, \\ \dfrac{1}{1+e^\varepsilon} & \text{if } x \notin T. \end{cases} \qquad Q(1|x) = \begin{cases} \dfrac{e^\varepsilon}{1+e^\varepsilon} & \text{if } x \notin T, \\ \dfrac{1}{1+e^\varepsilon} & \text{if } x \in T. \end{cases} \tag{20}$$

When there are multiple pairs, any pair (T, T^c) can be chosen to define the binary mechanism. All resulting binary mechanisms are equivalent from a utility maximization perspective.

In what follows, we will establish that this simple mechanism is the optimal mechanism in the high privacy regime. Intuitively, in the high privacy regime, we cannot release more than one bit of information, and hence, the input alphabet is reduced to a binary output alphabet. In this case we have to maximize the information contained in the released bit by maximizing its entropy: $T \in \arg\max_{A \subseteq \mathcal{X}} \big(-P(A)\log P(A) - P(A^c)\log P(A^c) \big) = \arg\max_{A \subseteq \mathcal{X}} |P(A) - 1/2|$ (see Section 9.1 for a proof).

Theorem 12 *For any distribution P, there exists a positive ε^* that depends on P such that for any positive $\varepsilon \leq \varepsilon^*$, the binary mechanism maximizes the mutual information between the input and the output of a privatization mechanism over all ε-locally differentially private mechanisms.*

This implies that in the high privacy regime, the binary mechanism is the optimal solution for (18).

Next, we show that the binary mechanism achieves near-optimal performance for all $(\mathcal{X}, P)$ and $\varepsilon \leq 1$ even when $\varepsilon^* < 1$. Let OPT denote the maximum value of (18) and BIN denote the mutual information achieved by the binary mechanism given in (20). The next theorem shows that

$$\text{BIN} \geq \frac{1}{1+e^\varepsilon} \text{OPT}.$$

Theorem 13 *For any $\varepsilon \leq 1$ and any distribution P, the binary mechanism is an $(1+e^\varepsilon)$-approximation of the maximum mutual information between the input and the output of a privatization mechanism among all ε-locally differentially private mechanisms.*

Note that $1 + e^\varepsilon \leq 4$ for $\varepsilon \leq 1$ which is a commonly studied regime in differential privacy applications. Therefore, we can always use the simple binary mechanism and the resulting mutual information is at most a constant factor away from the optimal.

In the low privacy regime ($\varepsilon \geq \varepsilon^*$), the *randomized response mechanism* defined in(15) is optimal.

Theorem 14 *There exists a positive ε^* that depends on P such that for any distribution P and all $\varepsilon \geq \varepsilon^*$, the randomized response mechanism maximizes the mutual information between the input and the output of as privatization mechanism over all ε-locally differentially private mechanisms.*

4.2 Numerical Experiments

For 100 instances of randomly chosen P defined over input alphabet of size $|\mathcal{X}| = 6$, we compare the average performance of the binary, randomized response, and the geometric mechanisms to the optimal mechanism. We plot (in Figure 6, left) the average performance measured by the normalized mutual information $I(X;Y)/H(X)$ for all 4 mechanisms. The average is taken over the 100 instances of P. In the low privacy (large ε) regime, the randomized response achieves optimal performance as predicted, which converges to one. In the high privacy regime (small ε), the binary mechanism achieves optimal performance as predicted. In all regimes, both mechanisms significantly improve over the geometric mechanism. To illustrate how much worse the binary and randomized response mechanisms can be (relative to the optimal staircase mechanism), we plot (in Figure 6, right) the mutual information under each mechanism normalized by the mutual information under the optimal staircase mechanism. This is done for all 100 instances of P. In all instances, the binary mechanism is optimal for small ε and the randomized response mechanism is optimal for large ε. However, $I(X;Y)$ under the randomized response mechanism can be as bad as 35% of the optimal one (for small ε). Similarly, $I(X;Y)$ under the binary mechanism can be as bad as 40% of the optimal one (for large ε).

For $|\mathcal{X}| \in \{3, 4, 6, 12\}$, we plot (in Figure 7) the performance of better between the binary and randomized response mechanisms normalized by the optimal mechanism for all 100 randomly generated instances of P. This mixed strategy achieves at least 75% for $|\mathcal{X}| = 6$ (and 65% for $|\mathcal{X}| = 12$) of the optimal mutual infirmation for all instances of P. Moreover, it is not sensitive to the size of the alphabet $|\mathcal{X}|$.

4.3 Lower bounds

In this section, we provide converse results on the fundamental limit of locally differentially private mechanisms when utility is measured via mutual information.

Corollary 15 *For any $\varepsilon \geq 0$, let Q be any conditional distribution that guarantees ε-local differential privacy. Then, for any distribution P and any positive $\delta > 0$, there exists a*

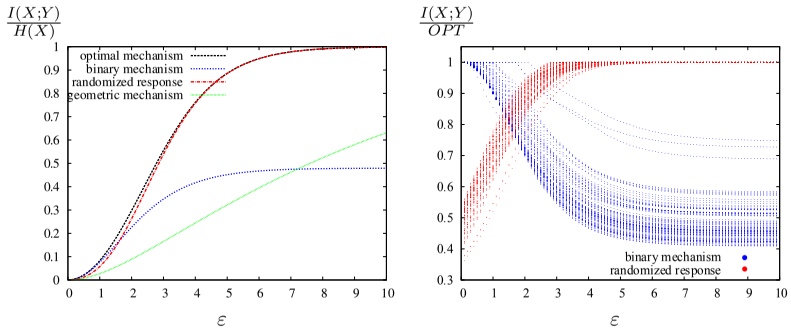

Figure 6: The binary and randomized response mechanisms are optimal in the high-privacy (small ε) and low-privacy (large ε) regimes, respectively, and improve over the geometric mechanism significantly (left). When the regimes are mismatched, $I(X;Y)$ under these mechanisms can each be as bad as 35% of the optimal one (right).

positive ε^* that depends on P and δ such that for any $\varepsilon \leq \varepsilon^*$ the following bound holds

$$I(X;Y) \leq (1+\delta)\frac{1}{2}P(T)P(T^c)\varepsilon^2, \tag{21}$$

where T is defined in (19).

This follows from Theorem 12 (optimality of the binary mechanism) and observing that the binary mechanism achieves

$$\begin{aligned} I(X;Y) &= \frac{1}{e^\varepsilon+1}\left\{P(T)e^\varepsilon \log\frac{e^\varepsilon}{P(T^c)+e^\varepsilon P(T)} + P(T^c)\log\frac{1}{P(T^c)+e^\varepsilon P(T)}\right\} \\ &\quad + \frac{1}{e^\varepsilon+1}\left\{P(T^c)e^\varepsilon \log\frac{e^\varepsilon}{P(T)+e^\varepsilon P(T^c)} + P(T)\log\frac{1}{P(T)+e^\varepsilon P(T^c)}\right\} \\ &= \frac{1}{2}P(T)P(T^c)\varepsilon^2 + O\left(\varepsilon^3\right). \end{aligned}$$

Similarly, in the low privacy regime, we can show the following converse result.

Corollary 16 *For any $\varepsilon \geq 0$, let Q be any conditional distribution that guarantees ε-local differential privacy. Then, for any distributions P and any positive $\delta > 0$, there exists a positive ε^* that depends on P and δ such that for any $\varepsilon \geq \varepsilon^*$ the following bound holds*

$$I(X;Y) \leq H(X) - (1-\delta)(k-1)\varepsilon e^{-\varepsilon}.$$

This follows directly from Theorem 14 (optimality of the randomized response mechanism) and observing that the randomized response mechanism achieves

$$I(X;Y) = H(X) - (k-1)\varepsilon e^{-\varepsilon} + O(e^{-2\varepsilon}). \tag{22}$$

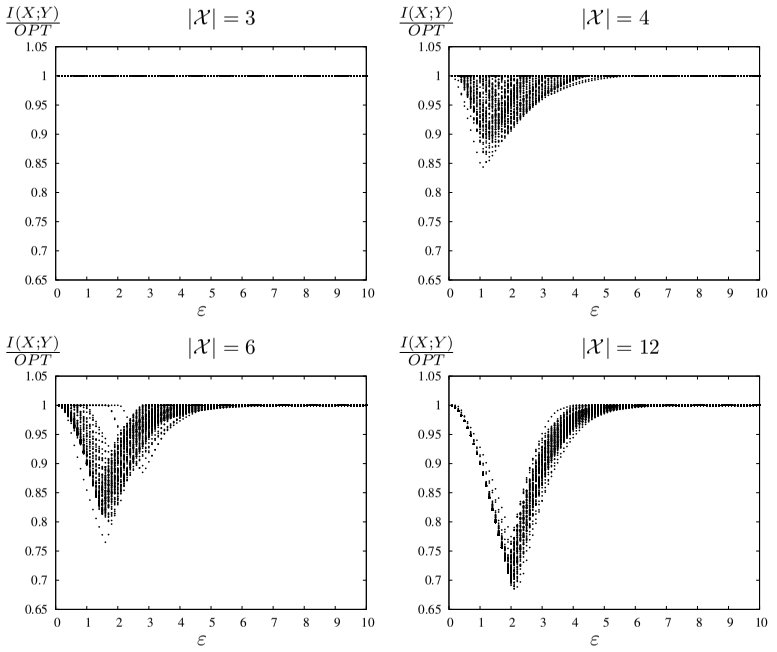

Figure 7: For varying input alphabet size $|\mathcal{X}| \in \{3,4,6,12\}$, at least 65% of the maximum $I(X;Y)$ can be achieved by taking the better one between the binary and the randomized response mechanisms.

Figure 8 illustrates the gap between the mutual information achieved by the geometric mechanism and the optimal mechanisms (the binary mechanism for the high privacy regime and the randomized response mechanism for the low privacy regime). For each instance of the 100 randomly generated P over input of size $k = 6$, we plot the resulting mutual information $I(X;Y)$ as a function of $P(T)P(T^c)$ for $\varepsilon = 0.1$, and as a function of $H(X)$ for $\varepsilon = 10$. The binary and the randomized response mechanisms exhibit the scaling predicted by Equations (21) and (22), respectively.

5. Generalizations to approximate differential privacy

In this section, we generalize the results of the previous sections in the following ways.

1. We consider the class of utility functions that obey the data processing inequality. Consider the composition of two privatization mechanisms $QW = Q \circ W$ where the

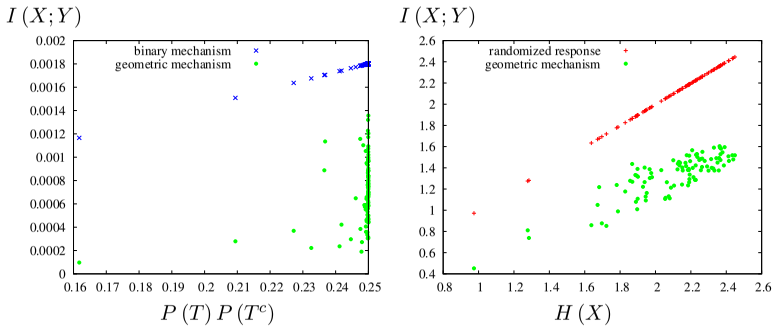

Figure 8: For $\varepsilon = 0.1$ (left) the binary mechanism achieves the maximum $I(X;Y)$, which scales as Equation (21). For $\varepsilon = 10$ (right) the randomized response mechanism achieves the optimal mutual information, which scales as Equation (22).

output of the first mechanism Q is applied to another mechanism W. We say that a utility function $U(\cdot)$ obeys the data processing inequality if the following inequality holds for all Q and W

$$U(QW) \quad \leq \quad U(Q) \, .$$

The following proposition, proved in Section 10, shows that the class of utilities obeying the data processing inequality includes all the utility functions we studied in Section 2.

Proposition 17 *Any utility function that can be written in the form of* $U(Q) = \sum_{\mathcal{Y}} \mu(Q_y)$*, where* μ *is any sublinear function, obeys the data processing inequality.*

2. We consider (ε, δ)-differential privacy which generalizes the notion of ε-differential privacy. (ε, δ)-differential privacy is commonly referred to as approximate differential privacy and it was first introduced in Dwork et al. (2006a). For the release of a random variable $X \in \mathcal{X}$, we say that a mechanism Q is (ε, δ)-locally differentially private if

$$Q(S|x) \leq e^{\varepsilon} Q\left(S|x'\right) + \delta, \tag{23}$$

for all $S \subseteq \mathcal{Y}$ and all $x, x' \in \mathcal{X}$. Note that ε-local differential privacy is a special case of (ε, δ)-local differential privacy where $\delta = 0$.

3. We prove that the *quaternary mechanism*, defined in Equation (24), is optimal for any ε and any δ. This is different from the treatment conducted in the previous sections where we proved the optimality of the binary (randomized response) mechanism for sufficiently small (large) ε and $\delta = 0$.

The treatment in this section, even though more general than the one in previous sections in the ways described above, holds only for binary alphabets (i.e., $|\mathcal{X}| = 2$). Finding optimal privatization mechanisms under (ε, δ)-local differential privacy for larger input alphabets (i.e., $|\mathcal{X}| > 2$) is an interesting open question. Unlike ε-local differential privacy, the privacy constraints under (ε, δ)-local differential privacy no longer decompose into separate constraints on each output y. This makes it difficult to generalize the techniques developed in previous sections of this paper. However, for the special case of binary input alphabets, we can prove the optimality of one mechanism for all values of (ε, δ) and all utility functions that obey the data processing inequality.

For a binary random variable $X \in \mathcal{X} = \{0, 1\}$, the *quaternary mechanism* maps X to a quaternary random variable $Y \in \mathcal{Y} = \{0, 1, 2, 3\}$ and is defined as

$$Q_{\mathrm{QT}}(0|x) = \begin{cases} \delta & \text{if } x = 0 \, , \\ 0 & \text{if } x = 1 \, . \end{cases} \quad Q_{\mathrm{QT}}(1|x) = \begin{cases} 0 & \text{if } x = 0 \, , \\ \delta & \text{if } x = 1 \, . \end{cases} \tag{24}$$

$$Q_{\mathrm{QT}}(2|x) = \begin{cases} (1-\delta)\frac{1}{1+e^{\varepsilon}} & \text{if } x = 0 \, , \\ (1-\delta)\frac{e^{\varepsilon}}{1+e^{\varepsilon}} & \text{if } x = 1 \, . \end{cases} \quad Q_{\mathrm{QT}}(3|x) = \begin{cases} (1-\delta)\frac{e^{\varepsilon}}{1+e^{\varepsilon}} & \text{if } x = 0 \, , \\ (1-\delta)\frac{1}{1+e^{\varepsilon}} & \text{if } x = 1 \, . \end{cases}$$

In other words, the quaternary mechanism passes X unchanged with probability δ and applies the binary mechanism (defined in previous sections) with probability $1 - \delta$. The main result of this section can be stated formally as follows.

Theorem 18 *If* $|\mathcal{X}| = 2$*, then for any* ε*, any* δ*, and any* $U(Q)$ *that obeys the data processing inequality, the quaternary mechanism maximizes* $U(Q)$ *subject to* $Q \in \mathcal{D}_{(\varepsilon,\delta)}$*, the set of all* (ε, δ)*-locally differentially private mechanism.*

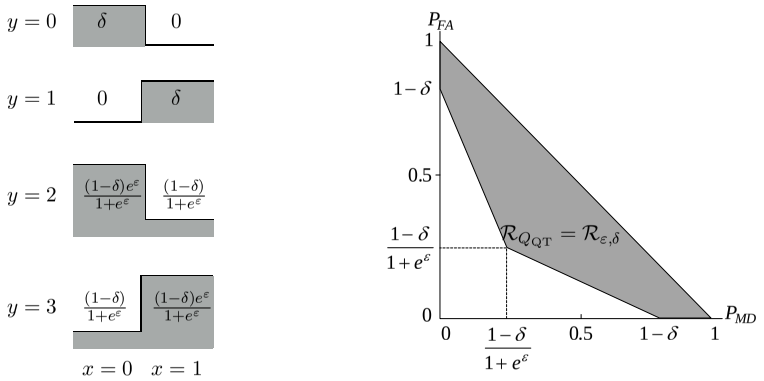
The proof of Theorem 18 depends on an *operational definition* of differential privacy which we describe next. Consider a privatization mechanism Q that maps $X \in \{0, 1\}$ stochastically to $Y \in \mathcal{Y}$. Given Y, construct a binary hypothesis test on whether $X = 0$ or $X = 1$. Any binary hypothesis test is completely described by a, possibly randomized, decision rule $\hat{X} : Y \to \{0, 1\}$. The two types of error associated with $\hat{X}$ are *false alarm:* $\hat{X} = 1$ when $X = 0$, and *miss detection:* $\hat{X} = 0$ when $X = 1$. The probability of false alarm is given by $P_{\mathrm{FA}} = \mathbb{P}(\hat{X} = 1|X = 0)$ while the probability of miss detection is given by $P_{\mathrm{MD}} = \mathbb{P}(\hat{X} = 0|X = 1)$. For a fixed Q, the convex hull of all pairs $(P_{\mathrm{MD}}, P_{\mathrm{FA}})$ for all decision rules $\hat{X}$ defines a two-dimensional *error region* where P_{MD} is plotted against P_{FA}. For example, the quaternary mechanism given in Figure 9a has an error region $\mathcal{R}_{Q_{\mathrm{QT}}}$ shown in Figure 9b.

It turns out that (ε, δ)-local differential privacy imposes the following conditions on the error region of all (ε, δ)-locally differentially private mechanisms

$$P_{\mathrm{FA}} + e^{\varepsilon} P_{\mathrm{MD}} \quad \geq \quad 1 - \delta \, , \quad \text{and} \quad e^{\varepsilon} P_{\mathrm{FA}} + P_{\mathrm{MD}} \quad \geq \quad 1 - \delta \, ,$$

for any decision rule $\hat{X}$. These two conditions define an error region $\mathcal{R}_{\varepsilon,\delta}$ shown in Figure 9b. Interestingly, the next theorem shows that the converse result is also true.

Theorem 19 *A mechanism* Q *is* (ε, δ)*-locally differentially private if and only if* $\mathcal{R}_Q \subseteq \mathcal{R}_{\varepsilon,\delta}$*.*



(a) Privatization mechanism (b) Error region

Figure 9: The quaternary mechanism

The proof of the above theorem can be found in Kairouz et al. (2013). Notice that it is no coincidence that $\mathcal{R}_{Q_{\mathrm{QT}}} = \mathcal{R}_{\varepsilon,\delta}$. This property will be essential in proving the optimality of the quaternary mechanism.

Theorem 19 allows us to benefit from the data processing inequality (DPI) and its converse, which follows from a celebrated result by Blackwell (1953). These inequalities, while simple by themselves, lead to surprisingly strong technical results. Indeed, there is a long line of such a tradition in the information theory literature (see Chapter 17 of Cover and Thomas (2012)). Consider two privatization mechanisms, $Q^{(1)}$ and $Q^{(2)}$. Let Y and Z denote the output of the mechanisms $Q^{(1)}$ and $Q^{(2)}$, respectively. We say that $Q^{(1)}$ dominates $Q^{(2)}$ if there exists a coupling of Y and Z such that X–Y–Z forms a Markov chain. In other words, we say $Q^{(1)}$ dominates $Q^{(2)}$ if there exists a stochastic mapping Q such that $Q^{(2)} = Q^{(1)} \circ Q$.

Theorem 20 *A mechanism $Q^{(1)}$ dominates a mechanism $Q^{(2)}$ if and only if $\mathcal{R}_{Q^{(2)}} \subseteq \mathcal{R}_{Q^{(1)}}$.*

The proof of the above theorem can be found in Blackwell (1953). Observe that by Theorems 20 and 19, and the fact that $\mathcal{R}_{Q_{\mathrm{QT}}} = \mathcal{R}_{\varepsilon,\delta}$, the quaternary mechanism dominates any other differentially private mechanism. In other words, for any differentially private mechanism Q, there exists a stochastic mapping W such that $Q = W \circ Q_{\mathrm{QT}}$. Therefore, for any (ε, δ) and any utility function $U(.)$ obeying the data processing inequality, we have that $U(Q) \leq U(Q_{\mathrm{QT}})$. This finishes the proof of Theorem 18.

6. Discussion

In this paper, we have considered a broad class of convex utility functions and assumed a setting where individuals cannot collaborate (communicate with each other) before releasing

their data. It turns out that the techniques developed in this work can be generalized to find optimal privatization mechanisms in a setting where different individuals can collaborate interactively and each individual can be an analyst (Kairouz et al., 2014b).

Binary hypothesis testing and information preservation are two canonical problems with a wide range of applications. However, there are a number of non-trivial and interesting extensions to our work.

Correlation among data. In some scenarios the X_i's could be correlated (e.g., when different individuals observe different functions of the same random variable). In this case, the data analyst is interested in inferring whether the data was generated from P_0^n or P_1^n, where P_ν^n is one of two possible joint priors on $X_1, ..., X_n$. This is a challenging problem because knowing X_i reveals information about X_j, $j \neq i$. Therefore, the utility maximization problems for different individuals are coupled in this setting.

Robust and m-ary hypothesis testing. In some cases the data analyst need not have access to P_0 and P_1, but rather two classes of prior distribution P_{θ_0} and P_{θ_1} for $\theta_0 \in \Lambda_0$ and $\theta_1 \in \Lambda_1$. Such problems are studied under the rubric of universal hypothesis testing and robust hypothesis testing. One possible direction is to select the privatization mechanism that maximizes the worst case utility: $Q^* = \arg\max_{Q \in \mathcal{D}_\varepsilon} \min_{\theta_0 \in \Lambda_0, \theta_1 \in \Lambda_1} D_f(M_{\theta_0} || M_{\theta_1})$, where M_{θ_ν} is the induced marginal under P_{θ_ν}.

The more general problem of private m-ary hypothesis testing is also an interesting but challenging one. In this setting, the X_i's can follow one of m distributions P_0, P_1, ..., P_{m-1}. Consequently, the Y_i's can follow one of m distributions M_0, M_1, ..., M_{m-1}. The utility can be defined as the average f-divergence between any two distributions: $1/(m(m-1)) \sum_{i \neq j} D_f(M_i || M_j)$, or the worst case one: $\min_{i \neq j} D_f(M_i || M_j)$.

Non-exchangeable utility functions. The utility studied in this paper was measured by functions that are exchangeable, i.e. the utility did not depend on the naming (labelling) of the private and privatized data (X and Y). This made sense for statistical learning applications that depend on information theoretic quantities such as f-divergences and mutual information. However, in some other applications, the utility might be defined over $\mathcal{X} \cup \mathcal{Y}$ in a metric space, where there exists a natural measure of distance (or distortion) between the data points. In this case, we can formulate the problem as a distortion minimization one

$$\text{minimize}_{Q \in \mathcal{D}_\varepsilon} \quad \sum_{x,y} d(x,y) P(x) Q(y|x) \ ,$$

where $d(x, y)$ is some distortion metric. Wang et al. (2014a) studied this problem, and showed that the mechanism $Q(y|x) \propto e^{\varepsilon(1-d(x,y))}/(k-1+e^\varepsilon)$ achieves near optimal performance when ε is large enough, which is the low privacy regime. Notice that when Hamming distance is used, $d(x, y) = \mathbb{I}(x \neq y)$, this recovers the randomized response mechanism exactly. This provides a starting point for generalizing the search for optimal mechanisms under non-exchangeable utility functions.

7. Proof of Theorems 2 and 4

We start the proof with a few definitions, a lemma, and a general result that applies to any convex utility function that obeys a mild assumption.

Recall that for an input alphabet $\mathcal{X}$ with $|\mathcal{X}| = k$, we represent the set of ε-locally differentially private mechanisms that lead to output alphabets $\mathcal{Y}$ with $|\mathcal{Y}| = \ell$ by $\mathcal{D}_{\varepsilon,\ell}$. The set of all ε-locally differentially private mechanisms is given by $\mathcal{D}_\varepsilon = \cup_{\ell\in\mathbb{N}}\mathcal{D}_{\varepsilon,\ell}$. A utility function $U(Q)$ is convex in Q if $U\left(\lambda Q^{(1)} + (1-\lambda)Q^{(2)}\right) \leq \lambda U\left(Q^{(1)}\right) + (1-\lambda)U\left(Q^{(2)}\right)$ for any $\lambda \in (0,1)$. Convex utility functions are ubiquitous in information theory and statistics.

Assumption 1 *If a $k\times\ell$ privatization mechanism $Q^{(1)} \in \mathcal{D}_{\varepsilon,\ell}$ is obtained by deleting an all-zero column of a $k\times\ell+1$ privatization mechanism $Q^{(2)} \in \mathcal{D}_{\varepsilon,\ell+1}$, then $U\left(Q^{(1)}\right) = U\left(Q^{(2)}\right)$.*

Naturally, one would expect that if we delete the zero columns of a privatization mechanism $Q^{(2)}$ to obtain a new privatization mechanism $Q^{(1)}$, we would still get the same utility. This is because a "reasonable" utility function should not depend on output alphabets with zero probability.

Theorem 21 *If $U(Q)$ is a convex utility function that satisfies Assumption 1, then the following holds*

$$\max_{Q\in\mathcal{D}_\varepsilon} U(Q) = \max_{Q\in\cup_{\ell=1}^k \mathcal{D}_{\varepsilon,\ell}} U(Q).$$

This theorem implies that among all ε-locally differentially private mechanisms, we only need to consider those that lead to output alphabets of size $\ell \leq k$. In other words, enlarging the input alphabet cannot further maximize the utility. The proof of Theorem 21 is given in Section 7.1.

Lemma 22 *A $k\times\ell$ conditional distribution Q is ε-locally differentially private if and only if it can be written as $Q = S\Theta$, where S is a $k\times\ell$ matrix with $S_{ij} \in [1, e^\varepsilon]$ and $\Theta = diag(\theta_1,\ldots,\theta_\ell)$ with its diagonal entries in $\mathbb{R}_+$.*

The proof of Lemma 22 is provided in Section 7.2. With the above results, we are now ready to prove Theorems 2 and 4. By Lemma 22, for any $Q \in \mathcal{D}_{\varepsilon,\ell}$ we have that $Q_j = \theta_j S_j$. Suppose $U(Q) = \sum_{j\in[\ell]}\mu(Q_j)$, where μ is a sublinear function. Since μ is sublinear, it is convex and $\mu(\theta_j S_j) = \theta_j\mu(S_j)$. $U(Q)$ is convex in Q because

$$\begin{aligned} U\left(\lambda Q^{(1)} + (1-\lambda)Q^{(2)}\right) &= \sum_{j\in[\ell]} \mu\left(\lambda\theta_j^{(1)}S_j^{(1)} + (1-\lambda)\theta_j^{(2)}S_j^{(2)}\right) \\ &\leq \sum_{j\in[\ell]} \lambda\mu\left(\theta_j^{(1)}S_j^{(1)}\right) + (1-\lambda)\mu\left(\theta_j^{(2)}S_j^{(2)}\right) \\ &= \lambda U\left(Q^{(1)}\right) + (1-\lambda)U\left(Q^{(2)}\right), \end{aligned} \tag{25}$$

for any $\lambda \in (0,1)$. Furthermore, $U(Q)$ satisfies Assumption 1 because $\mu(Q_j) = 0$ whenever $\theta_j = 0$. Let $Q^* = S^*\Theta^* \in \arg\max_{Q\in\cup_{\ell=1}^k\mathcal{D}_{\varepsilon,\ell}} U(Q)$ and note that by Theorem 21, $U(Q^*) =$

$\max_{Q\in\mathcal{D}_\varepsilon} U(Q)$. Suppose that Q^* is of dimensions $k\times\ell$, where $\ell \leq k$. Each of the ℓ columns of Q^* can be expressed as a convex combination of the columns of $S^{(k)}$, the staircase pattern matrix. This is because the 2^k columns of $S^{(k)}$ are the corner points of the cube $[1,e^\varepsilon]^k$ and each $S_j^* \in [1,e^\varepsilon]^k$. Therefore, $S_j^* = \sum_{i=1}^{2^k}\lambda_{ij}S_i^{(k)}$, where $\lambda_{ij} \geq 0$ for all i and j, and $\sum_{i=1}^{2^k}\lambda_{ij} = 1$ for all j. Create the 2^k-dimensional vector $\tilde\theta$ such that $\tilde\theta_i = \sum_{j=1}^{\ell}\lambda_{ij}\theta_j^*$ and let $\tilde Q = S^{(k)}\tilde\Theta$.

$$\begin{aligned} U(Q^*) - U(\tilde Q) &= \sum_{j=1}^{\ell}\mu\left(S_j^*\right)\theta_j^* - \sum_{i=1}^{2^k}\mu\left(\left(\sum_{j=1}^{\ell}\lambda_{ij}\theta_j^*\right)S_j^{(k)}\right) \\ &= \sum_{j=1}^{\ell}\mu\left(\sum_{i=1}^{2^k}\lambda_{ij}S_i^{(k)}\right)\theta_j^* - \sum_{i=1}^{2^k}\sum_{j=1}^{\ell}\lambda_{ij}\theta_j^*\mu\left(S_j^{(k)}\right) \\ &= \sum_{j=1}^{\ell}\theta_j^*\left\{\mu\left(\sum_{i=1}^{2^k}\lambda_{ij}S_i^{(k)}\right) - \sum_{i=1}^{2^k}\lambda_{ij}\mu\left(S_j^{(k)}\right)\right\} \\ &\leq 0, \end{aligned} \tag{26}$$

by the convexity of $\mu(z)$ and the non-negativity of θ_j^*'s. Moreover, observe that since $S^{(k)}\tilde\theta = \mathbb{1}$, $\tilde\theta$ is a valid choice for the linear program of (11). This implies that

$$\max_{S^{(k)}\theta=\mathbb{1},\theta\geq 0}\sum_{j=1}^{2^k}\mu\left(S_j^{(k)}\right)\theta_j \geq U(\tilde Q) \geq U(Q^*) = \max_{Q\in\mathcal{D}_\varepsilon} U(Q)$$

On the other hand, for any $\tilde Q = S^{(k)}\tilde\Theta$, where $\tilde\theta$ is valid for the linear program of (11), we have that $\tilde Q \in \mathcal{D}_{\varepsilon,2^k} \subset \mathcal{D}_\varepsilon$ and therefore, $\max_{S^{(k)}\theta=\mathbb{1},\theta\geq 0}\sum_{j=1}^{2^k}\mu\left(S_j^{(k)}\right)\theta_j \leq \max_{Q\in\mathcal{D}} U(Q)$. Thus, $\max_{S^{(k)}\theta=\mathbb{1},\theta\geq 0}\sum_{j=1}^{2^k}\mu\left(S_j^{(k)}\right)\theta_j = \max_{Q\in\mathcal{D}} U(Q)$. This proves Theorem 4.

The polytope given by $S^{(k)}\theta = \mathbb{1}$ and $\theta \geq 0$ is a closed and bounded one. Thus, the linear program of (11) is bounded and has a solution, say θ^*, at one of the corner points of the polytope. Since there are k equality constraints given by $S^{(k)}\theta = \mathbb{1}$ and 2^k inequality constraints given by $\theta \geq 0$, any corner point, including θ^*, cannot have more than k non-zero entries. Form $\tilde S$ by deleting the columns of $S^{(k)}$ corresponding to zero entries of θ^*. Similarly, form $\tilde\theta$ by deleting the zero entries of θ^* and let $\tilde Q = \tilde S\tilde\Theta$, where $\tilde\Theta = \text{diag}\tilde\theta$. It is easy to verify that $U(\tilde Q) = U(Q^*) = \mu^T\theta^*$; hence, $\tilde Q$ solves linear program of (11). Moreover, $\tilde Q$ has at most k columns and $\tilde S_{ij} = \{1, e^\varepsilon\}$. Therefore, $\tilde Q$ is a staircase mechanism of dimension $k\times\ell$, where $\ell \leq k$.

7.1 Proof of Theorem 21

We start the proof of Theorem 21 with an important lemma the proof of which is presented in Section 7.3.

Lemma 23 *The set of all $k\times\ell$, ε-locally differentially private mechanisms $\mathcal{D}_{\varepsilon,\ell}$ forms a closed and bounded polytope in $\mathbb{R}_+^{k\ell}$. Moreover, let Q be a corner point of the polytope formed by $\mathcal{D}_{\varepsilon,\ell}$, then Q has at most k non-zero columns.*

Fix an $\ell > k$. Since $U(Q)$ is convex in Q, it suffices to consider the corner points of $\mathcal{D}_{\varepsilon,\ell}$ when maximizing $U(Q)$ subject to $Q \in \mathcal{D}_{\varepsilon,\ell}$. By Lemma 23, any $Q^{(1)}$, a $k \times \ell$ corner point of $\mathcal{D}_{\varepsilon,\ell}$, has at most k non-zero columns. Therefore, the privatization mechanism $Q^{(2)}$, obtained by deleting the all-zero columns of $Q^{(1)}$, has at most k columns. Notice that $Q^{(2)} \in \cup_{i=1}^{k} \mathcal{D}_{\varepsilon,i}$. Since $U(Q)$ satisfies Assumption 1, we have that $U\left(Q^{(1)}\right) = U\left(Q^{(2)}\right)$ and therefore, it suffices to consider $Q \in \cup_{i=1}^{k} \mathcal{D}_{\varepsilon,i}$ when maximizing $U(Q)$ subject to $Q \in \mathcal{D}_{\varepsilon,\ell}$. Thus,

$$\begin{aligned} \sup_{Q \in \mathcal{D}_{\varepsilon}} U(Q) &= \sup_{\ell \in \mathbb{N}} \left\{ \max_{Q \in \mathcal{D}_{\varepsilon,\ell}} U(Q) \right\} \\ &= \sup_{\ell \in \mathbb{N}} \left\{ \max_{Q \in \cup_{i=1}^{k} \mathcal{D}_{\varepsilon,i}} U(Q) \right\} \\ &= \max_{Q \in \cup_{i=1}^{k} \mathcal{D}_{\varepsilon,i}} U(Q), \end{aligned} \tag{27}$$

which finishes the proof.

7.2 Proof of Lemma 22

Claim 1 *Let $Q \in \mathcal{D}_{\varepsilon,\ell}$. If $Q_{ij} = 0$ for some $j \in \{1, ..., \ell\}$ then $Q_{ij} = 0$ for all $i \in \{1, ..., k\}$.*

Proof Assume that $Q_{i_1 j} = 0$ and $Q_{i_2 j} \neq 0$ for some $i_1, i_2 \in \{1, ..., k\}$. It is obvious that $q(y_j|x_{i_2}) \leq q(y_j|x_{i_1}) e^{\varepsilon}$ is not satisfied. Therefore, Q is not a locally differentially private mechanism. ■

It is easy to check that any $k \times \ell$ stochastic matrix $Q = S\Theta$, where Θ is a diagonal matrix with non-negative entries and S is a $k \times \ell$ matrix with $S_{ij} \in [1, e^{\varepsilon}]$, satisfies the local differential privacy constraints. Thus, $Q \in \mathcal{D}_{\varepsilon,\ell}$. On the other hand, assume that $Q \in \mathcal{D}_{\varepsilon,\ell}$. If $Q_{ij} = 0$ for some j then by Claim 1 we have that $Q_{ij} = 0$ for all i and therefore, we can set $\theta_j = 0$ and $S_{ij} = 1$ for all i. If $Q_{ij} > 0$ then by Claim 1 we have that $Q_{ij} > 0$ for all i. In this case, let $\theta_j = \min_i Q_{ij}$ and observe that $\theta_j > 0$ since $Q_{ij} > 0$ for all i. Let $S_{ij} = Q_{ij}/\theta_i$, then it is clear (from the definition of θ_i) that $S_{ij} \geq 1$. On the other hand, from the differential privacy constraints, we have that $Q_{ij} \leq Q_{kj} e^{\varepsilon}$ for all k and thus, $Q_{ij} \leq \min_k Q_{kj} e^{\varepsilon}$ which proves that $S_{ij} = Q_{ij}/\min_k Q_{kj} \leq e^{\varepsilon}$. This establishes that any $Q \in \mathcal{D}_{\varepsilon,\ell}$ can be written as $Q = S\Theta$, where Θ is a diagonal matrix with non-negative entries and S is a $k \times \ell$ matrix with $S_{ij} \in [1, e^{\varepsilon}]$.

7.3 Proof of Lemma 23

We start by showing that $\mathcal{D}_{\varepsilon,\ell}$ forms a closed and bounded polytope in $\mathbb{R}_{+}^{k\ell}$. We are interested in studying the corner points of the polytope formed by $\mathcal{D}_{\varepsilon,\ell}$ because convex utility functions are maximized at one of these corner points whenever the space of privatization mechanisms is restricted to $\mathcal{D}_{\varepsilon,\ell}$.

Claim 2 *A privatization mechanism $Q \in \mathcal{D}_{\varepsilon,\ell}$ if and only if for all $x, x' \in \mathcal{X}$ and all $y \in \mathcal{Y}$ we have that $Q(y|x) \leq Q(y|x') e^{\varepsilon}$.*

Proof By definition, Q is differentially private if for all x, $x' \in \mathcal{X}$ and all $B \subseteq \mathcal{Y}$ we have that $Q(B|x) \leq Q(B|x') e^{\varepsilon}$. By choosing $B = \{y\}$ for some $y \in \mathcal{Y}$ the first direction of the above lemma is proven. In order to prove the other direction, assume that for all $x, x' \in \mathcal{X}$ and all $y \in \mathcal{Y}$ we have that $Q(y|x) \leq Q(y|x') e^{\varepsilon}$. Then for any $B \subseteq \mathcal{Y}$, the following holds

$$\begin{aligned} \sum_{y \in B} Q(y|x) &\leq \sum_{y \in B} Q\left(y|x'\right) e^{\varepsilon} \\ \Leftrightarrow \quad Q(B|x) &\leq Q\left(B|x'\right) e^{\varepsilon}. \end{aligned} \tag{28}$$

■

Let $Q \in \mathcal{D}_{\varepsilon,\ell}$, then by Claim 2, it is easy to see that Q must satisfy $\ell k(k-1)$ inequalities of the form $Q(y|x) \leq Q(y|x') e^{\varepsilon}$. These inequalities can be compactly represented by

$$\tilde{A} q \leq 0,$$

where $q = [Q(y_1|x_1), ..., Q(y_1|x_k), ..., Q(y_\ell|x_1), ..., Q(y_\ell|x_k)]^T$ and $\tilde{A}$ is a $\ell k(k-1) \times k\ell$ matrix that contains all the local differential privacy linear constraints. Observe that there is a one-to-one mapping between Q and q. Here is an example for the case when $k = \ell = 2$

$$\underbrace{\begin{bmatrix} 1 & -e^{\varepsilon} & 0 & 0 \\ -e^{\varepsilon} & 1 & 0 & 0 \\ 0 & 0 & 1 & -e^{\varepsilon} \\ 0 & 0 & -e^{\varepsilon} & 1 \end{bmatrix}}_{\tilde{A}} \begin{bmatrix} Q(y_1|x_1) \\ Q(y_1|x_2) \\ Q(y_2|x_1) \\ Q(y_2|x_2) \end{bmatrix} \leq 0.$$

Moreover, since Q is a row stochastic matrix (a conditional distribution) it satisfies $Q\mathbb{1} = \mathbb{1}$, where $\mathbb{1}$ represents the all ones vector of appropriate dimensions. This condition can be rewritten as

$$Bq = \mathbb{1},$$

where B is a $k \times k\ell$ binary matrix. For the case when $k = \ell = 2$, we have that

$$\underbrace{\begin{bmatrix} 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \end{bmatrix}}_{B} \begin{bmatrix} Q(y_1|x_1) \\ Q(y_1|x_2) \\ Q(y_2|x_1) \\ Q(y_2|x_2) \end{bmatrix} = \begin{bmatrix} 1 \\ 1 \end{bmatrix}.$$

Finally, observe that $Q(y|x) \geq 0$ for all $x \in \mathcal{X}$ and $y \in \mathcal{Y}$. These constraints can be incorporated as follows. Let $A = \left[\tilde{A}^T, -I_{\ell k}\right]^T$, where $I_{\ell k}$ is the $\ell k \times \ell k$ identity matrix, then $Aq \leq 0$. To summarize, $Q \in \mathcal{D}_{\varepsilon,\ell}$ if and only if

$$\begin{aligned} Aq &\leq 0 \\ Bq &= \mathbb{1}. \end{aligned} \tag{29}$$

Therefore, the set of all $k \times \ell$, ε-locally differentially private mechanisms $\mathcal{D}_{\varepsilon,\ell}$ forms a convex polytope in $\mathbb{R}_{+}^{k\ell}$.

We now proceed to proving that if Q is a corner point of the polytope formed by $\mathcal{D}_{\varepsilon,\ell}$, then Q has at most k non-zero columns. This claim is obvious for all $k \times \ell$ privatization mechanisms with $\ell \leq k$. Therefore, we restrict our attention to the case where $\ell > k$. Let A_j be the matrix including all the inequality constraints imposed on the j^{th} column of Q. Observe that the rows of A_j form a subset of the rows of A, defined in (29), and recall that there are $k(k-1)$ differential privacy and k non-negativity inequality constraints imposed on the j^{th} column of Q. Therefore, A_j is a $k^2 \times k$ matrix and we have that $A_j Q_j \leq 0$, where Q_j represents the j^{th} column of Q. By Claim 1, we know that Q_j is either equal to zero or contains non-zero entries.

Claim 3 *In what follows, the term linearly independent inequality constraints refers to linear independent rows of A_j.*

- *If $Q_j = 0$, then k linearly independent inequality constraints are achieved with equality.*
- *If $Q_j \neq 0$, then at most $k-1$ linearly independent inequality constraints can be achieved with equality.*

Proof In fact, the number of linearly independent inequality constraints (achieved or not) cannot exceed k because A_j has a rank less than or equal to k. If $Q_j = 0$, then the k non-negativity inequality constraints are achieved with equality and it is easy to see that they are all linearly independent (in fact, they form an orthonormal basis to $\mathbb{R}^k$). This proves the first part of the claim. We now establish the second part of the claim by showing that if $Q_j \neq 0$, we cannot have k linearly independent inequality constraints achieved with equality. Assume that $Q_j \neq 0$ and let $\tilde{A}_j$ be the matrix including the largest collection of linearly independent rows of A_j corresponding to the inequality constraints that are achieved with equality. In other words, $\tilde{A}_j Q_j = 0$. If $\tilde{A}_j$ contains k rows, then its rank is equal to k. However, this implies that $Q_j = 0$, a contradiction. Therefore, at most $k-1$ linearly independent inequality constraints can be achieved with equality when $Q_j \neq 0$. ■

Suppose that Q is a corner point of $\mathcal{D}_{\varepsilon,\ell}$ and out of its ℓ columns, $\ell_{>0}$ are non-zero and $\ell_{=0}$ ($\ell_{=0} = \ell - \ell_{>0}$) are zero. Moreover, assume that the number of non-zero columns of Q is larger than k (i.e., $\ell_{>0} > k$). In this case, from Claim 3, we can see that Q achieves at most $\ell_{>0}(k-1)+(\ell-\ell_{>0})k$ linearly independent inequality constraints with equality. Furthermore, at most k additional linearly independent equality constraints (linearly independent rows of the matrix B defined in (29)) can be met by Q. Therefore, the total number of linearly independent constraints that Q achieves with equality is at most $\ell_{>0}(k-1)+(\ell-\ell_{>0})k+k = -\ell_{>0} + (\ell+1)k < \ell k$, where the last strict inequality follows from the fact that $\ell_{>0} > k$. This implies that Q cannot be a corner point of $\mathcal{D}_{\varepsilon,\ell}$. Therefore, any corner point of $\mathcal{D}_{\varepsilon,\ell}$ must have at most k non-zero columns.

8. Proofs for Hypothesis Testing

8.1 Proof of Theorem 5

Let $T = \{x : P_0(x) \geq P_1(x)\}$. In other words, $P_0(T) - P_1(T) = \max_{A \subseteq \mathcal{X}} P_0(A) - P_1(A)$. Recall that for a given P_0 and P_1, the binary mechanism is defined as a staircase mechanism

with only two outputs $y \in \{0,1\}$ satisfying

$$Q(0|x) = \begin{cases} \frac{e^\varepsilon}{1+e^\varepsilon} & \text{if } P_0(x) \geq P_1(x)\,, \\ \frac{1}{1+e^\varepsilon} & \text{if } P_0(x) < P_1(x)\,. \end{cases} \quad Q(1|x) = \begin{cases} \frac{e^\varepsilon}{1+e^\varepsilon} & \text{if } P_0(x) < P_1(x)\,, \\ \frac{1}{1+e^\varepsilon} & \text{if } P_0(x) \geq P_1(x)\,. \end{cases} \tag{30}$$

Lemma 24 *For any pair of distributions P_0 and P_1, there exists a positive ε^* that depends on P_0 and P_1 such that for all $y \in \mathcal{Y}$, all $\ell \in \mathbb{N}$, and all $Q \in \mathcal{D}_{\varepsilon,\ell}$ with $\varepsilon \leq \varepsilon^*$, we have that*

$$\frac{(e^\varepsilon - 1)\,P_0\,(T^c) + 1}{(e^\varepsilon - 1)\,P_1\,(T^c) + 1} \leq \frac{M_0(y)}{M_1(y)} \leq \frac{(e^\varepsilon - 1)\,P_0\,(T) + 1}{(e^\varepsilon - 1)\,P_1\,(T) + 1}.$$

Moreover, the above upper and lower bounds are achieved by the binary mechanism given in (30).

Observe that because $P_0\,(T) \geq P_1\,(T)$ and $P_0\,(T^c) \leq P_1\,(T^c)$, the direction of the above inequalities makes sense.

Let $\tilde{M}_\nu$ be the induced marginal for the binary mechanism when P_ν is the original distribution. Following the analysis techniques developed in Kairouz et al. (2013), we define hypothesis testing region $R(\tilde{M}_0, \tilde{M}_1)$ as the convex hull of all achievable probabilities of missed detection and false alarm, when testing whether $\nu = 0$ or $\nu = 1$ based on Y_{bin} distributed as $\tilde{M}_\nu$:

$$R(\tilde{M}_0, \tilde{M}_1) \equiv \text{conv}\Big(\big\{(\tilde{M}_1(S), \tilde{M}_0(S^c)) : \forall S \subseteq \mathcal{Y}\big\}\Big)\,,$$

where $S \in \mathcal{Y}$ is the accept region for hypothesis $\nu = 0$. For the binary mechanism, this ends up being a very simple triangular region. The slopes defining the two sides of the triangular region are: $-\max_S \tilde{M}_0(S)/\tilde{M}_1(S) = -((e^\varepsilon - 1)P_0(T) + 1)/((e^\varepsilon - 1)P_1(T) + 1)$ and $-\min_S \tilde{M}_0(S^c)/\tilde{M}_1(S^c) = -((e^\varepsilon - 1)P_0(T^c) + 1)/((e^\varepsilon - 1)P_1(T^c) + 1)$.

For any other mechanism satisfying the ε-local differential privacy for $\varepsilon \leq \varepsilon^*$, the above lemma implies that for any choice of the rejection region S, the slopes satisfy $-M_0(S)/M_1(S) \geq -((e^\varepsilon - 1)P_0(T) + 1)/((e^\varepsilon - 1)P_1(T) + 1)$ and $-M_0(S^c)/M_1(S^c) \leq -((e^\varepsilon - 1)P_0(T^c) + 1)/((e^\varepsilon - 1)P_1(T^c) + 1)$. In the hypothesis testing region, this implies that

$$R(M_0, M_1) \subseteq R(\tilde{M}_0, \tilde{M}_1)\,,$$

as in the following Figure 10.

From Theorem 2.5 of Kairouz et al. (2013), we know that this implies a certain Markov property. Precisely, let Y_{bin} denote the output of the binary mechanism, and Y_{dp} denote the output of any ε-local differentially private mechanism. Then, it follows that there exists a coupling of Y_{bin} and Y_{dp} such that they form a Markov chain: ν–Y_{bin}–Y_{dp}, where ν is the hypothesis on P_ν whether the data was generated from $\nu = 0$ or $\nu = 1$. Then, it follows from the data processing inequality of f-divergences that

$$D_f(\tilde{M}_0, \tilde{M}_1) \geq D_f(M_0, M_1)\,.$$

It follows that there is no algorithm with larger f-divergence than the binary mechanism.

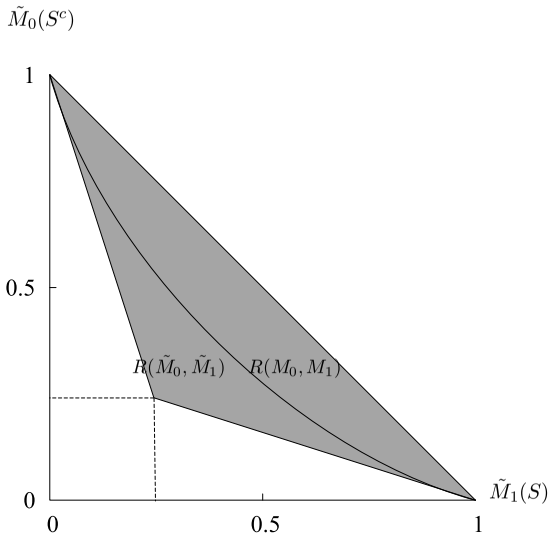


Figure 10: Hypothesis testing regions for two mechanisms.

8.2 Proof of Lemma 24

We start by showing that the binary mechanism achieves the upper and lower bounds presented in the statement of the lemma. Let M_0^B and M_1^B denote the induced marginals under the binary mechanism given in (30). For $\nu \in \{0,1\}$, we have that

$$\begin{aligned} M_\nu^B(0) &= \sum_{x\in\mathcal{X}} P_0(x)\, Q(0|x) = \frac{1}{e^\varepsilon+1}\left(\left(e^\varepsilon-1\right)P_\nu(T)+1\right) \\ M_\nu^B(1) &= \sum_{x\in\mathcal{X}} P_0(x)\, Q(1|x) = \frac{1}{e^\varepsilon+1}\left(\left(e^\varepsilon-1\right)P_\nu(T^c)+1\right). \end{aligned} \tag{31}$$

Computing $M_0^B(0)/M_1^B(0)$ and $M_0^B(1)/M_1^B(1)$ we see that the binary mechanism achieves the upper and lower bounds for all values of ε.

As in Lemma 22, for any $\ell \in \mathbb{N}$, $Q \in \mathcal{D}_{\varepsilon,\ell}$ can be represented as $Q = S\Theta$, where $S \in [1,e^\varepsilon]^{k\times\ell}$ and $\Theta = \operatorname{diag}(\theta_1,...,\theta_\ell)$ with its diagonal entries in $\mathbb{R}_+$. We now show that for any $\ell \in \mathbb{N}$ and any $Q \in \mathcal{D}_{\varepsilon,\ell}$, the following upper bound holds

$$\frac{M_0(y)}{M_1(y)} = \frac{\sum_{i\in[k]} P_0(x_i)\, S_{ij}}{\sum_{i\in[k]} P_1(x_i)\, S_{ij}} \leq \frac{\left(e^\varepsilon-1\right)P_0(T)+1}{\left(e^\varepsilon-1\right)P_1(T)+1},$$

for all $y \in \mathcal{Y}$ and sufficiently small ε. The above expression can be alternatively written as

$$\begin{aligned} \left(e^\varepsilon-1\right)\left(P_0(T)-P_1(T)\right) + \left(e^\varepsilon-1\right)\sum_{i\in[k]}\left(S_{ij}-1\right)\left(P_0(T)P_1(x_i)-P_1(T)P_0(x_i)\right) \\ -\sum_{i\in[k]}\left(S_{ij}-1\right)\left(P_0(x_i)-P_1(x_i)\right)\geq 0, \end{aligned} \tag{32}$$

where $S_j \in [1,e^\varepsilon]^k$. Equation (32) is linear in S_j and is therefore minimized (and maximized) at the corner points of $[1,e^\varepsilon]^{k\times\ell}$, a cube in $\mathbb{R}_+^{k\times\ell}$. The corner points of this cube are given by the staircase patterns: $S_j \in \{1,e^\varepsilon\}^k$. To begin with, let S_j be a staircase pattern with $T_j = \{x_i : S_{ij} = e^\varepsilon\} \neq T$. Then Equation (32) is equivalent to

$$\begin{aligned} \left(e^\varepsilon-1\right)\left\{\left(P_0(T)-P_1(T)\right)-\left(P_0(T_j)-P_1(T_j)\right)\right\} \\ +\left(e^\varepsilon-1\right)^2\left\{P_0(T)P_1(T_j)-P_1(T)P_0(T_j)\right\}\geq 0. \end{aligned} \tag{33}$$

Using the fact that $P_0(T)-P_1(T) > P_0(T_j)-P_1(T_j)$ for all $T_j \neq T$, the inequality in (32) holds true for all ε whenever $P_0(T)P_1(T_j) \geq P_1(T)P_0(T_j)$. If $P_0(T)P_1(T_j) < P_1(T)P_0(T_j)$, then the inequality in (32) holds true for all $\varepsilon \leq \varepsilon(j)$, where

$$\varepsilon(j) = \log\left(\frac{\left(P_0(T)-P_1(T)\right)-\left(P_0(T_j)-P_1(T_j)\right)}{P_1(T)P_0(T_j)-P_0(T)P_1(T_j)}+1\right) > 0.$$

On the other hand, it is easy to verify that when $T_j = T$, we have that

$$\begin{aligned} \left(e^\varepsilon-1\right)\left\{\left(P_0(T)-P_1(T)\right)-\left(P_0(T_j)-P_1(T_j)\right)\right. \\ \left.+\left(e^\varepsilon-1\right)\left(P_0(T)P_1(T_j)-P_1(T)P_0(T_j)\right)\right\} = 0, \end{aligned} \tag{34}$$

for all ε. In this case, set $\varepsilon(j) = 0$ and $\varepsilon_1 = \min_{j\in[2^k]}\varepsilon(j)$. Therefore, for any $\ell \in \mathbb{N}$ and any $Q \in \mathcal{D}_{\varepsilon,\ell}$, the upper bound in the statement of the lemma holds for all $\varepsilon \leq \varepsilon_1$.

We now show that for for any $\ell \in \mathbb{N}$ and any $Q \in \mathcal{D}_{\varepsilon,\ell}$, the following lower bound holds

$$\frac{\left(e^\varepsilon-1\right)P_0(T^c)+1}{\left(e^\varepsilon-1\right)P_1(T^c)+1} \leq \frac{M_0(y)}{M_1(y)} = \frac{\sum_{i\in[k]} P_0(x_i)\, S_{ij}}{\sum_{i\in[k]} P_1(x_i)\, S_{ij}},$$

for all $y \in \mathcal{Y}$ and sufficiently small ε. The above expression can be alternatively written as

$$\begin{aligned} \left(e^\varepsilon-1\right)\left(P_0(T)-P_1(T)\right) + \left(e^\varepsilon-1\right)\sum_{i\in[k]}\left(S_{ij}-1\right)\left(P_0(T)P_1(x_i)-P_1(T)P_0(x_i)\right) \\ +e^\varepsilon\sum_{i\in[k]}\left(S_{ij}-1\right)\left(P_0(x_i)-P_1(x_i)\right)\geq 0, \end{aligned} \tag{35}$$

where $S_j \in [1,e^\varepsilon]^k$. Equation (35) is linear in S_j and is therefore minimized at the corner points of $[1,e^\varepsilon]^k$, a cube in $\mathbb{R}_+^k$. The corner points of this cube are given by staircase patterns: $S_j \in \{1,e^\varepsilon\}^k$. To begin with, let S_j be a staircase pattern with $T_j = \{x_i : S_{ij} = e^\varepsilon\} \neq T^c$, then Equation (35) is equivalent to

$$\begin{aligned} \left(e^\varepsilon-1\right)\left\{\left(P_0(T)-P_1(T)\right)+e^\varepsilon\left(P_0(T_j)-P_1(T_j)\right)\right\} \\ +\left(e^\varepsilon-1\right)^2\left\{P_0(T)P_1(T_j)-P_1(T)P_0(T_j)\right\}\geq 0. \end{aligned} \tag{36}$$

Using the fact that $P_0(T) - P_1(T) > P_1(T_j) - P_0(T_j)$ for all $T_j \neq T^c$, then for sufficiently small ε, Equation (35) can be written as

$$\varepsilon\left\{(P_0(T) - P_1(T)) - (P_1(T_j) - P_0(T_j))\right\} + O\left(\varepsilon^2\right) > 0.$$

This proves that there exists a positive $\varepsilon(j)$ such that the left hand side of Equation (36) is positive for all $\varepsilon \leq \varepsilon(j)$. On the other hand, it is easy to verify that when $T_j = T^c$, we have that

$$\begin{aligned}(e^\varepsilon - 1)\left\{(P_0(T) - P_1(T)) + e^\varepsilon (P_0(T_j) - P_1(T_j))\right.\\ \left. + (e^\varepsilon - 1)(P_0(T) P_1(T_j) - P_1(T) P_0(T_j))\right\} = 0, \quad (37)\end{aligned}$$

for all ε. In this case, let $\varepsilon(j) = 0$ and let $\varepsilon_2 = \min_{j\in[2^k]} \varepsilon(j)$. Therefore, for any $\ell \in \mathbb{N}$ and any $Q \in \mathcal{D}_{\varepsilon,\ell}$, the lower bound in the statement of the lemma holds for all $\varepsilon \leq \varepsilon_2$. To conclude, let $\varepsilon^* = \min(\varepsilon_1, \varepsilon_2)$. Then both, the upper and lower bounds, hold for all $\varepsilon \leq \varepsilon^*$.

8.3 Proof of Theorem 6

The total variation (TV) distance $\|M_0 - M_1\|_{\text{TV}}$ is a special case of f-divergence $D_f(M_0||M_1)$ with $f(x) = \frac{1}{2}|x-1|$. Therefore, by Theorem 4, we have that

$$\max_{Q\in\mathcal{D}_\varepsilon} \left\|M_0 - M_1\right\|_{\text{TV}} = \begin{array}{ll}\underset{\theta}{\text{maximize}} & \mu^T\theta \\ \text{subject to} & S^{(k)}\theta = \mathbb{1} \\ & \theta \geq 0,\end{array} \quad (38)$$

where $\mu_j = \mu\left(S_j^{(k)}\right) = \frac{1}{2}\left|\sum_{i\in[k]} (P_0(x_i) - P_1(x_i)) S_{ij}^{(k)}\right|$ for $j \in \{1, \ldots, 2^k\}$ and $S^{(k)}$ is the $k \times 2^k$ staircase pattern matrix given in Definition 3.

The polytope given by $S^{(k)}\theta = \mathbb{1}$ and $\theta \geq 0$ is a closed and bounded one. Thus, there is no duality gap and solving the above linear program is equivalent to solving its dual

$$\begin{array}{ll}\underset{\alpha}{\text{minimize}} & \mathbb{1}^T\alpha \\ \text{subject to} & {S^{(k)}}^T\alpha \geq \mu.\end{array} \quad (39)$$

Note that any satisfiable solution α^* to (39) provides an upper bound to (38) since $\max \mu^T\theta = \min \mathbb{1}^T\alpha \leq \mathbb{1}^T\alpha^*$. Let $T = \{x : P_0(x) \geq P_1(x)\}$ and $T_j = \{x_i : S_{ij}^{(k)} = e^\varepsilon\}$ for $j \in [2^k]$. Consider the following choice of dual variable

$$\alpha_i^* = \frac{1}{2}\frac{e^\varepsilon - 1}{e^\varepsilon + 1}\left|P_0(x_i) - P_1(x_i)\right|,$$

for $i \in [k]$. Observe that

$$\begin{aligned}\mathbb{1}^T\alpha^* &= \frac{1}{2}\frac{e^\varepsilon - 1}{e^\varepsilon + 1}\sum_{i\in[k]}\left|P_0(x_i) - P_1(x_i)\right| \\ &= \frac{1}{2}\frac{e^\varepsilon - 1}{e^\varepsilon + 1}\left\|P_0 - P_1\right\|_1 \\ &= \frac{e^\varepsilon - 1}{e^\varepsilon + 1}\left\|P_0 - P_1\right\|_{\text{TV}}. \quad (40)\end{aligned}$$

We claim that α^* is a feasible dual variable for all values of ε. In order to prove that α^* is a feasible dual variable, we show that ${S^{(k)}}_j^T\alpha^* - \mu_j \geq 0$ for all $j \in [2^k]$ and all ε. For all $j \in [2^k]$, we have that

$$\begin{aligned}g_j &= 2\left({S^{(k)}}_j^T\alpha^* - \mu_j\right) \\ &= \frac{e^\varepsilon - 1}{e^\varepsilon + 1}\sum_{i\in[k]}\left|P_0(x_i) - P_1(x_i)\right| S_{ij}^{(k)} - \left|\sum_{i\in[k]}\left(P_0(x_i) - P_1(x_i)\right) S_{ij}^{(k)}\right| \\ &= \frac{e^\varepsilon - 1}{e^\varepsilon + 1}\left\{\sum_{x_i\in T}\left(P_0(x_i) - P_1(x_i)\right) S_{ij}^{(k)} + \sum_{x_i\in T^c}\left(P_1(x_i) - P_0(x_i)\right) S_{ij}^{(k)}\right\} \\ &\quad - \left|\sum_{x_i\in T}\left(P_0(x_i) - P_1(x_i)\right) S_{ij}^{(k)} - \sum_{x_i\in T^c}\left(P_1(x_i) - P_0(x_i)\right) S_{ij}^{(k)}\right|. \quad (41)\end{aligned}$$

Notice that we have arranged the equation such that all the summands are non-negative. Without loss of generality, we will assume that

$$\sum_{x_i\in T}\left(P_0(x_i) - P_1(x_i)\right) S_{ij}^{(k)} \geq \sum_{x_i\in T^c}\left(P_1(x_i) - P_0(x_i)\right) S_{ij}^{(k)}.$$

From the equality $\sum_{x_i\in T}(P_0(x_i) - P_1(x_i)) = \sum_{x_i\in T^c}(P_1(x_i) - P_0(x_i))$ and the fact that $S_{ij}^{(k)} \in \{1, e^\varepsilon\}$ for all i and j, it follows that

$$e^{-\varepsilon}\sum_{x_i\in T}\left(P_0(x_i) - P_1(x_i)\right) S_{ij}^{(k)} \leq \sum_{x_i\in T^c}\left(P_1(x_i) - P_0(x_i)\right) S_{ij}^{(k)}\ . \quad (42)$$

This is true because the right-hand side is minimized when the $S_{ij}^{(k)}$'s for $x_i \in T^c$ are all equal to 1 and the left-hand side is maximized when the $S_{ij}^{(k)}$'s for $x_i \in T$ are all equal to e^ε. Now, (41) can be written as

$$\begin{aligned}g_j &= \frac{1}{e^\varepsilon + 1}\left\{-2\sum_{x_i\in T}\left(P_0(x_i) - P_1(x_i)\right) S_{ij}^{(k)} + 2e^\varepsilon\sum_{x_i\in T^c}\left(P_1(x_i) - P_0(x_i)\right) S_{ij}^{(k)}\right\} \\ &\geq 0\,,\end{aligned}$$

where the last inequality follows from (42).

This establishes the satisfiability of α^* for all ε which, in turn, shows that (40) is indeed an upper bound to the primal problem. It remains to show that this upper bound can be achieved via the binary mechanism. To this extent, recall that for a given P_0 and P_1, the binary mechanism is defined as a staircase mechanism with only two outputs $y \in \{0, 1\}$ satisfying

$$Q(0|x) = \begin{cases}\frac{e^\varepsilon}{1+e^\varepsilon} & \text{if } P_0(x) \geq P_1(x)\,, \\ \frac{1}{1+e^\varepsilon} & \text{if } P_0(x) < P_1(x)\,.\end{cases} \quad Q(1|x) = \begin{cases}\frac{e^\varepsilon}{1+e^\varepsilon} & \text{if } P_0(x) < P_1(x)\,, \\ \frac{1}{1+e^\varepsilon} & \text{if } P_0(x) \geq P_1(x)\,.\end{cases} \quad (43)$$

Computing the TV distance between M_0 and M_1 under (43), we get that

$$\left\|M_0 - M_1\right\|_{\text{TV}} = \frac{e^\varepsilon - 1}{e^\varepsilon + 1}\left\|P_0 - P_1\right\|_{\text{TV}}.$$

Hence, the binary mechanism in (43) achieves the upper bound in (40). This proves the optimality of the binary mechanism for all ε.

8.4 Proof of Theorem 8

The Kullback-Leibler (KL) divergence $D_{\text{kl}}(M_0||M_1)$ is a special f-divergence $D_f(M_0||M_1)$ with $f(x) = x\log x$. Therefore, by Theorem 4, we have that

$$\begin{array}{rll} \max\limits_{Q\in\mathcal{D}_\varepsilon} D_{\text{kl}}(M_0||M_1) = & \underset{\theta}{\text{maximize}} & \mu^T\theta \\ & \text{subject to} & S^{(k)}\theta = \mathbb{1} \\ & & \theta \geq 0, \end{array} \tag{44}$$

where $\mu_j = \mu\left(S_j^{(k)}\right) = \sum_{i\in[k]} P_0(x_i)S_{ij}^{(k)}\log\left(\frac{\sum_{i\in[k]}P_0(x_i)S_{ij}^{(k)}}{\sum_{i\in[k]}P_1(x_i)S_{ij}^{(k)}}\right)$ for $j\in\{1,\ldots,2^k\}$ and $S^{(k)}$ is the $k\times 2^k$ staircase pattern matrix given in Definition 3.

