Observing that, $\widetilde{U}_B(q_{\widetilde{r}_B}) \leq 0$ by definition, we thus have with probability at least $1-\delta$:

$$\Lambda(\widetilde{r}_B) \leq \sqrt{\frac{2c\Lambda(\widetilde{r}_B)^\alpha \log(2M/\delta)}{n}} + \frac{4\log(2M/\delta)}{3n} + \sqrt{\frac{M + \log(2M/\delta)}{B}}.$$

Choosing finally $B = O(n^{2/(2-\alpha)})$, the desired result is obtained by solving the inequality above for $\Lambda(\widetilde{r}_B)$.

Appendix F. Proof of Theorem 13

As shown by the following lemma, which is a slight modification of Lemma 1 in Janson (1984), the deviation between the incomplete U-statistic and its complete version is of order $O_{\mathbb{P}}(1/\sqrt{B})$ for both sampling schemes.

Lemma 18 *Suppose that the assumptions of 13 are fulfilled. Then, we have:* $\forall H \in \mathcal{H}$,

$$\mathbb{E}\left[\left(\bar{U}_{HT}(H) - U_{\mathbf{n}}(H)\right)^2 \mid (\mathbf{X}_I)_{I\in\Lambda}\right] \leq 2\mathcal{M}_{\mathcal{H}}^2/B.$$

Proof Observe first that, in both cases (sampling without replacement and Bernoulli sampling), we have: $\forall I \neq J$ in Λ,

$$\mathbb{E}\left[\left(\Delta(I) - \frac{B}{\#\Lambda}\right)^2\right] \leq \frac{B}{\#\Lambda} \text{ and } \mathbb{E}\left[\left(\Delta(I) - \frac{B}{\#\Lambda}\right)\left(\Delta(J) - \frac{B}{\#\Lambda}\right)\right] \leq \frac{1}{\#\Lambda}\cdot\frac{B}{\#\Lambda}.$$

Hence, as $(\Delta(I))_{I\in\Lambda}$ and $(\mathbf{X}_I)_{I\in\Lambda}$ are independent by assumption, we have:

$$B^2\mathbb{E}\left[\left(\bar{U}_{HT}(H) - U_{\mathbf{n}(H)}\right)^2 \mid (\mathbf{X}_I)_{I\in\Lambda}\right] = \mathbb{E}\left[\left(\sum_{I\in\Lambda}\left(\Delta(I) - \frac{B}{\#\Lambda}\right)H(\mathbf{X}_I)\right)^2 \mid (\mathbf{X}_I)_{I\in\Lambda}\right]$$
$$\leq \mathcal{M}_{\mathcal{H}}^2 \sum_{I\in\Lambda}\mathbb{E}\left[\left(\Delta(I) - \frac{B}{\#\Lambda}\right)^2\right] + \mathcal{M}_{\mathcal{H}}^2 \sum_{I\neq J}\mathbb{E}\left[\left(\Delta(I) - \frac{B}{\#\Lambda}\right)\left(\Delta(J) - \frac{B}{\#\Lambda}\right)\right] \leq 2B\mathcal{M}_{\mathcal{H}}^2.$$

■

Consider first the case of Bernoulli sampling. By virtue of Bernstein inequality applied to the independent variables $(\Delta(I) - B/\#\Lambda)H(\mathbf{X}_I)$ conditioned upon $(\mathbf{X}_I)_{I\in\Lambda}$, we have: $\forall H \in \mathcal{H}$, $\forall t > 0$,

$$\mathbb{P}\left\{\left|\sum_{I\in\Lambda}(\Delta(I) - B/\#\Lambda)H(\mathbf{X}_I)\right| > t \mid (\mathbf{X}_I)_{I\in\Lambda}\right\} \leq 2\exp\left(-\frac{t^2}{4B\mathcal{M}_{\mathcal{H}}^2 + 2\mathcal{M}_{\mathcal{H}}t/3}\right).$$

Hence, combining this bound and the union bound, we obtain that: $\forall t > 0$,

$$\mathbb{P}\left\{\sup_{H\in\mathcal{H}}\left|\bar{U}_{HT}(H) - U_{\mathbf{n}(H)}\right| > t \mid (\mathbf{X}_I)_{I\in\Lambda}\right\} \leq 2(1+\#\Lambda)^V \exp\left(-\frac{Bt^2}{4\mathcal{M}_{\mathcal{H}}^2 + 2\mathcal{M}_{\mathcal{H}}t/3}\right).$$

Solving

$$\delta = 2(1+\#\Lambda)^V \exp\left(-\frac{Bt^2}{4\mathcal{M}_{\mathcal{H}}^2 + 2\mathcal{M}_{\mathcal{H}}t/3}\right)$$

yields the desired bound.

Consider next the case of the sampling without replacement scheme. Using the exponential inequality tailored to this situation proved in Serfling (1974) (see Corollary 1.1 therein), we obtain: $\forall H \in \mathcal{H}$, $\forall t > 0$,

$$\mathbb{P}\left\{\frac{1}{B}\left|\sum_{I\in\Lambda}(\Delta(I) - B/\#\Lambda)H(\mathbf{X}_I)\right| > t \mid (\mathbf{X}_I)_{I\in\Lambda}\right\} \leq 2\exp\left(-\frac{Bt^2}{2\mathcal{M}_{\mathcal{H}}^2}\right).$$

The proof can be then ended using the union bound, just like above.

Appendix G. Proof of Proposition 14

For simplicity, we focus on one sample U-statistics of degree two ($K = 1$, $d_1 = 2$) since the argument easily extends to the general case. Let $U_n(H)$ be a non-degenerate U-statistic of degree two:

$$U_n(H) = \frac{2}{n(n-1)}\sum_{i<j} H(x_i, x_j).$$

In order to express the variance of $U_n(H)$ based on its second Hoeffding decomposition (see Section 2.1), we first introduce more notations: $\forall (x, x') \in \mathcal{X}_1^2$,

$$H_1(x) \stackrel{\text{def}}{=} \mathbb{E}[H(x,X)] - \mu(H) \text{ and } H_2(x,x') \stackrel{\text{def}}{=} H(x,x') - \mu(H) - H_1(x) - H_1(x').$$

Equipped with these notations, the (orthogonal) Hoeffding/Hajek decomposition of $U_n(H)$ can be written as

$$U_n(H) = \mu(H) + 2T_n(H) + W_n(H),$$

involving centered and decorrelated random variables given by

$$T_n(H) = \frac{1}{n}\sum_{i=1}^n H_1(x_i),$$
$$W_n(H) = \frac{2}{n(n-1)}\sum_{i<j} H_2(x_i, x_j).$$

Recall that the U-statistic $W_n(H)$ is said to be degenerate, since $\mathbb{E}[H_2(x,X)] = 0$ for all $x \in \mathcal{X}_1$. Based on this representation and setting $\sigma_1^2 = \mathrm{Var}[H_1(X)]$ and $\sigma_2^2 = \mathrm{Var}[H_2(X,X')]$, the variance of $U_n(H)$ is given by

$$\mathrm{Var}[U_n(H)] = \frac{4\sigma_1^2}{n} + \frac{2\sigma_2^2}{n(n-1)}. \tag{50}$$

As already pointed out in Section 3.1, the variance of the incomplete U-statistic built by sampling with replacement is

$$\begin{aligned} \mathrm{Var}[\widetilde{U}_B(H)] &= \mathrm{Var}[U_n(H)] + \frac{1}{B}\left(1 - \frac{2}{n(n-1)}\right)\mathrm{Var}[H(X,X')] \\ &= \mathrm{Var}[U_n(H)] + \frac{1}{B}\left(1 - \frac{2}{n(n-1)}\right)(2\sigma_1^2 + \sigma_2^2). \end{aligned} \tag{51}$$

Take $B = n'(n'-1)$ for $n' \ll n$. It follows from (50) and (51) that in the asymptotic framework (4), the quantities $\mathrm{Var}[U_{n'}(H)]$ and $\mathrm{Var}[\widetilde{U}_B(H)]$ are of the order $O(1/n')$ and $O(1/n'^2)$ respectively as $n' \to +\infty$. Hence these convergence rates hold for $\widetilde{g}_{n'}(\theta)$ and $\widetilde{g}_B(\theta)$ respectively.

Abstract

We consider the problem of supervised learning with convex loss functions and propose a new form of iterative regularization based on the subgradient method. Unlike other regularization approaches, in iterative regularization no constraint or penalization is considered, and generalization is achieved by (early) stopping an empirical iteration. We consider a nonparametric setting, in the framework of reproducing kernel Hilbert spaces, and prove consistency and finite sample bounds on the excess risk under general regularity conditions. Our study provides a new class of efficient regularized learning algorithms and gives insights on the interplay between statistics and optimization in machine learning.

1. Introduction

Availability of large high-dimensional data sets has motivated an interest in the interplay between statistics and optimization, towards developing new and more efficient learning solutions (Bousquet and Bottou, 2008). Indeed, while much theoretical work has been classically devoted to study statistical properties of estimators defined by variational schemes (for example Empirical Risk Minimization (Vapnik, 1998) or Tikhonov regularization (Tikhonov and Arsenin, 1977)), and to the computational properties of optimization procedures to solve the corresponding minimization problems (see for example Sra et al., 2011), much less work has considered the integration of statistical and optimization aspects, see for example Chandrasekaran and Jordan (2013); Wainwright (2014); Orabona (2014).

With the latter objective in mind, in this paper, we focus on iterative regularization. This class of methods, originated in a series of work in the mid-eighties (Nemirovskii, 1986; Polyak, 1987), is based on the observation that early termination of an iterative optimization scheme applied to empirical data has a regularization effect. A critical implication of this fact is that the number of iterations serves as a regularization parameter, hence linking modeling and computational aspects: computational resources are directly linked to the generalization properties in the data, rather than their raw amount. Further, iterative regularization algorithms have a built-in "warm restart" property which allows to compute automatically a whole sequence of solutions corresponding to different levels of regularization (the regularization path). This latter property is especially relevant to efficiently determine the appropriate regularization level via model selection.

Iterative regularization techniques are well known in solving inverse problems, where several variants have been studied, see Engl et al. (1996); Kaltenbacher et al. (2008) and references therein. In machine learning, iterative regularization is often simply referred to as early stopping and is a well known "trick", for example in training neural networks (LeCun et al., 1998). Theoretical studies of iterative regularization in machine learning have mostly focused on the least square loss function (Buhlmann and Yu, 2003; Yao et al., 2007; Bauer et al., 2007; Blanchard and Nicole, 2010; Raskutti et al., 2014). Indeed, it is in this latter case that the connection to inverse problems can be made precise (De Vito et al., 2005). Interestingly, early stopping with the square loss has been shown to be related to boosting (Buhlmann and Yu, 2003) and also to be a special case of a large class of regularization approaches based on spectral filtering (Gerfo et al., 2008; Bauer et al., 2007). The regularizing effect of early stopping for loss functions other than the square loss has hardly been studied. Indeed, to the best of our knowledge the only papers considering related ideas are Bartlett and Traskin (2007); Bickel et al. (2006); Jiang (2004); Zhang and Yu (2005), where early stopping is studied in the context of boosting algorithms.

This paper is a different step towards understanding how early stopping can be employed with general convex loss functions. Within a statistical learning setting, we consider convex loss functions and propose a new form of iterative regularization based on the subgradient method, or the gradient descent if the loss is smooth. The resulting algorithms provide iterative regularization alternatives to Support Vector Machines or regularized logistic regression, and have built in the property of computing the whole regularization path. Our primary contribution in this paper is theoretical. By integrating optimization and statistical results, we establish consistency and non-asymptotic bounds quantifying the generalization properties of the proposed method under standard regularity assumptions. Interestingly, our study shows that considering the last iterate leads to essentially the same results as considering averaging, or selecting of the "best" iterate, as typically done in subgradient methods (Boyd and Vandenberghe, 2004). From a technical point of view, considering a general convex loss requires different error decompositions than the square loss. Moreover, operator theoretic techniques and matrix concentration inequalities need to be replaced by convex analysis and empirical process results. The error decomposition we consider, accounts for the contribution of both optimization and statistics to the error, and could be useful also for other methods.

The rest of the paper is organized as follows. We begin in Section 2 by briefly recalling the supervised learning problem, and then introduce our learning algorithm, discussing its numerical realization. In Section 3, after discussing the assumptions that underlie our analysis, we present and discuss our main theorems and illustrate the general error decom-

position which is composed of three error terms: computational, sample and approximation error. In Section 4, we will estimate the computational error, while in Section 5, we develop sample error bounds, and finally prove our main results.

2. Learning Algorithm

After briefly recalling the supervised learning problem, we introduce the algorithm we propose and give some comments on its numerical realization.

2.1 Problem Statement

In this paper we consider the problem of supervised learning. Let X be a separable metric space, $Y \subseteq \mathbb{R}$ and let ρ be a Borel probability measure on $Z = X \times Y$. Moreover, let $V : \mathbb{R} \times \mathbb{R} \to \mathbb{R}_+$ be a so-called loss function, measuring the *local error* $V(y, f(x))$ for $(x, y) \in Z$ and $f : X \to \mathbb{R}$. The *generalization error (or expected risk)* $\mathcal{E} = \mathcal{E}^V$ associated with V is given by

$$\mathcal{E}(f) = \int_Z V(y, f(x)) d\rho,$$

and is well defined for any measurable loss function V and measurable function f. We assume throughout that there exists a function f_ρ^V that minimizes the expected error $\mathcal{E}(f)$ among all measurable functions $f : X \to Y$. Roughly speaking, the goal of learning is to find an approximation of f_ρ^V when the measure ρ is known only through a sample $\mathbf{z} = \{z_i = (x_i, y_i)\}_{i=1}^m$ of size $m \in \mathbb{N}$ independently and identically drawn according to ρ. More precisely, given $\mathbf{z}$ the goal is to design a computational procedure to efficiently estimate a function $f_\mathbf{z}$, an estimator, for which it is possible to derive an explicitly probabilistic bound on the excess expected risk

$$\mathcal{E}(f_\mathbf{z}) - \mathcal{E}(f_\rho^V).$$

We end this section with a remark and an example.

Remark 1 *For several loss functions, it is possible to show that f_ρ^V exists, see the example below. However, as will be seen in the following, the search for an estimator in practice is often restricted to some hypothesis space $\mathcal{H}$ of measurable functions. In this case one should replace $\mathcal{E}(f_\rho^V)$ by $\inf_{f\in\mathcal{H}} \mathcal{E}(f)$. Interestingly, examples of hypothesis spaces are known for which $\mathcal{E}(f_\rho^V) = \inf_{f\in\mathcal{H}} \mathcal{E}(f)$, namely universal hypothesis spaces (Steinwart and Christmann, 2008). In the following, we consider $\mathcal{E}(f_\rho^V)$, with the understanding that it should be replaced by the infimum over $\mathcal{H}$, if the latter is not universal.*

Example 1 *The most classical example of loss function is probably the square loss $V(y, a) = (y - a)^2$, $y, a \in \mathbb{R}$. In this case, f_ρ^V is the regression function, defined at every point as the expectation of the conditional distribution of y given x (Cucker and Zhou, 2007; Steinwart and Christmann, 2008). Further examples include the absolute value loss $V(y, a) = |y - a|$ for which f_ρ^V is the median of the conditional distribution and more generally p-loss functions $V(y, a) = |y - a|^p$, $p \in \mathbb{N}$ [1]. Vapnik's ϵ-insensitive loss $V(y, a) = \max\{|y - a| - \epsilon, 0\}$, $\epsilon > 0$ and its generalizations $V(y, a) = \max\{|y - a|^p - \epsilon, 0\}$, $\epsilon > 0, p > 1$ provide yet other examples. For classification, i.e., $Y = \{\pm 1\}$, other examples of loss functions used include the hinge loss $V(y, a) = \max\{1 - ya, 0\}$, the logistic loss $V(y, a) = \log(1 + e^{-ya})$ and the exponential loss $V(y, a) = e^{-ya}$. For all these examples f_ρ^V can be characterized, see for example Steinwart and Christmann (2008), and its measurability is easy to check.*

1. We denote the set of positive integers by $\mathbb{N}$.

2.2 Learning via Subgradient Methods with Early Stopping

To present the proposed learning algorithm we need a few preliminary definitions. Consider a reproducing kernel $K : X \times X \to \mathbb{R}$, that is a symmetric function, such that the matrix $(K(u_i, u_j))_{i,j=1}^\ell$ is positive semidefinite for any finite set of points $\{u_i\}_{i=1}^\ell$ in X. Recall that a reproducing kernel K defines a reproducing kernel Hilbert space (RKHS) $(\mathcal{H}_K, \|\cdot\|_K)$ as the completion of the linear span of the set $\{K_x(\cdot) := K(x, \cdot) : x \in X\}$ with respect to the inner product $\langle K_x, K_u\rangle_K := K(x, u), x, u \in X$ (Aronszajn, 1950). Moreover, assume the loss function V to be measurable and convex in its second argument, so that the corresponding left derivative V'_- exists and is non-decreasing at every point.

For a stepsize sequence $\{\eta_t > 0\}$, a stopping iteration $T > 2$ and an initial value $f_1 = 0$, we consider the iteration

$$f_{t+1} = f_t - \eta_t \frac{1}{m} \sum_{j=1}^m V'_-(y_j, f_t(x_j)) K_{x_j}, \qquad t = 1, \ldots, T. \tag{1}$$

The above iteration corresponds to the subgradient method (Bertsekas, 1999; Boyd et al., 2003) for minimizing the *empirical error* $\mathcal{E}_\mathbf{z} = \mathcal{E}_\mathbf{z}^V$ with respect to the loss V, which is given by

$$\mathcal{E}_\mathbf{z}(f) = \frac{1}{m} \sum_{j=1}^m V(y_j, f(x_j)).$$

Indeed, it is easy to see that $\frac{1}{m}\sum_{j=1}^m V'_-(y_j, f(x_j))K_{x_j} \in \partial\mathcal{E}_\mathbf{z}(f)$, the subgradient of the empirical risk for $f \in \mathcal{H}_K$. In the special case where the loss function is smooth, then (1) reduces to the gradient descent algorithm. Since the subgradient method is not a descent algorithm, rather then the last iterate, the so-called Cesáro mean is often considered, corresponding, for $T \in \mathbb{N}$, to the following weighted average

$$a_T = \sum_{t=1}^T \omega_t f_t, \qquad \omega_t = \frac{\eta_t}{\sum_{t=1}^T \eta_t}, \quad t = 1, \ldots, T. \tag{2}$$

Alternatively, the *best iterate* is also often considered, which is defined for $T \in \mathbb{N}$ by

$$b_T = \operatorname*{arg\,min}_{f_t : t=1,\cdots,T} \mathcal{E}_\mathbf{z}(f_t). \tag{3}$$

In what follows, we will consider the learning algorithms obtained with these different choices.

We note that, classical results (Bertsekas, 1999; Boyd et al., 2003; Boyd and Vandenberghe, 2004) on the subgradient method focus on how the iteration (1) can be used to minimize $\mathcal{E}_\mathbf{z}$. Different to these studies, in the following we are interested in showing how iteration (1) can be used to define a *statistical estimator*, hence a learning algorithm to minimize the expected risk $\mathcal{E}$, rather than the empirical risk $\mathcal{E}_\mathbf{z}$. We add two remarks.

Remark 2 (Early Stopping SVM and Kernel Perceptron) *If we consider the hinge loss function in* (1)*, the corresponding algorithm is closely related to a batch (kernel) version of the perceptron (Rosenblatt, 1962; Aizerman et al., 1964), where an entire pass over the data is done before updating the solution. Such an algorithm can also be seen as an early stopping version of Support Vector Machines (Cortes and Vapnik, 1995). Interestingly, in this case the whole regularization path is computed incrementally albeit sparsity could be lost.*

Remark 3 (Multiple Passes SGD) *In practice stochastic/incremental approaches are often used. The latter correspond to considering the iteration*

$$f_{t+1} = f_t - \eta_t V'_-(y_{j_t}, f_t(x_{j_t}))K_{x_{j_t}}, \qquad t = 1, \dots, T.$$

given some initialization. Compared to (1) *in the above expression the "batch" gradient is replaced by a point-wise gradient. The sequence $(j_t)_t$ defines the order in which points are visited and can be stochastic. The obtained iteration is a form of stochastic gradient/subgradient method. When $T > n$ the algorithm visits the point multiple times. Each full pass over the data is called an epoch, or a cycle, and the obtained iteration corresponds to a form of incremental gradient/subgradient. The analysis in the paper can be modified to account for these iterations. However, to keep the paper self-contained we defer such an analysis to a future paper.*

2.3 Numerical Realization

The simplest case to derive a numerical procedure from Algorithm 1 is when $X = \mathbb{R}^d$ for some $d \in \mathbb{N}$ and K is the associated inner product. In this case it is straightforward to see that $f_{t+1}(x) = w_{t+1}^\top x$ for all $x \in X$, with $w_1 = 0_{d\times 1} \in \mathbb{R}^d$ and

$$w_{t+1} = w_t - \eta_t \frac{1}{m} \sum_{j=1}^m V'_-(y_j, w_t^\top x_j) x_j, \qquad t = 1, \dots, T.$$

Here, $w_t \in \mathbb{R}^d$ for all t. Beyond the linear kernel, it can be easily seen that given a finite *dictionary*

$$\{\phi_i : X \to \mathbb{R}, i = 1, \dots, p\}, \qquad p \in \mathbb{N},$$

one can consider the kernel $K(x, x') = \sum_{i=1}^p \phi_i(x')\phi_i(x)$. In this case, it holds $f_{t+1}(x) = \sum_{i=1}^p w_{t+1}^i \phi_i(x) = w_{t+1}^\top \Phi(x)$, $\Phi(x) = (\phi_1(x), \dots, \phi_p(x))^\top$ for all $x \in X$, with $w_1 = 0_{p\times 1} \in \mathbb{R}^p$ and

$$w_{t+1} = w_t - \eta_t \frac{1}{m} \sum_{j=1}^m V'_-(y_j, w_t^\top \Phi(x_j))\Phi(x_j), \qquad t = 1, \dots, T.$$

Finally, for a general kernel it is easy to prove by induction that $f_{t+1}(x) = \sum_{j=1}^m c_{t+1}^j K(x, x_j)$ for all $x \in X$, with

$$c_{t+1} = c_t - \eta_t \frac{1}{m} g_t, \qquad t = 1, \dots, T,$$

for $c_1 = 0_{m\times 1} \in \mathbb{R}^m$ and $g_t \in \mathbb{R}^m$ with its i-th component $g_t^i = V'_-(y_i, \sum_{j=1}^m c_t^j K(x_i, x_j)), \forall i = 1, \cdots, m$. Here, $c_t = (c_t^1, \cdots, c_t^m)^\top$ for $t \in \mathbb{N}$. Indeed, the base case is straightforward to

check and moreover by the inductive hypothesis

$$f_{t+1} = \sum_{j=1}^m c_t^j K_{x_j} - \eta_t \frac{1}{m} \sum_{j=1}^m V'_-(y_j, f_t(x_j))K_{x_j} = \sum_{j=1}^m K_{x_j} \left(c_t^j - \eta_t \frac{1}{m} V'_-(y_j, f_t(x_j)) \right).$$

3. Main Results with Discussions

After presenting our main assumptions, in this section we state and discuss our main results.

3.1 Assumptions

Our results will be stated under several conditions on the triplet (ρ, V, K), that we describe and comment next. We begin with a basic assumption.

Assumption 1 *We assume the kernel to be bounded, that is $\kappa = \sup_{x\in X} \sqrt{K(x,x)} < \infty$. Moreover $\|f_\rho^V\|_\infty < \infty$ and $|V|_0 := \sup_{y\in Y} V(y, 0) < \infty$. Furthermore, we consider the following growth condition for the left derivative $V'_-(y, \cdot)$. For some $q \geq 0$ and constant $c_q > 0$, it holds,*

$$\left|V'_-(y, a)\right| \leq c_q(1 + |a|^q), \qquad \forall a \in \mathbb{R}, y \in Y. \tag{4}$$

The boundedness conditions on K, f_ρ^V and V are fairly common (Cucker and Zhou, 2007; Steinwart and Christmann, 2008). They could probably be weakened by considering a more involved analysis which is outside the scope of this paper. Interestingly, the *growth* condition on the left derivative of V is weaker than assuming the loss, or its gradient, to be Lipschitz in its second entry which is standard both in learning theory (Cucker and Zhou, 2007; Steinwart and Christmann, 2008) and in optimization (Boyd and Vandenberghe, 2004). We note that the growth condition (4) is implied by the requirement for the loss function to be Nemitski when Y is bounded, as introduced in De Vito et al. (2004) (see also Steinwart and Christmann, 2008). This latter condition, which is satisfied by most loss functions, is natural to provide variational characterizations of the learning problem.

The second assumption refines the above boundedness condition by considering a variance-expectation bound which quantifies the noise (level) in the measure ρ with respect to *balls* in the RKHS $B_R = \{f \in \mathcal{H}_K : \|f\|_K \leq R\}$, $R > 0$ (Cucker and Zhou, 2007; Steinwart and Christmann, 2008).

Assumption 2 *We assume that there exists an exponent $\tau \in [0, 1]$ and a positive constant c_τ such that for any $R \geq 1$ and $f \in B_R$, we have*

$$\int_Z \left\{ \left(V(y, f(x)) - V(y, f_\rho^V(x)\right)^2 \right\} d\rho \leq c_\tau R^{2+q-\tau} \left\{ \mathcal{E}(f) - \mathcal{E}(f_\rho^V) \right\}^\tau. \tag{5}$$

Assumption 2 always holds true for the square loss with $q = \tau = 1$, the hinge loss with $q = \tau = 0$, and more generally for Lipschitz loss functions with $\tau = 0$ and c_τ depending on $\|f_\rho^V\|_\infty$. In classification, the above condition can be related to the so-called Tsybakov margin condition. The latter quantifies the intuition that a classification problem is hard if the conditional probability of y given x is close to $1/2$ for many input points. More precisely if we denote by $\rho(y|x)$ the conditional probability for all $(x, y) \in Z$ and by ρ_X the marginal

probability on X, then we say that ρ satisfies the Tsybakov margin condition with exponent s if there exists a constant $C > 0$ such that for all $\delta > 0$

$$\rho_X(\{x \in X \ : \ |\rho(1|x) - \frac{1}{2}| \leq \delta\}) \leq (C\delta)^s.$$

Interestingly, under the Tsybakov margin condition, Assumption 2 holds for the hinge loss with $\tau = \frac{s}{s+1}$ and c_τ depending only on C.

The third condition is about the decay of the approximation error (Smale and Zhou, 2003).

Assumption 3 *Let $\lambda > 0$ and f_λ be a minimizer of:*

$$f_\lambda := \arg\min_{f \in \mathcal{H}_K} \mathcal{E}(f) + \lambda \|f\|_K^2. \tag{6}$$

The approximation error associated with the triplet (ρ, V, K) is defined by

$$\mathcal{D}(\lambda) = \mathcal{E}(f_\lambda) - \mathcal{E}(f_\rho^V) + \lambda \|f_\lambda\|_K^2. \tag{7}$$

We assume that for some $\beta \in (0, 1]$ and $c_\beta > 0$, the approximation error satisfies

$$\mathcal{D}(\lambda) \leq c_\beta \lambda^\beta, \qquad \forall \ \lambda > 0. \tag{8}$$

The above assumption is standard when analyzing regularized empirical risk minimization schemes and is related to the definition of interpolation spaces by means of K- functional (Cucker and Zhou, 2007). Interestingly, we will see in the following that it is also important when analyzing the approximation properties of the subgradient algorithm (1).

Finally, the last condition characterizes the *capacity* of a RKHS $\mathcal{H}_K$ in terms of empirical covering numbers, and plays an essential role in sample error estimates. Recall that for a subset $\mathcal{G}$ of a metric space (H, d), the covering number $\mathcal{N}(\mathcal{G}, \epsilon, d)$ is defined by

$$\mathcal{N}(\mathcal{G}, \epsilon, d) = \inf \left\{ l \in \mathbb{N} : \exists f_1, f_2, \cdots, f_l \subset H \text{ such that } \mathcal{G} \subset \bigcup_{i=1}^{\ell} \{f \in \mathcal{G} : d(f, f_i) \leq \epsilon\} \right\}.$$

Assumption 4 *Let $\mathcal{G}$ be a set of functions on X. The metric $d_{2,\mathbf{z}}$ is defined on $\mathcal{G}$ by*

$$d_{2,\mathbf{z}}(f, g) = \left\{ \frac{1}{m} \sum_{i=1}^{m} (f(z_i) - g(z_i))^2 \right\}^{1/2}, \quad f, g \in \mathcal{G}.$$

We assume that for some $\zeta \in (0, 2)$, $c_\zeta > 0$, the covering number of the unit ball B_1 in $\mathcal{H}_K$ with respect to $d_{2,\mathbf{z}}$ satisfies

$$\mathbb{E}_{\mathbf{z}} \left[\log \mathcal{N}\left(B_1, \epsilon, d_{2,\mathbf{z}}\right) \right] \leq c_\zeta \left(\frac{1}{\epsilon} \right)^\zeta, \qquad \forall \ \epsilon > 0. \tag{9}$$

The smaller ζ, the more stringent is the capacity assumption. As ζ approaches 2 we are essentially considering a capacity independent scenario, that is an arbitrary RKHS. In what follows, we will briefly comment on the connection between the above assumption and

other related assumptions. Recall that capacity of the RKHS may be measured by various concepts: covering numbers of balls B_R in $\mathcal{H}_K$, (dyadic) entropy numbers and decay of the eigenvalues of the integral operator $L_K : L^2_\rho \to L^2_\rho$ given by $L_K(f) = \int_X f(x) K_x d\rho_X(x)$, where $L^2_\rho = \{f : X \to \mathbb{R} \ : \ \int |f(x)|^2 d\rho_X(x) < \infty\}$. For a subset $\mathcal{G}$ of a metric space (H, d), the n-th entropy number is defined by

$$e_n(\mathcal{G}, d) = \inf \left\{ \varepsilon > 0 : \exists f_1, f_2, \cdots, f_{2^{n-1}} \text{ such that } \mathcal{G} \subset \bigcup_{i=1}^{2^{n-1}} \{f \in \mathcal{G} : d(f, f_i) \leq \varepsilon\} \right\}.$$

First, note that the covering and entropy numbers are equivalent (see for example Steinwart and Christmann, 2008, Lemma 6.21). Indeed, for $\zeta > 0$, the covering number $\mathcal{N}(\mathcal{G}, \epsilon, d)$ satisfies

$$\log \mathcal{N}(\mathcal{G}, \epsilon, d) \leq a_\zeta \left(\frac{1}{\epsilon} \right)^\zeta, \qquad \forall \epsilon > 0,$$

for some $a_\zeta > 0$, if and only if the entropy number $e_n(\mathcal{G}, d)$ satisfies

$$e_n(\mathcal{G}, d) \leq a'_\zeta \left(\frac{1}{n} \right)^{\frac{1}{\zeta}},$$

for some $a'_\zeta > 0$. Second, it is shown in Steinwart (2009) that if the eigenvalues of the integral operator L_K satisfy

$$\lambda_n \leq \tilde{a}_\zeta \left(\frac{1}{n} \right)^{\frac{2}{\zeta}}, \qquad n \geq 1,$$

for some constants $\tilde{a}_\zeta \geq 1$ and $\zeta \in (0, 2)$, then the expectation of the random entropy number $\mathbb{E}_{\mathbf{z}}[e_n\left(B_1, d_{2,\mathbf{z}}\right)]$ satisfies

$$\mathbb{E}_{\mathbf{z}}[e_n\left(B_1, d_{2,\mathbf{z}}\right)] \leq a_\zeta \left(\frac{1}{n} \right)^{\frac{1}{\zeta}}, \qquad n \geq 1,$$

for some constant a_ζ. Hence, using the equivalence of covering and entropy numbers, $\mathbb{E}_{\mathbf{z}}\left[\log \mathcal{N}\left(B_1, \epsilon, d_{2,\mathbf{z}}\right)\right]$ can be estimated from the eigenvalue decay of the integral operator L_K. Finally, since $d_{2,\mathbf{z}}(f, g) \leq \|f - g\|_\infty$, one has that for any $\epsilon > 0$, $\mathcal{N}\left(B_1, \epsilon, d_{2,\mathbf{z}}\right)$ is bounded by $\mathcal{N}\left(B_1, \epsilon, \|\cdot\|_\infty\right)$, the uniform covering number of B_1 under the metric $\|\cdot\|_\infty$. Thus, the covering number $\mathcal{N}\left(B_1, \epsilon, d_{2,\mathbf{z}}\right)$ can be also estimated given the uniform smoothness of the kernel (Zhou, 2003).

3.2 Finite Sample Bounds for General Convex Loss Functions

Our main results, in Theorems 4, 7 and 8, provide general stopping rules and corresponding upper bounds involving all the parameters defining the problem. These results are then illustrated and discussed in a series of corollaries considering special cases that allow for simpler statements, see in particular Corollary 6 in this subsection, Corollaries 9 and 10 in Subsection 3.3, and Theorems 11 and 12 in Subsection 3.4.

The following is our main result providing a general finite sample bound for the iterative regularization induced by the subgradient method for convex loss functions considering the last iterate. Here, $\lceil x \rceil$ denotes the smallest integer greater than or equal to $x \in \mathbb{R}$.

Theorem 4 *Assume (4) with $q \geq 0$, (5) with $\tau \in [0,1]$, (8) with $\beta \in (0,1]$ and (9) with $\zeta \in (0,2)$. Let $\eta_t = \eta_1 t^{-\theta}$ with $\frac{q}{q+1} < \theta < 1$ and η_1 satisfying*

$$0 < \eta_1 \leq \min\left\{ \frac{\sqrt{1-\theta}}{\sqrt{2}c_q(\kappa+1)^{q+1}}, \frac{1-\theta}{4|V|_0} \right\}. \tag{10}$$

If $T = \lceil m^\gamma \rceil$, then for any $0 < \delta < 1$, with confidence $1-\delta$, we have

$$\mathcal{E}(f_T) - \mathcal{E}(f_\rho^V) \leq \begin{cases} \widetilde{C} m^{-\alpha} \log \frac{2}{\delta}, & \text{when } \theta > \frac{q+1}{q+2}, \\ \widetilde{C} m^{-\alpha} \log m \log \frac{2}{\delta}, & \text{when } \theta \leq \frac{q+1}{q+2}, \end{cases}$$

where the power indices γ and α are defined as

$$\gamma = \begin{cases} \frac{2}{1-\theta} \frac{1}{(1+2\beta)(2-\tau+\zeta\tau/2)+q(1+\zeta/2)}, & \text{when } \theta \geq \frac{q+1}{q+2}, \\ \frac{2}{1-\theta}\left(1+\frac{2\beta(\theta(1+q)-q)}{1-\theta}\right) \frac{1}{(2-\tau+\zeta\tau/2)+q(1+\zeta/2)}, & \text{when } \theta < \frac{q+1}{q+2}, \end{cases} \tag{11}$$

$$\alpha = \begin{cases} \frac{\beta}{\beta(2-\tau+\zeta\tau/2)+\left\{\frac{2-\tau+\zeta\tau/2}{2}+\frac{q(1+\zeta/2)}{2}\right\}}, & \text{when } \theta \geq \frac{q+1}{q+2}, \\ \frac{\beta}{\beta(2-\tau+\zeta\tau/2)+\frac{1-\theta}{\theta(1+q)-q}\left\{\frac{2-\tau+\zeta\tau/2}{2}+\frac{q(1+\zeta/2)}{2}\right\}}, & \text{when } \theta < \frac{q+1}{q+2}, \end{cases} \tag{12}$$

and $\widetilde{C}$ is a positive constant independent of m or δ (given explicitly in the proof).

The proof is deferred to Section 5 and is based on a novel error decomposition, discussed in Section 3.6, integrating statistical and optimization aspects. We begin illustrating the above result for Lipschitz loss functions, that is considering $q = 0$, as follows.

Corollary 5 *Assume (4) with $q = 0$, (9) with $\zeta \in (0,2)$ and (8) with $\beta \in (0,1]$. Let $\eta_t = \eta_1 t^{-\theta}$ with $0 < \theta < 1$ and η_1 satisfying $0 < \eta_1 \leq \min\left\{ \frac{\sqrt{1-\theta}}{\sqrt{2}c_q(\kappa+1)}, \frac{1-\theta}{4|V|_0} \right\}$. If $T = \lceil m^\gamma \rceil$, then for any $0 < \delta < 1$, with confidence $1-\delta$, we have*

$$\mathcal{E}(f_T) - \mathcal{E}(f_\rho^V) \leq \begin{cases} \widetilde{C} m^{-\alpha} \log \frac{2}{\delta}, & \text{when } \theta > \frac{1}{2}, \\ \widetilde{C} m^{-\alpha} \log m \log \frac{2}{\delta}, & \text{when } \theta \leq \frac{1}{2}, \end{cases}$$

where the power indices γ and α are defined as

$$\gamma = \begin{cases} \frac{2}{(1-\theta)(2\beta+1)(2-\tau+\zeta\tau/2)}, & \text{when } \theta \geq \frac{1}{2}, \\ \frac{2}{(1-\theta+2\beta\theta)(2-\tau+\zeta\tau/2)}, & \text{when } \theta < \frac{1}{2}, \end{cases}$$

$$\alpha = \begin{cases} \frac{2\beta}{(2\beta+1)(2-\tau+\zeta\tau/2)}, & \text{when } \theta \geq \frac{1}{2}, \\ \frac{2\theta\beta}{(1-\theta+2\beta\theta)(2-\tau+\zeta\tau/2)}, & \text{when } \theta < \frac{1}{2}, \end{cases}$$

and $\widetilde{C}$ is a positive constant independent of m or δ.

For Lipschitz loss functions, Assumption 2 always holds true for $\tau = 0$. Also, if $f_\rho^V \in \mathcal{H}_K$, then Assumption 3 holds for $\beta = 1$ and $c_\beta \leq \|f_\rho^V\|_K^2$. In this case, γ and α from the above theorem are given by

$$\gamma = \max\left\{ \frac{1}{3(1-\theta)}, \frac{1}{1+\theta} \right\} \quad \text{and} \quad \alpha = \min\left\{ \frac{1}{3}, \frac{\theta}{1+\theta} \right\}.$$

Setting $\theta = 1/2$, we get the following result.

Corollary 6 *Assume (4) with $q = 0$, (9) with $\zeta \in (0,2)$ and $f_\rho^V \in \mathcal{H}_K$. Let $\eta_t = \eta_1 t^{-1/2}$ with η_1 satisfying $0 < \eta_1 \leq \min\left\{ \frac{1}{2c_q(\kappa+1)}, \frac{1}{8|V|_0} \right\}$. If $T = \lceil m^{2/3} \rceil$, then for any $0 < \delta < 1$, with confidence $1-\delta$, we have*

$$\mathcal{E}(f_T) - \mathcal{E}(f_\rho^V) \leq \widetilde{C} m^{-1/3} \log m \log \frac{2}{\delta}.$$

The above results give finite sample bounds on the excess risk, provided that a suitable stopping rule is considered. While the stopping rule in the above theorems is distribution dependent, a data-driven stopping rule can be given by hold-out cross validation and adaptively achieves the same bounds. The proof of this latter result is straightforward using the techniques in Caponnetto and Yao (2010) and is omitted. The above bounds directly yield strong consistency (almost sure convergence) using standard arguments. Interestingly, our analysis suggests that a decaying stepsize needs to be chosen to achieve meaningful error bounds. The stepsize choice can influence both the early stopping rule and the error bounds. More precisely, if the stepsize decreases fast enough, i.e., $\theta \geq \frac{q+1}{q+2}$, the stopping rule depends on the decay speed but the error bound does not. In this case, the best possible choice for the early stopping rule is $\theta = \frac{q+1}{q+2}$, that is $\eta_t \sim 1/\sqrt{t}$ in the case of Lipschitz loss functions. With this choice, if for example we take the limit $\beta \to 1$, $\tau \to 0$, we have that the stopping rule scales as $O(m^{2/3})$ whereas the corresponding finite sample bounds are of order $O(m^{-1/3})$. A slower stepsize decay given by $\theta < \frac{q+1}{q+2}$ affects both the stopping rule and the error bounds, but these results are worse. A more detailed discussion of the obtained bounds in comparison to other learning algorithms is postponed to Section 3.5.

To see how the number of passes and the decaying rate θ of stepsize affects the performances of our algorithms, we carry out simple numerical simulations that complement the above result. In Fig. 1 we consider simulated data, i.e. simple binary classification problem where the input space is two dimensional. The training and test error as a function of the number of iterations are reported for different stepsize values. In Fig. 2 we consider a real benchmark data-set and again report the training and test error for different stepsize values. The same qualitative behavior can be observed in simulated and real data. The empirical error decreases as a function of the number of iterations while the expected (test) error as a minimum. The effect is more evident when the stepsize choice is more aggressive, that is for θ close to zero.

Next we discuss the behavior of different variants of the proposed algorithm. As mentioned before, in the subgradient method, when the goal is empirical risk minimization, the average or best iterates are often considered (see Equations (2), (3)). It is natural to ask what are the properties of the estimator obtained with these latter choices, that is when they are used as approximate minimizers of the expected, rather than the empirical risk. The following theorem provides an answer.

Theorem 7 *Under the assumptions of Theorem 4, if $T = \lceil m^\gamma \rceil$ and $g_T = a_T$ (or b_T) then for any $0 < \delta < 1$, with confidence $1-\delta$, we have*

$$\mathcal{E}(g_T) - \mathcal{E}(f_\rho^V) \leq \begin{cases} \overline{C} m^{-\alpha} \log \frac{2}{\delta}, & \text{when } \theta \neq \frac{q+1}{q+2}, \\ \overline{C} m^{-\alpha} \log m \log \frac{2}{\delta}, & \text{when } \theta = \frac{q+1}{q+2}, \end{cases}$$

where the power indices γ and α are defined as in Theorem 4 and $\overline{C}$ is a positive constant independent of m or δ (can be given explicitly).

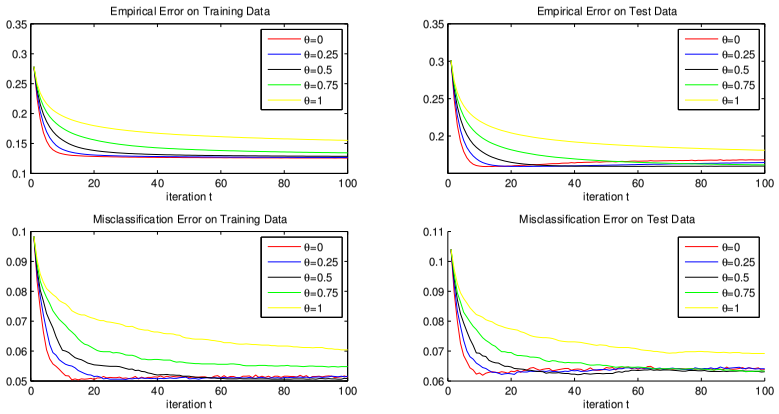

Figure 1: Performance of Algorithm (1) for the last iterates applied to synthetic data in binary classification with different θ, setting $\eta_1 = 1$, $V(y,f) = \max\{1-yf, 0\}$ and $\mathcal{H}_K = \mathbb{R}^2$. Samples for two classes are drawn from bivariate Gaussian distributions. The parameters for the Gaussian distributions are $\mu_1 = [2,0]^\top$, $\Sigma_1 = [5,3;3,5]/2$ and $\mu_{-1} = -\mu_1$, $\Sigma_{-1} = \Sigma_1$. For each given θ, we run Algorithm (1) 100 times for 100 independent training data, and calculate the corresponding test errors for 100 independent test data. In each trial, both of the training data and the test data are of 100. The errors averaged over these 100 trials are depicted as the above.

The above result shows, perhaps surprisingly, that the behavior of the average or best iterates is essentially the same as the last iterate. Indeed, there is only a subtle difference between the upper bounds in Theorem 7 and those in Theorem 4, since the latter have an extra $\log m$ factor when $\theta < \frac{q+1}{q+2}$.

In the next section, we consider the case where loss is not only convex but also smooth.

3.3 Finite Sample Bounds for Smooth Loss Functions

In this section, we additionally assume that $V(y,\cdot)$ is differentiable and $V'(y,\cdot)$ is Lipschitz continuous with constant $L > 0$, i.e., for any $y \in Y$ and $a, b \in \mathbb{R}$,

$$|V'(y,b) - V'(y,a)| \le L|b-a|.$$

For the logistic loss in binary classification (see Example 1), it is easy to prove that both $V(y,\cdot)$ and $V'(y,\cdot)$ are Lipschitz continuous with $L = 1$, for all $y \in Y$. With the above smoothness assumption, we prove the following convergence result.

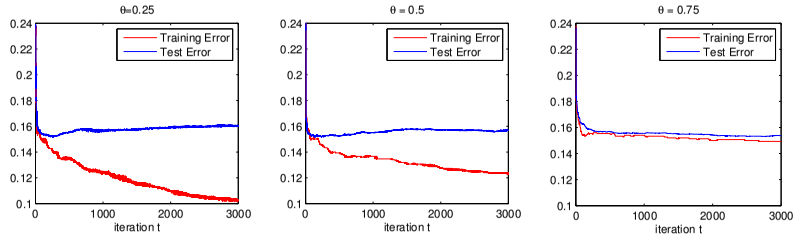

Figure 2: Misclassification errors of Algorithm (1) for the last iterates applied to Adult dataset with different values of θ, setting $V(y,f) = \max\{1-yf, 0\}$, $K(x,x') = \exp\{-\frac{\|x-x'\|_2^2}{2\sigma^2}\}$ and $m = 1500$. Here, σ is chosen as the median of the vector that consists of all Euclidean distances between training input vectors with different labels (Jaakkola et al., 1999). For each θ, η_1 is tuned using a holdout method.

Theorem 8 *Assume (4) with $q \ge 0$, (5) with $\tau \in [0,1]$, (8) with $\beta \in (0,1]$ and (9) with $\zeta \in (0,2)$. Assume that $V(y,\cdot)$ is differentiable and $V'(y,\cdot)$ is Lipschitz continuous with constant $L > 0$. Let $\eta_t = \eta_1 t^{-\theta}$ with $0 \le \theta < 1$ and $0 < \eta_1 \le \min(\frac{1-\theta}{2|V|_0}, (L\kappa^2)^{-1})$. If $T = \lceil m^\gamma \rceil$, then for any $0 < \delta < 1$, with confidence $1-\delta$, we have*

$$\mathcal{E}(f_T) - \mathcal{E}(f_\rho^V) \le \widetilde{C} m^{-\alpha} \log \frac{2}{\delta},$$

where the power indices γ and α are defined as

$$\gamma = \frac{2}{1-\theta} \frac{1}{(1+2\beta)(2-\tau+\zeta\tau/2) + q(1+\zeta/2)},$$
$$\alpha = \frac{\beta}{\beta(2-\tau+\zeta\tau/2) + \left\{\frac{2-\tau+\zeta\tau/2}{2} + \frac{q(1+\zeta/2)}{2}\right\}},$$

and $\widetilde{C}$ is a positive constant independent of m or δ.

The proof of this result will be given in Section 5. We can simplify the result by considering Lipschitz loss function ($q = 0$) and setting $\tau = 0$.

Corollary 9 *Under the assumptions of Theorem 8, let $q = 0$. If $T = \lceil m^{\frac{1}{(1-\theta)(2\beta+1)}} \rceil$, then for any $0 < \delta < 1$, with confidence $1-\delta$, we have*

$$\mathcal{E}(f_T) - \mathcal{E}(f_\rho^V) \le \widetilde{C} m^{-\frac{\beta}{2\beta+1}} \log \frac{2}{\delta},$$

where $\widetilde{C}$ is a positive constant independent of m or δ.

The finite sample bound obtained above is essentially the same as the best possible bound obtained for general convex loss functions. However, the important difference is that for

smooth loss functions, a constant stepsize can be chosen and allows to considerably improve the stopping rule. Indeed, if for example we can consider the limit $\beta \to 1$, $\tau \to 0$, we have that the stopping is $O(m^{1/3})$, rather than $O(m^{2/3})$, whereas the corresponding finite sample bound is again $O(m^{-1/3})$.

A similar simplification can be done for the square loss. Here, as mentioned in Example 1, f_ρ^V is the regression function f_ρ, and there holds $\mathcal{E}(f) - \mathcal{E}(f_\rho) = \|f - f_\rho\|^2_{L^2_{\rho_X}}$. In this case, Assumption 2 holds true for $\tau = 1$ and $c_\tau = 1$, and condition (8) can be characterized by requiring that $f_\rho \in L_K^{\beta/2}(L^2_{\rho_X})$ (Smale and Zhou, 2003; Caponnetto and De Vito, 2007), where $L_K^{\beta/2}$ is the $\frac{\beta}{2}$-th power of the positive operator L_K.

Corollary 10 *Let $V(y,a) = (y-a)^2$ and $|y| \leq |V|_0 < \infty$ almost surely. Assume $f_\rho \in L_K^{\beta/2}(L^2_{\rho_X})$ with $\beta \in (0,1]$ and (9) with $\zeta \in (0,2)$. Let $\eta_t = \eta_1 t^{-\theta}$ with $0 \leq \theta < 1$ and $0 < \eta_1 \leq \min(\frac{1-\theta}{2|V|_0}, \kappa^{-2})$. If $T = \lceil m^{\frac{2}{(1-\theta)(\beta+1)(\zeta+2)}} \rceil$, then for any $0 < \delta < 1$, with confidence $1-\delta$, we have*

$$\|f_T - f_\rho\|^2_{L^2_{\rho_X}} \leq \widetilde{C} m^{-\frac{2\beta}{(\beta+1)(\zeta+2)}} \log \frac{2}{\delta}.$$

In particular, if $f_\rho \in \mathcal{H}_K$,

$$\|f_T - f_\rho\|^2_{L^2_{\rho_X}} \leq \widetilde{C} m^{-\frac{1}{\zeta+2}} \log \frac{2}{\delta}.$$

Before comparing our bounds with obtained with other algorithms we last specialize our results to a binary classification setting.

3.4 Iterative Regularization for Classification: Surrogate Loss Functions and Hinge Loss

We briefly discuss how the above results allow to derive error bounds in binary classification problems. In this latter case $Y = \{1, -1\}$ and a natural choice for the loss function is the misclassification loss given by

$$V(y, b(x)) = \Theta\left(-y b(x)\right) \tag{13}$$

for $b : X \to Y$ and $\Theta(a) = 1$, if $a \geq 0$, and $\Theta(a) = 0$ otherwise. The corresponding generalization error, denoted by $\mathcal{R}$, is called misclassification risk, since it can be shown to be the probability of the event $\{(x,y) \in Z : y \neq b(x)\}$. The minimizer of the misclassification error is the Bayes rule $b_\rho : X \to Y$ given by

$$b_\rho(x) = \begin{cases} 1, & \text{if the conditional probability } \rho(1|x) \geq 1/2, \\ -1, & \text{otherwise.} \end{cases}$$

The misclassification loss (13) is neither convex nor smooth and thus leads to computationally intractable problems. In practice, a convex (so-called *surrogate*) loss function is typically considered and a classifier is obtained by estimating a real function f and then taking its sign defined as

$$\operatorname{sign}(f)(x) = \begin{cases} 1, & \text{if } f(x) \geq 0, \\ -1, & \text{otherwise.} \end{cases}$$

The question arises of if, and how, error bounds on the excess risk $\mathcal{E}(f) - \mathcal{E}(f_\rho^V)$ yields results on $\mathcal{R}(\operatorname{sign} f) - \mathcal{R}(b_\rho)$. Indeed, the so-called *comparison* results are known relating these different error measures, see for example Cucker and Zhou (2007); Steinwart and Christmann (2008) and references therein. We discuss in particular the case of the hinge loss function (see Example 1). In this case for all measurable functions f it holds that

$$\mathcal{R}(\operatorname{sign} f) - \mathcal{R}(b_\rho) \leq \mathcal{E}(f) - \mathcal{E}(f_\rho^V).$$

Indeed, the hinge loss satisfies Assumption (4) with $q = 0$ and, under Tsybakov noise condition, Assumption (5). Misclassification error bound, for iterative regularization with the hinge loss, can then be obtained as a corollary of Theorem 4.

Theorem 11 *Let $Y = \{1, -1\}$ and V be the hinge loss. Let $0 < \epsilon < \frac{1}{3}$ and (8) be satisfied with $\beta \in (0,1]$. Let $\eta_t = \eta_1 t^{-\theta}$ with $\theta > 1/2$ and $0 < \eta_1 \leq \min\left\{\frac{\sqrt{(1-\theta)}}{\sqrt{2}(\kappa+1)}, \frac{1-\theta}{4}\right\}$. If (9) is valid with $\zeta \in (0,2)$ and $T = \lceil m^{\frac{1}{(1-\theta)(2\beta+1)}} \rceil$, then with confidence $1-\delta$, we have*

$$\mathcal{R}\left(sign(f_T)\right) - \mathcal{R}(f_c) \leq \widetilde{C} m^{-\frac{\beta}{2\beta+1}} \log \frac{2}{\delta}. \tag{14}$$

In particular, if $\beta > \frac{1-3\epsilon}{1+6\epsilon}$ with $\epsilon \in (0, 1/3)$, then with confidence $1-\delta$,

$$\mathcal{R}\left(sign(f_T)\right) - \mathcal{R}(f_c) \leq \widetilde{C} m^{\epsilon - \frac{1}{3}} \log \frac{2}{\delta}.$$

The proof of the above result is given in Section 5, and comments on the obtained rates are given in the next section.

We end noting that, as illustrated by the next result where the stopping rule is kept fixed while the stepsize is chosen in a distribution dependent way. This observation is made precise by the following result.

Theorem 12 *Let $Y = \{1, -1\}$ and V be the hinge loss. Let $0 < \epsilon < \frac{1}{3}$ and (8) is satisfied with $1 > \beta > \frac{4-3\epsilon}{4+6\epsilon}$. Let $\eta_t = \eta_1 t^{-\theta}$ with $\theta = \frac{4\beta - 1 + 3\epsilon(2\beta+1)}{(2\beta+1)(2+3\epsilon)}$ and $0 < \eta_1 \leq \min\left\{\frac{\sqrt{2(1-\theta)}}{\kappa+1}, \frac{1-\theta}{4}\right\}$. If (9) is valid with $\zeta \in (0,2)$ and $T = \lceil m^{\frac{2}{3}+\epsilon} \rceil$, then with confidence $1-\delta$, we have*

$$\mathcal{R}\left(sign(f_T)\right) - \mathcal{R}(f_c) \leq \widetilde{C} m^{\frac{\epsilon}{4} - \frac{1}{3}} \log \frac{2}{\delta}.$$

3.5 Comparison with Other Learning Algorithms

As mentioned before iterative regularization has nice computational properties. The algorithm reduces to a simple first order method with low iteration cost and allows to easily compute the estimators corresponding to different regularization level (the regularization path), a crucial fact since model selection needs to be performed. In this view, the proposed procedure can be compared with standard approaches for example based on considering Support Vector Machines (SVM) or online variants such as Pegasos. In the former case, in principle a quadratic programming problem need to be solved for each regularization

parameter values. Our approach can be compared to more sophisticated approaches to compute the full SVM regularization path. In the latter case, the main difference is that in iterative regularization the early stopping rule is explicitly linked to the regularization level and in practice can be chosen by cross validation.

It is natural to compare the obtained statistical bounds with those for other learning algorithms. For general convex loss functions, the methods for which sharp bounds are available, are penalized empirical risk minimization (Tikhonov regularization), i.e.

$$f_{\mathbf{z},\lambda} = \arg\min_{f\in\mathcal{H}_K} \left\{ \mathcal{E}_{\mathbf{z}}(f) + \lambda \|f\|_K^2 \right\}, \quad \lambda > 0,$$

see for example Cucker and Zhou (2007); Steinwart and Christmann (2008) and references therein. The best error bounds for Tikhonov regularization with Lipschitz loss functions, see for example Steinwart and Christmann (2008, Chapter 7), are of order $O(m^{-\alpha'})$ with

$$\alpha' = \min\left\{ \frac{2\beta}{\beta+1}, \frac{\beta}{(2-\zeta/2-\tau+\tau\zeta/2)\beta+\zeta/2} \right\},$$

which reduces to

$$\alpha' = \frac{\beta}{\beta+1}$$

in the capacity independent limit ($\zeta \to 2$). From Corollary 5 for Lipschitz loss functions, we see that the bounds we obtain are of order $O(m^{-\alpha})$ with the exponent

$$\alpha = \frac{2\beta}{(2\beta+1)(2-\tau+\zeta\tau/2)},$$

reducing to

$$\alpha = \frac{\beta}{2\beta+1}$$

in the capacity independent limit. Hence, the obtained bounds are worse than the best ones available for Tikhonov regularization. However, the analysis of the latter does not take into account the optimization error and it is still an open question whether the best rate is preserved when such an error is incorporated. At this point we believe this gap to be a byproduct of our analysis rather than a fundamental fact, and addressing this point should be a subject of further work. Moreover, we note that our analysis allows to derive error bound for all Nemitski loss functions rather than only Lipschiz loss functions.

Beyond Tikhnov regularization, we can compare with the online regularization scheme for the hinge loss. The online learning algorithms with a regularization sequence $\{\lambda_t > 0\}_t$ defined by

$$f_{t+1} = \begin{cases} (1-\eta_t\lambda_t) f_t, & \text{if } y_t f_t(x_t) > 1, \\ (1-\eta_t\lambda_t) f_t + \eta_t y_t K_{x_t}, & \text{if } y_t f_t(x_t) \le 1. \end{cases} \tag{15}$$

were studied in Ying and Zhou (2006); Ye and Zhou (2007). Our results improve the results in Ying and Zhou (2006); Ye and Zhou (2007) in two aspects. The bound obtained in Ying and Zhou (2006) is of the form $O(T^{\epsilon-\frac{1}{4}})$ while the bound in Theorem 12 is of type $O(T^{\frac{9}{8}\epsilon-\frac{1}{2}})$ by substituting the expression $m^{\frac{2}{3}+\epsilon}$ for T. Moreover, our results are with high probability and promptly yield almost sure convergence whereas the results in Ying and

Zhou (2006) are only in expectation. We note that, interestingly, sharp bounds for Lipschitz loss functions are derived in Orabona (2014), although the obtained results do not take into account the capacity and variance assumptions that could lead to large improvements.

We next compare with the previous results on iterative regularization. The main results available thus far have been obtained for the square loss, for which bounds have been first derived for gradient descent in Buhlmann and Yu (2003), but only for a fixed design regression setting, and in Yao et al. (2007) for a general statistical learning setting. While the bounds in Yao et al. (2007) are suboptimal, they have later been improved in Bauer et al. (2007); Caponnetto and Yao (2010); Raskutti et al. (2014). Interestingly, sharp error bounds have also been proved for iterative regularization induced by other, potentially faster, iterative techniques, including incremental gradient (Rosasco and Villa, 2014), conjugate gradient (Blanchard and Nicole, 2010) and the so-called ν-method (Bauer et al., 2007; Caponnetto and Yao, 2010), an accelerated gradient descent technique related to Chebyshev method (Engl et al., 1996). The best obtained bounds are of order $O(m^{-\frac{2\beta}{2\beta+\zeta}})$ and can be shown to be optimal since they match the corresponding minimax lower bound (Caponnetto and De Vito, 2007). The bound obtained in Corollary 10 holds for all smooth Nemitski loss functions but is of order $O(m^{-\frac{2\beta}{(2+\zeta)(\beta+1)}})$, which is worse. In the capacity independent limit, the best available bound we obtain is of order $O(m^{-\frac{\beta}{2(\beta+1)}})$, whereas the optimal bound is of order $O(m^{-\frac{\beta}{\beta+1}})$. Also, in this case, the reason for the gap appears to be of technical reason and should be further studied.

Finally, before giving the detailed proofs, in the next subsection, we discuss the general error decomposition underlying our approach, which highlights the interplay between statistics and optimization and could be also useful in other contexts.

3.6 Error Decomposition

Theorems 4 and 8 rely on a natural error decomposition that we derive next. The goal is to estimate the excess risk $\mathcal{E}(f_T) - \mathcal{E}(f_\rho^V)$, and the starting point is to split the error by introducing a *reference* function $f_* \in \mathcal{H}_K$,

$$\mathcal{E}(f_T) - \mathcal{E}(f_\rho^V) = \mathcal{E}(f_T) - \mathcal{E}(f_*) + \mathcal{E}(f_*) - \mathcal{E}(f_\rho^V). \tag{16}$$

The above equation can be further developed by considering

$$\mathcal{E}(f_T) - \mathcal{E}(f_\rho^V) = (\mathcal{E}_{\mathbf{z}}(f_T) - \mathcal{E}_{\mathbf{z}}(f_*)) + (\mathcal{E}(f_T) - \mathcal{E}_{\mathbf{z}}(f_T) + \mathcal{E}_{\mathbf{z}}(f_*) - \mathcal{E}(f_*)) + \left(\mathcal{E}(f_*) - \mathcal{E}(f_\rho^V)\right). \tag{17}$$

Inspection of the above expression provides several insights. The first term is a computational error related to optimization. It quantifies the discrepancy between the empirical errors of the iterate defined by the subgradient method and that of the reference function. The second term is a sample error and can be studied using empirical process theory, provided that a bound on the norm of the iterates (and of the reference function) is available. Indeed, to get a sharper concentration estimate *recentering* can be considered (Cucker and Zhou, 2007; Steinwart and Christmann, 2008)

$$\left\{ \left(\mathcal{E}(f_T) - \mathcal{E}(f_\rho^V)\right) - \left(\mathcal{E}_{\mathbf{z}}(f_T) - \mathcal{E}_{\mathbf{z}}(f_\rho^V)\right) \right\} + \left\{ \left(\mathcal{E}_{\mathbf{z}}(f_*) - \mathcal{E}_{\mathbf{z}}(f_\rho^V)\right) - \left(\mathcal{E}(f_*) - \mathcal{E}(f_\rho^V)\right) \right\}.$$

Note that the second addend can be negative so that we effectively only need to control

$$\mathcal{F}_{\mathbf{z}}(f_*) = \max\left\{(\mathcal{E}_{\mathbf{z}}(f_*) - \mathcal{E}_{\mathbf{z}}(f_\rho^V)) - (\mathcal{E}(f_*) - \mathcal{E}(f_\rho^V)),\ 0\right\}. \tag{18}$$

Finally the last term suggests that a natural choice for the reference function is an *almost minimizer* of the expected risk, having bounded norm, and for which the approximation level can be quantified. While there is a certain degree of freedom in the latter choice, in the following we will consider $f_* = f_\lambda$, the minimizer of (6). With this latter choice we can control

$$\mathcal{A}(f_*) = \mathcal{E}(f_*) - \mathcal{E}(f_\rho^V)$$

by $\mathcal{D}(\lambda)$ given in Assumption 3.

Collecting some of the above observations, we have the following lemma.

Lemma 13 *For $f_* \in \mathcal{H}_K$, we have*

$$\begin{aligned}&\mathcal{E}(f_T) - \mathcal{E}(f_\rho^V)\\ &\le \left\{\left(\mathcal{E}(f_T) - \mathcal{E}(f_\rho^V)\right) - \left(\mathcal{E}_{\mathbf{z}}(f_T) - \mathcal{E}_{\mathbf{z}}(f_\rho^V)\right) + \mathcal{F}_{\mathbf{z}}(f_*)\right\} + (\mathcal{E}_{\mathbf{z}}(f_T) - \mathcal{E}_{\mathbf{z}}(f_*)) + \mathcal{A}(f_*).\end{aligned} \tag{19}$$

In the next sections, we proceed estimating the various error terms in the above error decomposition. We will first deal with the computational error, the analysis of which is the main technical contribution of the paper and then proceed to consider the sample and approximation error terms. The best stopping criterion and corresponding rates are derived by suitably balancing these different error terms.

4. Computational Error

In this section, we will bound the iterates and estimate the computational error from Lemma 13.

4.1 Bounds on Iterates

We introduce the following key lemma, which will be used several times in our analysis.

Lemma 14 *For any fixed $f \in \mathcal{H}_K$ and $t = 1, \dots, T$,*

$$\|f_{t+1} - f\|_K^2 \le \|f_t - f\|_K^2 + \eta_t^2 G_t^2 + 2\eta_t[\mathcal{E}_{\mathbf{z}}(f) - \mathcal{E}_{\mathbf{z}}(f_t)], \tag{20}$$

where

$$G_t^2 = \left\| \frac{1}{m}\sum_{j=1}^m V_-'(y_j, f_t(x_j))K_{x_j} \right\|_K^2 \le c_q^2(\kappa+1)^{2q+2}\max\left\{1, \|f_t\|_K^{2q}\right\}. \tag{21}$$

Proof Computing inner product $\langle f_{t+1} - f, f_{t+1} - f\rangle_K$ with f_{t+1} given by (1) yields

$$\|f_{t+1} - f\|_K^2 = \|f_t - f\|_K^2 + \eta_t^2 G_t^2 + \frac{2\eta_t}{m}\sum_{j=1}^m V_-'(y_j, f_t(x_j))\left\langle K_{x_j}, f - f_t\right\rangle_K.$$

Using the reproducing property

$$f(x) = \langle f, K_x\rangle_K, \qquad \forall f \in \mathcal{H}_K, x \in X, \tag{22}$$

and Assumption 1, we get

$$\|f\|_\infty \le \kappa\|f\|_K, \qquad \forall f \in \mathcal{H}_K, \tag{23}$$

and

$$\|f_{t+1} - f\|_K^2 = \|f_t - f\|_K^2 + \eta_t^2 G_t^2 + \frac{2\eta_t}{m}\sum_{j=1}^m V_-'(y_j, f_t(x_j))(f(x_j) - f_t(x_j)). \tag{24}$$

Since $V(y_j, \cdot)$ is a convex function, we have

$$V_-'(y_j, a)(b-a) \le V(y_j, b) - V(y_j, a), \qquad \forall a, b \in \mathbb{R}.$$

Using this expression to (24) gives

$$\|f_{t+1} - f\|_K^2 \le \|f_t - f\|_K^2 + \eta_t^2 G_t^2 + \frac{2\eta_t}{m}\sum_{j=1}^m \left[V(y_j, f(x_j)) - V(y_j, f_t(x_j))\right],$$

where the last term is exactly $2\eta_t[\mathcal{E}_{\mathbf{z}}(f) - \mathcal{E}_{\mathbf{z}}(f_t)]$.

By (4), (23), and the observation $\|K_{x_j}\|_K = \sqrt{K(x_j, x_j)} \le \kappa$, we find

$$\begin{aligned} G_t &= \left\| \frac{1}{m}\sum_{j=1}^m V_-'(y_j, f_t(x_j))K_{x_j} \right\|_K \le \frac{\kappa}{m}\sum_{j=1}^m \left|V_-'(y_j, f_t(x_j))\right| \\ &\le \frac{\kappa}{m}\sum_{j=1}^m c_q(1 + |f_t(x_j)|^q) \le \kappa c_q(1 + \kappa^q\|f_t\|_K^q), \end{aligned}$$

and the desired bound follows. ∎

Using the above lemma, we can bound the iterated sequence as follows.

Lemma 15 *Let $0 \le \theta < 1$ satisfying $\theta \ge \frac{q}{q+1}$ and $\eta_t = \eta_1 t^{-\theta}$ with η_1 satisfying (10). Then for $t = 1, \dots, T$,*

$$\|f_{t+1}\|_K \le t^{\frac{1-\theta}{2}}. \tag{25}$$

Proof We prove our statement by induction. Taking $f = 0$ in Lemma 14, we know that

$$\|f_{t+1}\|_K^2 \le \|f_t\|_K^2 + \eta_t^2 G_t^2 + 2\eta_t[\mathcal{E}_{\mathbf{z}}(0) - \mathcal{E}_{\mathbf{z}}(f_t)] \le \|f_t\|_K^2 + \eta_t^2 G_t^2 + 2\eta_t|V|_0.$$

This verifies (25) for the case $t = 1$ since $f_1 = 0$ and $\eta_1^2 c_q^2(\kappa+1)^{2q+2} + 2\eta_1|V|_0 \le 1$. Assume $\|f_t\|_K \le (t-1)^{\frac{1-\theta}{2}}$ with $t \ge 2$. Then

$$G_t^2 \le c_q^2(\kappa+1)^{2q+2}(t-1)^{(1-\theta)q}.$$

Hence,

$$\begin{aligned}\|f_{t+1}\|_K^2 &\leq (t-1)^{1-\theta} + \eta_1^2 t^{-2\theta} c_q^2 (\kappa+1)^{2q+2} t^{(1-\theta)q} + 2\eta_1 t^{-\theta}|V|_0 \\ &\leq t^{1-\theta}\left\{\left(1-\frac{1}{t}\right)^{1-\theta} + \frac{\eta_1^2 c_q^2(\kappa+1)^{2q+2}}{t^{(q+1)\theta+1-q}} + \frac{2\eta_1|V|_0}{t}\right\}.\end{aligned}$$

Since $\left(1-\frac{1}{t}\right)^{1-\theta} \leq 1-\frac{1-\theta}{t}$ and the condition $\theta \geq \frac{q}{q+1}$ implies $(q+1)\theta+1-q \geq 1$, we have

$$\|f_{t+1}\|_K^2 \leq t^{1-\theta}\left\{1-\frac{1-\theta}{t} + \frac{\eta_1^2 c_q^2(\kappa+1)^{2q+2}}{t} + \frac{2\eta_1|V|_0}{t}\right\}.$$

Finally we use the restriction (10) for η_1 and find $\|f_{t+1}\|_K^2 \leq t^{1-\theta}$. This completes the induction procedure and proves our conclusion. ■

By taking $f = f_t$ in (20), we see the following estimate for $\|f_{t+1} - f_t\|_K$ from Lemmas 14 and 15.

Corollary 16 *Under the assumptions of Lemma 15, we have for $t = 1, \ldots, T$,*

$$\|f_{t+1} - f_t\|_K \leq \eta_1 c_q (\kappa+1)^{q+1} t^{\frac{(1-\theta)q}{2}-\theta}. \tag{26}$$

Observe from the restriction $\theta \geq \frac{q}{q+1}$ in Lemma 15 that the power index in (26) satisfies $\frac{(1-\theta)q}{2} - \theta \leq -\frac{q}{2(q+1)} \leq 0$.

4.2 Computational Error for the Last Iterate

In this subsection, we estimate the computational error $\mathcal{E}_{\mathbf{z}}(f_T) - \mathcal{E}_{\mathbf{z}}(f_*)$ for an arbitrary $f_* \in \mathcal{H}_K$. Some ideas for estimating the average error in our proof are taken from Boyd et al. (2003); Shamir and Zhang (2013).

Lemma 17 *Assume (4) with $q \geq 0$. Let $f_* \in \mathcal{H}_K$. If $\eta_t = \eta_1 t^{-\theta}$ with $0 < \theta < 1$ satisfying $\theta > \frac{q}{q+1}$ and η_1 satisfying (10), then we have*

$$\begin{aligned}\mathcal{E}_{\mathbf{z}}(f_T) - \mathcal{E}_{\mathbf{z}}(f_*) \leq &\left(\frac{\|f_*\|_K^2}{2\eta_1} + \widetilde{C}_1\right)\Lambda_{T,\theta} \\ &+ \frac{T^\theta}{2\eta_1}\sum_{k=1}^{T-1}\frac{1}{k+1}\left[\frac{1}{k}\sum_{t=T-k+1}^{T} 2\eta_t - 2\eta_{T-k}\right]\{\mathcal{E}_{\mathbf{z}}(f_{T-k}) - \mathcal{E}_{\mathbf{z}}(f_*)\},\end{aligned} \tag{27}$$

where $\Lambda_{T,\theta}$ is defined by

$$\Lambda_{T,\theta} = \begin{cases} \frac{1}{(q+2)\theta-(q+1)}T^{-(1-\theta)}, & \text{when } \theta > \frac{q+1}{q+2}, \\ (\log T)T^{-(1-\theta)}, & \text{when } \theta = \frac{q+1}{q+2}, \\ \frac{1}{(q+1)-(q+2)\theta}(\log T)T^{-(\theta(1+q)-q)}, & \text{when } \theta < \frac{q+1}{q+2}, \end{cases} \tag{28}$$

and $\widetilde{C}_1$ is a positive constant depending on q, κ, θ (independent of T, m or f_* and given explicitly in the proof).

Proof Lemma 14 plays a key role in our proof. In particular, we shall apply the following equivalent form of inequality (20) from Lemma 14 several times with various choices of $f \in \mathcal{H}_K$:

$$2\eta_t\left[\mathcal{E}_{\mathbf{z}}(f_t) - \mathcal{E}_{\mathbf{z}}(f)\right] \leq \left\{\|f_t - f\|_K^2 - \|f_{t+1} - f\|_K^2\right\} + \eta_t^2 G_t^2. \tag{29}$$

Step 1: Error decomposition. Decompose the weighted empirical error $2\eta_T\mathcal{E}_{\mathbf{z}}(f_T)$ as

$$\begin{aligned}2\eta_T\mathcal{E}_{\mathbf{z}}(f_T) &= \frac{1}{2}\{2\eta_T\mathcal{E}_{\mathbf{z}}(f_T) + 2\eta_{T-1}\mathcal{E}_{\mathbf{z}}(f_{T-1})\} \\ &\quad + \frac{1}{2}2\eta_T\{\mathcal{E}_{\mathbf{z}}(f_T) - \mathcal{E}_{\mathbf{z}}(f_{T-1})\} + \frac{1}{2}\{2\eta_T - 2\eta_{T-1}\}\mathcal{E}_{\mathbf{z}}(f_{T-1}) \\ &= \frac{1}{3}\{2\eta_T\mathcal{E}_{\mathbf{z}}(f_T) + 2\eta_{T-1}\mathcal{E}_{\mathbf{z}}(f_{T-1}) + 2\eta_{T-2}\mathcal{E}_{\mathbf{z}}(f_{T-2})\} \\ &\quad + \frac{1}{2\times 3}\{2\eta_T[\mathcal{E}_{\mathbf{z}}(f_T) - \mathcal{E}_{\mathbf{z}}(f_{T-2})] + 2\eta_{T-1}[\mathcal{E}_{\mathbf{z}}(f_{T-1}) - \mathcal{E}_{\mathbf{z}}(f_{T-2})]\} \\ &\quad + \frac{1}{2}2\eta_T\{\mathcal{E}_{\mathbf{z}}(f_T) - \mathcal{E}_{\mathbf{z}}(f_{T-1})\} + \frac{1}{2}\{2\eta_T - 2\eta_{T-1}\}\mathcal{E}_{\mathbf{z}}(f_{T-1}) \\ &\quad + \frac{1}{2\times 3}\{[2\eta_T - 2\eta_{T-2}] + [2\eta_{T-1} - 2\eta_{T-2}]\}\mathcal{E}_{\mathbf{z}}(f_{T-2}).\end{aligned}$$

Repeating the above process by means of the decomposition

$$\begin{aligned}&\frac{1}{k}\sum_{j=0}^{k-1} 2\eta_{T-j}\mathcal{E}_{\mathbf{z}}(f_{T-j}) = \frac{1}{k+1}\sum_{j=0}^{k} 2\eta_{T-j}\mathcal{E}_{\mathbf{z}}(f_{T-j}) \\ &+\frac{1}{k(k+1)}\sum_{j=0}^{k-1} 2\eta_{T-j}\{\mathcal{E}_{\mathbf{z}}(f_{T-j}) - \mathcal{E}_{\mathbf{z}}(f_{T-k})\} + \frac{1}{k(k+1)}\sum_{j=0}^{k-1}\{2\eta_{T-j} - 2\eta_{T-k}\}\mathcal{E}_{\mathbf{z}}(f_{T-k})\end{aligned}$$

with $k = 3, \ldots, T-1$, we know that

$$\begin{aligned}2\eta_T\mathcal{E}_{\mathbf{z}}(f_T) &= \frac{1}{T}\sum_{j=0}^{T-1} 2\eta_{T-j}\mathcal{E}_{\mathbf{z}}(f_{T-j}) + \sum_{k=1}^{T-1}\frac{1}{k(k+1)}\sum_{j=0}^{k-1} 2\eta_{T-j}\{\mathcal{E}_{\mathbf{z}}(f_{T-j}) - \mathcal{E}_{\mathbf{z}}(f_{T-k})\} \\ &\quad + \sum_{k=1}^{T-1}\frac{1}{k(k+1)}\sum_{j=0}^{k-1}\{2\eta_{T-j} - 2\eta_{T-k}\}\mathcal{E}_{\mathbf{z}}(f_{T-k}).\end{aligned}$$

Applying the same process to the sequence $\{2\eta_t\mathcal{E}_{\mathbf{z}}(f_*)\}_{t=1}^T$ yields

$$2\eta_T\mathcal{E}_{\mathbf{z}}(f_*) = \frac{1}{T}\sum_{j=0}^{T-1} 2\eta_{T-j}\mathcal{E}_{\mathbf{z}}(f_*) + \sum_{k=1}^{T-1}\frac{1}{k(k+1)}\sum_{j=0}^{k-1}\{2\eta_{T-j} - 2\eta_{T-k}\}\mathcal{E}_{\mathbf{z}}(f_*).$$

Hence the following error decomposition holds true:

$$\begin{aligned}2\eta_T\left\{\mathcal{E}_{\mathbf{z}}(f_T)-\mathcal{E}_{\mathbf{z}}(f_*)\right\} &= \frac{1}{T}\sum_{t=1}^{T}2\eta_t\left\{\mathcal{E}_{\mathbf{z}}(f_t)-\mathcal{E}_{\mathbf{z}}(f_*)\right\}\\ &+\sum_{k=1}^{T-1}\frac{1}{k(k+1)}\sum_{t=T-k+1}^{T}2\eta_t\left\{\mathcal{E}_{\mathbf{z}}(f_t)-\mathcal{E}_{\mathbf{z}}(f_{T-k})\right\}\\ &+\sum_{k=1}^{T-1}\frac{1}{k+1}\left[\frac{1}{k}\sum_{t=T-k+1}^{T}2\eta_t-2\eta_{T-k}\right]\left\{\mathcal{E}_{\mathbf{z}}(f_{T-k})-\mathcal{E}_{\mathbf{z}}(f_*)\right\}.\end{aligned}\tag{30}$$

Step 2: Average error in the first term of (30). Choosing $f=f_*$ in (29) and taking summation over $t=1,\ldots,T$ together with (21) and Lemma 15 yield

$$\begin{aligned}\sum_{t=1}^{T}2\eta_t\left\{\mathcal{E}_{\mathbf{z}}(f_t)-\mathcal{E}_{\mathbf{z}}(f_*)\right\} &\le \|f_1-f_*\|_K^2-\|f_{T+1}-f_*\|_K^2+\sum_{t=1}^{T}\eta_t^2G_t^2\\ &\le \|f_*\|_K^2+\sum_{t=1}^{T}\eta_1^2c_q^2(\kappa+1)^{2q+2}t^{q(1-\theta)-2\theta}.\end{aligned}$$

Since $1>\theta>\frac{q}{q+1}$, we find $-2<q(1-\theta)-2\theta<0$. Moreover, $q(1-\theta)-2\theta<-1$ if and only if $\theta>\frac{q+1}{q+2}$. The following bound for the first term of (30) then follows

$$\begin{aligned}&\frac{1}{T}\sum_{t=1}^{T}2\eta_t\left\{\mathcal{E}_{\mathbf{z}}(f_t)-\mathcal{E}_{\mathbf{z}}(f_*)\right\}\\ &\le\begin{cases}\left(\|f_*\|_K^2+C_{q,\kappa}\frac{(2+q)\theta-q}{(2+q)\theta-q-1}\right)T^{-1}, & \text{when } \theta>\frac{q+1}{q+2},\\ \left(\|f_*\|_K^2+2C_{q,\kappa}\right)(\log T)T^{-1}, & \text{when } \theta=\frac{q+1}{q+2},\\ \left(\|f_*\|_K^2+C_{q,\kappa}\frac{2}{q+1-(2+q)\theta}\right)T^{q-(2+q)\theta}, & \text{when } \theta<\frac{q+1}{q+2},\end{cases}\end{aligned}$$

where $C_{q,\kappa}$ is the constant given by

$$C_{q,\kappa}=\eta_1^2c_q^2(\kappa+1)^{2q+2}.$$

Step 3: Moving average error in the second term of (30). Let $k\in\{1,\ldots,T-1\}$. Choosing $f=f_{T-k}$ in (29) and taking summation over $t=T-k+1,\ldots,T$ yield

$$\sum_{t=T-k+1}^{T}2\eta_t\left\{\mathcal{E}_{\mathbf{z}}(f_t)-\mathcal{E}_{\mathbf{z}}(f_{T-k})\right\}\le\|f_{T-k+1}-f_{T-k}\|_K^2+\sum_{t=T-k+1}^{T}\eta_t^2G_t^2$$

By Corollary 16,

$$\|f_{T-k+1}-f_{T-k}\|_K^2\le\eta_1^2c_q^2(\kappa+1)^{2(q+1)}(T-k)^{(1-\theta)q-2\theta}.$$

This bound is the term with $t=T-k+1$ of the following estimate which is a consequence of Lemma 15

$$\sum_{t=T-k+1}^{T}\eta_t^2G_t^2\le\sum_{t=T-k+1}^{T}\eta_1^2c_q^2(\kappa+1)^{2q+2}t^{q(1-\theta)-2\theta}.$$

Hence

$$\sum_{t=T-k+1}^{T}2\eta_t\left\{\mathcal{E}_{\mathbf{z}}(f_t)-\mathcal{E}_{\mathbf{z}}(f_{T-k})\right\}\le C_{q,\kappa}\sum_{t=T-k}^{T}t^{q(1-\theta)-2\theta}=C_{q,\kappa}\sum_{t=T-k}^{T}t^{-q^*},$$

where we denote $q^*=2\theta-q(1-\theta)$. We know that $0<q^*<2$ and $q^*=1$ when $\theta=\frac{q+1}{q+2}$. So

$$\sum_{t=T-k+1}^{T}t^{-q^*}\le\int_{T-k}^{T}x^{-q^*}dx\le\begin{cases}\frac{T^{1-q^*}-(T-k)^{1-q^*}}{1-q^*}, & \text{when } \theta\ne\frac{q+1}{q+2},\\ \log\frac{T}{T-k}, & \text{when } \theta=\frac{q+1}{q+2}.\end{cases}$$

When $\theta<\frac{q+1}{q+2}$, we have $q^*<1$ and for $k\le\frac{T}{2}$, we see from the mean value theorem that

$$\frac{T^{1-q^*}-(T-k)^{1-q^*}}{1-q^*}=T^{1-q^*}\frac{1-(1-\frac{k}{T})^{1-q^*}}{1-q^*}\le T^{1-q^*}\frac{(1-q^*)(1-\frac{k}{T})^{-q^*}\frac{k}{T}}{1-q^*}$$

which is exactly $(T-k)^{-q^*}k$. Thus,

$$\sum_{t=T-k}^{T}t^{-q^*}\le(T-k)^{-q^*}k+(T-k)^{-q^*}\le2k(T-k)^{-q^*}\le2\cdot2^{q^*}T^{-q^*}k.$$

For $k\ge\frac{T}{2}$,

$$\sum_{t=T-k}^{T}t^{-q^*}\le\frac{T^{1-q^*}-(T-k)^{1-q^*}}{1-q^*}+(T-k)^{-q^*}\le\frac{T^{1-q^*}}{1-q^*}.$$

It follows that

$$\begin{aligned}&\sum_{k=1}^{T-1}\frac{1}{k(k+1)}\sum_{t=T-k+1}^{T}2\eta_t\left\{\mathcal{E}_{\mathbf{z}}(f_t)-\mathcal{E}_{\mathbf{z}}(f_{T-k})\right\}\\ &\le C_{q,\kappa}\sum_{k\le T/2}\frac{1}{k(k+1)}\sum_{t=T-k}^{T}t^{-q^*}+C_{q,\kappa}\sum_{T-1\ge k>T/2}\frac{1}{k(k+1)}\sum_{t=T-k}^{T}t^{-q^*}\\ &\le 2C_{q,\kappa}\sum_{k\le T/2}\frac{1}{k(k+1)}2^{q^*}T^{-q^*}k+2C_{q,\kappa}\sum_{T-1\ge k>T/2}\frac{1}{k(k+1)}\frac{T^{1-q^*}}{1-q^*}\\ &\le 2C_{q,\kappa}\left(2^{q^*}+\frac{2}{1-q^*}\right)(\log T)T^{q(1-\theta)-2\theta}.\end{aligned}$$

When $\theta=\frac{q+1}{q+2}$, we see from the mean value theorem that

$$\log\frac{T}{T-k}=-\log\left(1-\frac{k}{T}\right)\le\frac{k}{T}\frac{1}{1-\frac{k}{T}}=\frac{k}{T-k}.$$

It follows that

$$\begin{aligned}&\sum_{k=1}^{T-1}\frac{1}{k(k+1)}\sum_{t=T-k+1}^{T}2\eta_t\left\{\mathcal{E}_{\mathbf{z}}(f_t)-\mathcal{E}_{\mathbf{z}}(f_{T-k})\right\}\\&\le C_{q,\kappa}\sum_{k=1}^{T-1}\frac{1}{(T-k)k}=C_{q,\kappa}\frac{1}{T}\sum_{k=1}^{T-1}\left\{\frac{1}{k}+\frac{1}{T-k}\right\}\\&\le 4C_{q,\kappa}\frac{\log T}{T}.\end{aligned}$$

When $\theta>\frac{q+1}{q+2}$, we have $q^*>1$ and for $k\le\frac{T}{2}$,

$$\frac{T^{1-q^*}-(T-k)^{1-q^*}}{1-q^*}=T^{1-q^*}\frac{(1-\frac{k}{T})^{1-q^*}-1}{q^*-1}\le 2^{q^*}T^{-q^*}k.$$

For $k>\frac{T}{2}$, $\sum_{t=T-k}^{T}t^{-q^*}\le(k+1)2^{q^*}T^{-q^*}$. Then,

$$\begin{aligned}&\sum_{k=1}^{T-1}\frac{1}{k(k+1)}\sum_{t=T-k+1}^{T}2\eta_t\left\{\mathcal{E}_{\mathbf{z}}(f_t)-\mathcal{E}_{\mathbf{z}}(f_{T-k})\right\}\\&\le 2^{q^*+1}C_{q,\kappa}T^{-q^*}\sum_{k=1}^{T-1}\frac{1}{k+1}\le 2^{q^*+1}C_{q,\kappa}T^{-q^*}\log T\\&\le 2^{q^*+1}C_{q,\kappa}\frac{1}{\mathrm{e}(q^*-1)}T^{-1}.\end{aligned}$$

Thus the second term of (30) can also be bounded as

$$\begin{aligned}&\sum_{k=1}^{T-1}\frac{1}{k(k+1)}\sum_{t=T-k+1}^{T}2\eta_t\left\{\mathcal{E}_{\mathbf{z}}(f_t)-\mathcal{E}_{\mathbf{z}}(f_{T-k})\right\}\\&\le\begin{cases}\frac{2^{q^*+1}C_{q,\kappa}}{\mathrm{e}(q^*-1)}T^{-1}, & \text{when } \theta>\frac{q+1}{q+2},\\ 4C_{q,\kappa}(\log T)T^{-1}, & \text{when } \theta=\frac{q+1}{q+2},\\ 2C_{q,\kappa}\left(2^{q^*}+\frac{2}{1-q^*}\right)(\log T)T^{q-(2+q)\theta}, & \text{when } \theta<\frac{q+1}{q+2}.\end{cases}\end{aligned}$$

Putting all the above estimates for the first two terms into (30), we see that the desired bound (27) holds true with the constant $\widetilde{C}_1$ given by

$$\widetilde{C}_1=\begin{cases}\eta_1c_q^2(\kappa+1)^{2q+2}\left((2+q)\theta-q+2^{(2+q)\theta-q}\right), & \text{when } \theta>\frac{q+1}{q+2},\\ 6\eta_1c_q^2(\kappa+1)^{2q+2}, & \text{when } \theta=\frac{q+1}{q+2},\\ \eta_1c_q^2(\kappa+1)^{2q+2}\left(2^{(2+q)\theta-q}+3\right), & \text{when } \theta<\frac{q+1}{q+2}.\end{cases}$$

The proof of Lemma 17 is complete. ∎

Lemma 17 is useful and can be used in a stochastic convex optimization problem, other than learning. In what follows, we shall see that how it can be used in our specified learning problems. For notational simplicity, with $\widetilde{R}>0$ we denote

$$\mathcal{M}_{\mathbf{z}}(\widetilde{R})=\sup_{f\in B_{\widetilde{R}}}\max\left\{\mathcal{E}_{\mathbf{z}}(f_\rho^V)-\mathcal{E}_{\mathbf{z}}(f),\ 0\right\}. \tag{31}$$

Proposition 18 *Under the assumptions of Lemma 17, we have*

$$\mathcal{E}_{\mathbf{z}}(f_T)-\mathcal{E}_{\mathbf{z}}(f_*)\le\frac{3}{1-\theta}\left\{\mathcal{M}_{\mathbf{z}}\left(T^{\frac{1-\theta}{2}}\right)+\mathcal{F}_{\mathbf{z}}(f_*)+\mathcal{A}(f_*)\right\}+\frac{\|f_*\|_K^2}{2\eta_1}\Lambda_{T,\theta}+\widetilde{C}_1\Lambda_{T,\theta}, \tag{32}$$

where $\Lambda_{T,\theta}$ and $\widetilde{C}_1$ are defined in Lemma 17.

Proof Note that by Lemma 17, we have (27). We only need to estimate the second term of (27) denoted as

$$J_{T,\mathbf{z}}:=\frac{T^\theta}{2\eta_1}\sum_{k=1}^{T-1}\frac{1}{k+1}\left[2\eta_{T-k}-\frac{1}{k}\sum_{t=T-k+1}^{T}2\eta_t\right]\left\{\mathcal{E}_{\mathbf{z}}(f_*)-\mathcal{E}_{\mathbf{z}}(f_{T-k})\right\}.$$

Denote $\widetilde{R}=T^{\frac{1-\theta}{2}}$. Lemma 15 tells us that $f_k\in B_{\widetilde{R}}$ for each $k=1,\cdots,T$. It follows that for $k=1,\cdots,T-1$,

$$\begin{aligned}\mathcal{E}_{\mathbf{z}}(f_*)-\mathcal{E}_{\mathbf{z}}(f_{T-k}) &= \left\{\left(\mathcal{E}_{\mathbf{z}}(f_*)-\mathcal{E}_{\mathbf{z}}(f_\rho^V)\right)-\left(\mathcal{E}(f_*)-\mathcal{E}(f_\rho^V)\right)\right\}\\&\quad+\left(\mathcal{E}(f_*)-\mathcal{E}(f_\rho^V)\right)+\mathcal{E}_{\mathbf{z}}(f_\rho^V)-\mathcal{E}_{\mathbf{z}}(f_{T-k})\\&\le \mathcal{F}_{\mathbf{z}}(f_*)+\mathcal{A}(f_*)+\mathcal{M}_{\mathbf{z}}(\widetilde{R}).\end{aligned}$$

By the choice of the stepsizes, $2\eta_{T-k}-\frac{1}{k}\sum_{t=T-k+1}^{T}2\eta_t\ge 0$ for any $k\in\{1,\dots,T-1\}$. Therefore, $J_{T,\mathbf{z}}$ can be bounded by

$$J_{T,\mathbf{z}}\le\frac{T^\theta}{2\eta_1}\sum_{k=1}^{T-1}\frac{1}{k+1}\left[2\eta_{T-k}-\frac{1}{k}\sum_{t=T-k+1}^{T}2\eta_t\right]\left\{\mathcal{F}_{\mathbf{z}}(f_*)+\mathcal{A}(f_*)+\mathcal{M}_{\mathbf{z}}(\widetilde{R})\right\}.$$

Now we need to bound the above summation. Note that, for each k,

$$2\eta_{T-k}-\frac{1}{k}\sum_{t=T-k+1}^{T}2\eta_t=\frac{2\eta_1}{k}\sum_{t=T-k+1}^{T}\left((T-k)^{-\theta}-t^{-\theta}\right).$$

Applying the mean value theorem to the function $g(x)=-x^{-\theta}$ on $[T-k,t]$ with $t\in\{T-k+1,\dots,T\}$, we find that for some $c\in[T-k,t]$,

$$(T-k)^{-\theta}-t^{-\theta}=g(t)-g(T-k)=(t-(T-k))g'(c)\le(t-(T-k))\theta(T-k)^{-\theta-1}.$$

Hence

$$\begin{aligned}&\sum_{k=1}^{T-1}\frac{1}{k+1}\left[2\eta_{T-k}-\frac{1}{k}\sum_{t=T-k+1}^{T}2\eta_t\right]\\&\le 2\eta_1\theta\sum_{k<T/2}\frac{(T-k)^{-\theta-1}}{k(k+1)}\sum_{t=T-k+1}^{T}(t-T+k)+\sum_{k\ge T/2}\frac{1}{k+1}2\eta_{T-k}\\&\le 2\eta_1\theta\sum_{k<T/2}\frac{(T-k)^{-\theta-1}}{k(k+1)}\frac{k(k+1)}{2}+\sum_{k\ge T/2}\frac{2}{T}2\eta_{T-k}\\&\le\eta_1\theta\sum_{k<T/2}(T-k)^{-\theta-1}+\frac{4\eta_1}{T}\sum_{k\ge T/2}(T-k)^{-\theta}\le\frac{6\eta_1}{1-\theta}T^{-\theta}.\end{aligned}$$

Thus

$$J_{T,\mathbf{z}} \leq \frac{3}{1-\theta}\left\{\mathcal{F}_{\mathbf{z}}(f_*) + \mathcal{A}(f_*) + \mathcal{M}_{\mathbf{z}}(\widetilde{R})\right\}.$$

Then the desired bound follows from Lemma 17. ■

4.3 Computational Errors for Weighted Average and Best Iterate

Lemma 19 *Under the assumptions of Lemma 17, let $g_T = a_T$ (or $g_T = b_T$). Then*

$$\mathcal{E}_{\mathbf{z}}(g_T) - \mathcal{E}_{\mathbf{z}}(f_*) \leq \left(\frac{2\|f_*\|_K^2}{\eta_1} + \overline{C}_1\right)\overline{\Lambda}_{T,\theta},$$

where $\overline{\Lambda}_{T,\theta}$ is given by

$$\overline{\Lambda}_{T,\theta} = \begin{cases} \frac{1}{(2+q)\theta-(q+1)}T^{-(1-\theta)}, & \text{when } \theta > \frac{q+1}{q+2}, \\ (\log T)T^{-(1-\theta)}, & \text{when } \theta = \frac{q+1}{q+2}, \\ \frac{1}{(q+1)-(2+q)\theta}T^{-(\theta(1+q)-q)}, & \text{when } \theta < \frac{q+1}{q+2}, \end{cases} \tag{33}$$

and $\overline{C}_1$ is a positive constant depending on q, κ and θ (independent of T, m or f_* and given explicitly in the proof.)

Note that there is a subtle difference between $\overline{\Lambda}_{T,\theta}$ and $\Lambda_{T,\theta}$ defined by (39), where the latter term has an extra $\log T$ for $\theta < \frac{q+1}{q+2}$.

Proof For any $u \in \mathbb{R}$, we have

$$\sum_{t=1}^T \eta_t(\mathcal{E}_{\mathbf{z}}(f_t) - u) \geq \left(\sum_{t=1}^T \eta_t\right)\min_{t=1,\ldots,T}\mathcal{E}_{\mathbf{z}}(f_t) - \left(\sum_{t=1}^T \eta_t\right)u,$$

and by convexity of $\mathcal{E}_{\mathbf{z}}$,

$$\mathcal{E}_{\mathbf{z}}(a_T) = \mathcal{E}_{\mathbf{z}}\left(\sum_{t=1}^T \omega_t f_t\right) \leq \sum_{t=1}^T \omega_t \mathcal{E}_{\mathbf{z}}(f_T) = \frac{1}{\sum_{t=1}^T \eta_t}\sum_{t=1}^T \eta_t \mathcal{E}_{\mathbf{z}}(f_t).$$

Therefor, we have

$$\mathcal{E}_{\mathbf{z}}(b_T) - u \leq \frac{1}{\sum_{t=1}^T \eta_t}\sum_{t=1}^T \eta_t(\mathcal{E}_{\mathbf{z}}(f_t) - u)$$

and

$$\mathcal{E}_{\mathbf{z}}(a_T) - u \leq \frac{1}{\sum_{t=1}^T \eta_t}\sum_{t=1}^T \eta_t(\mathcal{E}_{\mathbf{z}}(f_t) - u).$$

We thus get

$$\mathcal{E}_{\mathbf{z}}(g_T) - \mathcal{E}_{\mathbf{z}}(f^*) \leq \frac{1}{\sum_{t=1}^T \eta_t}\sum_{t=1}^T \eta_t(\mathcal{E}_{\mathbf{z}}(f_t) - \mathcal{E}_{\mathbf{z}}(f^*)). \tag{34}$$

Following Step 2 of the proof of Lemma 17, we have

$$\sum_{t=1}^T 2\eta_t\left\{\mathcal{E}_{\mathbf{z}}(f_t) - \mathcal{E}_{\mathbf{z}}(f_*)\right\}$$
$$\leq \begin{cases} \left(\|f_*\|_K^2 + C_{q,\kappa}\frac{(2+q)\theta-q}{(2+q)\theta-q-1}\right), & \text{when } \theta > \frac{q+1}{q+2}, \\ \left(\|f_*\|_K^2 + 2C_{q,\kappa}\right)(\log T), & \text{when } \theta = \frac{q+1}{q+2}, \\ \left(\|f_*\|_K^2 + C_{q,\kappa}\frac{2}{q+1-(2+q)\theta}\right)T^{(1+q)-(2+q)\theta}, & \text{when } \theta < \frac{q+1}{q+2}. \end{cases}$$

Introducing the above inequality into (34), and using $\sum_{t=1}^T \eta_t \geq \eta_1 \int_{t=1}^{T+1} u^{-\theta}du \geq \eta_1 T^{1-\theta}/\mathrm{e}$, we get our desired result with $\overline{C}_1$ given by

$$\overline{C}_1 = \begin{cases} 3\eta_1 c_q^2(\kappa+1)^{2q+2}\left((2+q)\theta - q\right), & \text{when } \theta > \frac{q+1}{q+2}, \\ 3\eta_1 c_q^2(\kappa+1)^{2q+2}, & \text{when } \theta = \frac{q+1}{q+2}, \\ 3\eta_1 c_q^2(\kappa+1)^{2q+2}, & \text{when } \theta < \frac{q+1}{q+2}. \end{cases}$$

■

While the above proof is shorter and easier than the proof of Lemma 17, it is surprising that the computational error bounds for the last iterate and the average (or the best one) are roughly of the same order.

4.4 Iterate Bound and Computational Error for Smooth Loss Functions

The following result can be proved by using the fact that $V'(y,\cdot)$ is Lipschitz. Its proof is a simple modification to RKHS of that in Nesterov (2004, Theorem 2.1.14), where the cases of Euclidean spaces are studied. For completeness, we provide the proof in Appendix A.

Lemma 20 *Assume that $V(y,\cdot)$ is differentiable and $V'(y,\cdot)$ is Lipschitz continuous with constant $L > 0$. Let $0 < \eta_t \leq (L\kappa^2)^{-1}$ for all $t \in \mathbb{N}$. Then we have*

$$\mathcal{E}_{\mathbf{z}}(f_T) - \mathcal{E}_{\mathbf{z}}(f_*) \leq \frac{\|f_*\|_K^2}{\sum_{k=1}^T 2\eta_k}.$$

In particular, if $\eta_t = \eta_1 t^{-\theta}$ with $\theta \in [0,1)$ satisfying $\eta_1 \leq (L\kappa^2)^{-1}$, then

$$\mathcal{E}_{\mathbf{z}}(f_T) - \mathcal{E}_{\mathbf{z}}(f_*) \leq \frac{2\|f_*\|_K^2}{\eta_1}T^{\theta-1}.$$

Using the above lemma, we can bound the iterates as follows.

Lemma 21 *Under the assumptions of Lemma 20, we have for $t = 1, \cdots, T$,*

$$\|f_{t+1}\|_K \leq \sqrt{2|V|_0\sum_{k=1}^t \eta_k}.$$

In particular, if $\eta_t = \eta_1 t^{-\theta}$ with $\theta \in [0,1)$ satisfying $\eta_1 \leq \frac{1-\theta}{2|V|_0}$, then

$$\|f_{t+1}\|_K \leq t^{\frac{1-\theta}{2}}.$$

Proof Choosing $f_* = 0$ in (46) (see Appendix A), we get for $k = 1, \cdots, t$,

$$\|f_{k+1}\|_K^2 \le \|f_k\|_K^2 + 2\eta_k(\mathcal{E}_{\mathbf{z}}(0) - \mathcal{E}_{\mathbf{z}}(f_{k+1})) \le \|f_k\|_K^2 + 2\eta_k|V|_0.$$

Applying this relationship iteratively for $k = t, \cdots, 1$, with $f_1 = 0$, we get

$$\|f_{t+1}\|_K^2 \le 2|V|_0 \sum_{k=1}^{t} \eta_k,$$

which leads to the first conclusion. The second inequality can be proved by noting that

$$\sum_{k=1}^{t} \eta_k = \eta_1 \sum_{k=1}^{t} k^{-\theta} \le \eta_1 \left(1 + \frac{t^{1-\theta} - 1}{1-\theta}\right) \le \eta_1 \frac{t^{1-\theta}}{1-\theta}.$$

■

5. Sample Error and Finite Sample Bounds

In this subsection, we will estimate sample errors and then prove our main results.

5.1 Sample Error

We first bound the sample error term $\mathcal{F}_{\mathbf{z}}(f_*)$ for some fixed $f_* \in \mathcal{H}_K$ as follows. This is done by applying Bernstein inequality, see Appendix B for the proof.

Lemma 22 *Assume conditions (4) and (5) hold. For any $f_* \in \mathcal{H}_K$ with $\|f_*\|_K \le R$, where $R \ge 1$, with confidence at least $1 - \frac{\delta}{2}$,*

$$\mathcal{F}_{\mathbf{z}}(f_*) \le (C_1' + 2\sqrt{c_\tau}) \log\frac{2}{\delta} \max\left\{\frac{R^{q+1}}{m}, \left(\frac{R^{2+q-\tau}}{m}\right)^{\frac{1}{2-\tau}}, \mathcal{A}(f_*)\right\}, \tag{35}$$

where C_1' is a positive constant independent of T, m, δ, given explicitly in the proof.

We next bound the empirical process over the ball $B_{\widetilde{R}}$ for some $\widetilde{R} > 0$ in the following lemma. It is essentially contained in Wu et al. (2007). We provide a short proof in Appendix B for the sake of completeness.

Lemma 23 *Assume (4) with $q \ge 0$, (5) with $\tau \in [0,1]$, (8) with $\beta \in (0,1]$ and (9) with $\zeta \in (0,2)$. Let $\widetilde{R} > 1$. Then with confidence at least $1 - \frac{\delta}{2}$, there holds for every $g \in B_{\widetilde{R}}$,*

$$\begin{aligned}
&\left(\mathcal{E}(g) - \mathcal{E}(f_\rho^V)\right) - \left(\mathcal{E}_{\mathbf{z}}(g) - \mathcal{E}_{\mathbf{z}}(f_\rho^V)\right) \\
\le &\frac{1}{2}\left(\mathcal{E}(g) - \mathcal{E}(f_\rho^V)\right) + C_3' \log\frac{2}{\delta} \max\left\{\left(\frac{\widetilde{R}^{\frac{q(2+\zeta)+(4-2\tau+\zeta\tau)}{2}}}{m}\right)^{\frac{2}{4-2\tau+\zeta\tau}}, \frac{\widetilde{R}^{q+1}}{m^{\frac{2}{2+\zeta}}}, \left(\frac{\widetilde{R}^{2+q-\tau}}{m}\right)^{\frac{1}{2-\tau}}\right\},
\end{aligned} \tag{36}$$

and

$$\mathcal{M}_{\mathbf{z}}(\widetilde{R}) \le C_3' \log\frac{2}{\delta} \max\left\{\left(\frac{\widetilde{R}^{\frac{q(2+\zeta)+(4-2\tau+\zeta\tau)}{2}}}{m}\right)^{\frac{2}{4-2\tau+\zeta\tau}}, \frac{\widetilde{R}^{q+1}}{m^{\frac{2}{2+\zeta}}}, \left(\frac{\widetilde{R}^{2+q-\tau}}{m}\right)^{\frac{1}{2-\tau}}\right\}. \tag{37}$$

Here C_3' is a positive constant independent of T, m, δ, given explicitly in the proof.

5.2 Deriving the Finite Sample Bounds

We have the following result, which will be used for the proof of Theorem 4.

Proposition 24 *Assume (4) with $q \ge 0$, (5) with $\tau \in [0,1]$, (8) with $\beta \in (0,1]$ and (9) with $\zeta \in (0,2)$. Let $\eta_t = \eta_1 t^{-\theta}$ with $0 < \theta < 1$ satisfying $\theta > \frac{q}{q+1}$ and η_1 satisfying (10). Let $f_* \in \mathcal{H}_K$ be such that $\|f_*\|_K \le R$, where $R \ge 1$. If $1 \le R \le T^{\frac{1-\theta}{2}}$ and $T^{\frac{q(1-\theta)}{2}} m^{-\frac{2}{2+\zeta}} \le 1$, then with confidence $1 - \delta$, we have*

$$\mathcal{E}(f_T) - \mathcal{E}(f_\rho^V) \le \widetilde{C}_3 \log\frac{2}{\delta} \max\left\{\left(\frac{T^{\frac{(1-\theta)(q(2+\zeta)+(4-2\tau+\zeta\tau))}{4}}}{m}\right)^{\frac{2}{4-2\tau+\zeta\tau}}, R^2\Lambda_T, \mathcal{A}(f_*)\right\}, \tag{38}$$

where Λ_T is defined by

$$\Lambda_T = \begin{cases} T^{-(1-\theta)}, & \text{when } \theta > \frac{q+1}{q+2}, \\ (\log T) T^{-(1-\theta)}, & \text{when } \theta = \frac{q+1}{q+2}, \\ (\log T) T^{-(\theta(1+q)-q)}, & \text{when } \theta < \frac{q+1}{q+2}, \end{cases} \tag{39}$$

and $\widetilde{C}_3$ is a positive constant independent of T, m, δ, given explicitly in the proof.

Proof Recall Lemma 13. Let $\tilde{R} = T^{\frac{1-\theta}{2}}$. Introducing with (32), we have

$$\begin{aligned}
\mathcal{E}(f_T) - \mathcal{E}(f_\rho^V) \le &\left\{\left(\mathcal{E}(f_T) - \mathcal{E}(f_\rho^V)\right) - \left(\mathcal{E}_{\mathbf{z}}(f_T) - \mathcal{E}_{\mathbf{z}}(f_\rho^V)\right)\right\} + \frac{3}{1-\theta}\mathcal{M}_{\mathbf{z}}\left(\tilde{R}\right) \\
&+ \frac{4-\theta}{1-\theta}\left(\mathcal{F}_{\mathbf{z}}(f_*) + \mathcal{A}(f_*)\right) + \frac{R^2}{2\eta_1}\Lambda_{T,\theta} + \widetilde{C}_1\Lambda_{T,\theta}.
\end{aligned}$$

Applying Lemmas 22 and 23 with $g = f_T$, with $R \in [1, \widetilde{R}]$ and the notation Λ_T defined by (39), we know that with confidence at least $1 - \delta$,

$$\begin{aligned}
\mathcal{E}(f_T) - \mathcal{E}(f_\rho^V) \le\ & C_4' \log\frac{2}{\delta} \max\left\{\left(\frac{\widetilde{R}^{\frac{q(2+\zeta)+(4-2\tau+\zeta\tau)}{2}}}{m}\right)^{\frac{2}{4-2\tau+\zeta\tau}}, \frac{\widetilde{R}^{q+1}}{m^{\frac{2}{2+\zeta}}}, \right. \\
&\left. \frac{\widetilde{R}^{\frac{2+q-\tau}{2-\tau}}}{m^{\frac{1}{2-\tau}}}, R^2\Lambda_T, \mathcal{A}(f_*)\right\} + \frac{1}{2}\left(\mathcal{E}(f_T) - \mathcal{E}(f_\rho^V)\right),
\end{aligned} \tag{40}$$

where C_4' is the constant given by

$$C_4' = \frac{4-\theta}{1-\theta}C_3' + \frac{4-\theta}{1-\theta}\left(1 + C_1' + 2\sqrt{c_\tau}\right) + \left(\frac{1}{2\eta_1} + \widetilde{C}_1\right) c_{\theta,q}.$$

Here $c_{\theta,q}$ is given by

$$c_{\theta,q} = \begin{cases} \frac{1}{|(q+2)\theta-(q+1)|}, & \text{when } \theta \neq \frac{q+1}{q+2}, \\ 1, & \text{when } \theta = \frac{q+1}{q+2}. \end{cases}$$

Since $\widetilde{R}^q m^{-2/(2+\zeta)} \leq 1$, $\tau \in [0,1]$ and $\zeta \in (0,2)$, one finds

$$\left(\frac{\widetilde{R}^{\frac{q(2+\zeta)+(4-2\tau+\zeta\tau)}{2}}}{m}\right)^{\frac{2}{4-2\tau+\zeta\tau}} \cdot \frac{m^{\frac{2}{2+\zeta}}}{\widetilde{R}^{q+1}} = \left\{\frac{\widetilde{R}^q}{m^{\frac{2}{2+\zeta}}}\right\}^{\frac{-(1-\tau)(2-\zeta)}{4-2\tau+\zeta\tau}} \geq 1,$$

and

$$\left(\frac{\widetilde{R}^{\frac{q(2+\zeta)+(4-2\tau+\zeta\tau)}{2}}}{m}\right)^{\frac{2}{4-2\tau+\zeta\tau}} \cdot \frac{m^{\frac{1}{2-\tau}}}{\widetilde{R}^{\frac{2+q-\tau}{2-\tau}}} = \left(\widetilde{R}^{2q(1-\tau)} m^{\tau}\right)^{\frac{\zeta}{(2-\tau)(4-2\tau+\zeta\tau)}} \geq 1.$$

Subtracting $\frac{1}{2}\left(\mathcal{E}(f_T) - \mathcal{E}(f_\rho^V)\right)$ from both sides of (40), and setting $\widetilde{C}_3 = 2C_4'$, we get the desired results. ■

Now we are in a position to prove the probabilistic upper bounds stated in Theorem 4.

Proof of Theorem 4 We use Proposition 24 with $f_* = f_\lambda$ to prove our result. Define a power index $\tilde{\theta}$ as

$$\tilde{\theta} = \begin{cases} 1-\theta, & \text{when } \theta \geq \frac{q+1}{q+2}, \\ \theta(1+q)-q, & \text{when } \theta < \frac{q+1}{q+2}. \end{cases} \tag{41}$$

Comparing this with the definition (39) for Λ_T, we see that

$$\Lambda_T = \begin{cases} T^{-\tilde{\theta}}, & \text{when } \theta > \frac{q+1}{q+2}, \\ T^{-\tilde{\theta}} \log T, & \text{when } \theta \leq \frac{q+1}{q+2}. \end{cases}$$

From the definition of $\mathcal{D}(\lambda)$, we have

$$\mathcal{A}(f_\lambda) \leq \mathcal{D}(\lambda) \qquad \text{and} \qquad \lambda \|f_\lambda\|_K^2 \leq \mathcal{D}(\lambda), \tag{42}$$

which imply $\|f_\lambda\|_K \leq \sqrt{\mathcal{D}(\lambda)/\lambda} = R$. Balancing the orders of the last two terms of (38) by setting

$$\lambda = \Lambda_T, \tag{43}$$

we find that the last two terms of (38) can be bounded as

$$\max\left\{R^2\Lambda_T,\ \mathcal{A}(f_\lambda)\right\} \leq \mathcal{D}(\lambda) \leq c_\beta \lambda^\beta \leq \begin{cases} c_\beta T^{-\beta\tilde{\theta}}, & \text{when } \theta > \frac{q+1}{q+2}, \\ c_\beta T^{-\beta\tilde{\theta}} \log T, & \text{when } \theta \leq \frac{q+1}{q+2}. \end{cases}$$

Then we balance the above main part with the first term of (38) by setting

$$\left(\frac{T^{\frac{(1-\theta)(q(2+\zeta)+(4-2\tau+\zeta\tau))}{4}}}{m}\right)^{\frac{2}{4-2\tau+\zeta\tau}} = T^{-\beta\tilde{\theta}}.$$

This leads us to choose T to be the integer part of

$$\lceil m^\gamma \rceil, \text{ where } \gamma := \frac{2}{\left(\frac{1-\theta}{2} + \beta\tilde{\theta}\right)(4-2\tau+\zeta\tau) + \frac{q(2+\zeta)(1-\theta)}{2}}. \tag{44}$$

With this choice, the main part of (38) can be bounded as

$$\max\left\{\left(\frac{T^{\frac{(1-\theta)(q(2+\zeta)+(4-2\tau+\zeta\tau))}{4}}}{m}\right)^{\frac{2}{4-2\tau+\zeta\tau}},\ R^2\Lambda_T,\ \mathcal{A}(f_*)\right\} \leq \begin{cases} 2c_\beta m^{-\beta\tilde{\theta}\gamma}, & \text{when } \theta > \frac{q+1}{q+2}, \\ 2\gamma c_\beta m^{-\beta\tilde{\theta}\gamma} \log m, & \text{when } \theta \leq \frac{q+1}{q+2}. \end{cases}$$

Noticing from the definition of $\tilde{\theta}$, one can easily prove that $\tilde{\theta} \leq 1-\theta$. Then $R/\sqrt{c_\beta} \leq \sqrt{\lambda^{\beta-1}} \leq \Lambda_T^{\frac{\beta-1}{2}} \leq T^{\frac{1-\theta}{2}}$ and the restriction for R in Theorem 24 is satisfied up to constants. The restriction $T^{\frac{q(1-\theta)}{2}} m^{-\frac{2}{2+\zeta}} \leq 1$ is also satisfied (up to a constant), because

$$T^{\frac{q(1-\theta)}{2}} \lesssim m^{\frac{q(1-\theta)\gamma}{2}} \lesssim m^{\frac{2}{2+\zeta}}.$$

Observe that $\gamma \leq \frac{2}{1-\theta}$. So by Proposition 24, with confidence $1-\delta$, we have

$$\mathcal{E}(f_T) - \mathcal{E}(f_\rho^V) \leq \begin{cases} 2c_\beta \widetilde{C}_3 m^{-\beta\tilde{\theta}\gamma} \log\frac{2}{\delta}, & \text{when } \theta > \frac{q+1}{q+2}, \\ \frac{4c_\beta\widetilde{C}_3}{1-\theta} m^{-\beta\tilde{\theta}\gamma} \log m \log\frac{2}{\delta}, & \text{when } \theta \leq \frac{q+1}{q+2}. \end{cases}$$

Observe that the power index $\beta\tilde{\theta}\gamma$ is

$$\beta\tilde{\theta}\gamma = \begin{cases} \frac{\beta}{\beta(2-\tau+\zeta\tau/2)+\left\{\frac{2-\tau+\zeta\tau/2}{2} + \frac{q(1+\zeta/2)}{2}\right\}}, & \text{when } \theta \geq \frac{q+1}{q+2}, \\ \frac{\beta}{\beta(2-\tau+\zeta\tau/2)+\frac{1-\theta}{\theta(1+q)-q}\left\{\frac{2-\tau+\zeta\tau/2}{2} + \frac{q(1+\zeta/2)}{2}\right\}}, & \text{when } \theta < \frac{q+1}{q+2}, \end{cases}$$

while the index γ can be expressed by (11). Then our desired learning rates are verified by setting the constant $\widetilde{C} = 2c_\beta\widetilde{C}_3$ when $\theta > \frac{q+1}{q+2}$ while $\widetilde{C} = \frac{4c_\beta\widetilde{C}_3}{1-\theta}$ when $\theta \leq \frac{q+1}{q+2}$. The proof of Theorem 4 is complete. ■

Proof of Theorem 7 We only sketch the proof for the case $g_T = a_T$. By applying Lemma 15, it is easy to prove that

$$\|a_T\|_K \leq T^{\frac{1-\theta}{2}}.$$

With the upper bound on a_T and Lemma 19, a similar argument as that for Theorem 4, one can prove the results. We omit the details. ■

Proof of Theorem 8 With Lemmas 20, 21, and a similar approach as that for Theorem 4, we can prove the convergence results for smooth loss functions. We omit the details. ■

Proof of Theorem 11 We use Theorem 4 to prove the results. The hinge loss satisfies (4) with $q = 0$ and $c_q = \frac{1}{2}$, $|V|_0 = 1$ and $\|f_\rho^V\|_\infty = 1$ where f_ρ^V is the Bayes rule f_c. Condition (5) is valid with $\tau = 0$ and $c_\tau = 1$. Since $\theta > 1/2$, by simple calculations, one finds that $\gamma = \frac{1}{(1-\theta)(2\beta+1)}$ and $\alpha = \frac{\beta}{2\beta+1}$.

Using the comparison theorem from Zhang (2004), we have

$$\mathcal{R}\left(\text{sign}(f_T)\right) - \mathcal{R}(f_c) \leq \mathcal{E}(f_T) - \mathcal{E}(f_\rho^V).$$

So the desired probabilistic upper bound (14) for the hinge loss follows from the above inequality and Theorem 4.

It remains to prove the second part of the theorem. Since $0 < \epsilon < \frac{1}{3}$, the restriction $\beta > \frac{1-3\epsilon}{1+6\epsilon}$ for the approximation order tells us that

$$\alpha = \frac{\beta}{2\beta+1} = \frac{1}{2+1/\beta} \geq \frac{1}{3} - \epsilon.$$

The proof of Theorem 11 is complete. ■

Proof of Theorem 12 Since $0 < \epsilon < \frac{1}{3}$, the restriction $\beta > \frac{4-3\epsilon}{4+6\epsilon}$ for the approximation order tells us that the parameter θ satisfies $\frac{1}{2} < \theta < 1$ and the index

$$\gamma = \frac{1}{(1-\theta)(2\beta+1)} = \frac{2}{3} + \epsilon.$$

Finally we find that the index

$$\alpha = \frac{\beta}{2\beta+1} = \frac{1}{2+1/\beta} \geq \frac{1}{3} - \frac{\epsilon}{4}.$$

So the desired probabilistic upper bound follows from the first conclusion of Theorem 11. The proof of Theorem 12 is complete. ■

6. Conclusions

This paper proposes and studies iterative regularization approaches for learning with convex loss functions. More precisely, we study how regularization can be achieved by early stopping an empirical iteration induced by the subgradient method, or gradient descent in the case that the loss is also smooth. Finite sample bounds are established providing indications on how to suitably choose the stepsize and the stopping rule. Different to classical results on the subgradient method, we analyze the behavior of the last iterate showing that it has essentially the same properties of the average, to the best, iterate. These results provide a theoretical foundation for early stopping with convex losses.

Beyond the analysis in the paper our error decomposition provides an approach to incorporating statistics and optimization aspects in the analysis of learning algorithms. While a natural development will be to sharpen the bounds and perform extensive empirical tests, we hope the study in the paper can help deriving novel and faster algorithms, for example analyzing accelerations (Nesterov, 2004), or distributed approaches, within the framework we propose.

Appendix A. Proof of Lemma 20

Proof Since $V'(y,\cdot)$ is Lipschitz with constant L for any $y \in Y$, we have for any $a, b \in \mathbb{R}$,

$$V(y,b) \le V(y,a) + V'(y,a)(b-a) + \frac{L}{2}(b-a)^2.$$

Choosing $y = y_j$, $b = f_{t+1}(x_j)$ and $a = f_t(x_j)$, according to the properties (22) and (23), we get for $j = 1, \cdots, m$ and $t \in \mathbb{N}$,

$$V(y_j, f_{t+1}(x_j)) \le V(y_j, f_t(x_j)) + V'(y_j, f_t(x_j))\langle f_{t+1} - f_t, K_{x_j}\rangle_K + \frac{L\kappa^2}{2}\|f_{t+1} - f_t\|_K^2.$$

Summing up over $j = 1, \cdots, m$, with $g_t = \frac{1}{m}\sum_{j=1}^m V'(y_j, f_t(x_j))K_{x_j}$, we get

$$\mathcal{E}_{\mathbf{z}}(f_{t+1}) \le \mathcal{E}_{\mathbf{z}}(f_t) + \langle f_{t+1} - f_t, g_t\rangle_K + \frac{L\kappa^2}{2}\|f_{t+1} - f_t\|_K^2.$$

Introducing with (1) and noting that $\eta_t \le (L\kappa^2)^{-1}$, we get

$$\mathcal{E}_{\mathbf{z}}(f_{t+1}) \le \mathcal{E}_{\mathbf{z}}(f_t) - \frac{\eta_t}{2}\|g_t\|_K^2. \tag{45}$$

By the convexity of $V(y,\cdot)$, it is easy to prove that

$$\mathcal{E}_{\mathbf{z}}(f_t) \le \mathcal{E}_{\mathbf{z}}(f_*) + \langle f_t - f_*, g_t\rangle_K.$$

Introducing this inequality into (45), we get

$$\begin{aligned}
\mathcal{E}_{\mathbf{z}}(f_{t+1}) &\le \mathcal{E}_{\mathbf{z}}(f_*) + \frac{1}{2\eta_t}\left(2\eta_t\langle f_t - f_*, g_t\rangle_K - \eta_t^2\|g_t\|_K^2\right) \\
&= \mathcal{E}_{\mathbf{z}}(f_*) + \frac{1}{2\eta_t}\left(\|f_t - f_*\|_K^2 - \|f_t - f_* - \eta_t g_t\|_K^2\right) \\
&= \mathcal{E}_{\mathbf{z}}(f_*) + \frac{1}{2\eta_t}\left(\|f_t - f_*\|_K^2 - \|f_{t+1} - f_*\|_K^2\right),
\end{aligned}$$

so that,

$$2\eta_t(\mathcal{E}_{\mathbf{z}}(f_{t+1}) - \mathcal{E}_{\mathbf{z}}(f_*)) \le \|f_t - f_*\|_K^2 - \|f_{t+1} - f_*\|_K^2. \tag{46}$$

Summing up over $t = 1 \cdots, T$, with $f_1 = 0$, we have

$$\sum_{t=1}^T 2\eta_t(\mathcal{E}_{\mathbf{z}}(f_{t+1}) - \mathcal{E}_{\mathbf{z}}(f_*)) \le \|f_1 - f_*\|_K^2 - \|f_{T+1} - f_*\|_K^2 \le \|f_*\|_K^2.$$

By (45), we have $\mathcal{E}_{\mathbf{z}}(f_{T+1}) \le \mathcal{E}_{\mathbf{z}}(f_{t+1})$ for all $t \le T$. It thus follows that

$$\sum_{t=1}^T 2\eta_t(\mathcal{E}_{\mathbf{z}}(f_{T+1}) - \mathcal{E}_{\mathbf{z}}(f_*)) \le \sum_{t=1}^T 2\eta_t(\mathcal{E}_{\mathbf{z}}(f_{t+1}) - \mathcal{E}_{\mathbf{z}}(f_*)) \le \|f_*\|_K^2,$$

which leads to the first argument of the lemma. The rest of the proof can be finished by noting that

$$\sum_{t=1}^T \eta_t \ge \eta_1 \int_1^{T+1} u^{-\theta} du \ge \eta_1 \frac{T^{1-\theta}}{\mathrm{e}}.$$

■

Appendix B. Proofs for the Sample Error

Proof of Lemma 22 We apply Bernstein inequality which asserts that, for a random variable ξ bounded by $\widetilde{M} > 0$ and for any $\epsilon > 0$,

$$\mathrm{Prob}\left\{\frac{1}{m}\sum_{i=1}^m \xi(z_i) - \mathbb{E}(\xi) > \epsilon\right\} \le \exp\left\{-\frac{m\epsilon^2}{2\left(\sigma^2(\xi) + \frac{1}{3}\widetilde{M}\epsilon\right)}\right\}. \tag{47}$$

Here the random variable ξ on Z is given by $\xi(x,y) = V(y, f_*(x)) - V(y, f_\rho^V(x))$. The increment condition (4) implies that ξ is bounded by $M := C_1' R^{q+1}$, where C_1' is the constant given by

$$C_1' := c_q\left(\kappa + \kappa^{q+1} + \|f_\rho^V\|_\infty + \|f_\rho^V\|_\infty^{q+1}\right). \tag{48}$$

By condition (5), its variance $\sigma^2(\xi)$ is bounded by

$$c_\tau R^{2+q-\tau}\left\{\mathcal{E}(f_*) - \mathcal{E}(f_\rho^V)\right\}^\tau \le c_\tau R^{2+q-\tau}(\mathcal{A}(f_*))^\tau.$$

Solving the quadratic equation from Bernstein inequality (47), we see that with confidence at least $1 - \frac{\delta}{2}$, there holds

$$\begin{aligned}
\mathcal{F}_{\mathbf{z}}(f_*) &\le \frac{2M\log\frac{2}{\delta}}{3m} + \sqrt{\frac{2\log\frac{2}{\delta}}{m}\sigma^2(\xi)} \\
&\le (C_1' + 2\sqrt{c_\tau})\log\frac{2}{\delta}\max\left\{\frac{R^{q+1}}{m},\ \frac{R^{1+\frac{q-\tau}{2}}(\mathcal{A}(f_*))^{\frac{\tau}{2}}}{\sqrt{m}}\right\}.
\end{aligned}$$

Applying the elementary inequality

$$x^\tau y^{1-\tau} \le \tau x + (1-\tau)y, \qquad \forall\, \tau \in [0,1],\ x, y \ge 0, \tag{49}$$

yields

$$\begin{aligned}
\frac{R^{1+\frac{q-\tau}{2}}(\mathcal{A}(f_*))^{\frac{\tau}{2}}}{\sqrt{m}} &= \left[\left(\frac{R^{2+q-\tau}}{m}\right)^{\frac{1}{2-\tau}}\right]^{1-\frac{\tau}{2}}(\mathcal{A}(f_*))^{\frac{\tau}{2}} \\
&\le \left(1 - \frac{\tau}{2}\right)\left(\frac{R^{2+q-\tau}}{m}\right)^{\frac{1}{2-\tau}} + \frac{\tau}{2}\mathcal{A}(f_*).
\end{aligned}$$

Then the desired result follows. ■

To bound the empirical process over the ball $B_{\widetilde{R}}$ for some $\widetilde{R} > 0$, we need the following concentration inequality. Its proof is similar to that of Proposition 6 in Wu et al. (2007), as well as applying Theorem 3.5 from Steinwart (2009) and Exercise 6.8 in Steinwart and Christmann (2008). We omit the proof.

Lemma 25 *Let $\mathcal{G}$ be a set of measurable functions on $\mathcal{Z}$, and $B, c > 0, \tau \in [0,1]$ be constants such that each function $f \in \mathcal{G}$ satisfies $\|f\|_\infty \le B$ and $\mathbb{E}(f^2) \le c(\mathbb{E}f)^\tau$. If for some $a \ge B^\zeta$ and $\zeta \in (0,2)$,*

$$\mathbb{E}_{\mathbf{z}}[\log\mathcal{N}(\mathcal{G}, \epsilon, d_{2,\mathbf{z}})] \le a\epsilon^{-\zeta}, \qquad \forall \epsilon > 0,$$

then there exists a positive constant c'_ζ depending only on ζ such that for any $b>0$, with probability at least $1-\mathrm{e}^{-b}$, there holds

$$\mathbb{E}f - \frac{1}{m}\sum_{i=1}^m f(z_i) \le \frac{1}{2}\eta^{1-\tau}(\mathbb{E}f)^\tau + c'_\zeta\eta + 2\Big(\frac{cb}{m}\Big)^{1/(2-\tau)} + \frac{18Bb}{m}, \qquad \forall f\in\mathcal{G},$$

where

$$\eta := \max\left\{c^{\frac{2-\zeta}{4-2\tau+\zeta\tau}}\Big(\frac{a}{m}\Big)^{\frac{2}{4-2\tau+\zeta\tau}},\ B^{\frac{2-\zeta}{2+\zeta}}\Big(\frac{a}{m}\Big)^{\frac{2}{2+\zeta}}\right\}.$$

Now, we are ready to prove Lemma 23.

Proof of Lemma 23 We first apply Lemma 25 to the function set

$$\mathcal{G} = \left\{f(x,y) = V(y,g(x)) - V(y,f_\rho^V(x)) :\ g\in B_{\widetilde{R}}\right\}.$$

Condition (5) tells us that with $c=c_\tau\widetilde{R}^{2+q-\tau}$, each function $f\in\mathcal{G}$ satisfies $\mathbb{E}(f^2)\le c(\mathbb{E}f)^\tau$. Also, condition (4) implies that $\|f\|_\infty$ is upper bounded by $\widetilde{M} := C'_1\widetilde{R}^{q+1}$, with C'_1 given by (48). Noticing from (4) that for $f,f'\in\mathcal{G}$,

$$|f(x,y)-f'(x,y)| = |V(y,g(x))-V(y,g'(x))| \le c_q(1+\kappa^q)\widetilde{R}^q|g(x)-g'(x)|,$$

there holds

$$\mathcal{N}(\mathcal{G},\epsilon,d_{2,\mathbf{z}}) \le \mathcal{N}\left(B_{\widetilde{R}}, \frac{\epsilon}{c_q(1+\kappa^q)\widetilde{R}^q}, d_{2,\mathbf{z}}\right) \le \mathcal{N}\left(B_1, \frac{\epsilon}{c_q(1+\kappa^q)\widetilde{R}^{q+1}}, d_{2,\mathbf{z}}\right).$$

Hence, condition (9) yields the covering number condition in Lemma 25 with $a=C''\widetilde{R}^{(q+1)\zeta}$, where

$$C'' = \max\{c_\zeta c_q^\zeta(1+\kappa^q)^\zeta, (C'_1)^\zeta\}$$

So we apply Lemma 25 and find that with confidence at least $1-\frac{\delta}{2}$, there holds for every $f\in\mathcal{G}$,

$$\mathbb{E}(f) - \frac{1}{m}\sum_{i=1}^m f(z_i) \le \frac{1}{2}\eta^{1-\tau}(\mathbb{E}f)^\tau + c'_\zeta\eta + 2\Big(\frac{c_\tau\widetilde{R}^{2+q-\tau}\log\frac{2}{\delta}}{m}\Big)^{\frac{1}{2-\tau}} + \frac{18\widetilde{M}\log\frac{2}{\delta}}{m},$$

where

$$\begin{aligned}\eta &= \max\left\{\left(c_\tau\widetilde{R}^{2+q-\tau}\right)^{\frac{2-\zeta}{4-2\tau+\zeta\tau}}\left(\frac{C''\widetilde{R}^{(q+1)\zeta}}{m}\right)^{\frac{2}{4-2\tau+\zeta\tau}},\right.\\ &\qquad \left.\widetilde{M}^{\frac{2-\zeta}{2+\zeta}}\left(\frac{C''\widetilde{R}^{(q+1)\zeta}}{m}\right)^{\frac{2}{2+\zeta}}\right\}\\ &\le C'_2\max\left\{\left(\frac{\widetilde{R}^{\frac{q(2+\zeta)+(4-2\tau+\zeta\tau)}{2}}}{m}\right)^{\frac{2}{4-2\tau+\zeta\tau}}, \frac{\widetilde{R}^{q+1}}{m^{\frac{2}{2+\zeta}}}\right\},\end{aligned}$$

where C'_2 is the constant given by

$$\left(c_\tau^{\frac{2-\zeta}{2}}C''\right)^{\frac{2}{4-2\tau+\zeta\tau}} + C_1'^{\frac{2-\zeta}{2+\zeta}}\left(C''\right)^{\frac{2}{2+\zeta}}.$$

Apply the elementary inequality (49) which yields $\eta^{1-\tau}(\mathbb{E}f)^\tau \le \eta + \mathbb{E}f$, and notice that $\mathbb{E}(f) = \mathcal{E}(g) - \mathcal{E}(f_\rho^V)$ while $\frac{1}{m}\sum_{i=1}^m f(z_i) = \mathcal{E}_{\mathbf{z}}(g) - \mathcal{E}_{\mathbf{z}}(f_\rho^V)$. We get that with confidence at least $1-\frac{\delta}{2}$, there holds for every $g\in B_{\widetilde{R}}$,

$$\begin{aligned}&\left(\mathcal{E}(g)-\mathcal{E}(f_\rho^V)\right) - \left(\mathcal{E}_{\mathbf{z}}(g)-\mathcal{E}_{\mathbf{z}}(f_\rho^V)\right)\\ &\le \left(\frac{1}{2}+c'_\zeta\right)\eta + \frac{1}{2}\left(\mathcal{E}(g)-\mathcal{E}(f_\rho^V)\right) + 2\Big(\frac{c_\tau\widetilde{R}^{2+q-\tau}}{m}\Big)^{\frac{1}{2-\tau}}\log\frac{2}{\delta} + \frac{18\widetilde{M}\log\frac{2}{\delta}}{m},\end{aligned}$$

which leads to (36) with

$$C'_3 = \left(\frac{1}{2}+c'_\zeta\right)C'_2 + 2c_\tau^{\frac{1}{2-\tau}} + 18\widetilde{M}.$$

Now, introducing (36) into the equality

$$\mathcal{E}_{\mathbf{z}}(f_\rho^V) - \mathcal{E}_{\mathbf{z}}(g) = \left\{\left(\mathcal{E}(g)-\mathcal{E}(f_\rho^V)\right) - \left(\mathcal{E}_{\mathbf{z}}(g)-\mathcal{E}_{\mathbf{z}}(f_\rho^V)\right)\right\} - \left(\mathcal{E}(g)-\mathcal{E}(f_\rho^V)\right),$$

with $\mathcal{E}(g)-\mathcal{E}(f_\rho^V)\ge 0$ and by recalling that $\mathcal{M}_{\mathbf{z}}(\widetilde{R})$ is given by (31), we can derive (37). The proof is completed. ■

Abstract

The rise of Internet-scale networks, such as web graphs and social media with hundreds of millions to billions of nodes, presents new scientific opportunities, such as overlapping community detection to discover the structure of the Internet, or to analyze trends in online social behavior. However, many existing probabilistic network models are difficult or impossible to deploy at these massive scales. We propose a scalable approach for modeling and inferring latent spaces in Internet-scale networks, with an eye towards overlapping community detection as a key application. By applying a succinct representation of networks as a bag of triangular motifs, developing a parsimonious statistical model, deriving an efficient stochastic variational inference algorithm, and implementing it as a distributed cluster program via the Petuum parameter server system, we demonstrate overlapping community detection on real networks with up to 100 million nodes and 1000 communities on 5 machines in under 40 hours. Compared to other state-of-the-art probabilistic network approaches, our method is several orders of magnitude faster, with competitive or improved accuracy at overlapping community detection.

Keywords: probabilistic network models, triangular modeling, stochastic variational inference, distributed computation, big data

1. Introduction

The rapid growth of the Internet, particularly the explosion of social media, has led to unprecedented increases in the volume of network data worldwide. Already, the Yahoo web graph collected in 2002 contains in excess of one billion URLs (Yahoo, 2013), the Facebook social network recently exceeded one billion users (Facebook, 2013), and numerous other social networks or online communities easily claim memberships in the millions of users (Leskovec and Krevl, 2014). To understand the structural and functional properties of massive networks, one important task in network analysis is unsupervised detection of community structure—a task that frequently occurs in social media and Internet studies (Palla et al., 2005; Newman, 2006; Prakash et al., 2010; Psorakis et al., 2011; Xie and Szymanski, 2012; Gopalan and Blei, 2013). Although there is no clear consensus in the literature on the definition of a network community, it is generally accepted that actors or nodes from the same community tend to interact more frequently with each other and share more common characteristics. In a social network, relevant characteristics might be "(people) going to the same school, social club, or workplace", while on the Internet, a characteristic might be "(websites) about a specific topic, such as politics, sports, or technology". It is well-understood that actors in a network can have multiple characteristics, resulting in multiple community memberships that usually overlap (Palla et al., 2005; Yang and Leskovec, 2012b); hence, it is widely accepted that overlapping communities provide a more accurate picture of network structure than disjoint communities (Xie et al., 2013).

To date, however, only a few overlapping community detection algorithms have been successfully applied to large graphs in excess of hundreds of millions of nodes (Prakash et al., 2010; Kang et al., 2011), and, to the best of our knowledge, none of them are based on a probabilistic formulation. Probabilistic methods are often more flexible in that they can serve as "building blocks" to more sophisticated models over additional non-network data sources—particularly text and feature data (Rosen-Zvi et al., 2004; Dietz et al., 2007; Nallapati et al., 2008; Chang and Blei, 2009; Balasubramanyan and Cohen, 2011; Ho et al., 2012a). They may also be extended to settings with multiple networks, e.g., the time-varying setting in which we are given snapshots of the same network at multiple time points (Fu et al., 2009; Ho et al., 2011), or to the nonparametric setting, which provides a principled way to automatically select the number of communities (Kemp et al., 2006; Ho et al., 2012a,b).

Despite some recent work showing that probabilistic methods can already be scaled up to networks with several million nodes (Gopalan and Blei, 2013), there are currently no probabilistic network models that have been reported to scale to hundreds of millions of nodes or more. In this paper, we develop a new probabilistic network model and accompanying inference algorithm for these massive scales. We take a latent space approach, in which each node is associated with an unobserved mixed-membership vector in the latent space that represents a mixture distribution over the multiple possible characteristics (roles or properties) it can have. The mixed-membership assumption can naturally capture the multi-faceted and heterogeneous nature of nodes in real networks—for example, actors in social networks tend to belong to multiple distinct social groups, depending on whom they are interacting with. This is in contrast to the single-membership assumption, where each node can only play a single latent role in its relationship with other nodes. We focus on probabilistic inference of mixed-membership vectors of individual nodes, taking as input the observed structural relation of Internet-scale networks with millions to hundreds of millions of nodes. The inferred mixed-membership position vectors can then be used for overlapping community detection. We demonstrate that our method can infer 1000 communities from a 101-million-node web graph in less than 40 hours using a small cluster of 5 machines, and that, on real-world networks with ground truth, our community recovery accuracy is competitive with or outperforms other scalable probabilistic models.

∗. Qirong Ho and Junming Yin contributed equally.

1.1 Challenges in Probabilistic Modeling of Large Networks

For a network with N nodes, its dense adjacency matrix representation contains $\Theta\left(N^2\right)$ elements. Although the network data itself can be stored in a sparse format (e.g., edge list or adjacency list), several popular probabilistic network models—such as mixed-membership stochastic blockmodels (Airoldi et al., 2008) and latent feature models (Miller et al., 2009)—associate latent variables to each of the N^2 elements in the adjacency matrix, essentially treating the network as non-sparse. Consequently, the inference algorithm naively requires $\Omega(N^2)$ computational complexity. This may still be acceptable for small networks, but is untenable for networks with hundreds of millions of nodes, as considered in this work.

A second difficulty is that larger networks have been observed to have more communities (Leskovec et al., 2005), so the number of hidden variables or parameters in the model often has to grow super-linearly in the number of communities K (in addition to N). Having super-linear growth in the state space can quickly render the inference algorithm computationally intractable, even at modest network scales. Such challenges have already been observed in the mixed-membership stochastic blockmodel (MMSB), which is infeasible for networks with $N \geq 100$ million nodes or $K \geq 100$ communities because of its $O(N^2K^2)$ per-iteration runtime. Recent work by Gopalan and Blei (2013) has brought the per-iteration inference complexity of MMSB down to $O(MK)$, where M is the number of edges. The resulting algorithm allows scalability of up to $N = 4$ million nodes and $K = 1000$ communities in about 1 week on a single machine. However, even that result remains about 1.4 orders of magnitude below our desired target of $N \geq 100$ million nodes.

1.2 Proposed Approach

From a scalability perspective, an ideal large-scale network inference algorithm would require only linear-time work in the number of nodes and communities. Towards this end, we take a different approach to data representation, model construction, and algorithm design that avoids the common edge-based representation of a network (e.g., adjacency matrices or adjacency lists), in favor of viewing the network in terms of *triangular motifs* (also known as triads, or subgraphs of size 3).

Our triangular motif representation captures certain edge patterns observed in node triples (i, j, k), such as the 2-edge triangle $i-j-k$ and the 3-edge triangle $i-j-k-i$. This is a hypergraph representation of the network, where every hyperedge is labeled with the edge pattern over (i, j, k)[1]. Hypergraph representations of networks have been studied in both the social networks (Ghoshal et al., 2009) and statistics (Stasi et al., 2014) literature, and there is an empirical evidence showing that triangles and higher-order subgraphs can substantially reveal the structure and communities within a network (Milo et al., 2002; Yang and Leskovec, 2012b). Moreover, this triangular representation has desirable properties for large-scale network analysis; in particular, it is possible to subsample triangular motifs in a manner that approximately preserves important network attributes such as the *clustering coefficient*, a popular measure of cluster strength.

In the following sections, we shall discuss how to build a scalable, linear-time network inference algorithm based on triangular motifs. We begin with the triangular data representation (Section 2), followed by statistical model design (Section 3), and then parallelizable

1. This is technically a 3-uniform hypergraph, where all hyperedges are associated with 3 nodes.

inference algorithm construction (Section 4). Finally, we implement the algorithm in the distributed, multi-machine cluster setting (Section 5), using a large-scale machine learning platform called Petuum (`www.petuum.org`). The resulting latent space inference algorithm can be used for overlapping community detection on networks with more than 100 million nodes and thousands of communities.

1.3 Related Work

Understanding network structure is highly important to a number of scientific domains, and each domain has developed its own unique tools to analyze the global and local properties of networks. Here, we provide a general overview of network analysis methods from the computer science and statistics literature, with a focus on how well they scale to very large networks with hundreds of millions of nodes or more.

In the general computer science literature, there has been an emphasis on achieving fast, linear-time overlapping community detection on medium-sized networks (usually millions of nodes). Examples include the GCE (Lee et al., 2010), Link (Ahn et al., 2010) and SLPA (Xie and Szymanski, 2012) algorithms. Although these algorithms are fast (less than one hour running time on 1 million nodes), their clustering strategies are not always based on a clearly defined optimization function or statistical model, and might be considered ad-hoc in a statistical or machine learning setting. For example, SLPA propagates community labels through the graph, and does not have an underlying statistical model or objective function. There is neither consensus on which approach works best nor on generalization guarantees to networks with different properties. Moreover, compared to a model-based approach, it is unclear how to incorporate additional network attributes in a principled manner, such as text or other meta-data associated with each node.

In statistics and machine learning, network algorithms are typically created by defining a formal model of the network, and deriving an inference or optimization algorithm to learn the model's parameters. Predominant statistical network models include exponential random graph models (ERGMs) (Morris et al., 2008; Hunter et al., 2008; Guo et al., 2007), stochastic blockmodels (Bickel et al., 2013; Anandkumar et al., 2014; Airoldi et al., 2008; Ho et al., 2011; Gopalan et al., 2012) and latent factor models (Miller et al., 2009; Handcock et al., 2007; Hoff et al., 2002). All of these models are popular for their ease of interpretability, but their inference algorithms generally require $\mathrm{O}(N^2)$ time due to how they model the adjacency matrix, making them patently unscalable to massive networks with $N \geq 100$ million. Exceptions to this trend include assortative MMSB (Gopalan et al., 2012; Gopalan and Blei, 2013), which applied stochastic gradient techniques to achieve linear runtime on the MMSB (Airoldi et al., 2008), and sparse block model (Parkkinen et al., 2009) with $\mathrm{O}(M)$ latent variables (M is the number of edges). Although these methods are scalable in their own right, they still treat *network edges* as the basis for the task of community detection. In this paper, we will argue that *triangular motifs* are a good, if not better, network representation for this task (Section 3), and design a network model based on these triangular motifs.

The natural language processing and information retrieval communities have extended the LDA topic model (Blei et al., 2003) to a variety of text-network models by exploring the links between documents. Examples include the relational topic model (Chang and

Blei, 2009), Link-PLSA-LDA (Nallapati et al., 2008), Block-LDA (Balasubramanyan and Cohen, 2011), the author-topic model (Rosen-Zvi et al., 2004), and the citation influence model (Dietz et al., 2007). While these models are scalable in that they require O(M) work on the network data, most of them (except for the Block-LDA model) cannot perform network inference in the absence of text data because they do not use a stand-alone network model.

In the data mining and machine learning literature, matrix factorization methods provide a principled framework for decomposing relational data (of which networks are one type) into simpler "basis" components. Although the basis components are sometimes less interpretable than the probability distributions that arise from statistical models (e.g., the basis components may have negative values), the optimization algorithms to perform matrix factorization are usually faster than the inference algorithms for statistical models. In particular, the HEigen algorithm (Kang et al., 2011) computes the rank-k singular value decomposition (SVD) on networks with $N \geq 1$ billion nodes, given a cluster with hundreds of Hadoop machines. Furthermore, matrix factorization can be reinterpreted in a probabilistic setting, as seen in the work of Singh and Gordon (2010), who have developed a probabilistic matrix factorization framework for an arbitrary number of relational matrices. To incorporate network context into such a coupled matrix factorization framework, one would require at least two matrices: the adjacency matrix and one or more matrices of nodes against their features. Whether the resulting algorithm is scalable strongly depends on how the objective function is constructed. If the objective function is dense in the adjacency matrix (i.e., work is performed even on the zeros) such as in Wang et al. (2011), then the algorithm requires at least $\Omega(N^2)$ work. It will not finish in a realistic amount of time on networks with 100 million nodes, even if a large computer cluster is used. On the other hand, if the objective function is sparse (i.e., no work performed on the zeros), then one may take advantage of existing software for distributed, large-scale coupled matrix factorization, such as FlexiFaCT (Beutel et al., 2014). Another example of coupled matrix factorization is the linear-time PICS network analysis algorithm (Akoglu et al., 2012), which can analyze networks with $N \approx 75$k nodes in about 1-2 hours.

2. Data Representation: Triangular Motif Representation of Networks

In many real-world problems where computational cost is a bottleneck, transforming the original raw data into a task-dependent representation might well suffice for subsequent analyses and save significantly on computational cost. Classical examples include: (1) the *bag-of-words* representation of a document, in which the ordering information of words is discarded—although much grammatical information is lost, this representation has proven effective in natural language processing tasks such as topic modeling (Blei et al., 2003); (2) the use of *superpixels* to represent images, in which adjacent pixels are grouped into larger superpixels—the resulting image representation is compact, and leads to faster and better-performing segmentation algorithms in computer vision (Cao and Fei-Fei, 2007; Fulkerson et al., 2009).

Similarly, in probabilistic modeling of networks, the traditional dense adjacency matrix representation (Figure 1) is not suitable for the massive scales ($N \geq 100$ million) considered in this work. In particular, many probabilistic network algorithms touch every entry of

	1	2	3	4	5
1	-	1	1	0	0
2	1	-	0	1	1
3	1	0	-	1	0
4	0	1	1	-	1
5	0	1	0	1	-

Figure 1: Three different representations of the same network: as a graph, as an adjacency matrix, and as a list of 2-edge and 3-edge triangular motifs.

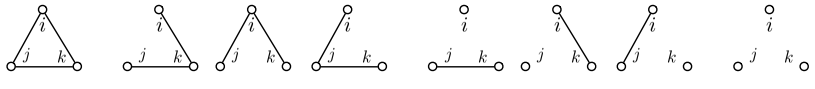

Figure 2: Four types of triangular motifs: (a) 3-edge triangle; (b) 2-edge triangle; (c) 1-edge triangle; (d) empty-triangle. For latent space inference of Internet-scale networks, we only focus on 3-edge and 2-edge triangles.

the adjacency matrix, leading to $\Theta(N^2)$ run-time complexity per iteration. To solve the representational and computational challenges of large-scale probabilistic network inference, we advocate the use of triangular motifs (Figures 1 and 2) as a foundation to achieve succinct yet informative representation of networks. Triangular motifs have historically played an important role in biological network analysis (Milo et al., 2002) as well as in social network analysis (Simmel and Wolff, 1950; Granovetter, 1973; Krackhardt and Handcock, 2007). After describing triangular motifs, we will show in the next few sections how they can be used to construct a mixed-membership network model with $O(CNK)$ per-iteration inference cost for a small constant C.

Given an *undirected* network[2] with N vertices, we shall use the term "1-edge" to refer to edges that exist between two vertices, and the term "0-edge" to refer to missing edges. A triangular motif E_{ijk} over 3 vertices $i < j < k$ is simply the type of subgraph exhibited by those 3 vertices. There are four basic classes of triangular motifs (Figure 2), distinguished by their number of 1-edges: 3-edge triangle Δ_3 (three 1-edges), 2-edge triangle Δ_2 (two 1-edges), 1-edge triangle Δ_1 (one 1-edge), and empty-triangle Δ_0 (no 1-edges). The total number of triangular motifs, over all four classes, is $\Theta(N^3)$. However, our goal is not to account for all four classes in a network representation; instead, we will focus on 3-edge and 2-edge triangles (Δ_3 and Δ_2) while ignoring 1-edge triangles and empty-triangles (Δ_1 and Δ_0). There are two key motivations for this approach:

2. Our approach can also be generalized to directed networks, though the analysis is more involved since directed networks can have more triangular motifs than undirected networks.

1. In the network literature, many important network measures and characteristics are quantified and captured by the three-node *connected* subgraphs (namely Δ_3 and Δ_2). To name a few: (1) the network clustering coefficient (Watts and Strogatz, 1998; Newman and Park, 2003), a common measure of triadic closure in social network theory (Simmel and Wolff, 1950; Granovetter, 1973; Krackhardt and Handcock, 2007), is defined as the relative number of 3-edge triangles compared to the total number of connected vertex triplets (i.e., 3-edge and 2-edge triangles); (2) the most significant and recurrent structural patterns in many complex networks, so-called "network motifs", are the three-node connected subgraphs (Milo et al., 2002). Therefore, one naturally expects the classes of 3-edge and 2-edge triangles to capture most of the informative structure in a large network.

2. The four classes of triangular motifs certainly contain redundant information, because in principle one needs only $\Theta(N^2)$ bits to fully describe a network. Though node triplets with only one or zero 1-edge (namely Δ_1 and Δ_0) are not uncommon in real-world networks (Leskovec et al., 2009), those information might already be contained in the list of Δ_3 and Δ_2 triangles. For instance, one can easily conclude from the 2/3-edge triangular motif representation of the network in Figure 1 that a 1-edge triangle Δ_1 is formed among the node triplet $\{1, 3, 5\}$. In fact, almost all network information found in an adjacency matrix representation is preserved by Δ_3 and Δ_2 triangles: every 1-edge that appears in some Δ_3 or Δ_2 can be identified in the corresponding triangular motif. The only exception is a set of isolated 1-edges. However, these small strongly connected components of size 2 can be easily detected and are less interesting from a large-scale community detection perspective.

One main advantage of characterizing a network in terms of triangular motifs Δ_3 and Δ_2 is that such representation is typically more compact than the adjacency matrix representation[3], via the following lemma:

Lemma 1 *The total number of Δ_3's and Δ_2's is $\Theta(\sum_i D_i^2)$, where D_i is vertex i's degree.*

Proof Let $\mathcal{N}_i$ be the neighbor set of vertex i. For each vertex i, form the set $\mathcal{T}_i$ of tuples (i, j, k) where $j < k$ and $j, k \in \mathcal{N}_i$, which represents the set of all pairs of neighbors of i. Because j and k are neighbors of i, the triangular motif formed among every tuple $(i, j, k) \in \mathcal{T}_i$ is either a 3-edge triangle Δ_3 or a 2-edge triangle Δ_2. It is easy to see that each Δ_2 is accounted for by exactly one $\mathcal{T}_i$, where i is the center vertex of the Δ_2, and that each Δ_3 is accounted for by three sets $\mathcal{T}_i, \mathcal{T}_j$ and $\mathcal{T}_k$, one for each vertex in the 3-edge triangle. Thus, $\sum_i |\mathcal{T}_i| = \sum_i \frac{1}{2}(D_i)(D_i - 1)$ is an upper bound to the total number of Δ_3's and Δ_2's. By modifying the preceding argument slightly, we can also show that the total number of Δ_3's and Δ_2's is bounded below by $\frac{1}{3}\sum_i |\mathcal{T}_i|$. ■

For networks with low maximum degree $D_{\max}$, $\Theta(\sum_i D_i^2) = O(ND_{\max}^2)$ is typically much smaller than $\Theta(N^2)$. Even in real-world networks with power-law behavior, the number of Δ_3's and Δ_2's tends to be still much smaller than the size of adjacency matrix N^2

3. Recall the size of data (including both 1-edges and 0-edges) in the adjacency matrix representation of a network is $\Theta(N^2)$, even if the data can be stored in a sparse manner.

Network	# nodes N	# edges M	adj matrix size N^2	Upper bound of $\#(\Delta_3, \Delta_2)$

Table 1: Networks used in this paper: number of 2-edge and 3-edge triangles versus adjacency matrix size. Many (though not all) probabilistic network models use the entire non-sparse adjacency matrix as input. The 2/3-edge triangular representation provides a more compact alternative—in all example networks, the upper bound for the number of Δ_3's and Δ_2's is at least 1000 times smaller than the full adjacency matrix.

(Table 1), and this allows us to construct a more efficient inference algorithm scalable to larger networks. However, the large number of triangles still poses storage and computational challenges. Our solution is to keep the triangular motifs in an *implicit* representation, and subsample a mini-batch of them only when they are needed (and discard them afterwards) in the stochastic variational inference algorithm. We will describe such technique in Section 5.1, and our results will surprisingly show that the inference algorithm only needs to touch a small fraction of triangles before converging to an accurate result.

3. Model: Scalable Network Model (STM) Based on Triangular Motifs

Given a network, now represented by a bag of triangular motifs Δ_3 and Δ_2 (Figure 1), the goal is to perform probabilistic inference of mixed-membership vectors of individual nodes, which can then be used for overlapping community detection. This is as opposed to traditional single-membership community detection, which assigns each vertex to exactly one community. By taking a mixed-membership approach, one gains many benefits over single-membership models, such as outlier detection, improved visualization, and better interpretability (Blei et al., 2003; Airoldi et al., 2008).

To construct the mixed-membership network model based on the triangular motif representation, which we call STM for scalable triangle model, we first establish some notation used throughout the paper. Recall that we are concerned only with 3-edge and 2-edge triangles (Δ_3 and Δ_2) in the triangular motif representation of networks. For each triplet of vertices $i, j, k \in \{1, \ldots, N\}, i < j < k$, if the subgraph on i, j, k is a 2-edge triangle with i, j, or k at the center, then let $E_{ijk} = 1$, 2, or 3 respectively; if a 3-edge triangle is formed among i, j, k, then let $E_{ijk} = 4$. In other words, E_{ijk} denotes the observed type of triangular motif on vertices i, j, k. Whenever the subgraph on i, j, k is a 1-edge triangle or an empty-triangle, we simply discard it (i.e., E_{ijk} is not part of the model) for the reasons that have been described in Section 2 .

Next, we assume K latent communities, and that each vertex takes a mixture distribution over them. The observed 2-edge and 3-edge triangles $\{E_{ijk}\}$ are generated according to a latent space model that defines (1) the mixture distribution over community memberships at each vertex, and (2) a tensor-like data structure of triangle-generating probabilities. More formally, each vertex i is associated with a community mixed-membership vector $\theta_i \in \Delta^{K-1}$ restricted to the $(K-1)$-simplex Δ^{K-1}. This mixed-membership vector θ_i is used to gen-

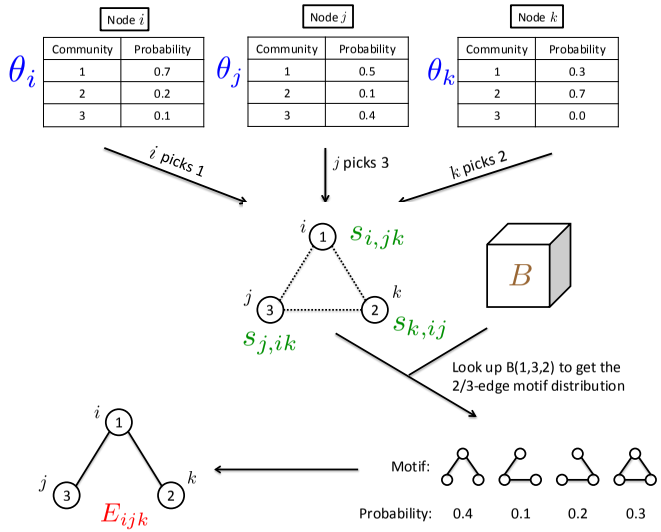

Figure 3: High-level generative process of how the mixed-membership vectors $\theta_i, \theta_j, \theta_k$ and a "tensor" of triangle-generating probabilities $\mathbf{B}$ are used to generate the triangular motif E_{ijk}. In this example, $(s_{i,jk} = 1, s_{j,ik} = 3, s_{k,ij} = 2)$ represents a context-dependent instantiation of communities for three vertices i, j, k when they are interacting, and the entry B_{132} is examined to obtain the multinomial parameter of generating E_{ijk}. All these probabilities are unobserved and need to be inferred from the observed triangular motifs.

erate community indicators $s_{i,jk} \in \{1, \ldots, K\}$, each of which represents the community chosen by vertex i when it is forming a triangle with vertices j and k. The probability of observing a triangular motif E_{ijk} depends on the community triplet $(s_{i,jk}, s_{j,ik}, s_{k,ij})$ and a tensor of triangle-generating parameters $\mathbf{B}$. Each element B_{xyz} of this tensor contains the multinomial probabilities of generating the four possible 2-edge and 3-edge triangles, when three vertices with respective communities x, y, z interact. A schematic of this generative process is illustrated in Figure 3.

3.1 Parsimonious Parameter Structure

The triangle-generating probability tensor $\mathbf{B}$ described above contains $O(K^3)$ distributions, one for each possible community combination (x, y, z). This presents challenging issues in both statistical estimation and computational complexity: (1) the large number of $O(K^3)$ parameters to be estimated leads to a loss of statistical efficiency (particularly when $K \geq 1000$); (2) inference requires $O(K^3)$ time per iteration, which is computationally intractable. An elegant solution to this problem is to reduce the number of triangle-generating

parameters by partitioning the $O(K^3)$ community combination space intro several groups, and then sharing parameters within the same group (Yin et al., 2013). Our parameter-sharing strategy is based on the number of distinct states in the configuration of the community triplet (x, y, z):

1. If all three communities are the same x, the triangle-generating probability is determined by B_{xxx} (this is identical to the diagonal of the $O(K^3)$ parameterization of $\mathbf{B}$ tensor). There are K such parameters $B_{111}, \ldots, B_{KKK}$.

2. If only two communities indices exhibit the same state x (called the majority community), the probability of triangles is governed by B_{xx}, no matter what the third, minority community y is. The intuition is that the identity of the majority community is the dominant factor in determining the triangle-generating probabilities, regardless of the minority community. As with any statistical assumption, this is never perfectly true for real data, but nevertheless turns out to be a good assumption, as our results will show. There are K such parameters $B_{11}, \ldots, B_{KK}$.

3. If the three community indices are all distinct, the probability of triangular motifs depends on B_0, a single parameter independent of the community identities. This is similar in spirit to the combined off-diagonal blockmatrix parameters used in hierarchical blockmodels (Ho et al., 2012a) and the assortative MMSB (Gopalan et al., 2012; Gopalan and Blei, 2013).

This sharing strategy yields just $O(K)$ parameters $B_0, B_{xx}, B_{xxx}, x \in \{1, \ldots, K\}$ (since there are at most four distinct 2-edge and 3-edge triangles), allowing STM to scale to far more communities than a naive $O(K^3)$ parameterization of $\mathbf{B}$ tensor.

3.2 Equivalence Classes of Triangles

For certain configurations of community triplet $(s_{i,jk}, s_{j,ik}, s_{k,ij})$, some of the triangular motifs can become indistinguishable. To illustrate, consider the example illustrated in Figure 4: suppose that nodes i and j take membership in community x (the majority community), while the node k takes community y—that is, we have $x = s_{i,jk} = s_{j,ik} \neq s_{k,ij} = y$. Under these assignments, one cannot distinguish the 2-edge triangle with i in the center (right panel, $E_{ijk} = 1$) from the triangle with j in the center (left panel, $E_{ijk} = 2$). This is because both are 2-edge triangles centered at a vertex with majority community x, and are thus *equivalent* with respect to the underlying community configuration $x - x - y$. Formally, this $x - x - y$ community configuration induces a set of triangle equivalence classes $\{\{1, 2\}, \{3\}, \{4\}\}$ of all possible triangular motifs $E_{ijk} \in \{1, 2, 3, 4\}$. We treat the triangular motifs within the same equivalence class as *stochastically equivalent*; that is, the conditional probabilities of events $E_{ijk} = 1$ and $E_{ijk} = 2$ are assumed to be the same if $x = s_{i,jk} = s_{j,ik} \neq s_{k,ij}$. All possible cases are enumerated as follows (see also Table 2):

1. If all three vertices have the same community x, all three 2-edge triangles are equivalent and the induced set of equivalence classes is $\{\{1, 2, 3\}, \{4\}\}$. The probability of E_{ijk} is determined by $B_{xxx} \in \Delta^1$, where $B_{xxx,1}$ represents the *total* probability of sampling an 2-edge triangle from $\{1, 2, 3\}$ and $B_{xxx,2}$ represents the 3-edge triangle probability. Thus, the probability of a particular 2-edge triangle is $B_{xxx,1}/3$.

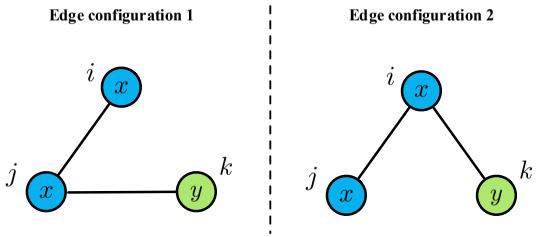

Figure 4: An example of two indistinguishable, equivalent motifs. Although the edge configuration is different in two motifs ($i-j-k$ on the left versus $j-i-k$ on the right), the motifs are indistinguishable under the given community combination, because they are both cases in which the central node (j and i respectively) has the majority community x.

2. If only two vertices have the same community x (majority community), the probability of E_{ijk} is governed by $B_{xx} \in \Delta^2$. Here, $B_{xx,1}$ and $B_{xx,2}$ represent the 2-edge triangle probabilities (for 2-edge triangles centered at a vertex in majority and minority community respectively), and $B_{xx,3}$ represents the 3-edge triangle probability. There are two possible 2-edge triangles with a vertex in majority community at the center, and hence each has probability $B_{xx,1}/2$.

3. If all three vertices have distinct community, the probability of E_{ijk} depends on $B_0 \in \Delta^1$, where $B_{0,1}$ represents the *total* probability of sampling an 2-edge triangle from $\{1,2,3\}$ (regardless of the center vertex's community) and $B_{0,2}$ represents the 3-edge triangle probability.

3.3 Generative Process for Scalable Triangular Model (STM)

We summarize the generative process for a bag of triangular motifs under the STM:

1. Draw $B_0 \in \Delta^1$, $B_{xx} \in \Delta^2$ and $B_{xxx} \in \Delta^1$ for each community $x \in \{1,\ldots,K\}$, according to symmetric Dirichlet distributions $\text{Dirichlet}(\lambda)$.

2. For each vertex $i \in \{1,\ldots,N\}$, draw a mixed-membership vector $\theta_i \sim \text{Dirichlet}(\alpha)$.

3. For each triplet of vertices $(i,j,k), i<j<k$,

   (a) Draw community configuration $s_{i,jk} \sim \text{Discrete}(\theta_i)$, $s_{j,ik} \sim \text{Discrete}(\theta_j)$, $s_{k,ij} \sim \text{Discrete}(\theta_k)$.

   (b) Draw an *equivalence class* of triangular motifs $\{E_{ijk}\}$ based on B_0, B_{xx}, B_{xxx} and the configuration of $(s_{i,jk}, s_{j,ik}, s_{k,ij})$. See Table 2 for the conditional probabilities of each equivalence class.

   (c) Draw a triangular motif E_{ijk} uniformly at random from the chosen equivalence class (this is what we meant by *stochastic equivalence* earlier).

$(s_{i,jk}, s_{j,ik}, s_{k,ij})$	Equivalence classes	Conditional probability of $E_{ijk} \in \{1,2,3,4\}$
$x = s_{i,jk} = s_{j,ik} = s_{k,ij}$	$\{1,2,3\},\{4\}$	$\text{Discrete}\big(\big[\frac{B_{xxx,1}}{3}, \frac{B_{xxx,1}}{3}, \frac{B_{xxx,1}}{3}, B_{xxx,2}\big]\big)$
$x = s_{i,jk} = s_{j,ik} \neq s_{k,ij}$	$\{1,2\},\{3\},\{4\}$	$\text{Discrete}\big(\big[\frac{B_{xx,1}}{2}, \frac{B_{xx,1}}{2}, B_{xx,2}, B_{xx,3}\big]\big)$
$x = s_{i,jk} = s_{k,ij} \neq s_{j,ik}$	$\{1,3\},\{2\},\{4\}$	$\text{Discrete}\big(\big[\frac{B_{xx,1}}{2}, B_{xx,2}, \frac{B_{xx,1}}{2}, B_{xx,3}\big]\big)$
$x = s_{j,ik} = s_{k,ij} \neq s_{i,jk}$	$\{2,3\},\{1\},\{4\}$	$\text{Discrete}\big(\big[B_{xx,2}, \frac{B_{xx,1}}{2}, \frac{B_{xx,1}}{2}, B_{xx,3}\big]\big)$
$s_{k,ij} \neq s_{i,jk} \neq s_{j,ik}$	$\{1,2,3\},\{4\}$	$\text{Discrete}\big(\big[\frac{B_{0,1}}{3}, \frac{B_{0,1}}{3}, \frac{B_{0,1}}{3}, B_{0,2}\big]\big)$

Table 2: Equivalence classes and conditional probabilities of E_{ijk} given $s_{i,jk}, s_{j,ik}, s_{k,ij}$ (see text for details).

It is worth noting that STM is not a generative model of networks since (a) empty-triangles and 1-edge triangles are not modeled, and (b) one can possibly generate a set of triangles that does not correspond to any network. This is a consequence of using a bag-of-triangles model in which the generative process does not force overlapping triangles to have consistent edge values. For example, generating a 2-edge triangle centered at i for (i,j,k) followed by a 3-edge triangle for (j,k,ℓ) can produce a mismatch on the edge (j,k). However, given a bag of triangular motifs $\mathbf{E}$ extracted from a network, the above procedure defines a valid probabilistic model $p(\mathbf{E} \mid \alpha, \lambda)$, and we can use it for performing posterior inference $p(\mathbf{s}, \boldsymbol{\theta}, \mathbf{B} \mid \mathbf{E}, \alpha, \lambda)$. We stress that our goal is fast and scalable latent space inference for overlapping community detection, not network simulation[4].

4. Inference: Efficient Stochastic Variational Inference (SVI) for STM

In this section, we present a stochastic variational inference (SVI) algorithm (Hoffman et al., 2013) with $O(CNK)$ per-iteration cost for performing approximate inference under our STM (where C is a small constant). The inferred posterior probability distribution of the latent variables, in particular the mixed-membership vectors θ_i, can then be used for overlapping community discovery. The high-level ideas are to (1) develop a structured mean-field approximation—a more accurate approximation to the true posterior than the naive mean-field solution explored in earlier mixed-membership network models (Airoldi et al., 2008), but requires $O(K^3)$ run-time per triangular motif; (2) refine the structured mean-field approximation to lower the run-time complexity to $O(K)$ while maintaining its high accuracy, inspired by a careful understanding of the typical structure of the posterior distribution; (3) apply stochastic variational inference (SVI) to yield a faster approximate inference algorithm; (4) propose a new stochastic subsampling strategy in the SVI algorithm that empirically achieves high-quality results without having to touch every 2/3-edge triangle in the network, thus ensuring scalability to very large networks which may have more than trillions (10^{12}) of triangles.

4. For applications in which simulation is vital, it is possible to design a variant of STM that sequentially generates motifs so as to have consistent edge values across overlapping triangles. In such model, all possible triples (i,j,k) are sequentially considered, and a new motif among them is simulated conditioning on the patterns of other motifs that have already been generated. This non-exchangeable model is, however, out of the scope of this work.

4.1 Structured Mean-field Approximation

As with other mixed-membership models, computing the true posterior of the latent variables $p(\mathbf{s}, \boldsymbol{\theta}, \mathbf{B} \mid \mathbf{E}, \alpha, \lambda)$ under the STM is intractable, and approximate inference must be employed. There are three common strategies to perform approximate inference in mixed-membership models: Markov chain Monte Carlo (MCMC) (Griffiths and Steyvers, 2004), variational inference (Blei et al., 2003; Airoldi et al., 2008), and spectral methods (Anandkumar et al., 2014). MCMC methods are typically viewed as the "gold standard" as they are guaranteed to eventually (but could be slow in practice) converge to the true posterior. Variational inference provides a fast approximation that can be accurate enough for the task at hand, provided care has been taken to design an appropriate factorized variational distribution. Spectral methods have shown much promise in terms of accuracy and scalability, but the $O(K^3)$ run-time complexity limits its application to the setting of $K \geq 1000$ we are considering.

Based on these considerations, we choose a structured mean-field approximation for the STM model. The corresponding inference algorithm proceeds via coordinate ascent update on an objective function known as "variational lower bound" that depends on a set of "variational parameters". To construct the variational lower bound, we begin by approximating the true (but intractable) posterior $p(\mathbf{s}, \boldsymbol{\theta}, \mathbf{B} \mid \mathbf{E}, \alpha, \lambda)$ by a *partially* factorized distribution $q(\mathbf{s}, \boldsymbol{\theta}, \mathbf{B})$,

$$\begin{aligned} q(\mathbf{s}, \boldsymbol{\theta}, \mathbf{B}) &= q(\mathbf{s} \mid \boldsymbol{\phi}) q(\boldsymbol{\theta} \mid \boldsymbol{\gamma}) q(\mathbf{B} \mid \boldsymbol{\eta}) \\ &= \left[\prod_{(i,j,k) \in I} q(s_{i,jk}, s_{j,ik}, s_{k,ij} \mid \phi_{ijk}) \right] \left[\prod_{i=1}^{N} q(\theta_i \mid \gamma_i) \right] \left[\prod_{x=1}^{K} q(B_{xxx} \mid \eta_{xxx}) \right] \left[\prod_{x=1}^{K} q(B_{xx} \mid \eta_{xx}) \right] [q(B_0 \mid \eta_0)], \end{aligned} \tag{1}$$

where I is the set of all 2/3-edge triangles in the network, i.e., $I = \{(i,j,k) : i < j < k, E_{ijk} \in \{1,2,3,4\}\}$. The factorized distribution $q(\mathbf{s}, \boldsymbol{\theta}, \mathbf{B})$ contains 3 types of terms:

1. Terms for the community triplet distribution for each triangle, $q(s_{i,jk}, s_{j,ik}, s_{k,ij} \mid \phi_{ijk})$;
2. Terms for the mixed-membership community distribution for each node, $q(\theta_i \mid \gamma_i)$;
3. Terms for the triangle-generating distributions, $q(B_{xxx} \mid \eta_{xxx})$, $q(B_{xx} \mid \eta_{xx})$, and $q(B_0 \mid \eta_0)$.

In particular, we have defined a *joint* (as opposed to fully factorized) distribution $q(s_{i,jk}, s_{j,ik}, s_{k,ij} \mid \phi_{ijk})$ over the community triplet $(s_{i,jk}, s_{j,ik}, s_{k,ij})$:

$$q(s_{i,jk} = x, s_{j,ik} = y, s_{k,ij} = z) \doteq q_{ijk}(x,y,z) = \phi_{ijk}^{xyz}, \quad x,y,z = 1, \ldots, K. \tag{2}$$

The posterior $q(\theta_i)$ is a Dirichlet(γ_i), and the posteriors of B_{xxx}, B_{xx}, B_0 are parameterized as: $q(B_{xxx}) = \text{Dirichlet}(\eta_{xxx}), q(B_{xx}) = \text{Dirichlet}(\eta_{xx})$, and $q(B_0) = \text{Dirichlet}(\eta_0)$.

Rationale for the Structured Approximation. Conditioning on the observed type of triangular motif E_{ijk} on vertex triplet (i,j,k)—either a 2-edge triangle Δ_2 or a 3-edge triangle Δ_3, the community indicators $(s_{i,jk},\ s_{j,ik},\ s_{k,ij})$ are often highly correlated. For example, suppose that nodes i,j,k form a 3-edge triangle, then it is empirically and sociologically far more likely that they all belong to the same community, as opposed to being a mix of different communities. As a result, the true posterior distribution $p(s_{i,jk}, s_{j,ik}, s_{k,ij} \mid \boldsymbol{\theta}, \mathbf{B}, \mathbf{E}, \alpha, \lambda)$—a discrete distribution over K^3 events—tend to concentrate around (some of) the K "all-the-same-community" events $\{s_{i,jk} = s_{j,ik} = s_{k,ij} = 1, 2, \ldots, K\}$. If we think of the posterior as a third-order tensor of dimension $K \times K \times K$ in which each element (x,y,z) represents the posterior probability $p(s_{i,jk} = x, s_{j,ik} = y, s_{k,ij} = z \mid \boldsymbol{\theta}, \mathbf{B}, \mathbf{E}, \alpha, \lambda)$, we see that it is very likely to be a tensor with rank greater than one due to its non-zero diagonal entries. Therefore, it cannot be accurately approximated by a fully factorized distribution $q(s_{i,jk} \mid \phi_{i,jk}) q(s_{j,ik} \mid \phi_{j,ik}) q(s_{k,ij} \mid \phi_{k,ij})$ as used in the naive mean-field approximation, because the outer product yields a rank-1 tensor. A similar argument holds for 2-edge triangles, whose nodes are likely to be in one or two communities, with a similar correlation structure as to the 3-edge case. For this reason, we have chosen a joint form $q(s_{i,jk}, s_{j,ik}, s_{k,ij} \mid \phi_{ijk})$ for the variational posterior, in order to capture the correlation structure of the true posterior $p(s_{i,jk}, s_{j,ik}, s_{k,ij} \mid \boldsymbol{\theta}, \mathbf{B}, \mathbf{E}, \alpha, \lambda)$.

However, having a structured approximation is computationally more expensive: the variational parameter ϕ_{ijk} used in the variational posterior $q(s_{i,jk}, s_{j,ik}, s_{k,ij} \mid \phi_{ijk})$ is a tensor containing K^3 entries, which would cause an unacceptable $O(K^3)$ run-time per triangular motif if handled naively. In the next section, we will discuss a more refined approximation strategy that maintains the high accuracy of the structured mean-field approximation but only requires $O(K)$ run-time per triangular motif, thus ensuring scalability to thousands of communities K.

4.2 Stochastic Variational Inference (SVI) Algorithm

The structured mean-field approximation (Wainwright and Jordan, 2008) aims to minimize the KL divergence $\text{KL}(q \parallel p)$ between the approximating distribution q and the true posterior p; it is equivalent to maximizing a lower bound $\mathcal{L}(\boldsymbol{\phi}, \boldsymbol{\eta}, \boldsymbol{\gamma})$ of the log marginal likelihood of the triangular motifs (based on Jensen's inequality) with respect to the variational parameters $\{\boldsymbol{\phi}, \boldsymbol{\eta}, \boldsymbol{\gamma}\}$ defined in Equation 1:

$$\log p(\mathbf{E} \mid \alpha, \lambda) \geq \mathbb{E}_q[\log p(\mathbf{E}, \mathbf{s}, \boldsymbol{\theta}, \mathbf{B} \mid \alpha, \lambda)] - \mathbb{E}_q[\log q(\mathbf{s}, \boldsymbol{\theta}, \mathbf{B})] \doteq \mathcal{L}(\boldsymbol{\phi}, \boldsymbol{\eta}, \boldsymbol{\gamma}). \tag{3}$$

To simplify the notation, we decompose the variational objective $\mathcal{L}(\boldsymbol{\phi}, \boldsymbol{\eta}, \boldsymbol{\gamma})$ into a "global" term and a summation of "local" terms, where each local term corresponds to one 2/3-edge triangle in the network (see Appendix A.1 for their exact forms).

$$\mathcal{L}(\boldsymbol{\phi}, \boldsymbol{\eta}, \boldsymbol{\gamma}) = g(\boldsymbol{\eta}, \boldsymbol{\gamma}) + \sum_{(i,j,k) \in I} \ell(\phi_{ijk}, \boldsymbol{\eta}, \boldsymbol{\gamma}). \tag{4}$$

The global term $g(\boldsymbol{\eta}, \boldsymbol{\gamma})$ depends only on the global variational parameters $\boldsymbol{\eta}$, which govern the posterior of the triangle-generating probabilities $\mathbf{B}$, as well as the per-node mixed-membership parameters $\boldsymbol{\gamma}$. Each local term $\ell(\phi_{ijk}, \boldsymbol{\eta}, \boldsymbol{\gamma})$ depends on per-triangle variational parameter ϕ_{ijk} as well as the global parameters. Our distributed and parallel implementation strategy will involve splitting the inferential work along disjoint sets of local variational parameters, as we will show in Algorithm 1.

To understand how an SVI algorithm accelerates approximate inference, let us consider Equation 4 with the local parameters $\boldsymbol{\phi}$ being maximized out. Define $\mathcal{L}(\boldsymbol{\eta}, \boldsymbol{\gamma}) \doteq$

$\max_{\boldsymbol{\phi}} \mathcal{L}(\boldsymbol{\phi}, \boldsymbol{\eta}, \boldsymbol{\gamma})$, i.e., the variational objective achieved by fixing the global parameters $\boldsymbol{\eta}, \boldsymbol{\gamma}$ and optimizing the local parameters $\boldsymbol{\phi}$:

$$\mathcal{L}(\boldsymbol{\eta}, \boldsymbol{\gamma}) = g(\boldsymbol{\eta}, \boldsymbol{\gamma}) + \sum_{(i,j,k)\in I} \max_{\phi_{ijk}} \ell(\phi_{ijk}, \boldsymbol{\eta}, \boldsymbol{\gamma}). \tag{5}$$

The idea behind SVI (Hoffman et al., 2013) is as follows: instead of computing the gradient $\nabla\mathcal{L}(\boldsymbol{\eta}, \boldsymbol{\gamma})$ to perform the variational inference of the global parameters $\boldsymbol{\eta}$ and $\boldsymbol{\gamma}$, which involves a costly summation over all triangular motifs as in Equation 5, an unbiased noisy approximation of the gradient can be obtained much more cheaply by summing over a small subsample of triangles. One can then use this approximate gradient in the stochastic gradient ascent algorithm (Bottou, 2004) to maximize the variational objective $\mathcal{L}(\boldsymbol{\eta}, \boldsymbol{\gamma})$. With this unbiased estimate of the gradient and a suitable adaptive step size, the algorithm is guaranteed to converge (in probability) to a stationary point of the variational objective $\mathcal{L}(\boldsymbol{\eta}, \boldsymbol{\gamma})$ (Robbins and Monro, 1951). It should be noted that the subsampling strategy comes at the cost of introducing a variance in gradient computation, and hence more iterations might be required for convergence. However, the time taken by each iteration can be greatly reduced to a small fraction of the original time; for example, if we subsample 10% of the triangles, then only 10% computation time is required to obtain the approximate gradient. In fact, there is significant empirical evidence that SVI algorithm can lead to faster convergence on various problems (Hoffman et al., 2013; Yin et al., 2013).

Subsampling Strategy. In our setting, the most natural way to obtain an unbiased gradient of $\mathcal{L}(\boldsymbol{\eta}, \boldsymbol{\gamma})$ is to sample a "mini-batch" of triangular motifs at each iteration, and then average the gradient of local terms in Equation 5 *only* for these sampled triangles. Formally, let $m = |I|$ be the total number of 2/3-edge triangles[5] and define

$$\mathcal{L}_S(\boldsymbol{\eta}, \boldsymbol{\gamma}) = g(\boldsymbol{\eta}, \boldsymbol{\gamma}) + \frac{m}{|S|} \sum_{(i,j,k)\in S} \max_{\phi_{ijk}} \ell(\phi_{ijk}, \boldsymbol{\eta}, \boldsymbol{\gamma}), \tag{6}$$

where S is a mini-batch of triangles sampled uniformly at random. It is easy to verify that $\mathbb{E}_S[\mathcal{L}_S(\boldsymbol{\eta}, \boldsymbol{\gamma})] = \mathcal{L}(\boldsymbol{\eta}, \boldsymbol{\gamma})$, hence $\nabla\mathcal{L}_S(\boldsymbol{\eta}, \boldsymbol{\gamma})$ is unbiased: $\mathbb{E}_S[\nabla\mathcal{L}_S(\boldsymbol{\eta}, \boldsymbol{\gamma})] = \nabla\mathcal{L}(\boldsymbol{\eta}, \boldsymbol{\gamma})$.

In our implementation, we subsample C pairs of neighbors for each node $i \in \{1, \ldots, N\}$ in parallel, where C is a small constant[6], resulting in a mini-batch set S containing CN triangles in each SVI iteration. Such fast parallel subsampling procedure, however, may induce a bias in the estimate of the gradient because the CN triangles in S are not necessarily sampled from the space of all triangles uniformly at random. We defer the discussion of this subtlety to Section 5.1, after the detailed description of our implementation. The performance on overlapping community detection in Section 6 shows that our SVI algorithm converges to a high-quality result without having to touch all 2/3-edge triangles in the network, i.e., $CNt_{\max} \ll m$, where $t_{\max}$ is the number of iterations until convergence.

5. The total number of 2/3-edge triangles in large networks may be computationally infeasible to count—in fact, triangle counting is a hard problem in its own right and an area of active research (Low et al., 2012). In Lemma 1, we have shown that $\frac{1}{3}T \le m \le T$ where $T = \sum_i \frac{1}{2}(D_i)(D_i - 1)$. In our implementation, we simply let $m \approx T$, thus approximating m to within a factor of 3 of its true value.
6. All our experiments are conducted with the minimum value $C = 1$, which is shown to be sufficiently accurate for large-scale networks (Section 6.4).

Exact Local Update. To obtain the gradient $\nabla\mathcal{L}_S(\boldsymbol{\eta}, \boldsymbol{\gamma})$, one needs to compute the optimal local variational parameters ϕ_{ijk} (keeping $\boldsymbol{\eta}$ and $\boldsymbol{\gamma}$ fixed) for each sampled triangle (i, j, k) in the mini-batch S; these optimal ϕ_{ijk}'s are then used in Equation 6 to compute $\nabla\mathcal{L}_S(\boldsymbol{\eta}, \boldsymbol{\gamma})$. Taking partial derivatives of Equation 4 with respect to each local term ϕ_{ijk}^{xyz} and setting them to zero, we get for distinct $x, y, z \in \{1, \ldots, K\}$,

$$\phi_{ijk}^{xyz} \propto \exp\Big\{\mathbb{E}_q[\log B_{0,2}]\mathbb{I}[E_{ijk} = 4] + \mathbb{E}_q[\log(B_{0,1}/3)]\mathbb{I}[E_{ijk} \neq 4] + \mathbb{E}_q[\log\theta_{i,x} + \log\theta_{j,y} + \log\theta_{k,z}]\Big\}.$$

See Appendix A.2 for the update equations of ϕ_{ijk}^{xxx} and ϕ_{ijk}^{xxy} $(x \neq y)$.

O(K) Approximation to Local Update. As explained earlier, because there are K^3 variational parameters ϕ_{ijk}^{xyz} for each sampled triangle (i, j, k), the exact local update requires $O(K^3)$ work to solve for all ϕ_{ijk}^{xyz}, making it unscalable. We now describe an $O(K)$ approximation that is almost as accurate as the exact $O(K^3)$ update (and is certainly far more accurate than a fully factorized approximation as in the naive mean-field approach). To enable a faster local update, we replace $q_{ijk}(x, y, z \mid \phi_{ijk})$ in Equation 2 with a simpler, but still structured (as opposed to fully factorized), "mixture-of-deltas" variational distribution,

$$q_{ijk}(x, y, z \mid \delta_{ijk}) = \sum_{(a,b,c)\in\mathcal{A}} \delta_{ijk}^{abc}\, \mathbb{I}[x = a, y = b, z = c],$$

where $\mathcal{A}$ is a set containing O(K) strategically chosen triples (a, b, c), and $\sum_{(a,b,c)\in\mathcal{A}} \delta_{ijk}^{abc} = 1$. In other words, this "mixture-of-deltas" variational distribution is still a discrete probability distribution over K^3 events, but its probability mass is assumed to fall entirely on the O(K) randomly chosen entries and community combinations not in $\mathcal{A}$ are assumed to have zero probability. Conveniently, the update equations for the O(K) free parameters δ_{ijk}^{abc} are practically identical to the full $O(K^3)$ update equations for ϕ_{ijk} (Equations 9, 10 and 11 in Appendix A.2). The only difference is normalization, which is now performed over the set of O(K) δ's instead of all K^3 events. Since we subsample CN triangles in each SVI iteration, the total time complexity of local update is $O(CNK)$ per iteration.

Careful selection of the O(K) entries $(a, b, c) \in \mathcal{A}$ is critical to the performance of the O(K) "mixture-of-deltas" approximation. In our implementation, we choose these entries in $\mathcal{A}$ based on the observation that most nodes in real networks belong to just a few communities (Yang and Leskovec, 2012b), and hence the true mixed-membership vectors are also concentrated around just a few entries. In fact, more than 90% of nodes in most real-world networks studied in this paper have no more than 10 ground-truth communities. This suggests that for any triangle (i, j, k), the number of plausible assignments to its community triplet $(s_{i,jk}, s_{j,ik}, s_{k,ij})$ is usually very small compared to K^3, and we should focus our choice on triplets (a, b, c) such that the variational posteriors $q(\theta_{i,a}), q(\theta_{j,b}), q(\theta_{k,c})$ are all large. Furthermore, it is reasonable to add $O(K)$ random community combinations into consideration so as to enable the SVI algorithm to explore other communities to avoid becoming stuck in a local optimum. We employ the following procedure to construct $\mathcal{A}$:

`STM-ChooseA:`

1. Find the U_0 largest communities in each of $q(\theta_i)$, $q(\theta_j)$ and $q(\theta_k)$, and insert them into a set R_{core} ($|R_{\text{core}}| \le 3U_0$). In our experiments, we use $U_0 = 10$ because empirically most nodes have no more than 10 communities.

2. Pick U_1 communities uniformly at random from $\{1, \ldots, K\}$, and put them into a set R_{random}. In our experiments, we use $U_1 = K/10$ so that $U_1 > U_0$ for large K, thus encouraging exploration.

3. Combine both sets: $R = R_{\text{core}} \cup R_{\text{random}}$. Note that $|R| = O(K)$.

4. Generate $|R|$ diagonal community combinations $\mathcal{A}_{\text{diag}} = \{(a, a, a) \text{ for all } a \in R\}$.

5. Generate $3|R|$ off-diagonal community combinations $\mathcal{A}_{\text{off}}$. Each combination is generated as follows: first draw $a \in R$ uniformly at random, then draw $b \in R$ where $b \neq a$. Finally, draw o uniformly at random from $\{1, 2, 3\}$. If $o = 1$, add (a, a, b); if $o = 2$, add (a, b, a); and if $o = 3$, add (b, a, a).

6. Generate $3|R|$ off-off-diagonal community combinations $\mathcal{A}_{\text{offoff}}$. Each combination is generated as follows: first draw $a \in R$ uniformly at random, then draw $b \in R$ where $b \neq a$, and finally draw $c \in R$ where $c \neq a, c \neq b$. Add (a, b, c) to $\mathcal{A}_{\text{offoff}}$.

7. Combine all three sets to obtain $\mathcal{A} = \mathcal{A}_{\text{diag}} \cup \mathcal{A}_{\text{off}} \cup \mathcal{A}_{\text{offoff}}$.

Note that we do not pick all possible community combinations for $\mathcal{A}_{\text{off}}$ and $\mathcal{A}_{\text{offoff}}$, which are of size $\mathrm{O}(K^2)$ and $\mathrm{O}(K^3)$, respectively. This is an intentional trade-off; we limit the size of $\mathcal{A}$ to $\mathrm{O}(K)$ to keep the inference feasible[7]. Because we re-select $\mathcal{A}$ every time we perform the local variational update for some triangle (i, j, k), the SVI algorithm still manages to explore the most likely community combinations with reasonably high probability, thus avoiding any bias due to a single choice of $\mathcal{A}$. In practice, we find that this $\mathrm{O}(K)$ "mixture-of-deltas" approximation works nearly as well as the full parameterization in Equation 2, while requiring only $O(K)$ work per sampled triangle. Finally, we stress that the "mixture-of-deltas" variational approximation is theoretically well-justified and not a heuristic. Standard variational inference theory states that any choice of $\mathcal{A}$ yields a valid lower bound to the log marginal likelihood at the current iteration, and therefore we are always updating variational parameters to maximize some variational lower bound.

Global Update. We appeal to stochastic natural gradient ascent (Amari, 1998; Sato, 2001; Hoffman et al., 2013) to optimize the global parameters $\boldsymbol{\eta}$ and $\boldsymbol{\gamma}$, as it greatly simplifies the update rules while maintaining the same asymptotic convergence properties as classical stochastic gradient. The natural gradient $\tilde{\nabla}\mathcal{L}_S(\boldsymbol{\eta}, \boldsymbol{\gamma})$ is obtained by a premultiplication of the ordinary gradient $\nabla\mathcal{L}_S(\boldsymbol{\eta}, \boldsymbol{\gamma})$ with the inverse of the Fisher information of the variational posterior q. See Appendix A.3 for the exact forms of the natural gradients with respect to $\boldsymbol{\eta}$ and $\boldsymbol{\gamma}$. To update the parameters $\boldsymbol{\eta}$ and $\boldsymbol{\gamma}$, we apply the stochastic natural gradient ascent rule

$$\boldsymbol{\eta}_{t+1} = \boldsymbol{\eta}_t + \rho_t \tilde{\nabla}_{\boldsymbol{\eta}} \mathcal{L}_S(\boldsymbol{\eta}_t, \boldsymbol{\gamma}_t), \quad \boldsymbol{\gamma}_{t+1} = \boldsymbol{\gamma}_t + \rho_t \tilde{\nabla}_{\boldsymbol{\gamma}} \mathcal{L}_S(\boldsymbol{\eta}_t, \boldsymbol{\gamma}_t), \tag{7}$$

7. A similar variational approximation was employed in our earlier development (Yin et al., 2013). The most salient difference is that the `STM-ChooseA` uses significantly fewer variational parameters (and is therefore faster), while still maintaining high experimental accuracy. In particular, for $K \geq 1000$, the choices of $U_0 = 10$ and $U_1 = K/10$ make the SVI algorithm almost 10 times faster than the method of Yin et al. (2013).

where the step size is given by $\rho_t = \tau_0(\tau_1 + t)^{-\kappa}$. To ensure convergence, the τ_0, τ_1, κ are set such that $\sum_t \rho_t^2 < \infty$ and $\sum_t \rho_t = \infty$. The specific values used in our experiments are $\tau_0 = 50$, $\tau_1 = 10000$, and $\kappa = 0.5$. The global update only costs $O(NK)$ time per iteration due to the parsimonious $O(K)$ parameterization of the triangle-generating probability tensor $\mathbf{B}$ (and hence its variational parameter $\boldsymbol{\eta}$) in our STM (Section 3.1).

Initialization. The SVI algorithm described above searches for a local maximum in a highly non-concave variational objective function (Equation 5). In principle, this makes it sensitive to the choice of initialization or seeding, a property shared by other overlapping community detection algorithms (Xie et al., 2013). If the initialization is not too far from the true community structure, then the algorithm will usually find the correct communities. However, a completely random initialization will often merge many neighboring communities into one giant community, which is undesirable.

To address this issue, we conduct the initialization of the SVI algorithm systematically, which is highly effective on all the ground-truth networks we test on (Section 6.1). It consists of two steps. First, we renumber all node indices via the following procedure:

`STM-CANONIZE`:

1. Initialize `MAP` to an empty dictionary and `COUNT` $= 1$. When the algorithm terminates, `MAP`$[i] = a$. In other words, we have renumbered the old node index i to the new node index a.

2. For each edge (i, j) in the edge list:

   (a) If i is not in `MAP`, then assign `MAP`$[i]$ = `COUNT` and `COUNT` = `COUNT` $+ 1$.

   (b) If j is not in `MAP`, then assign `MAP`$[j]$ = `COUNT` and `COUNT` = `COUNT` $+ 1$.

3. For each edge (i, j) in the edge list:

   (a) Output the re-indexed edge (`MAP`$[i]$, `MAP`$[j]$).

This procedure requires only linear-time work in the number of edges M, and executes in less than 10 minutes for all ground-truth networks in our experiments. In addition to renumbering all nodes in the range $[1, N]$, `STM-CANONIZE` often creates many sequences of contiguous node indices $a, a+1, a+2, \ldots, a+b$ such that a is connected to $a+1, a+2, \ldots, a+b$. The rationale is that nodes with numerically close indices are more likely to be close in terms of network distance, and thus are likely to be in the same community. This happens because the input edge list is not randomly ordered in practice, but rather usually groups adjacent edges together—as an example of how this may happen, when an adjacency matrix is converted to an edge list by scanning the rows one at a time, edges connecting to same node are adjacent in the edge list. When `STM-CANONIZE` encounters adjacent edges whose nodes have not been seen before, it gives those nodes contiguous indices.

The second step takes advantage of these contiguous sequences, by initializing contiguous blocks of node indices to different communities: the first N/K nodes are seeded to community 1, the second N/K nodes are seeded to community 2, and so on. Recall that γ_i's are the variational parameters for the mixed-membership vectors θ_i's; to seed node i to

community k, we initialize $\gamma_{i,k} = 10K$ and the remaining non-seeded elements of γ_i to be small, randomly-generated numbers close to 1.

For the variational parameters $\boldsymbol{\eta}$ corresponding to the triangle-generating probabilities $\mathbf{B}$, we initialize them as follows: $[\eta_{xxx,1}, \eta_{xxx,2}] = [1, 3]$, and $[\eta_{xx,1}, \eta_{xx,2}, \eta_{xx,3}] = [2, 1, 1]$ and $[\eta_{0,1}, \eta_{0,2}] = [3, 1]$. This reflects the intuition that three nodes with the same community are likely to form a 3-edge triangle, whereas for other cases (two nodes have the same community or three nodes have distinct community), it is likely to form a 2-edge triangle. Note that there is no need to initialize the local variational parameters $q_{ijk}(x, y, z)$, as they are solved through fixed-point iteration given the current values of $\boldsymbol{\gamma}, \boldsymbol{\eta}$ (Equations 9, 10 and 11). Finally, we fix the hyperparameters of $\boldsymbol{\theta}, \mathbf{B}$ to $\alpha = \lambda = 0.1$.

5. Distributed Implementation for Internet-Scale Networks

In order to apply our SVI algorithm to massive networks, we turn to its distributed implementation. The specific challenges we are facing include:

1. Big data: given that contemporary server machines only contain between 16GB to 256GB of memory, a massive network and its triangular representation cannot fit into the memory of a single machine. For example, the 101-million-node, 2-billion-edge web graph (Section 7) requires over 30GB to simply store it as an adjacency list, and the full triangular representation would be many orders of magnitude larger (in the TB range).

2. Big model: similarly, for a massive network, the STM parameters cannot fit into the memory of a single machine. With $N = 100$ million nodes and $K = 1000$ communities, we would need 400GB just to store the mixed-membership vectors θ_i's.

3. Slow inter-machine communication: typical network speeds range from 1Gbps to 10Gbps, hence inter-machine communication is several orders of magnitude slower than CPU-to-RAM communication. This means that we cannot synchronize parameters as frequently as in the single machine setting.

Unfortunately, the existing Hadoop MapReduce framework (Hadoop, 2012) is not well-suited to implement iterative convergent algorithms such as our SVI, because every map-reduce iteration incurs significant overheads and consequently takes orders of magnitude longer than other systems (Zaharia et al., 2010; Low et al., 2010). Another concern is that the map-reduce programming model does not provide a natural way to store model parameters in a persistent and distributed fashion, a challenge which has recently been addressed by high-performance parameter servers (Li et al., 2013; Ho et al., 2013). Based on these considerations, we develop our distributed-parallel SVI algorithm for STM (Algorithm 1) on top of the Petuum parameter server (Ho et al., 2013; Lee et al., 2014; Dai et al., 2015), a recent framework for general-purpose machine learning on big data and models. The high-level ideas to tackle challenges outlined above are to (1) keep the triangles in an implicit representation and use disk-based access to save machine memory; (2) partition the model over worker machines and exploit parameter sparsity to further reduce memory usage; (3) use a bounded-asynchronous communication technique to strike a balance between parameter accuracy and speed. We now discuss detailed approaches to each idea.

Algorithm 1 Distributed-parallel Stochastic Variational Inference for STM

1: $t = 0$. Initialize the global parameters $\boldsymbol{\eta}$ and $\boldsymbol{\gamma}$, and store them in the Petuum parameter server (`www.petuum.org`) for global access by any worker thread in the cluster.
2: Repeat the following steps in parallel until convergence. Parallelization is conducted in a data-parallel fashion: each worker thread in the cluster is responsible for a disjoint set of nodes, and all N nodes are collectively covered by all workers.
   (1) Sample CN triangles to form a mini-batch S. We do this by sampling C pairs of neighbors for each node $i \in \{1, \ldots, N\}$ in parallel (see Section 5.1 for details of implementation).
   (2) Optimize the local parameters $q_{ijk}(x, y, z)$ for all sampled triangles in parallel by Equations 9, 10 and 11.
   (3) Accumulate sufficient statistics for the natural gradients of $\boldsymbol{\eta}, \boldsymbol{\gamma}$, and then discard local parameters $q_{ijk}(x, y, z)$ and the mini-batch S. Since the sufficient statistics are additive, we use the Petuum parameter server to accumulate them in parallel at each worker thread.
   (4) Optimize the global parameters $\boldsymbol{\eta}$ and $\boldsymbol{\gamma}$ by the stochastic natural gradient ascent rule (Equations 7), and then distribute the new global parameters to the worker threads.
   (5) Update the step size for the next iteration: $\rho_t \leftarrow \tau_0(\tau_1 + t)^{-\kappa}$, $t \leftarrow t + 1$.

5.1 Handling Big Network Data and Trillions of Triangles

As shown in Lemma 1, the number of 2/3-edge triangles is bounded below by $\frac{1}{3}\sum_i \frac{1}{2}(D_i)(D_i - 1)$. This means even a single node with 1 million neighbors, which can occur in very large networks ($N \geq 100$ million nodes and $M \geq 1$ billion edges) with a power-law degree distribution, will contribute half a trillion triangles to the triangular representation and hence require TBs of storage.

Implicit Triangle Representation and Disk-based Storage. Our solution is to keep the triangles in an *implicit* representation, where we leverage the stochastic nature of the SVI algorithm and only sample triangles only when they are needed in step (1) of Algorithm 1 (and discard them afterwards). Specifically, we represent the original network using the following three data structures:

1. An adjacency list `Adj` represented as a dictionary (key-value) data structure. If the a-th neighbor of i is j, then the dictionary contains $\texttt{Adj}[(i, a)] = j$. While this key-value schema seems unorthodox compared to storing the entire neighbor set $\mathcal{N}_i$ as the value, they are easier to store at large scale and possibly can help improve CPU cache efficiency because values j are fixed-byte-size scalars whereas sets of neighbors $\mathcal{N}_i$ can have arbitrary byte length.

2. An edge list `Edg` represented as a set of edge tuples (i, j).

3. A degree list `Deg` represented as a vector, where $\texttt{Deg}[i]$ contains the degree of node i.

In order to conserve machine memory, we store these data structures in a disk-based key-value store—our implementation uses Google leveldb (`www.leveldb.org`), but any other disk database should work as well. Although storing the data on hard disks incurs significant read latencies in principle (around 10 milliseconds per read), we have observed that leveldb's memory cache amortizes latencies across multiple reads very well, and therefore disk-based access is not a bottleneck for our implementation of the SVI algorithm. In our large-scale experiments, leveldb could sustain 100s of thousands of reads per second per machine

(using multiple worker threads) on a standard hard drive. This throughput is more than sufficient for the SVI algorithm for STM. The use of disk-based storage frees up roughly 40GB of memory on each machine, when we run our implementation of the SVI algorithm on the 101-million-node web graph. Note that converting an edge list of a network with M edges to these disk-based data structures only costs $\mathrm{O}(M)$ (for hash-based dictionaries) or $\mathrm{O}(M \log M)$ (for tree-based dictionaries) work, and in practice this step takes only a small fraction of the time required by the SVI algorithm.

Subsampling CN Triangles from the Implicit Representation. We employ the following procedure to subsample a mini-batch S of CN triangles (step (1) in Algorithm 1), based on the aforementioned disk-based data structures.

`STM-SUBSAMPLE`:

- **For each node $i = 1$ to N in parallel:**
  - **For $c = 1$ to C:**
    1. Let $D_i := \texttt{Deg}[i]$.
    2. Draw two *distinct* indices $a, b \in \{1, \ldots, D_i\}$ uniformly at random.
    3. Let $j := \texttt{Adj}[(i, a)]$ and $k := \texttt{Adj}[(i, b)]$.
    4. Check if $(i, j) \in \texttt{Edg}$. If yes, output (i, j, k) as a 3-edge triangle. If no, output (i, j, k) as a 2-edge triangle centered at node i.

Because there is no need to keep all local variational parameters after accumulating all natural gradient sufficient statistics for the global parameters $\boldsymbol{\eta}, \boldsymbol{\gamma}$, we discard the mini-batch S after step (3) of Algorithm 1 in order to save memory. By combining implicit triangle representation and subsampling strategy in this manner, our SVI algorithm for STM avoids having to store trillions of triangles in an explicit form, thus saving TBs (or more) of disk storage and memory space.

Discussion of Subsampling Strategy. Our fast parallel procedure to subsample a mini-batch S of CN triangles may not provide an unbiased estimate of the natural gradient of the global parameters $\tilde{\nabla}\mathcal{L}_S(\boldsymbol{\eta}, \boldsymbol{\gamma})$ (Equation 6). The reason is that the CN triangles in S are not necessarily sampled from the space of all triangles uniformly at random—one can see that triangles adjacent to low-degree nodes tend to be more likely to be sampled than triangles attached to high-degree nodes. However, it is worth emphasizing that since low-degree neighbors of a high-degree node are very likely to sample triangles involving that high-degree node, the high-degree nodes are still well represented in the set of subsampled triangles. While this bias due to nonuniform sampling can be corrected by appropriately reweighting the subsampled triangles[8], we have counterintuitively observed that community detection performance is actually *more accurate* without the correction factor. Our hypothesis is that, by not reweighting the triangles, low-degree nodes are given more attention because our subsampling procedure is more likely to select their adjacent triangles, compared to uniform triangle sampling. This improves community detection accuracy on low-degree

8. One reweighting scheme is to divide each triangle's natural gradient contribution by its actual probability of being sampled. Similar techniques were employed to reweight the subsampled node pairs in the assortative MMSB inference algorithm (Gopalan et al., 2012; Gopalan and Blei, 2013).

nodes, which in turn improves overall accuracy because the majority of nodes in real-world scale-free networks are low-degree. For this reason, we choose to not reweight the triangles in our experiments.

Earlier development on triangular modeling (Ho et al., 2012c; Yin et al., 2013) advocated a triangle pre-selection technique called δ-subsampling, where a proper subset of all triangles is subsampled *prior to* inference. Our distributed-parallel SVI algorithm for STM differs in that we *never* pre-select triangles, allowing the inference algorithm to (in principle) access all triangles—thus eliminating one source of approximation. It also avoids the need to tune the parameter δ, the number of triangles to pre-select. From a practical standpoint, our new subsampling strategy is far more memory-efficient, as triangles are immediately discarded after use.

5.2 Handling Big STM Models with Over 100 Billion Parameters

At first estimation, the variational parameters γ_i's for all the mixed-membership vectors θ_i's require NK floating point values to be stored. If $N = 100$ million and $K = 1000$, we would need 100 billion 4-byte floating point values (400GB)[9]. Although the Petuum parameter server discussed in the next subsection can evenly distribute the memory load over all participating machines, it requires additional memory to cache for high performance because the parameter server is a caching system. Thus, the actual memory requirement of SVI algorithm for STM is much more than $NK \times 4$ bytes—we have observed that 400GB of γ_i's would require multiple TBs of memory across all machines.

To reduce memory usage to practical levels, we exploit the observation that most nodes in real networks belong to just a few communities, as seen in ground-truth data (Yang and Leskovec, 2012b). In other words, the mixed-membership vectors θ_i's and the corresponding variational parameters γ_i's are extremely sparse. Therefore, we use dictionary data structures to store γ_i's, and perform two approximations at every iteration of the SVI algorithm in order to reduce the memory requirement:

1. We delete elements of γ_i's that are already close to zero—defined as being less than $2\alpha = 0.2$ in the ground-truth experiments (Section 6). See Section 7.1 for an alternative threshold value used for a 101-million-node web graph.

2. During the global update for each γ_i (Equation 7), we only commit the U_0 largest vector elements in the natural gradient of γ_i and set the rest of elements to be zeros. We use $U_0 = 10$ in our experiments, because empirically most nodes exhibit no more than 10 communities and thus it suffices to retain the 10 most significant communities per node.

When the SVI algorithm terminates, we also output γ_i's in a sparse format in order to conserve hard disk space. Experimentally, we have observed that these approximations incur little impact on community detection accuracy, and they allow us to analyze a 101-million-node network with 1000 communities, using only 500GB of memory spread across 5 machines (i.e., 100GB per machine, which is readily available from cloud compute providers such as Amazon EC2).

9. Note that there are only $O(K)$ variational parameters $\boldsymbol{\eta}$ for the triangle-generating probability tensor $\mathbf{B}$, which is extremely small compared to the size of γ_i's.

5.3 Overcoming Slow Network Interfaces

Our distributed-parallel SVI algorithm for STM (Algorithm 1) adopts a data-parallel scheme: each worker thread in the cluster is responsible for a disjoint set of nodes and all N nodes are collectively covered by all workers, in order to update a single set of shared global parameters γ and η. This requires workers to frequently synchronize all parameter updates to each other. However, due to the higher latency and lower bandwidth of computer network interfaces (e.g., 1Gb or 10Gb Ethernet) compared to internal CPU-to-RAM communication, the workers are often forced to wait for communication to complete, thus wasting as much as $\geq 80\%$ of CPU power (Ho et al., 2013).

In order to alleviate this communication bottleneck, various bounded-asynchronous parameter synchronization systems have been developed (Ho et al., 2013; Li et al., 2013; Dai et al., 2015), which essentially reduce the frequency of communication so as to allow for much higher CPU utilization. The trade-off is that reduced communication leads to *staleness* (i.e., out-of-date values) in the workers' view of the model parameters, which could incur errors in algorithm execution. By using the right "consistency models", most iterative optimization and sampling-based algorithms can be made to theoretically and empirically converge despite staleness. Furthermore, while having stale values of the model parameters could decrease convergence progress per iteration, the increase in CPU utilization more than makes up by enabling more iterations per minute, thus yielding much faster distributed machine learning algorithm execution.

These considerations apply to our SVI algorithm for STM as well, because the global variational parameters γ and η are subject to frequent additive updates from all workers (Equation 7) due to the relatively small mini-batch sizes being used (CN triangles per iteration with $C = 1$ in our experiments). To overcome these challenges, we develop our C++ implementation of the SVI algorithm on top of the Petuum system for scalable distributed machine learning (Ho et al., 2013; Lee et al., 2014; Dai et al., 2015), using its bounded-asynchronous parameter server for data-parallel machine learning programming. Petuum features an machine-learning-specific "consistency model", Stale Synchronous Parallel (SSP), that exploits the concept of *bounded staleness* to speed up distributed computation while still providing theoretical guarantees on the convergence of various machine learning algorithms (e.g., stochastic gradient descent). More formally, a worker reading parameters at iteration c will see the effects of all updates from iteration 0 to $c - s - 1$, where $s \geq 0$ is a user-controlled staleness threshold. In our experiments, we found that configuring the SSP staleness setting to either $s = 0$ or $s = 1$ yielded very good, near-linear scaling from 1 through 5 machines (note that 5 machines are sufficient for performing community detection on a 101-million-node network).

6. Empirical Study on Networks with Ground-truth Communities

In this section, we evaluate the overlapping community detection performance of the SVI algorithm for STM, comparing it to both probabilistic and non-probabilistic baseline algorithms. It is also possible to use our algorithm to perform link prediction, although we do not pursue it in this paper. See Yin et al. (2013) for an appropriate procedure.

Network	# nodes N	# edges M	# communities	Edge density M/N^2	Fraction of closed triangles
DBLP	317,080	1,049,866	13,477	1.044×10^{-5}	0.1283

Youtube	1,134,890	2,987,624	8,385	2.320×10^{-6}	0.002081
Livejournal	3,997,962	34,681,189	287,512	2.170×10^{-6}	0.04559

Table 3: Basic statistics of the networks with ground-truth overlapping communities used in our evaluation. These networks are available at `http://snap.stanford.edu/data/`.

6.1 Ground-truth Data

Because there has been debate over the appropriateness of simulated networks in the community detection task (Leskovec et al., 2009; Yang and Leskovec, 2012b), we performed all our experiments on real-world networks with ground-truth communities provided by Yang and Leskovec (2012b), rather than using synthetic benchmarks such as Lancichinetti-Fortunato-Radicchi (LFR) (Lancichinetti and Fortunato, 2009). The ground-truth communities were constructed based on the publicly available meta-data associated with each network (e.g., self-declared interests, hobbies, and affiliations in social networks such as LiveJournal). The size of these networks ranges from $N \approx 300000$ to 65 million, and the number of created communities ranges from $K \approx 8000$ in a 1.1-million-node network to $K \approx 6.3$ million in a 3-million-node network. However, not all of the communities were well-defined. Thus, Yang and Leskovec (2012b) also provided the top 5000 communities with highest quality in each network, where the quality of a community is measured by averaging over several well-known community scoring functions such as conductance, modularity, and triangle-participation-ratio—the idea being that communities that score well on all functions are very likely to be of high quality. We do not claim these ground-truth communities are the only valid way to decompose the network, and acknowledge that there may exist alternative ways to extract plausible communities from large networks.

Table 3 provides basic statistics that are taken from the original directed form of each network in this evaluation. When our algorithm loaded a network, it converted the network to its undirected form via symmetrization because our STM is a probabilistic network model for undirected triangular motifs. When running those baselines that are able to to exploit directed form, we always provided the original directed network as input.

6.2 Evaluation by Normalized Mutual Information (NMI)

We used the normalized mutual information (NMI) (Lancichinetti and Fortunato, 2009), one of the most widely used measures, for evaluating the quality of discovered overlapping communities. The NMI is on a scale of 0 to 1, with 1 corresponding to a perfect matching with the ground-truth communities. In these ground-truth networks, the top 5000 communities were provided by Yang and Leskovec (2012b) as *hard assignments* of nodes: for a particular community, each node is either in that community or it is not (i.e., no partial membership). Two issues must be addressed before the outputs of different algorithms can be evaluated against the ground truth.

First, because the SVI algorithm for STM outputs the variational parameters γ_i's that are then normalized to produce continuous-valued mixed-membership vectors to represent soft community assignments, we must threshold to obtain hard community assignments

that can be compared to the ground truth. Based on the observation that more than 90% of nodes have no more than 10 ground-truth communities, we chose the threshold value to be 0.1, i.e., community k contains node i if $\hat{\theta}_{i,k} = \gamma_{i,k} / \sum_{k'} \gamma_{i,k'} \geq 0.1$. This allows us to detect up to 10 communities per node. We also applied this thresholding procedure to any baselines that output soft community assignments; baselines that output hard assignments were left as it is.

The second issue is that the top 5000 ground-truth communities only cover a small fraction of the network—in other words, the majority of nodes have missing ground-truth community assignments. However, all the algorithms being evaluated assign every node to at least one community, and the NMI cannot handle missing community assignments. Thus, for every node i without a ground-truth assignment in the top 5000 communities, we removed node i from its corresponding communities discovered by each algorithm. This ensures that the NMI is computed only on nodes found within the top 5000 ground-truth communities. We emphasize that such post-processing is fair because it is performed for all the algorithms being evaluated.

6.3 Experimental Settings

Termination Criterion. We monitored the convergence of the SVI algorithm by computing the variational mini-batch lower bound $\mathcal{L}_S(\boldsymbol{\eta}, \boldsymbol{\gamma})$ (Equation 6) at each iteration, which serves as an unbiased approximation to the true variational lower bound $\mathcal{L}(\boldsymbol{\eta}, \boldsymbol{\gamma})$ (Equation 5). We never compute the true lower bound as it involves all triangles in the network, which would be computationally prohibitive. In our ground-truth experiments, we terminated the algorithm when $\mathcal{L}_S(\boldsymbol{\eta}, \boldsymbol{\gamma})$ decreases for the first time. This signifies that the SVI algorithm is beginning to oscillate, and will not make much further progress. All our trials on ground-truth networks terminated with high-quality results within 200 iterations under this criterion (using $C = 1$ triangle subsampled for each node, per iteration); in other words, the SVI algorithm only had to process $< 200N$ triangles in total. The intuition is that node community memberships are empirically sparse—each node is unlikely to participate in more than a few communities, and thus a small number of subsampled adjacent triangles suffices to determine its community membership.

Baselines. For comparison with the SVI algorithm for STM, we selected baselines that (1) are able to perform overlapping community detection and (2) are scalable enough to analyze 1-million-node networks in at most a few days. These two criteria greatly narrow the list of candidate baselines, and eventually we considered the following four algorithms:

1. `a-MMSB`: the assortative MMSB (Gopalan et al., 2012; Gopalan and Blei, 2013), which requires the number of communities K to be input as a parameter. We used the single-machine C code available at `https://github.com/premgopalan/svinet`, and applied the "link-sampling" subsampling scheme, as recommended by the user manual.

2. `PM`: the Poisson model (Ball et al., 2011), which requires the number of communities K to be input as a parameter. We used the single-machine C code provided by the authors.

3. `SLPA`: the speaker-listener label propagation algorithm (SLPA) (Xie and Szymanski, 2012), which can automatically detect the number of communities in the network, given a threshold $r \in [0, 1]$. We found that the NMI score did not vary significantly with different choices of r, so we fixed $r = 0.25$ in all experiments. The single-machine Java code is available at `https://sites.google.com/site/communitydetectionslpa/ganxis` under the name GANXiS.

4. `SVD+M`: a baseline that first applies a rank-K SVD to the adjacency matrix and then extracts communities from the singular vectors using modularity as a stopping criterion, as proposed in Prakash et al. (2010) and Kang et al. (2011). As code was unavailable from the authors, we wrote our own single-machine MATLAB implementation, based on the multi-threaded `svds()` sparse low-rank SVD function.

Both a-MMSB and PM are mixed-membership models based on adjacency matrix representation of networks; SLPA is a message-passing algorithm, in which community labels are propagated along edges until convergence; SVD+M is a matrix factorization algorithm. We ran all algorithms with their default settings, unless otherwise stated. For algorithms that require the number of communities K as input (including our SVI algorithm for STM), we repeated the experiments for different values of K: 5000, 10000, 15000 and 20000.

Machine Configuration. We used server machines equipped with 128GB RAM and 2 Intel Xeon E5-2450 8-core processors, for a total of 16 CPU cores per machine running at 2.10GHz. We ran the distributed-parallel SVI algorithm using 4 such machines, for a total of 64 cores/worker threads and 512GB distributed RAM. The baselines a-MMSB, PM, and SLPA are all single-machine and single-threaded, while SVD+M is single-machine but multithreaded; we ran all algorithms using one machine with 128GB RAM.

6.4 Experimental Results

We first investigate how the mini-batch size CN influences the performance of the SVI algorithm for STM. Then we compare it to various baseline algorithms in terms of NMI score, runtime, and size of detected communities.

Why Choose $C = 1$? Table 4 shows NMI scores and time to convergence for running the SVI algorithm with $C = 1$ v.s. $C = 10$ on three networks. Note that using $C = 1$ is 5-10 times faster than $C = 10$, while maintaining comparable NMI scores. Accordingly, we set the mini-batch size to $C = 1$ triangle per node, resulting in a total of N triangles per iteration.

NMI Score and Runtime. Table 5 shows NMI scores and runtimes for all the algorithms being evaluated. Performing overlapping community detection at these large scales is extremely computationally intensive, and our distributed-parallel SVI algorithm for STM finished execution in far less time than the baselines. None of the baseline algorithms were able to finish the 4-million-node, 35-million-edge Livejournal network within our experimental limit of 5 days, and the SVD+M algorithm was not able to finish any experiment within this limit[10]. Given a larger compute cluster, we expect our approach to finish more rapidly,

10. The main reason is that high-rank SVD is expensive to compute in MATLAB. The call to `svds()` alone took 4 days to complete on the smallest DBLP network ($N = 317$K) for just $K = 5000$, despite being a multithreaded implementation. Furthermore, `svds()` simply ran out of memory on larger experiments, despite equipped with 128GB RAM.

	NMI		Time to convergence	
Network	$C = 1$	$C = 10$	$C = 1$	$C = 10$
DBLP ($N = 317$K)				
$K = 5000$	0.439	0.451	15min	2.8h
$K = 10000$	0.506	0.505	18min	1.5h
$K = 15000$	0.542	0.535	26min	2.1h
$K = 20000$	0.559	0.553	30min	3.1h
Amazon ($N = 334$K)				
$K = 5000$	0.790	0.791	38min	3.4h
$K = 10000$	0.758	0.771	18min	1.4h
$K = 15000$	0.743	0.752	24min	2.2h
$K = 20000$	0.733	0.739	31min	3.2h
Youtube ($N = 1.1$M)				
$K = 20000$	0.433	0.434	7.6h	93h

Table 4: NMI scores and time to convergence for running the SVI algorithm for STM with $C = 1$ v.s. $C = 10$ on three networks. Using $C = 1$ is nearly as accurate as $C = 10$, while requiring much less computational time.

allowing even larger networks to be analyzed in a matter of hours. The STM SVI algorithm is also memory-efficient, due to sparse data structures in the Petuum parameter server used for sharing the global variational parameters γ_i's. In particular, the largest experiment on the Livejournal network with $K = 20000$ only required 24GB RAM on each of the 4 machines (for a total of 96GB). The a-MMSB inference algorithm implementation does not use sparse storage, which caused it to run out of memory on relatively small experiments, even on a machine with 128GB RAM. We believe this underscores the importance of sparse memory management for large-scale problems (Section 5.2).

In terms of accuracy of recovering ground-truth overlapping communities, the STM SVI algorithm outperformed other mixed-membership models a-MMSB and PM, but had lower NMI scores than SLPA (a message-passing algorithm that is not based on a statistical model). This suggests that mixed-membership network models have some room for improvement. However, there are still two advantages of the STM SVI algorithm compared to SLPA: (1) the STM SVI algorithm finishes execution in far less time on a distributed compute cluster, allowing it to scale to much larger networks; (2) SLPA only outputs hard, binary community assignments, so it may not be suitable for analyses that require soft, probabilistic assignments, which the STM SVI algorithm can provide.

Though faster execution of our STM SVI algorithm hinges on the distributed implementation, we would like to point out that even on smaller networks (N ranges from 10000 to 200000) in the absence of distributed computing, our earlier development (Ho et al., 2012c; Yin et al., 2013) has demonstrated the benefits of triangular modeling over adjacency-matrix-based modeling in terms of scalability and accuracy. The single-machine SVI algorithm on these smaller networks usually converges after several passes on all triangles in the network (4-5 passes at most), and achieves competitive or improved accuracy for latent space recovery and link prediction compared to MMSB (Yin et al., 2013). This is compatible with our observation that, in the distributed setting, at most $200N$ triangles needed to be subsampled and processed to achieve the indicated NMI scores in Table 5.

	NMI					Time to completion				
Network	STM SVI	a-MMSB	PM	SLPA	SVD+M	STM SVI	a-MMSB	PM	SLPA	SVD+M
DBLP ($N = 317$K)										
$K = 5000$	0.439	0.379	0.251	0.581	DNF	15min	17.4h	8.9h	2.6h	> 5 days
$K = 10000$	0.506	0.437	0.294	(16874 coms)	DNF	18min	48h	18h		> 5 days
$K = 15000$	0.542	OOM	0.322		OOM	26min	OOM	51h		OOM
$K = 20000$	0.559	OOM	0.341		OOM	30min	OOM	96h		OOM
Amazon ($N = 335$K)										
$K = 5000$	0.790	0.750	0.483	0.867	DNF	38min	31h	4.4h	3.2h	> 5 days
$K = 10000$	0.758	OOM	0.548	(29021 coms)	DNF	18min	OOM	11h		> 5 days
$K = 15000$	0.743	OOM	0.571		OOM	24min	OOM	22h		OOM
$K = 20000$	0.733	OOM	0.576		OOM	31min	OOM	31h		OOM
Youtube ($N = 1.1$M)										
$K = 5000$	0.374	OOM	0.129	0.424	OOM	2.2h	OOM	76h	21h	OOM
$K = 10000$	0.422	OOM	DNF	(5972 coms)	OOM	3.2h	OOM	> 5 days		OOM
$K = 15000$	0.456	OOM	DNF		OOM	3.9h	OOM	> 5 days		OOM
$K = 20000$	0.433	OOM	DNF		OOM	7.6h	OOM	> 5 days		OOM
Livejournal ($N = 4.0$M)										
$K = 20000$	0.743	OOM	DNF	DNF	OOM	63h	OOM	> 5 days	> 5 days	OOM

Table 5: NMI scores and runtimes for all the algorithms being evaluated. "OOM" means the algorithm ran out of memory and failed, while "DNF" means the algorithm did not finish within a reasonable amount of time (5 days of continuous computation). Note that the SLPA algorithm can automatically select the number of communities K, thus we report only one NMI score and runtime per network (with the number of detected communities in parentheses).

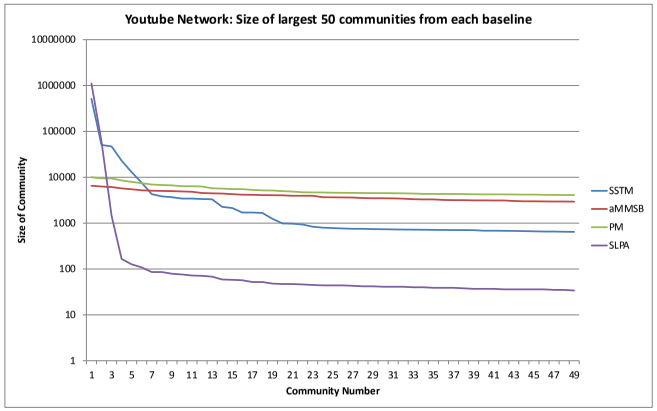

Figure 5: Youtube network: size of the largest 50 detected communities by STM SVI, a-MMSB, PM, and SLPA, plotted on a logarithmic scale.

Size of Detected Communities. Figure 5 plots the size of the largest 50 detected communities in the Youtube network by STM SVI, a-MMSB, PM, and SLPA, on a logarithmic scale. For algorithms that require the number of communities K as input, we set $K = 1000$. It was necessary for us to use the Youtube network with $K = 1000$ communities, in order to obtain a plot of community size for a-MMSB; otherwise, it ran out of memory (see Table 5). We observed that STM SVI and SLPA were able to detect several very large communities containing over 50K nodes, whereas a-MMSB and PM could not recover communities with more than 10K nodes. Furthermore, the vast majority of communities detected by STM SVI and SLPA are much smaller than the ones discovered by a-MMSB and PM. In other words, the distributions of STM SVI and SLPA community size are far more skewed (power-law-like) than a-MMSB's and PM's. We hypothesize that the better NMI performance of STM SVI and SLPA is partly due to their ability to detect very large and very small communities, which are present in real-world networks with power-law behavior (Leskovec et al., 2009). We also conjecture that because larger communities in real-world networks are likely to be edge-sparse, with intra-community edge probability p not much larger than the inter-community edge probability q (Leskovec et al., 2009), it would be theoretically difficult for models such as a-MMSB to detect these large communities (Anandkumar et al., 2014).

7. Empirical Study on a 101-million-node Web Graph

Our SVI algorithm for STM is intended for latent space inference in very large, Internet-scale networks. In that vein, we conclude with a brief analysis of the 101-million-node, 2-billion-edge Subdomain/Host web graph, from the Web Data Commons (available at `http://webdatacommons.org/hyperlinkgraph/`). This web graph was constructed from the Common Crawl 2012 web corpus, which originally contained 3.5 billion web pages and 128

billion hyperlinks. The 3.5 billion web pages were aggregated by their subdomain[11] or host, resulting in a new graph with 101 million nodes/subdomains. An edge was created between two subdomains if at least one hyperlink was found between their aggregated pages, resulting in 2 billion directed edges. When we ran our algorithm, it was treated as an undirected, unweighted network via symmetrization.

Our primary aim is to demonstrate that the our distributed-parallel SVI algorithm for STM finished execution on this massive web graph in an acceptable amount of time on a small cluster—37.3 hours using $K = 1000$ overlapping communities. This scale is 25 times larger than a recent experiment by Gopalan and Blei (2013), who ran the a-MMSB inference algorithm on an $N \approx 4$M patent network using $K = 1000$. We also performed light qualitative analysis to show that the discovered mixed-membership vectors $\hat{\theta}_i$'s reveal sensible insights about the structure of the web graph.

7.1 Experimental Settings

We used the experimental settings that were mostly similar to the experiments on ground-truth networks, with the following exceptions:

Number of Machines. We used 5 machines with 16 CPU cores and 128GB RAM per machine, configured identically to the 4 machines used in the ground-truth experiments. The extra machine was required because the algorithm ran out of memory on 4 machines.

Termination Criterion. On such a large network, the SVI algorithm may take a long time before the variational mini-batch lower bound starts oscillating, which is the termination criterion used in the ground-truth experiments. For this web graph, we observed that by iteration $t = 50$, the lower bound was only changing at the 5th significant figure (relative to the first few iterations). We thus concluded that the algorithm was no longer making significant progress, and stopped the algorithm at $t = 50$ iterations.

Threshold of γ_i's to Maintain Sparsity. As explained in Section 5.2, this massive web graph requires 100 billion floating point values for the variational parameters γ_i's, which is estimated at TBs of memory if stored densely (after accounting for algorithmic overheads). In order to keep the γ_i's sparse enough to fit on 5 machines with 640GB total RAM, we zeroed out any element $\gamma_{i,k} < 10$ at the end of every iteration. Though this is more aggressive than the threshold $2\alpha = 0.2$ used in the ground-truth experiments, it has little impact on the detected communities because of the way we obtain the final hard community assignments based on the inferred $\hat{\theta}_i$'s (Section 6.2). When the SVI algorithm terminated, the vast majority of nodes i had an unnormalized "total variational mass" $\sum_k \gamma_{i,k} > 100$. Thus, any zeroed-out element $\gamma_{i,k}$ would have been normalized to $\hat{\theta}_{i,k} = \gamma_{i,k}/(\sum_{k'} \gamma_{i,k'}) < 0.1$, which is below the threshold of being detected as part of community k.

7.2 Qualitative Analysis

To decide the size of detected communities, we treated the mixed-membership vectors $\hat{\theta}_{i,k}$ as an $N \times K$ continuous-valued matrix. The column sum of the kth column accounts for

11. A subdomain is an Internet host name with 3 or more levels. For example, `www.cmu.edu` and `www.ml.cmu.edu` are considered to be two distinct subdomains.

all partial memberships in community k, and thus is regarded as the effective number of nodes in that community.

To identify significant nodes associated with each community k, we computed a score $s_k(i) = \hat{\theta}_{i,k} \times D_i$ for each node i—its partial membership in community k multiplied by its node degree—and then sorted $s_k(1), \ldots, s_k(N)$ in descending order. Table 6 shows the top-scoring 10 nodes from each of the largest 5 communities, as well as the estimated fraction of 3-edge triangles in each community (i.e., the parameter $B_{kkk,2}$ in Table 2). The largest community is a giant core dominated by well-known websites including youtube.com, google.com, and twitter.com, with a much lower fraction of 3-edge triangles (0.062) than the other communities. The 2nd to 5th largest communities are:

- Community 2: mostly "online stores" that focus on specific products (kitchenware, phones, or cars). However, these are not real online stores as the entries all link to eBay auction pages. The community memberships $\hat{\theta}_{i,k}$ of the top 10 nodes are all perfect (1.0), which suggests that these sites (1) form a compact community with few outside links and (2) are probably copies of each other. It is likely that these sites are meant to increase the visibility of certain eBay auctions—essentially, a form of search engine optimization (SEO). It is unclear whether the auctions themselves are fraudulent or not.

- Community 3: dominated by webpages from Lycos/Tripod, two related companies in the search and website creation business. It also contains w3schools.com, a site that provides instructions for website creation. The top websites in this community do not appear suspicious.

- Community 4: Spanish-language websites, particularly Hispavista, an Internet firm based in Spain. The top websites in this community do not appear suspicious.

- Community 5: dominated by blackmagic.org/com, a website that maintains a large list of websites crawled from the Internet in 2006. It is likely that blackmagic.org/com acts as a hub for the other nodes in the community, which all have much smaller scores $s_k(i)$. The extremely high fraction of 3-edge triangles (0.985) suggests that this community is close to a full clique, or perhaps several cliques connected by one or two bridge nodes. Previous works have shown that such clique-like patterns in web graphs are highly indicative of web duplication or fraud (Kang et al., 2009, 2011); a cursory look at the websites in this community (such as the skimium.* nodes) reveals that many of them are near-exact copies of each other.

We also explored significant nodes that are in 2 or more communities in this web graph (recall that a node i is assigned to community k if $\hat{\theta}_{i,k} \geq 0.1$). Of these 700K websites, the one with the highest node degree, wordpress.org, has a partial membership 0.89 in the giant core and 0.11 in the 25th largest community. By examining the top websites in the 25th largest community, we found several domains of hostgator.com, a website hosting business. Further inspection revealed that the wordpress forums frequently recommend hostgator.com to host wordpress-powered blogs, and similarly, the hostgator support pages explain how to set up a wordpress blog on hostgator itself.

Table 6: Subdomain/Host web graph: the 10 top-scoring nodes in each of the largest 5 communities by mass (the effective number of nodes in the community). The score $s_k(i)$ is computed as $\hat{\theta}_{i,k} \times D_i$, i.e., the partial membership of node i in community k multiplied by its node degree. For each community, we also report the estimated fraction of 3-edge triangles. A quick look at the top websites in communities 2 and 5 reveals suspicious behavior (see main text for details).

8. Conclusion and Discussion

Massive Internet-scale networks are technically challenging to explore, manipulate, and visualize. One approach to understanding the structural and functional properties of massive networks is to perform latent space inference for overlapping community detection. At the time of writing, there are few inference algorithms that can scale to hundreds of millions of nodes in order to detect thousands of distinct communities, and almost none of them are based on a probabilistic model.

In this work, starting with the mixed-membership class of statistical models as a foundation, we systematically tackle the statistical and computational challenges associated with Internet-scale network inference. Our major contributions include: (1) characterization of the network as a more compact—and arguably more salient for community detection—triangular representation; (2) design of a parsimonious generative model with only $O(K)$ instead of K^2 or K^3 parameters; (3) construction of an efficient structured stochastic variational inference algorithm; (4) a careful consideration of the distributed implementation in order to handle big network data, big network model, and slow inter-machine communication. The resulting distributed-parallel STM SVI algorithm is able to detect 1000 communities from a 100-million-node network in 1.5 days on just 5 cluster machines, and we believe that networks with $N > 1$ billion nodes can be analyzed with a sufficiently large cluster, thus opening the door to Facebook-scale social networks and beyond.

We would like to end with some directions and open issues for future research. One limitation of STM is that it only applies to undirected and unweighted networks (and triangular motifs), although we have demonstrated good community detection NMI scores relative to baselines. We believe that accounting for edge direction and weights could further improve accuracy, which are more common in non-social-network domains such as biology and finance. Sensitivity to initialization is another issue that we would like to address: while the `STM-CANONIZE` procedure worked well in our experiments, we believe that there are more systematic ways to address the issue, such as augmenting the variational inference algorithm with split-merge-like search moves that can change many node community assignments at once. Finally, we believe that triangular modeling could also be extended to other probabilistic network model for overlapping community detection, such as the Community-Affiliation Graph Model (AGM) by Yang and Leskovec (2012a).

Appendix A. Details of Stochastic Variational Inference

In this section, we provide details of our SVI algorithm, including the exact form the variational lower bound, the exact and approximate local update equations, and the natural gradients with respect to the global parameters.

A.1 Exact Form of the Variational Lower Bound

The variational lower bound (Equation 3) of the log marginal likelihood of the triangular motifs based on the variational distribution (Equation 1) is

$$\log p(\mathbf{E} \mid \alpha, \lambda) \geq \mathbb{E}_q[\log p(\mathbf{E}, \mathbf{s}, \boldsymbol{\theta}, \mathbf{B} \mid \alpha, \lambda)] - \mathbb{E}_q[\log q(\mathbf{s}, \boldsymbol{\theta}, \mathbf{B})] \doteq \mathcal{L}(\boldsymbol{\phi}, \boldsymbol{\eta}, \boldsymbol{\gamma}) \tag{8}$$

$$\begin{aligned}
&= \mathbb{E}_q[\log p(B_0 \mid \lambda)] - E_q[\log q(B_0 \mid \eta_0)] + \sum_{x=1}^{K} \Big\{ \mathbb{E}_q[\log p(B_{xx} \mid \lambda)] - \mathbb{E}_q[\log q(B_{xx} \mid \eta_{xx})] \Big\} \\
&+ \sum_{x=1}^{K} \Big\{ \mathbb{E}_q[\log p(B_{xxx} \mid \lambda)] - \mathbb{E}_q[\log q(B_{xxx} \mid \eta_{xxx})] \Big\} + \sum_{i=1}^{N} \Big\{ \mathbb{E}_q[\log p(\theta_i \mid \alpha)] - \mathbb{E}_q[\log q(\theta_i \mid \gamma_i)] \Big\} \\
&+ \sum_{(i,j,k) \in I} \Big\{ \mathbb{E}_q[\log p(s_{i,jk} \mid \theta_i) + \log p(s_{j,ik} \mid \theta_j) + \log p(s_{k,ij} \mid \theta_k)] \Big\} \\
&+ \sum_{(i,j,k) \in I} \Big\{ \mathbb{E}_q[\log p(E_{ijk} \mid s_{i,jk}, s_{j,ik}, s_{k,ij}, \mathbf{B})] - \mathbb{E}_q[\log q(s_{i,jk}, s_{j,ik}, s_{k,ij} \mid \phi_{ijk})] \Big\}.
\end{aligned}$$

The first two lines of Equation 8 represent the global terms $g(\boldsymbol{\gamma}, \boldsymbol{\eta})$ that depend only the global variational parameters $\boldsymbol{\gamma}$ and $\boldsymbol{\eta}$, whereas the last two lines are a summation of the local terms $\ell(\phi_{ijk}, \boldsymbol{\gamma}, \boldsymbol{\eta})$, one for each triangle.

A.2 Local Update (Exact and Approximate)

For each sampled triangle (i, j, k) in a mini-batch, the exact local update algorithm updates all the K^3 entries of ϕ_{ijk}, and then renormalizes them to sum to one. The K^3 entries of ϕ_{ijk} can be segregated into three broad categories: ϕ_{ijk}^{xxx}, ϕ_{ijk}^{xxy}, ϕ_{ijk}^{xyz}, which correspond to the following cases:

1. ϕ_{ijk}^{xxx} corresponds to the case that all nodes choose the same community: $s_{i,jk} = s_{j,ik} = s_{k,ij} = x$;
2. ϕ_{ijk}^{xxy} (or ϕ_{ijk}^{xyx}, or ϕ_{ijk}^{yxx}) corresponds to the case that two nodes choose the same community: $s_{i,jk} = s_{j,ik} = x$ and $s_{k,ij} = y$ (with similar variations for ϕ_{ijk}^{xyx} and ϕ_{ijk}^{yxx});
3. ϕ_{ijk}^{xyz} corresponds to the case that all nodes choose different communities: $s_{i,jk} = x$, $s_{j,ik} = y$, $s_{k,ij} = z$.

The update equations for each category are:

1. For $x \in \{1, \ldots, K\}$,

$$\phi_{ijk}^{xxx} \propto \exp\Big\{ \mathbb{E}_q[\log B_{xxx,2}] \mathbb{I}[E_{ijk} = 4] + \mathbb{E}_q[\log(B_{xxx,1}/3)] \mathbb{I}[E_{ijk} \neq 4] + \mathbb{E}_q[\log \theta_{i,x} + \log \theta_{j,x} + \log \theta_{k,x}] \Big\}. \tag{9}$$

2. For $x, y \in \{1, \ldots, K\}$ and $x \neq y$,

$$\phi_{ijk}^{xxy} \propto \exp\Big\{\mathbb{E}_q[\log B_{xx,3}]\mathbb{I}[E_{ijk}=4] + \mathbb{E}_q[\log B_{xx,2}]\mathbb{I}[E_{ijk}=3] + \mathbb{E}_q[\log(B_{xx,1}/2)]\mathbb{I}[E_{ijk}=1 \text{ or } 2] \\ + \mathbb{E}_q[\log\theta_{i,x} + \log\theta_{j,x} + \log\theta_{k,y}]\Big\}. \tag{10}$$

   The update equations for ϕ_{ijk}^{xyx} and ϕ_{ijk}^{yxx} are similar to ϕ_{ijk}^{xxy} (up to a trivial rearrangement of variables), thus we omit their details.
3. For distinct $x, y, z \in \{1, \ldots, K\}$,

$$\phi_{ijk}^{xyz} \propto \exp\Big\{\mathbb{E}_q[\log B_{0,2}]\mathbb{I}[E_{ijk}=4] + \mathbb{E}_q[\log(B_{0,1}/3)]\mathbb{I}[E_{ijk}\neq 4] + \mathbb{E}_q[\log\theta_{i,x} + \log\theta_{j,y} + \log\theta_{k,z}]\Big\}. \tag{11}$$

The above are the *exact* update equations for ϕ_{ijk}, and they require $\mathrm{O}(K^3)$ run-time per triangle (i, j, k). The update equations for the $\mathrm{O}(K)$ "mixture-of-deltas" approximation (described in Section 4.2) are almost exactly equivalent to the exact $\mathrm{O}(K^3)$ update procedure, with two minor modifications: (1) we simply zero out entries (a, b, c) that are not in the chosen set $\mathcal{A}$, and (2) we renormalize the chosen entries $(a, b, c) \in \mathcal{A}$ amongst themselves so that they sum to 1. This follows because the "mixture-of-deltas" variational distribution is essentially a categorical or multinomial distribution with some elements constrained to be zero.

A.3 Global update

The global update (Equation 7) in our SVI algorithm requires computing the natural gradient $\tilde{\nabla}\mathcal{L}_S(\boldsymbol{\eta}, \boldsymbol{\gamma})$. For clarity, we decompose $\tilde{\nabla}\mathcal{L}_S(\boldsymbol{\eta}, \boldsymbol{\gamma})$ over each part of $\boldsymbol{\eta}, \boldsymbol{\gamma}$. The natural gradient with respect to $\boldsymbol{\eta}$ is:

- For $x \in \{1, \ldots, K\}$,

$$\tilde{\nabla}_{\eta_{xxx,1}}\mathcal{L}_S(\boldsymbol{\eta}, \boldsymbol{\gamma}) = \lambda + \frac{m}{|S|}\left[\sum_{(i,j,k)\in S} q_{ijk}(x,x,x)\mathbb{I}[E_{ijk}\neq 4]\right] - \eta_{xxx,1}, \tag{12}$$

$$\tilde{\nabla}_{\eta_{xxx,2}}\mathcal{L}_S(\boldsymbol{\eta}, \boldsymbol{\gamma}) = \lambda + \frac{m}{|S|}\left[\sum_{(i,j,k)\in S} q_{ijk}(x,x,x)\mathbb{I}[E_{ijk}=4]\right] - \eta_{xxx,2}. \tag{13}$$

- For $x \in \{1, \ldots, K\}$,

$$\tilde{\nabla}_{\eta_{xx,1}}\mathcal{L}_S(\boldsymbol{\eta}, \boldsymbol{\gamma}) = \lambda + \frac{m}{|S|}\Bigg[\sum_{(i,j,k)\in S}\sum_{y:y\neq x}\Big(q_{ijk}(x,x,y)\mathbb{I}[E_{ijk}=1,2] + q_{ijk}(x,y,x)\mathbb{I}[E_{ijk}=1,3] \\ + q_{ijk}(y,x,x)\mathbb{I}[E_{ijk}=2,3]\Big)\Bigg] - \eta_{xx,1}, \tag{14}$$

$$\tilde{\nabla}_{\eta_{xx,2}}\mathcal{L}_S(\boldsymbol{\eta}, \boldsymbol{\gamma}) = \lambda + \frac{m}{|S|}\Bigg[\sum_{(i,j,k)\in S}\sum_{y:y\neq x}\Big(q_{ijk}(x,x,y)\mathbb{I}[E_{ijk}=3] + q_{ijk}(x,y,x)\mathbb{I}[E_{ijk}=2] \\ + q_{ijk}(y,x,x)\mathbb{I}[E_{ijk}=1]\Big)\Bigg] - \eta_{xx,2}, \tag{15}$$

$$\tilde{\nabla}_{\eta_{xx,3}}\mathcal{L}_S(\boldsymbol{\eta}, \boldsymbol{\gamma}) = \lambda + \frac{m}{|S|}\left[\sum_{(i,j,k)\in S}\sum_{y:y\neq x}\Big(q_{ijk}(x,x,y) + q_{ijk}(x,y,x) + q_{ijk}(y,x,x)\Big)\mathbb{I}[E_{ijk}=4]\right] - \eta_{xx,3}. \tag{16}$$

- For the sole η_0 parameter:

$$\tilde{\nabla}_{\eta_{0,1}}\mathcal{L}_S(\boldsymbol{\eta}, \boldsymbol{\gamma}) = \lambda + \frac{m}{|S|}\left[\sum_{(i,j,k)\in S}\sum_{(x,y,z):x\neq y\neq z} q_{ijk}(x,y,z)\mathbb{I}[E_{ijk}\neq 4]\right] - \eta_{0,1}, \tag{17}$$

$$\tilde{\nabla}_{\eta_{0,2}}\mathcal{L}_S(\boldsymbol{\eta}, \boldsymbol{\gamma}) = \lambda + \frac{m}{|S|}\left[\sum_{(i,j,k)\in S}\sum_{(x,y,z):x\neq y\neq z} q_{ijk}(x,y,z)\mathbb{I}[E_{ijk}=4]\right] - \eta_{0,2}. \tag{18}$$

The natural gradient $\tilde{\nabla}\mathcal{L}_S(\boldsymbol{\eta}, \boldsymbol{\gamma})$ with respect to $\boldsymbol{\gamma}$ is, for each $i = 1, \ldots, N$ and $x = 1, \ldots, K$,

$$\tilde{\nabla}_{\gamma_{i,x}}\mathcal{L}_S(\boldsymbol{\eta}, \boldsymbol{\gamma}) = \alpha + \frac{m}{|S|}\Bigg[\sum_{(j,k):(i,j,k)\in S}\sum_{y,z} q_{ijk}(x,y,z) + \sum_{(j,k):(j,i,k)\in S}\sum_{y,z} q_{jik}(y,x,z) \\ + \sum_{(j,k):(j,k,i)\in S}\sum_{y,z} q_{jki}(y,z,x)\Bigg] - \gamma_{i,x}. \tag{19}$$

Abstract

The proliferation of electronic health records (EHRs) frames opportunities for using machine learning to build models that help healthcare providers improve patient outcomes. However, building useful risk stratification models presents many technical challenges including the large number of factors (both intrinsic and extrinsic) influencing a patient's risk of an adverse outcome and the inherent evolution of that risk over time. We address these challenges in the context of learning a risk stratification model for predicting which patients are at risk of acquiring a *Clostridium difficile* infection (CDI). We take a novel data-centric approach, leveraging the contents of EHRs from nearly 50,000 hospital admissions. We show how, by adapting techniques from multitask learning, we can learn models for patient risk stratification with unprecedented classification performance. Our model, based on thousands of variables, both time-varying and time-invariant, changes over the course of a patient admission. Applied to a held out set of approximately 25,000 patient admissions, we achieve an area under the receiver operating characteristic curve of 0.81 (95% CI 0.78-0.84). The model has been integrated into the health record system at a large hospital in the US, and can be used to produce daily risk estimates for each inpatient. While more complex than traditional risk stratification methods, the widespread development and use of such data-driven models could ultimately enable cost-effective, targeted prevention strategies that lead to better patient outcomes.

Keywords: risk stratification, time-varying coefficients, multitask learning, *Clostridium difficile*, healthcare-associated infections

1. Introduction

Over recent years, there has been enormous growth in 1) our capacity to gather clinically relevant data and 2) the availability of such data sets. The collection of these data, in particular electronic health records (EHRs), holds out the promise of using machine learning to build models that can be harnessed to improve patient outcomes. Transforming patient data into actionable knowledge presents a barrage of pragmatic and technical challenges. But if we are successful in addressing these challenges, the knowledge embedded in these data has the potential to revolutionize clinical medicine.

One way in which these data can be leveraged is in the development of accurate data-driven models for predicting potentially avoidable adverse outcomes and using such predictions to guide interventions aimed at reducing the probability of these outcomes. The hypothesis is that we can extract from the data generalizable information that can help accurately identify a patient's *future* pathological states. If pathologies are predicted far enough in advance, then it may be possible for healthcare workers to intervene. Such targeted interventions could, in turn, lead to better patient outcomes.

In recent years, there has been a significant amount of research effort devoted to using clinical data to predict patient outcomes (Shoeb and Guttag, 2010; Syed and Rubinfeld, 2010; Syed et al., 2011; Chia et al., 2012; Saria et al., 2010; Saeed et al., 2011; Kleinberg and Hripcsak, 2011; Aboukhalil et al., 2008; Kansagara et al., 2011). We focus on the specific task of predicting which patients in a hospital will acquire an infection with *Clostridium difficile* (*C. difficile*), a largely preventable adverse outcome (Yokoe et al., 2008). *C. difficile* is a type of bacteria that takes over a patient's gut when normal flora get wiped out (often from receipt of antimicrobials). *C. difficile* infection (CDI) can lead to severe diarrhea and intestinal diseases (e.g., colitis), or even death. The infection is often treated with specific antimicrobials: oral vancomycin and metronidazole (and less frequently, fidaxomicin). However, it is estimated that approximately 20% of cases relapse within 60 days (Pépin et al., 2005). The incidence of CDI in the US is estimated at 200,000 cases per year (Dubberke et al., 2009); this is on par with the number of new cases of invasive breast cancer discovered each year in the US (DeSantis et al., 2014).

Infection with *C. difficile* is a type of healthcare-associated infection (HAI). HAIs are a serious problem in healthcare facilities across the world. It is estimated that, on any given day, HAIs affect approximately 1 in every 25 inpatients in US acute care hospitals (Magill et al., 2014). In addition to *C. difficile*, other common HAIs include ventilator-associated pneumonia, surgical site infection, and infections with methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant *Enterococcus* (VRE). Though many risk factors are well-known (e.g., healthcare-associated exposure, age, underlying disease, etc.), HAIs continue to be a significant problem throughout the world (Klevens et al., 2007). In recent years there have been numerous articles citing our inability to prevent HAIs (Miller et al., 2011; Umscheid et al., 2011; Sievert et al., 2013). We hypothesize that one of the reasons HAIs remain so stubbornly prevalent is because we lack an effective clinical tool for accurately measuring patient risk. In this work, we chose to focus on infections with *C. difficile*, one of the most prevalent HAIs (Miller et al., 2011).

We take a data-centric approach to the problem of developing a model to predict a patient's daily risk of acquiring an infection with *C. difficile*. We leverage the contents of EHRs from over 50,000 patient admissions from a single hospital. These clinical data contain information regarding medications, procedures, in-hospital locations, healthcare staff, lab results, measurements of vitals, patient demographics, patient history and admission details.

We seek a mapping from this information describing a patient to an estimate of the patient's probability of acquiring an infection.

Automated patient risk stratification, based on the contents of the patient's EHR, can serve several purposes. Firstly, risk-stratification models can help clinicians match high-risk patients with the appropriate interventions, monitoring policies, or therapies. In the absence of effective risk stratification, widespread implementation of known interventions (e.g., isolating patients or performing specialized analyses of antibiotic regimens) is prohibitively expensive. Secondly, data-driven models can help generate hypotheses regarding potential risk factors, in turn improving our understanding of the disease. For example, the model could identify "hot-spots" within a hospital that could benefit from additional environmental cleanings. The construction of a predictive model can also help to frame new scientific hypotheses through the identification of discriminatory observations. Such insights can lead to the pursuit and confirmation of causal relationships. Thirdly, such models could aid in designing more efficient clinical trials by identifying a study population at higher risk for disease, increasing the fraction of patients expected to test positive in the trial. This could significantly reduce the cost of a clinical trial without compromising the statistical power of the study.

Learning accurate risk-stratification models from EHR data presents a number of technical challenges. Two main issues we focus on in our work include the high dimensionality of the problem and the complex temporal dependencies among the variables. There can be thousands of variables representing each day of a patient admission and it is likely that many of these variables affect a patient's risk of CDI. Moreover, many of these variables change over time. These time-varying data suggest that as a patient spends time in the hospital, his/her actual risk of CDI will vary. Furthermore, how these variables affect risk is likely to change over time. Recent efforts on building models for identifying patients at high risk of acquiring a CDI have ignored these issues. Prior work on risk-stratification models for CDI has centered on the consideration of a small number of risk factors selected by clinical experts and time-invariant parameters.

Our hospital-specific approach to patient risk stratification for CDI, produces *daily* estimates of patient risk. The novel aspects of our work and our main contributions are outlined as follows:

- We move beyond known risk factors to leverage the entire structured contents of the EHR. Our model is based on thousands of extracted binary variables, many of which are hospital-specific (e.g., the locations of patient rooms within the hospital).
- We include both time-varying and time-invariant variables and we explicitly consider the evolution of patient risk during admission, when estimating current risk.
- We develop a novel multitask learning approach to modeling the time-varying effects of risk factors, based on the domain adaptation techniques presented in Daumé III (2007).
- We propose an evaluation scheme that is representative of how the model will be applied in practice. In contrast to previous work, we do not evaluate how our model performs at a single point in time, but rather how the model performs when applied to each day of a patient's admission.

When tested on a holdout set consisting of 24,399 patient admissions from a single year, our proposed model achieved an area under the receiver operating characteristic curve (AUROC) of 0.81 (95%CI 0.78-0.84) and consistently outperformed a baseline model with time-invariant coefficients, for patients with longer risk periods. We have shown that our algorithm can be integrated into the health record system of a hospital and can be used to automatically calculate daily probabilities of risk of CDI for every adult inpatient. These estimates could in turn be used for the selective targeting of high-risk patients with specific interventions that could lead to changes in clinical practice and ultimately a reduction in the incidence of CDI and HAIs. Beyond HAIs, we believe the multitask approach for learning the time-dependent structure of risk factors is a promising methodology for building predicting models for other adverse outcomes.

2. Background and Related Work

In previous work, risk-stratification models for CDI considered no more than a dozen risk factors identified by experts and many of these risk factors pertained to time-invariant features (i.e., observations that do not change over the course of the hospitalization) and researchers ignored changes in patient risk over time (Tanner et al., 2009; Dubberke et al., 2011; Garey et al., 2008; Krapohl, 2011). In our work, we have shown how leveraging the entire structured contents of the EHR leads to significantly better predictions compared to a model based solely on a set of known risk factors easily extracted from the EHR (Wiens et al., 2014). Moreover, we have incorporated both time-varying (e.g., current medications) and time-invariant (e.g., gender) risk factors into the model. Dubberke et al. (2011) also consider a risk prediction model based on both variables collected at the time of admission and throughout the admission. However, they ignore any trend in patient risk. In contrast, we have investigated different methods for incorporating the evolution of patient risk into the current risk estimate, transforming the problem into a time-series classification task (Wiens et al., 2012a). These extensions lead to significant improvements in patient risk stratification.

While our previous work has touched on time-varying variables, to date, risk stratification models for CDI have only considered time-invariant model parameters. That is, although the patient changes over time, and so does the estimate of risk, the models used to compute patient risk do not. This approach does not allow the relative importance of risk factors to change over time as the patient spends more time the hospital. Models to date have not explicitly considered the time-dependence of such factors as a patient's susceptibility and exposure over time. We argue that, in addition to changes in patient state and hospital conditions, the relative importance of risk factors may change during an admission. For example, the important of evidence drawn from a patient's history may diminish as the patient spends more time in the hospital. We propose a methodology that can capture and represent such rich temporal dynamics of the relevance of risk factors in real-world healthcare settings.

Models with time-varying parameters have been studied in other contexts like survival analysis (Fan and Zhang, 2008). Over the years, standard approaches to survival analysis, like Cox proportional hazards, have been extended to include time-dependent parameters (Hastie and Tibshirani, 1993). Extensions typically involve the addition of interaction terms

between features and time-varying functions (Gray, 1992; Murphy and Sen, 1991; Zucker and Karr, 1990; Tian et al., 2005; Sun et al., 2009). In many cases, the user must specify these functions. Researchers have developed non-parametric extensions, but these methods can be computationally inefficient for large, high-dimensional data sets. In practice, researchers often end up partitioning time into intervals and analyze each time period with a simple model. Our proposed approach is similar in the sense that we break the problem up into multiple tasks. However, instead of learning the models independently, we propose learning the models jointly using a multitask learning (MTL) framework.

MTL is a popular branch of machine learning that leverages the intrinsic relatedness among different tasks (Caruana, 1997). It has been studied extensively in many different applications, including healthcare (Caruana, 1996). As an example, Zhou et al. (2014) employ multitask learning in a patient risk stratification context for handling missing features values. In other work, (Zhou et al., 2011) employed an MTL framework in their work on Alzheimer's disease progression, centering on the prediction of the cognitive functioning of patients at different times in the future. They consider each time point as a different regression task and learn the tasks jointly. The authors employ a temporal group LASSO regularization framework, which ensures that only a small subset of the variables are chosen while penalizing large deviations of predictions at neighboring time points. Similarly, we treat each time point of prediction as a different task. However, instead of predicting multiple points into the future based only on the covariates at baseline, we predict risk each day based on time-varying covariates. In our application, a patient's risk of CDI is affected by several external risk factors that can change over the course of the hospitalization e.g., exposure to disease. We incorporate these changes at each time point, since ignoring them is likely to lead to inaccurate predictions.

3. Study Population

We considered all adult inpatient admissions to a large private hospital in the US over a two year period. The statistical analysis of retrospective medical records was approved by the Institutional Review Board of the Office of Research Integrity of the hospital network's research institute. We considered patients admitted on or after 2011-04-12 and discharged on or before 2013-04-12 (n=73,454). We exclude admissions in which the patient was discharged or tested positive for *C. difficile* before the end of the third day (n=24,389) and admissions for which the patient had a positive test result for *C. difficile* within the 14 days preceding the current admission (n=59). This resulted in 49,006 unique admissions. These criteria exclude many predictable low-risk patients with shorter stays, and focus on those patients who we believe acquire the infection during the current hospital admission (as opposed to those who are already infected at the time of admission). Our final study population is described in Table 1.

	Study Population (n=49,006)
Age, median (IQR)	60 (46-73)
Female gender, %	55.25
Hospital Service (%)	
medicine	47.85
cardiology	11.98
surgery	9.60
obstetrics	8.12
psychiatry	5.4
LOS (days), median (IQR)	5.4 (3.8-4.4)
CDI (%)	
current visit	1.02
1-year history	1.11
any history	1.54

Table 1: Demographics of our study population.

CDI cases are typically defined as healthcare-associated if they occur within 48 hours of the time of admission. In our work, we exclude patients who test positive before the end of the third calendar day of admission. By defining the cutoff as the end of the third calendar day, we ensure that the minimum cutoff of 48 hours is achieved, while allowing for simultaneous predictions for every patient (at the end of the day). A uniform time of prediction makes sense from a clinical perspective, since it streamlines the risk-stratification process. Most recently, the Centers for Disease Control and Prevention (CDC) updated their definition of HAIs to include positive test results that occur on the third calendar day of admission (CDC, 2015). While we do not consider these cases here, this work could easily be extended to do so.

4. Methods

In this section, we begin with the problem setup and define notation that will be used throughout the paper. We then describe the feature extraction and learning algorithms used to train the risk prediction model.

4.1 Problem Setup & Notation

The task at hand is to learn a model to accurately predict an inpatient's risk of acquiring CDI during the current hospitalization. Predictions are made daily; we consider time at the granularity of a day, and each day t of an admission is represented by a d dimensional binary feature vector: $\mathbf{x}_t \in \{0,1\}^d$. While we focus on a binary representation of the data, we incorporate both continuous and discrete variables as discussed in Section 4.2. Since each admission in our study population consists of multiple days, the i^{th} patient admission is represented by a series of feature vectors: $(\mathbf{x}_1^{(i)}, \mathbf{x}_2^{(i)}, ..., \mathbf{x}_{m_i}^{(i)})$, where m_i varies across patient admissions since the length of a visit varies (note: $m_i \geq 3$ in our study population). We use boldface notation to denote vectors.

In addition to a series of feature vectors, each patient admission is also associated with a binary label $y \in \{+1, -1\}$. Each day of a visit in which the patient eventually tests positive is labeled $+1$ and -1 otherwise. Thus each patient admission $p^{(i)}$ consists of m_i (feature vector, label) pairs:

$$p^{(i)} = \{(\mathbf{x}_t^{(i)}, y_t^{(i)})\}_{t=1}^{m_i}$$

For patients who do not test positive, m_i is equal to one less than the length of the visit in calendar days. We do not consider the day of discharge in our analysis since by the

time a patient is discharged the prediction is meaningless. For patients who eventually test positive, we consider a patient admission up to and including the day before the day of the positive test result. Finally, our data set is defined as:

$$\mathcal{D} = \{p^{(i)}\}_{i=1}^{n}$$

where n represents the number of unique patient admissions in the data set. Note that a patient may be represented multiple times in our data set if he/she has multiple admissions during the time period we consider.

Data	Description
Admission details	Admission details (e.g., date and time of admission, date and time of discharge, and type of visit) and other information pertaining to the admission such as the financial class code, the source of the admission, the hospital service, and the attending doctor are extracted for each patient admission.
Patient demographics	Information pertaining to patient demographics such as age at the time of admission, gender, race, marital status, and city of residence are extracted. Aside from age, all data in this table are categorical.
Laboratory results	Results pertaining to ordered laboratory tests are extracted. Each entry in the database table is associated with a patient admission, an observation identifier, an observation value, an observation time, a reference range (e.g., 120-200 for cholesterol) and an abnormal flag (e.g., H=high, L=low, C=critical, or empty=normal). We represent time-stamped laboratory results based on the observation identifier and the associated flag.
Diagnoses	Patient diagnoses are encoded using ICD-9 codes (NCHS, 2008). Patient visits can be associated with multiple ICD-9 codes; in our data the average visit (including outpatient visits) is associated with two distinct ICD-9 codes. ICD-9 codes, widely used for billing purposes, can get coded well after a patient is discharged (Iezzoni, 1990). For this reason, we do not use the codes associated with a patient's current visit in our model. Instead, we consider only the codes from a patient's most recent hospital admission.
Medications	Orders for medications are associated with an admission identifier, an 8-digit medication identifier, and a start/stop time. Each medication identifier is associated with a medication, a dosage and a form (e.g., in solution). Since the dosage and form are encoded in the 8-digit medication identifier, we represent patient medications using only this identifier.
Locations	For each hospital admission we have time-stamped location data. Location data refer to the patient's location within the hospital. Locations are collected at both the unit and the room level. Using these time-stamped data we can trace a patient's path through the hospital.
Vitals	Each entry in the vitals table corresponds to a visit, an observation identifier (e.g., "BPSYSTOLIC" for systolic blood pressure), an observation value, a reference range, an abnormal flag, and an observation timestamp. When extracting information about vitals for a patient we encode the observations the same way we encode laboratory results, i.e., as a concatenation of the observation identifier and an abnormal flag (e.g., "BPSYSTOLIC_H" for high systolic blood pressure).
Procedures	In the EHR, procedures are encoded using both Current Procedural Terminology (CPT) codes and ICD-9 procedure codes. Each row in the procedures table records a procedure, an admission identifier, and a procedure timestamp. Since both coding systems are used to describe procedures, in our analysis we consider both CPT and ICD-9 codes.

Table 2: Relevant information extracted from the EHR.

4.2 Feature and Label Extraction

As Paxton et al. (2013) state, there are many challenges that come with working with EHR data in research. Addressing these challenges requires careful consideration of the data and the intended application. Moreover, electronic health information systems will continue to change and therefore it is important that researchers take this into consideration when

developing models based on EHR data. In our work these challenges motivated a simple, flexible, data-driven approach to extracting and representing EHR data.

4.2.1 Data Extraction

We represent each day of a patient's admission with a single feature vector, $\mathbf{x}_t$ for $t = 1...m_i$, composed of both *time-invariant* features collected at the time of admission and *time-varying* features collected over the course of each day. The time-invariant features aim to capture the baseline state of each patient while the time-varying features capture changes in patient state during the hospital admission. In the EHR, data are stored across different tables in several databases. We describe the relevant variables and how they are stored and extracted from the EHR in Table 2.

Each patient admission (i.e., encounter) is represented by a unique identifier, in addition each patient is associated with a unique identifier. These unique identifiers allow us to retrieve information across hospital databases for each admission, and across time for multiple admissions pertaining to the same patient. For each patient admission in our study population, we extract knowledge pertaining to the EHR data described above. We augment the data pertaining to the current admission with data extracted from previous admissions including diagnoses and medications.

4.2.2 Feature Engineering

The majority of the extracted data pertain to categorical features, e.g., medications or in-hospital locations. Vitals and laboratory results are also represented using categorical variables as described in Table 2. This eliminates the need to define our own cutoffs for discretization, since the cutoffs are encoded directly in the database using "reference ranges." Data pertaining to diagnoses were coded as ICD-9 codes, a hierarchical classification system with 13,000 unique codes. For our application, we do not expect that this level of granularity is informative. Diagnostic codes are used largely for billing purposes and are not timestamped, therefore their utility is limited. Given these limitations we focus on only diagnostic codes associated with the previous visit, and consider only the highest level of the codes.

We also consider a small number of continuous and discrete variables (e.g., age and statistics related to previous hospitalizations). We map all of these data to binary variables resulting in a high-dimensional feature space. Doing so allows us to later capture some of the nonlinear relationships that may be present in the data without using a nonlinear classifier. We discretize all continuous variables (except for age) using cutoffs based on quintiles from the training data.

From the laboratory data described in Table 2 and the in-hospital location data we were able to extract information regarding patient exposure to the disease throughout the hospitalization. *Colonization pressure* aims to measure the number of patients in a specific unit of the hospital colonized or infected with a particular disease. We define colonization pressure as in Wiens et al. (2014) and measure patient exposure over time based on the patient's location during the hospital admission. We measure exposure at both the hospital-wide and unit-wide level.

We focus on capturing events at the temporal resolution of a day. Thus, we do not consider the order of events within a single day. For example, we know which medications were ordered each day but not the temporal ordering of when the medications were taken. We handle cases where the same variable, e.g., blood pressure, is observed multiple times during a day by simply including all relevant values that were observed when building the daily feature vector. For our particular task this resolution suffices, though it may not be optimal.

4.2.3 Ground Truth

We label each example in our data set as either positive or negative depending on the laboratory data pertaining to positive stool tests for toxigenic *C. difficile*, as obtained during the hospital admission. Patient admissions with a positive test result are labeled positive in our data and negative otherwise. These laboratory results are time-stamped and thus we also noted the calendar day in which the patient tested positive. In the data set, patients are only tested if they exhibit symptoms. Thus, we expect the laboratory results to be highly sensitive and specific. However, since not all patients are tested every day for the disease there is a small possibility that some patients may have acquired an infection and yet were never tested.

4.3 Learning to Predict Daily Risk

We produce daily estimates of patient risk using a two-stage process as in Wiens et al. (2012a). However, in contrast to our previous work, our model in the first stage is not static but varies over the course of the hospitalization, incorporating time-varying model parameters. The first stage produces initial estimates of daily risk and the second stage incorporates risk estimates on previous days in order to capture the variation in risk over time. We explain both stages in detail below.

4.3.1 Baseline Approach

Given the set of labeled feature vectors $\mathcal{D} = \{(\mathbf{x}_t^{(i)}, y_t^{(i)})_{t=1}^{m_i}\}_{i=1}^{n}$ representing each day of a patient admission we can learn a classifier $\theta \in \mathbb{R}^d$, linear in $\mathbf{x}$, using $L2$-regularized logistic regression:

$$\min_{\theta} \frac{1}{2}\theta^T\theta + C\sum_{i=1}^{n}\sum_{t=1}^{m_i} log(1 + e^{-y_t^{(i)}\theta^T\mathbf{x}_t^{(i)}}) \quad (1)$$

Once we have learned θ we can produce an initial estimate of the i^{th} patient's risk on day t, $\hat{y}_t^{(i)} \in [0,1]$:

$$\hat{y}_t^{(i)} = \frac{1}{1 + e^{(-\theta^T\mathbf{x}_t^{(i)})}} \quad (2)$$

This formulation simply pools all training examples together and learns a single model, θ ignoring the index t. As a patient spends additional time in the hospital, we expect the factors contributing to patient risk to change. Therefore, we extend the learning framework to produce a model that changes as the patient spends more time in the hospital.

4.3.2 Proposed Approach

We divide the problem into T learning tasks, splitting $\mathcal{D}$ into separate tasks: $\mathcal{D}_1, \mathcal{D}_2, \mathcal{D}_3, ..., \mathcal{D}_T$. Where the task $\mathcal{D}_j$ is the task associated with the τ_j time period for $j = 1, 2, 3, ..., T$. The data are split into different tasks according to t, the index of the day of the visit, such that each task contains roughly an equal number of examples.

We could learn a separate model for each task independently of the others, but in doing so we would be limiting ourselves to using only $\frac{1}{T}$ of the original training data available. Moreover, the tasks themselves are related in time and thus are not independent. While the parameters may vary from one day to another, we do not expect large fluctuations in time. Therefore, we use a multitask learning framework to leverage the inherent relatedness among the different tasks and take advantage of the entire corpus of the training data.