The polytope given by $S^{(k)}\theta = \mathbb{1}$ and $\theta\geq 0$ is a closed and bounded one. Thus, there is no duality gap and solving the above linear program is equivalent to solving its dual

$$\begin{array}{ll} \underset{\alpha}{\text{minimize}} & \mathbb{1}^T\alpha \\ \text{subject to} & {S^{(k)}}^T\alpha \geq \mu. \end{array} \tag{45}$$

Note that any satisfiable solution α^* to (45) provides an upper bound to (44) since $\max\mu^T\theta = \min\mathbb{1}^T\alpha \leq \mathbb{1}^T\alpha^*$. Let $T = \{x : P_0(x)\geq P_1(x)\}$ and $T_j = \{x_i : S_{ij}^{(k)} = e^\varepsilon\}$ for $j\in[2^k]$. Set $j_i = \{j : T_j = x_i\}$ for $i\in[k]$, and consider the following choice of dual variable

$$\alpha_i^* = \frac{1}{(e^\varepsilon-1)(e^\varepsilon+k-1)}\left\{(e^\varepsilon+k-2)\,\mu\left(S_{j_i}^{(k)}\right) - \sum_{l\in[k],l\neq i}\mu\left(S_{j_l}^{(k)}\right)\right\},$$

for $i\in[k]$. Observe that since $T_{j_i} = x_i$ we have that $P_\nu(T_{j_i}) = P_\nu(x_i)$ and since

$$\begin{aligned} \mu_j &= \sum_{i\in[k]} P_0(x_i)S_{ij}^{(k)}\log\left(\frac{\sum_{i\in[k]}P_0(x_i)S_{ij}^{(k)}}{\sum_{i\in[k]}P_1(x_i)S_{ij}^{(k)}}\right) \\ &= (P_0(T_j)(e^\varepsilon-1)+1)\log\frac{(P_0(T_j)(e^\varepsilon-1)+1)}{(P_1(T_j)(e^\varepsilon-1)+1)} \end{aligned} \tag{46}$$

we have that

$$\begin{aligned} \mathbb{1}^T\alpha^* &= \frac{1}{(e^\varepsilon-1)(e^\varepsilon+k-1)}\sum_{i\in[k]}\left\{(e^\varepsilon+k-2)\,\mu\left(S_{j_i}^{(k)}\right) - \sum_{l\in[k],l\neq i}\mu\left(S_{j_l}^{(k)}\right)\right\} \\ &= \frac{1}{(e^\varepsilon-1)(e^\varepsilon+k-1)}\left\{(e^\varepsilon+k-2)\sum_{i\in[k]}\mu\left(S_{j_i}^{(k)}\right) - \sum_{i\in[k]}\sum_{l\in[k],l\neq i}\mu\left(S_{j_l}^{(k)}\right)\right\} \\ &= \frac{1}{(e^\varepsilon-1)(e^\varepsilon+k-1)}\left\{(e^\varepsilon+k-2)\sum_{i\in[k]}\mu\left(S_{j_i}^{(k)}\right) - (k-1)\sum_{i\in[k]}\mu\left(S_{j_i}^{(k)}\right)\right\} \\ &= \frac{1}{(e^\varepsilon+k-1)}\sum_{i\in[k]}\mu\left(S_{j_i}^{(k)}\right) \\ &= \frac{1}{(e^\varepsilon+k-1)}\sum_{i\in[k]}(P_0(x_i)(e^\varepsilon-1)+1)\log\frac{(P_0(x_i)(e^\varepsilon-1)+1)}{(P_1(x_i)(e^\varepsilon-1)+1)}. \end{aligned} \tag{47}$$

We claim that α^* is a feasible dual variable for sufficiently large ε. In order to prove that α^* is a feasible dual variable, we show that ${S^{(k)}}_j^T\alpha^* - \mu_j \geq 0$ for all $j\in[2^k]$ for all $\varepsilon\geq\varepsilon^*$, where ε^* is a positive quantity that depends on the priors P_0 and P_1. Using the facts that

$$\begin{aligned} \log(a+e^\varepsilon b) &= \varepsilon + \log b + O\left(e^{-\varepsilon}\right) \\ \frac{1}{e^\varepsilon+k-1} &= e^{-\varepsilon} + O\left(e^{-2\varepsilon}\right), \end{aligned} \tag{48}$$

for large ε, we get that

$$\begin{aligned} \mu_j &= (P_0(T_j)(e^\varepsilon-1)+1)\log\frac{(P_0(T_j)(e^\varepsilon-1)+1)}{(P_1(T_j)(e^\varepsilon-1)+1)} \\ &= \left(P_0(T_j)\log\frac{P_0(T_j)}{P_1(T_j)}\right)e^\varepsilon + (1-P_0(T_j))\log\frac{P_0(T_j)}{P_1(T_j)} + O\left(e^{-\varepsilon}\right). \end{aligned} \tag{49}$$

On the other hand,

$$\begin{aligned} {S^{(k)}}_j^T\alpha^* &= \frac{1}{(e^\varepsilon-1)(e^\varepsilon+k-1)}\left\{\sum_{i\in[k]}S_{ij}^{(k)}(e^\varepsilon+k-2)\left(P_0(x_i)\log\frac{P_0(x_i)}{P_1(x_i)}e^\varepsilon + O(1)\right)\right\} \\ &\quad - \frac{1}{(e^\varepsilon-1)(e^\varepsilon+k-1)}\left\{\sum_{i\in[k]}\sum_{l\in[k],l\neq i}S_{ij}^{(k)}\left(P_0(x_l)\log\frac{P_0(x_l)}{P_1(x_l)}e^\varepsilon + O(1)\right)\right\} \\ &= \frac{1}{(e^\varepsilon-1)(e^\varepsilon+k-1)}\left(\left(\sum_{x_i\in T_j}P_0(x_i)\log\frac{P_0(x_i)}{P_1(x_i)}\right)e^{3\varepsilon} + O\left(e^{2\varepsilon}\right)\right) \\ &= \left(\sum_{x_i\in T_j}P_0(x_i)\log\frac{P_0(x_i)}{P_1(x_i)}\right)e^\varepsilon + O(1). \end{aligned} \tag{50}$$

Assume, to begin with, that $j \neq \{j_1, j_2, ..., j_k\}$. Then

$$S^{(k)}{}_j^T \alpha^* - \mu_j = \left(P_0(T_j) \log \frac{P_0(T_j)}{P_1(T_j)} - \sum_{x_i \in T_j} P_0(x_i) \log \frac{P_0(x_i)}{P_1(x_i)} \right) e^\varepsilon + O(1).$$

Notice that for $j \neq \{j_1, j_2, ..., j_k\}$, $P_0(T_j) \log \frac{P_0(T_j)}{P_1(T_j)} > \sum_{x_i \in T_j} P_0(x_i) \log \frac{P_0(x_i)}{P_1(x_i)}$ by the log-sum inequality. Therefore, there exists a $\varepsilon(j) > 0$ such that $S^{(k)}{}_j^T \alpha^* - \mu_j \geq 0$ for all $\varepsilon \geq \varepsilon(j)$. If $j \in \{j_1, j_2, ..., j_k\}$, it is not hard to check that $S^{(k)}{}_j^T \alpha^* - \mu_j = 0$ for all ε. In this case, set $\varepsilon(j) = 0$. This establishes the satisfiability of α^* for all $\varepsilon \geq \varepsilon^* = \max_{j \in [2^k]} \varepsilon(j)$. The satisfiability of α^*, in turn, shows that (47) is indeed an upper bound to the primal problem. It remains to show that this upper bound can be achieved via the randomized response. To this extent, recall that the randomized response is given by

$$Q(y|x) = \begin{cases} \frac{e^\varepsilon}{|\mathcal{X}|-1+e^\varepsilon} & \text{if } y = x, \\ \frac{1}{|\mathcal{X}|-1+e^\varepsilon} & \text{if } y \neq x. \end{cases} \tag{51}$$

Computing the KL divergence between M_0 and M_1 under (51), we get that

$$D_{\mathrm{kl}}(M_0||M_1) = \frac{1}{(e^\varepsilon + k - 1)} \sum_{i \in [k]} (P_0(x_i)(e^\varepsilon - 1) + 1) \log \frac{(P_0(x_i)(e^\varepsilon - 1) + 1)}{(P_1(x_i)(e^\varepsilon - 1) + 1)}.$$

Hence, the randomized response in (51) achieves the upper bound in (47). This proves the optimality of the randomized response for all $\varepsilon \geq \varepsilon^*$.

8.5 Proof of Theorem 7

We start the proof with a fundamental bound on the symmetrized KL divergence between the M_0 and M_1.

Lemma 25 *For any $\varepsilon \geq 0$, let Q be any conditional distribution that guarantees ε differential privacy. Then for any pair of distributions P_0 and P_1, the induced marginals M_0 and M_1 must satisfy the bound*

$$D_{\mathrm{kl}}\big(M_0||M_1\big) + D_{\mathrm{kl}}\big(M_1||M_0\big) \leq 4(e^\varepsilon - 1)^2 \big\|P_0 - P_1\big\|_{\mathrm{TV}}^2.$$

The above lemma appears as Theorem 1 in Duchi et al. (2013). By Lemma 25, we have that

$$\mathrm{OPT} = \max_{Q \in \mathcal{D}_\varepsilon} D_{\mathrm{kl}}\big(M_0||M_1\big) \leq 4(e^\varepsilon - 1)^2 \big\|P_0 - P_1\big\|_{\mathrm{TV}}^2. \tag{52}$$

Let M_0^B and M_1^B be the marginals obtained by using the binary mechanism given in (14). By Corollary 11, we have that $\|M_0^B - M_1^B\|_{\mathrm{TV}} = \frac{e^\varepsilon - 1}{e^\varepsilon + 1} \|P_0 - P_1\|_{\mathrm{TV}}$. Consequently, by applying Pinsker's inequality to the KL divergence between M_0^B and M_1^B we get that

$$\begin{aligned} \mathrm{BIN} &= D_{\mathrm{kl}}\big(M_0^B||M_1^B\big) \\ &\geq 2\big\|M_0^B - M_1^B\big\|_{\mathrm{TV}}^2 \\ &= 2\left(\frac{e^\varepsilon - 1}{e^\varepsilon + 1}\right)^2 \big\|P_0 - P_1\big\|_{\mathrm{TV}}^2. \end{aligned} \tag{53}$$

Combining (52) and (53) we get that $\mathrm{BIN} \geq \frac{1}{2(e^\varepsilon+1)^2}\mathrm{OPT}$ which was to be shown.

9. Proofs for Information Preservation

9.1 Proof of Theorem 12

By Theorem 4, we have that

$$\begin{aligned} \max_{Q \in \mathcal{D}_\varepsilon} I(X;Y) = \quad & \underset{\theta}{\text{maximize}} && \mu^T \theta \\ & \text{subject to} && S^{(k)}\theta = \mathbb{1} \\ & && \theta \geq 0, \end{aligned} \tag{54}$$

where $\mu_j = \mu\left(S_j^{(k)}\right) = \sum_{i \in [k]} P(x_i) S_{ij}^{(k)} \log\left(\frac{S_{ij}^{(k)}}{\sum_{i \in [k]} P(x_i) S_{ij}^{(k)}}\right)$ for $j \in \{1, \ldots, 2^k\}$ and $S^{(k)}$ is the $k \times 2^k$ staircase pattern matrix given in Definition 3. The polytope given by $S^{(k)}\theta = \mathbb{1}$ and $\theta \geq 0$ is a closed and bounded one. Thus, there is no duality gap and solving the above linear program is equivalent to solving its dual

$$\begin{aligned} & \underset{\alpha}{\text{minimize}} && \mathbb{1}^T \alpha \\ & \text{subject to} && S^{(k)^T} \alpha \geq \mu. \end{aligned} \tag{55}$$

Note that any satisfiable solution α^* to (55) provides an upper bound to (54) since $\max \mu^T\theta = \min \mathbb{1}^T\alpha \leq \mathbb{1}^T\alpha^*$. Let $T_j = \{x_i : S_{ij}^{(k)} = e^\varepsilon\}$ and set $j_1 = \{j : T_j = T\}$ and $j_2 = \{j : T_j = T^c\}$. Consider the following choice of dual variable

$$\alpha_i^* = \frac{1}{(e^\varepsilon + 1)(e^\varepsilon - 1)} \begin{cases} \frac{e^\varepsilon \mu\left(S_{j_1}^{(k)}\right) - \mu\left(S_{j_2}^{(k)}\right)}{|T|} & \forall i \in T \\ \frac{e^\varepsilon \mu\left(S_{j_2}^{(k)}\right) - \mu\left(S_{j_1}^{(k)}\right)}{|T^c|} & \forall i \in T^c \end{cases}.$$

Observe that since $T_{j_1} = T$, $T_{j_2} = T^c$, and

$$\mu_j = P(T_j) e^\varepsilon \log \frac{e^\varepsilon}{P(T_j{}^c) + e^\varepsilon P(T_j)} + P(T_j{}^c) \log \frac{1}{P(T_j{}^c) + e^\varepsilon P(T_j)}, \tag{56}$$

we have that

$$\begin{aligned} \mathbb{1}^T\alpha^* &= \frac{1}{(e^\varepsilon+1)(e^\varepsilon-1)} \left\{ \sum_{i \in T} \frac{1}{|T|} \left(e^\varepsilon \mu\left(S_{j_1}^{(k)}\right) - \mu\left(S_{j_2}^{(k)}\right)\right) \right. \\ &= \left. + \sum_{i \in T^c} \frac{1}{|T^c|} \left(e^\varepsilon \mu\left(S_{j_2}^{(k)}\right) - \mu\left(S_{j_1}^{(k)}\right)\right) \right\} \\ &= \frac{1}{(e^\varepsilon+1)} \left(\mu\left(S_{j_1}^{(k)}\right) + \mu\left(S_{j_1}^{(k)}\right)\right) \\ &= \frac{1}{e^\varepsilon+1} \left\{ P(T) e^\varepsilon \log \frac{e^\varepsilon}{P(T^c) + e^\varepsilon P(T)} + P(T^c) \log \frac{1}{P(T^c) + e^\varepsilon P(T)} \right\} + \\ &\quad \frac{1}{e^\varepsilon+1} \left\{ P(T^c) e^\varepsilon \log \frac{e^\varepsilon}{P(T) + e^\varepsilon P(T^c)} + P(T) \log \frac{1}{P(T) + e^\varepsilon P(T^c)} \right\}. \end{aligned} \tag{57}$$

We claim that α^* is a feasible dual variable for sufficiently small ε. In order to prove that α^* is a feasible dual variable, we show that $\left(S^{(k)^T}\alpha^*\right)_j - \mu_j \geq 0$ for all $j \in \{1,\ldots,2^k\}$ and all $\varepsilon \leq \varepsilon^*$, where ε^* is a positive quantity that depends on P. Using the following facts

$$\begin{aligned} e^{\varepsilon} &= 1+\varepsilon+\frac{1}{2}\varepsilon+O\left(\varepsilon^3\right) \\ \log\left(a+e^{\varepsilon}b\right) &= b\varepsilon+\frac{b(1-b)}{2}\varepsilon^2+O\left(\varepsilon^3\right) \\ \frac{1}{1+e^{\varepsilon}} &= \frac{1}{2}-\frac{1}{4}\varepsilon+O\left(\varepsilon^2\right), \end{aligned} \tag{58}$$

for small ε, we get that

$$\begin{aligned} \mu_j &= P\left(T_j\right)e^{\varepsilon}\log\frac{e^{\varepsilon}}{P\left(T_j{}^c\right)+e^{\varepsilon}P\left(T_j\right)}+P\left(T_j{}^c\right)\log\frac{1}{P\left(T_j{}^c\right)+e^{\varepsilon}P\left(T_j\right)} \\ &= P\left(T_j\right)e^{\varepsilon}\varepsilon-\left(P\left(T_j\right)\left(e^{\varepsilon}-1\right)+1\right)\log\left(P\left(T_j\right)\left(e^{\varepsilon}-1\right)+1\right) \\ &= \frac{1}{2}P\left(T_j\right)P\left(T_j^c\right)\varepsilon^2+O\left(\varepsilon^3\right). \end{aligned} \tag{59}$$

On the other hand,

$$\begin{aligned} \left(S^{(k)^T}\alpha^*\right)_j &= S_j^{(k)^T}\alpha^* \\ &= \frac{1}{\left(e^{\varepsilon}+1\right)\left(e^{\varepsilon}-1\right)}\left\{\sum_{i\in T}\frac{S_{ij}^{(k)}}{|T|}\left(e^{\varepsilon}\mu\left(S_{j_1}^{(k)}\right)-\mu\left(S_{j_2}^{(k)}\right)\right)\right. \\ &\qquad \left.+\sum_{i\in T^c}\frac{S_{ij}^{(k)}}{|T^c|}\left(e^{\varepsilon}\mu\left(S_{j_2}^{(k)}\right)-\mu\left(S_{j_1}^{(k)}\right)\right)\right\} \\ &= \frac{1}{\left(e^{\varepsilon}+1\right)\left(e^{\varepsilon}-1\right)}\left(e^{\varepsilon}\mu\left(S_{j_1}^{(k)}\right)-\mu\left(S_{j_2}^{(k)}\right)\right)\left(\frac{|T_j\cap T|}{|T|}e^{\varepsilon}+\frac{|T_j^c\cap T|}{|T|}\right) \\ &\quad +\frac{1}{\left(e^{\varepsilon}+1\right)\left(e^{\varepsilon}-1\right)}\left(e^{\varepsilon}\mu\left(S_{j_2}^{(k)}\right)-\mu\left(S_{j_1}^{(k)}\right)\right)\left(\frac{|T_j\cap T^c|}{|T^c|}e^{\varepsilon}+\frac{|T_j^c\cap T^c|}{|T^c|}\right) \\ &= \frac{1}{\left(e^{\varepsilon}+1\right)}\left(\frac{1}{2}P\left(T\right)P\left(T^c\right)\varepsilon^2+O\left(\varepsilon^3\right)\right)\left\{\frac{|T_j\cap T^c|}{|T^c|}+\frac{|T_j^c\cap T^c|}{|T^c|}\right. \\ &\qquad \left.+\frac{|T_j\cap T|}{|T|}+\frac{|T_j^c\cap T|}{|T|}+O\left(\varepsilon\right)\right\} \\ &= \frac{1}{2}P\left(T\right)P\left(T^c\right)\varepsilon^2+O\left(\varepsilon^3\right), \end{aligned} \tag{60}$$

where we have used the facts that $T_{j_1}=T$, $T_{j_2}=T^c$, and

$$\begin{aligned} \mu\left(S_{j_1}^{(k)}\right) &= \frac{1}{2}P\left(T\right)P\left(T^c\right)\varepsilon^2+O\left(\varepsilon^3\right) \\ \mu\left(S_{j_2}^{(k)}\right) &= \frac{1}{2}P\left(T\right)P\left(T^c\right)\varepsilon^2+O\left(\varepsilon^3\right). \end{aligned} \tag{61}$$

Let $f(z)=|z-\frac{1}{2}|$, $g(z)=-z\log z-(1-z)\log(1-z)$, and $h(z)=z(1-z)$ for $0\leq z\leq 1$. On the one hand, g and h are monotonically increasing over $0\leq z\leq\frac{1}{2}$ and monotonically

decreasing over $\frac{1}{2}\leq z\leq 1$ but on the other hand, f is monotonically decreasing over $0\leq z\leq\frac{1}{2}$ and monotonically increasing over $\frac{1}{2}\leq z\leq 1$. Therefore,

$$\begin{aligned} T\in\arg\min_{A\subseteq\mathcal{X}}\left|P(A)-\frac{1}{2}\right| &\Leftrightarrow T\in\arg\max_{A\subseteq\mathcal{X}} -P(A)\log P(A)-P(A^c)\log P(A^c) \\ &\Leftrightarrow T\in\arg\max_{A\subseteq\mathcal{X}} P(A)P(A^c). \end{aligned} \tag{62}$$

Since the set T was chosen so that it maximizes $P\left(T\right)P\left(T^c\right)$, we have that $P\left(T\right)P\left(T^c\right)\geq P\left(T_j\right)P\left(T_j^c\right)$ for all $j\in\{1,\ldots,2^k\}$. Assume, to begin with, that $j\neq\{j_1,j_2\}$. Then by the uniqueness of the maximizer assumption stated in the theorem, we have that $P\left(T\right)P\left(T^c\right)>P\left(T_j\right)P\left(T_j^c\right)$.

$$\left(S^T\alpha^*\right)_j-\mu_j=\frac{1}{2}\left(P\left(T\right)P\left(T^c\right)-P\left(T_j\right)P\left(T_j^c\right)\right)\varepsilon^2+O\left(\varepsilon^3\right),$$

and thus, there exists an ε^* that depends on P such that $\left(S^{(k)^T}\alpha^*\right)_j-\mu_j\geq 0$ for all $\varepsilon\leq\varepsilon^*$. If $j=\{j_1,j_2\}$, it is not hard to check that $\left(S^{(k)^T}\alpha^*\right)_j-\mu_j=0$ for all ε. This establishes the satisfiability of α^* for all $\varepsilon\leq\varepsilon^*$ which proves an upper bound on the primal problem (given in (57)). It remains to show that the upper bound can be indeed achieved via the binary mechanism. To this extent, recall that the binary mechanism is given by

$$Q(0|x)=\begin{cases}\frac{e^{\varepsilon}}{1+e^{\varepsilon}} & \text{if } x\in T,\\ \frac{1}{1+e^{\varepsilon}} & \text{if } x\notin T.\end{cases}\qquad Q(1|x)=\begin{cases}\frac{e^{\varepsilon}}{1+e^{\varepsilon}} & \text{if } x\notin T,\\ \frac{1}{1+e^{\varepsilon}} & \text{if } x\in T.\end{cases} \tag{63}$$

Computing the $I\left(X;Y\right)$ under (63), we get that

$$\begin{aligned} I\left(X;Y\right) &= \frac{1}{e^{\varepsilon}+1}\left\{P\left(T\right)e^{\varepsilon}\log\frac{e^{\varepsilon}}{P\left(T^c\right)+e^{\varepsilon}P\left(T\right)}+P\left(T^c\right)\log\frac{1}{P\left(T^c\right)+e^{\varepsilon}P\left(T\right)}\right\}+ \\ &\quad \frac{1}{e^{\varepsilon}+1}\left\{P\left(T^c\right)e^{\varepsilon}\log\frac{e^{\varepsilon}}{P\left(T\right)+e^{\varepsilon}P\left(T^c\right)}+P\left(T\right)\log\frac{1}{P\left(T\right)+e^{\varepsilon}P\left(T^c\right)}\right\}. \end{aligned} \tag{64}$$

Hence, the binary mechanism in (63) achieves the upper bound in (57). This proves the optimality of the binary mechanism for all $\varepsilon\leq\varepsilon^*$.

9.2 Proof of Theorem 13

We start by proving an upper bound on $\max_{Q\in\mathcal{D}_\varepsilon}I\left(X;Y\right)$ which is tight for $\varepsilon\leq 1$. Recall that by Theorem 4, we have that

$$\begin{aligned} \text{OPT}=\max_{Q\in\mathcal{D}_\varepsilon}I\left(X;Y\right)= \quad & \underset{\theta}{\text{maximize}} && \sum_{j=1}^{2^k}\mu_j\theta_j \\ & \text{subject to} && S^{(k)}\theta=\mathbb{1} \\ & && \theta\geq 0, \end{aligned}$$

where

$$\begin{aligned}\mu_j &= \mu\left(S_j^{(k)}\right)\\ &= \sum_{i\in[k]} P(x_i)\, S_{ij}^{(k)} \log\left(\frac{S_{ij}^{(k)}}{\sum_{i\in[k]} P(x_i)\, S_{ij}^{(k)}}\right)\\ &= P(T_j)\, e^{\varepsilon}\varepsilon - \left(P(T_j)\left(e^{\varepsilon}-1\right)+1\right)\log\left(P(T_j)\left(e^{\varepsilon}-1\right)+1\right), \end{aligned} \tag{65}$$

$T_j = \{i : S_{ij}^{(k)} = e^{\varepsilon}\}$, and $S^{(k)}$ is the $k \times 2^k$ staircase pattern matrix given in Definition 3.

Lemma 26 *For all distributions P and all ε, the following bound holds*

$$\mathrm{OPT} = \max_{Q\in\mathcal{D}_\varepsilon} I(X;Y) \le \left(\max_j \mu_j\right)\frac{k}{e^{\varepsilon}+k-1}.$$

The proof of this lemma is given in Section 9.3. In what follows, we will make the dependency of μ_j on $P(T_j)$ and ε explicit by writing $\mu_j(P(T_j),\varepsilon)$ for μ_j. From the proof of Theorem 12, we have that the partition set T defined in (19) is given by $T \in \arg\max_{A\subseteq\mathcal{X}} P(A)P(A^c)$. It is easy to check that the binary mechanism given in (20) achieves the following utility

$$\mathrm{BIN} = \frac{\mu(P(T),\varepsilon) + \mu(P(T^c),\varepsilon)}{e^{\varepsilon}+1}.$$

Lemma 27 *For all distributions P and all $\varepsilon \le 1$, the following bound holds*

$$\frac{\max_j \mu_j}{\mu(P(T),\varepsilon)+\mu(P(T^c),\varepsilon)} \le 1.$$

The proof of the above lemma is given in Section 9.4. Combining the results of lemmas 26 and 27 we get that

$$\begin{aligned}\frac{\mathrm{OPT}}{\mathrm{BIN}} &\le \frac{\max_j \mu_j}{\mu(P(T),\varepsilon)+\mu(P(T^c),\varepsilon)}\frac{k}{e^{\varepsilon}+k-1}\left(e^{\varepsilon}+1\right)\\ &\le \frac{k}{e^{\varepsilon}+k-1}\left(e^{\varepsilon}+1\right)\\ &\le e^{\varepsilon}+1, \end{aligned} \tag{66}$$

for all $\varepsilon \le 1$. This concludes the proof.

9.3 Proof of Lemma 26

To begin with, since $S_1^{(k)} = \mathbb{1} = \frac{1}{e^{\varepsilon}} S_{2^k}^{(k)}$ and μ is homogenous, we have that $\theta_1\mu_1 + \theta_{2^k}\mu_{2^k} = \left(\frac{1}{e^{\varepsilon}}\theta_1 + \theta_{2^k}\right)\mu_{2^k}$. Therefore, the following two maximization problems are equivalent

$$\begin{array}{ll}\underset{\theta}{\text{maximize}} & \displaystyle\sum_{j=1}^{2^k}\mu_j\theta_j\\ \text{subject to} & S^{(k)}\theta = \mathbb{1}\\ & \theta \ge 0\end{array} \quad = \quad \begin{array}{ll}\underset{\theta}{\text{maximize}} & \displaystyle\sum_{j=1}^{2^k-1}\tilde{\mu}_j\theta_j\\ \text{subject to} & \tilde{S}^{(k)}\theta = \mathbb{1}\\ & \theta \ge 0,\end{array}$$

where $\tilde{\mu}_j = \mu_{j+1}$ and $\tilde{S}^{(k)}$ is obtained by deleting the first column of $S^{(k)}$. Moreover, using the fact that $\max_{j\in[2^k-1]}\tilde{\mu}_j \le \max_{j\in[2^k]}\mu_j$ and weak duality, we get that

$$\begin{array}{ll}\underset{\theta}{\text{maximize}} & \tilde{\mu}^T\theta\\ \text{subject to} & \tilde{S}^{(k)}\theta = \mathbb{1}\\ & \theta \ge 0\end{array} \quad \le \quad \left(\max_{j\in[2^k-1]}\tilde{\mu}_j\right)\begin{array}{ll}\underset{\theta}{\text{maximize}} & \mathbb{1}^T\theta\\ \text{subject to} & \tilde{S}^{(k)}\theta = \mathbb{1}\\ & \theta \ge 0\end{array}$$

$$\le \left(\max_{j\in[2^k]}\mu_j\right)\begin{array}{ll}\underset{\alpha}{\text{minimize}} & \mathbb{1}^T\alpha\\ \text{subject to} & \tilde{S}^{(k)^T}\alpha \ge \mathbb{1}.\end{array} \tag{67}$$

Consider the following choice of dual variable $\alpha_i^* = \frac{1}{e^{\varepsilon}+k-1}$. We claim that α^* is satisfiable. This can be easily verified by noting that

$$\left(\tilde{S}^{(k)^T}\alpha^*\right)_j = \tilde{S}_j^{(k)^T}\alpha^* = \frac{|T_j|e^{\varepsilon} + (k-|T_j|)}{e^{\varepsilon}+k-1} = \frac{|T_j|(e^{\varepsilon}-1)+k}{e^{\varepsilon}+k-1} \ge 1$$

where the last inequality holds since $|T_j| \ge 1$ (this is true because we have deleted the first column of $S^{(k)}$). Therefore, $\mathrm{OPT} \le (\max_j \mu_j)\mathbb{1}^T\alpha^* = (\max_j \mu_j)\frac{k}{e^{\varepsilon}+k-1}$ which was to be shown.

9.4 Proof of Lemma 27

Let $\mu(z,\varepsilon)$ be the function obtained by replacing $P(T_j)$ by the continuous variable $z \in [0,1]$ in $\mu_j(P(T_j),\varepsilon)$. Taking the derivative of $\mu(z,\varepsilon)$ with respect to z we get

$$\mu'(z,\varepsilon) = e^{\varepsilon}\varepsilon - \left(e^{\varepsilon}-1\right) - \left(e^{\varepsilon}-1\right)\log\left(z(e^{\varepsilon}-1)+1\right).$$

Observe that $\mu'(z,\varepsilon) > 0$ for all

$$z < z^*(\varepsilon) = \frac{1}{e^{\varepsilon}-1}\left(e^{\left\{\frac{e^{\varepsilon}\varepsilon}{e^{\varepsilon}-1}-1\right\}}-1\right),$$

$\mu'(z,\varepsilon) < 0$ for all $z > z^*(\varepsilon)$, and $\mu'(z,\varepsilon) = 0$ for $z = z^*(\varepsilon)$. Combining this with the fact that $\mu(0,\varepsilon) = \mu(1,\varepsilon) = 0$ we get that $\mu(z,\varepsilon) \ge 0$ for all $z \in [0,1]$ and for any fixed ε, $\mu(z,\varepsilon)$ is maximized at $z^*(\varepsilon)$.

Set $x^* \in \arg\max_{x\in\mathcal{X}} P(x)$ and fix an $\varepsilon \le 1$. We will treat the following three cases separately.

Case 1: $P(x^*) \in [1-z^*(\varepsilon), 1]$.

Claim 4 *Let $T = \{x^*\}$. Then $\{T, T^c\} = \arg\max_{A\subseteq\mathcal{X}} P(A)P(A^c)$ and $\max_{A\subseteq\mathcal{X}}\mu(P(A),\varepsilon) = \max\left(\mu(P(T),\varepsilon), \mu(P(T^c),\varepsilon)\right)$.*

Proof Observe that $z^*(\varepsilon) \le \frac{1}{2}$ for all ε and $T^c = \mathcal{X}\setminus\{x^*\}$. The function $f(z) = z(1-z)$ decreases over the range $[\frac{1}{2}, 1] \supseteq [1-z^*(\varepsilon), 1]$. Thus, for all $A \supset T$, $P(T)P(T^c) >$

$P(A)P(A^c)$ because $P(T) \geq 1 - z^*(\varepsilon)$. This proves that $T \in \arg\max_{A\subseteq\mathcal{X}} P(A)P(A^c)$ and for all $A \supset T$, $A \notin \arg\max_{A\subseteq\mathcal{X}} P(A)P(A^c)$. Using a similar approach, we can show that $T^c \in \arg\max_{A\subseteq\mathcal{X}} P(A)P(A^c)$ and for all $A \subset T^c$, $A \notin \arg\max_{A\subseteq\mathcal{X}} P(A)P(A^c)$. Therefore, $\{T, T^c\} = \arg\max_{A\subseteq\mathcal{X}} P(A)P(A^c)$. This proves the first part of the claim. The function $\mu(z,\varepsilon)$ increases over the range $[0, z^*(\varepsilon)]$. Thus, for all $A \subseteq T^c$, $\mu(P(A),\varepsilon) \leq \mu(P(T^c),\varepsilon)$ because $P(T^c) \leq z^*(\varepsilon)$. On the other hand, note that $\mu(z,\varepsilon)$ decreases over the range $[z^*(\varepsilon), 1]$ which includes the range $[1 - z^*(\varepsilon), 1]$. Thus, for all A such that $A \supseteq T$, $\mu(P(A),\varepsilon) \leq \mu(P(T),\varepsilon)$ because $P(T) \geq 1 - z^*(\varepsilon)$. This proves that $\max(\mu(P(T),\varepsilon), \mu(P(T^c),\varepsilon)) = \max_{A\subseteq\mathcal{X}} \mu(P(A),\varepsilon)$. ■

Using the above claim, we can conclude that the partition set T defined in (19) is equal to $\{x^*\}$ and

$$\begin{aligned}\frac{\max_j \mu_j}{\mu(P(T),\varepsilon) + \mu(P(T^c),\varepsilon)} &= \frac{\max_{A\subseteq\mathcal{X}} \mu(P(A),\varepsilon)}{\mu(P(T),\varepsilon) + \mu(P(T^c),\varepsilon)} \\ &\leq \frac{\max_{A\subseteq\mathcal{X}} \mu(P(A),\varepsilon)}{\max(\mu(P(T),\varepsilon), \mu(P(T^c),\varepsilon))} \\ &= 1. \end{aligned} \tag{68}$$

Case 2: $P(x^*) \in [\frac{1}{2}, 1 - z^*(\varepsilon)]$. Using the first part of the proof of Claim 4, we can show that if $T = \{x^*\}$, then $\{T, T^c\} = \arg\max_{A\subseteq\mathcal{X}} P(A)P(A^c)$. Therefore, the partition set T defined in (19) is equal to $\{x^*\}$ and

$$\begin{aligned}\frac{\max_j \mu_j}{\mu(P(T),\varepsilon) + \mu(P(T^c),\varepsilon)} &= \frac{\max_{A\subseteq\mathcal{X}} \mu(P(A),\varepsilon)}{\mu(P(T),\varepsilon) + \mu(P(T^c),\varepsilon)} \\ &\leq \frac{\mu(z^*(\varepsilon),\varepsilon)}{\mu(P(x^*),\varepsilon) + \mu(1 - P(x^*),\varepsilon)} \\ &\leq 1. \end{aligned} \tag{69}$$

Case 3: $P(x^*) \in [0, \frac{1}{2}]$.

Claim 5 *There exists a set $A \subset \mathcal{X}$ such that $\frac{1}{2} - P(x^*) \leq P(A) \leq \frac{1}{2}$.*

Proof Without loss of generality, assume that the sequence $P(x_i)$, $i \in [k]$, is sorted in increasing order. Let $l^* = \min\{l : \sum_{i=1}^{l} P(x_i) \geq \frac{1}{2}\}$. From the definition of l^*, $P(\{x_1, \ldots, x_{l^*-1}\}) < \frac{1}{2}$ and $P(\{x_1, \ldots, x_{l^*}\}) \geq \frac{1}{2}$. Further,

$$P(\{x_1, \ldots, x_{l^*-1}\}) = P(\{x_1, \ldots, x_{l^*}\}) - P(x_{l^*})$$

and since $x^* \in \arg\max_{x\in\mathcal{X}} P(x)$, $P(x_{l^*}) \leq P(x^*)$. Therefore, if $A = \{x_1, \ldots, x_{l^*-1}\}$, then $\frac{1}{2} - P(x^*) \leq P(A) \leq \frac{1}{2}$. ■

Let $P(T) = \min\{P(B) : B \in \arg\max_{A\subseteq\mathcal{X}} P(A)P(A^c)\}$. We claim that $\frac{1}{4} \leq P(T) \leq \frac{1}{2}$. The upper bound on $P(T)$ follows immediately from its definition. To prove the lower bound on $P(T)$, consider the set A given in Claim 5 and observe that

$$\begin{aligned} P(T) &\geq \max(P(x^*), P(A)) \\ &\geq \max(P(x^*), \frac{1}{2} - P(x^*)) \\ &\geq \frac{1}{4}. \end{aligned} \tag{70}$$

All the inequalities follow from Claim 5 and the fact that $P(x^*) \in [0, \frac{1}{2}]$.

Since $\frac{1}{4} \leq P(T) \leq \frac{1}{2}$, we have that $\frac{1}{2} \leq P(T^c) \leq \frac{3}{4}$. Moreover, the function $\mu(z,\varepsilon)$ decreases over the range $[z^*(\varepsilon), 1] \supset [\frac{1}{2}, \frac{3}{4}]$ and increases over the range $[\frac{1}{4}, z^*(\varepsilon)]$. Therefore, $\mu(P(T^c),\varepsilon) \geq \mu(\frac{3}{4},\varepsilon)$ and $\mu(P(T),\varepsilon) \geq \min\left(\mu(\frac{1}{2},\varepsilon), \mu(\frac{1}{4},\varepsilon)\right)$. Putting it all together, we have that

$$\begin{aligned}\frac{\max_j \mu_j}{\mu(P(T),\varepsilon) + \mu(P(T^c),\varepsilon)} &= \frac{\max_{A\subseteq\mathcal{X}} \mu(P(A),\varepsilon)}{\mu(P(T),\varepsilon) + \mu(P(T^c),\varepsilon)} \\ &\leq \frac{\mu(z^*(\varepsilon),\varepsilon)}{\min\left(\mu(\frac{1}{2},\varepsilon), \mu(\frac{1}{4},\varepsilon)\right) + \mu(\frac{3}{4},\varepsilon)} \\ &\leq 1. \end{aligned} \tag{71}$$

9.5 Proof of Theorem 14

By Theorem 4, we have that

$$\max_{Q\in\mathcal{D}_\varepsilon} I(X;Y) = \begin{aligned} &\underset{\theta}{\text{maximize}} && \mu^T\theta \\ &\text{subject to} && S^{(k)}\theta = \mathbb{1} \\ &&& \theta \geq 0, \end{aligned} \tag{72}$$

where $\mu_j = \mu\left(S_j^{(k)}\right) = \sum_{i\in[k]} P(x_i) S_{ij}^{(k)} \log\left(\frac{S_{ij}^{(k)}}{\sum_{i\in[k]} P(x_i) S_{ij}^{(k)}}\right)$ for $j \in \{1, \ldots, 2^k\}$ and $S^{(k)}$ is the $k \times 2^k$ staircase pattern matrix given in Definition 3. The polytope given by $S^{(k)}\theta = \mathbb{1}$ and $\theta \geq 0$ is a closed and bounded one. Thus, there is no duality gap and solving the above linear program is equivalent to solving its dual

$$\begin{aligned} &\underset{\alpha}{\text{minimize}} && \mathbb{1}^T\alpha \\ &\text{subject to} && {S^{(k)}}^T\alpha \geq \mu. \end{aligned} \tag{73}$$

Note that any satisfiable solution α^* to (73) provides an upper bound to (72) since $\max \mu^T\theta = \min \mathbb{1}^T\alpha \leq \mathbb{1}^T\alpha^*$. Let $T_j = \{x_i : S_{ij}^{(k)} = e^\varepsilon\}$ and set $j_i = \{j : T_j = i\}$ for $i \in \{1, \ldots, k\}$. Consider the following choice of dual variable

$$\alpha_i^* = \frac{1}{(e^\varepsilon - 1)(e^\varepsilon + k - 1)} \left\{ (e^\varepsilon + k - 2)\, \mu\left(S_{j_i}^{(k)}\right) - \sum_{l\in[k], l\neq i} \mu\left(S_{j_l}^{(k)}\right) \right\},$$

for $i \in \{1, \ldots, k\}$. Observe that since $T_{j_i} = i$ we have that $P(T_{j_i}) = P(x_i)$ and since

$$\mu_j = P(T_j)\, e^\varepsilon \log\frac{e^\varepsilon}{P(T_j{}^c) + e^\varepsilon P(T_j)} + P(T_j{}^c) \log\frac{1}{P(T_j{}^c) + e^\varepsilon P(T_j)}, \tag{74}$$

we have that

$$\begin{aligned}
\mathbb{1}^T\alpha^* &= \frac{1}{(e^\varepsilon-1)(e^\varepsilon+k-1)}\sum_{i\in[k]}\left\{(e^\varepsilon+k-2)\,\mu\left(S_{ji}^{(k)}\right)-\sum_{l\in[k],l\neq i}\mu\left(S_{jl}^{(k)}\right)\right\}\\
&= \frac{1}{(e^\varepsilon-1)(e^\varepsilon+k-1)}\left\{(e^\varepsilon+k-2)\sum_{i\in[k]}\mu\left(S_{ji}^{(k)}\right)-\sum_{i\in[k]}\sum_{l\in[k],l\neq i}\mu\left(S_{jl}^{(k)}\right)\right\}\\
&= \frac{1}{(e^\varepsilon-1)(e^\varepsilon+k-1)}\left\{(e^\varepsilon+k-2)\sum_{i\in[k]}\mu\left(S_{ji}^{(k)}\right)-(k-1)\sum_{i\in[k]}\mu\left(S_{ji}^{(k)}\right)\right\}\\
&= \frac{1}{(e^\varepsilon+k-1)}\sum_{i\in[k]}\mu\left(S_{ji}^{(k)}\right)\\
&= \frac{1}{(e^\varepsilon+k-1)}\sum_{i\in[k]}\left\{P(x_i)\,e^\varepsilon\log\frac{e^\varepsilon}{P(x_i)(e^\varepsilon-1)+1}\right.\\
&\qquad\left.+(1-P(x_i))\log\frac{1}{P(x_i)(e^\varepsilon-1)+1}\right\}. \quad (75)
\end{aligned}$$

We claim that α^* is a feasible dual variable for sufficiently large ε. In order to prove that α^* is a feasible dual variable, we show that $\left(S^{(k)^T}\alpha^*\right)_j-\mu_j\geq 0$ for all $j\in\{1,\ldots,2^k\}$ and all $\varepsilon\geq\varepsilon^*$, where ε^* is a positive quantity that depends on P. Using the fact that

$$\log(a+e^\varepsilon b)=\varepsilon+\log b+O\left(e^{-\varepsilon}\right),$$

for large ε, we get that

$$\begin{aligned}
\mu_j &= P(T_j)\,e^\varepsilon\log\frac{e^\varepsilon}{P(T_j{}^c)+e^\varepsilon P(T_j)}+P(T_j{}^c)\log\frac{1}{P(T_j{}^c)+e^\varepsilon P(T_j)}\\
&= P(T_j)\,e^\varepsilon\varepsilon-(P(T_j)(e^\varepsilon-1)+1)\log(P(T_j)(e^\varepsilon-1)+1)\\
&= P(T_j)\,e^\varepsilon\varepsilon-(P(T_j)(e^\varepsilon-1)+1)\left(\varepsilon+\log P(T_j)+O\left(e^{-\varepsilon}\right)\right)\\
&= -\left(P(T_j)\log P(T_j)\right)e^\varepsilon+O(\varepsilon). \quad (76)
\end{aligned}$$

On the other hand,

$$\begin{aligned}
\left(S^{(k)^T}\alpha^*\right)_j &= S_j^{(k)^T}\alpha^*\\
&= e^\varepsilon\sum_{i\in T_j}\alpha_i^*+\sum_{i\in T_j^c}\alpha_i^*\\
&= -\frac{1}{(e^\varepsilon-1)(e^\varepsilon+k-1)}\left\{\sum_{i\in[k]}S_{ij}^{(k)}(e^\varepsilon+k-2)\left(P(x_i)\log P(x_i)\,e^\varepsilon\right.\right.\\
&\qquad\left.\left.+O(\varepsilon)\right)\right\}\\
&\quad+\frac{1}{(e^\varepsilon-1)(e^\varepsilon+k-1)}\left\{\sum_{i\in[k]}\sum_{l\in[k],l\neq i}S_{ij}^{(k)}\left(\left(P(x_l)\log P(x_l)\right)e^\varepsilon+O(\varepsilon)\right)\right\}\\
&= -\frac{1}{(e^\varepsilon-1)(e^\varepsilon+k-1)}\left(\left(\sum_{i\in T_j}P(x_i)\log P(x_i)\right)e^{3\varepsilon}+O\left(e^{2\varepsilon}\varepsilon\right)\right)\\
&= -\left(\sum_{i\in T_j}P(x_i)\log P(x_i)\right)e^\varepsilon+O(\varepsilon). \quad (77)
\end{aligned}$$

Assume, to begin with, that $j\neq\{j_1,j_2,...,j_k\}$. Then

$$\left(S^{(k)^T}\alpha^*\right)_j-\mu_j=\left(P(T_j)\log P(T_j)-\sum_{i\in T_j}P(x_i)\log P(x_i)\right)e^\varepsilon+O(\varepsilon).$$

Notice that for $j\neq\{j_1,j_2,...,j_k\}$, $P(T_j)\log P(T_j)>\sum_{i\in T_j}P(x_i)\log P(x_i)$. Therefore, there exists an $\varepsilon^*>0$ such that $\left(S^{(k)^T}\alpha^*\right)_j-\mu_j\geq 0$ for all $\varepsilon\geq\varepsilon^*$. If $j\in\{j_1,j_2,...,j_k\}$, it is not hard to check that $\left(S^{(k)^T}\alpha^*\right)_j-\mu_j=0$ for all ε. This establishes the satisfiability of α^* for all $\varepsilon\geq\varepsilon^*$. It remains to show that the upper bound can be indeed achieved via the randomized response mechanism. To this extent, recall that the randomized response is given by

$$Q(y|x)=\begin{cases}\dfrac{e^\varepsilon}{|\mathcal{X}|-1+e^\varepsilon} & \text{if } y=x\,,\\ \dfrac{1}{|\mathcal{X}|-1+e^\varepsilon} & \text{if } y\neq x\,.\end{cases} \quad (78)$$

Computing the $I(X;Y)$ under (78), we get that

$$\begin{aligned}
I(X;Y) &= \frac{1}{e^\varepsilon+k-1}\sum_{i\in[k]}\left\{P(x_i)\,e^\varepsilon\log\frac{e^\varepsilon}{P(x_i)(e^\varepsilon-1)+1}\right.\\
&\qquad\left.+(1-P(x_i))\log\frac{1}{P(x_i)(e^\varepsilon-1)+1}\right\}. \quad (79)
\end{aligned}$$

Hence, the randomized response mechanism achieves the upper bound (75). This proves the optimality of the randomized response for all $\varepsilon \geq \varepsilon^*$.

10. Proof of Proposition 17

Let $U(Q)$ be a utility mechanism of the form $U(Q) = \sum_{\mathcal{Y}} \mu(Q_y)$, where μ is a sublinear function. Consider a stochastic mapping W of dimensions $\ell \times m$ and let QW be the stochastic mapping obtained by first applying Q to $X \in \mathcal{X}$ to obtain $Y \in \mathcal{Y}$ and then applying W to Y to obtain $Z \in \mathcal{Z}$.

$$\begin{aligned} U(QW) &= \sum_{\mathcal{Z}} \mu\left((QW)_z\right) \\ &= \sum_{\mathcal{Z}} \mu\left(\sum_{\mathcal{Y}} Q_y W_{y,z}\right) \\ &\leq \sum_{\mathcal{Y},\mathcal{Z}} W_{y,z} \mu\left(Q_y\right) \\ &= \sum_{\mathcal{Y}} \mu(Q_y) \\ &= U(Q), \end{aligned} \tag{80}$$

where the inequality follows from sublinearity and the second to last equality follows from the row stochastic property of W. Therefore, $U(Q)$ obeys the data processing inequality.

Abstract

This work studies applications and generalizations of a simple estimation technique that provides exponential concentration under heavy-tailed distributions, assuming only bounded low-order moments. We show that the technique can be used for approximate minimization of smooth and strongly convex losses, and specifically for least squares linear regression. For instance, our d-dimensional estimator requires just $\tilde{O}(d \log(1/\delta))$ random samples to obtain a constant factor approximation to the optimal least squares loss with probability $1-\delta$, without requiring the covariates or noise to be bounded or subgaussian. We provide further applications to sparse linear regression and low-rank covariance matrix estimation with similar allowances on the noise and covariate distributions. The core technique is a generalization of the median-of-means estimator to arbitrary metric spaces.

Keywords: Heavy-tailed distributions, unbounded losses, linear regression, least squares

1. Introduction

The minimax principle in statistical estimation prescribes procedures (*i.e.*, estimators) that minimize the worst-case risk over a large class of distributions generating the data. For a given loss function, the risk is the expectation of the loss of the estimator, where the expectation is taken over the data examined by the estimator. For example, for a large class of loss functions including squared loss, the empirical mean estimator minimizes the worst-case risk over the class of Gaussian distributions with known variance (Wolfowitz, 1950). In fact, Gaussian distributions with the specified variance are essentially the worst-case family of distributions for squared loss, at least up to constants (see, *e.g.*, Catoni, 2012, Proposition 6.1).

In this work, we are interested in estimators whose deviations from expected behavior are controlled with very high probability over the random draw of the data examined by the estimator. Deviations of the behavior of the estimator from its expected behavior are worrisome especially when data come from unbounded and/or heavy-tail distributions, where only very low order moments may be finite. For example, the Pareto distributions with shape parameter $\alpha > 0$ are unbounded and have finite moments only up to orders $< \alpha$; these distributions are commonly associated with the modeling of extreme events that manifest in data. Bounds on the expected behavior of an estimator are insufficient in these cases, since the high-probability guarantees that may be derived from such bounds (say, using Markov's inequality) are rather weak. For example, if the risk (*i.e.*, expected loss) of an estimator is bounded by ϵ, then all that we may derive from Markov's inequality is that the loss is no more than ϵ/δ with probability at least $1-\delta$. For small values of $\delta \in (0,1)$, the guarantee is not very reassuring, but it may be all one can hope for in these extreme scenarios—see Remark 7 in Section 3.1 for an example where this is tight. Much of the work in statistical learning theory is also primarily concerned with such high probability guarantees, but the bulk of the work makes either boundedness or subgaussian tail assumptions that severely limit the applicability of the results even in settings as simple as linear regression (see, *e.g.*, Srebro et al., 2010; Shamir, 2014).

Recently, it has been shown that it is possible to improve on methods which are optimal for expected behavior but suboptimal when high-probability deviations are concerned (Audibert and Catoni, 2011; Catoni, 2012; Brownlees et al., 2014). These improvements, which are important when dealing with heavy-tailed distributions, suggest that new techniques (*e.g.*, beyond empirical risk minimization) may be able to remove the reliance on boundedness or control of high-order moments. Bubeck et al. (2013) show how a more robust mean estimator can be used for solving the stochastic multi-armed bandit problem under heavy-tailed distributions.

This work applies and generalizes a technique for controlling large deviations from the expected behavior with high probability, assuming only bounded low-order moments such as variances. We show that the technique is applicable to minimization of smooth and strongly convex losses, and derive specific loss bounds for least squares linear regression, which match existing rates, but without requiring the noise or covariates to be bounded or subgaussian. This contrasts with several recent works (Srebro et al., 2010; Hsu et al., 2014; Shamir, 2014) concerned with (possibly regularized) empirical risk minimizers that require such assumptions. It is notable that in finite dimensions, our result implies that a constant factor approximation to the optimal loss can be achieved with a sample size that is independent of the size of the optimal loss. This improves over the recent work of Mahdavi and Jin (2013), which has a logarithmic dependence on the optimal loss, as well as a suboptimal dependence on specific problem parameters (namely condition numbers). We also provide a new generalization of the basic technique for general metric spaces, which we apply to least squares linear regression with heavy tail covariate and noise distributions, yielding an improvement over the computationally expensive procedure of Audibert and Catoni (2011).

The basic technique, found in the textbook of Nemirovsky and Yudin (1983, p. 243), is very simple, and can be viewed as a generalization of the median-of-means estimator used by Alon et al. (1999) and many others. The idea is to repeat an estimate several times, by splitting the sample into several groups, and then selecting a single estimator out of the resulting list of candidates. If an estimator from one group is good with noticeably better-than-fair chance, then the selected estimator will be good with probability exponentially close to one. This is remininscant of techniques from *robust statistics* (Huber, 1981),

although our aim is expressly different in that our aim is good performance on the same probability distribution generating the data, rather than an uncontaminated or otherwise better behaved distribution. Our new technique can be cast as a simple selection problem in general metric spaces that generalizes the scalar median.

We demonstrate the versatility of our technique by giving further examples in sparse linear regression (Tibshirani, 1996) under heavy-tailed noise and low-rank covariance covariance matrix approximation (Koltchinskii et al., 2011) under heavy-tailed covariate distributions. We also show that for prediction problems where there may not be a reasonable metric on the predictors, one can achieve similar high-probability guarantees by using median aggregation in the output space.

The initial version of this article (Hsu and Sabato, 2013, 2014) appeared concurrently with the simultaneous and independent work of Minsker (2013), which develops a different generalization of the median-of-means estimator for Banach and Hilbert spaces. We provide a new analysis and comparison of this technique to ours in Section 7. We have also since become aware of the earlier work by Lerasle and Oliveira (2011), which applies the median-of-means technique to empirical risks in various settings much like the way we do in Algorithm 3, although our metric formulation is more general. Finally, the recent work of Brownlees et al. (2014) vastly generalizes the techniques of Catoni (2012) to apply to much more general settings, although they retain some of the same deficiencies (such as the need to know the noise variance for the optimal bound for least squares regression), and hence their results are not directly comparable to ours.

2. Overview of Main Results

This section gives an overview of the main results.

2.1 Preliminaries

Let $[n] := \{1, 2, \ldots, n\}$ for any natural number $n \in \mathbb{N}$. Let $\mathbb{1}\{P\}$ take value 1 if the predicate P is true, and 0 otherwise. Assume an example space $\mathcal{Z}$, and a distribution $\mathcal{D}$ over the space. Further assume a space of predictors or estimators $\mathbb{X}$. We consider learning or estimation algorithms that accept as input an i.i.d. sample of size n drawn from $\mathcal{D}$ and a confidence parameter $\delta \in (0, 1)$, and return an estimator (or predictor) $\hat{\boldsymbol{w}} \in \mathbb{X}$. For a (pseudo) metric ρ on $\mathbb{X}$, let $B_\rho(\boldsymbol{w}_0, r) := \{\boldsymbol{w} \in \mathbb{X} : \rho(\boldsymbol{w}_0, \boldsymbol{w}) \leq r\}$ denote the ball of radius r around $\boldsymbol{w}_0$.

We assume a loss function $\ell : \mathcal{Z} \times \mathbb{X} \to \mathbb{R}_+$ that assigns a non-negative number to a pair of an example from $\mathcal{Z}$ and a predictor from $\mathbb{X}$, and consider the task of finding a predictor that has a small loss in expectation over the distribution of data points, based on an input sample of n examples drawn independently from $\mathcal{D}$. The expected loss of a predictor $\boldsymbol{w}$ on the distribution is denoted $L(\boldsymbol{w}) = \mathbb{E}_{Z \sim D}(\ell(Z, \boldsymbol{w}))$. Let $L_\star := \inf_{\boldsymbol{w}} L(\boldsymbol{w})$. Our goal is to find $\hat{\boldsymbol{w}}$ such that $L(\hat{\boldsymbol{w}})$ is close to $L_\star$.

In this work, we are interested in performance guarantees that hold with high probability over the random draw of the input sample and any internal randomization used by the estimation algorithm. Thus, for a given allowed probability of failure $\delta \in (0, 1)$, we study excess loss $L(\hat{\boldsymbol{w}}) - L_\star$ achieved by the predictor $\hat{\boldsymbol{w}} \equiv \hat{\boldsymbol{w}}(\delta)$ returned by the algorithm on a $1 - \delta$ probability subset of the sample space. Ideally, the excess loss only depends sub-

logarithmically on $1/\delta$, which is the dependence achieved when the distribution of the excess loss has exponentially decreasing tails. Note that we assume that the value of δ is provided as input to the estimation algorithm, and only demand the probabilistic guarantee for this given value of δ. Therefore, strictly speaking, the excess loss need not exhibit exponential concentration. Nevertheless, in this article, we shall say that an estimation algorithm achieves exponential concentration whenever it guarantees, on input δ, an excess loss that grows only as $\log(1/\delta)$.

2.2 Robust Distance Approximation

Consider an estimation problem, where the goal is to estimate an unknown parameter of the distribution, using a random i.i.d. sample from that distribution. We show throughout this work that for many estimation problems, if the sample is split into non-overlapping subsamples, and estimators are obtained independently from each subsample, then with high probability, this generates a set of estimators such that some fraction of them are close, under a meaningful metric, to the true, unknown value of the estimated parameter. Importantly, this can be guaranteed in many cases even under under heavy-tailed distributions.

Having obtained a set of estimators, a fraction of which are close to the estimated parameter, the goal is now to find a single good estimator based on this set. This goal is captured by the following general problem, which we term *Robust Distance Approximation*. A Robust Distance Approximation procedure is given a set of points in a metric space and returns a single point from the space. This single point should satisfy the following condition: If there is an element in the metric space that a certain fraction of the points in the set are close to, then the output point should also be close to the same element. Formally, let $(\mathbb{X}, \rho)$ be a metric space. Let $W \subseteq \mathbb{X}$ be a (multi)set of size k and let $w_\star$ be a distinguished element in $\mathbb{X}$. For $\alpha \in (0, \frac{1}{2})$ and $w \in \mathbb{X}$, denote by $\Delta_W(w, \alpha)$ the minimal number r such that $|\{v \in W \mid \rho(w, v) \leq r\}| > k(\frac{1}{2} + \alpha)$. We often omit the subscript W and write simply Δ when W is known.

We define the following problem:

Definition 1 (Robust Distance Approximation) *Fix $\alpha \in (0, \frac{1}{2})$. Given W and $(\mathbb{X}, \rho)$ as input, return $y \in \mathbb{X}$ such that $\rho(y, w_\star) \leq C_\alpha \cdot \Delta_W(w_\star, \alpha)$, for some constant $C_\alpha \geq 0$. C_α is the* approximation factor *of the procedure.*

In some cases, learning with heavy-tailed distributions requires using a metric that depends on the distribution. Then, the Robust Distance Estimation procedure has access only to noisy measurements of distances in the metric space, and is required to succeed with high probability. In Section 3 we formalize these notions, and provide simple implementations of Robust Distance Approximation for general metric spaces, with and without direct access to the metric. For the case of direct access to the metric our formulation is similar to that of Nemirovsky and Yudin (1983).

2.3 Convex Loss Minimization

The general approach to estimation described above has many applications. We give here the general form of our main results for applications, and defer the technical definitions and

results to the relevant sections. Detailed discussion of related work for each application is also provided in the appropriate sections.

First, we consider smooth and convex losses. We assume that the parameter space $\mathbb{X}$ is a Banach space with a norm $\|\cdot\|$ and a dual norm $\|\cdot\|_*$. We prove the following result:[1]

Theorem 2 *There exists an algorithm that accepts as input an i.i.d. sample of size n drawn from $\mathcal{D}$ and a confidence parameter $\delta \in (0,1)$, and returns $\hat{\boldsymbol{w}} \in \mathbb{X}$, such that if the following conditions hold:*

- *the dual norm $\|\cdot\|_*$ is γ-smooth;*
- *there exists $\alpha > 0$ and sample size n_α such that, with probability at least $1/2$, the empirical loss $\boldsymbol{w} \mapsto \hat{L}(\boldsymbol{w})$ is α-strongly convex with respect to $\|\cdot\|$ whenever the sample is of size at least n_α;*
- *$n \geq C \log(1/\delta) \cdot n_\alpha$ for some universal constant $C > 0$;*
- *$\boldsymbol{w} \mapsto \ell(z, \boldsymbol{w})$ is β-smooth with respect to $\|\cdot\|$ for all $z \in \mathcal{Z}$;*
- *$\boldsymbol{w} \mapsto L(\boldsymbol{w})$ is $\bar{\beta}$-smooth with respect to $\|\cdot\|$;*

then with probability at least $1-\delta$, for another universal constant $C' > 0$,

$$L(\hat{\boldsymbol{w}}) \leq \left(1 + \frac{C'\beta\bar{\beta}\gamma\lceil\log(1/\delta)\rceil}{n\alpha^2}\right) L_\star.$$

This gives a constant approximation of the optimal loss with a number of samples that does not depend on the value of the optimal loss. The full results for smooth convex losses are provided in Section 4. Theorem 2 is stated in full as Corollary 16, and we further provide a result with more relaxed smoothness requirements. As apparent in the result, the only requirements on the distribution are those that are implied by the strong convexity and smoothness parameters. This allows support for fairly general heavy-tailed distributions, as we show below.

2.4 Least Squares Linear Regression

A concrete application of our analysis of smooth convex losses is linear regression. In linear regression, $\mathbb{X}$ is a Hilbert space with an inner product $\langle\cdot,\cdot\rangle_{\mathbb{X}}$, and it is both the data space and the parameter space. The loss $\ell \equiv \ell^{\mathrm{sq}}$ is the squared loss

$$\ell^{\mathrm{sq}}((\boldsymbol{x}, y), \boldsymbol{w}) := \frac{1}{2}(\boldsymbol{x}^\top \boldsymbol{w} - y)^2.$$

L^{sq} and $L^{\mathrm{sq}}_\star$ are defined similarly to L and $L_\star$.

Unlike standard high-probability bounds for regression, we give bounds that make no assumption on the range or the tails of the distribution of the response variables, other than a trivial requirement that the optimal squared loss be finite. The assumptions on the distribution of the covariates are also minimal.

1. Formal definitions of terms used in the conditions are given in Section 4.

Let Σ be the second-moment operator $\boldsymbol{a} \mapsto \mathbb{E}(\boldsymbol{X}\langle \boldsymbol{X}, \boldsymbol{a}\rangle_{\mathbb{X}})$, where $\boldsymbol{X}$ is a random data point from the marginal distribution of $\mathcal{D}$ on $\mathbb{X}$. For a finite-dimensional $\mathbb{X}$, Σ is simply the (uncentered) covariance matrix $\mathbb{E}[\boldsymbol{X}\boldsymbol{X}^\top]$. First, consider the finite-dimensional case, where $\mathbb{X} = \mathbb{R}^d$, and assume Σ is not singular. Let $\|\cdot\|_2$ denote the Euclidean norm in $\mathbb{R}^d$. Under only bounded $4+\epsilon$ moments of the marginal on $\mathbb{X}$ (a condition that we specify in full detail in Section 5), we show the following guarantee.

Theorem 3 *Assume the marginal of $\mathbb{X}$ has bounded $4+\epsilon$ moments. There is a constant $C > 0$ and an algorithm that accepts as input a sample of size n and a confidence parameter $\delta \in (0,1)$, and returns $\hat{\boldsymbol{w}} \in \mathbb{X}$, such that if $n \geq Cd\log(1/\delta)$, with probability at least $1-\delta$,*

$$L^{\mathrm{sq}}(\hat{\boldsymbol{w}}) \leq L^{\mathrm{sq}}_\star + O\left(\frac{\mathbb{E}(\|\Sigma^{-1/2}\boldsymbol{X}(\boldsymbol{X}^\top\boldsymbol{w}_\star - Y)\|_2^2)\log(1/\delta)}{n}\right).$$

This theorem is stated in full as Theorem 19 in Section 5. Under standard finite fourth-moment conditions, this result translates to the bound

$$L^{\mathrm{sq}}(\hat{\boldsymbol{w}}) \leq \left(1 + O\left(\frac{d\log(1/\delta)}{n}\right)\right) L^{\mathrm{sq}}_\star,$$

with probability $\geq 1-\delta$. These results improve over recent results by Audibert and Catoni (2011), Catoni (2012), and Mahdavi and Jin (2013). We provide a full comparison to related work in Section 5.

Theorem 3 can be specialized for specific cases of interest. For instance, suppose $\boldsymbol{X}$ is bounded and well-conditioned in the sense that there exists $R < \infty$ such that $\Pr[\boldsymbol{X}^\top\Sigma^{-1}\boldsymbol{X} \leq R^2] = 1$, but Y may still be heavy-tailed. Under this assumption we have the following result.

Theorem 4 *Assume Σ is not singular. There exists an algorithm that accepts as input a sample of size n and a confidence parameter $\delta \in (0,1)$, and returns $\hat{\boldsymbol{w}} \in \mathbb{X}$, such that with probability at least $1-\delta$, for $n \geq O(R^2\log(R)\log(e/\delta))$,*

$$L^{\mathrm{sq}}(\hat{\boldsymbol{w}}) \leq \left(1 + O\left(\frac{R^2\log(1/\delta)}{n}\right)\right) L^{\mathrm{sq}}_\star.$$

This theorem is stated in full as Theorem 20 in Section 5. Note that

$$\mathbb{E}(\boldsymbol{X}^\top\Sigma^{-1}\boldsymbol{X}) = \mathbb{E}\,\mathrm{tr}(\boldsymbol{X}^\top\Sigma^{-1}\boldsymbol{X}) = \mathrm{tr}(\mathrm{Id}) = d,$$

so $R = \Omega(\sqrt{d})$. R^2 is closely related to a *condition number* for the distribution of $\boldsymbol{X}$. For instance, if $\mathbb{P}[\|\boldsymbol{X}\| = 1] = 1$, then $R^2 \leq d\frac{\lambda_{\max}(\Sigma)}{\lambda_{\min}(\Sigma)}$. This result is minimax optimal up to logarithmic factors (see, *e.g.*, Nussbaum, 1999). We also remark that the boundedness assumption can be replaced by a subgaussian assumption on $\boldsymbol{X}$, in which case the sample size requirement becomes $O(d\log(1/\delta))$. We give analogous guarantees for the case of regularized least squares in a possibly finite-dimensional Hilbert space in Theorem 21, Section 5.

2.5 Other Applications, Comparisons, and Extensions

The general method studied here allows handling heavy tails in other applications as well. We give two examples in Section 6. First, we consider parameter estimation using L^1-regularized linear least squares regression (Lasso) under random subgaussian design. We show that using the above approach, parameter estimation bounds can be guaranteed for general bounded variance noise, including heavy-tailed noise. This contrasts with standard results that assume sub-Gaussian noise. Second, we show that low-rank covariance matrix approximation can be obtained for heavy-tailed distributions, under a bounded $4+\epsilon$ moment assumption. These two applications have been analyzed also in the independent and simultaneous work of Minsker (2013).

All the results above are provided using a specific solution to the Robust Distance Approximation problem, which is easy to implement for any metric space. For the case of a fully known metric, in a Banach or a Hilbert space, Minsker (2013) proposed a different solution, which is based on the geometric median. In Section 7, we provide a detailed comparison of the approximation factor achieved by each approach, as well as some general lower bounds. Several interesting open questions remain regarding this general problem.

Lastly, in Section 8, we give a short proof to the intuitive fact that in some prediction problem, one can replace Robust Distance Approximation with taking the median of the predictions of the input estimators. This gives a possible improper-learning algorithm for relevant learning settings.

All of the techniques we have developed in this work are simple enough to implement and empirically evaluate, and indeed in some simulated experiments, we have verified the improvements over standard methods such as the empirical mean when the data follow heavy-tailed distributions. However, at present, the relatively large constant factors in our bounds are real enough to restrict the empirical improvements only to settings where very high confidence (*i.e.*, small values of δ) is required. By contrast, with an appropriately determined noise variance, the techniques of Catoni (2012) and Brownlees et al. (2014) may yield improvements more readily. Nevertheless, since our techniques are more general in some respects, it is worth investigating whether they can be made more practical (*e.g.*, with greater sample reuse or overlapping groups), and we plan to do this in future work.

3. The Core Techniques

In this section we present the core technique used for achieving exponential concentration. We first demonstrate the underlying principle via the median-of-means estimator, and then explain the generalization to arbitrary metric spaces. Finally, we show a new generalization that supports noisy feature measurements.