We extend the $L2$-regularized logistic regression framework presented above to incorporate multiple tasks. We specifically chose $L2$ regularization over other regularization frameworks (e.g., L1) since many factors contributing to the risk of CDI are not well understood and effective interventions and preventative measures for reducing patient risk are still being studied. Thus we are more interested in capturing/identifying perhaps novel risk factors, than selecting a sparse subset. Moreover, given the collinearity present in the data, there's a risk that $L1$ regularization could "select-out" such known risk factors. We want to be careful that we do not exclude known risk factors in the final model. Even if other factors that are highly correlated with known risk factors remain in the model, clinicians are unlikely to use or trust a model that does not consider known risk factors. We employ domain adaptation techniques from Daumé III (2007), remapping each feature vector $\mathbf{x}_t^{(i)}$ to a feature vector $\in \{0,1\}^{d(T+1)}$ using the mapping function $\Phi(\mathbf{x}_t^{(i)})$:

$$\Phi(\mathbf{x}_t^{(i)}) = \ [\mathbf{x}_t^{(i)}, \langle\mathbf{0}\rangle^{j-1}, \mathbf{x}_t^{(i)}, \langle\mathbf{0}\rangle^{T-j}] \quad \forall\ t \in \tau_j \quad \text{for } j = 1, 2, 3, ..., T$$

The new feature vectors consist of two copies of the original feature vector, padded with zeros $\mathbf{0} = [0_1, 0_2, 0_3, ..., 0_d]$. Here the notation $\langle\mathbf{0}\rangle^k$ represents k concatenated copies of the zero vector $\mathbf{0}$.

We then learn the regression parameters $\theta \in \mathbb{R}^{d(T+1)}$ using Equation (1) simply replacing $\mathbf{x}_t^{(i)}$ with $\Phi(\mathbf{x}_t^{(i)})$ in the objective function. One can decompose θ into $T+1$ vectors each in $\mathbb{R}^d$, the original dimensionality of the problem, $\theta = [\theta_0, \theta_1, \theta_2, ..., \theta_T]$. Here, θ_0 corresponds to a vector of shared feature weights since it is based on data from all days, where as θ_1 is based on only data from $t \in \tau_1$ and so on.

By substituting $\Phi(\mathbf{x}_t^{(i)})$ for $\mathbf{x}_t^{(i)}$ in Equation (2), the risk of patient i on day $t \in \tau_j$ becomes proportional to $(\theta_0 + \theta_j)^T\mathbf{x}_t^{(i)}$. Writing the function this way shows how learning the models jointly results in T different models all with a shared component θ_0.

$$\theta'_j = \ \theta_0 + \theta_j \quad \text{for } j = 1, 2, 3, ..., T$$

In general, we can estimate the risk of a new patient day $\mathbf{x}_t^{(i)}$ using Equation 2, but replacing θ with θ'_j, without having to remap the feature vector.

4.3.3 Temporal Smoothing

Applying the model described above to a patient's data results in a single estimate of risk for each day $\hat{y}_t^{(i)}$ of a patient's visit. This estimate is based on both the baseline state of the patient (as captured by the time-invariant features in $\mathbf{x}_t^{(i)}$) and the measured time-varying variables. In previous work, we showed that this *snapshot* approach to measuring patient risk, ignores important information contained in the evolution of patient risk. Thus, we incorporate risk estimates from previous days using a cumulative moving average. Given the initial risk estimates, the predicted risk for patient i on day t is calculated as $risk_t^{(i)} = \frac{\hat{y}_1+...+\hat{y}_t}{t}$. This biases new estimates toward the estimates from previous days; while large fluctuations in patient risk in close temporal proximity are possible, they are unlikely. In earlier work, we considered a formulation based on a weighted average in which days closer to the current day receive more weight. However, we found these methods did not yield better estimates than a simple cumulative average (Wiens et al., 2012b). The approach considered here is equivalent to the *RP+Average* approach described in Wiens et al. (2012a), the simplest of the investigated approaches that significantly outperformed the snapshot approach.

4.4 Risk Stratification Model Evaluation - Daily Predictions

In the clinical literature, risk stratification models are often evaluated at a single point in time e.g., two days before an index event or at the time of admission (Tanner et al., 2009; Dubberke et al., 2011). Evaluating a model's ability to risk stratify patients at the time of admission is fine. However, a patient's risk is likely to change over the course of the hospitalization. Evaluating a model at a specific point in time, e.g., n days before an index event, brings to the fore two additional issues. First, such an evaluation requires you to define an index event for negative patients. For risk stratification for CDI the index event is often defined as the first positive test result for patients who test positive and the day of discharge otherwise. However, the task of distinguishing between patients about to test positive for CDI and patients about to be discharged from the hospital is relatively easy since the patients tend to look quite different in the feature space. More importantly, the ability to distinguish such patients is of little clinical utility. Second, evaluating a model at a specific point in time does not yield an accurate representation of how the model will perform in a clinical setting. While such an evaluation scheme is useful for comparing classifier performance, in practice, clinicians have no way of knowing when a patient is n days from an index event.

In a clinical setting, we expect to apply the risk stratification model to each day of a patient's visit. This results in multiple predictions for each patient admission, one corresponding to each day of the admission. We consider a model evaluation scheme that takes all of these predictions into consideration, yet still yields a single measure of performance.

One could imagine a validation scheme in which the performance of a classifier is evaluated for each day independently. While complete, this evaluation still lacks relevance from a clinical perspective since it is not clear how to interpret the utility of a classifier that correctly classifies a patient m days out of a total of n days. Here, we consider an evaluation scheme that is driven by the use case of the model. We assume that once a patient is identified as high-risk s/he will receive some form of an intervention (e.g., relocated to

a private room or special stewardship of the patient's antibiotic protocol) and that this intervention will last for a certain period of time determined by the physicians treating the patient (e.g., 10 days or for the remainder of the visit). Thus, while the predicted risk remains low, we continue making daily predictions, each day deciding whether or not to intervene. However, once the predicted risk exceeds some threshold, we classify the patient as high-risk and discontinue making predictions, since the question of whether or not to intervene becomes irrelevant once physicians have intervened.

Thus, while the model's daily predictions are allowed to fluctuate (from low to high and high to low), when evaluating the model we choose a single decision threshold. We apply this decision threshold to each day of a patient's visit, up to the day before a positive test result is observed or the day before the day of discharge. If the patient's daily estimated risk ever exceeds the decision threshold they are classified as high risk, otherwise they are classified as low risk. This mimics the primary way we expect the model to be used in practice. By taking the maximum prediction for each patient and sweeping over different values of the decision threshold, we can evaluate the model in terms of the area under the receiver operating characteristic curve (AUROC). The AUROC alone is not enough to quantify the performance of the model; since there is high class-imbalance, we also consider the area under the precision recall curve (AUPR). We estimate 95% confidence intervals for these performance measures by applying a bootstrap method. Finally, in addition to these performance metrics, we also evaluate how *far in advance* we correctly identify positive cases. This is an important measure of performance that is often overlooked, but has crucial implication regarding the utility of the model in real-world clinical practice. The earlier we can identify a patient as high-risk, the earlier we can intervene, with the goal of reducing the likelihood of an adverse outcome for a patient and also reducing the spread of the pathogen.

5. Experiments and Results

Employing the methods described in the previous section, we learned and validated a risk stratification model for identifying inpatients at high-risk of acquiring an infection with *C. difficile* throughout their hospital admissions using data from our study population.

5.1 Learning the Risk Model

Our feature extraction yielded close to 10,000 binary variables for each patient day. To reduce the dimensionality, we filter out features that do not occur in at least 1% of the training set. This resulted in a lower dimensional feature vector, where each day is represented by a vector of 905 binary variables. The remaining variables are presented in Table 3. As shown in Table 3 the majority of the features pertain to laboratory results and medications, both time-varying variables.

We split the data into a training set and a holdout set based on time, training on data from the first year, and validating our model on data from the second year. The training data consisted of patient admissions from 2011-04-12 to 2012-04-11, totaling 190,675 visit days pertaining to 24,607 unique visits. Within the training data, 258 admissions had a positive test for *C. difficile* resulting in 2,608 training days with a positive label. To mitigate the influence of patients already showing symptoms, we removed patient days corresponding

Category	Feature Name	#Binary Features	Original Format

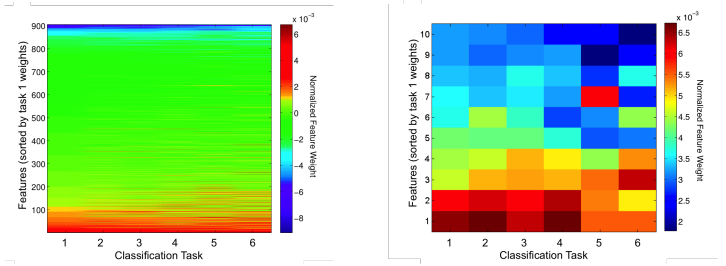
Table 3: High-level description of final features included in the model. The final feature vector consisted of 905 binary features belonging to four different categories.

to the day of and the day before the positive test result. In addition, when training the classifier, we randomly subsampled the data such that no patient contributed more than three days of the data to the training set. This is similar to reweighting samples such that each patient contributes equally to the overall classifier. If we had not done this, some patients would have been represented up to 10 times more often than other patients. Given the small number of positive examples, patients with longer visits could have significantly biased the classifier. In turn, this could have resulted in overfitting to patients with longer visits.

We selected the number of tasks T, and the corresponding temporal intervals τ_j for $j = 1, ..., T$ based on the number of training examples available for each interval. For our data, this resulted in six distinct tasks, corresponding to six distinct time periods: $\mathcal{D}_1, \mathcal{D}_2, \mathcal{D}_3, \mathcal{D}_4, \mathcal{D}_5, \mathcal{D}_6$. We learned a model for each time period using $L2$-regularized logistic regression and the multitask learning framework described in Section 4.3.2. To select the hyperparameter C in (1), we performed repeated five-fold cross validation on the training data, choosing a setting that maximized the AUROC. The model parameters, i.e., θ, were solved for using LIBLINEAR (Fan et al., 2008). This resulted in six different models, $\theta'_t \in \mathcal{R}^{905}$:

$$\theta'_t = \begin{cases} \theta_0 + \theta_1 & : t \in [1] \\ \theta_0 + \theta_2 & : t \in [2] \\ \theta_0 + \theta_3 & : t \in [3] \\ \theta_0 + \theta_4 & : t \in [4, 5] \\ \theta_0 + \theta_5 & : t \in [6, 9] \\ \theta_0 + \theta_6 & : t \in [10, \infty) \end{cases}$$

θ'_t is allowed to deviate from the shared model θ_0 based on the data collected during each time period. Thus, the relative importance of risk factors is allowed to vary over time. Figure 1 (a) shows the extent to which the weights vary across time. The columns correspond to the different time periods (i.e., tasks) and the rows correspond to the different features. The features are sorted in descending order according to their weight on the first day. The color of each cell is related to the weight of the corresponding feature for the specified task, normalized by the sum of the absolute value of all weights for that task. All cells corresponding to features that have high positive weight are red and those with high negative weight are dark blue. If the relative importance of the weights remains constant over time, each column would appear identical to the first column (i.e., solid horizontal bands of color). However, as Figure 1 (a) shows, the relative importance of features changes. Still, as we expected, we see great deal of continuity in the feature ranking across time periods as all of the models share a common component.



(a) All features (b) The top ten features

Figure 1: The changing relative importance of features over time. For each time period τ_j for $j = 1...6$ (i.e., task), the features are ranked according to the feature weight for the task associated with τ_1. The color represents the normalized feature weight for each task.

Figure 1 (b) shows that, even among the top ten features (from θ'_1), there are changes in the relative importance of features over time. In Figure 1 (b) the first two features become less important over time, while the third feature becomes more important. Table 4 lists the five features with the greatest positive weight in θ'_1 through θ'_6. Note that initially the most important feature is the patient's one year history of CDI. As a patient spends more time in the hospital, this feature loses importance relative to the location of the patient in the hospital.

Table 4: We show features with greatest weight for tasks 1 through 6, using color to highlight certain trends.

In Table 5, we note the 25 features with the greatest weight according to the shared model i.e., θ_0. We are not surprised that patient history of CDI appears at the top of this list. The medications that appear in Table 5 include drugs administered to patients receiving kidney dialysis, drugs for the treatment of high blood pressure and heart disease, and proton pump inhibitors. When interpreting these weights, it is important to keep in mind that many of the features in our model are highly correlated. These features may be directly or indirectly linked with an increased risk of CDI. Further analysis could generate hypotheses about causal relationships that could be tested in a randomized controlled trial.

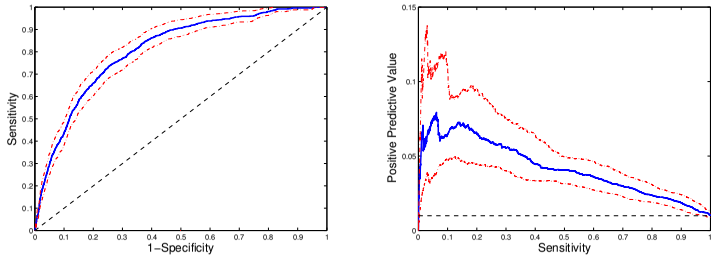
5.2 Evaluating the Model

In previous work, risk stratification models have been evaluated at a single point in time. Here, we employ a more realistic evaluation methodology (as described above). We believe this evaluation provides a more accurate representation of how the model will perform in a clinical setting.

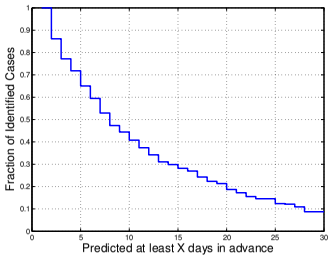


(a) Receiver Operating Characteristic Curve (b) Precision Recall Curve

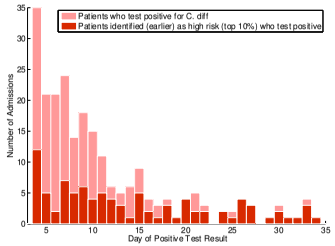
Figure 2: We plot two performance curves generated by applying the risk stratification method described in the previous section to the set of held-out patient admissions. We achieve an AUROC of 0.81 (95%CI 0.78-0.84) and a AUPR of 0.04 (95%CI 0.03-0.05). The 95% CI are represented by the red dashed lines. The performance of a random classifier is given by the black dashed lines. (A classifier no better than random achieves an AUROC=0.5 and AUPR=0.01)

We applied the model to the set of patient admissions held out for validation, which consisted of patient admissions from 2012-04-12 to 2013-04-12 and was composed of 24,399 admissions of which 242 had a positive test result for *C. difficile*. When validating the model, we did not subsample the test data as we did with the training data. Each patient admission in the held out set has at least three daily predictions of risk, since we considered only patients who were still present in the hospital at the end of the third day. However, we do not start applying the decision threshold until the end of the third day (given our exclusion criteria). Also, we do not evaluate the model on the final day of the admission (the day in which the patient was discharged) as such a prediction would be meaningless for guiding in-hospital interventions. Recall that the task is to predict a patient's probability of acquiring CDI during the current hospitalization and that predictions are made at the end of the day.

Figure 2 shows the ROC curve, and the precision recall curve for the held out patient admissions. Applied to the validation data, our model results in an AUROC of 0.81 (95%CI 0.78-0.84) and an area under the precision recall curve (AUPR) of 0.04 (95%CI 0.03-0.05). Although the AUPR appears low, the performance is significantly better than a baseline classifier (Precision=0.01), since the incidence of infection is approximately 1% in the study population.



(a) Fraction of correctly identified cases we can predict at least x days in advance of the patient testing positive for CDI.



(b) Distribution of time to positive test from admission (in days)

Figure 3: Classification performance resulting from a classifier based on the 90^{th} percentile.

To evaluate the ability of our model to distinguish high-risk patients from low-risk patients in the held out set set of patient admissions, we selected a decision threshold based on the 90^{th} percentile. We chose this cutoff to limit the number false positives, since CDI cases are relatively rare. Given this decision threshold, we correctly identify 103 patients out of 242 as high risk, and achieve a sensitivity of 0.43, a positive predictive value of 0.04, an F-score 0.08, and an odds ratio of 6.67 (confusion matrix TP=103 TN=21,820 FN=139 FP=2337). Lowering the decision threshold will increase the sensitivity and increase the number of false positives. Ultimately, the choice of decision threshold depends on the expected costs and benefits of the intervention that one intends to apply to high-risk patients.

Figure 3(a) illustrates how far in advance we can predict positive test results. We note that in approximately half of the cases correctly identified, we identify cases at least 7 days in advance of their testing positive for CDI. Figure 3(b) illustrates *when* patients are testing positive. While we identify more patients who test positive earlier, the *fraction* of patients we correctly identify increases as the length of stay increases.

Finally, in Figure 4, we illustrate the performance of our model (the *Multi-Task Joint* approach) compared to that of a model learned by simply pooling all the data (the *Single-Task* approach), in terms of the AUROC. In addition, we consider a third approach, *Multi-Task Independent*, that also learns multiple models, one for each day, but where the optimization is performed independently for each model. Applied to all patients in the held out set of patient admissions (risk period>3 days), the proposed approach, *Multi-Task Joint*, and the *Single-Task* classifier perform almost identically, with both achieving an AUROC of 0.81. In contrast, the *Multi-Task Independent* performs worse, achieving an AUROC of 0.80. We believe this reduction is due to the inability of the method to leverage all of the data as in the *Multi-Task Joint* approach. When we divide the patients into subsets based on their risk period the difference between the *Single-Task* and *Multi-Task* approaches be-

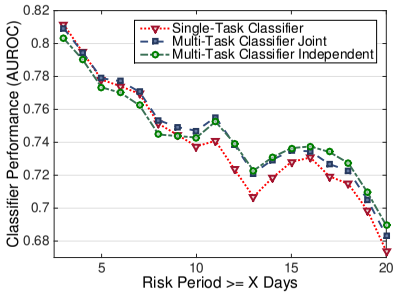


Figure 4: We compare a single-task classifier, where the model is time-invariant, to a multitask classifier where the model varies over time. The difference between the two classifiers is apparent for those patients who test positive later during the admission. These are the patients we are more interested in.

comes apparent. For patients with a longer risk period, the *Multi-Task* approach results in an improvement in performance over the *Single-Task* approach. While the difference is small, it is consistent. This difference is relevant, since the potential to intervene in a timely manner is greater for patients who test positive later in a visit. Therefore, the ability to identify such cases accurately is of considerable practical importance.

6. Discussion and Conclusion

In summary, we presented a novel data-driven patient risk stratification model for CDI that utilizes the entire structured contents of the EHR. The main contributions of our work are a novel approach to learning time-varying parameters and an evaluation scheme that is representative of how the model will be applied in practice.

The model provides estimates of patient risk daily based on time-varying parameters. We propose a multitask learning framework to efficiently learn the time-varying model. By learning the models jointly, we leverage the inherent relatedness among the different tasks. We observed changes in the ranking of features over time, suggesting that the proposed method could be used to further investigate the temporal effects of risk factors over the course of a hospital admission. These findings may shed new light on the relationship between risk factors and time, and in turn improve our understanding of the disease.

Furthermore, we demonstrated a consistent improvement in the classification performance using our multitask approach over a single-task approach, particularly among patients with longer risk periods. While consistent, the difference was not significant; this may be due to the fact that the number of cases with longer risk periods is small. We have approximately 5,000 visits in the heldout set with a risk period greater than 10 days, and only a small fraction of those patients end up testing positive. Additionally, in our formulation, we consider the same decision threshold every day. However, use of a variable

decision threshold could lead to better results. Furthermore, our results showed a clear overall improvement when learning the models jointly versus independently. However, on patients with very long risk periods e.g., greater than 15 days, the independent classifiers appear to perform slightly better. This may be an indication that the averaging or smoothing effect of the joint optimization approach is perhaps too strong. This may be addressed by only penalizing differences between successive models. In future work, such models could be improved by considering additional temporal smoothness constraints.

We proposed a new evaluation scheme motivated by a clinical use case in which the model is used daily to evaluate patients in the hospital and a decision is made about whether or not to intervene. Prior to this work, such models have only been evaluated at a single point in time during a hospital visit (e.g., at the time of admission or n days before the index event). We argue that evaluating the model over the entire course of the admission is a more accurate approximation of how the model would be used and would perform in practice. We also evaluated our final model in terms of how many days in advance we could predict high-risk cases. In a clinical setting, how far in advance one can predict an infection is as relevant as traditional performance metrics like sensitivity and specificity. This approach to evaluation is independent of both the disease and our method of building a classifier. With the increasing interest in applying machine learning to clinical problems, ensuring that evaluation criteria are clinically relevant will be of great importance.

In addition, we were careful to split our data temporally, learning on data from one year and evaluating the model on data from the next year. Over time, hospital populations, physical layouts, clinical protocols, and staff can change. Furthermore, EHR systems can change both in terms of what is collected and the precise meanings of variables. Thus, when evaluating predictive models in medicine, it is important to ensure that all examples in the training set precede all examples in the set held out for validation. Failure to do this can produce misleading results since future changes may be captured by the training set. To this end, we expect the predictive performance of our model will deteriorate over time, if such changes are not readily incorporated. An important future direction of study is how such models transfer across time, and best practices for building models that incorporate not only changes but also take into consideration possible interventions.

The models learned in this work are based on hospital-specific data, and thus may not generalize to hospitals with very different patient populations or clinical protocols. However, we expect the *methods* to generalize beyond this specific hospital. Our data-driven approach to feature engineering can be applied in straightforward manner to the structured contents of any hospital database. Such a data-driven approach can readily incorporate hospital-specific features resulting in more accurate predictive models. Here, we considered only the structured contents of the electronic health record. Future models, however, could incorporate features extracted from clinical notes or even genomic data pertaining to the microbiome of patients.

We focused on developing predictive models for CDI. However, our contributions extend to building models for other types of healthcare-associated infections and other patient populations. Once incorporated into the hospital workflow, risk stratification models, like the one presented here have the potential to reduce the incidence of adverse patient outcomes. Widespread development and use of such data-driven models promise to enable cost-effective, targeted prevention strategies that will ultimately improve patient care.

Abstract

We investigate a general framework of multiplicative multitask feature learning which decomposes individual task's model parameters into a multiplication of two components. One of the components is used across all tasks and the other component is task-specific. Several previous methods can be proved to be special cases of our framework. We study the theoretical properties of this framework when different regularization conditions are applied to the two decomposed components. We prove that this framework is mathematically equivalent to the widely used multitask feature learning methods that are based on a joint regularization of all model parameters, but with a more general form of regularizers. Further, an analytical formula is derived for the across-task component as related to the task-specific component for all these regularizers, leading to a better understanding of the shrinkage effects of different regularizers. Study of this framework motivates new multitask learning algorithms. We propose two new learning formulations by varying the parameters in the proposed framework. An efficient blockwise coordinate descent algorithm is developed suitable for solving the entire family of formulations with rigorous convergence analysis. Simulation studies have identified the statistical properties of data that would be in favor of the new formulations. Extensive empirical studies on various classification and regression benchmark data sets have revealed the relative advantages of the two new formulations by comparing with the state of the art, which provides instructive insights into the feature learning problem with multiple tasks.

Keywords: Multitask learning, regularization, sparse modeling, blockwise coordinate descent

1. Introduction

Multitask learning (MTL) improves the generalization of the estimated models for multiple related learning tasks by capturing and exploiting the task relationships. It has been theoretically and empirically shown to be more effective than learning tasks individually. Especially when single task learning suffers from limited sample size, multitask learning reinforces a single learning process with the transferable knowledge learned from the related tasks. Multi-task learning has been widely applied in many scientific fields, such as robotics (Zhang and Yeung, 2010), natural language processing (Ando and Zhang, 2005), computer aided diagnosis (Bi et al., 2008), and computer vision (Kang et al., 2011).

Research efforts have been devoted to various MultiTask Feature Learning (MTFL) algorithms. One direction of these works directly learns the dependencies among tasks, either by modeling the correlated regression or classification noise (Greene, 2002), or assuming that the model parameters share a common prior (Yu et al., 2005; Lee et al., 2007; Xue et al., 2007; Yu et al., 2007; Jacob et al., 2008), or by examining the tasks' covariance matrix (Bonilla et al., 2007; Zhang and Yeung, 2010; Guo et al., 2011; Yang et al., 2013). Another research direction relies on a basic assumption that the different tasks may share a substructure in the feature space. In order to exploit this shared substructure, Rai and Daume (2010) project the task parameters to explore the latent common substructure. Kang et al. (2011) form a shared low-dimensional representation of data by feature learning. More recent methods explore the latent basis that can be used to characterize the entire set of tasks and examine the potential clusters of tasks. For instance, Passos et al. (2012) assume that subsets of features may be shared only between tasks in the same cluster. Kumar and Daume III (2012) allow overlapping of tasks in different groups by having several bases in common. Maurer et al. (2013) exploit a dictionary allowing sparse representations of the tasks. Gong et al. (2012) detect if certain tasks are outliers from the majority of the tasks.

Regularization methods are widely used in MTFL to learn a shared subset of features. A common strategy is to impose a blockwise joint regularization (Meier et al., 2008; Zhao et al., 2009) on all task model parameters to shrink the effects of features across the tasks and simultaneously minimize the regression or classification loss. These methods employ the so-called $\ell_{1,p}$ matrix norm (Lee et al., 2010; Liu et al., 2009a; Obozinski and Taskar, 2006; Zhang et al., 2010; Zhou et al., 2010) that is the sum of the ℓ_p norms of the rows in a matrix. As a result, this regularizer encourages sparsity among the rows. If a row of the parameter matrix corresponds to a feature and a column represents an individual task, the $\ell_{1,p}$ regularizer intends to rule out the unrelated features across tasks by shrinking the entire rows of the matrix to zero. Typical choices for p are 2 (Obozinski and Taskar, 2006; Evgeniou and Pontil, 2004) and ∞ (Turlach et al., 2005). Effective algorithms have since then been developed for the $\ell_{1,2}$ (Liu et al., 2009a) and $\ell_{1,\infty}$ (Quattoni et al., 2009) regularization. Later, the $\ell_{1,p}$ norm is generalized to include $1 < p \leq \infty$ with a probabilistic interpretation that the resultant MTFL method solves a relaxed optimization problem with a generalized

normal prior for all tasks (Zhang et al., 2010). Although the matrix-norm based regularizers lead to convex learning formulations for MTFL, recent studies show that a convex regularizer may be too relaxed to approximate the ℓ_0-type regularizer for the shrinkage effects in the feature space and thus results in suboptimal performance (Gong et al., 2013). To address this problem, non-convex regularizers, such as the capped-ℓ_1, ℓ_1 regularizer (Gong et al., 2013), have been proposed for the multitask joint regularization. However, using non-convex regularizers may bring up computational challenges. For instance, non-convex formulations are usually difficult to solve, and require more complicated optimization algorithms to guarantee satisfactory performance.

For the existing MTFL methods based on joint regularization, a major limitation is that it either selects a feature as relevant to all tasks or excludes it from all models, which is very restrictive in practice where tasks may share some features but may also have their own specific features that are not relevant to other tasks. To overcome this limitation, one of the most effective strategies is to decompose the model parameters into either summation (Jalali et al., 2010; Chen et al., 2011; Gong et al., 2012) or multiplication (Xiong et al., 2006; Bi et al., 2008; Lozano and Swirszcz, 2012) of two components with separate regularizers applied to the two components. One regularizer is imposed on the component taking care of the task-specific model parameters and the other one is imposed on the component for mining the cross-feature sparsity. Specifically, for the methods that decompose the parameter matrix into summation of two matrices, the dirty model in (Jalali et al., 2010) employs $\ell_{1,1}$ and $\ell_{1,\infty}$ regularizers to the two components. A robust MTFL method in (Chen et al., 2011) uses the trace norm on one component for mining a low-rank structure shared by tasks and a column-wise $\ell_{1,2}$-norm on the other component for identifying task outliers. A more recent method applies the $\ell_{1,2}$-norm both row-wisely to one component and column-wisely to the other (Gong et al., 2012). For these additive decomposition methods, it requires the corresponding entries in both components to be zero in order to exclude a feature from a task.

For the methods that work with multiplicative decompositions, the parameter vector of each task is decomposed into an element-wise product of two vectors where one is used across tasks and the other is task-specific. To exclude a feature from a task, the multiplicative decomposition only requires one of the components to be zero. Existing methods of this line apply the same regularization to both of the component vectors, by either the ℓ_2-norm penalty (Bi et al., 2008), or the sparse ℓ_1-norm (i.e., multi-level LASSO (Lozano and Swirszcz, 2012)). The multi-level LASSO method has been analytically compared to the dirty model (Lozano and Swirszcz, 2012), showing that the multiplicative decomposition creates better shrinkage on the global and task-specific parameters. The across-task component can screen out the features irrelevant to all tasks. An individual task's component can further select features from those selected by the cross-task component for use in its corresponding model. Although there are different ways to regularize the two components in the product, no systematic work has been done to analyze the algorithmic and statistical properties of the different regularizers. It is insightful to answer the questions such as how these learning formulations differ from the early methods based on blockwise joint regularization, how the optimal solutions of the two components intervene, and how the resultant solutions are compared with those of other methods that also learn both shared and task-specific features. We highlight the contributions of this paper as follows:

- We propose and examine a general framework of the multiplicative decomposition that enables a variety of regularizers to be applied. The general form corresponds to a family of MTFL methods, including all early methods that decompose model parameters as a product of two components (Bi et al., 2008; Lozano and Swirszcz, 2012).

- Our theoretical analysis has revealed that this family of methods is actually equivalent to the joint regularization based approach but with a more general form of regularizers, including matrix-norm based and non-matrix-norm based regularizers. The non-matrix-norm based joint regularizers derived from the proposed framework have never been considered previously. If they are considered in the joint regularization form, the resultant optimization problems will be difficult to solve. However, our equivalent multiplicative MTFL framework in this case uses convex regularizers on the two components, which can be solved efficiently.

- Further analysis reveals that the optimal solution of the across-task component can be analytically computed by a formula of the optimal task-specific parameters. This analytical result facilitates a better understanding of the shrinkage effects of the different regularizers applied to the two components.

- Statistical justification is also derived for this family of formulations. It proves that the proposed framework is equivalent to maximizing a lower bound of the *maximum a posterior* solution under a probabilistic model that assumes generalized normal priors on model parameters.

- Two new MTFL formulations are derived from the proposed general framework. Unlike the existing methods (Bi et al., 2008; Lozano and Swirszcz, 2012) where the same kind of vector norm is applied to both components, the shrinkage of the global and task-specific parameters differs in the new formulations. We empirically illustrate the scenarios where the two new formulations are more suitable for solving the MTFL problems.

- An efficient blockwise coordinate descent algorithm is derived suitable for solving the entire family of the methods. Given some of the methods (including the two new formulations we study) correspond to non-matrix-norm based joint regularizers, our algorithm provides a powerful alternative to solving the related difficult optimization problems, allowing us to explore the behaviors and properties of these regularizers in an effective way. Convergence analysis is thoroughly discussed.

To depict the differences between our approach and previous methods, Table 1 summaries various regularizers used in the joint regularization based and model decomposition based MTFL methods. There are some fundamental connections among these methods. As studied in the present work, multiplicative MTFL models can be connected with the early blockwise joint regularization models. We also attempt to empirically compare the model behaviors between the multiplicative and additive MTFL methods, and particularly compare the applicability of the four different choices of regularization listed in Table 1 for multiplicative MTFL .

Table 1: The regularization terms used in various MTFL methods.

	Model	Methods	Norms
Joint regularization models	$\mathbf{A}$	Evgeniou and Pontil (2004)	$\ell_{1,2}$
		Turlach et al. (2005)	$\ell_{1,\infty}$
		Lee et al. (2010)	both $\ell_{1,1}$ and $\ell_{1,2}$
		Zhang et al. (2010)	$\ell_{1,p}, 1 < p \leq \infty$
		Gong et al. (2012)	capped $\ell_{1,1}$
Decomposed models	$\mathbf{A} = \mathbf{P} + \mathbf{Q}$	Jalali et al. (2010)	$\ell_{1,1}$ on $\mathbf{P}$, $\ell_{1,\infty}$ on $\mathbf{Q}$
		Gong et al. (2012)	$\ell_{1,2}$ on $\mathbf{P}$, $\ell_{1,2}$ on $\mathbf{Q}^T$
	$\mathbf{A} = \text{diag}(\mathbf{c}) \cdot \mathbf{B}$	**The proposed framework**	$(\ell_k)^k$ on $\mathbf{c}$, $(\ell_p)^p$ on $\mathbf{B}$
		Bi et al. (2008)	k=2, p=2
		Lozano and Swirszcz (2012)	k=1, p=1
		The new formulation 1	k=1, p=2
		The new formulation 2	k=2, p=1

The rest of the paper is organized as follows. Section 2 defines the mathematical notation and introduces the proposed models in detail. Section 3 discusses several important theoretical properties of the proposed models including equivalence analysis. Section 4 provides the statistical justification of the multiplicative MTFL models. In Section 5, we develop an efficient algorithm to solve the optimization problems in the proposed models with a convergence analysis. Section 6 shows the empirical results, in which simulations have been designed to examine the various feature sharing patterns for which a specific choice of regularizer may be preferred. Extensive experiments with a variety of classification and regression benchmark data sets are also described in Section 6. In Section 7, we conclude this work.

2. The Proposed Multiplicative MTFL

Given T tasks in total, for each task t, $t \in \{1, \cdots, T\}$, we have sample set ($\mathbf{X}_t \in \mathbb{R}^{\ell_t \times d}, \mathbf{y}_t \in \mathbb{R}^{\ell_t}$). The data set of $\mathbf{X}_t$ has ℓ_t examples, where the i-th row corresponds to the i-th example $\mathbf{x}_i^t$ of task t, $i \in \{1, \cdots, \ell_t\}$, and each column represents a feature and there are totally d features. The vector $\mathbf{y}_t$ contains y_i^t, the label of the i-th example of task t. We consider functions of the linear form $y_t = \boldsymbol{\alpha}_t^\top \mathbf{x}_i^t$ where $\boldsymbol{\alpha}_t \in \mathbb{R}^d$, which corresponds to computing $\mathbf{X}_t\boldsymbol{\alpha}_t$ on the training data as the estimate of $\mathbf{y}_t$. We define the parameter matrix or weight matrix $\mathbf{A} = [\boldsymbol{\alpha}_1, \cdots, \boldsymbol{\alpha}_T]$ and denote the rows of $\mathbf{A}$ by $\boldsymbol{\alpha}^j$, $j \in \{1, \cdots, d\}$.

The joint regularization based MTFL method with the $\ell_{1,p}$ regularizer minimizes

$$\sum_{t=1}^{T} L(\boldsymbol{\alpha}_t, \mathbf{X}_t, \mathbf{y}_t) + \lambda \sum_{j=1}^{d} ||\boldsymbol{\alpha}^j||_p, \tag{1}$$

for the best $\boldsymbol{\alpha}_{t:t=1,\cdots,T}$, where $L(\boldsymbol{\alpha}_t, \mathbf{X}_t, \mathbf{y}_t)$ is the loss function of task t which computes the discrepancy between the observed $\mathbf{y}_t$ and the model output $\mathbf{X}_t\boldsymbol{\alpha}_t$, and λ is a tuning parameter to balance between the loss and the regularizer. Although any suitable loss function can be used in the formulation (1), convex loss functions are the common choices such as the least squares loss $\sum_{i=1}^{\ell_t}(y_i^t - \boldsymbol{\alpha}_t^\top \mathbf{x}_i^t)^2$ for regression problems or the logistic loss

$\sum_{i=1}^{\ell_t} \log(1 + e^{-y_i^t(\boldsymbol{\alpha}_t^\top \mathbf{x}_i^t)})$ for classification problems. These loss functions are strictly convex with respect to the model parameters $\boldsymbol{\alpha}_t$. The ℓ_p norm is computed for each row of the matrix $\mathbf{A}$ corresponding to a feature (rather than a task) so to enforce sparsity on the features.

A family of multiplicative MTFL methods can be derived by rewriting $\boldsymbol{\alpha}_t = \text{diag}(\mathbf{c})\boldsymbol{\beta}_t$ where $\text{diag}(\mathbf{c})$ is a diagonal matrix with its diagonal elements composing a vector $\mathbf{c}$. The $\mathbf{c}$ vector is used across all tasks, indicating if a feature is useful for any of the tasks, and the vector $\boldsymbol{\beta}_t$ is only for task t. Let j index the entries in these vectors. We have $\alpha_j^t = c_j\beta_j^t$. Typically $\mathbf{c}$ comprises binary entries that are equal to 0 or 1, but the integer constraint is often relaxed to require just non-negativity ($\mathbf{c} \geq 0$). We minimize a regularized loss function as follows for the best $\mathbf{c}$ and $\boldsymbol{\beta}_{t:t=1,\cdots,T}$:

$$\min_{\boldsymbol{\beta}_t, \mathbf{c} \geq 0} \sum_{t=1}^{T} L(\mathbf{c}, \boldsymbol{\beta}_t, \mathbf{X}_t, \mathbf{y}_t) + \gamma_1 \sum_{t=1}^{T} ||\boldsymbol{\beta}_t||_p^p + \gamma_2 ||\mathbf{c}||_k^k, \tag{2}$$

where $L(\mathbf{c}, \boldsymbol{\beta}_t, \mathbf{X}_t, \mathbf{y}_t)$ is the same loss function used in Eq.(1) but with $\boldsymbol{\alpha}_t$ replaced by the new vector of $(c_j\beta_j^t)_{j=1,\cdots,d}$, $||\boldsymbol{\beta}_t||_p^p = \sum_{j=1}^{d} |\beta_j^t|^p$ and $||\mathbf{c}||_k^k = \sum_{j=1}^{d}(c_j)^k$, which are the ℓ_p-norm of $\boldsymbol{\beta}_t$ to the power of p and the ℓ_k-norm of $\mathbf{c}$ to the power of k if p and k are positive integers. The tuning parameters γ_1, γ_2 are used to balance the empirical loss and regularizers. At optimality, if $c_j = 0$, the j-th variable is removed for all tasks, and the corresponding row vector $\boldsymbol{\alpha}^j = \mathbf{0}$; otherwise the j-th variable is selected for use in at least one of the $\boldsymbol{\alpha}$'s. Then, a specific $\boldsymbol{\beta}_t$ can rule out the j-th variable from task t if $\beta_j^t = 0$.

If both $p = k = 2$, Problem (2) becomes the formulation used in Bi et al. (2008). Since the ℓ_2-norm regularization is applied on both $\boldsymbol{\beta}_t$ and $\mathbf{c}$, this model does not impose strong sparsity on the model parameters. According to our empirical study, this model may be suitable for the scenarios where only a few features can be excluded from all of the tasks, and the different models (tasks) share a lot features between each other. There could exist features that, although irrelevant to most of the tasks, cannot be completely excluded only due to few tasks.

If $p = k = 1$, Problem (2) becomes the formulation used in Lozano and Swirszcz (2012), where the ℓ_1-norm regularization is applied on $\boldsymbol{\beta}_t$ and $\mathbf{c}$ and thus it induces very strong sparsity both on task-specific parameters and the across-task component to select the features. Compared to the model in Bi et al. (2008), this model is more suitable for learning from the tasks with persistently sparse models. For example, many features are irrelevant to any of the tasks, and only a few of the features selected by $\mathbf{c}$ are used by an individual task, indicating the sparse pattern in sharing the selected features among tasks.

Besides the above two existing models, any other choices of p and k will derive into new formulations for MTFL. Note that the two existing methods discussed in Bi et al. (2008); Lozano and Swirszcz (2012) use $p = k$ in their formulations, which renders β_j^t and c_j the same amount of shrinkage. To explore other feature sharing patterns among tasks, we propose two new formulations where $p \neq k$.

Formulation 1:
If $p = 2$ but $k = 1$ in Problem (2), then we obtain the following optimization problem

$$\min_{\boldsymbol{\beta}_t, \mathbf{c} \geq 0} \sum_{t=1}^{T} L(\mathbf{c}, \boldsymbol{\beta}_t, \mathbf{X}_t, \mathbf{y}_t) + \gamma_1 \sum_{t=1}^{T} ||\boldsymbol{\beta}_t||_2^2 + \gamma_2 ||\mathbf{c}||_1. \tag{3}$$

When there exists a large subset of features irrelevant to any of the tasks, it requires a sparsity-inducing norm on $\mathbf{c}$. However, within the relevant features selected by $\mathbf{c}$, the majority of these features are shared between tasks. In other words, the features used in each task are not sparse relative to the features selected by $\mathbf{c}$, which requires a non-sparsity-inducing norm on $\boldsymbol{\beta}$. Hence, we use ℓ_1 norm on $\mathbf{c}$ and ℓ_2 norm on each $\boldsymbol{\beta}$ in our formulation (2).

Formulation 2:
If $p = 1$ but $k = 2$ in Problem (2), we obtain the following optimization problem

$$\min_{\boldsymbol{\beta}_t, \mathbf{c} \geq 0} \sum_{t=1}^{T} L(\mathbf{c}, \boldsymbol{\beta}_t, \mathbf{X}_t, \mathbf{y}_t) + \gamma_1 \sum_{t=1}^{T} ||\boldsymbol{\beta}_t||_1 + \gamma_2 ||\mathbf{c}||_2^2. \tag{4}$$

When the union of the features relevant to any given tasks includes many or even all features, the ℓ_2 norm penalty on $\mathbf{c}$ may be preferred. However, only a limited number of features are shared between tasks, i.e., the features used by individual tasks are sparse with respect to the features selected as useful across tasks by $\mathbf{c}$. We can impose the ℓ_1 norm penalty on $\boldsymbol{\beta}$.

Clearly, many other choices of p and k values can be used, such as those corresponding to higher order polynomials (e.g., $\sum_{j=1}^{d} c_j^3$). Our theoretical results in the next few sections apply to all positive value choices of p and k unless otherwise specified. In our empirical studies, however, we have implemented algorithms for the two existing models and the two new models for comparison. Some other choices of regularizers may require significant re-programming of our algorithms and we will leave them for more thorough individual examinations in the future.

3. Theoretical Analysis

We first extend the formulation (1) to allow more choices of regularizers. We introduce a new notation that is an operator applied to a vector, such as $\boldsymbol{\alpha}^j$. The operator $||\boldsymbol{\alpha}^j||_p^{p/q} = \sqrt[q]{\sum_{t=1}^{T} |\alpha_j^t|^p}$, $p, q \geq 0$, which corresponds to the ℓ_p norm if $p = q$ and both are positive integers. A joint regularized MTFL approach can solve the following optimization problem with pre-specified values of p, q and λ, for the best parameters $\boldsymbol{\alpha}_{t:t=1,\cdots,T}$:

$$\min_{\boldsymbol{\alpha}_t} \sum_{t=1}^{T} L(\boldsymbol{\alpha}_t, \mathbf{X}_t, \mathbf{y}_t) + \lambda \sum_{j=1}^{d} \sqrt{||\boldsymbol{\alpha}^j||_p^{p/q}}. \tag{5}$$

Our main results of this paper include (i) a theorem that establishes the equivalence between the models derived from solving Problem (2) and Problem (5) for properly chosen values of λ, q, k, γ_1 and γ_2; (ii) a theorem that delineates the conditions for (2) to impose a convex (or concave) regularizer on the model parameter matrix $\mathbf{A}$; and (iii) an analytical solution of Problem (2) for $\mathbf{c}$ which shows how the sparsity of the across-task component is relative to the sparsity of task-specific components.

Theorem 1 (Main Result 1) *Let $\hat{\boldsymbol{\alpha}}_t$ be the optimal solution to Problem (5) and ($\hat{\boldsymbol{\beta}}_t$, $\hat{\mathbf{c}}$) be the optimal solution to Problem (2). Then $\hat{\boldsymbol{\alpha}}_t = diag(\hat{\mathbf{c}})\hat{\boldsymbol{\beta}}_t$ when $\lambda = 2\sqrt{\gamma_1^{2-\frac{p}{kq}} \gamma_2^{\frac{p}{kq}}}$ and $q = \frac{k+p}{2k}$ (or equivalently, $k = \frac{p}{2q-1}$).*

Proof Theorem 1 can be proved by establishing the following two lemmas and two theorems. The two lemmas provide the basis for the proofs of the two theorems and then from the first theorem, we conclude that the solution $\hat{\boldsymbol{\alpha}}_t$ of Problem (5) also minimizes the following optimization problem:

$$\min_{\boldsymbol{\alpha}_t, \boldsymbol{\sigma} \geq 0} \sum_{t=1}^{T} L(\boldsymbol{\alpha}_t, \mathbf{X}_t, \mathbf{y}_t) + \mu_1 \sum_{j=1}^{d} \sigma_j^{-1} ||\boldsymbol{\alpha}^j||_p^{p/q} + \mu_2 \sum_{j=1}^{d} \sigma_j, \tag{6}$$

and the optimal solution of Problem (6) also minimizes Problem (5) when proper values of λ, μ_1 and μ_2 are chosen. The second theorem connects Problem (6) to the proposed formulation (2). We show that the optimal $\hat{\sigma}_j$ is equal to $(\hat{c}_j)^k$, and then the optimal $\hat{\boldsymbol{\alpha}}$ can be computed as $\text{diag}(\hat{\mathbf{c}})\hat{\boldsymbol{\beta}}_t$ from the optimal $\hat{\boldsymbol{\beta}}_t$. ■

Note that when $p = 2$ and $q = 1$, the intermediate problem (6) uses a similar regularizer to that in Micchelli et al. (2013) where $\frac{|\alpha^j|^2}{\sigma_j} + \sigma_j$ is used to approximate $|\alpha^j|$ in the ℓ_1-norm regularizer. Problem (6) extends the discussion in Micchelli et al. (2013) to include more general regularizers according to p and q.

Lemma 2 *For any given $\boldsymbol{\alpha}_{t:t=1,\cdots,T}$, Problem (6) can be optimized with respect to $\boldsymbol{\sigma}$ by the following analytical solution*

$$\sigma_j = \mu_1^{\frac{1}{2}} \mu_2^{-\frac{1}{2}} \sqrt{||\boldsymbol{\alpha}^j||_p^{p/q}}. \tag{7}$$

Proof By the Cauchy-Schwarz inequality, we can derive a lower bound for the sum of the two regularizers in Problem (6) as follows:

$$\mu_1 \sum_{j=1}^{d} \sigma_j^{-1} ||\boldsymbol{\alpha}^j||_p^{p/q} + \mu_2 \sum_{j=1}^{d} \sigma_j \geq 2\sqrt{\mu_1 \mu_2} \sum_{j=1}^{d} \sqrt{||\boldsymbol{\alpha}^j||_p^{p/q}}, \tag{8}$$

where the equality holds if and only if $\sigma_j = \mu_1^{\frac{1}{2}} \mu_2^{-\frac{1}{2}} \sqrt{||\boldsymbol{\alpha}^j||_p^{p/q}}$.

Using the method of proof by contradiction, suppose that $\boldsymbol{\sigma}^*$ optimizes Problem (6) with a given set of $\boldsymbol{\alpha}_{t:t=1,\cdots,T}$, but $\sigma_j^* \neq \mu_1^{\frac{1}{2}} \mu_2^{-\frac{1}{2}} \sqrt{||\boldsymbol{\alpha}^j||_p^{p/q}}$. Thus, $\boldsymbol{\sigma}^*$ does not make the regularization term reach its lower bound. Then, we can choose another $\tilde{\boldsymbol{\sigma}}$ where $\tilde{\sigma}_j = \mu_1^{\frac{1}{2}} \mu_2^{-\frac{1}{2}} \sqrt{||\boldsymbol{\alpha}^j||_p^{p/q}}$, so $\tilde{\boldsymbol{\sigma}}$ delivers the lower bound in Eq.(8). Because the lower bound (the right hand side of Eq.(8)) only depends on $\boldsymbol{\alpha}$, it is a constant for fixed $\boldsymbol{\alpha}_{t:t=1,\cdots,T}$. Hence, since the loss function is also fixed for given $\boldsymbol{\alpha}_{t:t=1,\cdots,T}$, $\tilde{\boldsymbol{\sigma}}$ reaches a lower objective value of Problem (6) than that of $\boldsymbol{\sigma}^*$, which contradicts to the optimality of $\boldsymbol{\sigma}^*$. Therefore, the optimal $\boldsymbol{\sigma}$ always takes the form of Eq.(7). ■

Remark 3 *Based on the proof of Lemma 2, we also know that the objective function of (5) is the lower bound of the objective function of (6) for any given $\boldsymbol{\alpha}_t$ (including the optimal $\hat{\boldsymbol{\alpha}}_t$) when $\lambda = 2\sqrt{\mu_1 \mu_2}$, and the lower bound can be attained if and only if $\boldsymbol{\sigma}$ is set according to the formula (7). Hence, we can also conclude that if $(\hat{\boldsymbol{\alpha}}_t, \hat{\boldsymbol{\sigma}})$ is the optimal solution of Problem (6), then $\hat{\sigma}_j = \mu_1^{\frac{1}{2}} \mu_2^{-\frac{1}{2}} \sqrt{||\hat{\boldsymbol{\alpha}}^j||_p^{p/q}}$.*

Lemma 4 *Let $\alpha_j^t = c_j\beta_j^t$ for all t and j. Replacing $\boldsymbol{\beta}_t$ by $\boldsymbol{\alpha}_t$ in Problem (2) yields the following optimization problem*

$$\min_{\boldsymbol{\alpha}_t, \mathbf{c}\geq 0} \sum_{t=1}^{T} L(\boldsymbol{\alpha}_t, \mathbf{X}_t, \mathbf{y}_t) + \gamma_1 \sum_{j=1}^{d} c_j^{-p}||\boldsymbol{\alpha}^j||_p^p + \gamma_2 \sum_{j=1}^{d}(c_j)^k. \tag{9}$$

For any given $\boldsymbol{\alpha}_{t:t=1,\cdots,T}$, Problem (9) can be optimized with respect to $\mathbf{c}$ by the following analytical solution

$$c_j = (\gamma_1\gamma_2^{-1}\sum_{t=1}^{T}(\alpha_j^t)^p)^{\frac{1}{p+k}}. \tag{10}$$

Proof This lemma can be proved following a similar argument in the proof of Lemma 2. By the Cauchy-Schwarz inequality, the sum of the two regularizers in (9) satisfies the following inequality

$$\gamma_1 \sum_{j=1}^{d} c_j^{-p}||\boldsymbol{\alpha}^j||_p^p + \gamma_2 \sum_{j=1}^{d} c_j^k \geq 2\gamma_1^{\frac{k}{p+k}}\gamma_2^{\frac{p}{p+k}} \sum_{j=1}^{d}(||\boldsymbol{\alpha}^j||_p^p)^{\frac{k}{p+k}}, \tag{11}$$

and the equality holds if and only if $\gamma_1 c_j^{-p}||\boldsymbol{\alpha}^j||_p^p = \gamma_2 c_j^k$ (and note that all parameters γ_1, γ_2, $||\hat{\boldsymbol{\alpha}}^j||_p^p$ and $\mathbf{c}$ are non-negative), which yields the following formula

$$c_j = (\gamma_1\gamma_2^{-1}\sum_{t=1}^{T}(\alpha_j^t)^p)^{\frac{1}{p+k}}.$$

Through proof by contradiction, we know that the optimal $\mathbf{c}$ has to take the above formula. ■

Based on Lemma 2, we will prove that Problem (5) is equivalent to Problem (6) in the sense that an optimal solution of Problem (5) is also an optimal solution of Problem (6) and vice versa when λ, μ_1, and μ_2 satisfy certain conditions.

Theorem 5 *The solution sets of Problem (5) and Problem (6) are identical when $\lambda = 2\sqrt{\mu_1\mu_2}$.*

Proof First, if $\hat{\mathbf{A}} = [\hat{\boldsymbol{\alpha}}_{t:t=1,\cdots,T}]$ minimizes Problem (5), we show that the pair $(\hat{\mathbf{A}}, \hat{\boldsymbol{\sigma}})$ minimizes Problem (6) where $\hat{\sigma}_j = \mu_1^{\frac{1}{2}}\mu_2^{-\frac{1}{2}}\sqrt{||\hat{\boldsymbol{\alpha}}^j||_p^{p/q}}$.

By Remark 3, the objective function of (5) is the lower bound of the objective function of (6) for any given $\mathbf{A}$ (including the optimal solution $\hat{\mathbf{A}}$). When $\hat{\sigma}_j = \mu_1^{\frac{1}{2}}\mu_2^{-\frac{1}{2}}\sqrt{||\hat{\boldsymbol{\alpha}}^j||_p^{p/q}}$, Problem (6) reaches the lower bound. In this case, Problem (5) at $\hat{\mathbf{A}}$ and Problem (6) at $(\hat{\mathbf{A}}, \hat{\boldsymbol{\sigma}})$ have the same objective value. Now, suppose that the pair $(\hat{\mathbf{A}}, \hat{\boldsymbol{\sigma}})$ does not minimize Problem (6), there exists another pair $(\tilde{\mathbf{A}}, \tilde{\boldsymbol{\sigma}}) \neq (\hat{\mathbf{A}}, \hat{\boldsymbol{\sigma}})$ that achieves a lower objective value than that of $(\hat{\mathbf{A}}, \hat{\boldsymbol{\sigma}})$. By Lemma 2, we have that $\tilde{\sigma}_j = \mu_1^{\frac{1}{2}}\mu_2^{-\frac{1}{2}}\sqrt{||\tilde{\boldsymbol{\alpha}}^j||_p^{p/q}}$, and then Problem (6), at $\tilde{\mathbf{A}}$, reaches the lower bound which is formulated as the objective of Problem (5)

when $\lambda = 2\sqrt{\mu_1\mu_2}$. In other words, the objective values of (6) and (5) are identical at $\tilde{\mathbf{A}}$. Hence, $\tilde{\mathbf{A}}$ achieves a lower objective value than that of $\hat{\mathbf{A}}$ for Problem (5), contradicting to the optimality of $\hat{\mathbf{A}}$.

Second, if $(\hat{\mathbf{A}}, \hat{\boldsymbol{\sigma}})$ minimizes Problem (6), we show that $\hat{\mathbf{A}}$ minimizes Problem (5).

Suppose that $\hat{\mathbf{A}}$ does not minimize Problem (5), which means that there exists $\tilde{\boldsymbol{\alpha}}^j$ ($\neq \hat{\boldsymbol{\alpha}}^j$ for some j) that achieves a lower objective value than that of $\hat{\boldsymbol{\alpha}}^j$. We set $\tilde{\sigma}_j = \mu_1^{\frac{1}{2}}\mu_2^{-\frac{1}{2}}\sqrt{||\tilde{\boldsymbol{\alpha}}^j||_p^{p/q}}$. Then $(\hat{\mathbf{A}}, \tilde{\boldsymbol{\sigma}})$ is an optimal solution of Problem (6) as proved in the first paragraph, and will bring the objective function of Problem (6) to a lower value than that of $(\hat{\mathbf{A}}, \hat{\boldsymbol{\sigma}})$, contradicting to the optimality of $(\hat{\mathbf{A}}, \hat{\boldsymbol{\sigma}})$.

Therefore, Problems (5) and (6) have identical solution sets when $\lambda = 2\sqrt{\mu_1\mu_2}$. ■

In order to link Problem (6) to our formulation (2), we let $\sigma_j = (c_j)^k$, $k \in \mathbb{R}$, $k \neq 0$ and $\alpha_j^t = c_j\beta_j^t$ for all t and j, and derive an equivalent objective function of Problem (6) based on Lemmas 2 and 4.

Theorem 6 *The optimal solution $(\hat{\mathbf{A}}, \hat{\boldsymbol{\sigma}})$ of Problem (6) is equivalent to the optimal solution $(\hat{\mathbf{B}}, \hat{\mathbf{c}})$ of Problem (2) where $\hat{\alpha}_j^t = \hat{c}_j\hat{\beta}_j^t$ and $\hat{\sigma}_j = (\hat{c}_j)^k$ when $\gamma_1 = \mu_1^{\frac{kq}{2kq-p}}\mu_2^{\frac{kq-p}{2kq-p}}$, $\gamma_2 = \mu_2$, and $k = \frac{p}{2q-1}$.*

Proof First, if $\hat{\alpha}_j^t$ and $\hat{\sigma}_j$ optimize Problem (6), we show that $\hat{c}_j = \sqrt[k]{\hat{\sigma}_j}$ and $\hat{\beta}_j^t = \hat{\alpha}_j^t/\hat{c}_j$ optimize Problem (2).

By a change of variables (replacing $\hat{\boldsymbol{\alpha}}_t$ and $\hat{\boldsymbol{\sigma}}$ by $\hat{\boldsymbol{\beta}}_t$ and $\hat{\mathbf{c}}$ in Problem (6)), we know that $\hat{\boldsymbol{\beta}}_t$ and $\hat{\mathbf{c}}$ minimize the following objective function

$$J(\hat{\beta}_j^t, \hat{c}_j) = \sum_{t=1}^{T} L(\hat{\mathbf{c}}, \hat{\boldsymbol{\beta}}_t, \mathbf{X}_t, \mathbf{y}_t) + \mu_1 \sum_{j=1}^{d} ||\hat{\boldsymbol{\beta}}^j||_p^{p/q}\hat{c}_j^{(p-kq)/q} + \mu_2 \sum_{j=1}^{d}(\hat{c}_j)^k. \tag{12}$$

By Lemma 2 and Remark 3, the optimal $\hat{\sigma}_j = \mu_1^{\frac{1}{2}}\mu_2^{-\frac{1}{2}}\sqrt{||\hat{\boldsymbol{\alpha}}^j||_p^{p/q}}$. Because $\hat{c}_j = \sqrt[k]{\hat{\sigma}_j}$, we derive that

$$\hat{c}_j = \left(\mu_1\mu_2^{-1}||\hat{\boldsymbol{\beta}}^j||_p^{p/q}\right)^{\frac{q}{2kq-p}}.$$

Substituting the formula of $\hat{c}_j$ into Eq.(12) yields the same objective function of Problem (2) after replacing μ_1 and μ_2 by γ_1 and γ_2 with the equations $\gamma_1 = \mu_1^{\frac{kq}{2kq-p}}\mu_2^{\frac{kq-p}{2kq-p}}$, $\gamma_2 = \mu_2$. Therefore, $\hat{\boldsymbol{\beta}}_t$ and $\hat{\mathbf{c}}$ optimize Problem (2) because otherwise, if any other solution $(\boldsymbol{\beta}, \mathbf{c})$ can further reduce the objective value of Problem (2), then the corresponding $\boldsymbol{\alpha}$ and $\boldsymbol{\sigma}$ will bring the objective function of Problem (6) to a lower value than $\hat{\boldsymbol{\alpha}}$ and $\hat{\boldsymbol{\sigma}}$.

Next, if $\hat{\beta}_j^t$ and $\hat{c}_j$ optimize Problem (2), we show that $\hat{\alpha}_j^t = \hat{c}_j\hat{\beta}_j^t$ and $\hat{\sigma}_j = (\hat{c}_j)^k$ optimize Problem (6).

Substituting $\hat{\alpha}_j^t$, $\hat{\sigma}_j$ for $\hat{\beta}_j^t$, $\hat{c}_j$ in Problem (2) yields an objective function

$$J(\hat{\alpha}_j^t, \hat{\sigma}_j) = \sum_{t=1}^{T} L(\hat{\boldsymbol{\alpha}}_t, \mathbf{X}_t, \mathbf{y}_t) + \gamma_1 \sum_{j=1}^{d} ||\hat{\boldsymbol{\alpha}}^j||_p^p\hat{\sigma}_j^{-(p/k)} + \gamma_2 \sum_{j=1}^{d}\hat{\sigma}_j. \tag{13}$$

We hence know that $\hat{\alpha}_j^t$ and $\hat{\sigma}_j$ minimize Eq.(13). Similar to the proof of Lemma 4, we can show that the optimal $\hat{\boldsymbol{\sigma}}$ takes the form of

$$\hat{\sigma}_j = (\gamma_1\gamma_2^{-1})^{\frac{k}{k+p}}(||\hat{\boldsymbol{\alpha}}^j||_p^p)^{\frac{k}{k+p}}.$$

Substituting the formula into Eq.(13) and setting $\gamma_1 = \mu_1^{\frac{kq}{2kq-p}}\mu_2^{\frac{kq-p}{2kq-p}}$ and $\gamma_2 = \mu_2$ transfer Eq.(13) to the objective function of Problem (6). Thus, $\hat{\alpha}_j^t$ and $\hat{\sigma}_j$ optimize Problem (6). ■

Now, based on the above two lemmas and two theorems, we can derive that when $\lambda = 2\sqrt{\gamma_1^{2-\frac{p}{kq}}\gamma_2^{\frac{p}{kq}}}$ and $q = \frac{k+p}{2k}$, the optimal solutions to Problems (2) and (5) are equivalent. Solving Problem (2) will yield an optimal solution $\hat{\boldsymbol{\alpha}}$ to Problem (5) and vice versa.

By the equivalence analysis, the proposed framework corresponds to a family of joint regularization methods as defined by Eq.(5). Assuming a convex loss function is used, this family includes some convex formulations when convex regularizers are applied to $\mathbf{A}$ in (5) and some other non-convex formulations when non-matrix-norm based regularizers are applied to $\mathbf{A}$. Particularly, when $q = p/2$, the regularization term on $\boldsymbol{\alpha}^j$ in (5) becomes the standard ℓ_p-norm. Correspondingly, when $k = p/(p-1)$ which is commonly not an integer except $p = 2$, our formulation (2) amounts to imposing a $\ell_{1,p}$-norm on $\mathbf{A}$. When both k and p take positive integers (except $p = k = 2$), Problem (2) is equivalent to using a non-matrix-norm regularizer in (5). Combinations of different p and k values will render the models different algorithmic behaviors.

Theorem 7 (Main Result 2) *For any positive k and p, if $kp \geq k+p$, then the formulation (2) imposes a convex regularizer on the model parameter matrix $\mathbf{A}$; or otherwise, it imposes a concave regularizer on $\mathbf{A}$.*

Proof According to Theorem 1, the formulation (2) is equivalent to the formulation (5) that imposes the following regularizer on $\mathbf{A}$:

$$\lambda\sum_{j=1}^{d}\sqrt{||\boldsymbol{\alpha}^j||_p^{p/q}} = \lambda\sum_{j=1}^{d}(||\boldsymbol{\alpha}^j||_p)^{\frac{p}{2q}} = \lambda\sum_{j=1}^{d}(||\boldsymbol{\alpha}^j||_p)^{\frac{kp}{k+q}}. \tag{14}$$

where $q = \frac{k+p}{2k}$ and $\lambda = 2\sqrt{\gamma_1^{2-\frac{p}{kq}}\gamma_2^{\frac{p}{kq}}}$.

A function x^a is a convex function in terms of $x > 0$ if $a \geq 1$; or otherwise, it is concave. Hence, if $kp \geq k+p$, Eq.(14) is a composite function of two functions: a convex function $x^{\frac{kp}{k+p}}$ and another convex function which is the ℓ_p vector norm of $\boldsymbol{\alpha}^j$. Thus, the overall regularizer is convex. Otherwise, if $kp < k+p$, the regularizer becomes a concave function in terms of $\boldsymbol{\alpha}$'s. ■

Remark 8 *For a particular choice of $p = 2$ and $k = 2$, Problem (2) is formulated as*

$$\min_{\boldsymbol{\beta}_t,\mathbf{c}\geq 0}\ \sum_{t=1}^{T}L(\mathbf{c},\boldsymbol{\beta}_t,\mathbf{X}_t,\mathbf{y}_t) + \gamma_1\sum_{t=1}^{T}||\boldsymbol{\beta}_t||_2^2 + \gamma_2||\mathbf{c}||_2^2, \tag{15}$$

which is used in Bi et al. (2008). This problem is equivalent to the following joint regularization method as used in Obozinski and Taskar (2006); Argyriou et al. (2007).

$$\min_{\boldsymbol{\alpha}_t}\sum_{t=1}^{T}L(\boldsymbol{\alpha}_t,\mathbf{X}_t,\mathbf{y}_t) + \lambda\sum_{j=1}^{d}\sqrt{\sum_{t=1}^{T}(\alpha_j^t)^2}, \tag{16}$$

when $\lambda = 2\sqrt{\gamma_1\gamma_2}$. Problem (16) uses the so called $\ell_{1,2}$-norm to regularize the matrix $\mathbf{A}$.

Remark 9 *For a particular choice of $p = 1$ and $k = 1$, Problem (2) is formulated as*

$$\min_{\boldsymbol{\beta}_t,\mathbf{c}\geq 0}\ \sum_{t=1}^{T}L(\mathbf{c},\boldsymbol{\beta}_t,\mathbf{X}_t,\mathbf{y}_t) + \gamma_1\sum_{t=1}^{T}||\boldsymbol{\beta}_t||_1 + \gamma_2||\mathbf{c}||_1, \tag{17}$$

which is used in Lozano and Swirszcz (2012). This problem is equivalent to the following joint regularization method

$$\min_{\boldsymbol{\alpha}_t}\sum_{t=1}^{T}L(\boldsymbol{\alpha}_t,\mathbf{X}_t,\mathbf{y}_t) + \lambda\sum_{j=1}^{d}\sqrt{\sum_{t=1}^{T}|\alpha_j^t|}, \tag{18}$$

when $\lambda = 2\sqrt{\gamma_1\gamma_2}$. Problem (17) imposes stronger sparsity on $\boldsymbol{\beta}$ and $\mathbf{c}$ (and correspondingly on $\boldsymbol{\alpha}$) than (15), which intends to shrink more model parameters to zero. Problem (18) uses a concave non-matrix-norm regularizer.

Remark 10 *For a particular choice of $p = 2$ and $k = 1$, which corresponds to the new formulation (3). This problem is equivalent to the following joint regularization method*

$$\min_{\boldsymbol{\alpha}_t}\sum_{t=1}^{T}L(\boldsymbol{\alpha}_t,\mathbf{X}_t,\mathbf{y}_t) + \lambda\sum_{j=1}^{d}\sqrt[3]{\sum_{t=1}^{T}(\alpha_j^t)^2}, \tag{19}$$

when $\lambda = 2\gamma_1^{\frac{1}{3}}\gamma_2^{\frac{2}{3}}$. Problem (19) uses a concave non-matrix-norm regularizer as well but the concavity is weaker than Problem (18) in the sense that the polynomial order is $\frac{2}{3}$ rather than $\frac{1}{2}$.

The proposed formulation (3) imposes stronger sparsity induction on the across-task component than on the task-specific component. Thus, it has stronger shrinkage effects to exclude many features for all the tasks. If the jth feature is considered as unrelated to most of the tasks, the model of $p = k = 2$ may shrink c_j to a small value but not zero, the new model (3) might shrink c_j to zero instead. Therefore this model would be more favorable to jointly learning from tasks where a large portion of noisy features exist that may be irrelevant or redundant to all of the tasks. Compared to the method in Lozano and Swirszcz (2012) where $p = k = 1$, the new formulation (3) may allow more selected features to be shared across different tasks.

Remark 11 *For a particular choice of $p = 1$ and $k = 2$, which corresponds to the new formulation (4). This problem is equivalent to the following joint regularization method*

$$\min_{\boldsymbol{\alpha}_t} \sum_{t=1}^{T} L(\boldsymbol{\alpha}_t, \mathbf{X}_t, \mathbf{y}_t) + \lambda \sum_{j=1}^{d} \sqrt[3]{\left(\sum_{t=1}^{T} |\alpha_j^t|\right)^2}, \tag{20}$$

when $\lambda = 2\gamma_1^{\frac{2}{3}}\gamma_2^{\frac{1}{3}}$. Problem (20) uses another concave non-matrix-norm regularizer that has the similar polynomial order of $\frac{2}{3}$ to Problem (19). In comparison with (19), the cross-task quadratic terms (e.g., $|\alpha_j^1||\alpha_j^2|$, $|\alpha_j^2||\alpha_j^3|$) are allowed inside the cube root in this formulation.

The new formulation (4) imposes stronger sparsity induction on task-specific component than on the across-task vector. This model can be favorable in the cases where few tasks share a limited number of selected features. As shown in our empirical results, for instance, when every two or three tasks share a limited subset of selected features but no common features are used by more than three tasks, this model performs the best among the four multiplicative MTFL formulations. In comparison to the model in Lozano and Swirszcz (2012), this model allows more of the features that are only relevant to a few tasks to be selected. In comparison with the model in Bi et al. (2008), this model can help to remove a lot of irrelevant or redundant features for individual tasks from the selected features.

We further derive another main result that characterizes the optimal across-task vector as a formula of the optimal task-specific vectors. This connection can be easily developed from the above equivalence analysis, and can help us understand the relationship and interaction between the two components.

Theorem 12 (Main Result 3) *Let $\hat{\boldsymbol{\beta}}_t$, $t = 1, \cdots, T$, be the optimal solutions of Problem (2), Let $\hat{\mathbf{B}} = [\hat{\boldsymbol{\beta}}_1, \cdots, \hat{\boldsymbol{\beta}}_T]$ and $\hat{\boldsymbol{\beta}}^j$ denote the j-th row of the matrix $\hat{\mathbf{B}}$. Then,*

$$\hat{c}_j = (\gamma_1/\gamma_2)^{\frac{1}{k}} \sqrt[k]{\sum_{t=1}^{T} (\hat{\beta}_j^t)^p}, \tag{21}$$

for all $j = 1, \cdots, d$, is optimal to Problem (2).

Proof This analytical formula can be directly derived from Theorem 5 and Theorem 6. When we set $\hat{\sigma}_j = (\hat{c}_j)^k$ and $\hat{\alpha}_j^t = \hat{c}_j \hat{\beta}_j^t$ in the proof of Theorem 6, we obtain $\hat{c}_j = \left(\mu_1 \mu_2^{-1} ||\hat{\boldsymbol{\beta}}^j||_p^{p/q}\right)^{\frac{q}{2kq-p}}$. In the same proof, we also show that $\mu_1 = \gamma_1^{\frac{2kq-p}{kq}} \gamma_2^{\frac{p-kq}{kq}}$ and $\mu_2 = \gamma_2$. Substituting these formulas into the formula of $\mathbf{c}$ yields $\hat{c}_j = (\gamma_1/\gamma_2)^{\frac{1}{k}} ||\hat{\boldsymbol{\beta}}^j||^{\frac{p}{2kq-p}}$. Moreover, to establish the equivalence between (2) and (5), we require $q = \frac{k+p}{2k}$, which leads to $k = 2kq - p$. Hence, $||\hat{\boldsymbol{\beta}}^j||^{\frac{p}{2kq-p}} = \sqrt[k]{\sum_{t=1}^{T} (\hat{\beta}_j^t)^p}$. We then obtain the formula (21). ■

Remark 13 *For particular choices of p and k, the relation between the optimal $\mathbf{c}$ and $\boldsymbol{\beta}$ can be computed according to Theorem 12. Table 2 summarizes the relation formula for the common choices when $p \in \{1, 2\}$ and $k \in \{1, 2\}$.*

Table 2: The shrinkage effect of $\mathbf{c}$ with respect to $\boldsymbol{\beta}$ for four common choices of p and k.

p	k	$\mathbf{c}$
2	2	$\hat{c}_j = \sqrt{\gamma_1\gamma_2^{-1}}\sqrt{\sum_{t=1}^{T}(\hat{\beta}_j^t)^2}$
1	1	$\hat{c}_j = \gamma_1\gamma_2^{-1}\sum_{t=1}^{T}\lvert\hat{\beta}_j^t\rvert$
2	1	$\hat{c}_j = \gamma_1\gamma_2^{-1}\sum_{t=1}^{T}(\hat{\beta}_j^t)^2$
1	2	$\hat{c}_j = \sqrt{\gamma_1\gamma_2^{-1}}\sqrt{\sum_{t=1}^{T}\lvert\hat{\beta}_j^t\rvert}$

4. Probabilistic Interpretation

In this section we show that the proposed multiplicative formalism is related to the *maximum a posteriori* (MAP) solution of a probabilistic model. Let $p(\mathbf{A}|\boldsymbol{\Delta})$ be the prior distribution of the weight matrix $\mathbf{A} = [\boldsymbol{\alpha}_1, \ldots, \boldsymbol{\alpha}_T] = [\boldsymbol{\alpha}^{1\top}, \ldots, \boldsymbol{\alpha}^{d\top}]^\top \in \mathbb{R}^{d\times T}$, where $\boldsymbol{\Delta}$ denote the parameter of the prior. Then the *a posteriori* distribution of $\mathbf{A}$ can be calculated via Bayes rule as

$$p(\mathbf{A}|\mathbf{X}, \mathbf{y}, \boldsymbol{\Delta}) \propto p(\mathbf{A}|\boldsymbol{\Delta}) \prod_{t=1}^{T} p(\mathbf{y}_t|\mathbf{X}_t, \boldsymbol{\alpha}_t). \tag{22}$$

Denote $z \sim \mathcal{GN}(\mu, \rho, p)$ the *univariate generalized normal distribution*, with the density function

$$p(z) = \frac{1}{2\rho\Gamma(1 + 1/p)} \exp\left(-\frac{|z-\mu|^p}{\rho^p}\right), \tag{23}$$

in which $\rho > 0$, $p > 0$, and $\Gamma(\cdot)$ is the Gamma function (Goodman and Kotz, 1973). Now let each element of $\mathbf{A}$, α_j^t, follow a generalized normal prior, $\alpha_j^t \sim \mathcal{GN}(0, \delta_j, p)$. Then with the *independent and identically distributed* assumption, the prior takes the form (also refer to Zhang et al. (2010) for a similar treatment)

$$p(\mathbf{A}|\boldsymbol{\Delta}) \propto \prod_{j=1}^{d}\prod_{t=1}^{T} \frac{1}{\delta_j} \exp\Big(-\frac{|\alpha_j^t|^p}{\delta_j^p}\Big) = \prod_{j=1}^{d} \frac{1}{\delta_j^T} \exp\Big(-\frac{\|\boldsymbol{\alpha}^j\|_p^p}{\delta_j^p}\Big), \tag{24}$$

where $\|\cdot\|_p$ denotes the vector p-norm. With an appropriately chosen likelihood function $p(\mathbf{y}_t|\mathbf{X}_t, \boldsymbol{\alpha}_t) \propto \exp(-L(\boldsymbol{\alpha}_t, \mathbf{X}_t, \mathbf{y}_t))$, finding the MAP solution is equivalent to solving the following problem:

$$\min_{\mathbf{A},\boldsymbol{\Delta}} \quad J = \sum_{t=1}^{T} L(\boldsymbol{\alpha}_t, \mathbf{X}_t, \mathbf{y}_t) + \sum_{j=1}^{d} \Big(\frac{\|\boldsymbol{\alpha}^j\|_p^p}{\delta_j^p} + T\ln\delta_j\Big). \tag{25}$$

Setting the derivative of J with respect to δ_j to zero, we obtain:

$$\delta_j = \Big(\frac{p}{T}\Big)^{1/p} \|\boldsymbol{\alpha}^j\|_p. \tag{26}$$

Bringing this back to (25), we have the following equivalent problem:

$$\min_{\mathbf{A}} \quad J = \sum\nolimits_{t=1}^{T} L(\boldsymbol{\alpha}_t, \mathbf{X}_t, \mathbf{y}_t) + T \sum\nolimits_{j=1}^{d} \ln \|\boldsymbol{\alpha}^j\|_p. \tag{27}$$

Now let us look at the multiplicative nature of α_j^t with different $p \in [1, \infty)$.

When $p = 1$, we have:

$$\begin{aligned}
\sum_{j=1}^{d} \ln \|\boldsymbol{\alpha}^j\|_1 &= \sum_{j=1}^{d} \ln \left(\sum_{t=1}^{T} |\alpha_j^t| \right) \\
&= \sum_{j=1}^{d} \ln \left(\sum_{t=1}^{T} |c_j \beta_j^t| \right) \\
&= \sum_{j=1}^{d} \left(\ln |c_j| + \ln \sum_{t=1}^{T} |\beta_j^t| \right) \\
&\leq \sum_{j=1}^{d} |c_j| + \sum_{j=1}^{d} \sum_{t=1}^{T} |\beta_j^t| - 2d,
\end{aligned}$$

where the inequality is because of the fact that $\ln z \leq z - 1$ for any $z > 0$. Therefore we can optimize an upper bound of J in (27),

$$\min_{\mathbf{A}} \; J_1 = \sum_{t=1}^{T} L(\boldsymbol{\alpha}_t, \mathbf{X}_t, \mathbf{y}_t) + T \sum_{j=1}^{d} |c_j| + T \sum_{j=1}^{d} \sum_{t=1}^{T} |\beta_j^t| - 2dT, \tag{28}$$

which is equivalent to the multiplicative formulation (2) where $\{p, k\} = \{1, 1\}$. This proves the following theorem:

Theorem 14 *When $\{p, k\} = \{1, 1\}$, optimizing the multiplicative formulation* (2) *is equivalent to maximizing a lower bound of the MAP solution under probabilistic model* (22) *with $p = 1$ in the prior definition.*

In the general case, we have:

$$\begin{aligned}
\sum_{j=1}^{d} \ln \|\boldsymbol{\alpha}^j\|_p &= \frac{1}{p} \sum_{j=1}^{d} \ln \left(\sum_{t=1}^{T} |c_j \beta_j^t|^p \right) \\
&= \frac{1}{p} \sum_{j=1}^{d} \ln \left((c_j^k)^{\frac{p}{k}} \cdot \sum_{t=1}^{T} |\beta_j^t|^p \right) \\
&= \frac{1}{k} \sum_{j=1}^{d} \ln |c_j|^k + \frac{1}{p} \sum_{j=1}^{d} \ln \sum_{t=1}^{T} |\beta_j^t|^p \\
&\leq \frac{1}{k} \sum_{j=1}^{d} |c_j|^k + \frac{1}{p} \sum_{t=1}^{T} \|\boldsymbol{\beta}_t\|_p^p - d(\frac{1}{k} + \frac{1}{p}).
\end{aligned}$$

These inequalities lead to an upper bound of J in (27). By minimizing the upper bound, the problem is formulated as:

$$\min_{\mathbf{A}} \quad J_{p,k} = \sum_{t=1}^{T} L(\boldsymbol{\alpha}_t, \mathbf{X}_t, \mathbf{y}_t) + \frac{T}{k} \|\mathbf{c}\|_k^k + \frac{T}{p} \sum_{t=1}^{T} \|\boldsymbol{\beta}_t\|_p^p, \tag{29}$$

which is equivalent to the general multiplicative formulation in (2). Therefore we have proved the following theorem:

Theorem 15 *Optimizing the multiplicative formulation* (2)*, in the form of* (29)*, is equivalent to maximizing a lower bound of the MAP solution under probabilistic model* (22) *with $p \in (1, \infty)$ in the prior definition.*

5. Optimization Algorithm

Alternating optimization algorithms have been used in both of the early methods (Bi et al., 2008; Lozano and Swirszcz, 2012) to solve Problem (2) which alternate between solving two subproblems: solve for $\boldsymbol{\beta}_t$ with fixed $\mathbf{c}$; solve for $\mathbf{c}$ with fixed $\boldsymbol{\beta}_t$. The convergence property of such an alternating algorithm has been analyzed in Bi et al. (2008); Lozano and Swirszcz (2012) that it converges to a local minimizer. In these early methods, both of the two subproblems have to be solved using iterative algorithms such as gradient descent, linear or quadratic program solvers.

Besides the algorithm that solves for $\mathbf{c}$ and $\boldsymbol{\beta}_t$ alternatively and can be applied to our formulations, we design an alternating optimization algorithm that utilizes the closed-form solution for $\mathbf{c}$ we have derived in Lemma 4 and the property that both Problems (2) and (5) are equivalent to the intermediate Problem (6) (or Problem (9)). In the algorithm to solve Problem (2), we start from an initial choice of $\mathbf{c}$. At iteration s, we start from $\mathbf{c}^s$, and solve for $\boldsymbol{\beta}_t^s$ with the fixed $\mathbf{c}^s$. We then compute the value of $\boldsymbol{\alpha}_t^s = \text{diag}(\mathbf{c}^s)\boldsymbol{\beta}_t^s$, which is used to update $\mathbf{c}^s$ to $\mathbf{c}^{s+1}$ according to Eq.(10) in Lemma 4. The overall procedure is summarized in **Algorithm 1**. As a central idea in designing this algorithm, at each iteration we update $\boldsymbol{\beta}$ to reduce the loss function, and update $\mathbf{c}$ to reduce the regularizer while maintaining the same loss function value. Note that if the value of $\boldsymbol{\alpha}$ is fixed, the loss will remain the same.

To analyze the convergence property of Algorithm 1, we utilize the fact that Problem (2) and Problem (9) are equivalent. For notational convenience, we denote the objective function of Problem (2) by $g(\mathbf{B}, \mathbf{c})$ that takes inputs $\boldsymbol{\beta}_t$ and $\mathbf{c}$. We denote the objective function of Problem (9) by $f(\mathbf{A}, \mathbf{c})$. Both objective functions comprise the sum of three parts. For instance, f can be written as follows:

$$f(\mathbf{A}, \mathbf{c}) = f_0(\mathbf{A}, \mathbf{c}) + f_{\mathbf{A}}(\mathbf{A}) + f_{\mathbf{c}}(\mathbf{c}), \tag{31}$$

where $f_0(\mathbf{A}, \mathbf{c}) = \gamma_1 \sum_{j=1}^{d} (c_j^{-p} \sum_{t=1}^{T} (\alpha_j^t)^p)$ is the part that involves both $\boldsymbol{\alpha}$ and $\mathbf{c}$, $f_{\mathbf{A}}(\mathbf{A}) = \sum_t L(\boldsymbol{\alpha}_t, \mathbf{X}_t, \mathbf{y}_t)$ is the part relying only on $\boldsymbol{\alpha}$, and $f_{\mathbf{c}}(\mathbf{c}) = \mu_2 \sum_{j=1}^{d} (c_j)^k$ is the part for $\mathbf{c}$ only. Let $\mathbf{z}$ be the vector consisting of all variables in Problem (9). Similar to what has been defined in Tseng (2001), we define that the point $\mathbf{z}$ is a stationary point of f if $\mathbf{z} \in dom\ f$ where $dom\ f$ is the feasible region of f, and

$$\lim_{\lambda \to 0} [f(\mathbf{z} + \lambda \mathbf{b}) - f(\mathbf{z})]/\lambda \geq 0, \quad \forall \mathbf{b} \quad \text{such that} \quad (\mathbf{z} + \lambda \mathbf{b}) \in dom\ f. \tag{32}$$

Algorithm 1 The blockwise coordinate descent algorithm for multiplicative MTFL

Input: $\mathbf{X}_t$, $\mathbf{y}_t$, $t = 1, \cdots, T$, as well as γ_1, γ_2, p and k
Initialize: $c_j = 1$, $\forall j = 1, \cdots, d$, and $s = 1$
repeat
  Compute $\tilde{\mathbf{X}}_t = \mathbf{X}_t \text{diag}(\mathbf{c}^s)$, $\forall\, t = 1, \cdots, T$
  for $t = 1, \cdots, T$ **do**
    Solve the following problem for $\boldsymbol{\beta}_t^s$

$$\min_{\boldsymbol{\beta}_t} L(\boldsymbol{\beta}_t, \tilde{\mathbf{X}}_t, \mathbf{y}_t) + \gamma_1 ||\boldsymbol{\beta}_t||_p^p \tag{30}$$

  end for
  Compute $\boldsymbol{\alpha}_t^s = \text{diag}(\mathbf{c}^s)\boldsymbol{\beta}_t^s$
  Set $s = s + 1$
  Compute $\mathbf{c}^{s+1}$ using $\boldsymbol{\alpha}_t^s$ according to Eq.(10)
until $\max_{t,j}(|(\alpha_j^t)^s - (\alpha_j^t)^{s-1}|) < \epsilon$ (or other proper termination rules)
Output: $\boldsymbol{\alpha}_t$, $\mathbf{c}$ and $\boldsymbol{\beta}_t$, $t = 1, \cdots, T$

where $\mathbf{b}$ denotes any feasible direction, (which corresponds to $\bigtriangledown f(\mathbf{z}) = 0$ if f is differentiable, or $\mathbf{0} \in \partial f(\mathbf{z})$ if f is non-differentiable where $\partial f(\mathbf{z})$ is the subgradient of f at $\mathbf{z}$). In our case, f is not differentiable at $\boldsymbol{\alpha} = 0$ or $\mathbf{c} = 0$ when p is set to an odd number. We also define that a point $\mathbf{z}$ is a coordinate-wise minimum point of f if $\mathbf{z} \in dom\ f$, and $\forall \mathbf{b}_k \in \mathbb{R}^{d_k}$ that makes $(0, \cdots, \mathbf{b}_k, \cdots, 0)$ a feasible direction, there exists a small $\epsilon > 0$, such that for all positive $\lambda \leq \epsilon$,

$$f(\mathbf{z} + \lambda(0, \cdots, \mathbf{b}_k, \cdots, 0)) \geq f(\mathbf{z}), \tag{33}$$

where k indexes the blocks of variables in our algorithm, which include $\boldsymbol{\alpha}_1, \cdots, \boldsymbol{\alpha}_T$ and $\mathbf{c}$, so $k = \{1, \cdots, T+1\}$, and the $(T+1)$-th block is for $\mathbf{c}$, d_k is the number of variables in the kth coordinate block and in our case $d_k = d$. The vector $(0, \cdots, \mathbf{b}_k, \cdots, 0)$ is a vector in $\mathbb{R}^{d \times (T+1)}$ and used to only vary $\mathbf{z}$ in the k-th block.

We first prove that for the sequence of points generated by Algorithm 1, the objective function f is monotonically non-increasing. Then we prove the sequence of points is bounded, because of which, the sequence will have accumulation points. We prove that each accumulation point is a coordinate-wise minimum point. Then according to Tseng (2001), if f is regular at an accumulation point $\mathbf{z}^*$, this $\mathbf{z}^*$ is a stationary point.

Lemma 16 *Let the sequence of iterates generated by Algorithm 1 be* $\mathbf{z}^s = \{\mathbf{A}^s, \mathbf{c}^s\}_{s=1,2,\cdots}$ *and the function* f *is defined by (31), then* $f(\mathbf{A}^{s+1}, \mathbf{c}^{s+1}) \leq f(\mathbf{A}^s, \mathbf{c}^s)$.

Proof First, note that for each $\{\mathbf{A}^s, \mathbf{c}^s\}$, we accordingly have $\{\mathbf{B}^s, \mathbf{c}^s\}$ where $\boldsymbol{\alpha}_t^s = \text{diag}(\mathbf{c}^s)\boldsymbol{\beta}_t^s$, $\forall t$, and we have $f(\mathbf{A}^s, \mathbf{c}^s) = g(\mathbf{B}^s, \mathbf{c}^s)$. Because we start with $\mathbf{c}$ so at each iteration $\mathbf{c}$ gets updated first (the order dose not matter actually). At iteration $s+1$, we compute $\mathbf{c}^{s+1}$ based on $\mathbf{A}^s$ according to Eq.(10). According to Lemma 4, $\mathbf{c}^{s+1}$ will reach the lower bound of f when $\mathbf{A}$ is fixed to $\mathbf{A}^s$. Hence $f(\mathbf{A}^s, \mathbf{c}^{s+1}) \leq f(\mathbf{A}^s, \mathbf{c}^s)$. Moreover, when $\mathbf{c}$ is updated, there is an implicit new value of $\tilde{\mathbf{B}}^s$ that is just computed as $(\tilde{\beta}_j^t)^s = (\alpha_j^t)^s/(c_j)^{s+1}$,

$\forall j$ and t. Then, $g(\tilde{\mathbf{B}}^s, \mathbf{c}^{s+1}) = f(\mathbf{A}^s, \mathbf{c}^{s+1})$. Next in Algorithm 1, we obtain $\mathbf{B}^{s+1}$ by solving Problem (30), i.e., by optimizing g with respect $\mathbf{B}$ when $\mathbf{c}$ is fixed to $\mathbf{c}^{s+1}$. Hence, $g(\mathbf{B}^{s+1}, \mathbf{c}^{s+1}) \leq g(\tilde{\mathbf{B}}^s, \mathbf{c}^{s+1})$. Then $\mathbf{A}$ will be updated by $\mathbf{A}^{s+1} = \text{diag}(\mathbf{c}^{s+1})\mathbf{B}^{s+1}$, which leads to $f(\mathbf{A}^{s+1}, \mathbf{c}^{s+1}) = g(\mathbf{B}^{s+1}, \mathbf{c}^{s+1})$. Overall, we have

$$f(\mathbf{A}^{s+1}, \mathbf{c}^{s+1}) = g(\mathbf{B}^{s+1}, \mathbf{c}^{s+1}) \leq g(\tilde{\mathbf{B}}^s, \mathbf{c}^{s+1}) = f(\mathbf{A}^s, \mathbf{c}^{s+1}) \leq f(\mathbf{A}^s, \mathbf{c}^s).$$

This proves that $f(\mathbf{A}^{s+1}, \mathbf{c}^{s+1}) \leq f(\mathbf{A}^s, \mathbf{c}^s)$. ■

Based on the proof of Lemma 16, we can also show that $g(\mathbf{B}^{s+1}, \mathbf{c}^{s+1}) \leq g(\mathbf{B}^s, \mathbf{c}^s)$ for the sequence of $\{\mathbf{B}^s, \mathbf{c}^s\}_{s=1,2,\cdots}$ that is also created by Algorithm 1.

Lemma 17 *The sequence of iterates generated by Algorithm 1,* $\mathbf{z}^s = \{\mathbf{A}^s, \mathbf{c}^s\}_{s=1,2,\cdots}$, *(or equivalently,* $\{\mathbf{B}^s, \mathbf{c}^s\}_{s=1,2,\cdots}$*) is bounded.*

Proof According to Lemma 16, we know that $f(\mathbf{A}^{s+1}, \mathbf{c}^{s+1}) \leq f(\mathbf{A}^s, \mathbf{c}^s)$, and $g(\mathbf{B}^{s+1}, \mathbf{c}^{s+1}) \leq g(\mathbf{B}^s, \mathbf{c}^s)$, $\forall s = 1, 2, \cdots$. Hence, $g(\mathbf{B}^s, \mathbf{c}^s) \leq g(\mathbf{B}^1, \mathbf{c}^1)$, $\forall s = 1, 2, \cdots$. Let $g(\mathbf{B}^1, \mathbf{c}^1) = C$. Then, $g(\mathbf{B}^s, \mathbf{c}^s)$ is upper bounded by C.

In our algorithm, we assume that the loss function in g can be either the least squares loss or the logistic regression loss of all the tasks. Hence, the loss terms are non-negative (actually most other loss functions, such as the hinge loss, are also non-negative). The two regularizers, one on $\boldsymbol{\beta}_t$ and the other on $\mathbf{c}$, are both non-negative. Thus, we have that $||\boldsymbol{\beta}_t^s||_p^p \leq C/\gamma_1$ and $||\mathbf{c}^s||_k^k \leq C/\gamma_2$, $\forall s = 1, 2, \cdots$. This shows that the sequence of $\{\mathbf{B}^s, \mathbf{c}^s\}_{s=1,2,\cdots}$ is bounded. Because $\boldsymbol{\alpha}_t^s = \text{diag}(\mathbf{c}^s)\boldsymbol{\beta}_t^s$, $||\boldsymbol{\alpha}_t^s||_p^p = \sum_{j=1}^d |(\alpha_j^t)^s|^p = \sum_{j=1}^d |(c_j^s(\beta_j^t)^s|^p \leq ||\mathbf{c}^s||_{2p}^{2p} + ||\boldsymbol{\beta}_t^s||_{2p}^{2p} \leq \tilde{C}$ where $\tilde{C}$ is a constant computed from C, γ_1 and γ_2. Thus, the sequence of $\mathbf{z}^s = \{\mathbf{A}^s, \mathbf{c}^s\}_{s=1,2,\cdots}$ is also bounded. ■

Theorem 18 *The sequence* $\mathbf{z}^s = \{\mathbf{A}^s, \mathbf{c}^s\}_{s=1,2,\cdots}$ *generated by Algorithm 1 has at least one accumulation point. For any accumulation point* $\mathbf{z}^* = \{\mathbf{A}^*, \mathbf{c}^*\}$, $\mathbf{z}^*$ *is a coordinate-wise minimum point of* f.

Proof According to Lemma 17, the sequence $\mathbf{z}^s$ is bounded, so there exists at least one accumulation point $\mathbf{z}^*$ and a subsequence of $\{\mathbf{z}^s\}_{s=1,2,\cdots}$ that converges to $\mathbf{z}^*$. Without loss of generality and for notational convenience, let us just assume that $\{\mathbf{z}^s\}_{s=1,2,\cdots}$ converges to $\mathbf{z}^*$. Because $\mathbf{z}^*$ is an accumulation point, if it is the iterate at the current iteration s, then in the next iteration $s+1$, the same iterate $\mathbf{z}^*$ will be obtained. Hence, $\boldsymbol{\beta}_t^*$ is the optimal solution of Problem (30) when $\mathbf{c}$ is set to $\mathbf{c}^*$ (and all other $\boldsymbol{\beta}_{k \neq t} = \boldsymbol{\beta}_k^*$). Correspondingly, $\mathbf{c}^*$ is the optimal solution of Problem (2) when $\mathbf{B}$ is set to $\mathbf{B}^*$. Hence, for any feasible direction $(0, \cdots, \mathbf{b}_t, \cdots, 0)$, $\forall t = 1, 2, \cdots, T+1$, we have

$$f(\mathbf{z}^* + \lambda(0, \cdots, \mathbf{b}_t, \cdots, 0)) \geq f(\mathbf{z}^*), \tag{34}$$

for small λ values. Hence, $\mathbf{z}^*$ is a coordinate-wise minimum point of f. ■

Theorem 19 *If both p and k are positive, and $k \geq 1$, the accumulation point $\mathbf{z}^*$ is a stationary point of f.*

Proof Due to Lemma 4, we know that the optimal solution of Problem (9) can only occur when $\mathbf{c}$ and $\boldsymbol{\alpha}_t$ satisfy Eq.(10), so any other points can be excluded from discussion. Hence, we define a new level set $Z^0 = \{\mathbf{z}|f(\mathbf{z}) \leq C\} \cap \{\mathbf{z}|c_j = (\gamma_1\gamma_2^{-1}\sum_{t=1}^{T}(\alpha_j^t)^p)^{\frac{1}{p+k}}, \forall \alpha_j^t\}$. We now prove that f is continuous on this set Z^0 and the gradient of f exists when p is even (differentiable case), and examine $\mathbf{0} \in \partial f$ at $\mathbf{z}^*$ for non-differentiable cases.

Given the definition of f, f is continuous with respect to α_j^t, $\forall j$ and t. Because f_0 is a division term that has a divisor based on c_j, we have the *division-by*-0 issue, so f is in general not continuous with respect to c_j at 0 (but continuous and differentiable at other values). However, using L'Hospital's rule (i.e., $\lim_{\phi\to 0}\frac{f_1(\phi)}{f_2(\phi}) = \lim_{\phi\to 0}\frac{f_1'(\phi)}{f_2'(\phi}$), we show that f is continuous with respect to c_j at $c_j = 0$ in the set Z^0. When $c_j = 0$, $||\boldsymbol{\alpha}^j||_p^p = \sum_{t=1}^{T}(\alpha_j^t)^p = 0$ due to Eq.(10). Let $\phi = ||\boldsymbol{\alpha}^j||_p^p$. Since the function f_0 is a ratio of two items both approaching 0 as functions of ϕ, we can apply L'Hospital's rule as follows

$$\lim_{\phi\to 0}\frac{||\boldsymbol{\alpha}^j||_p^p}{(c_j)^p} = \lim_{\phi\to 0}\frac{\phi}{(\gamma_1\gamma_2^{-1}\phi)^{\frac{p}{p+k}}} = \lim_{\phi\to 0}\frac{1}{\frac{p}{p+k}(\gamma_1\gamma_2^{-1})^{\frac{p}{p+k}}\phi^{-\frac{k}{p+k}}} = \lim_{\phi\to 0}\frac{(p+k)\phi^{\frac{k}{p+k}}}{p(\gamma_1\gamma_2^{-1})^{\frac{p}{p+k}}} = 0.$$

We then compute the partial derivative of f_0 with respect to c_j, which is $\frac{\partial f_0}{\partial c_j} = \frac{-p||\boldsymbol{\alpha}^j||_p^p}{(c_j)^{p+1}}$ for $c_j \neq 0$. Now when c_j approaches 0, we can prove continuity using L'Hospital's rule:

$$\frac{\partial f_0}{\partial c_j}|_{c_j\to 0} = \lim_{\phi\to 0}\frac{-p||\boldsymbol{\alpha}^j||_p^p}{(c_j)^{p+1}} = \lim_{\phi\to 0}\frac{-p\phi}{(\gamma_1\gamma_2^{-1}\phi)^{\frac{p+1}{p+k}}} = \lim_{\phi\to 0}\frac{-p(p+k)\phi^{\frac{k-1}{p+k}}}{(p+1)(\gamma_1\gamma_2^{-1})^{\frac{(p+1)}{p+k}}} = 0,$$

when $k > 1$. When $k = 1$, the limit is a finite number $-p(p+k)/((p+1)(\gamma_1\gamma_2^{-1})^{\frac{(p+1)}{p+k}})$. Note that when an odd p is taken, $||\boldsymbol{\alpha}_t||_p^p = \sum|\alpha_j^t|^p$ is not differentiable at 0. However, the above limit exists no matter f is differentiable or not because we take ϕ as the varying parameter. With the above conditions, we use the results in Tseng (2001) that when each subproblem has a unique minimum, which is the case in our algorithm because Subproblem (30) is strictly convex (for our chosen loss functions) and we have already proved the unique analytical solution of $\mathbf{c}$, $\mathbf{z}^*$ is a stationary point of f. ■

We briefly discuss the computation cost of Algorithm 1. Subproblem (30) is essentially for single task learning, which can be solved by many existing efficient algorithms, such as gradient-based optimization methods. The second subproblem has a closed-form solution for $\mathbf{c}$, which requires only a minimal level of computation. The computation cost of Algorithm 1 only linearly increases with the number of tasks. Due to the nature of Algorithm 1, it can be easily parallelizable and distributed to multiple processors when optimizing individual $\boldsymbol{\beta}_t$. More efficient algorithms may be designed for specific choices of p in the future.

6. Experiments

We empirically evaluated the performance of the multiplicative MTFL algorithms on both synthetic data sets and a variety of real-world data sets, where we solved either classification (using the logistic regression loss) or regression (using the least squares loss) problems. In the experiments, we implemented and compared Algorithm 1 for four parameter settings: $(p, k) = (2, 2)$, $(1, 1)$, $(2, 1)$, and $(1, 2)$, corresponding to four multiplicative MTFL (MMTFL) methods as listed in Table 2. Although when the values of (p, k) were (2,2) and (1,1), the two models corresponded respectively to the same methods in Bi et al. (2008) and Lozano and Swirszcz (2012), they were solved differently from prior methods using our Algorithm 1 with higher computational efficiency. When $(p, k) = (2, 1)$ and $(1, 2)$, the resultant models corresponded to the two new formulations.

In our experiments, the multiplicative MTFL methods were also compared with the additive MTFL methods that decompose the model parameters into an addition of two components, such as the Dirty model (DMTL) (Jalali et al., 2010) and the robust MTFL (rMTFL) (Gong et al., 2012). Single task learning (STL) approaches were also implemented as baselines and compared with all of the MTFL algorithms in the experiments. We list the various methods used for comparison in our experiments as follows:

- STL_lasso : Learning each task independently with $||\boldsymbol{\alpha}_t||_1$ as the regularizer.
- STL_ridge : Learning each task independently with $||\boldsymbol{\alpha}_t||_2^2$ as the regularizer.
- DMTL (Jalali et al., 2010) : The dirty model with regularizers $||\mathbf{P}||_{1,1}$ and $||\mathbf{Q}||_{1,\infty}$, where $\mathbf{A} = \mathbf{P} + \mathbf{Q}$.
- rMTFL (Gong et al., 2012) : Robust multitask feature learning with the regularizers $||\mathbf{P}||_{1,2}$ and $||\mathbf{Q}^T||_{1,2}$, where $\mathbf{A} = \mathbf{P} + \mathbf{Q}$.
- MMTFL$\{2, 2\}$ (Bi et al., 2008) : Multiplicative multitask feature learning with regularizers $||\mathbf{B}||_F^2$ and $||\mathbf{c}||_2^2$, where $\mathbf{A} = \text{diag}(\mathbf{c})\mathbf{B}$.
- MMTFL$\{1, 1\}$ (Lozano and Swirszcz, 2012) : Multiplicative multitask feature learning with regularizers $||\mathbf{B}||_{1,1}$ and $||\mathbf{c}||_1$, where $\mathbf{A} = \text{diag}(\mathbf{c})\mathbf{B}$.
- MMTFL$\{2, 1\}$(New formulation 1) : Multiplicative multitask feature learning with regularizers $||\mathbf{B}||_F^2$ and $||\mathbf{c}||_1$, where $\mathbf{A} = \text{diag}(\mathbf{c})\mathbf{B}$.
- MMTFL$\{1, 2\}$(New formulation 2) : Multiplicative multitask feature learning with regularizers $||\mathbf{B}||_{1,1}$ and $||\mathbf{c}||_2^2$, where $\mathbf{A} = \text{diag}(\mathbf{c})\mathbf{B}$.

In all experiments, unless otherwise noted, the original data set was partitioned to have 25%, 33% or 50% of the data in a training set and the rest used for testing. For each specified partition ratio (corresponding to a trial), we randomly partitioned the data 15 times and reported the average performance. The same tuning process was used to tune the hyperparameters (e.g.,γ_1 and γ_2) of every method in the comparison. In every trial, an internal three-fold cross validation (CV) was performed within the training data of the first partition to select a proper hyperparameter value for each of the methods from the choices of

2^k with $k = -10, -9, \cdots, 7$. In the subsequent partitions of each trial, the hyperparameters were fixed to the values that yielded the best performance in the CV.

The regression performance was measured by the coefficient of determination, denoted by R^2, which measures the explained variance of the data by the fitted model. In particular, we used the following formula to report performance $R^2 = 1 - \frac{\sum_{i=1}^{n}(y_i - f_i)^2}{\sum_{i=1}^{n}(y_i - \bar{y})^2}$ where $\bar{y}$ is the mean of the observed values of y and f_i is the prediction of the observed y_i. The reported values in our experiments were the averaged R^2 over all tasks. The R^2 value ranges from 0 to 1, and a higher value indicates better regression performance. The classification performance was measured by the F1 score, which is the harmonic mean of precision and recall. The numbers we reported in each trial was the F1 score averaged over all tasks. Similarly, the F1 score also ranges from 0 to 1 and higher values represent better classification performance.

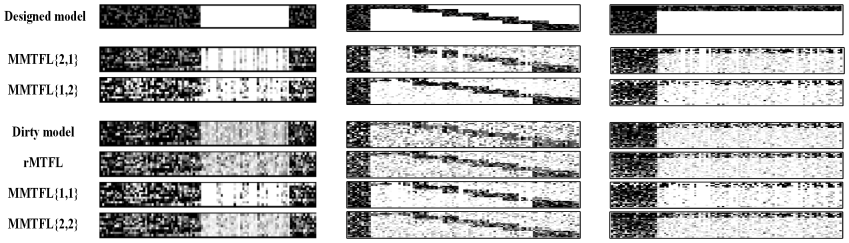
6.1 Simulation Studies

We created three categories of data sets, all of which were designed for regression experiments to evaluate the behaviors of the different methods. The data sets in each category were created with a pre-specified feature sharing structure. The first two categories were designed to validate the scenarios that we hypothesized for our two new formulations to work. We performed sensitivity analyses using these two categories of data sets, i.e., studying how performance was altered when the number of tasks or the number of features varied. Because we also empirically compared with a few additive decomposition based methods, it would be interesting to see how multiplicative MTFL behaved in a scenario that was actually in favor of additive MTFL. Hence, in the third category, the feature sharing structure was generated following the assumption that the robust MTFL method used (Gong et al., 2012).

In all experiments, we created input examples $\mathbf{X}_t$ for each task t using a number of features randomly drawn from the standard multivariate Gaussian distribution $\mathcal{N}(\mathbf{0}, \mathbf{1})$, and pre-defined $\mathbf{A} = [\boldsymbol{\alpha}_1, \cdots, \boldsymbol{\alpha}_T]$ across all tasks. The responses for each task was computed by $\mathbf{y}_t = \mathbf{X}_t\boldsymbol{\alpha}_t + \boldsymbol{\epsilon}_t$ where $\boldsymbol{\epsilon}_t \sim \mathcal{N}(0, 0.5)$ was the noise introduced to the model. If an entry of $\mathbf{A}$ was set to non-zero, its value was randomly sampled from a uniform distribution in the interval $[0.5, 1.5]$. As a side note, we transposed $\mathbf{A}$ in Figure 1 for better illustration.

6.1.1 Synthetic Datasets

Category 1 (C1). In the C1 experiments, 40% of the rows in the matrix $\mathbf{A}$ were set to 0. Since each row corresponded to a feature across the tasks, the zero rows made the features irrelevant to all tasks. All remaining features received non-zero values in $\mathbf{A}$ so that they were used in every task's model although with different combination weights. Hence, the individual models were sparse with respect to all synthesized features, but not sparse with respect to the selected features. The pre-defined $\mathbf{A}$ is demonstrated in Figure 1a(top), where we transpose $\mathbf{A}$ to have columns representing features and a darker spot indicates that the particular element of $\mathbf{A}$ had a larger absolute value. Note that this synthetic data follows the assumption that has motivated the early block-wise joint regularized methods that used matrix-norm-based regularizers. Those methods were developed with an assumption that a subset of features was shared by all tasks. However, we observed that the level of shrinkage needed would be different for $\mathbf{c}$ and $\boldsymbol{\beta}$, which corresponded to non-matrix-norm-



(a) Synthetic data C1 (b) Synthetic data C2 (c) Synthetic data C3

Figure 1: The true parameter matrix versus the parameter matrices constructed by the various methods on synthetic data. The figure shows the results when 200 examples and 100 features were created for 20 tasks each. Darker color indicates larger values in magnitude.

based regularizers. We hypothesized that the proposed new formulation (3) would produce better regression performance than existing models on this data category.

To examine how the number of tasks influenced the performance of different methods, we varied the number of tasks from 1, 5, 10, 50, and 100 to 1000. For each task, we created 200 examples, each represented by 100 features. We also tested the different methods when increasing the number of features. In this set of experiments, we used 20 tasks and each task contained 1000 examples. Each example was represented by a number of features ranging from 200 to 1000 with a step size of 200.

Category 2 (C2). In the C2 experiments, 10% of the rows in $\mathbf{A}$ were set to non-zero and these features were shared by all tasks. We then arranged the tasks to follow six different sparse structures (the staircases) as shown in Figure 1b(top), where we once again transpose $\mathbf{A}$. Each of the remaining features except the 10% common features was used by a comparatively small proportion of the tasks. Consecutive tasks were grouped such that the neighboring groups of tasks shared 7% of the features besides the 10% common features, whereas the non-neighboring groups of tasks did not share any features. Therefore, no feature could be excluded from all tasks, but a majority of individual features (90%) was only useful for few tasks (i.e., the useful features for one task were sparse). In this case, the non-sparsity-inducing norm was suitable for regularizing $\mathbf{c}$ and sparsity-inducing norm was more suitable for regularizing $\boldsymbol{\beta}$. We hypothesized that the new formulation (4) would produce better regression performance than the other models on this data set.

We created 20, 50, 100, 500 and 1000 tasks, respectively, to test the algorithms' sensitivity to the number of tasks. The numbers of tasks were chosen to make sure enough tasks in each of the six groups. The number of tasks in each group ranged from 3 to 170. We generated 200 examples and 100 features for each task. We also created another set of C2 data sets with the number of features changing from 200 to 1000 with a step size of 200 for 20 tasks and 1000 examples for each task.

Category 3 (D3). This category was synthesized following the model of the additive decomposition methods. It only contained one data set where 200 examples, each represented

Table 3: Comparison of the test R^2 values obtained by the different MTFL methods on synthetic data sets using different partition ratios for training data (where standard deviation 0 means that it is less than 0.01).

Dataset		STL_lasso	STL_ridge	DMTL	rMTFL	MMTFL(2,2)	MMTFL(1,1)	MMTFL(2,1)	MMTFL(1,2)

	50%	0.77±0.01	0.78±0.01	0.76±0.02	**0.83±0.01**	0.81±0.02	0.75±0.01	0.79±0.02	0.76±0.01

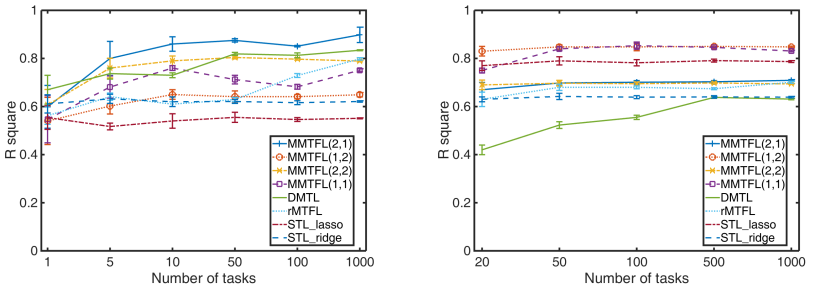
by 100 features, were generated for each of 20 tasks. The parameter matrix $\mathbf{A} = \mathbf{P} + \mathbf{Q}$ where 80 rows in $\mathbf{P}$ and 16 columns in $\mathbf{Q}$ were set to 0. The component $\mathbf{P}$ was used to indicate the subset of relevant features across all tasks, and the component $\mathbf{Q}$ was used to tell that there were outlier tasks that did not share features with other tasks. Given this simulation process, this data set would be in favor of the rMTFL model proposed in Gong et al. (2012). The designed model parameter matrix was shown in Figure 1c(top).

6.1.2 Performance on synthetic data sets

We first compared the regression performance of the different methods on the three categories of data sets. Table 3 shows the averaged R^2 values together with standard deviations for each method and each trial setting. The best results are shown in bold fonts. The results in Table 3 were obtained on synthetic data sets that had 20 tasks with 200 examples and 100 features for each task. We reported the test R^2 obtained on each data set when 25%, 33% and 50% of the data were used in training. From Table 3, we observe that the proposed formulation (3)(MMTFL(2,1)) consistently outperformed other models on *C1* data sets, whereas the proposed model (4)(MMTFL(1,2)) consistently outperformed on *C2* data sets. The results confirmed our hypotheses that the two proposed models could be more suitable for learning the type of sharing structures in *C1* and *C2*. As anticipated, rMTFL model constantly outperformed other models on the *C3* data set. Among the multiplicative MTFL methods, MMTFL(2,2) achieved similar performance to that of rMTFL (off only by $0.01 \sim 0.02$ for average R^2).

In order to elucidate the different shrinkage effects of the different decomposition strategies and regularizers, we compared the true parameter matrix with the constructed parameter matrices by the six MTFL methods used in our experiments in Figure 1. From the results on the *C1* and *C2* data sets, we observe that only MMTFL(2,1), MMTFL(1,2) and MMTFL(1,1) produced reasonably sparse structures. The two additive decomposition methods could not yield a sufficient level of sparsity in the models. Although the unused features did receive smaller weights in general, they were not completely excluded. To evaluate the accuracy of feature selection, we quantitatively measured the discrepancy between the estimated models and the true model by computing the mean squared error (MSE) $trace((\mathbf{A} - \mathbf{A}_{est})^\top(\mathbf{A} - \mathbf{A}_{est}))$ where $\mathbf{A}_{est}$ was the matrix estimated by a method. We compared MSE values of individual mothods.

On the *C1* data, MMTFL(2,1) learned better combination weights (darker areas) for the relevant features than MMTFL(1,1). MMTFL(1,1) appeared to be unnecessarily too



(a) On *C1* data (b) On *C2* data

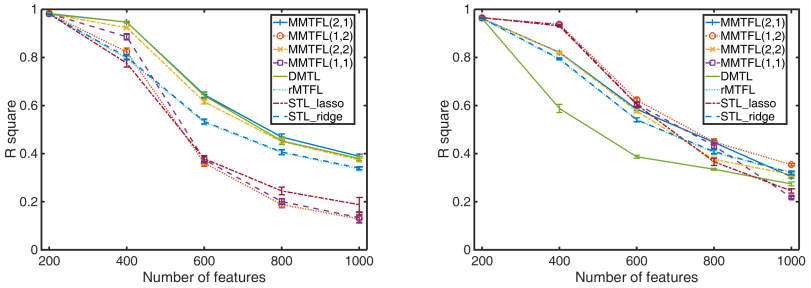
Figure 2: The regression performance of different models on synthetic data *C1* and *C2* when the number of tasks is varied.

sparse because the useful features received much smaller weights than needed (lighter than the true model). The smallest MSE was achieved by MMTFL(2,1) with a value of 0.1, and the second best model, MMTFL(1,1), had MSE = 0.2 whereas the rMTFL model had the largest MSE = 0.25.

On the *C2* data, MMTFL(1,2) learned a model that was most comparable to the true model. Both MMTFL(1,2) and MMTFL(1,1) eliminated well the irrelevant features. However, if we compared the two rows corresponding to these two models in Figure 1, we could see that MMTFL(1,1) broke the staircases in several places (e.g., towards the lower right and the up left corners) by excluding more features than necessary. Note that the feature sharing patterns (particularly in synthetic data *C2*) may not be revealed by the recent methods on clustered multitask learning that cluster tasks into groups (Kang et al., 2011; Jacob et al., 2008; Zhou et al., 2011) because no cluster structure is present in Figure 1b. Rather, the sharing pattern in Figure 1b is actually in between the consecutive groups of tasks. MMTFL(1,2) had the smallest MSE = 0.05, which was smaller than that of the second best model MMTFL(1,1) by 0.025. DMTL received the largest MSE = 0.19.

Figure 1c shows the results on the *C3* data set. MMTFL(2,1), MMTFL(1,2), and MMTFL(1,1) imposed excessive sparsity on the parameter matrix, which removed some useful features. The other three models, DMTL, rMTFL and MMTFL(2,2), produced similar parameter matrices, but rMTFL was originally designed to detect outlier tasks and thus was more favorable for this data set. The rMTFL model obtained the smallest MSE (0.03), and MMTFL(2,2) had a similar performance (MSE=0.04), which was the same as that of DMTL. On this data set, MMTFL(1,1) got the largest MSE (0.09). These results bring out an interesting observation that for the MTL scenarios that have outlier tasks but relevant tasks share the same set of features, MMTFL(2,2) (which corresponds to the very early joint regularized method using the $\ell_{1,2}$ matrix norm) is most suitable among the multiplicative MTFL methods.

Figure 2 compares the performance of different methods when we vary the number of tasks in the *C1* and *C2* categories. On each data set, we used 33% of the data in training



(a) On *C1* data (b) On *C2* data

Figure 3: The regression performance of different models on synthetic data *C1* and *C2* when the number of features is varied.

with 15 trials, and reported here the average R^2 values and standard deviation bars. From Figure 2, MMTFL(2,1) constantly performed the best among all methods on the *C1* data sets (but not in the single task learning) whereas MMTFL(1,2) outperformed the other models on the *C2* data sets. We also observed that on *C2* data, MMTFL(1,1) obtained very similar performance to that of MMTFL(1,2) after the number of tasks reached 50. On this data category, almost all methods reached a stable level of accuracy after the number of tasks reached 50 except DMTL. DMTL continued to gain knowledge from more relevant tasks until it reached 500 tasks but it produced the lowest R^2 values among all methods. Overall, the results indicate that with the fixed dimension and sample size, when the number of tasks reaches a certain level, the transferable knowledge learned from the tasks can be saturated for a specific feature sharing structure. On *C1* data, we observe that the performance was not always monotonically improved or non-degraded (for all methods) when more tasks were included, which may indicate that when an unnecessarily large number of tasks was used, it could add more uncertainty to the learning process.

Figure 3 compares the performance of different methods when we vary the number of features in the *C1* and *C2* categories. Obviously, when the problem dimension was higher, the learning problem became more difficult (especially when the number of tasks and sample size remained the same). All methods dropped their performance substantially with increasing numbers of features although MMTFL(2,1) and MMTFL(1,2) still outperformed other methods, respectively, on the *C1* and *C2* data sets. This figure also shows that MMTFL(1,1) performed well on the *C2* data sets but much worse on the *C1* data sets. DMTL produced good performance, close to that of MMTFL(2,1), on the *C1* data sets.

6.2 Experiments with Benchmark Data

Extensive empirical studies were conducted on benchmark data sets where we tested the proposed multiplicative MTFL algorithms on ten real-world data sets. Among these data sets, three were for regression experiments and all others were for classification experiments. Characteristics of these data sets are summarized in the next section.

6.2.1 Benchmark Datasets

Sarcos (Argyriou et al., 2007): Sarcos data were collected for a robotics problem of learning the inverse dynamics of a 7 degrees-of-freedom SARCOS anthropomorphic robot arm. Each observation has 21 features corresponding to 7 joint positions and their velocities and accelerations. We needed to map from the 21-dimensional input space to 7 joint torques, which corresponded to 7 tasks. For each task, we randomly selected 2000 cases for training and the remaining 5291 cases for test. Readers can consult with http://www.gaussianprocess.org/gpml/data/ for more details.

CollegeDrinking (Bi et al., 2013): The college drinking data were collected in order to identify alcohol use patterns of college students and the risk factors associated with the binge drinking. The data set contained daily responses from 100 college students to a survey questionnaire measuring various daily measures, such as drinking expectation, negative affects, and level of stress, every day in a 30 day period. The goal was to predict the amount of nighttime drinks based on 51 daily measures for each student, corresponding to 100 regression tasks. Because there were only 30 records for each person, we used 66%, 75% and 80% of the records to form the training set, and the rest for test.

QSAR (Ma et al., 2015): The quantitative structure-activity relationship (QSAR) methods are commonly used to predict biological activities of chemical compounds in the field of drug discovery. The data sets we used were collected from three different types of drug activities, including binding to cannabinoid receptor 1 (CB1), inhibition of dipeptidyl peptidase 4 (DPP4) and time dependent 3A4 inhibitions (TDI). For each activity, there were 200 molecule examples represented by 2618 features. Three regression models were constructed to simultaneously predict the targets $-log(\text{IC50})$) of the CB1, DPP4 and TDI effectiveness based on the molecular features.

C.M.S.C. (Lucas et al., 2013): The Climate Model Simulation Crashes (C.M.S.C.) data set contained records of simulated crashes encountered during climate model uncertainty quantification ensembles. The data set comprised 3 tasks. There were 180 examples for each task. Each example was represented by an 18-dimensional feature vector. Each task is formed by a binary classification problem, which was to predict simulation outcomes (either fail or succeed) from the input parameter values for a climate model.

Landmine (Xue et al., 2007): The original Landmine data contained 29 data sets where sets 1-15 corresponded to the geographical regions that were highly foliated and sets 16-29 corresponded to the regions with bare earth or desert. Each data set could be used to build a binary classifier. We used the data sets 1-10 and 16-25 to form 20 tasks where each example was represented by 9 features extracted from radar images. The number of examples varied between individual tasks ranging from 445 to 690.

Alphadigits (Maurer et al., 2013): This data set was composed of binary 20×16 images of the 10 digits and capital letters. We used all the images of digits to form 10 binary classification tasks. For each digit, there were 39 images in this data set. We labeled the images of a single digit as positive examples, and randomly selected other 39 images from other digits and labeled them as negative examples. All the pixels were concatenated to form a 320-dimensional feature vector for each image.

Underwatermine (Liu et al., 2009b): This data set was originally used in the underwater mine classification problem that aimed to detect mines from non-mines based on the

synthetic-aperture sonar images. The data set consisted of 8 tasks with sample sizes ranging from 756 to 3562 for each task, and each task was a binary classification problem. Each example was represented by 13 features.

Animal recognition (Kang et al., 2011): This data set consisted of images from 20 animal classes. Each image was originally represented by 2000 features extracted using the bag of word descriptors from the Scale-invariant Feature Transform (SIFT), and then the dimensionality was reduced to 202 by a principal component analysis, retaining 95% of the data variance. For each animal class, there were 100 images. We formed 20 binary classification tasks where for each task, 100 positive examples were from a specific animal class and 100 negative examples were randomly sampled from other classes.

HWMA_base and HWMA_peak (Qazi et al., 2007; Bi and Wang, 2015): The heart wall motion abnormality (HWMA) detection data set was used to analyze and predict if a heart had abnormal motion based on the image features extracted from stress test echocardiographs of 220 patients. The images were taken at the base dose and also peak dose of stress contrast. The wall of left ventricle was medically segmented into 16 segments, and 25 features were extracted from each segment. Every segment of every heart case was annotated by radiologists in terms of normal or abnormal motions. Thus, there were 16 binary classification tasks, each corresponding to one of the 16 heart segments, and each task comprised 220 examples.

6.2.2 Performance on real world data sets

Three real-world data sets, the Sarcos, CollegeDrinking and QSAR, were used in regression experiments. The performance of the different methods is summarized in Table 4 depicting the R^2 values averaged over the 15 re-partitions in each trial. MMTFL(2,1) achieved the best R^2 values on the Sarcos data set (in all of the 3 trials) and the CollegeDrinking data set (in 2 of the 3 trials). The Sarcos data appeared to be in favor of denser models given MMTFL(2,2) also performed reasonably well on this data set. MMTFL(1,2) models achieved the best performance on the QSAR data set consistently across all the 3 trial settings. On this data set, it was obvious that MMTFL(1,2) was more suitable, which indicated that most of the 2618 features were useful for some tasks, but the tasks shared few features between each other. The difference between the proposed models and the additively decomposed models ranged from 1 % to 10%, and most importantly, the trend was consistent for the proposed models to outperform on these data sets.

The other seven real-world data sets were used in classification experiments. Table 5 summarizes the results where the F1 scores were averaged across the 15 random splits in each trial together with standard derivations. MMTFL(2,1) models achieved consistently the best performance on the C.S.M.C. and Landmine data sets in comparison with other models. In particular, we observed both MMTFL(1,1) and the MMTFL(2,1) models produced the best F1 scores in the trial with 33% training split whereas MMTFL(2,1) outperformed all other models in the trial with other partition ratios. These two data sets may prefer across-task sparse models, indicating that many irrelevant features may exist in the data. For the remaining five data sets used in classification experiments, MMTFL(1,2) models showed generally better performance than all other models. The difference between the best model and other MMTFL models could reach 4% to 8%.

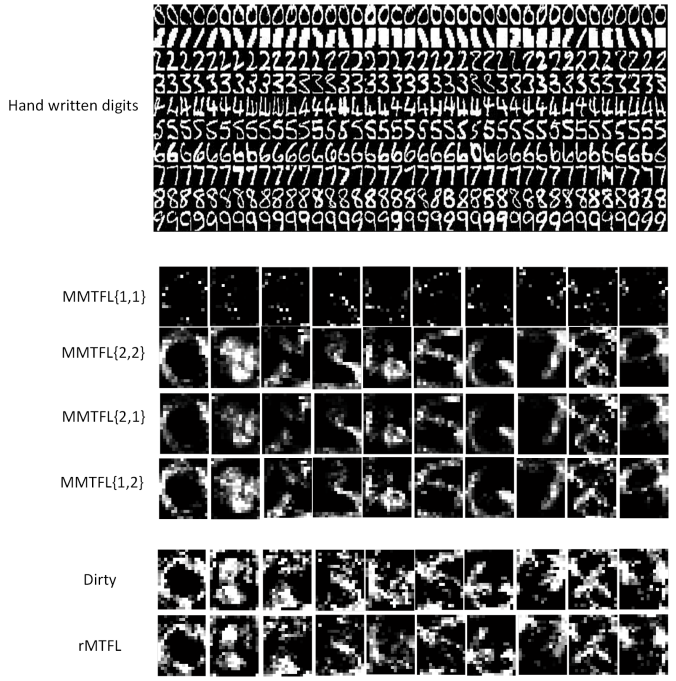


Figure 4: The models constructed by MTFL methods for individual digits using the pixels in hand written digit images. The models can be re-organized back into images. The pixel in the above images ranges from 0 to 1. The lighter, the closer to 1 for lucid illustration.

In particular, for the Alphadigits data set, we used the raw pixels of the hand written digits as the features to build models. Each task aimed to learn a linear model in the original pixel dimensions to distinguish a digit from other nine digits. Thus, each model, or equivalently the weight vector of the linear model, could be re-shaped back into an image. Figure 4 compares the constructed models for each digit by each of the six MTFL methods. In the top of Figure 4, we illustrate some sample images. In the middle, we show the results by the four MMTFL methods whereas at the bottom we include the constructed additively decomposed models. Clearly, the additively decomposed models were much noisier and selected many undesirable features. Among the multiplicative MTFL methods, MMTFL(1,1) models were too sparse to trace out the digits. Overall, MMTFL(1,2) models were the closest to the shapes of the different digits. If we compare MMTFL(2,1) and (1,2), MMTFL(2,1) excluded too many features from all digits. It indicated that most of the pixels were useful for predicting a digit but not many pixels were shared by multiple digits.

Table 4: Comparison of the R^2 values of the different MTFL methods on the benchmark regression data sets.

7. Conclusion

In this paper, we have studied a general framework of multiplicative multitask feature learning. By decomposing the model parameter of each task into a product of two components: the across-task feature indicator and task-specific parameters, and applying different regularizers to the two components, we can select features for individual tasks and also search for the shared features among tasks. We have examined the theoretical properties of this framework when different regularizers are applied and found that this family of methods creates models equivalent to those of the joint regularized multitask learning methods but with a more general form of regularization. Further, we show that this family consists of some convex and some non-convex formulations and specify the conditions to obtain convexity. An analytical formula is derived for the across-task component as related to the task-specific component, which sheds light on the different shrinkage effects in the various regularizers. An efficient algorithm is derived to solve the entire family of methods and also tested in our experiments for some chosen parameter values. Empirical results on synthetic data clearly show that there may not be a particular choice of regularizers that is universally better than other choices. We empirically show a few feature sharing patterns that are in favor of the two newly-proposed choices of regularizers. The extensive experimental results on real-world benchmark data sets also confirm the observation and demonstrate the advantages of the proposed two formulations over several existing methods.

Abstract

We discuss a general method to learn data representations from multiple tasks. We provide a justification for this method in both settings of multitask learning and learning-to-learn. The method is illustrated in detail in the special case of linear feature learning. Conditions on the theoretical advantage offered by multitask representation learning over independent task learning are established. In particular, focusing on the important example of half-space learning, we derive the regime in which multitask representation learning is beneficial over independent task learning, as a function of the sample size, the number of tasks and the intrinsic data dimensionality. Other potential applications of our results include multitask feature learning in reproducing kernel Hilbert spaces and multilayer, deep networks.

Keywords: learning-to-learn, multitask learning, representation learning, statistical learning theory, transfer learning

1. Introduction

Multitask learning (MTL) can be characterized as the problem of learning multiple tasks *jointly*, as opposed to learning each task in isolation. This problem is becoming increasingly important due to its relevance in many applications, ranging from modelling users' preferences for products, to multiple object classification in computer vision, to patient healthcare data analysis in health informatics, to mention but a few. Multitask learning algorithms which exploit structure and similarities across different learning problems have been studied by the machine learning community since the mid 90's, initially in connection to neural network models (see Baxter, 2000; Caruana, 1998; Thrun and Pratt, 1998, and reference therein). More recent approaches have been based on kernel methods (Evgeniou et al., 2005), structured sparsity and convex optimization (Argyriou et al., 2008), among others.

Closely related to multitask learning but more challenging is the problem of *learning-to-learn* (LTL), namely learning to perform a new task by exploiting knowledge acquired when solving previous tasks. Arguably, a solution to this problem would have major impact in Artificial Intelligence as we could build machines which learn from experience to perform new tasks, similar to what we observe in human behavior.

An influential line of research on multitask and transfer learning is based on the idea that the tasks are related by means of a common low dimensional representation, which is learned jointly with the tasks' parameters. This approach was first advocated in (Baxter, 2000; Caruana, 1998; Thrun and Pratt, 1998) and more recently reconsidered in (Argyriou et al., 2008) from the perspective of convex optimization and sparsity regularization. Representation learning is also a key problem in AI, and in the past years there has been much renewed interest in learning nonlinear hierarchical representations from multiple tasks using multilayer, deep networks. Researchers have shown improved results in a number of empirical domains; the case of computer vision is perhaps most remarkable, (see e.g. Girshick et al., 2014, and references therein). This success has increased interest in multitask representation learning (MTRL) as it is a core component of deep networks. Still, the understanding of why this methodology works remains largely unexplored.

In this paper we analyze a general method for MTRL and discuss its potential advantage in both the MTL setting, where the learned representation is applied to the same tasks used during training, and in the domain of LTL, where the representation is applied to new tasks. We derive upper bounds on the error of these methods and quantify their advantage over independent task learning. When the original data representation is high dimensional and the number of examples provided to solve a regression or classification problem is limited, any learning algorithm which does not use any sort of prior knowledge will perform poorly because there is not enough data to reliably estimate the model parameters. We make this statement precise by considering the example of half space learning.

1.1 Previous Work

Many papers have proposed multitask learning methods and studied their applications to specific problems (see Ando and Zhang, 2005; Argyriou et al., 2008; Baxter, 2000; Ben-David and Schuller, 2003; Caruana, 1998; Cavallanti et al., 2010; Kuzborskij and Orabona, 2013; Maurer et al., 2013; Pentina and Lampert, 2014; Widmer et al., 2013, and references therein). There is a vast literature on these subjects and the list of papers provided here is necessarily incomplete.

Despite the considerable success of multitask learning and in particular multitask representation learning there are only few theoretical investigations (Ando and Zhang, 2005; Baxter, 2000; Ben-David and Schuller, 2003). Other statistical learning bounds are restricted to linear multitask learning such as (Cavallanti et al., 2010; Lounici et al., 2011; Maurer, 2006a,a).

Learning-to-learn (also called inductive bias learning or transfer learning) has been proposed by Thrun and Pratt (1998) and theoretically studied by Baxter (2000) where an error analysis is provided, showing that a common representation which performs well on the training tasks will also generalize to new tasks obtained from the same "environment". More recent papers which present dimension independent bounds appear in Maurer (2006a,b); Maurer and Pontil (2013); Maurer et al. (2013); Pentina and Lampert (2014).

1.2 Our Contributions

There are two main contributions of this work. First we present bounds to both the MTL and LTL settings, which apply to a very general MTRL method. Our analysis goes well beyond linear representation learning considered in most previous works. It improves over the analysis by Baxter (2000) based on covering numbers. We use more recent techniques of empirical process theory to achieve bounds which are independent of the input dimension (hence also valid in reproducing kernel Hilbert spaces) and to avoid logarithmic factors. Furthermore our analysis can be made fully data dependent. When specialized to subspace learning (i.e. linear feature learning) we get best bounds valid for infinite dimensional input spaces.

As the second main contribution of this paper, we explain the advantage of MTRL in terms of specificity of feature maps and expose conditions when MTRL is beneficial or when it is not worth the effort. We further specialize our upper bounds to half-space learning (noiseless binary classification) and compare them to a general lower bound for learning isolated tasks. We observe that if the number of tasks grows then the performance of the method (both in the MTL and LTL setting) matches the performance of square norm regularization with best a priori known representation. This analysis highlights the advantage of multitask learning over learning the tasks independently. We also present numerical experiments for half-space learning, which indicate the good agreement between theory and experiments.

1.3 Organization

The paper is organized as follows. In Section 2, we introduce the problem and present our main results. In Section 3, we specialize these results to subspace learning and illustrate the role played by the data covariance matrices in our bounds. In Section 3.1 we further illustrate our results in the case of half-space learning, rigorously comparing our upper bounds to a general lower bound for orthogonal equivariant algorithms. In Section 4, we present the proof of our main results, developing in particular uniform bounds on the estimation error. Finally, in Section 5 we summarize our findings and suggest directions for future research.

2. Multitask Representation Learning

The set of possible observations is denoted by $\mathcal{Z} = (\mathcal{X}, \mathbb{R})$, where the members of $\mathcal{X}$ are interpreted as inputs and the members of $\mathbb{R}$ are interpreted as outputs, or labels. A learning task is modelled by a probability measure μ on $\mathcal{Z}$ where $\mu(x, y)$ is the probability to encounter the input-output pair $(x, y) \in \mathcal{Z}$ in the context of task μ. We want to learn how to predict outputs. If we predict y while the true output is y', we suffer a loss $\ell(y, y')$, where the loss function $\ell : \mathbb{R} \times \mathbb{R} \to [0, 1]$ is assumed to be 1-Lipschitz in the first argument for every value of the second argument. Different Lipschitz constants can be absorbed in the scaling of the predictors and different ranges than $[0, 1]$ can be handled by a simple scaling of our results.

If g is a real function defined on $\mathcal{X}$, then the values $g(x)$ can be interpreted as predictors and the expectation $\mathbb{E}_{(X,Y)\sim\mu}[\ell(g(X), Y)]$ is the risk associated with hypothesis g on the task μ.

Multitask learning simultaneously considers many tasks $\mu_1, \ldots, \mu_T$ and hopes to exploit some suspected common property of these tasks. For the purpose of this paper this property is the existence of a representation or common feature-map, which simultaneously simplifies the learning problem for most, or all of the tasks at hand. We consider predictors g which factorize

$$g = f \circ h,$$

where "$\circ$" stands for functional composition, that is, $(f \circ h)(x) = f(h(x))$, for every $x \in \mathcal{X}$. The function $h : \mathcal{X} \to \mathbb{R}^K$ is called the representation, or feature-map, and it is used across different tasks, while f is a function defined on $\mathbb{R}^K$, a predictor specialized to the task at hand. In the sequel K will always be the dimension of the representation space.

As usual in learning theory the functions $h : \mathcal{X} \to \mathbb{R}^K$ and $f : \mathbb{R}^K \to \mathbb{R}$ are chosen from respective hypothesis classes $\mathcal{H}$ and $\mathcal{F}$, which we refer to as the class of representations and the class of specialized predictors, respectively. These classes can be quite general, but we require that the functions in $\mathcal{F}$ have Lipschitz constant at most L, for some positive real number L.

The choice of representation and specialized predictors is based on the data observed for all the tasks. This data takes the form of a multi-sample $\bar{\mathbf{Z}} = (\mathbf{Z}_1, \ldots, \mathbf{Z}_T)$, with $\mathbf{Z}_t = (Z_{t1}, \ldots, Z_{tn}) \sim \mu_t^n$. Here and in the sequel an exponent on a measure indicates a product measure, so that μ_t^n is a measure on $\mathcal{Z}^n$ and $\mathbf{Z}_t$ is an iid sample of n random variables distributed as μ_t. We also write $Z_{ti} = (X_{ti}, Y_{ti})$, $\mathbf{Z}_t = (\mathbf{X}_t, \mathbf{Y}_t)$ and $\bar{\mathbf{Z}} = (\bar{\mathbf{X}}, \bar{\mathbf{Y}})$.

Multitask representation learning (MTRL) solves the optimization problem

$$\min\left\{\frac{1}{nT}\sum_{t=1}^{T}\sum_{i=1}^{n}\ell(f_t(h(X_{ti})), Y_{ti}) : h \in \mathcal{H},\ (f_1, \ldots, f_T) \in \mathcal{F}^T\right\}. \tag{1}$$

In this paper, we are not concerned with the algorithmics of this problem, but rather with the statistical properties of its solutions $\hat{h}$ and $\hat{f}_1, \ldots, \hat{f}_T$. Note that these are functional random variables in their dependence on $\bar{\mathbf{Z}}$.

We consider two possible applications of these solutions. One application, which we will refer to as multitask learning (MTL), retains both the representation $\hat{h}$ and the specializations $\hat{f}_1, \ldots, \hat{f}_T$ to be applied to the tasks at hand. The other, perhaps more important, application assumes that the tasks μ_t are related by a probabilistic law, called an *environment*, and keeps only the representation $\hat{h}$ to be used when specializing to new tasks obeying the same law. In this way the parametrization of a learning algorithm is learned, hence the name "learning-to-learn" (LTL).

We will give general statistical guarantees in both cases. Our bounds consist of three terms. The first term can be interpreted as the cost of estimating the representation h and decreases with the number T of tasks available for training. The second term corresponds to the cost of estimating task-specific predictors and decreases with the number n of training examples available for each task. The last term contains the confidence parameter and typically makes only a very small contribution.

It is not surprising that the complexity of the representation class $\mathcal{H}$ (first term in the bounds) plays a central role. We measure this complexity on the observed input data $\bar{\mathbf{X}} \in \mathcal{X}^{Tn}$. Define a random set $\mathcal{H}\left(\bar{\mathbf{X}}\right) \subseteq \mathbb{R}^{KTn}$ by

$$\mathcal{H}\left(\bar{\mathbf{X}}\right) = \left\{\left(h_k\left(X_{ti}\right)\right) : h \in \mathcal{H}\right\}.$$

The complexity measure relevant to estimation of the representation is the Gaussian average

$$G\left(\mathcal{H}\left(\bar{\mathbf{X}}\right)\right) = \mathbb{E}\left[\sup_{h\in\mathcal{H}} \sum_{kti} \gamma_{kti} h_k\left(X_{ti}\right) | X_{ti}\right], \tag{2}$$

where the γ_{kti} are independent standard normal variables. The Gaussian average is of order $\sqrt{nT}$ in T and n for many classes of interest. These include kernel machines with Lipschitz kernels (e.g. Gaussian RBF) and arbitrarily deep compositions thereof, see Maurer (2014) for a discussion. As we shall see, this increase of $O(\sqrt{nT})$ is compensated in our bounds and the cost of learning the representation vanishes in the multi-task limit $T \to \infty$.

The second term in the bounds is governed by the quantity

$$\sup_{h\in\mathcal{H}} \frac{1}{n\sqrt{T}} \left\|h\left(\bar{\mathbf{X}}\right)\right\| = \frac{1}{\sqrt{n}} \sup_{h\in\mathcal{H}} \sqrt{\frac{1}{nT} \sum_{kti} h_k\left(X_{ti}\right)^2} \tag{3}$$

or an equivalent distribution-dependent expression. If the feature-maps in $\mathcal{H}$ are very specific, in the sense that their components are appreciably different from zero only for very special data, the quantity in (3) can become much smaller than $1/\sqrt{n}$, a phenomenon which can give a considerable competitive edge to MTRL, in particular if the per-task sample size n is small. We will demonstrate this in Section 3, where we apply Theorems 1 and 2 to subspace-learning and show that the above quantity is related to the operator norm of the data covariance.

2.1 Bounding the Excess Task-averaged Risk (MTL)

If we make no further assumptions on the generation of the task-measures $\mu_1, \ldots, \mu_T$, a conceptually simple performance measure for a representation h and specialized predictors $f_1, \ldots, f_T$ is the task-averaged risk

$$\mathcal{E}_{\text{avg}}\left(h, f_1, \ldots, f_T\right) = \frac{1}{T} \sum_{t=1}^{T} \mathbb{E}_{(X,Y)\sim\mu_t} \ell\left(f_t\left(h\left(X\right)\right), Y\right).$$

We want to compare this to the very best we can do using the classes $\mathcal{H}$ and $\mathcal{F}$, given complete knowledge of the distributions $\mu_1, \ldots, \mu_T$. The minimal risk is clearly

$$\mathcal{E}^*_{\text{avg}} = \min_{h\in\mathcal{H}, (f_1,\ldots,f_T)\in\mathcal{F}^T} \mathcal{E}_{\text{avg}}\left(h, f_1, \ldots, f_T\right).$$

It is a fundamental hope underlying our approach that the classes $\mathcal{H}$ and $\mathcal{F}$ are large enough for this quantity to be sufficiently small for practical purposes. We use the words "hope" and "belief" because an "assumption" would imply a statement to be used in analytical

reasoning. Instead our approach is agnostic, and our results are valid independent of the size of the minimal risk above.

Our first result bounds the excess average risk, which measures the difference between the task-averaged true risk of the solutions to (1) and the theoretical optimum above.

Theorem 1 *Let $\mu_1, \ldots, \mu_T$, $\mathcal{H}$ and $\mathcal{F}$ be as above, and assume $0 \in \mathcal{H}$ and $f\left(0\right) = 0$ for all $f \in \mathcal{F}$. Then for $\delta > 0$ with probability at least $1-\delta$ in the draw of $\bar{\mathbf{Z}} \sim \prod_{t=1}^{T} \mu_t^n$ we have that*

$$\mathcal{E}_{\text{avg}}(\hat{h}, \hat{f}_1, \ldots, \hat{f}_T) - \mathcal{E}^*_{\text{avg}} \leq \frac{c_1 L\ G\left(\mathcal{H}\left(\bar{\mathbf{X}}\right)\right)}{nT} + \frac{c_2 Q \sup_{h\in\mathcal{H}} \left\|h\left(\bar{\mathbf{X}}\right)\right\|}{n\sqrt{T}} + \sqrt{\frac{8\ln\left(4/\delta\right)}{nT}},$$

where c_1 and c_2 are universal constants, $G(\mathcal{H}(\bar{\mathbf{X}}))$ is the Gaussian average in Equation (2), and Q is the quantity

$$Q \equiv Q(\mathcal{F}) \sup_{y\neq y'\in\mathbb{R}^{Kn}} \frac{1}{\|y-y'\|} \mathbb{E} \sup_{f\in\mathcal{F}} \sum_{i=1}^{n} \gamma_i \left(f\left(y_i\right) - f\left(y_i'\right)\right). \tag{4}$$

Remarks:

1. The assumptions $0 \in \mathcal{H}$ and $f\left(0\right) = 0$ for all $f \in \mathcal{F}$ are made to give the result a simpler appearance. They are not essential, as the reader can verify from the proof.
2. If $G\left(\mathcal{H}\left(\bar{\mathbf{x}}\right)\right)$ is of order $\sqrt{nT}$ then the first term on the right hand side above is of order $1/\sqrt{Tn}$ and vanishes in the *multi-task limit* $T \to \infty$ even for small values of n.
3. For reasonable classes $\mathcal{F}$ one can find a bound on Q, which is independent of n, because the $\|y-y'\|$ in the denominator balances the Gaussian average depending on the class $\mathcal{F}$.
4. The quantity $\sup_h \left\|h\left(\bar{\mathbf{X}}\right)\right\|$ is of order $\sqrt{nT}$ whenever $\mathcal{H}$ is uniformly bounded, a crude bound being $\sqrt{nT} \sup_{h\in\mathcal{H}} \max_{ti} \|h\left(x_{ti}\right)\|$. The second term is thus typically of order $1/\sqrt{n}$. As explained in the discussion of Equation (3) above it can be very small if the representation components in $\mathcal{H}$ are very data-specific.

2.2 Bounding the Excess Risk for Learning-to-learn (LTL)

Now we consider the case where we only retain the representation $\hat{h}$ obtained from (1) and specialize it to future, hitherto unknown tasks. This is of course only possible, if there is some common law underlying the generation of tasks. Following Baxter (2000) we suppose that the tasks originate in a common environment η, which is by definition a probability measure on the set of probability measures on $\mathcal{Z}$. The draw of $\mu \sim \eta$ models the encounter of a learning task μ in the environment η.

The environment η induces a measure μ_η on $\mathcal{Z}$ by

$$\mu_\eta\left(A\right) = \mathbb{E}_{\mu\sim\eta}\left[\mu\left(A\right)\right] \text{ for } A \subseteq \mathcal{Z}.$$

This simple mixture plays an important role in the interpretation of our results.

The measure η also induces a measure ρ_η on $\mathcal{Z}^n$ which corresponds to the draw of an n-sample from a random task in the environment. To draw a sample $\mathbf{Z} \in \mathcal{Z}^n$ from ρ_η we first draw a task μ from η and then generate the sample $\mathbf{Z} = (Z_1, \ldots, Z_T)$ from n independent draws from μ. Formally

$$\rho_\eta(A) = \mathbb{E}_{\mu\sim\eta}\left[\mu^n(A)\right] \text{ for } A \subseteq \mathcal{Z}^n.$$

We assume that the tasks $\mu_1, \ldots, \mu_T$ are drawn independently from η and, consequently, that the multisample $\bar{\mathbf{Z}} = (\mathbf{Z}_1, \ldots, \mathbf{T}_T)$ is obtained in T independent draws from ρ_η, that is, $\bar{\mathbf{Z}} \sim \rho_\eta^T$.

The way we plan to use a representation $h \in \mathcal{H}$ on a new task $\mu \sim \eta$ is as follows: we draw a training sample $\mathbf{Z} = (Z_1, \ldots, Z_n)$ from μ^n and solve the optimization problem

$$\min_{f\in\mathcal{F}} \frac{1}{n}\sum_{i=1}^{n} \ell\left(f\left(h\left(X_i\right)\right), Y_i\right).$$

Let $\hat{f}_{h,\mathbf{Z}}$ denote the minimizer and $m_{h,\mathbf{Z}}$ the corresponding minimum. We will then use the hypothesis $a(h)_{\mathbf{Z}} = \hat{f}_{h,\mathbf{Z}} \circ h = \hat{f}_{h,\mathbf{Z}}(h(\cdot))$ for the new task. In this way any representation $h \in \mathcal{H}$ parametrizes a learning algorithm, which is a function $a(h) : \mathcal{Z}^n \to \mathcal{F} \circ h$, defined, for every $\mathbf{Z} \in \mathcal{Z}^n$, as

$$a(h)_{\mathbf{Z}} = \hat{f}_{h,\mathbf{Z}} \circ h.$$

In this sense the problem of optimizing such a representation can properly be called "learning-to-learn". It can also be interpreted as "learning a hypothesis space" as in (Baxter, 2000), namely selecting a hypothesis space $\mathcal{F} \circ h$ from the collection of hypothesis spaces $\{\mathcal{F} \circ h : h \in \mathcal{H}\}$.

We can test the algorithm $a(h)$ on the environment η in the following way:

- we draw a task $\mu \sim \eta$,
- we draw a sample $\mathbf{Z} \in \mathcal{Z}^n$ from μ^n,
- we run the algorithm to obtain $a(h)_{\mathbf{Z}} = \hat{f}_{h,\mathbf{Z}} \circ h$,
- finally, we measure the loss of $a(h)_{\mathbf{Z}}$ on a random data-point $Z = (X, Y) \sim \mu$.

To define the risk $\mathcal{E}_\eta(h)$ associated with the algorithm $a(h)$ parametrized by h we just replace all random draws with corresponding expectations, so

$$\mathcal{E}_\eta(h) = \mathbb{E}_{\mu\sim\eta}\mathbb{E}_{\mathbf{Z}\sim\mu^n}\mathbb{E}_{(X,Y)\sim\mu}\left[\ell\left(a(h)_{\mathbf{Z}}(X), Y\right)\right].$$

The best value for any representation h in $a(h)$, given complete knowledge of the environment, is then

$$\min_{h\in\mathcal{H}} \mathcal{E}_\eta(h).$$

But, given complete knowledge of the environment, this is still not the best we can do using the classes $\mathcal{F}$ and $\mathcal{H}$, because for given μ and h we still use the expected performance

$\mathbb{E}_{\mathbf{Z}\sim\mu^n}\mathbb{E}_{Z\sim\mu}\,\ell\left(a(h)_{\mathbf{Z}}(X), Y\right)$ of the empirical risk minimization algorithm $a(h)$, instead of using knowledge of μ to replace it by $\min_{f\in\mathcal{F}} \mathbb{E}_{Z\sim\mu}\ell\left(f\left(h\left(X\right)\right), Y\right)$. The very best we can do is thus

$$\mathcal{E}_\eta^* = \min_{h\in\mathcal{H}} \mathbb{E}_{\mu\sim\eta}\left[\min_{f\in\mathcal{F}} \mathbb{E}_{Z\sim\mu}\ell\left(f\left(h\left(X\right)\right), Y\right)\right].$$

The excess risk associated with any representation h is thus

$$\mathcal{E}_\eta(h) - \mathcal{E}_\eta^*.$$

We give the following bound for the excess risk associated with the representation $\hat{h}$ found as solution to the optimization problem (1).

Theorem 2 *Let η be an environment on $\mathcal{Z}$ and $\mathcal{H}$ and $\mathcal{F}$ as above. Then: (i) with probability at least $1-\delta$ in the draw of $\bar{\mathbf{Z}} \sim \rho_\eta^T$*

$$\mathcal{E}_\eta(\hat{h}) - \mathcal{E}_\eta^* \le \frac{\sqrt{2\pi}L\; G\left(\mathcal{H}\left(\bar{\mathbf{X}}\right)\right)}{T\sqrt{n}} + \sqrt{2\pi}Q' \sup_{h\in\mathcal{H}} \sqrt{\frac{\mathbb{E}_{(X,Y)\sim\mu_\eta}\left[\|h(X)\|^2\right]}{n}} + \sqrt{\frac{8\ln\left(4/\delta\right)}{T}},$$

and (ii) with the same probability

$$\mathcal{E}_\eta(\hat{h}) - \mathcal{E}_\eta^* \le \frac{\sqrt{2\pi}L\; G\left(\mathcal{H}\left(\bar{\mathbf{X}}\right)\right)}{T\sqrt{n}} + \frac{\sqrt{2\pi}Q'\left(1/T\right)\sum_t \sup_{h\in\mathcal{H}}\|h\left(\mathbf{X}_t\right)\|}{n} + 5\sqrt{\frac{\ln\left(8/\delta\right)}{T}},$$

where $\hat{h}$ is solution to the problem (1), $G\left(\mathcal{H}\left(\bar{\mathbf{X}}\right)\right)$ is the Gaussian average introduced in (2), and Q' is the quantity

$$Q' \equiv Q'(\mathcal{F}) = \sup_{y\in\mathbb{R}^{Kn}\setminus\{0\}} \frac{1}{\|y\|}\mathbb{E}\sup_{f\in\mathcal{F}}\sum_{i=1}^{n}\gamma_i f\left(y_i\right). \tag{5}$$

We make some remarks and comparison to the previous result.

1. The constants are now explicit and small. For Theorem 1, uniform estimation had to be controlled simultaneously in $\mathcal{H}$ and $\mathcal{F}$, while for LTL the problem can be more easily decoupled.
2. The first term is equivalent to the first term in Theorem 1 except for $\sqrt{n}$ replacing n in the denominator. It is therefore typically of order $1/\sqrt{T}$ instead of $1/\sqrt{nT}$. The different order is due to the estimation of a hitherto unknown task, for which the sample sizes are irrelevant. To understand this point assume the η has the property that every $\mu \sim \eta$ is deterministic, that is supported on a single point $z_\mu \in \mathcal{Z}$. Then clearly the sample size n is irrelevant, and the problem becomes equivalent to learning a single task with a sample of size T.

3. The quantity Q' is very much like the quantity Q in Equation (4), and it is uniformly bounded in n for the classes we consider. For linear classes $Q = Q'$.

4. The bound in part (i) is not fully data-dependent, but more convenient for our applications below. The quantity

$$\sup_{h\in\mathcal{H}} \sqrt{\mathbb{E}_{(X,Y)\sim\mu_\eta} \|h(X)\|^2} = \sup_{h\in\mathcal{H}} \sqrt{\sum_k \mathbb{E}_{(X,Y)\sim\mu_\eta} \left[h_k(X)^2\right]}$$

plays a similar role to (3), which is its empirical counterpart. Again, if the features h_k are very specific, as the dictionary atoms of the next section or the atoms in a radial basis function network, then the above quantity can become very small.

2.3 Comparison to Previous Bounds

The first and most important theoretical study of MTL and LTL was carried out by Baxter (2000), where sample complexity bounds are given for both settings. Instead of a feature map a hypothesis space is selected from a class of hypothesis spaces. Clearly every feature map with values in $\mathbb{R}^K$ defines a hypothesis space while the reverse is not true in general, so Baxter's setting is certainly more general than ours. On the other hand the practical applications discussed in (Baxter, 2000) can be cast in the language of feature learning.

To prove his sample complexity bounds Baxter uses covering numbers. This classical method requires to cover a (meta-)hypothesis space (or its evaluation on a sample) with a set of balls in an appropriately chosen metric. The uniform bound is then obtained as a union bound over the cover and bounds valid on the individual balls. The latter bounds follow from Lipschitz properties L of the loss function relative to the chosen metric. For a bound of order ϵ the radius of the balls has to be of order ϵ/L. This leads to covering numbers of order ϵ^{-d}, where d is some exponent (see the last inequalities in the proof of in (Baxter, 2000), and has the consequence that the dominant term in the bound has an additional factor of $\ln(1/\epsilon)$. This is manifest in Theorem 8, Theorem 12 and Corollary 13 in (Baxter, 2000) and constitutes an essential weakness of the method of covering numbers. For bounds on the excess risk it implies that the orders of $\sqrt{1/T}$ and $\sqrt{1/n}$ obtained from Rademacher or Gaussian complexities have to be replaced by $\sqrt{\ln(T)/T}$ and $\sqrt{\ln(n)/n}$.

Rademacher and Gaussian complexities make it easy to handle infinite dimensional input spaces (see our Theorems 4 and 5 below). They also lead to data dependent bounds, which allows us to explain the benefits of multi-task learning in terms of the spectrum of the data covariance operator and the effective input dimension. Bounding Gaussian complexities for linear classes is comparatively simple, see the proof of our Lemma 3. There is a wealth of recent literature on the Rademacher complexity of matrices with spectral regularizers (see e.g. Kakade et al., 2012; Maurer and Pontil, 2013, and references therein), while it is unclear to us how Baxter's method could be applied if the feature map is constrained by a bound on, say, the trace norm of the associated matrix. In the case of LTL, our approach also leads to explicit and small constant factors.

On the other hand it must be admitted, that it is relatively easy to obtain bounds (also provided by Baxter) of order $\ln(n)/n$ or $\ln(T)/T$ with covering numbers in the realizable case. Such bounds would be more difficult to obtain with our techniques.

The work of Ando and Zhang (2005) proposes the use of MTL as a method of semi-supervised learning through the creation of artificial tasks from unlabelled data, for example predicting concealed components of vectors. They analyze a specific algorithm where the class of feature maps can be seen as a linear mixture of a fixed feature map with subspace projections as discussed in our paper. The bounds given apply to the task-averaged risk and not to LTL. The analysis is based on Rademacher averages and is independent of the input dimension. The bound itself is expressed as an entropy integral as given by Dudley (see e.g. Van Der Vaart and Wellner, 1996) but it is not very explicit. In particular the role of the spectrum of the data covariance is not apparent.

3. Multi-task Subspace Learning

We illustrate the general results of the previous section with an important special case. We assume that the input space $\mathcal{X}$ is a bounded subset of a Hilbert space H, which could for example be a reproducing kernel Hilbert space. We denote by $\langle\cdot,\cdot\rangle$ the inner product in H and by $\|\cdot\|$ the induced norm. We hope that sufficiently good results can be obtained by predictors of the form g, where $g : H \to \mathbb{R}$ is linear with bounded norm. We also suspect that only few linear features in H suffice for most tasks, so that the vectors defining the hypotheses g can all be chosen from one and the same, albeit unknown, K-dimensional subspace M of H.

Consequently we will factorize predictors as $f \circ h$, where h is a partial isometry $h : H \to \mathbb{R}^K$ and f is a linear functional on $\mathbb{R}^K$ chosen from some ball of bounded radius. Specifically, we introduce the classes

$$\begin{aligned}\mathcal{H} &= \left\{H \ni x \mapsto (\langle d_1, x\rangle, \ldots, \langle d_K, x\rangle) \in \mathbb{R}^K \ : \ D = (d_1, \ldots, d_K) \in H^K \text{ orthonormal}\right\}\\ \mathcal{F} &= \left\{\mathbb{R}^K \ni y \mapsto \sum_k w_k y_k \in \mathbb{R} \ : \ \sum_k w_k^2 \le B^2\right\}.\end{aligned}$$

The D's appearing in the definition of $\mathcal{H}$ are also called dictionaries and the individual d_k are called atoms (see Maurer et al., 2013).

It does no harm to our analysis if we immediately generalize the class $\mathcal{H}$ so as to include certain two-layer neural networks by allowing a nonlinear activation function ϕ with Lipschitz constant L_ϕ and satisfying $\phi(0) = 0$, to be applied with each atom. We can also drop the condition of orthonormality and allow the atoms to trade some of their norms when needed. The enlarged class of representations is

$$\mathcal{H} = \left\{x \in H \mapsto (\phi(\langle d_1, x\rangle), \ldots, \phi(\langle d_K, x\rangle)) \in \mathbb{R}^K : d_1, \ldots, d_K \in H, \ \sum_k \|d_k\|^2 \le K\right\}.$$

The results can then be re-specialized to subspace learning by setting ϕ to the identity and L_ϕ to one.

When applied to subspace learning, our bounds are expressed in terms of covariances. If ν is a probability measure on H the corresponding covariance operator C_ν is defined by

$$\langle C_\nu v, w\rangle = \mathbb{E}_{X\sim\nu} \langle v, X\rangle \langle X, w\rangle \ \text{ for } v, w \in H.$$

For an environment η we denote the covariance operator corresponding to the data-marginal of the mixture measure μ_η simply by C.

If $\mathbf{x} = (x_1, \ldots, x_m) \in H^m$ we define the empirical covariance operator $\hat{C}(\mathbf{x})$ by

$$\left\langle \hat{C}(\mathbf{x})\, v, w \right\rangle = \frac{1}{m} \sum_i \langle v, x_i \rangle \langle x_i, w \rangle \text{ for } v, w \in H,$$

in particular

$$\left\langle \hat{C}\left(\bar{\mathbf{X}}\right) v, w \right\rangle = \frac{1}{nT} \sum_{ti} \langle v, X_{ti} \rangle \langle X_{ti}, w \rangle .$$

The following lemma establishes the necessary ingredients for the application of Theorems 1 and 2 to the case of subspace learning. Recall that if A is a selfadjoint positive linear operator on H, we denote by $\|A\|_\infty$ and $\|A\|_1$ its spectral and trace norms, respectively. They are defined as $\|A\|_\infty = \sup_{\|z\|\leq 1} \|Az\|$ and $\|A\|_1 = \sum_{i\in\mathbb{N}} \langle e_i, Ae_i \rangle$, where $\{e_i\}_{i\in\mathbb{N}}$ is an orthonormal basis in H. Recall also the definition of $Q(\mathcal{F})$ and $Q'(\mathcal{F})$ given in Equations (4) and (5), respectively.

Lemma 3 *Let $\bar{\mathbf{x}} = (x_{ti})$ be a $T \times n$ matrix with values in a Hilbert space and let ϕ, $\mathcal{H}$ and $\mathcal{F}$ be defined as above. Then*

(i) $G(\mathcal{H}(\bar{\mathbf{x}})) \leq L_\phi K \sqrt{nT \left\| \hat{C}(\bar{\mathbf{x}}) \right\|_1}$.

(ii) For every $h \in \mathcal{H}$, $\|h(\bar{\mathbf{x}})\| \leq L_\phi \sqrt{KnT \left\| \hat{C}(\bar{\mathbf{x}}) \right\|_\infty}$.

(iii) For an environment η *and every* $h \in \mathcal{H}$

$$\mathbb{E}_{(X,Y)\sim\mu_\eta} \|h(X)\|^2 \leq L_\phi^2 K \|C\|_\infty .$$

(iv) $L(\mathcal{F}) \leq B$.

(v) $Q(\mathcal{F}) \leq B$ *and* $Q'(\mathcal{F}) \leq B$.

Proof *(i)* Using the contraction lemma, Corollary 11, in the first inequality and Cauchy-Schwarz and Jensen's inequality in the second we get

$$\begin{aligned}
G(\mathcal{H}(\bar{\mathbf{x}})) &\leq L_\phi \mathbb{E} \sup_{d\in\mathcal{H}} \sum_{kti} \gamma_{kti} \langle d_k, x_{ti} \rangle \\
&= L_\phi \mathbb{E} \sup_{d\in\mathcal{H}} \sum_k \left\langle d_k, \sum_{ti} \gamma_{kti} x_{ti} \right\rangle \\
&\leq L_\phi \sqrt{K} \left(\sum_k \mathbb{E} \left\| \sum_{ti} \gamma_{ti} x_{ti} \right\|^2 \right)^{1/2} \\
&\leq L_\phi K \left(\sum_{ti} \|x_{ti}\|^2 \right)^{1/2} = L_\phi K \sqrt{nT \left\| \hat{C}(\mathbf{x}) \right\|_1}.
\end{aligned}$$

(ii) For any $D \in \mathcal{H}$

$$\begin{aligned}
\sum_{kti} \phi(\langle d_k, x_{ti} \rangle)^2 &\leq L_\phi^2 \sum_{kti} \langle d_k, x_{ti} \rangle^2 \\
&= L_\phi^2 \sum_k \|d_k\|^2 \sum_{ti} \left\langle \frac{d_k}{\|d_k\|}, x_{ti} \right\rangle^2 \\
&\leq L_\phi^2 K \sup_{v:\|v\|\leq 1} \sum_{ti} \langle v, x_{ti} \rangle^2 \\
&= L_\phi^2 K nT \left\| \hat{C}(\bar{\mathbf{x}}) \right\|_\infty ,
\end{aligned}$$

where we used $\phi(0) = 0$ in the first step.

(iii) Similarly, we have that

$$\begin{aligned}
\mathbb{E}_{(X,Y)\sim\mu_\eta} \sum_k \phi(\langle d_k, X \rangle)^2 &\leq L_\phi^2 \sum_k \|d_k\|^2 \mathbb{E}_{(X,Y)\sim\mu_\eta} \left\langle \frac{d_k}{\|d_k\|}, X \right\rangle^2 \\
&\leq L_\phi^2 K \sup_{\|v\|\leq 1} \mathbb{E}_{(X,Y)\sim\mu_\eta} \langle v, X \rangle^2 \\
&= L_\phi^2 K \|C\|_\infty .
\end{aligned}$$

(iv) Let $y, y' \in \mathbb{R}^K$. Then

$$\sup_{w\in\mathcal{F}} \left\{ \sum_k w_k y_k - \sum_k w_k y'_k \right\} \leq \left(\sum_k w_k^2 \right)^{1/2} \|y - y'\| \leq B \|y - y'\| ,$$

so $L \leq B$.

(v) Similarly, we have that

$$\begin{aligned}
\mathbb{E} \sup_{w\in\mathcal{F}} \sum_i \gamma_i \left(\sum_k w_k y_{ki} - \sum_k w_k y_{ki} \right) &= \mathbb{E} \sup_{w\in\mathcal{F}} \sum_k w_k \sum_i \gamma_i (y_{ki} - y_{ki}) \\
&\leq \sup_{w\in\mathcal{F}} \sqrt{\sum_k w_k^2 \sum_k \mathbb{E} \left(\sum_i \gamma_i (y_{ki} - y_{ki}) \right)^2} \\
&\leq B \sqrt{\sum_{ki} (y_{ki} - y_{ki})^2} = B \|y - y'\| ,
\end{aligned}$$

so $Q \leq B$. The same proof works for Q'. ■

Substitution in Theorem 1 immediately gives

Theorem 4 (subspace MTL) *With probability at least $1 - \delta$ in $\bar{\mathbf{X}}$ the excess risk is bounded by*

$$\mathcal{E}_{\text{avg}}(\hat{h}, \hat{f}_1, \ldots, \hat{f}_T) - \mathcal{E}^*_{\text{avg}} \leq c_1 L_\phi B K \sqrt{\frac{\left\| \hat{C}(\bar{\mathbf{X}}) \right\|_1}{nT}} + c_2 L_\phi B \sqrt{\frac{K \left\| \hat{C}(\bar{\mathbf{X}}) \right\|_\infty}{n}} + \sqrt{\frac{8 \ln(2/\delta)}{nT}}. \tag{6}$$

We remark that in the linear case the best competing bound for MTL, obtained by Maurer and Pontil (2013) from noncommutative Bernstein inequalities, is

$$2B\sqrt{\frac{K\left\|\hat{C}\left(\bar{\mathbf{X}}\right)\right\|_1 \ln\left(Tn\right)}{nT}} + B\sqrt{\frac{8K\left\|\hat{C}\left(\bar{\mathbf{X}}\right)\right\|_\infty}{n}} + \sqrt{\frac{8\ln\left(2/\delta\right)}{nT}}. \tag{7}$$

If we disregard the constants this is worse than the bound (6) whenever $K < \ln(Tn)$. Its approach to the multitask limit is slower ($\sqrt{\ln(T)/T}$ as opposed to $\sqrt{1/T}$), but of course it has the advantage of smaller constants. The methods used to obtain (7), however, break down for nonlinear dictionaries.

For the LTL setting, we use the distribution dependent bound, Theorem 2 (i), and obtain

Theorem 5 (subspace LTL) *With probability at least $1-\delta$ in $\bar{\mathbf{X}}$, the excess risk is bounded by*

$$\mathcal{E}_\eta(\hat{h}) - \mathcal{E}_\eta^* \leq \sqrt{2\pi}L_\phi B\left(\frac{K\sqrt{\left\|\hat{C}\left(\bar{\mathbf{X}}\right)\right\|_1}}{\sqrt{T}} + \sqrt{\frac{K\left\|C\right\|_\infty}{n}}\right) + \sqrt{\frac{8\ln\left(4/\delta\right)}{T}}.$$

The two most important common features of Theorems 4 and 5 are the decay to zero of the first term, as $T \to \infty$, and the occurrence of the operator norm of the empirical or true covariances in the second term. The first implies that for very large numbers of tasks the bounds are dominated by the second term.

To understand the second term we must first realize that the ratio of trace and operator norms of the true covariances can be interpreted as an effective dimension of the distribution. This is easily seen if the mixture of task-marginals is concentrated and uniform on a d-dimensional unit-sphere. In this case $\left\|C\right\|_1 = 1$ and by isotropy all eigenvalues are equal, so $\left\|C\right\|_\infty = 1/d$, whence $\left\|C\right\|_1 / \left\|C\right\|_\infty = d$. In such a case the second term in Theorem 5 above becomes

$$B\sqrt{\frac{K}{dn}}. \tag{8}$$

The appropriate standard bound for learning the tasks independently would be $B\sqrt{1/n}$ (see Bartlett and Mendelson, 2002). The ratio $\sqrt{K/d}$ of the two bounds in the multitask limit is the quotient of utilized information (the dimension of the representation space) to available information (the dimension of the data). This highlights the potential advantages of MTRL: if the data is already low-dimensional in the order of K then multi-task learning isn't worth the extra computational labour. If the data is high dimensional however, then multi-task learning may be superior.

The expression (8) above might suggest that there really is a benefit of high dimensions for learning-to-learn. This is of course not the case, because the regularizer B has to be chosen large, in fact proportional to $\sqrt{d}$ to allow a small empirical error. The correct interpretation of (8) is that the burden of high dimensions vanishes in the limit $T \to \infty$. In the next section we will explain this point in more detail.

3.1 Learning to Learn Half-spaces

In this section, we illustrate the benefit of MTRL over independent task learning (ITL) in the case of noiseless linear binary classification (or half-space learning). We compare our upper bounds for LTL to a general lower bound on the performance of ITL algorithms and quantify the parameter regimes where LTL is superior to ITL.

We assume that all the input marginals are given by the uniform distribution σ on the unit sphere $\mathcal{S}_d$ in $\mathbb{R}^d$, and the objective is for each task μ to classify membership in the half-space $\{x : \langle x, u_\mu\rangle > 0\}$ defined by a task-specific (unknown) unit vector u_μ. In the given environment all the vectors u_μ are assumed to lie in some (unknown) K-dimensional subspace M of $\mathbb{R}^d$. We are interested in the regime that

$$K \ll n \ll d$$

and T grows. This is the safe regime in which our upper bounds for MTL or LTL (cf. Theorems 4 and 5) are smaller than a uniform lower bound for independent task learning, which we discuss below. We need $n \ll d$ for the lower bound to be large and $K \ll n$ for the middle term in our upper bounds to be small. If T is large enough, the second term in our upper bounds dominates the first (task dependent) term. A safe choice is $T \gg K^2 d$, see Equation (9) below.

The 0-1-loss is unsuited for our bounds because it is not Lipschitz. Instead we will use the truncated hinge loss with unit margin given by $\ell(y', y) = \xi(y'y)$, where ξ is the real function

$$\xi(t) = \begin{cases} 1 & \text{if} \quad t \leq 0, \\ 1-t & \text{if} \quad 0 < t \leq 1, \\ 0 & \text{if} \quad 1 < t. \end{cases}$$

This loss is an upper bound of the 0-1-loss, so upper bounds for this loss function are also upper bounds for the classification error.

Let $\mathcal{H}$ and $\mathcal{F}$ be as given at the beginning of Section 3 in its linear variant, where $\mathcal{H}$ is defined by orthonormal dictionaries without activation functions. Thus, $\mathcal{H}$ can be viewed as the set of partial isometries $D : H \to \mathbb{R}^K$.

Recall the definition of the minimal risk for LTL

$$\begin{aligned} \mathcal{E}_\eta^* &= \min_{h\in\mathcal{H}} \mathbb{E}_{\mu\sim\eta}\left[\min_{f\in\mathcal{F}} \mathbb{E}_{Z\sim\mu}\ell\Big(f\big(h\left(X\right)\big), Y\Big)\right] \\ &= \min_{D\in\mathcal{H}} \mathbb{E}_{\mu\sim\eta}\left[\min_{\|w\|\leq B} \mathbb{E}_{Z\sim\mu}\xi\big(\left\langle w, DX\right\rangle \operatorname{sgn}\left(\left\langle u_\mu, X\right\rangle\right)\big)\right]. \end{aligned}$$

Let D_M be the partial isometry mapping M onto $\mathbb{R}^K$. Then $D_M \in \mathcal{H}$ and for every unit vector $u \in H$ we have $D_M(Bu) \in \mathcal{F}$. Thus

$$\begin{aligned} \mathcal{E}_\eta^* &\leq \mathbb{E}_{\mu\sim\eta}\left[\mathbb{E}_{Z\sim\mu}\xi\big(\left\langle D_M\left(Bu_\mu\right), D_M X\right\rangle \operatorname{sgn}\left(\left\langle u_\mu, X\right\rangle\right)\big)\right] \\ &= \mathbb{E}_{\mu\sim\eta}\left[\mathbb{E}_{X\sim\sigma}\xi\left(B\left|\left\langle u_\mu, X\right\rangle\right|\right)\right] \\ &\leq \sup_{\|u\|\leq 1} \mathbb{E}_{X\sim\sigma}\xi\left(B\left|\left\langle u, X\right\rangle\right|\right). \end{aligned}$$

For any unit vector $u \in H$ the density of the distribution of $|\langle u, X\rangle|$ under σ has maximum A_{d-1}/A_d, where A_d is the volume of $\mathcal{S}_d$ in the metric inherited from $\mathbb{R}^d$. This density can

therefore be bounded by $\sqrt{d}/2$. Thus

$$\mathcal{E}_\eta^* \leq \sqrt{d} \int_{-\infty}^{\infty} \xi\left(B\,|s|\right) ds = \frac{\sqrt{d}}{2B} = \epsilon,$$

if we set $B = \sqrt{d}/\left(2\epsilon\right)$. This choice is made to ensure that the Lipschitz loss upper bounds the 0-1-loss.

Now let $\bar{\mathbf{Z}}$ be a multi-sample generated from the environment η and assume that we have solved the optimization problem (1) to obtain the representation (or feature-map) $\hat{D} \in \mathcal{H}$. Using the excess risk bound, Theorem 5, and the fact that $\|C\|_\infty = 1/d$ and $\|C\|_1 = 1$, we get with probability at least $1-\delta$ in the draw of $\bar{\mathbf{Z}}$, that

$$\begin{aligned} \mathcal{E}_\eta(\hat{D}) &\leq \epsilon + \frac{\sqrt{2\pi}}{2\epsilon}\left(K\sqrt{\frac{d}{T}} + \sqrt{\frac{K}{n}}\right) + \sqrt{\frac{8\ln\left(4/\delta\right)}{T}} \\ &\leq \sqrt{\sqrt{2\pi}\left(K\sqrt{\frac{d}{T}} + \sqrt{\frac{K}{n}}\right)} + \sqrt{\frac{8\ln\left(4/\delta\right)}{T}}, \end{aligned} \tag{9}$$

if we optimize ϵ. This guarantees the expected performance of future uses of the representation $\hat{D}$. The high dimension still is a hindrance to the estimation of the representation, but, as announced, its effect vanishes in the limit $T \to \infty$. The individual samples must only well outnumber the dimension K, roughly the number of shared features.

We compare this upper bound to a lower bound for a large class of algorithms which learn the tasks independently.

Definition 6 *An algorithm $f : \mathcal{S}_d \times \{-1,1\}^n \to \mathcal{S}_d$ is called* orthogonally equivariant *if*

$$f\left(V\mathbf{x}, \mathbf{y}\right) = Vf\left(\mathbf{x}, \mathbf{y}\right), \text{ for every orthogonal matrix } V \in \mathbb{R}^{d\times d}. \tag{10}$$

For data transformed by an orthogonal transformation an orthogonally equivariant algorithm produces a correspondingly transformed hypothesis. Any algorithm which does not depend on a specific coordinate system is orthogonally equivariant. This class of algorithms includes all kernel methods, but it excludes the Lasso (L1-norm regularization). If the known properties of the problem posses a rotation symmetry only equivariant algorithms make sense.

Below we denote by $\mathrm{err}(u,v)$ the misclassification error between the half-spaces associated with unit vectors u and v, that is $\mathrm{err}(u,v) = \Pr_{x\sim\sigma}\{\langle u,x\rangle\langle v,x\rangle < 0\}$. The following lower error bound is given in (Maurer and Pontil, 2008).

Theorem 7 *Let $n < d$ and suppose that $f : \mathcal{S}_d^n \times \{-1,1\}^n \to \mathcal{S}_d$ is an orthogonally equivariant algorithm. Then for $\delta > 0$ with probability at least $1-\delta$ in the draw of $\mathbf{X} \sim \boldsymbol{\sigma}^n$ we have for every $u \in \mathcal{S}_d$ that*

$$\mathrm{err}\big(u, f(\mathbf{X}, u(\mathbf{X}))\big) \geq \frac{1}{\pi}\left(\sqrt{\frac{d-n}{d}} - \sqrt{\frac{\ln\left(1/\delta\right)}{d}}\right),$$

where $u\left(\mathbf{X}\right) = \left(sgn\left\langle u, X_1\right\rangle, \ldots, sgn\left\langle u, X_n\right\rangle\right)$.

If we use a union bound to subtract the upper bound (9) from this lower bound we obtain high probability guarantees for the advantage of representation learning over other algorithms.

In the following section we plot the phase diagram derived here, namely the difference between the uniform lower bound and our upper bound, and compare it with empirical results (see Figure 4).

3.2 Numerical Experiments

The purpose of the experiments is to compare MTL and LTL to independent task learning (ITL) in the simple setting of linear feature learning (or subspace learning)[1]. We wish to study the regime in which MTL/LTL learning is beneficial over ITL as a function of the number of tasks T and the sample size per task n.

We consider noiseless linear binary classification tasks, namely halfspace learning. We generated the data in the following way. The ground truth weight vectors $u_1, \ldots, u_T$ are obtained by the equation $u_t = Dc_t$, where $c_t \in \mathbb{R}^K$ is sampled from the uniform distribution on the unit sphere in $\mathbb{R}^K$, and the dictionary $D \in \mathbb{R}^{d\times K}$ is created by first sampling a d-dimension orthonormal matrix from the Haar measure, and then selecting the first K columns (atoms). We create all input marginals by sampling from the uniform distribution on the $\sqrt{d}$ radius sphere in $\mathbb{R}^d$. For each task we sample n instances to build the training set, and 1000 instances for the test set.

We train the methods with the hinge loss function $h(z) := \max\{0, 1 - z/c\}$, where c is the margin. We choose $c = 2/\epsilon$, so that the true error relative to the best hypothesis is of order ϵ. We fixed the value of ϵ to be $(K/n)^{1/2}$. For ITL we optimize that loss function constraining the ℓ_2-norm of the weights, for MTL and LTL we constrain D to have a Frobenius norm less or equal than 1, and each c_t is constrained to have an ℓ_2 norm less or equal than 1. During testing we use the 0-1 loss. For example the task-average error is evaluated as

$$\frac{1}{T}\sum_{t=1}^{T}\frac{1}{1000}\sum_{i=1}^{1000} 1\{\mathrm{sign}(\langle u_t, x_i\rangle) \neq \mathrm{sign}(\langle \hat{u}_t, x_i\rangle)\} \tag{11}$$

where $\hat{u}_t$ are the weight vectors learned by the assessed method.

3.3 MTL Experiment

We first discuss the MTL experiment. We let $d = 50$, and vary $T \in \{5, 10, \ldots, 150\}$, $n \in \{5, 10, \ldots, 150\}$ considering the cases $K = 2$ and $K = 5$. In Figure 1 we report the difference between the classification error of the two methods. These results are obtained by repeating the experiment 10 times, reporting the average difference. In each trial a different set of input points and underlying weight vectors are generated for each task. In the MTL case the training error was always below 0.1 and on average it was smaller than 0.04. This suggests that despite the problem being non-convex, the gradient optimization algorithm finds a good suboptimal solution.

1. The code used for the experiments presented in this section is available at `http://romera-paredes.com/multitask-representation`.

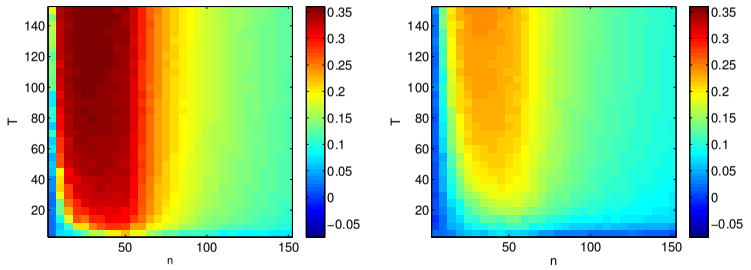

Figure 1: Difference of test classification error, computed according to eq. (11), between ITL and MTL. The vertical axis represents the number of training tasks, and the horizontal axis the number of training instances per task. In the left column $K = 2$, and in the right column $K = 5$.

We have made further experiments to assess the influence of other data settings on the difference between ITL and MTL. In the first of those experiments we have explored the cases in which the dictionary size is overestimated and underestimated. The results are shown in Figure 2. In the left plot the dictionary size is overestimated, in particular the ground truth number of atoms is 2, and the number of atoms used in the MTL method is 5. We can appreciate a similar pattern as the one we saw in Figure 1, although differences between ITL and MTL are not as high. The performance is slightly hampered, as expected due to an overestimation of the number of atoms. On the other hand in Figure 2 (right) we show the results when the number of atoms in the ground truth dictionary is 5, whereas the number of atoms used in the MTL approach is 2. In this case we see that the performance is severely affected by the underestimation of the size of the dictionary, yet we observe that MTL performs better than ITL in the same regime as in the previous experiments.

In the second of these experiments we study how the results are affected when the data are noisy. To do so, we have generated the data so that the ground truth label for instance x_i for task t is given by $\text{sign}(\langle u_t, x_i\rangle + \varepsilon_{ti})$, where $\varepsilon_{ti} \sim \mathcal{N}(0, 1)$. The dictionary size, for both the ground truth and the MTL approach, is $K = 2$. The results are shown in Figure 3, and we can see a similar behaviour as the one in Figure 1, with somewhat smaller differences between ITL and MTL.

3.4 LTL Experiment

In this experiment we test how the dictionary learned at the training stage helps learning new tasks, and we assess how similar the resultant figure is in comparison to the phase diagram derived in the previous section.

The data is generated according to the settings given in the MTL experiment. Furthermore, 50 new tasks are sampled following the same scheme previously described for the purpose of computing the LTL test error. We present the results in Figure 4 (Top). Similar

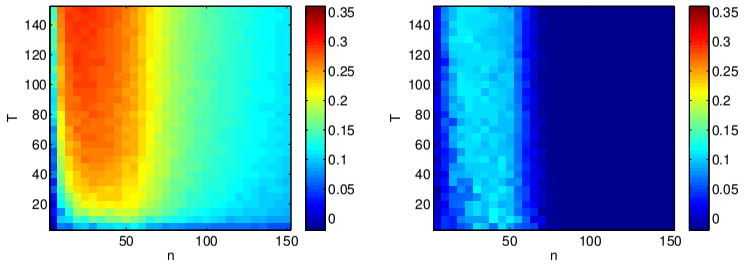

Figure 2: Difference of test classification error, computed according to eq. (11), between ITL and MTL, when the number of atoms of the ground truth dictionary does not match the number of atoms of the MTL model. The plot in the left shows the experiment in which the ground truth number of atoms is 2, whereas the number of atoms used in the MTL approach is 5. The plot in the right shows the opposite scenario: 5 atoms as ground truth, and 2 atoms in the MTL model. The vertical axis represents the number of training tasks, and the horizontal axis the number of training instances per task.

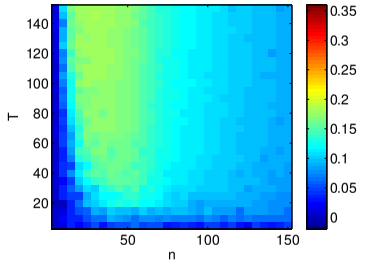

Figure 3: Difference of test classification error, computed according to eq. (11), between ITL and MTL, when adding Gaussian noise to the ground truth labels. The vertical axis represents the number of training tasks, and the horizontal axis the number of training instances per task.

to the previous experiment, we report the average difference between the test error of ITL and LTL after 10 trials.

In Figure 4 (Bottom) we present the theoretical phase diagram, which was generated using $1 \leq T \leq 10^{11}$, $1 \leq n \leq 10^5$, $d = 10^5$, $\delta = 0.0001$. We also plot as a dark line the points in which there is no difference in the performances between ITL and LTL.

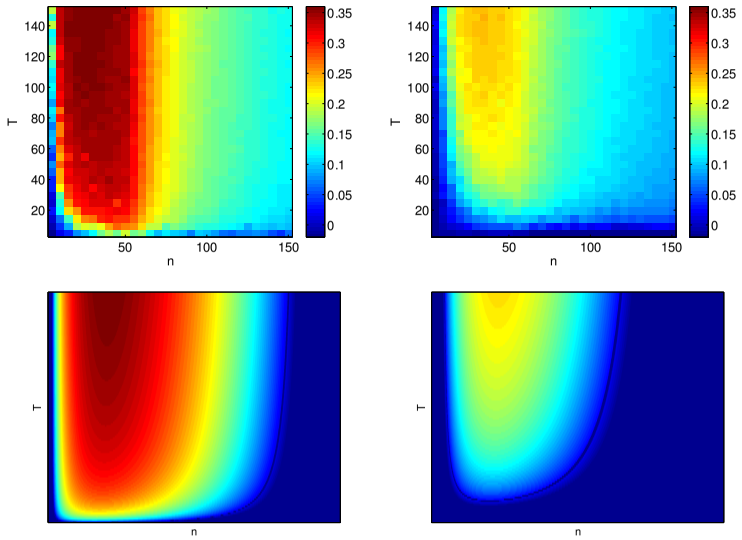

Figure 4: The vertical axis represents the number of training tasks, and the horizontal axis the number of training instances per task. Plots in the top row show the difference of test classification error, computed on 50 new tasks, between ITL and LTL. Plots in the bottom row show the region where the upper bound for LTL is smaller than the lower bound for any equivariant algorithm for ITL (see the discussion in Section 3.1, in particular Equation 9) using $1 \leq T \leq 10^{11}$, $1 \leq n \leq 10^5$, $d = 10^5$, and $\delta = 0.0001$. In the left column $K = 2$, and in the right column $K = 5$.

The reader may object about the much larger parameter values used to generate the plots of theoretical differences, in comparison to the experimental settings. These large parameters are partly a consequence of an accumulation of somewhat loose estimates in the derivation of both the upper and lower bounds. Another reason is that in applying it to a noiseless, finite-dimensional problem (for clarity) we have sacrificed two strong points of our results: independence of input dimension and its agnostic nature. Apart from the large parameter values the theoretical prediction shown in Figure 4 (Bottom) is in very good agreement with the experimental results in Figure 4 (Top).

We have also performed experiments in order to evaluate the influence of noise and under/overestimation of the dictionary size on the difference between ITL and LTL. We obtained similar results as the ones reported for MTL in Figures 2 and 3.

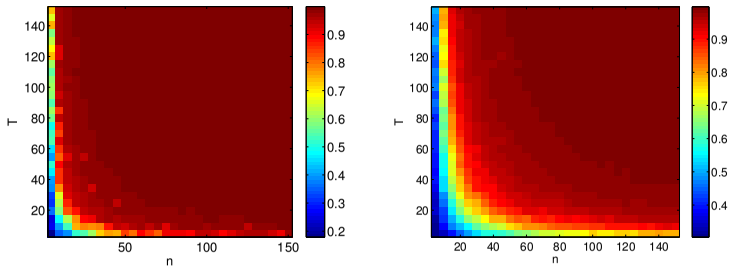

Figure 5: Similarity between the learned dictionary $\hat{D}$ and the ground truth dictionary D, according the similarity measure $s(\hat{D}, D)$ in Equation (12). The vertical axis represents the number of training tasks, and the horizontal axis the number of training instances per task. Left plot: $K = 2$. Right plot: $K = 5$.

Finally, we have compared the learned dictionary, $\hat{D}$, with the ground truth, D, in the same regime of parameters used for the previous experiments. Note that a dictionary could be correct up to permutations and changes of sign of its atoms. To overcome this issue we use the similarity measure

$$s(\hat{D}, D) = \frac{1}{K} \left\| D^\top \hat{D} \right\|_{\mathrm{tr}}, \tag{12}$$

where $\| \cdot \|_{\mathrm{tr}}$ is the sum of singular values of a matrix. Note that $s(\hat{D}, D) = 1$ if $\hat{D}$ and D are the same matrix up to permutation of columns and changes of sign, as requested. The results are found in Figure 5.

Figure 5 indicate that the learned dictionary is close to the true dictionary even for small sample sizes, provide T is large. This supports the results in Figure 1 and the top plots in Figure 4, where MTL or LTL are found to be superior to ITL in this regime, respectively.

4. Proofs of the Main Theorems

In this section we prove our principal results, Theorem 1 and Theorem 2. In preparation for the proofs we will first present some important auxiliary results.

4.1 Tools

We denote by γ a generic vector of independent standard normal variables, whose dimension will be clear from context. A central role in this paper is played by the Gaussian average $G(Y)$ of a set $Y \subseteq \mathbb{R}^n$, which is defined as

$$G(Y) = \mathbb{E} \sup_{y \in Y} \langle \gamma, y \rangle = \mathbb{E} \sup_{y \in Y} \sum_{i=1}^{n} \gamma_i y_i.$$

The reader who is concerned about the measurability of the random variable on the right hand side should replace Y by a countable dense subset of Y, with similar adjustments wherever the Gaussian averages occur.

Rademacher averages, where the γ_i are replaced by uniform $\{-1,1\}$-distributed variables, are somewhat more popular in the literature. We use Gaussian averages instead, because in most cases they are just as easy to bound and possess special properties (Theorem 10 and Theorem 12 below) which we need in our analysis.

The first result is a standard tool to prove uniform bounds on the estimation error in terms of Gaussian averages (Bartlett and Mendelson, 2002).

Theorem 8 *Let $\mathcal{F}$ be a real-valued function class on a space $\mathcal{X}$ and let $\mathbf{X} = (X_1, ..., X_n)$ be a vector of independent random variables and $\mathbf{X}'$ iid to $\mathbf{X}$. Then*

(i)

$$\mathbb{E}_{\mathbf{X}} \sup_{f \in \mathcal{F}} \frac{1}{n} \sum_{i=1}^{n} \left(\mathbb{E}_{\mathbf{X}'} \left[f\left(X_i'\right) \right] - f\left(X_i\right) \right) \leq \frac{\sqrt{2\pi} \mathbb{E}_{\mathbf{X}} G\left(\mathcal{F}\left(\mathbf{X}\right)\right)}{n}$$

(ii) if the members of $\mathcal{F}$ have values in $[0,1]$ then with probability greater than $1-\delta$ in $\mathbf{X}$ for all $f \in \mathcal{F}$

$$\frac{1}{n} \sum_{i=1}^{n} \left(\mathbb{E}_{\mathbf{X}'} \left[f\left(X_i'\right) \right] - f\left(X_i\right) \right) \leq \frac{\sqrt{2\pi} G\left(\mathcal{F}\left(\mathbf{X}\right)\right)}{n} + \sqrt{\frac{9 \ln\left(2/\delta\right)}{2n}}.$$

The following theorem is a vector-valued version of the above, is useful for bounds on the task-averaged estimation error (Ando and Zhang (2005), Maurer (2006b)).

Theorem 9 *Let $\mathcal{F}$ be a class of functions $f : \mathcal{X} \to [0,1]^T$, and let $\mu_1, ..., \mu_T$ be probability measures on $\mathcal{X}$ with $\bar{\mathbf{X}} = (\mathbf{X}_1, ..., \mathbf{X}_T) \sim \prod_{t=1}^{T} \left(\mu_t\right)^n$ where $\mathbf{X}_t = (X_{t1}, ..., X_{tn})$. Then with probability greater than $1-\delta$ in $\bar{\mathbf{X}}$ for all $f \in \mathcal{F}$*

$$\frac{1}{T} \sum_t \left(\mathbb{E}_{X \sim \mu_t} \left[f_t\left(X\right) \right] - \frac{1}{n} \sum_{ti} f_t\left(X_{ti}\right) \right) \leq \frac{\sqrt{2\pi} G\left(Y\right)}{nT} + \sqrt{\frac{9 \ln\left(2/\delta\right)}{2nT}},$$

where $Y \subset \mathbb{R}^{Tn}$ is the random set defined by $Y = \left\{ \left(f_t\left(X_{ti}\right) \right) : f \in \mathcal{F} \right\}$.

The previous two theorems replace the problem of proving uniform bounds by the problem of bounding Gaussian averages. One key result in the latter direction is known as Slepian's Lemma (Slepian (1962), Ledoux and Talagrand (1991)).

Theorem 10 *Let Ω and Ξ be mean zero, separable Gaussian processes indexed by a common set $\mathcal{S}$, such that*

$$\mathbb{E}\left(\Omega_{s_1} - \Omega_{s_2}\right)^2 \leq \mathbb{E}\left(\Xi_{s_1} - \Xi_{s_2}\right)^2 \text{ for all } s_1, s_2 \in \mathcal{S}.$$

Then

$$\mathbb{E} \sup_{s \in \mathcal{S}} \Omega_s \leq \mathbb{E} \sup_{s \in \mathcal{S}} \Xi_s.$$

The following corollary is the key to our bound for LTL.

Corollary 11 *Let $Y \subseteq \mathbb{R}^n$ and let $\phi : Y \to \mathbb{R}^m$ be (Euclidean) Lipschitz with Lipschitz constant L. Then*

$$G\left(\phi\left(Y\right)\right) \leq L G\left(Y\right).$$

Proof Define two Gaussian processes indexed by Y as

$$\Omega_y = \sum_{k=1}^{m} \gamma_k \phi\left(y\right)_k \text{ and } \Xi_y = L \sum_{i=1}^{n} \gamma_i' y_i,$$

with independent γ_k and γ_i'. Then for any $y, y' \in Y$

$$\mathbb{E}\left(\Omega_y - \Omega_{y'}\right)^2 = \left\| \phi\left(y\right) - \phi\left(y'\right) \right\|^2 \leq L^2 \left\| y - y' \right\|^2 = \mathbb{E}\left(\Xi_{s_1} - \Xi_{s_2}\right)^2,$$

so that, by Slepian's Lemma,

$$G\left(\phi\left(Y\right)\right) = \mathbb{E} \sup_{y \in Y} \Omega_y \leq \mathbb{E} \sup_{y \in Y} \Xi_y = L G\left(Y\right).$$

■

In many applications this is applied when $n = m$ and ϕ is defined by $\phi\left(y_1, ..., y_n\right) = \left(\phi_1\left(y_1\right), ..., \phi_n\left(y_n\right)\right)$ where the real functions $\phi_1, ..., \phi_n$ have Lipschitz constant L.

At one point we will need a generalization of the above corollary, which allows to select ϕ from an entire class of Lipschitz functions. We will use the following result, which is taken from Maurer (2014). It will play an important role in the proof of Theorem 13 below.

Theorem 12 *Let $Y \subseteq \mathbb{R}^n$ have (Euclidean) diameter $D\left(Y\right)$ and let $\mathcal{F}$ be a class of functions $f : Y \to \mathbb{R}^m$, all of which have Lipschitz constant at most $L\left(\mathcal{F}\right)$. Then for any $y_0 \in Y$*

$$G\left(\mathcal{F}\left(Y\right)\right) \leq c_1 L\left(\mathcal{F}\right) G\left(Y\right) + c_2 D\left(Y\right) Q\left(\mathcal{F}\right) + G\left(\mathcal{F}\left(y_0\right)\right),$$

where c_1 and c_2 are universal constants and

$$Q\left(\mathcal{F}\right) = \sup_{\mathbf{y}, \mathbf{y}' \in Y,\ \mathbf{y} \neq \mathbf{y}'} \mathbb{E} \sup_{f \in \mathcal{F}} \frac{\left\langle \boldsymbol{\gamma}, f\left(\mathbf{y}\right) - f\left(\mathbf{y}'\right) \right\rangle}{\left\| \mathbf{y} - \mathbf{y}' \right\|}.$$

Note that the result allows us to minimize the right hand side in y_0. Analogs of Theorem 10 and Theorem 12 are not available for Rademacher averages. This is the reason why we use the slightly more exotic Gaussian averages.

4.2 Proof of the Excess Risk Bound for the Average Risk

We first establish the following uniform bound. It is of some interest in its own right, in particular since the problem (1) is often non-convex, so that the excess risk bound may not be meaningful in practice. Recall the definition of Q given in Equation (4).

Theorem 13 *Let $\mu_1, \ldots, \mu_T$ be probability measures on $\mathcal{Z}$ and let $Z_{t1}, \ldots, Z_{tn}$ be i.i.d. from μ_t, for $t = 1, \ldots, T$. Let $\delta \in (0,1)$. With probability at least $1-\delta$ in the draw of a multisample $\bar{\mathbf{Z}}$, it holds for every $h \in \mathcal{H}$ and every $f_1, \ldots, f_T \in \mathcal{F}$ that*

$$\mathcal{E}_{\text{avg}}\left(h, f_1, ..., f_T\right) - \frac{1}{Tn}\sum_{ti} \ell\left(f_t\left(h\left(X_{ti}\right)\right), Y_{ti}\right) \leq c_1 \frac{LG(\mathcal{H}(\bar{\mathbf{X}}))}{nT} + c_2 \frac{Q \sup_{h\in\mathcal{H}} \left\|h\left(\bar{\mathbf{X}}\right)\right\|}{n\sqrt{T}} + \sqrt{\frac{9\ln\left(2/\delta\right)}{2nT}},$$

where c_1 and c_2 are universal constants.

Proof By Theorem 9, with probability at least $1-\delta$ in $\bar{\mathbf{Z}}$, for all $h \in \mathcal{H}$ and all $f_1, ..., f_T \in \mathcal{F}$, we have that

$$\mathcal{E}_{\text{avg}}\left(h, f_1, ..., f_T\right) - \frac{1}{Tn}\sum_{ti} \ell\left(f_t\left(h\left(X_{ti}\right)\right), Y_{ti}\right) \leq \frac{\sqrt{2\pi}}{nT} G\left(S\right) + \sqrt{\frac{9\ln\left(2/\delta\right)}{2nT}}, \tag{13}$$

where $S = \left\{\left(\ell\left(f_t\left(h\left(X_{ti}\right)\right), Y_{ti}\right)\right) : f \in \mathcal{F}^T \text{ and } h \in \mathcal{H}\right\} \subseteq \mathbb{R}^{Tn}$. By the Lipschitz property of the loss function ℓ and the contraction lemma Corollary 11 (recall the remark which follows its proof) we have $G\left(S\right) \leq G\left(S'\right)$, where $S' = \left\{\left(f_t\left(h\left(X_{ti}\right)\right)\right) : f \in \mathcal{F}^T \text{ and } h \in \mathcal{H}\right\} \subseteq \mathbb{R}^{Tn}$.

Recall that $\mathcal{H}\left(\bar{\mathbf{X}}\right) \subseteq \mathbb{R}^{KTn}$ is defined by

$$\mathcal{H}\left(\bar{\mathbf{X}}\right) = \left\{\left(h_k\left(X_{ti}\right)\right) : h \in \mathcal{H}\right\},$$

and define a class of functions $\mathcal{F}' : \mathbb{R}^{KTn} \to \mathbb{R}^{Tn}$ by

$$\mathcal{F}' = \left\{y \in \mathbb{R}^{KTn} \mapsto \left(f_t\left(y_{ti}\right)\right) : \left(f_1, ..., f_T\right) \in \mathcal{F}^T\right\}.$$

Then $S' = \mathcal{F}'\left(\mathcal{H}\left(\bar{\mathbf{X}}\right)\right)$, and by Theorem 12 for universal constants c_1' and c_2'

$$G\left(S'\right) \leq c_1' L\left(\mathcal{F}'\right) G\left(\mathcal{H}\left(\bar{\mathbf{X}}\right)\right) + c_2' D\left(\mathcal{H}\left(\bar{\mathbf{X}}\right)\right) Q\left(\mathcal{F}'\right) + \min_{y\in Y} G\left(\mathcal{F}\left(y\right)\right). \tag{14}$$

We now proceed by bounding the individual terms in the right hand side above. Let $y, y' \in \mathbb{R}^{KTn}$, where $y = \left(y_{ti}\right)$ with $y_{ti} \in \mathbb{R}^K$ and $y' = \left(y'_{ti}\right)$ with $y'_{ti} \in \mathbb{R}^K$. Then for $f = \left(f_1, ..., f_T\right) \in \mathcal{F}^T$

$$\begin{aligned}\left\|f\left(y\right) - f\left(y'\right)\right\|^2 &= \sum_{ti}\left(f_t\left(y_{ti}\right) - f_t\left(y'_{ti}\right)\right)^2 \\ &\leq L^2 \sum_{ti}\left\|y_{ti} - y'_{ti}\right\|^2 = L^2\left\|y - y'\right\|^2,\end{aligned}$$

so that $L\left(\mathcal{F}'\right) \leq L$. Also

$$\begin{aligned}&\mathbb{E}\sup_{g\in\mathcal{F}'}\left\langle\gamma, g\left(y\right) - g\left(y'\right)\right\rangle \\ =\ &\mathbb{E}\sup_{(f_1,...,f_T)\in\mathcal{F}^T}\sum_{ti}\gamma_{ti}\left(f_t\left(y_{ti}\right) - f_t\left(y'_{ti}\right)\right) \\ =\ &\sum_t \mathbb{E}\sup_{f\in\mathcal{F}}\sum_i \gamma_i\left(f\left(y_{ti}\right) - f\left(y'_{ti}\right)\right) \\ \leq\ &\sqrt{T}\left(\sum_t\left(\mathbb{E}\sup_{f\in\mathcal{F}}\sum_i\gamma_i\left(f\left(y_{ti}\right) - f\left(y'_{ti}\right)\right)\right)^2\right)^{1/2} \\ \leq\ &\sqrt{T}\left(\sum_t Q^2\sum_i\left\|y_{ti} - y'_{ti}\right\|^2\right)^{1/2} \\ =\ &\sqrt{T}Q\left\|y - y'\right\|,\end{aligned}$$

whence $Q\left(\mathcal{F}'\right) = \sqrt{T}Q$. Finally we take $y_0 = 0$ and the last term in (14) vanishes since $f\left(0\right) = 0$ for all $f \in \mathcal{F}$. Substitution in (14) and using $G\left(S\right) \leq G\left(S'\right)$ we arrive at

$$G\left(S\right) \leq c_1' L G\left(\mathcal{H}\left(\bar{\mathbf{X}}\right)\right) + c_2'\sqrt{T} D\left(\mathcal{H}\left(\bar{\mathbf{X}}\right)\right) Q.$$

Bounding $D\left(\mathcal{H}\left(\bar{\mathbf{X}}\right)\right) \leq 2\sup_h\left\|h\left(\bar{\mathbf{X}}\right)\right\|$ and substitution in (13) gives the result. ■

Proof of Theorem 1 Let h^* and $f_1^*, ..., f_T^*$ be the minimizers in the definition of $\mathcal{E}_{\text{avg}}^*$. Then

$$\begin{aligned}&\mathcal{E}_{\text{avg}}(\hat{h}, \hat{f}_1, ..., \hat{f}_T) - \mathcal{E}_{\text{avg}}^* \\ =\ &\left(\mathcal{E}_{\text{avg}}(\hat{h}, \hat{f}_1, ..., \hat{f}_T) - \frac{1}{nT}\sum_{ti}\ell(\hat{f}_t(\hat{h}(X_{ti})), Y_{ti})\right) \\ +\ &\left(\frac{1}{nT}\sum_{ti}\ell(\hat{f}_t(\hat{h}(X_{ti})), Y_{ti}) - \frac{1}{nT}\sum_{ti}\ell\left(f_t^*\left(h^*\left(X_{ti}\right)\right), Y_{ti}\right)\right) \\ +\ &\left(\frac{1}{nT}\sum_{ti}\ell\left(f_t^*\left(h^*\left(X_{ti}\right)\right), Y_{ti}\right) - \frac{1}{T}\sum_t \mathbb{E}_{(X,Y)\sim\mu_t}\ell\left(f_t^*\left(h^*\left(X\right)\right), Y\right)\right).\end{aligned}$$

The last term involves only the nT random variables $\ell\left(f_t^*\left(h^*\left(X_{ti}\right)\right), Y_{ti}\right)$ with values in $[0,1]$. It can be bounded with probability $1-\delta/2$ by $\sqrt{\ln\left(2/\delta\right)/\left(2Tn\right)}$ using Hoeffding's inequality. The middle term is non-positive by definition of $\hat{h}, \hat{f}_1, ..., \hat{f}_T$ being the corresponding minimizers. There remains the first term which we bound by

$$\sup_{h\in\mathcal{H}, f_1, ..., f_T\in\mathcal{F}} \mathcal{E}_{\text{avg}}\left(h, f_1, ..., f_T\right) - \frac{1}{Tn}\sum_{ti}\ell\left(f_t\left(h\left(X_{ti}\right)\right), Y_{ti}\right).$$

and appeal to Theorem 13 to bound the supremum. A union bound then completes the proof. ■

4.3 Proof of the Excess Risk Bound for Learning-to-learn

Recall the definition of the algorithm parametrized by $h \in \mathcal{H}$

$$a(h)_{\mathbf{Z}} = \arg\min_{f \in \mathcal{F}} \frac{1}{n} \sum_i \ell(f(h(X_i)), Y_i) \text{ for } \mathbf{Z} \in \mathcal{Z}^n$$

and the associated minimum $m(h)_{\mathbf{Z}}$. Also recall that

$$\mathcal{E}_\eta(h) = \mathbb{E}_{\mu\sim\eta}\mathbb{E}_{\mathbf{Z}\sim\mu^n}\mathbb{E}_{(X,Y)\sim\mu}\ell(a(h)_{\mathbf{Z}}(X), Y)$$

and the two measures μ_η and ρ_η induced by the environment η and defined by

$$\mu_\eta(A) = \mathbb{E}_{\mu\sim\eta}\mu(A) \text{ for } A \subseteq \mathcal{Z} \text{ and } \rho_\eta(A) = \mathbb{E}_{\mu\sim\eta}\mu^n(A) \text{ for } A \subseteq \mathcal{Z}^n.$$

Also recall the definition of Q' given in Equation (5). Again we begin with a uniform bound.

Theorem 14 *Let $\delta \in (0,1)$. (i) With probability at least $1-\delta$ in $\bar{\mathbf{Z}} \sim \rho_\eta^T$ it holds for every $h \in \mathcal{H}$ that*

$$\mathcal{E}_\eta(h) - \frac{1}{T}\sum_t m(h)_{\mathbf{Z}_t} \leq$$

$$\frac{\sqrt{2\pi}LG(\mathcal{H}(\bar{\mathbf{x}}))}{T\sqrt{n}} + \sqrt{2\pi}Q' \sup_{h\in\mathcal{H}} \sqrt{\frac{\mathbb{E}_{(X,Y)\sim\mu_\eta}\left[\|h(X)\|^2\right]}{n}} + \sqrt{\frac{9\ln(2/\delta)}{2T}}.$$

(ii) With probability at least $1-\delta$ in $\bar{\mathbf{Z}} \sim \rho_\eta^T$ it holds for every $h \in \mathcal{H}$ that

$$\mathcal{E}_\eta(h) - \frac{1}{T}\sum_t m(h)_{\mathbf{Z}_t} \leq$$

$$\frac{\sqrt{2\pi}LG(\mathcal{H}(\bar{\mathbf{x}}))}{T\sqrt{n}} + \frac{\sqrt{2\pi}Q'\sum_t \sup_{h\in\mathcal{H}}\|h(\mathbf{X}_t)\|}{nT} + \sqrt{\frac{16\ln(4/\delta)}{T}}.$$

Proof The key to the proof is the decomposition bound

$$\begin{aligned}\sup_{h\in\mathcal{H}} \mathcal{E}_\eta(h) - \frac{1}{T}\sum_t m(h)_{\mathbf{Z}_t} \leq & \sup_{h\in\mathcal{H}} \mathbb{E}_{\mu\sim\eta}\mathbb{E}_{\mathbf{Z}\sim\mu^n}\left[\mathbb{E}_{(X,Y)\sim\mu}\ell(a(h)_{\mathbf{Z}}(X), Y) - m(h)_{\mathbf{Z}}\right] \\ & + \sup_{h\in\mathcal{H}}\left[\mathbb{E}_{\mathbf{Z}\sim\rho_\eta}[m(h)_{\mathbf{Z}}] - \frac{1}{T}\sum_{t=1}^T m(h)_{\mathbf{Z}_t}\right]. \end{aligned} \quad (15)$$

In turn we will bound both terms on the right hand side above. A bound on the second term means that we can predict the empirical risk on the data of a future task uniformly in h. A bound on the first term means that we can predict the true risk from the empirical risk on the future task.

We first bound the second term in the right hand side of (15), and use Theorem 8-(ii) on the class of functions

$$\{\mathbf{z} \in \mathcal{Z}^n \mapsto m(h)_{\mathbf{z}} : h \in \mathcal{H}\}$$

to get with probability at least $1-\delta$ in $\bar{\mathbf{Z}} \sim \rho_\eta^T$ that

$$\sup_{h\in\mathcal{H}}\left[\mathbb{E}_{\mathbf{Z}\sim\rho_\eta}[m(h)_{\mathbf{Z}}] - \frac{1}{T}\sum_{t=1}^T m(h)_{\mathbf{Z}_t}\right] \leq \frac{\sqrt{2\pi}}{T}G(S) + \sqrt{\frac{9\ln(2/\delta)}{2T}},$$

where S is the subset of $\mathbb{R}^T$ defined by

$$S = \left\{\left(m(h)_{\mathbf{Z}_1}, ..., m(h)_{\mathbf{Z}_T}\right) : h \in \mathcal{H}\right\}.$$

We will bound the Gaussian average of S using Slepian's inequality (Theorem 10). Define two Gaussian processes indexed by $\mathcal{H}$ as

$$\Omega_h = \sum_t \gamma_t m(h)_{\mathbf{z}_t} \text{ and } \Xi_h = \frac{L}{\sqrt{n}}\sum_{kti}\gamma_{kti}h_k(x_{ti}).$$

Now for any $\mathbf{z} \in \mathcal{Z}^n$ and representations $h, h' \in \mathcal{H}$

$$\begin{aligned}\left(m(h)_{\mathbf{z}} - m\left(h'\right)_{\mathbf{z}}\right)^2 &= \left(\min_{f\in\mathcal{F}}\frac{1}{n}\sum_i \ell(f(h(x_i)), y_i) - \min_{f\in\mathcal{F}}\frac{1}{n}\sum_i \ell\left(f\left(h'(x_i)\right), y_i\right)\right)^2 \\ &\leq \left(\sup_{f\in\mathcal{F}}\frac{1}{n}\sum_i \ell(f(h(x_i)), y_i) - \ell\left(f\left(h'(x_i)\right), y_i\right)\right)^2 \\ &\leq \frac{1}{n}\sup_{f\in\mathcal{F}}\sum_i\left(\ell(f(h(x_i)), y_i) - \ell\left(f\left(h'(x_i)\right), y_i\right)\right)^2 \\ &\leq \frac{L^2}{n}\sum_{ki}\left(h_k(x_i) - h'_k(x_i)\right)^2,\end{aligned}$$

where in the last step we used the Lipschitz properties of the loss function ℓ and of the members in the class $\mathcal{F}$. It follows that

$$\begin{aligned}\mathbb{E}(\Omega_h - \Omega_{h'})^2 &= \sum_t\left(m(h)_{\mathbf{z}_t} - m\left(h'\right)_{\mathbf{z}_t}\right)^2 \\ &\leq \frac{L(\mathcal{F})^2}{n}\sum_{kti}\left(h_k(x_{ti}) - h'_k(x_{ti})\right)^2 = \mathbb{E}(\Xi_h - \Xi_{h'})^2,\end{aligned}$$

so by Theorem 10

$$G(S) = \mathbb{E}\sup_k \Omega_h \leq \mathbb{E}\sup_k \Xi_h = \frac{L}{\sqrt{n}}G(\mathcal{H}(\bar{\mathbf{x}})).$$

The second term in the right hand side of (15) is thus bounded with probability $1-\delta$ by

$$\frac{\sqrt{2\pi}LG(\mathcal{H}(\bar{\mathbf{x}}))}{T\sqrt{n}} + \sqrt{\frac{9\ln(2/\delta)}{2T}}. \quad (16)$$

We now bound the first term on the right hand side of (15) by

$$\begin{aligned}
&\sup_{h\in\mathcal{H}} \mathbb{E}_{\mu\sim\eta}\mathbb{E}_{\mathbf{Z}\sim\mu^n}\left[\mathbb{E}_{(X,Y)\sim\mu}\ell\left(a\left(h\right)_{\mathbf{X}}\left(X\right),Y\right) - m\left(h\right)_{\mathbf{Z}}\right] \\
\leq\ & \sup_{h\in\mathcal{H}} \mathbb{E}_{\mu\sim\eta}\mathbb{E}_{\mathbf{Z}\sim\mu^n} \sup_{f\in\mathcal{F}}\left[\mathbb{E}_{(X,Y)\sim\mu}\ell\left(f\left(h\left(X\right)\right),Y\right) - \frac{1}{n}\sum_i \ell\left(f\left(h\left(X_i\right)\right),Y_i\right)\right].
\end{aligned}$$

For $\mathbf{Z}=(\mathbf{X},\mathbf{Y})\in\mathcal{Z}^n$ and $h\in\mathcal{H}$ denote with $\ell\left(\mathcal{F}\circ h\left(\mathbf{X}\right),\mathbf{Y}\right)$ the subset of $\mathbb{R}^n$ defined by

$$\ell\left(\mathcal{F}\left(h\left(\mathbf{X}\right)\right),\mathbf{Y}\right) = \left\{\left(\ell\left(f\left(h\left(X_i\right)\right),Y_i\right)\right) : f\in\mathcal{F}\right\}.$$

Using Theorem 8-(i) and the contraction lemma, Corollary 11, we can bound the last expression above by

$$\begin{aligned}
&\sup_{h\in\mathcal{H}} \mathbb{E}_{\mu\sim\eta}\mathbb{E}_{\mathbf{Z}\sim\mu^n} \sup_{f\in\mathcal{F}}\left[\mathbb{E}_{(X,Y)\sim\mu}\ell\left(f\left(h\left(X\right)\right),Y\right) - \frac{1}{n}\sum_i \ell\left(f\left(h\left(X_i\right)\right),Y_i\right)\right] \\
\leq\ & \sqrt{2\pi}\sup_{h\in\mathcal{H}} \mathbb{E}_{\mathbf{Z}\sim\boldsymbol{\rho}_\eta}\frac{G\left(\ell\left(\mathcal{F}\left(h\left(\mathbf{X}\right)\right),\mathbf{Y}\right)\right)}{n} \\
\leq\ & \sqrt{2\pi}\sup_{h\in\mathcal{H}} \mathbb{E}_{\mathbf{Z}\sim\boldsymbol{\rho}_\eta}\frac{G\left(\mathcal{F}\left(h\left(\mathbf{X}\right)\right)\right)}{n} \\
=\ & \frac{\sqrt{2\pi}}{n}\sup_{h\in\mathcal{H}} \mathbb{E}_{\mathbf{Z}\sim\boldsymbol{\rho}_\eta}\frac{G\left(\mathcal{F}\left(h\left(\mathbf{X}\right)\right)\right)}{\left\|h\left(\mathbf{X}\right)\right\|}\left\|h\left(\mathbf{X}\right)\right\| \\
\leq\ & \frac{\sqrt{2\pi}}{n}Q'\sup_{h\in\mathcal{H}} \mathbb{E}_{\mathbf{Z}\sim\boldsymbol{\rho}_\eta}\left\|h\left(\mathbf{X}\right)\right\|,
\end{aligned}$$

using Hoelder's inequality and the definition of Q' in the last step. But, using Jensen's inequality,

$$\mathbb{E}_{\mathbf{Z}\sim\boldsymbol{\rho}_\eta}\left\|h\left(\mathbf{X}\right)\right\| \leq \sqrt{\mathbb{E}_{\mathbf{Z}\sim\rho_\eta}\sum_i\left\|h\left(X_i\right)\right\|^2} = \sqrt{n\,\mathbb{E}_{(X,Y)\sim\mu_\eta}\left\|h\left(X\right)\right\|^2},$$

since $\mathbf{Z}\sim\rho_\eta$ is iid. Inserting this in the previous chain of inequalities and combining with (16) gives the first part of the theorem.

To obtain the data dependent bound we use the fact that, with probability at least $1-\delta/4$,

$$\begin{aligned}
\sup_{h\in\mathcal{H}} \mathbb{E}_{\mathbf{Z}\sim\boldsymbol{\rho}_\eta}\frac{G\left(\ell\left(\mathcal{F}\left(h\left(\mathbf{X}\right)\right),\mathbf{Y}\right)\right)}{n} &\leq \mathbb{E}_{\mathbf{X}\sim\rho_\eta}\sup_{h\in\mathcal{H}}\frac{G\left(\ell\left(\mathcal{F}\left(h\left(\mathbf{X}\right)\right),\mathbf{Y}\right)\right)}{n} &(17)\\
&\leq \frac{1}{T}\sum_t \sup_{h\in\mathcal{H}}\frac{G\left(\ell\left(\mathcal{F}\left(h\left(\mathbf{X}_t\right)\right),\mathbf{Y}_t\right)\right)}{n} + \sqrt{\frac{\ln\left(4/\delta\right)}{2T}} &(18)
\end{aligned}$$

The last inequality follows from Hoeffding's inequality since for any $h\in\mathcal{H}$ and any sample $\mathbf{Z}\in\mathcal{Z}^n$

$$\begin{aligned}
0 \ \leq\ & \frac{G\left(\ell\left(\mathcal{F}\left(h\left(\mathbf{X}\right)\right),\mathbf{Y}\right)\right)}{n} = \frac{1}{n}\mathbb{E}_\gamma\sup_f\sum_i\gamma_i\ell\left(f\left(h\left(X_i\right)\right),Y_i\right) \\
\leq\ & \frac{1}{n}\mathbb{E}_\gamma\left(\sum_i\gamma_i^2\right)^{1/2}\sup_f\left(\sum_i\ell\left(f\left(h\left(X_i\right)\right),Y_i\right)^2\right)^{1/2} \leq 1,
\end{aligned}$$

where we have also used the fact that the loss function ℓ has range in $[0,1]$. Bounding

$$G\left(\ell\left(\mathcal{F}\circ h\left(\mathbf{X}_t\right),\mathbf{Y}_t\right)\right) \leq Q'\left\|h\left(\mathbf{X}_t\right)\right\|$$

as above and combining (18) and (16) in (15) with a union bound gives the second inequality of the theorem.

■

Remark: In the proof of the fully data-dependent part above the bound on

$$\sup_{h\in\mathcal{H}}\mathbb{E}_{\mathbf{Z}\sim\boldsymbol{\rho}_\eta}\frac{G\left(\ell\left(\mathcal{F}\left(h\left(\mathbf{X}\right)\right),\mathbf{Y}\right)\right)}{n}$$

is very crude. Instead we could have again invoked Theorem 8 to get a better bound with a more complicated expression involving nested Gaussian averages. We have chosen the simpler path for greater clarity.

Proof of Theorem 2 Recall that

$$\mathcal{E}_\eta^* = \min_{h\in\mathcal{H}}\mathbb{E}_{\mu\sim\eta}\left[\min_{f\in\mathcal{F}}\mathbb{E}_{(X,Y)\sim\mu}\ell\left(f\left(h\left(X\right)\right),Y\right)\right].$$

We denote with h^* the minimizer in $\mathcal{H}$ occurring in the definition of $\mathcal{E}_\eta^*$. We have the following decomposition

$$\begin{aligned}
\mathcal{E}_\eta(\hat{h}) - \mathcal{E}_\eta^* \ =\ & \left(\mathcal{E}_\eta(\hat{h}) - \frac{1}{T}\sum_t m(\hat{h})_{\mathbf{Z}_t}\right) &(19)\\
&+\left(\frac{1}{T}\sum_t m(\hat{h})_{\mathbf{Z}_t} - \frac{1}{T}\sum_t m(h^*)_{\mathbf{Z}_t}\right) &(20)\\
&+\left(\frac{1}{T}\sum_t m(h^*)_{\mathbf{Z}_t} - \mathbb{E}_{\mathbf{Z}\sim\rho_\eta}\left[m\left(h^*\right)_{\mathbf{Z}}\right]\right) &(21)\\
&+\mathbb{E}_{\mu\sim\eta}\left[\mathbb{E}_{\mathbf{Z}\sim\mu^n}\left[m\left(h^*\right)_{\mathbf{Z}}\right] - \min_{f\in\mathcal{F}}\mathbb{E}_{(X,Y)\sim\mu}\ell\left(f\left(h^*\left(X\right)\right),Y\right)\right]. &(22)
\end{aligned}$$

For a fixed distribution μ let f_μ^* be the minimizer in $\min_{f\in\mathcal{F}}\mathbb{E}_{(X,Y)\sim\mu}\ell\left(f\left(h^*\left(X\right)\right),Y\right)$. By definition of $m\left(h^*\right)_{\mathbf{Z}}$ we have for every $\mu\sim\eta$ that

$$\begin{aligned}
\mathbb{E}_{\mathbf{Z}\sim\mu^n}\left[m\left(h^*\right)_{\mathbf{Z}}\right] &= \mathbb{E}_{\mathbf{Z}\sim\mu^n}\min_{f\in\mathcal{F}}\frac{1}{m}\sum_{i=1}^m\ell\left(f\left(h^*\left(X_i\right)\right),Y_i\right) \\
&\leq \mathbb{E}_{\mathbf{Z}\sim\mu^n}\frac{1}{m}\sum_{i=1}^m\ell\left(f_\mu^*\left(h^*\left(X_i\right)\right),Y_i\right) \\
&= \mathbb{E}_{(X,Y)\sim\mu}\ell\left(f_\mu^*\left(h^*\left(X\right)\right),Y\right),
\end{aligned}$$

since $\mathbf{Z}$ is iid. The term in (22) is therefore non-positive.

The term in (21) involves the deviation of the empirical and true averages of the T iid $[0,1]$-valued random variables $m(h^*)_{\mathbf{Z}_t}$. With Hoeffding's inequality this can be bounded with probability at least $1-\delta/8$ by $\sqrt{\ln(8/\delta)/(2T)}$. The term (20) is non-positive by the definition of $\hat{h}$.

There remains the term (19), which we bound by Theorem 14. The result now follows by combining this bound with the bound on (21) in a union bound and some numerical simplifications. ■

5. Conclusion

Several works have advocated that sharing features among tasks as a means to learning representations which capture invariant properties to tasks can be highly beneficial. In this paper, we studied the statistical properties of a general MTRL method, presenting bounds on its learning performance in both settings of MTL and LTL. Our work provides a rigorous justification of the benefit offered by MTRL over learning the tasks independently. To give the paper a clear focus we have illustrated this advantage in the case of linear feature learning. Our results however apply to fairly general classes of representations $\mathcal{H}$ and specifications $\mathcal{F}$, and similar conclusions may be derived for other nonlinear MTRL methods. We conclude by sketching specific cases which deserve a separated study:

- *Deep networks.* As we noted our bounds directly apply to multilayer, deep architectures obtained by iteratively composing linear transformations with nonlinear activation functions, such as the rectifier linear unit or the sigmoid functions. The representations learned by such methods tend to be specific in that only a subset of components are "active" on each given input, which makes our bounds particularly attractive for further analysis.

- *Sparse coding.* Another interesting case of our framework is obtained when the specialized class $\mathcal{F}$ consists of sparse linear predictors. This case has been considered in Maurer et al. (2013); Ruvolo and Eaton (2014) when the representation class consists of linear functions. Different choices of sparse classes $\mathcal{F}$ could lead to interesting learning methods.

- *Representations in RKHS.* As we already noted the feature maps forming the class $\mathcal{H}$ could be vector-valued functions in a reproducing kernel Hilbert space. Although kernel methods are more difficult to apply to large datasets required for MTRL and need additional approximation steps, the representations learned using for example Gaussian kernels would be very specific and suitable for our bounds.

Abstract

Variable selection is popular in high-dimensional data analysis to identify the truly informative variables. Many variable selection methods have been developed under various model assumptions. Whereas success has been widely reported in literature, their performances largely depend on validity of the assumed models, such as the linear or additive models. This article introduces a model-free variable selection method via learning the gradient functions. The idea is based on the equivalence between whether a variable is informative and whether its corresponding gradient function is substantially non-zero. The proposed variable selection method is then formulated in a framework of learning gradients in a flexible reproducing kernel Hilbert space. The key advantage of the proposed method is that it requires no explicit model assumption and allows for general variable effects. Its asymptotic estimation and selection consistencies are studied, which establish the convergence rate of the estimated sparse gradients and assure that the truly informative variables are correctly identified in probability. The effectiveness of the proposed method is also supported by a variety of simulated examples and two real-life examples.

Keywords: group Lasso, high-dimensional data, kernel regression, learning gradients, reproducing kernel Hilbert space (RKHS), variable selection

1. Introduction

The rapid advance of technology has led to an increasing demand for modern statistical techniques, such as high-dimensional data analysis that has attracted tremendous interests in the past two decades. When analyzing high-dimensional data, it is often believed that only a small number of variables are truly informative while others are noise. Therefore, identifying the truly informative variables is regarded as one of the primary goals in high-dimensional data analysis as well as many real applications such as health studies.

In literature, a wide spectrum of variable selection methods have been proposed based on various model assumptions. For example, under the linear model assumption, regularized regression models are popularly used for variable selection, including the nonnegative garrote (Breiman and Friedman, 1985), the least absolute shrinkage and selection operator (Tibshirani, 1996), the smoothly clipped absolute deviation (Fan and Li, 2001), the adaptive Lasso (Zou, 2006), the combined L_0 and L_1 penalty (Liu and Wu, 2007), the truncated L_1 penalty (Shen et al., 2012), and many others. The main strategy is to associate the least square loss function with a sparsity-inducing penalty, leading to sparse representation of the resultant regression function. With the linear regression model, the sparse representation leads to variable selection based on whether the corresponding regression coefficient is zero.

The aforementioned variable selection methods have demonstrated superior performance in many real applications. Yet their success largely relies on the validity of the linear model assumption. To relax the model assumption, attempts have been made to extend the variable selection methods to a nonparametric regression context. For example, under the additive regression model assumption, a number of variable selection methods have been developed (Shively et al., 1999; Huang and Yang, 2004; Xue, 2009; Huang et al., 2010). Furthermore, higher-order additive models can be considered, allowing each functional component contain more than one variables, such as the component selection and smoothing operator (Cosso) method (Lin and Zhang, 2006). While this method provides a more flexible and still interpretable model compared to the classical additive models, the number of functional components increases exponentially with the dimension. Another stream of research on variable selection is to conduct screening (Fan et al., 2011; Zhu et al., 2011; Li et al., 2012), which treats each individual variable separately and assures the sure screening properties. To overcome the issue of ignoring interaction effects, a higher-order interaction screening method is also developed (Hao and Zhang, 2014). Model-free variable selection has also been approached in the context of sufficient dimension reduction (Li et al., 2005; Bondell and Li, 2009). More recently, Stefanski et al. (2014) introduced a novel measurement-error-model-based variable selection method that can be adapted to a nonparametric kernel regression.

In this article, we propose a novel model-free variable selection method, which requires no explicit model assumptions and allows for general variable effects. The method is based on the idea that a variable is truly informative with respect to the regression function if the gradient of the regression function along the corresponding coordinate is substantially different from zero. Thus the proposed variable selection method is formulated in a gradient learning framework equipped with a flexible reproducing kernel Hilbert space (Wahba, 1999). Learning gradients can be traced back to Härdle and Gasser (1985). Some of its recent developments include Jarrow et al. (2004), Mukherjee and Zhou (2006), Ye and Xie (2012), and Brabanter et al. (2013), where the main focus is to estimate the gradient functions.

As opposed to estimating the gradient functions, this article focuses on variable selection whose primary interest is to identify the truly informative variables corresponding to the non-zero gradient functions. To attain the sparsity in the estimated gradients, we consider a learning algorithm generated by a coefficient-based regularization scheme (Scholköpf and Smola, 2002), and a group Lasso penalty (Yuan and Lin, 2006) is enforced on the coefficients so that the proposed method can conduct gradient learning and variable selection

simultaneously. Specifically, the proposed variable selection method via gradient learning is formulated in a regularization form that consists of a pairwise loss function for estimating the gradient functions and a group Lasso penalty.

One of the main features of the proposed variable selection method is that it does not require any explicit model assumption and detect informative variables with various effects on the regression function. This is a major advantage over most existing model-based variable selection methods which need to pre-specify a working model. If higher-order variable effects are considered, the model-based methods need to enumerate the possible components, whose number increases exponentially with the dimension p. In sharp contrast, our proposed method only needs to estimate p components, while allowing for general variable effects.

Another interesting feature of the proposed method is the use of coefficient-based representation in estimating the gradient function. It follows directly from the representor theorem (Wahba, 1999) in a RKHS, and turns out to greatly facilitate variable selection in the gradient learning framework. With the coefficient-based representation, the group Lasso penalty can be naturally enforced on all the coefficients associated with the same variable. This leads to a well-structured optimization task, and can be efficiently solved through a blockwise coordinate descent algorithm (Yang and Zou, 2015). This is contrast to the existing gradient learning methods such as Ye and Xie (2012), where standard RHKS is used and a squared RKHS-norm penalty is enforced to attain the sparsity structure in the estimated gradients, and a forward-backward splitting algorithm is required for computation.

Finally, the effectiveness of the proposed method is supported by a variety of simulated and real examples. More importantly, its asymptotic estimation and selection consistencies are established, showing that the proposed method shall recover the truly informative variables with probability tending to one, and estimate the true gradient function at a fast convergence rate. Note that the variable selection consistency is not established in Ye and Xie (2012), and the estimation consistency of our method is more challenging due to the additional hypothesis error arises in the coefficient-based formulation. Also, as in many nonparametric variable selection methods (Lin and Zhang, 2006; Xue, 2009; Huang et al., 2010), the results are obtained in the sneario of fixed dimension, which are particlarly interesting given the fact that the variable selection consistency is obtained without assuming any explicit model.

The rest of the article is organized as follows. Section 2 presents a general framework of the proposed model-free variable selection method as well as an efficient computing algorithm to tackle the resultant large-scale optimization task. Section 3 establishes the asymptotic results of the proposed method in terms of both estimation and variable selection. The numerical experiments on the simulated examples and real applications are contained in Section 4. A brief discussion is provided in Section 5, and the Appendix is devoted to the technical proofs.

2. Model-free variable selection

2.1 Preambles

Suppose that a training set consists of $(\mathbf{x}_i, y_i)$; $i = 1, \ldots, n$, where $\mathbf{x}_i = (x_{i1}, \ldots, x_{ip})^T \in \mathcal{R}^p$ and $y_i \in \mathcal{R}$ are independently sampled from some unknown joint distribution. We consider

the following regression model,

$$y = f^*(\mathbf{x}) + \epsilon,$$

where $\mathrm{E}(\epsilon|\,\mathbf{x}) = 0$, $\mathrm{Var}(\epsilon|\,\mathbf{x}) = \sigma^2$, $\mathbf{x} = (x^{(1)}, \ldots, x^{(p)})^T$ is supported on a compact metric space $\mathcal{X}$, and f^* is the true regression function that is assumed to be twice differentiable everywhere.

When p is large, it is generally believed that only a small number of variables are truly informative. In literature, to define the truly informative variables, f^* is often assumed to be of certain form. For instance, if $f^*(\mathbf{x}) = \mathbf{x}^T\boldsymbol{\beta}^*$ with $\boldsymbol{\beta}^* = (\beta_1^*, \ldots, \beta_p^*)^T$, then $x^{(j)}$ is regarded as truly informative if $\beta_j^* \neq 0$. However, this linear model assumption on f^* can be too restrictive in practice, and whether a variable is informative shall not depend on the assumed model. In this article, a model-free variable selection method is developed without assuming any explicit form for f^*.

Since no explicit form is assumed for f^*, we note that if $x^{(l)}$ is non-informative in f^*, the corresponding gradient function $\nabla f_l^*(\mathbf{x}) = \partial f^*(\mathbf{x})/\partial x^{(l)} \equiv 0$ for any $\mathbf{x}$. This fact motivates the proposed model-free variable selection method in a gradient learning framework. Denote $\mathbf{g}^*(\mathbf{x}) = \nabla f^*(\mathbf{x}) = (\nabla f_1^*(\mathbf{x}), \ldots, \nabla f_p^*(\mathbf{x}))^T$ the true gradient function, and the estimation error as

$$\begin{aligned}\mathcal{E}(\mathbf{g}) &= E_{(\mathbf{x},y),(\mathbf{u},v)} w(\mathbf{x},\mathbf{u})(y - v - \mathbf{g}(\mathbf{x})^T(\mathbf{x}-\mathbf{u}))^2 \\ &= 2\sigma_s^2 + E_{\mathbf{x},\mathbf{u}} w(\mathbf{x},\mathbf{u})(f^*(\mathbf{x}) - f^*(\mathbf{u}) - \mathbf{g}(\mathbf{x})^T(\mathbf{x}-\mathbf{u}))^2, \end{aligned} \tag{1}$$

where $\sigma_s^2 = E_{(\mathbf{x},y),(\mathbf{u},v)}[w(\mathbf{x},\mathbf{u})(y - f^*(\mathbf{x}))^2]$ is independent of $\mathbf{g}$, and $w(\mathbf{x},\mathbf{u})$ is a weight function that decreases as $\|\,\mathbf{x}-\mathbf{u}\,\|$ increases and ensures the local neighborhood of $\mathbf{x}$ contributes more to estimating $\mathbf{g}^*(\mathbf{x})$. Typically, $w(\mathbf{x},\mathbf{u}) = e^{-\|\,\mathbf{x}-\mathbf{u}\,\|^2/\tau_n^2}$ with a pre-specified positive parameter τ_n^2, which plays a key role in the asymptotic estimation consistency and is to be elaborated.

2.2 Coefficient-based formulation

Given the training set $(\mathbf{x}_i, y_i)$; $i = 1, \ldots, n$, $\mathcal{E}(\mathbf{g})$ is approximated by its empirical version, and then the proposed variable selection method is formulated as

$$\underset{\mathbf{g}\in\mathcal{H}_K^p}{\operatorname{argmin}}\ s(\mathbf{g}) = \frac{1}{n(n-1)}\sum_{i,j=1}^{n} w_{ij}\Big(y_i - y_j - \mathbf{g}(\mathbf{x}_i)^T(\mathbf{x}_i - \mathbf{x}_j)\Big)^2 + J(\mathbf{g}), \tag{2}$$

where $w_{ij} = w(\mathbf{x}_i, \mathbf{x}_j)$, $\mathcal{H}_K$ denotes a RKHS induced by a pre-specified kernel $K(\cdot,\cdot)$, $J(\mathbf{g}) = \lambda_n \sum_{l=1}^p \pi_l J(g_l)$ is a penalty function on the complexity of $\mathbf{g}$, and π_l's are the adaptive tuning parameters to be specified. The representor theorem assures that the minimizer of (2) must be of the following coefficient-based representation,

$$g_l(\mathbf{x}) = \sum_{t=1}^{n} \alpha_t^l K(\mathbf{x}, \mathbf{x}_t);\ l = 1, \ldots, p.$$

Thanks to the explicit form of $g_l(\mathbf{x})$, it is clear that $g_l(\mathbf{x}) \equiv 0$ is equivalent to $\alpha_t^l = 0$ for all t's, or more concisely, $\|\boldsymbol{\alpha}^{(l)}\|_2 = 0$ with $\boldsymbol{\alpha}^{(l)} = (\alpha_1^l, ..., \alpha_n^l)^T$. A similar formulation connecting

between ridge regression with a coefficient-based representation and support vector machine (Cortes and Vapnik, 1995) is also established in Scholköpf and Smola (2002).

Furthermore, to exploit the sparse structure in the regression model, we propose to consider the following sparsity-inducing penalty,

$$J(g_l) = \inf\left\{\|\boldsymbol{\alpha}^{(l)}\|_2 : g_l(\cdot) = \sum_{t=1}^{n} \alpha_t^l K(\cdot, \mathbf{x}_t)\right\}. \tag{3}$$

Here the group Lasso type of penalty $\|\boldsymbol{\alpha}^{(l)}\|_2$ attains the effect of pushing all or none of α_t^l's to be exactly 0 and thus achieves the purpose of variable selection. The infimum is necessary for defining the penalty as the kernel basis $\{K(\cdot, \mathbf{x}_t)\}_{t=1}^n$ may not be linearly independent and thus the representation of g_l in $\mathcal{H}_K$ may not be unique. This penalty term differs from that in Ye and Xie (2012) in that our coefficient-based penalty does not rely on K and usually leads to sparser solutions. On the contrary, the penalty $\|g_l\|_K$ in Ye and Xie (2012) can be sensitive to the choice of K as its minimum eigenvalue can be very small. In addition, the finite dimensional hypothesis space is more flexible than the standard RHKS, and particularly the positive definite K is no longer needed. This relaxation can be critical in scenarios when such kernels are inappropriate.

With the coefficient-based representation and the group Lasso penalty, the proposed variable selection formulation can be rewritten as

$$\underset{\boldsymbol{\alpha}^{(1)},\ldots,\boldsymbol{\alpha}^{(p)}}{\operatorname{argmin}} \frac{1}{n(n-1)} \sum_{i,j=1}^{n} w_{ij}\left(y_i - y_j - \sum_{l=1}^{p} \mathbf{K}_i^T \boldsymbol{\alpha}^{(l)}(x_{il} - x_{jl})\right)^2 + \lambda_n \sum_{l=1}^{p} \pi_l \|\boldsymbol{\alpha}^{(l)}\|_2, \tag{4}$$

where $\mathbf{K}_i = (K(\mathbf{x}_i, \mathbf{x}_1), \ldots, K(\mathbf{x}_i, \mathbf{x}_n))^T$ is the i-th column of $\mathbf{K} = (K(\mathbf{x}_i, \mathbf{x}_j))_{n\times n}$, and λ_n is a tuning parameter. The infimum operator in (3) is absorbed in the minimization in (4). Clearly, (4) simplifies the original formulation (2) from a functional space to a finite-dimensional vector space. However, the vector space is of dimension np and thus still requires an efficient large-scale optimization scheme, which will be developed in the next section.

2.3 Computing algorithm

To solve (4), we develop a block coordinate descent algorithm as in Yang and Zou (2015). First, after dropping the $\boldsymbol{\alpha}$-unrelated terms, the cost function in (4) can be simplified as

$$\underset{\boldsymbol{\alpha}}{\operatorname{argmin}} \; -\boldsymbol{\alpha}^T \mathbf{U} + \frac{1}{2}\boldsymbol{\alpha}^T \mathbf{M} \boldsymbol{\alpha} + \lambda_n \sum_{l=1}^{p} \pi_l \|\boldsymbol{\alpha}^{(l)}\|_2, \tag{5}$$

where $\boldsymbol{\alpha}^T = \left((\boldsymbol{\alpha}^{(1)})^T, \ldots, (\boldsymbol{\alpha}^{(p)})^T\right)$, $\mathbf{U} = \frac{2}{n(n-1)} \sum_{i,j=1}^n w_{ij}\mathbf{U}_{ij}$, $\mathbf{M} = \frac{2}{n(n-1)} \sum_{i,j=1}^n w_{ij}\mathbf{M}_{ij}$,

$$\begin{aligned} \mathbf{U}_{ij} &= (y_i - y_j)(\mathbf{x}_i - \mathbf{x}_j) \otimes \mathbf{K}_i, \\ \mathbf{M}_{ij} &= \left((\mathbf{x}_i - \mathbf{x}_j)(\mathbf{x}_i - \mathbf{x}_j)^T\right) \otimes \left(\mathbf{K}_i \mathbf{K}_i^T\right), \end{aligned}$$

$\mathbf{K}_i$ is the i-th column of $\mathbf{K} = (K(\mathbf{x}_i, \mathbf{x}_j))_{n\times n}$, $\mathbf{I}_n$ is a n-dimensional identity matrix, and $\otimes$ denotes the kronecker product.

Then we update one $\boldsymbol{\alpha}^{(l)}$ at a time pretending others fixed, and the l-th subproblem becomes

$$\underset{\boldsymbol{\alpha}^{(l)}}{\operatorname{argmin}} \; L(\boldsymbol{\alpha}) + \lambda_n \pi_l \|\boldsymbol{\alpha}^{(l)}\|_2 = -\boldsymbol{\alpha}^T \mathbf{U} + \frac{1}{2}\boldsymbol{\alpha}^T \mathbf{M} \boldsymbol{\alpha} + \lambda_n \pi_l \|\boldsymbol{\alpha}^{(l)}\|_2,$$

To solve the subproblem, a similar approximation as in Yang and Zou (2015) can be employed, where the updated $\boldsymbol{\alpha}^{(l)}$ is obtained by solving

$$\underset{\boldsymbol{\alpha}^{(l)}}{\operatorname{argmin}} \nabla_l L(\widetilde{\boldsymbol{\alpha}})(\boldsymbol{\alpha}^{(l)} - \widetilde{\boldsymbol{\alpha}}^{(l)}) + \frac{\gamma^{(l)}}{2}(\boldsymbol{\alpha}^{(l)} - \widetilde{\boldsymbol{\alpha}}^{(l)})^T(\boldsymbol{\alpha}^{(l)} - \widetilde{\boldsymbol{\alpha}}^{(l)}) + \lambda_n \pi_l \|\boldsymbol{\alpha}^{(l)}\|_2. \tag{6}$$

Here $\widetilde{\boldsymbol{\alpha}}$ is the current estimate for $\boldsymbol{\alpha}$, $\widetilde{\boldsymbol{\alpha}}^{(l)}$ is the l-th column of $\widetilde{\boldsymbol{\alpha}}$,

$$\nabla L(\widetilde{\boldsymbol{\alpha}}) = \frac{2}{n(n-1)} \sum_{i,j=1}^{n} w_{ij}(\mathbf{M}_{ij}\widetilde{\boldsymbol{\alpha}} - \mathbf{U}_{ij}),$$

$\nabla_l L(\widetilde{\boldsymbol{\alpha}})$ denotes the l-th block vector of $\nabla L(\widetilde{\boldsymbol{\alpha}})$, and

$$\nabla_l L(\widetilde{\boldsymbol{\alpha}}) = \frac{2}{n(n-1)} \sum_{i,j=1}^{n} w_{ij}\left(\sum_{s=1}^{p}((\mathbf{x}_i - \mathbf{x}_j)(\mathbf{x}_i - \mathbf{x}_j)^T)_{ls}\mathbf{K}_i\mathbf{K}_i^T\widetilde{\boldsymbol{\alpha}}^{(s)} - (y_i - y_j)(x_{il} - x_{jl})\mathbf{K}_i\right),$$

where $((\mathbf{x}_i - \mathbf{x}_j)(\mathbf{x}_i - \mathbf{x}_j)^T)_{ls}$ is the (l,s)-th entry of $(\mathbf{x}_i - \mathbf{x}_j)(\mathbf{x}_i - \mathbf{x}_j)^T$. Furthermore, denote $\gamma^{(l)}$ the largest eigenvalue of

$$\mathbf{M}^{(l)} = \frac{2}{n(n-1)} \sum_{i,j=1}^{n} w_{ij}((\mathbf{x}_i - \mathbf{x}_j)(\mathbf{x}_i - \mathbf{x}_j)^T)_{ll}\mathbf{K}_i\mathbf{K}_i^T,$$

which is the l-th $n \times n$ block diagonal of $\mathbf{M}$.

It is straightforward to show that (6) has an analytical solution,

$$\boldsymbol{\alpha}^{(l)} = \left(\widetilde{\boldsymbol{\alpha}}^{(l)} - \frac{\nabla_l L(\widetilde{\boldsymbol{\alpha}})}{\gamma^{(l)}}\right)\left(1 - \frac{\lambda_n \pi_l}{\|\gamma^{(l)}\widetilde{\boldsymbol{\alpha}}^{(l)} - \nabla_l L(\widetilde{\boldsymbol{\alpha}})\|_2}\right)_+. \tag{7}$$

The proposed algorithm then iteratively updates $\boldsymbol{\alpha}^{(l)}$ for $l = 1, \ldots, p, 1, \ldots$ until convergence. The algorithm is guaranteed to converge to the global minimum, since the cost function in (5) is convex and its value is decreased in each updating step. Furthermore, the computational complexity of the block coordinate descent algorithm is $O(n^2p^2D)$ with D being the number of iterations until convergence, which can be substantially less than the complexity of solving (5) with standard optimization packages.

3. Asymptotic theory

This section presents the asymptotic estimation and variable selection consistencies of the proposed model-free variable selection method. The estimation consistency assures that the distance between $\hat{\mathbf{g}}$ and $\mathbf{g}^*$ converges to 0 at a fast rate, and the variable selection consistency assures that the truly informative variables can be exactly recovered with probability

tending to 1. Both consistency results are established for fixed p. For simplicity, we assume only the first p_0 variables $x^{(1)}, \ldots, x^{(p_0)}$ are truly informative. The following technical assumptions are made.

Assumption A1. The support $\mathcal{X}$ is a non-degenerate compact subset of $\mathcal{R}^p$, and there exists a cosntatnt c_1 such that $\sup_{\mathbf{x}} \| \mathbf{H}^*(\mathbf{x}) \|_2 \leq c_1$, where $\mathbf{H}^*(\mathbf{x}) = \nabla^2 f^*(\mathbf{x})$. Also, $\sup_{\mathbf{x}} |K(\mathbf{x}, \mathbf{x})| = 1$, and the largest eigenvalue of $\mathbf{K}$ is of order $O(n^{\psi})$ with $0 \leq \psi \leq 1$.

Assumption A2. For some constants c_2 and $\theta > 0$, the probability density $p(\mathbf{x})$ exists and satisfies

$$|p(\mathbf{x}) - p(\mathbf{u})| \leq c_2 d_X(\mathbf{x}, \mathbf{u})^{\theta}, \text{ for any } \mathbf{x}, \mathbf{u} \in \mathcal{X}, \tag{8}$$

where $d_X(\cdot, \cdot)$ is the Euclidean distance on $\mathcal{X}$.

Assumption A3. There exists some constant c_4 and c_5 such that $c_4 \leq \lim_{n\to\infty} \min_{1\leq l\leq p} \pi_l \leq \lim_{n\to\infty} \max_{1\leq l\leq p_0} \pi_l \leq c_5$ and $n^{-1/2}\lambda_n \min_{l>p_0} \pi_l \to \infty$.

Assumption A4. For any $j \leq p_0$, there exists a constant t such that $\int_{\mathcal{X}\setminus\mathcal{X}_t} \|g_j^*(\mathbf{x})\|_2 d\rho_X(\mathbf{x}) > 0$, and for any $j \geq p_0 + 1$, $g_j^*(\mathbf{x}) \equiv 0$ for any $\mathbf{x} \in \mathcal{X}$, where $\mathcal{X}_t = \{\mathbf{x} \in \mathcal{X} : d_X(\mathbf{x}, \partial\mathcal{X}) < t\}$.

In Assumption A1, the compact support is assumed for the technical simplicity, which has been often used in the literature of nonparametric models (Horowitz and Mammen, 2007; Ye and Xie, 2012). The non-degenerate $\mathcal{X}$ rules out the complete multicollinearity and thus assures the unique minimizer of (4) and the true gradient function $\mathbf{g}^*(\mathbf{x})$. And $\| \mathbf{H}^*(\mathbf{x}) \|_2$ is a matrix-2 norm of $\mathbf{H}^*(\mathbf{x})$ for any given $\mathbf{x}$, denoting its largest eigenvalue. The bounded assumption on $\| \mathbf{H}^*(\mathbf{x}) \|_2$ implies that $|f^*(\mathbf{u}) - f^*(\mathbf{x}) - (\mathbf{g}^*(\mathbf{x}))^T(\mathbf{u} - \mathbf{x})| \leq c_1 \| \mathbf{u} - \mathbf{x} \|_2^2$ for any $\mathbf{u}$ and $\mathbf{x}$, which is necessary to prevent the loss function from diverging at certain values. Furthermore, for the Gaussian Kernel, the assumption for its largest eigenvalue can be verified with $\psi = 1$. (Gregory et al., 2012). Assumption A2 introduces a Lipschitz condition on the density function, assuring the smoothness of the distribution of $\mathbf{x}$. Assumption A1 and A2 also imply that the probability density $p(\mathbf{x})$ is bounded. Assumption A3 provides some guideline on setting the adaptive weights, and is satisfied with $\pi_l = \| (\tilde{\boldsymbol{\alpha}}^{(l)})^T \mathbf{K} \tilde{\boldsymbol{\alpha}}^{(l)} \|_2^{-\gamma}$ and some positive γ. For example, the initializer $\tilde{\boldsymbol{\alpha}}^{(l)}$ can be obtained by solving (4) without the Lasso penalty and $\gamma = 3 - 2\psi$, which can be verified following Lemma 1 and Theorem 14 in Mukherjee and Zhou (2006). Other consistent estimators can also be employed to initialize the weights. Assumption A4 requires that the gradient function along a truly informative variable needs to be substantially different from 0, and that along a non-informative variable is 0 everywhere.

Lemma 1 *Let $\mathbf{g}^0$ be the minimizer of $\mathcal{E}(\mathbf{g})$ over all functionals. If Assumption A1-A2 are met, then as $\tau_n^2 \to 0$, $\mathbf{g}^0(\mathbf{x})$ converges to $\mathbf{g}^*(\mathbf{x})$ in probability, and $\mathcal{E}(\mathbf{g}^0) - 2\sigma_s^2 \to 0$.*

Lemma 1 is analogous to the Fisher consistency established for margin-based classification (Lin, 2004; Liu, 2007). It shows that the error measure $\mathcal{E}(\mathbf{g})$ in (1) is reasonable in the sense that its global minimizer well approximates the true gradient function $\mathbf{g}^*$ as τ_n^2 shrinks to 0. Note that it may not appropriate to set τ_n^2 to be exactly 0 in the gradient learning framework, but a sufficient small τ_n^2 is necessary in order to assure the estimation consistency.

Theorem 2 *Suppose Assumptions A1-A4 are met. Then there exists some constant M_0 and c_6 such that with probability at least $1 - \delta$,*

$$\mathcal{E}(\hat{\mathbf{g}}) - 2\sigma_s^2 \leq c_6 \sqrt{\log(4/\delta)} \Big(n^{-1/4} + n^{\frac{2\psi-1}{2}} \lambda_n^{-2} + \tau_n^{p+4} + n^{-\frac{1}{2(p+2)}} + n^{-\left(1-\frac{1}{2(p+2)}\right)} \lambda_n^2 \tau_n^{-4} \Big).$$

Theorem 2 establishes the estimation consistency of $\hat{\mathbf{g}}$ in terms of its estimation error $\mathcal{E}(\hat{\mathbf{g}}) - 2\sigma_s^2$, which is governed by the choice of λ_n and τ_n. Specifically, let $\lambda_n = n^{\frac{2\psi-1}{4} + \frac{1}{4(p+2)}}$ and $\tau_n = n^{-\frac{\theta}{4p(p+2)(p+4+3\theta)}}$, and we have $\mathcal{E}(\hat{\mathbf{g}}) - 2\sigma_s^2 \to 0$ in probability.

Next, let $\mathcal{A}_T = \{1, \cdots, p_0\}$ consist of all the truly informative variables, and $\widehat{\mathcal{A}} = \{j : \|\widehat{\boldsymbol{\alpha}}^{(j)}\|_2 > 0\}$ consist of all the estimated informative variables, where $\widehat{\boldsymbol{\alpha}}^{(j)}$ is the solution of (4).

Theorem 3 *Suppose all the assumptions in Theorem 2 are met. Let $\lambda_n = n^{\frac{2\psi-1}{4} + \frac{1}{4(p+2)}}$ and $\tau_n = n^{-\frac{\theta}{4p(p+2)(p+4+3\theta)}}$, then $P(\widehat{\mathcal{A}} = \mathcal{A}^*) \to 1$ as n diverges.*

Theorem 3 assures that the selected variables by the proposed method can exactly recover the true active set with probability tending to 1. In fact, $P(\widehat{\mathcal{A}} = \mathcal{A}^*)$ can be upper bounded by $1 - O(n^{-1/4})$ with an appropriate choice of δ. This result is particularly interesting given the fact that it is established without assuming any explicit model assumptions.

4. Numerical experiments

This section examines the effectiveness of the proposed model-free variable selection method, and compares it against some popular model based methods in literature, including variable selection with the additive model (Xue, 2009), Cosso (Lin and Zhang, 2006), sparse gradient learning (Ye and Xie, 2012) and multivariate adaptive regression splines (Friedman, 1991), denoted as MF, Add, Cosso, SGL and Mars respectively. In all the experiments, the Gaussian kernel $K(\mathbf{x}, \mathbf{u}) = e^{-\| \mathbf{x} - \mathbf{u} \|_2^2 / 2\sigma_n^2}$ is used, where the scalar parameters σ_n^2 and τ_n^2 in $w(\mathbf{x}, \mathbf{u})$ are set as the median over the pairwise distances among all the sample points (Mukherjee and Zhou, 2006). Other tuning parameters in these competitors, such as the number of knots in Xue (2009), are set as the default values in the available R and Matlab packages.

The tuning parameters in each method are determined by the stability-based selection criterion in Sun et al. (2013). The idea is to conduct a cross-validation-like scheme, and measure the stability as the agreement between two estimated active sets. It randomly splits the training set into two subsets, applies the candidate variable selection method to each subset, and obtains two estimated active sets, denoted as $\widehat{\mathcal{A}}_{1b}$ and $\widehat{\mathcal{A}}_{2b}$. The variable selection stability can approximated by $s_\lambda = \frac{1}{B} \sum_{b=1}^{B} \kappa(\widehat{\mathcal{A}}_{1b}, \widehat{\mathcal{A}}_{2b})$, where B is the number of splitting in the cross validation scheme, and $\kappa(\cdot, \cdot)$ is the standard Cohen's kappa statistic measuring the agreement between two sets. The tuning parameter λ is then selected as the one maximizing s_λ. Finally, the performance of all methods is evaluated by a number of measures regarding the variable selection accuracy.

4.1 Simulated examples

Two simulated examples are considered. The first example was used in Xue (2009) and Huang et al. (2010), where the true regression model is an additive model. The second example modifies the generating scheme of the first one and includes interaction terms.

Example 1: First generate p-dimensional variables $\mathbf{x}_i = (x_{i1}, \ldots, x_{ip})^T$ with $x_{ij} = \frac{W_{ij} + \eta U_i}{1 + \eta}$, where W_{ij} and U_i are independently from $U(-0.5, 0.5)$, for $i = 1, \ldots, n$ and

$j = 1, \ldots, p$. When $\eta = 0$ all variables are independent, whereas when $\eta = 1$ correlation presents among the variables. Next, set $f^*(\mathbf{x}_i) = 5f_1(x_{i1}) + 3f_2(x_{i2}) + 4f_3(x_{i3}) + 6f_4(x_{i4})$, with $f_1(u) = u$, $f_2(u) = (2u-1)^2$, $f_3(u) = \frac{\sin(\pi u)}{2-\sin(\pi u)}$, and $f_4(u) = 0.1\sin(\pi u) + 0.2\cos(\pi u) + 0.3\sin^2(\pi u) + 0.4\cos^3(\pi u) + 0.5\sin^3(\pi u)$. Finally, generate y_i by $y_i = f(x_i) + \epsilon_i$ with $\epsilon_i \sim N(0, 1.31^2)$. Clearly, the true underlying regression model is additive.

Example 2: The generating scheme is similar as Example 1, except that $f^*(\mathbf{x}_i) = (2x_{i1} - 1)(2x_{i2} - 1)$, W_{ij} and U_i are independently from $N(0, 1)$ and $\epsilon_i \sim N(0, 1)$. It is clear that the underlying regression model includes interaction terms, and thus the additive model assumption is no longer valid.

For each example, different scenarios are considered with $\eta = 0$ or 1, and $(n, p) = (100, 10)$, $(100, 20)$ or $(200, 50)$. Each scenario is replicated 50 times, and the averaged performance measures are summarized in Tables 1 and 2. Specifically, Size represents the averaged number of selected informative variables, TP represents the number of truly informative variables selected, FP represents the number of truly non-informative variables selected and C, U, O are the times of correct-fitting, under-fitting and over-fitting, respectively.

It is evident that the proposed MF method delivers superior selection performance against the other three competitors. In Table 1 where the true model is indeed additive, MF performs similarly as Add and SGL, whereas Cosso and Mars appear more likely to overfit. In Table 2 where the true model consists of interaction terms, the performance of MF becomes competitive, but Add tends to under-fit more frequently, and Cosso, Mars and SGL tend to overfit as the dimension increases. Furthermore, in both examples with $\eta = 1$, it is clear that the correlation among variables increases the difficulty of selecting the truly informative variables, yet the proposed MF method still outperforms its competitors. Furthermore, it is also noted that the estimation accuracy of MF outperforms SGL, but it is omitted here as only MF and SGL estimate the gradient function $\mathbf{g}$, whereas Add, Cosso and Mars estimate the regression function f.

4.2 Real examples

The proposed model-free variable selection method is applied to three real data examples, the Boston housing data, the Ozone concentration data, and the digit recognition data, all of which are publicly available. The Boston housing data concerns the median value of owner-occupied homes in each of the 506 census tracts in the Boston Standard Metropolitan Statistical Area in 1970. It consists of 13 variables, including per capita crime rate by town (CRIM), proportion of residential land zoned for lots over 25,000 square feet (ZN), proportion of non-retail business acres per town (INDUS), Charles River dummy variable (CHAS), nitric oxides concentration (NOX), average number of rooms per dwelling (RM), proportion of owner-occupied units built prior to 1940 (AGE), weighted distances to five Boston employment centers (DIS), index of accessibility to radial highways (RAD), full-value property-tax rate per $10000 (TAX), pupil-teacher ratio by town (PTRATIO), the proportion of blacks by town (B), lower status of the population (LSTAT), which may affect the housing price. The Ozone concentration data concerns the daily measurements of Ozone concentration in Los Angeles basin in 330 days. The Ozone concertration may be influenced by 11 meteorological quantities, such as month (M), day of month (DM), day of week

(DW), Vandenburg 500 millibar height (VDHT), wind speed (WDSP), humidity (HMDT), temperature at Sandburg (SBTH), inversion base height (IBHT), Daggett pressure gradient (DGPG), inversion base temperature (IBTP) and visibility (VSTY). These two datasets have been widely analyzed in literature, including Breiman and Friedman (1985), Xue (2009), and Lin and Zhang (2006). For the digit recognition data, each digit is described by a 8×8 gray-scale image with each entry ranging from 0 to 16. We focus on digits 3 and 5 due to their similarity, and the resultant dataset consists of 365 observations and 64 attributes.

Table 2: The averaged performance measures of various variable selection methods in Example 2.

In our analysis, all the variables and responses are standardized and the selected variables are summarized. The selected informative variables by MF, Add, Cosso and Mars are summarized in Tables 3 and 4. As the truly informative variables are unknown in real examples, averaged prediction errors with the selected variables are also reported to compare the performance. To compute the averaged prediction error, each dataset is randomly split into two parts: m observations for testing and the remaining for training. Specifically, $m = 30$ for the Boston housing data, $m = 50$ for the Ozone concentration data, and $m = 35$ for

digit recognition data. Each example is replicated 100 times, and the averaged prediction errors by MF, Add, Cosso and Mars are summarized in Tables 3-5.

Table 5: The number of selected variables and the prediction errors by various selection methods in the digit recognition dataset.

For the Boston housing data, MF and SGL select two informative variables, RM and LSTAT, whereas Add, Cosso and Mars tend to select more variables. However, the corresponding prediction errors of Add, Cosso and Mars appear to be larger than that of MF and SGL, implying that the additional selected variables by Add, Cosso and Mars may hinder the prediction performance. For the Ozone concentration data, both MF and Cosso

select four variables but Add and Mars select more. One discrepancy is the variable IBTP, which is selected by MF, Cosso, SGL and Mars but not by Add. As claimed in Gregory et al. (2012), M, SBTH and IBTP are three most important meteorological variables related to Ozone concentration as all of them describe the temperature changes. Meanwhile, MF and Cosso show smaller prediction error than SGL and Mars, which implies that SGL and Mars may include some non-informative variables. Figure 1 displays scatter plots of the responses against the selected variables by MF in the Boston housing data and the Ozone concentration data. It is clear that all the selected variables show moderate to strong relationship with the responses. For digit recognition data, MF selects much less variables than the other competitors and provides smaller prediction error. Figure 2 shows some randomly selected digits of 3 and 5 and the two selected informative variables, where the left informative variable is always contained in digit 5 and the right one is always contained in digit 3.

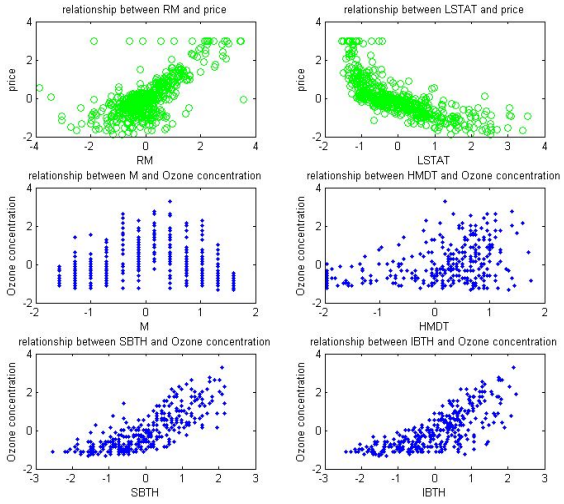

Figure 1: The scatter plots of the responses and the selected variables by MF in the Boston housing data (first row) and the Ozone concentration data (second and third rows).

Figure 2: Some randomly selected digit 3, digit 5 and the two selected informative variables.

5. Summary

This article proposes a model-free variable selection method, which is in sharp contrast to most existing methods relying on various model assumptions. The proposed method makes use of the natural connection between informative variables and sparse gradients, and formulates the variable selection task in a flexible framework of learning gradients. Additionally, we introduce a coefficient-based representation to facilitate variable selection in the learning framework. A block-wise coordinate decent algorithm is developed to make efficient computation for large-scale problems feasible. More importantly, we establish the estimation and variable selection consistencies of the proposed method without assuming any restrictive model assumption. The effectiveness of the proposed method is also supported by numerical experiments on simulated and real examples. It is worth pointing out that the computational cost of the proposed method can be expensive, as it allows for a more flexible modeling framework in RKHS. The extension of the proposed method to diverging dimension is also challenging as a model-free framework with diverging dimension can be too flexible to analyze. One possible remedy is to pre-screen the non-informative variables via some model-free screening methods (Li et al., 2012) to shrink the size of candidate variables.

Appendix A. technical proofs

Proof of Lemma 1: First, note that under Assumption A1 and A2, the probability density $p(\mathbf{x})$ is bounded, and thus there exists some constant c_7 such that $\sup_{\mathbf{x}\in\mathcal{X}} p(\mathbf{x}) \le c_7$. Moreover, denote $\mathcal{X}_t = \{\mathbf{x} \in \mathcal{X} : d_X(\mathbf{x}, \partial\mathcal{X}) < t\}$, then we have $\rho_X(\mathcal{X}_t) \le c_8 t$ for any t given a constant c_8, where $\partial\mathcal{X}$ is the boundary of the compact support $\mathcal{X}$, ρ_X is the marginal distribution and $d_X(\mathbf{x}, \partial\mathcal{X}) = \inf_{\mathbf{u}\in\partial\mathcal{X}} d_X(\mathbf{x}, \mathbf{u})$.

Since $\mathbf{g}^0$ is the minimizer of $\mathcal{E}(\mathbf{g})$, the functional derivative of $\mathcal{E}(\mathbf{g})$ at $\mathbf{g}^0$ yields that for any arbitrary function vector $\delta(\mathbf{x})$,

$$\int_{\mathcal{X}}\int_{\mathcal{X}} w(\mathbf{x},\mathbf{u})\big(f(\mathbf{x}) - f(\mathbf{u}) + \mathbf{g}^0(\mathbf{x})^T(\mathbf{u}-\mathbf{x})\big)(\mathbf{u}-\mathbf{x})^T\delta(\mathbf{x})d\rho_X(\mathbf{u})d\rho_X(\mathbf{x}) = \mathbf{0}_p,$$

where $\mathbf{0}_p$ is a p-dimensional vector with all zeros. As the above equality is true for any $\delta(\mathbf{x})$, it implies that for any given $\mathbf{x}$,

$$\int_{\mathcal{X}} w(\mathbf{x},\mathbf{u})\left(f(\mathbf{x}) - f(\mathbf{u}) + \mathbf{g}^0(\mathbf{x})^T(\mathbf{u}-\mathbf{x})\right)(\mathbf{u}-\mathbf{x})d\rho_X(\mathbf{u}) = \mathbf{0}_p.$$

For simplicity, denote $\mathbf{M}(\mathbf{x}) = \int_{\mathcal{X}} w(\mathbf{x},\mathbf{u})(\mathbf{u}-\mathbf{x})(\mathbf{u}-\mathbf{x})^T d\rho_X(\mathbf{u})$ a function matrix, and $\mathbf{d}(\mathbf{x}) = \int_{\mathcal{X}} w(\mathbf{x},\mathbf{u})(\mathbf{u}-\mathbf{x})\left(f(\mathbf{u}) - f(\mathbf{x})\right)d\rho_X(\mathbf{u})$ a function vector. Then $\mathbf{M}(\mathbf{x})\,\mathbf{g}^0(\mathbf{x}) - \mathbf{d}(\mathbf{x}) = 0$ for any given $\mathbf{x}$. Let $\mathcal{X}_\tau = \{\mathbf{x} : d_X(\mathbf{x}, \partial\mathcal{X}) \ge \tau_n, p(\mathbf{x}) \ge c_2\tau_n^\theta + \tau_n^{1/2}\}$, then by Assumption A2,

$$P(\mathcal{X}_\tau^c) \le P\left(d_X(\mathbf{x}, \partial\mathcal{X}) < \tau_n\right) + P\left(p(\mathbf{x}) < c_2\tau_n^\theta + \tau_n^{1/2}\right) \le c_8\tau_n + (c_2\tau_n^\theta + \tau_n^{1/2})|\mathcal{X}|,$$

where $|\mathcal{X}|$ denotes the Lebesgue measure of $\mathcal{X}$. For any $\mathbf{x} \in \mathcal{X}_\tau$,

$$\begin{aligned}\mathbf{M}(\mathbf{x}) &= \int w(\mathbf{x},\mathbf{u})(\mathbf{u}-\mathbf{x})(\mathbf{u}-\mathbf{x})^T p(\mathbf{u})d\,\mathbf{u}\\ &\ge \tau_n^{1/2}\int_{d_X(\mathbf{x},\mathbf{u})<\tau_n} e^{-\frac{\|\,\mathbf{x}-\mathbf{u}\,\|_2^2}{2\tau_n^2}}(\mathbf{u}-\mathbf{x})(\mathbf{u}-\mathbf{x})^T d\,\mathbf{u} = \tau_n^{p+5/2}\int_{\|\,\mathbf{t}\,\|_2<1} e^{-\frac{\|\,\mathbf{t}\,\|_2^2}{2}}\,\mathbf{t}\,\mathbf{t}^T d\,\mathbf{t},\end{aligned}$$

where $\mathbf{t} = (\mathbf{u}-\mathbf{x})/\tau_n$. The inequality follows from Assumption A2 and the fact that $p(\mathbf{u}) \ge p(\mathbf{x}) - |p(\mathbf{u}) - p(\mathbf{x})| \ge p(\mathbf{x}) - c_2 d(\mathbf{x},\mathbf{u})^\theta \ge \tau_n^{1/2}$ on $\mathcal{X}_\tau$. As the support $\mathcal{X}$ is non-degenerate by assumption A1, $\int_{\|\,\mathbf{t}\,\|_2<1} e^{-\frac{\|\,\mathbf{t}\,\|_2^2}{2}}\,\mathbf{t}\,\mathbf{t}^T d\,\mathbf{t}$ is always positive definite. So its smallest eigenvalue, denoted as ϕ_{min}, is positive, and thus the smallest eigenvalue of $\mathbf{M}(\mathbf{x})$ must be larger than $\phi_{min}\tau_n^{p+5/2}$, which is also positive.