3.1 Warm-up: Median-of-Means Estimator

We first motivate the estimation procedure by considering the special case of estimating a scalar population mean using a *median-of-means* estimator, given in Algorithm 1. This estimator, heavily used in the streaming algorithm literature (Alon et al., 1999) (though a similar technique also appears in Nemirovsky and Yudin (1983) as noted in Levin (2005)), partitions a sample into k equal-size groups, and returns the median of the sample means

Algorithm 1 Median-of-means estimator

input Sample $S \subset \mathbb{R}$ of size n, number of groups $k \in \mathbb{N}$ such that $k \leq n/4$.
output Population mean estimate $\hat{\mu} \in \mathbb{R}$.
1: Randomly partition S into k subsets $S_1, S_2, \ldots, S_k$, each of size at least $\lfloor n/k \rfloor$.
2: For each $i \in [k]$, let $\mu_i \in \mathbb{R}$ be the sample mean of S_i.
3: Return $\hat{\mu} := \text{median}\{\mu_1, \mu_2, \ldots, \mu_k\}$.

of each group. Note that the possible non-uniqueness of the median does not affect the result; the arguments below apply to any one of them. The input parameter k should be thought of as a constant determined by the desired confidence level (*i.e.*, $k = \Theta(\log(1/\delta))$ for confidence $\delta \in (0,1)$). It is well known that the median-of-means achieves estimation with exponential concentration. The following proposition gives a simple statement and proof. The constant 6 in the statement (see Eq. (1) below) is lower the constant in the analysis of Lerasle and Oliveira (2011, Proposition 1), which is $2\sqrt{6e} \approx 8.08$, but we require a larger value of n. By requiring an even larger n, the constant in the statement below can approach $3\sqrt{3}$.

Proposition 5 *Let x be a random variable with mean μ and variance $\sigma^2 < \infty$, and let S be a set of n independent copies of x. Assume $k \leq n/2$. With probability at least $1-e^{-k/4.5}$, the estimate $\hat{\mu}$ returned by Algorithm 1 on input (S,k) satisfies $|\hat{\mu}-\mu| \leq \sigma\sqrt{8k/n}$. Therefore, if $k = 4.5\lceil \log(1/\delta) \rceil$ and $n \geq 18\lceil \log(1/\delta) \rceil$, then with probability at least $1-\delta$,*

$$|\hat{\mu}-\mu| \leq 6\sigma\sqrt{\frac{\lceil \log(1/\delta) \rceil}{n}}. \tag{1}$$

Proof First, assume k divides n. Pick any $i \in [k]$, and observe that S_i is an i.i.d. sample of size n/k. Therefore, by Chebyshev's inequality, $\Pr[|\mu_i - \mu| \leq \sqrt{6\sigma^2 k/n}] \geq 5/6$. For each $i \in [k]$, let $b_i := \mathbb{1}\{|\mu_i - \mu| \leq \sqrt{6\sigma^2 k/n}\}$. Note that the b_i are independent indicator random variables, each with $\mathbb{E}(b_i) \geq 5/6$. By Hoeffding's inequality, $\Pr[\sum_{i=1}^k b_i > k/2] \geq 1-e^{-k/4.5}$. In the event that $\sum_{i=1}^k b_i > k/2$, at least half of the μ_i are within $\sqrt{6\sigma^2 k/n}$ of μ, which means that the same holds for the median of the μ_i. If k does not divide n then the analysis can be carried out by substituting n with $\lfloor n/k \rfloor k \geq n - k \geq \frac{3}{4}n$, which scales the guarantee by a factor of $\sqrt{4/3}$. ■

Using the terminology of Robust Distance Approximation with the metric $\rho(x,y) = |x-y|$, the proof shows that with high probability over the choice of W, $\Delta_W(\mu, 0) \leq \sqrt{12\sigma^2 k/n}$. The result then immediately follows because on the space $(\mathbb{R}, \rho)$, the median is a Robust Distance Approximation procedure with $C_0 = 1$.

Remark 6 (Catoni's M-estimator) *Catoni (2012) proposes a mean estimator $\hat{\mu}$ that satisfies $|\hat{\mu}-\mu| = O(\sigma\sqrt{\log(1/\delta)/n})$ with probability at least $1-\delta$. Remarkably, the leading constant in the bound is asymptotically optimal: it approaches $\sqrt{2}$ as $n \to \infty$. However, the estimator takes both δ and σ as inputs. Catoni also presents an estimator that takes only σ as an input; this estimator guarantees a $O(\sigma \log(1/\delta)/\sqrt{n})$ bound for all values of $\delta > \exp(1-n/2)$* simultaneously.

Remark 7 (Empirical mean) *Catoni (2012) shows that the empirical mean cannot provide a qualitatively similar guarantee. Specifically, for any $\sigma > 0$ and $\delta \in (0, 1/(2e))$, there is a distribution with mean zero and variance σ^2 such that the empirical average $\hat{\mu}_{\text{emp}}$ of n i.i.d. draws satisfies*

$$\Pr\left[|\hat{\mu}_{\text{emp}}| \geq \frac{\sigma}{\sqrt{2n\delta}}\left(1 - \frac{2e\delta}{n}\right)^{\frac{n-1}{2}}\right] \geq 2\delta. \tag{2}$$

Therefore the deviation of the empirical mean necessarily scales with $1/\sqrt{\delta}$ rather than $\sqrt{\log(1/\delta)}$ (with probability $\Omega(\delta)$).

3.2 Generalization to Arbitrary Metric Spaces

We now consider a simple generalization of the median-of-means estimator for arbitrary metric spaces, first mentioned in Nemirovsky and Yudin (1983). Let $\mathbb{X}$ be the parameter (solution) space, $\boldsymbol{w}_\star \in \mathbb{X}$ be a distinguished point in $\mathbb{X}$ (the target solution), and ρ a metric on $\mathbb{X}$ (in fact, a pseudometric suffices).

The first abstraction captures the generation of candidate solutions obtained from independent subsamples. We assume there is an oracle $\text{APPROX}_{\rho,\varepsilon}$ which satisfies the following assumptions.

Assumption 1 *A query to $\text{APPROX}_{\rho,\varepsilon}$ returns a random $\boldsymbol{w} \in \mathbb{X}$ such that*

$$\Pr\Big[\rho(\boldsymbol{w}_\star, \boldsymbol{w}) \leq \varepsilon\Big] \geq 2/3.$$

Note that the 2/3 could be replaced by another constant larger than half; we have not optimized the constants. The second assumption regards statistical independence. For an integer k, let $\boldsymbol{w}_1, \ldots, \boldsymbol{w}_k$ be responses to k separate queries to $\text{APPROX}_{\rho,\varepsilon}$.

Assumption 2 *$\boldsymbol{w}_1, \ldots, \boldsymbol{w}_k$ are statistically independent.*

The proposed procedure, given in Algorithm 2, generates k candidate solutions by querying $\text{APPROX}_{\rho,\varepsilon}$ k times, and then selecting a single candidate using a generalization of the median. Specifically, for each $i \in [k]$, the smallest ball centered at $\boldsymbol{w}_i$ that contains more than half of $\{\boldsymbol{w}_1, \boldsymbol{w}_2, \ldots, \boldsymbol{w}_k\}$ is determined; the $\boldsymbol{w}_i$ with the smallest such ball is returned. If there are multiple such $\boldsymbol{w}_i$ with the smallest radius ball, any one of them may be selected. This selection method is a Robust Distance Approximation procedure. The proof is given below and illustrated in Figure 1. Nemirovsky and Yudin (1983) proposed a similar technique, however their formulation relies on knowledge of ε.

Proposition 8 *Let $r_i := \min\{r \geq 0 : |B_\rho(\boldsymbol{w}_i, r) \cap W| > k/2\}$. Selecting $\boldsymbol{w}_{i_\star}$ such that $i_\star = \text{argmin}_i\, r_i$ is a Robust Distance Approximation procedure with $C_0 = 3$.*

Proof Assume that $\Delta(w_\star, 0) \leq \varepsilon$. Then $|B_\rho(\boldsymbol{w}_\star, \varepsilon) \cap W| > k/2$. For any $\boldsymbol{v} \in B_\rho(\boldsymbol{w}_\star, \varepsilon) \cap W$, by the triangle inequality, $|B_\rho(\boldsymbol{v}, 2\varepsilon) \cap W| > k/2$. This implies that $r_{i_\star} \leq 2\varepsilon$, and so $|B_\rho(\boldsymbol{w}_{i_\star}, 2\varepsilon) \cap W| > k/2$. By the pigeonhole principle, $B_\rho(\boldsymbol{w}_\star, \varepsilon) \cap B_\rho(\boldsymbol{w}_{i_\star}, 2\varepsilon) \neq \emptyset$. Therefore, by the triangle inequality again, $\rho(\boldsymbol{w}_\star, \boldsymbol{w}_{i_\star}) \leq 3\varepsilon$. ■

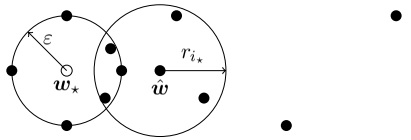

Figure 1: The argument in the proof of Proposition 8, illustrated on the Euclidean plane. If more than half of the $\boldsymbol{w}_i$ (depicted by full circles) are within ε of $\boldsymbol{w}_\star$ (the empty circle), then the selected $\boldsymbol{w}_{i_\star}$ is within $\varepsilon + r_{i_\star} \leq 3\varepsilon$ of $\boldsymbol{w}_\star$.

Algorithm 2 Robust approximation

input Number of candidates k, query access to $\text{APPROX}_{\rho,\varepsilon}$.

output Approximate solution $\hat{\boldsymbol{w}} \in \mathbb{X}$.

1: Query $\text{APPROX}_{\rho,\varepsilon}$ k times. Let $\boldsymbol{w}_1, \ldots, \boldsymbol{w}_k$ be the responses to the queries; set $W := \{\boldsymbol{w}_1, \boldsymbol{w}_2, \ldots, \boldsymbol{w}_k\}$.

2: For each $i \in [k]$, let $r_i := \min\{r \geq 0 : |B_\rho(\boldsymbol{w}_i, r) \cap W| > k/2\}$; set $i_\star := \arg\min_{i \in [k]} r_i$.

3: Return $\hat{\boldsymbol{w}} := \boldsymbol{w}_{i_\star}$.

Again, the number of candidates k determines the resulting confidence level. The following theorem provides a guarantee for Algorithm 2. We note that the resulting constants here might not be optimal in specific applications, since they depend on the arbitrary constant in Assumption 1.

Proposition 9 *Suppose that Assumption 1 and Assumption 2 hold. Then, with probability at least $1 - e^{-k/18}$, Algorithm 2 returns $\hat{\boldsymbol{w}} \in \mathbb{X}$ satisfying $\rho(\boldsymbol{w}_\star, \hat{\boldsymbol{w}}) \leq 3\varepsilon$.*

Proof For each $i \in [k]$, let $b_i := \mathbb{1}\{\rho(\boldsymbol{w}_\star, \boldsymbol{w}_i) \leq \varepsilon\}$. Note that the b_i are independent indicator random variables, each with $\mathbb{E}(b_i) \geq 2/3$. By Hoeffding's inequality, $\Pr[\sum_{i=1}^k b_i > k/2] \geq 1 - e^{-k/18}$. In the event that $\sum_{i=1}^k b_i > k/2$, more than half of the $\boldsymbol{w}_i$ are contained in the ball of radius ε around $\boldsymbol{w}_\star$, that is $\Delta_W(w_\star, 0) \leq \varepsilon$. The result follows from Proposition 8. ■

3.3 Random Distance Measurements

In some problems, the most appropriate metric on $\mathbb{X}$ in which to measure accuracy is not directly computable. For instance, the metric may depend on population quantities which can only be estimated; moreover, the estimates may only be relatively accurate with some constant probability. For instance, this is the case when the metric depends on the population covariance matrix, a situation we consider in Section 5.2.3.

To capture such cases, we assume access to a metric estimation oracle as follows. Let $\boldsymbol{w}_1, \ldots, \boldsymbol{w}_k$ be responses to k queries to $\text{APPROX}_{\rho,\epsilon}$. The metric estimation oracle, denoted DIST_ρ^j, provides (possibly via a random process) a function $f_j : \mathbb{X} \to \mathbb{R}_+$. $f_j(\boldsymbol{v})$ will be used

as an estimate of $\rho(\boldsymbol{v}, \boldsymbol{w}_j)$. This estimate is required to be weakly accurate, as captured by the following definition of the random variables Z_j. Let $f_1, \ldots, f_k$ be responses to queries to $\mathrm{DIST}^1_\rho, \ldots, \mathrm{DIST}^k_\rho$, respectively. For $j \in [k]$, define

$$Z_j := \mathbb{1}\{\forall \boldsymbol{v} \in \mathbb{X}, \quad (1/2)\rho(\boldsymbol{v}, \boldsymbol{w}_j) \le f_j(\boldsymbol{v}) \le 2\rho(\boldsymbol{v}, \boldsymbol{w}_j)\}.$$

$Z_j = 1$ indicates that f_j provides a sufficiently accurate estimate of the distances from $\boldsymbol{w}_j$. Note that f_j need not correspond to a metric. We assume the following.

Assumption 3 *For any $j \in [k]$, $\Pr[Z_j = 1] \ge 8/9$.*

We further require the following independence assumption.

Assumption 4 *The random variables $Z_1, \ldots, Z_k$ are statistically independent.*

Note that there is no assumption on the statistical relationship between $Z_1, \ldots, Z_k$ and $\boldsymbol{w}_1, \ldots, \boldsymbol{w}_k$.

Algorithm 3 is a variant of Algorithm 2 that simply replaces computation of ρ-distances with computations using the functions returned by querying the DIST^j_ρ's. The resulting selection procedure is, with high probability, a Robust Distance Approximation.

Lemma 10 *Consider a run of Algorithm 3, with output $\hat{\boldsymbol{w}}$. Let $Z_1, \ldots, Z_k$ as defined above, and suppose that Assumption 3 and Assumption 4 hold. Then, with probability at least $1 - e^{-k/648}$,*

$$\rho(\hat{\boldsymbol{w}}, \boldsymbol{w}_\star) \le 9 \cdot \Delta_W(\boldsymbol{w}_\star, \frac{5}{36}),$$

where $W = \{\boldsymbol{w}_1, \ldots, \boldsymbol{w}_k\}$.

Proof By Assumptions 3 and 4, and by Hoeffding's inequality,

$$\Pr\left[\sum_{j=1}^{k} Z_j > \frac{31}{36}k\right] \ge 1 - e^{-k/648} \tag{3}$$

Assume this event holds, and denote $\varepsilon = \Delta_W(\boldsymbol{w}_\star, \frac{5}{36})$. We have $|B(\boldsymbol{w}_\star, \varepsilon) \cap W| \ge \frac{23}{36}k$.

Let $i \in [k]$ such that $\boldsymbol{w}_i \in B_\rho(\boldsymbol{w}_\star, \varepsilon)$. Then, for any $j \in [k]$ such that $\boldsymbol{w}_j \in B_\rho(\boldsymbol{w}_\star, \varepsilon)$, by the triangle inequality $\rho(\boldsymbol{w}_i, \boldsymbol{w}_j) \le 2\varepsilon$. There are at least $\frac{23}{36}k$ such indices j, therefore for more than $k/2$ of the indices j, we have

$$\rho(\boldsymbol{w}_i, \boldsymbol{w}_j) \le 2\varepsilon \text{ and } Z_j = 1.$$

For j such that this holds, by the definition of Z_j, $f_j(\boldsymbol{w}_i) \le 4\varepsilon$. It follows that $r_i := \mathrm{median}\{f_j(\boldsymbol{w}_i) \mid j \in [k]\} \le 4\epsilon$.

Now, let $i \in [k]$ such that $\boldsymbol{w}_i \notin B(\boldsymbol{w}_\star, 9\epsilon)$. Then, for any $j \in [k]$ such that $\boldsymbol{w}_j \in B_\rho(\boldsymbol{w}_\star, \varepsilon)$, by the triangle inequality $\rho(\boldsymbol{w}_i, \boldsymbol{w}_j) \ge \rho(\boldsymbol{w}_\star, \boldsymbol{w}_i) - \rho(\boldsymbol{w}_\star, \boldsymbol{w}_j) > 8\varepsilon$. As above, for more than $k/2$ of the indices j,

$$\rho(\boldsymbol{w}_i, \boldsymbol{w}_j) > 8\varepsilon \text{ and } Z_j = 1.$$

For j such that this holds, by the definition of Z_j, $f_j(\boldsymbol{w}_i) > 4\varepsilon$. It follows that $r_i := \mathrm{median}\{f_j(\boldsymbol{w}_i) \mid j \in [k]\} > 4\epsilon$.

By Eq. (3), We conclude that with probability at least $1 - \exp(-k/648)$,

Algorithm 3 Robust approximation with random distances

input Number of candidates k, query access to $\mathrm{APPROX}_{\rho,\varepsilon}$, query access to DIST_ρ.
output Approximate solution $\hat{\boldsymbol{w}} \in \mathbb{X}$.

1: Query $\mathrm{APPROX}_{\rho,\varepsilon}$ k times. Let $\boldsymbol{w}_1, \ldots, \boldsymbol{w}_k$ be the responses to the queries; set $W := \{\boldsymbol{w}_1, \boldsymbol{w}_2, \ldots, \boldsymbol{w}_k\}$.
2: For $i \in [k]$, let f_i be the response of DIST^j_ρ, and set $r_i := \mathrm{median}\{f_j(\boldsymbol{w}_i) : j \in [k]\}$; set $i_\star := \arg\min_{i \in [k]} r_i$.
3: Return $\hat{\boldsymbol{w}} := \boldsymbol{w}_{i_\star}$.

1. $r_i \le 4\varepsilon$ for all $\boldsymbol{w}_i \in W \cap B_\rho(\boldsymbol{w}_\star, \varepsilon)$, and
2. $r_i > 4\varepsilon$ for all $\boldsymbol{w}_i \in W \setminus B_\rho(\boldsymbol{w}_\star, 9\varepsilon)$.

In this event the $\boldsymbol{w}_i \in W$ with the smallest r_i satisfies $\boldsymbol{w}_i \in B_\rho(\boldsymbol{w}_\star, 9\varepsilon)$. ■

The properties of the approximation procedure and of $\mathrm{APPROX}_{\rho,\epsilon}$ are combined to give a guarantee for Algorithm 3.

Theorem 11 *Suppose that Assumptions 1,2,3,4 all hold. With probability at least $1 - 2e^{-k/648}$, Algorithm 3 returns $\hat{\boldsymbol{w}} \in \mathbb{X}$ satisfying $\rho(\boldsymbol{w}_\star, \hat{\boldsymbol{w}}) \le 9\varepsilon$.*

Proof For each $i \in [k]$, let $b_i := \mathbb{1}\{\rho(\boldsymbol{w}_\star, \boldsymbol{w}_i) \le \varepsilon\}$. By Assumptions 1 and 2, the b_i are independent indicator random variables, each with $\mathbb{E}(b_i) \ge 2/3$. By Hoeffding's inequality, $\Pr[\sum_{i=1}^k b_i > \frac{23}{36}k] \ge 1 - e^{-k/648}$. The result follows from Lemma 10 and a union bound. ■

In the following sections we show several applications of these general techniques.

4. Minimizing Strongly Convex Losses

In this section we apply the core techniques to the problem of approximately minimizing strongly convex losses, which includes least squares linear regression as a special case.

4.1 Preliminaries

Suppose $(\mathbb{X}, \|\cdot\|)$ is a Banach space, with the metric ρ induced by the norm $\|\cdot\|$. We sometimes denote the metric by $\|\cdot\|$ as well. Denote by $\|\cdot\|_*$ the dual norm, so $\|\boldsymbol{y}\|_* = \sup\{\langle \boldsymbol{y}, \boldsymbol{x}\rangle \colon \boldsymbol{x} \in \mathbb{X}, \|\boldsymbol{x}\| \le 1\}$ for $\boldsymbol{y} \in \mathbb{X}^*$.

The derivative of a differentiable function $f \colon \mathbb{X} \to \mathbb{R}$ at $\boldsymbol{x} \in \mathbb{X}$ in direction $\boldsymbol{u} \in \mathbb{X}$ is denoted by $\langle \nabla f(\boldsymbol{x}), \boldsymbol{u}\rangle$. We say f is *α-strongly convex with respect to* $\|\cdot\|$ if

$$f(\boldsymbol{x}) \ge f(\boldsymbol{x}') + \langle \nabla f(\boldsymbol{x}'), \boldsymbol{x} - \boldsymbol{x}'\rangle + \frac{\alpha}{2}\|\boldsymbol{x} - \boldsymbol{x}'\|^2$$

for all $\boldsymbol{x}, \boldsymbol{x}' \in \mathbb{X}$; it is *$\beta$-smooth with respect to* $\|\cdot\|$ if for all $\boldsymbol{x}, \boldsymbol{x}' \in \mathbb{X}$

$$f(\boldsymbol{x}) \le f(\boldsymbol{x}') + \langle \nabla f(\boldsymbol{x}'), \boldsymbol{x} - \boldsymbol{x}'\rangle + \frac{\beta}{2}\|\boldsymbol{x} - \boldsymbol{x}'\|^2.$$

We say $\|\cdot\|$ is γ-*smooth* if $\boldsymbol{x} \mapsto \frac{1}{2}\|\boldsymbol{x}\|^2$ is γ-smooth with respect to $\|\cdot\|$. We define n_α to be the smallest sample size such that the following holds: With probability $\geq 5/6$ over the choice of an i.i.d. sample T of size $|T| \geq n_\alpha$ from $\mathcal{D}$, for all $\boldsymbol{w} \in \mathbb{X}$,

$$L_T(\boldsymbol{w}) \geq L_T(\boldsymbol{w}_\star) + \langle \nabla L_T(\boldsymbol{w}_\star), \boldsymbol{w} - \boldsymbol{w}_\star \rangle + \frac{\alpha}{2}\|\boldsymbol{w} - \boldsymbol{w}_\star\|^2. \tag{4}$$

In other words, the sample T induces a loss L_T which is α-strongly convex around $\boldsymbol{w}_\star$.[2] We assume that $n_\alpha < \infty$ for some $\alpha > 0$.

We use the following facts in our analysis.

Proposition 12 (Srebro et al., 2010) *If a non-negative function $f\colon \mathbb{X} \to \mathbb{R}_+$ is β-smooth with respect to $\|\cdot\|$, then $\|\nabla f(\boldsymbol{x})\|_*^2 \leq 4\beta f(\boldsymbol{x})$ for all $\boldsymbol{x} \in \mathbb{X}$.*

Proposition 13 (Juditsky and Nemirovski, 2008) *Let $\boldsymbol{X}_1, \boldsymbol{X}_2, \ldots, \boldsymbol{X}_n$ be independent copies of a zero-mean random vector $\boldsymbol{X}$, and let $\|\cdot\|$ be γ-smooth. Then $\mathbb{E}\|n^{-1}\sum_{i=1}^n \boldsymbol{X}_i\|^2 \leq (\gamma/n)\mathbb{E}\|\boldsymbol{X}\|^2$.*

Recall that $\mathcal{Z}$ is a data space, and $\mathcal{D}$ is a distribution over $\mathcal{Z}$. Let Z be a $\mathcal{Z}$-valued random variable with distribution $\mathcal{D}$. Let $\ell\colon \mathcal{Z} \times \mathbb{X} \to \mathbb{R}_+$ be a non-negative loss function, and for $\boldsymbol{w} \in \mathbb{X}$, let $L(\boldsymbol{w}) := \mathbb{E}(\ell(Z, \boldsymbol{w}))$ be the expected loss. Also define the empirical loss with respect to a sample T from $\mathcal{Z}$, $L_T(\boldsymbol{w}) := |T|^{-1}\sum_{z\in T}\ell(z, \boldsymbol{w})$. To simplify the discussion throughout, we assume ℓ is differentiable, which is anyway our primary case of interest. We assume that L has a unique minimizer $\boldsymbol{w}_\star := \arg\min_{\boldsymbol{w}\in\mathbb{X}} L(\boldsymbol{w})$.[3] Let $L_\star := \min_{\boldsymbol{w}} L(\boldsymbol{w})$. Set $\boldsymbol{w}_\star$ such that $L_\star = L(\boldsymbol{w}_\star)$.

4.2 Subsampled Empirical Loss Minimization

To use Algorithm 2, we implement $\text{APPROX}_{\|\cdot\|_*,\varepsilon}$ based on loss minimization over subsamples, as follows: Given a sample $S \subseteq \mathcal{Z}$, randomly partition S into k groups $S_1, S_2, \ldots, S_k$, each of size at least $\lfloor |S|/k \rfloor$, and let the response to the i-th query to $\text{APPROX}_{\|\cdot\|_*,\varepsilon}$ be the loss minimizer on S_i, *i.e.*, $\boldsymbol{w}_i = \arg\min_{\boldsymbol{w}\in\mathbb{X}} L_{S_i}(\boldsymbol{w})$. We call this implementation *subsampled empirical loss minimization*. Clearly, if S is an i.i.d. sample from $\mathcal{D}$, then $\boldsymbol{w}_1, \ldots, \boldsymbol{w}_k$ are statistically independent, and so Assumption 2 holds. Thus, to apply Proposition 9, it is left to show that Assumption 1 holds as well.[4]

The following lemma proves that Assumption 1 holds under these assumptions with

$$\varepsilon := \sqrt{\frac{32\gamma k \mathbb{E}\|\nabla\ell(Z, \boldsymbol{w}_\star)\|_*^2}{n\alpha^2}}. \tag{5}$$

Lemma 14 *Let ε be as defined in Eq. (5). Assume $k \leq n/4$, and that S is an i.i.d. sample from $\mathcal{D}$ of size n such that $\lfloor n/k \rfloor \geq n_\alpha$. Then subsampled empirical loss minimization using the sample S is a correct implementation of $\text{APPROX}_{\|\cdot\|_*,\varepsilon}$ for up to k queries.*

2. Technically, we only need the sample size to guarantee Eq. (4) for all $\boldsymbol{w} \in B_{\|\cdot\|}(\boldsymbol{w}_\star, r)$ for some $r > 0$.
3. This holds, for instance, if L is strongly convex.
4. An approach akin to the bootstrap technique (Efron, 1979) could also seem natural here: In this approach, $S_1, \ldots, S_k$ would be generated by randomly sub-sampling from S, with possible overlap between the subsamples. However, this approach does not satisfy Assumption 2, since loss minimizers of overlapping samples are not statistically independent.

Proof Let $T = \lfloor n/k \rfloor$. Since $n \geq 4k$, we have $\lfloor n/k \rfloor k \geq n - k \geq \frac{3}{4}n$, therefore $1/T \leq \frac{4k}{3n}$. It is clear that $\boldsymbol{w}_1, \boldsymbol{w}_2, \ldots, \boldsymbol{w}_k$ are independent by the assumption. Fix some $i \in [k]$. Observe that $\nabla L(\boldsymbol{w}_\star) = \mathbb{E}(\nabla\ell(Z, \boldsymbol{w}_\star)) = 0$, and therefore by Proposition 13:

$$\mathbb{E}\|\nabla L_{S_i}(\boldsymbol{w}_\star)\|_*^2 \leq (\gamma/T)\mathbb{E}\|\nabla\ell(Z, \boldsymbol{w}_\star)\|_*^2 \leq \frac{4\gamma k}{3n}\mathbb{E}\|\nabla\ell(Z, \boldsymbol{w}_\star)\|_*^2.$$

By Markov's inequality,

$$\Pr\left[\|\nabla L_{S_i}(\boldsymbol{w}_\star)\|_*^2 \leq \frac{8\gamma k}{n}\mathbb{E}(\|\nabla\ell(Z, \boldsymbol{w}_\star)\|_*^2)\right] \geq \frac{5}{6}.$$

Moreover, the assumption that $\lfloor n/k \rfloor \geq n_\alpha$ implies that with probability at least 5/6, Eq. (4) holds for $T = S_i$. By a union bound, both of these events hold simultaneously with probability at least 2/3. In the intersection of these events, letting $\boldsymbol{w}_i := \arg\min_{\boldsymbol{w}\in\mathbb{X}} L_{S_i}(\boldsymbol{w})$,

$$\begin{aligned}(\alpha/2)\|\boldsymbol{w}_i - \boldsymbol{w}_\star\|^2 &\leq -\langle \nabla L_{S_i}(\boldsymbol{w}_\star), \boldsymbol{w}_i - \boldsymbol{w}_\star\rangle + L_{S_i}(\boldsymbol{w}_i) - L_{S_i}(\boldsymbol{w}_\star)\\ &\leq \|\nabla L_{S_i}(\boldsymbol{w}_\star)\|_*\|\boldsymbol{w}_i - \boldsymbol{w}_\star\|,\end{aligned}$$

where the last inequality follows from the definition of the dual norm, and the optimality of $\boldsymbol{w}_i$ on L_{S_i}. Rearranging and combining with the above probability inequality implies

$$\Pr\left[\|\boldsymbol{w}_i - \boldsymbol{w}_\star\| \leq \varepsilon\right] \geq \frac{2}{3}$$

as required. ■

Combining Lemma 14 and Proposition 9 gives the following theorem.

Theorem 15 *Let n_α be as defined in Section 4.1, and assume that $\|\cdot\|_*$ is γ-smooth. Also, assume $k := 18\lceil\log(1/\delta)\rceil$, $n \geq 72\lceil\log(1/\delta)\rceil$, and that S is an i.i.d. sample from $\mathcal{D}$ of size n such that $\lfloor n/k \rfloor \geq n_\alpha$. Finally, assume Algorithm 3 uses the subsampled empirical loss minimization to implement $\text{APPROX}_{\|\cdot\|_*,\varepsilon}$, where ε is as in Eq. (5). Then with probability at least $1 - \delta$, the parameter $\hat{\boldsymbol{w}}$ returned by Algorithm 2 satisfies*

$$\|\hat{\boldsymbol{w}} - \boldsymbol{w}_\star\| \leq 72\sqrt{\frac{\gamma\lceil\log(1/\delta)\rceil\mathbb{E}\|\nabla\ell(Z, \boldsymbol{w}_\star)\|_*^2}{n\alpha^2}}.$$

We give an easy corollary of Theorem 15 for the case where ℓ is smooth. This is the full version of Theorem 2.

Corollary 16 *Assume the same conditions as Theorem 15, and also that:*

- *$\boldsymbol{w} \mapsto \ell(z, \boldsymbol{w})$ is β-smooth with respect to $\|\cdot\|$ for all $z \in \mathcal{Z}$;*
- *$\boldsymbol{w} \mapsto L(\boldsymbol{w})$ is $\bar{\beta}$-smooth with respect to $\|\cdot\|$.*

Then with probability at least $1 - \delta$,

$$L(\hat{\boldsymbol{w}}) \leq \left(1 + \frac{10368\beta\bar{\beta}\gamma\lceil\log(1/\delta)\rceil}{n\alpha^2}\right)L(\boldsymbol{w}_\star).$$

Proof This follows from Theorem 15 by first concluding that $\mathbb{E}[\|\nabla\ell(Z,\boldsymbol{w}_\star)\|_*^2] \le 4\beta L(\boldsymbol{w}_\star)$, using the β-strong smoothness assumption on ℓ and Proposition 12, and then noting that $L(\hat{\boldsymbol{w}}) - L(\boldsymbol{w}_\star) \le \frac{\bar\beta}{2}\|\hat{\boldsymbol{w}} - \boldsymbol{w}_\star\|^2$, due to the strong smoothness of L and the optimality of $L(\boldsymbol{w}_\star)$. ■

Corollary 16 implies that for smooth losses, Algorithm 2 provides a constant factor approximation to the optimal loss with a sample size $\max\{n_\alpha, \gamma\beta\bar\beta/\alpha^2\} \cdot O(\log(1/\delta))$ (with probability at least $1-\delta$). In subsequent sections, we exemplify cases where the two arguments of the max are roughly of the same order, and thus imply a sample size requirement of $O(\gamma\bar\beta\beta/\alpha^2 \log(1/\delta))$. Note that there is no dependence on the optimal loss $L(\boldsymbol{w}_\star)$ in the sample size, and the algorithm has no parameters besides $k = O(\log(1/\delta))$.

We can also obtain a variant of Theorem 15 based on Algorithm 3 and Theorem 11, in which we assume that there exists some sample size $n_{k,\mathrm{DIST}_{\|\cdot\|}}$ that allows $\mathrm{DIST}_{\|\cdot\|}$ to be correctly implemented using an i.i.d. sample of size at least $n_{k,\mathrm{DIST}_{\|\cdot\|}}$. Under such an assumption, essentially the same guarantee as in Theorem 15 can be afforded to Algorithm 3 using the subsampled empirical loss minimization to implement $\mathrm{APPROX}_{\|\cdot\|,\varepsilon}$ (for ε as in Eq. (5)) and the assumed implementation of $\mathrm{DIST}_{\|\cdot\|}$. Note that since Theorem 11 does not require $\mathrm{APPROX}_{\|\cdot\|,\varepsilon}$ and $\mathrm{DIST}_{\|\cdot\|}$ to be statistically independent, both can be implemented using the same sample.

Theorem 17 *Let n_α be as defined in Section 4.1, $n_{k,\mathrm{DIST}_{\|\cdot\|}}$ be as defined above, and assume that $\|\cdot\|_*$ is γ-smooth. Also, assume $k := 648\lceil\log(2/\delta)\rceil$, S is an i.i.d. sample from $\mathcal{D}$ of size n such that $n \ge \max\{4k, n_{k,\mathrm{DIST}_{\|\cdot\|}}\}$, and $\lfloor n/k\rfloor \ge n_\alpha$. Further, assume Algorithm 3 implements $\mathrm{APPROX}_{\|\cdot\|,\varepsilon}$ using S with subsampled empirical loss minimization, where ε is as in Eq. (5), and implements $\mathrm{DIST}_{\|\cdot\|}$ using S as well. Then with probability at least $1-\delta$, the parameter $\hat{\boldsymbol{w}}$ returned by Algorithm 3 satisfies*

$$\|\hat{\boldsymbol{w}} - \boldsymbol{w}_\star\| \le 1296\sqrt{\frac{\gamma\lceil\log(2/\delta)\rceil\mathbb{E}\|\nabla\ell(Z,\boldsymbol{w}_\star)\|_*^2}{n\alpha^2}}.$$

Remark 18 (Mean estimation and empirical risk minimization) *The problem of estimating a scalar population mean is a special case of the loss minimization problem, where $\mathcal{Z} = \mathbb{X} = \mathbb{R}$, and the loss function of interest is the square loss $\ell(z,w) = (z-w)^2$. The minimum population loss in this setting is the variance σ^2 of Z,* i.e., *$L(w_\star) = \sigma^2$. Moreover, in this setting, we have $\alpha = \beta = \bar\beta = 2$, so the estimate $\hat w$ returned by Algorithm 2 satisfies, with probability at least $1-\delta$,*

$$L(\hat w) = \left(1 + O\Big(\frac{\log(1/\delta)}{n}\Big)\right)L(w_\star).$$

*In Remark 7 a result from Catoni (2012) is quoted which implies that if $n = o(1/\delta)$, then the empirical mean $\hat w_{\mathrm{emp}} := \arg\min_{w\in\mathbb{R}} L_S(w) = |S|^{-1}\sum_{z\in S} z$ (*i.e., *empirical risk (loss) minimization for this problem) incurs loss*

$$L(\hat w_{\mathrm{emp}}) = \sigma^2 + (\hat w_{\mathrm{emp}} - w_\star)^2 = (1+\omega(1))L(w_\star)$$

with probability at least 2δ. Therefore empirical risk minimization cannot provide a qualitatively similar guarantee as Corollary 16. It is easy to check that minimizing a regularized objective also does not work, since any non-trivial regularized objective necessarily provides an estimator with a positive error for some distribution with zero variance.

In the next section we use the analysis for general smooth and convex losses to derive new algorithms and bounds for linear regression.

5. Least Squares Linear Regression

In linear regression, the parameter space $\mathbb{X}$ is a Hilbert space with inner product $\langle\cdot,\cdot\rangle_{\mathbb{X}}$, and $\mathcal{Z} := \mathbb{X}\times\mathbb{R}$, where in the finite-dimensional case, $\mathbb{X} = \mathbb{R}^d$ for some finite integer d. The loss here is the squared loss, denoted by $\ell = \ell^{\mathrm{sq}}$, and defined as

$$\ell^{\mathrm{sq}}((\boldsymbol{x},y),\boldsymbol{w}) := \frac{1}{2}(\boldsymbol{x}^\top\boldsymbol{w} - y)^2.$$

The regularized squared loss, for $\lambda \ge 0$, is denoted

$$\ell^\lambda((\boldsymbol{x},y),\boldsymbol{w}) := \frac{1}{2}(\langle\boldsymbol{x},\boldsymbol{w}\rangle_{\mathbb{X}} - y)^2 + \frac{1}{2}\lambda\langle\boldsymbol{w},\boldsymbol{w}\rangle_{\mathbb{X}}.$$

Note that $\ell^0 = \ell^{\mathrm{sq}}$. We analogously define L^{sq}, L_T^{sq}, $L_\star^{\mathrm{sq}}$, L^λ, *etc.* as the squared-loss equivalents of $L, L_T, L_\star$. Finally, denote by Id the identity operator on $\mathbb{X}$.

The proposed algorithm for regression (Algorithm 4) is as follows. Set $k = C\log(1/\delta)$, where C is a universal constant. First, draw k independent random samples i.i.d. from $\mathcal{D}$, and perform linear regression with λ-regularization on each sample separately to obtain k linear regressors. Then, use the same k samples to generate k estimates of the covariance matrix of the marginal of $\mathcal{D}$ on the data space. Finally, use the estimated covariances to select a single regressor from among the k at hand. The slightly simpler variants of steps 4 and 5 can be used in some cases, as detailed below.

In Section 5.1, the full results for regression, mentioned in Section 2, are listed in full detail, and compared to previous work. The proofs are provided in Section 5.2.

5.1 Results

Let $\boldsymbol{X} \in \mathbb{X}$ be a random vector drawn according to the marginal of $\mathcal{D}$ on $\mathbb{X}$, and let $\Sigma : \mathbb{X}\to\mathbb{X}$ be the second-moment operator $\boldsymbol{a} \mapsto \mathbb{E}(\boldsymbol{X}\langle\boldsymbol{X},\boldsymbol{a}\rangle_{\mathbb{X}})$. For a finite-dimensional $\mathbb{X}$, Σ is simply the (uncentered) covariance matrix $\mathbb{E}[\boldsymbol{X}\boldsymbol{X}^\top]$. For a sample $T := \{\boldsymbol{X}_1, \boldsymbol{X}_2, \ldots, \boldsymbol{X}_m\}$ of m independent copies of $\boldsymbol{X}$, denote by $\Sigma_T : \mathbb{X}\to\mathbb{X}$ the empirical second-moment operator $\boldsymbol{a} \mapsto m^{-1}\sum_{i=1}^m \boldsymbol{X}_i\langle\boldsymbol{X}_i,\boldsymbol{a}\rangle_{\mathbb{X}}$.

Consider first the finite-dimensional case, where $\mathbb{X} = \mathbb{R}^d$, and assume Σ is not singular. Let $\|\cdot\|_2$ denote the Euclidean norm in $\mathbb{R}^d$. In this case we obtain a guarantee for ordinary least squares with $\lambda = 0$. The guarantee holds whenever the empirical estimate of Σ is close to the true Σ *in expectation*, a mild condition that requires only bounded low-order moments. For concreteness, we assume the following condition.[5]

5. As shown by Srivastava and Vershynin (2013), Condition 1 holds for various heavy-tailed distributions (*e.g.*, when $\boldsymbol{X}$ has a product distribution with bounded $4+\epsilon$ moments for some $\epsilon > 0$). Condition 1 may be easily substituted with other moment conditions, yielding similar results, at least up to logarithmic factors.

Algorithm 4 Regression for heavy-tails

input $\lambda \geq 0$, sample size n, confidence $\delta \in (0,1)$.

output Approximate predictor $\hat{\boldsymbol{w}} \in \mathbb{X}$.

1: Set $k := \lceil C \ln(1/\delta) \rceil$.

2: Draw k random i.i.d. samples $S_1, \ldots, S_k$ from D, each of size $\lfloor n/k \rfloor$.

3: For each $i \in [k]$, let $\boldsymbol{w}_i \in \operatorname{argmin}_{\boldsymbol{w} \in \mathbb{X}} L^{\lambda}_{S_i}(\boldsymbol{w})$.

4: For each $i \in [k]$, $\Sigma_{S_i} \leftarrow \frac{1}{|S_i|} \sum_{(\boldsymbol{x},\cdot) \in S_i} \boldsymbol{x}\boldsymbol{x}^\top$.
[**Variant**: $S \leftarrow \cup_{i \in [k]} S_i$; $\Sigma_S \leftarrow \frac{1}{|S|} \sum_{(\boldsymbol{x},\cdot) \in S} \boldsymbol{x}\boldsymbol{x}^\top$].

5: For each $i \in [k]$, let r_i be the median of the values in

$$\{\langle \boldsymbol{w}_i - \boldsymbol{w}_j, (\Sigma_{S_j} + \lambda \operatorname{Id})(\boldsymbol{w}_i - \boldsymbol{w}_j) \rangle \mid j \in [k] \setminus \{i\}\}.$$

[**Variant**: Use Σ_S instead of Σ_{S_j}].

6: Set $i_\star := \arg\min_{i \in [k]} r_i$.

7: Return $\hat{\boldsymbol{w}} := \boldsymbol{w}_{i_\star}$.

Condition 1 (Srivastava and Vershynin 2013) *There exists $c, \eta > 0$ such that*

$$\Pr\left[\|\Pi \Sigma^{-1/2} \boldsymbol{X}\|_2^2 > t\right] \;\leq\; c t^{-1-\eta}, \quad \text{for } t > c \cdot \operatorname{rank}(\Pi)$$

for every orthogonal projection Π in $\mathbb{R}^d$.

Under this condition, we show the following guarantee for least squares regression.

Theorem 19 *Assume Σ is not singular. If $\boldsymbol{X}$ satisfies Condition 1 with some fixed parameters $c > 0$ and $\eta > 0$, then if Algorithm 4 is run with $n \geq O(d \log(1/\delta))$ and $\delta \in (0,1)$, with probability at least $1 - \delta$,*

$$L^{\mathrm{sq}}(\hat{\boldsymbol{w}}) \leq L^{\mathrm{sq}}_\star + O\left(\frac{\mathbb{E}\|\Sigma^{-1/2}\boldsymbol{X}(\boldsymbol{X}^\top \boldsymbol{w}_\star - Y)\|_2^2 \log(1/\delta)}{n}\right).$$

Our loss bound is given in terms of the following population quantity

$$\mathbb{E}\|\Sigma^{-1/2}\boldsymbol{X}(\boldsymbol{X}^\top \boldsymbol{w}_\star - Y)\|_2^2 \tag{6}$$

which we assume is finite. This assumption only requires bounded low-order moments of $\boldsymbol{X}$ and Y and is essentially the same as the conditions from Audibert and Catoni (2011) (see the discussion following their Theorem 3.1). Define the following finite fourth-moment conditions:

$$\kappa_1 := \frac{\sqrt{\mathbb{E}\|\Sigma^{-1/2}\boldsymbol{X}\|_2^4}}{\mathbb{E}\|\Sigma^{-1/2}\boldsymbol{X}\|_2^2} = \frac{\sqrt{\mathbb{E}\|\Sigma^{-1/2}\boldsymbol{X}\|_2^4}}{d} < \infty \quad \text{and}$$

$$\kappa_2 := \frac{\sqrt{\mathbb{E}(\boldsymbol{X}^\top \boldsymbol{w}_\star - Y)^4}}{\mathbb{E}(\boldsymbol{X}^\top \boldsymbol{w}_\star - Y)^2} = \frac{\sqrt{\mathbb{E}(\boldsymbol{X}^\top \boldsymbol{w}_\star - Y)^4}}{L^{\mathrm{sq}}_\star} < \infty.$$

Under these conditions, $\mathbb{E}\|\Sigma^{-1/2}\boldsymbol{X}(\boldsymbol{X}^\top \boldsymbol{w}_\star - Y)\|_2^2 \leq \kappa_1 \kappa_2 d L^{\mathrm{sq}}_\star$ (via Cauchy-Schwartz); if κ_1 and κ_2 are constant, then we obtain the bound

$$L^{\mathrm{sq}}(\hat{\boldsymbol{w}}) \leq \left(1 + O\left(\frac{d \log(1/\delta)}{n}\right)\right) L^{\mathrm{sq}}_\star$$

with probability $\geq 1 - \delta$. In comparison, the recent work of Audibert and Catoni (2011) proposes an estimator for linear regression based on optimization of a robust loss function which achieves essentially the same guarantee as Theorem 19 (with only mild differences in the moment conditions, see the discussion following their Theorem 3.1). However, that estimator depends on prior knowledge about the response distribution, and removing this dependency using Lepski's adaptation method (Lepski, 1991) may result in a suboptimal convergence rate. It is also unclear whether that estimator can be computed efficiently.

Other analyses for linear least squares regression and ridge regression by Srebro et al. (2010) and Hsu et al. (2014) consider specifically the empirical minimizer of the squared loss, and give sharp rates of convergence to $L^{\mathrm{sq}}_\star$. However, both of these require either boundedness of the loss or boundedness of the approximation error. In Srebro et al. (2010), the specialization of the main result to square loss includes additive terms of order $O(\sqrt{L(\boldsymbol{w}_\star) b \log(1/\delta)/n} + b \log(1/\delta)/n)$, where $b > 0$ is assumed to bound the square loss of any predictions almost surely. In Hsu et al. (2014), the convergence rate includes an additive term involving almost-sure bounds on the approximation error/non-subgaussian noise (The remaining terms are comparable to Eq. (9) for $\lambda = 0$, and Eq. (7) for $\lambda > 0$, up to logarithmic factors). The additional terms preclude multiplicative approximations to $L(\boldsymbol{w}_\star)$ in cases where the loss or approximation error is unbounded. In recent work, Mendelson (2014) proposes a more subtle 'small-ball' criterion for analyzing the performance of the risk minimizer. However, as evident from the lower bound in Remark 18, the empirical risk minimizer cannot obtain the same type of guarantees as our estimator.

The next result is for the case where there exists $R < \infty$ such that $\Pr[\boldsymbol{X}^\top \Sigma^{-1} \boldsymbol{X} \leq R^2] = 1$ (and, here, we do not assume Condition 1). In contrast, Y may still be heavy-tailed. Then, the following result can be derived using Algorithm 4. Moreover, the simpler **variant** of Algorithm 4 suffices here.

Theorem 20 *Assume Σ is not singular. Let $\hat{\boldsymbol{w}}$ be the output of the variant of Algorithm 4 with $\lambda = 0$. With probability at least $1 - \delta$, for $n \geq O(R^2 \log(R) \log(1/\delta))$,*

$$L^{\mathrm{sq}}(\hat{\boldsymbol{w}}) \leq \left(1 + O\left(\frac{R^2 \log(2/\delta)}{n}\right)\right) L^{\mathrm{sq}}_\star.$$

Note that $\mathbb{E}(\boldsymbol{X}^\top \Sigma^{-1} \boldsymbol{X}) = \mathbb{E} \operatorname{tr}(\boldsymbol{X}^\top \Sigma^{-1} \boldsymbol{X}) = \operatorname{tr}(\operatorname{Id}) = d$, therefore $R = \Omega(\sqrt{d})$. If indeed $R = \Theta(\sqrt{d})$, then a total sample size of $O(d \log(d) \log(1/\delta))$ suffices to guarantee a constant factor approximation to the optimal loss. This is minimax optimal up to logarithmic factors (Nussbaum, 1999). We also remark that the boundedness assumption can be replaced by a subgaussian assumption on $\boldsymbol{X}$, in which case the sample size requirement becomes $O(d \log(1/\delta))$.

In recent work of Mahdavi and Jin (2013), an algorithm based on stochastic gradient descent obtains multiplicative approximations to $L_\star$, for general smooth and strongly convex

losses ℓ, with a sample complexity scaling with $\log(1/\tilde{L})$. Here, $\tilde{L}$ is an upper bound on $L_\star$, which must be known by the algorithm. The specialization of Mahdavi and Jin's main result to square loss implies a sample complexity of $\tilde{O}(dR^8\log(1/(\delta L_\star^{\mathrm{sq}}))$ if $L_\star^{\mathrm{sq}}$ is known. In comparison, Theorem 20 shows that $\tilde{O}(R^2\log(1/\delta))$ suffice when using our estimator. It would be interesting to understand whether the bound for the stochastic gradient method of Mahdavi and Jin (2013) can be improved, and whether knowledge of $L_\star$ is actually necessary in the stochastic oracle model. We note that the main result of Mahdavi and Jin (2013) can be more generally applicable than Theorem 15, because Mahdavi and Jin (2013) only assumes that the population loss $L(\boldsymbol{w})$ is strongly convex, whereas Theorem 15 requires the empirical loss $L_T(\boldsymbol{w})$ to be strongly convex for large enough samples T. While our technique is especially simple for the squared loss, it may be more challenging to implement well for other losses, because the local norm around $\boldsymbol{w}_\star$ may be difficult to approximate with an observable norm. We thus leave the extension to more general losses as future work.

Finally, we also consider the case where $\mathbb{X}$ is a general, infinite-dimensional Hilbert space, $\lambda > 0$, the norm of $\boldsymbol{X}$ is bounded, and Y again may be heavy-tailed.

Theorem 21 *Let $V > 0$ such that $\Pr[\langle \boldsymbol{X}, \boldsymbol{X}\rangle_{\mathbb{X}} \le V^2] = 1$. Let $\hat{\boldsymbol{w}}$ be the output of the variant of Algorithm 4 with $\lambda > 0$. With probability at least $1-\delta$, as soon as $n \ge O((V^2/\lambda)\log(V/\sqrt{\lambda})\log(2/\delta))$,*

$$L^{\lambda}(\hat{\boldsymbol{w}}) \le \left(1 + O\left(\frac{(1+V^2/\lambda)\log(2/\delta)}{n}\right)\right) L_\star^{\lambda}.$$

If the optimal unregularized squared loss $L_\star^{\mathrm{sq}}$ is achieved by $\bar{\boldsymbol{w}} \in \mathbb{X}$ with $\langle \bar{\boldsymbol{w}}, \bar{\boldsymbol{w}}\rangle_{\mathbb{X}} \le B^2$, the choice $\lambda = \Theta(\sqrt{L_\star^{\mathrm{sq}} V^2 \log(2/\delta)/(B^2 n)})$ yields that if $n \ge \tilde{O}(B^2V^2\log(2/\delta)/L_\star^{\mathrm{sq}})$ then

$$L^{\mathrm{sq}}(\hat{\boldsymbol{w}}) \le L_\star^{\mathrm{sq}} + O\left(\sqrt{\frac{L_\star^{\mathrm{sq}} B^2 V^2 \log(1/\delta)}{n}} + \frac{(L_\star^{\mathrm{sq}} + B^2V^2)\log(1/\delta)}{n}\right). \tag{7}$$

By this analysis, a constant factor approximation for $L_\star^{\mathrm{sq}}$ is achieved with a sample of size $\tilde{O}(B^2V^2\log(1/\delta)/L_\star^{\mathrm{sq}})$. As in the finite-dimensional setting, this rate is known to be optimal up to logarithmic factors (Nussbaum, 1999). It is interesting to observe that in the non-parametric case, our analysis, like previous analyses, does require knowledge of $L_\star$ if λ is to be set correctly, as in Mahdavi and Jin (2013).

5.2 Analysis

We now show how the analysis of Section 4 can be applied to analyze Algorithm 4. For a sample $T \subseteq \mathcal{Z}$, if L_T is twice-differentiable (which is the case for squared loss), by Taylor's theorem, for any $\boldsymbol{w} \in \mathbb{X}$, there exist $t \in [0,1]$ and $\tilde{\boldsymbol{w}} = t\boldsymbol{w}_\star + (1-t)\boldsymbol{w}$ such that

$$L_T(\boldsymbol{w}) = L_T(\boldsymbol{w}_\star) + \langle \nabla L_T(\boldsymbol{w}_\star), \boldsymbol{w} - \boldsymbol{w}_\star\rangle_{\mathbb{X}} + \frac{1}{2}\langle \boldsymbol{w} - \boldsymbol{w}_\star, \nabla^2 L_T(\tilde{\boldsymbol{w}})(\boldsymbol{w} - \boldsymbol{w}_\star)\rangle_{\mathbb{X}},$$

Therefore, to establish a bound on n_α, it suffices to control

$$\Pr\left[\inf_{\boldsymbol{\delta}\in\mathbb{X}\setminus\{\boldsymbol{0}\}, \tilde{\boldsymbol{w}}\in\mathbb{R}^d} \frac{\langle \boldsymbol{\delta}, \nabla^2 L_T(\tilde{\boldsymbol{w}})\boldsymbol{\delta}\rangle_{\mathbb{X}}}{\|\boldsymbol{\delta}\|^2} \ge \alpha\right] \tag{8}$$

for an i.i.d. sample T from $\mathcal{D}$. The following lemma allows doing just that.

Lemma 22 (Specialization of Lemma 1 from Oliveira 2010) *Fix any $\lambda \ge 0$, and assume $\langle \boldsymbol{X}, (\Sigma + \lambda\,\mathrm{Id})^{-1}\boldsymbol{X}\rangle_{\mathbb{X}} \le r_\lambda^2$ almost surely. For any $\delta \in (0,1)$, if $m \ge 80 r_\lambda^2 \ln(4m^2/\delta)$, then with probability at least $1-\delta$, for all $\boldsymbol{a} \in \mathbb{X}$,*

$$\frac{1}{2}\langle \boldsymbol{a}, (\Sigma + \lambda\,\mathrm{Id})\boldsymbol{a}\rangle_{\mathbb{X}} \le \langle \boldsymbol{a}, (\Sigma_T + \lambda\,\mathrm{Id})\boldsymbol{a}\rangle_{\mathbb{X}} \le 2\langle \boldsymbol{a}, (\Sigma + \lambda\,\mathrm{Id})\boldsymbol{a}\rangle_{\mathbb{X}}.$$

We use the boundedness assumption for sake of simplicity; it is possible to remove the boundedness assumption, and the logarithmic dependence on the cardinality of T, under different conditions on $\boldsymbol{X}$ (*e.g.*, assuming $\Sigma^{-1/2}\boldsymbol{X}$ has subgaussian projections, see Litvak et al. 2005). We now prove Theorem 20, Theorem 21 and Theorem 19.

5.2.1 Ordinary Least Squares in Finite Dimensions

Consider first ordinary least squares in the finite-dimensional case. In this case $\mathbb{X} = \mathbb{R}^d$, the inner product $\langle \boldsymbol{a}, \boldsymbol{b}\rangle_{\mathbb{X}} = \boldsymbol{a}^\top\boldsymbol{b}$ is the usual coordinate dot product, and the second-moment operator is $\Sigma = \mathbb{E}(\boldsymbol{X}\boldsymbol{X}^\top)$. We assume that Σ is non-singular, so L has a unique minimizer. Here Algorithm 4 can be used with $\lambda = 0$. It is easy to see that Algorithm 4 with the **variant** steps is a specialization of Algorithm 2 with subsampled empirical loss minimization when $\ell = \ell^{\mathrm{sq}}$, with the norm defined by $\|\boldsymbol{a}\| = \sqrt{\boldsymbol{a}^\top\Sigma_S\boldsymbol{a}}$. We now prove the guarantee for finite dimensional regression.

Proof [of Theorem 20] The proof is derived from Corollary 16 as follows. First, suppose for simplicity that $\Sigma_s = \Sigma$, so that $\|\boldsymbol{a}\| = \sqrt{\boldsymbol{a}^\top\Sigma\boldsymbol{a}}$. It is easy to check that $\|\cdot\|_*$ is 1-smooth, ℓ is R^2-smooth with respect to $\|\cdot\|$, and L^{sq} is 1-smooth with respect to $\|\cdot\|$. Moreover, consider a random sample T. By definition

$$\frac{\boldsymbol{\delta}^\top\nabla^2 L_T(\tilde{\boldsymbol{w}})\boldsymbol{\delta}}{\|\boldsymbol{\delta}\|^2} = \frac{\boldsymbol{\delta}^\top\Sigma_T\boldsymbol{\delta}}{\boldsymbol{\delta}^\top\Sigma\boldsymbol{\delta}}.$$

By Lemma 22 with $\lambda = 0$, $\Pr[\inf\{\boldsymbol{\delta}^\top\Sigma_T\boldsymbol{\delta}/(\boldsymbol{\delta}^\top\Sigma\boldsymbol{\delta}) : \boldsymbol{\delta} \in \mathbb{R}^d \setminus \{\boldsymbol{0}\}\} \ge 1/2] \ge 5/6$, provided that $|T| \ge 80R^2\log(24|S|^2)$. Therefore $n_{0.5} = O(R^2\log R)$. We can thus apply Corollary 16 with $\alpha = 0.5$, $\beta = R^2$, $\bar{\beta} = 1$, $\gamma = 1$, and $n_{0.5} = O(R^2\log R)$, so with probability at least $1-\delta$, the parameter $\hat{\boldsymbol{w}}$ returned by Algorithm 4 satisfies

$$L(\hat{\boldsymbol{w}}) \le \left(1 + O\left(\frac{R^2\log(1/\delta)}{n}\right)\right) L(\boldsymbol{w}_\star), \tag{9}$$

as soon as $n \ge O(R^2\log(R)\log(1/\delta))$.

Now, by Lemma 22, if $n \ge O(R^2\log(R/\delta))$, with probability at least $1-\delta$, the norm induced by Σ_S satisfies $(1/2)\boldsymbol{a}^\top\Sigma\boldsymbol{a} \le \boldsymbol{a}^\top\Sigma_S\boldsymbol{a} \le 2\boldsymbol{a}^\top\Sigma\boldsymbol{a}$ for all $\boldsymbol{a} \in \mathbb{R}^d$. Therefore, by a union bound, the norm used by the algorithm is equivalent to the norm induced by the true Σ up to constant factors, and thus leads to the same guarantee as given above (where the constant factors are absorbed into the big-O notation). ■

The rate achieved in Eq. (9) is well-known to be optimal up to logarithmic factors (Nussbaum, 1999). A standard argument for this, which we reference in the sequel, is as follows. Consider a distribution over $\mathbb{R}^d \times \mathbb{R}$ where $\boldsymbol{X} \in \mathbb{R}^d$ is distributed uniformly over some

orthonormal basis vectors $\boldsymbol{e}_1, \boldsymbol{e}_2, \ldots, \boldsymbol{e}_d$, and $Y := \boldsymbol{X}^\top \boldsymbol{w}_\star + Z$ for $Z \sim \mathcal{N}(0, \sigma^2)$ independent of $\boldsymbol{X}$. Here, $\boldsymbol{w}_\star$ is an arbitrary vector in $\mathbb{R}^d$, $R = \sqrt{d}$, and the optimal square loss is $L(\boldsymbol{w}_\star) = \sigma^2$. Among n independent copies of $(\boldsymbol{X}, Y)$, let n_i be the number of copies with $\boldsymbol{X} = \boldsymbol{e}_i$, so $\sum_{i=1}^d n_i = n$. Estimating $\boldsymbol{w}_\star$ is equivalent to d Gaussian mean estimation problems, with a minimax loss of

$$\inf_{\hat{\boldsymbol{w}}} \sup_{\boldsymbol{w}_\star} \mathbb{E}\big(L(\hat{\boldsymbol{w}})\big) - L(\boldsymbol{w}_\star) \;=\; \inf_{\hat{\boldsymbol{w}}} \sup_{\boldsymbol{w}_\star} \mathbb{E}\left(\frac{1}{d}\|\hat{\boldsymbol{w}} - \boldsymbol{w}_\star\|_2^2\right)$$
$$= \frac{1}{d}\sum_{i=1}^d \frac{\sigma^2}{n_i} \;\geq\; \frac{d\sigma^2}{n} \;=\; \frac{dL(\boldsymbol{w}_\star)}{n}. \tag{10}$$

Note that this also implies a lower bound for any estimator with exponential concentration. That is, for any estimator $\hat{\boldsymbol{w}}$, if there is some $A > 0$ such that for any $\delta \in (0,1)$, $\mathbb{P}[L(\hat{\boldsymbol{w}}) > L(\boldsymbol{w}_\star) + A\log(1/\delta)] < \delta$, then $A \geq \mathbb{E}(L(\hat{\boldsymbol{w}}) - L(\boldsymbol{w}_\star)) \geq dL(\boldsymbol{w}_\star)/n$.

5.2.2 Ridge Regression

In a general, possibly infinite-dimensional, Hilbert space $\mathbb{X}$, Algorithm 4 can be used with $\lambda > 0$. In this case, Algorithm 4 with the **variant** steps is again a specialization of Algorithm 2 with subsampled empirical loss minimization when $\ell = \ell^\lambda$, with the norm defined by $\|\boldsymbol{a}\| = \sqrt{\boldsymbol{a}^\top(\Sigma_S + \lambda \mathrm{Id})\boldsymbol{a}}$.

Proof [of Theorem 21] As in the finite-dimensional case, assume first that $\Sigma_S = \Sigma$, and consider the norm $\|\cdot\|$ defined by $\|\boldsymbol{a}\| := \sqrt{\langle \boldsymbol{a}, (\Sigma + \lambda \mathrm{Id})\boldsymbol{a}\rangle_{\mathbb{X}}}$. It is easy to check that $\|\cdot\|_*$ is 1-smooth. Moreover, since we assume that $\Pr[\langle \boldsymbol{X}, \boldsymbol{X}\rangle_{\mathbb{X}} \leq V^2] = 1$, we have $\langle \boldsymbol{x}, (\Sigma + \lambda I)^{-1}\boldsymbol{x}\rangle_{\mathbb{X}} \leq \langle \boldsymbol{x}, \boldsymbol{x}\rangle_{\mathbb{X}}/\lambda$ for all $\boldsymbol{x} \in \mathbb{X}$, so $\Pr[\langle \boldsymbol{X}, (\Sigma + \lambda I)^{-1}\boldsymbol{X}\rangle_{\mathbb{X}} \leq V^2/\lambda] = 1$. Therefore ℓ^λ is $(1 + V^2/\lambda)$-smooth with respect to $\|\cdot\|$. In addition, L^λ is 1-smooth with respect to $\|\cdot\|$. Using Lemma 22 with $r_\lambda = V/\lambda$, we have, similarly to the proof of Theorem 20, $n_{0.5} = O((V^2/\lambda)\log(V/\sqrt{\lambda}))$. Setting $\alpha = 0.5$, $\beta = 1 + V^2/\lambda$, $\bar{\beta} = 1$, $\gamma = 1$, and $n_{0.5}$ as above, we conclude that with probability $1 - \delta$,

$$L^\lambda(\hat{\boldsymbol{w}}) \leq \left(1 + O\left(\frac{(1 + V^2/\lambda)\log(1/\delta)}{n}\right)\right) L^\lambda(\boldsymbol{w}_\star),$$

as soon as $n \geq O((V^2/\lambda)\log(V/\sqrt{\lambda})\log(1/\delta))$. Again as in the proof of Theorem 20, by Lemma 22 Algorithm 4 may use the observable norm $\boldsymbol{a} \mapsto \langle \boldsymbol{a}, (\Sigma_S + \lambda I)\boldsymbol{a}\rangle_{\mathbb{X}}^{1/2}$ instead of the unobservable norm $\boldsymbol{a} \mapsto \langle \boldsymbol{a}, (\Sigma + \lambda I)\boldsymbol{a}\rangle_{\mathbb{X}}^{1/2}$ by applying a union bound, if $n \geq O((V^2/\lambda)\log(2V/(\delta\sqrt{\lambda})))$, losing only constant factors, .

We are generally interested in comparing to the minimum square loss $L_\star^{\mathrm{sq}} := \inf_{\boldsymbol{w}\in\mathbb{X}} L^{\mathrm{sq}}(\boldsymbol{w})$, rather than the minimum regularized square loss $\inf_{\boldsymbol{w}\in\mathbb{X}} L^\lambda(\boldsymbol{w})$. Assuming the minimizer is achieved by some $\bar{\boldsymbol{w}} \in \mathbb{X}$ with $\langle \bar{\boldsymbol{w}}, \bar{\boldsymbol{w}}\rangle_{\mathbb{X}} \leq B^2$, the choice $\lambda = \Theta(\sqrt{L_\star^{\mathrm{sq}} V^2 \log(2/\delta)/(B^2 n)})$ yields

$$L^{\mathrm{sq}}(\hat{\boldsymbol{w}}) + \lambda\langle \hat{\boldsymbol{w}}, \hat{\boldsymbol{w}}\rangle_{\mathbb{X}} \leq L_\star^{\mathrm{sq}} + O\left(\sqrt{\frac{L_\star^{\mathrm{sq}} B^2 V^2 \log(2/\delta)}{n}} + \frac{(L_\star^{\mathrm{sq}} + B^2V^2)\log(2/\delta)}{n}\right)$$

as soon as $n \geq \tilde{O}(B^2V^2\log(2/\delta)/L_\star^{\mathrm{sq}})$. ∎

By this analysis, a constant factor approximation for $L_\star^{\mathrm{sq}}$ is achieved with a sample of size $\tilde{O}(B^2V^2\log(1/\delta)/L_\star^{\mathrm{sq}})$. As in the finite-dimensional setting, this rate is known to be optimal up to logarithmic factors (Nussbaum, 1999). Indeed, a similar construction to that from Section 5.2.1 implies

$$\inf_{\hat{\boldsymbol{w}}} \sup_{\boldsymbol{w}_\star} \mathbb{E}\big(L(\hat{\boldsymbol{w}}) - L(\boldsymbol{w}_\star)\big) \;\geq\; \Omega\left(\frac{1}{d}\cdot\frac{L_\star B^2V^2\sum_{i=1}^d n_i^{-1}}{B^2V^2 + L_\star\sum_{i=1}^d n_i^{-1}}\right) \;\geq\; \Omega\left(\frac{1}{d}\cdot\frac{L_\star B^2V^2 d^2/n}{B^2V^2 + L_\star d^2/n}\right) \tag{11}$$

(here, $\boldsymbol{X} \in \{V\boldsymbol{e}_i : i \in [d]\}$ has Euclidean length V almost surely, and B is a bound on the Euclidean length of $\boldsymbol{w}_\star$). For $d = \sqrt{B^2V^2n/\sigma^2}$, the bound becomes

$$\inf_{\hat{\boldsymbol{w}}} \sup_{\boldsymbol{w}_\star} \mathbb{E}\big(L(\hat{\boldsymbol{w}}) - L(\boldsymbol{w}_\star)\big) \;\geq\; \Omega\left(\sqrt{\frac{L_\star B^2V^2}{n}}\right).$$

As before, this minimax bound also implies a lower bound on any estimator with exponential concentration.

5.2.3 Heavy-tail Covariates

When the covariates are not bounded or subgaussian, the empirical second-moment matrix may deviate significantly from its population counterpart with non-negligible probability. In this case it is not possible to approximate the norm $\|\boldsymbol{a}\| = \sqrt{\boldsymbol{a}^\top(\Sigma + \lambda\mathrm{Id})\boldsymbol{a}}$ in Step 2 of Algorithm 2 using a single small sample (as discussed in Section 5.2.1 and Section 5.2.2). However, we may use Algorithm 3 instead of Algorithm 2, which only requires the stochastic distance measurements to be relatively accurate with some constant probability. The full version of Algorithm 4 is exactly such an implementation.