As $\mathbf{M}(\mathbf{x})$ is invertible for any $\mathbf{x} \in \mathcal{X}_\tau$, we have $\mathbf{g}^0(\mathbf{x}) = \mathbf{M}(\mathbf{x})^{-1}\mathbf{d}(\mathbf{x})$, and thus

$$\|\mathbf{g}^0(\mathbf{x}) - \mathbf{g}^*(\mathbf{x})\|_2 \le \|(\mathbf{M}(\mathbf{x}))^{-1}\|_2\|\mathbf{d}(\mathbf{x}) - \mathbf{M}(\mathbf{x})\mathbf{g}^*(\mathbf{x})\|_2.$$

Furthermore,

$$\begin{aligned}\|\mathbf{d}(\mathbf{x}) - \mathbf{M}(\mathbf{x})\mathbf{g}^*(\mathbf{x})\|_2 &= \int_{\mathcal{X}} w(\mathbf{x},\mathbf{u})(\mathbf{u}-\mathbf{x})\left(f(\mathbf{u}) - f(\mathbf{x}) - \mathbf{g}^*(\mathbf{x})^T(\mathbf{u}-\mathbf{x})\right)d\rho_X(\mathbf{u})\\ &\le \int\left|w(\mathbf{x},\mathbf{u})(\mathbf{u}-\mathbf{x})\left(f(\mathbf{u}) - f(\mathbf{x}) - \mathbf{g}^*(\mathbf{x})^T(\mathbf{u}-\mathbf{x})\right)\right|p(\mathbf{u})d\,\mathbf{u}\\ &\le c_1c_8\int w(\mathbf{x},\mathbf{u})\|\,\mathbf{u}-\mathbf{x}\,\|_2^3 d\,\mathbf{u} \le c_1c_8\tau_n^{p+3}\int e^{-\frac{\|\,\mathbf{t}\,\|_2^2}{2}}\|\,\mathbf{t}\,\|_2^3 d\,\mathbf{t}\,.\end{aligned}$$

Therefore, for any $\mathbf{x} \in \mathcal{X}_\tau$,

$$\|\mathbf{g}^0(\mathbf{x}) - \mathbf{g}^*(\mathbf{x})\|_2 \le \|\mathbf{M}(\mathbf{x})^{-1}\|_2\|\mathbf{d}(\mathbf{x}) - \mathbf{M}(\mathbf{x})\mathbf{g}^*(\mathbf{x})\|_2 \le \frac{c_1c_8\tau_n^{1/2}}{\phi_{min}}\int e^{-\frac{\|\,\mathbf{t}\,\|_2^2}{2}}\|\,\mathbf{t}\,\|_2^3 d\,\mathbf{t},$$

which converges to 0 for any $\mathbf{x} \in \mathcal{X}_\tau$. Since $P(\mathbf{x} \in \mathcal{X}_\tau) \to 1$ as $\tau_n \to 0$, the desired result follows immediately.

Next, as $\mathcal{E}(\mathbf{g}) - 2\sigma_s^2 > 0$ for any $\mathbf{g}$, we have $0 \le \mathcal{E}(\mathbf{g}^0) - 2\sigma_s^2 \le \mathcal{E}(\mathbf{g}^*) - 2\sigma_s^2$. By Proposition 3 in Ye and Xie (2012), $\mathcal{E}(\mathbf{g}^*) - 2\sigma_s^2 \le O(\tau_n^{p+4}) \to 0$ as $\tau_n \to 0$. Therefore, $\mathcal{E}(\mathbf{g}^0) - 2\sigma_s^2 \to 0$ as $\tau_n \to 0$. ■

To proceed further, we note that the proof of Theorem 2 is substantially different from conventional error analysis as in Mukerjee and Zhou (2006) and Ye and Xie (2012). In our setting, we consider the coefficient-based space $\mathcal{H}_\mathbf{z} = \{\mathbf{g} : \mathbf{g}(x) = \sum_{i=1}^n a_i K(\mathbf{x}_i, \mathbf{x}),\ a_i \in \mathcal{R}\}$ as the candidate functional space, which depends on $\{\mathbf{x}_i\}_{i=1}^n$. One difficulty arises is that $\mathbf{g}^*$ may not be contained in $\mathcal{H}_\mathbf{z}^p$ and thus $J(\mathbf{g}^*)$ can not be defined. To circumvent this difficulty, we introduce an intermediate learning algorithm as a bridge for the error analysis, so that standard empirical process and approximation theories can be used.

Define a vector-valued functional space as $\mathcal{H}_K^p = \{\mathbf{g} = (g_1, ..., g_p)^T, g_j \in \mathcal{H}_K\}$, and $\mathcal{H}_\mathbf{z}^p = \{\mathbf{g} = (g_1, ..., g_p)^T, g_j \in \mathcal{H}_\mathbf{z}\}$. Furthermore, denote the empirical error used in our algorithm as

$$\mathcal{E}_\mathbf{z}(\mathbf{g}) = \frac{1}{n(n-1)}\sum_{i,j=1}^n \omega_{ij}\Big(y_j - y_i - \mathbf{g}(\mathbf{x}_i)^T(\mathbf{x}_j - \mathbf{x}_i)\Big)^2.$$

Clearly, $E(\mathcal{E}_\mathbf{z}(\mathbf{g})) = \mathcal{E}(\mathbf{g})$ for any $\mathbf{g} \in \mathcal{H}_K^p$.

In order to establish the consistency results, we introduce an intermediate learning algorithm,

$$\bar{\mathbf{g}} = \underset{\mathbf{g}\in\mathcal{H}_K^p}{\operatorname{argmin}}\ \frac{1}{n(n-1)}\sum_{i,j=1}^n w_{ij}\Big(y_i - y_j - \mathbf{g}(\mathbf{x}_i)(\mathbf{x}_i - \mathbf{x}_j)\Big)^2 + \rho_n\sum_{l=1}^p \pi_l\|g_l\|_K^2, \tag{9}$$

where $\rho_n = n^{-\eta}$ with $\eta = \frac{1}{4(p+2)}$. Note that (9) is a weighted version of the original gradient learning in Mukherjee and Zhou (2006). By the representor theorem, each element of $\bar{\mathbf{g}}$ in (9) has a closed solution with the form

$$\bar{g}_l = \sum_{t=1}^n \bar{\alpha}_t^l K(\mathbf{x}, \mathbf{x}_t), \quad \text{for} \quad l = 1, ..., p.$$

Denote $\bar{\boldsymbol{\alpha}}^l = (\bar{\alpha}_1^l, ..., \bar{\alpha}_n^l)^T$ satisfies the linear system

$$\rho_n\pi_l\,\mathbf{K}\,\bar{\boldsymbol{\alpha}}^l + \frac{1}{n(n-1)}\sum_{i,j=1}^n \omega_{ij}\Big(y_j - y_i - \bar{\mathbf{g}}(\mathbf{x}_i)^T(\mathbf{x}_j - \mathbf{x}_i)\Big)(\mathbf{K})_i^T[\mathbf{x}_j - \mathbf{x}_i]_l = 0, \tag{10}$$

where $(\mathbf{K})_i$ represents the i-th row of $\mathbf{K}$. Without loss of generality, we assume that $\mathbf{K}$ is invertible. In this case, we can solve for $\bar{\alpha}_t^l$ as follows:

$$\rho_n\pi_l\bar{\alpha}_t^l = -\frac{1}{n(n-1)}\sum_{j=1}^n \omega_{tj}\Big(y_j - y_t - \bar{\mathbf{g}}(\mathbf{x}_t)^T(\mathbf{x}_j - \mathbf{x}_t)\Big)[\mathbf{x}_j - \mathbf{x}_t]_l. \tag{11}$$

With these preparations, we are now in the position to decompose the excess error as follows.

Proposition 4 *Let $\varphi_0(\mathbf{z}) = \mathcal{E}_{\mathbf{z}}(\mathbf{g}^*) - \mathcal{E}(\mathbf{g}^*)$ and $\varphi_1(\mathbf{z}) = \mathcal{E}(\hat{\mathbf{g}}) - \mathcal{E}_{\mathbf{z}}(\hat{\mathbf{g}})$. Then the following inequality holds for any $0 < \varepsilon \leq 1$,*

$$\mathcal{E}(\hat{\mathbf{g}}) + \lambda_n \sum_{l=1}^{p} \pi_l J(\hat{g}_l) \leq \varphi_1(\mathbf{z}) + 2\varphi_0(\mathbf{z}) + \Lambda_n(\varepsilon, \rho, K),$$

where

$$\Lambda_n(\varepsilon, \rho, K) = (1+\varepsilon)\mathcal{E}(\mathbf{g}^*) + \sum_{l=1}^{p_0} \rho_n \pi_l (\|g_l^*\|_K^2 - \|\bar{g}_l\|_K^2) + c_n^2/\varepsilon, \tag{12}$$

with $c_n = \frac{c_x p \lambda_n}{\rho_n \sqrt{n-1}}$ and $c_x \geq \sup_{\mathbf{x}} \|\mathbf{x}\|$. In the literature of statistical learning theory, $\varphi_0(\mathbf{z})$, $\varphi_1(\mathbf{z})$ are called the sample error and $\Lambda(\lambda_n)$ is the approximation error.

Proof of Proposition 4: First of all, by the Hölder inequality, it follows from 11 that:

$$J(\bar{g}_l) \leq \frac{c_x}{\rho_n \pi_l \sqrt{n-1}} \sqrt{\mathcal{E}_{\mathbf{z}}(\bar{\mathbf{g}})}, \quad l = 1, ..., p. \tag{13}$$

The above inequality in connection with the definition of $\hat{\mathbf{g}}$ yields that

$$\begin{aligned}
\mathcal{E}(\hat{\mathbf{g}}) + \lambda_n \sum_{l=1}^{p} \pi_l J(\hat{g}_l) &= \mathcal{E}(\hat{\mathbf{g}}) - \mathcal{E}_{\mathbf{z}}(\hat{\mathbf{g}}) + \mathcal{E}_{\mathbf{z}}(\hat{\mathbf{g}}) + \lambda_n \sum_{l=1}^{p} \pi_l J(\hat{g}_l) \\
&\leq \mathcal{E}(\hat{\mathbf{g}}) - \mathcal{E}_{\mathbf{z}}(\hat{\mathbf{g}}) + \mathcal{E}_{\mathbf{z}}(\bar{\mathbf{g}}) + \lambda_n \sum_{l=1}^{p} \pi_l J(\bar{g}_l) \\
&\leq \mathcal{E}(\hat{\mathbf{g}}) - \mathcal{E}_{\mathbf{z}}(\hat{\mathbf{g}}) + \mathcal{E}_{\mathbf{z}}(\bar{\mathbf{g}}) + \Big(\frac{c_x \lambda_n}{\sqrt{n-1}} \sum_{l=1}^{p} \frac{1}{\rho_n}\Big) \sqrt{\mathcal{E}_{\mathbf{z}}(\bar{\mathbf{g}})} \\
&\leq \mathcal{E}(\hat{\mathbf{g}}) - \mathcal{E}_{\mathbf{z}}(\hat{\mathbf{g}}) + (1+\varepsilon)\mathcal{E}_{\mathbf{z}}(\bar{\mathbf{g}}) + c_n^2/\varepsilon \\
&\leq \mathcal{E}(\hat{\mathbf{g}}) - \mathcal{E}_{\mathbf{z}}(\hat{\mathbf{g}}) + (1+\varepsilon)\mathcal{E}_{\mathbf{z}}(\mathbf{g}^*) + 2\sum_{l=1}^{p} \rho_n \pi_l (\|g_l^*\|_K^2 - \|\bar{g}_l\|_K^2) + c_n^2/\varepsilon \\
&\leq \mathcal{E}(\hat{\mathbf{g}}) - \mathcal{E}_{\mathbf{z}}(\hat{\mathbf{g}}) + (1+\varepsilon)\mathcal{E}_{\mathbf{z}}(\mathbf{g}^*) + 2\sum_{l=1}^{p_0} \rho_n \pi_l (\|g_l^*\|_K^2 - \|\bar{g}_l\|_K^2) + c_n^2/\varepsilon,
\end{aligned}$$

where the first inequality follows from the definition of $\hat{\mathbf{g}}$, the second inequality is derived based on 13, the third inequality follows from the fact $\sqrt{xy} \leq \frac{\varepsilon x + y/\varepsilon}{2}$ for any $\varepsilon > 0$, the fourth inequality follows from the definition of $\bar{\mathbf{g}}$, and the last inequality is due to the assumption that $g_l^* = 0$ for any $l > p_0$. ■

Next, For any given value $R > 0$, define the functional subspace with bounded $J(\mathbf{g})$ as

$$\mathcal{H}_R^p = \{\mathbf{g} \in \mathcal{H}_{\mathbf{z}}^p, \text{ with } J(\mathbf{g}) \leq R\},$$

and

$$\mathcal{S}(R, \lambda_n) = \sup_{\mathbf{g} \in \mathcal{H}_R^p} |\mathcal{E}(\mathbf{g}) - \mathcal{E}_{\mathbf{z}}(\mathbf{g})|.$$

Then the quantity $\mathcal{S}(R, \lambda_n)$ can be bounded using the McDiarmid's inequality (McDiarmid, 1989).

Lemma 5 *(McDiarmid's Inequality) Let $Z_1, ..., Z_n$ be independent random variables taking values in a set $\mathcal{Z}$, and assume that $\mathbf{f} : \mathcal{Z}^n \to \mathbb{R}$ satisfies*

$$\sup_{z_1, ..., z_n, z_i' \in \mathcal{Z}} |\mathbf{f}(z_1, ..., z_n) - \mathbf{f}(z_1, ..., z_i', ..., z_n)| \leq C_i,$$

for every $i \in \{1, 2, ..., n\}$. Then, for every $t > 0$,

$$\mathbb{P}\{|\mathbf{f}(z_1, ..., z_n) - \mathbb{E}\left(\mathbf{f}(z_1, ..., z_n)\right)| \geq t\} \leq 2\exp\left(-\frac{2t^2}{\sum_{i=1}^n C_i^2}\right).$$

This result implies that, as soon as one has a function of n independent random variables, whose variation is bounded when only one variable is modified, the function will satisfy a Hoeffding-type inequality.

Lemma 6 *If $|y| \leq M_n$ and Assumptions A1-A3 hold, then for any constant $R > 0$ and $\varepsilon > 0$, there holds*

$$P(|\mathcal{S}(R, \lambda_n) - \mathbb{E}(\mathcal{S}(R, \lambda_n))| \geq \varepsilon) \leq 2\exp\left(-\frac{n\varepsilon^2}{8(M_n + \frac{c_x n^{\psi/2} R}{c_4 \lambda_n})^4}\right).$$

In addition, there exists a constant c_5, such that

$$P(|\mathcal{E}_{\mathbf{z}}(\mathbf{g}^*) - \mathcal{E}(\mathbf{g}^*)| \geq \varepsilon) \leq 2\exp\left(-\frac{n\varepsilon^2}{8(M_n + c_x \sum_{l=1}^p \|g_l^*\|_K)^4}\right). \tag{14}$$

Proof of Lemma 6: It suffices to verify the conditions required by the McDiarmid's inequality. For this purpose, we define $(\mathbf{x}', y')$ as a sample point drawn from the distribution $\rho(\mathbf{x}, y)$ and independent of $(\mathbf{x}_i, y_i)$. Denote by $\mathbf{z}'$ the modified training sample which is the same as $\mathbf{z}$ except that the i-th observation $(\mathbf{x}_i, y_i)$ is replaced with $(\mathbf{x}', y')$. Let $h(\mathbf{z}_i, \mathbf{z}_j) = \omega_{ij}(y_j - y_i - \mathbf{g}(\mathbf{x}_i)^T(\mathbf{x}_j - \mathbf{x}_i))^2$ with any fixed $\mathbf{g} \in \mathcal{H}_R^p$, then we decompose $\mathcal{E}_{\mathbf{z}}(\mathbf{g})$ as follows,

$$\mathcal{E}_{\mathbf{z}}(\mathbf{g}) = \frac{1}{n(n-1)} \sum_{k \neq i, j \neq i}^{n} h(\mathbf{z}_k, \mathbf{z}_j) + \frac{1}{n(n-1)} \sum_{j=1}^{n} h(\mathbf{z}_i, \mathbf{z}_j) + \frac{1}{n(n-1)} \sum_{k=1}^{n} h(\mathbf{z}_k, \mathbf{z}_i).$$

Note that if $\mathbf{z}$ is replaced by $\mathbf{z}'$, the difference between $\mathcal{E}_{\mathbf{z}}(\mathbf{g})$ and $\mathcal{E}_{\mathbf{z}'}(\mathbf{g})$ boils down to the differences between the second and third components of the above decomposition. By Assumption A3, we see that $\pi_l > c_4$ for any l. Then it follows that

$$\mathcal{E}_{\mathbf{z}}(\mathbf{g}) - \mathcal{E}_{\mathbf{z}'}(\mathbf{g}) \leq \frac{4(M_n + c_x \sum_{l=1}^p \|g_l\|_K)^2}{n} \leq \frac{4(M_n + c_x n^{\psi/2} \sum_{l=1}^p \|\boldsymbol{\alpha}^{(l)}\|_2)^2}{n} \leq \frac{4(M_n + \frac{c_x n^{\psi/2} R}{c_4 \lambda_n})^2}{n},$$

where the second inequality follows from the Hölder inequality and Assumption A1. Interchanging the roles of $\mathbf{z}$ and $\mathbf{z}'$ yields that

$$|\mathcal{E}_{\mathbf{z}}(\mathbf{g}) - \mathcal{E}_{\mathbf{z}'}(\mathbf{g})| \leq \frac{4(M_n + \frac{c_x n^{\psi/2} R}{c_4 \lambda_n})^2}{n}, \quad \forall\ \mathbf{g} \in \mathcal{H}_R^p.$$

Then applying the McDiarmid's inequality, we have

$$P(|\mathcal{S}(R,\lambda_n) - \mathbb{E}(\mathcal{S}(R,\lambda_n))| \geq \varepsilon) \leq 2\exp\left(-\frac{n\varepsilon^2}{8(M_n + \frac{c_x n^{\psi/2} R}{c_4\lambda_n})^4}\right).$$

In contrast with the first one, it is easier to obtain the second result in Lemma 6, since it only involves the fixed function $\mathbf{g}^*$. As a similar argument to the first one, we can set $C_i = \frac{4(M_n + c_x \sum_{l=1}^p \|g_l^*\|_K)^2}{n}$. Thus plugging C_i into the McDiarmid's inequality, our desired result follows immediately. ■

Proposition 7 *Assume the assumptions of Theorem 2 are met. If* $\mathcal{E}_{\mathbf{z}}(0) = \frac{1}{n(n-1)}\sum_{i,j=1}^n (y_i - y_j)^2$ *is upper bounded by* M_0*, then there exists a constant* c_9 *such that for any* $\delta \in (0,1)$*, with probability at least* $1-\delta$*,*

$$J(\hat{\mathbf{g}}) \leq c_9\sqrt{\log(4/\delta)}\left\{M_n^2 n^{-1/2} + n^{\frac{2\psi-1}{2}} M_0^2 \lambda_n^{-2} + \varepsilon\tau_n^p + \max_{l\leq p_0}\rho_n\pi_l\|g_l^* - \bar{g}_l\|_K + c_n^2/\varepsilon\right\}$$

where c_n *is defined as Proposition 4. In addition, there holds*

$$\mathcal{E}(\hat{\mathbf{g}}) - 2\sigma_s^2 \leq c_9\sqrt{\log(4/\delta)}\left\{M_n^2 n^{-1/2} + n^{\frac{2\psi-1}{2}}\lambda_n^{-2} + \varepsilon\tau_n^p + \max_{l\leq p_0}\rho_n\pi_l\|g_l^* - \bar{g}_l\|_K + c_n^2/\varepsilon\right\}$$

Proof of Proposition 7: By Lemma 2 of Ye and Xie (2012), we have

$$\mathbb{E}(\mathcal{S}(R,\lambda_n)) \leq \frac{(M_n + \frac{c_x n^{\psi/2} R}{c_4\lambda_n})^2}{\sqrt{n}},$$

which, together with Lemma 6, implies that with probability at least $1-\delta$,

$$\varphi_1(\mathbf{z}) \leq |\mathcal{S}(R,\lambda_n)| \leq 3\sqrt{\frac{\log(2/\delta)}{n}}\Big(M_n + \frac{c_x n^{\psi/2} R}{c_4\lambda_n}\Big)^2. \tag{15}$$

By Proposition 4, we recall that

$$J(\hat{\mathbf{g}}) + \mathcal{E}(\hat{\mathbf{g}}) \leq \varphi_1(\mathbf{z}) + 2\varphi_0(\mathbf{z}) + \Lambda_n(\varepsilon,\rho,K),$$

where $\Lambda_n(\varepsilon,\rho,K) = (1+\varepsilon)\mathcal{E}(\mathbf{g}^*) + \sum_{l=1}^{p_0}\rho_n\pi_l(\|g_l^*\|_K^2 - \|\bar{g}_l\|_K^2) + c_n^2/\varepsilon$. In addition, note that the Hessian matrix $\mathbf{H}^*(\mathbf{x})$ of f^* is bounded uniformly on $\mathbf{x}$, it is easy to verify that

$$\mathcal{E}(\mathbf{g}^*) - 2\sigma_s^2 = O(\tau_n^{4+p}),$$

which implies that

$$\Lambda_n(\varepsilon,\rho,K) - 2\sigma_s^2 \leq O(\varepsilon\tau_n^p + \max_{l\leq p_0}\rho_n\pi_l\|g_l^* - \bar{g}_l\|_K + c_n^2/\varepsilon), \tag{16}$$

since $\sigma_s^2 = O(\tau_n^p)$ by definition.

Thus, combining 14 in Lemma 6, 15 with 16 , for some constant c_9, we have

$$\begin{aligned} & J(\hat{\mathbf{g}}) + \mathcal{E}(\hat{\mathbf{g}}) - 2\sigma_s^2 \\ \leq\ & c_9\sqrt{\log(4/\delta)}\left\{M_n^2 n^{-1/2} + n^{\frac{2\psi-1}{2}}R^2\lambda_n^{-2} + \varepsilon\tau_n^p + \max_{l\leq p_0}\rho_n\pi_l\|g_l^* - \bar{g}_l\|_K + c_n^2/\varepsilon\right\} \end{aligned}$$

with probability at least $1-\delta$. Finally, we give an explicit bound for R. Following the definition of $\hat{\mathbf{g}}$, we have

$$\mathcal{E}_{\mathbf{z}}(\hat{\mathbf{g}}) + J(\hat{\mathbf{g}}) \leq \mathcal{E}_{\mathbf{z}}(0) + J(0) \leq M_0,$$

which implies $\hat{\mathbf{g}} \in \mathcal{H}_{M_0}^p$, and thus $R = M_0$. As a consequence, the first and the second desired inequalities follow immediately after the fact that $\mathcal{E}(\hat{\mathbf{g}}) - 2\sigma_s^2 \geq 0$ and $J(\hat{\mathbf{g}}) \geq 0$. ■

Proof of Theorem 2: For given constant $c_6 > 0$, $\mathcal{C}$ is denoted to be the following event,

$$\mathcal{C} = \Big\{\hat{\mathbf{g}} : \mathcal{E}(\hat{\mathbf{g}}) - 2\sigma_s^2 > c_6\sqrt{\log(4/\delta)}\Big(n^{-1/4} + n^{\frac{2\psi-1}{2}}\lambda_n^{-2} + \varepsilon\tau_n^p + n^{-\frac{1}{2(p+2)}} + n^{-\left(1-\frac{1}{2(p+2)}\right)}\lambda_n^2/\varepsilon\Big).\Big\}.$$

Then, we split $\mathcal{C}$ into three different events as follows,

$$\begin{aligned} P(\mathcal{C}) &= P\Big(\mathcal{C}\cap\{|y| \leq n^{1/8}, U \leq M_0\}^c\Big) + P\Big(\mathcal{C}\cap\{|y| \leq n^{1/8}, U \leq M_0\}\Big) \\ &\leq P(|y| > n^{1/8}) + P(|y| \leq n^{1/8}, U > M_0) + P\Big(\mathcal{C}\cap\{|y| \leq n^{1/8}, U \leq M_0\}\Big), \end{aligned}$$

where $U = \frac{1}{n(n-1)}\sum_{i,j=1}^n (y_i - y_j)^2$ and $M_0 = 4B^2 + 2\sigma^2 + 1$ with B an upper bound of $f^*(\mathbf{x})$. The existence of B is due to the assumptions that $\mathbf{x}$ has a compact support and f^* is continuous Now we bound these three probabilities one by one.

First, by Chebyshev inequality, $P(|y| > n^{\frac{1}{8}}) = E(P(f^*(\mathbf{x}) + \epsilon > n^{\frac{1}{8}}|\,\mathbf{x})) \leq O(n^{-\frac{1}{4}})$, where the last inequality is due to bounded $f^*(\mathbf{x})$. For the second probability, note that U is a U-statistic with mean $E(U) = E(E(U|\,\mathbf{x}_i,\mathbf{x}_j)) = E(f^*(\mathbf{x}_i) - f^*(\mathbf{x}'))^2 + 2\sigma^2 \leq 4B^2 + 2\sigma^2$. By Bernstein's inequality for U-statistic (Janson, 2004),

$$P(|y| \leq n^{1/8}, U > M_0) \leq P(U > E(U) + 1 | |y| \leq n^{1/8}) \leq \exp\left\{-\frac{1}{16}n^{3/4}\right\},$$

where $(y_i - y_j)^2$ is upper bounded by $4n^{1/4}$, which completes the second term.

Now we turn to the third term. Within the set $\{|y| \leq n^{1/8}, U \leq M_0\}$, by Proposition 7,

$$\mathcal{E}(\hat{\mathbf{g}}) - 2\sigma_s^2 \leq c_9\sqrt{\log(4/\delta)}\Big(n^{-1/4} + n^{\frac{2\psi-1}{2}}M_0^2\lambda_n^{-2} + \varepsilon\tau_n^p + \max_{l\leq p_0}\rho_n\pi_l\|g_l^* - \bar{g}_l\|_K + c_n^2/\varepsilon\Big).$$

With the choice of $\rho_l = n^{-\eta}$ with $\eta = \frac{1}{4(p+2)}$ for all l, we have $\|g_l^* - \bar{g}_l\|_K = O(n^{-\frac{1}{4(p+2)}})$ according to theorems 14, 17, 19 in Mukherjee and Zhou (2006). In addition, $c_n = \frac{c_x p\lambda_n}{\rho_n\sqrt{n-1}} = O(n^{-(\frac{1}{2}-\eta)}\lambda_n)$. Thus with probability at least $1-\delta$, for some constant c_6,

$$\mathcal{E}(\hat{\mathbf{g}}) - 2\sigma_s^2 \leq c_6\sqrt{\log(4/\delta)}\Big(n^{-1/4} + n^{\frac{2\psi-1}{2}}\lambda_n^{-2} + \varepsilon\tau_n^p + n^{-\frac{1}{2(p+2)}} + n^{-\left(1-\frac{1}{2(p+2)}\right)}\lambda_n^2/\varepsilon\Big).$$

Specifically, with $\lambda_n = n^{\frac{2\psi-1}{4}+\frac{1}{4(p+2)}}$, $\tau_n = n^{-\frac{\theta}{4p(p+2)(p+4+3\theta)}}$ and $\varepsilon = \tau_n^4$, we have

$$\mathcal{E}(\hat{\mathbf{g}}) - 2\sigma_s^2 \leq c_6\sqrt{\log(4/\delta)}n^{-\Theta},$$

where $\Theta = \min\Big\{\frac{\theta(p+4)}{4p(p+2)(p+4+3\theta)}, \frac{1}{2(p+2)}, \frac{p^2(p+4+3\theta)-2\theta}{2p(p+2)(p+4+3\theta)}\Big\}$. ■

Proof of Theorem 3: First, we show that $\|\hat{\boldsymbol{\alpha}}^{(l)}\|_2 = 0$ for any $l > p_0$ by contradiction. Suppose that $\|\hat{\boldsymbol{\alpha}}^{(l)}\|_2 > 0$ for some $l > p_0$. Taking the first derivative of (4) with respect to $\boldsymbol{\alpha}^{(l)}$ yields that

$$\frac{2}{n(n-1)}\sum_{i,j=1}^{n} w_{ij}(y_i - y_j - \hat{\mathbf{g}}(\mathbf{x}_i)^T(\mathbf{x}_i - \mathbf{x}_j))(x_{il} - x_{jl})\mathbf{K}_l = -\frac{\lambda_n\pi_l\hat{\boldsymbol{\alpha}}^{(l)}}{\|\hat{\boldsymbol{\alpha}}^{(l)}\|_2}. \tag{17}$$

Note that the norm of the right-hand side divided by $n^{1/2}$ is $n^{-1/2}\lambda_n\pi_l$, which diverges to ∞ by Assumption A3. Then the contradiction can be concluded by showing the norm of the left-hand side is smaller than $O(n^{1/2})$.

For simplicity, denote $\mathcal{B}_{\mathbf{z}}(\mathbf{g}) = \frac{2}{n(n-1)}\sum_{i,j=1}^{n} w_{ij}(y_i - y_j - \mathbf{g}(\mathbf{x}_i)^T(\mathbf{x}_i - \mathbf{x}_j))$. As the elements in both $\mathbf{x}$ and $\mathbf{K}_l$ are bounded by Assumption A1, it suffices to show $|\mathcal{B}_{\mathbf{z}}(\hat{\mathbf{g}})|$ is bounded. Denote $\mathcal{C} = \Big\{\hat{\mathbf{g}} : |\mathcal{B}_{\mathbf{z}}(\hat{\mathbf{g}})| > c_{10}\sqrt{\log(4/\delta)}(n^{-\Theta/2} + n^{\frac{\psi-1}{2}}\lambda_n^{-1} + n^{-3/8})\Big\}$. As in the proof of Theorem 2, we decompose $P(\mathcal{C})$ as

$$\begin{aligned} P(\mathcal{C}) &= P\Big(\mathcal{C}\cap\{|y| \leq n^{1/8}, U \leq M_0\}^c\Big) + P\Big(\mathcal{C}\cap\{|y| \leq n^{1/8}, U \leq M_0\}\Big) \\ &\leq P(|y| > n^{1/8}) + P(|y| \leq n^{1/8}, U > M_0) + P\Big(\mathcal{C}\cap\{|y| \leq n^{1/8}, U \leq M_0\}\Big). \end{aligned}$$

where U and M_0 are the same as in Theorem 2.

Following the proof of Theorem 2, the first two probabilities can be bounded as $P(|y| > n^{1/8}) \leq O(n^{-1/4})$ and $P(|y| \leq n^{1/8}, U > M_0) \leq \exp\{-\frac{1}{16}n^{3/4}\}$. To bound the third probability, a slight modification of the proof of Proposition 7 yields that when $|y| \leq n^{1/8}$ and $U \leq M_0$, we have $J(\hat{\mathbf{g}}) \leq M_0$ and with probability at least $1 - \delta/2$,

$$|\mathcal{B}_{\mathbf{z}}(\hat{\mathbf{g}}) - E(\mathcal{B}_{\mathbf{z}}(\hat{\mathbf{g}})| \leq 3\sqrt{\frac{\log(4/\delta)}{n}}\Big(n^{1/8} + \frac{c_x n^{\psi/2}M_0}{c_4\lambda_n}\Big).$$

We then bound $|E(\mathcal{B}_{\mathbf{z}}(\hat{\mathbf{g}})|$ as follows,

$$\begin{aligned} |E(\mathcal{B}_{\mathbf{z}}(\hat{\mathbf{g}}))| &= \Big|\int_{\mathcal{X}}\int_{\mathcal{X}} w(\mathbf{x},\mathbf{u})\Big(f^*(\mathbf{x}) - f^*(\mathbf{u}) + \hat{\mathbf{g}}(\mathbf{x})^T(\mathbf{u}-\mathbf{x})\Big)d\rho_X(\mathbf{x})d\rho_X(\mathbf{u})\Big| \\ &\leq \Big(\int_{\mathcal{X}}\int_{\mathcal{X}}\Big|w(\mathbf{x},\mathbf{u})\Big(f^*(\mathbf{x}) - f^*(\mathbf{u}) + \hat{\mathbf{g}}(\mathbf{x})^T(\mathbf{u}-\mathbf{x})\Big)\Big|^2 d\rho_X(\mathbf{x})d\rho_X(\mathbf{u})\Big)^{1/2} \\ &\leq \Big(\int_{\mathcal{X}}\int_{\mathcal{X}} w(\mathbf{x},\mathbf{u})\Big(f^*(\mathbf{x}) - f^*(\mathbf{u}) + \hat{\mathbf{g}}(\mathbf{x})^T(\mathbf{u}-\mathbf{x})\Big)^2 d\rho_X(\mathbf{x})d\rho_X(\mathbf{u})\Big)^{1/2} \\ &= \Big(\mathcal{E}(\hat{\mathbf{g}}) - 2\sigma_s^2\Big)^{1/2}. \end{aligned}$$

The first inequality follows from Hölder inequality, and the second inequality follows from the fact that $w(\mathbf{x},\mathbf{u}) \leq 1$ for any $\mathbf{x}$ and $\mathbf{u}$. Therefore, within the set $\{|y| \leq n^{1/8}, U \leq M_0\}$,

we have with probability at least $1 - \delta/2$ that

$$|\mathcal{B}_{\mathbf{z}}(\hat{\mathbf{g}})| \leq c_{10}\sqrt{\log(4/\delta)}(n^{-\Theta/2} + n^{\frac{\psi-1}{2}}\lambda_n^{-1} + n^{-3/8}). \tag{18}$$

This implies that $P(\mathcal{C}) \leq \delta/2 + O(n^{-1/4})$ for any given δ. Then it is clear that the norm of the left-hand side of (17) divided by $n^{1/2}$ will converge to 0 in probability, which contradicts with the fact that the norm of the right-hand side divided by $n^{1/2}$ diverges to ∞. Therefore, we have $\|\hat{\boldsymbol{\alpha}}^{(l)}\|_2 = 0$ for any $l > p_0$.

Next, we show that $\|\hat{\boldsymbol{\alpha}}^{(l)}\|_2 > 0$ for any $l \leq p_0$. Let $\bar{\mathcal{X}}_\tau = \{\mathbf{x} \in \mathcal{X} : d(\mathbf{x}, \partial\mathcal{X}) > \tau_n, p(\mathbf{x}) > \tau_n + c_2\tau_n^\theta\}$. Same as the proof of Theorem 5 in Ye and Xie (2012), for some given constant c_{11}, we have

$$\int_{\bar{\mathcal{X}}_\tau} \|\hat{\mathbf{g}}(\mathbf{x}) - \mathbf{g}^*(\mathbf{x})\|_2^2 d\rho_X(\mathbf{x}) \leq c_{11}\tau_n^{-(p+3)}\Big(\tau_n^{p+4} + \mathcal{E}(\hat{\mathbf{g}}) - 2\sigma_s^2\Big).$$

According to Theorem 2, it can be showed that

$$\int_{\bar{\mathcal{X}}_\tau} \|\hat{\mathbf{g}}(\mathbf{x}) - \mathbf{g}^*(\mathbf{x})\|_2^2 d\rho_X(\mathbf{x}) \to 0.$$

Now suppose $\|\hat{\boldsymbol{\alpha}}^{(l)}\|_2 = 0$ for some $l \leq p_0$, which implies

$$\int_{\bar{\mathcal{X}}_\tau} \|\hat{\mathbf{g}}(\mathbf{x}) - \mathbf{g}^*(\mathbf{x})\|_2^2 d\rho_X(\mathbf{x}) = \int_{\bar{\mathcal{X}}_\tau} \|g_l^*(\mathbf{x})\|_2^2 d\rho_X(\mathbf{x}).$$

As $\tau_n \to 0$, $\int_{\bar{\mathcal{X}}_\tau} \|g_l^*(\mathbf{x})\|_2^2 d\rho_X(\mathbf{x}) \geq \int_{\mathcal{X}\setminus\mathcal{X}_l} \|g_l^*(\mathbf{x})\|_2^2 d\rho_X(\mathbf{x})$, which is a positive constant by Assumption A4, and then leads to the contradiction. Combining the above two statements implies the desired variable selection consistency. ■

Stephen Boyd BOYD@STANFORD.EDU
Departments of Computer Science and Electrical Engineering
Stanford University
Stanford, CA 94305, USA

Editor: Antti Honkela

Abstract

CVXPY is a domain-specific language for convex optimization embedded in Python. It allows the user to express convex optimization problems in a natural syntax that follows the math, rather than in the restrictive standard form required by solvers. CVXPY makes it easy to combine convex optimization with high-level features of Python such as parallelism and object-oriented design. CVXPY is available at `http://www.cvxpy.org/` under the GPL license, along with documentation and examples.

Keywords: convex optimization, domain-specific languages, Python, conic programming, convexity verification

1. Introduction

Convex optimization has many applications to fields as diverse as machine learning, control, finance, and signal and image processing (Boyd and Vandenberghe, 2004). Using convex optimization in an application requires either developing a custom solver or converting the problem into a standard form. Both of these tasks require expertise, and are time-consuming and error prone. An alternative is to use a domain-specific language (DSL) for convex optimization, which allows the user to specify the problem in a natural way that follows the math; this specification is then automatically converted into the standard form required by generic solvers. CVX (Grant and Boyd, 2014), YALMIP (Lofberg, 2004), QCML (Chu et al., 2013), PICOS (Sagnol, 2015), and Convex.jl (Udell et al., 2014) are examples of such DSLs for convex optimization.

CVXPY is a new DSL for convex optimization. It is based on CVX (Grant and Boyd, 2014), but introduces new features such as signed disciplined convex programming analysis and parameters. CVXPY is an ordinary Python library, which makes it easy to combine convex optimization with high-level features of Python such as parallelism and object-oriented design.

CVXPY has been downloaded by thousands of users and used to teach multiple courses (Boyd, 2015). Many tools have been built on top of CVXPY, such as an extension for stochastic optimization (Ali et al., 2015).

2. CVXPY Syntax

CVXPY has a simple, readable syntax inspired by CVX (Grant and Boyd, 2014). The following code constructs and solves a least squares problem where the variable's entries are constrained to be between 0 and 1. The problem data $A \in \mathbf{R}^{m \times n}$ and $b \in \mathbf{R}^m$ could be encoded as NumPy ndarrays or one of several other common matrix representations in Python.

```
# Construct the problem.
x = Variable(n)
objective = Minimize(sum_squares(A*x - b))
constraints = [0 <= x, x <= 1]
prob = Problem(objective, constraints)

# The optimal objective is returned by prob.solve().
result = prob.solve()
# The optimal value for x is stored in x.value.
print x.value
```

The variable, objective, and constraints are each constructed separately and combined in the final problem. In CVX, by contrast, these objects are created within the scope of a particular problem. Allowing variables and other objects to be created in isolation makes it easier to write high-level code that constructs problems (see §6).

3. Solvers

CVXPY converts problems into a standard form known as conic form (Nesterov and Nemirovsky, 1992), a generalization of a linear program. The conversion is done using graph implementations of convex functions (Grant and Boyd, 2008). The resulting cone program is equivalent to the original problem, so by solving it we obtain a solution of the original problem.

Solvers that handle conic form are known as cone solvers; each one can handle combinations of several types of cones. CVXPY interfaces with the open-source cone solvers CVXOPT (Andersen et al., 2015), ECOS (Domahidi et al., 2013), and SCS (O'Donoghue et al., 2016), which are implemented in combinations of Python and C. These solvers have different characteristics, such as the types of cones they can handle and the type of algorithms employed. CVXOPT and ECOS are interior-point solvers, which reliably attain high accuracy for small and medium scale problems; SCS is a first-order solver, which uses OpenMP to target multiple cores and scales to large problems with modest accuracy.

4. Signed DCP

Like CVX, CVXPY uses disciplined convex programming (DCP) to verify problem convexity (Grant et al., 2006). In DCP, problems are constructed from a fixed library of functions with known curvature and monotonicity properties. Functions must be composed according to a simple set of rules such that the composition's curvature is known. For a visualization of the DCP rules, visit `dcp.stanford.edu`.

CVXPY extends the DCP rules used in CVX by keeping track of the signs of expressions. The monotonicity of many functions depends on the sign of their argument, so keeping track of signs allows more compositions to be verified as convex. For example, the composition `square(square(x))` would not be verified as convex under standard DCP because the `square` function is nonmonotonic. But the composition is verified as convex under signed DCP because `square` is increasing for nonnegative arguments and `square(x)` is nonnegative.

5. Parameters

Another improvement in CVXPY is the introduction of parameters. Parameters are constants whose symbolic properties (*e.g.*, dimensions and sign) are fixed but whose numeric value can change. A problem involving parameters can be solved repeatedly for different values of the parameters without redoing computations that do not depend on the parameter values. Parameters are an old idea in DSLs for optimization, appearing in AMPL (Fourer et al., 2002).

A common use case for parameters is computing a trade-off curve. The following code constructs a LASSO problem (Boyd and Vandenberghe, 2004) where the positive parameter γ trades off the sum of squares error and the regularization term. The problem data are $A \in \mathbf{R}^{m\times n}$ and $b \in \mathbf{R}^m$.

```
x = Variable(n)
gamma = Parameter(sign="positive") # Must be positive due to DCP rules.
error = sum_squares(A*x - b)
regularization = norm(x, 1)
prob = Problem(Minimize(error + gamma*regularization))
```

Computing a trade-off curve is trivially parallelizable, since each problem can be solved independently. CVXPY can be combined with Python multiprocessing (or any other parallelism library) to distribute the trade-off curve computation across many processes.

```
# Assign a value to gamma and find the optimal x.
def get_x(gamma_value):
    gamma.value = gamma_value
    result = prob.solve()
    return x.value

# Get a range of gamma values with NumPy.
gamma_vals = numpy.logspace(-4, 6)
# Do parallel computation with multiprocessing.
pool = multiprocessing.Pool(processes = N)
x_values = pool.map(get_x, gamma_vals)
```

6. Object-Oriented Convex Optimization

CVXPY enables an object-oriented approach to constructing optimization problems. As an example, consider an optimal flow problem on a directed graph $G = (V, E)$ with vertex

set V and (directed) edge set E. Each edge $e \in E$ carries a flow $f_e \in \mathbf{R}$, and each vertex $v \in V$ has an internal source that generates $s_v \in \mathbf{R}$ flow. (Negative values correspond to flow in the opposite direction, or a sink at a vertex.) The (single commodity) flow problem is (with variables f_e and s_v)

$$\begin{array}{ll} \text{minimize} & \sum_{e\in E} \phi_e(f_e) + \sum_{v\in V} \psi_v(s_v), \\ \text{subject to} & s_v + \sum_{e\in I(v)} f_e = \sum_{e\in O(v)} f_e, \quad \text{for all } v \in V, \end{array}$$

where the ϕ_e and ψ_v are convex cost functions and $I(v)$ and $O(v)$ give vertex v's incoming and outgoing edges, respectively.

To express the problem in CVXPY, we construct vertex and edge objects, which store local information such as optimization variables, constraints, and an associated objective term. These are exported as a CVXPY problem for each vertex and each edge.

```
class Vertex(object):
    def __init__(self, cost):
        self.source = Variable()
        self.cost = cost(self.source)
        self.edge_flows = []

    def prob(self):
        net_flow = sum(self.edge_flows) + self.source
        return Problem(Minimize(self.cost), [net_flow == 0])

class Edge(object):
    def __init__(self, cost):
        self.flow = Variable()
        self.cost = cost(self.flow)

    def connect(self, in_vertex, out_vertex):
        in_vertex.edge_flows.append(-self.flow)
        out_vertex.edge_flows.append(self.flow)

    def prob(self):
        return Problem(Minimize(self.cost))
```

The vertex and edge objects are composed into a graph using the edges' `connect` method. To construct the single commodity flow problem, we sum the vertices and edges' local problems. (Addition of problems is overloaded in CVXPY to add the objectives together and concatenate the constraints.)

```
prob = sum([object.prob() for object in vertices + edges])
prob.solve() # Solve the single commodity flow problem.
```

Acknowledgments

We thank the many contributors to CVXPY. This work was supported by DARPA XDATA.

Abstract

We introduce the *Lenient Multiagent Reinforcement Learning 2* (LMRL2) algorithm for independent-learner stochastic cooperative games. LMRL2 is designed to overcome a pathology called *relative overgeneralization*, and to do so while still performing well in games with stochastic transitions, stochastic rewards, and miscoordination. We discuss the existing literature, then compare LMRL2 against other algorithms drawn from the literature which can be used for games of this kind: traditional ("Distributed") Q-learning, Hysteretic Q-learning, WoLF-PHC, SOoN, and (for repeated games only) FMQ. The results show that LMRL2 is very effective in both of our measures (complete and correct policies), and is found in the top rank more often than any other technique. LMRL2 is also easy to tune: though it has many available parameters, almost all of them stay at default settings. Generally the algorithm is optimally tuned with a single parameter, if any. We then examine and discuss a number of side-issues and options for LMRL2.

Keywords: multiagent learning, reinforcement learning, game theory, lenient learning, independent learner

1. Introduction

In a cooperative game, as we use the term here, some $N \geq 2$ players simultaneously choose an action from among those actions each is permitted to make, and then each receives the same (potentially stochastic) reward arising from their joint action. It is this equally-shared reward that makes the game cooperative: agents succeed or fail together. Such cooperative games are very common in multiagent systems: for example, a group of robots might work together to map out a room; a swarm of game agents might collaborate to defeat a hard-coded Bad Guy; or a team of wireless beacons might work together to form an optimal ad-hoc routing network.

We are interested in the situation where the agents in question do not know the reward function over their joint actions and must *learn* to collaboratively explore this space and ultimately adapt to the highest-reward joint action. Furthermore, the agents are *independent learners* in the sense that they do not know what actions the other agents are performing (although they may assume that other agents *exist*). In a primary alternative, where the agents are told the others' action choices along with the rewards received, the agents are known as *joint-action learners*.

From a game theoretic perspective, there are two common types of games in which such agents may learn to optimize their actions. First, a game may be *repeated*, meaning that the agents play the same game over and over again, potentially choosing new actions each time. Second, there is the so-called *stochastic* game, where not only does a joint action affect the reward received, but it also changes the game played next time. In a stochastic game there is a set of possible sub-games (or *states*) for the agents to play, each with potentially different kinds of actions available to the agents, and each with their own reward function. Furthermore, each joint action in each state is associated with a transition function which maps joint actions to distributions over states: from the appropriate distribution the next state will be selected. There is a distinguished initial state for the game, and there may optionally be a special end state: the game simply terminates when it reaches this state. The agents know in which state they are playing, but not its reward function nor its transition functions. A repeated game is just a stochastic game with only one state.

There is significant literature in applying multiagent versions of reinforcement learning, policy search, or similar methods to repeated and stochastic games. Much of the literature has focused on general-sum or zero-sum learners, and the remainder has focused nearly entirely on the pathology of *miscoordination* in cooperative scenarios, as discussed later. But there is another critical pathology which arises specially in cooperative games, known as *relative overgeneralization*. Overcoming relative overgeneralization may require a more explorative approach than simple epsilon-greedy action selection: indeed as shown by Wiegand (2004), relative overgeneralization can cause players to not just hill-climb into local optima but get actively sucked into them despite action selection with a high degree of randomness. We discuss these pathologies in more detail in Section 3.

Perhaps because relative overgeneralization as a phenomenon necessitates at least three actions available per player, and ideally more, it has not shown up much in the small problems common to the multiagent reinforcement learning (MARL) literature, though it has been studied at some length in the related field of cooperative co-evolutionary algorithms (Panait, 2006; Panait et al., 2006a, 2008, 2004), which involve very large numbers of actions. We are interested in solving both relative overgeneralization and miscoordination. To this end we present and discuss a *lenient* learning algorithm meant for independent learning in stochastic cooperative games (and also repeated cooperative games) with any number $N \geq 2$ of agents. We call this algorithm *Lenient Multiagent Reinforcement Learning 2*, or LMRL2 for short. This is a heavy revision of the original LMRL algorithm, which was originally meant only for repeated games (Panait et al., 2006b).

As we will show, LMRL2 performs well across a spectrum of stochastic and repeated games when compared to other algorithms from the literature, and is able to deal robustly with overgeneralization, miscoordination, and high degrees of stochasticity in the reward and transition functions with relatively little parameter tuning. In this paper we will discuss issues in MARL which lenient learning is meant to address, then survey previous work and alternative approaches. We will then detail LMRL2, compare it to other methods, and discuss various side issues which arise.

2. Previous Work

Reinforcement Learning is a popular approach to solving multiagent learning problems (Busoniu et al., 2008), because many such problems may be readily cast into normal-form games, which themselves map straightforwardly into Markov Decision Processes (MDPs) for which reinforcement learning is well suited. Use of reinforcement learning in the multiagent context is, not suprisingly, known as *Multiagent Reinforcement Learning*, or MARL.

Many MARL methods may be organized according to three different characteristics. First, there is the *reward structure* involved: MARL algorithms may be designed for zero-sum (or constant-sum), cooperative, and general-sum games. Second, there is the *type of information* being provided to the algorithms. Here we distinguish between *joint action* and *independent learner* algorithms, following Claus and Boutilier (1998). Third, there is the *game type*: some MARL algorithms are meant only for repeated games, while others are meant for more general stochastic games. LMRL2 itself is an independent learner, cooperative, stochastic game algorithm.

Joint Action Learners In a *joint action learner* scenario, after playing a game, each agent receives a reward, is told which game is to be played next (the next *state*), and is also told what actions were chosen by the other agents. There is significant joint action learner literature.

Only a small portion of the literature focuses on pure zero-sum games. One of the first zero-sum joint-action-learning algorithms was Minimax-Q (Littman, 1994), which assumes that the alternative agent is attempting to minimize one's own reward. Thus, rather than select the action which with the maximum reward achievable, Minimax-Q uses a minimax approach: it selects the highest reward achievable assuming that the alternative agent will select its action so as to minimize that reward. This solution may be determined by solving a linear program.

There are many general-sum joint-action learners. However, learning in general-sum games is very complicated due to the wide variety in reward structure. Even the goal of learning in this kind of game can be hard to define in some cases (Shoham et al., 2004). To simplify the issue, much of the literature simply aims to converge to an equilibrium of some sort during self-play (that is, playing against other agents who use the same algorithm as yourself). The most well-known algorithm of this kind is called Nash Q-Learning (Hu and Wellman, 2003), which has been proven to converge to the Q-values in some Nash Equilibrium under very restricted conditions, such as if each state has a global joint optimum. Other learning algorithms which have been designed to converge to equilibria include Wellman and Hu (1998); Greenwald et al. (2003); Jafari et al. (2001). Rather than convergence, some work has instead proposed playing a best response against some restricted classes of opponents (Weinberg and Rosenschein, 2004; Tesauro, 2004). There has also been work in combining the two, where the learner converges to Nash Equilibrium in self-play, and plays a best response when not in self-play (Conitzer and Sandholm, 2007).

Like the zero-sum game literature, the pure cooperative game literature is limited. Littman (2001b) introduced Team Q-learning, but as it is a straightforward extension of Q-Learning to cooperative games, it fails to handle miscoordination. To address this Wang and Sandholm proposed OAL (2002), which is guaranteed to converge to the optimal Nash Equilibrium in cooperative games: but due to necessary constraints on the reward function, converging to the optimal policy is not particularly interesting for joint action learners in cooperative games. Other work has imported techniques from the reinforcement learning community to enhance online performance. Notably Chalkiadakis and Boutilier applied Bayesian Reinforcement Learning to the multiagent scenario (2003). Here, agents have some prior knowledge on distributions of the game model and also the possible strategies that can be used by other learners. Each iteration of the game, an agent chooses a best action with respect to the distributions it is maintaining, and the distributions are then updated based on the individual actions of the other agents and the results from the joint action. Typical of Bayesian Reinforcement Learning methods, a bad prior can make the algorithm converge to a suboptimal policy in some cases, but Bayesian methods in general may help agents accumulate more reward while learning. Bayesian methods have also been used with policy search in a MARL context (Wilson et al., 2010), where the distributions are instead over policy parameters and possible roles of other agents. Unusually, agents here make decisions sequentially rather than simultaneously, which is rare in the MARL literature.

Another way to incorporate prior knowledge into learning is to construct the policy as a hierarchy. Hierarchical reinforcement learning has been shown to accelerate learning in the single agent case by allowing state abstraction and by reusing learned policy (Dietterich, 2000). This has been extended to the multiagent setting (Makar et al., 2001; Ghavamzadeh et al., 2006) by manually specifying the cooperation task at a higher level in the task hierarchy. This allows non-cooperative subtasks to be learned separately, and efficiently as single-agent learning problems. The authors have further used this idea in a setting where knowing the actions of other agents incurs a communication cost (Ghavamzadeh and Mahadevan, 2004).

Independent Learners An *independent learner* scenario differs from a joint action scenario in that, after playing a game, each agent is *not* told what action was chosen by each of the other agents. He is only told the reward he received and the game (state) to be played next time. This is a much more difficult learning problem. Additionally, because they are designed for a more general scenario, independent learners may participate in joint action games, but not the other way around.

Perhaps the best-known example of a general-sum independent learner is WoLF-PHC (Bowling and Veloso, 2001b, 2002). This algorithm is designed to meet two criteria for learning in general sum games: first, a learner should learn to play optimally against stationary opponents, and second, a learner should converge to a Nash Equilibrium when in self-play. WoLF-PHC is an independent-learning policy search approach which uses one of two different learning rates depending on whether the player is in some sense "winning" or "losing". This "WoLF" (Win or Learn Fast) principle has since been applied to other algorithms (Bowling and Veloso, 2001a; Banerjee and Peng, 2003; Bowling, 2005).

Other approaches, based on gradient descent, also try to converge to Nash Equilibria in self play (Abdallah and Lesser, 2008; Zhang and Lesser, 2010). Additionally, Kaisers and Tuyls linked evolutionary game theory to reinforcement learning to study the dynamic of Q-learning in multiagent problems. Their proposed algorithm, Frequency Adjusted Q-learning (FAQ), resembles regular Q-learning except that it changes the update method to compensate for the fact that actions are updated at different frequencies (Kaisers and Tuyls, 2010).

Cooperative learning presents a variety of special problems for independent learners as opposed to joint-action learners. Fulda and Ventura (2007) identified three problematic factors — "poor individual behavior", "action shadowing" (related to relative overgeneralization, as discussed later), and "equilibrium selection" (miscoordination) — and suggested that optimal performance might be achieved by solving them. However in their survey, Matignon et al. (2012) identified at least two more problems, and compared several independent learners in several games along with different exploration strategies to overcome these problems.

Some work has been done in cooperative games. Lauer and Riedmiller introduced Distributed Q-learning (2000), which addresses two major problems mentioned in (Fulda and Ventura, 2007). It tackles relative overgeneralization problem by only updating using the maximum Q-value — an approach we will develop further with LMRL2 — and it tackles the miscoordination problem by only changing the policy when the Q-value is updated. However this learner is vulnerable to games with stochastic rewards or transitions. Building on Distributed Q-learning, Hysteretic Q-learning (Matignon et al., 2007) uses two different learning rates to address stochasticity. One study (Bloembergen et al., 2010) adds our concept of leniency into FAQ, using a slightly different approach from what we do here. Leniency seems to help FAQ solve initial miscoordination difficulties in cooperative games.

Instead of changing the update procedure, researchers have also investigated the possibility of using different exploration strategies. Frequency Maximum Q-Value heuristic (FMQ), meant only for repeated games, used a form version of Boltzmann action selection where the Q-value was substituted by an expectation (Kapetanakis and Kudenko, 2002). FMQ was modified by Matignon et al. to handle stochasticity in repeated games (2008) and stochastic games (2009). The latter version of this algorithm was called *Swing between Optimistic or Neutral*, or SOoN.

Learners Based on the Nature of the Other Agents Most of the literature discussed so far focuses on learning in a certain kind of game. However, instead of making assumptions about the nature of a game, some methods are based on the nature of the other agents. In so-called Friend-or-Foe Q-learning (Littman, 2001a), the learner is essentially a mixture of two different Q-learners: one which updates the Q-table like a regular Q-learner if the other agent is thought to be a friend, and one which updates the Q-table using Minimax-Q if the agent is thought to be an opponent. Asymmetric Q-learning (Könönen, 2004), distinguishes between "leaders" and "followers" in the game, where a "leader" knows what action a "follower" will choose can guide the action selection of the "follower" (see also the leader-follower reward shaping in Babes et al. 2008). CMLeS provides different performance guarantees depending on different set of agents in the game (Chakraborty and Stone, 2013a,b). Specifically, if the agents are doing self-play, the algorithm will achieve a Nash Equilibrium joint policy; if the alternative agents are opponents with limited memory, the algorithm can guarantee a near-optimal response in polynomial time steps; and in other cases, the algorithm will play similarly to Minimax-Q.

Another area of research has studied adaptation to arbitrary agents of unknown type. Sullivan et al. (2006) studied FMQ and Lenient Learners in non-self play scenarios, and showed that while these learners could easily converge to an optimal Nash Equilbrium in self-play for various games, it was difficult for them to do so when paired with learners from entirely different algorithms. Stone et al. (2010) consider ad-hoc teams of multiple agents

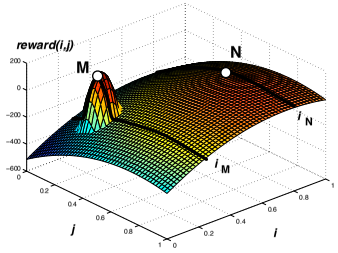

Figure 1: The relative overgeneralization pathology in multiagent learning. The axes i and j are the various actions that agents A_i and A_j may perform, and the axis $reward(i, j)$ is the joint reward received by the agents from a given joint action $\langle i, j \rangle$. Higher rewards are better. Joint action M has a higher reward than joint action N. However, the average (or sum) of all possible rewards for action i_M, of agent A_i is lower than the average of all possible rewards for action i_N. To illustrate this, bold lines show the set of outcomes from pairing i_M or i_N instead with other possible actions in j.

with different capabilities whose goals and utilities are aligned but which have had no prior coordination. They give a method to evaluate the performance of an agent in this scenario, and provide theoretical approaches to building a perfect ad hoc team. Additional follow-on methods have since been suggested (Stone and Kraus, 2010; Agmon et al., 2014; Genter et al., 2015; Barrett and Stone, 2015).

3. Lenient Learning

The notion of lenient learning, and the pathology it is meant to tackle, did not start in multiagent reinforcement learning research, but rather in an unexpected but surprisingly related topic: cooperative coevolutionary algorithms (CCEAs) (Potter and De Jong, 1994). CCEAs are multiagent stochastic optimization procedures and exhibit nearly identical pathologies to those found in repeated games.

Relative Overgeneralization Lenient learning was originally designed to combat a particular pathology in repeated games and CCEAs called *relative overgeneralization* (Wiegand, 2004). Relative overgeneralization occurs when a suboptimal Nash Equilibrium in the joint space of actions is preferred over an optimal Nash Equilibrium because each agents' action in the suboptimal equilibrium is a better choice when matched with *arbitrary* actions from the collaborating agents. Consider Figure 1, showing the reward over the joint action space for a two-agent game for agents A_i and A_j. Here, the joint candidate solution labeled M should clearly be preferred over another one, N. However if one assessed the quality of individual actions based on the sum or average reward received when paired with all possible other actions from the collaborating agent, then agent A_i's portion of the joint action N

(called i_N) would be preferred over its portion of the joint action M (called i_M). That is, quality$(i_M) = \sum_j \text{reward}(i_M, j) <$ quality$(i_N) = \sum_j \text{reward}(i_N, j)$. We will call such an approach an *average-based* algorithm.

This situation can easily arise in cooperative, repeated games for independent learners. Here is an example of relative overgeneralization in a repeated game:

		Agent 2		
		a	b	c
Agent 1	a	10	0	0
	b	0	5	6
	c	0	6	7

In this game, though $\langle a, a\rangle$ is clearly the best joint move for the two agents, if the agents sampled their actions randomly and based decisions on the average reward, action a would have the worst score, action c would have the best score, and b would be in the middle. Thus the agents would tend to converge to $\langle c, c\rangle$.

The obvious alternative this is to base the quality of a solution not on its *average* reward, but rather on its *best* reward when paired with various other actions. That is, quality$(i_M) = \max_j \text{reward}(i_M, j)$. In this case, a would be the best action, c the next highest, and b the worst. Thus the agents would tend to converge to the proper equilibrium, $\langle a, a\rangle$. We call this a *maximum-based* approach.

Relative overgeneralization is a specific and problematic subcase of the slightly more general notion of *action shadowing*, occasionally used by the MARL community, but has only been relatively recently studied (Panait et al., 2006b; Panait, 2006; Fulda and Ventura, 2007; Panait et al., 2008). One possible reason for this might be that common MARL test problems are relatively low in number of actions, and relative overgeneralization can only arise if each agent has at least three actions available, ideally many more. In contrast, in CCEAs the number of "actions", so to speak, is very high and often infinite, and so the pathology is a common occurrence there.

Stochastic Rewards and Lenient Learners Some reinforcement learning methods, so-called *optimistic methods* (Matignon et al., 2012), are generally maximum-based learners, or at least prefer superior results, for example, updating superior results with a higher learning rate. In a repeated game with deterministic rewards, these techniques are likely to perform very well. However, games with stochastic rewards will mislead such learners, since the highest rewards they see will often be due to noise. This problem isn't likely to occur with average-based learners.

Our approach instead begins with a maximum-reward learner and gradually shifts to an average-reward learner. The idea here is that early on none of the agents have a good understanding of their best joint actions, and so each agent must initially be *lenient* to the foolish and arbitrary actions being made by its collaborators. Later on, each agent focuses more on average reward, which helps escape the trap laid by stochastic rewards. We call this approach a *lenient multiagent reinforcement learning* algorithm.

Miscoordination Another common pathology which appears in repeated games is *miscoordination*, where two or more equivalent equilibria are offset in such a way that agents, each selecting what appears to be an optimal action, wind up with poor joint actions. For

example, in the game below, both actions a and b are reasonable for each agent. But if one agent chooses a while the other agent chooses b, they receive a low reward.

		Agent 2	
		a	b
Agent 1	a	10	0
	b	0	10

Stochastic Games and Deception Stochastic games add some new wrinkles to the above pathologies, because, at least for temporal difference learners, Q-values come partly from accumulated reward and partly from the backed-up rewards from follow-on states. This means that both miscoordination and relative overgeneralization, among other challenges, can arrive via backed-up rewards as well as immediate rewards.

The probabilistic transitions common in stochastic games present an additional hurdle for lenient learners, since such learners may consider only the highest backed-up rewards, even if they are very unlikely to occur. As was the case for probabilistic rewards, probabilistic transitions are largely overcome by the learner's gradual shift from being maximum-based to being average-based.

This hurdle leads to *deception*, another pathology which can arise in stochastic games. A deceptive game is one in which certain states have a high local reward but lead ultimately to states with poor future rewards: this is also known as the *delayed reward* problem. This creates a garden-path scenario where greedy agents are deceptively led away from the truly high-performing states.

4. The LMRL2 Algorithm

In (Panait et al., 2006b, 2013) we demonstrated a lenient learning algorithm, LMRL, for repeated games with independent learners, comparing it favorably to the FMQ algorithm (Kapetanakis and Kudenko, 2002) for variations of the Climb and Penalty games (Claus and Boutilier, 1998). We begin here with a slight modification of the algorithm, LMRL2, which is the degenerate case (for repeated games) of the full LMRL2 algorithm for stochastic games. We will then extend it to the stochastic game scenario.

LRML2 is a modified version of Q-learning which maintains per-action *temperatures* which are slowly decreased throughout the learning process. An action's temperature affects two things. First, it affects the degree of randomness of action selection: with high temperatures, action selection is largely random, and with low temperatures, action selection is greedily based on the actions with the highest Q-values. To do this, LRML2 applies a temperature-based Boltzmann Selection common in other algorithms in the literature. However, when the average temperature drops below a certain *minimum temperature*, and LRML2's action selection will suddenly become purely greedy. This minimum temperature was originally added to avoid floating point overflows common in Boltzmann Selection; but we have found that it also is beneficial for nearly all games.

Second, temperature affects the lenience of the algorithm: high temperatures cause LRML2 to be lenient, and so only mix rewards into Q-values if they are better than or equal to the current Q-value. With a low temperature LRML2 mixes all rewards into the

Q-values no matter what. Unlike action selection, lenience is not affected by the minimum temperature bound.

Repeated Games LRML2 for repeated games relies on the following parameters. Except for θ and ω, all of them will be fixed to the defaults shown, and will not be modified:

$\alpha \leftarrow 0.1$	learning rate
$\gamma \leftarrow 0.9$	discount for infinite horizon
$\delta \leftarrow 0.995$	temperature decay coefficient
$\mathit{MaxTemp} \leftarrow 50.0$	maximum temperature
$\mathit{MinTemp} \leftarrow 2.0$	minimum temperature
$\omega > 0$	action selection moderation factor (by default 1.0)
$\theta > 0$	lenience moderation factor (by default 1.0)

The α and γ parameters are standard parameters found in Q-learning, and their values here are typical settings from the literature. The parameters *MaxTemp,* δ, and *MinTemp* are also generally constants. The parameter ω determines the degree to which temperature affects the randomness of the Boltzmann action selection. In all cases but two (discussed later) we set this to 1.0. Finally and crucially, the θ parameter determines the degree to which temperature affects the dropoff in lenience. This parameter is the primary, and usually only, parameter which must be tuned, as different problems require different amounts of lenience.

LMRL2 maintains two tables: Q, a table of Q-values per action a, and T, a table of temperatures per-action. Initially $\forall a$:

$$Q(a) \leftarrow \text{initialize}(a) \qquad \triangleleft \textit{ See discussion below}$$
$$T(a) \leftarrow \mathit{MaxTemp}$$

In lenient learning, the choice of initial Q values is important to the operation of the algorithm. Consider if $\forall a : Q(a) = 0$ initially. What if a game consisted only of negative rewards? The lenient learner, at least during its high-temperature period, would refuse to merge *any* of them into the Q-values because they are too small. We have two strategies for initializing Q:

- **Initialize to Infinity** $\forall a : Q(a) = \infty$. This signals to LMRL2 to later reinitialize each Q value to the first reward received. Furthermore, as long as one or more action has an infinite Q-value, LRML2 will only select among such actions. This forces the algorithm to try every action at least once initially in order to initialize them. The disadvantage of this initialization approach is that if the game has stochastic rewards, and first reward received is high, LMRL2 will be locked to this high reward early on.
- **Initialize to Minimum** $\forall a : Q(a) =$ the minimum possible reward over any action the game. The disadvantage of this approach is that it requires that LMRL2 know the minimum reward beforehand.

We will by default initialize to the minimum possible reward in the game.

LMRL2 then iterates for some n times through the following four steps. First, it computes a mean temperature $\overline{T}$. Second, using this mean temperature it selects an action to perform. Third, it performs the action and receives a reward resulting from the joint actions of all agents (all agents perform this step simultaneously and synchronously). Fourth, it updates the Q and T tables. This iteration is:

1. Compute the mean temperature as: $\overline{T} \leftarrow \text{mean}_a\, T(a)$
2. Select a as follows. If $\overline{T} < \mathit{MinTemp}$, or if $\max_a Q(a) = \infty$, select $\text{argmax}_a\, Q(a)$, breaking ties randomly. Otherwise use Boltzmann Selection:
   (a) Compute the action selection weights as: $\forall a : W_a \leftarrow e^{\frac{Q(a)}{\omega \overline{T}}}$
   (b) Normalize to the action selection probabilities as: $\forall a : P_a \leftarrow \frac{W_a}{\sum_i W_i}$
   (c) Use the probability distribution P to select action a.
3. The agent does action a and receives reward r.
4. Update $Q(a)$ and $T(a)$ only for the performed action a as:

$$\mathit{Rand} \leftarrow \text{random real value between 0 and 1}$$
$$Q(a) \leftarrow \begin{cases} r & \text{if } Q(a) = \infty \qquad \text{(initialization was to infinity)} \\ (1-\alpha)Q(a) + \alpha r & \text{else if } Q(a) \leq r \text{ or } (\mathit{Rand} < 1 - e^{\frac{-1}{\theta T(a)}}) \\ Q(a) & \text{else} \end{cases}$$
$$T(a) \leftarrow \delta T(a)$$

5. Go to 1.

Note that each action has its own separate temperature which is decreased only when that action is selected. This allows LMRL2 to keep temperatures high for actions which have not been visited much and still require lenience and exploration, while permitting other actions to cool down.

Stochastic Games In stochastic games, the agents are at any particular time in some state s; and after performing their joint action, receive a reward r and transition to some new state s'. Accordingly, the extension of LMRL2 to stochastic games is largely the same as the repeated game version, except that the $Q(a)$ and $T(a)$ tables are modified to include the current state s: that is, they are now defined as $Q(s,a)$ and $T(s,a)$ respectively.

The iteration is largely the same, except in how $Q(s,a)$ and $T(s,a)$ are updated. First, $Q(s,a)$ is updated in standard Q-learning style to incorporate both the reward and expectation of future utility, as $r + \gamma \max_{a'} Q(s',a')$. However, if not all actions have been explored in s', then $\max_{a'} Q(s',a')$ will still be infinite, in which case it is ignored and $Q(s,a)$ just incorporates r.

Second and more interestingly, not only do we decrease $T(s,a)$, but we also fold into it some portion τ of the mean temperatures found for s'. τ is a new constant, fixed like α to 0.1. The idea is as follows: in many games (particularly episodic ones), early states are often explored much more than later states, and thus cool down faster. We want to keep

these early states hot long enough that propagation of future rewards from the later states will inform the Q-values of the early states before they are set in stone as the temperature falls. To do this, we take some of the temperature s' of the later state and back it up into s.

Because stochastic games can terminate, we wrap the entire process in an outer loop to repeatedly play the game:

Parameters:

$\alpha \leftarrow 0.1$	learning rate
$\gamma \leftarrow 0.9$	discount for infinite horizon
$\tau \leftarrow 0.1$	temperature diffusion coefficient
$\delta \leftarrow 0.995$	temperature decay coefficient
$MaxTemp \leftarrow 50.0$	maximum temperature
$MinTemp \leftarrow 2.0$	minimum temperature
$\omega > 0$	action selection moderation factor (by default 1.0)
$\theta > 0$	lenience moderation factor (by default 1.0)

Initially $\forall s, a$:

$Q(s,a) \leftarrow \text{initialize}(s,a)$ $\quad\quad$ $\triangleleft$ *See Previous Discussion*
$T(s,a) \leftarrow MaxTemp$

Repeat:

1. Current state $s \leftarrow$ initial state.
2. Repeat until the current state s is the end state (if any):
   (a) Compute the mean temperature for current state s as: $\overline{T}(s) \leftarrow \text{mean}_a\, T(s,a)$
   (b) Select a as follows. If $\overline{T}(s) < MinTemp$, or if $\max_a Q(s,a) = \infty$, select $\text{argmax}_a\, Q(s,a)$, breaking ties randomly. Otherwise use Boltzmann Selection:
      i. Compute the action selection weights in current state s as: $\forall a : W_a \leftarrow e^{\frac{Q(s,a)}{\omega T(s)}}$
      ii. Normalize to the action selection probabilities in current state s as: $\forall a : P_a \leftarrow \frac{W_a}{\sum_i W_i}$
      iii. Use the probability distribution P to select action a.
   (c) The agent, in current state s, does action a, receives reward r, and transitions to new state s'.

   (d) Update $Q(s,a)$ and $T(s,a)$ only for the performed action a as:

$$Rand \leftarrow \text{random real value between 0 and 1}$$

$$R \leftarrow \begin{cases} r & \text{if } \max_{a'} Q(s',a') = \infty \\ r + \gamma \max_{a'} Q(s',a') & \text{else} \end{cases}$$

$$Q(s,a) \leftarrow \begin{cases} R & \text{if } Q(s,a) = \infty \text{ (initialization was to infinity)} \\ (1-\alpha)Q(s,a) + \alpha R & \text{else if } Q(s,a) \leq R \text{ or } (Rand < 1 - e^{\frac{-1}{\theta T(s,a)}}) \\ Q(s,a) & \text{else} \end{cases}$$

$$T(s,a) \leftarrow \delta \times \begin{cases} (1-\tau)T(s,a) + \tau\overline{T}(s') & \text{if } s' \text{ is not the end state (if any)} \\ T(s,a) & \text{else} \end{cases}$$

   (e) $s \leftarrow s'$

If we defined a repeated game as consisting of an initial state s which always transitions to the end state as s', this algorithm degenerates to the repeated version of LMRL2 discussed earlier.

5. Comparison with Other Methods

We begin with a comparison of LMRL2 against six other independent-learner algorithms in self-play in several cooperative test problems. The algorithms are standard (classic) Q-Learning, Distributed Q-Learning, Hysteretic Q-Learning, WoLF-PHC, SOoN (Swing between Optimistic or Neutral), and FMQ. The different techniques use a variety of parameters and have several action selection methods as options. We note that WoLF-PHC is a general-sum algorithm rather than strictly a cooperative one, and that FMQ can only be applied to repeated games. In a MARL context, standard Q-Learning is sometimes known as *Decentralized Q-Learning*. We briefly discuss all except for standard Q-Learning below.

Distributed Q-Learning We believe that Distributed Q-Learning (Lauer and Riedmiller, 2000) was the earliest independent-learner algorithm specifically designed for cooperative multiagent learning scenarios. In Distributed Q-Learning, each learner has a Q-table and a policy table. Unlike the regular Q-Learning, where a value in the Q-table is updated by combining it with some portion of the reward and follow-on utility, in Distributed Q-Learning the Q-value is completely replaced by the new reward and follow-on utility (that is, the learning rate is effectively 1.0), but only if doing so would increase it. This makes Distributed Q-Learning a maximum-based learner; and it is intended to address relative overgeneralization. Because it is highly optimistic, the algorithm has problems with stochasticity: indeed Lauer and Riedmiller (2000) acknowledged that this was still an open question.

To deal with miscoordination, Distributed Q-Learning has another trick up its sleeve: its policy is only updated when the Q-value of the policy's chosen action is no longer the highest such value. At this point a new action for the policy is chosen at random among those with the highest Q-values. The idea here is to cause agents to lock onto the earliest-discovered good action (and Nash Equilibrium) even when other equivalent Equilibria exist. Through this implicit agreement among agents, miscoordination can be avoided.

Hysteretic Learning Matignon et al. (2007) proposed Hysteretic Learning to address Distributed Q-Learning's vulnerability to stochasticity. Hysteretic Learning is not a fully maximum-based learner: rather, if updating the Q-value would reduce it, it is reduced with a smaller learning rate than when it would be if it were increased. Hysteretic Learning does not attempt to solve miscoordination explicitly, but experiments suggest that the algorithm is very robust to miscoordination issues, in part due to the randomization in its exploration strategy (Matignon et al., 2012).

FMQ Rather than change the update strategy, as is done in the previous two methods, the Frequency Maximum Q-Value (FMQ) heuristic instead tries changing the action-selection (exploration) strategy (Kapetanakis and Kudenko, 2002). FMQ is only meant for repeated games. FMQ uses a modified version of Boltzmann exploration, similar to the one used in LMRL2 as discussed later: the value produced via Boltzmann is sometimes called the *expected reward* or *estimated value*. However, this alone is not sufficiently informative to deal with relative overgeneralization. Thus, FMQ adds an additional term to its Q-value when using it during action selection. This additional term is the product of the *highest reward* seen so far when selecting that action, the *frequency* of getting that reward, and a *weighting factor* c which controls how much this term affects action selection: that is, how much action selection is based on the "average" reward versus typical "high" rewards.

FMQ are designed to deal with stochasticity in relative overgeneralization problems, but its learned policy can still be wrong if the variance of the reward function is high.

SOoN SOoN may be thought as a heavily modified FMQ. First, the frequency term is broken into two terms. The *myopic frequency* is the the same frequency term in original FMQ algorithm, and the *farsighted frequency* is used to deal with deception in games. Both frequency values are updated using temporal-difference style methods rather than a simple average. Additionally, the estimated value is computed as a linear interpolation between an Optimistic Q-value (the Q-value in Distributed Q-Learning) and an Average Q-value (the classical Q-Learning value). The algorithm introduces two new parameters, α_f and α_g, to replace the weighting factor c in FMQ to control the impact of the frequency terms.

WoLF-PHC Given its notoriety, we chose WoLF-PHC as our exemplar general-sum algorithm to compare against. WoLF-PHC is a policy hill-climbing algorithm and so is somewhat different from the various Q-Learning methods (Bowling and Veloso, 2001b). WoLF-PHC compares the expected value of current policy with the expected value of the average policy. If the former is lower, then the agent is "losing", else it is "winning". WoLF-PHC then uses one of two different learning rates depending on whether it is winning or losing (the "winning" learning rate is higher). As it is meant for general-sum games, WoLF-PHC can be straightforwardly applied to cooperative games: but obviously since it is more general-purpose, a comparison against it is somewhat unfair.

5.1 Test Problems

We tested against twelve games, either from the literature or of our own devising. This collection was meant to test a diverse array of situations, including: stochastic and repeated games, recurrent and episodic games, deterministic and stochastic rewards, deterministic and stochastic state transition functions, deceptive problems, miscoordination, and relative

overgeneralization. The games are defined in Appendix **??**, but their various features are summarized here.

We tested with four repeated-game test problems from the literature. The widely used *Climb* and *Penalty* games (Claus and Boutilier, 1998) are designed to test some degree of relative overgeneralization and miscoordination. We also included versions of the Climb game with partially stochastic and fully stochastic rewards, here designated *Climb-PS* and *Climb-FS* respectively (Kapetanakis and Kudenko, 2002). In these versions, the reward for a joint action was potentially one of two different values with certain probabilities; though the expected reward was always the same as in the original Climb game. Stochasticity greatly complicates the problem: we noticed that no existing algorithm can completely solve Climb-FS.

We also tested against several stochastic games. The *Boutilier* game (Boutilier, 1999) was a repeated game with deterministic transitions which distributed a miscoordination situation among several stages. The *Common Interest* game (Vrancx et al., 2008) is also recurrent, but with stochastic transitions and some miscoordination. This game is notable in that its rewards are unusually close to zero compared to other games; this is the reason that LMRL2 required a modification of its ω parameter to perform well in this game.

The remaining games are of our own design. The *Gradient 1* game is a deterministic episodic game designed to be highly deceptive and to cause miscoordination. *Gradient 2* is similar, except that it incorporates fully stochastic rewards. The *Heaven and Hell* game also causes miscoordination and deception, but is recurrent. This game has a high-reward state ("heaven"), a low-reward state ("hell"), and two medium ("purgatory") states of different levels of reward. Choice of a high-reward action will deceptively transition to a lower-reward future state, and the converse is also true. The *Relative Overgeneralization 1* game (or RO 1) causes miscoordination and relative overgeneralization not in local rewards but in propagated utilities from later states. *Relative Overgeneralization 2* (or RO 2) causes relative overgeneralization in both local rewards *and* in propagated utilities. Finally *Relative Overgeneralization 3* (or RO 3) causes miscoordination and relative overgeneralization from propagated utilities, but does so entirely through a stochastic transition function. We summarize the properties of each game in Table 1.

5.2 Parameters

All the techniques had a variety of tunable parameters, and many of them could apply different action selection methods. We considered two such methods, *epsilon-greedy selection* and *Boltzmann selection*. Epsilon-greedy selection is characterized by an initial random action selection probability ϵ which is optionally reduced each timestep by multiplying it by a cut-down factor ν. The version of Boltzmann selection was the one we employed in the LMRL2 algorithm, and so was characterized by the *MaxTemp, MinTemp,* δ, and ω parameters. Boltzmann selection could be feasibly used by LMRL2, Q-Learning, and Hysteretic Q-Learning, though usually only LMRL2 benefitted from it (other learners generally worked better with Epsilon-greedy). FMQ used its own algorithmic-specific version of Boltzmann selection. Table 2 shows the default (baseline) parameter settings we set for each of the techniques.

Test Problem	Repeated Game	Episodic Game	Deception	Stochastic Transitions	Stochastic Rewards	Relative Overgeneralization	Miscoordination

Table 1: Properties of each test problem

Test Problem	Default Parameters
LMRL2	$\alpha : 0.1,\ \gamma : 0.9,\ \tau : 0.1,\ \delta : 0.995,$ MaxTemp : 50, MinTemp : 2, $\omega : 1,\ \theta : 1,$ Boltzmann
Q	$\alpha : 0.1,\ \gamma : 0.9,\ \epsilon : 0.1,\ \nu : 1.0,$ Epsilon-greedy
Distributed Q	$\gamma : 0.9,\ \epsilon : 0.1,\ \nu : 1.0,$ Epsilon-greedy
Hysteretic Q	$\alpha : 0.1,\ \gamma : 0.9,\ \epsilon : 0.1,\ \nu : 1.0,\ \beta : 0.01,$ Epsilon-greedy
WoLF-PHC	$\alpha : 0.1,\ \gamma : 0.9,\ \epsilon : 0.1,\ \nu : 1.0,\ \delta_w : 0.03,\ \delta_l : 0.06,$ Epsilon-greedy
SOoN	$\alpha : 0.1,\ \gamma : 0.9,\ \epsilon : 0.1,\ \alpha_f : 0.05,\ \alpha_g : 0.3,$ Epsilon-greedy
FMQ	$\alpha : 0.1,\ \gamma : 0.9,\ c : 10,$ MaxTemp : 500, MaxMove : 2000, FMQ-specific Boltzmann

Table 2: Default Parameter Settings for each technique.

To make the comparison as fair as possible, we then optimized the above parameter settings and action selection method choices on a per-problem, per-technique basis, through a combination of manual tuning and automated hill-climbing. Table 3 shows the resulting optimized parameter changes.

5.3 Comparison

We compared all the aforementioned techniques using all appropriate test problems (FMQ was included only for repeated games). We considered two possible measures of successful convergence on a problem. First, a technique may converge to the *correct policy* for a given game, meaning that it is optimal if it follows this policy. Second, a technique may converge to the more general *complete policy*, meaning that it determines the correct joint action for *every state*, even ones which would never be visited if it followed a correct policy. For some games (all repeated games, and games with fully stochastic transitions) correct and complete policies are the same.

One might imagine that the superior technique would be the one which converged to the complete policy the most often. However what if in doing so it also converged to a great many entirely wrong policies? Consider the following exaggerated scenario. Technique A converged to 2 complete policies, 98 correct policies, and no incorrect policies; while technique B converged to 3 complete policies but 97 incorrect policies. Would we then

Table 4: Summary of Statistically Significant differences among methods for complete and correct solution counts on different test problems. Techniques are ordered left to right in decreasing performance. $\overline{\text{Overbars}}$ group together settings with no statistically significant differences among them. In the Common Interest, Penalty, and various Climb games, correct solutions are by definition complete. Also shown is the number of iterations run on each test problem.

really consider Technique B to be superior? For this reason, we must consider *both* of these approaches as comparison measures.

Our interest is not in convergence time so much as quality of the converged result. As such we ran each technique for until both the value function stabilized and the policy remained unchanged. We used the largest iteration number required among all learners for our formal experiments. This often benefitted LMRL2: being based on a temperature schedule, LMRL2 converges more slowly than other (greedier) techniques. However, it also benefitted other methods which occasionally needed large numbers of iterations and small settings of ϵ to produce good results. Not surprisingly, the number of iterations needed was closely correlated to the maximum path length of the game.

Because the results are from Bernoulli trials, we needed a large number of runs to do proper statistical comparison. We chose 10,000 iterations up front, and compared differences in complete or correct solution counts. Statistical significance was verified using the Marasquilo procedure for χ^2. We used $p = 0.05$ for the entire experiment, Bonferroni-corrected to $p = 0.0026315789$ per problem.

5.4 Results

Table 4 summarizes the rank order among the methods and statistically significant differences. Table 5 shows the actual results.

- LMRL2 fell in the top statistical significance tier for "complete" eight times, two times more than the next-best method (Distributed Q-Learning).

* With $\alpha = 0.05$ this value rose to 9207. This changed the ranking of "complete" results such that LMRL2 moved from worse than Q-Learning to better than Q-Learning (both statistically significant differences).

† With $\alpha = 0.05$ this value rose to 9750, but did not change any ranking.

Table 5: Complete/Correct solution counts among methods on various test problems. Boldface values indicate methods which were not statistically significantly different with the highest-performing method for a given problem. Note that in the Common Interest, Penalty, and various Climb games, correct solutions are by definition complete.

- LMRL2 fell in the top statistical significance tier for "correct" eleven times, three times more than the next-best method (Swing between Optimistic or Neutral).
- LMRL2 was uniquely statistically significantly best in RO 1 and Climb-FS.
- SOoN was uniquely statistically significantly best in Climb-PS.
- The Gradient 2 game proved very challenging to all methods. Yet WoLF-PHC, which often failed in other games, was statistically significantly best at Gradient 2 in "complete". LMRL2 underperformed WoLF-PHC on Gradient 2 in "complete", but outperformed it (and all others) in "correct".
- Changing α improved LMRL2 twice, and once statistically significantly, but not by much.
- All methods easily solved the Boutilier game.

In short, LMRL2 performed very well. It often did not reach 100%, but it was usually easily close enough to fall in the top statistical significance tier for "complete", and almost always in the top tier for "correct". No other method was as consistent across games. Furthermore, LMRL2 did so with very few changes to its default parameters: in all cases at most one parameter needed to be tuned. We are particularly interested in the fact that while LMRL2 performed very well in RO 2 and RO 3 — games which exhibit the relative overgeneralization pathology for which LMRL2 was designed — it underperformed in RO 1!

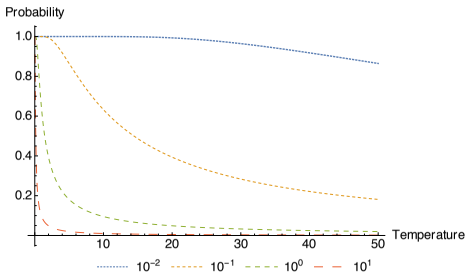

Figure 2: Probability that LMRL2 will accept poor results, by current temperature, for various θ values.

6. Analysis and Discussion

We have experimented with a number of variations of LMRL2 and have examined different issues which arise when using it. In the following section, we discuss five of these issues. First, we discuss the critical issue of initialization of Q-values and its impact on LMRL2's success. Second, we discuss how LMRL2 deals with issues in miscoordination. Third, we examine the disadvantages of Boltzmann selection and compare alternatives. Fourth, we consider the impact of *latching*, whereby temperature is propagated to earlier states only when it is hotter than those states. Finally, we examine what happens when LMRL2 is paired with other techniques in non-self-play, and so consider if, so to speak, two heads are better than one.

6.1 Lenience and Q-value Initialization

We first consider how θ affects lenience. LMRL2 (initially), Hysteretic Q-learning, and Distributed Q-learning are all *optimistic learners*, meaning that they unilaterally update the Q-values to more closely reflect new results if the new results are superior: but they are more conservative when the new results are inferior. That is, they incorporate some portion of maximum-based learning. More specifically: LMRL2 updates to inferior results only with a certain probability (which increases over time). Hysteretic Q-learning updates to inferior results at a fixed, slower rate. And Distributed Q-learning never updates to inferior results.

In LMRL2, optimism is controlled by θ. Figure 2 shows the probability curves of doing a Q-value update corresponding to different θ values and different temperatures. We can see that, with some given initial temperature (perhaps 50), a higher θ value has *two* effects: a higher initial probability of doing Q-value updates and a different probability curve shape. With very high θ, the curve approaches the maximum-learner rule employed by Distributed Q-learning. On the other hand, with a very low θ value, the curve approaches the averaging-learner rule employed by standard Q-learning. We note that a similar relationship can also be made with Hysteretic Q-learning. In Hysteretic Q-learning, improved results are updated

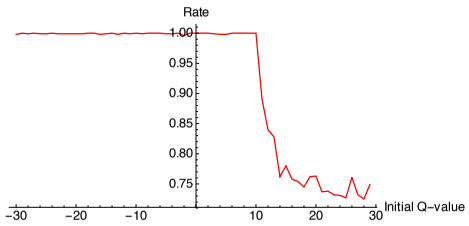

Figure 3: Rate of complete solutions for the LMRL2 in the Climb game, by various initial Q-values. Each point reflects the average of 1000 independent runs.

using α as usual, but worse results are updated using a smaller learning rate $\beta \leq \alpha$. If $\beta = 0$, Hysteretic Q-learning more or less degenerates to regular Q-learning.

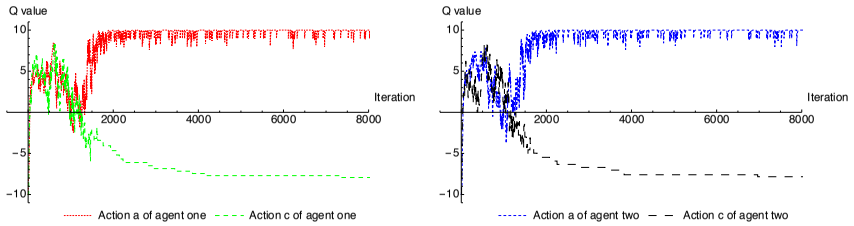
As a lenient learner, LMRL2's optimism is also tempered by the current *temperature*. As can be seen in Figure 2, the initial temperature has a significant effect on the progression of lenience in the system: and indeed if the temperature is infinity, LMRL2 becomes fairly similar to Distributed Q-learning.

In Section 4 we spent significant time discussing Q-value initialization options: this is because optimistic learners, and the like, are very sensitive to initialization. If the Q-values are initialized too high, then these learners have no easy way to adjust them to correct settings: indeed Distributed Q-learning may be completely unable to learn at all. Because in traditional average-based Q-learning the initial estimate of Q-value is less of a concern for proper convergence (Jaakkola et al., 1994), many algorithms simply ignore the discussion of initialization, setting the initial value to 0.

LMRL2 is initially highly optimistic, and so poor initialization can severely hinder it. If the Q-value is greater than the actual feedback, initially the lenient learner will largely refuse to update the Q-value, and so the Q-value won't change, and LMRL2 will thus just pick randomly from among actions during action selection. The temperature of all of the actions then will drop roughly the same rate. Only when the temperature drops enough that LMRL2 shifts to an average-based mode will it start to properly update the Q-values at all. Figure 3 shows how strongly the choice of initial Q values can effect performance: here LMRL2 quickly drops off in performance when the initial value rises to above 10.

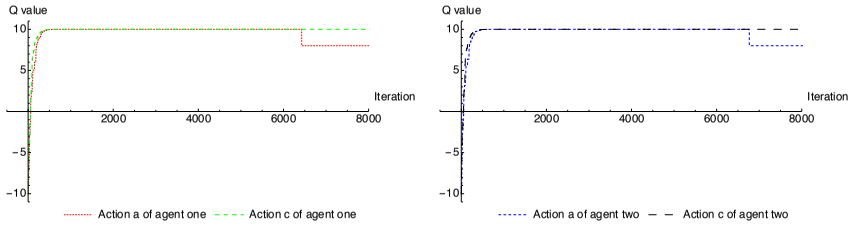
6.2 Miscoordination

To solve the miscoordination problem, an algorithm must break the symmetry among the various optimal equilibria. One way to do this is to always ϵ-greedily select the action with best Q-value, (crucially) breaking ties by selecting the action used last time. This is the approach used in Distributed Q-learning: but this method will only work in self-play. Another way to break symmetry is via different convergence times, which we will talk about in Section 6.5. LMRL2 at present simply relies on the fact that miscoordination is unstable, and that with enough random action, it will likely eventually work its way out.



(a) Agent One (b) Agent Two

Figure 4: Q-values of two agents in the Penalty game with $\theta = 0.1$



(a) Agent One (b) Agent Two

Figure 5: Q-values of two agents in the Penalty game with $\theta = 10^7$

Miscoordination is primarily a problem for a lenient learner early on, when miscoordinated actions both appear to have the same Q-values due to the use of maximum-based learning. However at some point one action will randomly have a slightly higher Q-value than the other, and as the temperature drops, action selection will increasingly choose that action. We have found that this tends to create a sudden collapse to one equilibrium or another. What often happens is that one agent starts using a given action more often, which quickly makes the miscoordinated action a bad deal for the other agent.

Figure 4 shows the Q-value of two LMRL2 agents playing the Penalty game, which has two miscoordinated equillibria, $\langle a, a\rangle$ and $\langle c, c\rangle$. During the first several hundred iterations, the Q-value of both actions increases due to lenience, though neither reaches the actual value of 10, due to a low lenience factor ($\theta = 0.1$). Thereafter, the Q-value of both actions for both agents start to drop, as lenience starts to wear off. At some point, action a is slightly preferred by at least one agent, which at this point is sufficient to quickly lock the agents into the equilibrium $\langle a, a\rangle$.

If learners are being lenient for a very long time, this lock-in could also take a long time: but it will eventually happen. In our experiments, we have found that low lenience is not necessary: even with a high value of θ, lock-in to a given equilibrium will occur at some point. We experimented with θ values of 1, 10, 100, 1000, 10,000, and 100,000 on the Penalty game: in every case, LMRL2 worked around miscoordination and found the correct policy in 1000 out of 1000 runs.

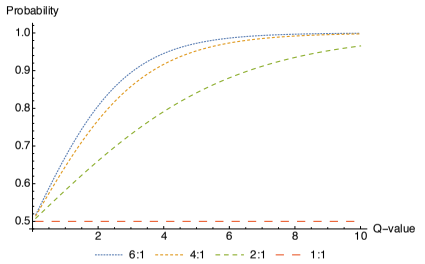


Figure 6: Given two actions A and B, with Q-values $Q_A \geq Q_B$, the probability of selecting action A over B using Boltzmann Selection, for various settings of Q_A. The different lines reflect the ratio of $Q_A : Q_B$, that is, how much larger Q_A is compared to Q_B.

Here is a typical example. Figure 5 shows the Q-values of the agent in the same game but with *extreme* lenience level $\theta = 10^7$. In this run, both miscoordinated equilibria have converged to near 10, and stay like this for a long time, but at about 6500 iterations, Agent 1 suddenly collapses to action a. This then forces Agent 2 to collapse to action a about 250 iterations later.

6.3 Exploration Strategy

A reinforcement learner may be roughly divided into two parts, the *learning policy* (or *action selection*) and the *update rule* (Singh et al., 2000). When applied to cooperative MARL, significant effort has been expended in the literature on the update rule, but the learning policy has received less attention; but coordination among learners involves both parts. Here we examine LMRL2's choices of learning policy as part of its exploration strategy.

LMRL2 begins using a modified version of Boltzmann Selection (Kaelbling et al., 1996), but when the temperature drops below some minimum value, it suddenly jumps to a fully greedy strategy (that is, $\epsilon = 0$). Our original reason to have LMRL2 do this was that with low temperatures, Boltzmann Selection is subject to floating-point overflow problems. However we have found that this scheme also happens to perform quite well compared to a traditional Boltzmann Selection algorithm. We begin here with an analysis of Boltzmann Selection as used in LMRL2, and particularly with the use of the ω action-selection tuning parameter. We then go on to some analysis of why jumping to a fully greedy strategy later on seems to be an effective mechanism.

Boltzmann Selection Strategy In two of the games, LMRL2 must adjust the parameter ω to achieve good performance. One of the difficulties with Boltzmann Selection is that when Q-values are close (and importantly, when they are all small), Boltzmann Selection does not distinguish among them well (Kaelbling et al., 1996). For example, Figure 6 shows a simple repeated game with two actions A and B, where the Q value of action A

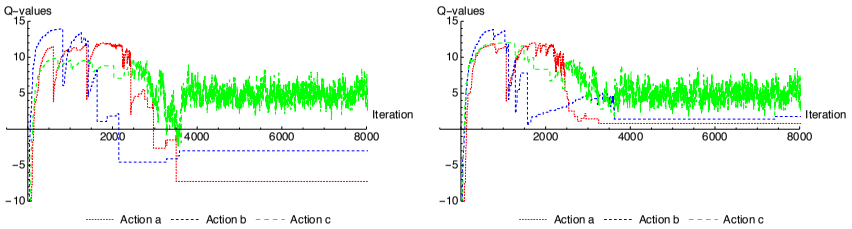
is some n times that of B (that is, the ratio between the two is $n : 1$). We note that even for large ratio differences between the two actions, as the Q-values become relatively small, Boltzmann quickly approaches uniform selection (0.5 probability for each). We believe this explains the necessity to change ω for LMRL2 in the Common Interest game: it has very small rewards, hence very small Q-values.

To experiment with this, we designed a new version of Boltzmann Selection called *Ranked Boltzmann Selection*. Here, when selecting an action, we first rank-ordered the possible actions by their current Q-values, breaking ties arbitrarily. We then stretched the rank orderings uniformly under some maximum value w. For example, if there were four actions, their values would be set to $1/4w$, $1/2w$, $3/4w$, and w. We then performed Boltzmann Selection using these resulting values. The point of Ranked Boltzmann Selection is that, given a value of n, it is insensitive to the exact Q-values in question, and thus to "close" Q-values among actions. w is essentially a rigorous, tunable replacement for ω in the ranked case.



(a) Agent One (b) Agent Two

Figure 8: Q-values of actions of two agents using Boltzmann Selection in the Fully Stochastic Climb game, with no minimum temperature. Note that optimal joint action $\langle a, a\rangle$ is abandoned at about step 2500 in favor of suboptimal joint action $\langle c, c\rangle$.

We tested this procedure on the Common Interest game for various values of w from 1 to 100, with 1000 trials each. Figure 7 shows the average rate of complete policy solutions. As can be seen, the algorithm performed much better for certain values than others: and for sufficiently low values of w it performed poorly.

We hoped that Ranked Boltzmann Selection might permit us to eliminate ω entirely as a parameter, since with a good selection of w it would be insensitive to variations among Q-values. To this end, we chose the highest-performing setting from the previous experiment ($w = 10$) and applied it to every test problem. Table 6 compares this against the original results from Table 5. Unfortunately, although some games saw an improvement, many others dropped significantly in performance. Indeed for RO3, which also required a tuned ω value, Ranked Boltzmann Selection performed quite poorly.

Uncoordinated Exploration and Greedy Strategies Uncoordinated exploration in independent learners occurs when one or more agents is selecting an explorative action while the remaining agents are selecting exploitative (greedy) actions. As a result, exploitative agents may receive misleadingly poor reward due to other agents' exploration. As the number of agents increases, this becomes much more likely. For example, with an ϵ-greedy strategy, with n agents in the game, the probability that all agents are exploit is $(1-\epsilon)^n$, and the probability that all the agents are explore is ϵ^n. As n increases, these probabilities become exponentially smaller.

Besides posing a scaling problem, uncoordinated exploration can also cause a difficulty we call *optimal policy destruction*. Here, the agents have found and converged to the optimal policy, but because certain agents then choose to do exploration, the learning process is destabilized and the agents as a whole wind up re-converging to some inferior solution. This may be particularly easy in relative overgeneralization scenarios, and in strongly stochastic games, where optimal solutions can be made to look bad by a single wayward agent or random reward.

Figure 8 shows a situation like this. Here we used a pure Boltzmann Selection strategy (that is, no minimum temperature) in the Fully Stochastic Climb game. We can see that at

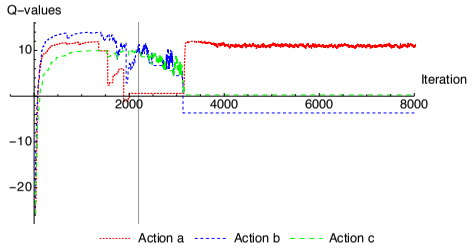


Figure 9: Q-values of actions of one LMRL2 agent in the Fully Stochastic Climb game. The vertical bar indicates where the agent commits to a fully greedy selection strategy, even though the optimal action (a) has not yet been discovered.

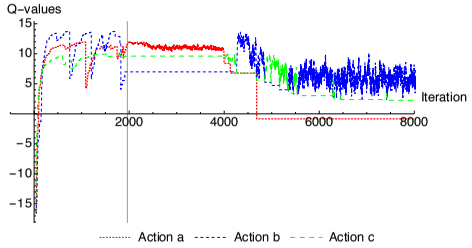

Figure 10: Q-values of actions of one LMRL2 agent in the Fully Stochastic Climb game. The vertical bar indicates where the agent commits to a fully greedy selection strategy.

around 2000 steps, Action a has the highest Q-value for both agents ($\langle a, a\rangle$ is the optimal joint solution). If we switched to fully greedy selection at this point, the agent would stick with this optimal policy. But in this experimental run, the Q-value then decreases enough that it can never recover, and the agents reconverge to $\langle c, c\rangle$. The only plausible source of this optimal policy destruction phenomenon is the uncoordinated exploration from the Boltzmann Selection strategy.

This lock-in would naturally occur when agents are no longer very lenient, but are still fairly explorative. We believe this is the reason that jumping to fully greedy selection strategy is effective in LMRL2: it occurs at the point where optimal policy destruction often shows up. It's possible to converge to the correct solution even when lock-in has occurred *before* discovery of the solution. If the agents lock into suboptimal actions, repeated play may still bring the Q-values low enough that greedy selection then selects a different joint action. This "optimism in the face of uncertainty" (Kaelbling et al., 1996) technique is widely used in many RL algorithms. Figure 9 shows an example run where has this occurred. Action

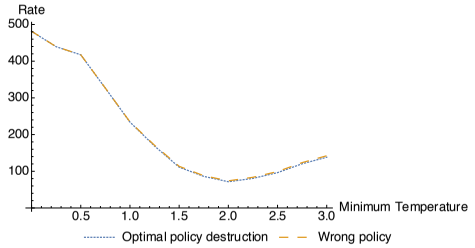

Figure 11: Optimal policy destruction and wrong-policy rates (out of 1000 runs) for different minimum temperature settings. Results shown are the average of ten 1000-run trials.

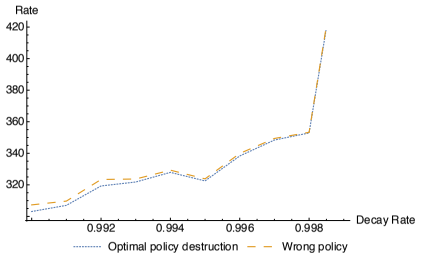
a is the optimal action. After the greedy selection began, only the action with the highest Q-value is updated (and this is presently not a). Eventually the other actions worsen to the point that a is then tried.

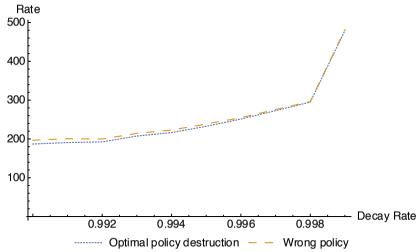
However, this greedy selection lock-in is not a silver bullet for two reasons. First, agents will not adopt the greedy strategy simultaneously: one will become greedy while the other is still exploring. Second, occasionally when the reward function of the optimal Nash Equilibrium has a very large variance, or punishment for uncoordinated behavior is very high, the Q-value of the optimal action can also accidentally be pulled down irrevocably. Figure 10 shows an example. Here we see that the Q-value of action a drops several times after the greedy selection begins, eventually causing other actions to be preferred.

However, generally the greedy strategy usually helps to reduce the rate of optimal policy destruction, particularly when the right minimum temperature is chosen (hence the right lock-in time). Figure 11 shows the optimal policy destruction and incorrect-policy rates, out of 1000 runs, for different minimum temperatures. It is clear that the two rates are strongly linked, and with a suitable minimum temperature (here 2.0), by reducing optimal policy destruction we think we can also eliminate most incorrect policies.

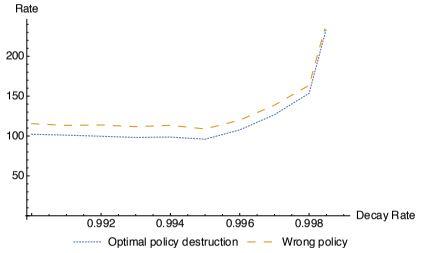
We also studied optimal policy destruction under different combinations of decay rate and minimum temperature. Figure 12 shows the resulting optimal policy destruction and wrong-policy rates. We note that many of the plots form partially bowl-shaped curves, which suggests that there is reasonable range of temperature decay for various minimum temperatures: often this is somewhere around $0.996 - 0.998$. This can be seen as the complement to Figure 11, where we had a range of good minimum temperatures for a fixed decay. However with very low minimum temperatures, the "lowest" points on curve simply slide towards the minimum temperature decay rate. This is expected, since a lower minimum temperature means later lock-in time, and thus a smaller decay rate is preferred. We also note that the difference between the optimal policy destruction and wrong-policy rates can become large, but will rapidly converge after reaching the "lowest" point on the curve. We think the reason for this is that the lower temperature decay rate drops the temperature too rapidly, thus the "optimal action" cannot reach its "optimum" given the short lenience period.



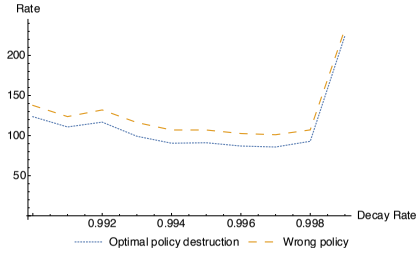
(a) minimum temperature = 0.5



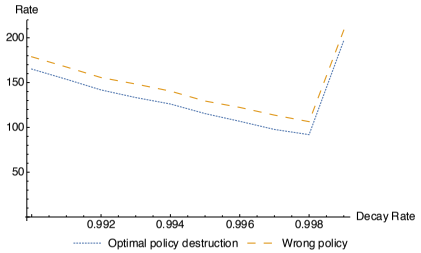
(b) minimum temperature = 1.0



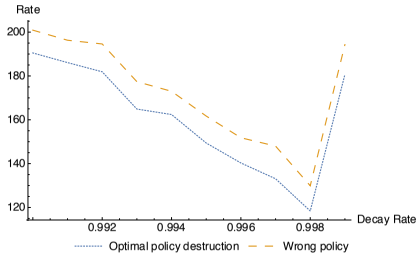
(a) minimum temperature = 1.5



(b) minimum temperature = 2.0



(a) minimum temperature = 2.5



(b) minimum temperature = 3.0

RO 3	**7332**/ **7332**	767/ 767

Table 7: Learning result of using latching in games with same parameter settings.

6.4 Latching

One of the critical features of LMRL2 is its propagation of temperatures from state to state, notionally in order to keep earlier states "hot" long enough to be lenient to late propagated utilities. Given a previous state s, action a, and next state s', this is done as:

$$T(s,a) \leftarrow \delta \times \begin{cases} (1-\tau)T(s,a) + \tau \operatorname{mean}_{a'} T(s',a') & \text{if } s' \text{ is not the end state (if any)} \\ T(s,a) & \text{else} \end{cases}$$

This can not only heat up states, but cool them down as well, which would seem to be an undesirable quality. We have considered an alternative (called *latching*), where states can only be heated up:

$$T(s,a) \leftarrow \delta \times \begin{cases} (1-\tau)T(s,a) + \tau \operatorname{mean}_{a'} T(s',a') & \text{if } s' \text{ is not the end state (if any)} \\ & \quad \text{and } T(s,a) < \operatorname{mean}_{a'} T(s',a') \\ T(s,a) & \text{else} \end{cases}$$

It turns out that this method does not work particularly well. Table 7 compares LMRL2 with and without latching on the various stochastic games from our testbed (latching is irrelevant to repeated games). This is a very counterintuitive result. Our experiment shows that latching only does better in two cases, and considerably worse in the Gradient games and in RO 3. (Note that in Table 7 we purposely maintained the same (difficult) level of Bonferroni correction to be consistent with other results in the paper). Finer-grained examination on a per-state basis (not reported here) did not reveal a conclusive reason as to why.

6.5 Non-self play

Last, we were interested in knowing how well LMRL2 performed when faced with a learning method of some other kind (that is, not in self-play). This is a follow-on to similar work we did using LMRL (Sullivan et al., 2006). To test the performance of LMRL2 when paired with some other learner, we re-ran all the test problems where LMRL2 was paired with some other algorithm. As we wanted to see what would happen to LMRL2 if simply faced with a different kind of learner, and so we did *not* re-tune the parameters of the other agents, but rather kept them at their default settings (from Table 2).

Table 8: LMRL2 performance when paired with an alternative learning algorithm. Results shown are Complete/Correct solution counts for various test problems. Note that in the Common Interest, Penalty, and various Climb games, correct solutions are by definition complete.

As shown in Table 8, for most of the games and most of the learners, LMRL2 performed best when in self-play. There was one chief exception: for two problems (RO1 and Common Interest), the combination of LMRL2 and Distributed Q-learning outperformed LMRL2 in self-play by a statistically significant margin. To understand why Distributed Q-learning would help LMRL2 in some cases, we plotted the Q-values for the two learners in State 1 of the Common Interest game. State 1 is the state that LMRL2 would normally fail. In State 1, there are two optimal Nash Equilibria, $\langle a, b\rangle$ and $\langle b, a\rangle$, and the primary difficulty in avoiding miscoordination, which which our lenient learner sometimes fails at due to the sensitivity of Boltzmann selection.

The Q-values are shown in Figure 13. It is easy to see that Distributed Q-learning converges much faster than LMRL2. After it has converged, we are effectively dealing with single-agent rather than multiagent reinforcement learning: LMRL2 is just trying to get the best result it can in an essentially fixed environment. This fast convergence doesn't restrict LMRL2's ability to find an optimal Nash Equilibrium, however, since it will converge to which ever Equilibrium Distributed Q-learning has chosen. Here, Distributed Q-learning has effectively forced LMRL2 into its decision.

This result reveals another way we might solve miscoordination. The way Distributed Q-learning normally approaches the miscoordination problem is to make an implicit deal that agents will stick with the first Nash Equilibrium they have chosen. But an alternative would be for one learner to converge to a Nash Equilibrium faster than the other learner, forcing the second learner to adopt its decision.

7. Conclusions

We have introduced LMRL2, a reinforcement learning algorithm for stochastic cooperative independent-learner games, and which can also be used for repeated games. LMRL2 is

Table 9: Comparison of LMRL2 in self play, Distributed Q-Learning in Self-Play, and the scenario where LMRL2 controls one agent and Distributed Q-Learning controls the other. Results shown are Complete/Correct solution counts for various test problems. Note that in the Common Interest, Penalty, and various Climb games, correct solutions are by definition complete.

particularly meant to overcome the *relative overgeneralization* pathology which can appear in cooperative multiagent games of three or more actions per agent, and to do so successfully in the face of stochasticity in the reward or transition function. The algorithm is an extension of an earlier version of ours, LMRL, which was meant only for repeated games.

We compared LMRL2 against several other algorithms which may be applied to cooperative independent-learner games, both stochastic and repeated. This comparison was done over a collection of test problems drawn from the literature and our own devising, and meant to test a wide variety of scenarios and pathologies. Our results have shown that LRML2 is an effective and robust learner, generally outperforming the other algorithms on the test problems in several different ways. LMRL2 placed in the top statistical significance tier for "complete" policies for eight problems, two more times than other algorithms. Further, it placed in the top tier for "correct" policies for eleven problems, three more times than other algorithms. And LMRL2 was uniquely best for two problems. And unlike some other methods, it did so with only a small amount of tuning: though LMRL2 has many available parameters, it performs well even when almost all of them are fixed to default values.

Future Work Because it works on a temperature schedule, LMRL2 is not a particularly fast algorithm. It often takes rather more time to converge than other more greedy methods. Because we are more interested in the converged result than in the speed of learning, this was not a vital issue for us: but as future work, we wish to examine how to speed up LMRL2's convergence without hurting its performance. We also want to investigate other possible stable exploration methods which achieve coordinated exploration: while LMRL2's current exploration strategy is generally fixed, it is nonetheless overcomplicated.

We have also been surprised by our *latching* results. We would have expected to get better performance by restricting pushed-back temperature to only those situations where it would heat up the earlier states, but the results are mixed and disappointing. We intend to examine this more carefully as future work.

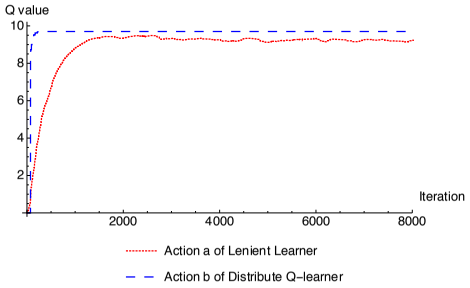

Figure 13: Q-values of two learners in State 1 of Common Interest game

Finally, we note that while the work in this paper reflects somewhat larger and more complex games than are found in much of the MARL literature, it does not scale beyond the literature in important ways. For example, while the algorithm works for any $N \geq 2$ number of agents, the test problems presented are for $N = 2$. In future work, we will extend the research to more complex and more practical domains, scaling both in terms of agent numerosity and heterogeneity, and involving continuous state and action spaces. To this end, we wish to adapt lenience with function approximation and policy gradient methods.

Appendix A. Game Defintions

Below we provide tables defining each game in this study, accompanied by illustrations. Each table shows a state S, two agent actions A_1 and A_2, a resulting joint *reward*, and a resulting transition to new state S'.

Actions Actions may be explicitly labeled, such as b or c, or they may have the word *any*, meaning "any action", or (for agent 2) they may have the word *same*, meaning "the same action that agent 1 selected", or they may have the word *other*, meaning "a different action than agent 1 selected". **Boldface** actions indicate members of a complete policy. **Boldface** actions shown in circled states (such as②) indicate members of a correct policy.

States, Rewards, and Transitions The *start state* is always state 1. The absorbing *end state* (if any) is indicated with the word "end". All other states are numbered. If indicated with a single number (or "end"), then rewards and transitions are deterministic. Otherwise, a distribution is shown. For example, 1 (10%), 2 (90%) means "10% of the time choose 1, 90% of the time choose 2".

Illustrations Tables are accompanied by illustrations, which show the games as finite-state automata. States are shown by their numbers: the start state is 1. The absorbing state, if any, is *End*. Each state has a two-player game reward matrix corresponding to the actions

$\langle a,a\rangle$	$\langle a,b\rangle$
$\langle b,a\rangle$	$\langle b,b\rangle$

or

$\langle a,a\rangle$	$\langle a,b\rangle$	$\langle a,c\rangle$
$\langle b,a\rangle$	$\langle b,b\rangle$	$\langle b,c\rangle$
$\langle c,a\rangle$	$\langle c,b\rangle$	$\langle c,c\rangle$

actions for players $\langle A_1, A_2\rangle$ respectively. Values in the matrices indicate rewards for joint actions. If the values are of the form x/y, this indicates that 50% of the time value x is rewarded, and 50% of the time y is rewarded. **Boldface** values indicate joint actions which are part of correct policies. Some states have their state number circled: **boldface** values in these states are part of complete policies. Directed transition edges between states are labeled with the joint actions which trigger those transitions. In some cases a joint action will trigger a transition with a certain probability, else it will trigger some other transition. Transitions may also be labeled ⟨any, any⟩, indicating that all joint actions trigger that transition.

Abstract

Predicting breast cancer risk has long been a goal of medical research in the pursuit of precision medicine. The goal of this study is to develop novel penalized methods to improve breast cancer risk prediction by leveraging structure information in electronic health records. We conducted a retrospective case-control study, garnering 49 mammography descriptors and 77 high-frequency/low-penetrance single-nucleotide polymorphisms (SNPs) from an existing personalized medicine data repository. Structured mammography reports and breast imaging features have long been part of a standard electronic health record (EHR), and genetic markers likely will be in the near future. Lasso and its variants are widely used approaches to integrated learning and feature selection, and our methodological contribution is to incorporate the dependence structure among the features into these approaches. More specifically, we propose a new methodology by combining group penalty and ℓ^p $(1 \leq p \leq 2)$ fusion penalty to improve breast cancer risk prediction, taking into account structure information in mammography descriptors and SNPs. We demonstrate that our method provides benefits that are both statistically significant and potentially significant to people's lives.

Keywords: structure information, breast cancer risk prediction, mammography descriptors, genetic variants, personalized medicine

1. Introduction

Breast cancer is the most common non-skin malignancy affecting women, with approximately 1.67 million cases diagnosed annually worldwide (Ferlay et al., 2013). If an individual's risk of breast cancer could be predicted, then screening, prevention, and treatment strategies could be targeted toward those women to maximize survival benefit and minimize harm. Risk prediction models are important tools to improve breast cancer care by leveraging multi-dimensional electronic health data. Traditional breast cancer risk prediction models use demographic risk factors to estimate breast cancer risk, but they demonstrate only limited discriminatory power. In clinical practice, mammography is the most common breast cancer screening test, and the only imaging modality supported by randomized trials demonstrating reduction in mortality rate. However, its effectiveness is not universally accepted (Freedman et al., 2004). Recent advances in genome-wide association studies (GWAS) have revitalized the quest for genetic variants (single-nucleotide polymorphisms—SNPs) in risk prediction. However, the optimism of these studies has been tempered by disappointment and caution (Gail, 2008, 2009; Wacholder et al., 2010).

Although many breast cancer risk prediction models have been developed, current applications of these models are inadequate in the following respects: (1) due to the rare occurrence of breast cancer, many seemingly 'large' studies have small effective sample size to adequately model a large number of variables; (2) even for large studies, investigators often fail to systematically model risk factor interactions to avoid overly complicated models which are hard to interpret; and (3) they do not take available structure information into consideration. For example, there are five descriptors for mass margins in mammogram: circumscribed, microlobulated, obscured, indistinct, and spiculated, with an order of increasing probability of malignancy. However, few models utilize this structure information (group structure and dependence structure) to improve predictive performance. The quest for novel breast cancer risk prediction models is motivated to address these shortcomings.

In this paper, we propose to develop novel penalized methods to improve breast cancer risk prediction by incorporating unique structure information embedded in electronic health record data. Regularization is a common technique used in regression and classification problems. The lasso (Tibshirani, 1996) is one of the most popular penalized method and

has achieved great success in various fields. However, lasso does not take into account the prior structure information among features. The group lasso (Yuan and Lin, 2006) is a natural extension of the lasso by taking advantage of the underlying group structure of features. It leads to the selection for groups of features and can improve the predictive performance in many real applications such as microarray data analysis (Ma et al., 2007) and GWAS (Liu et al., 2013). To incorporate the dependence structure of features, fused lasso (Tibshirani et al., 2005; Tibshirani and Wang, 2008) is introduced by penalizing the ℓ^1 norm of both the coefficients and their successive differences. To the best of our knowledge, no breast cancer prediction models utilize group penalty and within-group ℓ^p fusion penalty simultaneously to improve risk prediction by leveraging structure information.

The rest of the paper is organized as follows. Section 2 describes our data, proposed methods, and study design. Section 3 presents the results. The conclusions are described in Section 4.

2. Materials and Methods

The main purpose of this paper is to take into account both the group structure and the dependence structure within each group of features by imposing both group penalty and ℓ^p fusion penalty simultaneously.

2.1 Data

The Marshfield Clinic Institutional Review Board approved the use of Marshfield Clinic's Personalized Medicine Research Project (PMRP) (McCarty et al., 2005) cohort in our study.

2.1.1 Subjects

The population-based PMRP cohort, details of which have been previously published (McCarty et al., 2005), was used in this study. Though the details of this population have been described previously (Burnside et al., 2015), we will summarize here, in brief, for the convenience of the reader. Women with an available DNA sample, a mammogram, and a breast biopsy within 12 months after the mammogram were included in the study. For this case/control study, cases were defined as women having a confirmed diagnosis of breast cancer obtained from the institutional cancer registry. Controls were confirmed through the Marshfield Clinic electronic medical records as never having had a breast cancer diagnosis (and absence from cancer registry).

We identified 362 cases and 376 controls (738 in total) who have both genetics and mammogram data available. The majority of mammograms were performed between 1993 and 2005 (Burnside et al., 2015). The age range for the subjects in this study was 29 to 90 years of age, with mean 62 and standard deviation 12.8. Among the cases, there were 358 Caucasians, three non-Caucasians and one case whose race information was unknown. Among the controls, there were 372 Caucasians and four non-Caucasians. These race distributions are consistent with that of the general population in this area. For the family history of breast cancer, we observed a considerably larger proportion of people with family

history in the case group (45.30%) than in the control group (33.51%), which demonstrated the family aggregation of breast cancer (Table 1).

Family history	Cases	Controls	All
Yes	164(45.30%)	126(33.51%)	290(39.30%)
No	188(51.93%)	236(62.77%)	424(57.45%)
N/A	10(2.77%)	14(3.72%)	24(3.25%)

Table 1: Family aggregation of breast cancer.

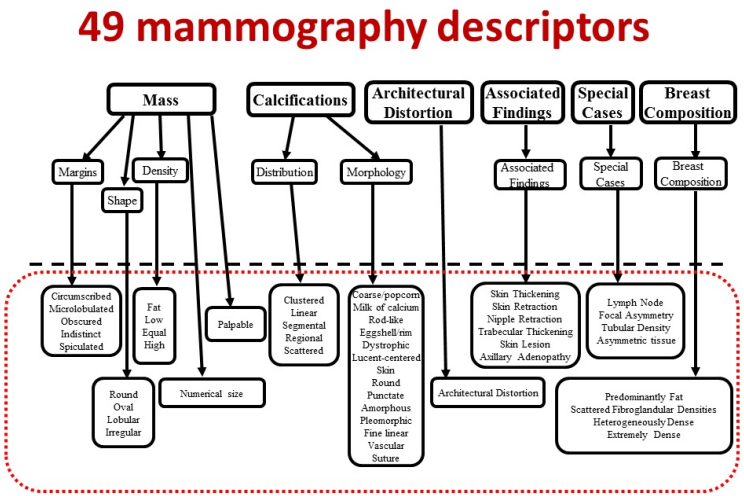

Figure 1: Mammography descriptors described in BI-RADS lexicon.

2.1.2 Mammography features

Mammography features are recorded in the Breast Imaging Reporting and Data System (BI-RADS) lexicon (BI-RADS, 2014) developed by the American College of Radiology. The BI-RADS lexicon consists of 49 descriptors, including the characteristics of masses and microcalcifications, breast composition and other associated findings (Figure 1). In this study, mammography data was recorded as free text reports in the electronic health record, from which we used a parser to extract these mammography features (Nassif et al., 2009).

Table 2: The 77 SNPs identified to be associated with breast cancer

2.1.3 Genetic variants

We decided to focus on high-frequency/low-penetrance SNPs that affect breast cancer risk as opposed to low frequency SNPs with high penetrance or intermediate penetrance. We consolidated a list of 77 common genetic variants (Table 2) which were identified by recent large-scale GWAS studies or used to generate published predictive models (Liu et al., 2014). The list included 41 SNPs identified by COGS through a meta-analysis of 9 GWAS studies (Michailidou et al., 2013). Recently, a similar set of 77 breast cancer-associated SNPs is also studied for risk prediction (Mavaddat et al., 2015).

2.2 Logistic Regression

Assume that we have independent and identical distributed subjects $\{(x_i, y_i)\}_{i=1}^n$, where the explanatory variable $X \in \mathcal{R}^d$ and the binary response variable $Y \in \{-1, 1\}$. Note that the conditional probability $\eta(x) = \mathbb{P}(Y = 1|X = x)$ plays an important role in the classification problem. Denote $x_i = (x_{i1}, ..., x_{id})^T$, and linear logistic regression model is defined by

$$\log \frac{\eta(x_i)}{1 - \eta(x_i)} = x_i^T \beta, \quad i = 1, ..., n,$$

where $\beta = (\beta_1, ..., \beta_d)^T$ is the slope parameter. And the logistic regression estimator $\hat{\beta}$ is given by the minimizer of the negative log-likelihood function

$$L(\beta) = \frac{1}{n} \sum_{i=1}^{n} \log(1 + \exp(-y_i \cdot x_i^T \beta)). \tag{1}$$

With $\hat{\beta}$, we then estimate the conditional probability $\eta(x_i)$ by

$$\hat{\eta}(x_i) = \frac{\exp(x_i^T \hat{\beta})}{1 + \exp(x_i^T \hat{\beta})} = \frac{1}{1 + \exp(-x_i^T \hat{\beta})}.$$

Then we should predict $y_i = 1$ if $\hat{\eta}(x_i) \geq 0.5$ and $y_i = -1$ if $\hat{\eta}(x_i) < 0.5$.

2.3 Group Penalty and ℓ^p Fusion Penalty

Note that there exist natural group structure and dependence structure in mammography features (Figure 1), which allows us to include the structure information into our risk prediction models directly. For genetic variants, group structures also exist (Liu et al., 2012, 2013). In this paper, we apply hierarchical clustering to cluster the 77 SNPs based on their dissimilarity matrix obtained by computing Spearman's correlation or Hamming distance among them. More details are provided in Section 2.5.

Suppose that d features are divided into G groups with d_g the number of features in group g. Define $\beta_g \in \mathbb{R}^{d_g}$ to be the corresponding coefficient vector in group g. The group lasso logistic regression (Meier et al., 2008) is defined as the following optimization problem

$$\min_{\beta \in \mathbb{R}^d} \left\{ L(\beta) + \lambda_1 \sum_{g=1}^{G} \sqrt{d_g} \|\beta_g\|_2 \right\},$$

where $L(\beta)$ is defined by (1) and $\lambda_1 \geq 0$ is the tuning parameter. It includes lasso as a special case with $G = d$.

The fact that there exist dependence structure within each mammography feature group and each SNP group encourages us to propose the following novel method by combining group lasso logistic regression and ℓ^p fusion penalty.

$$\min_{\beta\in\mathbb{R}^d}\left\{L(\beta)+\sum_{g=1}^{G}\left(\lambda_1\sqrt{d_g}\|\beta_g\|_2+\lambda_2\|D_g\beta_g\|_p^p\right)\right\}, \tag{2}$$

where D_g is a $(d_g-1)\times d_g$ sparse matrix with only $D[i,i]=1$ and $D[i,i+1]=-1$, $\lambda_2\geq 0$ is the tuning parameter, and $1\leq p\leq 2$ is the shrinkage parameter.

Moreover, if the within-group dependence structures are different for groups $\{1,...,G_1\}$ and $\{G_1+1,...,G\}$, we can split the ℓ^p fusion penalty into two parts as

$$\min_{\beta\in\mathbb{R}^d}\left\{L(\beta)+\lambda_1\sum_{g=1}^{G}\sqrt{d_g}\|\beta_g\|_2+\lambda_2\left(\sum_{g=1}^{G_1}\|D_g\beta_g\|_{p_1}^{p_1}+\sum_{g=G_1+1}^{G}\|D_g\beta_g\|_{p_2}^{p_2}\right)\right\}, \tag{3}$$

where $1\leq p_1,p_2\leq 2$ are selected based on cross validation.

The novelty of our method compared to previous works is three-fold: First, it includes within-group fusion penalty in the model and makes the coefficients of features in the same group close to each other, which reflects the dependence structure of features and improves the risk prediction; Second, in breast cancer risk prediction, we find that the dependence structures are different for mammography features and SNPs, which are actually two different views of the same data. And the utilization of method (3) will improve the predictive performance further; At last, we find that genetic variants improve risk prediction on mammography features, which provides some insight regarding personalized breast cancer diagnosis.

2.4 Computational Algorithms

Many algorithms have been proposed in the literatures to solve the logistic regression with fused lasso regularization (Lin, 2015; Yu et al., 2015). In this subsection we adopt the fast iterative shrinkage thresholding algorithm (Beck and Teboulle, 2009) to solve (2) as

$$\beta^{k+1}=\arg\min_{\beta\in\mathbb{R}^d}L(\beta^k)+\langle\beta-\beta^k,\nabla L(\beta^k)\rangle+\frac{\tau}{2}\|\beta-\beta^k\|_2^2+\sum_{g=1}^{G}\left(\lambda_1\sqrt{d_g}\|\beta_g\|_2+\lambda_2\|D_g\beta_g\|_p^p\right)$$

with $\beta=(\beta_1,\cdots,\beta_d)^T$ and $\tau>0$ the Lipschitz constant of $L(\cdot)$.

And the iteration step is equivalent to solving

$$\min_{\beta\in\mathbb{R}^d}\left\{\frac{1}{2}\|\beta-(\beta^k-\frac{1}{\tau}\nabla L(\beta^k))\|_2^2+\sum_{g=1}^{G}\left(\frac{\lambda_1\sqrt{d_g}}{\tau}\|\beta_g\|_2+\frac{\lambda_2}{\tau}\|D_g\beta_g\|_p^p\right)\right\}. \tag{4}$$

Therefore, it suffices to solve the following optimization problem within each group

$$\min_{\beta_g\in\mathbb{R}^{d_g}}\left\{\frac{1}{2}\|\beta_g-z\|_2^2+\rho_1\|\beta_g\|_2+\rho_2\|D_g\beta_g\|_p^p\right\}, \tag{5}$$

where $z=\beta_g^k-\frac{1}{\tau}\nabla L(\beta_g^k)$, $\rho_1=\frac{\lambda_1\sqrt{d_g}}{\tau}$ and $\rho_2=\frac{\lambda_2}{\tau}$.

The proximity operator (Polson et al., 2015) of a function f is defined as

$$P_f(z)=\arg\min_t\left\{\frac{1}{2}\|t-z\|^2+\lambda f(t)\right\}.$$

- For $f(t)=|t|$ and $z\in\mathbb{R}$, $P_f(z):=S_1(z,\lambda)=sign(z)\max\{|z|-\lambda,0\}$, which is also called soft threshold operator.
- For $f(t)=|t|^p$ with $1<p\leq 2$ and $z\in\mathbb{R}$, $P_f(z):=S_p(z,\lambda)=sign(z)\xi$, where ξ is the unique nonnegative solution to $\xi+p\lambda\xi^{p-1}=|\xi|$. In particular, we have $S_2(z,\lambda)=\frac{z}{2\lambda+1}$, $S_{3/2}(z,\lambda)=z+9\lambda^2 sign(z)(1-\sqrt{1+16|z|/(9\lambda^2)})/8$ and $S_{4/3}(z,\lambda)=z+\frac{4\lambda}{32^{\frac{1}{3}}}((\chi-z)^{1/3}-(\chi+z)^{1/3})$ with $\chi=\sqrt{z^2+256\lambda^3/729}$.
- For $f(t)=\|t\|_2$ and $z\in\mathbb{R}^d$, $P_f(z):=S_{2,1}(z,\lambda)=\max\{1-\frac{\lambda}{\|z\|_2},0\}*z$.

With the help of these proximity operators and Bregman splitting algorithm (Ye and Xie, 2011), we can solve (5) by iteratively solving the following procedures:

$$\begin{cases}\beta^{k+1}=\arg\min_{\beta_g}\frac{1}{2}\|\beta_g-z\|_2^2+\langle u^k,\beta_g-a^k\rangle+\langle v^k,D_g\beta_g-b^k\rangle\\ \qquad\qquad +\frac{\mu}{2}\|\beta_g-a^k\|_2^2+\frac{\mu}{2}\|D_g\beta_g-b^k\|_2^2\\ a^{k+1}=\arg\min_a\rho_1\|a\|_2+\langle u^k,\beta^{k+1}-a\rangle+\frac{\mu}{2}\|\beta^{k+1}-a\|_2^2\\ b^{k+1}=\arg\min_b\rho_2\|b\|_p^p+\langle v^k,D_g\beta^{k+1}-b\rangle+\frac{\mu}{2}\|D_g\beta^{k+1}-b\|_2^2\\ u^{k+1}=u^k+\mu(\beta^{k+1}-a^{k+1})\\ v^{k+1}=v^k+\mu(D_g\beta^{k+1}-b^{k+1})\end{cases}$$

where μ acts like a step size in this algorithm.

Remark 1 *The minimization over β, a and b can all be solved in closed form.*

- $\beta^{k+1}=[(\mu+1)I+\mu D_g^TD_g]^{-1}[z+\mu(a^k-u^k/\mu)+\mu D_g^T(b^k-v^k/\mu)]$
- $a^{k+1}=S_{2,1}(\beta^{k+1}+u^k/\mu,\rho_1/\mu)$
- $b^{k+1}=S_p(D_g\beta^{k+1}+v^k/\mu,\rho_2/\mu)$

Note that $(\mu+1)I+\mu D_g^TD_g$ is a tridiagonal positive definite matrix.

Remark 2 *For $p=1$, we can solve (5) more efficiently by the algorithm proposed in Zhou et al. (2012) based on the fact*

$$P_{\|\cdot\|_2+\|D_g(\cdot)\|_1}=P_{\|\cdot\|_2}\circ P_{\|D_g(\cdot)\|_1}.$$

However, we cannot show this equation for $1<p\leq 2$.

Remark 3 *For $p = 2$, since $\|\cdot\|_2^2$ is Lipschitz continuous, we can rewrite (4) as*

$$\min_{\beta\in\mathbb{R}^d}\left\{\frac{1}{2}\left\|\beta-\left(\beta^k-\frac{1}{\tilde{\tau}}(\nabla L(\beta^k)+2\lambda_2\sum_{g=1}^{G}D_g^TD_g\beta_g^k)\right)\right\|_2^2+\sum_{g=1}^{G}\frac{\lambda_1\sqrt{d_g}}{\tilde{\tau}}\|\beta_g\|_2\right\},$$

where $\tilde{\tau}$ is the Lipschitz constant of $L(\beta)+\lambda_2\sum_{g=1}^{G}\|D_g\beta_g\|_2^2$. Then we can solve it efficiently via the proximity operator of $\|\cdot\|_2$.

2.5 Study Design and Statistical Analysis

We apply the ℓ^p fused group lasso logistic regression algorithm to the Marshfield breast cancer data set. There are 11 groups for 49 mammography features (Figure 1). For SNPs, we compute the Hamming distances (Wang et al., 2015) of 77 SNPs to get the dissimilarity matrix and then apply hierarchical clustering to obtain 10 groups.

We built three prediction models based on different sets of risk factors: the Mammo model developed by using mammography features only, the SNP77 model developed by using 77 SNPs only, and the Combined model developed by using both mammography features and 77 SNPs. We furthermore apply five methods for each model: logistic regression (LR), lasso in logistic regression (LR+Lasso), ℓ^p fused lasso logistic regression (LR+fusedLasso), group lasso logistic regression (LR+groupLasso), and ℓ^p fused group lasso logistic regression (LR+Structure).

The ℓ^p fused group lasso logistic regression method has several parameters. For the tuning parameters λ_1 and λ_2, we let them vary among a given set of values, and the shrinkage parameter p (or p_1 and p_2) among $\{1, 4/3, 3/2, 2\}$. Each combination of these parameters is evaluated using stratified 5-fold cross-validation, and AUC (the area under the receiver operating characteristic (ROC) curve) is used as the performance measure. All 738 samples are randomly partitioned into five equal sized folds with approximately equal proportions of cases and controls. In each iteration (totally five iterations), four folds are used as training set and the rest one as validation set to compute AUC. And the parameters with the best average AUC are selected. At last we repeat this process ten times and report the average AUC. We obtain p-value by performing two-tailed-two-sample t-test when we compare AUCs.

3. Experimental Results

In this section, we demonstrate the performance of the ℓ^p fused group lasso logistic regression method from three aspects: the significant improvement of AUCs by considering the structure information, the predictive performance under different p (or p_1 and p_2), and the detected important mammography features and SNPs.

3.1 Performance of Fused Group Lasso

The result is summarized in Table 3.

Models/Methods	LR	Lasso	fusedLasso	groupLasso	Structure	p-value
Mammo	0.700	0.710	0.710	0.716	0.723	< 0.001
SNP77	0.590	0.598	0.676	0.614	0.684	< 0.001
Combined	0.697	0.721	0.754	0.727	0.766	< 0.001

Table 3: Predictive performance of three prediction models by using five different methods. The p-values represent the differences between AUCs of LR and LR+Structure.

1) The fifth column describes the predictive performance of the three prediction models by considering structure information in the logistic regression method. We find that the predictive performance of the three prediction models has been improved respectively, compared to those described in the first column. For each prediction model, the difference of the predictive performance is significant between LR+Structure and LR (p-value < 0.001), which demonstrates that breast cancer prediction models utilizing structure information can improve risk prediction significantly. We also find that mammography descriptors demonstrate a significantly higher predictive performance than 77 SNPs in terms of AUC (0.723 vs. 0.684, p-value < 0.001). The Combined model demonstrates significant improvement of the prediction performance, compared to the Mammo model (0.766 vs. 0.723, p-value < 0.001).

2) The first column describes the predictive performance of the three prediction models by using the logistic regression method. Mammography descriptors demonstrate a significantly higher predictive performance than 77 SNPs in terms of AUC (0.700 vs. 0.590, p-value$<$ 0.001). We find that the difference of predictive performance between the Combined model and the Mammo model is negligible (0.697 vs. 0.700, p-value=0.277).

3) The second column describes the predictive performance of the three prediction models by using lasso in the logistic regression method. The predictive performance of the three prediction models has been improved, compared to those without lasso (using logistic regression method only). Mammography descriptors still demonstrate a significantly higher predictive performance than 77 SNPs in terms of AUC (0.710 vs. 0.598, p-value$<$ 0.001). However, the Combined model demonstrates modest improvement of prediction performance, compared to the Mammo model (0.721 vs. 0.710, p-value=0.0057).

4) The third and fourth columns describe the predictive performance of the three prediction models by considering group structure or dependence structure in the logistic regression method. For the SNP77 model, fused lasso demonstrates a significantly higher performance than group lasso in terms of AUC (0.676 vs. 0.614, p-value$<$ 0.001). For the Mammo model, group lasso plays a more important role than fused lasso (0.716 vs. 0.710, p-value=0.0073). Moreover, both fused lasso and group lasso demonstrate improved prediction performance compared to lasso.

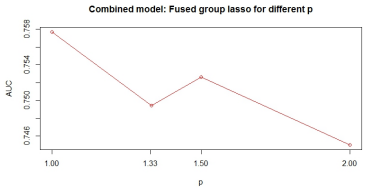

Figure 2: The AUCs under different values of p by using method (2).

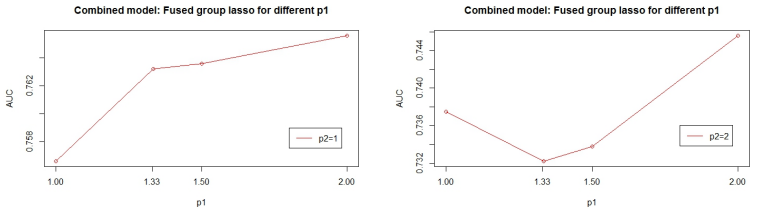

(a) Fix $p_2 = 1$ (b) Fix $p_2 = 2$

(c) Fix $p_1 = 1$ (d) Fix $p_1 = 2$

Figure 3: The AUCs under different values of p_1 and p_2 by using method (3).

3.2 Performance under Different Values of p

Figure 2 and Figure 3 describe the the pattern of predictive performance for ℓ^p fused group lasso logistic regression over the shrinkage parameter p (or p_1 and p_2) in terms of AUC.

1)The Combined model demonstrates a higher predictive performance for $p = 1$ compared to $p = 2$ in terms of AUC (0.757 vs. 0.745, p-value$<$ 0.001), see Figure 2.

2) Figure 3 describes the prediction performance of method (3) under different values of p_1 for mammography descriptors and p_2 for 77 SNPs.

- Fix $p_2 = 1$ or $p_2 = 2$, the fused group lasso with $p_1 = 2$ demonstrates higher predictive performance compared to $p_1 = 1$, see Figure 3(a) and 3(b).
- Fix $p_1 = 1$ or $p_1 = 2$, the predictive performance of the fused group lasso logistic regression decreases as p_2 increases, see Figure 3(c) and 3(d).
- The fused group lasso logistic regression with $p_1 = 2$ and $p_2 = 1$ demonstrates higher predictive performance than $p_1 = p_2 = 1$ (0.766 vs. 0.757, p-value=0.0053) and $p_1 = p_2 = 2$ (0.766 vs. 0.745, p-value$<$ 0.001).

3.3 Important Features Detected by Fused Group Lasso

To take into account both group and dependence structure information in mammography features and SNPs, two penalty terms (group penalty and fusion penalty) are introduced into the logistic regression model. The idea of group penalty is to force the coefficients of features in the same group to be all zero or nonzero in order to achieve the goal of selecting features within a group simultaneously. The idea of fusion penalty is to shrink the successive difference of coefficients of features in the same group in order to take advantage of the dependence structure information. Applying fusion penalty with $p = 1$ tends to result in zero successive difference of coefficients, while $p = 2$ tends to small but nonzero successive difference of coefficients.

From a feature selection point of view, we can get the order of feature groups selected by fused group lasso via choosing the tuning parameters appropriately. We list below the feature groups selected from high to low in terms of predictive performance.

1) For mammography descriptors, the following features are predictive of malignancy (from most to least): "Mass Size", "Mass Margins", "Mass Shape", "Architectural Distortion" and "Mass Palpability", consistent with the literature (BI-RADS, 2014).

2) For 77 SNPs, three groups are selected in order, see Table 4.

Feature Group	SNPs
Group 1	rs2016394 rs1432679, rs13281615, rs4666451 rs981782, rs1292011, rs1436904, rs527616
Group 2	rs11249433 rs13387042, rs4973768, rs10069690 rs7904519, rs8051542, rs3760982
Group 3	rs2981579, rs2981582

Table 4: SNP groups selected by fused group lasso.

Remark 4 *It verifies that "Mass size", "Mass Margins" and "Mass Shape" are the most important mammography descriptors in breast cancer diagnosis. These results are consistent with previous studies about comparing the importance of mammography features and SNPs in breast cancer risk prediction(Wu et al., 2013, 2014).*

4. Discussion and Conclusions

This study demonstrates that models utilizing the novel combination of clinically relevant structure and ℓ^p fused group lasso logistic regression can improve breast cancer risk prediction significantly. Our study also shows that both mammography features and SNPs contribute to this improvement.

The structure information of the mammography features is derived from the BI-RADS lexicon, which is used widely in breast imaging practice. Thus, our model would likely be generalizable to other practices. On the other hand, we extracted the structure information of SNPs by computing Hamming distances (Wang et al., 2015). This method may not perform as well in small sample sizes, which may affect our results perhaps making our predictive performance results conservative.

Our methods for SNPs may not take advantage of biological knowledge that currently exists. For example, it may be possible to utilize the biological information available in HapMap (which encodes linkage disequilibrium) to more accurately emulate the patterns or dependence structure of SNPs, as in (Liu et al., 2012). Furthermore, we realize that taking into account more complicated structure information such as graph or tree structure (Sun and Wang, 2012) may further improve predictive performance of risk prediction models. We leave these promising directions for future work.

In conclusion, our results demonstrate that including structure information in the computational methods we test improves breast cancer risk prediction. Our models use diverse breast cancer risk factors including demographics, genetics, and imaging and leverage structure found in a standardized lexicon that is universally captured in electronic health records (EHRs) throughout the US. This information will increasingly be combined in complex ways. Merging imaging features, clinical notes and genetic data with models that accurately predict disease risk has the potential to provide powerful knowledge to practicing physicians.

Abstract

Matrix factorization (MF) plays a key role in many applications such as recommender systems and computer vision, but MF may take long running time for handling large matrices commonly seen in the big data era. Many parallel techniques have been proposed to reduce the running time, but few parallel MF packages are available. Therefore, we present an open source library, LIBMF, based on recent advances of parallel MF for shared-memory systems. LIBMF includes easy-to-use command-line tools, interfaces to C/C++ languages, and comprehensive documentation. Our experiments demonstrate that LIBMF outperforms state of the art packages. LIBMF is BSD-licensed, so users can freely use, modify, and redistribute the code.

Keywords: Matrix factorization, non-negative matrix factorization, binary matrix factorization, logistic matrix factorization, one-class matrix factorization, stochastic gradient method, adaptive learning rate, parallel computation

1. Introduction

Matrix factorization (MF) and its variants cover a wide range of applications including recommender systems, link prediction, image processing, and document clustering. Although parallel MF has been widely investigated in recent years, it is still not easy to find an MF package supporting both rich formulations and parallel computation. For example, the parallel MF algorithm in LIBPMF[1] is known to be state of the art, but LIBPMF can only solve real-valued matrix factorization with a squared loss and L2-norm regularization. Some packages (e.g., scikit-learn,[2] mlpack,[3] and nimfa[4]) support a variety of MF problems, but unfortunately they do not implement parallel MF algorithms published in recent five years. We thus develop LIBMF for solving a family of MF problems based on the techniques proposed in Chin et al. (2015a) and Chin et al. (2015b) targeting at shared-memory systems with multi-core CPUs (e.g., mordern PCs). Many computational issues were addressed to make LIBMF efficient. Our experiments show that LIBMF is faster than state of the art packages. Moreover, LIBMF allows users to use their disk as a buffer to factorize a huge matrix that may not fit into their memory. LIBMF is released under BSD license at

`http://www.csie.ntu.edu.tw/~cjlin/libmf/` .

This paper is organized as follows. Section 2 introduces LIBMF in detail. Problems solved by LIBMF are presented in Section 2.1 and we demonstrate the practical usage in Section 2.2. The documentation is summarized in Section 2.3. Comparisons of LIBMF and state of the art packages are shown in Section 3. Finally, we conclude in Section 4. We provide the implementation details in a supplementary document.[5]

2. The Software Package

LIBMF provides efficient parallel MF solvers with rich documentation for a family of MF problems. For practical usage, users can directly run LIBMF using command-line instructions, make a C/C++ function call, or use the third-party R interface. LIBMF is portable by following the C++11 standard and can be complied on Unix-like systems as well as Microsoft Windows.

2.1 Problems Solved by LIBMF

In general, MF is a process to find two factor matrices, $P \in \mathbb{R}^{k\times m}$ and $Q \in \mathbb{R}^{k\times n}$, to describe a given m-by-n training matrix R in which some entries may be missing. MF can be found in many applications, but we only use collaborative filtering in recommender systems as examples. We further assume that the entries of R are the historical users' preferences for merchandises, and the task on hand is to predict unobserved user behavior (i.e., missing entries in R) to make a suitable recommendation. Let u and v stand for row index and column index, respectively. For rating prediction (e.g., Koren et al., 2009), the entry value $r_{u,v} \in \mathbb{R}$ indicates that the vth item was rated $r_{u,v}$ by the uth user. Once P and Q are learned, a missing rating at the (u', v') entry can be predicted by the inner product of the u'th column of P (i.e., $\boldsymbol{p}_{u'}$) and the v'th column of Q (i.e., $\boldsymbol{q}_{v'}$). It means that we can generate the predicted scores on all items for a user, and then the one with highest score may be recommended. Sometimes, the users preferences recorded may be binary signals (e.g., "like" or "dislike"); for example, Das et al. (2007). The entry $r_{u,v}$ is positive if we know that the uth user likes the vth item, and vice versa. In this case, we can use the sign of $\boldsymbol{p}_{u'}^T \boldsymbol{q}_{v'}$ as the prediction value of an unobserved signal $r_{u',v'}$. As a result, the domain of the entries in R is allowed to be either real values $\mathbb{R}$ or a binary set $\{-1, 1\}$ to cover the two scenarios.

LIBMF supports two types of matrix factorization, real-valued matrix factorization (RVMF) and binary matrix factorization (BMF). RVMF aims to find P and Q to approximate the values of entries as accurate as possible while BMF focuses on learning the correct signs of entries. Both RVMF and BMF can be formulated as a non-convex optimization

problem

$$\min_{P,Q} \sum_{(u,v)\in R} \left[f\left(\boldsymbol{p}_u, \boldsymbol{q}_v; r_{u,v}\right) + \mu_p \left\|\boldsymbol{p}_u\right\|_1 + \mu_q \left\|\boldsymbol{q}_v\right\|_1 + \frac{\lambda_p}{2}\left\|\boldsymbol{p}_u\right\|_2^2 + \frac{\lambda_q}{2}\left\|\boldsymbol{q}_v\right\|_2^2 \right], \quad (1)$$

where $r_{u,v}$ is the (u,v) entry of R, $f(\cdot)$ is a non-convex loss function of $\boldsymbol{p}_u$ and $\boldsymbol{q}_v$, and μ_p, μ_q, λ_p, and λ_q are regularization coefficients. For RVMF, the loss function can be a squared loss, an absolute loss, or generalized KL-divergence. If R is a binary matrix, users may select among logistic loss, hinge loss, and squared hinge loss to perform BMF. Note that, the non-negative constraints, $P \in \mathbb{R}_+^{k\times m}$ and $Q \in \mathbb{R}_+^{k\times n}$, can be activated for (1). With the general setting in (1), currently LIBMF can solve more problems than its previous versions. The newly covered problems include, for example, NMF with generalized KL-divergence (Lee and Seung, 2001), sparse NMF (Lee et al., 2007), logistic NMF (Tomé et al., 2015), and maximum-margin MF (Srebro et al., 2005).

A special case of BMF is one-class matrix factorization (OCMF) in which the training matrix is still binary but contains only positive entries. OCMF is worthy to be considered as in some online activities (e.g., Pan et al., 2008) only positive feedbacks (i.e., purchase or click) from users can be monitored. The OCMF model in LIBMF is Bayesian personalized ranking (BPR) proposed by Rendle et al. (2009).

Refer to the supplementary materials for details of RVMF, BMF, and OCMF.

2.2 Practical Usage

In a sub-directory `demo`, we prepare three data sets for helping users to understand the data format and demonstrating RVMF, BMF, and OCMF. Each data set has training and test files, of which each line is a 3-tuple of row index, column index, and the value. For RVMF, the value is a real number. For BMF, any value greater than zero would be treated as a positive label and a negative label otherwise. For OCMF, the training file should contain only positive entries. A shell script `demo.sh` contains the training and prediction commands for different types of MF problems. For example, we may use the following command to perform RVMF on `train_file` and save the result to a model file `model`.

```
$ ./mf-train train_file model
```

The model file contains two parts: the columns of $P \in \mathbb{R}^{k\times m}$ and then the columns of $Q \in \mathbb{R}^{k\times n}$. To evaluate the model on a test set, users may run

```
$ ./mf-predict test_file model out
```

The file `out` contains predictions of the entries specified in `test_file`, and the default evaluation measure, root mean square error (RMSE), is printed. Users can also choose absolute error, generalized KL-divergence, logarithmic loss, accuracy, mean percentile rank, or area under the curve.

2.3 Documentation

The script `demo.sh` mentioned in Section 2.2 is a quick start guide. The README file covers information including an installation guide, a C/C++ API guide, and examples of command line usages. Users can refer to Chin et al. (2015b) to see how we select parameters for some representative data sets. The two files `mf-train.cpp` and `mf-predict.cpp` for the

Figure 1: Comparisons with state of the art packages. The figure is generated from the results in Chin et al. (2015b). The platform for the experiments is a Linux server with two Intel Xeon 2620 CPUs and 64GB memory. Twelve threads are used for all packages.

training and prediction commands, respectively, are good examples demonstrating the use of API functions. For the parallel stochastic gradient methods used in LIBMF, details are in Chin et al. (2015a), Chin et al. (2015b), and the supplementary material.

3. Comparisons

We compare LIBMF with state of the art packages, LIBPMF (Yu et al., 2012) and NOMAD (Yun et al., 2014), for parallel matrix factorization using a squared loss and L2-regularization. Results in Figure 1 indicate that LIBMF is efficient.

4. Conclusions

We develop LIBMF for fully using the computational power of modern multi-core machines to solve several MF problems. The newly added features listed below make LIBMF significantly improved in compared with its previous versions.

1. More loss functions are supported for RVMF.
2. The framework is extended to cover BMF, OCMF, and L1 regularization.
3. For different type of MF problems, we implement suitable evaluation criteria such as mean percentile rank and area under the curve.
4. LIBMF can use disk to cache the training matrix, so the capability to handle huge matrices is largely enhanced.

Abstract

It is known that for a certain class of single index models (SIMs) $Y = f(\boldsymbol{X}_{p\times 1}^{\intercal}\boldsymbol{\beta}_0, \varepsilon)$, support recovery is impossible when $\boldsymbol{X} \sim \mathcal{N}(0, \mathbb{I}_{p\times p})$ and a *model complexity adjusted sample size* is below a critical threshold. Recently, optimal algorithms based on Sliced Inverse Regression (SIR) were suggested. These algorithms work provably under the assumption that the design $\boldsymbol{X}$ comes from an i.i.d. Gaussian distribution. In the present paper we analyze algorithms based on covariance screening and least squares with L_1 penalization (i.e. LASSO) and demonstrate that they can also enjoy optimal (up to a scalar) rescaled sample size in terms of support recovery, albeit under slightly different assumptions on f and ε compared to the SIR based algorithms. Furthermore, we show more generally, that LASSO succeeds in recovering the signed support of $\boldsymbol{\beta}_0$ if $\boldsymbol{X} \sim \mathcal{N}(0, \boldsymbol{\Sigma})$, and the covariance $\boldsymbol{\Sigma}$ satisfies the irrepresentable condition. Our work extends existing results on the support recovery of LASSO for the linear model, to a more general class of SIMs.

Keywords: Single index models, Sparsity, Support recovery, High-dimensional statistics, LASSO

1. Introduction

Modern data applications often require scientists to deal with high-dimensional problems in which the sample size n could be much less than the dimensionality of the covariates p. To handle such challenging problems, structural assumptions on the data generating mechanism are often imposed. Such assumptions are motivated by the fact that classical procedures such as linear regression provably fail, unless the ratio p/n converges to 0. However, modern procedures based on regularization may work well under the high dimensional setting with additional sparsity assumptions. In the sparse high dimensional setting, it is often of interest to uncover the sparsity pattern, or in other words to select the relevant variables for the model. Under generalized linear models, support recovery can be achieved by fitting these models with penalized optimization procedures such as LASSO (Tibshirani, 1996) or Dantzig Selector (Candes and Tao, 2007), which are computationally inexpensive compared to exhaustive search approaches. The LASSO algorithm's variable selection/support recovery capabilities under generalized linear models, have been extensively studied (Meinshausen and Bühlmann, 2006; Zhao and Yu, 2006; Wainwright, 2009; Lee et al., 2013, e.g. among others). However, much less is known under potential mis-specification of these commonly used models or under more general models.

In this paper, we focus on recovering the support of the regression coefficients $\boldsymbol{\beta}_0$ under a *single index model* (SIM):

$$Y = f(\boldsymbol{X}^{\intercal}\boldsymbol{\beta}_0, \varepsilon), \quad \varepsilon \perp\!\!\!\perp \boldsymbol{X} \tag{1}$$

where both the link function f and the distribution of ε are left unspecified. Throughout, we assume that $\boldsymbol{\beta}_0^{\intercal}\boldsymbol{\Sigma}\boldsymbol{\beta}_0 = 1$ for identifiability and $E(\boldsymbol{X}) = 0$, where $\boldsymbol{\Sigma} = E(\boldsymbol{X}\boldsymbol{X}^{\intercal})$. We are specifically interested in the case where $\boldsymbol{X} \in \mathbb{R}^p \sim \mathcal{N}(0, \boldsymbol{\Sigma})$ and $\boldsymbol{\beta}_0$ is s-sparse with $s < p$. Obviously, the SIM includes many commonly used parametric or semi-parametric regression models such as the linear regression model as special cases. Under (1) and the sparsity assumption, we aim to show that the standard least squares LASSO algorithm,

$$\widehat{\boldsymbol{\beta}} = \underset{\boldsymbol{\beta}\in\mathbb{R}^p}{\operatorname{argmin}} \left\{ \frac{1}{2n}\sum_{i=1}^{n}(Y_i - \boldsymbol{X}_i^{\intercal}\boldsymbol{\beta})^2 + \lambda\|\boldsymbol{\beta}\|_1 \right\}, \tag{2}$$

can successfully recover the support of $\boldsymbol{\beta}_0$ provided standard regularity conditions and that the *model complexity adjusted effective sample size,*

$$n_{p,s} = n/\{s\log(p-s)\},$$

is sufficiently large. Obviously, for most choices of f, fitting (2) is essentially making inference under the mis-specified linear regression model.

The least squares LASSO algorithm has been used frequently in practice to perform variable selection for analyzing genomic data (Cantor et al., 2010; Zhao et al., 2011; Wang et al., 2013, e.g.). However, the linear model with Gaussian error is unlikely to be the true model in many such cases. Hence it is of practical importance to theoretically establish that the LASSO's support recovery capabilities are in fact robust to mis-specification. In addition to arguing that LASSO is robust, and perhaps even more surprisingly, we demonstrate that fitting the mis-specified linear model with LASSO penalty can optimally (up to a scalar) achieve support recovery with respect to the effective sample size $n_{p,s}$, for certain classes of $\boldsymbol{\Sigma}$ and SIMs in a minimax sense. In the special case when $\boldsymbol{\Sigma} = \mathbb{I}_{p\times p}$, the LASSO algorithm can be slightly modified into a simple covariance screening procedure which possesses similar properties as the LASSO procedure.

1.1 Overview of Related Work

When the dimension p is small, inference under a SIM has been studied extensively in the literature (Xia and Li, 1999; Horowitz, 2009; Peng and Huang, 2011; McCullagh and Nelder,

1989, e.g.) among many others. In the highly relevant line of work on sufficient dimension reduction, many seminal insights can be found in Li and Duan (1989); Li (1991); Cook and Ni (2005). When $\boldsymbol{X} \sim \mathcal{N}(0, \boldsymbol{\Sigma})$, results given in Li and Duan (1989) can be used to show that $\operatorname{argmin}_{\boldsymbol{\beta}}\{\sum_{i=1}^n (Y_i - \boldsymbol{X}_i^\intercal \boldsymbol{\beta})^2\}$ consistently estimates $\boldsymbol{\beta}_0$ up to a scalar. When $\boldsymbol{\beta}_0$ is sparse, the sparse sliced inverse regression procedure given in Li and Nachtsheim (2006) can be used to effectively recover $\boldsymbol{\beta}_0$ under model (1) although their procedure requires a consistent estimator of $\boldsymbol{\Sigma}^{-1/2}$.

In the high dimensional setting with diverging p, Alquier and Biau (2013) were the first to consider the sparse SIM, and proposed an estimation framework using a PAC-Bayesian approach. Wang and Zhu (2015) and Wang et al. (2012) demonstrated that when support recovery can be achieved when $p = O(n^k)$ under a SIM via optimizations in the form of $\widehat{\boldsymbol{\beta}} = \operatorname{argmin}_{\boldsymbol{\beta} \in \mathbb{R}^p} \frac{1}{2n} \sum_{i=1}^n (F_n(Y_i) - 1/2 - \boldsymbol{X}_i^\intercal \boldsymbol{\beta})^2 + \sum_{j=1}^p J_\lambda(\beta_j)$, where J_λ is a penalty function and $F_n(x) = \frac{1}{n}\sum_{i=1}^n \mathbb{1}(Y_i \leq x)$. Regularized procedures have also been proposed for specific choices of f and Y. For example, Yi et al. (2015) study consistent estimation under the model $\mathbb{P}(Y = 1|\boldsymbol{X}) = \{f(\boldsymbol{\beta}^\intercal \boldsymbol{X}) + 1\}/2$ with binary Y, where $f : \mathbb{R} \mapsto [-1, 1]$. Yang et al. (2015) consider the model $Y = f(\boldsymbol{X}^\intercal \boldsymbol{\beta}) + \varepsilon$ with known f, and develop estimation and inferential procedures based on the L_1 regularized least squares loss.

With p potentially growing with n exponentially and under a general SIM, Radchenko (2015) proposed a non-parametric least squares with an equality L_1 constraint to handle simultaneous estimation of $\boldsymbol{\beta}$ as well as f. The support recovery properties of this procedure are not investigated, and in addition the results do not exhibit the optimal scaling of the triple (n, p, s). Han and Wang (2015) suggest a penalized approach, in which they use a loss function related to Kendall's tau correlation coefficient. They also establish the L_2 consistency for the coefficient $\boldsymbol{\beta}$ but do not consider support recovery. Neykov et al. (2015) analyzed two algorithms based on Sliced Inverse Regression (Li, 1991) under the assumption that $\boldsymbol{X} \sim \mathcal{N}(0, \mathbb{I}_{p\times p})$, and demonstrated that they can uncover the support optimally in terms of the rescaled sample size. Plan and Vershynin (2015) and Thrampoulidis et al. (2015) demonstrated that a constrained version of LASSO can be used to obtain an L_2 consistent estimator of $\boldsymbol{\beta}_0$. None of these procedures provide results on the performance of the LASSO algorithm in support recovery, which relates to L_2 consistency but is a fundamentally different theoretical aspect. In addition, no existing work on the SIM estimation procedures demonstrates that the performance depends on (n, p, s) only through the effective sample size $n_{p,s}$.

1.2 Organization

The rest of the paper is organized as follows. Our main results are formulated in section 2. In particular, we show results on the covariance screening algorithm when $\boldsymbol{\Sigma} = \mathbb{I}_{p\times p}$ in section 2.2 and our main result on the LASSO support recovery in section 2.3. Proof for the main results are given in section 3. In addition we demonstrate that for a class of SIMs, any algorithm provably fails to recover the support, unless the rescaled sample size $n_{p,s}$ is large enough. Numerical studies, confirming our main result are shown in section 4. We discuss potential future directions in section 5. Technical proofs are deferred to the appendixes.

2. Main Results

In this section we formulate our main results, which include the analysis of a simple covariance screening algorithm, and the LASSO algorithm for SIMs. Before we move on to the algorithms we summarize notation that we use throughout the paper and discuss several useful definitions and preliminary results.

2.1 Preliminary and Notation

For a (sparse) vector $\mathbf{v} = (v_1, \ldots, v_p)^\intercal$, we let $S(\mathbf{v}) := \operatorname{supp}(\mathbf{v}) = \{j : v_j \neq 0\}$ denote its support, $S_\pm(\mathbf{v}) := \{(\operatorname{sign}(v_j), j) : v_j \neq 0\}$ be its signed support, $\|\mathbf{v}\|_p$ denote the L_p norm, $\|\mathbf{v}\|_0 = |\operatorname{supp}(\mathbf{v})|$, and $\mathbf{v}^{\min} = \min_{i\in\operatorname{supp}(\mathbf{v})} |v_i|$. For a real random variable X, define

$$\|X\|_{\psi_2} = \sup_{p\geq 1} p^{-1/2}(\mathbb{E}|X|^p)^{1/p}, \quad \|X\|_{\psi_1} = \sup_{p\geq 1} p^{-1}(\mathbb{E}|X|^p)^{1/p}.$$ [1]

Recall that a random variable is called *sub-Gaussian* if $\|X\|_{\psi_2} < \infty$ and *sub-exponential* if $\|X\|_{\psi_1} < \infty$. For any integer $k \in \mathbb{N}$ we use the shorthand notation $[k] = \{1, \ldots, k\}$. For a matrix $\mathbf{M} \in \mathbb{R}^{d_1\times d_2}$, sets $S_1, S_2 \subseteq [d]$, we let $\mathbf{M}_{,S_2} = [M_{ij}]_{i\in[d_1]}^{j\in S_2}$ and $\mathbf{M}_{S_1,S_2} = [M_{ij}]_{i\in S_1}^{j\in S_2}$. For a vector $\boldsymbol{Z} = (Z_1, \ldots, Z_d)^\intercal$ and set $S \subseteq [d]$, $\boldsymbol{Z}_S$ denotes the subvector corresponding to the set S. Furthermore, let $\|\mathbf{M}\|_{p,q} = \sup_{\|\mathbf{v}\|_p=1} \|\mathbf{M}\mathbf{v}\|_q$. In particular, we have $\|\mathbf{M}\|_{2,2} = \max_{i\in[\max(d_1,d_2)]}\{s_i(\mathbf{M})\}$, where $s_i(\mathbf{M})$ is the i^{th} singular value of $\mathbf{M}$, and $\|\mathbf{M}\|_{\infty,\infty} = \max_{i\in[d_1]} \sum_{j=1}^{d_2} |M_{ij}|$. For a matrix $\mathbf{M} \in \mathbb{R}^{d\times d}$, we put $D_{\max}(\mathbf{M}) = \max_{i\in[d]} |M_{ii}|$ for its maximal diagonal element, and $\operatorname{diag}(\mathbf{M}) = [M_{ii}]_{i\in[d]}$ for the collection of diagonal entries of $\mathbf{M}$. We also use standard asymptotic notations. Given two sequences $\{a_n\}, \{b_n\}$ we write $a_n = O(b_n)$ if there exists a constant $C < \infty$ such that $a_n \leq Cb_n$; $a_n = \Omega(b_n)$ if there exists a positive constant $c > 0$ such that $a_n \geq cb_n$, $a_n = o(b_n)$ if $a_n/b_n \to 0$, and $a_n \asymp b_n$ if there exists positive constants c and C such that $c < a_n/b_n < C$. Throughout, we also assume that there exists a constant $0 < \iota < 1$ such that $s < p - p^\iota$, which implies that $\frac{\log(p-s)}{\log(p)} \geq \iota$.

We assume that data for analysis consists of n independent and identically distributed (i.i.d.) random vectors $\mathcal{D} = \{(Y_i, \boldsymbol{X}_i^\intercal)^\intercal, i = 1, \ldots, n\}$ and we focus primarily on $\boldsymbol{X} \sim \mathcal{N}(0, \boldsymbol{\Sigma})$. In matrix form, we let $\mathbb{X} = [\boldsymbol{X}_1, \ldots, \boldsymbol{X}_n]_{n\times p}^\intercal = [X_{ij}]_{i\in[n]}^{j\in[p]}$, $\boldsymbol{Y} = (Y_1, \ldots, Y_n)^\intercal$, and $\boldsymbol{\varepsilon} = (\varepsilon_1, \ldots, \varepsilon_n)^\intercal$. The recovery of $\boldsymbol{\beta}_0$ under SIM often relies on the linearity of expectation assumption given in Li and Duan (1989) and Li (1991):

Definition 2.1.1 (Linearity of Expectation) *A p-dimensional random variable $\boldsymbol{X}$ is said to satisfy linearity of expectation in the direction $\boldsymbol{\beta}$ if for any direction $\boldsymbol{b} \in \mathbb{R}^p$:*

$$\mathbb{E}[\boldsymbol{X}^\intercal \boldsymbol{b} | \boldsymbol{X}^\intercal \boldsymbol{\beta}] = c_{\boldsymbol{b}} \boldsymbol{X}^\intercal \boldsymbol{\beta} + a_{\boldsymbol{b}},$$

where $a_{\boldsymbol{b}}, c_{\boldsymbol{b}} \in \mathbb{R}$ are some real constants which might depend on the direction $\boldsymbol{b}$.

Remark 2.1.2 *Note that if additionally $\mathbb{E}[\boldsymbol{X}] = 0$, then by taking expectation it is evident that $a_{\boldsymbol{b}} \equiv 0$. Clearly, linearity of expectation is direction specific by definition. Elliptical*

1. There are multiple equivalent (up to universal constants) definitions of the so-called Orlicz or ψ norms. See Vershynin (2010) Lemma 5.5 for a succinct formal treatment of this.

distributions (Fang et al., 1990) including multiviariate normal are known to satisfy the linearity in expectation uniformly in all directions (Cambanis et al., 1981, e.g.).

Next, we record a simple but very useful observation, which forms the basis of our work. From Theorem 2.1 of Li and Duan (1989), we note that under a SIM and normality of $\boldsymbol{X}$ with covariance $\boldsymbol{\Sigma} > 0$,

$$\operatorname*{argmin}_{\boldsymbol{b}} \mathbb{E}(Y - \boldsymbol{b}^\intercal \boldsymbol{X})^2 = c_0 \boldsymbol{\beta}_0,$$

for some $c_0 \in \mathbb{R}$. More generally, we have

Lemma 2.1.3 *Assume that the SIM (1) holds, $\boldsymbol{\Sigma} = \mathbb{E}(\boldsymbol{X}\boldsymbol{X}^\intercal) > 0$, and $\boldsymbol{X}$ satisfies the linearity in expectation condition in the direction $\boldsymbol{\beta}_0$ such that $\mathbb{E}[(\boldsymbol{X}^\intercal \boldsymbol{\beta}_0)^2] > 0$. Then we have $\boldsymbol{\Sigma}^{-1}\mathbb{E}(Y\boldsymbol{X}) = c_0\boldsymbol{\beta}_0$, where $c_0 := \mathbb{E}(Y\boldsymbol{X}^\intercal\boldsymbol{\beta}_0)$. Obviously, $\mathbb{E}(Y\boldsymbol{X}) = c_0\boldsymbol{\beta}_0$ when $\boldsymbol{\Sigma} = \mathbb{I}_{p\times p}$.*

In view of Lemma 2.1.3, under sparsity assumptions, an L_1 regularized least square estimator can recover $\boldsymbol{\beta}_0$ proportionally and hence the support of $\boldsymbol{\beta}_0$. Furthermore, when $\boldsymbol{\Sigma} = \mathbb{I}_{p\times p}$, the covariance $\mathbb{E}(Y\boldsymbol{X})$ can be directly used to recover $\boldsymbol{\beta}_0$. It is noteworthy to remark that in the special case $\boldsymbol{X} \sim \mathcal{N}(0, \boldsymbol{\Sigma})$, a simple application of Stein's Lemma (Stein, 1981) can help quantify the constant c_0 precisely:

$$c_0 = \mathbb{E}(Y\boldsymbol{X}^\intercal\boldsymbol{\beta}_0) = \mathbb{E}(Z\underbrace{[\mathbb{E}f(Z,\varepsilon)|Z]}_{\varphi(Z)}) = \int D\varphi(z)\frac{\exp(-z^2/2)}{\sqrt{2\pi}}dz = \mathbb{E}D\varphi(Z),$$

where $D\varphi$ is the distributional derivative of φ, $Z \sim \mathcal{N}(0,1)$ and we abused the notation slightly in the last equality for simplicity.

The remaining of this section is structured as follows — in section 2.2 we study a simple covariance thresholding algorithm, which is a manifestation of program (2) under the assumption $\boldsymbol{\Sigma} = \mathbb{I}_{p\times p}$. In section 2.3 we consider the full-fledged least squares LASSO algorithm (2) with a general covariance matrix $\boldsymbol{\Sigma}$. Throughout, we assume $E(\boldsymbol{X}) = 0$ and let $\sigma^2 = E(Y^2)$, $\eta = \mathrm{Var}(Y^2)$,

$c_0 = \mathbb{E}(Y\boldsymbol{X}^\intercal\boldsymbol{\beta}_0)$, $\gamma = \mathrm{Var}(Y\boldsymbol{X}^\intercal\boldsymbol{\beta}_0)$, $\xi^2 = \mathbb{E}\{(Y - c_0\boldsymbol{X}^\intercal\boldsymbol{\beta}_0)^2\}$, and $\theta^2 = \mathrm{Var}\{(Y - c_0\boldsymbol{X}^\intercal\boldsymbol{\beta}_0)^2\}$.

In addition, to simplify the presentation we will assume that the above constants are not scaling with (n, p, s), and belong to a compact set which is bounded away from 0.

2.2 Covariance Screening under $\boldsymbol{\Sigma} = \mathbb{I}_{p\times p}$

In this section, we propose a simple covariance screening procedure for signed support recovery of $\boldsymbol{\beta}_0$ under a SIM with $\boldsymbol{\Sigma} = \mathbb{I}_{p\times p}$, which relates to the sure independence screening procedures (Fan and Lv, 2008; Fan et al., 2010) under the linear model. Note that the LASSO procedure (2) can equivalently be expressed as:

$$\widehat{\boldsymbol{\beta}} = \operatorname*{argmin}_{\boldsymbol{\beta}\in\mathbb{R}^p}\left\{-\frac{1}{n}\sum_{i=1}^n Y_i\boldsymbol{X}_i^\intercal\boldsymbol{\beta} + \frac{1}{2n}\boldsymbol{\beta}^\intercal\sum_{i=1}^n \boldsymbol{X}_i\boldsymbol{X}_i^\intercal\boldsymbol{\beta} + \lambda\|\boldsymbol{\beta}\|_1\right\}.$$

Under the assumption $\boldsymbol{\Sigma} = \mathbb{I}_{p\times p}$, we replace $\frac{1}{n}\sum_{i=1}^n \boldsymbol{X}_i\boldsymbol{X}_i^\intercal$ with $\mathbb{I}_{p\times p}$ and instead consider

$$\widehat{\boldsymbol{\beta}} = \operatorname*{argmin}_{\boldsymbol{\beta}\in\mathbb{R}^p}\left\{-\frac{1}{n}\sum_{i=1}^n Y_i\boldsymbol{X}_i^\intercal\boldsymbol{\beta} + \frac{1}{2}\boldsymbol{\beta}^\intercal\boldsymbol{\beta} + \lambda\|\boldsymbol{\beta}\|_1\right\}.$$

It is well known that the solution to the above program takes the form:

$$\widehat{\beta}_j = \mathrm{sign}\left(n^{-1}\sum_{i=1}^n Y_iX_{ij}\right)\left(\left|n^{-1}\sum_{i=1}^n Y_iX_{ij}\right| - \lambda\right)_+,$$

where $x_+ = x\mathbb{1}(x \geq 0)$. Hence, in this special case, the regularization parameter can be equivalently interpreted as a thresholding parameter, filtering all small $|n^{-1}\sum_{i=1}^n Y_iX_{ij}|$. Motivated by this, we consider the following simple covariance screening procedure, which acts as a filter taking covariances and their corresponding signs, only if they pass a critical threshold:

Algorithm 1: Covariance Screening Algorithm

input: $(Y_i, \boldsymbol{X}_i)_{i=1}^n$: data; tuning parameter $\nu > 0$

1. Calcluate $\boldsymbol{V} := \widehat{\mathrm{Cov}}(Y, \boldsymbol{X}) := n^{-1}\sum_{i=1}^n Y_i\boldsymbol{X}_i$,
2. Set $\widehat{S} := \left\{V_j : |V_j| > \nu\sqrt{\frac{\log p}{n}}\right\}$;
3. Output the set $\{(\mathrm{sign}(V_j), j) : |V_j| \in \widehat{S}\}$.

The following proposition shows that the algorithm recovers the support with probability approaching 1 provided that the effective sample size $n_{p,s}$ is sufficiently large under the normality assumption of $\boldsymbol{X} \sim \mathcal{N}(0, \mathbb{I}_{p\times p})$.

Proposition 2.2.1 *Assume that $\boldsymbol{X} \sim \mathcal{N}(0, \mathbb{I}_{p\times p})$, $c_0 \neq 0$, $E(Y^4) < \infty$, and $\beta_{0j} \in \{\pm\frac{1}{\sqrt{s}}, 0\}$ for all $j \in [p]$ and some $s \in \mathbb{N}$. Set $\nu = \frac{1}{\sqrt{s}} + 2\sqrt{2}\sigma$. Then as long as*

$$n_{p,s} \geq \Upsilon,$$

for a large enough $\Upsilon = O(1)$ (depending on c_0, σ^2) Algorithm 1 recovers the signed support of $c_0\boldsymbol{\beta}_0$ with asymptotic probability 1.

The proof of Proposition 2.2.1 can be found in Appendix D. We note that this result does not require Y to be sub-Gaussian. When sub-Gaussianity is assumed, the convergence rate of the probability approaching 1 can be improved. Furthermore, under sub-Gaussianity of Y, we can relax the normality assumption of $\boldsymbol{X}$. Specifically, one may instead consider the following assumptions

Assumption 2.2.2 (Spherical Distribution of $\boldsymbol{X}$ and sub-Gaussian of Y) *Let $\boldsymbol{X}$ be a spherically distributed p dimensional random variable with $\mathbb{E}[\boldsymbol{X}] = 0, \mathrm{Var}[\boldsymbol{X}] = \mathbb{I}_{p\times p}$, whose moment generating function exists, and takes the form $\mathbb{E}\{\exp(\boldsymbol{t}^\intercal\boldsymbol{X})\} \equiv \Psi(\boldsymbol{t}^\intercal\boldsymbol{t}), \boldsymbol{t} \in \mathbb{R}^p$, and in addition $\Psi : \mathbb{R} \mapsto \mathbb{R}$ is such that $\Psi(t) \leq \exp(Ct)$ for some $C > 0$ for all $t \in \mathbb{R}^+$. In addition, we assume that Y is sub-Gaussian, i.e. $\|Y\|_{\psi_2} \leq K_Y$.*

Note that (Vershynin, 2010, see Lemma 5.5. e.g.) assumption 2.2.2 implies $\max_{j\in[p]}\|X_j\|_{\psi_2} < \infty$. Let $K := \max_{j\in[p]}\|X_j\|_{\psi_2}$. In parallel to Proposition 2.2.1, we have

Proposition 2.2.3 *In addition to Assumption 2.2.2, we assume that s, $c_0 \neq 0$ and $\beta_{0j} \in \{\pm\frac{1}{\sqrt{s}}, 0\}$ for all $j \in [p]$ and some $s \in \mathbb{N}$. Set the tuning parameter $\nu = \omega K_Y K$ for some absolute constant $\omega > 0$. Then there exits an absolute constant $\Upsilon \in \mathbb{R}$ depending on c_0, C, K and K_Y such that if:*

$$n_{p,s} \geq \Upsilon,$$

Algorithm 1 recovers the signed support of $c_0\boldsymbol{\beta}_0$ with asymptotic probability 1.

2.3 LASSO Algorithm with General $\boldsymbol{\Sigma}$

In this section we consider the LASSO algorithm (2),

$$\widehat{\boldsymbol{\beta}} = \underset{\boldsymbol{\beta}\in\mathbb{R}^p}{\operatorname{argmin}} \frac{1}{2n}\|\boldsymbol{Y} - \mathbb{X}\boldsymbol{\beta}\|_2^2 + \lambda\|\boldsymbol{\beta}\|_1, \tag{3}$$

under the assumption $\boldsymbol{X} \sim \mathcal{N}(0, \boldsymbol{\Sigma})$ with a generic and unknown covariance matrix $\boldsymbol{\Sigma}$. Under certain sufficient conditions our goal is to show that (2) recovers the support of $\boldsymbol{\beta}_0$ with asymptotic probability 1 in optimal (up to a scalar) effective sample size. In contrast to section 2.2, we also no longer require each of the signals of $\boldsymbol{\beta}$ to be of the same magnitude.

We first summarize a primal dual witness (PDW) construction which we borrow from Wainwright (2009). The PDW construction lays out steps allowing one to prove sign consistency for L_1 constrained quadratic programming (3). We will only provide the sufficient conditions to show sign-consistency, and the interested reader can check Wainwright (2009) for the necessary conditions. We note that the validity of the PDW construction is generic, in that it does not rely on the distribution of the residual $\mathbf{w} = \boldsymbol{Y} - c_0\mathbb{X}\boldsymbol{\beta}_0$, and hence extends to the current framework. Note that unlike the linear regression case, in our setting $\mathbf{w}$ does not necessarily have mean 0 although $\mathbb{E}[\mathbb{X}^\intercal\mathbf{w}] = 0$.

Recall that a vector $\mathbf{z}$ is a subgradient of the L_1 norm evaluated at a vector $\mathbf{v} \in \mathbb{R}^p$ (i.e. $\mathbf{z} \in \partial\|\mathbf{v}\|_1$) if we have $z_j = \operatorname{sign}(v_j), v_j \neq 0$ and $z^j \in [-1, 1]$ otherwise. It follows from Karush-Kuhn-Tucker's theorem that a vector $\widehat{\boldsymbol{\beta}} \in \mathbb{R}^p$ is optimal for the LASSO problem (3) iff there exists a subgradient $\widehat{\mathbf{z}} \in \partial\|\widehat{\boldsymbol{\beta}}\|_1$ such that:

$$\frac{1}{n}\mathbb{X}^\intercal\mathbb{X}(\widehat{\boldsymbol{\beta}} - c_0\boldsymbol{\beta}_0) - \frac{1}{n}\mathbb{X}^\intercal\mathbf{w} + \lambda\widehat{\mathbf{z}} = 0. \tag{4}$$

Put $S_0 := S(\boldsymbol{\beta}_0)$ for brevity. In what follows we will assume that the matrix $\mathbb{X}_{\cdot,S_0}^\intercal\mathbb{X}_{\cdot,S_0}$ is invertible (which it is with probability 1), even though this is not required by the PDW. The PDW method constructs a pair $(\check{\boldsymbol{\beta}}, \check{\mathbf{z}}) \in \mathbb{R}^p \times \mathbb{R}^p$ by following the steps:

- Solve:
$$\check{\boldsymbol{\beta}}_{S_0} = \underset{\boldsymbol{\beta}_{S_0}\in\mathbb{R}^s}{\operatorname{argmin}} \frac{1}{2n}\|\boldsymbol{Y} - \mathbb{X}_{\cdot,S_0}\boldsymbol{\beta}_{S_0}\|_2^2 + \lambda\|\boldsymbol{\beta}_{S_0}\|_1,$$
where $s = |S_0|$. This solution is unique under the invertibility of $\mathbb{X}_{\cdot,S_0}^\intercal\mathbb{X}_{\cdot,S_0}$ since in this case the function is strictly convex. Set $\check{\boldsymbol{\beta}}_{S_0^c} = 0$.

- Choose a $\check{\mathbf{z}}_{S_0} \in \partial\|\check{\boldsymbol{\beta}}_{S_0}\|_1$.
- For $j \in S_0^c$ set $Z_j := \mathbb{X}_{\cdot,j}^\intercal[\mathbb{X}_{\cdot,S_0}(\mathbb{X}_{\cdot,S_0}^\intercal\mathbb{X}_{\cdot,S_0})^{-1}\check{\mathbf{z}}_{S_0} + \mathbf{P}_{\mathbb{X}_{\cdot,S_0}^\perp}\left(\frac{\mathbf{w}}{\lambda n}\right)]$[2], where $\mathbf{P}_{\mathbb{X}_{\cdot,S_0}^\perp} = \mathbb{I} - \mathbb{X}_{\cdot,S_0}(\mathbb{X}_{\cdot,S_0}^\intercal\mathbb{X}_{\cdot,S_0})^{-1}\mathbb{X}_{\cdot,S_0}^\intercal$ is an orthogonal projection. Checking that $|Z_j| < 1$ for all $j \in S_0^c$ ensures that there is a unique solution $\check{\boldsymbol{\beta}} = (\check{\boldsymbol{\beta}}_{S_0}^\intercal, \check{\boldsymbol{\beta}}_{S_0^c}^\intercal)^\intercal$ satisfying $S(\check{\boldsymbol{\beta}}) \subseteq S(c_0\boldsymbol{\beta}_0)$.
- To check sign consistency we need $\check{\mathbf{z}}_{S_0} = \operatorname{sign}(c_0\boldsymbol{\beta}_{0S_0})$. For each $j \in S_0$, define:
$$\Delta_j := \mathbf{e}_j^\intercal(n^{-1}\mathbb{X}_{\cdot,S_0}^\intercal\mathbb{X}_{\cdot,S_0})^{-1}\left[n^{-1}\mathbb{X}_{\cdot,S_0}^\intercal\mathbf{w} - \lambda\operatorname{sign}(c_0\boldsymbol{\beta}_{0S_0})\right],$$ [3]
where $\mathbf{e}_j \in \mathbb{R}^s$ is a canonical unit vector with 1 at the j^{th} position. Checking $\check{\mathbf{z}}_{S_0} = \operatorname{sign}(c_0\boldsymbol{\beta}_{0S_0})$ is equivalent to checking:
$$\operatorname{sign}(c_0\beta_{0j} + \Delta_j) = \operatorname{sign}(c_0\beta_{0j}),\ \forall j \in S_0.$$

To this end we require several restrictions on $\boldsymbol{\Sigma}$ and moment conditions on Y. We partition the covariance matrix

$$\boldsymbol{\Sigma} = \begin{bmatrix} \boldsymbol{\Sigma}_{S_0,S_0} & \boldsymbol{\Sigma}_{S_0,S_0^c} \\ \boldsymbol{\Sigma}_{S_0^c,S_0} & \boldsymbol{\Sigma}_{S_0^c,S_0^c} \end{bmatrix},$$

where $\boldsymbol{\Sigma}_{S_0,S_0}$ corresponds to the covariance of $\boldsymbol{X}_{S_0}$. Furthermore, we let

$$\boldsymbol{\Sigma}_{S_0^c|S_0} := \boldsymbol{\Sigma}_{S_0^c,S_0^c} - \boldsymbol{\Sigma}_{S_0^c,S_0}\boldsymbol{\Sigma}_{S_0,S_0}^{-1}\boldsymbol{\Sigma}_{S_0,S_0^c}, \tag{5}$$

$$\rho_\infty(\boldsymbol{\Sigma}_{S_0,S_0}^{1/2}) := \|\boldsymbol{\Sigma}_{S_0,S_0}^{-1/2}\|_{\infty,\infty}\|\boldsymbol{\Sigma}_{S_0,S_0}^{1/2}\|_{\infty,\infty}, \tag{6}$$

be the conditional covariance matrix of $\boldsymbol{X}_{S_0^c}|\boldsymbol{X}_{S_0}$, and the condition number of $\boldsymbol{\Sigma}_{S_0,S_0}^{1/2}$ with respect to $\|\cdot\|_{\infty,\infty}$, respectively. We assume that

Assumption 2.3.1 (Irrepresentable Condition)

$$\|\boldsymbol{\Sigma}_{S_0^c,S_0}\boldsymbol{\Sigma}_{S_0,S_0}^{-1}\|_{\infty,\infty} \leq (1-\kappa), \quad \textit{for some } \kappa > 0.$$

Assumption 2.3.2 (Bounded Spectrum) *For some fixed $0 < \lambda_{\min} \leq \lambda_{\max} < \infty$,*

$$\lambda_{\min} \leq \boldsymbol{\Sigma}_{S_0,S_0} \leq \lambda_{\max}.$$

Assumption 2.3.3 (Bounded 4$^{\text{th}}$ Moment) $\mathbb{E}(Y^4) < \infty$, *and does not scale with* (n, p, s).

Recall that the irrepresentable condition is proved to be necessary for successful support recovery (Wainwright, 2009, Theorem 4) in the linear model, and hence one should not expect that Assumption 2.3.1 can be weakened. Assumption 2.3.3 guarantees that σ^2, η, c_0, γ, ξ^2 and θ^2 are well defined and finite. Finally, successful support recovery will depend on the strength of the minimal signal of $\boldsymbol{\beta}_0$. Recall that $\boldsymbol{\beta}_0^{\min} := \min_{j\in S_0}|\beta_{0j}|$, is the minimal non-zero signal in the vector $\boldsymbol{\beta}_0$. We are now ready to provide sufficient conditions for the LASSO signed support recovery, in the setting of SIMs

2. Z_j are derived by simply plugging in $\check{\boldsymbol{\beta}}$ and $\check{\mathbf{z}}_{S_0}$ and solving (4) for $\check{\mathbf{z}}_{S_0^c}$.
3. Δ_j can be seen to equal $\check{\beta}_j - c_0\beta_{0j}$ for $j \in S_0$, when $\check{\mathbf{z}}_{S_0} = \operatorname{sign}(c_0\boldsymbol{\beta}_0)$.

Theorem 2.3.4 *Let Assumptions 2.3.1 — 2.3.3 hold. Then for the LASSO estimator given in (3) under a SIM (1), we have the following sufficient conditions:*

i. If

$$n_{p,s} \geq \frac{4D_{\max}(\mathbf{\Sigma}_{S_0^c|S_0})\left(\frac{4}{\lambda_{\min}} + \frac{\xi^2+1}{\lambda^2 s}\right)}{\kappa^2},$$

then $S(\widehat{\boldsymbol{\beta}}) \subset S(c_0\boldsymbol{\beta}_0)$, with probability at least $1 - O\{p^{-1} + n^{-1} + e^{-\Omega(s)}\}$.

ii. Let further, for some positive constant $\alpha > 0$ we have $n_{p,s} \geq \alpha$. Then there exist some positive constants $\Upsilon_0, \Upsilon_1, \Upsilon_2 > 0$ which may depend[1] on c_0, σ such that if:

$$\boldsymbol{\beta}_0^{\min} \geq \|\mathbf{\Sigma}_{S_0,S_0}^{-1/2}\|_{\infty,\infty}^2 \lambda \Upsilon_0 + \left[\Upsilon_1 \rho_\infty(\mathbf{\Sigma}_{S_0,S_0}^{1/2})\sqrt{\frac{s}{n\log(p-s)}}\|\boldsymbol{\beta}_0\|_\infty + \frac{\Upsilon_2 \|\mathbf{\Sigma}_{S_0,S_0}^{-1/2}\|_{\infty,\infty}}{\sqrt{s}}\right] n_{p,s}^{-1/2} \tag{7}$$

we have $S_\pm(\widehat{\boldsymbol{\beta}}) = S_\pm(c_0\boldsymbol{\beta}_0)$ with probability at least $1 - O\{e^{-\Omega(s \wedge \log(p-s))} + (\log p)^{-1} + n^{-1}\}$.

Before we proceed with the proof of our main result, we would like to mention a few remarks on our sufficient conditions, in particular the ones suggested in ii.

Remark 2.3.5 *Firstly, the slow probability convergence rate $(\log p)^{-1}$ in part ii. is purely due to the fact we are not willing to assume that Y is coming from a sub-Gaussian distribution. If such an assumption is made the rate reduces to the usual p^{-1}. Secondly, observe that $\lambda_{\max}^{-1} \leq \|\boldsymbol{\beta}_0\|_2 \leq \lambda_{\min}^{-1}$. Hence the value of $\boldsymbol{\beta}_0^{\min}$ is of "largest" order when $\boldsymbol{\beta}_0^{\min} \asymp \|\boldsymbol{\beta}_0\|_\infty \asymp \frac{1}{\sqrt{s}}$. Setting*

$$\lambda := \lambda_T = \sqrt{(\xi^2+1)\frac{4C_T D_{\max}(\mathbf{\Sigma}_{S_0^c|S_0})}{\kappa^2}\frac{\log(p-s)}{n}},$$

for some $C_T > 1$ gives us that the condition from i. is equivalent to:

$$n_{p,s} \geq \frac{16 D_{\max}(\mathbf{\Sigma}_{S_0^c|S_0})}{(1 - C_T^{-1})\kappa^2 \lambda_{\min}}.$$

Note that due to positive definiteness: $D_{\max}(\mathbf{\Sigma}_{S_0^c|S_0}) \leq D_{\max}(\mathbf{\Sigma}_{S_0^c,S_0^c})$, and hence it is reasonable to assume $D_{\max}(\mathbf{\Sigma}_{S_0^c|S_0}) = O(1)$. Assume additionally that $\|\mathbf{\Sigma}_{S_0,S_0}^{-1/2}\|_{\infty,\infty} = O(1)$, $\rho_\infty(\mathbf{\Sigma}_{S_0,S_0}^{1/2}) = O(1)$, and let $\boldsymbol{\beta}_0^{\min} \asymp \frac{1}{\sqrt{s}}$. Notice that the space of matrices satisfying assumptions 2.3.1 — 2.3.3 and the latter assumptions is non-empty as one can easily show that Toeplitz matrices with entries $\Sigma_{kj} = \rho^{|k-j|}$ with $|\rho| < 1$ satisfy these conditions e.g. Using the same $\lambda = \lambda_T$ we can clearly achieve the sufficient condition in ii. provided that the model complexity adjusted sample size $n_{p,s}$ is large enough. On the other hand, this scaling can no longer be guaranteed if $\boldsymbol{\beta}_0^{\min} \asymp \frac{1}{\sqrt{s}}$ fails to hold. In any case, it is clear that when $\mathbf{\Sigma} = \mathbb{I}_{p\times p}$ all conditions required are met, and hence Theorem 2.3.4 shows that the LASSO algorithm will work optimally (up to a scalar) in terms of the rescaled sample size. Below we formulate a result which allows us to claim certain optimality for the LASSO algorithm in the case of a more general $\mathbf{\Sigma}$ matrix whenever we have approximately equally sized coefficients.

4. The dependency is inversely proportional to $|c_0|$ and proportional to σ; For more details refer to the proof.

Proposition 2.3.6 *Consider a special example of a SIM with $Y = G\{h(\boldsymbol{X}^\intercal\boldsymbol{\beta}_0) + \varepsilon\}$ for $\boldsymbol{X} \sim \mathcal{N}(0, \mathbf{\Sigma})$, and G, h are known strictly increasing continuous functions and in addition h is an L-Lipschitz function. Assume that there exists a set $S \subset [p], |S| = s$ such that $\|\mathbf{\Sigma}_{S,S}\|_{\infty,\infty} < R$, Assumptions 2.3.1 and 2.3.2 hold on S and $0 < d \leq \operatorname{diag}(\mathbf{\Sigma}_{S^c,S^c}) \leq D < \infty$. In addition, assume that ε is a continuously distributed random variable with density p_ε satisfying:*

$$p_\varepsilon(x) \propto \exp(-P(x^2)), \tag{8}$$

where P is any non-zero polynomial with non-negative coefficients such that $P(0) = 0$. We restrict the parameter space to $\left\{\boldsymbol{\beta} \in \mathbb{R}^p : \boldsymbol{\beta}^\intercal\mathbf{\Sigma}\boldsymbol{\beta} = 1, \|\boldsymbol{\beta}\|_0 = s, \frac{\boldsymbol{\beta}^{\min}}{\|\boldsymbol{\beta}\|_\infty} \geq c_{\mathbf{\Sigma}}\right\}$, where $c_{\mathbf{\Sigma}} > 0$ is a sufficiently small constant depending solely on $\mathbf{\Sigma}$ (see (20) for details). If

$$n_{p,s} < C,$$

for some constant $C > 0$ (depending on $P, G, h, \mathbf{\Sigma}$) and s is sufficiently large, any algorithm for support recovery makes errors with probability at least $\frac{1}{2}$ asymptotically.

Proposition 2.3.6 justifies that the LASSO is sample size optimal even when more generic covariance matrices than identity are considered, provided that we can show the class of SIMs defined satisfy the assumptions of this section. We do so in the following Remark.

Remark 2.3.7 *We will now argue that if we have a model as described in Proposition 2.3.6, the LASSO will recover the support provided that the the covariance matrix $\mathbf{\Sigma}$ satisfies Assumptions 2.3.1 and 2.3.2, $\mathbb{E}(Y^4) < \infty$ and the minimal signal strength is sufficiently strong as required by Remark 2.3.5. Notice that by Chebyshev's association inequality (Boucheron et al., 2013), we have:*

$$\mathbb{E}(Y\boldsymbol{X}^\intercal\boldsymbol{\beta}_0) > \mathbb{E}(Y)\mathbb{E}(\boldsymbol{X}^\intercal\boldsymbol{\beta}_0) = 0,$$

where the inequality is strict since G and h are strictly increasing and $\boldsymbol{X}^\intercal\boldsymbol{\beta}_0 \sim \mathcal{N}(0,1)$. In fact, using exactly the same argument, one can show more generally that if $r(z) = \mathbb{E}[Y|\boldsymbol{X}^\intercal\boldsymbol{\beta}_0 = z]$ is a strictly monotone function it follows that $\mathbb{E}(Y\boldsymbol{X}^\intercal\boldsymbol{\beta}_0) \neq 0$. We close this remark by pointing out that the logistic regression model $P(Y = 1 \mid \boldsymbol{X}) = g(\boldsymbol{X}^\intercal\boldsymbol{\beta}_0)$ with $g(x) = e^x/(1+e^x)$ satisfies the condition since $r(z) = g(z)$ is strictly monotone, and hence using the LASSO algorithm one can recover the support correctly. This is an example that even discrete valued Y outcomes can be solved by the least squares LASSO algorithm.

2.3.1 Outcome Transformations

In this subsection we provide brief comments on possible strategies to transform the data in view of the results of Theorem 2.3.4. A crucial condition in order for the signed support recovery of $\boldsymbol{\beta}_0$ to hold is $c_0 \neq 0$, which should not be expected to hold in general, but nevertheless naturally occurs in many cases. If this condition does not hold, one can potentially transform the outcome $\widetilde{Y} = g(Y)$ by a function g in order to achieve $\mathbb{E}(\widetilde{Y}\boldsymbol{X}^\intercal\boldsymbol{\beta}_0) \neq 0$ even if $\mathbb{E}(Y\boldsymbol{X}^\intercal\boldsymbol{\beta}_0) = 0$. If we use $\widetilde{Y}_i = g(Y_i)$ instead of Y_i then clearly LASSO succeeds under the assumptions from Theorem 2.3.4, only with assumptions on Y_i being replaced by $\widetilde{Y}_i$. The following proposition characterizes when one should expect a correlation inducing transformation g to exist.

Proposition 2.3.8 *There exists a measurable function $g : \mathbb{R} \mapsto \mathbb{R}$ such that $\mathbb{E}\{g(Y)\boldsymbol{X}^\intercal\boldsymbol{\beta}_0\} \neq 0$ if and only if $\mathrm{Var}\{\mathbb{E}(\boldsymbol{X}^\intercal\boldsymbol{\beta}_0|Y)\} > 0$.*

Another potential advantage of performing a transformation is to ensure that $\widetilde{Y} = g(Y)$ is sub-Gaussian. For example, if we let $g(y) = F(y) = P(Y \leq y)$, then the sub-Gaussianity of $\widetilde{Y}$ is guaranteed, which would improve the rate of support recovery. For many choices of g such as F, the transformation may be defined at the population level and is unknown a priori. Thus it would be desirable to employ data dependent estimate $\widehat{g}$ of g. In other words we consider fitting the following LASSO to recover the support:

$$\widehat{\boldsymbol{\beta}} = \underset{\boldsymbol{\beta}\in\mathbb{R}^p}{\operatorname{argmin}} \frac{1}{2n}\|\widehat{g}(\boldsymbol{Y}) - \mathbb{X}\boldsymbol{\beta}\|_2^2 + \lambda\|\boldsymbol{\beta}\|_1, \tag{9}$$

where $\widehat{g}(\boldsymbol{Y})$ should be understood as element-wise application of $\widehat{g}$. The following Corollary extends Theorem 2.3.4 to allow for data dependent transformations.

Corollary 2.3.9 *Let the assumptions of Theorem 2.3.4 hold for $\widetilde{Y}_i = g(Y_i)$ in place of Y_i and assume additionally that:*

$$\|\widehat{g}(\boldsymbol{Y}) - g(\boldsymbol{Y})\|_2 \leq O(\sqrt{\log p}), \tag{10}$$

with probability at least $1 - O(p^{-1})$, then if (7) holds we have $S_\pm(\widehat{\boldsymbol{\beta}}) = S_\pm(c_0\boldsymbol{\beta}_0)$ with probability at least $1 - O\{e^{-\Omega(s\wedge\log(p-s))} + (\log p)^{-1} + n^{-1}\}$.

Remark 2.3.10 *Akin to (2), we do not require an intercept in the model after doing a transformation in (9). This is possible since $\boldsymbol{X}$ is assumed to have mean 0. In practice if this were not the case, one would have to either center $\boldsymbol{X}$ or include an intercept which is not penalized.*

3. Proof of Theorem 2.3.4

Our proof follows similar steps as Theorem 3 of Wainwright (2009) although many critical modifications are needed, since the error term $\mathbf{w} = \mathbf{Y} - c_0\mathbb{X}\boldsymbol{\beta}_0$ is no longer independent of $\mathbb{X}$ and is not mean 0.

3.1 Verifying Strict Dual Feasibility

For $j \in S_0^c$ decompose

$$\mathbb{X}_{\cdot j}^\intercal = \boldsymbol{\Sigma}_{\{j\},S_0}\boldsymbol{\Sigma}_{S_0,S_0}^{-1}\mathbb{X}_{\cdot S_0}^\intercal + \boldsymbol{E}_j^\intercal, \tag{11}$$

where the entries of the prediction error vector $\boldsymbol{E}_j = (E_{1j}, \ldots, E_{nj})^\intercal \in \mathbb{R}^n$ are i.i.d. with $E_{ij} \sim \mathcal{N}(0, [\boldsymbol{\Sigma}_{S_0^c|S_0}]_{jj}), i \in [n]$. In addition, observe that by this construction we have that $\boldsymbol{E}_j$ is independent of $\mathbb{X}_{\cdot S_0}$ which can be verified upon multiplication by $\mathbb{X}_{\cdot S_0}$ in (11) and taking expectation. Following the definition of Z_j gives us that $Z_j = A_j + B_j$, where:

$$A_j := \boldsymbol{E}_j^\intercal\left[\mathbb{X}_{\cdot S_0}(\mathbb{X}_{\cdot S_0}^\intercal\mathbb{X}_{\cdot S_0})^{-1}\check{\mathbf{z}}_{S_0} + \mathbf{P}_{\mathbb{X}_{\cdot S_0}^\perp}\left(\frac{\mathbf{w}}{\lambda n}\right)\right], \tag{12}$$

$$B_j := \boldsymbol{\Sigma}_{\{j\},S_0}(\boldsymbol{\Sigma}_{S_0,S_0})^{-1}\check{\mathbf{z}}_{S_0}. \tag{13}$$

Under the irrepresentable condition, we have that $\max_{j\in S^c}|B_j| \leq (1-\kappa)$. Conditional on $\mathbb{X}_{\cdot S_0}$ and $\boldsymbol{\varepsilon}$ (which determine $\mathbf{w} = \boldsymbol{Y} - c_0\mathbb{X}\boldsymbol{\beta}_0$) we have that the gradient $\check{\mathbf{z}}_{S_0}$ is independent of the vector $\boldsymbol{E}_j$ because the gradient is deterministic after conditioning on these quantities. We have that $\mathrm{Var}(E_{ij}) \leq D_{\max}(\boldsymbol{\Sigma}_{S_0^c|S_0})$, and thus conditionally on $\mathbb{X}_{\cdot S_0}$ and $\boldsymbol{\varepsilon}$ we get:

$$\begin{aligned}\mathrm{Var}(A_j) &\leq D_{\max}(\boldsymbol{\Sigma}_{S_0^c|S_0})\left\|\mathbb{X}_{\cdot S_0}(\mathbb{X}_{\cdot S_0}^\intercal\mathbb{X}_{\cdot S_0})^{-1}\check{\mathbf{z}}_{S_0} + \mathbf{P}_{\mathbb{X}_{\cdot S_0}^\perp}\left(\frac{\mathbf{w}}{\lambda n}\right)\right\|_2^2 \\ &= D_{\max}(\boldsymbol{\Sigma}_{S_0^c|S_0})\left[\check{\mathbf{z}}_{S_0}^\intercal(\mathbb{X}_{\cdot S_0}^\intercal\mathbb{X}_{\cdot S_0})^{-1}\check{\mathbf{z}}_{S_0} + \left\|\mathbf{P}_{\mathbb{X}_{\cdot S_0}^\perp}\left(\frac{\mathbf{w}}{\lambda n}\right)\right\|_2^2\right].\end{aligned}$$

Next we need a lemma, which is a slight modification of Lemma 4 in Wainwright (2009). The reason for this modification is that in our case $\mathbf{w}$ is no longer $\sim\mathcal{N}(0,\sigma^2\mathbb{I})$.

Lemma 3.1.1 *Assume that $\frac{s}{n} \leq \frac{1}{16}$. Then we have:*

$$\max_{j\in S_0^c}\mathrm{Var}(A_j) \leq \underbrace{D_{\max}(\boldsymbol{\Sigma}_{S_0^c|S_0})\left(\frac{4s}{\lambda_{\min}n} + \frac{\xi^2+1}{\lambda^2 n}\right)}_{M},$$

with probability at least $1 - 2e^{-s/2} - n^{-1}\theta^2$.

Now since conditionally on $\mathbb{X}_{\cdot S_0}$ and $\boldsymbol{\varepsilon}$ we have $A_j \sim \mathcal{N}(0, \mathrm{Var}(A_j))$, using a standard normal tail bound and the union bound we conclude:

$$\mathbb{P}(\max_{j\in S_0^c}|A_j| \geq \kappa) \leq 2(p-s)e^{-\frac{\kappa^2}{2M}} + 2e^{-\frac{s}{2}} + n^{-1}\theta^2.$$

We need to select M so that the exponential term is decaying in the above display. A sufficient condition for this is $\kappa^2/(2M) \geq 2\log(p-s)$. The last is equivalent to:

$$n_{p,s} \geq \frac{4D_{\max}(\boldsymbol{\Sigma}_{S_0^c|S_0})\left(\frac{4}{\lambda_{\min}} + \frac{\xi^2+1}{\lambda^2 s}\right)}{\kappa^2}.$$

3.2 Verifying Sign Consistency

The first part of the proof shows that the LASSO has a unique solution $\widehat{\boldsymbol{\beta}}$ which satisfies $S(\widehat{\boldsymbol{\beta}}) \subseteq S(c_0\boldsymbol{\beta}_0)$ with high probability. Now we need to verify the sign-consistency, in order to show that the supports coincide. We have the following:

$$\max_{j\in S_0}|\Delta_j| \leq \underbrace{\lambda\left\|(n^{-1}\mathbb{X}_{\cdot,S_0}^{\intercal}\mathbb{X}_{\cdot,S_0})^{-1}\operatorname{sign}(c_0\boldsymbol{\beta}_{0S_0})\right\|_{\infty}}_{\boldsymbol{I}_1} + \underbrace{\left\|(\mathbb{X}_{\cdot,S_0}^{\intercal}\mathbb{X}_{\cdot,S_0})^{-1}\mathbb{X}_{\cdot,S_0}^{\intercal}\mathbf{w}\right\|_{\infty}}_{\boldsymbol{I}_2}.$$

To deal with the first term we need the following:

Lemma 3.2.1 *There exist positive constants $K_1, C_2 > 0$, such that the following holds:*

$$\mathbb{P}(\boldsymbol{I}_1 \geq \lambda K_1\|\boldsymbol{\Sigma}_{S_0,S_0}^{-1/2}\|_{\infty,\infty}^2) \leq 4\exp(-C_2(s\wedge\log(p-s))),$$

The proof of this lemma is part of the proof of Theorem 3 in Wainwright (2009) and we omit the details. Next we turn to bounding the term $\boldsymbol{I}_2$. Here our proof departs substantially from the proof in Wainwright (2009), as $\boldsymbol{I}_2$ no longer has a simple structure required in the original argument. In our case $\mathbf{w}$ depends on $\mathbb{X}_{\cdot,S_0}$, and it is not mean 0. We will make usage of the following result, whose proof is provided in the appendix

Lemma 3.2.2 *Let $\|\boldsymbol{\beta}_0\|_2 = 1$. We have n i.i.d. observations $Y = f(\boldsymbol{X}_{S_0}^{\intercal}\boldsymbol{\beta}_{0S_0}, \varepsilon)$ from a SIM, where $\boldsymbol{X}_{S_0} \sim \mathcal{N}(0, \mathbb{I}_{s\times s})$, with $s < n$ and $n_{p,s} \geq \alpha > 0$ for some positive constant α. Then there exist some positive constants $\Upsilon_1, \Upsilon_2 > 0$ (depending on σ and $|c_0|$), such that:*

$$\|[\mathbb{X}_{\cdot,S_0}^{\intercal}\mathbb{X}_{\cdot,S_0}]^{-1}\mathbb{X}_{\cdot,S_0}^{\intercal}\boldsymbol{Y} - c_0\boldsymbol{\beta}_{0S_0}\|_{\infty} \leq \Big(\Upsilon_1\frac{s}{n}\|\boldsymbol{\beta}_{0S_0}\|_{\infty} + \Upsilon_2\sqrt{\frac{\log(p-s)}{n}}\Big).$$

with probability at least $1 - O\{e^{-s/2} + (\log p)^{-1} + n^{-1} + p^{-1}\}$. Denote for brevity the RHS of the inequality as $\delta(\|\boldsymbol{\beta}_{0S_0}\|_{\infty}, n, s, p)$.

While Lemma 3.2.2 is stated in terms of standard multivariate normal distribution $\mathcal{N}(0, \mathbb{I}_{s\times s})$, we can easily adapt it to more general situations where we observe non-standard normal random variables $\mathcal{N}(0, \boldsymbol{\Sigma}_{S_0,S_0})$. Recall that the rows of $\mathbb{X}_{\cdot,S_0}$ are distributed as $\mathcal{N}(0, \boldsymbol{\Sigma}_{S_0,S_0})$, $Y_i = f(\boldsymbol{X}_i^{\intercal}\boldsymbol{\beta}_0, \varepsilon)$, and $\boldsymbol{\beta}_{0S_0}^{\intercal}\boldsymbol{\Sigma}_{S_0,S_0}\boldsymbol{\beta}_{0S_0} = 1$. Denote with $\mathbf{Z} = \mathbb{X}_{\cdot,S_0}\boldsymbol{\Sigma}_{S_0,S_0}^{-1/2}$. Then we have the following inequality, with high probability:

$$\begin{aligned}\boldsymbol{I}_2 = \|[\mathbb{X}_{\cdot,S_0}^{\intercal}\mathbb{X}_{\cdot,S_0}]^{-1}\mathbb{X}_{\cdot,S_0}^{\intercal}\boldsymbol{Y} - c_0\boldsymbol{\beta}_{0S_0}\|_{\infty} &= \|\boldsymbol{\Sigma}_{S_0,S_0}^{-1/2}[\mathbf{Z}^{\intercal}\mathbf{Z}]^{-1}\mathbf{Z}^{\intercal}\boldsymbol{Y} - c_0\boldsymbol{\beta}_{0S_0}\|_{\infty}\\ &\leq \|\boldsymbol{\Sigma}_{S_0,S_0}^{-1/2}\|_{\infty,\infty}\|[\mathbf{Z}^{\intercal}\mathbf{Z}]^{-1}\mathbf{Z}^{\intercal}\boldsymbol{Y} - c_0\boldsymbol{\Sigma}_{S_0,S_0}^{1/2}\boldsymbol{\beta}_{0S_0}\|_{\infty}\\ &\leq \|\boldsymbol{\Sigma}_{S_0,S_0}^{-1/2}\|_{\infty,\infty}\delta(\|\boldsymbol{\Sigma}_{S_0,S_0}^{1/2}\boldsymbol{\beta}_{0S_0}\|_{\infty}, s, n, p).\end{aligned}$$

The last two inequalities imply that:

$$\max_{j\in S}|\Delta_j| \leq \lambda K_1\|\boldsymbol{\Sigma}_{S_0,S_0}^{-1/2}\|_{\infty,\infty}^2 + \|\boldsymbol{\Sigma}_{S_0,S_0}^{-1/2}\|_{\infty,\infty}\delta(\|\boldsymbol{\Sigma}_{S_0,S_0}^{1/2}\boldsymbol{\beta}_{0S_0}\|_{\infty}, s, n, p).$$

Hence as long as for $\boldsymbol{\beta}_0^{\min} = \min\{|\beta_{0j}| : j \in S_0\}$ we have:

$$|c_0|\boldsymbol{\beta}_0^{\min} \geq \lambda K_1\|\boldsymbol{\Sigma}_{S_0,S_0}^{-1/2}\|_{\infty,\infty}^2 + \|\boldsymbol{\Sigma}_{S_0,S_0}^{-1/2}\|_{\infty,\infty}\delta(\|\boldsymbol{\Sigma}_{S_0,S_0}^{1/2}\|_{\infty,\infty}\|\boldsymbol{\beta}_0\|_{\infty}, s, n, p),$$

the LASSO will recover the support with high-probability. This concludes the proof.

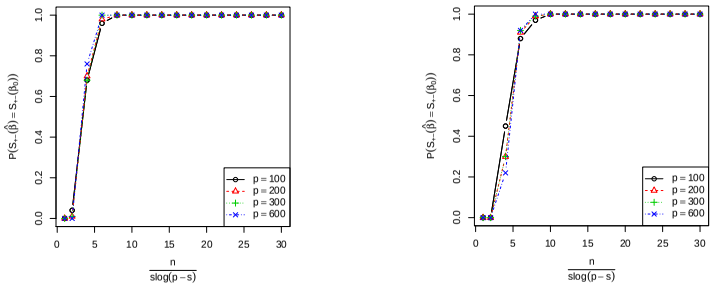
4. Numerical Studies

To support our theoretical claims, and in particular Theorem 2.3.4 we provide brief numeric analysis in this section. We consider the following models:

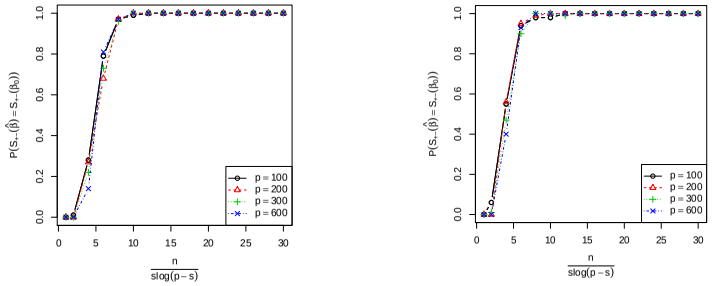
$$Y = \boldsymbol{X}^{\intercal}\boldsymbol{\beta}_0 + \sin(\boldsymbol{X}^{\intercal}\boldsymbol{\beta}_0) + \mathcal{N}(0,1), \tag{14}$$
$$Y = 2\operatorname{atan}(\boldsymbol{X}^{\intercal}\boldsymbol{\beta}_0) + \mathcal{N}(0,1), \tag{15}$$
$$Y = (\boldsymbol{X}^{\intercal}\boldsymbol{\beta}_0)^3 + \mathcal{N}(0,1), \tag{16}$$
$$Y = \sinh(\boldsymbol{X}^{\intercal}\boldsymbol{\beta}_0) + \mathcal{N}(0,1). \tag{17}$$

We use a Toeplitz covariance matrix for the simulations $\boldsymbol{\Sigma} = \mathbb{I}$ and $\Sigma_{kj} = 2^{-|k-j|}$. The vector $\boldsymbol{\beta}_0$ is selected so that $\boldsymbol{\beta}_0^{\intercal}\boldsymbol{\Sigma}\boldsymbol{\beta}_0 = 1$, and its entries have equal magnitude, with the first one having a negative sign, and the remaining being positive. We check whether the solution path of the LASSO contains an s-sparse vector $\boldsymbol{\beta}_0$ whose support coincides with the support of $\boldsymbol{\beta}_0$. This verifies the validity of one implication of our theory, as it shows that the solution path indeed contains the true signed support of $\boldsymbol{\beta}_0$.

Figure 1: LASSO, $s = \sqrt{p}$, $\boldsymbol{\Sigma} = \mathbb{I}_{p\times p}$



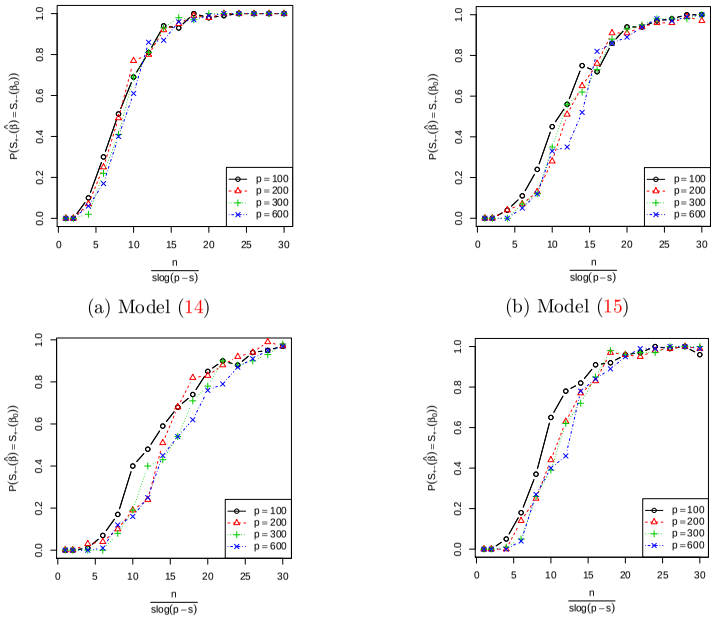
(a) Model (14) (b) Model (15)



(c) Model (16) (d) Model (17)

In Figure 1, we show results of signed support recovery for different values of p, in the regime $s = \sqrt{p}$ in the case of an identity covariance matrix $\mathbf{\Sigma} = \mathbb{I}_{p\times p}$. Similarly, Figure 2 shows results for the case of Toeplitz covaraince matrix $\Sigma_{kj} = 2^{-|k-j|}$. As expected, the support recovery is harder in the presence of correlation between the variables. These results illustrate different phase transitions occurring for the four different models. We observe empirically that values of $n_{p,s}$ achieving reasonable success probability can be large in some cases. It could be the case that using a transformed version of Y might lead to better results for the model complexity adjusted sample size, as suggested in Section 2.3.1. Figure 2 supports the result of Theorem 2.3.4 as all curves merge when the effective sample size $n_{p,s}$ becomes sufficiently large. In addition, these results suggest that the performance of the support recovery is largely determined by (n, p, s) through the magnitude of $n_{p,s}$.

Figure 2: LASSO, $s = \sqrt{p}$, $\Sigma_{kj} = 2^{-|k-j|}$



(a) Model (14) (b) Model (15)

(c) Model (16) (d) Model (17)

In addition to the verification of our theory, we also compare the vanilla least squares LASSO to a *version* of the sparse sliced inverse regression (SSIR) algorithm suggested by Li and Nachtsheim (2006). The SSIR algorithm is also based on a LASSO estimation. In its original form however, this algorithm is not applicable for high-dimensional settings such as ours, since it needs an estimate of the matrix $\mathbf{\Sigma}^{-1/2}$. To make use of the SSIR under the

high-dimensional setting, we estimate $\mathbf{\Sigma}^{-1/2}$ by the CLIME procedure (Cai et al., 2011) to $\widehat{\mathbf{\Sigma}}^{1/2}$ under sparsity assumptions. Due to space considerations we only show comparisons for models (14) and (17), and the plots are attached in Appendix F. In the majority of cases LASSO outperforms the SSIR algorithm substantially for small values of $n_{p,s}$, although it seems that both approaches reach perfect support recovery at similar rescaled sample sizes. We would like to emphasize that the SSIR algorithm requires solving an extra optimization problem, and that furthermore, there are no theoretical results ensuring that SSIR in general recovers the support. On an important note, the SSIR algorithm is designed to estimate the central space of the more general class of multi-index models, which we do not discuss in the present paper. For a brief discussion on how our work can be related to multi-index model please refer to section 5.

5. Discussion

In this paper, we demonstrate that under a high dimensional SIM, L_1-regularized least squares, including a simplified covariance screening procedure under orthogonal design, is robust in terms of model selection consistency, in that it correctly recovers the support of the true regression parameter $\boldsymbol{\beta}_0$ provided that $c_0 = \mathbb{E}(Y\boldsymbol{X}^\intercal\boldsymbol{\beta}_0) \neq 0$, the minimal signal strength is sufficiently large and $\boldsymbol{X} \sim \mathcal{N}(0, \mathbf{\Sigma})$ under standard assumptions on $\mathbf{\Sigma}$ which are necessary even in the linear regression case. Thus, our results extend known results on the support recovery performance of LASSO under linear models to a much broader class of SIMs. We furthermore demonstrate that the support recovery is achieved in a sample size optimal $n_{p,s}$ manner within a certain class of SIMs.

As we indicated in section 2.3.1, the assumption $c_0 \neq 0$ does not always hold, and in addition it cannot be easily verified. A potential remedy for this approach will be to transform the Y variable. From theoretical point of view it is of interest to develop procedures which can adaptively estimate a "good" outcome transformation. Additionally, a downside of the L_1-regularization is the fact that the irrepresentable condition on the covariance matrix is unavoidable. This could potentially be remedied by using more general and non-convex penalties such as the SCAD penalty (Fan and Li, 2001). We focused on the setting with $\boldsymbol{X} \sim \mathcal{N}(0, \mathbf{\Sigma})$, however we suspect that the support recovery holds in more general cases where $\boldsymbol{X}$ comes from an elliptical distribution. It is less clear, however, whether sample size optimality continues to hold in such situations, as we crucially rely on the normality of $\boldsymbol{X}$, in particular when using Lemma A.0.1 which follows by Gordon's comparison theorem, and through numerous projection-independence properties which are characteristic of the Gaussian distribution.

The proposed method focuses on SIMs as the true underlying model. Extensions to incorporate general multi-index models are not straightforward. For the special case of multi-index models of the form

$$Y = \sum_{j=1}^{k} f_j(\boldsymbol{X}^\intercal\boldsymbol{\beta}_j, \varepsilon_j),$$

our method should also be able to recover the support, assuming that k is fixed and the vectors $\boldsymbol{\beta}_j$ have disjoint supports, and $\mathbb{E}(Y\boldsymbol{X}^\intercal\boldsymbol{\beta}_j) \neq 0$ for all $j \in [k]$. When applied to such a model, the LASSO estimate $\widehat{\boldsymbol{\beta}}$ will include the union of the supports of $\boldsymbol{\beta}_j$, provided that

sufficiently strong minimal signal (or sufficiently large sample size) and an irrepresantable condition are present. How to apply the LASSO algorithm for support recovery under the more general class of multi-index models warrants further research.

A note on the choice of the tuning parameter λ in practice is also in order. According to Remark 2.3.5 and optimal choice of λ may depend on the unknowable parameter ξ^2. A procedure which we found to work well in practice is based on simple cross validation. To find a good tuning parameter λ, from a grid of ℓ values of λ: $\{\lambda_1, \ldots, \lambda_\ell\}$ which are of $\sqrt{\frac{\log p}{n}}$ magnitude, we recommend using K-fold cross validation, and setting λ to the value minimizing the average least squares loss across (i.e. mean squared-error) the K folds. Notice that according to Lemma 2.1.3, this criteria is very sensible. An important question is whether one can arrive at a procedure with theoretical guarantees for λ selection, and we hope to address this problem in our future work.

Finally, under a SIM and proper distributional assumptions on $\boldsymbol{X}$, one may also recover $\boldsymbol{\beta}_0$ proportionally using other convex loss functions. For example, when Y is binary, the logistic log-likelihood loss may be more efficient than the L_2 loss. Thus, it is of interest to investigate the support recovery properties of the LASSO (or more general penalization procedures) with other convex losses — such as the logistic/hinge losses, which could be less susceptible to outliers.

Acknowledgments

The authors would like to thank the Associate Editor and anonymous reviewers for their insightful remarks which led to the improvement of this manuscript. We are also grateful to Professor Noureddine El Karoui, who among other observations, brought to our attention that outcome transformations may be performed to facilitate the usage of LASSO even when $c_0 = 0$ for the original outcome Y. Appendix A. Auxiliary Lemmas

In this section, for convenience of the reader, we state couple of lemmas that we use often in our analysis.

Lemma A.0.1 (Corollary 5.35 Vershynin (2010)) *Let $\mathbf{A}_{n\times s}$ matrix whose entries are i.i.d. standard normal random variables. Then for every $t \geq 0$, with probability at least $1 - 2\exp(-t^2/2)$ one has:*

$$\sqrt{n} - \sqrt{s} - t \leq s_{\min}(\mathbf{A}) \leq s_{\max}(\mathbf{A}) \leq \sqrt{n} + \sqrt{s} + t,$$

where $s_{\min}(\mathbf{A})$ and $s_{\max}(\mathbf{A})$ are the smallest and largest singular values of $\mathbf{A}$ correspondingly.

Lemma A.0.2 *Consider a fixed nonzero vector $\mathbf{z} \in \mathbb{R}^s$ and a random matrix $\mathbf{A}_{n\times s}$, whose entries are i.i.d. standard normal random variables. If p, s, n are such that $s \geq 2$, $\frac{s}{n} \leq \frac{1}{64}$ and $\frac{\log p}{n-s+1} \leq \frac{1}{32}$, there are positive absolute constants C_1 and C_2 satisfying:*

$$\mathbb{P}\left(\|[(n^{-1}\mathbf{A}^\intercal\mathbf{A})^{-1} - \mathbb{I}_{s\times s}]\mathbf{z}\|_\infty \geq C_1\frac{s}{n}\|\mathbf{z}\|_\infty + C_2\|\mathbf{z}\|_2\sqrt{\frac{\log p}{n}} \right) \leq 4p^{-1}.$$

Proof [Proof of Lemma A.0.2] This Lemma is a generalization/modification of Lemma 5 of Wainwright (2009), allowing us to make usage of the L_2 norm $\|\mathbf{z}\|_2$ to obtain more precise bounds. For self-content we spell out the full details of the proof. Using the spectral theorem, decompose the matrix $(n^{-1}\mathbf{A}^\intercal\mathbf{A})^{-1} - \mathbb{I} = \mathbf{V}\mathbf{D}\mathbf{V}^\intercal$, where $\mathbf{D}$ is a diagonal matrix and $\mathbf{V}$ is an independent of $\mathbf{D}$ unitary matrix. Define the random variables:

$$U_i = \mathbf{e}_i^\intercal\mathbf{V}\mathbf{D}\mathbf{V}^\intercal\mathbf{z} = z_i\mathbf{v}_i^\intercal\mathbf{D}\mathbf{v}_i + \mathbf{v}_i^\intercal\mathbf{D}\sum_{j\neq i} z_j\mathbf{v}_j,$$

where $\mathbf{v}_i^\intercal$ is the i^{th} row vector of the matrix $\mathbf{V}$. To bound $\max_i |U_i|$ we deal with these two terms in turn. First notice that $\mathbf{v}_i^\intercal\mathbf{D}\mathbf{v}_i$ is the i^{th} diagonal entry of the matrix $(n^{-1}\mathbf{A}^\intercal\mathbf{A})^{-1} - \mathbb{I}$. By the assumption $(\mathbf{A}^\intercal\mathbf{A})^{-1} \sim \mathcal{W}^{-1}(\mathbb{I}_{s\times s}, n)$ where $\mathcal{W}^{-1}$ is an inverse Wishart distribution. By the properties of the inverse Wishart distribution we conclude that $\mathbf{v}_i^\intercal\mathbf{D}\mathbf{v}_i \sim n\chi^{-2}(n-s+1) - 1$, where χ^{-2} is the inverse χ^2 distribution. Hence using Lemma 1 of Laurent and Massart (2000) and the union bound we have:

$$\mathbb{P}(\max_i |1 - ((\mathbf{v}_i^\intercal\mathbf{D}\mathbf{v}_i + 1)(n-s+1)/n)^{-1}| \geq 2\sqrt{y} + 2y) \leq 2s\exp(-(n-s+1)y).$$

Selecting $y = \frac{2\log p}{n-s+1}$ bounds the above probability by $2s/p^2 \leq 2/p$. For values of $y < 1/32$ we can lump $2\sqrt{y} + 2y < \left(2 + \frac{\sqrt{2}}{4}\right)\sqrt{y}$. Thus inverting the inequality inside the probability we conclude that for each $i \in [s]$:

$$\frac{n}{(n-s+1)(1 + \left(2+\frac{\sqrt{2}}{4}\right)\sqrt{\frac{2\log p}{n-s+1}})} \leq \mathbf{v}_i^\intercal\mathbf{D}\mathbf{v}_i + 1 \leq \frac{n}{(n-s+1)(1 - \left(2+\frac{\sqrt{2}}{4}\right)\sqrt{\frac{2\log p}{n-s+1}})}$$

It is simple to see that when $\frac{\log(p)}{n-s+1} \leq \frac{1}{32}$ the above implies:

$$\max_i |z_i \mathbf{v}_i^\mathsf{T} \mathbf{D} \mathbf{v}_i| < \|\mathbf{z}\|_\infty \widetilde{c}_1 \frac{s}{n-s} + \|\mathbf{z}\|_2 \widetilde{c}_2 \sqrt{\frac{\log p}{n-s+1}}, \tag{18}$$

where $\widetilde{c}_1 = (1-(1/2+\sqrt{2}/16))^{-1}$ and $\widetilde{c}_2 = (2+\sqrt{2}/4)\widetilde{c}_1$. Next we show that the function $F(\mathbf{v}_i) = \mathbf{v}_i^\mathsf{T} \mathbf{D} \sum_{j \neq i} z_j \mathbf{v}_j$ is Lipschitz with a constant $8\sqrt{s/n}\|\mathbf{z}\|_2$. We have:

$$\|\nabla F\|_2 \leq \|\mathbf{D}\|_{2,2} \Big\| \sum_{j \neq i} z_j \mathbf{v}_j \Big\|_2 \leq 9\sqrt{\frac{s}{n}} \|\mathbf{z}\|_2,$$

with the last inequality holding with probability at least $1 - 2\exp(-s/2)$ when $\frac{s}{n} \leq \frac{1}{64}$. We used that $\mathbf{v}_j$ are orthonormal, and we bounded the maximum eigenvalue of $\mathbf{D}$, which follows just as in the proof of Lemma E.0.2 so we omit the details. Since the variables $\{\mathbf{v}_j\}_{j \neq i}$ are uniformly distributed on a $(s-1)$-dimensional sphere, the proof is completed by invoking the concentration of Lipschitz functions on the sphere to bound $\max_{i \in [s]} |F(\mathbf{v}_i)|$:

$$\mathbb{P}(\max_{i \in [s]} |F(\mathbf{v}_i)| \geq t) \leq 2s \exp\left(-\widetilde{c}(s-1) \frac{t^2}{81 \frac{s}{n} \|\mathbf{z}\|_2^2} \right),$$

for an absolute constant $\widetilde{c}$. Under the assumption $s \geq 2$, we can select $t = 18\|\mathbf{z}\|_2 \sqrt{\frac{\log p}{\widetilde{c} n}}$ and taking into account that $p > s$ completes the proof, after noticing that we can absorb the second term of (18) to the above expression. ■

Appendix B. Preliminary Results

Proof [Proof of Lemma 2.1.3] First let $\mathbf{\Sigma} = \mathbb{I}_{p \times p}$ (hence by assumption $\|\boldsymbol{\beta}_0\|_2 = 1$) and take any $\boldsymbol{b} \perp \boldsymbol{\beta}_0$. Note that by the linearity of expectation:

$$\mathbb{E}[\boldsymbol{X}^\mathsf{T}\boldsymbol{\beta}_0 \boldsymbol{X}^\mathsf{T}\boldsymbol{b} | \boldsymbol{X}^\mathsf{T}\boldsymbol{\beta}_0] = c_{\boldsymbol{b}} (\boldsymbol{X}^\mathsf{T}\boldsymbol{\beta}_0)^2.$$

Taking another expectation above we have $\mathbb{E}[\boldsymbol{X}^\mathsf{T}\boldsymbol{\beta}_0 \boldsymbol{X}^\mathsf{T}\boldsymbol{b}] = c_{\boldsymbol{b}} \mathbb{E}[(\boldsymbol{X}^\mathsf{T}\boldsymbol{\beta}_0)^2]$. However

$$\mathbb{E}[\boldsymbol{X}^\mathsf{T}\boldsymbol{\beta}_0 \boldsymbol{X}^\mathsf{T}\boldsymbol{b}] = \boldsymbol{b}^\mathsf{T}\boldsymbol{\beta}_0 = 0,$$

and hence $c_{\boldsymbol{b}} = 0$. Thus if $\boldsymbol{b} \perp \boldsymbol{\beta}_0$, $\mathbb{E}[\boldsymbol{X}^\mathsf{T}\boldsymbol{b} | \boldsymbol{X}^\mathsf{T}\boldsymbol{\beta}_0] = 0$. Next, for any $\boldsymbol{b} \perp \boldsymbol{\beta}_0$ we have:

$$\mathbb{E}[Y \boldsymbol{X}^\mathsf{T}\boldsymbol{b}] = \mathbb{E}[\mathbb{E}[Y \boldsymbol{X}^\mathsf{T}\boldsymbol{b} | \boldsymbol{X}^\mathsf{T}\boldsymbol{\beta}_0]] = \mathbb{E}[\mathbb{E}[Y | \boldsymbol{X}^\mathsf{T}\boldsymbol{\beta}_0] \mathbb{E}[\boldsymbol{X}^\mathsf{T}\boldsymbol{b} | \boldsymbol{X}^\mathsf{T}\boldsymbol{\beta}_0]] = 0.$$

Hence $\mathbb{E}[Y\boldsymbol{X}] \propto \boldsymbol{\beta}_0$. Finally, a projection on $\boldsymbol{\beta}_0$ yields

$$c_0 \|\boldsymbol{\beta}_0\|_2^2 = \mathbb{E}[Y \boldsymbol{X}^\mathsf{T}\boldsymbol{\beta}_0].$$

This completes the proof in the case when $\mathbf{\Sigma} = \mathbb{I}_{p \times p}$. For the more general case observe that $Y = f(\boldsymbol{X}^\mathsf{T}\boldsymbol{\beta}_0, \varepsilon) = f(\boldsymbol{X}^\mathsf{T}\mathbf{\Sigma}^{-1/2}\mathbf{\Sigma}^{1/2}\boldsymbol{\beta}_0, \varepsilon)$, and thus by what we just saw we have:

$$\mathbb{E}[Y \mathbf{\Sigma}^{-1/2} \boldsymbol{X}] = c_0 \mathbf{\Sigma}^{1/2} \boldsymbol{\beta}_0,$$

which becomes what we wanted to show after multiplying by $\mathbf{\Sigma}^{-1/2}$ on the left. ■

Appendix C. Lower Bound

For two probability measures P and Q, which are absolutely continuous with respect to a third probability measure μ (i.e. $P, Q \ll \mu$), define their KL divergence by $D_{\mathrm{KL}}(P\|Q) = \int p \log \frac{p}{q} d\mu$, where $p = \frac{dP}{d\mu}$, $q = \frac{dQ}{d\mu}$.

Lemma C.0.1 *Assume conditions required in Proposition 2.3.6. In addition, let for any fixed $u, v \in \mathbb{R}$ and some positive constant Ξ, $f(u,\varepsilon)$ and $f(v,\varepsilon)$ satisfy*

$$D_{KL}(p(f(u,\varepsilon)) \| p(f(v,\varepsilon))) \leq \exp(\Xi(u-v)^2) - 1, \tag{19}$$

Then if

$$n_{p,s} < \frac{1}{8\Xi}, \quad \textit{and} \quad s \geq 8\Xi,$$

any algorithm recovering the support of $\boldsymbol{\beta}_0$ under (1) will have errors with probability at least $\frac{1}{2}$ asymptotically.

Proof [Proof of Lemma C.0.1] We start by constructing a set of $p-s$ vectors $\boldsymbol{B} = \{\boldsymbol{\beta}_1, \ldots, \boldsymbol{\beta}_{p-s}\}$, belonging to the parameter space $\{\boldsymbol{\beta} \in \mathbb{R}^p : \boldsymbol{\beta}^\mathsf{T}\mathbf{\Sigma}\boldsymbol{\beta} = 1, \|\boldsymbol{\beta}\|_0 = s, \frac{\boldsymbol{\beta}^{\min}}{\|\boldsymbol{\beta}\|_\infty} \geq c_{\mathbf{\Sigma}}\}$, for a sufficiently small (to be chosen) $c_{\mathbf{\Sigma}} > 0$, such that $\mathrm{Var}(\boldsymbol{X}^\mathsf{T}(\boldsymbol{\beta}_k - \boldsymbol{\beta}_j)) \leq \frac{4}{s}$ for all $k, j \in [p-s]$. Once this set is constructed we will use standard Fano type of argument to finish the proof.

Without loss of generality let us assume that $S_0 = [s]$. To construct the set $\boldsymbol{B}$, first focus on the sub-matrix $\mathbf{\Sigma}_{S_0,S_0}$. We take the s dimensional vector $\boldsymbol{\gamma} = a(1/\sqrt{s}, \ldots, 1/\sqrt{s}, 0)^\mathsf{T}$ where $a > 0$ is selected so that $\boldsymbol{\gamma}^\mathsf{T}\mathbf{\Sigma}_{S_0,S_0}\boldsymbol{\gamma} = \frac{s-1}{s}$. Since $\mathbf{\Sigma}_{S_0,S_0}$ is assumed to have bounded eigenvalues we know that such a indeed exists, and can be chosen in the interval $a \in [\frac{1}{2}\frac{1}{\sqrt{\lambda_{\max}}}, \frac{1}{\sqrt{\lambda_{\min}}}]$ for $s \geq 2$. Next to construct $\boldsymbol{\beta}_k$ we use:

$$\beta_{kr} = \gamma_r \mathbb{1}(r \in S_0) + b_k \mathbb{1}(r = k+s)/\sqrt{s},$$

where b_k is chosen so that $\boldsymbol{\beta}_k^\mathsf{T}\mathbf{\Sigma}\boldsymbol{\beta}_k = 1$. Below we argue that such b_k indeed exists. By Hölder's inequality we have $\|\mathbf{\Sigma}_{S_0,S_0}\boldsymbol{\gamma}\|_\infty \leq a\|\mathbf{\Sigma}_{S_0,S_0}\|_{\infty,\infty}/\sqrt{s} \leq aR/\sqrt{s}$. Hence using Assumption 2.3.1 we have:

$$\|\mathbf{\Sigma}_{S_0^c,S_0}\mathbf{\Sigma}_{S_0,S_0}^{-1}\mathbf{\Sigma}_{S_0,S_0}\boldsymbol{\gamma}\|_\infty \leq \|\mathbf{\Sigma}_{S_0^c,S_0}\mathbf{\Sigma}_{S_0,S_0}^{-1}\|_{\infty,\infty} aR/\sqrt{s} \leq (1-\kappa)aR/\sqrt{s}.$$

Note that due to the last inequality, for any $k \in [p-s]$ we have:

$$\boldsymbol{\beta}_k^\mathsf{T}\mathbf{\Sigma}\boldsymbol{\beta}_k = \boldsymbol{\gamma}^\mathsf{T}\mathbf{\Sigma}_{S_0,S_0}\boldsymbol{\gamma} + 2\mathbf{\Sigma}_{\{k+s\},S_0}\boldsymbol{\gamma}\frac{b_k}{\sqrt{s}} + \frac{b_k^2\Sigma_{k+s,k+s}}{s} \leq \frac{s-1}{s} + 2\frac{(1-\kappa)a|b_k|R}{s} + \frac{b_k^2\Sigma_{k+s,k+s}}{s},$$

where we remind the reader that $k+s \in S_0^c$. We chose b_k such that $\mathrm{sign}(b_k) = \mathrm{sign}(\mathbf{\Sigma}_{\{k+s\},S_0}\boldsymbol{\gamma})$. Hence we also have:

$$\frac{s-1}{s} + \frac{b_k^2\Sigma_{k+s,k+s}}{s} \leq \boldsymbol{\beta}_k^\mathsf{T}\mathbf{\Sigma}\boldsymbol{\beta}_k.$$

Combining the last two inequalities we conclude that there exists:

$$|b_k| \in \Big[\frac{\sqrt{(1-\kappa)^2a^2R^2 + \Sigma_{k+s,k+s}} - (1-\kappa)aR}{\Sigma_{k+s,k+s}}, \Sigma_{k+s,k+s}^{-1/2} \Big],$$

with the desired properties. One can easily check that when:

$$c_{\boldsymbol{\Sigma}} \leq \min\left(\frac{1}{2}\sqrt{\frac{d}{\lambda_{\max}}}, \frac{\sqrt{(1-\kappa)^2R^2 + d\lambda_{\min}} - (1-\kappa)R}{D}\right), \tag{20}$$

we have that $\min_{j\in[p-s]} \frac{\boldsymbol{\beta}_j^{\min}}{\|\boldsymbol{\beta}_j\|_\infty} \geq c_{\boldsymbol{\Sigma}}$, and in addition as we promised we have:

$$\mathrm{Var}(\boldsymbol{X}^\mathsf{T}(\boldsymbol{\beta}_k - \boldsymbol{\beta}_j)) = \frac{\Sigma_{k+s,k+s}b_k^2 - 2\Sigma_{k+s,j+s}b_kb_j + \Sigma_{j+s,j+s}b_j^2}{s} \leq \frac{4}{s}.$$

Next, let $\mathcal{J}$ be a uniform distribution on $\boldsymbol{B}$. Under the $0-1$ loss the risk equals the probability of error:

$$\frac{1}{p-s}\sum_{j\in[p-s]} P_{\boldsymbol{\beta}_j}\{\widehat{S} \neq S(\boldsymbol{\beta}_j)\}, \tag{21}$$

where by $P_{\boldsymbol{\beta}_j}$ we are measuring the probability under a dataset generated with $\boldsymbol{\beta}_j$, and $\widehat{S}$ is an estimate of the true support produced by any (possibly randomized) algorithm. By Fano's inequality that:

$$\mathbb{P}(\text{error}) \geq 1 - \frac{\mathcal{I}(\mathcal{J};\mathcal{D}) + \log(2)}{\log|\boldsymbol{B}|}, \tag{22}$$

where $\mathcal{I}(\mathcal{J};\mathcal{D})$ is the mutual information between the sample $\mathcal{J}$ and the sample $\mathcal{D}$. Note now that for the mutual information we have

$$\begin{aligned}\mathcal{I}(\mathcal{J};\mathcal{D}) &= \mathcal{I}(\mathcal{J};[\{f(\boldsymbol{X}_j^\mathsf{T}\boldsymbol{\beta}_0,\varepsilon_j),\boldsymbol{X}_j\}, j=1,\ldots,n]) \\ &\leq n\mathcal{H}[\{f(\boldsymbol{X}^\mathsf{T}\boldsymbol{\beta}_0,\varepsilon),\boldsymbol{X}\}] - n\mathcal{H}[\{f(\boldsymbol{X}^\mathsf{T}\boldsymbol{\beta}_0,\varepsilon),\boldsymbol{X}\}|\mathcal{J}] \\ &\leq n\max_{k,j\in[p-s]} D_{\mathrm{KL}}\big(p[\{f(\boldsymbol{X}^\mathsf{T}\boldsymbol{\beta}_k,\varepsilon),\boldsymbol{X}\}]\|p[\{f(\boldsymbol{X}^\mathsf{T}\boldsymbol{\beta}_j,\varepsilon),\boldsymbol{X}\}]\big),\end{aligned}$$

where $\mathcal{H}(\cdot)$ denotes the marginal entropy, $\mathcal{H}(\cdot\mid\cdot)$ denotes the conditional entropy, D_{KL} denotes the KL divergence, the first inequality follows from the chain inequality of entropy and the second inequality follows from a standard bound. Since the KL divergence is invariant under change of variables, we let $U_k = \boldsymbol{X}^\mathsf{T}\boldsymbol{\beta}_k$ and $\boldsymbol{W}_{kj} = \mathbf{P}_{\boldsymbol{\Sigma},\{\boldsymbol{\beta}_k,\boldsymbol{\beta}_j\}^\perp}\boldsymbol{X}$, where $\mathbf{P}_{\boldsymbol{\Sigma},\{\boldsymbol{\beta}_k,\boldsymbol{\beta}_j\}^\perp} \in \mathbb{R}^{(p-2)\times p}$ is chosen such that $\mathbf{P}_{\boldsymbol{\Sigma},\{\boldsymbol{\beta}_k,\boldsymbol{\beta}_j\}^\perp}\boldsymbol{\Sigma}\boldsymbol{\beta}_k = 0$ and $\mathbf{P}_{\boldsymbol{\Sigma},\{\boldsymbol{\beta}_k,\boldsymbol{\beta}_j\}^\perp}\boldsymbol{\Sigma}\boldsymbol{\beta}_j = 0$. Noting that $\boldsymbol{W}_{kj}$ is independent of $U_k, U_j, \varepsilon, U_k - U_j \sim \mathcal{N}(0,V)$ with $V \leq 4/s$, and applying assumption (19), we have

$$\begin{aligned}n^{-1}\mathcal{I}(\mathcal{J};\mathcal{D}) &\leq \max_{k,j\in[p-s]} D_{\mathrm{KL}}\big(p[\{f(U_k,\varepsilon),U_k,U_j\}]\|p[\{f(U_j,\varepsilon),U_k,U_j\}]\big) \\ &\leq \max_{k,j\in[p-s]} \mathbb{E}\exp(\Xi(U_k-U_j)^2) - 1 \leq \sqrt{\frac{s}{s-8\Xi}} - 1 \leq \frac{8\Xi}{s}.\end{aligned}$$

where the second inequality can be obtained by conditioning on U_k, U_j, and we assume that the value of s is large enough so that $s \geq 16\Xi$. We conclude that:

$$\mathcal{I}(\mathcal{J};\mathcal{D}) \leq \frac{8\Xi n}{s}.$$

Consequently by (22) if $n_{p,s} < 1/(8\Xi)$ we will have errors with probability at least $\frac{1}{2}$, asymptotically. This is what we wanted to show. ■

Proof [Proof of Proposition 2.3.6] Note that all moments of the random variable ε exist. Next we verify that condition (19) of Lemma C.0.1 holds in this setup. Since G is 1-1 and KL divergence is invariant under changes of variables WLOG we can assume our model is simply $Y = h(\boldsymbol{X}^\mathsf{T}\boldsymbol{\beta}_0) + \varepsilon$ or in other words $f(u,\varepsilon) = h(u) + \varepsilon$. This is a location family for $u \in \mathbb{R}$ and thus the normalizing constant of the densities will stay the same regardless of the value of u. Direct calculation yields:

$$D_{\mathrm{KL}}[p\{f(u,\varepsilon)\}\|p\{f(v,\varepsilon)\}] = \mathbb{E}[P((\xi + h(u) - h(v))^2) - P(\xi^2)] = \widetilde{P}((h(u)-h(v))^2),$$

where ξ has a density $p_\xi(x) \propto \exp(-P(x^2))$, and $\widetilde{P}$ is another non-zero polynomial with nonnegative coefficients, with $\widetilde{P}(0) = 0$ of the same degree as P. The last observation follows from the fact that all odd moments of ξ are 0, since ξ is a symmetric about 0 distribution. Since h is L-Lipschitz we conclude that:

$$D_{\mathrm{KL}}[p\{f(u,\varepsilon)\}\|p\{f(v,\varepsilon)\}] \leq \widetilde{P}(L^2(u-v)^2).$$

The last can be clearly dominated by $\exp(C(u-v)^2) - 1$ for a large enough constant C. ■

Appendix D. Covariance Thresholding

Proof [Proof of Proposition 2.2.3] Using the fact that for any two random variables R, T we have $\|RT\|_{\psi_1} \leq 2\|R\|_{\psi_2}\|T\|_{\psi_2}$ we can conclude that the random vector $Y\boldsymbol{X}$ is coordinate-wise sub-exponentially distributed since $\sup_{j\in[p]}\|YX_j\|_{\psi_1} \leq \mathcal{K} := 2K_YK$. An application of Proposition 5.16 of Vershynin (2010) and the union bound then gives us that:

$$\mathbb{P}\left(\left\|\frac{1}{n}\sum_{i=1}^n Y_i\boldsymbol{X}_i - \mathbb{E}[Y\boldsymbol{X}]\right\|_\infty \geq t\right) \leq 2p\exp\left[-\widetilde{c}\min\left(\frac{nt^2}{\mathcal{K}^2}, \frac{nt}{\mathcal{K}}\right)\right],$$

where $\widetilde{c} > 0$ is some absolute constant. This inequality then implies:

$$\sup_{j\in[p]}\left|\frac{1}{n}\sum_{i=1}^n Y_iX_{ij} - \mathbb{E}(YX_j)\right| \leq \mathcal{K}\sqrt{\frac{2\log p}{\widetilde{c}n}},$$

with probability at least $1 - 2p^{-1}$ for values of n, p such that $\frac{\log p}{n} \leq \frac{\widetilde{c}}{2}$. Note that the inequality in the preceding display implies that if:

$$\frac{|c_0|}{\sqrt{s}} > R\mathcal{K}\sqrt{\frac{2\log p}{\widetilde{c}n}},$$

for any $R > 2$ there will be a gap in the absolute values of the coefficients of $U_j = |n^{-1}\sum_{i=1}^n Y_iX_{ij}|$ for $j \in S_0$ and $j \notin S_0$. The latter happens because:

$$\frac{|c_0|}{\sqrt{s}} - \mathcal{K}\sqrt{\frac{2\log p}{\widetilde{c}n}} \geq (R-1)\mathcal{K}\sqrt{\frac{2\log p}{\widetilde{c}n}} > \mathcal{K}\sqrt{\frac{2\log p}{\widetilde{c}n}}.$$

This also shows that the coefficients will achieve the correct sign. Thus, as long as $\frac{n}{s\log p} \geq \Upsilon$, for $\Upsilon = \frac{2R^2K^2}{c_0^2\tilde{c}^2}$ signed support recovery happens with asymptotic probability 1. Under our assumption the latter is implied by $n_{p,s} > \Upsilon/\iota$ which completes the proof. ■

Proof [Proof of Proposition 2.2.1] We follow the same steps as the proof of Proposition 2.2.3. We will use the following Lemma which we justify after the proof:

Lemma D.0.1 *Let us observe n data points from the model described in Proposition 2.2.1 with $\boldsymbol{\beta}$ being an arbitrary unit vector. Then with probability at least $1 - \frac{\eta}{n\sigma^4} - \frac{\gamma}{\log p} - \frac{2}{p}$ the following event holds:*

$$\left\| \frac{1}{n}\sum_{i=1}^{n} Y_i \boldsymbol{X}_i - \mathbb{E}(Y\boldsymbol{X}) \right\|_\infty \leq \left(\|\boldsymbol{\beta}_0\|_\infty + 2\sqrt{2\sigma^2} \right) \sqrt{\frac{\log p}{n}}.$$

Using the fact that in our case $\mathbb{E}(Y\boldsymbol{X}) = c_0\boldsymbol{\beta}_0$, and that $\|\boldsymbol{\beta}_0\|_\infty = \frac{1}{\sqrt{s}}$, we have that if:

$$\left(\|\boldsymbol{\beta}_0\|_\infty + 2\sqrt{2\sigma^2} \right) \sqrt{\frac{\log p}{n}} \leq (1 + 2\sqrt{2}\sigma)\frac{1}{\sqrt{s}} \sqrt{\frac{s\log p}{n}} < \frac{|c_0|}{2}\frac{1}{\sqrt{s}}$$

there will be a gap between the coefficients corresponding to $j \in S_0 := S(\boldsymbol{\beta}_0)$ and $j \notin S_0$. Note that the last inequality holds if $\frac{s\log p}{n} < \frac{c_0^2}{4(1+2\sqrt{2}\sigma)^2}$. ■

Remark D.0.2 *The slow convergence in probability rate $(\log p)^{-1}$ observed in Lemma D.0.1 is due to the fact that we are not requiring that Y is sub-Gaussian. If we do require it, the convergence rate of the probability can be seen to reduce to the usual p^{-1} level.*

Proof [Proof of Lemma D.0.1] Note that, sub-exponential concentration bounds do not apply in this case. However, observe that by the properties of the multivariate normal distribution the random variable $(\mathbb{I} - \boldsymbol{\beta}_0\boldsymbol{\beta}_0^\intercal)\boldsymbol{X}$ is independent of $\boldsymbol{X}^\intercal\boldsymbol{\beta}_0$ and hence is independent of Y. Furthermore it is clear that the random variable $Y(\mathbb{I} - \boldsymbol{\beta}_0\boldsymbol{\beta}_0^\intercal)\boldsymbol{X}$ has mean 0. Note that conditional on $Y_i, i \in [n]$ we have that $\frac{1}{n}\sum_{i=1}^n Y_i(\mathbb{I} - \boldsymbol{\beta}_0\boldsymbol{\beta}_0^\intercal)\boldsymbol{X}_i \sim \mathcal{N}(0, n^{-2}\sum_{i=1}^n Y_i^2(\mathbb{I} - \boldsymbol{\beta}_0\boldsymbol{\beta}_0^\intercal))$. Thus by a standard Gaussian tail bound:

$$\mathbb{P}\left(\left\| \frac{1}{n}\sum_{i=1}^{n} Y_i(\mathbb{I} - \boldsymbol{\beta}_0\boldsymbol{\beta}_0^\intercal)\boldsymbol{X}_i \right\|_\infty \geq t \middle| \boldsymbol{Y} \right) \leq 2p\exp\left[-\frac{nt^2}{2\overline{Y^2}} \right],$$

where $\overline{Y^2} = n^{-1}\sum_{i=1}^n Y_i^2$, and we used that $\|\mathbb{I} - \boldsymbol{\beta}_0\boldsymbol{\beta}_0^\intercal\|_{2,2} \leq 1$. By Chebyshev's inequality $\mathbb{P}(|\overline{Y^2} - \sigma^2| \geq r) \leq \frac{\eta}{nr^2}$. Hence selecting $r = \sigma^2$ will keep the above probability going to 1 at rate $\frac{1}{n}$ and moreover for large n we have $\overline{Y^2} \leq 2\sigma^2$. Using this bound in the tail bound above yields that for a choice of $t = 2\sqrt{2\sigma^2\frac{\log p}{n}}$ the tail bound will go to 0 at rate $2p^{-1}$ as claimed.

Next consider controlling:

$$\mathbb{P}\left(\left\| \frac{1}{n}\sum_{i=1}^{n} Y_i\boldsymbol{\beta}_0\boldsymbol{\beta}_0^\intercal\boldsymbol{X}_i - c_0\boldsymbol{\beta}_0 \right\|_\infty \geq t \right) = \mathbb{P}\left(\left| \frac{1}{n}\sum_{i=1}^{n} Y_i\boldsymbol{X}_i^\intercal\boldsymbol{\beta}_0 - c_0 \right| \geq t/\|\boldsymbol{\beta}_0\|_\infty \right),$$

where recall that $\mathbb{E}(Y\boldsymbol{X}) = c_0\boldsymbol{\beta}_0$, and c_0 is defined in the main text. Applying Chebyshev's inequality once again we get that $t = \|\boldsymbol{\beta}_0\|_\infty\sqrt{\frac{\log p}{n}}$ suffices to keep the above probability going to 0. By the triangle inequality we conclude that, with probability going to 1:

$$\left\| \frac{1}{n}\sum_{i=1}^{n} Y_i\boldsymbol{X}_i - \mathbb{E}(Y\boldsymbol{X}) \right\|_\infty \leq \|\boldsymbol{\beta}_0\|_\infty\sqrt{\frac{\log p}{n}} + 2\sqrt{2\sigma^2\frac{\log p}{n}}.$$

This is what we claimed. ■

Appendix E. LASSO Support Recovery

Proof [Proof of Lemma 3.1.1] Note that since $\mathbf{P}_{\mathbb{X}_{,S_0}^\perp}$ is an orthogonal projection matrix it contracts length and hence:

$$\left\| \mathbf{P}_{\mathbb{X}_{,S_0}^\perp}\left(\frac{\mathbf{w}}{\lambda n} \right) \right\|_2^2 \leq \frac{\|\mathbf{w}\|_2^2}{\lambda^2 n^2}.$$

Next observe that $\mathbf{w} = \boldsymbol{Y} - c_0\mathbf{X}\boldsymbol{\beta}_0$ is a vector with non-zero mean. However, by Chebyshev's inequality we have:

$$\mathbb{P}\left(\left| \frac{\|\mathbf{w}\|_2^2}{n} - \xi^2 \right| \geq t \right) \leq \frac{\theta^2}{nt^2}.$$

Then setting $t = 1$ brings the above probability to 0 at a rate $\frac{\theta^2}{n}$. Next:

$$n^{-1}\check{\mathbf{z}}_{S_0}^\intercal(n^{-1}\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0})^{-1}\check{\mathbf{z}}_{S_0} \leq \frac{1}{\lambda_{\min}(1 - 2\sqrt{\frac{s}{n}})^2}\frac{\|\check{\mathbf{z}}_{S_0}\|_2^2}{n} \leq \frac{1}{\lambda_{\min}(1 - 2\sqrt{\frac{s}{n}})^2}\frac{s}{n},$$

with probability at least $1 - 2\exp(-s/2)$, where we used Lemma A.0.1. This completes the proof. ■

Proof [Proof of Lemma 3.2.2] First, we note the following decomposition:

$$[\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0}]^{-1}\mathbb{X}_{,S_0}^\intercal\boldsymbol{Y} - c_0\boldsymbol{\beta}_{0S_0} = (n[\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0}]^{-1} - \mathbb{I})n^{-1}\mathbb{X}_{,S_0}^\intercal\boldsymbol{Y} + (n^{-1}\mathbb{X}_{,S_0}^\intercal\boldsymbol{Y} - c_0\boldsymbol{\beta}_{0S_0}).$$

Note that the second term is mean 0. Applying Lemma D.0.1 gives us a bound on the second term. We next move on to consider the first term.

Consider a "symmetrization" transformation of the predictor matrix $\widetilde{\mathbb{X}}_{,S_0}^\intercal = (\mathbb{I} - \boldsymbol{\beta}_{0S_0}\boldsymbol{\beta}_{0S_0}^\intercal)\mathbb{X}_{,S_0}^\intercal + \boldsymbol{\beta}_{0S_0}\boldsymbol{\beta}_{0S_0}^\intercal\mathbb{X}_{,S_0}^{*\intercal}$, where $[\mathbb{X}_{,S_0}^*]_{n\times s}$ is an i.i.d. copy of $\mathbb{X}_{,S_0}$, or in other words the columns of $\mathbb{X}_{,S_0}^*$: $\boldsymbol{X}_j^* \sim \mathcal{N}(0, \mathbb{I}_{n\times n}), j = 1, \ldots, s$ and are independent of $\mathbb{X}_{,S_0}$. Note that in doing this

construction, we guarantee that $\widetilde{\mathbb{X}}_{,S_0}$ is independent of $\mathbb{X}^\intercal_{,S_0}\boldsymbol{\beta}_{0S_0}$. Now we further decompose the first term as follows:

$$\begin{aligned}(n[\mathbb{X}^\intercal_{,S_0}\mathbb{X}_{,S_0}]^{-1}-\mathbb{I})n^{-1}\mathbb{X}^\intercal_{,S_0}\boldsymbol{Y} &= \underbrace{(n[\mathbb{X}^\intercal_{,S_0}\mathbb{X}_{,S_0}]^{-1}-\mathbb{I})\boldsymbol{\beta}_{0S_0}\boldsymbol{\beta}^\intercal_{0S_0}n^{-1}\mathbb{X}^\intercal_{,S_0}\boldsymbol{Y}}_{\boldsymbol{I}_1}\\ &+\underbrace{n([\mathbb{X}^\intercal_{,S_0}\mathbb{X}_{,S_0}]^{-1}-[\widetilde{\mathbb{X}}^\intercal_{,S_0}\widetilde{\mathbb{X}}_{,S_0}]^{-1})(\mathbb{I}-\boldsymbol{\beta}_{0S_0}\boldsymbol{\beta}^\intercal_{0S_0})n^{-1}\mathbb{X}^\intercal_{,S_0}\boldsymbol{Y}}_{\boldsymbol{I}_2}\\ &+\underbrace{(n[\widetilde{\mathbb{X}}^\intercal_{,S_0}\widetilde{\mathbb{X}}_{,S_0}]^{-1}-\mathbb{I})n^{-1}\widetilde{\mathbb{X}}^\intercal_{,S_0}\boldsymbol{Y}}_{\boldsymbol{I}_3}\\ &-\underbrace{(n[\widetilde{\mathbb{X}}^\intercal_{,S_0}\widetilde{\mathbb{X}}_{,S_0}]^{-1}-\mathbb{I})\boldsymbol{\beta}_{0S_0}\boldsymbol{\beta}^\intercal_{0S_0}n^{-1}\mathbb{X}^{*\intercal}_{,S_0}\boldsymbol{Y}}_{\boldsymbol{I}_4}.\end{aligned}$$

We next deal with each of these terms separately. For the first and last terms we can directly apply Lemma A.0.2. Under the same event as in Lemma E.0.1, taking into account that $\|\boldsymbol{\beta}_{0S_0}\|_2=1$ we have that $\|([n^{-1}\mathbb{X}^\intercal_{,S_0}\mathbb{X}_{,S_0}]^{-1}-\mathbb{I})\boldsymbol{\beta}_{0S_0}\|_\infty \leq C_1\frac{s}{n}\|\boldsymbol{\beta}_{0S_0}\|_\infty + C_2\sqrt{\frac{\log p}{n}}$ and $\|([n^{-1}\widetilde{\mathbb{X}}^\intercal_{,S_0}\widetilde{\mathbb{X}}_{,S_0}]^{-1}-\mathbb{I})\boldsymbol{\beta}_{0S_0}\|_\infty \leq C_1\frac{s}{n}\|\boldsymbol{\beta}_{0S_0}\|_\infty + C_2\sqrt{\frac{\log p}{n}}$. Furthermore, $\boldsymbol{\beta}^\intercal_{0S_0}\mathbb{X}^\intercal_{,S_0}\boldsymbol{Y}/n$ is a mean c_0 random variable. Just as in the proof of Lemma D.0.1 by Chebyshev's inequality we have that with probability at least $1-\frac{\gamma}{\log p}$ we have $|\boldsymbol{\beta}^\intercal_{0S_0}\mathbb{X}^\intercal_{,S_0}\boldsymbol{Y}/n| \leq |c_0|+\sqrt{\frac{\log p}{n}}$.

Furthermore, notice that $n^{-1}\boldsymbol{\beta}^\intercal_{0S_0}\mathbb{X}^{*\intercal}_{,S_0}\boldsymbol{Y}$ is a mean 0 random variable. Conditionally on $\boldsymbol{Y}$ it has a $\mathcal{N}(0, n^{-2}\sum Y_i^2)$ distribution. With exactly the same argument as in the proof of Lemma D.0.1 we conclude that with probability at least $1-\frac{\eta}{n\sigma^4}-\frac{2}{p}$:

$$|n^{-1}\boldsymbol{\beta}^\intercal_{0S_0}\mathbb{X}^{*\intercal}_{,S_0}\boldsymbol{Y}| \leq 2\sqrt{\sigma^2\frac{\log p}{n}}.$$

Hence, combining the above results we obtain:

$$\|\boldsymbol{I}_1\|_\infty+\|\boldsymbol{I}_4\|_\infty \leq \left(C_1\frac{s}{n}\|\boldsymbol{\beta}_{0S_0}\|_\infty + C_2\sqrt{\frac{\log p}{n}}\right)\left(|c_0|+\sqrt{\frac{\log p}{n}}+2\sqrt{\sigma^2\frac{\log p}{n}}\right). \tag{23}$$

To deal with the term $\boldsymbol{I}_2$ first note that by Hölder's inequality we have:

$$\|\boldsymbol{I}_2\|_\infty \leq \|n([\mathbb{X}^\intercal_{,S_0}\mathbb{X}_{,S_0}]^{-1}-[\widetilde{\mathbb{X}}^\intercal_{,S_0}\widetilde{\mathbb{X}}_{,S_0}]^{-1})\|_{\infty,\infty}\|(\mathbb{I}-\boldsymbol{\beta}_{0S_0}\boldsymbol{\beta}^\intercal_{0S_0})n^{-1}\mathbb{X}^\intercal_{,S_0}\boldsymbol{Y}\|_\infty. \tag{24}$$

To deal with the first term we make usage of the following result:

Lemma E.0.1 *Suppose that s,n satisfy $\frac{s}{n}\leq\frac{1}{16}$. The following bound holds:*

$$\|[n^{-1}\mathbb{X}^\intercal_{,S_0}\mathbb{X}_{,S_0}]^{-1}-[n^{-1}\widetilde{\mathbb{X}}^\intercal_{,S_0}\widetilde{\mathbb{X}}_{,S_0}]^{-1}\|_{\infty,\infty} \leq 40\sqrt{s}\left(C_1\frac{s}{n}\|\boldsymbol{\beta}_{0S_0}\|_\infty+\widetilde{C}_2\sqrt{\frac{\log p}{n}}\right),$$

with probability at least $1-4\exp(-s/2)-\frac{12}{p}-\frac{4}{n}$, where $C_1>0$ and $\widetilde{C}_2=C_2+4$ are the same constants as in (23).

Note that the second term is a mean 0 random variable since $(\mathbb{I}-\boldsymbol{\beta}_{0S_0}\boldsymbol{\beta}^\intercal_{0S_0})\mathbb{X}_{,S_0}$ is independent of $\boldsymbol{Y}$. Just as in Lemma D.0.1 we can show that $\|(\mathbb{I}-\boldsymbol{\beta}_{0S_0}\boldsymbol{\beta}^\intercal_{0S_0})n^{-1}\mathbb{X}^\intercal_{,S_0}\boldsymbol{Y}\|_\infty \leq 2\sqrt{2\sigma^2\frac{\log p}{n}}$ with probability at least $1-\frac{2s}{p^2}\geq 1-\frac{2}{p}$ (this event is in fact a sub-event of the bounds of the first term $n^{-1}\mathbb{X}^\intercal_{,S_0}\boldsymbol{Y}-c_0\boldsymbol{\beta}_{0S_0}$). Lemma E.0.1 gives us a bound on $\|n([\mathbb{X}^\intercal_{,S_0}\mathbb{X}_{,S_0}]^{-1}-[\widetilde{\mathbb{X}}^\intercal_{,S_0}\widetilde{\mathbb{X}}_{,S_0}]^{-1})\|_{\infty,\infty}$ which in conjunction with the previous inequality suffices to control the term $\boldsymbol{I}_2$.

Finally, to deal with the term $\boldsymbol{I}_4$ we will make use of the following:

Lemma E.0.2 *Let $\frac{s}{n}\leq\frac{1}{64}$. Then there exists a constant $\Upsilon\asymp\sigma>0$, such that the term:*

$$\|(n[\widetilde{\mathbb{X}}^\intercal_{,S_0}\widetilde{\mathbb{X}}_{,S_0}]^{-1}-\mathbb{I})n^{-1}\widetilde{\mathbb{X}}^\intercal_{,S_0}\boldsymbol{Y}\|_\infty \leq \Upsilon\sqrt{\frac{\log p}{n}},$$

with probability at least $1-\frac{2}{p}-\frac{\eta}{n\sigma^4}-2\exp(-s/2)$.