We now prove Theorem 19. Define $c_\eta := 512(48c)^{2+2/\eta}(6 + 6/\eta)^{1+4/\eta}$ (which is C_{main} from Srivastava and Vershynin, 2013). The following lemma shows that $O(d)$ samples suffice so that the expected spectral norm distance between the empirical second-moment matrix and Σ is bounded.

Lemma 23 (Implication of Corollary 1.2 from Srivastava and Vershynin, 2013) *Let $\boldsymbol{X}$ satisfy Condition 1, and let $\boldsymbol{X}_1, \boldsymbol{X}_2, \ldots, \boldsymbol{X}_n$ be independent copies of $\boldsymbol{X}$. Let $\widehat{\Sigma} := \frac{1}{n}\sum_{i=1}^n \boldsymbol{X}_i\boldsymbol{X}_i^\top$. For any $\epsilon \in (0,1)$, if $n \geq c_\eta\epsilon^{-2-2/\eta}d$, then*

$$\mathbb{E}\|\Sigma^{-1/2}\widehat{\Sigma}\Sigma^{-1/2} - \mathrm{Id}\,\|_2 \;\leq\; \epsilon.$$

Lemma 23 implies that $n_{0.5} = O(c'_\eta d)$ where $c'_\eta = c_\eta \cdot 2^{O(1+1/\eta)}$. Therefore, for $k = O(\log(1/\delta))$, subsampled empirical loss minimization requires $n \geq k \cdot n_{0.5} = O(c'_\eta d\log(1/\delta))$ samples to correctly implement $\mathrm{APPROX}_{\|\cdot\|,\varepsilon}$, for ε as in Eq. (5).

Step 5 in Algorithm 4 implements $\mathrm{DIST}^j_{\|\cdot\|}$ as returning f_j such that $f_j(\boldsymbol{v}) := \|\Sigma_{S_j}^{1/2}(\boldsymbol{v} - \boldsymbol{w}_j)\|_2$. First, we show that Assumption 3 holds. By Lemma 23, an i.i.d. sample T of size $O(c'_\eta d)$ suffices so that with probability at least 8/9, for every $\boldsymbol{v} \in \mathbb{R}^d$,

$$(1/2)\|\Sigma^{1/2}(\boldsymbol{v} - \boldsymbol{w}_j)\|_2 \leq \|\Sigma_T^{1/2}(\boldsymbol{v} - \boldsymbol{w}_j)\|_2 \leq 2\|\Sigma^{1/2}(\boldsymbol{v} - \boldsymbol{w}_j)\|_2.$$

In particular, this holds for $T = S_j$, as long as $|S_j| \geq O(c'_\eta d)$. Thus, for $k = O(\log(1/\delta))$, Assumption 3 holds if $n \geq O(c'_\eta d \log(1/\delta))$. Assumption 4 (independence) also holds, since f_j depends only on S_j, and $S_1, \ldots, S_k$ are statistically independent.

Putting everything together, we have (as in Section 5.2.1) $\alpha = 0.5$ and $\gamma = 1$. We obtain the final bound from Theorem 17 as follows: if $n \geq O(c'_\eta d \log(1/\delta))$, then with probability at least $1 - \delta$,

$$L(\hat{\boldsymbol{w}}) - L(\boldsymbol{w}_\star) = \|\Sigma^{1/2}(\hat{\boldsymbol{w}} - \boldsymbol{w}_\star)\|_2^2 \leq O\left(\frac{\mathbb{E}\|\Sigma^{-1/2}\boldsymbol{X}(\boldsymbol{X}^\top \boldsymbol{w}_\star - Y)\|_2^2 \log(1/\delta)}{n}\right). \quad (12)$$

6. Other Applications

In this section we show how the core techniques we discuss can be used for other applications, namely Lasso and low-rank matrix approximation.

6.1 Sparse Parameter Estimation with Lasso

In this section we consider L^1-regularized linear least squared regression (Lasso) (Tibshirani, 1996) with a random subgaussian design, and show that Algorithm 2 achieves the same fast convergence rates for sparse parameter estimation as Lasso, even when the noise is heavy-tailed.

Let $\mathcal{Z} = \mathbb{R}^d \times \mathbb{R}$ and $\boldsymbol{w}_\star \in \mathbb{R}^d$. Let D be a distribution over $\mathcal{Z}$, such that for $(\boldsymbol{X}, Y) \sim D$, we have $Y = \boldsymbol{X}^\top \boldsymbol{w}_\star + \varepsilon$ where ε is an independent random variable with $\mathbb{E}[\varepsilon] = 0$ and $\mathbb{E}[\varepsilon^2] \leq \sigma^2$. We assume that $\boldsymbol{w}_\star$ is sparse: Denote the support of a vector $\boldsymbol{w}$ by $\operatorname{supp}(\boldsymbol{w}) := \{j \in [d] : \boldsymbol{w}_j \neq 0\}$. Then $s := |\operatorname{supp}(\boldsymbol{w}_\star)|$ is assumed to be small compared to d. The *design matrix* for a sample $S = \{(\boldsymbol{x}_1, y_1), \ldots, (\boldsymbol{x}_n, y_n)\}$ is an $l \times d$ matrix with the rows $\boldsymbol{x}_i^\top$.

For $\lambda > 0$, consider the Lasso loss $\ell((\boldsymbol{x}, y), \boldsymbol{w}) = \frac{1}{2}(\boldsymbol{x}^\top \boldsymbol{w} - y)^2 + \lambda\|\boldsymbol{w}\|_1$. Let $\|\cdot\|$ be the Euclidean norm in $\mathbb{R}^d$. A random vector $\boldsymbol{X}$ in $\mathbb{R}^d$ is *subgaussian* (with moment 1) if for every vector $\boldsymbol{u} \in \mathbb{R}^d$, $\mathbb{E}[\exp(\boldsymbol{X}^\top \boldsymbol{u})] \leq \exp(\|\boldsymbol{u}\|_2^2/2)$.

The following theorem shows that when Algorithm 2 is used with subsampled empirical loss minimization over the Lasso loss, and D generates a subgaussian random design, then $\boldsymbol{w}$ can be estimated for any type of noise ε, including heavy-tailed noise.

In order to obtain guarantees for Lasso the design matrix must satisfy some regularity conditions. We use the *Restricted Eigenvalue condition* (RE) proposed in Bickel et al. (2009), which we presently define. For $\boldsymbol{w} \in \mathbb{R}^d$ and $J \subseteq [d]$, let $[\boldsymbol{w}]_J$ be the $|J|$-dimensional vector which is equal to $\boldsymbol{w}$ on the coordinates in J. Denote by $\boldsymbol{w}_{[s]}$ the s-dimensional vector with coordinates equal to the s largest coordinates (in absolute value) of $\boldsymbol{w}$. Let $\boldsymbol{w}_{[s]^C}$ be the $(d-s)$-dimensional vector which includes the coordinates not in $\boldsymbol{w}_{[s]}$. Define the set $E_s = \{\boldsymbol{u} \in \mathbb{R}^d \setminus \{0\} \mid \|\boldsymbol{u}_{[s]^C}\|_1 \leq 3\|\boldsymbol{u}_{[s]}\|_1\}$. For an $l \times d$ matrix Ψ (for some integer l), let $\gamma(\Psi, s) = \min_{\boldsymbol{u} \in E_s} \frac{\|\Psi \boldsymbol{u}\|_2}{\|\boldsymbol{u}_{[s]}\|_2}$. The RE condition for Ψ with sparsity s requires that $\gamma(\Psi, s) > 0$. We further denote $\eta(\Psi, s) = \max_{\boldsymbol{u} \in \mathbb{R}^d \setminus \{0\} : |\operatorname{supp}(\boldsymbol{u})| \leq s} \frac{\|\Psi \boldsymbol{u}\|_2}{\|\boldsymbol{u}\|_2}$.

Theorem 24 *Let $C, c > 0$ be universal constants. Let $\Sigma \in \mathbb{R}^{d \times d}$ be a positive semi definite matrix. Denote $\eta := \eta(\Sigma^{\frac{1}{2}}, s)$ and $\gamma := \gamma(\Sigma^{\frac{1}{2}}, s)$. Assume the random design setting defined above, with $\boldsymbol{X} = \Sigma^{\frac{1}{2}}\boldsymbol{Z}$, where $\boldsymbol{Z}$ is a subgaussian random vector. Suppose Algorithm 2 uses subsampled empirical loss minimization with the empirical Lasso loss, with $\lambda = 2\sqrt{\sigma^2 \eta^2 \log(2d)\log(1/\delta)/n}$. If $n \geq cs\frac{\eta^2}{\gamma^2}\log(d)\log(1/\delta)$, then with probability $1 - \delta$, The vector $\hat{\boldsymbol{w}}$ returned by Algorithm 2 satisfies*

$$\|\hat{\boldsymbol{w}} - \boldsymbol{w}_\star\|_2 \leq \frac{C\sigma\eta}{\gamma^2}\sqrt{\frac{s\log(2d)\log(1/\delta)}{n}}.$$

For the proof of Theorem 24, we use the following theorem, adapted from Bickel et al. (2009) and Zhang (2009). The proof is provided in Appendix A for completeness.

Theorem 25 (Bickel et al. (2009); Zhang (2009)) *Let $\Psi = [\Psi_1|\Psi_2|\ldots|\Psi_d] \in \mathbb{R}^{n \times d}$ and $\boldsymbol{\varepsilon} \in \mathbb{R}^n$. Let $y = \Psi \boldsymbol{w}_\star + \boldsymbol{\varepsilon}$ and $\hat{\boldsymbol{w}} \in \operatorname{argmin}_{\boldsymbol{w}} \frac{1}{2}\|\Psi \boldsymbol{w} - y\|_2^2 + \lambda\|\boldsymbol{w}\|_1$. Assume that $|\operatorname{supp}(\boldsymbol{w}_\star)| = s$ and that $\gamma(\Psi, s) > 0$. If $\|\Psi^\top \boldsymbol{\varepsilon}\|_\infty \leq \lambda/2$, then*

$$\|\hat{\boldsymbol{w}} - \boldsymbol{w}_\star\|_2 \leq \frac{12\lambda\sqrt{s}}{\gamma^2(\Psi, s)}.$$

Proof [of Theorem 24] Fix $i \in [k]$, and let $n_i = n/k$. Let $\Psi \in \mathbb{R}^{n_i \times d}$ be the design matrix for S_i and let $\boldsymbol{w}_i$ be the vector returned by the algorithm in round i, $\boldsymbol{w}_i \in \operatorname{argmin} \frac{1}{2n}\|\Psi \boldsymbol{w} - \boldsymbol{y}\|_2^2 + \lambda\|\boldsymbol{w}\|_1$. It is shown in Zhou (2009) that if $n_i \geq C\frac{\eta^2}{\gamma^2}s\log(d)$ for a universal constant C, then with probability 5/6, $\min_{\boldsymbol{u} \in E_s} \frac{\|\Psi \boldsymbol{u}\|_2}{\|\Sigma^{\frac{1}{2}}\boldsymbol{u}\|_2} \geq \sqrt{n_i}/2$. Call this event $\mathcal{E}$. By the definition of γ, we have that under $\mathcal{E}$,

$$\gamma(\Psi, s) = \min_{\boldsymbol{u} \in E_s} \frac{\|\Psi \boldsymbol{u}\|_2}{\|\boldsymbol{u}_{[s]}\|_2} = \min_{\boldsymbol{u} \in E_s} \frac{\|\Psi \boldsymbol{u}\|_2}{\|\Sigma^{\frac{1}{2}}\boldsymbol{u}\|_2}\frac{\|\Sigma^{\frac{1}{2}}\boldsymbol{u}\|_2}{\|\boldsymbol{u}_{[s]}\|_2} \geq \sqrt{n}\gamma/2.$$

If $\mathcal{E}$ holds and $\|\Psi^\top \boldsymbol{\varepsilon}\|_\infty \leq n\lambda/2$, then we can apply Theorem 25 (with $n\lambda$ instead of λ). We now show that this inequality holds with a constant probability. Fix the noise vector $\boldsymbol{\varepsilon} = \boldsymbol{y} - \Psi \boldsymbol{w}_\star$. For $l \in [d]$, since the coordinates of $\boldsymbol{\varepsilon}$ are independent and each row of Ψ is an independent copy of the vector $\boldsymbol{X} = \Sigma^{\frac{1}{2}}\boldsymbol{Z}$, we have

$$\mathbb{E}[\exp([\Psi^\top \boldsymbol{\varepsilon}]_l) \mid \boldsymbol{\varepsilon}] = \prod_{j \in [n]} \mathbb{E}[\exp(\Psi_{j,l}\boldsymbol{\varepsilon}_j) \mid \boldsymbol{\varepsilon}] = \prod_{j \in [n]} \mathbb{E}[\exp(\boldsymbol{Z}(\boldsymbol{\varepsilon}_j \Sigma^{\frac{1}{2}}\boldsymbol{e}_l)) \mid \boldsymbol{\varepsilon}].$$

Since $\|\boldsymbol{\varepsilon}_j \Sigma^{\frac{1}{2}}\boldsymbol{e}_l\|_2 \leq \boldsymbol{\varepsilon}_j \eta$, we conclude that

$$\mathbb{E}[\exp([\Psi^\top \boldsymbol{\varepsilon}]_l) \mid \boldsymbol{\varepsilon}] \leq \prod_{j \in [n]} \exp(\boldsymbol{\varepsilon}_j^2/2) = \exp(\eta^2\|\boldsymbol{\varepsilon}\|_2^2/2).$$

Therefore, for $\xi > 0$

$$\begin{aligned}
\xi\mathbb{E}[\|\Psi^\top \boldsymbol{\varepsilon}\|_\infty \mid \boldsymbol{\varepsilon}] &= \mathbb{E}[\max_l(\xi|[\Psi^\top \boldsymbol{\varepsilon}]_l|) \mid \boldsymbol{\varepsilon}] = \mathbb{E}[\log \max_l \exp(\xi|[\Psi^\top \boldsymbol{\varepsilon}]_l|) \mid \boldsymbol{\varepsilon}] \\
&\leq \mathbb{E}[\log\left(\sum_l \exp(\xi[\Psi^\top \boldsymbol{\varepsilon}]_l) + \exp(-\xi[\Psi^\top \boldsymbol{\varepsilon}]_l)\right) \mid \boldsymbol{\varepsilon}] \\
&\leq \log\left(\sum_l \mathbb{E}[\exp(\xi[\Psi^\top \boldsymbol{\varepsilon}]_l) \mid \boldsymbol{\varepsilon}] + \mathbb{E}[\exp(-\xi[\Psi^\top \boldsymbol{\varepsilon}]_l) \mid \boldsymbol{\varepsilon}]\right) \\
&\leq \log(2d) + \xi^2\eta^2\|\boldsymbol{\varepsilon}\|_2^2/2.
\end{aligned}$$

Since $\mathbb{E}[\boldsymbol{\varepsilon}_j^2] \le \sigma^2$ for all j, we have $\mathbb{E}[\|\boldsymbol{\varepsilon}\|^2] \le n_i\sigma^2/2$. Therefore

$$\mathbb{E}[\|\Psi^\top \boldsymbol{\varepsilon}\|_\infty] \le \frac{\log(2d)}{\xi} + \xi n_i \eta^2 \sigma^2/2.$$

Minimizing over $\xi > 0$ we get $\mathbb{E}[\|\Psi^\top\boldsymbol{\varepsilon}\|_\infty] \le 2\sqrt{\sigma^2\eta^2\log(2d)n_i/2}$. therefore by Markov's inequality, with probability at least 5/6, $\frac{1}{n_i}\|\Psi^\top\boldsymbol{\varepsilon}\|_\infty \le 2\sqrt{\sigma^2\eta^2\log(2d)/n_i} = \lambda$. With probability at least 2/3 this holds together with $\mathcal{E}$.

In this case, by Theorem 25,

$$\|\boldsymbol{w}_i - \boldsymbol{w}_\star\|_2 \le \frac{12\lambda\sqrt{s}}{\gamma^2(\Psi,s)} \le \frac{24}{\gamma^2}\sqrt{\frac{s\sigma^2\eta^2\log(2d)}{n_i}}.$$

Therefore $\mathrm{APPROX}_{\|\cdot\|,\epsilon}$ satisfies Assumption 1 with ϵ as in the right hand side above. The statement of the theorem now follows by applying Proposition 9 with $k = O(\log(1/\delta)$, and noting that $n_i = O(n/\log(1/\delta))$. ■

It is worth mentioning that we can apply our technique to the fixed design setting, where design matrix $X \in \mathbb{R}^{n\times d}$ is fixed and not assumed to come from any distribution. If X satisfies the RE condition, as well as a certain low-leverage condition—specifically, that the *statistical leverage scores* (Chatterjee and Hadi, 1986) of any $n \times O(s)$ submatrix of X be roughly $O(1/(ks\log d))$—then Algorithm 2 can be used with the subsampled empirical loss minimization implementation of $\mathrm{APPROX}_{\|\cdot\|,\varepsilon}$ to obtain similar guarantees as in the random subgaussian design setting.

We note that while standard analyses of sparse estimation with mean-zero noise assume light-tailed noise (Zhang, 2009; Bickel et al., 2009), there are several works that analyze sparse estimation with heavy-tailed noise under various assumptions. For example, several works assume that the median of the noise is zero (*e.g.*, Wang 2013; Belloni and Chernozhukov 2011; Zou and Yuan 2008; Wu and Liu 2009; Wang et al. 2007; Fan et al. 2012). van de Geer and Müller (2012) analyze a class of optimization functions that includes the Lasso and show polynomial convergence under fourth-moment bounds on the noise. Chatterjee and Lahiri (2013) study a two-phase sparse estimator for mean-zero noise termed the Adaptive Lasso, proposed in Zou (2006), and show asymptotic convergence results under mild moment assumptions on the noise.

6.2 Low-rank Matrix Approximation

The proposed technique can be easily applied also to low-rank covariance matrix approximation for heavy tailed distributions. Let $\mathcal{D}$ be a distribution over $\mathcal{Z} = \mathbb{R}^d$ and suppose our goal is to estimate $\Sigma = \mathbb{E}[\boldsymbol{X}\boldsymbol{X}^\top]$ to high accuracy, assuming that Σ is (approximately) low rank. Here $\mathbb{X}$ is the space of $\mathbb{R}^{d\times d}$ matrices, and $\|\cdot\|$ is the spectral norm. Denote the Frobenius norm by $\|\cdot\|_F$ and the trace norm by $\|\cdot\|_{\mathrm{tr}}$. For $S = \{\boldsymbol{X}_1,\ldots,\boldsymbol{X}_n\} \subseteq \mathbb{R}^d$, define the empirical covariance matrix $\Sigma_S = \frac{1}{n}\sum_{i\in[n]}\boldsymbol{X}_i\boldsymbol{X}_i^\top$. We have the following result for low-rank estimation:

Lemma 26 (Koltchinskii et al. 2011) *Let $\hat{\Sigma} \in \mathbb{R}^{d\times d}$. Assume $\lambda \ge \|\hat{\Sigma} - \Sigma\|$, and let*

$$\Sigma_\lambda \in \operatorname*{argmin}_{A\in\mathbb{R}^{d\times d}} \frac{1}{2}\|\hat{\Sigma} - A\|_F^2 + \lambda\|A\|_{\mathrm{tr}}, \tag{13}$$

If $\lambda \ge \|\hat{\Sigma} - \Sigma\|$, then

$$\frac{1}{2}\|\hat{\Sigma}_\lambda - \Sigma\|_F^2 \le \inf_{A\in\mathbb{R}^{d\times d}}\left\{\frac{1}{2}\|A-\Sigma\|_F^2 + \frac{1}{2}(\sqrt{2}+1)^2\lambda^2\,\mathrm{rank}(A)\right\}.$$

Now, assume condition 1 holds for $\mathcal{X} \sim \mathcal{D}$, and suppose for simplicity that $\|\Sigma\| \le 1$. In this case, by Lemma 23, A random sample S of size $n' = c'_\eta\epsilon^{-2-2/\eta}d$, where $c'_\eta = c_\eta(3/2)^{2+2/\eta}$ suffices to get an empirical covariance matrix Σ_S such that $\|\Sigma_S - \Sigma\| \le \epsilon$ with probability at least 2/3.

Given a sample of size n from $\mathcal{D}$, We can thus implement $\mathrm{APPROX}_{\|\cdot\|,\varepsilon}$ that simply returns the empirical covariance matrix of a sub-sample of size $n' = n/k$, so that Assumption 1 holds for an appropriate ε. By Proposition 9, Algorithm 2 returns $\hat{\Sigma}$ such that with probability at least $1-\exp(-k/18)$, $\|\hat{\Sigma} - A\| \le 3\epsilon$. The resulting $\hat{\Sigma}$ can be used to minimize Eq. (13) with $\lambda = 3\epsilon := O\left((c'_\eta d\log(1/\delta)/n)^{1/2(1+1/\eta)}\right)$. The output matrix Σ_λ satisfies, with probability at least $1-\delta$,

$$\frac{1}{2}\|\Sigma_\lambda - \Sigma\|_F^2 \le \inf_{A\in\mathbb{R}^{d\times d}}\left\{\frac{1}{2}\|A-\Sigma\|_F^2 + O\left((c'_\eta d\log(1/\delta)/n)^{1/(1+1/\eta)}\right)\cdot\mathrm{rank}(A)\right\}.$$

7. A Comparison of Robust Distance Approximation Methods

The approach described in Section 3 for selecting a single $\boldsymbol{w}_i$ out of the set $\boldsymbol{w}_1,\ldots,\boldsymbol{w}_k$, gives one Robust Distance Approximation procedure (see Def. 1), in which the $\boldsymbol{w}_i$ with the lowest median distance from all others is selected. In this section we consider other Robust Distance Approximation procedures and their properties. We distinguish between procedures that return $y \in W$, which we term *set-based*, and procedures that might return any $y \in \mathbb{X}$, which we term *space-based*.

Recall that we consider a metric space $(\mathbb{X},\rho)$, with $W \subseteq \mathbb{X}$ a (multi)set of size k and $w_\star$ a distinguished element. Let $W_+ := W \cup \{w_\star\}$. In this formalization, the procedure used in Algorithm 2 is to simply select $y \in \operatorname{argmin}_{w\in W}\Delta_W(w,0)$, a set-based procedure. A natural variation of this is the space-based procedure: select $y \in \operatorname{argmin}_{w\in\mathbb{X}}\Delta_W(w,0)$.[6] A different approach, proposed by Minsker (2013), is to select $y \in \operatorname{argmin}_{w\in\mathbb{X}}\sum_{\bar{w}\in W}\rho(w,\bar{w})$, that is to minimize the geometric median over the space. Minsker analyzes this approach for Banach and Hilbert spaces. We show that minimizing the geometric median also achieves similar guarantees in general metric spaces.

In the following, we provide detailed guarantees for the approximation factor C_α of the two types of procedures, for general metric spaces as well as for Banach and Hilbert spaces, and for set-based and sample-based procedures. We further provide lower bounds for specific procedures, as well as lower bounds that hold for any procedure. In Section 7.4

6. The space-based median distance approach might not always be computationally feasible; see discussion in Section 7.4.

we summarize the results and compare the guarantees of the two procedures and the lower bounds. For a more useful comparison, we take into account the fact that the value of α usually affects not only the approximation factor, but also the upper bound obtained for $\Delta_W(w_\star, \alpha)$.

7.1 Minimizing the Median Distance

Minimizing the median distance over the set of input points was shown in Proposition 8 to achieve an approximation factor of 3. In this section we show that this upper bound on the approximation factor is tight for this procedure, even in a Hilbert space. Here and below, we say that an approximation factor upper bound is *tight* if for any constant smaller than this upper bound, there are a suitable space and a set of points in that space, such that the procedure achieves for this input a larger approximation factor than said constant.

The approximation factor can be improved to 2 for a sample-based procedure. This factor is tight as well, even assuming a Hilbert space. The following theorem summarizes these facts.

Theorem 27 *Let $k \geq 2$, and suppose that $\Delta_W(w_\star, \gamma) \leq \epsilon$ for some $\gamma > 0$. Let $y \in \operatorname{argmin}_{w \in W} \Delta_W(w, 0)$. Further, suppose that $W_+ \subseteq \mathbb{X}$, and let $\bar{y} \in \operatorname{argmin}_{w \in \mathbb{X}} \Delta_W(w, 0)$. Then*

- *For any metric space, $\rho(w_\star, y) \leq 3\epsilon$;*
- *For any metric space, $\rho(w_\star, \bar{y}) \leq 2\epsilon$;*
- *There exists a set on the real line such that $\rho(w_\star, y) = 3\epsilon$, where ρ is the distance induced by the inner product;*
- *There exists a set on the real line such that $\rho(w_\star, \bar{y}) = 2\epsilon$, where ρ is the distance induced by the inner product.*

Proof First, we prove the two upper bounds. Since $\Delta_W(w_\star, \gamma) \leq \epsilon$, we have $|B(w_\star, \epsilon) \cap W| > k/2$. Let $w \in |B(w_\star, \epsilon) \cap W|$. Then by the triangle inequality, $B(w, 2\epsilon) \supseteq B(w_\star, \epsilon)$. Therefore $\Delta_W(w, 0) \leq 2\epsilon$. It follows that $\Delta_W(y, 0) \leq 2\epsilon$, hence $|B(y, 2\epsilon) \cap W| \geq k/2$. By the pigeon hole principle, $|B(w_\star, \epsilon) \cap B(y, 2\epsilon)| > 0$, therefore $\rho(w_\star, y) \leq 3\epsilon$.

As for $\bar{y}$, since this is a minimizer over the entire space $\mathbb{X}$ which includes $w_\star$, we have $\Delta_W(y, \gamma) \leq \Delta_W(w_\star, \gamma) \leq \epsilon$. Therefore, similarly to the argument for y, we have $\rho(w_\star, y) \leq 2\epsilon$.

To see that these bounds are tight, we construct simple examples on the real line. For y, suppose $w_\star = \epsilon$, and consider W with k points as follows: $k/2-1$ points at 0, 2 points at 2ϵ, and $k/2-1$ points at 4ϵ. The points at 4ϵ are clearly in $\operatorname{argmin}_{w \in W} \Delta_W(w, 0)$, therefore $\rho(w_\star, y) = 3\epsilon$.

For $\bar{y}$, suppose $w_\star = \epsilon$, and consider W with k points as follows: 2 points at 0, $k/2-1$ points at 2ϵ, and $k/2-1$ points at 3ϵ. The points at 3ϵ are clearly in $\operatorname{argmin}_{w \in W_+} \Delta_W(w, 0)$, therefore $\rho(w_\star, \bar{y}) = 2\epsilon$. ■

The non-uniqueness of the median distance minimizer is exploited in the lower bounds in Theorem 27. This suggests that some kind of aggregation of the median distance minimizers may provide a smaller bound at least in certain scenarios.

7.2 The Geometric Median

For $w \in \mathbb{X}$, denote the sum of distances from points in the input set by $\operatorname{sumd}(w) := \sum_{v \in W} \rho(w, v)$. Minsker (2013) suggests to minimize the sum of distances over the entire space, that is, to select the geometric median. Minsker shows that when this procedure is applied in a Hilbert space, $C_\alpha \leq \frac{\frac{1}{2}+\alpha}{\sqrt{2\alpha}}$, and for a Banach space $C_\alpha \leq 1 + \frac{1}{2\alpha}$. Here we show that in fact $C_\alpha \leq 1 + \frac{1}{2\alpha}$ for general metric spaces. The proof holds, in particular, for Banach spaces, and thus this provide a more direct argument that does not require the special properties of Banach spaces. We further show that for general metric spaces, this upper bound on the approximation factor is tight.

Minimizing over the entire space is a computationally intensive procedure, involving convex approximation. Moreover, if the only access to the metric is via estimated distances based on samples, as in Algorithm 3, then there are additional statistical challenges. It is thus of interest to also consider the simpler set-based procedure, and we provide approximation guarantees for this procedure as well. We show that an approximation factor of $2 + \frac{1}{2\alpha}$ can be guaranteed for set-based procedures in general metric spaces, and this is also tight, even for Banach spaces.

The following theorem provides a bound that holds in several of these settings.

Theorem 28 *Let $k \geq 2$. Let $y \in \operatorname{argmin}_{w \in W} \operatorname{sumd}(w)$, and let $\bar{y} \in \operatorname{argmin}_{w \in W_+} \operatorname{sumd}(w)$. Then*

1. *For any metric space $(\mathbb{X}, \rho)$ and W, W_+,*

$$\rho(w_\star, y) \leq \left(2 + \frac{1}{2\alpha}\right) \Delta_W(w_\star, \alpha).$$

2. *For any constant $C < (2 + \frac{1}{2\alpha})$, there exists a problem in a Banach space such that $\rho(w_\star, y) > C \cdot \Delta_W(w_\star, \alpha)$. Thus the upper bound above is tight.*

3. *For any metric space $(\mathbb{X}, \rho)$ and W, W_+,*

$$\rho(w_\star, \bar{y}) \leq \left(1 + \frac{1}{2\alpha}\right) \Delta_W(w_\star, \alpha).$$

4. *For any constant $C < (1 + \frac{1}{2\alpha})$, there exists a problem in a metric space such that $\rho(w_\star, \bar{y}) > C \cdot \Delta_W(w_\star, \alpha)$. Thus the upper bound above is tight for general metric spaces.*

Proof Let $w \in \operatorname{argmin}_{w \in B(w_\star, \epsilon) \cap W} \rho(w, y)$. Let $Z \subset B(w_\star, \epsilon) \cap W$ such that $|Z| = k(\frac{1}{2} + \alpha)$ (we assume for simplicity that $k(\frac{1}{2} + \alpha)$ is an integer; the proof can be easily modified to

accommodate the general case). For $v \in Z$, $\rho(w,v) \le \rho(w,w_\star) + \rho(w_\star,v)$. For $v \in W \setminus Z$, $\rho(w,v) \le \rho(w,y) + \rho(y,v)$. Therefore

$$\mathrm{sumd}(w) \le \sum_{v\in Z}(\rho(w,w_\star)+\rho(w_\star,v)) + \sum_{v\in W\setminus Z}(\rho(w,y)+\rho(y,v)).$$

By the definition of w as a minimizer, for $v \in Z$, $\rho(y,v) \ge \rho(y,w)$. Thus

$$\mathrm{sumd}(y) \ge \sum_{v\in Z}\rho(y,w) + \sum_{v\in W\setminus Z}\rho(y,v).$$

Since $\mathrm{sumd}(y) \le \mathrm{sumd}(w)$, we get

$$\sum_{v\in Z}\rho(y,w) + \sum_{v\in W\setminus Z}\rho(y,v) \le \sum_{v\in Z}(\rho(w,w_\star)+\rho(w_\star,v)) + \sum_{v\in W\setminus Z}(\rho(w,y)+\rho(y,v)).$$

Hence, since $\rho(v,w_\star) \le \epsilon$ for $v \in Z$,

$$(|Z| - |W\setminus Z|)\rho(w,y) \le 2|Z|\epsilon.$$

Since $|Z| = k(\frac{1}{2}+\alpha)$ it follows that $\rho(w,y) \le (1+\frac{1}{2\alpha})\epsilon$. In addition,

$$\rho(w_\star,y) \le \rho(w,w_\star) + \rho(w,y) \le \epsilon + \rho(w,y),$$

therefore

$$\rho(w_\star,y) \le \left(2+\frac{1}{2\alpha}\right)\epsilon.$$

This shows that for any metric space, the set-based geometric median gives an approximation factor of $2+\frac{1}{2\alpha}$, proving item 1.

For the space-based geometric median, consider $\bar{w} \in \mathrm{argmin}_{w\in B(w_\star,\epsilon)\cap W}\rho(w,\bar{y})$. We have $\mathrm{sumd}(\bar{y}) \le \mathrm{sumd}(w_\star)$. In addition,

$$\mathrm{sumd}(w_\star) \le \sum_{v\in Z}\rho(w_\star,v) + \sum_{v\in W\setminus Z}(\rho(w_\star,\bar{w})+\rho(\bar{w},\bar{y})+\rho(\bar{y},v)).$$

Therefore,

$$\sum_{v\in Z}\rho(\bar{y},\bar{w}) + \sum_{v\in W\setminus Z}\rho(\bar{y},v) \le \sum_{v\in Z}\rho(w_\star,v) + \sum_{v\in W\setminus Z}(\rho(w_\star,w)+\rho(w,\bar{y})+\rho(\bar{y},v)).$$

Since $\rho(w_\star,v) \le \epsilon$ for $v \in Z$, and $\rho(w_\star,\bar{w}) \le \epsilon$, it follows

$$(|Z| - |W\setminus Z|)\rho(\bar{w},\bar{y}) \le k\epsilon.$$

Therefore $\rho(\bar{w},\bar{y}) \le \frac{1}{2\alpha}\epsilon$, hence

$$\rho(w_\star,\bar{y}) \le \rho(w_\star,\bar{w}) + \rho(\bar{w},\bar{y}) \le \left(1+\frac{1}{2\alpha}\right)\epsilon.$$

This gives an approximation factor of $1+\frac{1}{2\alpha}$ for space-based geometric median, proving item 3.

To see that both of these bounds are tight, let $n = k(\frac{1}{2}+\alpha)$, and let $\mathbb{X} = W_+ = \{v_1,\ldots,v_n,y_1,\ldots,y_{k-n},w_\star\}$. Define $\rho(\cdot,\cdot)$ as follows (for all pairs $i \ne j$, $l \ne t$):

$$\begin{aligned}\rho(w_\star,v_i) &= \epsilon\\ \rho(w_\star,y_l) &= \beta\\ \rho(v_i,v_j) &= 2\epsilon\\ \rho(v_i,y_t) &= \beta-\epsilon\\ \rho(y_t,y_l) &= 0.\end{aligned}$$

One can verify that for any $\beta \le (2+\frac{1}{2\alpha}-\frac{1}{k\alpha})\epsilon$, $\mathrm{sumd}(y_l) \le \mathrm{sumd}(v_i)$ for all l,i. Therefore, the approximation factor for set-based geometric median in a general metric space is lower-bounded by $2+\frac{1}{2\alpha}$ for general k. This holds also for Banach spaces as well, Since any metric space can be embedded into a Banach space (Kuratowski, 1935). This proves item 2.

For space-based geometric median, note that if $\beta \le (1+\frac{1}{2\alpha})\epsilon$, then $\mathrm{sumd}(w_\star) \ge \mathrm{sumd}(y_l)$. Therefore the space-based upper bound is tight for a general metric space. This proves item 4. ■

Since $\alpha \in (0,\frac{1}{2})$, the guarantee for the geometric median in these settings is always worse than the guarantee for minimizing the median distance. Factoring in the dependence on α, the difference is even more pronounced. The full comparison is given in Section 7.4 below.

7.3 Optimal Approximation Factor

In this section we give lower bounds that hold for any robust distance approximation procedure. A lower bound of $C > 0$ for a category of metric spaces and a type of procedure indicates that if a procedure of this type guarantees a distance approximation C_α for all metric spaces of the given category, then necessarily $C_\alpha \ge C$. As shown below, in many cases the lower bounds provided here match the upper bounds obtained by either the median distance or the geometric median.

The following theorem gives a lower bound of 3 for the achievable approximation factor of set-based procedures in Banach spaces (and so, also in general metric spaces). This factor is achieved by the median distance minimizer, as shown in Theorem 27.

Theorem 29 *Consider set-based robust distance approximation procedures. For any $\alpha \in (0,\frac{1}{2})$, and for any such procedure, there exists a problem in a Banach space for which the approximation factor of the procedure is at least 3.*

Proof Fix α, and let $n = \lceil \frac{1}{\frac{1}{2}-\alpha} \rceil$. Define the metric space $\mathbb{X} = \{a_1,\ldots,a_n,b_1,\ldots,b_n\}$ with the metric $\rho(\cdot,\cdot)$ defined as follows: For all $i \ne j$, $\rho(a_i,a_j) = 2$, $\rho(a_i,b_j) = 1$, $\rho(b_i,b_j) = 2$. For all i, $\rho(a_i,b_i) = 3$. See Figure 2 for illustration.

Consider the multi-set W with k/n elements at every b_i. It is easy to check that for every a_i, $\Delta_W(a_i,\alpha) \le \Delta_W(a_i,1/2-1/n) = 1$. On the other hand, since the problem is

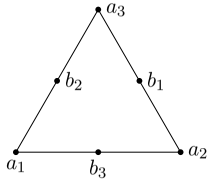

Figure 2: The metric defined in Theorem 29 for $n = 3$. The distances are shortest paths on the underlying undirected graph, where all edges are the same length.

symmetric for permutations of the indices $1, \ldots, n$, no procedure can distinguish the cases $w_\star = a_i$ for different $i \in [n]$. For any choice $y = b_i \in W$, if $w_\star = a_i$ then $\rho(w_\star, y) = 3$. Therefore the approximation factor of any procedure is at least 3. Since any metric space can be embedded into a Banach space (Kuratowski, 1935) this result holds also for Banach spaces. ■

Next, we give a lower bound of 2 for space-based procedures over general metric spaces. Theorem 27 shows that this factor is also achieved by minimizing the median distance.

Theorem 30 *Consider robust space-based distance approximation procedures. For any $\alpha \in (0, \frac{1}{2})$, and for any such procedure, there exists a problem for which the approximation factor of the procedure is at least* 2.

Proof Fix α, and let $n = \lceil \frac{1}{\frac{1}{2}-\alpha} \rceil$. Define the metric space $\mathbb{X} = \{a_1, \ldots, a_n, b_1, \ldots, b_n\}$ with the metric $\rho(\cdot, \cdot)$ defined as follows: For all $i \neq j$, $\rho(a_i, a_j) = 2$, $\rho(a_i, b_j) = 1$, $\rho(b_i, b_j) = 1$. For all i, $\rho(a_i, b_i) = 2$. See Figure 3 for illustration.

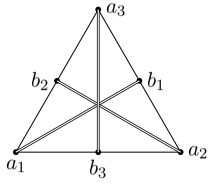

Figure 3: The metric defined in Theorem 29 for $n = 3$. The distances are shortest paths on the underlying undirected graph. The full lines are edges of length 1, the double lines from a_i to b_i are edges of length 2.

Consider the multi-set W with k/n points at every b_i. It is easy to check that for every a_i, $\Delta_W(a_i, \alpha) \leq \Delta_W(a_i, 1/2 - 1/n) = 1$. On the other hand, since the problem is symmetric

for permutations of the indices $1, \ldots, n$, no procedure can distinguish the cases $w_\star = a_i$ for different $i \in [n]$. Moreover, any point y in the space has $\rho(a_i, y) = 2$ for at least one $i \in [n]$. Therefore the approximation factor of any procedure is at least 2. ■

For lower bounds on Hilbert spaces and Banach spaces, we require the following lemma, which gives the radius of the ball inscribing the regular simplex in a p-normed space.

Lemma 31 *Consider $\mathbb{R}^n$ with the p-norm for $p > 1$. Let $e_1, \ldots, e_n$ be the standard basis vectors, and let $r_{n,p}$ be the minimal number for which there exists an $x \in \mathbb{R}^n$ such that $B(x, r) \supseteq \{e_1, \ldots, e_n\}$. Then $r_{n,p} = ((1+(n-1)^{-1/(p-1)})^{-p} + (n-1)(1+(n-1)^{1/(p-1)})^{-p})^{1/p}$. This radius is obtained with the center x such that for all i, $x_i = (1 + (n-1)^{1/(p-1)})^{-1}$.*

Proof It is easy to see that due to symmetry, $x = (a, a, \ldots, a)$ for some real number a. Thus $r_{n,p} = \inf_{a \in \mathbb{R}} \|e_1 - (a, \ldots, a)\|_p$. We have $\|e_1 - (a, \ldots, a)\|_p^p = |1 - a|^p + (n-1)|a|^p$. Minimizing over a gives $a = (1 + (n-1)^{1/(p-1)})^{-1}$, and

$$r_{n,p}^p = |1 - a|^p + (n-1)|a|^p = (1 + (n-1)^{-1/(p-1)})^{-p} + (n-1)(1 + (n-1)^{1/(p-1)})^{-p}.$$

■

We now prove a lower bound for robust distance approximation in Hilbert spaces. Unlike the previous lower bounds, this lower bound depends on the value of α.

Theorem 32 *Consider robust distance approximation procedures for $(\mathbb{X}, \rho)$ a Hilbert space. For any $\alpha \in (0, \frac{1}{2})$, the following holds:*

- *For any set-based procedure, there exists a problem such that the procedure achieves an approximation factor at least*

$$\sqrt{1 + \frac{2}{\left\lceil \frac{1}{\frac{1}{2}-\alpha} \right\rceil - 2}}.$$

- *For any space-based procedure, there exists a problem such that the procedure achieves an approximation factor at least*

$$\sqrt{1 + \frac{1}{\left\lceil \frac{1}{\frac{1}{2}-\alpha} \right\rceil^2 - 2\left\lceil \frac{1}{\frac{1}{2}-\alpha} \right\rceil}}.$$

The space-based bound given in Theorem 32 is tight for $\alpha \to 1/2$. This can be seen by noting that the limit of the space-based lower bound for $\alpha \to 1/2$ is $(\frac{1}{2} + \alpha)/\sqrt{2\alpha}$, which is exactly the guarantee provided in Minsker (2013) for the space-based geometric median procedure. For smaller α, there is a gap between the guarantee of Minsker for the geometric median and our lower bound.

Proof Fix α, and let $n = \lceil \frac{1}{\frac{1}{2}-\alpha} \rceil$. Consider the Euclidean space $\mathbb{R}^n$ with $\rho(x, y) = \|x - y\|$. Let $e_1, \ldots, e_n$ be the standard basis vectors. These are the vertices of a regular simplex

with side length $\|e_i - e_j\| = \sqrt{2}$. Let $b_1, \ldots, b_n$ such that b_i is the center of the hyperface of the simplex opposing e_i. Then $\|b_i - e_j\| = r_{n-1,2}$ for all $j \neq i$, where $r_{n,2} = \sqrt{\frac{n-1}{n}}$ is as defined in Lemma 31. (see Figure 4).

Consider W with k/n points at each of $b_1, \ldots, b_n$. Then $\Delta_W(e_i, \alpha) \leq \Delta_W(e_i, 1 - \frac{1}{n}) = \|e_i - b_j\| = r_{n-1,2}$ for any $j \neq i$. Any set-based procedure must select b_i for some i. if $w_\star = e_i$, the resulting approximation factor is $\|e_i - b_i\|/r_{n-1,2} = \sqrt{\frac{n-2}{n-1}}\|e_i - b_i\|$. For $\|b_i - e_i\|$, consider for instance b_1 and e_1. We have $b_1 = (0, \frac{1}{n-1}, \ldots, \frac{1}{n-1})$, therefore $\|b_1 - e_1\| = \sqrt{\frac{n}{n-1}}$. The approximation factor of the procedure is thus at least $\sqrt{\frac{n}{n-2}}$.

For a set-based procedure, whatever y it returns, there exists at least one i such that $\|y - a_i\| \geq r_{n,2}$. Therefore the approximation factor is at least $r_{n,2}/r_{n-1,2} = \sqrt{\frac{n-1}{n}}/\sqrt{\frac{n-2}{n-1}} = \sqrt{1 + \frac{1}{n^2-2n}}$.

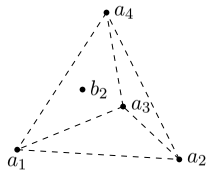

Figure 4: The regular simplex in $\mathbb{R}^3$, $n = 4$. a_i is a vertex, b_i is the center of the face opposite a_i.

■

For space-based procedures, we have seen that while there exists a lower bound of 2 for general metric spaces, in a Hilbert space better approximation factors can be achieved. Is it possible that in Banach spaces the same approximation factor can also be achieved? The following theorem shows that the answer is no.

Theorem 33 *Let $\alpha = 1/6$. There exists a Banach space for which an approximation factor of $(\frac{1}{2} + \alpha)/\sqrt{2\alpha}$ cannot be achieved.*

Proof Consider the space $\mathbb{R}^n$ with the distance defined by a p-norm. Let $n = 1/(\frac{1}{2} - \alpha) = 3$. Construct W as in the proof of Theorem 32, with k/n points in each of $b_1, \ldots, b_n$, where b_i is the center (in the p-norm) of the hyperface opposing the basis vector e_i. As in the proof of Theorem 32, the approximation factor for any space-based procedure for this problem is at least $r_{n,p}/r_{n-1,p}$. For $p = 3/2$, we have $r_{n,p}/r_{n-1,p} = \frac{2}{5^{1/3}} > \frac{2}{\sqrt{3}} = \frac{\frac{1}{2}+\alpha}{\sqrt{2\alpha}}$. ■

7.4 Comparison of Selection Procedures

The results provided above are summarized in Table 1. When comparing different procedures for different values of α, it is useful to compare not only the respective approximation factors but also the upper bound that can be obtained for $\Delta_W(w_\star, \alpha)$. Typically, as in the proof of Proposition 9, this upper bound will stem from first bounding $\mathbb{E}[\rho(w_\star, w)] \leq \epsilon$, where the expectation is taken over random i.i.d. draws of w, and then applying Markov's inequality to obtain $\mathbb{P}[\rho(w_\star, w) \leq \frac{\epsilon}{\frac{1}{2}-\alpha}] \geq \frac{1}{2} + \alpha$. In the final step Hoeffding's inequality guarantees that if k is large enough, $|B(w_\star, \epsilon/(\frac{1}{2}-\alpha)) \cap W|$ approaches $k(\frac{1}{2}+\alpha)$. Therefore, for a large k and a procedure for α with an approximation factor C_α, the guarantee approaches $\rho(y, w_\star) \leq \frac{C_\alpha}{(\frac{1}{2}-\alpha)} \cdot \epsilon$. For a procedure with an approximation factor C_α, we call $\frac{C_\alpha}{(\frac{1}{2}-\alpha)}$ the *normalized* approximation factor of the procedure. This is the approximation factor with respect to $\mathbb{E}[\rho(w_\star, \alpha)]$. When the procedure supports a range of α, the optimal normalized factor can be found by minimizing $\frac{C_\alpha}{(\frac{1}{2}-\alpha)}$ over $\alpha \in (0, \frac{1}{2})$. If $C_\alpha = C$ is a constant, the optimal normalized approximation factor is $2C$, achieved when $\alpha = 0$. The optimal normalized approximation factors, based on the known approximation factors as a function of α, are given in Table 2.

We observe that for set-based procedures, the median distance is superior to the geometric median for general metric spaces as well as for general Banach spaces. It is an open question whether better results can be achieved for Hilbert spaces using set-based procedures.

For space-based procedures, the median distance is again superior, except in the case of a Hilbert space, where the geometric median is superior. The case of a Hilbert space is arguably the most useful in common applications such as linear regression. Nevertheless, gaps still remain and it would be interesting to develop optimal methods.

Implementing the geometric median procedure in a space-based formulation is computationally efficient for Hilbert spaces when accurate distances are available Minsker (2013). However, it is unknown whether and how the procedure can be implemented when only unreliable distance estimations are available, as in Section 3.3. A useful implementation should be both computationally feasible and statistically efficient, while degrading the approximation factors as little as possible.

8. Predicting Without a Metric on Predictors

The core technique presented above allows selecting a good candidate out of a set that includes mostly good candidates, in the presence of a metric between candidates. If the final goal is prediction of a scalar label, good prediction can still be achieved without access to a metric between candidates, using the following simple procedure: For every input data point, calculate the prediction of every candidate, and output the median of the predictions. This is a straight-forward generalization of voting techniques for classification such as when using bagging (Breiman, 1996).[7] The following lemma shows that this approach leads to guarantees similar to those achieved by Proposition 9.

7. Note, however, that the usual implementation of bagging for regression involves averaging over the outputs of the classifiers, and not taking the median.

Lemma 34 *Let D, $\ell : \mathcal{Z} \times \mathbb{X} \to \mathbb{R}_+$ and $L : \mathbb{X} \to \mathbb{R}_+$ be defined as in Section 4. Assume that $\mathcal{Z} = \mathcal{X} \times \mathcal{Y}$, and there are functions $f : \mathcal{X} \times \mathbb{X} \to \mathbb{R}$ (the prediction function) and $g : \mathbb{R} \times \mathbb{R}$ (the link function) such that $\ell((\boldsymbol{x}, y), \boldsymbol{w}) = g(f(\boldsymbol{x}, \boldsymbol{w}), y)$. Assume that g is convex its first argument. Suppose that we have k predictors $w_1, \ldots, w_k$ such that for at least $(\frac{1}{2}+\gamma)k$ of them, $L(\boldsymbol{w}) \leq \bar{\ell}$. For $x \in \mathcal{X}, y \in \mathcal{Y}$, let $\hat{y}(\boldsymbol{x})$ be the median of $f(\boldsymbol{x}, \boldsymbol{w}_1), \ldots, f(\boldsymbol{x}, \boldsymbol{w}_k)$, and let $\hat{\ell}(\boldsymbol{x}, y) = g(\hat{y}(\boldsymbol{x}), y)$. Let $\hat{L} := \mathbb{E}[\hat{\ell}(\hat{y}(\boldsymbol{x}))]$. Then*

$$\hat{L} \leq \left(\frac{1}{2\gamma} + 1\right)\bar{\ell}.$$

Proof Let $I = \{i : L(\boldsymbol{w}_i) \leq \bar{\ell}\}$. Assume without loss of generality that for $i \in [k-1]$, $f(\boldsymbol{x}, \boldsymbol{w}_i) \leq f(\boldsymbol{x}, \boldsymbol{w}_{i+1})$. Let $t \in [k]$ such that $\hat{y}(\boldsymbol{x}) = f(\boldsymbol{x}, \boldsymbol{w}_t)$. By the convexity of g, at least one of $g(f(\boldsymbol{x}, \boldsymbol{w}_t), y) \leq g(f(\boldsymbol{x}, \boldsymbol{w}_{t-1}, y))$ and $g(f(\boldsymbol{x}, \boldsymbol{w}_t), y) \leq g(f(\boldsymbol{x}, \boldsymbol{w}_{t+1}, y))$ holds. assume without loss of generality that the first inequality holds. It follows that for all $i \in [t]$, $g(f(\boldsymbol{x}, \boldsymbol{w}_i), y) \geq g(f(\boldsymbol{x}, \boldsymbol{w}_t, y))$. Therefore,

$$\begin{aligned}\hat{\ell}(\boldsymbol{x}, y) = g(f(\boldsymbol{x}, \boldsymbol{w}_t), y)) &\leq \frac{1}{|I \cap [t]|} \sum_{i \in I \cap [t]} g(f(\boldsymbol{x}, \boldsymbol{w}_i), y) \\ &\leq \frac{1}{|I \cap [t]|} \sum_{i \in I} g(f(\boldsymbol{x}, \boldsymbol{w}_i), y) = \frac{1}{|I \cap [t]|} \sum_{i \in I} \ell((\boldsymbol{x}, y), \boldsymbol{w}_i).\end{aligned}$$

Taking expectation over $(\boldsymbol{x}, y)$,

$$\hat{L} \leq \frac{1}{|I \cap [t]|} \sum_{i \in I} L(\boldsymbol{w}_i) \leq \frac{|I|}{|I \cap [t]|}\bar{\ell} \leq \frac{\frac{1}{2}+\gamma}{\gamma}\bar{\ell},$$

where the last inequality follows from the assumption that $|I| \geq (\frac{1}{2}+\gamma)k$. ■

A downside of this approach is that each prediction requires many applications of a predictor. If there is also access to unlimited unlabeled data, a possible approach to circumvent this issue is to generate predictions for a large set of random unlabeled data points based on the aggregate predictor, and then use the resulting labeled pairs as a training set to find a single predictor with a loss that approaches the loss of the aggregate predictor. A similar approach for derandomizing randomized classifiers was suggested by Kääriäinen (2005).

9. Conclusion

In this paper we show several applications of a generalized median-of-means approach to estimation. In particular, for linear regression we establish convergence rates for heavy-tailed distributions that match the min-max rates up to logarithmic factors. We further show conditions that allow parameter estimation using the Lasso under heavy-tailed noise, and cases under which low-rank covariance matrix approximation is possible for heavy-tailed distributions.

The core technique is based on performing independent estimates on separate random samples, and then combining these estimates. Other works have considered approaches

which resemble this general scheme but provide other types of guarantees. For instance, in Zhang et al. (2013), faster parallel kernel ridge regression is achieved by performing loss minimizations on independent samples and then averaging the resulting estimators. In Rakhlin et al. (2013), faster rates of convergence for regression for some classes of estimators are achieved, using linear combinations of risk minimizers over subsets of the class of estimators. These works, together with ours, demonstrate that empirical risk minimization can be used as a black box to generate new algorithms with improved statistical performance.

Appendix A. Proof of Theorem 25

From the definition of $\hat{\boldsymbol{w}}$ as a minimizer we have

$$\|\Psi(\boldsymbol{w}_\star - \hat{\boldsymbol{w}})\|_2^2 + 2\lambda\|\hat{\boldsymbol{w}}\|_1 \leq 2\lambda\|\boldsymbol{w}_\star\|_1 + 2\varepsilon^\top\Psi(\hat{\boldsymbol{w}} - \boldsymbol{w}_\star). \tag{14}$$

By Hölder's inequality the assumptions of the theorem, $2\varepsilon^\top\Psi(\hat{\boldsymbol{w}} - \boldsymbol{w}_\star) \leq 2\|\varepsilon^\top\Psi\|_\infty\|\hat{\boldsymbol{w}} - \boldsymbol{w}_\star\|_1 \leq \lambda\|\hat{\boldsymbol{w}} - \boldsymbol{w}_\star\|_1$. Combining this with Eq. (14) gives

$$\|\Psi(\boldsymbol{w}_\star - \hat{\boldsymbol{w}})\|_2^2 \leq 2\lambda\|\boldsymbol{w}_\star\|_1 - 2\lambda\|\hat{\boldsymbol{w}}\|_1 + \lambda\|\hat{\boldsymbol{w}} - \boldsymbol{w}_\star\|_1.$$

Adding $\lambda\|(\hat{\boldsymbol{w}} - \boldsymbol{w})\|_1$ to both sides we get

$$\begin{aligned}
\|\Psi(\boldsymbol{w}_\star - \hat{\boldsymbol{w}})\|_2^2 + \lambda\|\hat{\boldsymbol{w}} - \boldsymbol{w}_\star\|_1 &\leq 2\lambda\Big(\|\hat{\boldsymbol{w}} - \boldsymbol{w}_\star\|_1 + \|\boldsymbol{w}_\star\|_1 - \|\hat{\boldsymbol{w}}\|_1\Big) \\
&= 2\lambda\sum_{j=1}^{d}\Big(|\hat{\boldsymbol{w}}[j] - \boldsymbol{w}_\star[j]| + |\boldsymbol{w}_\star[j]| - |\hat{\boldsymbol{w}}[j]|\Big) \\
&= 2\lambda\sum_{j\in\mathrm{supp}(\boldsymbol{w})}\Big(|\hat{\boldsymbol{w}}[j] - \boldsymbol{w}_\star[j]| + |\boldsymbol{w}_\star[j]| - |\hat{\boldsymbol{w}}[j]|\Big) \\
&\leq 4\lambda\sum_{j\in\mathrm{supp}(\boldsymbol{w})}|\hat{\boldsymbol{w}}[j] - \boldsymbol{w}_\star[j]| \\
&= 4\lambda\|[\hat{\boldsymbol{w}} - \boldsymbol{w}_\star]_{\mathrm{supp}(\boldsymbol{w})}\|_1.
\end{aligned}$$

It follows that

$$\|[\hat{\boldsymbol{w}} - \boldsymbol{w}_\star]_{\mathrm{supp}(\boldsymbol{w}_\star)^C}\|_1 \leq 3\|[\hat{\boldsymbol{w}} - \boldsymbol{w}_\star]_{\mathrm{supp}(\boldsymbol{w}_\star)}\|,$$

therefore $\hat{\boldsymbol{w}} - \boldsymbol{w}_\star \in E_s$. Denote $\boldsymbol{\delta} = \hat{\boldsymbol{w}} - \boldsymbol{w}$. The above derivation also implies

$$\|\Psi\boldsymbol{\delta}\|_2^2 \leq 3\lambda\|[\boldsymbol{\delta}]_{\mathrm{supp}(\boldsymbol{w}_\star)}\|_1 \leq 3\lambda\|\boldsymbol{\delta}_{[s]}\|_1 \leq 3\lambda\sqrt{s}\|\boldsymbol{\delta}_{[s]}\|_2.$$

Denote for brevity $\gamma = \gamma(\Psi, s)$. From the definition of γ,

$$\|\boldsymbol{\delta}_{[s]}\|_2^2 \leq \frac{1}{\gamma^2}\|\Psi\boldsymbol{\delta}\|_2^2 \leq \frac{3\lambda\sqrt{s}\|\boldsymbol{\delta}_{[s]}\|_2}{\gamma^2},$$

Therefore $\|\boldsymbol{\delta}_{[s]}\|_2 \leq \frac{3\lambda\sqrt{s}}{\gamma^2}$. Now,

$$\|\boldsymbol{\delta}\|_2 = \|\boldsymbol{\delta}_{[s]^C}\|_2 + \|\boldsymbol{\delta}_{[s]}\|_2 \leq \sqrt{\|\boldsymbol{\delta}_{[s]^C}\|_1\|\boldsymbol{\delta}_{[s]^C}\|_\infty} + \|\boldsymbol{\delta}_{[s]}\|_2.$$

From $\boldsymbol{\delta} \in E_s$ we get $\|\boldsymbol{\delta}_{[s]^C}\|_1 \leq 3\|\boldsymbol{\delta}_{[s]}\|_1$. In addition, since $\boldsymbol{\delta}_{[s]}$ spans the largest coordinates of $\boldsymbol{\delta}$ in absolute value, $\|\boldsymbol{\delta}_{[s]^C}\|_\infty \leq \|\boldsymbol{\delta}_{[s]}\|_1/s$. Combining these with the inequality above we get

$$\|\boldsymbol{\delta}\|_2 \leq 3\|\boldsymbol{\delta}_{[s]}\|_1/\sqrt{s} + \|\boldsymbol{\delta}_{[s]}\|_2 \leq 4\|\boldsymbol{\delta}_{[s]}\|_2 \leq \frac{12\lambda\sqrt{s}}{\gamma^2}.$$

Abstract

We introduce a variant of the classification-based approach to policy iteration which uses a cost-sensitive loss function weighting each classification mistake by its actual *regret*, that is, the difference between the action-value of the greedy action and of the action chosen by the classifier. For this algorithm, we provide a full finite-sample analysis. Our results state a performance bound in terms of the number of policy improvement steps, the number of rollouts used in each iteration, the capacity of the considered policy space (classifier), and a capacity measure which indicates how well the policy space can approximate policies that are greedy with respect to any of its members. The analysis reveals a tradeoff between the estimation and approximation errors in this classification-based policy iteration setting. Furthermore it confirms the intuition that classification-based policy iteration algorithms could be favorably compared to value-based approaches when the policies can be approximated more easily than their corresponding value functions. We also study the consistency of the algorithm when there exists a sequence of policy spaces with increasing capacity.

Keywords: reinforcement learning, policy iteration, classification-based approach to policy iteration, finite-sample analysis.

1. Introduction

Policy iteration (Howard, 1960) is a method of computing an optimal policy for any given Markov decision process (MDP). It is an iterative procedure that discovers a deterministic optimal policy by generating a sequence of monotonically improving policies. Each iteration k of this algorithm consists of two phases: *policy evaluation* in which the action-value function Q^{π_k} of the current policy π_k is computed (i.e., the expected sum of discounted rewards collected by acting according to policy π_k), and *policy improvement* in which the new (improved) policy π_{k+1} is generated as the greedy policy w.r.t. Q^{π_k}, that si, $\pi_{k+1}(x) = \arg\max_{a \in \mathcal{A}} Q^{\pi_k}(x,a)$. Unfortunately, in MDPs with large (or continuous) state and action spaces, the policy evaluation problem cannot be solved exactly and approximation techniques are required. In approximate policy iteration (API), a function approximation scheme is usually employed in the policy evaluation phase. The most common approach is to find a good approximation of the value function of π_k in a real-valued function space (see e.g., Bradtke and Barto 1996; Lagoudakis and Parr 2003a). The main drawbacks of this approach are: **1)** the action-value function, Q^{π_k}, is not known in advance and its high-quality samples are often very expensive to obtain, if this option is possible at all, **2)** it is often difficult to find a function space rich enough to represent the action-value function accurately, and thus, careful hand-tuning is needed to achieve satisfactory results, **3)** for the success of policy iteration, it is not necessary to estimate Q^{π_k} accurately at every state-action pair, what is important is to have an approximation of the action-value function whose greedy policy improves over the previous policy, and **4)** this method may not be the right choice in domains where good policies are easier to represent and learn than the corresponding value functions.

To address the above issues, mainly **3** and **4**,[1] variants of API have been proposed that replace the usual value function learning step (approximating the action-value function over the entire state-action space) with a learning step in a policy space (Lagoudakis and Parr, 2003b; Fern et al., 2004). The main idea is to cast the policy improvement step as a *classification* problem. The training set is generated using rollout estimates of Q^π over a finite number of states $\mathcal{D} = \{x_i\}_{i=1}^N$, called the *rollout set*, and for any action $a \in \mathcal{A}$.[2] For each $x \in \mathcal{D}$, if the estimated value $\widehat{Q}^\pi(x, a^+)$ for action a^+ is greater than the estimated value of all other actions with *high confidence*, the state-action pair (x, a^+) is added to the training set with a positive label. In this case, (x, a) for the rest of the actions are labeled negative and added to the training set. The policy improvement step thus reduces to solving a classification problem to find a policy in a given hypothesis space that best predicts the greedy action at every state. Although whether selecting a suitable policy space is any easier than a value function space is highly debatable, we can argue that the classification-based API methods can be advantageous in problems where good policies are easier to represent and learn than their value functions.

The classification-based API algorithms can be viewed as a type of reduction from reinforcement learning (RL) to classification, that is, solving a MDP by generating and solving a series of classification problems. There have been other proposals for reducing RL to classification. Langford and Zadrozny (2005) provided a formal reduction from RL to classification, showing that ϵ-accurate classification implies near optimal RL. This approach uses an optimistic variant of sparse sampling to generate h classification problems, one for each horizon time step. The main limitation of this work is that it does not provide a practical method for generating training examples for these classification problems. Bagnell et al. (2003) introduced an algorithm, called policy search by dynamic programming (PSDP) for learning non-stationary policies in RL. For a specified horizon h, their approach learns a sequence of h policies. At each iteration, all policies are fixed except for one, which is optimized by forming a classification problem via policy rollout. Perhaps the closest approach to the classification-based API methods proposed and analyzed in this paper is the group of algorithms that are introduced and analyzed in (Kakade and Langford, 2002) and (Kakade, 2003) under the name *conservative policy iteration* (CPI).[3] The main algorithmic difference between CPI and the classification-based API methods studied in

1. The first drawback is shared by all reinforcement learning algorithms and the second one is common to all practical applications of machine learning methods.
2. It is worth stressing that Q^π is estimated just on states in $\mathcal{D}$ and not over the entire state-action space.
3. While in (Kakade and Langford, 2002) the algorithm is presented as a rollout value function based approach, in the more detailed description and analysis of CPI found in (Kakade, 2003), the algorithm is presented as a classification-based API method.

this paper is that while the output of the classifier is directly assigned to the next policy in our algorithms, CPI algorithms perform a more conservative policy update in which the new policy π_{k+1} is a mixture distribution of the current policy π_k and the output of the classifier (policies might be stochastic). This conservative update gives CPI two desirable properties: **1)** it guarantees to improve the policy at each iteration, that is, the value function of π_{k+1} is larger than the value function of π_k, and **2)** it has a stopping condition based on the quality of the generated policy (it stops whenever it cannot guarantee that the new policy has a better performance than the previous one). These properties can potentially make CPI a very appealing API algorithm, mainly because other API methods have no guarantee to generate monotonically improving policies and they only converge to a region (i.e., they may repeatedly oscillate among different policies). This includes both value function based API algorithms such as LSPI (Lagoudakis and Parr, 2003a) and classification-based API methods. However, Ghavamzadeh and Lazaric (2012) showed that CPI's desirable properties do not come for free. The analysis of Ghavamzadeh and Lazaric (2012) reveals that in order to achieve the same level of accuracy, CPI requires more iterations, and thus, more samples than the classification-based API algorithms proposed in this paper. This indicates that although CPI's conservative update allows it to have a monotonically improving behavior, it slows down the algorithm and increases its sample complexity. On the other hand, CPI retains the advantage of a concentrability coefficient (or density ratios), which can be much smaller for CPI whenever prior knowledge about the stationary distribution of the optimal policy is used to properly tune the sampling distribution.[4] Nonetheless, Ghavamzadeh and Lazaric (2012) further show that CPI may converge to suboptimal policies whose performance is not better than those returned by the algorithms studied in this paper. Given the advantages and disadvantages, the classification-based API algorithm proposed in this paper and CPI remain two valid alternatives to implement the general approximate policy iteration scheme.

Although the classification-based API algorithms have been successfully applied to benchmark problems (Lagoudakis and Parr, 2003b; Fern et al., 2004) and have been modified to become more computationally efficient (Dimitrakakis and Lagoudakis, 2008b), a full theoretical understanding of them is still lacking. Fern et al. (2006) and Dimitrakakis and Lagoudakis (2008a) provide a preliminary theoretical analysis of their algorithm. In particular, they both bound the difference in performance at each iteration between the learned policy and the true greedy policy. Their analysis is limited to one step policy update (they do not show how the error in the policy update is propagated through the iterations of the API algorithm) and either to finite class of policies (in Fern et al., 2006) or to a specific architecture (a uniform grid in Dimitrakakis and Lagoudakis, 2008a). Moreover, the bound reported in (Fern et al., 2006) depends inversely on the minimum Q-value gap between a greedy and a sub-greedy action over the state space. In some classes of MDPs this gap can be arbitrarily small so that the learned policy can be arbitrarily worse than the greedy policy. In order to deal with this problem Dimitrakakis and Lagoudakis (2008a) assume the action-value functions to be smooth and the probability of states with a small Q-value gap to be small.

4. In Section 4.2 we show that the same concentrability coefficient describes the performance loss of DPI whenever it converges to a fixed point.