Applying Lemma E.0.2 we have in conjunction with our previous bounds (23) and (24) we get:

$$\begin{aligned}\|[\mathbb{X}^\intercal_{,S_0}\mathbb{X}_{,S_0}]^{-1}\mathbb{X}^\intercal_{,S_0}\boldsymbol{Y}-c_0\boldsymbol{\beta}_{0S_0}\|_\infty &\leq \left(C_1\frac{s}{n}\|\boldsymbol{\beta}_{0S_0}\|_\infty+C_2\sqrt{\frac{\log p}{n}}\right)\left(|c_0|+\sqrt{\frac{\log p}{n}}+2\sqrt{\sigma^2\frac{\log p}{n}}\right)\\ &+80\sqrt{s}\left(C_1\frac{s}{n}\|\boldsymbol{\beta}_{0S_0}\|_\infty+\widetilde{C}_2\sqrt{\frac{\log p}{n}}\right)\sqrt{2\sigma^2\frac{\log p}{n}}\\ &+\Upsilon\sqrt{\frac{\log p}{n}}+\|\boldsymbol{\beta}_{0S_0}\|_\infty\sqrt{\frac{\log p}{n}}+2\sqrt{\sigma^2\frac{\log p}{n}},\end{aligned}$$

with probability at least $1-4\exp(-s/2)-\frac{4}{n}-\frac{18}{p}-2\frac{\eta}{n\sigma^4}-2\frac{\gamma}{\log p}$[5], which finishes the proof, after grouping terms and recalling the fact that $\log(p-s)\asymp\log p$. ■

Proof [Proof of Lemma E.0.1] We first compare $[n^{-1}\mathbb{X}^\intercal_{,S_0}\mathbb{X}_{,S_0}]^{-1}$ to $[n^{-1}\widetilde{\mathbb{X}}^\intercal_{,S_0}\mathbb{X}_{,S_0}+\boldsymbol{\beta}_{0S_0}\boldsymbol{\beta}^\intercal_{0S_0}]^{-1}$. The latter matrix might happen to be non-invertible but this is irrelevant for our proof as we argue below. Using Woodbury's matrix identity we have:

$$[n^{-1}\widetilde{\mathbb{X}}^\intercal_{,S_0}\mathbb{X}_{,S_0}+\boldsymbol{\beta}_{0S_0}\boldsymbol{\beta}^\intercal_{0S_0}]^{-1}-[n^{-1}\mathbb{X}^\intercal_{,S_0}\mathbb{X}_{,S_0}]^{-1}=\frac{[n^{-1}\mathbb{X}^\intercal_{,S_0}\mathbb{X}_{,S_0}]^{-1}\boldsymbol{\beta}_{0S_0}\boldsymbol{\beta}^\intercal_{0S_0}\mathbf{M}[n^{-1}\mathbb{X}^\intercal_{,S_0}\mathbb{X}_{,S_0}]^{-1}}{1-\boldsymbol{\beta}^\intercal_{0S_0}\mathbf{M}[n^{-1}\mathbb{X}^\intercal_{,S_0}\mathbb{X}_{,S_0}]^{-1}\boldsymbol{\beta}_{0S_0}},$$

where $\mathbf{M}=n^{-1}\mathbb{X}^\intercal_{,S_0}\mathbb{X}_{,S_0}-\mathbb{I}-n^{-1}\mathbb{X}^{*\intercal}_{,S_0}\mathbb{X}_{,S_0}$. Note that whenever the right hand side of Woodbury's identity is well defined, the matrix $n^{-1}\widetilde{\mathbb{X}}^\intercal_{,S_0}\mathbb{X}_{,S_0}+\boldsymbol{\beta}_{0S_0}\boldsymbol{\beta}^\intercal_{0S_0}$ is indeed invertible, and the inverse satisfies the above identity. As we argue below the right hand side is well defined (i.e. the denominator is non-zero) with high probability hence the proof goes through. Next we handle the term $\boldsymbol{\beta}^\intercal_{0S_0}\mathbf{M}[n^{-1}\mathbb{X}^\intercal_{,S_0}\mathbb{X}_{,S_0}]^{-1}$. By the triangle inequality have:

$$\|\boldsymbol{\beta}^\intercal_{0S_0}\mathbf{M}[n^{-1}\mathbb{X}^\intercal_{,S_0}\mathbb{X}_{,S_0}]^{-1}\|_\infty \leq \|\boldsymbol{\beta}^\intercal_{0S_0}([n^{-1}\mathbb{X}^\intercal_{,S_0}\mathbb{X}_{,S_0}]^{-1}-\mathbb{I})\|_\infty+\|\boldsymbol{\beta}^\intercal_{0S_0}n^{-1}\mathbb{X}^{*\intercal}_{,S_0}\mathbb{X}_{,S_0}[n^{-1}\mathbb{X}^\intercal_{,S_0}\mathbb{X}_{,S_0}]^{-1}\|_\infty.$$

5. Here we are recognizing the fact that the events of some probability bounds we derived above, in fact coincide.

For the first term Lemma A.0.2 is directly applicable. Applying this lemma gives us the existence of constants C_1 and C_2 such that:

$$\|([n^{-1}\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0}]^{-1}-\mathbb{I})\boldsymbol{\beta}_{0S_0}\|_\infty \leq C_1\frac{s}{n}\|\boldsymbol{\beta}_{0S_0}\|_\infty + C_2\sqrt{\frac{\log p}{n}},$$

with probability at least $1-4p^{-1}$. For the second term, we have that conditionally on $\mathbb{X}_{,S_0}$ it has a normal distribution: $\mathcal{N}(0, n^{-1}(n^{-1}\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0})^{-1})$. Since $\mathbb{X}_{,S_0}$ is standard normal, we can apply Lemma A.0.1 to claim that $\|n(\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0})^{-1}\|_{2,2} \leq \left(\frac{1}{1-\sqrt{\frac{s}{n}}-t}\right)^2$ with probability at least $1-2\exp(-nt^2/2)$. Taking $t=\sqrt{\frac{s}{n}}$ gives us that $\|n(\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0})^{-1}\|_{2,2} \leq \frac{1}{(1-2\sqrt{\frac{s}{n}})^2}$ with probability at least $1-2\exp(-s/2)$. Thus conditioning on this event, by a standard normal tail bound and a union bound we have:

$$\mathbb{P}(\|\boldsymbol{\beta}_{0S_0}^\intercal n^{-1}\mathbb{X}^{*\intercal}_{,S_0}\mathbb{X}_{,S_0}[n^{-1}\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0}]^{-1}\|_\infty \geq t) \leq 2s\exp\left(-t^2n\left(1-2\sqrt{\frac{s}{n}}\right)^2/2\right).$$

Selecting $t=4\sqrt{\frac{\log p}{n}}$, we get the probability above is bounded by $\frac{2s}{p^2}\leq\frac{2}{p}$ (where we used the assumption $\sqrt{\frac{s}{n}}\leq\frac{1}{4}$). So finally on the intersection event we have:

$$\|\boldsymbol{\beta}_{0S_0}^\intercal\mathbf{M}[n^{-1}\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0}]^{-1}\|_\infty \leq C_1\frac{s}{n}\|\boldsymbol{\beta}_{0S_0}\|_\infty + \widetilde{C}_2\sqrt{\frac{\log p}{n}},$$

with probability at least $1-6p^{-1}-2\exp(-s/2)$ where $\widetilde{C}_2=C_2+4$. Let us now consider the denominator:

$$\begin{aligned}
&1-\boldsymbol{\beta}_{0S_0}^\intercal\mathbf{M}[n^{-1}\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0}]^{-1}\boldsymbol{\beta}_{0S_0}\\
=&1-\boldsymbol{\beta}_{0S_0}^\intercal(\mathbb{I}-[n^{-1}\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0}]^{-1})\boldsymbol{\beta}_{0S_0}+n^{-1}\boldsymbol{\beta}_{0S_0}^\intercal\mathbb{X}^{*\intercal}_{,S_0}\mathbb{X}_{,S_0}[n^{-1}\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0}]^{-1}\boldsymbol{\beta}_{0S_0}\\
=&\boldsymbol{\beta}_{0S_0}^\intercal[n^{-1}\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0}]^{-1}\boldsymbol{\beta}_{0S_0}+n^{-1}\boldsymbol{\beta}_{0S_0}^\intercal\mathbb{X}^{*\intercal}_{,S_0}\mathbb{X}_{,S_0}[n^{-1}\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0}]^{-1}\boldsymbol{\beta}_{0S_0}.
\end{aligned}$$

Using Lemma A.0.1 we have $\lambda_{\min}([n^{-1}\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0}]^{-1}) \geq \frac{1}{(1+2\sqrt{\frac{s}{n}})^2} > \frac{1}{4}$ with the last bound holding since $\frac{s}{n}<\frac{1}{4}$. Hence $\boldsymbol{\beta}_{0S_0}^\intercal[n^{-1}\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0}]^{-1}\boldsymbol{\beta}_{0S_0}\geq\frac{1}{4}$. For the second term just as before, conditionally on $\mathbb{X}_{,S_0}$ we have

$$n^{-1}\boldsymbol{\beta}_{0S_0}^\intercal\mathbb{X}^{*\intercal}_{,S_0}\mathbb{X}_{,S_0}[n^{-1}\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0}]^{-1}\boldsymbol{\beta}_{0S_0} \sim \mathcal{N}(0, n^{-1}\boldsymbol{\beta}_{0S_0}^\intercal[n^{-1}\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0}]^{-1}\boldsymbol{\beta}_{0S_0}).$$

Then (given that $\|n(\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0})^{-1}\|_{2,2}\leq\frac{1}{(1-2\sqrt{\frac{s}{n}})^2}$) by a standard tail bound we have that the second term is $\leq 4\sqrt{\frac{\log n}{n}}$ with probability at least $1-\frac{2}{n}$. Putting everything together we have:

$$1-\boldsymbol{\beta}_{0S_0}^\intercal\mathbf{M}[n^{-1}\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0}]^{-1}\boldsymbol{\beta}_{0S_0}\geq\frac{1}{4}-4\sqrt{\frac{\log n}{n}}.$$

The last expression is clearly bigger than $\frac{1}{5}$ for large enough values of n. Hence we conclude that with high probability we have:

$$\begin{aligned}
&\|[n^{-1}\widetilde{\mathbb{X}}_{,S_0}^\intercal\mathbb{X}_{,S_0}+\boldsymbol{\beta}_{0S_0}\boldsymbol{\beta}_{0S_0}^\intercal]^{-1}-[n^{-1}\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0}]^{-1}\|_{\infty,\infty}\\
&\leq 5\|[n^{-1}\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0}]^{-1}\boldsymbol{\beta}_{0S_0}\|_1\|\boldsymbol{\beta}_{0S_0}^\intercal\mathbf{M}[n^{-1}\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0}]^{-1}\|_\infty
\end{aligned}$$

For the first term, by the definition of matrix $\|\cdot\|_{2,2}$ norm we further have:

$$\begin{aligned}
\|[n^{-1}\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0}]^{-1}\boldsymbol{\beta}_{0S_0}\|_1 &\leq \sqrt{s}\|[n^{-1}\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0}]^{-1}\boldsymbol{\beta}_{0S_0}\|_2 \leq \sqrt{s}\|\boldsymbol{\beta}_{0S_0}\|_2\|[n^{-1}\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0}]^{-1}\|_{2,2}\\
&\leq \frac{\sqrt{s}}{(1-2\sqrt{\frac{s}{n}})^2}.
\end{aligned}$$

Combining this inequality with our previous bound we get:

$$\|[n^{-1}\widetilde{\mathbb{X}}_{,S_0}^\intercal\mathbb{X}_{,S_0}+\boldsymbol{\beta}_{0S_0}\boldsymbol{\beta}_{0S_0}^\intercal]^{-1}-[n^{-1}\mathbb{X}_{,S_0}^\intercal\mathbb{X}_{,S_0}]^{-1}\|_{\infty,\infty} \leq \frac{5\sqrt{s}}{(1-2\sqrt{\frac{s}{n}})^2}\left(C_1\frac{s}{n}\|\boldsymbol{\beta}_{0S_0}\|_\infty+\widetilde{C}_2\sqrt{\frac{\log p}{n}}\right).$$

Next we show that $[n^{-1}\widetilde{\mathbb{X}}_{,S_0}^\intercal\mathbb{X}_{,S_0}+\boldsymbol{\beta}_{0S_0}\boldsymbol{\beta}_{0S_0}^\intercal]^{-1}$ is also close to $[n^{-1}\widetilde{\mathbb{X}}_{,S_0}^\intercal\widetilde{\mathbb{X}}_{,S_0}]^{-1}$. Another usage of Woodbury's matrix identity yields:

$$[n^{-1}\widetilde{\mathbb{X}}_{,S_0}^\intercal\mathbb{X}_{,S_0}+\boldsymbol{\beta}_{0S_0}\boldsymbol{\beta}_{0S_0}^\intercal]^{-1}-[n^{-1}\widetilde{\mathbb{X}}_{,S_0}^\intercal\widetilde{\mathbb{X}}_{,S_0}]^{-1} = \frac{[n^{-1}\widetilde{\mathbb{X}}_{,S_0}^\intercal\widetilde{\mathbb{X}}_{,S_0}]^{-1}\widetilde{\mathbf{M}}\boldsymbol{\beta}_{0S_0}\boldsymbol{\beta}_{0S_0}^\intercal[n^{-1}\widetilde{\mathbb{X}}_{,S_0}^\intercal\widetilde{\mathbb{X}}_{,S_0}]^{-1}}{1-\boldsymbol{\beta}_{0S_0}^\intercal[n^{-1}\widetilde{\mathbb{X}}_{,S_0}^\intercal\widetilde{\mathbb{X}}_{,S_0}]^{-1}\widetilde{\mathbf{M}}\boldsymbol{\beta}_{0S_0}},$$

where $\widetilde{\mathbf{M}}=n^{-1}\widetilde{\mathbb{X}}_{,S_0}^\intercal\widetilde{\mathbb{X}}_{,S_0}-\mathbb{I}-n^{-1}\widetilde{\mathbb{X}}_{,S_0}^\intercal\mathbb{X}_{,S_0}$. Note that since $\widetilde{\mathbb{X}}_{,S_0}^\intercal \perp\!\!\!\perp \mathbb{X}_{,S_0}\boldsymbol{\beta}_{0S_0}$, the same argument as before goes through. Combining the bounds with a triangle inequality completes the proof, using the fact that $\sqrt{\frac{s}{n}}\leq\frac{1}{4}$. ■

Proof [Proof of Lemma E.0.2] We first perform a singular value decomposition on the $\widetilde{\mathbb{X}}_{,S_0}=\mathbf{U}_{n\times s}\mathbf{D}_{s\times s}\mathbf{V}_{s\times s}^\intercal$ matrix. Note that since multiplying $\widetilde{\mathbb{X}}_{,S_0}$ by a unitary $s\times s$ matrix on the right, or by a unitary $n\times n$ matrix on the left doesn't change the distribution of $\widetilde{\mathbb{X}}_{,S_0}$ we conclude that the matrices $\mathbf{U},\mathbf{D}$ and $\mathbf{V}$ are independent. This representation gives us that $(n^{-1}\widetilde{\mathbb{X}}_{,S_0}^\intercal\widetilde{\mathbb{X}}_{,S_0})^{-1}-\mathbb{I}=\mathbf{V}(n\mathbf{D}^{-2}-\mathbb{I})\mathbf{V}^\intercal$. With this notation we can rewrite:

$$(n[\widetilde{\mathbb{X}}_{,S_0}^\intercal\widetilde{\mathbb{X}}_{,S_0}]^{-1}-\mathbb{I})n^{-1}\widetilde{\mathbb{X}}_{,S_0}^\intercal\boldsymbol{Y}=\mathbf{V}\underbrace{(n\mathbf{D}^{-2}-\mathbb{I})n^{-1/2}\mathbf{D}}_{\mathbf{W}}n^{-1/2}\mathbf{U}^\intercal\boldsymbol{Y}.$$

We recall that by construction $\widetilde{\mathbb{X}}_{,S_0}$ is independent of $\boldsymbol{Y}$. The elements of the matrix $\mathbf{W}$ can be bounded in a simple manner. We have $\|\mathbf{W}\|_{2,2}\leq\|(n\mathbf{D}^{-2}-\mathbb{I})\|_{2,2}\|n^{-1/2}\mathbf{D}\|_{2,2}$, and by Lemma A.0.1, as before we have: $\|(n\mathbf{D}^{-2}-\mathbb{I})\|_{2,2}\leq\frac{1}{(1-2\sqrt{\frac{s}{n}})^2}-1\leq\frac{4\sqrt{\frac{s}{n}}}{(1-2\sqrt{\frac{s}{n}})^2}$ and $\|n^{-1/2}\mathbf{D}\|_{2,2}\leq 1+2\sqrt{\frac{s}{n}}$ with probability at least $1-2\exp(-s/2)$. We will condition on the event $\|\mathbf{W}\|_{2,2}\leq\frac{4\sqrt{\frac{s}{n}}}{(1-2\sqrt{\frac{s}{n}})^2}(1+2\sqrt{\frac{s}{n}})<9\sqrt{\frac{s}{n}}$, with the last inequality holding for $\sqrt{\frac{s}{n}}\leq\frac{1}{8}$. Since every random variable in the above display is independent from $\mathbf{W}$, the distributions of $\mathbf{V},\mathbf{U}$ and $\boldsymbol{Y}$ stay unchanged under this conditioning. Let $\mathbf{e}_i$ be a unit vector with 1 on the i^{th} position. Since we are interested in bounding the $\|\cdot\|_\infty$ we will start with the following:

$$\mathbf{e}_i^\intercal(n[\widetilde{\mathbb{X}}_{,S_0}^\intercal\widetilde{\mathbb{X}}_{,S_0}]^{-1}-\mathbb{I})n^{-1}\widetilde{\mathbb{X}}_{,S_0}^\intercal\boldsymbol{Y}=\mathbf{v}_i^\intercal\mathbf{W}[n^{-1/2}\mathbf{U}^\intercal\boldsymbol{Y}],$$

where $\mathbf{v}_i^\intercal$ is the i^{th} row of the matrix $\mathbf{V}$. Condition on the vector $n^{-1/2}\mathbf{U}^\intercal\boldsymbol{Y}$. Since $\mathbf{v}_i$ is independent of $n^{-1/2}\mathbf{U}^\intercal\boldsymbol{Y}$ it follows that the distribution of $\mathbf{v}_i$ is uniform on the unit

sphere in $\mathbb{R}^s$. We next show that the function $F(\mathbf{v}_i) = \mathbf{v}_i^\intercal \mathbf{W}[n^{-1/2}\mathbf{U}^\intercal \boldsymbol{Y}]$ is Lipschitz. We have:

$$\|\nabla F\|_2 \leq \|\mathbf{W}\|_{2,2}\|n^{-1/2}\mathbf{U}^\intercal \boldsymbol{Y}\|_2 \leq 9\sqrt{\frac{s}{n}}n^{-1/2}\sqrt{\sum_{i=1}^{s}(\mathbf{u}_i^\intercal \boldsymbol{Y})^2}$$
$$\leq 9\sqrt{\frac{s}{n}}n^{-1/2}\|\boldsymbol{Y}\|_2,$$

where the last inequality follows from the fact that the vectors $\mathbf{u}_i$ are orthonormal and hence $\sum_{i=1}^{s}(\mathbf{u}_i^\intercal \boldsymbol{Y})^2 \leq \|\boldsymbol{Y}\|_2^2$. Since Y_i are assumed to have finite second moment, by Chebyshev's inequality we have that:

$$\mathbb{P}(|n^{-1}\|\boldsymbol{Y}\|_2^2 - \sigma^2| \geq t) \leq \frac{\eta}{nt^2}.$$

Selecting $t = \sigma^2$ is sufficient to keep the above probability going to 0, and furthermore for n large enough guarantees that $n^{-1}\|\boldsymbol{Y}\|_2^2 \leq 2\sigma^2$ and hence $n^{-1/2}\|\boldsymbol{Y}\|_2 \leq \sqrt{2}\sigma$. Thus conditional on this event the function F is Lipschitz with a constant equal to $\sqrt{2}9\sigma\sqrt{\frac{s}{n}}$. Since the expectation of the function F is 0, by concentration of measure for Lipschitz functions on the sphere (Ledoux, 2005; Ledoux and Talagrand, 2013), for any $t > 0$ we have:

$$\mathbb{P}(|F(\mathbf{v}_i)| \geq t\sigma) \leq 2\exp\left(-\widetilde{c}s\frac{t^2}{162\frac{s}{n}}\right),$$

for some absolute constant $\widetilde{c} > 0$. Taking a union bound the above becomes:

$$\mathbb{P}(\max_{i\in[s]}|F(\mathbf{v}_i)| \geq t\sigma) \leq 2s\exp\left(-\widetilde{c}\frac{t^2 n}{162}\right).$$

Selecting $t = 18\sqrt{\frac{\log p}{\widetilde{c}n}}$, keeps the probability vanishing at a rate faster than $2s/p^2 \leq 2/p$ and completes the proof. ■

Proof [Proof of Corollary 2.3.9] Tracing the proof of Theorem 2.3.4 we realize that it suffices to show the following two quantities remain well controlled under the usage of $\widehat{g}$:

i. $|n^{-1}\sum_{i=1}^{n}\boldsymbol{X}_i^\intercal\boldsymbol{\beta}_0\widehat{g}(Y_i) - c_0| \leq O(\sqrt{\log p/n})$,

ii. $n^{-1}\sum_{i=1}^{n}\widehat{g}^2(Y_i) = O(1)$,

with probability at least $1-O(p^{-1})$ and $1-O(n^{-1})$ correspondingly. To deal with i. observe that:

$$\left|n^{-1}\sum_{i=1}^{n}\boldsymbol{X}_i^\intercal\boldsymbol{\beta}_0\widehat{g}(Y_i) - c_0\right| \leq \left|n^{-1}\sum_{i=1}^{n}\boldsymbol{X}_i^\intercal\boldsymbol{\beta}_0 g(Y_i) - c_0\right| + \left|n^{-1}\sum_{i=1}^{n}\boldsymbol{X}_i^\intercal\boldsymbol{\beta}_0(g(Y_i) - \widehat{g}(Y_i))\right|$$
$$\leq \underbrace{\left|n^{-1}\sum_{i=1}^{n}\boldsymbol{X}_i^\intercal\boldsymbol{\beta}_0 g(Y_i) - c_0\right|}_{I_1}$$
$$+ \underbrace{\left\{n^{-1}\sum_{i=1}^{n}(\boldsymbol{X}_i^\intercal\boldsymbol{\beta}_0)^2\right\}^{1/2}\left\{n^{-1}\sum_{i=1}^{n}(\widehat{g}(Y_i) - g(Y_i))^2\right\}^{1/2}}_{I_2}.$$

The term I_1 remains controlled by the proof of Theorem 2.3.4, while for the term I_2 we have:

$$I_2 \leq O(\sqrt{\log p/n}),$$

with probability at least $1 - O(p^{-1})$, where we used the assumption on $\widehat{g}$ and the fact that the random variables $(\boldsymbol{X}_i^\intercal\boldsymbol{\beta}_0)^2 \sim \chi_1^2$ and hence concentrate exponentially about their mean — 1, by a standard tail bound (Boucheron et al., 2013).

Next, for ii., by the triangle inequality we have:

$$\sqrt{n^{-1}\sum_{i=1}^{n}\widehat{g}^2(Y_i)} \leq \sqrt{n^{-1}\sum_{i=1}^{n}g^2(Y_i)} + \sqrt{n^{-1}\sum_{i=1}^{n}(\widehat{g}(Y_i) - g(Y_i))^2}.$$

The first term is well controlled as before and is $O(1)$ with probability at least $1 - O(n^{-1})$ and the second term is at most $O(\sqrt{\log p/n})$ with probability at least $1 - O(p^{-1})$ by assumption which concludes the proof. ■

Proof [Proof of Proposition 2.3.8] First let g be such that $\mathbb{E}\{g(Y)\boldsymbol{X}^\intercal\boldsymbol{\beta}_0\} \neq 0$. Recall that $\mathbb{E}(\boldsymbol{X}^\intercal\boldsymbol{\beta}_0) = 0$. Hence by Cauchy-Schwartz we have:

$$0 < [\mathbb{E}\{g(Y)\boldsymbol{X}^\intercal\boldsymbol{\beta}_0\}]^2 = (\mathbb{E}[g(Y)\mathbb{E}\{\boldsymbol{X}^\intercal\boldsymbol{\beta}_0|Y\}])^2 \leq \mathrm{Var}\{g(Y)\}\,\mathrm{Var}\{\mathbb{E}(\boldsymbol{X}^\intercal\boldsymbol{\beta}_0|Y)\},$$

and therefore $\mathrm{Var}\{\mathbb{E}(\boldsymbol{X}^\intercal\boldsymbol{\beta}_0|Y)\} > 0$. In the reverse case put $g(Y) = \mathbb{E}\{\boldsymbol{X}^\intercal\boldsymbol{\beta}_0|Y\}$ and apply conditional expectation to obtain $\mathbb{E}\{g(Y)\boldsymbol{X}^\intercal\boldsymbol{\beta}_0\} = \mathrm{Var}\{\mathbb{E}(\boldsymbol{X}^\intercal\boldsymbol{\beta}_0|Y)\} > 0$. ■

Abstract

We describe a seriation algorithm for ranking a set of items given pairwise comparisons between these items. Intuitively, the algorithm assigns similar rankings to items that compare similarly with all others. It does so by constructing a similarity matrix from pairwise comparisons, using seriation methods to reorder this matrix and construct a ranking. We first show that this spectral seriation algorithm recovers the true ranking when all pairwise comparisons are observed and consistent with a total order. We then show that ranking reconstruction is still exact when some pairwise comparisons are corrupted or missing, and that seriation based spectral ranking is more robust to noise than classical scoring methods. Finally, we bound the ranking error when only a random subset of the comparions are observed. An additional benefit of the seriation formulation is that it allows us to solve semi-supervised ranking problems. Experiments on both synthetic and real datasets demonstrate that seriation based spectral ranking achieves competitive and in some cases superior performance compared to classical ranking methods.

Keywords: Ranking, seriation, spectral methods

1. Introduction

We study the problem of ranking a set of n items given pairwise comparisons between these items[1]. The problem of aggregating binary relations has been formulated more than two centuries ago, in the context of emerging social sciences and voting theories (de Borda, 1781; de Condorcet, 1785). The setting we study here goes back at least to (Zermelo, 1929; Kendall and Smith, 1940) and seeks to reconstruct a ranking of items from pairwise comparisons reflecting a total ordering. In this case, the directed graph of all pairwise comparisons, where every pair of vertices is connected by exactly one of two possible directed edges, is usually called a *tournament* graph in the theoretical computer science literature or a "round robin" in sports, where every player plays every other player once and each preference marks victory or defeat. The motivation for this formulation often stems from the fact that in many applications, e.g. music, images, and movies, preferences are easier to express in relative terms (e.g. a is better than b) rather than absolute ones (e.g. a should be ranked fourth, and b seventh). In practice, the information about pairwise comparisons is usually *incomplete*, especially in the case of a large set of items, and the data may also be *noisy*, that is some pairwise comparisons could be incorrectly measured and inconsistent with a total order.

Ranking is a classical problem but its formulations vary widely. In particular, assumptions about how the pairwise preference information is obtained vary a lot from one reference to another. A subset of preferences is measured adaptively in (Ailon, 2011; Jamieson and Nowak, 2011), while (Freund et al., 2003; Negahban et al., 2012) extract them at random. In other settings, the full preference matrix is observed, but is perturbed by noise: in e.g. (Bradley and Terry, 1952; Luce, 1959; Herbrich et al., 2006), a parametric model is assumed over the set of permutations, which reformulates ranking as a maximum likelihood problem.

Loss functions, performance metrics and algorithmic approaches vary as well. Kenyon-Mathieu and Schudy (2007), for example, derive a PTAS for the minimum feedback arc set problem on tournaments, i.e. the problem of finding a ranking that minimizes the number of upsets (a pair of players where the player ranked lower on the ranking beats the player ranked higher). In practice, the complexity of this method is relatively high, and other authors (see e.g. Keener, 1993; Negahban et al., 2012) have been using spectral methods to produce more efficient algorithms (each pairwise comparison is understood as a link pointing to the preferred item). In other cases, such as the classical Analytic Hierarchy Process (AHP) (Saaty, 1980; Barbeau, 1986) preference information is encoded in a "reciprocal" matrix whose Perron-Frobenius eigenvector provides the global ranking. Simple scoring methods such as the point difference rule (Huber, 1963; Wauthier et al., 2013) produce efficient estimates at very low computational cost. Website ranking methods such as PageRank (Page et al., 1998) and HITS (Kleinberg, 1999) seek to rank web pages based on the hyperlink structure of the web, where links do not necessarily express consistent preference relationships (e.g. a can link to b and b can link c, and c can link to a). (Negahban et al., 2012) adapt the PageRank argument to the ranking from pairwise comparisons and Vigna (2009) provides a review of ranking algorithms given pairwise comparisons, in particular those involving the estimation of the stationary distribution of a Markov chain. Ranking has also been approached as a prediction problem, i.e. learning to rank (Schapire et al., 1998; Rajkumar and Agarwal, 2014), with (Joachims, 2002) for example using support vector machines to learn a score function. Finally, in the Bradley-Terry-Luce framework, where multiple observations on pairwise preferences are observed and assumed to be generated by a generalized linear model, the maximum likelihood problem is usually solved using fixed point algorithms or EM-like majorization-minimization techniques (Hunter, 2004). Jiang et al. (2011) describes the HodgeRank algorithm, which formulates ranking given pairwise comparisons as a least-square problem. This formulation is based on Hodge theory and provides tools to measure the consistency of a set of pairwise comparisons with the existence of a global ranking. Duchi et al. (2010, 2013) analyze the consistency of various ranking algorithms given pairwise comparisons and a query. Preferences are aggregated through standard procedures, e.g., computing the mean of comparisons from different users, then

1. A subset of these results appeared at NIPS 2014.

ranking are derived using classical algorithms, e.g., Borda Count, Bradley-Terry-Model maximum likelihood estimation, least squares, odd-ratios (Saaty, 2003).

Here, we show that the ranking problem is directly related to another classical ordering problem, namely *seriation*. Given a similarity matrix between a set of n items and assuming that the items can be ordered along a chain (path) such that the similarity between items decreases with their distance within this chain (i.e. a total order exists), the seriation problem seeks to reconstruct the underlying linear ordering based on unsorted, possibly noisy, pairwise similarity information. Atkins et al. (1998) produced a spectral algorithm that exactly solves the seriation problem in the noiseless case, by showing that for similarity matrices computed from serial variables, the ordering of the eigenvector corresponding to the second smallest eigenvalue of the Laplacian matrix (a.k.a. the Fiedler vector) matches that of the variables. In practice, this means that performing spectral ordering on the similarity matrix exactly reconstructs the correct ordering provided items are organized in a chain.

We adapt these results to ranking to produce a very efficient *spectral ranking algorithm with provable recovery and robustness guarantees*. Furthermore, the seriation formulation allows us to handle semi-supervised ranking problems. Fogel et al. (2013) show that seriation is equivalent to the 2-SUM problem and study convex relaxations to seriation in a semi-supervised setting, where additional structural constraints are imposed on the solution. Several authors (Blum et al., 2000; Feige and Lee, 2007) have also focused on the directly related Minimum Linear Arrangement (MLA) problem, for which excellent approximation guarantees exist in the noisy case, albeit with very high polynomial complexity.

The main contributions of this paper can be summarized as follows. We link seriation and ranking by showing how to construct a consistent similarity matrix based on consistent pairwise comparisons. We then recover the true ranking by applying the spectral seriation algorithm in (Atkins et al., 1998) to this similarity matrix (we call this method SerialRank in what follows). In the noisy case, we then show that spectral seriation can perfectly recover the true ranking even when some of the pairwise comparisons are either corrupted or missing, provided that the pattern of errors is somewhat unstructured. We show in particular that, in a regime where a high proportion of comparisons are observed, some incorrectly, the spectral solution is more robust to noise than classical scoring based methods. On the other hand, when only few comparisons are observed, we show that for Erdös-Rényi graphs, i.e., when pairwise comparisons are observed independently with a given probability, $\Omega(n \log^4 n)$ comparisons suffice for ℓ_2 consistency of the Fiedler vector and hence ℓ_2 consistency of the retreived ranking w.h.p. On the other hand we need $\Omega(n^{3/2} \log^4 n)$ comparisons to retrieve a ranking whose local perturbations are bounded in ℓ_∞ norm. Since for Erdös-Rényi graphs the induced graph of comparisons is connected with high probability only when the total number of pairs sampled scales as $\Omega(n \log n)$ (aka the coupon collector effect), we need at least that many comparisons in order to retrieve a ranking, therefore the ℓ_2 consistency result can be seen as optimal up to a polylogarithmic factor. Finally, we use the seriation results in (Fogel et al., 2013) to produce semi-supervised ranking solutions.

The paper is organized as follows. In Section 2 we recall definitions related to seriation, and link ranking and seriation by showing how to construct well ordered similarity matrices from well ranked items. In Section 3 we apply the spectral algorithm of (Atkins et al., 1998) to reorder these similarity matrices and reconstruct the true ranking in the noiseless case.

In Section 4 we then show that this spectral solution remains exact in a noisy regime where a random subset of comparisons is corrupted. In Section 5 we analyze ranking perturbation results when only few comparisons are given following an Erdös-Rényi graph. Finally, in Section 6 we illustrate our results on both synthetic and real datasets, and compare ranking performance with classical MLE, spectral and scoring based approaches.

2. Seriation, Similarities & Ranking

In this section we first introduce the seriation problem, i.e. reordering items based on pairwise similarities. We then show how to write the problem of ranking given pairwise comparisons as a seriation problem.

2.1 The Seriation Problem

The seriation problem seeks to reorder n items given a similarity matrix between these items, such that the more similar two items are, the closer they should be. This is equivalent to supposing that items can be placed on a chain where the similarity between two items decreases with the distance between these items in the chain. We formalize this below, following (Atkins et al., 1998).

Definition 1 *We say that a matrix $A \in \mathbf{S}_n$ is an R-matrix (or Robinson matrix) if and only if it is symmetric and $A_{i,j} \leq A_{i,j+1}$ and $A_{i+1,j} \leq A_{i,j}$ in the lower triangle, where $1 \leq j < i \leq n$.*

Another way to formulate R-matrix conditions is to impose $A_{ij} \geq A_{kl}$ if $|i-j| \leq |k-l|$ off-diagonal, i.e. the coefficients of A decrease as we move away from the diagonal. We also introduce a definition for strict R-matrices A, whose rows and columns cannot be permuted without breaking the R-matrix monotonicity conditions. We call *reverse identity* permutation the permutation that puts rows and columns $1, 2, \ldots, n$ of a matrix A in reverse order $n, n-1, \ldots, 1$.

Definition 2 *An R-matrix $A \in \mathbf{S}_n$ is called strict-R if and only if the identity and reverse identity permutations of A are the only permutations reordering A as an R-matrix.*

Any R-matrix with only strict R-constraints is a strict R-matrix. Following (Atkins et al., 1998), we will say that A is *pre-R* if there is a permutation matrix Π such that $\Pi A \Pi^T$ is an R-matrix. Given a pre-R matrix A, the seriation problem consists in finding a permutation Π such that $\Pi A \Pi^T$ is an R-matrix. Note that there might be several solutions to this problem. In particular, if a permutation Π is a solution, then the reverse permutation is also a solution. When only two permutations of A produce R-matrices, A will be called *pre-strict-R*.

2.2 Constructing Similarity Matrices from Pairwise Comparisons

Given an ordered input pairwise comparison matrix, we now show how to construct a similarity matrix which is *strict-R* when all comparisons are given and consistent with the identity ranking (i.e., items are ranked in increasing order of indices). This means that the

similarity between two items decreases with the distance between their ranks. We will then be able to use the spectral seriation algorithm by (Atkins et al., 1998) described in Section 3 to reconstruct the true ranking from a disordered similarity matrix.

We first show how to compute a pairwise similarity from pairwise comparisons between items by counting the number of matching comparisons. Another formulation allows us to handle the generalized linear model. These two examples are only two particular instances of a broader class of ranking algorithms derived here. Any method which produces R-matrices from pairwise preferences yields a valid ranking algorithm.

2.2.1 Similarities from Pairwise Comparisons

Suppose we are given a matrix of pairwise comparisons $C \in \{-1,0,1\}^{n\times n}$ such that $C_{i,j} = -C_{j,i}$ for every $i \neq j$ and

$$C_{i,j} = \begin{cases} 1 & \text{if } i \text{ is ranked higher than } j \\ 0 & \text{if } i \text{ and } j \text{ are not compared or in a draw} \\ -1 & \text{if } j \text{ is ranked higher than } i \end{cases} \tag{1}$$

setting $C_{i,i} = 1$ for all $i \in \{1,\dots,n\}$. We define the pairwise similarity matrix S^{match} as

$$S^{\text{match}}_{i,j} = \sum_{k=1}^{n} \left(\frac{1 + C_{i,k}C_{j,k}}{2} \right). \tag{2}$$

Since $C_{i,k}C_{j,k} = 1$, if $C_{i,k}$ and $C_{j,k}$ have matching signs, and $C_{i,k}C_{j,k} = -1$ if they have opposite signs, $S^{\text{match}}_{i,j}$ counts the number of matching comparisons between i and j with other reference items k. If i or j is not compared with k, then $C_{i,k}C_{j,k} = 0$ and the term $(1 + C_{i,k}C_{j,k})/2$ has an neutral effect on the similarity of $1/2$. Note that we also have

$$S^{\text{match}} = \frac{1}{2}\left(n\mathbf{1}\mathbf{1}^T + CC^T \right). \tag{3}$$

The intuition behind the similarity S^{match} is easy to understand in a tournament setting: players that beat the same players and are beaten by the same players should have a similar ranking.

The next result shows that when all comparisons are given and consistent with the identity ranking, then the similarity matrix S^{match} is a strict R-matrix. Without loss of generality, we assume that items are ranked in increasing order of their indices. In the general case, we can simply replace the *strict-R* property by the *pre-strict-R* property.

Proposition 3 *Given all pairwise comparisons between items ranked according to the identity permutation (with no ties), the similarity matrix S^{match} constructed in (2) is a strict R-matrix and*

$$S^{\text{match}}_{i,j} = n - |i - j| \tag{4}$$

for all $i, j = 1,\dots,n$.

Proof Since items are ranked as $1, 2, \dots, n$ with no ties and all comparisons given, $C_{i,j} = -1$ if $i < j$ and $C_{i,j} = 1$ otherwise. Therefore we obtain from definition (2)

$$\begin{aligned} S^{\text{match}}_{i,j} &= \sum_{k=1}^{\min(i,j)-1} \left(\frac{1+1}{2}\right) + \sum_{k=\min(i,j)}^{\max(i,j)-1} \left(\frac{1-1}{2}\right) + \sum_{k=\max(i,j)}^{n} \left(\frac{1+1}{2}\right) \\ &= n - (\max(i,j) - \min(i,j)) \\ &= n - |i-j| \end{aligned}$$

This means in particular that S^{match} is strictly positive and its coefficients are strictly decreasing when moving away from the diagonal, hence S^{match} is a strict R-matrix. ■

2.2.2 Similarities in the Generalized Linear Model

Suppose that paired comparisons are generated according to a generalized linear model (GLM), i.e., we assume that the outcomes of paired comparisons are independent and for any pair of distinct items, item i is observed ranked higher than item j with probability

$$P_{i,j} = H(\nu_i - \nu_j) \tag{5}$$

where $\nu \in \mathbb{R}^n$ is a vector of skill parameters and $H : \mathbb{R} \to [0,1]$ is a function that is increasing on $\mathbb{R}$ and such that $H(-x) = 1 - H(x)$ for all $x \in \mathbb{R}$, and $\lim_{x\to-\infty} H(x) = 0$ and $\lim_{x\to\infty} H(x) = 1$. A well known special instance of the generalized linear model is the Bradley-Terry-Luce model for which $H(x) = 1/(1+e^{-x})$, for $x \in \mathbb{R}$.

Let $m_{i,j}$ be the number of times items i and j were compared, $C^s_{i,j} \in \{-1,1\}$ be the outcome of comparison s and Q be the matrix of corresponding sample probabilities, i.e. if $m_{i,j} > 0$ we have

$$Q_{i,j} = \frac{1}{m_{i,j}} \sum_{s=1}^{m_{i,j}} \frac{C^s_{i,j} + 1}{2}$$

and $Q_{i,j} = 1/2$ in case $m_{i,j} = 0$. We define the similarity matrix S^{glm} from the observations Q as

$$S^{\text{glm}}_{i,j} = \sum_{k=1}^{n} \mathbf{1}_{\{m_{i,k}m_{j,k}>0\}} \left(1 - |Q_{i,k} - Q_{j,k}|\right) + \frac{\mathbf{1}_{\{m_{i,k}m_{j,k}=0\}}}{2}. \tag{6}$$

Since the comparison observations are independent we have that $Q_{i,j}$ converges to $P_{i,j}$ as $m_{i,j}$ goes to infinity and the central limit theorem implies that $S^{\text{glm}}_{i,j}$ converges to a Gaussian variable with mean

$$\sum_{k=1}^{n} \left(1 - |P_{i,k} - P_{j,k}|\right).$$

The result below shows that this limit similarity matrix is a strict R-matrix when items are properly ordered.

Proposition 4 *If items are ordered according to the order in decreasing values of the skill parameters, the similarity matrix S^{glm} is a strict R matrix with high probability as the number of observations goes to infinity.*

Proof Without loss of generality, we suppose the true order is $1, 2, \ldots, n$, with $\nu(1) > \ldots > \nu(n)$. For any i, j, k such that $i > j$, using the GLM assumption (i) we get

$$P_{i,k} = H(\nu(i) - \nu(k)) < H(\nu(j) - \nu(k)) = P_{j,k}.$$

Since empirical probabilities $Q_{i,j}$ converge to $P_{i,j}$, when the number of observations is large enough, we also have $Q_{i,k} < Q_{j,k}$ for any i, j, k such that $i > j$ (we focus w.l.o.g. on the lower triangle), and we can therefore remove the absolute value in the expression of $S^{\text{glm}}_{i,j}$ for $i > j$. Hence for any $i > j$ we have

$$\begin{aligned} S^{\text{glm}}_{i+1,j} - S^{\text{glm}}_{i,j} &= -\sum_{k=1}^{n} |Q_{i+1,k} - Q_{j,k}| + \sum_{k=1}^{n} |Q_{i,k} - Q_{j,k}| \\ &= \sum_{k=1}^{n} (Q_{i+1,k} - Q_{j,k}) - (Q_{i,k} - Q_{j,k}) \\ &= \sum_{k=1}^{n} Q_{i+1,k} - Q_{i,k} < 0. \end{aligned}$$

Similarly for any $i > j$, $S^{\text{glm}}_{i,j-1} - S^{\text{glm}}_{i,j} < 0$, so S^{glm} is a strict R-matrix. ■

Notice that we recover the original definition of S^{match} in the case of binary comparisons, though it does not fit in the Generalized Linear Model. Note also that these definitions can be directly extended to the setting where multiple comparisons are available for each pair and aggregated in comparisons that take fractional values (e.g., a tournament setting where participants play several times against each other).

3. Spectral Algorithms

We first recall how spectral ordering can be used to recover the true ordering in seriation problems. We then apply this method to the ranking problem.

3.1 Spectral Seriation Algorithm

We use the spectral computation method originally introduced in (Atkins et al., 1998) to solve the seriation problem based on the similarity matrices defined in the previous section. We first recall the definition of the Fiedler vector (which is shown to be unique in our setting in Lemma 7).

Definition 5 *The Fiedler value of a symmetric, nonnegative and irreducible matrix A is the smallest non-zero eigenvalue of its Laplacian matrix $L_A = \mathbf{diag}(A\mathbf{1}) - A$. The corresponding eigenvector is called Fiedler vector and is the optimal solution to* $\min\{y^T L_A y : y \in \mathbb{R}^n, y^T \mathbf{1} = 0, \|y\|_2 = 1\}$.

The main result from (Atkins et al., 1998), detailed below, shows how to reorder pre-R matrices in a noise free case.

Proposition 6 *(Atkins et al., 1998, Th. 3.3) Let $A \in \mathbf{S}_n$ be an irreducible pre-R-matrix with a simple Fiedler value and a Fiedler vector v with no repeated values. Let $\Pi_1 \in \mathcal{P}$ (respectively, Π_2) be the permutation such that the permuted Fiedler vector $\Pi_1 v$ is strictly increasing (decreasing). Then $\Pi_1 A \Pi_1^T$ and $\Pi_2 A \Pi_2^T$ are R-matrices, and no other permutations of A produce R-matrices.*

The next technical lemmas extend the results in Atkins et al. (1998) to strict R-matrices and will be used to prove Theorem 10 in next section. The first one shows that without loss of generality, the Fiedler value is simple.

Lemma 7 *If A is an irreducible R-matrix, up to a uniform shift of its coefficients, A has a simple Fiedler value and a monotonic Fiedler vector.*

Proof We use (Atkins et al., 1998, Th. 4.6) which states that if A is an irreducible R-matrix with $A_{n,1} = 0$, then the Fiedler value of A is a simple eigenvalue. Since A is an R-matrix, $A_{n,1}$ is among its minimal elements. Subtracting it from A does not affect the nonnegativity of A and we can apply (Atkins et al., 1998, Th. 4.6). Monotonicity of the Fiedler vector then follows from (Atkins et al., 1998, Th. 3.2). ■

The next lemma shows that the Fiedler vector is strictly monotonic if A is a strict R-matrix.

Lemma 8 *Let $A \in \mathbf{S}_n$ be an irreducible R-matrix. Suppose there are no distinct indices $r < s$ such that for any $k \notin [r, s]$, $A_{r,k} = A_{r+1,k} = \ldots = A_{s,k}$, then, up to a uniform shift, the Fiedler value of A is simple and its Fiedler vector is strictly monotonic.*

Proof By Lemma 7, the Fiedler value of A is simple (up to a uniform shift of A). Let x be the corresponding Fiedler vector of A, x is monotonic by Lemma 7. Suppose $[r, s]$ is a nontrivial maximal interval such that $x_r = x_{r+1} = \ldots = x_s$, then by (Atkins et al., 1998, lemma 4.3), for any $k \notin [r, s]$, $A_{r,k} = A_{r+1,k} = \ldots = A_{s,k}$, which contradicts the initial assumption. Therefore x is strictly monotonic. ■

In fact, we only need a small portion of the R-constraints to be strict for the previous lemma to hold. We now show that the main assumption on A in Lemma 8 is equivalent to A being strict-R.

Lemma 9 *An irreducible R-matrix $A \in \mathbf{S}_n$ is strictly R if and only if there are no distinct indices $r < s$ such that for any $k \notin [r, s]$, $A_{r,k} = A_{r+1,k} = \ldots = A_{s,k}$.*

Proof Let $A \in \mathbf{S}_n$ an R-matrix. Let us first suppose there are no distinct indices $r < s$ such that for any $k \notin [r, s]$, $A_{r,k} = A_{r+1,k} = \ldots = A_{s,k}$. By Lemma 8 the Fiedler value of A is simple and its Fiedler vector is strictly monotonic. Hence by Proposition 6, only the identity and reverse identity permutations of A produce R-matrices. Now suppose there exist two distinct indices $r < s$ such that for any $k \notin [r, s]$, $A_{r,k} = A_{r+1,k} = \ldots = A_{s,k}$. In addition to the identity and reverse identity permutations, we can locally reverse the order of rows and columns from r to s, since the sub matrix $A_{r:s,r:s}$ is an R-matrix and for any

Algorithm 1 (SerialRank)

Input: A set of pairwise comparisons $C_{i,j} \in \{-1, 0, 1\}$ or $[-1, 1]$.

1: Compute a similarity matrix S as in §2.2

2: Compute the Laplacian matrix

$$L_S = \mathbf{diag}(S\mathbf{1}) - S \qquad \text{(SerialRank)}$$

3: Compute the Fiedler vector of S.

Output: A ranking induced by sorting the Fiedler vector of S (choose either increasing or decreasing order to minimize the number of upsets).

$k \notin [r, s], A_{r,k} = A_{r+1,k} = \ldots = A_{s,k}$. Therefore at least four different permutations of A produce R-matrices, which means that A is not strictly R. ■

3.2 SerialRank: a Spectral Ranking Algorithm

In Section 2, we showed that similarities S^{match} and S^{glm} are *pre-strict-R* when all comparisons are available and consistent with an underlying ranking of items. We now use the spectral seriation method in (Atkins et al., 1998) to reorder these matrices and produce a ranking. Spectral ordering requires computing an extremal eigenvector, at a cost of $O(n^2 \log n)$ flops (Kuczynski and Wozniakowski, 1992). We call this algorithm SerialRank and prove the following result.

Theorem 10 *Given all pairwise comparisons for a set of totally ordered items and assuming there are no ties between items, algorithm SerialRank, i.e., sorting the Fiedler vector of the matrix* S^{match} *defined in* (3)*, recovers the true ranking of items.*

Proof From Proposition 3, under assumptions of the proposition S^{match} is a pre-strict R-matrix. Now combining the definition of strict-R matrices in Lemma 9 with Lemma 8, we deduce that Fiedler value of S^{match} is simple and its Fiedler vector has no repeated values. Hence by Proposition 6, only the two permutations that sort the Fiedler vector in increasing and decreasing order produce strict R-matrices and are candidate rankings (by Proposition 3 S^{match} is a strict R-matrix when ordered according to the true ranking). Finally we can choose between the two candidate rankings (increasing and decreasing) by picking the one with the least upsets. ■

Similar results apply for S^{glm} given enough comparisons in the Generalized Linear Model. This last result guarantees recovery of the true ranking of items in the noiseless case. In the next section, we will study the impact of corrupted or missing comparisons on the inferred ranking of items.

4. Exact Recovery with Corrupted and Missing Comparisons

In this section we study the robustness of SerialRank using S^{match} with respect to noisy and missing pairwise comparisons. We will see that noisy comparisons cause ranking ambiguities for the point score method and that such ambiguities are to be lifted by the spectral ranking algorithm. We show in particular that the SerialRank algorithm recovers the exact ranking when the pattern of errors is random and errors are not too numerous. We first study the impact of one corrupted comparison on SerialRank, then extend the result to multiple corrupted comparisons. A similar analysis is provided for missing comparisons as Corollary 27. in the Appendix. Finally, Proposition 14 provides an estimate of the number of randomly corrupted entries that can be tolerated for perfect recovery of the true ranking. We begin by recalling the definition of the *point score* of an item.

Definition 11 *The* point score w_i *of an item* i*, also known as point-difference, or* row-sum *is defined as* $w_i = \sum_{k=1}^{n} C_{k,i}$*, which corresponds to the number of wins minus the number of losses in a tournament setting.*

In the following we will denote by w the point score vector.

Proposition 12 *Given all pairwise comparisons* $C_{s,t} \in \{-1, 1\}$ *between items ranked according to their indices, suppose the sign of one comparison* $C_{i,j}$ *(and its counterpart* $C_{j,i}$*) is switched, with* $i < j$*. If* $j - i > 2$ *then* S^{match} *defined in* (3) *remains* strict-R*, whereas the point score vector* w *has ties between items* i *and* $i+1$ *and items* j *and* $j-1$*.*

Proof We give some intuition for the result in Figure 1. We write the true score and comparison matrix w and C, while the observations are written $\hat{w}$ and $\hat{C}$ respectively. This means in particular that $\hat{C}_{i,j} = -C_{i,j} = 1$ and $\hat{C}_{j,i} = -C_{j,i} = -1$. To simplify notations we denote by S the similarity matrix S^{match} (respectively $\hat{S}$ when the similarity is computed from observations). We first study the impact of a corrupted comparison $C_{i,j}$ for $i < j$ on the point score vector $\hat{w}$. We have

$$\hat{w}_i = \sum_{k=1}^{n} \hat{C}_{k,i} = \sum_{k=1}^{n} C_{k,i} + \hat{C}_{j,i} - C_{j,i} = w_i - 2 = w_{i+1},$$

similarly $\hat{w}_j = w_{j-1}$, whereas $\hat{w}_k = w_k$ for $k \neq i, j$. Hence, the incorrect comparison induces two ties in the point score vector w. Now we show that the similarity matrix defined in (3) breaks these ties, by showing that it is a strict R-matrix. Writing $\hat{S}$ in terms of S, we get for any $t \neq i, j$

$$[\hat{C}\hat{C}^T]_{i,t} = \sum_{k \neq j} \left(\hat{C}_{i,k}\hat{C}_{t,k}\right) + \hat{C}_{i,j}\hat{C}_{t,j} = \sum_{k \neq j} (C_{i,k}C_{t,k}) + \hat{C}_{i,j}C_{t,j} = \begin{cases} [CC^T]_{i,t} - 2 & \text{if } t < j \\ [CC^T]_{i,t} + 2 & \text{if } t > j. \end{cases}$$

Thus we obtain

$$\hat{S}_{i,t} = \begin{cases} S_{i,t} - 1 & \text{if } t < j \\ S_{i,t} + 1 & \text{if } t > j, \end{cases}$$

(remember there is a factor $1/2$ in the definition of S). Similarly we get for any $t \neq i, j$

$$\hat{S}_{j,t} = \begin{cases} S_{j,t} + 1 & \text{if } t < i \\ S_{j,t} - 1 & \text{if } t > i. \end{cases}$$

Finally, for the single corrupted index pair (i,j), we get

$$\hat{S}_{i,j} = \frac{1}{2}\left(n + \sum_{k\neq i,j}\left(\hat{C}_{i,k}\hat{C}_{j,k}\right) + \hat{C}_{i,i}\hat{C}_{j,i} + \hat{C}_{i,j}\hat{C}_{j,j}\right) = S_{i,j} - 1 + 1 = S_{i,j}.$$

The diagonal of S is not impacted since $[\hat{C}\hat{C}^T]_{i,i} = \sum_{k=1}^{n}\left(\hat{C}_{i,k}\hat{C}_{i,k}\right) = n$. For all other coefficients (s,t) such that $s,t \neq i,j$, we also have $\hat{S}_{s,t} = S_{s,t}$, which means that all rows or columns outside of i,j are left unchanged. We first observe that these last equations, together with our assumption that $j-i>2$ and the fact that the elements of the exact S in (4) differ by at least one, imply that

$$\hat{S}_{s,t} \leq \hat{S}_{s+1,t} \quad \text{and} \quad \hat{S}_{s,t+1} \leq \hat{S}_{s,t}, \quad \text{for } s<t$$

so $\hat{S}$ remains an R-matrix. Note that this result remains true even when $j-i=2$, but we need some strict inequalities to show uniqueness of the retrieved order. Indeed, because $j-i>2$ all these R constraints are strict except between elements of rows i and $i+1$, and rows $j-1$ and j (and similarly for columns). These ties can be broken using the fact that

$$\hat{S}_{i,j-1} = S_{i,j-1} - 1 < S_{i+1,j-1} - 1 = \hat{S}_{i+1,j-1} - 1 < \hat{S}_{i+1,j-1}$$

which means that $\hat{S}$ is still a strict R-matrix (see Figure 1) since $j-1>i+1$ by assumption. ■

We now extend this result to multiple errors.

Proposition 13 *Given all pairwise comparisons $C_{s,t} \in \{-1,1\}$ between items ranked according to their indices, suppose the signs of m comparisons indexed $(i_1,j_1),\ldots,(i_m,j_m)$ are switched. If the following condition* (7) *holds true,*

$$|s-t|>2, \text{ for all } s,t \in \{i_1,\ldots,i_m,j_1,\ldots,j_m\} \text{ with } s\neq t, \tag{7}$$

then S^{match} defined in (3) *remains* strict-R*, whereas the point score vector w has $2m$ ties.*

Proof We write the true score and comparison matrix w and C, while the observations are written $\hat{w}$ and $\hat{C}$ respectively, and without loss of generality we suppose $i_l<j_l$. This implies that $\hat{C}_{i_l,j_l} = -C_{i_l,j_l} = 1$ and $\hat{C}_{j_l,i_l} = -C_{j_l,i_l} = -1$ for all l in $\{1,\ldots,m\}$. To simplify notations, we denote by S the similarity matrix S^{match} (respectively $\hat{S}$ when the similarity is computed from observations).

As in the proof of Proposition 12, corrupted comparisons indexed (i_l,j_l) induce shifts of ±1 on columns and rows i_l and j_l of the similarity matrix S^{match}, while $S^{\text{match}}_{i_l,j_l}$ values remain the same. Since there are several corrupted comparisons, we also need to check the values of $\hat{S}$ at the intersections of rows and columns with indices of corrupted comparisons. Formally, for any $(i,j) \in \{(i_1,j_1),\ldots(i_m,j_m)\}$ and $t \notin \{i_1,\ldots,i_m,j_1,\ldots,j_m\}$

$$\hat{S}_{i,t} = \begin{cases} S_{i,t}+1 & \text{if } t<j \\ S_{i,t}-1 & \text{if } t>j, \end{cases}$$

Similarly for $t \notin \{i_1,\ldots,i_m,j_1,\ldots,j_m\}$

$$\hat{S}_{j,t} = \begin{cases} S_{j,t}-1 & \text{if } t<i \\ S_{j,t}+1 & \text{if } t>i. \end{cases}$$

Let (s,s') and $(t,t') \in \{(i_1,j_1),\ldots(i_m,j_m)\}$, we have

$$\begin{aligned} \hat{S}_{s,t} &= \tfrac{1}{2}\left(n + \textstyle\sum_{k\neq s',t'}\left(\hat{C}_{s,k}\hat{C}_{t,k}\right) + \hat{C}_{s,s'}\hat{C}_{t,s'} + \hat{C}_{s,t'}\hat{C}_{t,t'}\right) \\ &= \tfrac{1}{2}\left(n + \textstyle\sum_{k\neq s',t'}\left(C_{s,k}C_{t,k}\right) - C_{s,s'}C_{t,s'} - C_{s,t'}C_{t,t'}\right) \end{aligned}$$

Without loss of generality we suppose $s<t$, and since $s<s'$ and $t<t'$, we obtain

$$\hat{S}_{s,t} = \begin{cases} S_{s,t} & \text{if } t>s' \\ S_{s,t}+2 & \text{if } t<s'. \end{cases}$$

Similar results apply for other intersections of rows and columns with indices of corrupted comparisons (i.e., shifts of 0, +2, or −2). For all other coefficients (s,t) such that $s,t \notin \{i_1,\ldots,i_m,j_1,\ldots,j_m\}$, we have $\hat{S}_{s,t} = S_{s,t}$. We first observe that these last equations, together with our assumption that $j_l - i_l > 2$, mean that

$$\hat{S}_{s,t} \leq \hat{S}_{s+1,t} \quad \text{and} \quad \hat{S}_{s,t+1} \leq \hat{S}_{s,t}, \quad \text{for any } s<t$$

so $\hat{S}$ remains an R-matrix. Moreover, since $j_l - i_l > 2$ all these R constraints are strict except between elements of rows i_l and i_l+1, and rows j_l-1 and j_l (similar for columns). These ties can be broken using the fact that for $k = j_l - 1$

$$\hat{S}_{i_l,k} = S_{i_l,k} - 1 < S_{i_l+1,k} - 1 = \hat{S}_{i_l+1,k} - 1 < \hat{S}_{i_l+1,k}$$

which means that $\hat{S}$ is still a strict R-matrix since $k = j_l - 1 > i_l + 1$. Moreover, using the same argument as in the proof of Proposition 12, corrupted comparisons induces $2m$ ties in the point score vector w. ■

For the case of one corrupted comparison, note that the separation condition on the pair of items (i,j) is necessary. When the comparison $C_{i,j}$ between two adjacent items is corrupted, no ranking method can break the resulting tie. For the case of arbitrary number of corrupted comparisons, condition (7) is a sufficient condition only. We study exact ranking recovery conditions with missing comparisons in the Appendix, using similar arguments. We now estimate the number of randomly corrupted entries that can be tolerated while maintaining exact recovery of the true ranking.

Proposition 14 *Given a comparison matrix for a set of n items with m corrupted comparisons selected uniformly at random from the set of all possible item pairs. Algorithm SerialRank guarantees that the probability of recovery $p(n,m)$ satisfies $p(n,m) \geq 1-\delta$, provided that $m = O(\sqrt{\delta n})$. In particular, this implies that $p(n,m) = 1 - o(1)$ provided that $m = o(\sqrt{n})$.*

Proof Let $\mathcal{P}$ be the set of all distinct pairs of items from the set $\{1, 2, \dots, n\}$. Let $\mathcal{X}$ be the set of all admissible sets of pairs of items, i.e. containing each $X \subseteq \mathcal{P}$ such that X satisfies condition (7). We consider the case of $m \geq 1$ distinct pairs of items sampled from the set $\mathcal{P}$ uniformly at random without replacement. Let X_i denote the set of sampled pairs given that i pairs are sampled. We seek to bound $p(n, m) = \mathbf{Prob}(X_m \in \mathcal{X})$. Given a set of pairs $X \in \mathcal{X}$, let $T(X)$ be the set of non-admissible pairs, i.e. containing $(i, j) \in \mathcal{P} \setminus X$ such that $X \cup (i, j) \notin \mathcal{X}$. We have

$$\mathbf{Prob}(X_m \in \mathcal{X}) = \sum_{x \in \mathcal{X} : |x| = m-1} \left(1 - \frac{|T(x)|}{|\mathcal{P}| - (m-1)}\right) \mathbf{Prob}(X_{m-1} = x). \tag{8}$$

Note that every selected pair from $\mathcal{P}$ contributes at most $15n$ non-admissible pairs. Indeed, given a selected pair (i, j), a non-admissible pair (s, t) should respect one of the following conditions $|s - i| \leq 2$, $|s - j| \leq 2$, $|t - i| \leq 2$, $|t - j| \leq 2$ or $|s - t| \leq 2$. Given any item s, there are 15 possible choice of t to output a non-admissible pair (s, t), resulting in at most $15n$ non-admissible pairs for the selected pair (i, j).

Hence, for every $x \in \mathcal{X}$ we have

$$|T(x)| \leq 15n|x|.$$

Combining this with (8) and the fact that $|\mathcal{P}| = \binom{n}{2}$, we have

$$\mathbf{Prob}(X_m \in \mathcal{X}) \geq \left(1 - \frac{15n}{\binom{n}{2} - (m-1)}(m-1)\right) \mathbf{Prob}(X_{m-1} \in \mathcal{X}).$$

From this it follows

$$\begin{aligned} p(n, m) &\geq \prod_{i=1}^{m-1} \left(1 - \frac{15n}{\binom{n}{2} - (i-1)} i\right) \\ &\geq \prod_{i=1}^{m-1} \left(1 - \frac{i}{a(n, m)}\right) \end{aligned}$$

where

$$a(n, m) = \frac{\binom{n}{2} - (m-1)}{15n}.$$

Notice that when $m = o(n)$ we have $\left(1 - \frac{i}{a(n,m)}\right) \sim \exp(-30i/n)$ and

$$\prod_{i=1}^{m-1} \left(1 - \frac{i}{a(n, m)}\right) \sim \prod_{i=1}^{m-1} \exp(-30i/n) \sim \exp\left(-\frac{15m^2}{n}\right) \text{ for large } n.$$

Hence, given $\delta > 0$, $p(n, m) \geq 1 - \delta$ provided that $m = O(\sqrt{n\delta})$. If $\delta = o(1)$, the condition is $m = o(\sqrt{n})$. ■

5. Spectral Perturbation Analysis

In this section we analyze how SerialRank performs when only a small fraction of pairwise comparisons are given. We show that for Erdös-Rényi graphs, i.e., when pairwise comparisons are observed independently with a given probability, $\Omega(n \log^4 n)$ comparisons suffice for ℓ_2 consistency of the Fiedler vector and hence ℓ_2 consistency of the retreived ranking w.h.p. On the other hand we need $\Omega(n^{3/2} \log^4 n)$ comparisons to retrieve a ranking whose local perturbations are bounded in ℓ_∞ norm. Since Erdös-Rényi graphs are connected with high probability only when the total number of pairs sampled scales as $\Omega(n \log n)$, we need at least that many comparisons in order to retrieve a ranking, therefore the ℓ_2 consistency result can be seen as optimal up to a polylogarithmic factor.

Our bounds are mostly related to the work of (Wauthier et al., 2013). In its simplified version (Theorem 4.2 Wauthier et al., 2013) shows that when ranking items according to their point score, for any precision parameter $\mu \in (0, 1)$, sampling independently with fixed probability $\Omega\left(\frac{n \log n}{\mu^2}\right)$ comparisons guarantees that the maximum displacement between the retrieved ranking and the true ranking, i.e., the ℓ_∞ distance to the true ranking, is bounded by μn with high probability for n large enough.

Sample complexity bounds have also been studied for the Rank Centrality algorithm (Dwork et al., 2001; Negahban et al., 2012). In their analysis, (Negahban et al., 2012) suppose that some pairs are sampled independently with fixed probability, and then k comparisons are generated for each sampled pair, under a Bradley-Terry-Luce model (BTL). When ranking items according to the stationary distribution of a transition matrix estimated from comparisons, sampling $\Omega(n \cdot \text{polylog}(n))$ pairs are enough to bound the relative ℓ_2 norm perturbation of the stationary distribution. However, as pointed out by (Wauthier et al., 2013), repeated measurements are not practical, e.g., if comparisons are derived from the outcomes of sports games or the purchasing behavior of a customer (a customer typically wants to purchase a product only once). Moreover, (Negahban et al., 2012) do not provide bounds on the relative ℓ_∞ norm perturbation of the ranking.

We also refer the reader to the recent work of Rajkumar and Agarwal (2014), who provide a survey of sample complexity bounds for Rank Centrality, maximum likelihood estimation, least-square ranking and an SVM based ranking, under a more flexible sampling model. However, those bounds only give the sampling complexity for exact recovery of ranking, which is usually prohibitive when n is large, and are more difficult to interpret.

Finally, we refer the interested reader to (Huang et al., 2008; Shamir and Tishby, 2011) for sampling complexity bounds in the context of spectral clustering.

Limitations. We emphasize that sampling models based on Erdös-Rényi graphs are not the most realistic, though they have been studied widely in the literature (see for instance Feige et al., 1994; Braverman and Mossel, 2008; Wauthier et al., 2013). Indeed, pairs are not likely to be sampled independently. For instance, when ranking movies, popular movies in the top ranks are more likely to be compared. Corrupted comparisons are also more likely between items that have close rankings. We hope to extend our perturbation analysis to more general models in future work.

A second limitation of our perturbation analysis comes from the setting of ordinal comparisons, i.e., binary comparisons, since in many applications, several comparisons are provided for each sampled pair. Nevertheless, the setting of ordinal comparisons is interesting

for the analysis of SerialRank, since numerical experiments suggest that it is the setting for which SerialRank provides the best results compared to other methods. Note that in practice, we can easily get rid of this limitation (see Section 2.2.2 and 6). We refer the reader to numerical experiments in Section 6, as well as a recent paper by Cucuringu (2015), which introduces another ranking algorithm called SyncRank, and provides extensive numerical experiments on state-of-the-art ranking algorithms, including SerialRank.

Choice of Laplacian: normalized vs. unnormalized. In the spectral clustering literature, several constructions for the Laplacian operators are suggested, namely the unnormalized Laplacian (used in SerialRank), the symmetric normalized Laplacian, and the non-symmetric normalized Laplacian. Von Luxburg et al. (2008) show stronger consistency results for spectral clustering by using the non-symmetric normalized Laplacian. Here, we show that the Fiedler vector of the normalized Laplacian is an affine function of the ranking, hence sorting the Fiedler vector still guarantees exact recovery of the ranking, when all comparisons are observed and consistent with a global ranking. In contrast, we only get an asymptotic expression for the unnormalized Laplacian (*cf.* section A). This motivated us to provide an analysis of SerialRank robustness based on the normalized Laplacian, though in practice the use of the unnormalized Laplacian is valid and seems to give better results (*cf.* Figures 2 and 5).

Notations. Throughout this section, we only focus on the similarity S^{match} in (3) and write it S to simplify notations. W.l.o.g. we assume in the following that the true ranking is the identity, hence S is an R-matrix. We write $\|\cdot\|_2$ the operator norm of a matrix, which corresponds to the maximal absolute eigenvalue for symmetric matrices. $\|\cdot\|_F$ denotes the Frobenius norm. We refer to the eigenvalues of the Laplacian as λ_i, with $\lambda_1 = 0 \leq \lambda_2 \leq \ldots \leq \lambda_n$. For any quantity x, we denote by $\tilde{x}$ its perturbed analogue. We define the residual matrix $R = \tilde{S} - S$ and write f the normalized Fiedler vector of the Laplacian matrix L_S. We define the degree matrix $D_S = \mathbf{diag}(D\mathbf{1})$ the diagonal matrix whose elements are the row-sums of matrix S. Whenever we use the abreviation w.h.p., this means that the inequality is true with probability greater than $1 - 2/n$. Finally, we will use $c > 0$ for absolute constants, whose values are allowed to vary from one equation to another.

We assume that our information on preferences is both incomplete and corrupted. Specifically, pairwise comparisons are independently sampled with probability q and these sampled comparisons are consistent with the underlying total ranking with probability p. Let us define $\tilde{C} = B \circ C$ the matrix of observed comparisons, where C is the true comparison matrix defined in (1), $\circ$ is the Hadamard product and B is a symmetric matrix with entries

$$B_{i,j} = \begin{cases} 0 & \text{with probability } 1-q \\ 1 & \text{with probability } qp \\ -1 & \text{with probability } q(1-p). \end{cases}$$

In order to obtain an unbiased estimator of the comparison matrix defined in (1), we normalize $\tilde{C}$ by its mean value $q(2p-1)$ and redefine $\tilde{S}$ as

$$\tilde{S} = \frac{1}{q^2(2p-1)^2}\tilde{C}\tilde{C}^T + n\mathbf{1}\mathbf{1}^T.$$

For ease of notations we have dropped the factor $1/2$ in (3) w.l.o.g. (positive multiplicative factors of the Laplacian do not affect its eigenvectors).

5.1 Results

We now state our main results. The first one bounds ℓ_2 perturbations of the Fiedler vector f with both missing and corrupted comparisons. Note that f and $\tilde{f}$ are normalized.

Theorem 21 *For every $\mu \in (0,1)$ and n large enough, if $q > \frac{\log^4 n}{\mu^2(2p-1)^4 n}$, then*

$$\|\tilde{f} - f\|_2 \leq c\frac{\mu}{\sqrt{\log n}}$$

with probability at least $1 - 2/n$, where $c > 0$ is an absolute constant.

As n goes to infinity the perturbation of the Fiedler vector goes to zero, and we can retrieve the "true" ranking by reordering the Fiedler vector. Hence this bounds provides ℓ_2 consistency of the ranking, with an optimal sampling complexity (up to a polylogarithmic factor).

The second result bounds local perturbations of the ranking with π referring to the "true" ranking and $\tilde{\pi}$ to the ranking retrieved by SerialRank.

Theorem 24 *For every $\mu \in (0,1)$ and n large enough, if $q > \frac{\log^4 n}{\mu^2(2p-1)^4\sqrt{n}}$, then*

$$\|\tilde{\pi} - \pi\|_\infty \leq c\mu n$$

with probability at least $1 - 2/n$, where $c > 0$ is an absolute constant.

This bound quantifies the maximum displacement of any item's ranking. μ can be seen a "precision" parameter. For instance, if we set $\mu = 0.1$, Theorem 24 means that we can expect the maximum displacement of any item's ranking to be less than $0.1 \cdot n$ when observing $c^2 \cdot 100 \cdot n\sqrt{n} \cdot \log^4 n$ comparisons (with $p = 1$).

We conjecture Theorem 24 still holds true if the condition $q > \log^4 n/\mu^2(2p-1)^4\sqrt{n}$ is replaced by the weaker condition $q > \log^4 n/\mu^2(2p-1)^4 n$.

5.2 Sketch of the proof.

The proof of these results relies on classical perturbation arguments and is structured as follows.

- **Step 1:** Bound $\|\tilde{D}_S - D_S\|_2$, $\|\tilde{S} - S\|_2$ with high probability using concentration inequalities on quadratic forms of Bernoulli variables and results from (Achlioptas and McSherry, 2007).
- **Step 2.** Show that the normalized Laplacian $L = \mathbf{I} - D^{-1}S$ has a linear Fiedler vector and bound the eigengap between the Fiedler value and other eigenvalues.
- **Step 3.** Bound $\|\tilde{f} - f\|_2$ using Davis-Kahan theorem and bounds of steps 1 and 2.
- **Step 4.** Use the linearity of the Fiedler vector to translate this result into a bound on the maximum displacement of the retrieved ranking $\|\tilde{\pi} - \pi\|_\infty$.

We now turn to the proof itself.

5.3 Step 1: Bounding $\|\tilde{D}_S - D_S\|_2$ and $\|\tilde{S} - S\|_2$

Here, we seek to bound $\|\tilde{D}_S - D_S\|_2$ and $\|\tilde{S} - S\|_2$ with high probability using concentration inequalities.

5.3.1 Bounding the norm of the degree matrix

We first bound perturbations of the degree matrix with both missing and corrupted comparisons.

Lemma 15 *For every $\mu \in (0,1)$ and $n \geq 100$, if $q \geq \frac{\log^4 n}{\mu^2(2p-1)^4 n}$ then*

$$\|\tilde{D}_S - D_S\|_2 \leq \frac{3\mu n^2}{\sqrt{\log n}}$$

with probability at least $1 - 1/n$.

Proof Let $R = \tilde{S} - S$ and $\delta = \mathbf{diag}\, D_R = \mathbf{diag}((\tilde{S} - S)\mathbf{1})$. Since D_S and $\tilde{D}_S$ are diagonal matrices, $\|\tilde{D}_S - D_S\|_2 = \max|\delta_i|$. We first seek a concentration inequality for each δ_i and then derive a bound on $\|\tilde{D}_S - D_S\|_2$.

By definition of the similarity matrix S and its perturbed analogue $\tilde{S}$ we have

$$R_{ij} = \sum_{k=1}^{n} C_{ik}C_{jk}\left(\frac{B_{ik}B_{jk}}{q^2(2p-1)^2} - 1\right).$$

Hence

$$\delta_i = \sum_{j=1}^{n} R_{ij} = \sum_{j=1}^{n}\sum_{k=1}^{n} C_{ik}C_{jk}\left(\frac{B_{ik}B_{jk}}{q^2(2p-1)^2} - 1\right).$$

Notice that we can arbitrarily fix the diagonal values of R to zeros. Indeed, the similarity between an element and itself should be a constant by convention, which leads to $R_{ii} = \tilde{S}_{ii} - S_{ii} = 0$ for all items i. Hence we could take $j \neq i$ in the definition of δ_i, and we can consider B_{ik} independent of B_{jk} in the associated summation.

We first seek a concentration inequality for each δ_i. Notice that

$$\begin{aligned}\delta_i &= \sum_{j=1}^{n}\sum_{k=1}^{n} C_{ik}C_{jk}\left(\frac{B_{ik}B_{jk}}{q^2(2p-1)^2} - 1\right) \\ &= \underbrace{\sum_{k=1}^{n}\left(\frac{C_{ik}B_{ik}}{q(2p-1)}\sum_{j=1}^{n} C_{jk}\left(\frac{B_{jk}}{q(2p-1)} - 1\right)\right)}_{\text{Quad}} + \underbrace{\sum_{k=1}^{n}\sum_{j=1}^{n} C_{ik}C_{jk}\left(\frac{B_{ik}}{q(2p-1)} - 1\right)}_{\text{Lin}}.\end{aligned}$$

The first term (denoted Quad in the following) is quadratic with respect to the B_{jk} while the second term (denoted Lin in the following) is linear. Both terms have mean zero since the B_{ik} are independent of the B_{jk}. We begin by bounding the quadratic term Quad. Let $X_{jk} = C_{jk}\left(\frac{1}{q(2p-1)}B_{jk} - 1\right)$. We have

$$\mathbf{E}(X_{jk}) = C_{jk}\left(\tfrac{qp - q(1-p)}{q(2p-1)} - 1\right) = 0,$$

$$\mathbf{var}(X_{jk}) = \frac{\mathbf{var}(B_{jk})}{q^2(2p-1)^2} = \frac{1}{q^2(2p-1)^2}(q - q^2(2p-1)^2) = \frac{1}{q(2p-1)^2} - 1 \leq \frac{1}{q(2p-1)^2},$$

and

$$|X_{jk}| = \left|\frac{B_{jk}}{q(2p-1)} - 1\right| \leq 1 + \frac{1}{q(2p-1)} \leq \frac{2}{q(2p-1)} \leq \frac{2}{q(2p-1)^2}.$$

By applying Bernstein's inequality for any $t > 0$

$$\mathbf{Prob}\left(\left|\sum_{j=1}^{n} X_{jk}\right| > t\right) \leq 2\exp\left(\frac{-q(2p-1)^2t^2}{2(n + 2t/3)}\right) \leq 2\exp\left(\frac{-q(2p-1)^2t^2}{2(n+t)}\right). \quad (9)$$

Now notice that

$$\begin{aligned}\mathbf{Prob}(|\text{Quad}| > t) &= \mathbf{Prob}\left(\left|\sum_{k=1}^{n}\left(C_{ik}\frac{B_{ik}}{q(2p-1)}\sum_{j=1}^{n} X_{jk}\right)\right| > t\right) \\ &\leq \mathbf{Prob}\left(\sum_{k=1}^{n}\left(\frac{|B_{ik}|}{q(2p-1)}\right)\max_l\left|\sum_{j=1}^{n} X_{jl}\right| > t\right).\end{aligned}$$

By applying a union bound to the first Bernstein inequality (9), for any $t > 0$

$$\mathbf{Prob}\left(\max_l\left|\sum_{j=1}^{n} X_{jl}\right| > \sqrt{t}\right) \leq 2n\exp\left(\frac{-tq(2p-1)^2}{2(n+\sqrt{t})}\right).$$

Moreover, since $\mathbf{E}\,|B_{ik}| = q$ we also get from Bernstein's inequality that for any $t > 0$

$$\mathbf{Prob}\left(\sum_{k=1}^{n}\frac{|B_{ik}|}{q(2p-1)} > \frac{n}{2p-1} + \sqrt{t}\right) \leq \exp\left(\frac{-tq(2p-1)^2}{2(n+\sqrt{t})}\right).$$

We deduce from these last three inequalities that for any $t > 0$

$$\mathbf{Prob}(|\text{Quad}| > t) \leq (2n+1)\exp\left(\frac{-tq(2p-1)^2}{2(n+\sqrt{t})}\right).$$

Taking $t = \mu^2(2p-1)^2n^2/\log n$ and $q \geq \frac{\log^4 n}{\mu^2(2p-1)^4 n}$, with $\mu \leq 1$, we have $\sqrt{t} \leq n$ and we deduce that

$$\mathbf{Prob}\left(|\text{Quad}| > \frac{2\mu n^2}{\sqrt{\log n}}\right) \leq (2n+1)\exp\left(-\frac{\log^3 n}{4}\right). \quad (10)$$

We now bound the linear term Lin.

$$\begin{aligned}\mathbf{Prob}(|\text{Lin}| > t) &= \mathbf{Prob}\left(\left|\sum_{j=1}^{n}\sum_{k=1}^{n} C_{ik}C_{jk}\left(\frac{B_{ik}}{q(2p-1)} - 1\right)\right| > t\right) \\ &\leq \mathbf{Prob}\left(\sum_{k=1}^{n}|C_{ik}|\max_l\left|\sum_{j=1}^{n} X_{jl}\right| > t\right) \\ &\leq \mathbf{Prob}\left(\max_k\left|\sum_{j=1}^{n} X_{jk}\right| > t/n\right),\end{aligned}$$

hence

$$\mathbf{Prob}(|\mathrm{Lin}| > t) \leq 2n \exp\left(\frac{-t^2 q(2p-1)^2}{2n^2(n+t/n)}\right).$$

Taking $t = \mu n^2/(\log n)^{1/2}$ and $q \geq \frac{\log^4 n}{\mu^2(2p-1)^4 n}$, with $\mu \leq 1$, we have $t \leq n^2$ and we deduce that

$$\mathbf{Prob}(|\mathrm{Lin}| > t) \leq 2n \exp\left(-\frac{\log^3 n}{4}\right). \tag{11}$$

Finally, combining equations (10) and (11), we obtain for $q \geq \frac{\log^4 n}{\mu^2(2p-1)^4 n}$, with $\mu \leq 1$

$$\mathbf{Prob}\left(|\delta_i| > \frac{3\mu n^2}{\sqrt{\log n}}\right) \leq (4n+1) \exp\left(-\frac{\log^3 n}{4}\right).$$

Now, using a union bound, this shows that for $q \geq \frac{\log^4 n}{\mu^2(2p-1)^4 n}$,

$$\mathbf{Prob}\left(\max|\delta_i| > \frac{3\mu n^2}{\sqrt{\log n}}\right) \leq n(4n+1) \exp\left(-\frac{\log^3 n}{4}\right),$$

which is less than $1/n$ for $n \geq 100$. ■

5.3.2 Bounding perturbations of the comparison matrix C

Here, we adapt results in (Achlioptas and McSherry, 2007) to bound perturbations of the comparison matrix. We will then use bounds on the perturbations of C to bound $\|\tilde{S} - S\|_2$.

Lemma 16 *For $n \geq 104$ and $q \geq \frac{\log^3 n}{n}$,*

$$\|C - \tilde{C}\|_2 \leq \frac{c}{2p-1}\sqrt{\frac{n}{q}}, \tag{12}$$

with probability at least $1 - 2/n$, where c is an absolute constant.

Proof The main argument of the proof is to use the independence of the C_{ij} for $i < j$ in order to bound $\|\tilde{C} - C\|_2$ by a constant times $\sigma\sqrt{n}$, where σ is the standard deviation of C_{ij}. To isolate independent entries in the perturbation matrix, we first need to break the anti-symmetry of $\tilde{C} - C$ by decomposing $X = \tilde{C} - C$ into its upper triangular part and its lower triangular part, i.e., $\tilde{C} - C = X_{\mathrm{up}} + X_{\mathrm{low}}$, with $X_{\mathrm{up}} = -X_{\mathrm{low}}^T$ (diagonal entries of $\tilde{C} - C$ can be arbitrarily set to 0). Entries of X_{up} are all independent, with variance less than the variance of $\tilde{C}_{ij}$. Indeed, lower entries of X_{up} are equal to 0 and hence have variance 0. Notice that

$$\|\tilde{C} - C\|_2 = \|X_{\mathrm{up}} + X_{\mathrm{low}}\|_2 \leq \|X_{\mathrm{up}}\|_2 + \|X_{\mathrm{low}}\|_2 \leq 2\|X_{\mathrm{up}}\|_2,$$

so bounding $\|X_{\mathrm{up}}\|_2$ will give us a bound on $\|X\|_2$. In the rest of the proof we write X_{up} instead of X to simplify notations. We can now apply (Achlioptas and McSherry, 2007, Th. 3.1) to X. Since

$$X_{ij} = \tilde{C}_{ij} - C_{ij} = C_{ij}\left(\frac{B_{ij}}{q(2p-1)} - 1\right),$$

we have (*cf.* proof of Lemma 15) $\mathbf{E}(X_{ij}) = 0$, $\mathbf{var}(X_{ij}) \leq \frac{1}{q(2p-1)^2}$, and $|X_{ij}| \leq \frac{2}{q(2p-1)}$. Hence for a given $\epsilon > 0$ such that

$$\frac{4}{q(2p-1)} \leq \left(\frac{\log(1+\epsilon)}{2\log(2n)}\right)^2 \frac{\sqrt{2n}}{\sqrt{q}(2p-1)}, \tag{13}$$

for any $\theta > 0$ and $n \geq 76$,

$$\mathbf{Prob}\left(\|X\|_2 \geq 2(1+\epsilon+\theta)\frac{1}{\sqrt{q}(2p-1)}\sqrt{2n}\right) < 2\exp\left(-16\frac{\theta^2}{\epsilon^4}\log^3 n\right). \tag{14}$$

For $q \geq \frac{(\log 2n)^3}{n}$ and taking $\epsilon \geq \exp(\sqrt{(16/\sqrt{(2)})}) - 1$ (so $\log(1+\epsilon)^2 \geq 16/\sqrt{2}$) means inequality (13) holds. Taking (14) with $\epsilon = 30$ and $\theta = 30$ we get

$$\mathbf{Prob}\left(\|X\|_2 \geq \frac{2\sqrt{2}(1+30+30)}{2p-1}\sqrt{\frac{n}{q}}\right) < 2\exp\left(-10^{-2}\log^3 n\right). \tag{15}$$

Hence for $n \geq 104$, we have $\log^3 n > 100$ and

$$\mathbf{Prob}\left(\|X\|_2 \geq \frac{173}{2p-1}\sqrt{\frac{n}{q}}\right) < 2/n.$$

Noting that $\log 2n \leq 1.15 \log n$ for $n \geq 104$, we obtain the desired result by choosing $c = 2 \times 173 \times \sqrt{1.15} \leq 371$. ■

5.3.3 Bounding the perturbation of the similarity matrix $\|S\|$.

We now seek to bound $\|\tilde{S} - S\|$ with high probability.

Lemma 17 *For every $\mu \in (0,1)$, $n \geq 104$, if $q > \frac{\log^4 n}{\mu^2(2p-1)^2 n}$, then*

$$\|\tilde{S} - S\|_2 \leq c\frac{\mu n^2}{\sqrt{\log n}},$$

with probability at least $1 - 2/n$, where c is an absolute constant.

Proof Let $X = \tilde{C} - C$. We have

$$\tilde{C}\tilde{C}^T = (C+X)(C+X)^T = CC^T + XX^T + XC^T + CX^T,$$

hence

$$\tilde{S} - S = XX^T + XC^T + CX^T,$$

and

$$\|\tilde{S} - S\|_2 \leq \|XX^T\|_2 + \|XC^T\|_2 + \|CX^T\|_2 \leq \|X\|_2^2 + 2\|X\|_2\|C\|_2.$$

From Lemma 16 we deduce that for $n \geq 104$ and $q \geq \frac{\log^4 n}{n}$, with probability at least $1 - 2/n$

$$\|\tilde{S} - S\|_2 \leq \frac{c^2 n}{q(2p-1)^2} + \frac{2c}{2p-1}\sqrt{\frac{n}{q}}\|C\|_2. \tag{16}$$

Notice that $\|C\|_2^2 \leq \mathbf{Tr}(CC^T) = n^2$, hence $\|C\|_2 \leq n$ and

$$\|\tilde{S} - S\|_2 \leq \frac{c^2 n}{q(2p-1)^2} + \frac{2cn}{2p-1}\sqrt{\frac{n}{q}}. \tag{17}$$

By taking $q > \frac{\log^4 n}{\mu^2(2p-1)^2 n}$, we get for $n \geq 104$ with probability at least $1 - 2/n$

$$\|\tilde{S} - S\|_2 \leq \frac{c^2\mu^2 n^2}{\log^4 n} + \frac{2c\mu n^2}{\log^2 n}.$$

Hence setting a new constant c with $c = \max(c^2(\log 104)^{-7/2}, 2c(\log 104)^{-3/2}) \leq 270$,

$$\|\tilde{S} - S\|_2 \leq c\frac{\mu n^2}{\sqrt{\log n}}$$

with probability at least $1 - 2/n$, which is the desired result. ■

5.4 Step 2: Controlling the eigengap

In the following proposition we show that the normalized Laplacian of the similarity matrix S has a constant Fiedler value and a linear Fiedler vector. We then deduce bounds on the eigengap between the first, second and third smallest eigenvalues of the Laplacian.

Proposition 18 *Let $L^{\text{norm}} = \mathbf{I} - D^{-1}S$ be the non-symmetric normalized Laplacian of S. L^{norm} has a linear Fiedler vector, and its Fiedler value is equal to $2/3$.*

Proof Let $x_i = i - \frac{n+1}{2}$ (x is linear with mean zero). We want to show that $L^{\text{norm}}x = \lambda_2 x$ or equivalently $Sx = (1-\lambda_2)Dx$. We develop both sides of the last equation, and use the following facts

$$S_{i,j} = n - |j - i|, \quad \sum_{k=1}^{n} k = \frac{n(n+1)}{2}, \quad \sum_{k=1}^{n} k^2 = \frac{n(n+1)(2n+1)}{6}.$$

We first get an expression for the degree of S, defined by $d = S\mathbf{1} = \sum_{i=1}^n S_{i,k}$, with

$$\begin{aligned} d_i &= \sum_{k=1}^{i-1} S_{i,k} + \sum_{k=i}^{n} S_{i,k} \\ &= \sum_{k=1}^{i-1}(n - i + k) + \sum_{k=i}^{n}(n - k + i) \\ &= \frac{n(n-1)}{2} + i(n - i + 1). \end{aligned}$$

Similarly we have

$$\begin{aligned} \sum_{k=1}^{n} kS_{i,k} &= \sum_{k=1}^{i-1} k(n - i + k) + \sum_{k=i}^{n} k(n - k + i) \\ &= \frac{n^2(n+1)}{2} + \frac{i(i-1)(2i-1)}{3} - \frac{n(n+1)(2n+1)}{6} - i^2(i-1) + i\frac{n(n+1)}{2}. \end{aligned}$$

Finally, setting $\lambda_2 = 2/3$, notice that

$$\begin{aligned} [Sx]_i &= \sum_{k=1}^{n} S_{i,k}\left(k - \frac{n+1}{2}\right) \\ &= \sum_{k=1}^{n} kS_{i,k} - \frac{n+1}{2}d_i \\ &= \frac{1}{3}\left(\frac{n(n-1)}{2} + i(n-i+1)\right)\left(i - \frac{n+1}{2}\right) \\ &= (1-\lambda_2)d_i x_i, \end{aligned}$$

which shows that $Sx = (1-\lambda_2)Dx$. ■

The next corollary will be useful in following proofs.

Corollary 19 *The Fiedler vector f of the unperturbed Laplacian satisfies $\|f\|_\infty \leq 2/\sqrt{n}$.*

Proof We use the fact that f is collinear to the vector x defined by $x_i = i - \frac{n+1}{2}$ and verifies $\|f\|_2 = 1$. Let us consider the case of n odd. The Fiedler vector verifies $f_i = \frac{i-(n+1)/2}{a_n}$, with

$$a_n^2 = 2\sum_{k=0}^{(n-1)/2} k^2 = \frac{2}{6}\frac{n-1}{2}\left(\frac{n-1}{2} + 1\right)((n-1)+1) = \frac{n^3 - n}{12}.$$

Hence

$$\|f\|_\infty = f_n = \frac{n-1}{2a_n} \leq \sqrt{\frac{3}{n-1}} \leq \frac{2}{\sqrt{n}} \quad \text{for} \quad n \geq 5.$$

A similar reasoning applies for n even. ■

Lemma 20 *The minimum eigengap between the Fiedler value and other eigenvalues is bounded below by a constant for n sufficiently large.*

Proof The first eigenvalue of the Laplacian is always 0, so we have for any n, $\lambda_2 - \lambda_1 = \lambda_2 = 2/3$. Moreover, using results from (Von Luxburg et al., 2008), we know that eigenvalues of the normalized Laplacian that are different from one converge to an asymptotic spectrum, and that the limit eigenvalues are "isolated". Hence there exists $n_0 > 0$ and $c > 0$ such that for any $n \geq n_0$ we have $\lambda_3 - \lambda_2 > c$. ■

Numerical experiments show that λ_3 converges to $0.93\ldots$ very fast when n grows towards infinity.

5.5 Step 3: Bounding the perturbation of the Fiedler vector $\|\tilde{f} - f\|_2$

We can now compile results from previous sections to get a first perturbation bound and show ℓ_2 consistency of the Fiedler vector when comparisons are both missing and corrupted.

Theorem 21 *For every $\mu \in (0,1)$ and n large enough, if $q > \frac{\log^4 n}{\mu^2(2p-1)^4 n}$, then*

$$\|\tilde{f} - f\|_2 \leq c\frac{\mu}{\sqrt{\log n}},$$

with probability at least $1 - 2/n$.

Proof In order to use Davis-Kahan theorem, we need to relate perturbations of the normalized Laplacian matrix to perturbations of the similarity and degree matrices. To simplify notations, we write $L = \mathbf{I} - D^{-1}S$ and $\tilde{L} = \mathbf{I} - \tilde{D}^{-1}\tilde{S}$.

Since the normalized Laplacian is not symmetric, we will actually apply Davis-Kahan theorem to the symmetric normalized Laplacian $L_{sym} = \mathbf{I} - D^{-1/2}SD^{-1/2}$. It is easy to see that L_{sym} and L have the same Fiedler value, and that the Fiedler vector f_{sym} of L_{sym} is equal to $D^{1/2}f$ (up to normalization). Indeed, if v is the eigenvector associated to the i^{th} eigenvalue of L (denoted by λ_i), then

$$L_{sym}D^{1/2}v = D^{-1/2}(D-S)D^{-1/2}D^{1/2}v = D^{-1/2}(D-S)v = D^{1/2}(\mathbf{I} - D^{-1}S)v = \lambda_i D^{1/2}v.$$

Hence perturbations of the Fiedler vector of L_{sym} are directly related to perturbations of the Fiedler vector of L.

The proof relies mainly on Lemma 15, which states that for $n \geq 100$, denoting by d the vector of diagonal elements of D_S,

$$\|D_R\|_2 = \max |\tilde{d}_i - d_i| \leq \frac{3\mu n^2}{\sqrt{\log n}}$$

with probability at least $1 - \frac{2}{n}$. Combined with the fact that $d_i = \frac{n(n-1)}{2} + i(n-i+1)$ (*cf.* proof of Proposition 18), this guarantees that d_i and $\tilde{d}_i$ are strictly positive. Hence $D^{-1/2}$ and $\tilde{D}^{-1/2}$ are well defined. We now decompose the perturbation of the Laplacian matrix. Let $\Delta = D^{-1/2}$, we have

$$\begin{aligned}
\|\tilde{L}_{sym} - L_{sym}\|_2 &= \|\tilde{\Delta}\tilde{S}\tilde{\Delta} - \Delta S \Delta\|_2 \\
&= \|\tilde{\Delta}\tilde{S}\tilde{\Delta} - \tilde{\Delta}S\tilde{\Delta} + \tilde{\Delta}S\tilde{\Delta} - \Delta S\Delta\|_2 \\
&= \|\tilde{\Delta}(\tilde{S}-S)\tilde{\Delta} + \tilde{\Delta}S\tilde{\Delta} - \Delta S\tilde{\Delta} + \Delta S\tilde{\Delta} - \Delta S\Delta\|_2 \\
&= \|\tilde{\Delta}(\tilde{S}-S)\tilde{\Delta} + (\tilde{\Delta}-\Delta)S\tilde{\Delta} + \Delta S(\tilde{\Delta}-\Delta)\|_2 \\
&\leq \|\tilde{\Delta}\|_2^2\|\tilde{S}-S\|_2 + \|S\|_2(\|\tilde{\Delta}\|_2 + \|\Delta\|_2)\|\tilde{\Delta}-\Delta\|_2.
\end{aligned}$$

We first bound $\|\tilde{\Delta} - \Delta\|_2$. Notice that

$$\|\tilde{\Delta} - \Delta\|_2 = \max_i |\tilde{d}_i^{-1/2} - d_i^{-1/2}|,$$

where d_i (respectively $\tilde{d}_i$) is the sum of elements of the i^{th} row of S (respectively $\tilde{S}$). Hence

$$\|\tilde{\Delta} - \Delta\|_2 = \max_i \frac{\left|\sqrt{\tilde{d}_i} - \sqrt{d_i}\right|}{\sqrt{\tilde{d}_i d_i}} = \max_i \frac{\left|\tilde{d}_i - d_i\right|}{\sqrt{\tilde{d}_i d_i}(\sqrt{\tilde{d}_i} + \sqrt{d_i})}.$$

Using Lemma 15 we obtain

$$\|\tilde{\Delta} - \Delta\|_2 \leq \max_i \frac{\frac{3\mu n^2}{\sqrt{\log n}}}{\sqrt{d_i}(d_i - \frac{3\mu n^2}{\sqrt{\log n}}) + d_i\sqrt{d_i - \frac{3\mu n^2}{\sqrt{\log n}}}}, \quad i = 1, \ldots, n, \text{ w.h.p.}$$

Since $d_i = \frac{n(n-1)}{2} + i(n-i+1)$ (*cf.* proof of Proposition 18), for $\mu < 1$ there exists a constant c such that $d_i > d_i - \frac{3\mu n^2}{\sqrt{\log n}} > cn^2$. We deduce that there exists an absolute constant c such that

$$\|\tilde{\Delta} - \Delta\|_2 \leq \frac{c\mu}{n\sqrt{\log n}} \text{ w.h.p.} \tag{18}$$

Similarly we obtain that

$$\|\Delta\|_2 \leq \frac{c}{n} \text{ w.h.p,} \tag{19}$$

and

$$\|\tilde{\Delta}\|_2 \leq \frac{c}{n} \text{ w.h.p.} \tag{20}$$

Moreover, we have

$$\|S\|_2 = \|CC^T + n\mathbf{1}\mathbf{1}^T\|_2 \leq \|C\|_2^2 + n\|\mathbf{1}\mathbf{1}^T\|_2 \leq 2n^2.$$

Hence,

$$\|S\|_2(\|\tilde{\Delta}\|_2 + \|\Delta\|_2)\|\tilde{\Delta} - \Delta\|_2 \leq \frac{c\mu}{\sqrt{\log n}} \text{ w.h.p,}$$

where $c := 4c^2$. Using Lemma 17, we can similarly bound $\|\tilde{\Delta}\|_2^2\|\tilde{S} - S\|_2$ and obtain

$$\|\tilde{L}_{sym} - L_{sym}\|_2 \leq \frac{c\mu}{\sqrt{\log n}} \text{ w.h.p,} \tag{21}$$

where c is an absolute constant. Finally, for small μ, Weyl's inequality, equation (21) together with Lemma 20 ensure that for n large enough with high probability $|\tilde{\lambda}_3 - \lambda_2| > |\lambda_3 - \lambda_2|/2$ and $|\tilde{\lambda}_1 - \lambda_2| > |\lambda_1 - \lambda_2|/2$. Hence we can apply Davis-Kahan theorem. Compiling all constants into c we obtain

$$\|\tilde{f}_{sym} - f_{sym}\|_2 \leq \frac{c\mu}{\sqrt{\log n}} \text{ w.h.p.} \tag{22}$$

Finally we relate the perturbations of f_{sym} to the perturbations of f. Since $f_{sym} = \frac{D^{1/2}f}{\|D^{1/2}f\|_2}$, letting $\alpha_n = \|D^{1/2}f\|$, we deduce that

$$\begin{aligned}
\|\tilde{f} - f\|_2 &= \|\tilde{\alpha}_n\tilde{\Delta}\tilde{f}_{sym} - \alpha_n\Delta f_{sym}\|_2 \\
&= \|\Delta(\tilde{\alpha}_n\tilde{f}_{sym} - \alpha_n f_{sym}) + \tilde{\alpha}_n(\tilde{\Delta} - \Delta)\tilde{f}_{sym}\|_2 \\
&\leq \|\Delta\|_2\|\tilde{\alpha}_n\tilde{f}_{sym} - \alpha_n f_{sym}\|_2 + \|\tilde{\alpha}_n\|_2\|\tilde{\Delta} - \Delta\|_2.
\end{aligned}$$

Similarly as for inequality (18), we can show that $\|\tilde{D}^{1/2}\|$ and $\|D^{1/2}\|$ are of the same order $O(n)$. Since $\|f\|_2 = \|\tilde{f}\|_2 = 1$, this is also true for $\|\alpha_n\|_2$ and $\|\tilde{\alpha}_n\|_2$. We conclude the proof using inequalities (18), (19) and (22). ■

5.6 Bounding ranking perturbations $\|\tilde{\pi} - \pi\|_\infty$

SerialRank's ranking is derived by sorting the Fiedler vector. While the consistency result in Theorem 21 shows the ℓ_2 estimation error going to zero as n goes to infinity, this is not sufficient to quantify the maximum displacement of the ranking. To quantify the maximum displacement of the ranking, as in (Wauthier et al., 2013), we need to bound $\|\tilde{\pi} - \pi\|_\infty$ instead.

We bound the maximum displacement of the ranking here with an extra factor $\sqrt{n}$ compared to the sampling rate in (Wauthier et al., 2013). We would only need a better component-wise bound on $\tilde{S} - S$ to get rid of this extra factor $\sqrt{n}$, and we hope to achieve it in future work.

The proof is in two parts: we first bound the ℓ_∞ norm of the perturbation of the Fiedler vector, then translate this perturbation of the Fiedler vector into a perturbation of the ranking.

5.6.1 Bounding the ℓ_∞ norm of the Fiedler vector perturbation

We start by a technical lemma bounding $\|(\tilde{S} - S)f\|_\infty$.

Lemma 22 *Let $r > 0$, for every $\mu \in (0,1)$ and n large enough, if $q > \frac{\log^4 n}{\mu^2(2p-1)^4 n}$, then*

$$\|(\tilde{S} - S)f\|_\infty \leq \frac{3\mu n^{3/2}}{\sqrt{\log n}}$$

with probability at least $1 - 2/n$.

Proof The proof is very much similar to the proof of Lemma 15 and can be found the Appendix (section A.2). ■

We now prove the main result of this section, bounding $\|\tilde{f} - f\|_\infty$ with high probability when roughly $O(n^{3/2})$ comparisons are sampled.

Lemma 23 *For every $\mu \in (0,1)$ and n large enough, if $q > \frac{\log^4 n}{\mu^2(2p-1)^4\sqrt{n}}$, then*

$$\|\tilde{f} - f\|_\infty \leq c\frac{\mu}{\sqrt{n \log n}}$$

with probability at least $1 - 2/n$, where c is an absolute constant.

Proof Notice that by definition $\tilde{L}\tilde{f} = \tilde{\lambda}_2\tilde{f}$ and $Lf = \lambda_2 f$. Hence for $\tilde{\lambda}_2 > 0$

$$\begin{aligned}\tilde{f} - f &= \frac{\tilde{L}\tilde{f}}{\tilde{\lambda}_2} - f \\ &= \frac{\tilde{L}\tilde{f} - Lf}{\tilde{\lambda}_2} + \frac{(\lambda_2 - \tilde{\lambda}_2)f}{\tilde{\lambda}_2}.\end{aligned}$$

Moreover

$$\begin{aligned}\tilde{L}\tilde{f} - Lf &= (\mathbf{I} - \tilde{D}^{-1}\tilde{S})\tilde{f} - (\mathbf{I} - D^{-1}S)f \\ &= (\tilde{f} - f) + D^{-1}Sf - \tilde{D}^{-1}\tilde{S}\tilde{f} \\ &= (\tilde{f} - f) + D^{-1}Sf - \tilde{D}^{-1}\tilde{S}f + \tilde{D}^{-1}\tilde{S}f - \tilde{D}^{-1}\tilde{S}\tilde{f} \\ &= (\tilde{f} - f) + (D^{-1}S - \tilde{D}^{-1}\tilde{S})f + \tilde{D}^{-1}\tilde{S}(f - \tilde{f})\end{aligned}$$

Hence

$$(\mathbf{I}(\tilde{\lambda}_2 - 1) + \tilde{D}^{-1}\tilde{S})(\tilde{f} - f) = (D^{-1}S - \tilde{D}^{-1}\tilde{S} + (\lambda_2 - \tilde{\lambda}_2)\mathbf{I})f. \tag{23}$$

Writing S_i the i^{th} row of S and d_i the degree of row i, using the triangle inequality, we deduce that

$$|\tilde{f}_i - f_i| \leq \frac{1}{|\tilde{\lambda}_2 - 1|}\left(|(d_i^{-1}S_i - \tilde{d}_i^{-1}\tilde{S}_i)f| + |\lambda_2 - \tilde{\lambda}_2||f_i| + |\tilde{d}_i^{-1}\tilde{S}_i(\tilde{f} - f)|\right). \tag{24}$$

It remains to bound each term separately, using Weyl's inequality for the denominator and previous lemmas for numerator terms, which is detailed in the Appendix (section A.2). ■

5.6.2 Bounding the ℓ_∞ norm of the ranking perturbation

First note that the ℓ_∞-norm of the ranking perturbation is equal to the number of pairwise disagreements between the true ranking and the retrieved one, i.e., for any i

$$|\tilde{\pi}_i - \pi_i| = \sum_{j<i} \mathbf{1}_{\tilde{f}_j > \tilde{f}_i} + \sum_{j>i} \mathbf{1}_{\tilde{f}_j < \tilde{f}_i}.$$

Now we will argue that when i and j are far apart, with high probability

$$\tilde{f}_j - \tilde{f}_i = (\tilde{f}_j - f_j) + (f_j - f_i) + (f_i - \tilde{f}_i)$$

will have the same sign as $j - i$. Indeed $|\tilde{f}_j - f_j|$ and $|\tilde{f}_i - f_i|$ can be bounded with high probability by a quantity less than $|f_j - f_i|/2$ for i and j sufficiently "far apart". Hence, $|\tilde{\pi}_i - \pi_i|$ is bounded by the number of pairs that are not sufficiently "far apart". We quantify the term "far apart" in the following proposition.

Theorem 24 *For every $\mu \in (0,1)$ and n large enough, if $q > \frac{\log^4 n}{\mu^2(2p-1)^2\sqrt{n}}$, then*

$$\|\tilde{\pi} - \pi\|_\infty \leq c\mu n,$$

with probability at least $1 - 2/n$, where c is an absolute constant.

Proof We assume w.l.o.g. in the following that the true ranking is the identity, hence the unperturbed Fiedler vector f is strictly increasing. We first notice that for any $j > i$

$$\tilde{f}_j - \tilde{f}_i = (\tilde{f}_j - f_j) + (f_j - f_i) + (f_i - \tilde{f}_i).$$

Hence for any $j > i$

$$\|\tilde{f} - f\|_\infty \leq \frac{|f_j - f_i|}{2} \implies \tilde{f}_j \geq \tilde{f}_i.$$

Consequently, fixing an index i_0,

$$\sum_{j>i_0} \mathbf{1}_{\tilde{f}_j < \tilde{f}_{i_0}} \leq \sum_{j>i_0} \mathbf{1}_{\|\tilde{f}-f\|_\infty > \frac{|f_j - f_{i_0}|}{2}}.$$

Now recall that by Lemma 23, for $q > \frac{\log^4 n}{\mu^2 (2p-1)^2 \sqrt{n}}$

$$\|\tilde{f} - f\|_\infty \leq c \frac{\mu}{\sqrt{n \log n}}$$

with probability at least $1 - 2/n$. Hence

$$\sum_{j>i_0} \mathbf{1}_{\tilde{f}_j < \tilde{f}_{i_0}} \leq \sum_{j>i_0} \mathbf{1}_{\|\tilde{f}-f\|_\infty > \frac{|f_j - f_{i_0}|}{2}} \leq \sum_{j>i_0} \mathbf{1}_{\frac{c\mu}{\sqrt{n \log n}} > \frac{|f_j - f_{i_0}|}{2}} \quad \text{w.h.p.}$$

We now consider the case of n odd (a similar reasoning applies for n even). We have $f_j = \frac{j-(n+1)/2}{a_n}$ for all j, with

$$a_n^2 = 2 \sum_{k=0}^{(n-1)/2} k^2 = \frac{2}{6} \frac{n-1}{2} \left(\frac{n-1}{2} + 1 \right) ((n-1)+1) = \frac{n^3 - n}{12}.$$

Therefore

$$\frac{c\mu}{\sqrt{n \log n}} > \frac{|f_j - f_{i_0}|}{2} \iff \frac{c\mu}{\sqrt{n \log n}} > \frac{|j - i_0| \sqrt{3}}{n^{3/2}} \iff \frac{c\mu n}{\sqrt{3 \log n}} > |j - i_0|.$$

Dividing c by $\sqrt{3}$, we deduce that

$$\sum_{j>i_0} \mathbf{1}_{\tilde{f}_j < \tilde{f}_{i_0}} \leq \sum_{j>i_0} \mathbf{1}_{\frac{c\mu n}{\sqrt{\log n}} > |j - i_0|} = \left\lfloor \frac{c\mu n}{\sqrt{\log n}} \right\rfloor \leq \frac{c\mu n}{\sqrt{\log n}} \quad \text{w.h.p.}$$

Similarly

$$\sum_{j<i_0} \mathbf{1}_{\tilde{f}_j > \tilde{f}_{i_0}} \leq \frac{c\mu n}{\sqrt{\log n}} \quad \text{w.h.p.}$$

Finally, we obtain

$$|\tilde{\pi}_{i_0} - \pi_{i_0}| = \sum_{j<i_0} \mathbf{1}_{\tilde{f}_j > \tilde{f}_{i_0}} + \sum_{j>i_0} \mathbf{1}_{\tilde{f}_j < \tilde{f}_{i_0}} \leq \frac{c\mu n}{\sqrt{\log n}} \quad \text{w.h.p.},$$

where c is an absolute constant. Since the last inequality relies on $\|\tilde{f} - f\|_\infty \leq \frac{c\mu}{\sqrt{n \log n}}$, it is true for all i_0 with probabilty $1 - 2/n$, which concludes the proof. ■

6. Numerical Experiments

We now describe numerical experiments using both synthetic and real datasets to compare the performance of SerialRank with several classical ranking methods.

6.1 Synthetic Datasets

The first synthetic dataset consists of a matrix of pairwise comparisons derived from a given ranking of n items with uniform, randomly distributed corrupted or missing entries. A second synthetic dataset consists of a full matrix of pairwise comparisons derived from a given ranking of n items, with added "local" noise on the similarity between nearby items. Specifically, given a positive integer m, we let $C_{i,j} = 1$ if $i < j - m$, $C_{i,j} \sim \text{Unif}[-1, 1]$ if $|i - j| \leq m$, and $C_{i,j} = -1$ if $i > j + m$. In Figure 2, we measure the Kendall τ correlation coefficient between the true ranking and the retrieved ranking, when varying either the percentage of corrupted comparisons or the percentage of missing comparisons. Kendall's τ counts the number of agreeing pairs minus the number of disagreeing pairs between two rankings, scaled by the total number of pairs, so that it takes values between -1 and 1. Experiments were performed with $n = 100$ and reported Kendall τ values were averaged over 50 experiments, with standard deviation less than 0.02 for points of interest (i.e., with Kendall $\tau > 0.8$).

Results suggest that SerialRank (SR, full red line) produces more accurate rankings than point score (PS, (Wauthier et al., 2013) dashed blue line), Rank Centrality (RC (Negahban et al., 2012) dashed green line), and maximum likelihood (BTL (Bradley and Terry, 1952), dashed magenta line) in regimes with limited amount of corrupted and missing comparisons. In particular SerialRank seems more robust to corrupted comparisons. On the other hand, the performance deteriorates more rapidly in regimes with very high number of corrupted/missing comparisons. For a more exhaustive comparison of SerialRank to state-of-the art ranking algorithms, we refer the interested reader to a recent paper by Cucuringu (2015), which introduces another ranking algorithm called SyncRank, and provides extensive numerical experiments.

6.2 Real Datasets

The first real dataset consists of pairwise comparisons derived from outcomes in the TopCoder algorithm competitions. We collected data from 103 competitions among 2742 coders over a period of about one year. Pairwise comparisons are extracted from the ranking of each competition and then averaged for each pair. TopCoder maintains ratings for each participant, updated in an online scheme after each competition, which were also included in the benchmarks. To measure performance in Figure 3, we compute the percentage of upsets (i.e. comparisons disagreeing with the computed ranking), which is closely related to the Kendall τ (by an affine transformation if comparisons were coming from a consistent ranking). We refine this metric by considering only the participants appearing in the top k, for various values of k, i.e. computing

$$l_k = \frac{1}{|\mathcal{C}_k|} \sum_{i,j \in \mathcal{C}_k} \mathbf{1}_{r(i) > r(j)} \mathbf{1}_{C_{i,j} < 0}, \tag{25}$$

where $\mathcal{C}$ are the pairs (i, j) that are compared and such that i, j are both ranked in the top k, and $r(i)$ is the rank of i. Up to scaling, this is the loss considered in (Kenyon-Mathieu and Schudy, 2007).

This experiment shows that SerialRank gives competitive results with other ranking algorithms. Notice that rankings could probably be refined by designing a similarity matrix taking into account the specific nature of the data.

Table 1: Ranking of teams in the England premier league season 2013-2014.

Official	**Row-sum**	**RC**	**BTL**	**SerialRank**	**Semi-Supervised**
Man City (86)	Man City	Liverpool	Man City	Man City	Man City
Liverpool (84)	Liverpool	Arsenal	Liverpool	Chelsea	Chelsea
Chelsea (82)	Chelsea	Man City	Chelsea	Liverpool	Liverpool
Arsenal (79)	Arsenal	Chelsea	Arsenal	Arsenal	Everton
Everton (72)	Everton	Everton	Everton	Everton	Arsenal
Tottenham (69)	Tottenham	Tottenham	Tottenham	Tottenham	Tottenham
Man United (64)	Man United	Man United	Man United	Southampton	Man United
Southampton (56)	Southampton	Southampton	Southampton	Man United	Southampton
Stoke (50)	Stoke	Stoke	Stoke	Stoke	Newcastle
Newcastle (49)	Newcastle	Newcastle	Newcastle	Swansea	Stoke
Crystal Palace (45)	Crystal Palace	Swansea	Crystal Palace	Newcastle	West Brom
Swansea (42)	Swansea	Crystal Palace	Swansea	West Brom	Swansea
West Ham (40)	West Brom	West Ham	West Brom	Hull	Crystal Palace
Aston Villa (38)	West Ham	Hull	West Ham	West Ham	Hull
Sunderland (38)	Aston Villa	Aston Villa	Aston Villa	Cardiff	West Ham
Hull (37)	Sunderland	West Brom	Sunderland	Crystal Palace	Fulham
West Brom (36)	Hull	Sunderland	Hull	Fulham	Norwich
Norwich (33)	Norwich	Fulham	Norwich	Norwich	Sunderland
Fulham (32)	Fulham	Norwich	Fulham	Sunderland	Aston Villa
Cardiff (30)	Cardiff	Cardiff	Cardiff	Aston Villa	Cardiff

6.3 Semi-Supervised Ranking

We illustrate here how, in a semi-supervised setting, one can interactively enforce some constraints on the retrieved ranking, using e.g. the semi-supervised seriation algorithm in (Fogel et al., 2013). We compute rankings of England Football Premier League teams for season 2013-2014 (*cf.* figure 4 for seasons 2011-2012 and 2012-2013). Comparisons are defined as the averaged outcome (win, loss, or tie) of home and away games for each pair of teams. As shown in Table 1, the top half of SerialRank ranking is very close to the official ranking calculated by sorting the sum of points for each team (3 points for a win, 1 point for a tie). However, there are significant variations in the bottom half, though the number of upsets is roughly the same as for the official ranking. To test semi-supervised ranking, suppose for example that we are not satisfied with the ranking of Aston Villa (last team when ranked by the spectral algorithm), we can explicitly enforce that Aston Villa appears before Cardiff, as in the official ranking. In the ranking based on the corresponding semi-supervised seriation problem, Aston Villa is not last anymore, though the number of disagreeing comparisons remains just as low (*cf.* Figure 3, *right*).

7. Conclusion

We have formulated the problem of ranking from pairwise comparisons as a seriation problem, i.e. the problem of ordering from similarity information. By constructing an adequate similarity matrix, we applied a spectral relaxation for seriation to a variety of synthetic and real ranking datasets, showing competitive and in some cases superior performance compared to classical methods, especially in low noise environments. We derived performance bounds for this algorithm in the presence of corrupted and missing (ordinal) comparisons showing that SerialRank produces state-of-the art results for ranking based on ordinal comparisons, e.g. showing exact reconstruction w.h.p. when only $O(\sqrt{n})$ comparisons are missing. On the other hand, performance deteriorates when only a small fraction of comparisons are observed, or in the presence of very high noise. In this scenario, we showed that local ordering errors can be bounded if the number of samples is of order $O(n^{1.5}\text{polylog}(n))$ which is significantly above the optimal bound of $O(n \log n)$.

A few questions thus remain open, which we pose as future research directions. First of all, from a theoretical perspective, is it possible to obtain an ℓ_∞ bound on local perturbations of the ranking using only $O(n\,\text{polylog(n)})$ sampled pairs? Or, on the contrary, can we find a lower bound for spectral algorithms (i.e. perturbation arguments) imposing more than $\Omega(n\,\text{polylog(n)})$ sampled pairs? Note that those questions hold for all current spectral ranking algorithms.

Another line of research concerns the generalization of spectral ordering methods to more flexible settings, e.g., enforcing structural or a priori constraints on the ranking. Hierarchical ranking, i.e. running the spectral algorithm on increasingly refined subsets of the original data should be explored too. Early experiments suggests this works quite well, but no bounds are available at this point.

Finally, it would be interesting to investigate how similarity measures could be tuned for specific applications in order to improve SerialRank predictive power, for instance to take into account more information than win/loss in sports tournaments. Additional experiments in this vein can be found in Cucuringu (2015).

Appendix A.

We now detail several complementary technical results.

A.1 Exact recovery results with missing entries

Here, as in Section 4, we study the impact of one missing comparison on SerialRank, then extend the result to multiple missing comparisons.

Proposition 25 *Given pairwise comparisons $C_{s,t} \in \{-1, 0, 1\}$ between items ranked according to their indices, suppose only one comparison $C_{i,j}$ is missing, with $j - i > 1$ (i.e., $C_{i,j} = 0$), then S^{match} defined in* (3) *remains* strict-R *and the point score vector remains strictly monotonic.*

Proof We use the same proof technique as in Proposition 12. We write the true score and comparison matrix w and C, while the observations are written $\hat{w}$ and $\hat{C}$ respectively. This means in particular that $\hat{C}_{i,j} = 0$. To simplify notations we denote by S the similarity

matrix S^{match} (respectively $\hat{S}$ when the similarity is computed from observations). We first study the impact of the missing comparison $C_{i,j}$ for $i < j$ on the point score vector $\hat{w}$. We have

$$\hat{w}_i = \sum_{k=1}^{n} \hat{C}_{k,i} = \sum_{k=1}^{n} C_{k,i} + \hat{C}_{j,i} - C_{j,i} = w_i + 1,$$

similarly $\hat{w}_j = w_j - 1$, whereas for $k \neq i, j$, $\hat{w}_k = w_k$. Hence, w is still strictly increasing if $j > i+1$. If $j = i+1$ there is a tie between w_i and w_{i+1}. Now we show that the similarity matrix defined in (3) is an R-matrix. Writing $\hat{S}$ in terms of S, we get

$$[\hat{C}\hat{C}^T]_{i,t} = \sum_{k \neq j} \left(\hat{C}_{i,k}\hat{C}_{t,k} \right) + \hat{C}_{i,j}\hat{C}_{t,j} = \sum_{k \neq j} (C_{i,k}C_{t,k}) = \begin{cases} [CC^T]_{i,t} - 1 & \text{if } t < j \\ [CC^T]_{i,t} + 1 & \text{if } t > j. \end{cases}$$

We thus get

$$\hat{S}_{i,t} = \begin{cases} S_{i,t} - \frac{1}{2} & \text{if } t < j \\ S_{i,t} + \frac{1}{2} & \text{if } t > j, \end{cases}$$

(remember there is a factor $1/2$ in the definition of S). Similarly we get for any $t \neq i$

$$\hat{S}_{j,t} = \begin{cases} S_{j,t} + \frac{1}{2} & \text{if } t < i \\ S_{j,t} - \frac{1}{2} & \text{if } t > i. \end{cases}$$

Finally, for the single corrupted index pair (i, j), we get

$$\hat{S}_{i,j} = \frac{1}{2} \left(n + \sum_{k \neq i,j} \left(\hat{C}_{i,k}\hat{C}_{j,k} \right) + \hat{C}_{i,i}\hat{C}_{j,i} + \hat{C}_{i,j}\hat{C}_{j,j} \right) = S_{i,j} - 0 + 0 = S_{i,j}.$$

For all other coefficients (s, t) such that $s, t \neq i, j$, we have $\hat{S}_{s,t} = S_{s,t}$. Meaning all rows or columns outside of i, j are left unchanged. We first observe that these last equations, together with our assumption that $j - i > 2$, mean that

$$\hat{S}_{s,t} \geq \hat{S}_{s+1,t} \quad \text{and} \quad \hat{S}_{s,t+1} \geq \hat{S}_{s,t}, \quad \text{for any } s < t$$

so $\hat{S}$ remains an R-matrix. To show uniqueness of the retrieved order, we need $j - i > 1$. Indeed, when $j - i > 1$ all these R constraints are strict, which means that $\hat{S}$ is still a strict R-matrix, hence the desired result. ■

We can extend this result to the case where multiple comparisons are missing.

Proposition 26 *Given pairwise comparisons $C_{s,t} \in \{-1, 0, 1\}$ between items ranked according to their indices, suppose m comparisons indexed $(i_1, j_1), \ldots, (i_m, j_m)$ are missing, i.e., $C_{i_l,j_j} = 0$ for $i = l, \ldots, m$. If the following condition* (26) *holds true,*

$$|s - t| > 1 \text{ for all } s \neq t \in \{i_1, \ldots, i_m, j_1, \ldots, j_m\} \tag{26}$$

then S^{match} defined in (3) *remains* strict-R *and the point score vector remains strictly monotonic.*

Proof Proceed similarly as in the proof of Proposition 13, except that shifts are divided by two. ■

We also get the following corollary.

Corollary 27 *Given pairwise comparisons $C_{s,t} \in \{-1, 0, 1\}$ between items ranked according to their indices, suppose m comparisons indexed $(i_1, j_1), \ldots, (i_m, j_m)$ are either corrupted or missing. If condition* (7) *holds true then S^{match} defined in* (3) *remains* strict-R.

Proof Proceed similarly as the proof of Proposition 13, except that shifts are divided by two for missing comparisons. ■

A.2 Standard theorems and technical lemmas used in spectral perturbation analysis (section 5)

We first recall Weyl's inequality and a simplified version of Davis-Kahan theorem which can be found in (Stewart and Sun, 1990; Stewart, 2001; Yu et al., 2015).

Theorem 28 (Weyl's inequality) *Consider a symmetric matrix A with eigenvalues $\lambda_1, \ldots, \lambda_n$ and $\tilde{A}$ a symmetric perturbation of A with eigenvalues $\tilde{\lambda}_1, \ldots, \tilde{\lambda}_n$,*

$$\max_i |\tilde{\lambda}_i - \lambda_i| \leq \|\tilde{A} - A\|_2.$$

Theorem 29 (Variant of Davis-Kahan theorem (Corollary 3 Yu et al., 2015)) *Let $A, \tilde{A} \in \mathbb{R}^n$ be symmetric, with eigenvalues $\lambda_1 \leq \ldots \leq \lambda_n$ and $\tilde{\lambda}_1 \leq \ldots \leq \tilde{\lambda}_n$ respectively. Fix $j \in \{1, \ldots, n\}$, and assume that $\min(\lambda_j - \lambda_{j-1}, \lambda_{j+1} - \lambda_j) > 0$, where $\lambda_{n+1} := \infty$ and $\lambda_0 := -\infty$. If $v, \tilde{v} \in \mathbb{R}^n$ satisfy $Av = \lambda_j v$ and $\tilde{A}\tilde{v} = \tilde{\lambda}_j \tilde{v}$, then*

$$\sin \Theta(\tilde{v}, v) \leq \frac{2\|\tilde{A} - A\|_2}{\min(\lambda_j - \lambda_{j-1}, \lambda_{j+1} - \lambda_j)}.$$

Moreover, if $\tilde{v}^T v \geq 0$, then

$$\|\tilde{v} - v\|_2 \leq \frac{2\sqrt{2}\|\tilde{A} - A\|_2}{\min(\lambda_j - \lambda_{j-1}, \lambda_{j+1} - \lambda_j)}.$$

When analyzing the perturbation of the Fiedler vector f, we may always reverse the sign of $\tilde{f}$ such that $\tilde{f}^T f \geq 0$ and obtain

$$\|\tilde{f} - f\|_2 \leq \frac{2\sqrt{2}\|\tilde{L} - L\|_2}{\min(\lambda_2 - \lambda_1, \lambda_3 - \lambda_2)}.$$

Lemma 30 *Let $r > 0$, for every $\mu \in (0, 1)$ and n large enough, if $q > \frac{\log^4 n}{\mu^2(2p-1)^4 n}$, then*

$$\|(\tilde{S} - S)f\|_\infty \leq \frac{3\mu n^{3/2}}{\sqrt{\log n}}$$

with probability at least $1 - 2/n$.

Proof The proof is very much similar to the proof of Lemma 15. Let $R = \tilde{S} - S$. We have

$$R_{ij} = \sum_{k=1}^{n} C_{ik}C_{jk}\left(\frac{B_{ik}B_{jk}}{q^2(2p-1)^2} - 1\right).$$

Therefore, let $\delta = Rf$

$$\delta_i = \sum_{j=1}^{n} R_{ij}f_j = \sum_{j=1}^{n}\sum_{k=1}^{n} C_{ik}C_{jk}\left(\frac{B_{ik}B_{jk}}{q^2(2p-1)^2} - 1\right)f_j.$$

Notice that we can arbitrarily fix the diagonal values of R to zeros. Indeed, the similarity between an element and itself should be a constant by convention, which leads to $R_{ii} = \tilde{S}_{ii} - S_{ii} = 0$ for all items i. Hence we could take $j \neq i$ in the definition of d_i, and we can consider B_{ik} independent of B_{jk} in the associated summation.

We first obtain a concentration inequality for each δ_i. We will then use a union bound to bound $\|\delta\|_\infty = \max|\delta_i|$. Notice that

$$\begin{aligned}\delta_i &= \sum_{j=1}^{n}\sum_{k=1}^{n} C_{ik}C_{jk}\left(\frac{B_{ik}B_{jk}}{q^2(2p-1)^2} - 1\right)f_j \\ &= \sum_{k=1}^{n}\left(\frac{C_{ik}B_{ik}}{q(2p-1)}\sum_{j=1}^{n} C_{jk}\left(\frac{B_{jk}}{q(2p-1)} - 1\right)f_j\right) + \sum_{k=1}^{n}\sum_{j=1}^{n} C_{ik}C_{jk}\left(\frac{B_{ik}}{q(2p-1)} - 1\right)f_j.\end{aligned}$$

The first term is quadratic while the second is linear, both terms have mean zero since the B_{ik} are independent of the B_{jk}. We begin by bounding the quadratic term. Let $X_{jk} = C_{jk}(\frac{1}{q(2p-1)}B_{jk} - 1)f_j$. We have

$$\mathbf{E}(X_{jk}) = f_j C_{jk}(\tfrac{qp-q(1-p)}{q(2p-1)} - 1) = 0,$$

$$\mathbf{var}(X_{jk}) = \frac{f_j^2\,\mathbf{var}(B_{jk})}{q^2(2p-1)^2} = \frac{f_j^2}{q^2(2p-1)^2}(q - q^2(2p-1)^2) \leq \frac{f_j^2}{q(2p-1)^2},$$

$$|X_{jk}| = |f_j||\frac{B_{jk}}{q(2p-1)} - 1| \leq \frac{2|f_j|}{q(2p-1)} \leq \frac{2\|f\|_\infty}{q(2p-1)^2}.$$

From corollary 19 $\|f\|_\infty \leq 2/\sqrt{n}$. Moreover $\sum_{j=0}^{n} f_j^2 = 1$ since f is an eigenvector. Hence, by applying Bernstein inequality we get for any $t > 0$

$$\mathbf{Prob}\left(|\sum_{j=1}^{n} X_{jk}| > t\right) \leq 2\exp\left(\frac{-q(2p-1)^2t^2}{2(1+2t/(3\sqrt{n}))}\right) \leq 2\exp\left(\frac{-q(2p-1)^2t^2n}{2(n+\sqrt{n}t)}\right). \quad (27)$$

The rest of the proof is identical to the proof of Lemma 15, replacing t by $\sqrt{n}t$. ■

Lemma 31 *For every $\mu \in (0,1)$ and n large enough, if $q > \frac{\log^4 n}{\mu^2(2p-1)^4\sqrt{n}}$, then*

$$\|\tilde{f} - f\|_\infty \leq c\frac{\mu}{\sqrt{n\log n}}$$

with probability at least $1 - 2/n$, where c is an absolute constant.

Proof Notice that by definition $\tilde{L}\tilde{f} = \tilde{\lambda}_2\tilde{f}$ and $Lf = \lambda_2 f$. Hence for $\tilde{\lambda}_2 > 0$

$$\begin{aligned}\tilde{f} - f &= \frac{\tilde{L}\tilde{f}}{\tilde{\lambda}_2} - f \\ &= \frac{\tilde{L}\tilde{f} - Lf}{\tilde{\lambda}_2} + \frac{(\lambda_2 - \tilde{\lambda}_2)f}{\tilde{\lambda}_2}.\end{aligned}$$

Moreover

$$\begin{aligned}\tilde{L}\tilde{f} - Lf &= (\mathbf{I} - \tilde{D}^{-1}\tilde{S})\tilde{f} - (\mathbf{I} - D^{-1}S)f \\ &= (\tilde{f} - f) + D^{-1}Sf - \tilde{D}^{-1}\tilde{S}\tilde{f} \\ &= (\tilde{f} - f) + D^{-1}Sf - \tilde{D}^{-1}\tilde{S}f + \tilde{D}^{-1}\tilde{S}f - \tilde{D}^{-1}\tilde{S}\tilde{f} \\ &= (\tilde{f} - f) + (D^{-1}S - \tilde{D}^{-1}\tilde{S})f + \tilde{D}^{-1}\tilde{S}(f - \tilde{f})\end{aligned}$$

Hence

$$(\mathbf{I}(\tilde{\lambda}_2 - 1) + \tilde{D}^{-1}\tilde{S})(\tilde{f} - f) = (D^{-1}S - \tilde{D}^{-1}\tilde{S} + (\lambda_2 - \tilde{\lambda}_2)\mathbf{I})f. \quad (28)$$

Writing S_i the i^{th} row of S and d_i the degree of row i, using the triangle inequality, we deduce that

$$|\tilde{f}_i - f_i| \leq \frac{1}{|\tilde{\lambda}_2 - 1|}\left(|(d_i^{-1}S_i - \tilde{d}_i^{-1}\tilde{S}_i)f| + |\lambda_2 - \tilde{\lambda}_2||f_i| + |\tilde{d}_i^{-1}\tilde{S}_i(\tilde{f} - f)|\right). \quad (29)$$

We will now bound each term separately. Define

$$\begin{aligned}&\text{Denom} = |\tilde{\lambda}_2 - 1|, \\ &\text{Num1} = |(d_i^{-1}S_i - \tilde{d}_i^{-1}\tilde{S}_i)f|, \\ &\text{Num2} = |\lambda_2 - \tilde{\lambda}_2||f_i|, \\ &\text{Num3} = |\tilde{d}_i^{-1}\tilde{S}_i(\tilde{f} - f)|.\end{aligned}$$

Bounding Denom First notice that using Weyl's inequality and equation (21) (*cf.* proof of Theorem 21), we have with probability at least $1 - 2/n$ $|\tilde{\lambda}_2 - \lambda_2| \leq \|L_R\|_2 \leq \frac{c\mu}{\sqrt{\log n}}$. Therefore there exists an absolute constant c such that with probability at least $1 - 2/n$

$$|\tilde{\lambda}_2 - 1| > c.$$

We now proceed with the numerator terms.

Bounding Num2 Using Weyl's inequality, corollary 19 and equation (21) (*cf.* proof of Theorem 21), we deduce that w.h.p.

$$|\lambda_2 - \tilde{\lambda}_2||f_i|| \leq \frac{c\mu}{\sqrt{n\log n}},$$

where c is an absolute constant.

Bounding Num1 We now bound $|d_i^{-1}S_i - \tilde{d}_i^{-1}\tilde{S}_i|$. We have

$$\begin{aligned}|(\tilde{d}_i^{-1}\tilde{S}_i - d_i^{-1}S_i)f| &= |(\tilde{d}_i^{-1}\tilde{S}_i - \tilde{d}_i^{-1}S_i + \tilde{d}_i^{-1}S_i - d_i^{-1}S_i)f| \\ &\leq |\tilde{d}_i^{-1}||(\tilde{S}_i - S_i)f| + |(\tilde{d}_i^{-1} - d_i^{-1})S_i f|.\end{aligned}$$

Using equation (18) from the proof of Theorem 21, we have w.h.p.

$$|\tilde{d}_i^{-1} - d_i^{-1}| \leq \frac{c\mu}{n^2\sqrt{\log n}}.$$

Moreover

$$|\tilde{d}_i^{-1}| \leq |\tilde{d}_i^{-1} - d_i^{-1}| + |d_i^{-1}| \leq \frac{c_1\mu}{n^2\sqrt{\log n}} + \frac{c_2}{n^2} \leq \frac{c}{n^2}$$

w.h.p., where c is an absolute constant. Therefore

$$|(\tilde{d}_i^{-1}\tilde{S}_i - d_i^{-1}S_i)f| \leq \frac{c\mu}{n^2\sqrt{\log n}}|S_i f| + \frac{c}{n^2}|(\tilde{S}_i - S_i)f| \text{ w.h.p.} \tag{30}$$

Using the definition of S and corollary 19, we get

$$|S_i f| \leq \sum_{j=1}^{n} S_{ij} \max_i |f_i| \leq c\frac{n^2}{\sqrt{n}} \leq cn^{3/2}, \tag{31}$$

where c is an absolute constant. Using Lemma 22, we get

$$|(\tilde{S}_i - S_i)f| \leq \frac{3\mu n^{3/2}}{\sqrt{\log n}} \text{ w.h.p.} \tag{32}$$

Combining (30), (31) and (32) we deduce that there exists a constant c such that

$$|(\tilde{d}_i^{-1}\tilde{S}_i - d_i^{-1}S_i)f| \leq \frac{c\mu}{\sqrt{n\log n}} \text{ w.h.p.}$$

Bounding Num3 Finally we bound the remaining term $|\tilde{d}_i^{-1}\tilde{S}_i(\tilde{f} - f)|$. By Cauchy-Schwartz inequality we have,

$$|\tilde{d}_i^{-1}\tilde{S}_i(\tilde{f} - f)| \leq |\tilde{d}_i^{-1}|\|\tilde{S}_i\|_2\|\tilde{f} - f\|_2.$$

Notice that

$$\|\tilde{S}_i\|_2 \leq \|S_i\|_2 + \|\tilde{S}_i - S_i\|_2 \leq \|S_i\|_2 + \|\tilde{S} - S\|_2.$$

Since $\|S_i\|_2^2 \leq \|S_1\|_2^2 \leq \frac{n(n+1)(2n+1)}{6}$ and $q > \frac{\log^4 n}{\mu^2(2p-1)^2\sqrt{n}}$ we deduce from Lemma 17 that w.h.p. $\|\tilde{S}_i\|_2 \leq \frac{c\mu n^{7/4}}{\sqrt{\log n}}$, where c is an absolute constant, for n large enough. Moreover, as shown above, $|\tilde{d}_i^{-1}| \leq \frac{c}{n^2}$ and we also get from Theorem 21 that $\|\tilde{f} - f\|_2 \leq \frac{c\mu}{n^{1/4}\sqrt{\log n}}$ w.h.p. Hence we have

$$|\tilde{d}_i^{-1}\tilde{S}_i(\tilde{f} - f)| \leq \frac{c\mu^2 n^{7/4}}{n^2 n^{1/4}(\log n)} \leq \frac{c\mu}{\sqrt{n\log n}} \text{ w.h.p.},$$

where c is an absolute constant. Combining bounds on the denominator and numerator terms yields the desired result. ■

A.3 Numerical experiments with normalized Laplacian

As shown in figure 5, results are very similar to those of SerialRank with unnormalized Laplacian. We lose a bit of performance in terms of robustness to corrupted comparisons.