In this paper, we derive a full finite-sample analysis of a classification-based API algorithm, called *direct policy iteration* (DPI). It is based on a cost-sensitive loss function weighting each classification error by its actual *regret*, that is, the difference between the action-value of the greedy action and of the action chosen by DPI. A partial analysis of DPI is developed in (Lazaric et al., 2010) where it is shown that using this loss, we are able to derive a performance bound with no dependency on the minimum Q-value gap and no assumption on the probability of states with small Q-value gap. In this paper we provide a more thorough analysis which further extends those in (Fern et al., 2006) and (Dimitrakakis and Lagoudakis, 2008a) by considering arbitrary policy spaces, and by showing how the error at each step is propagated through the iterations of the API algorithm. We also analyze the consistency of DPI when there exists a sequence of policy spaces with increasing capacity. We first use a counterexample and show that DPI is not consistent in general, and then prove its consistency for the class of Lipschitz MDPs. We conclude the paper with a discussion on different theoretical and practical aspects of DPI. Since its introduction by Lagoudakis and Parr (2003b) and Fern et al. (2004) and its extension by Lazaric et al. (2010), the idea of classification-based API has been integrated in a variety of different dynamic programming algorithms (see e.g., Gabillon et al. 2011; Scherrer et al. 2012; Farahmand et al. 2013) and it has been shown to be empirically competitive in a series of testbeds and challenging applications (see e.g., Farahmand et al. 2013; Gabillon et al. 2013).

The rest of the paper is organized as follows. In Section 2, we define the basic concepts and set up the notation used in the paper. Section 3 introduces the general classification-based approach to policy iteration and details the DPI algorithm. In Section 4, we provide a finite-sample analysis for the DPI algorithm. The approximation error and the consistency of the algorithm are discussed in Section 5. While all the main results are derived in case of two actions, that is, $|\mathcal{A}| = 2$, in Section 6 we show how they can be extended to the general case of multiple actions. In Section 7, we conclude the paper and discuss the obtained results.

2. Preliminaries

In this section, we set the notation used throughout the paper. A discounted Markov decision process (MDP) $\mathcal{M}$ is a tuple $\langle \mathcal{X}, \mathcal{A}, r, p, \gamma \rangle$, where the state space $\mathcal{X}$ is a bounded closed subset of a Euclidean space $\mathbb{R}^d$, the set of actions $\mathcal{A}$ is finite ($|\mathcal{A}| < \infty$), the reward function $r : \mathcal{X} \times \mathcal{A} \to \mathbb{R}$ is uniformly bounded by $R_{\max}$, the transition model $p(\cdot|x,a)$ is a distribution over $\mathcal{X}$, and $\gamma \in (0,1)$ is a discount factor. Let $\mathcal{B}^V(\mathcal{X}; V_{\max})$ and $\mathcal{B}^Q(\mathcal{X} \times \mathcal{A}; Q_{\max})$ be the space of Borel-measurable value and action-value functions bounded by $V_{\max}$ and $Q_{\max}$ ($V_{\max} = Q_{\max} = \frac{R_{\max}}{1-\gamma}$), respectively. We also use $\mathcal{B}^\pi(\mathcal{X})$ to denote the space of deterministic policies $\pi : \mathcal{X} \to \mathcal{A}$. The value function of a policy π, V^π, is the unique fixed-point of the Bellman operator $\mathcal{T}^\pi : \mathcal{B}^V(\mathcal{X}; V_{\max}) \to \mathcal{B}^V(\mathcal{X}; V_{\max})$ defined by

$$(\mathcal{T}^\pi V)(x) = r\big(x, \pi(x)\big) + \gamma \int_{\mathcal{X}} p\big(dy|x, \pi(x)\big) V(y).$$

The action-value function Q^π is defined as

$$Q^\pi(x,a) = r(x,a) + \gamma \int_{\mathcal{X}} p(dy|x,a) V^\pi(y).$$

Similarly, the optimal value function, V^*, is the unique fixed-point of the optimal Bellman operator $\mathcal{T} : \mathcal{B}^V(\mathcal{X}; V_{\max}) \to \mathcal{B}^V(\mathcal{X}; V_{\max})$ defined as

$$(\mathcal{T}V)(x) = \max_{a \in \mathcal{A}} \left[r(x,a) + \gamma \int_{\mathcal{X}} p(dy|x,a) V(y) \right],$$

and the optimal action-value function Q^* is defined by

$$Q^*(x,a) = r(x,a) + \gamma \int_{\mathcal{X}} p(dy|x,a) V^*(y).$$

We say that a deterministic policy $\pi \in \mathcal{B}^\pi(\mathcal{X})$ is *greedy* w.r.t. an action-value function Q, if $\pi(x) \in \arg\max_{a \in \mathcal{A}} Q(x,a), \forall x \in \mathcal{X}$. Greedy policies are important because any greedy policy w.r.t. Q^* is optimal. We define the greedy policy operator $\mathcal{G} : \mathcal{B}^\pi(\mathcal{X}) \to \mathcal{B}^\pi(\mathcal{X})$ as[5]

$$(\mathcal{G}\pi)(x) = \arg\max_{a \in \mathcal{A}} Q^\pi(x,a). \tag{1}$$

In the analysis of this paper, $\mathcal{G}$ plays a role similar to the one played by the optimal Bellman operator, $\mathcal{T}$, in the analysis of the fitted value iteration algorithm (Munos and Szepesvári 2008, Section 5).

3. The DPI Algorithm

In this section, we outline the direct policy iteration (DPI) algorithm. DPI shares the same structure as the algorithms in (Lagoudakis and Parr, 2003b) and (Fern et al., 2004). Although it can benefit from improvements in **1)** selecting states for the rollout set $\mathcal{D}$, **2)** the criteria used to add a sample to the training set, and **3)** the rollout strategy, as discussed in (Lagoudakis and Parr, 2003b) and (Dimitrakakis and Lagoudakis, 2008b), here we consider its basic form in order to ease the analysis.

DPI receives as input a policy space Π and starting from an arbitrary policy $\pi_0 \in \Pi$, at each iteration k, it computes a new policy π_{k+1} from π_k, as the best approximation of $\mathcal{G}\pi_k$, by solving a cost-sensitive classification problem. More formally, DPI is based on the following loss function:

Definition 1 *The loss function at iteration k for a policy π is denoted by $\ell_{\pi_k}(\cdot;\pi)$ and is defined as*

$$\ell_{\pi_k}(x;\pi) = \max_{a \in \mathcal{A}} Q^{\pi_k}(x,a) - Q^{\pi_k}\big(x, \pi(x)\big), \qquad \forall x \in \mathcal{X}.$$

Given a distribution ρ over $\mathcal{X}$, we define the expected error as the expectation of the loss function $\ell_{\pi_k}(\cdot;\pi)$ according to ρ,[6]

$$\mathcal{L}_{\pi_k}(\rho;\pi) = \int_{\mathcal{X}} \ell_{\pi_k}(x;\pi)\rho(dx) = \int_{\mathcal{X}} \Big[\max_{a \in \mathcal{A}} Q^{\pi_k}(x,a) - Q^{\pi_k}\big(x,\pi(x)\big) \Big] \rho(dx). \tag{2}$$

5. In (1), ties among the actions maximizing $Q^\pi(x,a)$ are broken in an arbitrary but consistent manner.
6. The expected error $\mathcal{L}_{\pi_k}(\rho;\pi)$ can be seen as the $L_{1,\rho}$-norm of the loss function $\ell_{\pi_k}(\cdot;\pi)$.

Input: policy space $\Pi \subseteq \mathcal{B}^\pi(\mathcal{X})$, state distribution ρ, number of rollout states N, number of rollouts per state-action pair M, rollout horizon H
Initialize: Let $\pi_0 \in \Pi$ be an arbitrary policy
for $k = 0, 1, 2, \ldots$ **do**
  Construct the rollout set $\mathcal{D}_k = \{x_i\}_{i=1}^N$, $x_i \overset{\text{iid}}{\sim} \rho$
  for all states $x_i \in \mathcal{D}_k$ and actions $a \in \mathcal{A}$ **do**
    for $j = 1$ to M **do**
      Perform a rollout according to policy π_k and return
      $$R_j^{\pi_k}(x_i,a) = r(x_i,a) + \sum_{t=1}^{H-1} \gamma^t r\big(x^t, \pi_k(x^t)\big),$$
      with $x^t \sim p\big(\cdot\,|x^{t-1}, \pi_k(x^{t-1})\big)$ and $x^1 \sim p(\cdot|x_i,a)$
    end for
    $\widehat{Q}^{\pi_k}(x_i,a) = \frac{1}{M}\sum_{j=1}^M R_j^{\pi_k}(x_i,a)$
  end for
  $\pi_{k+1} = \arg\min_{\pi \in \Pi} \widehat{\mathcal{L}}_{\pi_k}(\widehat{\rho};\pi)$ **(classifier)**
end for

Figure 1: The Direct Policy Iteration (DPI) algorithm.

While in (Lagoudakis and Parr, 2003b) the goal is to minimize the number of misclassifications using a 0/1 loss function, DPI learns a policy trying to minimize the error $\mathcal{L}_{\pi_k}$. Similar to other classification-based RL algorithms (Bagnell et al., 2003; Kakade, 2003; Fern et al., 2004; Langford and Zadrozny, 2005; Li et al., 2007), DPI does not focus on finding a uniformly accurate approximation of the actions taken by the greedy policy, but rather on finding actions leading to a similar performance. This is consistent with the final objective of policy iteration, which is to obtain a policy with similar performance to an optimal policy, and not necessarily one that takes actions similar to an optimal policy.[7]

As illustrated in Figure 1, for each state $x_i \in \mathcal{D}_k$ and for each action $a \in \mathcal{A}$, an estimate of the action-value function of the current policy is computed through M independent rollouts. A H-horizon rollout of a policy π_k for a state-action pair (x_i, a) is

$$R^{\pi_k}(x_i,a) = r(x_i,a) + \sum_{t=1}^{H-1} \gamma^t r\big(x^t, \pi_k(x^t)\big), \tag{3}$$

where $x^t \sim p\big(\cdot\,|x^{t-1}, \pi_k(x^{t-1})\big)$ and $x^1 \sim p(\cdot|x_i,a)$. The action-value function estimation is then obtained by averaging M independent rollouts $\{R_j^{\pi_k}(x_i,a)\}_{1 \le j \le M}$ as

$$\widehat{Q}^{\pi_k}(x_i,a) = \frac{1}{M}\sum_{j=1}^M R_j^{\pi_k}(x_i,a). \tag{4}$$

Given the outcome of the rollouts, the empirical loss is defined as follows:

7. We refer the readers to (Li et al., 2007) for a simple example in which a good approximation (in terms of the number of mismatch in selecting actions) of the greedy policy has a very poor performance w.r.t. it.

Definition 2 *For any $x \in \mathcal{D}_k$, the empirical loss function at iteration k for a policy π is*

$$\widehat{\ell}_{\pi_k}(x;\pi) = \max_{a\in\mathcal{A}} \widehat{Q}^{\pi_k}(x,a) - \widehat{Q}^{\pi_k}\big(x,\pi(x)\big),$$

where $\widehat{Q}^{\pi_k}(x,a)$ is a H-horizon rollout estimation of the action-value of π_k in (x,a) as defined by Equations 3 and 4. Similar to Definition 1, the empirical error is defined as the average over states in $\mathcal{D}_k$ of the empirical loss,[8]

$$\widehat{\mathcal{L}}_{\pi_k}(\widehat{\rho};\pi) = \frac{1}{N}\sum_{i=1}^{N}\Big[\max_{a\in\mathcal{A}} \widehat{Q}^{\pi_k}(x_i,a) - \widehat{Q}^{\pi_k}\big(x_i,\pi(x_i)\big)\Big],$$

where $\widehat{\rho}$ is the empirical distribution induced by the samples in $\mathcal{D}_k$.

Finally, DPI makes use of a classifier which returns a policy that minimizes the empirical error $\widehat{\mathcal{L}}_{\pi_k}(\widehat{\rho};\pi)$ over the policy space Π (see Section 6.2 for further details on the implementation of such a classifier). Note that this gap-weighted loss function has been previously used in other algorithms such as PSDP (Bagnell et al., 2003) and CPI (Kakade, 2003). Furthermore, while here we use a loss perspective, the minimization of the empirical loss $\widehat{\mathcal{L}}_{\pi_k}(\widehat{\rho};\pi)$ is equivalent to the maximization of the average Q-value and the theoretical development in the next sections would apply mostly unchanged.

4. Finite-sample Analysis of DPI

In this section, we first provide a finite-sample analysis of the error incurred at each iteration of DPI in Theorem 5, and then show how this error is propagated through the iterations of the algorithm in Theorem 7. In the analysis, we explicitly assume that the action space contains only two actions, that is, $\mathcal{A} = \{a_1, a_2\}$ and $|\mathcal{A}| = 2$. We will discuss this assumption and other theoretical and practical aspects of DPI in Section 6.

4.1 Error Bound at Each Iteration

Here we study the error incurred at each iteration k of the DPI algorithm. In particular, we compare the quality of the policy π_{k+1} obtained by minimizing the empirical loss $\widehat{\mathcal{L}}_{\pi_k}(\widehat{\rho};\cdot)$ to the policy that better approximate the greedy policy $\mathcal{G}\pi_k$ among the policies in Π (i.e., the policy minimizing the expected loss $\mathcal{L}_{\pi_k}(\rho;\cdot)$). Comparing the definition of the expected and empirical errors, we notice that there are three sources of error in the algorithm of Figure 1. The first one depends on the use of a finite number of samples, i.e., N states in the rollout set, to approximate the expectation w.r.t. the distribution ρ. The second one is due to using rollouts with finite horizon H to approximate the action-value function Q^{π_k} of the current policy π_k. Finally, the third one depends on the use of M rollouts to approximate the action-value function of the current policy for any of the N states in the rollout set $\mathcal{D}_k$ and any action in the action space $\mathcal{A}$. Before stating our main result, i.e., Theorem 5, we prove bounds for the first and third sources of errors in Lemmas 3 and 4, and have a discussion on the effect of finite horizon rollouts to approximate the action-value function.

8. Alternatively, the empirical error $\widehat{\mathcal{L}}_{\pi_k}(\widehat{\rho};\pi)$ can be seen as the $L_{1,\widehat{\rho}}$-norm of the empirical loss $\widehat{\ell}_{\pi_k}(\cdot;\pi)$.

The proofs of the lemmas rely on tools from concentration inequalities of empirical processes and statistical learning theory (notably VC-bounds), and they are reported in Appendix A. Lemma 3 shows that the difference between the approximation obtained by averaging over the samples in the rollout set and the true expectation can be controlled and reduces to zero as the number of states in the rollout set N grows.

Lemma 3 *Let Π be a policy space with finite VC-dimension $h = VC(\Pi) < \infty$ and $N > 0$ be the number of states in the rollout set $\mathcal{D}_k$, drawn i.i.d. from the state distribution ρ at iteration k, then*

$$\mathbb{P}_{\mathcal{D}_k}\left[\sup_{\pi\in\Pi}\Big|\mathcal{L}_{\pi_k}(\widehat{\rho};\pi) - \mathcal{L}_{\pi_k}(\rho;\pi)\Big| > \epsilon\right] \le \delta\,,$$

where $\mathbb{P}_{\mathcal{D}_k}[\cdot]$ is the probability w.r.t. the random rollout set $\mathcal{D}_k$ conditioned on all the previous iterations[9] *and $\epsilon = 16 Q_{\max}\sqrt{\frac{2}{N}\left(h\log\frac{eN}{h} + \log\frac{8}{\delta}\right)}$.*

Proof See Appendix A. ■

The second source of error in the algorithm of Figure 1 is due to the use of finite horizon rollout estimates of the action-value function on the states in the rollout set. We define the true action-value for a state-action pair (x,a) with a finite horizon H as

$$Q_H^{\pi_k}(x,a) = \mathbb{E}\left[r(x,a) + \sum_{t=1}^{H-1}\gamma^t r\big(x^t,\pi_k(x^t)\big)\right].$$

It is easy to see that the H-horizon rollout estimates are stochastic estimations of $Q_H^{\pi_k}(x,a)$ which in turn satisfy

$$|Q^{\pi_k}(x,a) - Q_H^{\pi_k}(x,a)| = \left|\mathbb{E}\left[\sum_{t=H}^{\infty}\gamma^t r\big(x^t,\pi_k(x^t)\big)\right]\right| \le \gamma^H Q_{\max}. \tag{5}$$

In the proof of the main theorem we also need to bound the difference between the action values (of the N states in the rollout set $\mathcal{D}_k$ and all the actions in the action space $\mathcal{A}$) estimated with M rollouts and their true values. We thus report the following lemma to bound this source of error.

Lemma 4 *Let Π be a policy space with finite VC-dimension $h = VC(\Pi) < \infty$ and $x_1,\ldots,x_N$ be an arbitrary sequence of states. In each state we simulate M independent truncated rollouts, then*

$$\mathbb{P}_{\mathcal{D}_k}\left[\sup_{\pi\in\Pi}\Big|\frac{1}{N}\sum_{i=1}^{N}\frac{1}{M}\sum_{j=1}^{M}R_j^{\pi_k}(x_i,\pi(x_i)) - \frac{1}{N}\sum_{i=1}^{N}Q_H^{\pi_k}(x_i,\pi(x_i))\Big| > \epsilon\right] \le \delta\,,$$

with $\epsilon = 8(1-\gamma^H)Q_{\max}\sqrt{\frac{2}{MN}\left(h\log\frac{eMN}{h} + \log\frac{8}{\delta}\right)}$.

9. More precisely, the conditioning is w.r.t. all the rollout sets $\mathcal{D}_0, \mathcal{D}_1, \ldots, \mathcal{D}_{k-1}$, which define all the policies returned at iterations 0 to $k-1$, including π_k.

Proof See Appendix A. ■

We are now ready to prove the main result of this section. We show a high probability bound on $\mathcal{L}_{\pi_k}(\rho;\pi_{k+1})$, the expected error at any iteration k of the DPI algorithm.

Theorem 5 *Let Π be a policy space with finite VC-dimension $h = VC(\Pi) < \infty$ and ρ be a distribution over the state space $\mathcal{X}$. Let N be the number of states in $\mathcal{D}_k$ drawn i.i.d. from ρ at each iteration, H be the horizon of the rollouts, and M be the number of rollouts per state-action pair used in the estimation of the action-value functions. Let $\pi_{k+1} = \arg\min_{\pi\in\Pi} \widehat{\mathcal{L}}_{\pi_k}(\widehat{\rho};\pi)$ be the policy computed at the k-th iteration of* DPI. *Then, for any $\delta > 0$, we have*

$$\mathcal{L}_{\pi_k}(\rho;\pi_{k+1}) \le \inf_{\pi\in\Pi} \mathcal{L}_{\pi_k}(\rho;\pi) + 2(\epsilon_1+\epsilon_2+\gamma^H Q_{\max}), \tag{6}$$

with probability $1-\delta$, where

$$\epsilon_1 = 16Q_{\max}\sqrt{\frac{2}{N}\left(h\log\frac{eN}{h}+\log\frac{32}{\delta}\right)}, \quad \epsilon_2 = 8(1-\gamma^H)Q_{\max}\sqrt{\frac{2}{MN}\left(h\log\frac{eMN}{h}+\log\frac{32}{\delta}\right)}.$$

Remark (dependency on M and N). The bound in Equation 6 can be decomposed into an approximation error ($\inf_{\pi\in\Pi}\mathcal{L}_{\pi_k}(\rho;\pi)$) and an estimation error consisting of three terms ϵ_1, ϵ_2, and $\gamma^H Q_{\max}$. This is similar to generalization bounds in classification, where the approximation error is the distance between the target function (here the greedy policy w.r.t. π_k) and the function space Π. The first estimation term, ϵ_1, grows with the capacity of Π, measured by its VC-dimension h, and decreases with the number of sampled states N. Thus in order to avoid overfitting, we should have $N \gg h$. The second estimation term, ϵ_2, comes from the error in the estimation of the action-values due to the finite number of rollouts M. It is important to note the nice rate of $1/\sqrt{MN}$ instead of $1/\sqrt{M}$. This is due to the fact that we do not need a uniformly good estimation of the action-value function at all sampled states, but only an averaged estimation of those values at the sampled points. An important consequence of this is that the algorithm works perfectly well if we consider only $M = 1$ rollout per state-action. Therefore, given a fixed budget (number of rollouts per iteration) and a fixed rollout horizon H, the best allocation of M and N would be to choose $M = 1$ and sample as many states as possible, thus, reducing the risk of overfitting. The third estimation term, $\gamma^H Q_{\max}$, is due to the fact that we consider a finite horizon H for the rollouts. This term decreases exponentially fast as the rollout horizon H grows.

Remark (choice of the parameters). In Remark 1, we considered the tradeoff between the number of states, N, and the number of rollouts at each state-action pair, M, when a finite budget (number of rollouts per iteration) is given. It is also interesting to analyze the tradeoff with the rollout horizon, H, when the number of interactions with the generative model is fixed to a maximum value $S = N \times M \times H$. The term γ^H decreases exponentially with a rate depending on γ, thus, it easy to see that by setting $M = 1$, a rough optimization of the bound in Theorem 5 leads to $H = O(\frac{\log S}{\log 1/\gamma})$ and $N = O(S/H)$. Similar to the tradeoff between M and N, this suggests that most of the resources should be allocated so as to have

a large number of states, while the rollouts may have a fairly short horizon. Nonetheless, it is clear from the value of H that the discount factor is critical, and when it approaches 1 the horizon increases correspondingly.

Remark (comparison with other classification-based methods). The performance of classification-based methods have been analyzed before by Fern et al. (2006) and Dimitrakakis and Lagoudakis (2008a). As discussed in the Introduction, the bound reported in Theorem 5 for DPI improves existing results over multiple dimensions. Using a regret-based loss function allows DPI to remove the inverse dependency on the smallest gap appearing in the analysis by Fern et al. (2006). Furthermore, this also allows us to drop the Lipschitz and the separability assumptions employed by Dimitrakakis and Lagoudakis (2008a) and extend the result to any sampling strategy ρ. In this sense, Theorem 5 provides a stronger and more general guarantee on the performance of DPI, where the only constraint is relative to using a policy space with finite VC-dimension, conditioned enjoyed by many standard classifiers (e.g., linear separators, neural networks).

Proof *[Theorem 5]* Let $a^+(x) = \arg\max_{a\in\mathcal{A}} Q^{\pi_k}(x,a)$ be the greedy action in state x.[10] We prove the following series of inequalities:

$$\begin{aligned}
\mathcal{L}_{\pi_k}(\rho;\pi_{k+1}) &\overset{(a)}{\le} \mathcal{L}_{\pi_k}(\widehat{\rho};\pi_{k+1}) + \epsilon_1 && \text{w.p. } 1-\delta' \\
&= \frac{1}{N}\sum_{i=1}^N \Big[Q^{\pi_k}(x_i,a^+) - Q^{\pi_k}\big(x_i,\pi_{k+1}(x_i)\big)\Big] + \epsilon_1 \\
&\overset{(b)}{\le} \frac{1}{N}\sum_{i=1}^N \Big[Q^{\pi_k}(x_i,a^+) - Q_H^{\pi_k}\big(x_i,\pi_{k+1}(x_i)\big)\Big] + \epsilon_1 + \gamma^H Q_{\max} && \text{w.p. } 1-\delta' \\
&\overset{(c)}{\le} \frac{1}{N}\sum_{i=1}^N \Big[Q^{\pi_k}(x_i,a^+) - \widehat{Q}^{\pi_k}\big(x_i,\pi_{k+1}(x_i)\big)\Big] + \epsilon_1 + \epsilon_2 + \gamma^H Q_{\max} && \text{w.p. } 1-2\delta' \\
&\overset{(d)}{\le} \frac{1}{N}\sum_{i=1}^N \Big[Q^{\pi_k}(x_i,a^+) - \widehat{Q}^{\pi_k}\big(x_i,\pi^+(x_i)\big)\Big] + \epsilon_1 + \epsilon_2 + \gamma^H Q_{\max} \\
&\overset{(e)}{\le} \frac{1}{N}\sum_{i=1}^N \Big[Q^{\pi_k}(x_i,a^+) - Q_H^{\pi_k}\big(x_i,\pi^+(x_i)\big)\Big] + \epsilon_1 + 2\epsilon_2 + \gamma^H Q_{\max} && \text{w.p. } 1-3\delta' \\
&\overset{(f)}{\le} \frac{1}{N}\sum_{i=1}^N \Big[Q^{\pi_k}(x_i,a^+) - Q^{\pi_k}\big(x_i,\pi^+(x_i)\big)\Big] + \epsilon_1 + 2(\epsilon_2 + \gamma^H Q_{\max}) && \text{w.p. } 1-3\delta' \\
&= \mathcal{L}_{\pi_k}(\widehat{\rho};\pi^+) + \epsilon_1 + 2(\epsilon_2+\gamma^H Q_{\max}) \\
&\overset{(g)}{\le} \mathcal{L}_{\pi_k}(\rho;\pi^+) + 2(\epsilon_1+\epsilon_2+\gamma^H Q_{\max}) && \text{w.p. } 1-4\delta' \\
&= \inf_{\pi'\in\Pi} \mathcal{L}_{\pi_k}(\rho;\pi') + 2(\epsilon_1+\epsilon_2+\gamma^H Q_{\max}).
\end{aligned}$$

The statement of the theorem is obtained by setting $\delta' = \delta/4$.

10. To simplify the notation, we remove the dependency of a^+ on states and use a^+ instead of $a^+(x)$ in the following.

(a) It is an immediate application of Lemma 3, bounding the difference between $\mathcal{L}_{\pi_k}(\rho;\pi)$ and $\mathcal{L}_{\pi_k}(\widehat{\rho};\pi)$ for any policy $\pi \in \Pi$.
(b) We use the inequality in Equation 5.
(c) Here we introduce the estimated action-value function $\widehat{Q}^{\pi_k}$ by bounding

$$\sup_{\pi\in\Pi}\left[\frac{1}{N}\sum_{i=1}^{N}\widehat{Q}^{\pi_k}\big(x_i,\pi(x_i)\big)-\frac{1}{N}\sum_{i=1}^{N}Q_H^{\pi_k}\big(x_i,\pi(x_i)\big)\right],$$

i.e., the maximum over all the policies in the policy space[11] of the difference between the true action-value function with horizon H and its rollout estimates averaged over the states in the rollout set $\mathcal{D}_k=\{x_i\}_{i=1}^N$. We bound this term using the result of Lemma 4.
(d) From the definition of π_{k+1} in the DPI algorithm (see Figure 1), we have

$$\pi_{k+1}=\arg\min_{\pi\in\Pi}\widehat{\mathcal{L}}_{\pi_k}(\widehat{\rho};\pi)=\arg\max_{\pi\in\Pi}\frac{1}{N}\sum_{i=1}^{N}\widehat{Q}^{\pi_k}\big(x_i,\pi(x_i)\big),$$

thus, $-\frac{1}{N}\sum_{i=1}^{N}\widehat{Q}^{\pi_k}\big(x_i,\pi_{k+1}(x_i)\big)$ can be maximized by replacing π_{k+1} with any other policy, particularly with

$$\pi^+=\arg\inf_{\pi'\in\Pi}\int_{\mathcal{X}}\Big(\max_{a\in\mathcal{A}}Q^{\pi_k}(x,a)-Q^{\pi_k}\big(x,\pi'(x)\big)\Big)\rho(dx).$$

(e)-(f)-(g) The final result follows by the same arguments in steps (a), (b), and (c) but in reversed order. ■

4.2 Error Propagation

In this section, we first show how the expected error is propagated through the iterations of DPI. We then analyze the error between the value function of the policy obtained by DPI after K iterations and the optimal value function. Unlike the per-iteration analysis, in the propagation we consider the general case where the error is evaluated according to a *testing* distribution μ which may differ from the *sampling* distribution ρ used to construct the rollout sets $\mathcal{D}_k$ over iterations.

Before stating the main result, we define the *inherent greedy error* of a policy space Π.

Definition 6 *We define the inherent greedy error of a policy space* $\Pi\subseteq\mathcal{B}^\pi(\mathcal{X})$ *as*

$$d(\Pi,\mathcal{G}\Pi)=\sup_{\pi\in\Pi}\inf_{\pi'\in\Pi}\mathcal{L}_\pi(\rho;\pi').$$

The inherent greedy error is the worst expected error that a error-minimizing policy $\pi'\in\Pi$ can incur in approximating the greedy policy $\mathcal{G}\pi$, for any policy $\pi\in\Pi$. This measures how well Π is able to approximate policies that are greedy w.r.t. any policy in Π.

11. The supremum over all the policies in the policy space Π is due to the fact that π_{k+1} is a random object, whose randomness comes from all the randomly generated samples at the k-th iteration (i.e., the states in the rollout set and all the generated rollouts).

In order to simplify the notation, we introduce P^π as the transition kernel for policy π, i.e., $P^\pi(dy|x)=p\big(dy|x,\pi(x)\big)$. We define the right-linear operator, $P^\pi\cdot$, which maps any $V\in\mathcal{B}^V(\mathcal{X};V_{\max})$ to $(P^\pi V)(x)=\int V(y)P^\pi(dy|x)$, i.e., the expected value of V w.r.t. the next states achieved by following policy π in state x.

From the definitions of ℓ_{π_k}, $\mathcal{T}^\pi$, and $\mathcal{T}$, we have $\ell_{\pi_k}(\pi_{k+1})=\mathcal{T}V^{\pi_k}-\mathcal{T}^{\pi_{k+1}}V^{\pi_k}$. We deduce the following pointwise inequalities:

$$\begin{aligned}V^{\pi_k}-V^{\pi_{k+1}}&=\mathcal{T}^{\pi_k}V^{\pi_k}-\mathcal{T}^{\pi_{k+1}}V^{\pi_k}+\mathcal{T}^{\pi_{k+1}}V^{\pi_k}-\mathcal{T}^{\pi_{k+1}}V^{\pi_{k+1}}\\&\le\ell_{\pi_k}(\pi_{k+1})+\gamma P^{\pi_{k+1}}(V^{\pi_k}-V^{\pi_{k+1}}),\end{aligned}\tag{7}$$

which gives us $V^{\pi_k}-V^{\pi_{k+1}}\le(I-\gamma P^{\pi_{k+1}})^{-1}\ell_{\pi_k}(\pi_{k+1})$. Since $\mathcal{T}V^{\pi_k}\ge\mathcal{T}^{\pi^*}V^{\pi_k}$, we also have

$$\begin{aligned}V^*-V^{\pi_{k+1}}&=\mathcal{T}^{\pi^*}V^*-\mathcal{T}V^{\pi_k}+\mathcal{T}V^{\pi_k}-\mathcal{T}^{\pi_{k+1}}V^{\pi_k}+\mathcal{T}^{\pi_{k+1}}V^{\pi_k}-\mathcal{T}^{\pi_{k+1}}V^{\pi_{k+1}}\\&\le\gamma P^*(V^*-V^{\pi_k})+\ell_{\pi_k}(\pi_{k+1})+\gamma P^{\pi_{k+1}}(V^{\pi_k}-V^{\pi_{k+1}}),\end{aligned}$$

where $P^*=P^{\pi^*}$. Using Equation 7 this yields to

$$\begin{aligned}V^*-V^{\pi_{k+1}}&\le\gamma P^*(V^*-V^{\pi_k})+\big[\gamma P^{\pi_{k+1}}(I-\gamma P^{\pi_{k+1}})^{-1}+I\big]\ell_{\pi_k}(\pi_{k+1})\\&=\gamma P^*(V^*-V^{\pi_k})+(I-\gamma P^{\pi_{k+1}})^{-1}\ell_{\pi_k}(\pi_{k+1}).\end{aligned}$$

Finally, by defining the operator $E_k=(I-\gamma P^{\pi_{k+1}})^{-1}$, which is well defined since $P^{\pi_{k+1}}$ is a stochastic kernel and $\gamma<1$, and by induction, we obtain

$$V^*-V^{\pi_K}\le(\gamma P^*)^K(V^*-V^{\pi_0})+\sum_{k=0}^{K-1}(\gamma P^*)^{K-k-1}E_k\ell_{\pi_k}(\pi_{k+1}).\tag{8}$$

Equation 8 shows how the error at each iteration k of DPI, $\ell_{\pi_k}(\pi_{k+1})$, is propagated through the iterations and appears in the final error of the algorithm: $V^*-V^{\pi_K}$. In particular, the previous equation reveals the final performance loss in a state x is influenced by all the iterations where the losses in different states are combined and weighted according to the distribution obtained as the combination of the P^* and E_k operators. Since we are interested in bounding the final error in μ-norm, which might be different from the sampling distribution ρ, we need to state some assumptions. We first introduce the left-linear operator of the kernel P^π as $\cdot P^\pi$ such that $(\mu P^\pi)(dy)=\int P^\pi(dy|x)\mu(dx)$ for any distribution μ over $\mathcal{X}$. In words, μP^π correspond to the distribution over states obtained by starting from a random state drawn from μ and then taking the action suggested by π.

Assumption 1 *For any policy* $\pi\in\mathcal{B}^\pi(\mathcal{X})$ *and any non-negative integers* s *and* t*, there exists a constant* $C_{\mu,\rho}(s,t)<\infty$ *such that* $\mu(P^*)^s(P^\pi)^t\le C_{\mu,\rho}(s,t)\rho$.[12] *We assume that the cumulative coefficient* $C_{\mu,\rho}=(1-\gamma)^2\sum_{s=0}^{\infty}\sum_{t=0}^{\infty}\gamma^{s+t}C_{\mu,\rho}(s,t)$ *is bounded, i.e.,* $C_{\mu,\rho}<\infty$.

Assumption 2 *For any* $x\in\mathcal{X}$ *and any* $a\in\mathcal{A}$*, there exist a constant* $C_\rho<\infty$ *such that* $p(\cdot|x,a)\le C_\rho\rho(\cdot)$.

12. Given two distributions P and Q on $\mathcal{X}$ and a real constant $c>0$, $P\le cQ$ is equivalent to the condition $\forall B\subseteq\mathcal{X}$, $P(B)\le cQ(B)$.

Note that *concentrability coefficients* similar to $C_{\mu,\rho}$ and C_ρ were previously used in the L_p-analysis of fitted value iteration (Munos, 2007; Munos and Szepesvári, 2008) and approximate policy iteration (Antos et al., 2008). See also Farahmand et al. (2010) for a more refined analysis. We now state our main result.

Theorem 7 *Let Π be a policy space with finite VC-dimension h and π_K be the policy generated by* DPI *after K iterations. Let M be the number of rollouts per state-action and N be the number of samples drawn i.i.d. from a distribution ρ over $\mathcal{X}$ at each iteration of* DPI. *Then, for any $\delta > 0$, we have*

$$||V^* - V^{\pi_K}||_{1,\mu} \le \frac{C_{\mu,\rho}}{(1-\gamma)^2}\Big[d(\Pi, \mathcal{G}\Pi) + 2(\epsilon_1 + \epsilon_2 + \gamma^H Q_{\max})\Big] + \frac{2\gamma^K R_{\max}}{1-\gamma}, \quad \textit{(under Asm. 1)}$$

$$||V^* - V^{\pi_K}||_{\infty} \le \frac{C_{\rho}}{(1-\gamma)^2}\Big[d(\Pi, \mathcal{G}\Pi) + 2(\epsilon_1 + \epsilon_2 + \gamma^H Q_{\max})\Big] + \frac{2\gamma^K R_{\max}}{1-\gamma}, \quad \textit{(under Asm. 2)}$$

with probability $1-\delta$, where

$$\epsilon_1 = 16 Q_{\max}\sqrt{\frac{2}{N}\left(h\log\frac{eN}{h} + \log\frac{32K}{\delta}\right)} \quad \textit{and} \quad \epsilon_2 = 8(1-\gamma^H)Q_{\max}\sqrt{\frac{2}{MN}\left(h\log\frac{eMN}{h} + \log\frac{32K}{\delta}\right)}.$$

Remark (sample complexity). From the previous bound on the performance loss of DPI after K iterations, we can deduce the full sample complexity of the algorithm. Let ϵ be the desired performance loss when stopping the algorithm, from the remarks of Theorem 5 and the previous bound, we see that a logarithmic number of iterations $K(\epsilon) = O(\log(1/\epsilon)/(1-\gamma))$ is enough to reduce the last term to $O(\epsilon)$. On the other hand, for the leading term, if we ignore the inherent greedy error, which is a constant bias term and set $M = 1$, the number of samples required per iteration is[13]

$$N(\epsilon) = O\left(\frac{hQ_{\max}^2}{\epsilon^2(1-\gamma)^4}\right),$$

which amounts to a total of $N(\epsilon)K(\epsilon)$ samples across iterations. In this case, the final bound is $||V^* - V^{\pi_K}||_{1,\mu} \le C_{\mu,\rho}(d(\Pi, \mathcal{G}\Pi) + \epsilon)$. As discussed in the Introduction and analyzed in details by Ghavamzadeh and Lazaric (2012), this result is competitive with other approximate policy iteration (API) schemes such as conservative policy iteration (CPI).

Remark (comparison with other value-function-based API). Although a direct and detailed comparison between classification-based and value-function-based approaches to API is not straightforward, it is interesting to discuss their similarities and differences. For value-function-based API, we refer to, e.g., LSPI (Lagoudakis and Parr, 2003a) and in particular the theoretical analysis developed by Lazaric et al. (2012) (see Theorem 8 therein). Although here we analyzed DPI for a generic policy space Π and the performance is evaluated in L_1-norm, while LSPI explicitly relies on linear spaces and the norm is L_2, high-level similarities and differences can be remarked in the performance of the two methods. The structure of the bounds is similar for both methods and notably the dependency on

13. Note that the range of the Q-values $Q_{\max}$ contains an additional factor $1/(1-\gamma)$.

the number of samples N, number of iterations K, and discount factor γ is the same. The major difference lays in the concentrability coefficients and in the shape of the approximation error. While assumption on the coefficients $C_{\mu,\rho}(s,t)$ for DPI is less tight since it requires to bound the distribution $\mu(P^*)^s(P^\pi)^t$ instead of the distribution $\mu P^{\pi_1}\dots P^{\pi_m}$ obtained for any possible sequence of policies, the final coefficients $C_{\mu,\rho}$ are more involved and difficult to compare. On the other hand, it is interesting to notice that the approximation errors share the same structure. In fact, they both consider the worst approximation error w.r.t. all the possible approximation problems that could be faced across iterations. While this reveals the importance of the choice of an appropriate approximation space in both cases, it also supports the claim that a classification-based method may be preferable whenever it is easier to design a set of "good" policies rather than a set of "good" value functions.

Remark (convergence). Similar to other API algorithms, Theorem 7 states that DPI may oscillate over different policies whose performance loss in bounded. Nonetheless, depending on the policy space Π and the MDP at hand, in practice DPI sometimes converges to a fixed policy $\bar\pi$. Let $\mathcal{D} : \mathcal{B}^\pi(\mathcal{X}) \to \mathcal{B}^\pi(\mathcal{X})$ be the policy operator corresponding to the approximation performed by DPI at each iteration (i.e., constructing rollouts from a given policy and solving the classification problem), then DPI can be written compactly as $\pi_{k+1} = \mathcal{D}\mathcal{G}\pi_k$. If DPI converges to $\bar\pi$, then the joint operator $\mathcal{D}\mathcal{G}$ admits $\bar\pi$ as a fixed point, i.e., $\bar\pi = \mathcal{D}\mathcal{G}\bar\pi$ and the per-iteration error $\ell_{\pi_k}(\pi_{k+1})$, which is propagated in the analysis of Theorem 7, converges to $\ell_{\bar\pi}(\bar\pi)$. In this case, the performance loss of $\bar\pi$ can be directly studied as a function of the error $\mathcal{L}_{\bar\pi}(\rho, \bar\pi)$ as (see Munos, 2007, Section 5.2 for a similar argument for approximate value iteration)

$$\begin{aligned} V^* - V^{\bar\pi} &= \mathcal{T}^{\pi^*}V^* - \mathcal{T}V^{\bar\pi} + \mathcal{T}V^{\bar\pi} - V^{\bar\pi} \\ &\le \mathcal{T}^{\pi^*}V^* - \mathcal{T}^{\pi^*}V^{\bar\pi} + \mathcal{T}V^{\bar\pi} - V^{\bar\pi} \\ &= \gamma P^*(V^* - \mathcal{T}^{\pi^*}V^{\bar\pi}) + \mathcal{T}V^{\bar\pi} - \mathcal{T}^{\bar\pi}V^{\bar\pi}. \end{aligned}$$

Using the definition of $\ell_{\bar\pi}(\bar\pi)$ we obtain the following component-wise performance loss

$$V^* - V^{\bar\pi} \le (I - \gamma P^*)^{-1}\ell_{\bar\pi}(\bar\pi).$$

Finally, integrating on both sides w.r.t. the measure μ we have

$$||V^* - V^{\bar\pi}||_{1,\mu} \le \frac{C^*_{\mu,\rho}}{1-\gamma}\Big[\inf_{\pi'\in\Pi}\mathcal{L}_{\bar\pi}(\rho;\pi') + 2(\epsilon_1 + \epsilon_2 + \gamma^H Q_{\max})\Big],$$

where the concentrability coefficient $C^*_{\mu,\rho}$ is such that $\mu\sum_{t=0}^\infty(\gamma P^*)^t \le C^*_{\mu,\rho}\rho$. Unlike the coefficients introduced in Assumption 1, $C^*_{\mu,\rho}$ only involves the optimal policy and notably the discounted stationary distribution of π^*. This term coincides with the coefficient appearing in the performance of CPI and it can be made small by appropriately choosing the sampling distribution ρ when prior knowledge about the states visited by the optimal policy is available.[14] Furthermore, in case of convergence, the dependency on the discount

14. Consider a simple pole balancing problem. In this case, given the desired target distribution μ, it is relatively easy to guess that the optimal policy will mostly visit states close to the equilibrium and define the sampling distribution ρ accordingly.

factor reduces by a factor of $1/(1-\gamma)$ and the approximation error appearing in the final bound no longer depends on the inherent greedy error. It only depends on the loss of the policy that better approximates $\mathcal{G}\bar{\pi}$ in Π.

Proof [Theorem 7] We have $C_{\mu,\rho} \leq C_\rho$ for any μ. Thus, if the L_1-bound holds for any μ, choosing μ to be a Dirac at each state implies that the L_∞-bound holds as well. Hence, we only need to prove the L_1-bound. By taking the absolute value point-wise in Equation 8 we obtain

$$|V^* - V^{\pi_K}| \leq (\gamma P^*)^K |V^* - V^{\pi_0}| + \sum_{k=0}^{K-1} (\gamma P^*)^{K-k-1} (I - \gamma P^{\pi_{k+1}})^{-1} |\ell_{\pi_k}(\pi_{k+1})| \,.$$

From the fact that $|V^* - V^{\pi_0}| \leq \frac{2}{1-\gamma} R_{\max} \mathbf{1}$, and by integrating both sides w.r.t. μ, and expanding $(I - \gamma P^{\pi^{k+1}})^{-1} = \sum_{t=0}^{\infty} (\gamma P^{\pi_{k+1}})^t$ we have

$$||V^* - V^{\pi_K}||_{1,\mu} \leq \frac{2\gamma^K}{1-\gamma} R_{\max} + \sum_{k=0}^{K-1} \sum_{t=0}^{\infty} \gamma^{K-k-1} \gamma^t \int_{\mathcal{X}} \left[\mu (P^*)^{K-k-1} (P^{\pi^{k+1}})^t\right](dx) |\ell_{\pi_k}(dx; \pi_{k+1})| \,.$$

The integral in the second term corresponds to the expected loss w.r.t. to the distribution over states obtained by starting from μ and then applying $K-k-1$ steps of the optimal policy and t steps of policy π^{k+1}. This term does not correspond to what is actually minimized by DPI at each iteration, and thus, we need to apply Assumption 1 and obtain

$$||V^* - V^{\pi_K}||_{1,\mu} \leq \frac{2\gamma^K}{1-\gamma} R_{\max} + \sum_{k=0}^{K-1} \sum_{t=0}^{\infty} \gamma^{K-k-1} \gamma^t C_{\mu,\rho}(K-k-1, t) \mathcal{L}_{\pi_k}(\rho; \pi_{k+1}) \,.$$

From the definition of $C_{\mu,\rho}$ we obtain

$$||V^* - V^{\pi_K}||_{1,\mu} \leq \frac{2\gamma^K}{1-\gamma} R_{\max} + \frac{C_{\mu,\rho}}{(1-\gamma)^2} \max_{0 \leq k \leq K} \mathcal{L}_{\pi_k}(\rho; \pi_{k+1}) \,.$$

The claim follows from bounding $\mathcal{L}_{\pi_k}(\rho; \pi_{k+1})$ using Theorem 5 with a union bound argument over the K iterations and from the definition of the inherent greedy error. ■

5. Approximation Error

In Section 4.2, we analyzed how the expected error at each iteration k of DPI, $\mathcal{L}_{\pi_k}(\rho; \pi_{k+1})$, propagates through iterations. The final approximation error term in Theorem 7 is the inherent greedy error of Definition 6, $d(\Pi, \mathcal{G}\Pi)$, which depends on the MDP and the richness of the policy space Π. The main question in this section is whether this approximation error can be made small by increasing the capacity of the policy space Π. The answer is not obvious because when the policy space Π grows, on the one hand we can expect it to better approximate any greedy policy w.r.t. a policy in Π, but on the other hand the number of such greedy policies itself grows as well. We start our analysis of this approximation error by introducing the notion of *universal family of policy spaces*.

Definition 8 *A sequence of policy spaces $\{\Pi_n\}$ is a universal family of policy spaces, if there exists a sequence of real numbers $\{\beta_n\}$ with $\lim_{n\to\infty} \beta_n = 0$, such that for any $n > 0$, Π_n is induced by a partition $P_n = \{\mathcal{X}_i\}_{i=1}^{S_n}$ over the state space $\mathcal{X}$ (i.e., for each S_n-tuple $(b_1, \ldots, b_{S_n})$ with $b_i \in \{0,1\}$, there exists a policy $\pi \in \Pi_n$ such that $\pi(x) = b_i$ for all $x \in \mathcal{X}_i$ and for all $i \in \{1, \ldots, S_n\}$) in such a way that*

$$\max_{1 \leq i \leq S_n} \max_{x,y \in \mathcal{X}_i} ||x - y|| \leq \beta_n.$$

This definition requires that for any $n > 0$, Π_n is the space of policies induced by a partition P_n and the diameters of the elements $\mathcal{X}_i$ of this partition shrink to zero as n goes to infinity. The main property of such a sequence of spaces is that any fixed policy π can be approximated arbitrary well by policies of Π_n when $n \to \infty$. Although other definitions of universality could be used, Definition 8 seems natural and it is satisfied by widely-used classifiers such as k-nearest neighbor, uniform grid, and histogram.

In the next section, we first show that the universality of a policy space (Definition 8) does not guarantee that $d(\Pi_n, \mathcal{G}\Pi_n)$ converges to zero in a general MDP. In particular, we present an MDP in which $d(\Pi_n, \mathcal{G}\Pi_n)$ is constant (does not depend on n) even when $\{\Pi_n\}$ is a universal family of classifiers. We then prove that in Lipschitz MDPs, $d(\Pi_n, \mathcal{G}\Pi_n)$ converges to zero for a universal family of policy spaces.

5.1 Counterexample

In this section, we illustrate a simple example in which $d(\Pi_n, \mathcal{G}\Pi_n)$ does not go to zero, even when $\{\Pi_n\}$ is a universal family of classifiers. We consider an MDP with state space $\mathcal{X} = [0,1]$, action space $\mathcal{A} = \{0,1\}$, and the following transitions and rewards

$$x_{t+1} = \begin{cases} \min(x_t + 0.5, 1) & \text{if } a = 1, \\ x_t & \text{otherwise,} \end{cases} \qquad r(x,a) = \begin{cases} 0 & \text{if } x = 1, \\ R_1 & \text{else if } a = 1, \\ R_0 & \text{otherwise,} \end{cases}$$

where $(1-\gamma^2)R_1 < R_0 < R_1$. (9)

We consider the policy space Π_n of piecewise constant policies obtained by uniformly partitioning the state space $\mathcal{X}$ into n intervals. This family of policy spaces is universal. The inherent greedy error of Π_n, $d(\Pi_n, \mathcal{G}\Pi_n)$, can be decomposed into the sum of the expected errors at each interval

$$d(\Pi_n, \mathcal{G}\Pi_n) = \sup_{\pi \in \Pi_n} \inf_{\pi' \in \Pi_n} \sum_{i=1}^{n} \mathcal{L}_\pi^{(i)}(\rho; \pi') \,,$$

where $\mathcal{L}_\pi^{(i)}(\rho; \pi')$ is the same as $\mathcal{L}_\pi(\rho; \pi')$, but with the integral limited to the i-th interval instead of the entire state space $\mathcal{X}$. In the following we show that for the MDP and the universal class of policies considered here, $d(\Pi_n, \mathcal{G}\Pi_n)$ does not converge to zero as n grows.

Let n be odd and $\pi \in \Pi_n$ be one in odd and zero in even intervals (see Figure 2). For any $x > 0.5$, the agent either stays in the same state forever by taking action 0, or goes

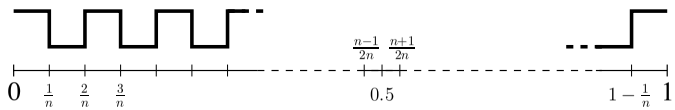

Figure 2: The policy used in the counterexample. It is one in odd and zero in even intervals. Note that the number of intervals, n, is assumed to be odd.

out of bound in one step by taking action 1. Thus, given the assumption of Equation 9, it can be shown that for any x belonging to the intervals $i \geq \frac{n+1}{2}$ (the interval containing 0.5 and above), $(\mathcal{G}\pi)(x) = 0$. This means that there exists a policy $\pi' \in \Pi_n$ such that $\mathcal{L}_\pi^{(i)}(\rho;\pi') = 0$ for all the intervals $i \geq \frac{n+1}{2}$. However, $\mathcal{G}\pi$ does not remain constant in the intervals $i \leq \frac{n-1}{2}$, and changes its value in the middle of the interval. Using Equation 9, we can show that

$$\inf_{\pi' \in \Pi_n} \sum_{i=1}^{n} \mathcal{L}_\pi^{(i)}(\rho;\pi') = C\Big(1 + \frac{1}{1-\gamma}\Big)\frac{n-1}{8n} \geq \frac{C}{16}\Big(1 + \frac{1}{1-\gamma}\Big),$$

where $C = \min\big\{(1-\gamma)(R_1 - R_0), R_0 - (1-\gamma^2)R_1\big\}$. This means that for any odd n, it is always possible to find a policy $\pi \in \Pi_n$ such that $\inf_{\pi' \in \Pi_n} \mathcal{L}_\pi(\rho;\pi')$ is lower bounded by a constant independent of n, and thus, $\lim_{n\to\infty} d(\Pi_n, \mathcal{G}\Pi_n) \neq 0$.

5.2 Lipschitz MDPs

In this section, we prove that for Lipschitz MDPs, $d(\Pi_n, \mathcal{G}\Pi_n)$ goes to zero when $\{\Pi_n\}$ is a universal family of classifiers. We start by defining a Lipschitz MDP.

Definition 9 *A MDP is Lipschitz if both its transition probability and reward functions are Lipschitz, i.e.,* $\forall (B, x, x', a) \in \mathcal{B}(\mathcal{X}) \times \mathcal{X} \times \mathcal{X} \times \mathcal{A}$

$$|r(x,a) - r(x',a)| \leq L_r \|x - x'\|,$$
$$|p(B|x,a) - p(B|x',a)| \leq L_p \|x - x'\|,$$

with L_r and L_p being the Lipschitz constants of the transitions and reward, respectively.

An important property of Lipschitz MDPs is that for any function $Q \in \mathcal{B}^Q(\mathcal{X}\times\mathcal{A}; Q_{\max})$, the function obtained by applying the Bellman operator $\mathcal{T}^\pi$ to $Q(\cdot,a)$, $(\mathcal{T}^\pi Q)(\cdot,a)$, is Lipschitz with constant $L = (L_r + \gamma Q_{\max} L_p)$, for any action $a \in \mathcal{A}$. In fact, for any policy π, any action $a \in \mathcal{A}$ and any pair $x, x' \in \mathcal{X}$ we have

$$\begin{aligned}
&(\mathcal{T}^\pi Q)(x,a) - (\mathcal{T}^\pi Q)(x',a) \\
&\quad = r(x,a) + \gamma \int_{\mathcal{X}} p(dy|x,a) Q^\pi(y,\pi(y)) - r(x',a) - \gamma \int_{\mathcal{X}} p(dy|x',a) Q^\pi(y,\pi(y)) \\
&\quad \leq L_r \|x - x'\| + \gamma \int_{\mathcal{X}} \big|p(dy|x,a) - p(dy|x',a)\big| Q(y,\pi(y)) \\
&\quad \leq (L_r + \gamma L_p Q_{\max}) \|x - x'\|.
\end{aligned}$$

As a result, the function $Q^\pi(\cdot,a)$, which is the unique fixed point of the Bellman operator $\mathcal{T}^\pi$, is Lipschitz with constant L, for any policy $\pi \in \mathcal{B}^\pi(\mathcal{X})$ and any action $a \in \mathcal{A}$.

Theorem 10 *Let $\mathcal{M}$ be a Lipschitz MDP with $|\mathcal{A}| = 2$ and $\{\Pi_n\}$ be a universal family of policy spaces (Definition 8). Then $\lim_{n\to\infty} d(\Pi_n, \mathcal{G}\Pi_n) = 0$.*

Proof

$$\begin{aligned}
d(\Pi_n, \mathcal{G}\Pi_n) &= \sup_{\pi \in \Pi_n} \inf_{\pi' \in \Pi_n} \int_{\mathcal{X}} \ell_\pi(x;\pi') \rho(dx) \\
&\overset{(a)}{=} \sup_{\pi \in \Pi_n} \inf_{\pi' \in \Pi_n} \int_{\mathcal{X}} \mathbb{I}\big\{(\mathcal{G}\pi)(x) \neq \pi'(x)\big\} \Delta^\pi(x) \rho(dx) \\
&\overset{(b)}{=} \sup_{\pi \in \Pi_n} \inf_{\pi' \in \Pi_n} \sum_{i=1}^{S_n} \int_{\mathcal{X}_i} \mathbb{I}\big\{(\mathcal{G}\pi)(x) \neq \pi'(x)\big\} \Delta^\pi(x) \rho(dx) \\
&\overset{(c)}{=} \sup_{\pi \in \Pi_n} \sum_{i=1}^{S_n} \min_{a \in \mathcal{A}} \int_{\mathcal{X}_i} \mathbb{I}\big\{(\mathcal{G}\pi)(x) \neq a\big\} \Delta^\pi(x) \rho(dx) \\
&\overset{(d)}{\leq} \sup_{\pi \in \Pi_n} \sum_{i=1}^{S_n} \min_{a \in \mathcal{A}} \int_{\mathcal{X}_i} \mathbb{I}\big\{(\mathcal{G}\pi)(x) \neq a\big\} 2L \inf_{y:\Delta^\pi(y)=0} \|x - y\| \, \rho(dx) \\
&\overset{(e)}{\leq} 2L \sup_{\pi \in \Pi_n} \sum_{i=1}^{S_n} \min_{a \in \mathcal{A}} \int_{\mathcal{X}_i} \mathbb{I}\big\{(\mathcal{G}\pi)(x) \neq a\big\} \beta_n \rho(dx) \\
&\overset{(f)}{\leq} 2L\beta_n \sum_{i=1}^{S_n} \int_{\mathcal{X}_i} \rho(dx) = 2L\beta_n.
\end{aligned}$$

(a) We rewrite Definition 6, where $\Delta^\pi(x) = \max_{a\in\mathcal{A}} Q^\pi(x,a) - \min_{a' \in \mathcal{A}}(x,a')$ is the regret of choosing the wrong action in state x.
(b) Since Π_n contains piecewise constants policies induced by the partition $P_n = \{\mathcal{X}_i\}$, we split the integral as the sum over the regions.
(c) Since the policies in Π_n can take any action in each possible region, the policy π' minimizing the loss is the one which takes the best action in each region.
(d) Since $\mathcal{M}$ is Lipschitz, both $\max_{a\in\mathcal{A}} Q^\pi(\cdot,a)$ and $\min_{a'\in\mathcal{A}} Q^\pi(\cdot,a')$ are Lipschitz, and thus, $\Delta^\pi(\cdot)$ is $2L$-Lipschitz. Furthermore, Δ^π is zero in all the states in which the policy $\mathcal{G}\pi$ changes (see Figure 3). Thus, for any state x the value $\Delta^\pi(x)$ can be bounded using the Lipschitz property by taking y as the closest state to x in which $\Delta^\pi(y) = 0$.
(e) If $\mathcal{G}\pi$ is constant in a region $\mathcal{X}_i$, the integral can be made zero by setting a to the greedy action (thus making $\mathbb{I}\{(\mathcal{G}\pi)(x) \neq a\} = 0$ for any $x \in \mathcal{X}_i$). Otherwise, if $\mathcal{G}\pi$ changes in a state $y \in \mathcal{X}_i$, then $\Delta^\pi(y) = 0$ and we can replace $\|x-y\|$ by the diameter of the region which is bounded by β_n according to the definition of the universal family of spaces (Definition 8).
(f) We simply take $\mathbb{I}\{(\mathcal{G}\pi)(x) \neq a\} = 1$ in each region.
The claim follows using the definition of the universal family of policy spaces. ■

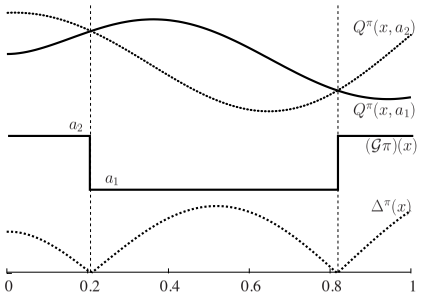

Figure 3: This figure is used as an illustrative example in the proof of Theorem 10. It shows the action-value function of a Lipschitz MDP for a policy π, $Q^\pi(\cdot, a_1)$ and $Q^\pi(\cdot, a_2)$ (top), the corresponding greedy policy $\mathcal{G}\pi$ (middle), and the regret of selecting the wrong action, Δ^π, (bottom).

Theorem 10 together with the counter-example in Section 5.1 show that the assumption on the policy space is not enough to guarantee a small approximation error and additional assumptions on the smoothness of the MDP (e.g., Lipschitz condition) must be satisfied.

5.3 Consistency of DPI

A highly desirable property of any learning algorithm is *consistency*, i.e., as the number of samples grows to infinity, the error of the algorithm converges to zero. It can be seen that as the number of samples N and the rollout horizon H grow in Theorem 5, ϵ_1 and ϵ_2 become arbitrarily small, and thus, the expected error at each iteration, $\mathcal{L}_{\pi_k}(\rho; \pi_{k+1})$, is bounded by the inherent greedy error $d(\Pi_n, \mathcal{G}\Pi_n)$. We can conclude from the results of this section that DPI is not consistent in general, but it is consistent for the class of Lipschitz MDPs, when a universal family of policy spaces is used and n tends to infinite and $d(\Pi_n, \mathcal{G}\Pi_n)$ can be reduced to zero. However, it is important to note that as we increase the index n to reduce the inherent greedy error, the capacity of the policy space Π (its VC-dimension h is indeed a function of n) grows as well, and thus, the error terms ϵ_1 and ϵ_2 may no longer decrease to zero. As a result, to guarantee consistency, we need to link the growth of the policy space Π to the number of samples N, so that as N goes to infinity, the capacity of Π grows at a lower rate and the estimation errors still vanish. More formally, for any number of samples N, we choose an index n so that the corresponding space Π has a VC-dimension $h(N)$ such that $\lim_{N\to\infty} h(N)/N = 0$. We deduce the following result.

Corollary 11 *Let $\mathcal{M}$ be a Lipschitz MDP with $|\mathcal{A}| = 2$, $\{\Pi_n\}$ be a universal family of policy spaces (Definition 8). We define a mapping from the number of samples N to the index n, so that the VC-dimension $h(N)$ is such that $\lim_{N\to\infty} \frac{h(N)}{N} = 0$. Then under either*

Assumption 1 or 2, DPI *is consistent:*

$$\lim_{\substack{N,H,K\to\infty \\ \delta\to 0}} V^{\pi_K} = V^* , \qquad w.p.\ 1.$$

Notice that the result in the previous corollary is possible because the Assumption 1 already covers any policy π in $\mathcal{B}^\pi(\mathcal{X})$ and is not limited to the policies in Π_n.

6. Extension to Multiple Actions

The analysis of Sections 4 and 5 are for the case that the action space contains only two actions. In Section 6.1 we extend the previous theoretical analysis to the general case of an action space with $|\mathcal{A}| > 2$. While the theoretical analysis is completely independent from the specific algorithm used to solve the empirical error minimization problem (see DPI algorithm of Figure 1), in Section 6.2 we discuss which algorithms could be employed to solve this problem in the case of multiple actions.

6.1 Theoretical Analysis

From the theoretical point of view, the extension of the previous results to multiple actions is straightforward. The definitions of loss and error functions do not change and we just need to use an alternative complexity measure for multi-class classification. We rely on the following definitions from (Ben-David et al., 1995).

Definition 12 *Let $\Pi \subseteq \mathcal{B}^\pi(\mathcal{X})$ be a set of deterministic policies and $\Psi = \{\psi : \mathcal{A} \to \{0,1,*\}\}$ be a set of mappings from the action space to the set $\{0,1,*\}$. A finite set of N states $\mathcal{X}_N = \{x_i\}_{i=1}^N \subseteq \mathcal{X}$ is Ψ-shattered by Π if there exists a vector of mappings $\psi^N = \left(\psi^{(1)}, \dots, \psi^{(N)}\right)^\top \in \Psi^N$ such that for any vector $v \in \{0,1\}^N$, there exist a policy $\pi \in \Pi$ such that $\psi^{(i)} \circ \pi(x_i) = v_i, \quad 1 \le i \le N$. The Ψ-dimension of Π is the maximal cardinality of a subset of $\mathcal{X}$, Ψ-shattered by Π.*

Definition 13 *Let $\Pi \subseteq \mathcal{B}^\pi(\mathcal{X})$ be a set of deterministic policies and $\Psi = \{\psi_{k,l} : \mathcal{A} \to \{0,1,*\},\ 1 \le k \ne l \le L\}$ be a set of possible mappings such that*

$$\psi_{k,l}(a) = \begin{cases} 1 & \text{if } a = k, \\ 0 & \text{if } a = l, \\ * & \text{otherwise,} \end{cases}$$

then the Natarajan dimension of Π, N-dim(Π), is the Ψ-dimension of Π.

By using a policy space with finite Natarajan dimension, we derive the following corollary to Theorem 5.

Corollary 14 *Let $\Pi \subseteq \mathcal{B}^\pi(\mathcal{X})$ be a policy space with finite Natarajan dimension $h =$ N-dim(Π) $< \infty$. Let ρ be a distribution over the state space $\mathcal{X}$, N be the number of states in $\mathcal{D}_k$ drawn i.i.d. from ρ, and M be the number of rollouts per state-action pair used by*

DPI *in the estimation of the action-value functions. Let* $\pi_{k+1} = \arg\min_{\pi\in\Pi} \widehat{\mathcal{L}}_{\pi_k}(\widehat{\rho};\pi)$ *be the policy computed at the* k*-th iteration of* DPI*. Then, for any* $\delta > 0$*, we have*

$$\mathcal{L}_{\pi_k}(\rho;\pi_{k+1}) \le \inf_{\pi\in\Pi} \mathcal{L}_{\pi_k}(\rho;\pi) + 2(\epsilon_1 + \epsilon_2 + \gamma^H Q_{\max}), \tag{10}$$

with probability $1-\delta$*, where*

$$\epsilon_1 = 16Q_{\max}\sqrt{\frac{2}{N}\left(h\log\frac{|\mathcal{A}|e(N+1)^2}{h} + \log\frac{32}{\delta}\right)}, \quad \epsilon_2 = (1-\gamma^H)Q_{\max}\sqrt{\frac{2}{MN}\log\frac{4|\mathcal{A}|}{\delta}}\ .$$

Proof In order to prove this corollary we just need a minor change in Lemma 3, which now becomes a concentration of measures inequality for a space of multi-class classifiers Π with finite Natarajan dimension. By using similar steps as in the proof of Lemma 3 and by recalling the Sauer's lemma for finite Natarajan dimension spaces (Ben-David et al., 1995), we obtain

$$\mathbb{P}\left[\sup_{\pi\in\Pi}\left|\mathcal{L}_{\pi_k}(\widehat{\rho};\pi) - \mathcal{L}_{\pi_k}(\rho;\pi)\right| > \epsilon\right] \le \delta\ ,$$

with $\epsilon = 16Q_{\max}\sqrt{\frac{2}{N}\left(h\log\frac{|\mathcal{A}|e(N+1)^2}{h} + \log\frac{8}{\delta}\right)}$. The rest of the proof is exactly the same as in Theorem 5. ■

Similarly, the consistency analysis in case of Lipschitz MDPs remains mostly unaffected by the introduction of multiple actions.

Corollary 15 *Let* $\{\Pi_n\}$ *be a universal family of policy spaces (Definition 8), and* $\mathcal{M}$ *be a Lipschitz MDP (Definition 9). Then* $\lim_{n\to\infty} d(\Pi_n, \mathcal{G}\Pi_n) = 0$*.*

Proof The critical part in the proof is the definition of the gap function, which now compares the performance of the greedy action to the performance of the action chosen by the policy π':

$$\Delta^{\pi,\pi'}(x) = \max_{a\in\mathcal{A}} Q^\pi(x,a) - Q^\pi\big(x,\pi'(x)\big).$$

Note that $\Delta^{\pi,\pi'}(\cdot)$ is no longer a Lipschitz function because it is a function of x through the policy π'. However, $\Delta^{\pi,\pi'}(x)$ is Lipschitz in each region $\mathcal{X}_i$, $i = 1\ldots,S_n$, because in each region $\mathcal{X}_i$, by the definition of the policy space, π' is forced to be constant. Therefore, in a region $\mathcal{X}_i$ in which $\pi'(x) = a$, $\forall x \in \mathcal{X}_i$, $\Delta^{\pi,\pi'}(x)$ may be written as

$$\Delta^{\pi,\pi'}(x) = \Delta^{\pi,a}(x) = \max_{a'\in\mathcal{A}} Q^\pi(x,a') - Q^\pi(x,a).$$

The proof here is exactly the same as in Theorem 10 up to step **(c)**, and then we have

$$\begin{aligned}
d(\Pi_n,\mathcal{G}\Pi_n) &= \sup_{\pi\in\Pi_n}\inf_{\pi'\in\Pi_n}\int_{\mathcal{X}} \ell_\pi(x;\pi')\rho(dx)\\
&= \sup_{\pi\in\Pi_n}\inf_{\pi'\in\Pi_n}\int_{\mathcal{X}} \mathbb{I}\big\{(\mathcal{G}\pi)(x)\neq\pi'(x)\big\}\,\Delta^{\pi,\pi'}(x)\rho(dx)\\
&= \sup_{\pi\in\Pi_n}\inf_{\pi'\in\Pi_n}\sum_{i=1}^{S_n}\int_{\mathcal{X}_i} \mathbb{I}\big\{(\mathcal{G}\pi)(x)\neq\pi'(x)\big\}\,\Delta^{\pi,\pi'}(x)\rho(dx)\\
&= \sup_{\pi\in\Pi_n}\sum_{i=1}^{S_n}\min_{a\in\mathcal{A}}\int_{\mathcal{X}_i} \mathbb{I}\{(\mathcal{G}\pi)(x)\neq a\}\,\Delta^{\pi,a}(x)\rho(dx)\\
&\le \sup_{\pi\in\Pi_n}\sum_{i=1}^{S_n}\min_{a\in\mathcal{A}}\int_{\mathcal{X}_i} \Delta^{\pi,a}(x)\rho(dx).
\end{aligned}\tag{11}$$

If the greedy action does not change in a region $\mathcal{X}_i$, i.e., $\forall x\in\mathcal{X}_i$, $(\mathcal{G}\pi)(x) = a'$, for an action $a'\in\mathcal{A}$, then the minimizing policy π' must select action a' in $\mathcal{X}_i$, and thus, the loss will be zero in $\mathcal{X}_i$. Now let assume that the greedy action changes at a state $y\in\mathcal{X}_i$ and the action $b_i \in \arg\max_{a\in\mathcal{A}} Q^\pi(y,a)$. In this case, we have

$$\min_{a\in\mathcal{A}}\int_{\mathcal{X}_i}\Delta^{\pi,a}(x)\rho(dx) \le \int_{\mathcal{X}_i}\Delta^{\pi,b_i}(x)\rho(dx) \le \int_{\mathcal{X}_i}\big(\Delta^{\pi,b_i}(y) + 2L\|x-y\|\big)\rho(dx),$$

since the function $x\mapsto\Delta^{\pi,b_i}(x)$ is $2L$-Lipschitz. Now since $\Delta^{\pi,b_i}(y) = 0$, we deduce from Equation 11 that

$$d(\Pi_n,\mathcal{G}\Pi_n) \le \sup_{\pi\in\Pi_n}\sum_{i=1}^{S_n}\int_{\mathcal{X}_i} 2L||x-y||\rho(dx) \le \sup_{\pi\in\Pi_n}\sum_{i=1}^{S_n}\int_{\mathcal{X}_i} 2L\beta_n\rho(dx) = 2L\beta_n.$$

The claim follows using the definition of the universal family of policy spaces. ■

6.2 Algorithmic Approaches

From an algorithmic point of view, the most critical part of the DPI algorithm (Figure 1) is minimizing the empirical error, which in the case of $|\mathcal{A}| > 2$ is in the following form:

$$\begin{aligned}
\min_{\pi\in\Pi}\widehat{\mathcal{L}}_{\pi_k}(\widehat{\rho};\pi) &= \min_{\pi\in\Pi}\frac{1}{N}\sum_{i=1}^{N}\Big[\max_{a\in\mathcal{A}}\widehat{Q}^{\pi_k}(x_i,a) - \widehat{Q}^{\pi_k}\big(x_i,\pi(x_i)\big)\Big]\\
&= \min_{\pi\in\Pi}\sum_{i=1}^{N}\mathbb{I}\left\{\arg\max_{a\in\mathcal{A}}\widehat{Q}^{\pi_k}(x_i,a)\neq\pi(x_i)\right\}\Big[\max_{a\in\mathcal{A}}\widehat{Q}^{\pi_k}(x_i,a) - \widehat{Q}^{\pi_k}\big(x_i,\pi(x_i)\big)\Big].
\end{aligned}$$

Unlike the two-action case, this is a multi-class cost-sensitive (MCCS) classification problem in which any classification mistake is weighted by a cost function that depends on the action

taken by policy π. It is important to note that here the main difference with regression is that the goal is not to have a good approximation of the action-value function over the entire state and action space. The main objective is to have a good enough estimate of the action-value function to find the greedy action in each state. A thorough discussion on the possible approaches to MCCS classification is out of the scope of this paper, and thus, we only mention a few recent methods that could be suitable for our problem. The reduction methods proposed by Beygelzimer et al. (2005, 2009) reduce the MCCS classification problem to a series of weighted binary classification problems (which in turn can be reduced to binary classification as in Zadrozny et al. 2003), whose solutions can be combined to obtain a multi-class classifier. The resulting multi-class classifier is guaranteed to have a performance which is upper-bounded by the performance of each binary classifier used in solving the weighted binary problems. Another common approach to MCCS classification is to use boosting-based methods (e.g., Lozano and Abe 2008; Busa-Fekete and Kégl 2010). A recent regression-based approach has been proposed by Tu and Lin (2010), which reduces the MCCS classification to a one-sided regression problem that can be effectively solved by a variant of SVM. Finally, a theoretical analysis of the risk bound for MCCS classification is derived by Ávila Pires et al. (2013), while Mineiro (2010) studies error bounds in the case of a reduction from MCCS to regression.

7. Conclusions

In this paper, we presented a variant of the classification-based approach to approximate policy iteration (API) called direct policy iteration (DPI) and provided its finite-sample performance bounds. To the best of our knowledge, this is the first complete finite-sample analysis for this class of API algorithms. The main difference of DPI with the existing classification-based API algorithms (Lagoudakis and Parr, 2003b; Fern et al., 2004) is in weighting each classification error by its actual regret, i.e., the difference between the action-values of the greedy action and the action selected by DPI. Our results extend the only theoretical analysis of a classification-based API algorithm (Fern et al., 2006) by **1)** having a performance bound for the full API algorithm instead of being limited to one step policy update, **2)** considering any policy space instead of finite class of policies, and **3)** deriving a bound which does not depend on the Q-advantage, i.e., the minimum Q-value gap between a greedy and a sub-greedy action over the state space, which can be arbitrarily small in a large class of MDPs. Note that the final bound in (Fern et al., 2006) depends inversely on the Q-advantage. We also analyzed the consistency of DPI and showed that although it is not consistent in general, it is consistent for the class of Lipschitz MDPs. This is similar to the consistency results for fitted value iteration in (Munos and Szepesvári, 2008).

One of the main motivations of this work is to have a better understanding of how the classification-based API methods can be compared with their widely-used regression-based counterparts. It is interesting to note that the bound of Equation 6 shares the same structure as the error bounds for the API algorithm in (Antos et al., 2008) and the fitted value iteration in (Munos and Szepesvári, 2008). The error at each iteration can be decomposed into an approximation error, which depends on the MDP and the richness of the hypothesis space – the inherent greedy error in Equation 6 and the inherent Bellman error in (Antos et al., 2008) and (Munos and Szepesvári, 2008), and an estimation error

which mainly depends on the number of samples and rollouts. The difference between the approximation error of the two approaches depends on how well the hypothesis space fits the MDP at hand. This confirms the intuition that whenever the policies generated by policy iteration are easier to represent and learn than their value functions, a classification-based approach can be preferable to regression-based methods.

Possible directions for future work are:

- *The classification problem:* As discussed in Section 6.2 the main issue in the implementation of DPI is the solution of the multi-class cost-sensitive classification problem at each iteration. Although some existing algorithms might be applied to this problem, further investigation is needed to identify which one is better suited for DPI. In particular, the main challenge is to solve the classification problem without first solving a regression problem on the cost function which would eliminated the main advantage of classification-based approaches (i.e., no approximation of the action-value function over the whole state-action space).

- *Rollout allocation:* In DPI, the rollout set is build with states drawn i.i.d. from an arbitrary distribution and the rollouts are performed the same number of times for each action in $\mathcal{A}$. A significant advantage could be obtained by allocating resources (i.e., the rollouts) to regions of the state space and to actions whose action-values are more difficult to estimate. This would result in a more accurate training set for the classification problem and a better approximation of the greedy policy at each iteration. Although some preliminary results in (Dimitrakakis and Lagoudakis, 2008b) and (Gabillon et al., 2010) show encouraging results, a full analysis of what is the best allocation strategy of rollouts over the state-action space is still missing.

Appendix A. Proofs

Proof [Lemma 3] Although Π is a space of binary policies, standard VC bounds (see e.g.,Vapnik, 1998) cannot be directly employed since the loss function ℓ is not a 0-1 loss function. Let $\mathcal{F}_k$ be the space of the loss functions at iteration k induced by the policies in Π, i.e., $\mathcal{F}_k = \{\ell_{\pi_k}(\cdot;\pi)|\ \pi \in \Pi\}$. We first introduce the notion of the L_1-cover number (Györfi et al., 2002, Section 9.2) of a space $\mathcal{F} = \{f : \mathcal{X} \to [0; B]\}$ of bounded functions on a set of N points $X_1, \dots, X_N$. Given a desired level of accuracy $\epsilon > 0$, $\bar{\mathcal{F}} \subseteq \mathcal{F}$ is an *ϵ-covered* of $\mathcal{F}$ if for any function $f \in \mathcal{F}$ there exists a $\bar{f} \in \bar{\mathcal{F}}$ such that

$$\left|\frac{1}{N}\sum_{i=1}^{N} f(X_i) - \frac{1}{N}\sum_{i=1}^{N} \bar{f}(X_i)\right| \le \epsilon.$$

The number of functions in $\bar{\mathcal{F}}$, denoted by $\mathcal{N}(\mathcal{F}, \epsilon, X_1^N)$, is the cover number of $\mathcal{F}$. Note that all the functions $\ell_{\pi_k}(\cdot;\pi) \in \mathcal{F}_k$ are uniformly bounded by $2Q_{\max}$. As a result, we can apply the Pollard's inequality (Pollard, 1984, Thm. 24) to the bounded space $\mathcal{F}_k$ and obtain

$$\mathbb{P}_{\mathcal{D}_k}\left[\sup_{\ell_{\pi_k}\in\mathcal{F}_k}\left|\frac{1}{N}\sum_{i=1}^{N}\ell_{\pi_k}(x_i) - \int \ell_{\pi_k}(x)\rho(dx)\right| > \epsilon\right] \le 8\mathbb{E}\left[\mathcal{N}_1\left(\frac{\epsilon}{8}, \mathcal{F}_k, X_1^N\right)\right]\exp\left(-\frac{N\epsilon^2}{128(2Q_{\max})^2}\right).$$

Note that at each iteration k, the policy π_k is a random variable because it is the minimizer of the empirical error $\widehat{\mathcal{L}}_{\pi_{k-1}}(\widehat{\rho};\pi)$. However, π_k depends only on the previous policies and rollout sets up to $\mathcal{D}_{k-1}$, and is completely independent of the samples in $\mathcal{D}_k$, thus Pollard's inequality applies conditioned on all the previous iterations. We now show how the covering number of the space $\mathcal{F}_k$ can be directly related to the VC-dimension of Π. Since $\mathcal{A}$ only contains two actions, we can rewrite the loss function as $\ell_{\pi_k}(x;\pi) = \mathbb{I}\{(\mathcal{G}\pi_k)(x) \neq \pi(x)\}\,\Delta^{\pi_k}(x)$, where

$$\Delta^{\pi_k}(x) = \max_{a\in\mathcal{A}} Q^{\pi_k}(x,a) - \min_{a'\in\mathcal{A}} Q^{\pi_k}(x,a')$$

is the gap between the two available actions (i.e., the regret of choosing the wrong action). Let $\bar{\Pi}$ be an $\frac{\epsilon}{2Q_{\max}}$-cover of Π over the states $\{x_i\}_{i=1}^N$ such that for any policy $\pi \in \Pi$ there exists a policy $\bar{\pi} \in \bar{\Pi}$ for which we have

$$\left|\frac{1}{N}\sum_{i=1}^{N}\mathbb{I}\{(\pi(x_i) \neq \bar{\pi}(x_i)\}\right| \le \frac{\epsilon}{2Q_{\max}}.$$

Then $\bar{\mathcal{F}}_k = \{\bar{\ell}_{\pi_k}(\cdot) = \ell_{\pi_k}(\cdot;\bar{\pi})|\bar{\pi} \in \bar{\Pi}\}$ is an ϵ-cover of $\mathcal{F}_k$. In fact for any $\ell_{\pi_k} \in \mathcal{F}_k$, there exist a $\bar{\ell}_{\pi_k} \in \bar{\mathcal{F}}_k$ such that

$$\begin{aligned}
\frac{1}{N}\sum_{i=1}^{N}\left|\ell_{\pi_k}(x_i) - \bar{\ell}_{\pi_k}(x_i)\right| &= \frac{1}{N}\sum_{i=1}^{N}\Big|\mathbb{I}\{(\mathcal{G}\pi_k)(x_i) \neq \pi(x_i)\}\,\Delta^{\pi_k}(x_i) \\
&\quad -\mathbb{I}\{(\mathcal{G}\pi_k)(x_i) \neq \bar{\pi}(x_i)\}\,\Delta^{\pi_k}(x_i)\Big| \\
&\le 2Q_{\max}\frac{1}{N}\sum_{i=1}^{N}\left|\mathbb{I}\{(\mathcal{G}\pi_k)(x_i) \neq \pi(x_i)\} - \mathbb{I}\{(\mathcal{G}\pi_k)(x_i) \neq \bar{\pi}(x_i)\}\right| \\
&= 2Q_{\max}\frac{1}{N}\sum_{i=1}^{N}\mathbb{I}\{(\pi(x_i) \neq \bar{\pi}(x_i)\} \le 2Q_{\max}\frac{\epsilon}{2Q_{\max}} = \epsilon,
\end{aligned}$$

where the last inequality follows from the fact that $\bar{\mathcal{F}}$ is an ϵ-cover of Π. We can now relate the covering number of $\mathcal{F}_k$ to the VC-dimension of Π as

$$\mathcal{N}_1\left(\frac{\epsilon}{8}, \mathcal{F}_k, X_1^N\right) \le \mathcal{N}_1\left(\frac{\epsilon}{16Q_{\max}}, \Pi, X_1^N\right) \le S_\Pi(N) \le \left(\frac{eN}{h}\right)^h,$$

where the first inequality follows from the relationship between the cover numbers of $\mathcal{F}$ and Π, the second inequality bounds the cover number of Π by its growth function $S_\Pi(N)$ (Haussler, 1995), and the last inequality follows from the Sauer's lemma. Since $\mathcal{L}_{\pi_k}(\widehat{\rho};\pi) = \frac{1}{N}\sum_{i=1}^N \ell_{\pi_k}(x_i;\pi)$ and $\mathcal{L}_{\pi_k}(\rho;\pi) = \int \ell_{\pi_k}(x;\pi)\rho(dx)$, the final statement is obtained by inverting the Pollard's bound. ■

Proof [Lemma 4] Similar to the proof of Lemma 3, we rely on the Pollard's inequality to prove the statement. We first introduce a sequence of random events ω_{ij} such that for any $i = 1, \dots, N$ the event ω_{ij} is independently drawn from a suitable distribution ν_i. As a result, we may rewrite the rollout random variables as $R_j^{\pi_k}\big(x_i, \pi(x_i)\big) = R^{\pi_k}(\omega_{ij};\pi)$ and the statement of the theorem as

$$\mathbb{P}\left[\sup_{\pi\in\Pi}\left|\frac{1}{MN}\sum_{i,j}R^{\pi_k}(\omega_{ij};\pi) - \frac{1}{MN}\sum_{i,j}\mathbb{E}_{\nu_i}\left[R^{\pi_k}(\omega_{ij};\pi)\right]\right| > \epsilon\right] \le \delta.$$

Let $\mathcal{H}_k$ be the space of the rollout functions induced by the policies in Π at iteration k, i.e., $\mathcal{H}_k = \{R^{\pi_k}(\cdot;\pi)|\ \pi \in \Pi\}$. Note that all the functions $R^{\pi_k}(\cdot;\pi) \in \mathcal{H}_k$ are uniformly bounded by $(1-\gamma^H)Q_{\max}$. By Pollard's inequality (Pollard, 1984), for the bounded space $\mathcal{H}_k$, we have[15]

$$\mathbb{P}\left[\sup_{\pi\in\Pi}\left|\frac{1}{MN}\sum_{i,j}R^{\pi_k}(\omega_{ij};\pi) - \frac{1}{MN}\sum_{i,j}\mathbb{E}_{\nu_i}[R^{\pi_k}(\omega_{ij};\pi)]\right| > \epsilon\right] \le 8\mathbb{E}\left[\mathcal{N}_1\left(\frac{\epsilon}{8}, \mathcal{H}_k, \omega_1^{MN}\right)\right]\exp\left(-\frac{MN\epsilon^2}{128(1-\gamma^H)^2Q_{\max}^2}\right).$$

15. Note that since here the samples are independent but not identically distributed, we use a slight variation of the standard Pollard's inequality. We refer the reader to the proof of Pollard's inequality (e.g., Pollard 1984 or Devroye et al. 1996) to see that the standard proof can be easily extended to this case.

We now show how the covering number of the space $\mathcal{H}_k$ is related to the VC-dimension of Π. Let $\bar{\Pi}$ be an $\frac{\epsilon}{2(1-\gamma^H)Q_{\max}}$-cover of Π using the empirical distance defined at the states $\{x_i\}_{i=1}^N$, then $\bar{\mathcal{H}}_k = \{\bar{R}^{\pi_k}(\cdot) = R^{\pi_k}(\cdot;\bar{\pi}) | \bar{\pi} \in \bar{\Pi}\}$ is an ϵ-cover of $\mathcal{H}_k$. In fact for any $R^{\pi_k} \in \mathcal{H}_k$, there exist a $\bar{R}^{\pi_k} \in \bar{\mathcal{H}}_k$ such that

$$\frac{1}{MN}\sum_{i,j}\left|R^{\pi_k}(\omega_{ij}) - \bar{R}^{\pi_k}(\omega_{ij})\right| = \frac{1}{MN}\sum_{i=1}^{N}\sum_{j=1}^{M}\left|R_j^{\pi_k}\big(x_i,\pi(x_i)\big) - R_j^{\pi_k}\big(x_i,\bar{\pi}(x_i)\big)\right|$$
$$\leq 2(1-\gamma^H)Q_{\max}\frac{1}{N}\sum_{i=1}^{N}\mathbb{I}\left\{\pi(x_i)\neq\bar{\pi}(x_i)\right\} \leq 2(1-\gamma^H)Q_{\max}\frac{\epsilon}{2(1-\gamma^H)Q_{\max}} = \epsilon.$$

We can now relate the covering number of $\mathcal{F}_k$ to the VC-dimension of Π

$$\mathcal{N}_1\left(\frac{\epsilon}{8},\mathcal{F}_k,\omega_1^{MN}\right) \leq \mathcal{N}_1\left(\frac{\epsilon}{16(1-\gamma^H)Q_{\max}},\Pi,\omega_1^{MN}\right) \leq S_\Pi(MN) \leq \left(\frac{eMN}{h}\right)^h,$$

where $S_\Pi(N)$ is the growth function of Π and the last inequality follows from the Sauer's lemma. The final statement is obtained by inverting the Pollard's bound. ■

Abstract

In this paper[1] we consider the problems of supervised classification and regression in the case where attributes and labels are functions: a data is represented by a set of functions, and the label is also a function. We focus on the use of reproducing kernel Hilbert space theory to learn from such functional data. Basic concepts and properties of kernel-based learning are extended to include the estimation of function-valued functions. In this setting, the representer theorem is restated, a set of rigorously defined infinite-dimensional operator-valued kernels that can be valuably applied when the data are functions is described, and a learning algorithm for nonlinear functional data analysis is introduced. The methodology is illustrated through speech and audio signal processing experiments.

Keywords: nonlinear functional data analysis, operator-valued kernels, function-valued reproducing kernel Hilbert spaces, audio signal processing

1. Introduction

In this paper, we consider the supervised learning problem in a functional setting: each attribute of a data is a function, and the label of each data is also a function. For the sake of simplicity, one may imagine real functions, though the work presented here is much more general; one may also think about those functions as being defined over time, or space, though again, our work is not tied to such assumptions and is much more general. To this end, we extend the traditional scalar-valued attribute setting to a function-valued attribute setting.

This shift from scalars to functions is required by the simple fact that in many applications, attributes are functions: functions may be one dimensional such as economic curves (variation of the price of "actions"), load curve of a server, a sound, etc., or two or higher dimensional (hyperspectral images, etc.). Due to the nature of signal acquisition, one may consider that in the end, a signal is always acquired in a discrete fashion, thus providing a real vector. However, with the resolution getting finer and finer in many sensors, the amount of discrete data is getting huge, and one may reasonably wonder whether a functional point of view may not be better than a vector point of view. Now, if we keep aside the application point of view, the study of functional attributes may simply come as an intellectual question which is interesting for its own sake.

From a mathematical point of view, the shift from scalar attributes to function attributes will come as a generalization from scalar-valued functions to function-valued functions, a.k.a."operators". Reproducing Kernel Hilbert Spaces (RKHS) has become a widespread tool to deal with the problem of learning a function mapping the set $\mathbb{R}^p$ to the set of real numbers $\mathbb{R}$. Here, we have to deal with RKHS of operators, that are functions that map a function, belonging to a certain space of functions, to a function belonging to an other space of functions. This shift in terminology is accompanied with a dramatic shift in concepts, and technical difficulties that have to be properly handled.

This *functional regression problem*, or *functional supervised learning*, is a challenging research problem, from statistics to machine learning. Most previous work has focused on the discrete case: the multiple-response (finite and discrete) function estimation problem. In the machine learning literature, this problem is better known under the name of vector-valued function learning (Micchelli and Pontil, 2005a), while in the field of statistics, researchers prefer to use the term multiple output regression (Breiman and Friedman, 1997). One possible solution is to approach the problem from a univariate point of view, that is, assuming only a single response variable output from the same set of explanatory variables. However it would be more efficient to take advantage of correlation between the response variables by considering all responses simultaneously. For further discussion of this point, we refer the reader to Hastie et al. (2001) and references therein. More recently, relevant works in this context concern regularized regression with a sequence of ordered response variables. Many variable selection and shrinkage methods for single response regression are extended to the multiple response data case and several algorithms following the corresponding solution paths are proposed (Turlach et al., 2005; Simila and Tikka, 2007; Hesterberg et al., 2008).

Learning from multiple responses is closely related to the problem of multi-task learning where the goal is to improve generalization performance by learning multiple tasks simultaneously. There is a large literature on this subject, in particular Evgeniou and Pontil (2004); Jebara (2004); Ando and Zhang (2005); Maurer (2006); Ben-david and Schuller-Borbely (2008); Argyriou et al. (2008) and references therein. One paper that has come to our attention is that of Evgeniou et al. (2005) who showed how Hilbert spaces of vector-valued

1. This is a combined and expanded version of previous conference papers (Kadri et al., 2010, 2011c).

functions (Micchelli and Pontil, 2005a) and matrix-valued reproducing kernels (Micchelli and Pontil, 2005b; Reisert and Burkhardt, 2007) can be used as a theoretical framework to develop nonlinear multi-task learning methods.

A primary motivation for this paper is to build on these previous studies and provide a similar framework for addressing the general case where the output space is infinite dimensional. In this setting, the output space is a space of functions and elements of this space are called functional response data. Functional responses are frequently encountered in the analysis of time-varying data when repeated measurements of a continuous response variable are taken over a small period of time (Faraway, 1997; Yao et al., 2005). The relationships among the response data are difficult to explore when the number of responses is large, and hence one might be inclined to think that it could be helpful and more natural to consider the response as a smooth real function. Moreover, with the rapid development of accurate and sensitive instruments and thanks to the currently available large storage resources, data are now often collected in the form of curves or images. The statistical framework underlying the analysis of these data as a single function observation rather than a collection of individual observations is called functional data analysis (FDA) and was first introduced by Ramsay and Dalzell (1991).

It should be pointed out that in earlier studies a similar but less explicit statement of the functional approach was addressed in Dauxois et al. (1982), while the first discussion of what is meant by "functional data" appears to be by Ramsay (1982). Functional data analysis deals with the statistical description and modeling of random functions. For a wide range of statistical tools, ranging from exploratory and descriptive data analysis to linear models and multivariate techniques, a functional version has been recently developed. Reviews of theoretical concepts and prospective applications of functional data can be found in the two monographs by Ramsay and Silverman (2005, 2002). One of the most crucial questions related to this field is "What is the correct way to handle large data? Multivariate or Functional?" Answering this question requires better understanding of complex data structures and relationship among variables. Until now, arguments for and against the use of a functional data approach have been based on methodological considerations or experimental investigations (Ferraty and Vieu, 2003; Rice, 2004). However, we believe that without further improvements in theoretical issues and in algorithm design of functional approaches, exhaustive comparative studies will remain hard to conduct.

This motivates the general framework we develop in this paper. To the best of our knowledge, nonlinear methods for functional data is a topic that has not been sufficiently addressed in the FDA literature. Unlike previous studies on nonlinear supervised classification or real response regression of functional data (Rossi and Villa, 2006; Ferraty and Vieu, 2004; Preda, 2007), this paper addresses the problem of learning tasks where the output variables are functions. From a machine learning point of view, the problem can be viewed as that of learning a function-valued function $f : \mathcal{X} \longrightarrow \mathcal{Y}$ where $\mathcal{X}$ is the input space and $\mathcal{Y}$ the (possibly infinite-dimensional) Hilbert space of the functional output data. Various situations can be distinguished according to the nature of input data attributes (scalars or/and functions). We focus in this work on the case where input attributes are functions, too, but it should be noted that the framework developed here can also be applied when the input data are either discrete, or continuous. Lots of practical applications involve a blend of both functional and non functional attributes, but we do not mix non functional

attributes with functional attributes in this paper. This point has been discussed in (Kadri et al., 2011b). To deal with non-linearity, we adopt a kernel-based approach and we design operator-valued kernels that perform the mapping between the two spaces of functions. Our main results demonstrate how basic concepts and properties of kernel-based learning known in the case of multivariate data can be restated for functional data.

Extending learning methods from multivariate to functional response data may lead to further progress in several practical problems of machine learning and applied statistics. To compare the proposed nonlinear functional approach with other multivariate or functional methods and to apply it in a real world setting, we are interested in the problems of speech inversion and sound recognition, which have attracted increasing attention in the speech processing community in the recent years (Mitra et al., 2010; Rabaoui et al., 2008). These problems can be cast as a supervised learning problem which include some components (predictors or responses) that may be viewed as random curves. In this context, though some concepts on the use of RKHS for functional data similar to those presented in this work can be found in Lian (2007), the present paper provides a much more complete view of learning from functional data using kernel methods, with extended theoretical analysis and several additional experimental results.

This paper is a combined and expanded version of our previous conference papers (Kadri et al., 2010, 2011c). It gives the full justification, additional insights as well as new and comprehensive experiments that strengthen the results of these preliminary conference papers. The outline of the paper is as follows. In Section 2, we discuss the connection between the two fields Functional Data Analysis and Machine Learning, and outline our main contributions. Section 3 defines the notation used throughout the paper. Section 4, describes the theory of reproducing kernel Hilbert spaces of function-valued functions and shows how vector-valued RKHS concepts can be extended to infinite-dimensional output spaces. In Section 5, we exhibit a class of operator-valued kernels that perform the mapping between two spaces of functions and discuss some ideas for understanding their associated feature maps. In Section 6, we provide a function-valued function estimation procedure based on inverting block operator kernel matrices, propose a learning algorithm that can handle functional data, and analyze theoretically its generalization properties. Finally in Section 7, we illustrate the performance of our approach through speech and audio processing experiments.

2. The Interplay of FDA and ML Research

To put our work in context, we begin by discussing the interaction between functional data analysis (FDA) and machine learning (ML). Then, we give an overview of our contributions.

Starting from the fact that "new types of data require new tools for analysis", FDA emerges as a well-defined and suitable concept to further improve classical multivariate statistical methods when data are functions (Levitin et al., 2007). This research field is currently very active, and considerable progress has been made in recent years in designing statistical tools for infinite-dimensional data that can be represented by real-valued functions rather than by discrete, finite dimensional vectors (Ramsay and Silverman, 2005; Ferraty and Vieu, 2006; Shi and Choi, 2011; Horváth and Kokoszka, 2012). While the FDA viewpoint is conventionally adopted in the mathematical statistics community to deal

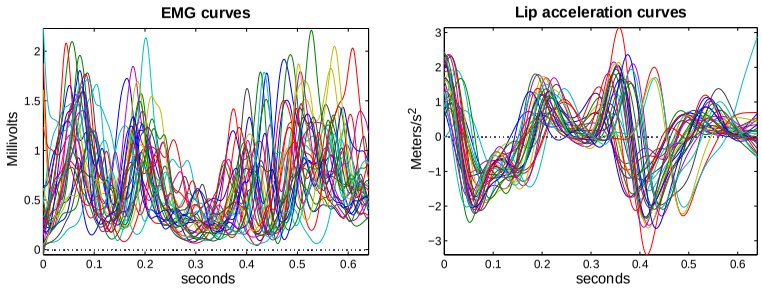

Figure 1: Electromyography (EMG) and lip acceleration curves. The left panel displays EMG recordings from a facial muscle that depresses the lower lip, the depressor labii inferior. The right panel shows the accelerations of the center of the lower lip of a speaker pronouncing the syllable "bob", embedded in the phrase "Say bob again", for 32 replications (Ramsay and Silverman, 2002, Chapter 10).

with data in infinite-dimensional spaces, it does not appear to be commonplace for machine learners. One possible reason for this lack of success is that the formal use of infinite dimensional spaces for practical ML applications may seem unjustified; because in practice traditional measurement devices are limited in providing discrete and not functional data, and a machine learning algorithm can process only finitely represented objects. We believe that for applied machine learners it should be vital to know the full range of applicability of functional data analysis and infinite-dimensional data representations. But due to limitation of space we shall say only few words about the occurrence of functional data in real applications and about the real learning task lying behind this kind of approach. The reader is referred to Ramsay and Silverman (2002) for more details and references. Areas of application discussed and cited there include medical diagnosis, economics, meteorology, biomechanics, and education. For almost all these applications, the high-sampling rate of today's acquisition devices makes it natural to directly handle functions/curves instead of discretized data. Classical multivariate statistical methods may be applied to such data, but they cannot take advantage of the additional information implied by the smoothness of the underlying functions. FDA methods can have beneficial effects in this direction by extracting additional information contained in the functions and their derivatives, not normally available through traditional methods (Levitin et al., 2007).

To get a better idea about the natural occurrence of functional data in ML tasks, Figure 1 depicts a functional data set introduced by Ramsay and Silverman (2002). The data set consists of 32 records of the movement of the center of the lower lip when a subject was repeatedly required to say the syllable "bob", embedded in the sentence, "Say bob again" and the corresponding EMG activities of the primary muscle depressing the lower lip, the depressor labii inferior (DLI)[2]. The goal here is to study the dependence of the acceleration

2. The data set is available at `http://www.stats.ox.ac.uk/~silverma/fdacasebook/lipemg.html`. More information about the data collection process can be found in Ramsay and Silverman (2002, Chapter 10).

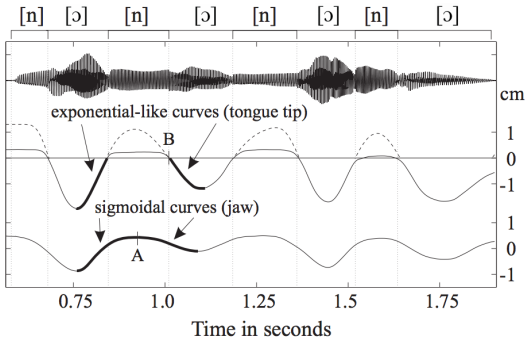

Figure 2: "Audio signal (top), tongue tip trajectory (middle), and jaw trajectory (bottom) for the utterance [ˌnɔnɔˈnɔnɔ]. The trajectories were measured by electromagnetic articulography (EMA) for coils on the tongue tip and the lower incisors. Each trajectory shows the displacement along the first principal component of the original two-dimensional trajectory in the midsagittal plane. The dashed curves show hypothetical continuations of the tongue tip trajectory towards and away from virtual targets during the closure intervals." (Birkholz et al., 2010).

of the lower lip in speech on neural activity. EMG and lip accelerations curves can be well modeled by continuous functions of time that allow to capture functional dependencies and interactions between samples (feature values). Thus, we face a regression problem where both input and output data are functions. In much the same way, Figure 2 also shows a "natural" representation of data in terms of functions [3]. It represents a speech signal used for acoustic-articulatory speech inversion and produced by a subject pronouncing a sequence of [ˌCVCVˈCVCV] (C=consonant, V=vowel) by combining the vowel {/ɔ/} with the consonant {/n/}. The articulatory trajectories are represented by the upper and lower solid curves that show the displacement of fleshpoints on the tongue tip and the jaw along the main movement direction of these points during the repeated opening and closing gestures. This example is from a recent study on the articulatory modeling of speech signals (Birkholz et al., 2010). The concept of articulatory gestures in the context of speech-to-articulatory inversion will be explained in more details in Section 7. As shown in the figure, the observed articulatory trajectories are typically modeled by smooth functions of time with periodicity properties and exponential or sigmoidal shape, and the goal of speech inversion is to predict and recover geometric data of the vocal tract from the speech information.

In both examples given above, response data clearly present a functional behavior that should be taken into account during the learning process. We think that handling these data as what they really are, that is functions, is a promising way to tackle prediction problems and design efficient ML systems for continuous data variables. Moreover, ML methods which

3. This figure is from Birkholz et al. (2010).

can handle functional features can open up plenty of new areas of application, where the flexibility of functional and infinite-dimensional spaces would allow to enable us to achieve significantly better performance while managing huge amounts of training data.

In the light of these observations, there is an interest in overcoming methodological and practical problems that hinder the wide adoption and use of functional methods built for infinite-dimensional data. Regarding the practical issue related to the application and implementation of infinite-dimensional spaces, a standard means of addressing it is to choose a functional space *a priori* with a known predefined set of basis functions in which the data will be mapped. This may include a preprocessing step, which consists in converting the discretized data into functional objects using interpolation or approximation techniques. Following this scheme, parametric FDA methods have emerged as a common approach to extend multivariate statistical analysis in functional and infinite-dimensional situations (Ramsay and Silverman, 2005). More recently, nonparametric FDA methods have received increasing attention because of their ability to avoid fixing a set of basis functions for the functional data beforehand (Ferraty and Vieu, 2006). These methods are based on the concept of semi-metrics for modeling functional data. The reason for using a semi-metric rather than a metric is that the coincidence axiom, namely $d(x_i, x_j) = 0 \Leftrightarrow x_i = x_j$, may result in curves with very similar shapes being categorized as distant (not similar to each other). To define closeness between functions in terms of shape rather than location semi-metrics can be used. In this spirit, Ferraty and Vieu (2006) provided a semi-metric based methodology for nonparametric functional data analysis and argued that this can be a sufficiently general theoretical framework to tackle infinite-dimensional data without being "too heavy" in terms of computational time and implementation complexity.

Thus, although both parametric and nonparametric functional data analyses deal with infinite-dimensional data, they are computationally feasible and quite practical since the observed functional data are approximated in a basis of the function space with possibly finite number of elements. What we really need is the inner or semi-inner product of the basis elements and the representation of the functions with respect to that basis. We think that Machine Learning research can profit from exploring other representation formalisms that support the expressive power of functional data. Machine learning methods which can accommodate functional data should open up new possibilities for handling practical applications for which the flexibility of infinite-dimensional spaces could be exploited to achieve performance benefits and accuracy gains. On the other hand, in the FDA field, there is clearly a need for further development of computationally efficient and understandable algorithms that can deliver near-optimal solutions for infinite-dimensional problems and that can handle a large number of features. The transition from infinite-dimensional statistics to efficient algorithmic design and implementation is of central importance to FDA methods in order to make them more practical and popular. In this sense, Machine Learning can have a profound impact on FDA research.

In reality, ML and FDA have more in common than it might seem. There are already existing machine learning algorithms that can also be viewed as FDA methods. For example, these include kernel methods which use a certain type of similarity measure (called a kernel) to map observed data in a high dimensional feature space, in which linear methods are used for learning problems (Shawe-Taylor and Cristanini, 2004; Schölkopf and Smola,

2002). Depending on the choice of the kernel function, the feature space can be infinite-dimensional. The kernel trick is used, allowing to work with finite Gram matrix of inner products between the possibly infinite-dimensional features which can be seen as functional data. This connection between kernel and FDA methods is clearer with the concept of kernel embedding of probability distributions, where, instead of (observed) single points, kernel means are used to represent probability distributions (Smola et al., 2007; Sriperumbudur et al., 2010). The kernel mean corresponds to a mapping of a probability distribution in a feature space which is rich enough so that its expectation uniquely identifies the distribution. Thus, rather than relying on large collections of vector data, kernel-based learning can be adapted to probability distributions that are constructed to meaningfully represent the discrete data by the use of kernel means (Muandet et al., 2012). In some sense, this represents a similar design to FDA methods, where data are assumed to lie in a functional space even though they are acquired in a discrete manner. There are also other papers that deal with machine learning problems where covariates are probability distributions and discuss their relation with FDA (Poczos et al., 2012, 2013; Oliva et al., 2013). At that point, however, the connection between ML and FDA is admittedly weak and needs to be bolstered by the delivery of more powerful and flexible learning machines that are able to deal with functional data and infinite-dimensional spaces.

In the FDA field, linear models have been explored extensively. Nonlinear modeling of functional data is, however, a topic that has not been sufficiently investigated, especially when response data are functions. Reproducing kernels provide a powerful tool for solving learning problems with nonlinear models, but to date they have been used more to learn scalar-valued or vector-valued functions than function-valued functions. Consequently, kernels for functional response data and their associated function-valued reproducing kernel Hilbert spaces have remained mostly unknown and poorly studied. In this work, we aim to rectify this situation, and highlight areas of overlap between the two fields FDA and ML, particularly with regards to the applicability and relevance of the FDA paradigm coupled with machine learning techniques. Specifically, we provide a learning methodology for nonlinear FDA based on the theory of reproducing kernels. The main contributions are as follows:

- we introduce a set of rigorously defined operator-valued kernels suitable for functional response data, that can be valuably applied to model dependencies between samples and take into account the functional nature of the data, like the smoothness of the curves underlying the discrete observations,
- we propose an efficient algorithm for learning function-valued functions (operators) based on the spectral decomposition of block operator matrices,
- we study the generalization performance of our learned nonlinear FDA model using the notion of algorithmic stability,
- we show the applicability and suitability of our framework to two problems in audio signal processing, namely speech inversion and sound recognition, where features are functions that are dependent on each other.

3. Notations and Conventions

We start by some standard notations and definitions used all along the paper. Given a Hilbert space $\mathcal{H}$, $\langle \cdot, \cdot \rangle_{\mathcal{H}}$ and $\| \cdot \|_{\mathcal{H}}$ refer to its inner product and norm, respectively. $H^n = \underbrace{\mathcal{H} \times \ldots \times \mathcal{H}}_{n \text{ times}}$, $n \in \mathbb{N}_+$, denotes the topological product of n spaces $\mathcal{H}$. We denote by $\mathcal{X} = \{x : \Omega_x \longrightarrow \mathbb{R}\}$ and $\mathcal{Y} = \{y : \Omega_y \longrightarrow \mathbb{R}\}$ the separable Hilbert spaces of input and output real-valued functions whose domains are Ω_x and Ω_y, respectively. In functional data analysis domain, the space of functions is generally assumed to be the Hilbert space of equivalence classes of square integrable functions, denoted by L^2. Thus, in the rest of the paper, we consider $\mathcal{Y}$ to be the space $L^2(\Omega_y)$, where Ω_y is a compact set. The vector space of functions from $\mathcal{X}$ into $\mathcal{Y}$ is denoted by $\mathcal{Y}^{\mathcal{X}}$ endowed with the topology of uniform convergence on compact subsets of $\mathcal{X}$. We denote by $\mathcal{C}(\mathcal{X}, \mathcal{Y})$ the vector space of continuous functions from $\mathcal{X}$ to $\mathcal{Y}$, by $\mathcal{F} \subset \mathcal{Y}^{\mathcal{X}}$ the Hilbert space of function-valued functions $F : \mathcal{X} \longrightarrow \mathcal{Y}$, and by $\mathcal{L}(\mathcal{Y})$ the set of bounded linear operators from $\mathcal{Y}$ to $\mathcal{Y}$.

We now fix the following conventions for bounded linear operators and block operator matrices.

Definition 1 *(adjoint, self-adjoint, and positive operators)*
Let $A \in \mathcal{L}(\mathcal{Y})$. Then:

(i) *A^*, the adjoint operator of A, is the unique operator in $\mathcal{L}(\mathcal{Y})$ that satisfies*

$$\langle Ay, z \rangle_{\mathcal{Y}} = \langle y, A^* z \rangle_{\mathcal{Y}} \ , \ \forall y \in \mathcal{Y}, \forall z \in \mathcal{Y},$$

(ii) *A is self-adjoint if $A = A^*$,*

(iii) *A is positive if it is self-adjoint and $\forall y \in \mathcal{Y}$, $\langle Ay, y \rangle_{\mathcal{Y}} \geq 0$ (we write $A \geq 0$),*

(iv) *A is larger or equal than $B \in \mathcal{L}(\mathcal{Y})$, if $A - B$ is positive, i.e., $\forall y \in \mathcal{Y}$, $\langle Ay, y \rangle_{\mathcal{Y}} \geq \langle By, y \rangle_{\mathcal{Y}}$ (we write $A \geq B$).*

Definition 2 *(block operator matrix)*
Let $n \in \mathbb{N}$, let $\mathcal{Y}^n = \underbrace{\mathcal{Y} \times \ldots \times \mathcal{Y}}_{n \text{ times}}$.

(i) *$\mathbf{A} \in \mathcal{L}(\mathcal{Y}^n)$, given by*

$$\mathbf{A} = \begin{pmatrix} A_{11} & \ldots & A_{1n} \\ \vdots & & \vdots \\ A_{n1} & \ldots & A_{nn} \end{pmatrix}$$

where each $A_{ij} \in \mathcal{L}(\mathcal{Y})$, $i, j = 1, \ldots, n$, is called a block operator matrix,

(ii) *the adjoint (or transpose) of $\mathbf{A}$ is the block operator matrix $\mathbf{A}^* \in \mathcal{L}(\mathcal{Y}^n)$ such that $(A^*)_{ij} = (A_{ji})^*$,*

(iii) *self-adjoint and order relations of block operator matrices are defined in the same way as for bounded operators (see Definition 1).*

real numbers	α, β, γ, ...	Greek characters
integers	i, j, m, n	
vector spaces[4]	$\mathcal{X}$, $\mathcal{Y}$, $\mathcal{H}$, ...	Calligraphic letters

Table 1: Notations used in this paper.

Note that item (ii) in Definition 2 is obtained from the definition of adjoint operator. It is easy to see that $\forall \mathbf{y} \in \mathcal{Y}^n$ and $\forall \mathbf{z} \in \mathcal{Y}^n$; we have: $\langle \mathbf{Ay}, \mathbf{z} \rangle_{\mathcal{Y}^n} = \sum_{i,j} \langle A_{ij} y_j, z_i \rangle_{\mathcal{Y}} = \sum_{i,j} \langle y_j, A_{ij}^* z_i \rangle_{\mathcal{Y}} = \sum_{i,j} \langle y_j, (A^*)_{ji} z_i \rangle_{\mathcal{Y}} = \langle \mathbf{y}, \mathbf{A}^* \mathbf{z} \rangle_{\mathcal{Y}^n}$, where $(A^*)_{ji} = (A_{ij})^*$.

To help the reader, notations frequently used in the paper are summarized in Table 1.

4. Reproducing Kernel Hilbert Spaces of Function-valued Functions

Hilbert spaces of scalar-valued functions with reproducing kernels were introduced and studied in Aronszajn (1950). Due to their crucial role in designing kernel-based learning methods, these spaces have received considerable attention over the last two decades (Shawe-Taylor and Cristanini, 2004; Schölkopf and Smola, 2002). More recently, interest has grown in exploring reproducing Hilbert spaces of vector functions for learning vector-valued functions (Micchelli and Pontil, 2005a; Carmeli et al., 2006; Caponnetto et al., 2008; Carmeli et al., 2010; Zhang et al., 2012), even though the idea of extending the theory of Reproducing Kernel Hilbert Spaces from the scalar-valued case to the vector-valued one is not new and dates back to at least Schwartz (1964). For more details, see the review paper by Álvarez et al. (2012).

In the field of machine learning, Evgeniou et al. (2005) have shown how Hilbert spaces of vector-valued functions and matrix-valued reproducing kernels can be used in the context of multi-task learning, with the goal of learning many related regression or classification tasks simultaneously. Since this seminal work, it has been demonstrated that these kernels and their associated spaces are capable of solving various other learning problems such as multiple output learning (Baldassarre et al., 2012), manifold regularization (Minh and Sindhwani, 2011), structured output prediction (Brouard et al., 2011; Kadri et al., 2013a), multi-view learning (Minh et al., 2013; Kadri et al., 2013b) and network inference (Lim et al., 2013, 2015).

4. We also use the standard notations such as $\mathbb{R}^n$ and L^2.
5. We denote by small Latin characters scalar-valued functions. Operator-valued functions (or kernels) are denoted by capital Latin characters $A(\cdot, \cdot)$, $B(\cdot, \cdot)$, $K(\cdot, \cdot)$, ...

In contrast to most of these previous works, here we are interested in the general case where the output space is a space of vectors with infinite dimension. This may be valuable from a variety of perspectives. Our main motivation is the supervised learning problem when output data are functions that could represent, for example, one-dimensional curves (this was mentioned as future work in Szedmak et al. 2006). One of the simplest ways to handle these data is to treat them as multivariate vectors. However this method does not consider any dependency of different values over subsequent time-points within the same functional datum and suffers when data dimension is very large. Therefore, we adopt a functional data analysis viewpoint (Zhao et al., 2004; Ramsay and Silverman, 2005; Ferraty and Vieu, 2006) in which multiple curves are viewed as functional realizations of a single function. It is important to note that matrix-valued kernels for infinite-dimensional output spaces, commonly known as operator-valued kernels, have been considered in previous studies (Micchelli and Pontil, 2005a; Caponnetto et al., 2008; Carmeli et al., 2006, 2010); however, they have been only studied in a theoretical perspective. Clearly, further investigations are needed to illustrate the practical benefits of the use of operator-valued kernels, which is the main focus of this work.

We now describe how RKHS theory can be extended from real or vector to functional response data. In particular, we focus on reproducing kernel Hilbert spaces whose elements are function-valued functions (or operators) and we demonstrate how basic properties of real-valued RKHS can be restated in the functional case, if appropriate conditions are satisfied. Extension to the functional case is not so obvious and requires tools from functional analysis (Rudin, 1991). Spaces of operators whose range is infinite-dimensional can exhibit unusual behavior, and standard topological properties may not be preserved in the infinite-dimensional case because of functional analysis subtleties. So, additional restrictions imposed on these spaces are needed for extending the theory of RKHS towards infinite-dimensional output spaces. Following Carmeli et al. (2010), we mainly focus on separable Hilbert spaces with reproducing operator-valued kernels whose elements are continuous functions. This is a sufficient condition to avoid topological and measurability problems encountered with this extension. For more details about vector or function-valued RKHS of measurable and continuous functions, see Carmeli et al. (2006, Sections 3 and 5). Note that the framework developed in this section should be valid for any type of input data (vectors, functions, or structures). In this paper, however, we consider the case where both input and output data are functions.

Definition 3 *(Operator-valued kernel)*
An $\mathcal{L}(\mathcal{Y})$-valued kernel K on $\mathcal{X}^2$ is a function $K(\cdot,\cdot) : \mathcal{X} \times \mathcal{X} \longrightarrow \mathcal{L}(\mathcal{Y})$;

(i) *K is Hermitian if $\forall x, z \in \mathcal{X}$, $K(w,z) = K(z,w)^*$, (where the superscript * denotes the adjoint operator),*

(ii) *K is nonnegative on $\mathcal{X}$ if it is Hermitian and for every natural number r and all $\{(w_i, u_i)_{i=1,\dots,r}\} \in \mathcal{X} \times \mathcal{Y}$, the matrix with ij-th entry $\langle K(w_i, w_j)u_i, u_j\rangle_{\mathcal{Y}}$ is nonnegative (positive-definite).*

Definition 4 *(Block operator kernel matrix)*
Given a set $\{w_i\} \in \mathcal{X}$, $i = 1, \dots, n$ with $n \in \mathbb{N}_+$, and an operator-valued kernel K, the corresponding block operator kernel matrix is the matrix $\mathbf{K} \in \mathcal{L}(\mathcal{Y}^n)$ with entries

$$\mathbf{K}_{ij} = K(w_i, w_j).$$

The block operator kernel matrix is simply the kernel matrix associated to an operator-valued kernel. Since the kernel outputs an operator, the kernel matrix is in this case a block matrix where each block is an operator in $\mathcal{L}(\mathcal{Y})$. It is easy to see that an operator-valued kernel K is nonnegative if and only if the associated block operator kernel matrix $\mathbf{K}$ is positive.

Definition 5 *(Function-valued RKHS)*
A Hilbert space $\mathcal{F}$ of functions from $\mathcal{X}$ to $\mathcal{Y}$ is called a reproducing kernel Hilbert space if there is a nonnegative $\mathcal{L}(\mathcal{Y})$-valued kernel K on $\mathcal{X}^2$ such that:

(i) *the function $z \longmapsto K(w,z)g$ belongs to $\mathcal{F}, \forall z, w \in \mathcal{X}$ and $g \in \mathcal{Y}$,*

(ii) *for every $F \in \mathcal{F}, w \in \mathcal{X}$ and $g \in \mathcal{Y}$, $\langle F, K(w,\cdot)g\rangle_{\mathcal{F}} = \langle F(w), g\rangle_{\mathcal{Y}}$.*

On account of (ii), the kernel is called the reproducing kernel of $\mathcal{F}$. In Carmeli et al. (2006, Section 5), the authors provided a characterization of RKHS with operator-valued kernels whose functions are continuous and proved that $\mathcal{F}$ is a subspace of $\mathcal{C}(\mathcal{X}, \mathcal{Y})$, the vector space of continuous functions from $\mathcal{X}$ to $\mathcal{Y}$, if and only if the reproducing kernel K is locally bounded and separately continuous. Such a kernel is qualified as Mercer (Carmeli et al., 2010). In the following, we will only consider separable RKHS $\mathcal{F} \subset \mathcal{C}(\mathcal{X}, \mathcal{Y})$.

Theorem 1 *(Uniqueness of the reproducing operator-valued kernel)*
If a Hilbert space $\mathcal{F}$ of functions from $\mathcal{X}$ to $\mathcal{Y}$ admits a reproducing kernel, then the reproducing kernel K is uniquely determined by the Hilbert space $\mathcal{F}$.

Proof: Let K be a reproducing kernel of $\mathcal{F}$. Suppose that there exists another reproducing kernel K' of $\mathcal{F}$. Then, for all $\{w, w'\} \in \mathcal{X}$ and $\{h, g\} \in \mathcal{Y}$, applying the reproducing property for K and K' we get

$$\langle K'(w',\cdot)h, K(w,\cdot)g\rangle_{\mathcal{F}} = \langle K'(w',w)h, g\rangle_{\mathcal{Y}}, \tag{1}$$

we have also

$$\begin{aligned} \langle K'(w',\cdot)h, K(w,\cdot)g\rangle_{\mathcal{F}} &= \langle K(w,\cdot)g, K'(w',\cdot)h\rangle_{\mathcal{F}} &&= \langle K(w,w')g, h\rangle_{\mathcal{Y}} \\ &= \langle g, K(w,w')^*h\rangle_{\mathcal{Y}} &&= \langle g, K(w',w)h\rangle_{\mathcal{Y}}. \end{aligned} \tag{2}$$

(1) and (2) $\Rightarrow K(w,w') \equiv K'(w,w'), \forall w, w' \in \mathcal{X}$. ■

A key point for learning with kernels is the ability to express functions in terms of a kernel providing the way to evaluate a function at a given point. This is possible because there exists a bijection relationship between a large class of kernels and associated reproducing kernel spaces which satisfy a regularity property. Bijection between scalar-valued kernels and RKHS was first established by Aronszajn (1950, Part I, Sections 3 and 4). Then Schwartz (1964, Chapter 5) shows that this is a particular case of a more general situation. This bijection in the case where input and output data are continuous and belong to the infinite-dimensional functional spaces $\mathcal{X}$ and $\mathcal{Y}$, respectively, is still valid and is given by the following theorem (see also Theorem 4 of Senkene and Tempel'man, 1973).

Theorem 2 *(Bijection between function-valued RKHS and operator-valued kernel)*
A $\mathcal{L}(\mathcal{Y})$-valued Mercer kernel K on $\mathcal{X}^2$ is the reproducing kernel of some Hilbert space $\mathcal{F}$, if and only if it is nonnegative.

We give a proof of this theorem by extending the scalar-valued case $\mathcal{Y} = \mathbb{R}$ in Aronszajn (1950) to the domain of functional data analysis domain where $\mathcal{Y}$ is $L^2(\Omega_y)$.[6] The proof is performed in two steps. The necessity is an immediate result from the reproducing property. For the sufficiency, the outline of the proof is as follows: we assume $\mathcal{F}_0$ to be the space of all $\mathcal{Y}$-valued functions F of the form $F(\cdot) = \sum_{i=1}^{n} K(w_i, \cdot)u_i$, where $w_i \in \mathcal{X}$ and $u_i \in \mathcal{Y}$, with the following inner product $\langle F(\cdot), G(\cdot)\rangle_{\mathcal{F}_0} = \sum_{i=1}^{n}\sum_{j=1}^{m}\langle K(w_i, z_j)u_i, v_j\rangle_{\mathcal{Y}}$ defined for any $G(\cdot) = \sum_{j=1}^{m} K(z_j, \cdot)v_j$ with $z_j \in \mathcal{X}$ and $v_j \in \mathcal{Y}$. We show that $(\mathcal{F}_0, \langle\cdot,\cdot\rangle_{\mathcal{F}_0})$ is a pre-Hilbert space. Then we complete this pre-Hilbert space via Cauchy sequences $\{F_n(\cdot)\} \subset \mathcal{F}_0$ to construct the Hilbert space $\mathcal{F}$ of $\mathcal{Y}$-valued functions. Finally, we conclude that $\mathcal{F}$ is a reproducing kernel Hilbert space, since $\mathcal{F}$ is a real inner product space that is complete under the norm $\|\cdot\|_{\mathcal{F}}$ defined by $\|F(\cdot)\|_{\mathcal{F}} = \lim_{n\to\infty} \|F_n(\cdot)\|_{\mathcal{F}_0}$, and has $K(\cdot,\cdot)$ as reproducing kernel.

Proof: *Necessity.* Let K be the reproducing kernel of a Hilbert space $\mathcal{F}$. Using the reproducing property of the kernel K we obtain for any $\{w_i, w_j\} \in \mathcal{X}$ and $\{u_i, u_j\} \in \mathcal{Y}$

$$\sum_{i,j=1}^{n}\langle K(w_i, w_j)u_i, u_j\rangle_Y = \sum_{i,j=1}^{n}\langle K(w_i,\cdot)u_i, K(w_j,\cdot)u_j\rangle_{\mathcal{F}}$$
$$= \langle\sum_{i=1}^{n} K(w_i,\cdot)u_i, \sum_{i=1}^{n} K(w_i,\cdot)u_i\rangle_{\mathcal{F}} = \|\sum_{i=1}^{n} K(w_i,\cdot)u_i\|_{\mathcal{F}}^2 \;\geq\; 0.$$

Sufficiency. Let $\mathcal{F}_0 \subset \mathcal{Y}^{\mathcal{X}}$ be the space of all $\mathcal{Y}$-valued functions F of the form $F(\cdot) = \sum_{i=1}^{n} K(w_i,\cdot)u_i$, where $w_i \in \mathcal{X}$ and $u_i \in \mathcal{Y}$, $i = 1, \ldots, n$. We define the inner product of the functions $F(\cdot) = \sum_{i=1}^{n} K(w_i,\cdot)u_i$ and $G(\cdot) = \sum_{j=1}^{m} K(z_j,\cdot)v_j$ from $\mathcal{F}_0$ as follows

$$\langle F(\cdot), G(\cdot)\rangle_{\mathcal{F}_0} = \langle\sum_{i=1}^{n} K(w_i,\cdot)u_i, \sum_{j=1}^{m} K(z_j,\cdot)v_j\rangle_{\mathcal{F}_0} = \sum_{i=1}^{n}\sum_{j=1}^{m}\langle K(w_i, z_j)u_i, v_j\rangle_{\mathcal{Y}}.$$

$\langle F(\cdot), G(\cdot)\rangle_{\mathcal{F}_0}$ is a symmetric bilinear form on $\mathcal{F}_0$ and due to the positivity of the kernel K, $\|F(\cdot)\|$ defined by

$$\|F(\cdot)\| = \sqrt{\langle F(\cdot), F(\cdot)\rangle_{\mathcal{F}_0}}$$

is a quasi-norm in $\mathcal{F}_0$. The reproducing property in $\mathcal{F}_0$ is verified with the kernel K. In fact, if $F \in \mathcal{F}_0$ then

$$F(\cdot) = \sum_{i=1}^{n} K(w_i,\cdot)u_i,$$

6. The proof should be applicable to arbitrarily separable output Hilbert spaces $\mathcal{Y}$.

and $\forall\ (w, u) \in \mathcal{X} \times \mathcal{Y}$,

$$\langle F, K(w,\cdot)u\rangle_{\mathcal{F}_0} = \langle\sum_{i=1}^{n} K(w_i,\cdot)u_i, K(w,\cdot)u\rangle_{\mathcal{F}_0} = \langle\sum_{i=1}^{n} K(w_i, w)u_i, u\rangle_{\mathcal{Y}} = \langle F(w), u\rangle_{\mathcal{Y}}.$$

Moreover using the Cauchy-Schwartz inequality, we have: $\forall\ (w, u) \in \mathcal{X} \times \mathcal{Y}$,

$$\langle F(w), u\rangle_{\mathcal{Y}} = \langle F(\cdot), K(w,\cdot)u\rangle_{\mathcal{F}_0} \leq \|F(\cdot)\|_{\mathcal{F}_0}\|K(w,\cdot)u\|_{\mathcal{F}_0}.$$

Thus, if $\|F\|_{\mathcal{F}_0} = 0$, then $\langle F(w), u\rangle_{\mathcal{Y}} = 0$ for any w and u, and hence $F \equiv 0$. Thus $(\mathcal{F}_0, \langle.,.\rangle_{\mathcal{F}_0})$ is a pre-Hilbert space. This pre-Hilbert space is in general not complete, but it can be completed via Cauchy sequences to build the $\mathcal{Y}$-valued Hilbert space $\mathcal{F}$ which has K as reproducing kernel, which concludes the proof. The completion of $\mathcal{F}_0$ is given in Appendix A (we refer the reader to the monograph by Rudin, 1991, for more details about completeness and the general theory of topological vector spaces). ■

We now give an example of a function-valued RKHS and its operator-valued kernel. This example serves to illustrate how these spaces and their associated kernels generalize the standard scalar-valued case or the vector-valued one to functional and infinite-dimensional output data. Thus, we first report an example of a scalar-valued RKHS and the corresponding scalar-valued kernel. We then extend this example to the case of vector-valued Hilbert spaces with matrix-valued kernels, and finally to function-valued RKHS where the output space is infinite dimensional. For the sake of simplicity, the input space $\mathcal{X}$ in these examples is assumed to be a subset of $\mathbb{R}$.

Example 1 *(Scalar-valued RKHS and its scalar-valued kernel; see Canu et al. (2003))*
Let $\mathcal{F}$ be the space defined as follows:

$$\begin{cases} \mathcal{F} = \big\{f : [0,1] \longrightarrow \mathbb{R} \text{ absolutely continuous},\ \exists f' \in L^2([0,1]), f(x) = \displaystyle\int_0^x f'(z)dz\big\}, \\ \langle f_1, f_2\rangle_{\mathcal{H}} = \langle f_1', f_2'\rangle_{L^2([0,1])}. \end{cases}$$

$\mathcal{F}$ is the Sobolev space of degree 1, also called the Cameron-Martin space, and is a scalar-valued RKHS of functions $f : [0,1] \longrightarrow \mathbb{R}$ with the scalar-valued reproducing kernel $k(x,z) = min(x,z)$, $\forall x, z \in \mathcal{X} = [0,1]$.

Example 2 *(Vector-valued RKHS and its matrix-valued kernel)*
Let $\mathcal{X} = [0,1]$ and $\mathcal{Y} = \mathbb{R}^n$. Consider the matrix-valued kernel K defined by:

$$K(x,z) = \begin{cases} diag(x) & if \quad x \leq z, \\ diag(z) & otherwise, \end{cases} \tag{3}$$

where, $\forall a \in \mathbb{R}$, $diag(a)$ is the $n \times n$ diagonal matrix with diagonal entries equal to a. Let $\mathcal{M}$ be the space of vector-valued functions from $\mathcal{X}$ onto $\mathbb{R}^n$ whose norm $\|g\|_{\mathcal{M}}^2 = \sum_{i=1}^{n}\int_{\mathcal{X}}[g(x)]_i^2 dx$ is finite.

The matrix-valued mapping K is the reproducing kernel of the vector-valued RKHS $\mathcal{F}$ defined as follows:

$$\begin{cases} \mathcal{F} = \left\{ f : [0,1] \longrightarrow \mathbb{R}^n,\ \exists f' = \dfrac{df(x)}{dx} \in \mathcal{M}, [f(x)]_i = \displaystyle\int_0^x [f'(z)]_i dz, \forall i = 1, \ldots, n \right\}, \\ \langle f_1, f_2 \rangle_{\mathcal{F}} = \langle f_1', f_2' \rangle_{\mathcal{M}}. \end{cases}$$

Indeed, K is nonnegative and we have, $\forall x \in \mathcal{X}$, $y \in \mathbb{R}^n$ and $f \in \mathcal{F}$,

$$\begin{aligned} &\langle f, K(x,\cdot)y \rangle_{\mathcal{F}} = \langle f', [K(x,\cdot)y]' \rangle_{\mathcal{M}} \\ &= \sum_{i=1}^n \int_0^1 [f'(z)]_i [K(x,z)y]_i' dz \\ &= \sum_{i=1}^n \int_0^x [f'(z)]_i y_i dz \quad (dK(x,z)/dz = diag(1) \text{ if } z \leq x, \text{ and } = diag(0) \text{ otherwise}) \\ &= \sum_{i=1}^n [f(x)]_i y_i dz \ = \ \langle f(x), y \rangle_{\mathbb{R}^n}. \end{aligned}$$

■

Example 3 *(Function-valued RKHS and its operator-valued kernel)*

Here we extend Example 2 to the case where the output space is infinite dimensional. Let $\mathcal{X} = [0,1]$ and $\mathcal{Y} = L^2(\Omega)$ the space of square integrable functions on a compact set $\Omega \subset \mathbb{R}$. We denote by $\mathcal{M}$ the space of $L^2(\Omega)$-valued functions on $\mathcal{X}$ whose norm $\|g\|_{\mathcal{M}}^2 = \displaystyle\int_\Omega \int_{\mathcal{X}} [g(x)(t)]^2 dx dt$ is finite.

Let $(\mathcal{F}; \langle \cdot, \cdot \rangle_{\mathcal{F}})$ be the space of functions from $\mathcal{X}$ to $L^2(\Omega)$ such that:

$$\begin{cases} \mathcal{F} = \left\{ f,\ \exists f' = \dfrac{df(x)}{dx} \in \mathcal{M}, f(x) = \displaystyle\int_0^x f'(z) dz \right\}, \\ \langle f_1, f_2 \rangle_{\mathcal{F}} = \langle f_1', f_2' \rangle_{\mathcal{M}}. \end{cases}$$

$\mathcal{F}$ is a function-valued RKHS with the operator-valued kernel $K(x,z) = M_{\varphi(x,z)}$. M_φ is the multiplication operator associated with the function φ where $\varphi(x,z)$ is equal to x if $x \leq z$ and z otherwise. Since φ is a positive-definite function, K is Hermitian and nonnegative. Indeed,

$$\begin{aligned} \langle K(z,x)^* y, w \rangle_{\mathcal{Y}} &= \langle y, K(z,x)w \rangle_{\mathcal{Y}} = \int_0^1 \varphi(z,x) w(t) y(t) dt = \int_0^1 \varphi(x,z) y(t) z(t) dt \\ &= \langle K(x,z)y, w \rangle_{\mathcal{Y}}, \end{aligned}$$

and

$$\begin{aligned} \sum_{i,j} \langle K(x_i,x_j) y_i, y_j \rangle_{\mathcal{Y}} &= \sum_{i,j} \int_0^1 \varphi(x_i,x_j) y_i(t) y_j(t) dt \\ &= \int_0^1 \sum_{i,j} y_i(t) \varphi(x_i,x_j) y_j(t) dt \ \geq \ 0 \ (\text{since } \varphi \geq 0). \end{aligned}$$

Now we show that the reproducing property holds for any $f \in \mathcal{F}$, $y \in L^2(\Omega)$ and $x \in \mathcal{X}$:

$$\begin{aligned} &\langle f, K(x,\cdot)y \rangle_{\mathcal{F}} = \langle f', [K(x,\cdot)y]' \rangle_{\mathcal{M}} \\ &= \int_\Omega \int_0^1 [f'(z)](t) [K(x,z)y]'(t) dz dt \\ &\overset{\text{kern. def}}{=} \int_\Omega \int_0^x [f'(z)](t) y(t) dz dt = \int_\Omega [f(x)](t) y(t) dt \\ &= \langle f(x), y \rangle_{L^2(\Omega)}. \end{aligned}$$

■

Theorem 2 states that it is possible to construct a pre-Hilbert space of operators from a nonnegative operator-valued kernel and with some additional assumptions it can be completed to obtain a function-valued reproducing kernel Hilbert space. Therefore, it is important to consider the problem of constructing nonnegative operator-valued kernels. This is the focus of the next section.

5. Operator-valued Kernels for Functional Data

Reproducing kernels play an important role in statistical learning theory and functional estimation. Scalar-valued kernels are widely used to design nonlinear learning methods which have been successfully applied in several machine learning applications (Schölkopf and Smola, 2002; Shawe-Taylor and Cristanini, 2004). Moreover, their extension to matrix-valued kernels has helped to bring additional improvements in learning vector-valued functions (Micchelli and Pontil, 2005a; Reisert and Burkhardt, 2007; Caponnetto and De Vito, 2006). The most common and most successful applications of matrix-valued kernel methods are in multi-task learning (Evgeniou et al., 2005; Micchelli and Pontil, 2005b), even though some successful applications also exist in other areas, such as image colorization (Minh et al., 2010), link prediction (Brouard et al., 2011) and network inference (Lim et al., 2015). A basic, albeit not obvious, question which is always present with reproducing kernels concerns how to build these kernels and what is the optimal kernel choice. This question has been studied extensively for scalar-valued kernels, however it has not been investigated enough in the matrix-valued case. In the context of multi-task learning, matrix-valued kernels are constructed from scalar-valued kernels which are carried over to the vector-valued setting by a positive definite matrix (Micchelli and Pontil, 2005b; Caponnetto et al., 2008).

In this section we consider the problem from a more general point of view. We are interested in the construction of operator-valued kernels, generalization of matrix-valued kernels in infinite dimensional spaces, that perform the mapping between two spaces of functions and which are suitable for functional response data. Our motivation is to build operator-valued kernels that are capable of giving rise to nonlinear FDA methods. It is worth recalling that previous studies have provided examples of operator-valued kernels with infinite-dimensional output spaces (Micchelli and Pontil, 2005a; Caponnetto et al., 2008; Carmeli et al., 2010); however, they did not focus either on building methodological connections with the area of FDA, or on the practical impact of such kernels on real-world applications.

Motivated by building kernels that capture dependencies between samples of functional (infinite-dimensional) response variables, we adopt a FDA modeling formalism. The

design of such kernels will doubtless prove difficult, but it is necessary to develop reliable nonlinear FDA methods. Most FDA methods in the literature are based on linear parametric models. Extending these methods to nonlinear contexts should render them more powerful and efficient. Our line of attack is to construct operator-valued kernels from operators already used to build linear FDA models, particularly those involved in functional response models. Thus, it is important to begin by looking at these models.

5.1 Linear Functional Response Models

FDA is an extension of multivariate data analysis suitable when data are functions. In this framework, a data is a single function observation rather than a collection of observations. It is true that the data measurement process often provides a vector rather than a function, but the vector is a discretization of a real attribute which is a function. Hence, a functional datum i is acquired as a set of discrete measured values, $y_{i1}, \ldots, y_{ip}$; the first task in parametric (linear) FDA methods is to convert these values to a function y_i with values $y_i(t)$ computable for any desired argument value t. If the discrete values are assumed to be noiseless, then the process is interpolation; but if they have some observational error, then the conversion from discrete data to functions is a regression task (*e.g.*, smoothing) (Ramsay and Silverman, 2005).

A functional data model takes the form $y_i = f(x_i) + \epsilon_i$ where one or more of the components y_i, x_i and ϵ_i are functions. Three subcategories of such models can be distinguished: predictors x_i are functions and responses y_i are scalars; predictors are scalars and responses are functions; both predictors and responses are functions. In the latter case, which is the context we face, the function f is a compact operator between two infinite-dimensional Hilbert spaces. Most previous works on this model suppose that the relation between functional responses and predictors is linear; for more details, see Ramsay and Silverman (2005) and references therein.

For functional input and output data, the functional linear model commonly found in the literature is an extension of the multivariate linear one and has the following form:

$$y(t) = \alpha(t) + \beta(t)x(t) + \epsilon(t), \tag{4}$$

where α and β are the functional parameters of the model (Ramsay and Silverman, 2005, Chapter 14). This model is known as the "concurrent model" where "concurrent" means that $y(t)$ only depends on x at t. The concurrent model is similar to the varying coefficient model proposed by Hastie and Tibshirani (1993) to deal with the case where the parameter β of a multivariate regression model can vary over time. A main limitation of this model is that the response y and the covariate x are both functions of the same argument t, and the influence of a covariate on the response is concurrent or point-wise in the sense that x only influences $y(t)$ through its value $x(t)$ at time t. To overcome this restriction, an extended linear model in which the influence of a covariate x can involve a range of argument values $x(s)$ was proposed; it takes the following form:

$$y(t) = \alpha(t) + \int x(s)\beta(s,t)ds + \epsilon(t), \tag{5}$$

where, in contrast to the concurrent model, the functional parameter β is now a function of both s and t, and $y(t)$ depends on $x(s)$ for an interval of values of s (Ramsay and Silverman,

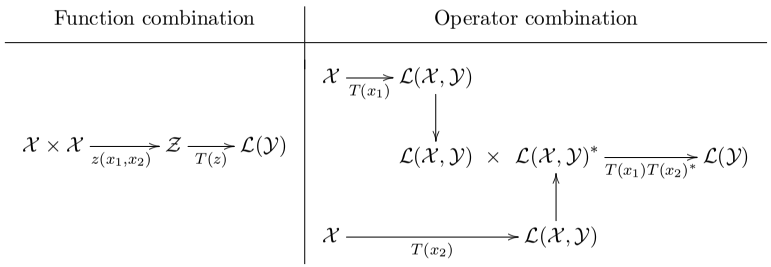

Figure 3: Illustration of building an operator-valued kernel from $\mathcal{X} \times \mathcal{X}$ to $\mathcal{L}(\mathcal{Y})$ using a combination of functions or a combination of operators. (left) The operator-valued kernel is constructed by combining two functions (x_1 and x_2) and by applying a positive $\mathcal{L}(\mathcal{Y})$-valued mapping T to the combination. (right) the operator-valued kernel is generated by combining two operators ($T(x_1)$ and $T(x_2)^*$) built from an $\mathcal{L}(\mathcal{X},\mathcal{Y})$-valued mapping T.

2005, Chapter 16). Estimation of the parameter function $\beta(\cdot,\cdot)$ is an inverse problem and requires regularization. Regularization can be implemented in a variety of ways, for example by penalized splines (James, 2002) or by truncation of series expansions (Müller, 2005). A review of functional response models can be found in Chiou et al. (2004).

The operators involved in the functional data models described above are the multiplication operator (Equation 4) and the integral operator (Equation 5). We think that operator-valued kernels constructed using these operators could be a valid alternative to extend linear FDA methods to nonlinear settings. In Subsection 5.4 we provide examples of multiplication and integral operator-valued kernels. Before that, we identify building schemes that can be common to many operator-valued kernels and applied to functional data.

5.2 Operator-valued Kernel Building Schemes

In our context, constructing an operator-valued kernel turns out to build an operator that maps a couple of functions to a function: in $\mathcal{X} \times \mathcal{X} \to \mathcal{L}(\mathcal{Y})$ from two functions x_1 and x_2 in $\mathcal{X}$. This can be performed in one of two ways: either combining the two functions x_1 and x_2 into a variable $z \in \mathcal{Z}$ and then adding an operator function $T : \mathcal{Z} \longrightarrow \mathcal{L}(\mathcal{Y})$ that performs the mapping from space $\mathcal{Z}$ to $\mathcal{L}(\mathcal{Y})$, or building an $\mathcal{L}(\mathcal{X},\mathcal{Y})$-valued function T, where $\mathcal{L}(\mathcal{X},\mathcal{Y})$ is the set of bounded operators from $\mathcal{X}$ to $\mathcal{Y}$, and then combining the resulting operators $T(x_1)$ and $T(x_2)$ to obtain the operator in $\mathcal{L}(\mathcal{Y})$. In the latter case, a natural way to combine $T(x_1)$ and $T(x_2)$ is to use the composition operation and the kernel $K(x_1,x_2)$ will be equal to $T(x_1)T(x_2)^*$. Figure 3 describes the construction of an operator-valued kernel function using the two schemes which are based on combining functions (x_1 and x_2) or operators ($T(x_1)$ and $T(x_2)$), respectively. Note that separable operator-valued kernels (Álvarez et al., 2012), which are kernels that can be formulated as a product of

a scalar-valued kernel function for the input space alone and an operator that encodes the interactions between the outputs, are a particular case of the function combination building scheme, when we take $\mathcal{Z}$ as the set of real numbers $\mathbb{R}$ and the scalar-valued kernel as combination function. In contrast, the operator combination scheme is particularly amenable to the design of nonseparable operator-valued kernels. This scheme was already used in various problems of operator theory, system theory and interpolation (Alpay et al., 1997; Dym, 1989).

To build an operator-valued kernel and then construct a function-valued reproducing kernel Hilbert space, the operator T is of crucial importance. Choosing T presents two major difficulties. Computing the adjoint operator is not always easy to do, and then, not all operators verify the Hermitian condition of the kernel. On the other hand, since the kernel must be nonnegative, we suggest to construct operator-valued kernels from positive definite scalar-valued kernels which can be the reproducing kernels of real-valued Hilbert spaces. In this case, the reproducing property of the operator-valued kernel allows us to compute an inner product in a space of operators by an inner product in a space of functions which can be, in turn, computed using the scalar-valued kernel. The operator-valued kernel allows the mapping between a space of functions and a space of operators, while the scalar one establishes the link between the space of functions and the space of measured values. It is also useful to define combinations of nonnegative operator-valued kernels that allow to build a new nonnegative one.

5.3 Combinations of Operator-valued Kernels

We have shown in Section 4 that there is a bijection between nonnegative operator-valued kernels and function-valued reproducing kernel Hilbert spaces. So, as in the scalar case, it will be helpful to characterize algebraic transformations, like sum and product, that preserve the nonnegativity of operator-valued kernels. Theorem 3 stated below gives some building rules to obtain a positive operator-valued kernel from combinations of positive existing ones. Similar results for the case of matrix-valued kernels can be found in Reisert and Burkhardt (2007), and for a more general context we refer the reader to Caponnetto et al. (2008) and Carmeli et al. (2010). In our setting, assuming H and G be two nonnegative kernels constructed as described in the previous subsection, we are interested in constructing a nonnegative kernel K from H and G.

Theorem 3 *Let $H : \mathcal{X} \times \mathcal{X} \longrightarrow \mathcal{L}(\mathcal{Y})$ and $G : \mathcal{X} \times \mathcal{X} \longrightarrow \mathcal{L}(\mathcal{Y})$ two nonnegative operator-valued kernels*

(i) *$K \equiv H + G$ is a nonnegative kernel,*

(ii) *if $H(w,z)G(w,z) = G(w,z)H(w,z)$, $\forall w, z \in \mathcal{X}$, then $K \equiv HG$ is a nonnegative kernel,*

(iii) *$K \equiv THT^*$ is a nonnegative kernel for any $\mathcal{L}(\mathcal{Y})$-valued function $T(\cdot)$.*

Proof: Obviously (i) follows from the linearity of the inner product. (ii) can be proved by showing that the "element-wise" multiplication of two positive block operator matrices can be positive (see below). For the proof of (iii), we observe that

$$K(w,z)^* = [T(z)H(w,z)T(w)^*]^* = T(w)H(z,w)T(z)^* = K(z,w),$$

and

$$\begin{aligned}\sum_{i,j}\langle K(w_i,w_j)u_i,u_j\rangle &= \sum_{i,j}\langle T(w_j)H(w_i,w_j)T(w_i)^*u_i,u_j\rangle \\ &= \sum_{i,j}\langle H(w_i,w_j)T(w_i)^*u_i, T(w_j)^*u_j\rangle,\end{aligned}$$

which implies the nonnegativity of the kernel K since H is nonnegative.

To prove (ii), i.e., the kernel $K \equiv HG$ is nonnegative in the case where H and G are nonnegative kernels such that $H(w,z)G(w,z) = G(w,z)H(w,z)$, $\forall w, z \in \mathcal{X}$, we show below that the block operator matrix $\mathbf{K}$ associated to the operator-valued kernel K for a given set $\{w_i\}, i = 1, \ldots, n$ with $n \in \mathbb{N}$, is positive. By construction, we have $\mathbf{K} = \mathbf{H} \circ \mathbf{G}$ where $\mathbf{H}$ and $\mathbf{G}$ are the block operator kernel matrices corresponding to the kernels H and G, and '$\circ$' denotes the "element-wise" multiplication defined by $(\mathbf{H} \circ \mathbf{G})_{ij} = H(w_i,w_j)G(w_i,w_j)$. $\mathbf{K}$, $\mathbf{H}$ and $\mathbf{G}$ are all in $\in \mathcal{L}(\mathcal{Y}^n)$.

Since the kernels H and G are Hermitian and $HG = GH$, it is easy to see that

$$\begin{aligned}(\mathbf{K}^*)_{ij} = (\mathbf{K}_{ji})^* = K(w_j,w_i)^* &= \big(H(w_j,w_i)G(w_j,w_i)\big)^* = G(w_j,w_i)^*H(w_j,w_i)^* \\ &= G(w_i,w_j)H(w_i,w_j) = H(w_i,w_j)G(w_i,w_j) \\ &= \mathbf{K}_{ij}.\end{aligned}$$

Thus, $\mathbf{K}$ is self-adjoint. It remains, then, to prove that $\langle \mathbf{Ku}, \mathbf{u}\rangle \geq 0$, $\forall \mathbf{u} \in \mathcal{Y}^n$, in order to show the positivity of $\mathbf{K}$.

The "element-wise" multiplication can be rewritten as a tensor product. Indeed, we have

$$\mathbf{K} = \mathbf{H} \circ \mathbf{G} = \mathbf{L}^*(\mathbf{H} \otimes \mathbf{G})\mathbf{L},$$

where $\mathbf{L} : \mathcal{Y}^n \longrightarrow \mathcal{Y}^n \otimes \mathcal{Y}^n$ is the mapping defined by $\mathbf{Le_i} = \mathbf{e_i} \otimes \mathbf{e_i}$ for an orthonormal basis $\{\mathbf{e_i}\}$ of the separable Hilbert space $\mathcal{Y}^n$, and $\mathbf{H} \otimes \mathbf{G}$ is the tensor product defined by $(\mathbf{H} \otimes \mathbf{G})(\mathbf{u} \otimes \mathbf{v}) = \mathbf{Hu} \otimes \mathbf{Gv}$, $\forall \mathbf{u}, \mathbf{v} \in \mathcal{Y}^n$. To see this, note that

$$\begin{aligned}\langle \mathbf{L}^*(\mathbf{H} \otimes \mathbf{G})\mathbf{Le_i}, \mathbf{e_j}\rangle = \langle (\mathbf{H} \otimes \mathbf{G})\mathbf{Le_i}, \mathbf{Le_j}\rangle &= \langle (\mathbf{H} \otimes \mathbf{G})(\mathbf{e_i} \otimes \mathbf{e_i}), \mathbf{e_j} \otimes \mathbf{e_j}\rangle \\ &= \langle \mathbf{He_i} \otimes \mathbf{Ge_i}, \mathbf{e_j} \otimes \mathbf{e_j}\rangle = \langle \mathbf{He_i}, \mathbf{e_j}\rangle\langle \mathbf{Ge_i}, \mathbf{e_j}\rangle \\ &= \mathbf{H}_{ij}\mathbf{G}_{ij} = \langle (\mathbf{H} \circ \mathbf{G})\mathbf{e_i}, \mathbf{e_j}\rangle.\end{aligned}$$

Now since H and G are positive, we have

$$\begin{aligned}\langle \mathbf{Ku}, \mathbf{u}\rangle &= \langle \mathbf{L}^*(\mathbf{H} \otimes \mathbf{G})\mathbf{Lu}, \mathbf{u}\rangle = \langle \mathbf{L}^*(\mathbf{H}^{\frac{1}{2}}\mathbf{H}^{\frac{1}{2}} \otimes \mathbf{G}^{\frac{1}{2}}\mathbf{G}^{\frac{1}{2}})\mathbf{Lu}, \mathbf{u}\rangle \\ &= \langle \mathbf{L}^*(\mathbf{H}^{\frac{1}{2}} \otimes \mathbf{G}^{\frac{1}{2}})(\mathbf{H}^{\frac{1}{2}} \otimes \mathbf{G}^{\frac{1}{2}})\mathbf{Lu}, \mathbf{u}\rangle = \langle (\mathbf{H}^{\frac{1}{2}} \otimes \mathbf{G}^{\frac{1}{2}})\mathbf{Lu}, (\mathbf{H}^{\frac{1}{2}} \otimes \mathbf{G}^{\frac{1}{2}})^*\mathbf{Lu}\rangle \\ &= \langle (\mathbf{H}^{\frac{1}{2}} \otimes \mathbf{G}^{\frac{1}{2}})\mathbf{Lu}, (\mathbf{H}^{\frac{1}{2}} \otimes \mathbf{G}^{\frac{1}{2}})\mathbf{Lu}\rangle = \|(\mathbf{H}^{\frac{1}{2}} \otimes \mathbf{G}^{\frac{1}{2}})\mathbf{Lu}\|^2 \geq 0.\end{aligned}$$

This concludes the proof. ■

5.4 Examples of Nonnegative Operator-valued Kernels

We provide here examples of operator-valued kernels for functional response data. All these examples deal with operator-valued kernels constructed following the schemes described above and assuming that $\mathcal{Y}$ is an infinite-dimensional function space. Motivated by building kernels suitable for functional data, the first two examples deal with operator-valued kernels constructed from the multiplication and the integral self-adjoint operators in the case where $\mathcal{Y}$ is the Hilbert space $L^2(\Omega_y)$ of square integrable functions on Ω_y endowed with the inner product $\langle \phi, \psi \rangle = \int_{\Omega_y} \phi(t)\psi(t)dt$. We think that these kernels represent an interesting alternative to extend linear functional models to nonlinear settings. The third example based on the composition operator shows how to build such kernels from non self-adjoint operators (this may be relevant when the functional linear model is based on a non self-adjoint operator). It also illustrates the kernel combination defined in Theorem 3(iii).

1. Multiplication operator:

   In Kadri et al. (2010), the authors attempted to extend the widely used Gaussian kernel to functional data domain using a multiplication operator and assuming that input and output data belong to the same space of functions. Here we consider a slightly different setting, where the input space $\mathcal{X}$ can be different from the output space $\mathcal{Y}$.

   A multiplication operator on $\mathcal{Y}$ is defined as follows:

$$\begin{array}{rccc} T^h: & \mathcal{Y} & \longrightarrow & \mathcal{Y} \\ & y & \longmapsto & T^h_y \;\; ; \;\; T^h_y(t) \triangleq h(t)y(t). \end{array}$$

   The operator-valued kernel $K(\cdot,\cdot)$ is the following:

$$\begin{array}{rccc} K: & \mathcal{X}\times\mathcal{X} & \longrightarrow & \mathcal{L}(\mathcal{Y}) \\ & x_1, x_2 & \longmapsto & k_x(x_1,x_2)T^{k_y}, \end{array}$$

   where $k_x(\cdot,\cdot)$ is a positive definite scalar-valued kernel and k_y a positive real function. It is easy to see that $\langle T^h x, y\rangle = \langle x, T^h y\rangle$, then T^h is a self-adjoint operator. Thus $K(x_2,x_1)^* = K(x_2,x_1)$ and K is Hermitian since $K(x_1,x_2) = K(x_2,x_1)$.

   Moreover, we have

$$\begin{aligned} \sum_{i,j}\langle K(x_i,x_j)y_i, y_j\rangle_{\mathcal{Y}} &= \sum_{i,j} k_x(x_i,x_j)\langle k_y(\cdot)y_i(\cdot), y_j(\cdot)\rangle_{\mathcal{Y}} \\ &= \sum_{i,j} k_x(x_i,x_j)\int k_y(t)y_i(t)y_j(t)dt = \int \sum_{i,j} y_i(t)[k_x(x_i,x_j)k_y(t)]y_j(t)dt \geq 0, \end{aligned}$$

   since the product of two positive-definite scalar-valued kernels is also positive-definite. Therefore K is a nonnegative operator-valued kernel.

2. Hilbert-Schmidt integral operator:

   A Hilbert-Schmidt integral operator on $\mathcal{Y}$ associated with a kernel $h(\cdot,\cdot)$ is defined as follows:

$$\begin{array}{rccc} T^h: & \mathcal{Y} & \longrightarrow & \mathcal{Y} \\ & y & \longmapsto & T^h_y \;\; ; \;\; T^h_y(t) \triangleq \int h(s,t)y(s)ds. \end{array}$$

   In this case, an operator-valued kernel K is a Hilbert-Schmidt integral operator associated with positive definite scalar-valued kernels k_x and k_y, and it takes the following form:

$$\begin{array}{rccc} K(x_1,x_2)[\cdot]: & \mathcal{Y} & \longrightarrow & \mathcal{Y} \\ & f & \longmapsto & g \end{array}$$

   where $g(t) = k_x(x_1,x_2)\int k_y(s,t)f(s)ds$.

   The Hilbert-Schmidt integral operator is self-adjoint if k_y is Hermitian. This condition is verified and then it is easy to check that K is also Hermitian. K is nonnegative since

$$\sum_{i,j}\langle K(x_i,x_j)y_i, y_j\rangle_{\mathcal{Y}} = \iint \sum_{i,j} y_i(s)[k_x(x_i,x_j)k_y(s,t)]y_j(t)dsdt,$$

   which is positive because of the positive-definiteness of the scalar-valued kernels k_x and k_y.

3. Composition operator:

   Let φ be an analytic map. The composition operator associated with φ is the linear map:

$$C_\varphi : f \longmapsto f\circ\varphi$$

   First, we look for an expression of the adjoint of the composition operator C_φ acting on $\mathcal{Y}$ in the case where $\mathcal{Y}$ is a scalar-valued RKHS of functions on Ω_y and φ an analytic map of Ω_y into itself. For any f in the space $\mathcal{Y}$ associated with the real kernel k,

$$\begin{array}{rcccc} \langle f, C^*_\varphi k_t(\cdot)\rangle & = & \langle C_\varphi f, k_t\rangle & = & \langle f\circ\varphi, k_t\rangle \\ & = & f(\varphi(t)) & = & \langle f, k_{\varphi(t)}\rangle. \end{array}$$

   This is true for any $f\in\mathcal{Y}$ and then $C^*_\varphi k_t = k_{\varphi(t)}$. In a similar way, $C^*_\varphi f$ can be computed at each point of the function f:

$$(C^*_\varphi f)(t) = \langle C^*_\varphi f, k_t\rangle = \langle f, C_\varphi k_t\rangle = \langle f, k_t\circ\varphi\rangle$$

   Once we have expressed the adjoint of a composition operator in a reproducing kernel Hilbert space, we consider the following operator-valued kernel:

$$\begin{array}{rccc} K: & \mathcal{X}\times\mathcal{X} & \longrightarrow & \mathcal{L}(\mathcal{Y}) \\ & x_1, x_2 & \longmapsto & C_{\psi(x_1)}C^*_{\psi(x_2)} \end{array}$$

   where $\psi(x_1)$ and $\psi(x_2)$ are maps of Ω_y into itself. It is easy to see that the kernel K is Hermitian. Using Theorem 3(iii) we obtain the nonnegativity property of the kernel.

5.5 Multiple Functional Data and Kernel Feature Map

Until now, we discussed operator-valued kernels and their corresponding RKHS from the perspective of extending Aronszajn (1950) pioneering work from scalar-valued or vector-valued cases to the function-valued case. However, it is also interesting to explore these kernels from a feature space point of view (Schölkopf et al., 1999; Caponnetto et al., 2008). In this subsection, we provide some ideas targeted at advancing the understanding of feature spaces associated with operator-valued kernels and we show how these kernels can design more suitable feature maps than those associated with scalar-valued kernels, especially when input data are infinite dimensional objects like curves. To explore the potential of adopting an operator-valued kernel feature space approach, we consider a supervised learning problem with multiple functional data where each observation is composed of more than one functional variable (Kadri et al., 2011b,c). Working with multiple functions allows to deal in a natural way with a lot of applications. There are many practical situations where a number of potential functional covariates are available to explain a response variable. For example, in audio and speech processing where signals are converted into different functional features providing information about their temporal, spectral and cepstral characteristics, or in meteorology where the interaction effects between various continuous variables (such as temperature, precipitation, and winds) is of particular interest.

Similar to the scalar case, operator-valued kernels provide an elegant way of dealing with nonlinear algorithms by reducing them to linear ones in some feature space F nonlinearly related to input space. A feature map associated with an operator-valued kernel K is a continuous function

$$\Phi : \mathcal{X} \times \mathcal{Y} \longrightarrow \mathcal{L}(\mathcal{X}, \mathcal{Y}),$$

such that for every $x_1, x_2 \in \mathcal{X}$ and $y_1, y_2 \in \mathcal{Y}$

$$\langle K(x_1, x_2)y_1, y_2\rangle_{\mathcal{Y}} = \langle \Phi(x_1, y_1), \Phi(x_2, y_2)\rangle_{\mathcal{L}(\mathcal{X},\mathcal{Y})},$$

where $\mathcal{L}(\mathcal{X}, \mathcal{Y})$ is the set of linear mappings from $\mathcal{X}$ into $\mathcal{Y}$. By virtue of this property, Φ is called a *feature map associated with* K. Furthermore, from the reproducing property, it follows that in particular

$$\langle K(x_1, \cdot)y_1, K(x_2, \cdot)y_2\rangle_{\mathcal{F}} = \langle K(x_1, x_2)y_1, y_2\rangle_{\mathcal{Y}},$$

which means that any operator-valued kernel admits a feature map representation Φ with a feature space $\mathcal{F} \subset \mathcal{L}(\mathcal{X}, \mathcal{Y})$ defined by $\Phi(x_1, y_1) = K(x_1, \cdot)y_1$, and corresponds to an inner product in another space.

From this feature map perspective, we study the geometry of a feature space associated with an operator-valued kernel and we compare it with the geometry obtained by a scalar-valued kernel. More precisely, we consider two reproducing kernel Hilbert spaces $\mathcal{F}$ and $\mathcal{H}$. $\mathcal{F}$ is a RKHS of function-valued functions on $\mathcal{X}$ with values in $\mathcal{Y}$. $\mathcal{X} \subset (L^2(\Omega_x))^p$ [7], $\mathcal{Y} \subset L^2(\Omega_y)$ and let K be the reproducing operator-valued kernel of $\mathcal{F}$. $\mathcal{H}$ is also a RKHS, but of scalar-valued functions on $\mathcal{X}$ with values in $\mathbb{R}$, and k its reproducing scalar-valued

7. p is the number of functions that represent input data. In the field of FDA, such data are called multivariate functional data.

kernel. The mappings Φ_K and Φ_k associated, respectively, with the kernels K and k are defined as follows

$$\Phi_K : (L^2)^p \to \mathcal{L}((L^2)^p, L^2), \quad x \mapsto K(x, \cdot)y,$$

and

$$\Phi_k : (L^2)^p \to \mathcal{L}((L^2)^p, \mathbb{R}), \quad x \mapsto k(x, \cdot).$$

These feature maps can be seen as a mapping of the input data x_i, which are vectors of functions in $(L^2)^p$, into a feature space in which the inner product can be computed using the kernel functions. This idea leads to design nonlinear methods based on linear ones in the feature space. In a supervised classification problem for example, since kernels map input data into a higher dimensional space, kernel methods deal with this problem by finding a linear separation in the feature space. We now compare the dimension of feature spaces obtained by the maps Φ_K and Φ_k. To do this, we adopt a functional data analysis point of view where observations are composed of sets of functions. Direct understanding of this FDA viewpoint comes from the consideration of the "atom" of a statistical analysis. In a basic course in statistics, atoms are "numbers", while in multivariate data analysis the atoms are vectors and methods for understanding populations of vectors are the focus. FDA can be viewed as the generalization of this, where the atoms are more complicated objects, such as curves, images or shapes represented by functions (Zhao et al., 2004). Based on this, the dimension of the input space is p since $x_i \in (L^2)^p$ is a vector of p functions. The feature space obtained by the map Φ_k is a space of functions, so its dimension from a FDA viewpoint is equal to one. The map Φ_K projects the input data into a space of operators $\mathcal{L}(\mathcal{X}, \mathcal{Y})$. This means that using the operator-valued kernel K corresponds to mapping the functional data x_i into a higher, possibly infinite, dimensional space $(L^2)^d$ with $d \to \infty$. In a binary functional classification problem, we have higher probability to achieve linear separation between the classes by projecting the functional data into a higher dimensional feature space rather than into a lower one (Cover's theorem), that is why we think that it is more suitable to use operator-valued than scalar-valued kernels in this context.

6. Function-valued Function Learning

In this section, we consider the problem of estimating an unknown function F such that $F(x_i) = y_i$ when observed data $(x_i(s), y_i(t))_{i=1}^n \in \mathcal{X} \times \mathcal{Y}$ are assumed to be elements of the space of square integrable functions L^2. $X = \{x_1, \ldots, x_n\}$ denotes the training set with corresponding targets $Y = \{y_1, \ldots, y_n\}$. Since $\mathcal{X}$ and $\mathcal{Y}$ are spaces of functions, the problem can be thought of as an operator estimation problem, where the desired operator maps a Hilbert space of factors to a Hilbert space of targets. Among all functions in a linear space of operators $\mathcal{F}$, an estimate $\widetilde{F} \in \mathcal{F}$ of F may be obtained by minimizing:

$$\widetilde{F} = \arg\min_{F \in \mathcal{F}} \sum_{i=1}^{n} \|y_i - F(x_i)\|_{\mathcal{Y}}^2.$$

Depending on $\mathcal{F}$, this problem can be ill-posed and a classical way to turn it into a well-posed problem is to use a regularization term. Therefore, we may consider the solution of

the problem as the function $\widetilde{F} \in \mathcal{F}$ that minimizes:

$$\widetilde{F}_\lambda = \arg\min_{F\in\mathcal{F}} \sum_{i=1}^{n} \|y_i - F(x_i)\|_{\mathcal{Y}}^2 + \lambda \|F\|_{\mathcal{F}}^2, \tag{6}$$

where $\lambda \in \mathbb{R}^+$ is a regularization parameter. Existence of $\widetilde{F}_\lambda$ in the optimization problem (6) is guaranteed for $\lambda > 0$ by the generalized Weierstrass theorem and one of its corollary that we recall from Kurdila and Zabarankin (2005).

Theorem 4 *Let $\mathcal{Z}$ be a reflexive Banach space and $\mathcal{C} \subseteq \mathcal{Z}$ a weakly closed and bounded set. Suppose $J : \mathcal{C} \to \mathbb{R}$ is a proper lower semi-continuous function. Then J is bounded from below and has a minimizer on $\mathcal{C}$.*

Corollary 5 *Let $\mathcal{H}$ be a Hilbert space and $J : \mathcal{H} \to \mathbb{R}$ is a strongly lower semi-continuous, convex and coercive function. Then J is bounded from below and attains a minimizer.*

This corollary can be straightforwardly applied to problem (6) by defining:

$$J_\lambda(F) = \sum_{i=1}^{n} \|y_i - F(x_i)\|_{\mathcal{Y}}^2 + \lambda \|F\|_{\mathcal{F}}^2,$$

where F belongs to the Hilbert space $\mathcal{F}$. It is easy to note that J_λ is continuous and convex. Besides, J_λ is coercive for $\lambda > 0$ since $\|F\|_{\mathcal{F}}^2$ is coercive and the sum involves only positive terms. Hence $\widetilde{F}_\lambda = \arg\min_{F\in\mathcal{F}} J_\lambda(F)$ exists.

6.1 Learning Algorithm

We are now interested in solving the minimization problem (6) in a reproducing kernel Hilbert space $\mathcal{F}$ of function-valued functions. In the scalar case, it is well-known that under general conditions on real-valued RKHS, the solution of this minimization problem can be written as:

$$\widetilde{F}(x) = \sum_{i=1}^{n} \alpha_i k(x_i, x),$$

where $\alpha_i \in \mathbb{R}$ and k is the reproducing kernel of a real-valued Hilbert space (Wahba, 1990). An extension of this solution to the domain of functional data analysis takes the following form:

$$\widetilde{F}(\cdot) = \sum_{i=1}^{n} K(x_i, \cdot) u_i, \tag{7}$$

where $u_i(\cdot)$ are in $\mathcal{Y}$ and the reproducing kernel K is a nonnegative operator-valued function. With regards to the classical representer theorem, here the kernel K outputs an operator and the "weights" u_i are functions. A proof of the representer theorem in the case of function-valued reproducing kernel Hilbert spaces is given in Appendix B (see also Micchelli and Pontil, 2005a).

Substituting (7) in (6) and using the reproducing property of $\mathcal{F}$, we come up with the following minimization problem over the scalar-valued functions $u_i \in \mathcal{Y}$ ($\mathbf{u}$ is the vector of functions $(u_i)_{i=1,\ldots,n} \in (\mathcal{Y})^n$) rather than the function-valued function (or operator) F:

$$\widetilde{\mathbf{u}}_\lambda = \arg\min_{\mathbf{u}\in(\mathcal{Y})^n} \sum_{i=1}^{n} \|y_i - \sum_{j=1}^{n} K(x_i, x_j) u_j\|_{\mathcal{Y}}^2 + \lambda \sum_{i,j}^{n} \langle K(x_i, x_j) u_i, u_j \rangle_{\mathcal{Y}}. \tag{8}$$

Problem (8) can be solved in three ways:

1. Assuming that the observations are made on a regular grid $\{t_1, \ldots, t_m\}$, one can first discretize the functions x_i and y_i and then solve the problem using multivariate data analysis techniques (Kadri et al., 2010). However, as this is well-known in the FDA domain, this has the drawback of not taking into consideration the relationships that exist between samples.

2. The second way consists in considering the output space $\mathcal{Y}$ to be a scalar-valued reproducing Hilbert space. In this case, the functions u_i can be approximated by a linear combination of a scalar-valued kernel $\hat{u}_i = \sum_{l=1}^{m} \alpha_{il} k(s_l, \cdot)$ and then the problem (8) becomes a minimization problem over the real values α_{il} rather than the discrete values $u_i(t_1), \ldots, u_i(t_m)$. In the FDA literature, a similar idea has been adopted by Ramsay and Silverman (2005) and by Prchal and Sarda (2007) who expressed not only the functional parameters u_i but also the observed input and output data in a basis functions specified a priori (*e.g.*, Fourier basis or B-spline basis).

3. Another possible way to solve the minimization problem (8) is to compute its derivative using the directional derivative and setting the result to zero to find an analytic solution of the problem. It follows that the vector of functions $\mathbf{u} \in \mathcal{Y}^n$ satisfies the system of linear operator equations:

$$(\mathbf{K} + \lambda I)\mathbf{u} = \mathbf{y}, \tag{9}$$

where $\mathbf{K} = [K(x_i, x_j)]_{i,j=1}^n$ is a $n \times n$ block operator kernel matrix ($\mathbf{K}_{ij} \in \mathcal{L}(\mathcal{Y})$) and $\mathbf{y} \in \mathcal{Y}^n$ the vector of functions $(y_i)_{i=1}^n$. In this work, we are interested in this third approach which extends to functional data analysis domain results and properties known from multivariate statistical analysis. One main obstacle for this extension is the inversion of the block operator kernel matrix $\mathbf{K}$. Block operator matrices generalize block matrices to the case where the block entries are linear operators between infinite dimensional Hilbert spaces. These matrices and their inverses arise in some areas of mathematics (Tretter, 2008) and signal processing (Asif and Moura, 2005). In contrast to the multivariate case, inverting such matrices is not always feasible in infinite dimensional spaces. To overcome this problem, we study the eigenvalue decomposition of a class of block operator kernel matrices obtained from operator-valued kernels having the following form:

$$K(x_i, x_j) = g(x_i, x_j) T, \quad \forall x_i, x_j \in \mathcal{X}, \tag{10}$$

where g is a scalar-valued kernel and T is an operator in $\mathcal{L}(\mathcal{Y})$. This separable kernel construction is adapted from Micchelli and Pontil (2005a,b). The choice of T depends

on the context. For multi-task kernels, T is a finite dimensional matrix which models relations between tasks. In FDA, Lian (2007) suggested the use of the identity operator, while in Kadri et al. (2010) the authors showed that it is better to choose other operators than identity to take into account functional properties of the input and output spaces. They introduced a functional kernel based on the multiplication operator. In this work, we are more interested in kernels constructed from the integral operator. This seems to be a reasonable choice since functional linear model (see Equation 5) are based on this operator (Ramsay and Silverman, 2005, Chapter 16). So we can consider for example the following positive definite operator-valued kernel:

$$(K(x_i, x_j)y)(t) = g(x_i, x_j) \int_{\Omega_y} e^{-|t-s|} y(s) ds, \tag{11}$$

where $y \in \mathcal{Y} = L^2(\Omega_y)$ and $\{s, t\} \in \Omega_y = [0, 1]$. Note that a similar kernel was proposed as an example in Caponnetto et al. (2008) for linear spaces of functions from $\mathbb{R}$ to $\mathcal{G}_y$.

The $n \times n$ block operator kernel matrix $\mathbf{K}$ of operator-valued kernels having the form (10) can be expressed as a Kronecker product between the Gram matrix $G = \big(g(x_i, x_j)\big)_{i,j=1}^{n}$ in $\mathbb{R}^{n \times n}$ and the operator $T \in \mathcal{L}(\mathcal{Y})$, and is defined as follows:

$$\mathbf{K} = \begin{pmatrix} g(x_1, x_1)T & \dots & g(x_1, x_n)T \\ \vdots & \ddots & \vdots \\ g(x_n, x_1)T & \dots & g(x_n, x_n)T \end{pmatrix} = G \otimes T.$$

It is easy to show that basic properties of the Kronecker product between two finite matrices can be restated for this case. So, $\mathbf{K}^{-1} = G^{-1} \otimes T^{-1}$ and the eigendecomposition of the matrix $\mathbf{K}$ can be obtained from the eigendecompositions of G and T (see Algorithm 1).

Theorem 6 *If $T \in \mathcal{L}(\mathcal{Y})$ is a compact, normal operator ($TT^* = T^*T$) on the Hilbert space $\mathcal{Y}$, then there exists an orthonormal basis of eigenfunctions $\{\phi_i, i \geq 1\}$ corresponding to eigenvalues $\{\lambda_i, i \geq 1\}$ such that*

$$Ty = \sum_{i=1} \lambda_i \langle y, \phi_i \rangle \phi_i, \quad \forall y \in \mathcal{Y}.$$

Proof: See Naylor and Sell (1971)[theorem 6.11.2] ■

Let θ_i and $\mathbf{z_i}$ be, respectively, the eigenvalues and the eigenfunctions of $\mathbf{K}$. From Theorem 6 it follows that the inverse operator $\mathbf{K}^{-1}$ is given by

$$\mathbf{K}^{-1}\mathbf{c} = \sum_i \theta_i^{-1} \langle \mathbf{c}, \mathbf{z_i} \rangle \mathbf{z_i}, \quad \forall \mathbf{c} \in \mathcal{Y}^n.$$

Now we are able to solve the system of linear operator equations (9) and the functions u_i can be computed from eigenvalues and eigenfunctions of the matrix $\mathbf{K}$, as described in Algorithm 1.

Algorithm 1 L^2-Regularized Function-valued Function Learning Algorithm

Input
Examples:
(function) data $x_i \in (L^2([0,1]))^p$, size n
(function) labels $y_i \in L^2([0,1])$, size n
Parameters: g, T, κ, λ
Eigendecomposition of G, the Gram matrix of the scalar-valued kernel g
Comment: $G = g(x_i, x_j)_{i,j=1}^{n} \in \mathbb{R}^{n \times n}$
Let $\alpha_i \in \mathbb{R}$ the n eigenvalues
Let $v_i \in \mathbb{R}^n$ the n eigenvectors
Eigendecomposition of the operator $T \in \mathcal{L}(Y)$
Choose κ, the number of computed eigenfunctions
Compute κ $(\delta_i \in \mathbb{R}, w_i \in L^2([0,1]))$ pairs of (eigenvalue, eigenfunction)
Eigendecomposition of $\mathbf{K} = G \otimes T$
Comment: $\mathbf{K} = K(x_i, x_j)_{i,j=1}^{n} \in (\mathcal{L}(Y))^{n \times n}$
The eigenvalues $\theta_i \in \mathbb{R}$, size $n \times \kappa$, are obtained as: $\theta = \alpha \otimes \delta$
The eigenfunctions $\mathbf{z_i} \in (L^2([0,1]))^n$, size $n \times \kappa$, are obtained as: $\mathbf{z} = v \otimes w$
Solution of problem (8) $\mathbf{u} = (\mathbf{K} + \lambda I)^{-1}\mathbf{y}$
Initialize λ: regularization parameter
$\mathbf{u} = \sum_{i=1}^{n \times \kappa} [(\theta_i + \lambda)^{-1} \sum_{j=1}^{n} \langle z_{ij}, y_j \rangle \mathbf{z}_i]$

To put our algorithm into context, we remind that a crucial question about the applicability of functional data is how one can find an appropriate space and a basis in which the functions can be decomposed in a computationally feasible way while taking into account the functional nature of the data. This is exactly what Algorithm 1 does. In contrast to parametric FDA methods, the basis function here is not fixed in advance but implicitly defined by choosing a *reproducing operator-valued kernel* acting on both input and output data. The spectral decomposition of the block operator kernel matrix naturally allows the assignment of an appropriate basis function to the learning process for representing input and output functions. Moreover, the formulation is flexible enough to be used with different operators and then to be adapted for various applications involving functional data. Also, in the context of nonparametric FDA where the notion of semi-metric plays an important role in modeling functional data, we note that Algorithm 1 is based on computing and choosing a finite number of eigenfunctions. This is strongly related to the semi-metric building scheme in Ferraty and Vieu (2006) which is based on, for example, functional principal components or successive derivatives. Operator-valued kernels constructed from the covariance operator (Kadri et al., 2013b) or the derivative operator will allow to design semi-metrics similar to those just mentioned. In this sense, the eigendecomposition of the block operator kernel matrix offers a new way of producing semi-metrics.

6.2 Generalization Analysis

Here, we provide an analysis of the generalization error of the function-valued function learning model (6) using the notion of algorithmic stability. For more details and results

with the least squares loss and other loss function (including ϵ-sensitive loss and logistic loss), see Audiffren and Kadri (2013). In the case of vector-valued functions, the effort in this area has already produced several successful results, including Baxter (2000), Ando and Zhang (2005), Maurer (2006), and Maurer and Pontil (2013). Yet, these studies have considered only the case of finite-dimensional output spaces, and have focused rather on linear machines than on nonlinear ones. To our knowledge, the first work investigating the generalization performance of nonlinear vector-valued function learning methods when output spaces can be infinite-dimensional is that of Caponnetto and De Vito (2006). In their study, from a theoretical analysis based on the concept of effective dimension, the authors have derived generalization bounds for the learning model (6) when the hypothesis space is an RKHS with operator-valued kernels.

The convergence rates in Caponnetto and De Vito (2006), although optimal in the case of finite-dimensional output spaces, require assumptions on the kernel that can be restrictive in the infinite-dimensional case. Indeed, their proof depends upon the fact that the trace of the operator $K(x,x)$ is finite (K is the operator-valued kernel function), and this restricts the applicability of their results when the output space is infinite-dimensional. To illustrate this, let us consider the identity operator-valued kernel $K(\cdot,\cdot) = k(\cdot,\cdot)I$, where k is a scalar-valued kernel and I is the identity operator. This simple kernel does not satisfy the finite trace condition and therefore the results of Caponnetto and De Vito (2006) cannot be applied in this case. Regarding the examples of operator-valued kernels given in Subsection 5.4, the kernel built from the integral operator satisfies the finite trace condition, while that based on the multiplication operator does not. To address this issue, we first show that our learning algorithm is uniformly stable, and then we derive under mild assumption on the kernel, using a result from Bousquet and Elisseeff (2002), a generalization bound which holds even when the finite trace condition is not satisfied.

We now state and discuss the main assumptions we need to prove a stability-based bound on the generalization error of our method. In the following, we consider a training set $Z = \{(x_1, y_1), ..., (x_n, y_n)\}$ of size n in $\mathcal{X} \times \mathcal{Y}$ drawn i.i.d. from an unknown distribution P, and we denote by $Z^i = Z \setminus (x_i, y_i)$ the set Z from which the couple (x_i, y_i) is removed. We will use a cost function $c : \mathcal{Y} \times \mathcal{Y} \to \mathbb{R}_+$. The loss of an hypothesis F with respect to an example (x, y) is then defined as $\ell(y, F, x) = c(F(x), y)$. The generalization error is defined as:

$$R(F) = \int \ell(y, F(x), x) dP(x, y),$$

and the empirical error as:

$$R_{emp}(F, Z) = \frac{1}{n} \sum_{i=1}^{n} \ell(y_i, F, x_i).$$

A learning algorithm can be viewed as a function which maps a training set Z onto a function F_Z from $\mathcal{X}$ to $\mathcal{Y}$ (Bousquet and Elisseeff, 2002). In our case, F_Z is the solution of the optimization problem (6) which is an instance of the following scheme

$$F_Z = \arg\min_{F \in \mathcal{F}} R_{reg}(F, Z), \tag{12}$$

where $R_{reg}(F, Z) = R_{emp}(F, Z) + \lambda \|F\|^2_{\mathcal{F}}$.

Assumption 1 *$\exists \kappa > 0$ such that $\forall x \in \mathcal{X}$,*

$$\|K(x,x)\|_{op} \leq \kappa^2,$$

where $\|K(x,x)\|_{op} = \sup_{y \in \mathcal{Y}} \frac{\|K(x,x)y\|_{\mathcal{Y}}}{\|y\|_{\mathcal{Y}}}$ is the operator norm of $K(x,x)$ on $L(\mathcal{Y})$.

Assumption 2 *The real function from $\mathcal{X} \times \mathcal{X} \to \mathbb{R}$*

$$(x_1, x_2) \mapsto \langle K(x_1, x_2)y_1, y_2 \rangle_{\mathcal{Y}} \text{ is measurable } \forall y_1, y_2 \in \mathcal{Y}.$$

Assumption 3 *The application $(y, f, x) \mapsto \ell(y, F, x)$ is σ-admissible, i.e. convex with respect to F and Lipschitz continuous with respect to $F(x)$, with σ its Lipschitz constant.*

Assumption 4 *$\exists \xi > 0$ such that $\forall (x, y) \in \mathcal{X} \times \mathcal{Y}$ and $\forall Z$ a training set,*

$$\ell(y, F_Z, x) \leq \xi.$$

Note that Assumption 1 is a direct extension from the scalar-valued to the operator-valued case of the boundedness condition of the kernel function. It replaces and weakens the finite trace assumption of the operator $K(x,x)$ used in Caponnetto and De Vito (2006); see Remark 1 for more details. Assumption 2 was also used by Caponnetto and De Vito (2006) to avoid problems with measurability. This assumption with the fact that $\mathcal{F}$ is separable ensures that all functions in $\mathcal{F}$ are measurable from $\mathcal{X}$ to $\mathcal{Y}$. Assumptions 3 and 4 are the same as those used by Bousquet and Elisseeff (2002) for learning scalar-valued functions. As a consequence of Assumption 1, we immediately obtain the following elementary lemma which allows to control $\|F(x)\|_{\mathcal{Y}}$ with $\|F\|_{\mathcal{F}}$.

Lemma 1 *Let K be a nonnegative operator-valued kernel satisfying Assumption 1. Then $\forall F \in \mathcal{F}$, $\|F(x)\|_{\mathcal{Y}} \leq \kappa \|F\|_{\mathcal{F}}$.*

Proof:

$$\begin{aligned}
\|F(x)\|_{\mathcal{Y}} &= \sup_{\|y\|=1} |\langle F(x), y \rangle_{\mathcal{Y}}| = \sup_{\|y\|=1} |\langle F(\cdot), K(x,\cdot)y \rangle_{\mathcal{F}}| \\
&\leq \|F(\cdot)\|_{\mathcal{F}} \sup_{\|y\|=1} \|K(x,\cdot)y\|_{\mathcal{F}} \leq \|F(\cdot)\|_{\mathcal{F}} \sup_{\|y\|=1} \sqrt{\langle K(x,x)y, y \rangle_{\mathcal{Y}}} \\
&\leq \|F(\cdot)\|_{\mathcal{F}} \sup_{\|y\|=1} \|K(x,x)y\|^{\frac{1}{2}}_{\mathcal{Y}} \leq \|F(\cdot)\|_{\mathcal{F}} \|K(x,x)\|^{\frac{1}{2}}_{op} \leq \kappa \|F\|_{\mathcal{F}}
\end{aligned}$$

■

Now we are ready to state the stability theorem for our function-valued function learning algorithm. This result is a straightforward extension of Theorem 22 in Bousquet and Elisseeff (2002) to the case of infinite-dimensional output spaces. It is worth pointing out that the proof does not differ much from the scalar-valued case and requires only minor modifications to fit the operator-valued kernel approach. For the convenience of the reader, we present in Appendix C the proof taking into account these modifications. Before stating the theorem we would like to recall the definition of uniform algorithmic stability from Bousquet and Elisseeff (2002).

Definition 6 *A learning algorithm $Z \mapsto F_Z$ has uniform stability β with respect to the loss function ℓ if the following holds*

$$\forall n \geq 1,\ \forall 1 \leq i \leq n,\ \forall Z \text{ a training set},\ \ \|\ell(\cdot, F_Z, \cdot) - \ell(\cdot, F_{Z^i}, \cdot)\|_\infty \leq \beta$$

Theorem 7 *Under Assumptions 1, 2 and 3, a learning algorithm that maps a training set Z to the function F_Z defined in (12) is β stable with*

$$\beta = \frac{\sigma^2 \kappa^2}{2\lambda n}.$$

Proof: See Appendix C. ■

β scales as $1/n$. This allows to get a bound on the generalization error using a result from Bousquet and Elisseeff (2002).

Theorem 8 *Let $Z \mapsto F_Z$ be a learning algorithm with uniform stability β with respect to a loss ℓ that satisfies Assumption 4. Then, $\forall n \geq 1$, $\forall\ 0 \leq \delta \leq 1$, the following bound holds with probability at least $1 - \delta$ over the random draw of training samples*

$$R \leq R_{emp} + 2\beta + (4n\beta + \xi)\sqrt{\frac{\ln(1/\delta)}{2n}}.$$

Proof: See Theorem 12 in Bousquet and Elisseeff (2002). ■

For our learning model (6), we should note that Assumption 3 is in general not satisfied with the least squares loss function $\ell(y, F, x) = \|y - F(x)\|^2_{\mathcal{Y}}$. To address this issue, one can add a boundedness assumption on $\mathcal{Y}$, which is a sufficient condition to prove the uniform stability when Assumption 1 is satisfied.

Assumption 5 *$\exists \sigma_y > 0$ such that $\|y\|_{\mathcal{Y}} < \sigma_y$, $\forall y \in \mathcal{Y}$.*

Lemma 2 *Let $\ell(y, F, x) = \|y - F(x)\|^2_{\mathcal{Y}}$. If Assumptions 1 and 5 hold, then*

$$|\ell(y, F_Z, x) - \ell(y, F_{Z^i}, x)| \leq \sigma \|F_Z(x) - F_{Z^i}(x)\|_{\mathcal{Y}},$$

with $\sigma = 2\sigma_y(1 + \frac{\kappa}{\sqrt{\lambda}})$.

Proof: See Appendix D. ■

This Lemma can replace the Lipschitz property of ℓ in the proof of Theorem 7. Moreover, Assumptions 1 and 5 are sufficient to satisfy Assumption 4 with $\xi = (\sigma/2)^2$ (see Appendix D). We can then use Theorem 7 to prove the uniform stability of our function-valued function learning algorithm with

$$\beta = \frac{2\kappa^2 \sigma_y^2 (1 + \frac{\kappa}{\sqrt{\lambda}})^2}{\lambda n}.$$

Theorem 8 thus gives us a bound on the generalization error of our method equal, with probability at least $1 - \delta$, to

$$R \leq R_{emp} + \frac{4\kappa^2 \sigma_y^2 (1 + \frac{\kappa}{\sqrt{\lambda}})^2}{\lambda n} + \sigma_y^2 (1 + \frac{\kappa}{\sqrt{\lambda}})^2 (\frac{8\kappa^2}{\lambda} + 1)\sqrt{\frac{\ln(1/\delta)}{2n}}.$$

Remark 1 *It is important to stress that even though the stability analysis of function-valued function learning algorithms follows in a quite straightforward fashion from the earlier results presented in Bousquet and Elisseeff (2002) and provides convergence rates which are not optimal, it allows to derive generalization error bounds with operator-valued kernels for which the trace of the operator $K(x, x)$ is not necessarily finite. Assumption 1 is weaker than the one used in Caponnetto and De Vito (2006) which requires that the operator K_x is Hilbert-Schmidt[8] and $\sup_{x \in \mathcal{X}} Tr(K(x, x)) < \kappa$. While the two assumptions are equivalent when the output space $\mathcal{Y}$ is finite dimensional, this is no longer the case when, as in this paper, $\dim \mathcal{Y} = +\infty$. Moreover, we observe that if the assumption of Caponnetto and De Vito (2006) is satisfied, then our Assumption 1 holds (see proof in Appendix E). The converse is not true (see Remark 2 for a counterexample).*

Remark 2 *Note that the operator-valued kernel based on the multiplication operator and described in Subsection 5.4 satisfies Assumption 1 but not the finite trace condition as assumed in Caponnetto and De Vito (2006). Let k be a positive-definite scalar-valued kernel such that $\sup_{x \in \mathcal{X}} k(x, x) < +\infty$, $\mathcal{I}$ an interval of $\mathbb{R}$, $\mu > 0$, and $\mathcal{Y} = L^2(\mathcal{I}, \mathbb{R})$. Let $f \in L^\infty(\mathcal{I}, \mathbb{R})$ be such that $\|f\|_\infty < \mu$. Consider the following multiplication operator-valued kernel K:*

$$K(x, z)y(\cdot) = k(x, z) f^2(\cdot) y(\cdot) \in \mathcal{Y}.$$

K is a nonnegative operator-valued kernel. While K always satisfies Assumption 1, the Hilbert-Schmidt property of K_x depends on the choice of f and does not hold in general. For instance, let $f(t) = \frac{\mu}{2}(\exp(-t^2) + 1)$, then

$$\|K(x, x)\|_{op} \leq \mu^2 k(x, x),$$

and

$$Tr(K(x, x)) = \sum_{j \in \mathbb{N}} \langle K(x, x) y_j, y_j \rangle \geq k(x, x) \frac{\mu}{2} \sum_{i \in \mathbb{N}} \|y_j\|_2^2 = \infty,$$

where $(y_j)_{j \in \mathbb{N}}$ is an orthonormal basis of $\mathcal{Y}$ (which exists since $\mathcal{Y}$ is separable).

7. Experiments

In this experimental section, we essentially aim at illustrating the potential of adopting a functional data analysis perspective for learning multi-output functions when the data are curves. First, we are interested in the problem of acoustic-to-articulatory speech inversion where the goal is to learn vocal tract (VT) time functions from the acoustic speech signal (Mitra et al., 2010). Then we show, through experiments on sound recognition (Rabaoui et al., 2008), that the proposed framework can be applied beyond functional response regression, for problems like multiple functional classification where each sound to be classified is represented by more than one functional parameters.

8. The operator K_x from $\mathcal{Y}$ to $\mathcal{F}$, defined by $y \mapsto K(x, \cdot)y$, $\forall y \in \mathcal{Y}$, is a Hilbert-Schmidt operator if, for some any basis $(y_j)_{j \in \mathbb{N}}$ of $\mathcal{Y}$, it holds that $Tr(K_x^* K_x) = \sum_j \langle K(x, \cdot)y_j, K(x, \cdot)y_j \rangle_{\mathcal{F}} < +\infty$. This is equivalent to saying that the operator $K(x, x) \in \mathcal{L}(\mathcal{Y})$ is of trace class, since by the reproducing property we have $\langle K(x, \cdot)y_j, K(x, \cdot)y_j \rangle = \langle K(x, x)y_j, y_j \rangle_{\mathcal{Y}}$.

The operator-valued kernel used in these experiments is the kernel K defined by Equation (11). We use the inner product in $\mathcal{X}^p$ for the scalar-valued kernel g, where p is the number of functional parameters of a speech or a sound signal. Also, extending real-valued functional kernel, as in Rossi and Villa (2006), to multiple functional inputs could be possible. Eigenvalues δ_i and eigenfunctions w_i of the Hilbert-Schmidt integral operator T associated with the operator-valued kernel K are equal to $\frac{2}{1+\mu_i^2}$ and $\mu_i \cos(\mu_i x) + \sin(\mu_i x)$ respectively, where μ_i are solutions of the equation $\cot \mu = \frac{1}{2}(\mu - \frac{1}{\mu})$. Eigendecomposition of an infinite dimensional operator T is computed in general by solving a differential equation obtained from the equality $Tw_i = \delta_i w_i$.

In order to choose the regularization parameter λ and the number of eigenfunctions κ that guarantee optimal solutions, one may use the cross-validation score based on the one-curve-leave-out prediction error (Rice and Silverman, 1991). Then we choose λ and κ so as to minimize the cross-validation score based on the squared prediction error

$$CV(\lambda) = \sum_{i=1}^{n} \sum_{j=1}^{N_i} \{y_{ij} - \hat{y}_i^{(-i)}(t_{ij})\}^2, \tag{13}$$

where n is the number of functions y_i, y_{ij} is the observed value at time t_{ij}, N_i the number of measurements made on y_i and $\hat{y}_i^{(-i)}$ the predicted curve for the i^{th} function, computed after removing the data for this function.

7.1 Speech Inversion

The problem of speech inversion has received increasing attention in the speech processing community in the recent years (see Schroeter and Sondhi (1994); Mitra et al. (2010); Kadri et al. (2011a) and references therein). This problem, aka acoustic-articulatory inversion, involves inverting the forward process of speech production (see Figure 4). In other words, for a given acoustic speech signal we aim at estimating the underlying sequence of articulatory configurations which produced it (Richmond, 2002). Speech inversion is motivated by several applications in which it is required to estimate articulatory parameters from the acoustic speech signal. For example, in speech recognition, the use of articulatory information has been of interest since speech recognition efficiency can be significantly improved (Kirchoff, 1999). This is due to the fact that automatic speech recognition (ASR) systems suffer from performance degradation in the presence of noise and spontaneous speech. Moreover, acoustic-to-articulatory speech inversion is also useful in many other interesting applications such as speech analysis and synthesis (Toda et al., 2004) or helping individuals with speech and hearing disorders by providing visual feedback (Toutios and Margaritis, 2005).

Most of current research on acoustic-to-articulatory inversion focuses on learning Electromagnetic Articulography (EMA) trajectories from acoustic parameters and frequently uses the MOCHA `fsew0` data set as training and test data (Richmond, 2002). In a recent work, Mitra et al. (2010) suggest the use of the TAsk Dynamics Application (TADA) model (Nam et al., 2004) to generate acoustic-articulatory database which contains synthetic speech and the corresponding vocal tract time functions. Their results show that tract variables can be better candidates than EMA trajectories for articulatory feature based ASR systems. In our experiments, we follow this work by addressing the issue of

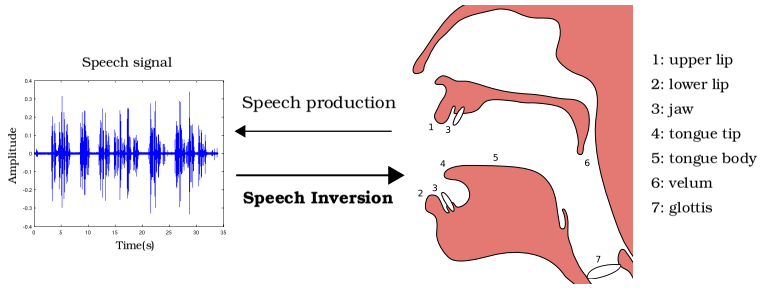

Figure 4: Principle of speech inversion (a.k.a. acoustic-articulatory inversion). Human beings produce an audible speech signal by moving their articulators (*e.g.* tongue, lips, velum, etc.) to modify a source of sound energy in the vocal tract. In performing the inversion mapping, we aim to invert this forward direction of speech production. In other words, we aim to take a speech signal and estimate the underlying articulatory movements which are likely to have created it (Richmond, 2002).

finding the mapping between acoustic parameters and vocal tract variables. In this context, we use Mel-Frequency Cepstral Coefficients (MFCCs) as input and consider as output eight different vocal tract constriction variables, lip aperture (LA), lip protrusion (LP), tongue tip constriction degree (TTCD), tongue tip constriction location (TTCL), tongue body constriction degree (TBCD), tongue body constriction location (TBCL), Velum (VEL) and Glottis (GLO). Table 2 shows the eight vocal tract variables we used in this study and the corresponding constriction organs and articulators (Mitra et al., 2009).

Moreover, articulators move relatively slowly and smoothly, and their movements are continuous. Indeed, the mouth cannot "jump" from one configuration to a completely different one (Richmond, 2002). For this reason, functional data analysis approaches are well suited for the speech inversion task. In other words, even if the measurement process itself is discrete, vocal tract variables are really smooth functions (see Figure 5) rather than vectors and taking into account such prior knowledge on the nature of the data can significantly improve performance. In our proposed method, smoothness is guaranteed by the use of smooth eigenfunctions obtained from the spectral decomposition of the integral operator associated with a Mercer kernel used to construct the operator-valued kernel defined in Equation 11. By this way, our approach does not need the filtering post-processing step, which is necessary in vectorial vocal-tract learning methods to transform the predicted functions on smooth curves and which has the drawback of changing the behavior of the predicted vocal tract time functions.

Various nonlinear acoustic-to-articulatory inversion techniques (Richmond, 2002; Mitra et al., 2010), and particularly kernel-based methods (Toutios and Margaritis, 2005; Mitra

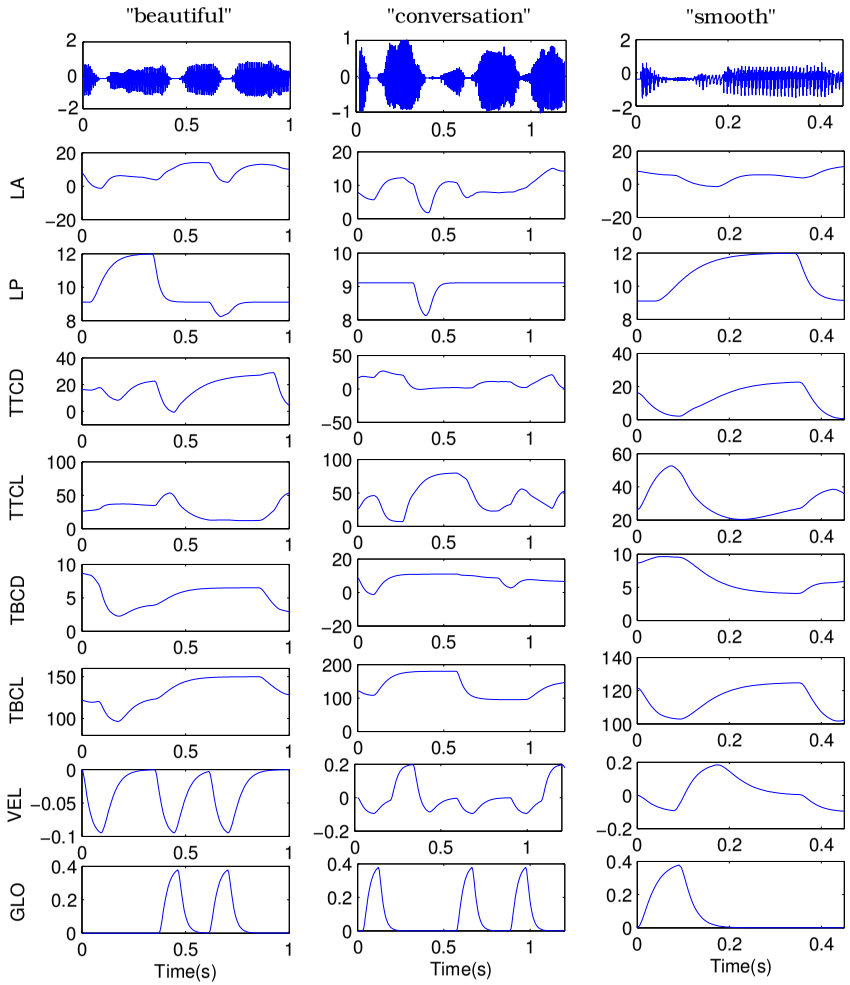

Figure 5: Acoustic waveforms and derived vocal tract time functions for the utterances "beautiful", "conversation" and "smooth". The vocal tract variables are: lip aperture (LA), lip protrusion (LP), tongue tip constriction degree (TTCD), tongue tip constriction location (TTCL), tongue body constriction degree (TBCD), tongue body constriction location (TBCL), Velum (VEL) and Glottis (GLO).

Constriction organ	VT variables	Articulators
lip	lip aperture (LA)	upper lip, lower lip, jaw
	lip protrusion (LP)	
tongue tip	tongue tip constriction degree (TTCD)	tongue body, tip, jaw
	tongue tip constriction location (TTCL)	
tongue body	tongue body constriction degree (TBCD)	tongue body, jaw
	tongue body constriction location (TBCL)	
velum	velum (VEL)	velum
glottis	glottis (GLO)	glottis

Table 2: Constriction organ, vocal-tract (VT) variables and involved articulators (Mitra et al., 2009).

et al., 2009), have been proposed in the literature. In most cases, these works address the articulatory estimation problem within a single-task learning perspective. However, in Richmond (2007) and more recently in Kadri et al. (2011a), the authors put forward the idea that we can benefit from viewing the acoustic-articulatory inversion problem from a multi-task learning perspective. Motivated by comparing our functional operator-valued kernel based approach with multivariate kernel methods, we report on experiments similar to those performed by Mitra et al. (2009) and Kadri et al. (2011a). The tract variables learning technique proposed by Mitra et al. (2009) is based on a hierarchical ε-SVR architecture constructed by associating different SVRs, a SVR for each tract variable. To consider the dependencies between VT time functions, the SVRs corresponding to independent VT variables are first created and then used for constructing the others. Otherwise, the acoustic-to-articulatory method in Kadri et al. (2011a) is based on learning a vector-valued function using a matrix-valued kernel proposed in Caponnetto et al. (2008).

Following Mitra et al. (2010), acoustic-articulatory database is generated by the TADA model (Nam et al., 2004) which is a computational implementation of articulatory phonology. The generated data set consists of acoustic signals for 416 words chosen from the Wisconsin X-ray microbeam data (Westbury et al., 1994) and corresponding Vocal Tract (VT) trajectories sampled at 5 ms. The speech signal was parameterized into 13 Mel-Frequency Cepstral Coefficients. These cepstral coefficients were acquired each 5 ms (synchronized with the TVs) with window duration of 10 ms.

For evaluating the performance of the VT time functions estimation, we use the residual sum of squares error (RSSE) defined as follows

$$RSSE = \int \sum_i \{y_i(t) - \widehat{y}_i(t)\}^2 dt, \tag{14}$$

VT variables	ε-SVR	Multi-task	Functional
LA	2.763	2.341	**1.562**
LP	0.532	**0.512**	0.528
TTCD	3.345	1.975	**1.647**
TTCL	7.752	5.276	**3.463**
TBCD	2.155	2.094	**1.582**
TBCL	15.083	9.763	**7.215**
VEL	0.032	0.034	**0.029**
GLO	**0.041**	0.052	0.064
Total	3.962	2.755	**2.011**

Table 3: Average RSSE for the tract variables using hierarchical ε-SVR (Mitra et al., 2009), the multi-task kernel method (Kadri et al., 2011a) and the proposed functional operator-valued kernel based approach.

where $\widehat{y}_i(t)$ is the prediction of the VT curve $y_i(t)$. Table 3 reports average RSSE results obtained using the hierarchical ε-SVR algorithm (Mitra et al., 2009), the multi-task kernel method (Kadri et al., 2011a) after smoothing the estimated VT trajectories using a Kalman filter as described in Mitra et al. (2009), and the functional operator-valued kernel based approach. The proposed functional approach consistently produced significant performance improvements over the supervised baseline ε-SVR. It also outperforms the discrete multi-task method (Evgeniou et al., 2005; Kadri et al., 2011a) except for the LP and GLO variables. The multi-task and also the ε-SVR methods perform well for these two vocal tract variables and slightly improve our functional approach. This can be explained by the fact that, contrary to other vocal tract variables, LP and GLO time functions are not completely smooth for all times and positions, while our method with the integral operator-valued kernel, as defined in Equation 11, tends to favor the prediction of smooth functions. Building operator-valued kernels suitable for heterogeneous functions, i.e., smooth in some parts and non-smooth in others, could be a good alternative to improve the prediction of these two vocal tract time functions. Note that the number of eigenfunctions κ affects performance. κ has to be well chosen to provide a reasonable approximation of the infinite-dimensional process. In the case of complex output functions, like heterogeneous functions, we need to use many eigenfunctions to have a good approximation, but even for this case, κ remains (very) small compared to the number of examples n.

7.2 Sound Recognition

A second application of the ideas that we present in this paper is sound recognition. Many previous works in the context of sound recognition problem have concentrated on classifying environmental sounds other than speech and music (Dufaux et al., 2000; Peltonen et al., 2002). Such sounds are extremely versatile, including signals generated in domestic, business, and outdoor environments. A system that is able to recognize such sounds may be of great importance for surveillance and security applications (Istrate et al., 2006; Rabaoui et al., 2008). The classification of a sound is usually performed in two steps. First, a pre-

Classes	Number	Train	Test	Total	Duration (s)
Human screams	C1	40	25	65	167
Gunshots	C2	36	19	55	97
Glass breaking	C3	48	25	73	123
Explosions	C4	41	21	62	180
Door slams	C5	50	25	75	96
Phone rings	C6	34	17	51	107
Children voices	C7	58	29	87	140
Machines	C8	40	20	60	184
Total		327	181	508	18mn 14s

Table 4: Classes of sounds and number of samples in the database used for performance evaluation.

processor applies signal processing techniques to generate a set of features characterizing the signal to be classified. Then, in the feature space, a decision rule is implemented to assign a class to a pattern.

Operator-valued kernels can be used in a classification setting by considering the labels y_i to be functions in some function space rather than real values. Similarly to the scalar case, a natural choice for y_i would seem to be the Heaviside step function in $L^2([0,1])$ scaled by a real number. In this context, our method can be viewed as an extension of the Regularized Least Squares Classification (RLSC) algorithm (Rifkin et al., 2003) to the FDA domain (we called it Functional RLSC (Kadri et al., 2011c)). The performance of the proposed algorithm described in Section 6 is evaluated on a data set of sounds collected from commercial databases which include sounds ranging from screams to explosions, such as gun shots or glass breaking, and compared with the RLSC method.

7.2.1 Database Description

As in Rabaoui et al. (2008), the major part of the sound samples used in the recognition experiments is taken from two sound libraries (Leonardo Software; Real World Computing Paternship, 2000). All signals in the database have a 16 bits resolution and are sampled at 44100 Hz, enabling both good time resolution and a wide frequency band, which are both necessary to cover harmonic as well as impulsive sounds. The selected sound classes are given in Table 4, and they are typical of surveillance applications. The number of items in each class is deliberately not equal.

Note that this database includes impulsive and harmonic sounds such as phone rings (C6) and children voices (C7). These sounds are quite likely to be recorded by a surveillance system. Some sounds are very similar to a human listener: in particular, explosions (C4) are pretty similar to gunshots (C2). Glass breaking sounds include both bottle breaking and window breaking situations. Phone rings are either electronic or mechanic alarms.

Temporal representations and spectrograms of some sounds are depicted in Figures 6 and 7. Power spectra are extracted through the Fast Fourier Transform (FFT) every 10 ms from 25 ms frames. They are represented vertically at the corresponding frame indexes.

The frequency range of interest is between 0 and 22 kHz. A lighter shade indicates a higher power value. These figures show that in the considered database we can have both: (1) many similarities between sounds belonging to different classes, (2) diversities within the same class of sounds.

7.2.2 Sound Classification Results

Following Rifkin and Klautau (2004), the 1-vs-all multi-class classifier is selected in these experiments. So we train N (number of classes) different binary classifiers, each one trained to distinguish the data in a single class from the examples in all remaining classes. We run the N classifiers to classify a new example.

The adopted sound data processing scheme is the following. Let $\mathcal{X}$ be the set of training sounds, shared in N classes denoted $\mathcal{C}_1, \ldots, \mathcal{C}_N$. Each class contains m_i sounds, $i = 1, \ldots, N$. Sound number j in class $\mathcal{C}_i$ is denoted $\mathbf{s}_{i,j}$, $(i = 1, \ldots, N, j = 1, \ldots, m_i)$. The pre-processor converts a recorded acoustic signal $\mathbf{s}_{i,j}$ into a time/frequency localized representation. In multivariate methods, this representation is obtained by splitting the signal $\mathbf{s}_{i,j}$ into $T_{i,j}$ overlapping short frames and computing a vector of features $z_{t,i,j}$, $t = 1, \ldots, T_{i,j}$ which characterize each frame. Since the pre-processor is a series of continuous time-localized features, it will be useful to take into account the relationships between feature samples along the time axis and consider dependencies between features. That is why we use a FDA-based approach in which features representing a sound are modeled by functions $z_{i,j}(t)$. In this work, Mel Frequency Cepstral Coefficients (MFCCs) features are used to describe the spectral shape of each signal. These coefficients are obtained using 23 channels Mel filterbank and a Hamming analysis window of length 25 ms with 50% overlap. We also use the energy parameter measured for each window along all the sound signal. So, each sound is characterized by 14 functional parameters: 13 cepstral functions and 1 energy function.

Performance of the proposed functional approach in the context of classification is compared to the results obtained by the RLSC algorithm, see Tables 5 and 6. The performance is measured as the percentage number of sounds correctly recognized and it is given by $(\mathrm{W_r}/\mathrm{T_n}) \times 100\%$, where $\mathrm{W_r}$ is the number of well recognized sounds and $\mathrm{T_n}$ is the total number of sounds to be recognized. The use of the Functional RLSC is fully justified by the results presented here, as it yields consistently a high classification accuracy for the major part of the sound classes.

RLSC setup is similar to that of FLRSC. The major difference is in the modeling of sound features. In RLSC, all the functional parameters which characterize a sound are combined in the same vector which is considered to be in $\mathbb{R}^d$. Functional RLSC considers each input sound as a vector of functions in $(L^2([0,1]))^p$ where p is the number of functional parameters. By using operator-valued kernels rather than scalar-valued ones, we project these functional data into a higher dimensional feature space in which we define a distance measure from the spectral decomposition of the operator-valued kernel, suitable for functions and which allows the learning module to take into account the sequential nature of the data and the dependencies along the time-axis. Moreover, compared to RLSC, κ the number of eigenfunctions in FRLSC can be seen as one more degree of freedom which can be used to improve performance when input data are complex and not represented by a vector in $\mathbb{R}^d$ as usual. Note that the usual scalar case (output space is $\mathbb{R}$ and then $\kappa = 1$) can be recovered

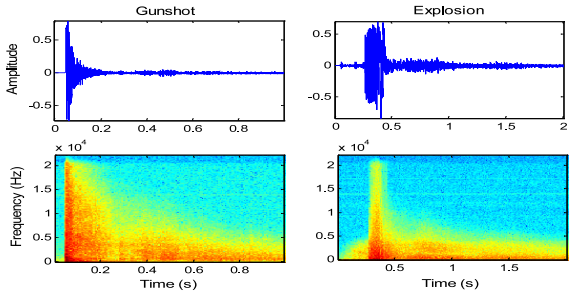

Figure 6: Structural similarities between two different classes. Gunshot and Explosion are two sound signals belonging to two different classes, but they have similar temporal and spectral representations.

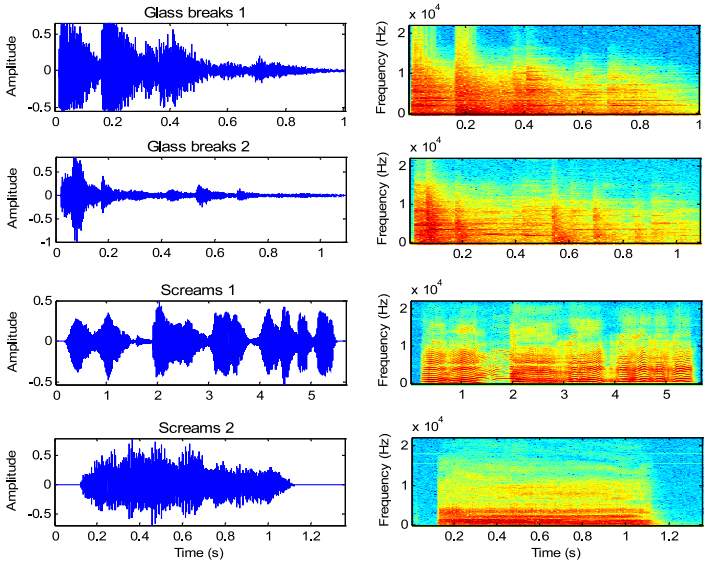

Figure 7: Structural diversity inside the same sound class and between classes. Glass breaks 1 and 2 (resp. Screams 1 and 2) are two sounds from the same class, however they present different temporal (resp. spectral) properties.

from the functional case; for example when the operator-valued kernel is constructed from the identity operator or/and the output space is the space of constant functions.

8. Conclusion

We have presented a learning methodology for nonlinear functional data analysis, which is an extension of scalar-valued and matrix-valued kernel based methodologies to the functional response setting. The problem of functional supervised learning is formalized as the problem of learning an operator between two infinite dimensional scalar-valued Hilbert spaces in a reproducing kernel Hilbert space of function-valued functions. We have introduced a set of rigorously defined operator-valued kernels that can be valuably applied to nonparametric operator learning when input and output data are continuous smooth functions, and we have

showed their use for solving the problem of minimizing a regularized risk functional in the case of functional outputs without the need to discretize covariate and target functions. Our fully functional approach has been successfully applied to the problems of speech inversion and sound recognition, showing that the proposed framework is particularly relevant for audio signal processing applications where attributes are functions and dependent of each other.

In future work, it would be interesting to explore further the potential of our proposed method in other machine learning problems such as collaborative filtering (Abernethy et al., 2009) and structured output prediction (Brouard et al., 2011; Kadri et al., 2013b) by building operator-valued kernels that can capture not only the functional information of responses, but also other types of output structure. In this context, learning the operator-valued kernel would be interesting to find the right model of dependencies between outputs. Recent works in this direction includes the papers of Dinuzzo et al. (2011), Kadri et al. (2012), Sindhwani et al. (2013) and Lim et al. (2015), but further investigations are needed in this area. On the algorithmic side, possible extensions of this work include on-line implementations to deal with the case where the functional data set is made available step by step (Audiffren and Kadri, 2015). Learning, sequentially and without re-training from scratch at each iteration, a new function-valued function for each new observed pair of functional samples would be of practical interest. Finally, although not covered in this paper, the analysis we present is likely to be applicable to learning problems that involve functional data with different functional profiles (*e.g.*, both smooth and spiky functions). Designing nonseparable operator-valued kernels that can exhibit better ability to characterize different smoothing levels is also an interesting future research direction.

Acknowledgments

We thank the anonymous reviewers for several insightful comments that helped improve the original version of this paper. We also thank M. Mbekhta for fruitful discussions on the spectral theory of block operator matrices and A. Rabaoui for providing the sound recognition data set. A large part of this research was done while H.K. was at SequeL (INRIA-Lille) and J.A. at Aix-Marseille Université and LIF. This work was supported by Ministry of Higher Education and Research, Nord-Pas-de-Calais Regional Council and FEDER through the 'Contrat de Projets Etat Region (CPER) 2007-2013'. H.K. acknowledges the support of a Junior Researcher Contract No. 4297 from the Nord-Pas-de-Calais region. H.K. and P.P. acknowledge the support of the French National Research Agency (ANR-09-EMER-007 project LAMPADA). H.K. was also supported in part by French grants from the CNRS-LAGIS (ANR KernSig Project). A.R. was supported by the PASCAL2 Network of Excellence, ICT-216886, ANR Project ASAP ANR-09-EMER-001 and the INRIA ARC MABI. P.P. also acknowledges the support of INRIA.

Appendix A. Proof of Theorem 2 - Completion of $\mathcal{F}_0$

We show below how to construct the Hilbert space $\mathcal{F}$ of $\mathcal{Y}$-valued functions, that is the completion of the function-valued pre-Hilbert space $\mathcal{F}_0$. $\mathcal{F}_0 \subset \mathcal{Y}^{\mathcal{X}}$ is the space of all $\mathcal{Y}$-

valued functions F of the form $F(\cdot) = \sum_{i=1}^{n} K(w_i, \cdot)u_i$, where $w_i \in \mathcal{X}$ and $u_i \in \mathcal{Y}$, $i = 1, \ldots, n$. Consider the inner product of the functions $F(\cdot) = \sum_{i=1}^{n} K(w_i, \cdot)u_i$ and $G(\cdot) = \sum_{j=1}^{m} K(z_j, \cdot)v_j$ from $\mathcal{F}_0$ defined as follows

$$\langle F(\cdot), G(\cdot)\rangle_{\mathcal{F}_0} = \langle \sum_{i=1}^{n} K(w_i, \cdot)u_i, \sum_{j=1}^{m} K(z_j, \cdot)v_j\rangle_{\mathcal{F}_0} = \sum_{i=1}^{n}\sum_{j=1}^{m} \langle K(w_i, z_j)u_i, v_j\rangle_{\mathcal{Y}}.$$

We have shown that $(\mathcal{F}_0, \langle ., .\rangle_{\mathcal{F}_0})$ is a pre-Hilbert space. This pre-Hilbert space is in general not complete, but It can be completed via Cauchy sequences to build the $\mathcal{Y}$-valued reproducing kernel Hilbert space $\mathcal{F}$.

Consider any Cauchy sequence $\{F_n(\cdot)\} \subset \mathcal{F}_0$, for every $w \in \mathcal{X}$ the functional $F(w)$ is bounded, since

$$\begin{aligned}
\|F(w)\|_{\mathcal{Y}} &= \sup_{\|u\|=1} |\langle F(w), u\rangle_{\mathcal{Y}}| = \sup_{\|u\|=1} |\langle F(\cdot), K(w, \cdot)u\rangle_{\mathcal{F}_0}| \\
&\leq \|F(\cdot)\|_{\mathcal{F}_0} \sup_{\|u\|=1} \|K(w, \cdot)u\|_{\mathcal{F}_0} \leq \|F(\cdot)\|_{\mathcal{F}_0} \sup_{\|u\|=1} \sqrt{\langle K(w, w)u, u\rangle_{\mathcal{Y}}} \\
&\leq M_w \|F(\cdot)\|_{\mathcal{F}_0} \text{ with } M_w = \sup_{\|u\|=1} \sqrt{\langle K(w, w)u, u\rangle_{\mathcal{Y}}}.
\end{aligned}$$

Moreover, if the kernel K is Mercer, it is locally bounded (see Carmeli et al., 2010, Proposition 2). It is easy to see that in this case $\|F(w)\|_{\mathcal{Y}} \leq M\|F(\cdot)\|_{\mathcal{F}_0}$, where M here does not depend on w. Consequently,

$$\|F_n(w) - F_m(w)\|_{\mathcal{Y}} \leq M\|F_n(\cdot) - F_m(\cdot)\|_{\mathcal{F}_0}.$$

It follows that $\{F_n(w)\}$ is a Cauchy sequence in $\mathcal{Y}$ and by the completeness of the space $\mathcal{Y}$, there exists a $\mathcal{Y}$-valued function F where, $\forall w \in \mathcal{X}$, $F(w) = \lim_{n\to\infty} F_n(w)$. So the Cauchy sequence $\{F_n(\cdot)\}$ defines a function $F(\cdot)$ to which it is convergent at every point of $\mathcal{X}$.

Let us denote $\mathcal{F}$ the linear space containing all the functions $F(\cdot)$, the limits of Cauchy sequences $\{F_n(\cdot)\} \subset \mathcal{F}_0$, and consider the norm in $\mathcal{F}$ defined by $\|F(\cdot)\|_{\mathcal{F}} = \lim_{n\to\infty} \|F_n(\cdot)\|_{\mathcal{F}_0}$, where $F_n(\cdot)$ is a Cauchy sequence of $\mathcal{F}_0$ converging to $F(\cdot)$. This norm is well defined since it does not depend on the choice of the Cauchy sequence. In fact, suppose that two Cauchy sequences $\{F_n(\cdot)\}$ and $\{G_n(\cdot)\}$ in $\mathcal{F}_0$ define the same function $F(\cdot) \in \mathcal{F}$. Then $\{F_n(\cdot) - G_n(\cdot)\}$ is also a Cauchy sequence and $\forall w \in \mathcal{X}$, $\lim_{n\to\infty} F_n(w) - G_n(w) = 0$. Hence, $\lim_{n\to\infty} \langle F_n(w) - G_n(w), u\rangle_{\mathcal{Y}} = 0$ for any $u \in \mathcal{G}_y$ and using the reproducing property, it follows that $\lim_{n\to\infty} \langle F_n(\cdot) - G_n(\cdot), H(\cdot)\rangle_{\mathcal{F}_0} = 0$ for any function $H(\cdot) \in \mathcal{F}_0$ and thus

$$\lim_{n\to\infty} \|F_n(\cdot) - G_n(\cdot)\|_{\mathcal{F}_0} = 0.$$

Consequently,

$$|\lim_{n\to\infty} \|F_n\| - \lim_{n\to\infty} \|G_n\| | = \lim_{n\to\infty} | \|F_n\| - \|G_n\| | \leq \lim_{n\to\infty} \|F_n - G_n\| = 0.$$

So that for any function $F(\cdot) \in \mathcal{F}$ defined by two different Cauchy sequences $\{F_n(\cdot)\}$ and $\{G_n(\cdot)\}$ in $\mathcal{F}_0$, we have $\lim_{n\to\infty} \|F_n(\cdot)\|_{\mathcal{F}_0} = \lim_{n\to\infty} \|G_n(\cdot)\|_{\mathcal{F}_0} = \|F(\cdot)\|_{\mathcal{F}}$. $\|.\|_{\mathcal{F}}$ has all the

properties of a norm and defines in $\mathcal{F}$ an inner product which on $\mathcal{F}_0$ coincides with $\langle ., .\rangle_{\mathcal{F}_0}$ already defined. It remains to be shown that $\mathcal{F}_0$ is dense in $\mathcal{F}$ which is a complete space.

For any $F(\cdot)$ in $\mathcal{F}$ defined by the Cauchy sequence $F_n(\cdot)$, we have $\lim_{n\to\infty} \|F(\cdot) - F_n(\cdot)\|_{\mathcal{F}} = \lim_{n\to\infty} \lim_{m\to\infty} \|F_m(\cdot) - F_n(\cdot)\|_{\mathcal{F}_0} = 0$. It follows that $F(\cdot)$ is a strong limit of $F_n(\cdot)$ in $\mathcal{F}$ and then $\mathcal{F}_0$ is dense in $\mathcal{F}$. To prove that $\mathcal{F}$ is a complete space, we consider $\{F_n(\cdot)\}$ any Cauchy sequence in $\mathcal{F}$. Since $\mathcal{F}_0$ is dense in $\mathcal{F}$, there exists a sequence $\{G_n(\cdot)\} \subset \mathcal{F}_0$ such that $\lim_{n\to\infty} \|G_n(\cdot) - F_n(\cdot)\|_{\mathcal{F}} = 0$. Besides $\{G_n(\cdot)\}$ is a Cauchy sequence in $\mathcal{F}_0$ and thus defines a function $H(\cdot) \in \mathcal{F}$ which verifies $\lim_{n\to\infty} \|G_n(\cdot) - h(\cdot)\|_{\mathcal{F}} = 0$. So $\{G_n(\cdot)\}$ converges strongly to $H(\cdot)$ and then $\{F_n(\cdot)\}$ also converges strongly to $H(\cdot)$ which means that the space $\mathcal{F}$ is complete. In addition, $K(\cdot, \cdot)$ has the reproducing property in $\mathcal{F}$. To see this, let $F(\cdot) \in \mathcal{F}$, then $F(\cdot)$ is defined by a Cauchy sequence $\{F_n(\cdot)\} \subset \mathcal{F}_0$ and we have from the continuity of the inner product in $\mathcal{F} \subset \mathcal{Y}^{\mathcal{X}}$ (endowed with the uniform topology) that, for all $w \in \mathcal{X}$ and $u \in \mathcal{Y}$,

$$\begin{aligned}
\langle F(w), u\rangle_{\mathcal{Y}} &= \langle \lim_{n\to\infty} F_n(w), u\rangle_{\mathcal{Y}} = \lim_{n\to\infty} \langle F_n(w), u\rangle_{\mathcal{Y}} = \lim_{n\to\infty} \langle F_n(\cdot), K(w, \cdot)u\rangle_{\mathcal{F}_0} \\
&= \langle \lim_{n\to\infty} F_n(\cdot), K(w, \cdot)u\rangle_{\mathcal{F}} = \langle F(\cdot), K(w, \cdot)u\rangle_{\mathcal{F}}.
\end{aligned}$$

Finally, we conclude that $\mathcal{F}$ is a reproducing kernel Hilbert space since $\mathcal{F}$ is a real inner product space that is complete under the norm $\|.\|_{\mathcal{F}}$ defined above, and has $K(\cdot, \cdot)$ as reproducing kernel. ■

Appendix B. Representer Theorem

We provide here a proof of the analog of the representer theorem in the case of function-valued reproducing kernel Hilbert spaces.

Theorem 9 *(representer theorem)*
Let K a nonnegative Mercer operator-valued kernel and $\mathcal{F}$ its corresponding function-valued reproducing kernel Hilbert space. The solution $\widetilde{F}_\lambda \in \mathcal{F}$ of the regularized optimization problem

$$\widetilde{F}_\lambda = \arg\min_{F\in\mathcal{F}} \sum_{i=1}^{n} \|y_i - F(x_i)\|_{\mathcal{Y}}^2 + \lambda\|F\|_{\mathcal{F}}^2$$

has the following form

$$\widetilde{F}_\lambda(\cdot) = \sum_{i=1}^{n} K(x_i, \cdot)u_i,$$

where $u_i \in \mathcal{Y}$.

Proof: We use the Frechet derivative which is the strongest notion of derivative in a normed linear space; see, for example, Chapter 4 of Kurdila and Zabarankin (2005). We use the standard notation D_F for the Frechet derivative operator. Let $J_\lambda(F) = \sum_{i=1}^{n} \|y_i - F(x_i)\|_{\mathcal{Y}}^2 + \lambda\|F\|_{\mathcal{F}}^2$ be the functional to be minimized. $\widetilde{F}$ is the operator in $\mathcal{F}$ such that

$\widetilde{F} = \arg\min_{F\in\mathcal{F}} J_\lambda(F) \Rightarrow D_F J_\lambda(\widetilde{F}) = 0$. To compute $D_F J_\lambda(F)$, we use the Gateaux derivative D_G of J_λ with respect to F in the direction H, which is defined by:

$$D_G J_\lambda(F,H) = \lim_{\tau\longrightarrow 0} \frac{J_\lambda(F+\tau H) - J_\lambda(F)}{\tau}.$$

J_λ can be written as $J_\lambda(F) = \sum_{i=1}^{n} G_i(F) + \lambda L(F)$ and using the fact that $D_G J_\lambda(F,H) = \langle D_G J_\lambda(F), H\rangle$ we obtain

i. $L(F) = \|F\|_{\mathcal{F}}^2$

$$\lim_{\tau\longrightarrow 0} \frac{\|F+\tau H\|_{\mathcal{F}}^2 - \|F\|_{\mathcal{F}}^2}{\tau} = 2\langle F, H\rangle \implies D_G L(F) = 2F.$$

ii. $G_i(F) = \|y_i - F(x_i)\|_{\mathcal{Y}}^2$

$$\lim_{\tau\longrightarrow 0} \frac{\|y_i - F(x_i) - \tau H(x_i)\|_{\mathcal{Y}}^2 - \|y_i - F(x_i)\|_{\mathcal{Y}}^2}{\tau} = -2\langle y_i - F(x_i), H(x_i)\rangle_{\mathcal{Y}}$$
$$= -2\langle K(x_i,\cdot)(y_i - F(x_i)), H\rangle_{\mathcal{F}} = -2\langle K(x_i,\cdot)u_i, H\rangle_{\mathcal{F}} \text{ with } u_i = y_i - F(x_i)$$
$$\implies D_G G_i(F) = -2K(x_i,\cdot)u_i.$$

When the kernel K is Mercer, Corollary 4.1.1 in Kurdila and Zabarankin (2005) can be applied to show that J_λ is Fréchet differentiable and that, $\forall F \in \mathcal{F}$, $D_F J_\lambda(F) = D_G J_\lambda(F)$. Using (i), (ii), and $D_F J_\lambda(\widetilde{F}) = 0 \implies \widetilde{F}(\cdot) = \frac{1}{\lambda}\sum_{i=1}^{n} K(x_i,\cdot)u_i$. ■

Appendix C. Proof of Theorem 7

We show here that under Assumptions 1, 2 and 3, a learning algorithm that maps a training set Z to the function F_Z defined in (12) is β stable with $\beta = \frac{\sigma^2\kappa^2}{2n\lambda}$. First, since ℓ is convex with respect to F, we have $\forall 0 \le t \le 1$

$$\ell(y, F_Z + t(F_{Z^i} - F_Z), x) - \ell(y, F_Z, x) \le t\left(\ell(y, F_{Z^i}, x) - \ell(y, F_Z, x)\right).$$

Then, by summing over all couples (x_k, y_k) in Z^i,

$$R_{emp}(F_Z + t(F_{Z^i} - F_Z), Z^i) - R_{emp}(F_Z, Z^i) \le t\left(R_{emp}(F_{Z^i}, Z^i) - R_{emp}(F_Z, Z^i)\right). \quad (15)$$

Symmetrically, we also have

$$R_{emp}(F_{Z^i} + t(F_Z - F_{Z^i}), Z^i) - R_{emp}(F_{Z^i}, Z^i) \le t\left(R_{emp}(F_Z, Z^i) - R_{emp}(F_{Z^i}, Z^i)\right). \quad (16)$$

Thus, by summing (15) and (16), we obtain

$$\begin{aligned} &R_{emp}(F_Z + t(F_{Z^i} - F_Z), Z^i) - R_{emp}(F_Z, Z^i) \\ &\quad + R_{emp}(F_{Z^i} + t(F_Z - F_{Z^i}), Z^i) - R_{emp}(F_{Z^i}, Z^i) \le 0. \end{aligned} \quad (17)$$

Now, by definition of F_Z and F_{Z^i},

$$\begin{aligned} &R_{reg}(F_Z, Z) - R_{reg}(F_Z + t(F_{Z^i} - F_Z), Z) \\ &\quad + R_{reg}(F_{Z^i}, Z^i) - R_{reg}(F_{Z^i} + t(F_Z - F_{Z^i}), Z^i) \le 0. \end{aligned} \quad (18)$$

Combining (17) and (18), we find

$$\begin{aligned} &\ell(y_i, F_Z, x_i) - \ell(y_i, F_Z + t(F_{Z^i} - F_Z), x_i) \\ &\quad + n\lambda\left(\|F_Z\|_{\mathcal{F}}^2 - \|F_Z + t(F_{Z^i} - F_Z)\|_{\mathcal{F}}^2 + \|F_{Z^i}\|_{\mathcal{F}}^2 - \|F_{Z^i} + t(F_Z - F_{Z^i})\|_{\mathcal{F}}^2\right) \le 0. \end{aligned} \quad (19)$$

Moreover, we have

$$\begin{aligned} &\|F_Z\|_{\mathcal{F}}^2 - \|F_Z + t(F_{Z^i} - F_Z)\|_{\mathcal{F}}^2 + \|F_{Z^i}\|_{\mathcal{F}}^2 - \|F_{Z^i} + t(F_Z - F_{Z^i})\|_{\mathcal{F}}^2 \\ &\quad = \|F_Z\|_{\mathcal{F}}^2 - \|F_Z\|_{\mathcal{F}}^2 - t^2\|F_{Z^i} - F_Z\|_{\mathcal{F}}^2 - 2t\langle F_Z, F_{Z^i} - F_z\rangle_{\mathcal{F}} \\ &\quad + \|F_{Z^i}\|_{\mathcal{F}}^2 - \|F_{Z^i}\|_{\mathcal{F}}^2 - t^2\|F_Z - F_{Z^i}\|_{\mathcal{F}}^2 - 2t\langle F_{Z^i}, F_Z - F_{Z^i}\rangle_{\mathcal{F}} \\ &\quad = -2t^2\|F_{Z^i} - F_Z\|_{\mathcal{F}}^2 - 2t\langle F_Z, F_{Z^i} - F_z\rangle_{\mathcal{F}} - 2t\langle F_{Z^i}, F_Z - F_{Z^i}\rangle_{\mathcal{F}} \\ &\quad = -2t^2\|F_{Z^i} - F_Z\|_{\mathcal{F}}^2 + 2t\|F_{Z^i} - F_Z\|_{\mathcal{F}}^2 \\ &\quad = 2t(1-t)\|F_{Z^i} - F_Z\|_{\mathcal{F}}^2. \end{aligned} \quad (20)$$

Hence, since ℓ is σ-Lipschitz continuous with respect to $F(x)$, we obtain from (19) and (20), $\forall t \in]0,1[$,

$$\begin{aligned} \|F_Z - F_{Z^i}\|_{\mathcal{F}}^2 &\le \frac{1}{2t(1-t)}\left(\|F_Z\|_{\mathcal{F}}^2 - \|F_Z + t(F_{Z^i} - F_Z)\|_{\mathcal{F}}^2 + \|F_{Z^i}\|_{\mathcal{F}}^2 - \|F_{Z^i} + t(F_Z - F_{Z^i})\|_{\mathcal{F}}^2\right) \\ &\le \frac{1}{2t(1-t)n\lambda}\left(\ell(y_i, F_Z + t(F_{Z^i} - F_Z), x_i) - \ell(y_i, F_Z, x_i)\right) \\ &\le \frac{\sigma}{2(1-t)n\lambda}\|F_{Z^i}(x_i) - F_Z(x_i)\|_{\mathcal{Y}}. \end{aligned}$$

In particular, when t tends to 0, we have

$$\|F_Z - F_{Z^i}\|_{\mathcal{F}}^2 \le \frac{\sigma}{2n\lambda}\|F_{Z^i}(x_i) - F_Z(x_i)\|_{\mathcal{Y}} \le \frac{\sigma\kappa}{2n\lambda}\|F_{Z^i} - F_Z\|_{\mathcal{F}},$$

which gives that

$$\|F_Z - F_{Z^i}\|_{\mathcal{F}} \le \frac{\sigma\kappa}{2n\lambda}.$$

This implies that, $\forall (x,y)$,

$$|\ell(y, F_Z, x) - \ell(y, F_{Z^i}, x)| \le \sigma\|F_Z(x) - F_{Z^i}(x)\|_{\mathcal{Y}} \le \sigma\kappa\|F_Z - F_{Z^i}\|_{\mathcal{F}} \le \frac{\sigma^2\kappa^2}{2n\lambda},$$

which concludes the proof. ■

Appendix D. Proof of Lemma 2

We show here that Assumption 4 is satisfied for the least squares loss function when Assumption 5 holds and use that to prove Lemma 2. First, note that ℓ is convex with respect to its second argument. Since $\mathcal{F}$ is a vector space, $0 \in \mathcal{H}$. Thus,

$$\lambda \|F_Z\|^2 \leq R_{reg}(F_Z, Z) \leq R_{reg}(0, Z) \leq \frac{1}{n}\sum_{k=1}^{n} \|y_k\|^2 \leq \sigma_y^2, \tag{21}$$

where we used the definition of F_Z (see Equation 12) and the bound on Y (Assumption 5). This inequality is uniform over Z, and thus holds for F_{Z^i}. Moreover, $\forall x \in \mathcal{X}$,

$$\|F_Z(x)\|_{\mathcal{Y}}^2 = \langle F_Z(x), F_Z(x)\rangle_{\mathcal{Y}} = \langle K(x,x)F_Z, F_Z\rangle_{\mathcal{F}} \leq \|K(x,x)\|_{op}\|F_Z\|_{\mathcal{F}}^2 \leq \kappa^2 \frac{\sigma_y^2}{\lambda}.$$

Hence, using Lemma 1 and (21), we obtain

$$\|y - F_Z(x)\|_{\mathcal{Y}} \leq \|y\|_{\mathcal{Y}} + \|f_Z(x)\|_{\mathcal{Y}} \leq \sigma_y + \kappa\frac{\sigma_y}{\sqrt{\lambda}},\ \forall (x,y) \in \mathcal{X}\times\mathcal{Y}.$$

Then it follows that

$$\begin{aligned}
&\left|\|y - F_Z(x)\|_{\mathcal{Y}}^2 - \|y - F_{Z^i}(x)\|_{\mathcal{Y}}^2\right| \\
&= \left|\|y - F_Z(x)\|_{\mathcal{Y}} - \|y - F_{Z^i}(x)\|_{\mathcal{Y}}\right| \left|\|y - F_Z(x)\|_{\mathcal{Y}} + \|y - F_{Z^i}(x)\|_{\mathcal{Y}}\right| \\
&\leq 2\sigma_y(1 + \frac{\kappa}{\sqrt{\lambda}})\|F_Z(x) - F_{Z^i}(x)\|_{\mathcal{Y}}.
\end{aligned}$$

■

Appendix E. Proof of Remark 1

We show here that if the finite trace assumption of the operator $K(x,x)$ in Caponnetto and De Vito (2006) is satisfied, then our Assumption 1 on the kernel holds. Let K be an operator-valued kernel satisfying the hypotheses of Caponnetto and De Vito (2006), i.e K_x is Hilbert-Schmidt and $\sup_{x\in\mathcal{X}} Tr(K(x,x)) < +\infty$. Then, $\exists \eta > 0$, $\forall x \in \mathcal{X}$, $\exists \left(e_j^x\right)_{j\in\mathbb{N}}$ an orthonormal basis of $\mathcal{Y}$, $\exists \left(h_j^x\right)_{j\in\mathbb{N}}$ an orthogonal family of $\mathcal{F}$ with $\sum_{j\in\mathbb{N}} \|h_j^x\|_{\mathcal{F}}^2 \leq \eta$ such that $\forall y \in \mathcal{Y}$,

$$K(x,x)y = \sum_{j,\ell} \left\langle h_j^x, h_\ell^x\right\rangle_{\mathcal{F}} \left\langle y, e_j^x\right\rangle_{\mathcal{Y}} e_\ell^x.$$

Thus, $\forall i \in \mathbb{N}$,

$$K(x,x)e_i^x = \sum_{j,\ell} \left\langle h_j^x, h_\ell^x\right\rangle_{\mathcal{F}} \left\langle e_i^x, e_j^x\right\rangle_{\mathcal{Y}} e_\ell^x = \sum_{\ell} \langle h_i^x, h_\ell^x\rangle_{\mathcal{F}}\, e_\ell^x.$$

Hence

$$\begin{aligned}
\|K(x,x)\|_{op}^2 &= \sup_{i\in\mathbb{N}} \|K(x,x)e_i^x\|_{\mathcal{Y}}^2 = \sup_{i\in\mathbb{N}} \sum_{j,\ell} \langle h_i^x, h_\ell^x\rangle_{\mathcal{F}} \left\langle h_i^x, h_j^x\right\rangle_{\mathcal{F}} \left\langle e_j^x, e_\ell^x\right\rangle_{\mathcal{Y}} \\
&= \sup_{i\in\mathbb{N}} \sum_{\ell} (\langle h_i^x, h_\ell^x\rangle_{\mathcal{F}})^2 \leq \sup_{i\in\mathbb{N}} \|h_i^x\|_{\mathcal{F}}^2 \sum_{\ell} \|h_\ell^x\|_{\mathcal{F}}^2 \leq \eta^2.
\end{aligned}$$

Editor: Balazs Kegl

Abstract

Multi-label classification has rapidly attracted interest in the machine learning literature, and there are now a large number and considerable variety of methods for this type of learning. We present Meka: an open-source Java framework based on the well-known Weka library. Meka provides interfaces to facilitate practical application, and a wealth of multi-label classifiers, evaluation metrics, and tools for multi-label experiments and development. It supports multi-label and multi-target data, including in incremental and semi-supervised contexts.

Keywords: classification, learning, multi-label, multi-target, incremental

1. Introduction

In *multi-label learning* a data instance may be associated with multiple binary class labels. This is as opposed to the traditional task of single-label (i.e., multi-class, or binary) classification where each instance is only associated with a single class label. The multi-label context is receiving a lot of attention and is relevant to a wide variety of domains, including text, music, images and video, and bioinformatics; as reviewed by Tsoumakas et al. (2010).

The multi-label learning problem is in fact a special case of *multi-target* learning (also known as multi-dimensional or multi-objective), where each label can take multiple values, as opposed to binary labels indicating relevance or not (Bielza et al., 2011; Appice and Džeroski, 2007).

The context of multiple target variables has important implications for classification (how to model dependencies between variables) and evaluation (how to score multiple target classifications for each instance) that traditional single-label frameworks do not deal with. Meka has been designed specifically for this context.

2. The Meka Framework

Meka was created to perform and evaluate multi-label classification using the popular and effective family of *problem transformation* methods, which make use of existing off-the-shelf single-label (binary or multi-class) methods as 'base classifiers'. The Weka framework (Hall et al., 2009) contains a plethora of well-documented single-label classifiers used by the machine learning community for many years that can be used as such.

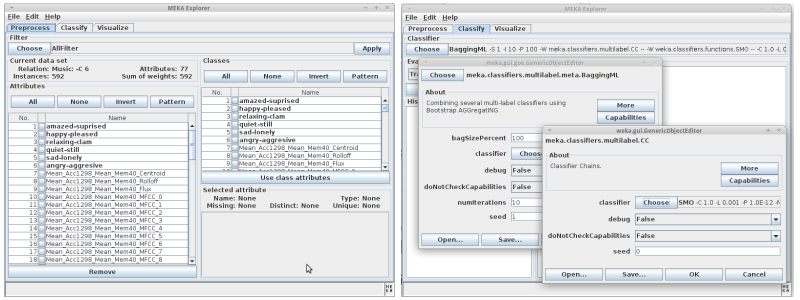

Figure 1: MEKA's GUI interface; having loaded and setup the Music data set (left) and selecting and configuring a classifier (right).

Meka contains all the basic problem transformation methods as reviewed by Tsoumakas et al. (2010), advanced methods including many of those surveyed by Madjarov et al. (2012) and Zhang and Zhou (2013), many varieties of classifier chains (Read et al., 2011) which have often been used as a benchmark in the recent multi-label literature, and also algorithm adaptations such as multi-label neural networks and deep neural networks (Hinton and Salakhutdinov, 2006). It includes two strategies for automatic threshold calibration, and a variety of evaluation metrics from the literature.

Meka is easily used from either the command line interface (CLI) or graphical user interface (GUI). Thus no programming is required to parameterize, run, and evaluate classifiers, making it suitable for practitioners unfamiliar with Java. However, it is straightforward to extend Meka with new classifiers and integrate it in other frameworks. Those familiar with Weka will have almost no learning curve (much of Weka's documentation and modus operandi is directly applicable). Any new Meka classifier can also be combined within any of Meka's existing ensemble schemes and any Weka base classifier without writing extra code, and be compared easily with benchmark and state-of-the-art methods. Meka also offers support for semi-supervised and incremental classification in the multi-label context (Read et al., 2015), as well as the general multi-target context considered by Appice and Džeroski (2007), making it a good platform for working in these areas.

2.1 Using Meka

Meka can be run on any machine with Java installed (version 1.7 or above). Everything needed to run Meka is included in the distribution package and detailed instructions and examples on how to setup data sets and run experiments are included in the tutorial. Figure 1 shows screen captures of Meka's GUI.

Meka uses Weka's thoroughly-documented ARFF file format,[1] using multiple binary attributes to specify the label relevances (or nominal attributes in the case of multi-target). The target attributes can easily be configured using the GUI, or directly from within the ARFF file (optionally using Weka's filters).

Meka's CLI follows the style of Weka. For example, to run five fold cross validation of an ensemble of 50 chain classifiers (Read et al., 2011) on the Music data set with support vector machines as the base classifier (as also shown on the right of Figure 1):

```
java meka.classifiers.multilabel.meta.BaggingML -x 5 -t data/Music.arff -I 50 \
    -W meka.classifiers.multilabel.CC -- -W weka.classifiers.trees.SMO
```

A list of methods implemented in Meka along with examples, is given at `http://meka.sourceforge.net/methods.html`. Further examples and documentation can be found in the tutorial and API reference, where relevant publications are also mentioned. Meka also includes a wrapper to Mulan (the `MULAN` class) to allow additional classifiers to be run from Meka's interfaces. Meka includes over a dozen evaluation metrics, including Hamming loss, 0/1 loss, Jaccard index, rank loss, log loss, and F1-measure (macro and micro averages). Several metrics can be output overall and per-label.

2.2 Extending Meka

Meka can be extended by writing classifiers that implement the `MultiLabelClassifier` interface. A multi-label classifier uses the same methods as a Weka classifier, namely the `buildClassifier(Instances)` and `distributionForInstance(Instance)` methods. The difference in Meka is that `classIndex()` will indicate the *number* of target attributes. As in Weka, the `distributionForInstance` method returns a vector which may be votes or posterior probabilities. In the latter case, a threshold or thresholds can automatically be calibrated, or defined ad-hoc according to user preference, to produce 0/1 label relevances. The tutorial deals with the general multi-target case.

Incremental classifiers simply implement `IncrementalMultiLabelClassifier` and thus, as with Weka's `UpdateableClassifier` interface, have an `updateClassifier(Instance)` method. Meka automatically carries out incremental learning and evaluation for any updateable classifiers. Semi-supervised classifiers implement `SemisupervisedClassifier` interface and must implement the method `setUnlabelledData(Instances)` which is called by the evaluation routine.

3. Related frameworks

Mulan (Tsoumakas et al., 2011) is a programmatic API also based on Weka providing a number of multi-label algorithms implemented from the literature. There is some overlap in terms of classifiers available, but the usage and performance is different. Mulan is an API, whereas Meka provides both graphical and command-line interfaces and this allows novel classifier and ensemble combinations and parameterizations thereof to be trialled rapidly without writing any code; allowing much flexibility when tackling a multi-label problem. A single command line is often sufficient to reproduce the results of publications. Both frameworks have attracted considerable interest and both are mentioned in the literature.

1. See, for example, `http://weka.wikispaces.com/ARFF`.

	Clus	Mulan	Meka
interface	config. file		CLI, GUI
multi-target	✓	regression	classification
hierarchical	✓	✓	✓
incremental	✓		✓
semi-supervised	✓		✓
num. of classifiers	2+	20+	20+
classification paradigms	decision trees/rules	Weka+others	Weka+others

Table 1: Comparing Meka with related frameworks.

Data set	Meka	Mulan
Enron	8	33
Corel-5k	10	35
MediaMill	449	2104

Table 2: Running time (s) of `RAkEL` under Meka and Mulan, with `SMO`, $k = 3, m = 10$.

Meka specializes in the problem transformation methods, in particular the classifier chains paradigm, implementing at least 10 variations; and also meta methods for combining them together in many combinations.

Clus is a decision tree and rule learning system (Appice and Džeroski, 2007) that can also carry out multi-label and multi-target classification. Classifiers are configured in a text file. Clus's implementations of decision tree and rule algorithms are scalable and competitive; but it does not include many of the popular problem transformation methods.

Table 1 roughly compares the frameworks in terms of features. Clus has fewer classification paradigms, but can be used in many different contexts. Mulan has a similar number of classifiers but Meka has different methods. Meka is noticeably faster than Mulan in some implementations under the same configurations, for example `RAkEL`, see Table 2.

Meka itself integrates well in other frameworks. For example, it is already part of the Moa (data streams), DKPro (text classification), and ADAMS (workflow engine) frameworks, and available via Maven Central.[2]

4. Summary and Further Notes

Meka provides a multi-label and multi-target framework with comfortable command line and graphical interfaces. This includes traditional, benchmark, and state of the art algorithms; and a multitude of multi-label specific evaluation measures. It also includes methods for incremental, multi-target, and semi-supervised learning, and is easy to use and extend. Meka is released under the GNU GPL 3 licence; can run on any Java (1.7 or above) machine. The software with source code, API reference, data sets, list of methods with examples, and a tutorial can be found at at `http://meka.sourceforge.net`, along with links to additional material about learning from multi-label and multi-target data.

Abstract

In regression problems over $\mathbb{R}^d$, the unknown function f often varies more in some coordinates than in others. We show that weighting each coordinate i according to an estimate of the variation of f along coordinate i – e.g. the L_1 norm of the ith-directional derivative of f – is an efficient way to significantly improve the performance of distance-based regressors such as kernel and k-NN regressors. The approach, termed Gradient Weighting (GW), consists of a first pass regression estimate f_n which serves to evaluate the directional derivatives of f, and a second-pass regression estimate on the re-weighted data. The GW approach can be instantiated for both regression and classification, and is grounded in strong theoretical principles having to do with the way regression bias and variance are affected by a generic feature-weighting scheme. These theoretical principles provide further technical foundation for some existing feature-weighting heuristics that have proved successful in practice.

We propose a simple estimator of these derivative norms and prove its consistency. The proposed estimator computes efficiently and easily extends to run online. We then derive a classification version of the GW approach which evaluates on real-worlds datasets with as much success as its regression counterpart.

Keywords: Nonparametric learning, feature selection, feature weighting, nonparametric sparsity, metric learning.

1. Introduction

High-dimensional regression is the problem of inferring an unknown function f from data pairs (X_i, Y_i), $i = 1, 2, \dots n$, where the input X_i belongs to a Euclidean subspace $\mathcal{X} \subset \mathbb{R}^d$ and the output Y_i is a noisy version of $f(X_i)$. The problem is significantly harder for larger dimension d, and various pre-processing approaches have been devised over time to alleviate this so-called *curse of dimension*. A simple and common approach is that of reducing the dimension of the input X by properly selecting a few coordinate-variables with the most influence on the problem. The general motivating assumption for these methods is that of (approximate) *sparsity*: the unknown function f only varies along a few relevant coordinates in some subset R of $[d] \doteq \{1, 2, \dots, d\}$, that is $f(X) = f\left(X_{(R)}\right)$ where $X_{(R)}$ picks out the set of relevant coordinates. However, as illustrated by Fig. 3, there are many real-world examples in which f varies significantly along all coordinates, but varies more in some coordinates than in others. The natural approach in this case, implicit in some methods and heuristics (see Section 1.2), is to *weight* each coordinate according to some measure of relevance learned from data. The learned coordinate-relevance would typically rely on various assumptions on the form of f, for example f might be assumed linear.

In the case of nonparametric regression, where little is assumed about the form of f, the question of how to properly weight coordinates has not received much theoretical attention. We present and analyze a simple approach termed Gradient Weighting (GW), consisting of weighting each coordinate i according to the (unknown) variation of f along i. To this end, f is estimated from data in a first pass as f_n, where f_n serves to assess the coordinate-wise variation of f and accordingly weight the data; the transformed data is then used to re-estimate f in a second pass. This procedure can be iterated into a multi-pass procedure, although we only consider the two-pass version just described. We show that such weighting can be learned efficiently, is easily extended online, and can significantly improve the performance of distance-based regressors (e.g. kernel and k-NN regression) in real-world applications. Moreover the method easily extends to distance-based classification methods such as k-NN classification and ϵ-NN classification.

The GW approach is grounded in strong theoretical principles (developed in Section 2) having to do with the way regression bias and variance are affected by the distribution of weights in a generic feature-weighting method. We argue in Section 2 that a good situation for distance-based regressors is one where the unknown function f varies in a few coordinates more than in others, and the weights correlate with the variation of f along coordinates. The theoretical intuition developed is kept general enough to also explain the practical success of some existing heuristics (see Section 6.2) which inherently learn weights that are correlated with the variation of the unknown f along coordinates. We validate the theoretical intuition in extensive experiments on many real-world datasets in Section 5.

There are many possible ways of capturing the variation of f along coordinates, thus the particular instantiations of GW considered here are simply ones that work well in practice. Our aim is therefore not of arguing in favor of a particular way of capturing the coordinate-wise variation of f, but rather that the general approach of weighting coordinates according to this variation of f can yield significant improvements in learning performance. The theoretical intuition developed in Section 2 uses, as a measure of the variation of f along i, the maximum variation $|f_i'|_{\text{sup}} \triangleq \sup_x |f_i'(x)|$ along coordinate i. The maximum variation is a natural measure of smoothness and as such is intuitive to argue about; however it is hard to estimate. Therefore, for practical instantiations of the GW approach, we instead measure the average variation of f along coordinates, specifically we estimate the norms $\|f_i'\|_{1,\mu} = \mathbb{E}_{X\sim\mu} |f_i'(X)|$, where μ denotes the marginal measure over X.

A significant portion of this work is dedicated to efficiently estimating the gradient-norms $\|f_i'\|_{1,\mu}$. The aim is to obtain a simple, practical and successful procedure grounded in the theoretical intuition developed. We show in Section 3 that these gradient-norms can be estimated efficiently (a brief overview is introduced in the subsection below), and we prove in Section 4 that the resulting method is statistically consistent. As previously mentioned, the resulting instantiations of GW evaluate successfully in practice as shown in Section 5.

*. A significant part of this work was conducted when the authors were at the Max Planck Institute for Intelligent Systems, Tuebingen, Germany.

1.1 GW for distance-based nonparametric methods

For distance-based methods, the weights can be incorporated into a distance function of the form

$$\rho(x,x') \triangleq \left((x-x')^\top \mathbf{W}(x-x')\right)^{1/2}, \quad (1)$$

where each element $\mathbf{W}_i$ of the diagonal matrix $\mathbf{W}$ is an estimate of the variation of f along coordinate i, as captured for instance by $\|f_i'\|_{1,\mu}$. In our evaluations we set $\mathbf{W}_i$ to an estimate $\nabla_{n,i}$ of $\|f_i'\|_{1,\mu}$, or to the square estimate $\nabla^2_{n,i}$.

To estimate $\|f_i'\|_{1,\mu}$, one does not need to estimate f_i' well everywhere, just well on average. While many elaborate derivative estimators exist (see e.g. (Härdle and Gasser, 1985)), we have to keep in mind our need for a fast but consistent estimator of $\|f_i'\|_{1,\mu}$. We propose a simple estimator $\nabla_{n,i}$ which averages the differences along i of an estimator $f_{n,h}$ of f. More precisely (see Section 3) $\nabla_{n,i}$ has the form $\mathbb{E}_n\left|f_{n,h}(X+te_i)-f_{n,h}(X-te_i)\right|/2t$ where $\mathbb{E}_n$ denotes empirical expectation over a sample $\{X_i\}_1^n$. $\nabla_{n,i}$ can therefore be updated online at the cost of just two estimates of $f_{n,h}$, given a proper online version of $f_{n,h}$ (see e.g. Gu and Lafferty (2012)).

In this paper $f_{n,h}$ is a kernel estimator, although any regression method might be used in estimating $\|f_i'\|_{1,\mu}$. We prove in Section 4 that, under mild conditions, $\mathbf{W}_i$ is a consistent estimator of the unknown norm $\|f_i'\|_{1,\mu}$. Moreover we prove finite sample convergence bounds to help guide the practical tuning of the two parameters t and h.

1.2 Related Work

The GW approach is close in spirit to *metric learning* (Weinberger and Tesauro, 2007; Xiao et al., 2009; Shalev-shwartz et al., 2004; Davis et al., 2007), where the best metric ρ is found by optimizing over a sufficiently large space of possible metrics. Clearly metric learning can only yield better performance, but the optimization over a larger space will result in heavier preprocessing time, often $O(n^2)$ on datasets of size n. Yet, preprocessing time is especially important in many modern applications where data sizes are large, or where training and prediction have real-time constraints (e.g. robotics, finance, advertisement, recommendation systems). Here we do not optimize over a space of metrics, but rather estimate a *single* metric ρ based on the coordinate-wise variation of f. Our metric ρ is efficiently obtained, can be estimated online, and still significantly improves the performance of distance-based regressors.

We also note that there are actually few metric learning approaches for regression and these are typically designed around a particular regression approach or problem. The method by Weinberger and Tesauro (2007) is designed for Gaussian-kernel regression, the one by Xiao et al. (2009) is tuned to the particular problem of age estimation. For the problem of classification, the metric-learning approaches of Shalev-shwartz et al. (2004); Davis et al. (2007) are meant for online applications – they are therefore relatively efficient methods – but cannot be used in regression.

In the case of kernel regression and local polynomial regression, multiple bandwidths can be used, one for each coordinate. However, tuning d bandwidth parameters requires searching a d-dimensional grid, i.e. the number of possible settings is exponential in d, which is impractical even in batch mode. The *RODEO* method of Lafferty and Wasserman (2005) alleviates this problem, however only in the particular case of local linear regression. Our method applies to any distance-based regressor.

The ideas presented here are related to recent notions of nonparametric sparsity where it is assumed that the target function is well approximated by a *sparse* function, i.e. one which varies in

just a few coordinates (e.g. Hoffmann and Lepski (2002); Lafferty and Wasserman (2005); Rigollet and Tsybakov (2011); Rosasco et al. (2012)). The method of Rosasco et al. (2012) is most related to the present work in that they employ a penalized learning objective based on the coordinate-wise variation of f, as captured by the L_2 gradient norms $\|f_i'\|_{2,\mu}$. However, as in the other works on sparsity just mentioned, Rosasco et al. (2012) relies on f being actually sparse or at least close to sparse. In the present work we do not need sparsity, instead we only need the target function f to vary in some coordinates more than in others which is most likely the case in practice. Our approach therefore works in practice even in cases where the target function is far from sparse.

One line of work which also does away with the assumption of sparsity of f, is that of *anisotropic* regression (Nusbaum (1983); Hoffmann and Lepski (2002)). Anisotropic regression assumes that the target function f does not have the same degree of smoothness in all coordinate directions, where smoothness is roughly captured by the number of bounded derivatives of f. The attainable rates in anisotropic regression are better than the usual minimax rates for nonparametric regression (e.g. Stone (1980)) which consider the worst-case degree of smoothness across all coordinates. In the present work, we only consider the first derivatives of f across coordinates, in other words f is allowed to have the same degree of smoothness across coordinates, but we are interested in the case where these coordinate-wise derivatives have different magnitudes. We show in Section 2 that this is enough to attain better rates than the usual minimax rates, in particular by using the GW approach proposed here.

As previously mentioned, the theoretical intuition developed in this work helps explain the practical success of some existing heuristics. In particular the popular Relief family of heuristics (e.g. Kira and Rendell (1992); Kononenko (1994); Robnik-Šikonja and Kononenko (2003)) can be viewed as inherently learning weights that are correlated with the coordinate-wise variation of f. Our work therefore offers new insights about existing heuristics and opens possible avenues of further development of these heuristics. This theme is further developed in Section 6.2.

Finally, part of this work appeared as a conference version Kpotufe and Boularias (2012) covering the case of regression. The present work covers both regression and classification and further differs in the technical motivation offered for the GW approach. While Kpotufe and Boularias (2012) argues for GW under strong uniform assumptions on the marginal distribution μ on $\mathcal{X}$, the theoretical intuition developed in the present work assumes a general distribution μ. The more general assumptions are made possible by introducing a new set of techniques dealing with the covering numbers of the space $\mathcal{X}$ after data weighting.

1.3 Paper Outline

In summary, we develop theoretical intuition for GW in Section 2. In Section 3 we derive a concrete method for estimating the coordinate-wise variablity of f; the method is both simple and efficient. We show in Section 4 that the method is a consistent estimator of the gradient norms $\|f_i'\|_{1,\mu}$. In Section 5 we validate our theory on various real-world applications. We finish with a general discussion of our results in Section 6, including possible future directions.

2. Theoretical Justification of GW

In this section we develop theoretical intuition about why GW works. We focus on the problem of nonparametric regression since the same intuition is easily implied for the case of nonparametric classification (see Section 2.3). We will argue that it is possible to attain good regression rates

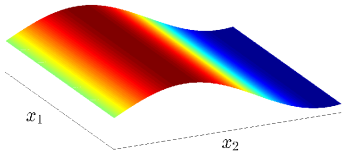

Figure 1: Illustration of a sparse function. Here $x = (x_1, x_2)$, and $f(x) = f(x_2)$. There is no variation in f along coordinate 1, in other words $|f_1'|_{\sup} = 0$ and $\|f_1'\|_{1,\mu} = 0$.

even when the target function f depends on all coordinates, provided f does not vary equally in all coordinates, and the gradient weights $\mathbf{W}_i$ are correlated with the coordinate-wise variation in f. The coordinate-wise variation will be captured in this discussion by the quantities $|f_i'|_{\sup} \triangleq \sup_{x\in\mathcal{X}} |f_i'(x)|$, $i \in [d]$, as previously mentioned.

We will consider the metric ρ generally: instead of assuming a particular form, we will let the analysis uncover a form of ρ which yields *improved* regression rates. Improvement is measured here in a minimax sense which will soon be made clear. The analysis of this section will thus yield intuition not only about GW, but about coordinate-weighting generally.

We have the following assumption throughout the section.

Assumption 2.1 *The input space $\mathcal{X}$ is full-dimensional in $\mathbb{R}^d$, connected*[1]*, and has bounded diameter $\|\mathcal{X}\| \triangleq \sup_{x,x'\in\mathcal{X}} \|x - x'\| = 1$. The output space is $\mathcal{Y} = [0, 1]$.*

2.1 Rough Intuition: the sparse case

We start with a simple case where the unknown function is actually R-sparse, i.e. depends on a small set of coordinates $R \subsetneq [d]$ (illustrated in Figure 2.1). The function f then varies only along coordinates in R, i.e. $f_i' \neq 0$ only for coordinates $i \in R$. Hence if the metric ρ is defined by setting the gradient weights $\mathbf{W}_i$ to either $|f_i'|_{\sup}$ and $\|f_i'\|_{1,\mu}$, the resulting space $(\mathcal{X}, \rho)$ is a (weighted) projection of the original Euclidean $\mathcal{X}$ down to just the relevant coordinates $R \subsetneq [d]$. Thus regression or classification on $(\mathcal{X}, \rho)$ would have performance depending on the lower-dimension $|R|$ of this space, rather than the high-dimension d of the original space.

To make this intuition precise, we introduce the following definition and minimax theorem.

Definition 1 (The class $\mathcal{F}_\lambda$) *Given $\lambda > 0$, we let $\mathcal{F}_\lambda$ denote all distributions $P_{X,Y}$ on $\mathcal{X} \times [0, 1]$ such that, for all $i \in [d]$, the directional derivatives of $f(x) \triangleq \mathbb{E}[Y|X = x]$ satisfy $|f_i'|_{sup} \triangleq \sup_{x\in\mathcal{X}} |f_i'(x)| \leq \lambda$.*

The worst-case rate for the class $\mathcal{F}_\lambda$ is given in the following minimax theorem of Stone.

Theorem 2 (Minimax rate for $\mathcal{F}_\lambda$: Stone (1982)) *There exists $\tilde{c} < 1$, independent of n, such that for all sample sizes $n \in \mathbb{N}$,*

$$\inf_{f_n} \sup_{f\in\mathcal{F}_\lambda} \mathbb{E}_{\mathbf{X}^n,\mathbf{Y}^n} \|f_n - f\|^2 \geq 2\tilde{c}^{2/(2+d)}(d\lambda)^{2d/(2+d)} n^{-2/2+d},$$

1. This is needed so that $\|f_i'\|_{1,\mu} = 0$ implies that f is a.e. constant along coordinate i.

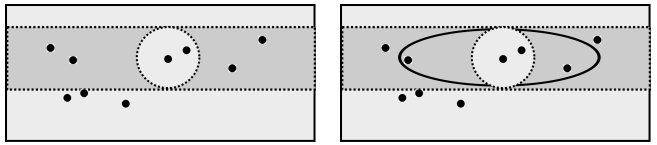

Figure 2: Balls $B(x, h)$ before and after projection or reweighting. The dotted points are sample $\{X_i\}$. **Left:** after projection onto 1 dimension, the new ball $B(x, h)$ contains all the points shown in the dotted rectangle, much more than the original ball (dotted circle). **Right:** feature-reweighting has the approximate effect of a projection; the new ball $B(x, h)$ is an ellipsoid containing more points in the directions with small weight.

where the infimum is taken over all regressors f_n mapping samples $\mathbf{X}^n, \mathbf{Y}^n$ to an L_2 measureable function (also denoted f_n for simplicity of notation), and the expectation is taken over the draw of an n-sample from a distribution where $\mathbb{E}[Y|X = x] = f(x)$.

Thus, in a minimax sense, the best rate achievable for (non-sparse) Lipschitz functions is f the form $O\left(n^{-2/(2+d)}\right)$. However when the unknown function happens to be R-sparse, the better rate of $O\left(n^{-2/(2+|R|)}\right)$ is achievable (see e.g. Lafferty and Wasserman (2005)). The better rates are achieved for instance by performing regression on the data projected to the span of R. This is the same as setting the weights $\mathbf{W}_i$, $i \notin R$, to 0. In other words, we would let $\mathbf{W}_i$ be correlated with the variation of f along coordinate i as discussed earlier.

To better understand why better rates are possible after a dimension reduction to the span of R as described above, let's consider the case of a kernel estimate $f_{n,h}(x)$ using a bandwidth h. The error of $f_{n,h}(x)$ depends on its variance and bias. The variance itself decreases with the number of points contributing most to the estimate: this is roughly (depending on the kernel) the number of points falling in the ball $B(x, h)$ in the given metric space. Since balls of a fixed radius have larger mass in smaller dimensional space (illustrated in Fig. 2), projection decreases the variance of the kernel estimate $f_{n,h}(x)$. In addition, if the unknown f does not vary along those directions $i \notin R$ eliminated by the projection, the bias of the estimate $f_{n,h}(x)$ remains unaffected; in other words, the projection loses no information about the unknown f. This combined effect on variance and bias decreases the error of the estimate.

But what if f is not actually sparse, but close to being sparse? i.e. f varies in all coordinates, but varies little in most coordinates. Intuitively, given the above discussion, better rates should also be achievable in this case. More interestingly, what if f varies considerably in all coordinates but much more in some than in most? This is a more practical situation which is more realistic with real-world data (see e.g. Figure 3). The above variance-bias intuition still applies if we reweight coordinates according to how f varies; as illustrated in Figure 2 (right), this acts as an approximate dimension reduction which also reduces the variance of regression estimates while keeping the bias relatively unaffected. We formalize this intuition in the next section.

Figure 3: Typical gradient norms (estimates of $\|f_i'\|_{1,\mu}$, $i \in [d]$) for some real-world datasets.

2.2 Technical intuition: the non-sparse case

In this section we aim to understand how regression performance is affected by the distribution of weights $\mathbf{W}_i$ with respect to the variation of f along coordinates. The main situation of interest is one where f varies in all coordinates, but in some coordinates more than in others. This situation is captured by assuming the quantities $|f_i'|_{\text{sup}}$ are all nonzero but some are considerably smaller than others. We also assume that the weights $\mathbf{W}_i$ are nonzero for all $i \in [d]$.

We will be bounding the error of a box-kernel regressor operating on the transformed space $(\mathcal{X}, \rho)$, in terms of how the weights $\mathbf{W}_i$ scale relative to each other, and relative to the variation $|f_i'|_{\text{sup}}$. We will see that, even in non-sparse situations where all $|f_i'|_{\text{sup}}$ are far from 0, it is possible to achieve finite-sample rates better than the minimax rate of Theorem 2, provided (i) the weights $\mathbf{W}_i$ are sufficiently larger in scale for a small subset R of the coordinates (for low variance), and (ii) each $\mathbf{W}_i$ is sufficiently correlated with $|f_i'|_{\text{sup}}$ (for low bias).

The results of this section uncover an interesting phenomenon, also observed in experiments, that improvement might only be possible in a specific mid-range sample size regime depending on problem parameters. This is unsurprising: when the sample size is too small, any algorithm will likely only fit noise and good rates would not be possible; as the sample size gets quite large, algorithms operating in the original space tend to also do well, and the advantage of operating in $(\mathcal{X}, \rho)$ becomes negligible (see Remark below). We believe this behavior is not limited to the GW approach, because the results here are not directly tied to GW since our analysis is in terms of a general metric ρ of the form (1).

We will see that the attainable convergence rates are smaller than the minimax rate of $\Omega(n^{-2/(2+d)})$ for n greater than some problem-specific n_0 (Corollary 8). These rates tend towards the minimax rate from below as $n \to \infty$.

Remark 2.1 *There is theoretical intuition as to why improvement over the minimax rate is unlikely in the asymptotic regime where $n \to \infty$. Remember that the metric ρ is norm-induced and all norms are equivalent on finite-dimensional spaces. In other words there exist C, C' such that for all $x, x' \in \mathbb{R}^d$, $C\|x - x'\| \leq \rho(x, x') \leq C'\|x - x'\|$. As a consequence there exists C'' such that, for ϵ sufficiently small, any ϵr-cover of a ρ-ball $B(x, r)$ centered on $x \in \mathcal{X}$ has size at least $C''\epsilon^{-d}$. Here C'' depends on the metric $(\mathcal{X}, \rho)$. It is known (see e.g. the lower-bound of Kpotufe (2011)) that such space covering properties influence the attainable regression rates, where larger data sizes n correspond to finer coverings of the space, hence to small ϵ. We therefore postulate that, for large n, the worst-case asymptotic rate is no better than $\Omega\left(n^{-2/(2+d)}\right)$. Thus we can only expect improvements over the minimax rate in small sample regimes, where* small *is problem-specific. Note that this remark is of independent interest since other approaches such as metric learning would typically use norm-induced metrics.*

The analysis in this section, although focusing on kernel regression, yields general intuition about the behavior of other related distance-based regressors such as k-NN, since such regressors are similarly affected by characteristics of the regression problem (e.g. smoothness of f, intrinsic dimension of $(\mathcal{X}, \rho)$).

We start by defining quantities which serve to describe the distribution of weights $\mathbf{W}_i$.

Definition 3 *For any subset of coordinates $R \subset [d]$, define $\kappa_R \triangleq \sqrt{\max_{i \in R} \mathbf{W}_i / \min_{i \in R} \mathbf{W}_i}$, and let $\epsilon_{R\!\!R} \triangleq 2\sqrt{\max_{i \notin R} \mathbf{W}_i}$. Finally we define the* ρ**-diameter** *of $\mathcal{X}$ as $\rho(\mathcal{X}) \triangleq \sup_{x,x' \in \mathcal{X}} \rho(x, x')$.*

As discussed earlier, regression variance is small if there exists a small subset R for which the weights $\mathbf{W}_i$ are relatively larger than those for coordinates not in R. Formally, we want the quantities $|R|$, $\epsilon_{R\!\!R}$ and κ_R relatively small for some $R \subset [d]$. How small will become gradually clearer.