A.4 Spectrum of the unnormalized Laplacian matrix

A.4.1 Asymptotic Fiedler value and Fiedler vector

We use results on the convergence of Laplacian operators to provide a description of the spectrum of the unnormalized Laplacian in SerialRank. Following the same analysis as in (Von Luxburg et al., 2008) we can prove that asymptotically, once normalized by n^2, apart from the first and second eigenvalue, the spectrum of the Laplacian matrix is contained in the interval $[0.5, 0.75]$. Moreover, we can characterize the eigenfunctions of the limit Laplacian operator by a differential equation, enabling to have an asymptotic approximation for the Fiedler vector.

Taking the same notations as in (Von Luxburg et al., 2008) we have here $k(x,y) = 1 - |x-y|$. The degree function is

$$d(x) = \int_0^1 k(x,y)d\,\mathbf{Prob}(y) = \int_0^1 k(x,y)d(y)$$

(samples are uniformly ranked). Simple calculations give

$$d(x) = -x^2 + x + 1/2.$$

We deduce that the range of d is $[0.5, 0.75]$. Interesting eigenvectors (i.e., here the second eigenvector) are not in this range. We can also characterize eigenfunctions f and corresponding eigenvalues λ by

$$\begin{aligned}& Uf(x) = \lambda f(x) \quad \forall x \in [0,1] \\ \Leftrightarrow\ & Mdf(x) - Sf(x) = \lambda f(x) \\ \Leftrightarrow\ & d(x)f(x) - \int_0^1 k(x,y)f(y)d(y) = \lambda f(x) \\ \Leftrightarrow\ & f(x)(-x^2 + x + 1/2) - \int_0^1 (1 - |x-y|)f(y)d(y) = \lambda f(x)\end{aligned}$$

Differentiating twice we get

$$f''(x)(1/2 - \lambda + x - x^2) + 2f'(x)(1 - 2x) = 0. \tag{33}$$

The asymptotic expression for the Fiedler vector is then a solution to this differential equation, with $\lambda < 0.5$. Let γ_1 and γ_2 be the roots of $(1/2 - \lambda + x - x^2)$ (with $\gamma_1 < \gamma_2$). We can suppose that $x \in (\gamma_1, \gamma_2)$ since the degree function is nonnegative. Simple calculations show that

$$f'(x) = \frac{A}{(x-\gamma_1)^2(x-\gamma_2)^2}$$

is solution to (33), where A is a constant. Now we note that

$$\begin{aligned}\frac{1}{(x-\gamma_1)^2(x-\gamma_2)^2} &= \frac{1}{(\gamma_1-\gamma_2)^2(\gamma_2-x)^2}+\frac{1}{(\gamma_1-\gamma_2)^2(\gamma_1-x)^2}\\ &\quad -\frac{2}{(\gamma_1-\gamma_2)^3(\gamma_2-x)}+\frac{2}{(\gamma_1-\gamma_2)^3(\gamma_1-x)}.\end{aligned}$$

We deduce that the solution f to (33) satisfies

$$f(x) = B + \frac{A}{(\gamma_1-\gamma_2)^2}\left(\frac{1}{\gamma_1-x}+\frac{1}{\gamma_2-x}\right) - \frac{2A}{(\gamma_1-\gamma_2)^3}\left(\log(x-\gamma_1)-\log(\gamma_2-x)\right),$$

where A and B are two constants. Since f is orthogonal to the unitary function for $x \in (0,1)$, we must have $f(1/2)=0$, hence B=0 (we use the fact that $\gamma_1 = \frac{1-\sqrt{1+4\alpha}}{2}$ and $\gamma_2 = \frac{1+\sqrt{1+4\alpha}}{2}$, where $\alpha = 1/2-\lambda$).

As shown in figure 6 , the asymptotic expression for the Fiedler vector is very accurate numerically, even for small values of n. The asymptotic Fiedler value is also very accurate (2 digits precision for $n=10$, once normalized by n^2).

A.4.2 Bounding the eigengap

We now give two simple propositions on the Fiedler value and the third eigenvalue of the Laplacian matrix, which enable us to bound the eigengap between the second and the third eigenvalues.

Proposition 32 *Given all comparisons indexed by their true ranking, let λ_2 be the Fiedler value of S^{match}, we have*

$$\lambda_2 \leq \frac{2}{5}(n^2+1).$$

Proof Consider the vector x whose elements are uniformly spaced and such that $x^T\mathbf{1}=0$ and $\|x\|_2 = 1$. x is a feasible solution to the Fiedler eigenvalue minimization problem. Therefore,

$$\lambda_2 \leq x^T L x.$$

Simple calculations give $x^TLx = \frac{2}{5}(n^2+1)$. ■

Numerically the bound is very close to the true Fiedler value: $\lambda_2/n^2 \approx 0.39$ and $2/5 = 0.4$.

Proposition 33 *Given all comparisons indexed by their true ranking, the vector $v = [\alpha, -\beta, \ldots, -\beta, \alpha]^T$ where α and β are such that $v^T\mathbf{1}=0$ and $\|v\|_2=1$ is an eigenvector of the Laplacian matrix L of S^{match} The corresponding eigenvalue is $\lambda = n(n+1)/2$.*

Proof Check that $Lv = \lambda v$. ■

A.5 Other choices of similarities

The results in this paper shows that forming a similarity matrix (R-matrix) from pairwise preferences will produce a valid ranking algorithm. In what follows, we detail a few options extending the results of Section 2.2.

A.5.1 Cardinal comparisons

When input comparisons take continuous values between -1 and 1, several choice of similarities can be made. First possibility is to use S^{glm}. An other option is to directly provide $1-\text{abs}(C)$ as a similarity to SerialRank. This option has a much better computational cost.

A.5.2 Adjusting contrast in S^{match}

Instead of providing S^{match} to SerialRank, we can change the "contrast" of the similarity, i.e., take the similarity whose elements are powers of the elements of S^{match}.

$$S^{\text{contrast}}_{i,j} = (S^{\text{match}}_{i,j})^{\alpha}.$$

This construction gives slightly better results in terms of robustness to noise on synthetic datasets.

A.6 Hierarchical Ranking

In a large dataset, the goal may be to rank only a subset of top items. In this case, we can first perform spectral ranking, then refine the ranking of the top set of items using either the SerialRank algorithm on the top comparison submatrix, or another seriation algorithm such as the convex relaxation in (Fogel et al., 2013). This last method also allows us to solve semi-supervised ranking problems, given additional information on the structure of the solution.

Abstract

We consider a learning algorithm generated by a regularization scheme with a concave regularizer for the purpose of achieving sparsity and good learning rates in a least squares regression setting. The regularization is induced for linear combinations of empirical features, constructed in the literatures of kernel principal component analysis and kernel projection machines, based on kernels and samples. In addition to the separability of the involved optimization problem caused by the empirical features, we carry out sparsity and error analysis, giving bounds in the norm of the reproducing kernel Hilbert space, based on a priori conditions which do not require assumptions on sparsity in terms of any basis or system. In particular, we show that as the concave exponent q of the concave regularizer increases to 1, the learning ability of the algorithm improves. Some numerical simulations for both artificial and real MHC-peptide binding data involving the ℓ^q regularizer and the SCAD penalty are presented to demonstrate the sparsity and error analysis.

Keywords: Sparsity, concave regularizer, reproducing kernel Hilbert space, regularization with empirical features, ℓ^q-penalty, SCAD penalty.

1. Introduction

Kernel methods provide efficient learning algorithms for analyzing nonlinear features, processing complex data, and studying data structures or relations. One may use a (unknown) probability measure ρ_X to model the distribution and structures of data on a compact metric space X (input space) and a Mercer kernel $K : X \times X \to \mathbb{R}$ to quantify by its value $K(x, u)$ similarities between two data points x and u. Then some ideas of kernel methods may be understood (Cristianini and Shawe-Taylor, 2000) in terms of eigenfunctions $\{\phi_i\}$ of the integral operator L_K defined by $L_K(f) = \int_X K(\cdot, x)f(x)d\rho_X(x)$ on the reproducing kernel Hilbert space (RKHS) $(\mathcal{H}_K, \|\cdot\|_K)$ of functions on X induced by the kernel K. These eigenfunctions can be used to represent a feature map and provide insightful, generally nonlinear, features regarding a particular learning problem. As the data distribution ρ_X is unknown, one needs to learn or approximate the features from a data set $\mathbf{x} = \{x_i\}_{i=1}^m \subset X$ and then carries out learning tasks based on the learned data dependent approximate features.

Here we are interested in a class of data dependent features $\{\phi_i^{\mathbf{x}}\}_{i=1}^\infty$ on X, called empirical features, constructed from the data set $\mathbf{x}$ and the kernel K. They have been used in kernel principal component analysis (Schölkopf et al., 1998), kernel ridge regression (Cristianini and Shawe-Taylor, 2000; Hastie et al., 2001), kernel projection machines (Blanchard et al., 2004), and spectral algorithms (Lo Gerfo et al., 2008; Caponnetto and Yao, 2010). They are defined by means of an *empirical integral operator* $L_K^{\mathbf{x}}$ on $\mathcal{H}_K$ expressed as

$$L_K^{\mathbf{x}} f = \frac{1}{m}\sum_{i=1}^m f(x_i)K_{x_i}, \qquad f \in \mathcal{H}_K, \tag{1}$$

where $K_x := K(\cdot, x)$ is a function in $\mathcal{H}_K$ for $x \in X$. It can be seen from the reproducing property $f(x_i) = \langle f, K_{x_i}\rangle_K$ that the operator $L_K^{\mathbf{x}}$ is symmetric, positive and of rank at most m. Denote $\{(\lambda_i^{\mathbf{x}}, \phi_i^{\mathbf{x}})\}_i$ the normalized eigenpairs of $L_K^{\mathbf{x}}$ with (possibly multiple) eigenvalues $\lambda_1^{\mathbf{x}} \ge \lambda_2^{\mathbf{x}} \ge \cdots \ge \lambda_m^{\mathbf{x}} \ge 0 = \lambda_{m+1}^{\mathbf{x}} = \cdots$, then the eigenfunctions $\{\phi_i^{\mathbf{x}}\}_i$ form an orthonormal basis of $\mathcal{H}_K$ and they are called *empirical features*.

In this paper we consider some empirical feature-based regularization schemes in a regression setting and study sparsity of these learning algorithms when the regularizer is a concave function. Here the output space is $Y = \mathbb{R}$. With a sample $\mathbf{z} = \{(x_i, y_i)\}_{i=1}^m \in (X \times Y)^m$, the learning algorithm producing the output function

$$f^{\mathbf{z}} = \sum_{i=1}^\infty c_i^{\mathbf{z}} \phi_i^{\mathbf{x}} \tag{2}$$

is given in terms of its coefficient sequence $c^{\mathbf{z}} = (c_i^{\mathbf{z}})_{i=1}^\infty$ by the regularization scheme

$$c^{\mathbf{z}} = \arg\min_{c \in \ell^2} \left\{ \frac{1}{m}\sum_{i=1}^m \left(\sum_{j=1}^\infty c_j \phi_j^{\mathbf{x}}(x_i) - y_i \right)^2 + \gamma \sum_{j=1}^\infty \Omega(|c_j|) \right\}, \tag{3}$$

where $\gamma > 0$ is a regularization parameter and $\Omega : [0, \infty) \to [0, \infty)$ is a nonzero *concave* function satisfying $\Omega(0) = 0$. We shall show under some regularity assumptions that the above learning algorithm has *strong sparsity* in the sense that with confidence, the number of nonzero coefficients in the expression (2) is of order $O(m^{\theta_{sp}})$ with $0 < \theta_{sp} < 1$, much smaller than the sample size m.

The scheme (3) with special forms of regularizers can be found in the literature of kernel methods. When the regularization on the sequence $c = (c_j)_j$ is replaced by the restriction $c_j = 0$ for $j > N$, the scheme is the kernel principal component regression (Schölkopf et al., 1998) or spectral cut-off algorithm (Lo Gerfo et al., 2008; Caponnetto and Yao, 2010) where detailed error analysis can be found. The case $\Omega(|c|) = |c|^2$ corresponds to the kernel ridge regression (Cristianini and Shawe-Taylor, 2000; Hastie et al., 2001) with error analysis well conducted in a large literature (Caponnetto and De Vito, 2007; Bauer et al., 2007; Smale

and Zhou, 2007). The kernel projection machines can be expressed (Blanchard et al., 2004) by taking Ω to be the indicator function of the set $(0,\infty)$ and $\sum \Omega(|c_j|)$ to be the number of nonzero terms in the sequence c, hence correspond to the classical variable subset selection method. These algorithms were applied and analyzed for classification and regression in (Zwald, 2005; Zwald and Blanchard, 2006; Blanchard and Zwald, 2008).

A main choice of the regularizer in scheme (3) is $\Omega(|c|) = |c|^q$ with $0 < q < 2$. It can be viewed as a kernel version of the classical bridge regression (Frank and Friedman, 1993) which has advantages in some applications. To describe more details, we express the empirical features explicitly in terms of eigenpairs of the kernel (Gramian) matrix $\mathbb{K} := (K(x_i, x_j))_{i,j=1}^m$ (see e.g. Schölkopf et al. (1998); Guo and Zhou (2012)): if $\widehat{\lambda}_i^{\mathbf{x}} > 0$ is the i-th largest eigenvalue of $\mathbb{K}$ with a corresponding normalized eigenvector $\widehat{\mu}_i \in \mathbb{R}^m$, then $\lambda_i^{\mathbf{x}} = \widehat{\lambda}_i^{\mathbf{x}}/m$ and $\phi_i^{\mathbf{x}} = \sum_{j=1}^m (\widehat{\mu}_i)_j K_{x_j}/\sqrt{\widehat{\lambda}_i^{\mathbf{x}}}$. In particular, when $X \subset \mathbb{R}^n$ and K is the linear kernel $K(x,y) = x \cdot y$, we know that $\phi_i^{\mathbf{x}}$ is exactly the i-th principal component of the data matrix $A_{\mathbf{x}} = [x_1, \ldots, x_m]^T \in \mathbb{R}^{m\times n}$ and $\mathbb{K}$ is the kernel matrix $\mathbb{K} = A_{\mathbf{x}} A_{\mathbf{x}}^T$. So the scheme (3) may be viewed as regularized kernel principal component analysis (RKPCA). Moreover, a large statistical literature with the linear kernel on $\mathbb{R}^n$ reveals advantages of various methods (Frank and Friedman, 1993): principal component regression and ridge regression perform well in reducing variances when many variables together collectively effect the response with no small variable subset standing out. In particular, ridge regression (with $q = 2$ in $\Omega(|c|) = |c|^q$) has the best performance when a prior distribution of the regression vector in a Bayesian framework is Gaussian or rotationally invariant setting no preference for any particular directions. A Gaussian process interpretation can be used to understand some advantages of the kernel ridge regression. On the other hand, the variable subset selection method (with $q = 0$) has an optimal performance when the prior distribution puts the entire probability mass on the variable axes, only a few variables have influences on the response, but no information as to which ones is available. Bridge regression may have advantages when the prior distribution is concentrated along some favored directions. It also provides ways for automatic variable selection, for optimizing the power index $q \in (0,2)$ and expanding the model selection criterion by estimating jointly the optimal values of q and γ. As an extension to deal with nonlinear features in RKHSs, it is expected that the kernel bridge regression included in (3) has the same flexibility and some advantages, which will be simulated for real MHC-peptide binding data in subsection 5.2 and discussed in our sparsity and error analysis.

A crucial property of empirical features is their orthogonality with respect to the discrete measure $\frac{1}{m}\sum_{i=1}^m \delta_{x_i}$ stated as $\frac{1}{m}\sum_{i=1}^m \phi_j^{\mathbf{x}}(x_i)\phi_l^{\mathbf{x}}(x_i) = \delta_{j,l}\lambda_j^{\mathbf{x}}$. This is a classical fact and simplifies the empirical error term in (3) as $\frac{1}{m}\sum_{i=1}^m \left(\sum_{j=1}^\infty c_j \phi_j^{\mathbf{x}}(x_i) - y_i\right)^2 = \sum_{i=1}^m \lambda_i^{\mathbf{x}} c_i^2 - 2\sum_{i=1}^m \lambda_i^{\mathbf{x}} S_i^{\mathbf{z}} c_i + \frac{1}{m}\sum_{i=1}^m y_i^2$, where $S_i^{\mathbf{z}}$ is a number defined in terms of the sample $\mathbf{z}$ as

$$S_i^{\mathbf{z}} = \begin{cases} \frac{1}{m\lambda_i^{\mathbf{x}}}\sum_{j=1}^m y_j \phi_i^{\mathbf{x}}(x_j), & \text{if } \lambda_i^{\mathbf{x}} > 0, \\ 0, & \text{otherwise.} \end{cases} \tag{4}$$

This simplification easily implies that the optimization problem (3) can be solved separately for each coefficient c_i, and $c_i^{\mathbf{z}} = 0$ for $i \geq m+1$. So we may replace the summations in (2) and (3) by those up to m (we keep them for the convenience of the proofs).

Theorem 1 *Let $\Omega : [0,\infty) \to [0,\infty)$, $\gamma > 0$ and $\mathbf{z} \in (X \times Y)^m$. Then a sequence $c^{\mathbf{z}} = (c_i^{\mathbf{z}})_{i=1}^\infty$ is a solution to (3) if and only if for each i, $c_i^{\mathbf{z}}$ is a minimizer of the univariate function defined by*

$$h_i(c) = h_{\lambda_i^{\mathbf{x}}, S_i^{\mathbf{z}}, \gamma, \Omega}(c) = \lambda_i^{\mathbf{x}}(c - S_i^{\mathbf{z}})^2 + \gamma\Omega(|c|), \qquad c \in \mathbb{R}. \tag{5}$$

2. Main Results on Sparsity and Error Analysis

The main purpose of this paper is to show that both strong sparsity and fast learning rate can be achieved by the learning algorithm (2) when the regularizing function Ω in (3) is concave. We describe the main ideas in this section and will provide detailed general analysis in Section 4 while some numerical simulations for both artificial and real data will be presented in Section 5.

2.1 Concave regularizing functions

The concavity of regularizing functions plays a central role in achieving sparsity in this paper. It has the following nice property.

Theorem 2 *If $\Omega : [0,\infty) \to [0,\infty)$ is a nonzero continuous concave function satisfying $\Omega(0) = 0$, then $\Omega(1) > 0$, and that*

$$\Omega(c) \geq \Omega(1)c, \qquad \forall c \in (0,1] \tag{6}$$

and

$$\Omega(c) \leq \Omega(1)c, \qquad \forall c \in [1,\infty). \tag{7}$$

Theorem 2 is part of Proposition 10 in Section 3 which will give more properties for concave regularizing functions.

Note that (6) is a lower bound for Ω on $(0,1]$. Our error bounds will be presented by means of the asymptotic behavior of the concave regularizing function Ω near the origin, which is characterized by a concave exponent $q \in [0,1]$.

Definition 3 *We say that a concave regularizing function Ω has a concave exponent $q \in [0,1]$ if there is a positive constant C_Ω^* such that*

$$\Omega(c) \leq C_\Omega^* c^q, \qquad \forall c \in (0,1]. \tag{8}$$

Theorem 2 tells us that the concave exponent q in (8) is at most 1. We also know from Proposition 10 in Section 3 that (8) is always true with $q = 0$ and $C_\Omega^* = \Omega(1)$. Sharper error bounds with better q are possible. The following are two such families of concave regularizing functions: ℓ^q-regularizer ($0 < q \leq 1$) which is well studied for bridge regression (Frank and Friedman, 1993; Fu and Knight, 2000; Liu et al., 2007; Xu et al., 2012), and SCAD penalties (Fan and Li, 2001).

Example 1 *Let $0 < q \leq 1$ and $\Omega : [0,\infty) \to [0,\infty)$ be the ℓ^q-regularizer given by $\Omega(c) = c^q$. Then (8) is satisfied with $C_\Omega^* = 1$.*

Example 2 *Let $b > 2$ and $\Omega : [0,\infty) \to [0,\infty)$ be a SCAD penalty given as a concave continuous function by $\Omega(0) = 0$ and*

$$\Omega'(c) = \begin{cases} 1, & \text{for } 0 < c < 1, \\ \frac{c-b}{1-b}, & \text{for } 1 < c < b, \\ 0, & \text{for } c > b. \end{cases}$$

Then $\Omega(c) = c$ for $c \in [0,1]$, $\Omega(c) = \frac{1+b}{2} - \frac{(c-b)^2}{2(b-1)}$ for $c \in (1,b]$ and $\Omega(c) = \frac{1+b}{2}$ for $c \in (b,\infty)$. Hence (8) is satisfied with $q = 1$ and $C^*_\Omega = 1$. Moreover, we have $\Omega(c) \le \frac{1+b}{2}$ for every $c \in [1,\infty)$.

In our results for sparsity and error analysis, we shall use a general power index $q \in [0,1]$ instead of the universal choice of $q = 0$.

2.2 Sparsity and learning rates

Throughout the paper, we assume that the sample set $\mathbf{z}$ is drawn independently according to a Borel probability measure ρ on $X \times Y$ and that for some constant $M > 0$, $|y| \le M$ almost surely. The regression function in our regression setting is defined as a function f_ρ on X given by

$$f_\rho(x) = \int_Y y d\rho(y|x), \qquad x \in X,$$

where $\rho(\cdot|x)$ is the conditional measure induced by ρ at $x \in X$. The regularity assumption we shall take for the regression function is

$$f_\rho = L_K^r(g_\rho) \quad \text{for some } r > 0 \text{ and } g_\rho \in \mathcal{H}_K. \tag{9}$$

Here L_K is a compact, self-adjoint and positive operator on $\mathcal{H}_K$ having eigenpairs $\{(\lambda_i, \phi_i)\}_i$ with the eigenvalues $\{\lambda_i\}$ forming a nonincreasing sequence tending to 0 and and eigenfunctions $\{\phi_i\}$ an orthonormal basis of $\mathcal{H}_K$. Its r-th power L_K^r is given by $L_K^r(\sum_i c_i\phi_i) = \sum_i c_i\lambda_i^r\phi_i$ and assumption (9) means $f_\rho = \sum_i d_i\lambda_i^r\phi_i$ for some sequence $\{d_i\} \in \ell^2$ representing $g_\rho = \sum_i d_i\phi_i$. The exponent r in (9) measures the decay of the coefficients $\{d_i\lambda_i^r\}$ of f_ρ with respect to the orthonormal basis $\{\phi_i\}$ of $\mathcal{H}_K$, and thereby the regularity of the regression function f_ρ.

Let us illustrate our general analysis for strong sparsity and learning rates by two special cases, derived from Corollary 16 (with $\alpha_1 = \alpha_2 = \alpha$) and Corollary 17 (with $\beta_1 = \beta_2 = \beta$) in Section 4, for which the eigenvalues of the integral operator L_K decay polynomially or exponentially.

Theorem 4 *Assume (9) with $r > \frac{1}{2}$, and that Ω has a concave exponent $q \in [0,1]$ with (8) valid. Suppose that for some positive constants D_1, D_2 and α, the eigenvalues $\{\lambda_i\}$ of L_K decay polynomially as*

$$D_1 i^{-\alpha} \le \lambda_i \le D_2 i^{-\alpha}, \qquad \forall i \in \mathbb{N} \tag{10}$$

with $2\alpha\max\{r,1\} > 1$. Let $0 < \delta < 1$. If we choose

$$\gamma = C_1(D_2/\lambda_1)^{r+1}\left(\log\frac{4m}{\delta}\right)^{1+2r} m^{-\frac{1+r}{1+2r}}, \tag{11}$$

then with confidence $1-\delta$ we have

$$c_i^{\mathbf{z}} = 0, \qquad \forall\ m^{\theta_{sp}} + 1 \le i \le m \quad \text{with } \theta_{sp} = \frac{1}{\alpha(1+2r)} < 1 \tag{12}$$

and

$$\|f^{\mathbf{z}} - f_\rho\|_K \le C_2\left(\log\frac{4m}{\delta}\right)^{1+2r} m^{-\theta_{rate}}, \qquad \theta_{rate} = \frac{\alpha\min\{4r, 4r(2-q)\} - 2(2-q)}{4(2r+1)(2-q)\alpha},$$

where C_1 and C_2 are constants independent of m or δ (to be specified in the proof).

The eigenvalue decay condition (10) is typical for Sobolev smooth kernels on domains in Euclidean spaces, with the power index α depending on the smoothness of the kernel (Reade, 1984).

The regularity assumptions (9) and (10) impose restrictions on the concave exponent $q \in [0,1]$. To see this, we express $g_\rho = \sum_i d_i\phi_i$ with $(d_i)_i \in \ell^2$ and $f_\rho = L_K^r(g_\rho) = \sum_i \lambda_i^r d_i\phi_i$. A natural requirement for f_ρ corresponding to the ℓ^q-regularizer is $(\lambda_i^r d_i)_i \in \ell^q$. Imposing this uniformly with respect to the coefficient sequence $(d_i)_i$ is the same as the boundedness from ℓ^2 to ℓ^q of the diagonal operator D_{λ^r} associated with the fixed non-indreasing sequence $(\lambda_i^r)_i$. This problem together with asymptotic behaviors of the entropy numbers of D_{λ^r} has been widely studied in the literature of function spaces and approximation theory (Edmunds and Triebel, 1996; Kühn, 2008) and the boundedness can be characterized by the condition

$$(\lambda_i^r)_i \in \ell^s \text{ with } \frac{1}{s} = \frac{1}{q} - \frac{1}{2}. \tag{13}$$

Under the eigenvalue decay assumption (10), the characterization condition (13) is equivalent to $\sum_{i=1}^\infty i^{-\alpha r s} = \sum_{i=1}^\infty i^{-\frac{2\alpha r q}{2-q}} < \infty$, which can be stated as

$$q > \frac{2}{2\alpha r + 1}. \tag{14}$$

Thus the concave exponent q is tailored to the regularity assumption and the eigenvalue decay, and a larger regularity index r leads to a wider range of the concave exponent q.

Combining the regularity assumption (9) and the eigenvalue decay condition (10) has been an approach for error analysis of learning algorithms. In particular, the minimax rates of convergence in the $L^2_{\rho_X}$ metric was derived in (Caponnetto and De Vito, 2007) under these conditions with the restrictions $\alpha > 1$ and $0 < r \le \frac{1}{2}$. Moreover, the well-known regularized least squares regression (RLS) scheme

$$f^{\mathbf{z}} = \arg\min_{f\in\mathcal{H}_K}\left\{\frac{1}{m}\sum_{i=1}^m (f(x_i) - y_i)^2 + \gamma\|f\|_K^2\right\} \tag{15}$$

achieves these rates in probability as $\|f^{\mathbf{z}} - f_\rho\|^2_{L^2_{\rho_X}} = O(m^{-\frac{\alpha(2r+1)}{\alpha(2r+1)+1}})$. Error estimates in the $\mathcal{H}_K$ metric provide error analysis for the distribution mismatch problem (where the distribution for predictions might be different from the sampling distribution ρ_X) and

for sampling processes with nonidentical distributions (Smale and Zhou, 2009; Zhou, 2003). Such estimates for the RLS algorithm (15) were conducted in (Smale and Zhou, 2007; Bauer et al., 2007) where the learning rates are $\|f^{\mathbf{z}}-f_\rho\|_K = O(m^{-\frac{r}{2r+2}})$ under the same restriction $0 < r \le \frac{1}{2}$ and the maximum exponent is $\frac{1}{6}$ when $r = \frac{1}{2}$. The maximum exponent for the RLS algorithm (15) cannot be improved further for $r > \frac{1}{2}$ and this is called a saturation effect in the theory of inverse problems (Bauer et al., 2007).

As pointed out in (Bauer et al., 2007; Lo Gerfo et al., 2008), spectral cut-off algorithms do not suffer from the saturation phenomenon. Theorem 4 confirms this advantage for the algorithm (2) in the range $r > \frac{1}{2}$ (the range $0 < r \le \frac{1}{2}$ is covered by Corollary 16 in Section 4). To be specific, let $\frac{1}{2} < q \le 1$ and $r \ge \frac{1}{4q-2}$. Then the power index θ_{rate} for the learning rate in Theorem 4 is

$$\theta_{rate} = \frac{2r\alpha - 2 + q}{2(2r+1)(2-q)\alpha} \tag{16}$$

which becomes larger as the regularity index r increases, and can be arbitrarily close to $\frac{1}{2}$ when r is large enough (f_ρ is smooth enough) and $q = 1$. This applied to the case when Ω is the SCAD penalty given in Example 2. Even in the range $0 < q \le \frac{1}{2}$, for a sufficiently large r, the power index θ_{rate} in Theorem 4 can be arbitrarily close to $\frac{1}{2(2-q)}$.

The estimate (12) for sparsity in Theorem 4 tells us that with confidence, the output function $f^{\mathbf{z}} = \sum c_i^{\mathbf{z}} \phi_i^{\mathbf{z}}$ has at most $m^{\theta_{sp}}$ nonzero coefficients with a sparsity exponent $\theta_{sp} < 1$, a small proportion of the m coefficients in the expression (2). Moreover, θ_{sp} decreases, leading to better sparsity, as r increases. Note that by our analysis, the restriction (14) is the only influence of the concave exponent q for the sparsity.

Theorem 5 *Assume (9) with $r > \frac{1}{2}$, and that Ω has a concave exponent $q \in [0,1]$ with (8) valid. Suppose that for some positive constants D_1, D_2 and β, the eigenvalues $\{\lambda_i\}$ of L_K decay exponentially as*

$$D_1\beta^{-i} \le \lambda_i \le D_2\beta^{-i}, \qquad \forall i \in \mathbb{N}. \tag{17}$$

Let $0 < \delta < 1$. If we choose γ as (11), then with confidence $1-\delta$ we have

$$c_i^{\mathbf{z}} = 0, \qquad \forall\ \frac{\log(m+1)}{(1+2r)\log\beta} + 1 \le i \le m \tag{18}$$

and

$$\|f^{\mathbf{z}} - f_\rho\|_K \le C_2 \left(\log\frac{4m}{\delta}\right)^{2r+1} m^{-\theta_{rate}}, \quad \theta_{rate} = \min\left\{\frac{r}{(2-q)(1+2r)}, \frac{(2-q)r}{(2-q)(1+2r)}\right\},$$

where C_2 is a constant independent of m or δ (to be specified in the proof).

Remark 6 *The eigenvalue decay condition (17) is typical for analytic kernels on domains in Euclidean spaces (Reade, 1984). When the regularity index r is large enough, the power index θ_{rate} for the learning rate is $\frac{1}{2(2-q)} - \epsilon$ with an arbitrarily small $\epsilon > 0$. So the learning rate depends on the concave exponent q, better as q increases. On the other hand, (18) tells us that with confidence, the output function $f^{\mathbf{z}} = \sum c_i^{\mathbf{z}} \phi_i^{\mathbf{z}}$ has at most $\frac{\log(m+1)}{(1+2r)\log\beta}$ nonzero coefficients, a logarithmic proportion of the m coefficients in the expression (2).*

2.3 Minimax lower bound

The learning rate stated in Theorem 4 is close to be optimal when r is large. One might use some existing methods for dealing with the $L^2_{\rho_X}$ error in the literature (Yang and Barron, 1999; Bauer et al., 2007; Caponnetto and De Vito, 2007; DeVore et al., 2004; Suzuki et al., 2012; Raskutti et al., 2012; Steinwart et al., 2009) to give lower bounds. Here we focus on the error in the $\mathcal{H}_K$-metric and present a minimax lower bound. Denote $\kappa = \max_{x\in X}\sqrt{K(x,x)}$.

Definition 7 *Let $\mathcal{P}(\alpha, r, M, R, D_1, D_2)$ be the set of all Borel probability measures ρ on $X \times Y$ such that the regularity assumption (9) is satisfied with $\|g_\rho\|_K \le R$, (10) holds true, and the conditional measure $\rho(\cdot|x)$ is supported on $[-M, M]$ for almost all $x \in X$.*

Theorem 8 *Let α, r, R, D_1, D_2 be positive constants and $M \ge 4\kappa^{r+\frac{1}{2}}R$. Let $f^{\mathbf{z}} \in \mathcal{H}_K$ be the output of an arbitrary learning algorithm based on the sample $\mathbf{z} = \{(x_i, y_i)\}_{i=1}^m$. Then for every $0 < \delta < 1$, there exists a positive constant $C_{\delta,\alpha,r,M,R,D_1,D_2}$ such that*

$$\lim_{m\to\infty}\inf_{f^{\mathbf{z}}}\sup_{\rho\in\mathcal{P}(\alpha,r,M,R,D_1,D_2)} \mathbb{P}_{\mathbf{z}\sim\rho^m}\left\{\|f^{\mathbf{z}} - f_\rho\|_K \ge C_{\delta,\alpha,r,M,R,D_1,D_2} m^{-\frac{\alpha r}{\alpha(1+2r)+1}}\right\} \ge 1-\delta.$$

The proof of Theorem 8 follows from a more general result to be given in Appendix B. The power index $\frac{\alpha r}{\alpha(2r+1)+1}$ for the minimax lower bound stated in Theorem 8 corresponds to the upper bound index (16) in Theorem 4 for a smoother regularity class with $r' = r + \frac{2-q}{2\alpha}$. This shows the gap between our upper bound and the minimax lower bound. It would be interesting to derive minimax rates of convergence in the $\mathcal{H}_K$-metric which can be achieved by the learning algorithm (2) with $\Omega(c) = c^q$ for $0 < q \le 1$.

2.4 Connections to ridge regression and some other learning algorithms

The classical RLS algorithm (15) can be stated as the scheme (2) by taking the regularizer $\Omega(c) = c^2$ corresponding to the ridge regression. This follows from a representer theorem for (15), the identities $\mathrm{span}\{K_{x_j}\}_{j=1}^m = \mathrm{span}\{\phi_j^{\mathbf{x}}\}_{j=1}^m$ and $\left\|\sum_{j=1}^\infty c_j\phi_j^{\mathbf{x}}\right\|_K^2 = \sum_{j=1}^\infty |c_j|^2$.

The regularizer $\Omega(c) = c^q$ with $0 < q \le 2$ correspond to the bridge regression. When $1 < q \le 2$, this regularizer is convex instead of being concave. It has the special property that $\Omega'_+(0) = 0$ where $\Omega'_+(c)$ denotes the right-side derivative of Ω at $c \in [0,\infty)$. This leads to the observation that sparsity is hardly achieved for the learning algorithm (2) associated with such a convex regularizer.

Theorem 9 *Let $\Omega : [0,\infty) \to [0,\infty)$, $\gamma > 0$ and $\Omega(0) = 0$. If $\Omega'_+(0) = 0$, then for each i, $c_i^{\mathbf{z}}$ vanishes if and only if either $\lambda_i^{\mathbf{x}} = 0$ or $S_i^{\mathbf{z}} = 0$.*

An elastic net learning algorithm (Zou and Hastie, 2005) can be introduced by taking the regularizer in (3) as

$$\Omega^{en}(c) = c + \zeta c^2, \tag{19}$$

where $\zeta > 0$ is an elastic net parameter controlling the proportion of the ℓ^2-norm square in the regularizer Ω^{en}. Though the regularizer Ω^{en} is strictly convex, it does not satisfy the assumption $\Omega'_+(0) = 0$ in Theorem 9. When ζ is small, this regularizer is actually close to

the ℓ^1-penalty. Hence we would expect that the corresponding learning algorithm with a strictly convex regularizer has strong sparsity. This is beyond the discussion in this paper.

Let us mention that the learning scheme (2) is closely related to spectral algorithms (Lo Gerfo et al., 2008; Caponnetto and Yao, 2010) which can be stated in terms of the empirical features $\{\phi_j^{\mathbf{x}}\}_{j=1}^m$ and a filter function $g_\gamma : [0,1] \to \mathbb{R}$ as

$$f^{\mathbf{z}} = \sum_{j=1}^m \sqrt{\lambda_j^{\mathbf{x}}/m} \left(\sum_{i=1}^m (\widehat{\mu}_j)_i y_i \right) g_\gamma(\lambda_j^{\mathbf{x}}) \phi_j^{\mathbf{x}},$$

where $\{(m\lambda_j^{\mathbf{x}}, \widehat{\mu}_j)\}$ are the normalized eigenpairs of the kernel matrix $\mathbb{K}$.

Our analysis relies heavily on the special form of the least squares loss, as seen from Theorem 1. It would be interesting to establish similar analysis for schemes associated with other loss functions such as those in the minimum error entropy principle, at least when the scaling parameter is large (Hu et al., 2015).

3. Properties of Concave Regularizing Functions

In this section we give some properties of concave regularizing functions, and then estimate the solution $c^{\mathbf{z}}$ to (3) by means of the explicit expression stated in Theorem 1.

Proposition 10 *Let $\Omega : [0,\infty) \to [0,\infty)$ be a nonzero continuous concave function satisfying $\Omega(0) = 0$. Then it has the following properties.*

(a) The function Ω is nondecreasing on $[0,\infty)$, and $\Omega(c) > 0$ for $c \in (0,\infty)$. The right-hand derivative Ω'_+ is well defined, nonincreasing, finite, and nonnegative on $(0,\infty)$. At the origin, $\Omega'_+(0) \in (0,\infty]$.

(b) We have $\Omega(c) \ge \Omega(1)c$ for $c \in [0,1]$, and $\Omega(c) \le \Omega(1)c$ for $c \in [1,\infty)$.

(c) There holds $\Omega(a+b) \le \Omega(a) + \Omega(b)$ for any $a, b > 0$.

(d) The positive function $\frac{\Omega(c)}{c}$ defined on $(0,\infty)$ is nonincreasing and satisfies $\lim_{c\to 0^+} \frac{\Omega(c)}{c} = \Omega'_+(0)$.

(e) The positive function $\frac{\Omega(c)}{c^2}$ defined on $(0,\infty)$ is continuous and strictly decreasing from $\lim_{c\to 0^+} \frac{\Omega(c)}{c^2} = +\infty$ to $\lim_{c\to\infty} \frac{\Omega(c)}{c^2} = 0$.

Proposition 10 will be proved in Appendix C.

For our analysis, we need the following two auxiliary functions.

Definition 11 *Define an auxiliary function $\Omega^* : (0,\infty) \to (0,\infty)$ of a positive function Ω as*

$$\Omega^*(\lambda) = \inf_{c\in(0,\infty)} \left\{ \frac{\Omega(c)}{c} + \lambda c \right\}, \qquad \lambda \in (0,\infty).$$

Define another auxiliary function $\widetilde{\Omega} : (0,\infty) \to (0,\infty)$ as

$$\widetilde{\Omega}(\lambda) = \arg\sup \left\{ c \in (0,\infty) : \frac{\Omega(c)}{c^2} \ge \lambda \right\}, \qquad \lambda \in (0,\infty).$$

Remark 12 *The value $-\Omega^*(\lambda)$ is exactly equal to the value at the point $-\lambda$ of the conjugate function of $\frac{\Omega(c)}{c}$ defined in the literature of optimization.*

We can now estimate the solution $c^{\mathbf{z}}$ to (3) in terms of $S_i^{\mathbf{z}}, \lambda_i^{\mathbf{x}}$ and γ, by means of the explicit expression stated in Theorem 1.

Theorem 13 *Let $\gamma > 0$ and $\Omega : [0,\infty) \to [0,\infty)$ be a nonzero continuous concave function satisfying $\Omega(0) = 0$.*

(a) Both functions Ω^* and $\widetilde{\Omega}$ are well-defined and positive on $(0,\infty)$. The function Ω^* is nondecreasing while $\widetilde{\Omega}$ is non-increasing.

(b) Let $i \in \mathbb{N}$. If

$$|S_i^{\mathbf{z}}| < \frac{\Omega^*(\frac{\lambda_i^{\mathbf{x}}}{\gamma})}{2\frac{\lambda_i^{\mathbf{x}}}{\gamma}}, \tag{20}$$

then $c_i^{\mathbf{z}} = 0$. If $|S_i^{\mathbf{z}}| > \frac{\Omega^*(\frac{\lambda_i^{\mathbf{x}}}{\gamma})}{2\frac{\lambda_i^{\mathbf{x}}}{\gamma}}$, then $c_i^{\mathbf{z}}$ has the same sign as $S_i^{\mathbf{z}}$ and satisfies $|S_i^{\mathbf{z}}| - \widetilde{\Omega}\left(\frac{\lambda_i^{\mathbf{x}}}{\gamma}\right) \le |c_i^{\mathbf{z}}| \le |S_i^{\mathbf{z}}|$.

(c) Let $d^{\mathbf{x}} \le m$ be the rank of the Gramian matrix $\mathbb{K}$. Then $\lambda_i^{\mathbf{x}} = 0$ if and only if $i > d^{\mathbf{x}}$. Hence $c_i^{\mathbf{z}} = 0$ for $i > d^{\mathbf{x}}$.

Proof (a) The first statement follows easily from the definitions of the auxiliary functions and Proposition 10.

(b) Since $\gamma > 0$, when $\lambda_i^{\mathbf{x}} = 0$ or $S_i^{\mathbf{z}} = 0$, our statement follows from Theorem 1. So we consider the case that $\lambda_i^{\mathbf{x}} > 0$ and $S_i^{\mathbf{z}} \ne 0$. By symmetry we only need to prove our statement for the case $S_i^{\mathbf{z}} > 0$.

With $\lambda_i^{\mathbf{x}} > 0$ and $S_i^{\mathbf{z}} > 0$, we find that the left-side derivative of the function h_i is $(h_i)'_-(c) = 2\lambda_i^{\mathbf{x}}(c - S_i^{\mathbf{z}}) - \gamma\Omega'_+(|c|) < 0$ for $c \in (-\infty, 0]$, hence all its possible minimizers are achieved on $[0,\infty)$. Let us consider the difference function $h_i(c) - h_i(0)$ for $c > 0$ and factorize it as

$$h_i(c) - h_i(0) = c g_i(c), \quad \text{where} \quad g_i(c) := \gamma\frac{\Omega(c)}{c} + \lambda_i^{\mathbf{x}} c - 2\lambda_i^{\mathbf{x}} S_i^{\mathbf{z}}. \tag{21}$$

If $|S_i^{\mathbf{z}}| < \frac{\Omega^*(\frac{\lambda_i^{\mathbf{x}}}{\gamma})}{2\frac{\lambda_i^{\mathbf{x}}}{\gamma}}$, then $\inf_{c>0} g_i(c) > 0$ which implies $h_i(c) - h_i(0) = c g_i(c) > 0$ for every $c > 0$. Hence in this case h_i has the only minimizer at $0 = c_i^{\mathbf{z}}$.

If $|S_i^{\mathbf{z}}| > \frac{\Omega^*(\frac{\lambda_i^{\mathbf{x}}}{\gamma})}{2\frac{\lambda_i^{\mathbf{x}}}{\gamma}}$, then $\gamma \inf_{c>0} \left\{ \frac{\Omega(c)}{c} + \frac{\lambda_i^{\mathbf{x}}}{\gamma} c \right\} < 2\lambda_i^{\mathbf{x}} S_i^{\mathbf{z}}$ meaning that $\inf_{c>0} g_i(c) < 0$. It follows that a minimizer c_* of the function g_i on $(0,\infty)$ satisfies $g_i(c_*) < 0$. Hence $h_i(c_*) - h_i(0) = c_* g_i(c_*) < 0$. So 0 is not a minimizer of h_i.

Since Ω is nondecreasing on $[0,\infty)$, we know that h_i is strictly increasing on $(S_i^{\mathbf{z}}, \infty)$. Hence the minimizer $c_i^{\mathbf{z}}$ of h_i satisfies $0 < c_i^{\mathbf{z}} \le S_i^{\mathbf{z}}$. We also know from $h_i(c_i^{\mathbf{z}}) \le h_i(S_i^{\mathbf{z}})$ that

$$h_i(c_i^{\mathbf{z}}) = \lambda_i^{\mathbf{x}} (c_i^{\mathbf{z}} - S_i^{\mathbf{z}})^2 + \gamma\Omega(c_i^{\mathbf{z}}) \le h_i(S_i^{\mathbf{z}}) = \lambda_i^{\mathbf{x}} (S_i^{\mathbf{z}} - S_i^{\mathbf{z}})^2 + \gamma\Omega(S_i^{\mathbf{z}}) = \gamma\Omega(S_i^{\mathbf{z}}).$$

Express $S_i^{\mathbf{z}}$ as $S_i^{\mathbf{z}} - c_i^{\mathbf{z}} + c_i^{\mathbf{z}}$. Proposition 10 (c) yields $\Omega(S_i^{\mathbf{z}}) = \Omega(S_i^{\mathbf{z}} - c_i^{\mathbf{z}} + c_i^{\mathbf{z}}) \le \Omega(c_i^{\mathbf{z}}) + \Omega(S_i^{\mathbf{z}} - c_i^{\mathbf{z}})$. It follows that

$$\lambda_i^{\mathbf{x}} \left(c_i^{\mathbf{z}} - S_i^{\mathbf{z}}\right)^2 \le \gamma \Omega(S_i^{\mathbf{z}} - c_i^{\mathbf{z}}).$$

Therefore,

$$\frac{\Omega(S_i^{\mathbf{z}} - c_i^{\mathbf{z}})}{\left(S_i^{\mathbf{z}} - c_i^{\mathbf{z}}\right)^2} \ge \frac{\lambda_i^{\mathbf{x}}}{\gamma}.$$

By the definition of the function $\widetilde{\Omega}$, this implies that $S_i^{\mathbf{z}} - c_i^{\mathbf{z}} \le \widetilde{\Omega}\left(\frac{\lambda_i^{\mathbf{x}}}{\gamma}\right)$. This proves the range of $c_i^{\mathbf{z}}$ and verifies out second statement.

(c) It is well-known (e. g. Guo and Zhou (2012)) that the first $d^{\mathbf{x}}$ eigenvalues of the matrix $\mathbb{K}$ are given by $\{m\lambda_i^{\mathbf{x}}\}_{i=1}^{d^{\mathbf{x}}}$ while $\lambda_i^{\mathbf{x}} = 0$ for $i \ge d^{\mathbf{x}} + 1$. So $\lambda_i^{\mathbf{x}} = 0$ if and only if $i > d^{\mathbf{x}}$. In this case, condition (20) is satisfied and by the conclusion in part (b), $c_i^{\mathbf{z}} = 0$. The proof of Theorem 13 is thus complete. ■

4. General Analysis for Sparsity and Error Bounds

In this section we present a general result on sparsity and error bounds for the learning algorithm (2) generated by the regularization scheme (3) based on empirical features and concave regularizing functions. To this end, we need the following bounds for the auxiliary functions Ω^* and $\widetilde{\Omega}$.

Lemma 14 *If $\Omega : [0,\infty) \to [0,\infty)$ is a nonzero continuous concave function satisfying $\Omega(0) = 0$, then there exists a positive constant $C_{\Omega,1}$ such that*

$$\Omega^*(\lambda) \ge C_{\Omega,1} \min\{\sqrt{\lambda}, 1\}, \qquad \forall \lambda > 0. \tag{22}$$

If moreover, Ω has a concave exponent $q \in [0,1]$ with (8) valid, then there exists a positive constant $C_{\Omega,2}$ such that

$$\widetilde{\Omega}(\lambda) \le C_{\Omega,2} \max\left\{\left(\frac{1}{\lambda}\right)^{1/(2-q)}, \frac{1}{\lambda}\right\} \qquad \forall \lambda > 0. \tag{23}$$

Proof For $c \in (0,1]$, we apply Proposition 10 (d) and find

$$\frac{\Omega(c)}{c} + \lambda c \ge \Omega(1) + \lambda c \ge \Omega(1) \ge \Omega(1) \min\{\sqrt{\lambda}, 1\}.$$

For $c \in (1,\infty)$, we have $\Omega(c) \ge \Omega(1)$. Then $\frac{\Omega(c)}{c} + \lambda c \ge \frac{\Omega(1)}{c} + \lambda c \ge 2\sqrt{\Omega(1)\lambda} \ge 2\sqrt{\Omega(1)} \min\{\sqrt{\lambda}, 1\}$. Thus (22) holds with $C_{\Omega,1} = \max\{\Omega(1), 2\sqrt{\Omega(1)}\}$.

To prove (23), we let $\lambda \in (0,\infty)$. Denote $\widetilde{\Omega}(\lambda)$ as c^*. We know from the definition of $\widetilde{\Omega}(\lambda)$ that $\frac{\Omega(c^*)}{(c^*)^2} \ge \lambda$.

When $c^* \le 1$, we use condition (8) and find $\Omega(c^*) \le C_\Omega^* (c^*)^q$. But $\Omega(c^*) \ge \lambda (c^*)^2$. So $C_\Omega^* (c^*)^q \ge \lambda (c^*)^2$ and $c^* \le (C_\Omega^*)^{1/(2-q)} \left(\frac{1}{\lambda}\right)^{1/(2-q)}$.

When $c^* > 1$, we apply (7) in Theorem 2 to c^* and obtain $\lambda \le \frac{\Omega(c^*)}{(c^*)^2} \le \frac{\Omega(1)c^*}{(c^*)^2} \le \frac{\Omega(1)}{c^*}$ and thereby $c^* \le \frac{\Omega(1)}{\lambda}$. Combing the above two cases, we know that (23) is valid with $C_{\Omega,2} = \max\{(C_\Omega^*)^{1/(2-q)}, \Omega(1)\}$. This proves the lemma. ■

Theorem 15 *Assume (9) with $r > 0$, and that Ω has a concave exponent $q \in [0,1]$ with (8) valid. If $0 < \delta \le 1$ and for some $1 \le p \le m$, the regularization parameter γ satisfies*

$$\gamma \ge \begin{cases} C_1 \left(\log \frac{4m}{\delta}\right)^{1+2r} \left(\max\left\{\frac{\lambda_p}{\lambda_1}, \frac{1}{\sqrt{m}}\right\}\right)^{r+1}, & \text{if } 0 < r \le \frac{1}{2}, \\ C_1 \left(\log \frac{4m}{\delta}\right)^{1+2r} \max\left\{\left(\frac{\lambda_p}{\lambda_1}\right)^{r+\frac{1}{2}}, \frac{1}{\sqrt{m}}\right\} \left(\max\left\{\frac{\lambda_p}{\lambda_1}, \frac{1}{\sqrt{m}}\right\}\right)^{\frac{1}{2}}, & \text{if } r > \frac{1}{2}, \end{cases} \tag{24}$$

then with confidence $1 - \delta$ we have

$$c_i^{\mathbf{z}} = 0, \quad \forall i = p+1, \ldots, m$$

and

$$\begin{aligned} \|f^{\mathbf{z}} - f_\rho\|_K \;\le\; & C_{\Omega,2}\sqrt{p}\left\{\left(\frac{2\gamma}{\lambda_p}\right)^{\frac{1}{2-q}} + \frac{2\gamma}{\lambda_p}\right\} + \|g_\rho\|_K \lambda_p^r + C_3 \frac{\sqrt{p}\log\frac{4m}{\delta}}{\sqrt{m}} \lambda_p^{\min\{-1/2, r-1\}} \\ & + C_4 \lambda_p^{\min\{r-1,0\}} \left(\sum_{i=p+1}^{\infty} \lambda_i^{2\max\{r,1\}}\right)^{1/2}, \end{aligned} \tag{25}$$

where $C_1 \ge 1$, C_3 and C_4 are constants independent of γ, p, δ, or m.

The detailed proof of Theorem 15 will be given in Appendix A where the constants C_1, C_3 and C_4 will be specified explicitly. Here we outline the ideas of the proof by referring to three lemmas, Lemmas 18, 19 and 20 to be given in Appendix A, for estimating three quantities $|\lambda_i^{\mathbf{x}} - \lambda_i|$, $\sqrt{\lambda_i^{\mathbf{x}}}|S_i^{\mathbf{z}} - \langle f_\rho, \phi_i^{\mathbf{x}}\rangle_K|$ and $\sqrt{\lambda_i^{\mathbf{x}}}|\langle f_\rho, \phi_i^{\mathbf{x}}\rangle_K|$.

Step 1. To achieve the desired sparsity, we apply (22) in Lemma 14 and know that for verifying condition (20) in Theorem 13, it is sufficient to show that for $i \ge p+1$,

$$|S_i^{\mathbf{z}}| < \frac{C_{\Omega,1}}{2} \frac{\min\{\sqrt{\lambda_i^{\mathbf{x}}/\gamma}, 1\}}{\lambda_i^{\mathbf{x}}/\gamma}$$

or equivalently,

$$\sqrt{\lambda_i^{\mathbf{x}}}|S_i^{\mathbf{z}}| < \frac{C_{\Omega,1}}{2} \min\left\{\sqrt{\gamma}, \gamma/\sqrt{\lambda_i^{\mathbf{x}}}\right\}. \tag{26}$$

Step 2. Our desired bound (26) is verified by estimating

$$\lambda_i^{\mathbf{x}} \le |\lambda_i^{\mathbf{x}} - \lambda_i| + \lambda_i$$

by Lemma 18 and the decay of $\{\lambda_i\}$, and estimating

$$\sqrt{\lambda_i^{\mathbf{x}}}|S_i^{\mathbf{z}}| \le \sqrt{\lambda_i^{\mathbf{x}}}|S_i^{\mathbf{z}} - \langle f_\rho, \phi_i^{\mathbf{x}}\rangle_K| + \sqrt{\lambda_i^{\mathbf{x}}}|\langle f_\rho, \phi_i^{\mathbf{x}}\rangle_K|$$

by Lemma 19 and Lemma 20.

Step 3. To prove the error bound (25), we expand the error function $f^{\mathbf{z}} - f_\rho$ with respect to the orthonormal basis $\{\phi_i^{\mathbf{x}}\}$ of $\mathcal{H}_K$ and express the norm as

$$\|f^{\mathbf{z}} - f_\rho\|_K^2 = \sum_{i\in\mathbb{N}} \left(\langle f^{\mathbf{z}} - f_\rho, \phi_i^{\mathbf{x}}\rangle_K\right)^2 = \sum_{i\in\mathbb{N}} \left(c_i^{\mathbf{z}} - \langle f_\rho, \phi_i^{\mathbf{x}}\rangle_K\right)^2.$$

Split

$$c_i^{\mathbf{z}} - \langle f_\rho, \phi_i^{\mathbf{x}}\rangle_K = \{c_i^{\mathbf{z}} - S_i^{\mathbf{z}}\} + \left\{S_i^{\mathbf{z}} - \langle f_\rho, \phi_i^{\mathbf{x}}\rangle_K\right\}.$$

While the term $|c_i^{\mathbf{z}} - S_i^{\mathbf{z}}|$ can be bounded by $\widetilde{\Omega}\left(\frac{\lambda_i^{\mathbf{x}}}{\gamma}\right)$ according to Theorem 13, the other term will be expressed as

$$|S_i^{\mathbf{z}} - \langle f_\rho, \phi_i^{\mathbf{x}}\rangle_K| = \frac{\sqrt{\lambda_i^{\mathbf{x}}}|S_i^{\mathbf{z}} - \langle f_\rho, \phi_i^{\mathbf{x}}\rangle_K|}{\sqrt{\lambda_i^{\mathbf{x}}}}.$$

Step 4. We can control the denominator of the above expression by introducing a set with large $\lambda_i^{\mathbf{x}}$ as $\mathcal{S} := \{i \in \{1,\dots,p\}, \lambda_i^{\mathbf{x}} > \lambda_p/2\}$, and then bound the expression by Lemma 19. This together with our previous estimate Guo and Zhou (2012) for the terms involving $i \in \mathbb{N}\setminus\mathcal{S}$ finally yields the desired error bound.

Let us demonstrate how to apply our general analysis in Theorem 15 by two special cases where the eigenvalues of the integral operator L_K decay polynomially and exponentially.

Corollary 16 *Assume (9) with $r > 0$, and that Ω has a concave exponent $q \in [0,1]$ with (8) valid. Suppose that for some positive constants D_1, D_2, $\alpha_1 \geq \alpha_2$, the eigenvalues $\{\lambda_i\}$ of L_K decay polynomially as*

$$D_1 i^{-\alpha_1} \leq \lambda_i \leq D_2 i^{-\alpha_2}, \qquad \forall i \in \mathbb{N} \tag{27}$$

with $2\alpha_2 \max\{r,1\} > 1$. Let $0 < \delta < 1$. If we choose

$$\gamma = C_1 (D_2/\lambda_1)^{r+1} \left(\log\frac{4m}{\delta}\right)^{1+2r} m^{-\min\{\frac{1+r}{2}, \frac{1+r}{1+2r}\}}, \tag{28}$$

then with confidence $1-\delta$ we have

$$c_i^{\mathbf{z}} = 0 \qquad \forall\ m^{\frac{1}{\alpha_2 \max\{2,1+2r\}}} + 1 \leq i \leq m \tag{29}$$

and

$$\|f^{\mathbf{z}} - f_\rho\|_K \leq C_2 \left(\log\frac{4m}{\delta}\right)^{1+2r} m^{-\theta_{rate}},$$

where $\theta_{rate} = \min\{\theta_1, \theta_2\}$ with

$$\begin{aligned}
\theta_1 &= \begin{cases} \frac{2(r+1)\alpha_2 - 2\alpha_1 - 2 + q}{4(2-q)\alpha_2}, & \text{if } 0 < r \leq 1/2, \\ \frac{2(2r+2)\alpha_2 - 4\alpha_1 - 2(2-q)}{4(2r+1)(2-q)\alpha_2}, & \text{if } r > 1/2, \end{cases} \\
\theta_2 &= \frac{2\alpha_2 r - 1 - 2(\alpha_1 - \alpha_2)\max\left\{1-r, \frac{1}{2}\right\}}{2\alpha_2 \max\{2, 1+2r\}},
\end{aligned}$$

and C_1 and C_2 are constants independent of m or δ (given explicitly in the proof).

Proof Denote $\mu = \max\{2, 1+2r\}$. Take $p = \lceil m^{\frac{1}{\alpha_2\mu}}\rceil$, the smallest integer greater than or equal to $m^{\frac{1}{\alpha_2\mu}}$. Then we have

$$m^{\frac{1}{\alpha_2\mu}} \leq p \leq 2m^{\frac{1}{\alpha_2\mu}}$$

and by (27),

$$\lambda_p \leq D_2 p^{-\alpha_2} \leq D_2 m^{-\frac{\alpha_2}{\alpha_2\mu}} = D_2 m^{-\frac{1}{\mu}}.$$

It follows that $\frac{\lambda_p}{\lambda_1} \leq \frac{D_2}{\lambda_1} m^{-\frac{1}{\mu}} \leq \frac{D_2}{\lambda_1}\frac{1}{\sqrt{m}}$ for $0 < r \leq \frac{1}{2}$ and for $r > \frac{1}{2}$, there holds $(\lambda_p/\lambda_1)^{r+\frac{1}{2}} \leq (D_2/\lambda_1)^{r+\frac{1}{2}}\frac{1}{\sqrt{m}}$. Note that (27) implies $\lambda_1 \leq D_2$. Then (24) is satisfied if we choose γ by (28). Hence the conclusion of Theorem 15 holds true. In particular, the statement (29) about the sparsity follows from the choice of p. What is left is to bound the right-hand side of (25) by estimating the four terms separately.

The first term of (25) can be estimated by bounding $\frac{2\gamma}{\lambda_p}$ from the choice of γ and the lower bound of λ_p as

$$\frac{2\gamma}{\lambda_p} \leq \frac{2C_1}{D_1}(D_2/\lambda_1)^{r+1}\left(\log\frac{4m}{\delta}\right)^{1+2r} m^{-\min\{\frac{1+r}{2}, \frac{1+r}{1+2r}\}} \left(2m^{\frac{1}{\alpha_2\mu}}\right)^{\alpha_1}.$$

Observe that

$$\min\left\{\frac{1+r}{2}, \frac{1+r}{1+2r}\right\} - \frac{\alpha_1}{\alpha_2\mu} = \begin{cases} \frac{1+r}{2} - \frac{\alpha_1}{2\alpha_2} = \frac{(r+1)\alpha_2 - \alpha_1}{2\alpha_2}, & \text{if } 0 < r \leq 1/2, \\ \frac{1+r}{1+2r} - \frac{\alpha_1}{(2r+1)\alpha_2} = \frac{2(2r+2)\alpha_2 - 4\alpha_1}{4(2r+1)\alpha_2}, & \text{if } r > 1/2. \end{cases}$$

Therefore,

$$C_{\Omega,2}\sqrt{p}\left\{\left(\frac{2\gamma}{\lambda_p}\right)^{\frac{1}{2-q}} + \frac{2\gamma}{\lambda_p}\right\} \leq C_{\Omega,2}\sqrt{2}2^{\alpha_1+2}\frac{C_1}{D_1}(D_2/\lambda_1)^{r+1}\left(\log\frac{4m}{\delta}\right)^{1+2r} m^{-\theta_1},$$

where

$$\theta_1 = \begin{cases} \frac{(r+1)\alpha_2 - \alpha_1}{2(2-q)\alpha_2} - \frac{1}{4\alpha_2} = \frac{2(r+1)\alpha_2 - 2\alpha_1 - 2 + q}{4(2-q)\alpha_2}, & \text{if } 0 < r \leq 1/2, \\ \frac{2(2r+2)\alpha_2 - 4\alpha_1 - 2(2-q)}{4(2r+1)(2-q)\alpha_2}, & \text{if } r > 1/2. \end{cases}$$

The second term of (25) can be estimated by the choice of γ and the upper bound of λ_p as

$$\|g_\rho\|_K \lambda_p^r \leq \|g_\rho\|_K D_2^r p^{-\alpha_2 r} \leq \|g_\rho\|_K D_2^r m^{-\frac{2\alpha_2 r}{2\alpha_2\mu}} \leq \|g_\rho\|_K D_2^r m^{-\theta_2},$$

where θ_2 is the power index defined in the statement of the theorem.

The third term of (25) can be estimated by the choice of p and the lower bound of λ_p as

$$\begin{aligned}
&C_3\frac{\sqrt{p}\log\frac{4m}{\delta}}{\sqrt{m}}\lambda_p^{\min\{-1/2, r-1\}} \\
&\leq C_3 D_1^{\min\{-1/2, r-1\}} p^{\frac{1}{2} - \alpha_1\min\{-1/2, r-1\}}\left(\log\frac{4m}{\delta}\right) m^{-1/2} \\
&\leq C_3\sqrt{2}\left(2^{-\alpha_1}D_1\right)^{\min\{-1/2, r-1\}}\left(\log\frac{4m}{\delta}\right) m^{-\frac{1}{2} + \frac{1}{\alpha_2\mu}\left(\frac{1}{2} - \alpha_1\min\left\{-\frac{1}{2}, r-1\right\}\right)}.
\end{aligned}$$

From the identity $\mu - 2r = \max\{2, 2r+1\} - 2r = 2\max\{1-r, 1/2\}$, we see that the power index of m equals

$$\begin{aligned}
&-\frac{1}{2} + \frac{1}{\alpha_2 \mu}\left(\frac{1}{2} + \alpha_1 \max\left\{\frac{1}{2}, 1-r\right\}\right) \\
&= -\frac{1}{2\alpha_2\mu}\left(2\alpha_2 r - 1 + \alpha_2(\mu - 2r) - 2\alpha_1 \max\{1/2, 1-r\}\right) \\
&= -\frac{1}{2\alpha_2\mu}\left(2r\alpha_2 - 1 - 2(\alpha_1 - \alpha_2)\max\{1/2, 1-r\}\right)
\end{aligned}$$

which is exactly $-\theta_2$.

Turn to the last term of (25). By the restriction $2\alpha_2 \max\{r,1\} > 1$, we can bound the series as

$$\begin{aligned}
\sum_{i=p+1}^{\infty} \lambda_i^{2\max\{r,1\}} &\le \sum_{i=p+1}^{\infty} D_2^{2\max\{r,1\}} i^{-2\alpha_2 \max\{r,1\}} \\
&\le D_2^{2\max\{r,1\}} \int_p^{\infty} x^{-2\alpha_2\max\{r,1\}}\, \mathrm{d}x = \frac{D_2^{2\max\{r,1\}} p^{1-2\alpha_2\max\{r,1\}}}{2\alpha_2 \max\{r,1\} - 1}.
\end{aligned}$$

This combining with the choice of p and the lower bound of λ_p yields

$$\begin{aligned}
&C_4 \lambda_p^{\min\{r-1,0\}} \left(\sum_{i=p+1}^{\infty} \lambda_i^{2\max\{r,1\}}\right)^{1/2} \\
&\le \frac{C_4 D_1^{\min\{r-1,0\}} D_2^{\max\{r,1\}}}{\sqrt{2\alpha_2\max\{r,1\} - 1}} m^{\frac{1}{2\alpha_2\mu}(1 - 2\alpha_2\max\{r,1\} - 2\alpha_1 \min\{r-1,0\})}.
\end{aligned}$$

But

$$\begin{aligned}
&\frac{1}{2\alpha_2\mu}\left(1 - 2\alpha_2\max\{r,1\} - 2\alpha_1 \min\{r-1, 0\}\right) \\
&= -\frac{1}{2\alpha_2\mu}\left(2r\alpha_2 - 1 - 2(\alpha_1 - \alpha_2)\max\{0, 1-r\}\right) \le -\theta_2.
\end{aligned}$$

So we can combine this bound with the above estimates for the first three terms of (25) and verify the learning rate stated in the theorem by taking

$$\begin{aligned}
C_2 = \quad & C_{\Omega,2}\sqrt{2} 2^{\alpha_1+2} \frac{C_1}{D_1}(D_2/\lambda_1)^{r+1} + \|g_\rho\|_K D_2^r \\
& + C_3\sqrt{2}\left(2^{-\alpha_1} D_1\right)^{\min\{-1/2, r-1\}} + \frac{C_4 D_1^{\min\{r-1,0\}} D_2^{\max\{r,1\}}}{\sqrt{2\alpha_2\max\{r,1\} - 1}}.
\end{aligned}$$

The proof of Corollary 16 is complete. ∎

Corollary 17 *Assume (9) with $r > 0$, and that Ω has a concave exponent $q \in [0,1]$ with (8) valid. Suppose that for some positive constants D_1, D_2, $\beta_1 \ge \beta_2$, the eigenvalues $\{\lambda_i\}$ of L_K decay exponentially as*

$$D_1 \beta_1^{-i} \le \lambda_i \le D_2 \beta_2^{-i}, \qquad \forall i \in \mathbb{N}. \tag{30}$$

Let $0 < \delta < 1$. If we choose γ as (28), then with confidence $1-\delta$ we have

$$c_i^{\mathbf{z}} = 0, \qquad \forall\ \frac{\log(m+1)}{\max\{2, 1+2r\}\log\beta_2} + 1 \le i \le m \tag{31}$$

and

$$\|f^{\mathbf{z}} - f_\rho\|_K \le C_2 \left(\log\frac{4m}{\delta}\right)^{2r+1} m^{-\theta_{rate}},$$

where

$$\begin{aligned}
\theta_{rate} = \quad & \frac{1}{(2-q)\max\{2, 1+2r\}} \min\left\{1 + r - \frac{\log\beta_1}{\log\beta_2}, \right. \\
& \left. (2-q)r - \frac{(2-q)\log(\beta_1/\beta_2)}{\log\beta_2} \max\left\{1-r, \frac{1}{2}\right\}\right\}
\end{aligned}$$

and C_2 is a constant independent of m or δ (specified in the proof).

Proof Take $\mu = \max\{2, 1+2r\}$ and $p = \lceil \frac{\log(m+1)}{\mu\log\beta_2} \rceil$. Then

$$\frac{\log(m+1)}{\mu\log\beta_2} \le p < 1 + \frac{\log(m+1)}{\mu\log\beta_2},$$

which implies $m^{1/\mu} \le \beta_2^p \le \beta_1^p \le \beta_1 (2m)^{\frac{\log\beta_1}{\mu\log\beta_2}}$. Hence $\frac{\lambda_p}{\lambda_1} \le \frac{D_2}{\lambda_1}\beta_2^{-p} \le \frac{D_2}{\lambda_1}\frac{1}{\sqrt{m}}$ for $0 < r \le \frac{1}{2}$ and for $r > \frac{1}{2}$, there holds $(\lambda_p/\lambda_1)^{r+\frac{1}{2}} \le (D_2/\lambda_1)^{r+\frac{1}{2}} \frac{1}{\sqrt{m}}$. Then (24) is satisfied and the conclusion of Theorem 15 holds true. The statement (31) about the sparsity follows from the choice of p, and the next step is to estimate the four summing terms of the error bound (25).

For the first term, we notice

$$\frac{2\gamma}{\lambda_p} \le \frac{2C_1}{D_1}(D_2/\lambda_1)^{r+1} \left(\log\frac{4m}{\delta}\right)^{1+2r} m^{-\min\{\frac{1+r}{2}, \frac{1+r}{1+2r}\}} \beta_1 (2m)^{\frac{\log\beta_1}{\mu\log\beta_2}}.$$

So the first term can be bounded as

$$C_{\Omega,2}\sqrt{p}\left\{\left(\frac{2\gamma}{\lambda_p}\right)^{\frac{1}{2-q}} + \frac{2\gamma}{\lambda_p}\right\} \le C_{\Omega,2} C_5 \sqrt{\log(2m)} \left(\log\frac{4m}{\delta}\right)^{1+2r} m^{-\frac{1}{2-q}\min\{\frac{1+r}{2}, \frac{1+r}{1+2r}\} + \frac{\log\beta_1}{(2-q)\mu\log\beta_2}},$$

where C_5 is the constant given by

$$C_5 = 2\sqrt{\frac{1}{\log 2} + \frac{1}{\mu\log\beta_2}} \max\left\{\frac{2C_1}{D_1}(D_2/\lambda_1)^{r+1}\beta_1 2^{\frac{\log\beta_1}{\mu\log\beta_2}}, 1\right\}.$$

The second term of (25) is easy to handle:

$$\|g_\rho\|_K \lambda_p^r \le \|g_\rho\|_K D_2^r \beta_2^{-pr} \le \|g_\rho\|_K D_2^r m^{-r/\mu}.$$

The third term of (25) can be estimated by the choice of p and the lower bound of λ_p as

$$C_3 \frac{\sqrt{p}\log\frac{4m}{\delta}}{\sqrt{m}} \lambda_p^{\min\{-1/2, r-1\}} \le C_6 \sqrt{\log(2m)} \left(\log\frac{4m}{\delta}\right) m^{-\frac{1}{2}+\frac{\log\beta_1}{\mu\log\beta_2}\max\{1/2,1-r\}},$$

where

$$C_6 = C_3 \sqrt{\frac{1}{\log 2} + \frac{1}{\mu\log\beta_2}} D_1^{\min\{-1/2,r-1\}} \left(\beta_1 2^{\frac{\log\beta_1}{\mu\log\beta_2}}\right)^{\max\{1/2,1-r\}}.$$

Observe that $\max\{1/2, 1-r\} + r = \mu/2$. The power index of m equals

$$\begin{aligned} &-\frac{1}{2} + \frac{\log\beta_1}{\mu\log\beta_2}\max\{1/2, 1-r\} = -\frac{r}{\mu} + \frac{r\log\beta_2 - \frac{\mu}{2}\log\beta_2 + \frac{\mu}{2}\log\beta_1 - r\log\beta_1}{\mu\log\beta_2} \\ &= -\frac{r}{\mu} + \frac{\log\frac{\beta_1}{\beta_2}}{\mu\log\beta_2}\max\{1/2, 1-r\}. \end{aligned}$$

Finally, we bound the series in the last term of (25) and find

$$\begin{aligned} &C_4 \lambda_p^{\min\{r-1,0\}} \left(\sum_{i=p+1}^\infty \lambda_i^{2\max\{r,1\}}\right)^{1/2} \\ &\le C_4 (\beta_1/D_1)^{\max\{1-r,0\}} (2m)^{\frac{\log\beta_1}{\mu\log\beta_2}\max\{1-r,0\}} D_2^{\max\{r,1\}} \left(\sum_{i=p+1}^\infty \beta_2^{-2i\max\{r,1\}}\right)^{1/2} \\ &\le C_4 \left(\frac{\beta_1}{D_1}\right)^{\max\{1-r,0\}} (2m)^{\frac{\log\beta_1}{\mu\log\beta_2}\max\{1-r,0\}} D_2^{\max\{r,1\}} \frac{\beta_2^{-p\max\{r,1\}}}{\sqrt{\beta_2^{2\max\{r,1\}} - 1}} \\ &\le C_4 \left(\frac{\beta_1}{D_1}\right)^{\max\{1-r,0\}} \frac{D_2^{\max\{r,1\}}}{\sqrt{\beta_2^{2\max\{r,1\}} - 1}} (2m)^{\frac{\max\{1-r,0\}(\log\beta_1)}{\mu\log\beta_2}} m^{-\frac{\max\{r,1\}}{\mu}}. \end{aligned}$$

Note that the power index of m is

$$\frac{\max\{1-r,0\}\log\beta_1}{\mu\log\beta_2} - \frac{\max\{r,1\}}{\mu} = \frac{\max\{1-r,0\}\log(\beta_1/\beta_2) - r\log\beta_2}{\mu\log\beta_2}.$$

Then the desired learning rate is verified by observing $\min\{\frac{1+r}{2}, \frac{1+r}{1+2r}\}\mu = 1 + r$ and taking

$$C_2 = C_{\Omega,2}C_5 + \|g_\rho\|_K D_2^r + C_6 + C_4 \left(\frac{\beta_1}{D_1} 2^{\frac{\log\beta_1}{\mu\log\beta_2}}\right)^{\max\{1-r,0\}} \frac{D_2^{\max\{r,1\}}}{\sqrt{\beta_2^{2\max\{r,1\}} - 1}}.$$

The proof of Corollary 17 is complete. ∎

5. Simulations

In this section we give some simulations for both artificial and real data. We demonstrate that with either the ℓ^q-regularizer or the SCAD penalty, RKPCA is comparable with the regularized least squares in learning error, and achieves satisfactory sparsity.

5.1 Simulation on artificial data

We start with a simulation on artificial data. For simplicity we take $X = [0, 1]$. Let ρ be a Borel probability measure on $X \times Y$ to be specified later and $\mathbf{z} = \{(x_i, y_i)\}_{i=1}^m$ be a sample of size m divisible by 5. We divide $\mathbf{z}$ evenly into five disjoint subsets $\mathbf{z} = \cup_{j=1}^5 \mathbf{z}_j$, and do 5-fold cross-validation to select the parameter γ^* from a geometric sequence $\{10^{-10}, \cdots, 10^{-2}\}$ of length 60, to minimize the root-mean-square error (RMSE). Here, with a fixed γ the RMSE score is defined by

$$\mathcal{E}_{\mathsf{RMSE},\mathbf{z}}(\gamma) = \left(\sum_{j=1}^5 \sum_{(x,y)\in\mathbf{z}\setminus\mathbf{z}_j} \left(f_\gamma^{\mathbf{z}_j}(x) - y\right)^2\right)^{1/2}. \tag{32}$$

Then RKPCA is trained with γ^* on $\mathbf{z}$ and outputs $f^{\mathbf{z}}$. Sparsity is evaluated by the percentage of the non-zero coefficients in (2). The prediction performance is evaluated with the oracle RMSE defined by

$$\mathcal{E}_{\mathsf{RMSE},f_\rho}(f^{\mathbf{z}}) = \left(\int_0^1 (f^{\mathbf{z}}(x) - f_\rho(x))^2 \,\mathrm{d}x\right)^{1/2}, \tag{33}$$

where the integral is computed with 1000 equispaced points.

First, we simulate with the Gaussian kernel

$$K_{\mathsf{G}} = \exp\left(-\frac{(x-y)^2}{0.6^2}\right).$$

We use the regression model $f_\rho(x) = \mathrm{e}^{-(x-1/3)^2/0.7^2}$. Let ρ_X be the uniform distribution on $[0, 1]$, and $\rho(\cdot|x)$ be the uniform distribution on $[f_\rho(x) - 0.1, f_\rho(x) + 0.1]$. The simulation is summarized in Table 1. We find that the behavior of the SCAD penalty is comparable on this data set with the penalty $\Omega(|c|) = |c|$, and despite of very strong sparsity, RKPCA achieves comparable precision with that of RLS.

Next, we simulate with the Sobolev kernel

$$K_{\mathsf{S}}(x, y) = \mathrm{e}^{-|x-y|}.$$

The regression function is set as $f_\rho(x) = |2x - 1|^\tau$. The marginal and conditional probabilities ρ_X and $\rho(\cdot|x)$ are defined as above. We use $\tau = 1$, 1.5, 2.5, and 4.5. Note that in addition to $\mathcal{E}_{\mathsf{RMSE},f_\rho}$, the RKHS norm is now also easy to compute as another measurement. In fact, one has for $f, g \in \mathcal{H}_{K_{\mathsf{S}}}$,

$$2\langle f, g\rangle_{K_{\mathsf{S}}} = f(0)g(0) + f(1)g(1) + \int_0^1 f(t)g(t)\,\mathrm{d}t + \int_0^1 f'(t)g'(t)\,\mathrm{d}t.$$

The simulation is summarized in Table 2, from which we have the following observations:

sample size	RKPCA				RLS
	$q=1$	$q=2/3$	$q=1/3$	SCAD	
100	3.5(2.0)%	3.2(1.7)%	3.2(1.9)%	3.3(1.5)%	100(0)%
	0.013(0.006)	0.012(0.005)	0.012(0.007)	0.011(0.005)	0.012(0.005)
300	1.4(1.2)%	1.2(1.4)%	1.1(0.7)%	1.1(0.5)%	100(0)%
	0.007(0.004)	0.007(0.006)	0.007(0.003)	0.006(0.002)	0.007(0.003)
1000	0.4(0.4)%	0.4(0.3)%	0.3(0.2)%	0.4(0.2)%	100(0)%
	0.004(0.002)	0.004(0.002)	0.004(0.002)	0.004(0.001)	0.004(0.002)

Table 1: A simulation with Gaussian kernel. Here SCAD and $q = 1$, $2/3$, and $1/3$ stand for RKPCA with penalty SCAD (as defined in Example 2, and we set $b = 2.5$) and $\Omega(|c|) = |c|^q$ respectively. The scores of RLS are also listed for comparison. In each cell, the top percentage gives the proportion of the non-zero coefficients, and the bottom score is $\mathcal{E}_{\mathsf{RMSE},f_\rho}$ as defined in (33). Each simulation is repeated 100 times. We present the mean scores in the table, and give the sample standard deviation in parentheses.

(a) The sparsity and learning error of RKPCA with the SCAD penalty is again comparable on this data set to that with the penalty $\Omega(|c|) = |c|$. This shows that the expression of the SCAD penalty near the origin (the same as that for $\Omega(|c|) = |c|$) and the concave exponent q play a crucial role in its performance.

(b) Compared with RLS, RKPCA achieves very strong sparsity while its approximation ability with $\Omega(|c|) = |c|$ in terms of the RKHS metric is consistently better. This might be caused by the orthogonality of the empirical features in the RKHS. The learning ability in terms of the root-mean-square error defined by (33) is comparable.

5.2 Simulation on MHC-peptide binding data

We apply RKPCA to the quantitative Immune Epitope Database (IEDB) benchmark data of human leukocyte antigen (HLA)–peptide binding affinities, introduced in (Nielsen et al., 2008). Nielsen and Lund (2009) developed an artificial neural network-based algorithm called NN-align, which gave on this data set the state-of-the-art prediction in 2009. Later, Shen et al. (2012) designed a string kernel denoted in their paper by $\hat{K}^3$, and applied it with the regularized least squares (RLS), which produced better prediction than NN-align on the same data set. We use this $\hat{K}^3$ in RKPCA, and show that RKPCA achieves some sparsity in addition to the precision comparable with that in (Shen et al., 2012).

Here are more details of our simulation. The quantitative IEDB benchmark data set in (Nielsen et al., 2008) as mentioned above, consists of 14 groups, each containing the affinities of a set of peptides to a specific HLA allele. We use the 14 groups separately. Now fix an allele a and denote $X = \mathscr{P}_a$ the set of peptides given in the data set. For $p \in \mathscr{P}_a$, the affinity $y_p \in [0,1] \subset Y = \mathbb{R}$ is a real number (see Nielsen and Lund (2009); Shen et al. (2012)). We divide $\mathscr{P}_a$ into 5 disjoint subsets $\mathscr{P}_a = \cup_{j=1}^5 \mathscr{P}_a^j$, following exactly the division in (Nielsen and Lund, 2009) and (Shen et al., 2012), for a 5-fold cross-validation. In the jth cross-validation round ($j = 1, \cdots, 5$), we take $\mathscr{P}_a^j$ as testing data and $\mathscr{P}_a \backslash \mathscr{P}_a^j$ as training data. Within the training data, another 5-fold cross-validation is employed to select the

parameter γ_j^* in (3), from a geometric sequence $\{10^{-8}, \cdots, 10^{-2}\}$ of length 60 to minimize the RMSE score defined in (32). Then RKPCA is trained on $\mathscr{P}_a \backslash \mathscr{P}_a^j$ with γ_j^* to predict the affinities on $\mathscr{P}_a^j$. After all the five rounds, each peptide $p \in \mathscr{P}_a$ has a predicted affinity $\tilde{y}_p$ obtained during the jth round where $\mathscr{P}_a^j \ni p$. Note that $\tilde{y}_p$ may not always fall in $[0,1]$, and might be projected back onto $[0,1]$ to increase precision. However we do not adopt the projection, for being consistent and comparable with (Shen et al., 2012) where they did not either. Since there is no oracle information, we use

$$\mathcal{E}_{\mathsf{RMSE},a} = \left(\frac{1}{\#\mathscr{P}_a} \sum_{p \in \mathscr{P}_a} (\tilde{y}_p - y_p)^2 \right)^{1/2} \tag{34}$$

as the RMSE score. A lower RMSE score indicates a better performance.

The area under the receiver operating characteristic (ROC) curve (AUC), defined as

$$\mathcal{E}_{\mathsf{AUC},a} = \frac{\#\left\{(p,p') : p \in \mathscr{P}_{a,B}, p' \in \mathscr{P}_{a,N}, \tilde{y}_p > \tilde{y}_{p'}\right\}}{(\#\mathscr{P}_{a,B})\,(\#\mathscr{P}_{a,N})} \in [0,1], \tag{35}$$

is another performance index. Here $\mathscr{P}_{a,B} = \{p \in \mathscr{P}_a : y_p > 0.426\}$ and $\mathscr{P}_{a,N} = \mathscr{P}_a \backslash \mathscr{P}_{a,B}$ are the sets of binding peptides and non-binding ones respectively, with the threshold 0.426 used in (Nielsen and Lund, 2009). A higher AUC score indicates a better performance. The above scores (34) and (35) are used in (Shen et al., 2012). See also (Nielsen and Lund, 2009) for details.

We test the RKPCA with $\Omega(c) = |c|^q$, where q is set to be 1, 2/3, and 1/3 in three separated tests, and with the SCAD penalty. For defining $\hat{K}^3$, the Hadamard power index is fixed to be 0.11387 for simplicity, as suggested in (Shen et al., 2012).

The simulation is summarized in Table 3, from which we have the following observations:

(a) In terms of AUC on this real data set, RLS (Shen et al., 2012) has better performance than NN-align (Nielsen and Lund, 2009). The improvement is 0.55% on average, with better AUC scores for 9 out of 14 test groups while the score difference is always at the second significant figure. RKPCA with $\Omega(c) = |c|$ has even slightly better performance, giving an improvement of 0.11% on average, and better AUC scores for 8 out of 14 test groups with the score difference always at the third significant figure only. Improvements in (Shen et al., 2012) and in our simulation seem to be small, but we regard the results to be valuable because this data set has been well investigated in the immunological literature and any improvement is difficult. In particular, the dissimilarity metric BLOSUM62-2 among the 20 basic amino-acids, based on which the string kernel $\hat{K}^3$ is constructed in (Shen et al., 2012), was obtained in a very tight form after long-term effort and a vast biological literature (see, e.g., Henikoff and Henikoff (1992)).

(b) Sparsity and error bounds in terms of both AUC and root-mean-square error for the simulation with the SCAD penalty is almost the same on this real data set as that with $\Omega(|c|) = |c|$, verifying again the role of the concave exponent $q = 1$.

Table 2: A simulation with Sobolev kernel. Here SCAD and $q = 1$, $2/3$, and $1/3$ stand for RKPCA with penalty SCAD (as defined in Example 2, and we set $b = 2.5$) and $\Omega(|c|) = |c|^q$ respectively. The scores of RLS are also listed for comparison. In each cell, the top percentage gives the proportion of the non-zero coefficients, the middle score is $\mathcal{E}_{\mathsf{RMSE},f_\rho}$ as defined in (33), and the bottom score gives the RKHS distance of $f^{\mathbf{z}}$ to f_ρ. Each simulation is repeated 100 times. We present the mean scores in the table, and give the sample standard deviation in parentheses.

Table 3: Comparison of sparsity and error. Each cell consists of the average of proportions of the non-zero coefficients in the five rounds of test (the top percentage), RMSE defined by (34) (the middle number), and AUC defined by (35) (the bottom number). We cite the scores of NN-align from (Nielsen and Lund, 2009) and that of RLS from (Shen et al., 2012).

Acknowledgments

We would like to sincerely thank the referees for their constructive suggestions and comments. The work described in this paper was supported by the Research Grants Council of Hong Kong [Project No. CityU 105011] and by the National Natural Science Foundation of China under Grants 11461161006 and 11471292. The corresponding author is Ding-Xuan Zhou.

Appendix A. Proof of Theorem 15

In this appendix, we prove our general result on sparsity and error bounds stated in Theorem 15.

The following three lemmas are needed for proving Theorem 15. The first one is cited from (Zwald and Blanchard, 2006). See also (Koltchinskii and Giné, 2000; Guo and Zhou, 2012).

Lemma 18 *(a) We have*

$$\sum_{i=1}^{\infty}(\lambda_i-\lambda_i^{\mathbf{x}})^2 \le \|L_K - L_K^{\mathbf{x}}\|_{HS}^2. \tag{36}$$

(b) For any $0<\delta<1$, with confidence $1-\delta$ we have

$$\|L_K - L_K^{\mathbf{x}}\|_{HS} \le \frac{4\kappa^2\log\frac{2}{\delta}}{\sqrt{m}}. \tag{37}$$

The second lemma needed for proving Theorem 15 improves our previous estimate $\|\{\lambda_i^{\mathbf{x}}|S_i^{\mathbf{z}}-\langle f_\rho,\phi_i^{\mathbf{x}}\rangle_K|\}\|_{\ell^2} \le \frac{8M\kappa\log\frac{2}{\delta}}{\sqrt{m}}$ given in (Guo and Zhou, 2012) for the case of ℓ^1-penalty. The significant improvement we make here is to reduce the power of $\lambda_i^{\mathbf{x}}$ from 1 to $\frac{1}{2}$. Hence a different method for the proof is needed.

Lemma 19 *Let $f_\rho\in\mathcal{H}_K$. For $0<\delta<1$, with confident $1-\delta$ we have*

$$\sqrt{\lambda_i^{\mathbf{x}}}\left|S_i^{\mathbf{z}}-\langle f_\rho,\phi_i^{\mathbf{x}}\rangle_K\right| \le \frac{2\sqrt{2}M}{\sqrt{m}}\sqrt{\log\frac{2m}{\delta}}, \qquad \forall\, i\in\mathbb{N}. \tag{38}$$

Proof When $\lambda_i^{\mathbf{x}}=0$, (38) is obvious. When $i\ge m+1$, $\lambda_i^{\mathbf{x}}=0$ since the rank of $L_K^{\mathbf{x}}$ is not greater than m. For any fixed $\lambda_i^{\mathbf{x}}>0$, denote

$$\eta_j=\frac{y_j-f_\rho(x_j)}{\sqrt{m}}, \qquad a_j=\frac{\phi_i^{\mathbf{x}}(x_j)}{\sqrt{m\lambda_i^{\mathbf{x}}}}.$$

Then by the definition of $S_i^{\mathbf{z}}$, $\sqrt{\lambda_i^{\mathbf{x}}}\left(S_i^{\mathbf{z}}-\langle f_\rho,\phi_i^{\mathbf{x}}\rangle_K\right)=\sum_{j=1}^m\eta_j a_j$. Also, $\sum_{j=1}^m a_j^2=1$. Since $|y|\le M$ almost surely, we have $|a_j\eta_j|\le 2M|a_j|/\sqrt{m}$ almost surely. By Hoeffding's inequality, we have for any $\varepsilon>0$,

$$\mathbb{P}\left\{\left|\sum_{j=1}^m a_j\eta_j\right|\ge\varepsilon\right\}\le 2\exp\left(-\frac{m\varepsilon^2}{8M^2}\right).$$

Taking the union of the above at most m events, we know that

$$\mathbb{P}\left\{\max_{i=1,\dots,m}\left|\sqrt{\lambda_i^{\mathbf{x}}}\left(S_i^{\mathbf{z}}-\langle f_\rho,\phi_i^{\mathbf{x}}\rangle_K\right)\right|\ge\varepsilon\right\}\le 2m\exp\left(-\frac{m\varepsilon^2}{8M^2}\right).$$

One completes the proof by taking $\varepsilon>0$ to be the positive solution to the equation $2m\exp(-\frac{m\varepsilon^2}{8M^2})=\delta$. ■

Lemma 20 *Let $I\subset\mathbb{N}$ be a finite index set. If $f_\rho=L_K^r g_\rho$ for some $g_\rho\in\mathcal{H}_K$, then when $0<r<1/2$,*

$$\left(\sum_{i\in I}(\sqrt{\lambda_i^{\mathbf{x}}}\langle f_\rho,\phi_i^{\mathbf{x}}\rangle_K)^2\right)^{1/2} \le 2^r\|g_\rho\|_K(\#I)^{(1-2r)/4}\|L_K-L_K^{\mathbf{x}}\|_{\mathrm{HS}}^{(1+2r)/2} + 2^r\|g_\rho\|_K\left(\sum_{i\in I}(\lambda_i^{\mathbf{x}})^{1+2r}\right)^{1/2}, \tag{39}$$

and when $r\ge 1/2$,

$$\left(\sum_{i\in I}(\sqrt{\lambda_i^{\mathbf{x}}}\langle f_\rho,\phi_i^{\mathbf{x}}\rangle_K)^2\right)^{1/2} \le \sqrt{2}\lambda_1^{r-\frac{1}{2}}\|g_\rho\|_K\|L_K-L_K^{\mathbf{x}}\|_{\mathrm{HS}} + 2^r\|g_\rho\|_K\left(\sum_{i\in I}(\lambda_i^{\mathbf{x}})^{1+2r}\right)^{1/2}. \tag{40}$$

Proof Let $g_\rho=\sum_{j=1}^\infty d_j\phi_j$ with $\{d_j\}\in\ell^2$. Then $\|\{d_j\}\|_{\ell^2}=\|g_\rho\|_K$ and $f_\rho=\sum_{j=1}^\infty\lambda_j^r d_j\phi_j$. For $i\in I$, since whenever $\lambda_i^{\mathbf{x}}=0$, $\sqrt{\lambda_i^{\mathbf{x}}}\langle f_\rho,\phi_i^{\mathbf{x}}\rangle_K=0$, without loss of generality we assume $\lambda_i^{\mathbf{x}}>0$. Then we expand $\sqrt{\lambda_i^{\mathbf{x}}}\langle f_\rho,\phi_i^{\mathbf{x}}\rangle_K$ as

$$\sqrt{\lambda_i^{\mathbf{x}}}\langle f_\rho,\phi_i^{\mathbf{x}}\rangle_K=\left(\sum_{j:\lambda_j\ge 2\lambda_i^{\mathbf{x}}}+\sum_{j:\lambda_j<2\lambda_i^{\mathbf{x}}}\right)\sqrt{\lambda_i^{\mathbf{x}}}\lambda_j^r d_j\langle\phi_j,\phi_i^{\mathbf{x}}\rangle_K. \tag{41}$$

The second sum in (41) is easy to handle:

$$\left|\sum_{j:\lambda_j<2\lambda_i^{\mathbf{x}}}\sqrt{\lambda_i^{\mathbf{x}}}\lambda_j^r d_j\langle\phi_j,\phi_i^{\mathbf{x}}\rangle_K\right| \le 2^r(\lambda_i^{\mathbf{x}})^{(1+2r)/2}\|\{d_j\}\|_{\ell^2}\left(\sum_{j=1}^\infty\langle\phi_j,\phi_i^{\mathbf{x}}\rangle_K^2\right)^{1/2} = 2^r\|g_\rho\|_K(\lambda_i^{\mathbf{x}})^{(1+2r)/2}. \tag{42}$$

When $r\ge 1/2$ and $\lambda_j\ge 2\lambda_i^{\mathbf{x}}$, since $\sqrt{\lambda_i^{\mathbf{x}}\lambda_j}\le\frac{\lambda_j}{\sqrt{2}}\le\sqrt{2}(\lambda_j-\lambda_i^{\mathbf{x}})$, the first sum in (41) can be bounded as

$$\left|\sum_{j:\lambda_j\ge 2\lambda_i^{\mathbf{x}}}\sqrt{\lambda_i^{\mathbf{x}}}\lambda_j^r d_j\langle\phi_j,\phi_i^{\mathbf{x}}\rangle_K\right| \le \sum_{j:\lambda_j\ge 2\lambda_i^{\mathbf{x}}}\lambda_j^{r-\frac{1}{2}}\sqrt{2}\left|(\lambda_j-\lambda_i^{\mathbf{x}})\langle\phi_j,\phi_i^{\mathbf{x}}\rangle_K d_j\right| \le \sqrt{2}\lambda_1^{r-\frac{1}{2}}\|g_\rho\|_K\left(\sum_{j=1}^\infty(\lambda_j-\lambda_i^{\mathbf{x}})^2\langle\phi_j,\phi_i^{\mathbf{x}}\rangle_K^2\right)^{1/2}. \tag{43}$$

When $0 < r < 1/2$ and $\lambda_j \geq 2\lambda_i^{\mathbf{x}}$, we observe that

$$\frac{\sqrt{\lambda_i^{\mathbf{x}}}\lambda_j^r}{|\lambda_j - \lambda_i^{\mathbf{x}}|^{r+\frac{1}{2}}} \leq \frac{\lambda_j^{r+\frac{1}{2}}/\sqrt{2}}{(\lambda_j/2)^{r+\frac{1}{2}}} = 2^r.$$

So in this case the first sum in (41) can also be bounded as

$$\begin{aligned}
&\left| \sum_{j:\lambda_j \geq 2\lambda_i^{\mathbf{x}}} \sqrt{\lambda_i^{\mathbf{x}}}\lambda_j^r d_j \langle \phi_j, \phi_i^{\mathbf{x}} \rangle_K \right| \leq \sum_{j:\lambda_j \geq 2\lambda_i^{\mathbf{x}}} 2^r |\lambda_j - \lambda_i^{\mathbf{x}}|^{r+\frac{1}{2}} \left| d_j \langle \phi_j, \phi_i^{\mathbf{x}} \rangle_K \right| \\
&\leq 2^r \left(\sum_j d_j^2 \right)^{1/2} \left(\sum_j \left| (\lambda_j - \lambda_i^{\mathbf{x}}) \langle \phi_j, \phi_i^{\mathbf{x}} \rangle_K \right|^{(r+\frac{1}{2})\frac{2}{r+\frac{1}{2}}} \right)^{\frac{r+\frac{1}{2}}{2}} \left(\sum_j \left| \langle \phi_j, \phi_i^{\mathbf{x}} \rangle_K \right|^{(\frac{1}{2}-r)\frac{2}{\frac{1}{2}-r}} \right)^{\frac{\frac{1}{2}-r}{2}} \\
&= 2^r \|g_\rho\|_K \left(\sum_{j=1}^\infty (\lambda_j - \lambda_i^{\mathbf{x}})^2 \langle \phi_j, \phi_i^{\mathbf{x}} \rangle_K^2 \right)^{(1+2r)/4}. \qquad (44)
\end{aligned}$$

By (41), (42), and the triangle inequality,

$$\begin{aligned}
\left(\sum_{i\in I} |\sqrt{\lambda_i^{\mathbf{x}}} \langle f_\rho, \phi_i^{\mathbf{x}} \rangle_K|^2 \right)^{1/2} &\leq \left(\sum_{i\in I} \left(\sum_{j:\lambda_j \geq 2\lambda_i^{\mathbf{x}}} \sqrt{\lambda_i^{\mathbf{x}}}\lambda_j^r d_j \langle \phi_j, \phi_i^{\mathbf{x}} \rangle_K \right)^2 \right)^{1/2} \\
&+ 2^r \|g_\rho\|_K \left(\sum_{i\in I} (\lambda_i^{\mathbf{x}})^{1+2r} \right)^{1/2}. \qquad (45)
\end{aligned}$$

We denote the first term of the right-hand side of (45) as Υ. The definition of the Hilbert-Schmidt norm tells us that

$$\|L_K - L_K^{\mathbf{x}}\|_{HS}^2 = \sum \|(L_K - L_K^{\mathbf{x}})\phi_i^{\mathbf{x}}\|_K^2 = \sum_{i,j=1}^\infty (\lambda_j - \lambda_i^{\mathbf{x}})^2 \langle \phi_i^{\mathbf{x}}, \phi_j \rangle_K^2. \qquad (46)$$

So when $r \geq 1/2$, (43) and (46) give

$$\begin{aligned}
\Upsilon &\leq \sqrt{2}\lambda_1^{r-\frac{1}{2}} \|g_\rho\|_K \left(\sum_{i\in I} \sum_{j=1}^\infty (\lambda_j - \lambda_i^{\mathbf{x}})^2 \langle \phi_j, \phi_i^{\mathbf{x}} \rangle_K^2 \right)^{1/2} \\
&\leq \sqrt{2}\lambda_1^{r-\frac{1}{2}} \|g_\rho\|_K \|L_K - L_K^{\mathbf{x}}\|_{\mathrm{HS}},
\end{aligned}$$

which proves (40). When $0 < r < 1/2$, by (44), (46) and Hölder's inequality, we have

$$\begin{aligned}
\Upsilon &\leq 2^r \|g_\rho\|_K \left(\sum_{i\in I} \left(\sum_{j=1}^\infty (\lambda_j - \lambda_i^{\mathbf{x}})^2 \langle \phi_j, \phi_i^{\mathbf{x}} \rangle_K^2 \right)^{(1+2r)/2} \right)^{1/2} \\
&\leq 2^r \|g_\rho\|_K \left(\sum_{i\in I} \sum_{j=1}^\infty (\lambda_j - \lambda_i^{\mathbf{x}})^2 \langle \phi_j, \phi_i^{\mathbf{x}} \rangle_K^2 \right)^{(1+2r)/4} \left(\sum_{i\in I} 1^{\frac{2}{1-2r}} \right)^{(1-2r)/4} \\
&\leq 2^r \|g_\rho\|_K \|L_K - L_K^{\mathbf{x}}\|_{\mathrm{HS}}^{(1+2r)/2} (\#I)^{(1-2r)/4},
\end{aligned}$$

which verifies (39). The proof of the lemma is complete. ∎

We are now in a position to prove Theorem 15.

Proof of Theorem 15. By Lemmas 18 and 19, we know that for any $0 < \delta < \frac{1}{2}$ there exists a subset Z_δ of Z^m of measure at least $1 - 2\delta$ such that both (37) and (38) hold for each $\mathbf{z} \in Z_\delta$.

Let $\mathbf{z} \in Z_\delta$.

To prove $c_i^{\mathbf{z}} = 0$ for $i = p+1, \ldots, m$, we show that condition (50) for γ, to be defined below which is the same as condition (24) in the statement of the theorem after scaling δ to $\delta/2$, implies (26) and thereby (20) in Theorem 13, according to (22) in Lemma 14. To this end, we estimate $\sqrt{\lambda_i^{\mathbf{x}}}|S_i^{\mathbf{z}}|$ and $\sqrt{\lambda_i^{\mathbf{x}}}|S_i^{\mathbf{z}}| \cdot \sqrt{\lambda_i^{\mathbf{x}}}$.

We first apply Lemma 20 to the set $I = \{i\} \subset \{p+1, \ldots, m\}$ and Lemma 18 and see that in either case of $0 < r < 1/2$ and $r \geq 1/2$, there holds

$$\begin{aligned}
\sqrt{\lambda_i^{\mathbf{x}}} |\langle f_\rho, \phi_i^{\mathbf{x}} \rangle_K| &\leq \left(2^r + \sqrt{2}\lambda_1^{\max\{r-\frac{1}{2},0\}} \right) \|g_\rho\|_K \|L_K - L_K^{\mathbf{x}}\|_{\mathrm{HS}}^{\min\{\frac{1+2r}{2},1\}} + 2^r \|g_\rho\|_K (\lambda_i^{\mathbf{x}})^{\frac{1+2r}{2}} \\
&\leq C_1' \left(\lambda_i^{(1+2r)/2} + \left(\log \frac{2}{\delta} \right)^{(1+2r)/2} m^{-\min\{1/2,(1+2r)/4\}} \right),
\end{aligned}$$

where

$$C_1' = \left(2^r + \sqrt{2}\lambda_1^{\max\{r-\frac{1}{2},0\}} \right) (2\kappa)^{\min\{1+2r,2\}} \|g_\rho\|_K + 2^{2r+\frac{1}{2}} \|g_\rho\|_K (2\kappa+1)^{1+2r}.$$

This together with (38) in Lemma 19 gives

$$\begin{aligned}
&\sqrt{\lambda_i^{\mathbf{x}}}|S_i^{\mathbf{z}}| \leq \sqrt{\lambda_i^{\mathbf{x}}}|S_i^{\mathbf{z}} - \langle f_\rho, \phi_i^{\mathbf{x}} \rangle_K| + \sqrt{\lambda_i^{\mathbf{x}}} |\langle f_\rho, \phi_i^{\mathbf{x}} \rangle_K| \\
&\leq C_1' \lambda_i^{r+\frac{1}{2}} + \left(2\sqrt{2}M + C_1' \right) \left(\log \frac{2m}{\delta} \right)^{(1+2r)/2} m^{-\min\{1/2,(1+2r)/4\}} \\
&\leq \left(2\sqrt{2}M + 2C_1' \right) \left(\log \frac{2m}{\delta} \right)^{(1+2r)/2} \max\left\{ \left(\max\left\{ \lambda_p, \frac{1}{\sqrt{m}} \right\} \right)^{r+\frac{1}{2}}, \frac{1}{\sqrt{m}} \right\}. \qquad (47)
\end{aligned}$$

It follows that the first inequality $\sqrt{\lambda_i^{\mathbf{x}}}|S_i^{\mathbf{z}}| < \frac{C_{\Omega,1}}{2}\sqrt{\gamma}$ of (26) is valid if γ satisfies

$$\gamma > \left(\frac{4\sqrt{2}M + 4C_1'}{C_{\Omega,1}} \right)^2 \left(\log \frac{2m}{\delta} \right)^{1+2r} \max\left\{ \left(\max\left\{ \lambda_p, \frac{1}{\sqrt{m}} \right\} \right)^{2r+1}, \frac{1}{m} \right\}. \qquad (48)$$

Then we estimate $\lambda_i^{\mathbf{x}}$ by Lemma 18 as

$$\sqrt{\lambda_i^{\mathbf{x}}} \leq \sqrt{\lambda_i} + \sqrt{|\lambda_i - \lambda_i^{\mathbf{x}}|} \leq (2\kappa+1) \sqrt{\log \frac{2}{\delta}} \left(\max\left\{ \lambda_p, \frac{1}{\sqrt{m}} \right\} \right)^{\frac{1}{2}}.$$

Combining this with (47), we know that the second inequality $\sqrt{\lambda_i^{\mathbf{x}}}|S_i^{\mathbf{z}}| \cdot \sqrt{\lambda_i^{\mathbf{x}}} < \frac{C_{\Omega,1}}{2}\gamma$ of (26) is valid if γ satisfies

$$\gamma > \frac{4\sqrt{2}M + 4C_1'}{C_{\Omega,1}} (2\kappa+1) \left(\log\frac{2m}{\delta}\right)^{1+r} \max\left\{ \left(\max\left\{\lambda_p, \frac{1}{\sqrt{m}}\right\}\right)^{r+1}, \frac{1}{\sqrt{m}}\left(\max\left\{\lambda_p, \frac{1}{\sqrt{m}}\right\}\right)^{\frac{1}{2}} \right\}. \tag{49}$$

Now we can choose the constant C_1 from (48) and (49) by

$$C_1 = \max\left\{ \left(\frac{4\sqrt{2}M + 4C_1'}{C_{\Omega,1}}\right)^2 (1+\lambda_1)^{2r+1}, \frac{4\sqrt{2}M + 4C_1'}{C_{\Omega,1}} (2\kappa+1)(1+\lambda_1)^{2r+1}, 1 \right\}.$$

With this choice, we know that for γ satisfying

$$\gamma \geq \begin{cases} C_1 \left(\log\frac{2m}{\delta}\right)^{1+2r} \left(\max\left\{\frac{\lambda_p}{\lambda_1}, \frac{1}{\sqrt{m}}\right\}\right)^{r+1}, & \text{if } 0 < r \leq \frac{1}{2}, \\ C_1 \left(\log\frac{2m}{\delta}\right)^{1+2r} \max\left\{ \left(\frac{\lambda_p}{\lambda_1}\right)^{r+\frac{1}{2}}, \frac{1}{\sqrt{m}} \right\} \left(\max\left\{\frac{\lambda_p}{\lambda_1}, \frac{1}{\sqrt{m}}\right\}\right)^{\frac{1}{2}}, & \text{if } r > \frac{1}{2}, \end{cases} \tag{50}$$

both (48) and (49) are valid, which implies (26). Then by (22) in Lemma 14, we see that condition (20) in Theorem 13 is valid and hence $c_i^{\mathbf{z}} = 0$ for $i = p+1, \ldots, m$.

Now we turn to the desired error bound. Assume (50) for γ. Define an index set $\mathcal{S}$ by $\mathcal{S} = \{i \in \{1, \cdots, p\} : \lambda_i^{\mathbf{x}} > \lambda_p/2\}$.

When $i \in \{1, \cdots, p\}$ but $\lambda_i^{\mathbf{x}} \leq \lambda_p/2$, we check the process in proving (47) and see from the restriction $\lambda_i^{\mathbf{x}} \leq \lambda_p/2$ that condition (50) for γ ensures (26). Then by (22) in Lemma 14, we see that condition (20) is valid for i. Hence $c_i^{\mathbf{z}} = 0$ for $i \in \mathbb{N}\backslash\mathcal{S}$. So we can expand $\|f_\rho - f^{\mathbf{z}}\|_K$ with respect to the orthonormal basis $\{\phi_i^{\mathbf{x}}\}$ of $\mathcal{H}_K$ as

$$\|f_\rho - f^{\mathbf{z}}\|_K^2 = \sum_{i\in\mathbb{N}\backslash\mathcal{S}} \left(\langle f_\rho, \phi_i^{\mathbf{x}}\rangle_K\right)^2 + \sum_{i\in\mathcal{S}} \left(c_i^{\mathbf{z}} - \langle f_\rho, \phi_i^{\mathbf{x}}\rangle_K\right)^2. \tag{51}$$

For any $i \in \mathcal{S}$, we have $\lambda_i^{\mathbf{x}} > \lambda_p/2 > 0$ and

$$|c_i^{\mathbf{z}} - \langle f_\rho, \phi_i^{\mathbf{x}}\rangle_K| \leq |c_i^{\mathbf{z}} - S_i^{\mathbf{z}}| + \frac{\sqrt{\lambda_i^{\mathbf{x}}}|S_i^{\mathbf{z}} - \langle f_\rho, \phi_i^{\mathbf{x}}\rangle_K|}{\sqrt{\lambda_p/2}}.$$

Applying Theorem 13 (b), Lemma 14 and Lemma 19 gives

$$|c_i^{\mathbf{z}} - \langle f_\rho, \phi_i^{\mathbf{x}}\rangle_K| \leq C_{\Omega,2} \max\left\{ \left(\frac{2\gamma}{\lambda_p}\right)^{\frac{1}{2-q}}, \frac{2\gamma}{\lambda_p} \right\} + \frac{2\sqrt{2}M}{\sqrt{m\lambda_p/2}} \sqrt{\log\frac{2m}{\delta}}.$$

It follows that

$$\sqrt{\sum_{i\in\mathcal{S}} \left(c_i^{\mathbf{z}} - \langle f_\rho, \phi_i^{\mathbf{x}}\rangle_K\right)^2} \leq C_{\Omega,2}\sqrt{p} \left\{ \left(\frac{2\gamma}{\lambda_p}\right)^{\frac{1}{2-q}} + \frac{2\gamma}{\lambda_p} \right\} + \frac{4\sqrt{p}M}{\sqrt{m\lambda_p}} \sqrt{\log\frac{2m}{\delta}}.$$

To estimate the first sum in (51) we cite an estimate from Guo and Zhou (2012) for the quantity $\left(\sum_{i\in\mathbb{N}\backslash\mathcal{S}} (\langle f_\rho, \phi_i^{\mathbf{x}}\rangle_K)^2\right)^{1/2}$ which is independent of the regularizing function Ω and know that it can be bounded by

$$\|g_\rho\|_K \lambda_{p+1}^r + 2^{\max\{r,1\}} \|g_\rho\|_K \lambda_p^{\min\{r-1,0\}} \left((\sum_{i=p+1}^\infty \lambda_i^{\max\{2r,2\}})^{\frac{1}{2}} + c_{r,\lambda_1} \|L_K - L_K^{\mathbf{x}}\|_{HS} \right),$$

where c_{r,λ_1} is the constant given by

$$c_{r,\lambda_1} = \begin{cases} 2^{1+r}\lambda_1^{r-1}, & \text{if } r \geq 1, \\ 2, & \text{if } r < 1. \end{cases}$$

Therefore

$$\begin{aligned} \|f^{\mathbf{z}} - f_\rho\|_K &\leq C_{\Omega,2}\sqrt{p} \left\{ \left(\frac{2\gamma}{\lambda_p}\right)^{\frac{1}{2-q}} + \frac{2\gamma}{\lambda_p} \right\} + \|g_\rho\|_K \lambda_{p+1}^r + \frac{2\sqrt{p}M}{\sqrt{m\lambda_p}} \sqrt{\log\frac{2m}{\delta}} \\ &\quad + 2^{\max\{r,1\}} \|g_\rho\|_K \lambda_p^{\min\{r-1,0\}} \left(\left(\sum_{i=p+1}^\infty \lambda_i^{\max\{2r,2\}} \right)^{1/2} + \frac{4c_{r,\lambda_1}\kappa^2 \log\frac{2}{\delta}}{\sqrt{m}} \right) \\ &\leq C_{\Omega,2}\sqrt{p} \left\{ \left(\frac{2\gamma}{\lambda_p}\right)^{\frac{1}{2-q}} + \frac{2\gamma}{\lambda_p} \right\} + \|g_\rho\|_K \lambda_{p+1}^r + C_3 \frac{\sqrt{p}\log\frac{2m}{\delta}}{\sqrt{m}} \lambda_p^{\min\{-\frac{1}{2}, r-1\}} \\ &\quad + C_4 \lambda_p^{\min\{r-1,0\}} \left(\sum_{i=p+1}^\infty \lambda_i^{\max\{2r,2\}} \right)^{1/2}, \end{aligned}$$

where

$$C_3 = 2M\lambda_1^{\max\{\frac{1}{2}-r, 0\}} + 2^{\max\{r,1\}+2} \|g_\rho\|_K c_{r,\lambda_1} \kappa^2 \lambda_1^{\max\{r-\frac{1}{2}, 0\}}$$

and $C_4 = 2^{\max\{r,1\}} \|g_\rho\|_K$. After scaling δ to $\delta/2$, the proof of Theorem 15 is completed. ■

Appendix B. Minimax Lower Bounds

In this appendix, we derive a general minimax lower bound which includes Theorem 8 as a special case. First we define two sets of Borel probability measures.

Definition 21 *Let $\mathcal{P}(\alpha_1, \alpha_2, r, M, R, D_1, D_2)$ be the set of all Borel probability measures ρ on $X \times Y$ satisfying the following three conditions:*

1. *$|y| \leq M$ almost surely,*
2. *$f_\rho = L_K^r(g_\rho)$ for some $g_\rho \in \mathcal{H}_K$ with $\|g_\rho\|_K \leq R$,*
3. *$D_1 i^{-\alpha_1} \leq \lambda_i \leq D_2 i^{-\alpha_2}$ for each i.*

Let $\mathcal{P}(\beta_1,\beta_2,r,M,R,D_1,D_2)$ be the same as $\mathcal{P}(\alpha_1,\alpha_2,r,M,R,D_1,D_2)$ except that the last condition is replaced by $D_1\beta_1^{-i}\le\lambda_i\le D_2\beta_2^{-i}$ for each i.

For simplicity, we abbreviate these two sets as $\mathcal{P}(\alpha_1,\alpha_2,r)$ and $\mathcal{P}(\beta_1,\beta_2,r)$, respectively. Now we state the general minimax lower bound for the error in the $\mathcal{H}_K$-metric following the idea of (Caponnetto and De Vito, 2007). Our proof is mainly based on Lemma 2.9, Theorem 2.5 and the approach from (Tsybakov, 2009).

Theorem 22 *Assume $R>0$ and $M\ge 4\kappa^{2r+1}R$. Let $f^{\mathbf{z}}\in\mathcal{H}_K$ be the output of an arbitrary learning algorithm based on the sample $\boldsymbol{z}=\{(x_i,y_i)\}_{i=1}^m$. Then for every $0<\delta<\frac{1}{8}$, there exist positive constants τ_1,τ_2, independent of δ or m, such that*

$$\lim_{m\to\infty}\inf_{f^{\mathbf{z}}}\sup_{\rho\in\mathcal{P}(\alpha_1,\alpha_2,r)}\mathbb{P}_{\mathbf{z}\sim\rho^m}\left\{\|f^{\mathbf{z}}-f_\rho\|_K\ge\tau_1\delta^{\frac{\alpha_1 r}{\alpha_2(2r+1)+1}}m^{-\frac{\alpha_1 r}{\alpha_2(2r+1)+1}}\right\}\ge 1-2\delta \tag{52}$$

and

$$\lim_{m\to\infty}\inf_{f^{\mathbf{z}}}\sup_{\rho\in\mathcal{P}(\beta_1,\beta_2,r)}\mathbb{P}_{\mathbf{z}\sim\rho^m}\left\{\|f^{\mathbf{z}}-f_\rho\|_K\ge\tau_2\delta^{\frac{1}{2}}m^{-\frac{1}{2}}\sqrt{\log m}\right\}\ge 1-2\delta. \tag{53}$$

Proof First, we associate a probability measure $\rho_f\in\mathcal{P}(\alpha_1,\alpha_2,r)$ to a pair (μ,f) where μ is a Borel measure on Y such that the eigenvalues of the associated integral operator L_K satisfy $D_1 i^{-\alpha_1}\le\lambda_i\le D_2 i^{-\alpha_2}$, and $f=L_K^r g$ for some $g\in\mathcal{H}_K$ with $\|g\|_K\le R$. Define a probability measure ρ_f by

$$d\rho_f(x,y)=\left[\frac{B+f(x)}{2B}d\delta_B(y)+\frac{B-f(x)}{2B}d\delta_{-B}(y)\right]d\mu(x),$$

where $B=4\kappa^{2r+1}R$ and $d\delta_\xi$ denotes the Dirac delta with unit mass at ξ. By the reproducing property, $\|f\|_\infty\le\kappa\|L_K^r g\|_K\le\kappa^{2r+1}R=\frac{B}{4}$. It follows that ρ_f is a probability measure on $X\times Y$ with μ being the marginal distribution and f the regression function. Moreover, $M\ge 4\kappa^{2r+1}R$ ensures $|y|\le M$ almost surely. Hence $\rho_f\in\mathcal{P}(\alpha_1,\alpha_2,r)$.

Then we construct a finite sequence $f_0,...,f_N$ in the set $\{L_K^r g: g\in\mathcal{H}_K,\|g\|_K\le R\}$ based on the Varshamov-Gilbert bound (Lemma 2.9 in (Tsybakov, 2009)) which asserts that for any integer $\gamma\ge 8$, there exists a set $\Theta=\{w_0,w_1,...,w_N\}\subset\{0,1\}^\gamma$ such that

1. $w_0=(0,...,0)$.
2. For any $i\ne j$, $H(w_i,w_j)>\gamma/8$, where $H(\cdot,\cdot)$ is the Hamming distance.
3. $N\ge 2^{\gamma/8}$.

For $0<\delta<\frac{1}{8}$, let γ be the smallest integer greater than or equal to $c_\delta m^{\frac{1}{\alpha_2(2r+1)+1}}$ with a constant $c_\delta>0$ to be specified later. For $w_i=(w_i^{\gamma+1},...,w_i^{2\gamma})\in\Theta$ with $i\in\{0,\dots,N\}$, define $f_i=L_K^r g_i$ with

$$g_i=\sum_{k=\gamma+1}^{2\gamma}w_i^k R\gamma^{-\frac{1}{2}}\phi_k.$$

Note that $g_i\in\mathcal{H}_K$ and

$$\|g_i\|_K^2=\left\|\sum_{k=\gamma+1}^{2\gamma}w_i^k R\gamma^{-\frac{1}{2}}\phi_k\right\|_K^2=\sum_{k=\gamma+1}^{2\gamma}(w_i^k)^2\gamma^{-1}R^2\|\phi_k\|_K^2\le R^2.$$

Hence $\{f_0,...,f_N\}\subset\{L_K^r g: g\in\mathcal{H}_K,\|g\|_K\le R\}$, which implies $\{\rho_{f_0},...,\rho_{f_N}\}\subset\mathcal{P}(\alpha_1,\alpha_2,r)$.

Now we adopt Theorem 2.5 in (Tsybakov, 2009) to establish our desired lower bound.

Observe that for $0\le i<j\le N$, the Kullback-Leibler distance $\mathcal{D}_{KL}(\rho_{f_i}\|\rho_{f_j})$ between ρ_{f_i} and ρ_{f_j} satisfies

$$\begin{aligned}
&\mathcal{D}_{KL}(\rho_{f_i}\|\rho_{f_j})\\
&=\int_X\left\{\frac{B+f_i(x)}{2B}\ln\left(1+\frac{f_i(x)-f_j(x)}{B+f_j(x)}\right)+\frac{B-f_i(x)}{2B}\ln\left(1-\frac{f_i(x)-f_j(x)}{B-f_j(x)}\right)\right\}d\mu(x)\\
&\le\frac{f_i(x)-f_j(x)}{2B}\left\{\frac{B+f_i(x)}{B+f_j(x)}-\frac{B-f_i(x)}{B-f_j(x)}\right\}\\
&\le\frac{16}{15B^2}\lambda_\gamma^{2r+1}R^2\gamma^{-1}\sum_{k=\gamma+1}^{2\gamma}(w_i^k-w_j^k)^2\le\frac{D_2^{2r+1}}{15\kappa^{4r+2}}\gamma^{-\alpha_2(2r+1)},
\end{aligned}$$

which implies

$$\begin{aligned}
\frac{1}{N}\sum_{i=1}^N\mathcal{D}_{KL}((\rho_{f_i})^m\|(\rho_{f_0})^m) &\le \frac{D_2^{2r+1}}{15\kappa^{4r+2}}m\gamma^{-\alpha_2(2r+1)}\le\frac{D_2^{2r+1}}{15\kappa^{4r+2}}c_\delta^{-\alpha_2(2r+1)}m^{\frac{1}{\alpha_2(2r+1)+1}}\\
&\le\frac{D_2^{2r+1}}{15\kappa^{4r+2}c_\delta^{1+\alpha_2(2r+1)}}\gamma=\delta\log 2^{\gamma/8}\le\delta\log N
\end{aligned}$$

by taking

$$c_\delta=\left(\frac{8D_2^{2r+1}}{15\kappa^{4r+2}\log 2}\right)^{1/(\alpha_2(2r+1)+1)}\delta^{-1/(\alpha_2(2r+1)+1)}.$$

On the other hand, for any $0\le i<j\le N$.

$$\begin{aligned}
\|f_i-f_j\|_K^2 &= \|L_K^r(g_i-g_j)\|_K^2\\
&= \sum_{k=\gamma+1}^{2\gamma}R^2\gamma^{-1}\lambda_k^{2r}(w_i^k-w_j^k)^2\\
&\ge R^2\gamma^{-1}\lambda_{2\gamma}^{2r}\sum_{k=\gamma+1}^{2\gamma}(w_i^k-w_j^k)^2\\
&= R^2\gamma^{-1}\lambda_{2\gamma}^{2r}H(w_i,w_j)\\
&\ge \frac{R^2\lambda_{2\gamma}^{2r}}{8}\\
&\ge 2^{-(2\alpha_1 r+3)}R^2D_1^{2r}\gamma^{-2\alpha_1 r}\\
&\ge 2\tau_1^2\delta^{\frac{2\alpha_1 r}{\alpha_2(2r+1)+1}}m^{-\frac{2\alpha_1 r}{\alpha_2(2r+1)+1}}
\end{aligned}$$

for some constant $\tau_1 > 0$.

Therefore, as shown in (Tsybakov, 2009) we have

$$\inf_{f^{\mathbf{z}}} \sup_{\rho \in \mathcal{P}(\alpha_1,\alpha_2,r)} \mathbb{P}_{\mathbf{z}\sim\rho^m} \left\{ \|f^{\mathbf{z}} - f_\rho\|_K \geq \tau_1 \delta^{\frac{\alpha_1 r}{\alpha_2(2r+1)+1}} m^{-\frac{\alpha_1 r}{\alpha_2(2r+1)+1}} \right\}$$
$$\geq \frac{\sqrt{N}}{\sqrt{N}+1} \left(1 - 2\delta - \sqrt{\frac{2\delta}{\log N}} \right).$$

This completes the proof for the statement about $\mathcal{P}(\alpha_1, \alpha_2, r)$. The proof for the statement about $P(\beta_1, \beta_2, r)$ is similar. The proof of the theorem is complete. ■

Appendix C. Proof of Proposition 10

(a). Let $0 \leq \xi_1 < \xi_2 < \xi_3 < \xi_4$. For $i = 2$ or 3, one has

$$\Omega(\xi_i) \geq \frac{(\xi_{i+1} - \xi_i)\Omega(\xi_{i-1})}{\xi_{i+1} - \xi_{i-1}} + \frac{(\xi_i - \xi_{i-1})\Omega(\xi_{i+1})}{\xi_{i+1} - \xi_{i-1}}. \tag{54}$$

Let $i = 2$ in (54) to give

$$\begin{aligned} (\xi_2 - \xi_1)\Omega(\xi_3) &\leq (\xi_3 - \xi_1)\Omega(\xi_2) - (\xi_3 - \xi_2)\Omega(\xi_1) \\ &= \xi_3[\Omega(\xi_2) - \Omega(\xi_1)] - \xi_1\Omega(\xi_2) + \xi_2\Omega(\xi_1). \end{aligned} \tag{55}$$

If $\Omega(\xi_2) < \Omega(\xi_1)$, let $\xi_3 \to \infty$ to give $\Omega(\xi_3) \to -\infty$, which contradicts $\Omega([0,\infty)) \subset [0,\infty)$. So Ω is nondecreasing. Similarly we have $(\xi_3 - \xi_1)\Omega(\xi_2) \geq (\xi_3 - \xi_1 + \xi_1 - \xi_2)\Omega(\xi_1) + (\xi_2 - \xi_1)\Omega(\xi_3)$, so

$$\frac{\Omega(\xi_2) - \Omega(\xi_1)}{\xi_2 - \xi_1} \geq \frac{\Omega(\xi_3) - \Omega(\xi_1)}{\xi_3 - \xi_1} \geq 0. \tag{56}$$

If $\Omega(\xi_2) = 0$, since Ω is nondecreasing, $\Omega(\xi_1) = 0$ for all $0 \leq \xi_1 < \xi_2$, and (56) gives $\Omega(\xi_3) = 0$ for all $\xi_3 > \xi_2$, so we have $\Omega = 0$, a contradiction. Therefore $\Omega(c) > 0$ for $c > 0$.

From (56), the function $[\Omega(c) - \Omega(\xi_1)]/(c - \xi_1)$ of c is nonincreasing when $c > \xi_1$, so the right-hand derivative Ω'_+ is well-defined on $[0,\infty)$, taking values in $[0,\infty]$. We get from (55) that

$$\infty > \frac{\Omega(\xi_2) - \Omega(\xi_1)}{\xi_2 - \xi_1} \geq \frac{\Omega(\xi_3) - \Omega(\xi_2)}{\xi_3 - \xi_2}. \tag{57}$$

Let $\xi_3 \to \xi_2^+$ to give $\Omega'_+(\xi_2) < \infty$. Therefore $\Omega'_+(c)$ is finite for $c \in (0,\infty)$. Let $i = 3$. We have the analogue of (57),

$$\frac{\Omega(\xi_3) - \Omega(\xi_2)}{\xi_3 - \xi_2} \geq \frac{\Omega(\xi_4) - \Omega(\xi_3)}{\xi_4 - \xi_3}, \tag{58}$$

which, together with (57), gives that as $\xi_2 \to \xi_1^+$ and $\xi_4 \to \xi_3^+$, $\Omega'_+(\xi_1) \geq \Omega'_+(\xi_3)$. This proves that Ω'_+ is nonincreasing on $[0,\infty)$. If $\Omega'_+(0) = 0$, since $0 \leq \frac{\Omega(c)-\Omega(0)}{c-0}$ is nonincreasing

for $c > 0$ as we proved before, we have $\Omega(c) = 0$ for all $c > 0$, a contradiction again. So $\Omega'_+(0) \in (0,\infty]$.

(b). Let $\xi_1 = 0$ and $\xi_3 = 1$, then (55) gives $\Omega(\xi_2) \geq \xi_2\Omega(1)$, so for all $c \in (0,1]$, $\Omega(c) \geq c\Omega(1)$. In (55) let $\xi_1 = 0$ and $\xi_2 = 1$ to give $\Omega(\xi_3) \leq \xi_3\Omega(1)$, so for any $c \in [1,\infty)$, $\Omega(c) \leq \Omega(1)c$.

The properties stated in (c) and (d) follow immediately from the concavity of the function Ω.

(e). Write the function $\frac{\Omega(c)}{c^2}$ as $\frac{\Omega(c)}{c} \cdot \frac{1}{c}$. We see from (d) that this function is strictly decreasing on $(0,\infty)$. By (a), we obtain the limit $\lim_{c\to 0^+} \frac{\Omega(c)}{c^2} \geq \underline{\lim}_{c\to 0^+} \frac{\Omega(1)c}{c^2} = +\infty$. By (b), $\lim_{c\to\infty} \frac{\Omega(c)}{c^2} \leq \overline{\lim}_{c\to\infty} \frac{\Omega(1)c}{c^2} = 0$. The proof of Proposition 10 is complete. ■

Abstract

Information spreads across social and technological networks, but often the network structures are hidden from us and we only observe the traces left by the diffusion processes, called *cascades*. Can we recover the hidden network structures from these observed cascades? What kind of cascades and how many cascades do we need? Are there some network structures which are more difficult than others to recover? Can we design efficient inference algorithms with provable guarantees?

Despite the increasing availability of cascade data and methods for inferring networks from these data, a thorough theoretical understanding of the above questions remains largely unexplored in the literature. In this paper, we investigate the network structure inference problem for a general family of continuous-time diffusion models using an ℓ_1-regularized likelihood maximization framework. We show that, as long as the cascade sampling process satisfies a natural incoherence condition, our framework can recover the correct network structure with high probability if we observe $O(d^3 \log N)$ cascades, where d is the maximum number of parents of a node and N is the total number of nodes. Moreover, we develop a simple and efficient soft-thresholding network inference algorithm which demonstrate the match between our theoretical prediction and empirical results. In practice, this new algorithm also outperforms other alternatives in terms of the accuracy of recovering hidden diffusion networks.

1. Introduction

Diffusion of information, behaviors, diseases, or irrepresentabilitymore generally, *contagions* can be naturally modeled as a stochastic process that occur over the edges of an underlying network (Rogers, 1995). In this scenario, we often observe the temporal traces that the diffusion generates, called *cascades*, but the edges of the network that gave rise to the diffusion remain unobservable (Adar and Adamic, 2005). For example, blogs or media sites often publish a new piece of information without explicitly citing their sources. Marketers may note when a social media user decides to adopt a new behavior but cannot tell which neighbor in the social network influenced them to do so. Epidemiologist observe when a person gets sick but usually cannot tell who infected her. In all these cases, given a set of cascades and a diffusion model, the network inference problem consists of inferring the edges (and model parameters) of the unobserved underlying network (Gomez-Rodriguez, 2013).

The network inference problem has attracted significant attention in recent years (Saito et al., 2009; Gomez-Rodriguez et al., 2010, 2011, 2013b, 2014; Snowsill et al., 2011; Du et al., 2012a, 2013; Zhou et al., 2013), since it is essential to reconstruct and predict the paths over which information can spread, and to maximize sales of a product or stop infections. Most previous work has focused on developing network inference algorithms and evaluating their performance experimentally on different synthetic and real networks, and a rigorous theoretical analysis of the problem has been missing. However, such analysis is of outstanding interest since it would enable us to answer many fundamental open questions. For example, which conditions are sufficient to guarantee that we can recover a network given a large number of cascades? If these conditions are satisfied, how many cascades are sufficient to infer the network with high probability? Until recently, there has been only two pieces of work along this direction (Netrapalli and Sanghavi, 2012; Abrahao et al., 2013), which leverage less realistic diffusion models. Moreover, none of them is able to identify a recovery condition relating the interaction between the network structure and the cascade sampling process, which we make precise in our paper.

1.1 Overview of results

We consider the network inference problem under the continuous-time diffusion model recently introduced by Gomez-Rodriguez et al. (2011), which has been extensively validated in real diffusion data, and, due to its flexibility, has been extended to support textual information (Wang et al., 2012), nonparametric pairwise likelihoods (Du et al., 2012a), topic modeling (Du et al., 2012b), dynamic networks (Gomez-Rodriguez et al., 2013a). We identify a natural irrepresentability condition for such a model which depends on both the network structure, the diffusion parameters and the sampling process of the cascades. This condition captures the intuition that we can recover the network structure if the co-occurrence of a node and its non-parent nodes is small in the cascades. Furthermore, we show that, if this condition holds for the population case, we can recover the network structure using

an ℓ_1-regularized maximum likelihood estimator and $O(d^3 \log N)$ cascades, where N is the number of nodes in the network and d is the maximum number of parents of a node, with the probability of success approaching 1 in a rate exponential in the number of cascades. Importantly, if this condition also holds for the finite sample case, then the guarantee can be improved to $O(d^2 \log N)$ cascades. Beyond theoretical results, we also propose a new, efficient and simple proximal gradient algorithm to solve the ℓ_1-regularized maximum likelihood estimation. The algorithm is especially well-suited for our problem since it is highly scalable and naturally finds sparse estimators, as desired, by using soft-thresholding. Using this algorithm, we perform various experiments illustrating the consequences of our theoretical results and demonstrating that it typically outperforms other state-of-the-art algorithms.

1.2 Related work

Netrapalli and Sanghavi (2012) propose a maximum likelihood network inference method for a variation of the discrete-time independent cascade model (Kempe et al., 2003) and show that, for general networks satisfying a *correlation decay*, the estimator recovers the network structure given $O(d^2 \log N)$ cascades, and the probability of success is approaching 1 in a rate exponential in the number of cascades. The rate they obtained is on a par with our results. However, their discrete diffusion model is less realistic in practice, and the correlation decay condition implies that, on average, each node can only infect one single node per cascade. Instead, we use a general continuous-time diffusion model (Gomez-Rodriguez et al., 2011), which has been extensively validated in real diffusion data and extended in various ways by different authors (Wang et al., 2012; Du et al., 2012a,b).

Abrahao et al. (2013) propose a simple network inference method, First-Edge, for a slightly different continuous-time independent cascade model (Gomez-Rodriguez et al., 2010), and show that, for general networks, if the cascade sources are chosen uniformly at random, the algorithm needs $O(Nd \log N)$ cascades to recover the network structure and the probability of success is approaching 1 in a rate polynomial in the number of cascades. Additionally, they study trees and bounded-degree networks and show that, if the cascade sources are chosen uniformly at random, the error decreases polynomially as long as $O(\log N)$ and $\Omega(d^9 \log^2 d \log N)$ cascades are recorded respectively. In our work, we show that, for general networks satisfying a natural irrepresentability condition, our method outperforms the First-Edge algorithm and the algorithm for bounded-degree networks in terms of rate and sample complexity.

Gripon and Rabbat (2013) propose a network inference method for unordered cascades, in which nodes that are infected together in the same cascade are connected by a path containing exactly the nodes in the trace, and give necessary and sufficient conditions for network inference. However, they consider a restrictive scenario in which cascades are all three nodes long.

2. Continuous-Time Diffusion Model

In this section, we revisit the continuous-time generative model for cascade data introduced by Gomez-Rodriguez et al. (2011). The model associates each edge $j \to i$ with a transmission function, $f(t_i|t_j;\alpha_{ji}) = f(t_i - t_j;\alpha_{ji})$, a density over time parameterized by α_{ji}. This is

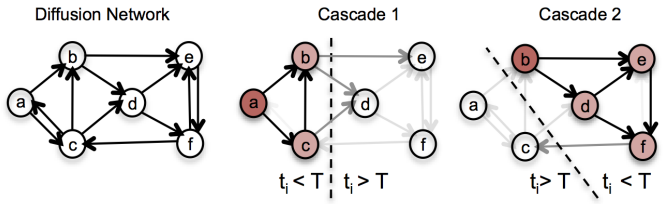

Figure 1: The diffusion network structure (left) is unknown and we only observe cascades, which are N-dimensional vectors recording the times when nodes get infected by contagions that spread (right). Cascade 1 is $(t_a, t_b, t_c, \infty, \infty, \infty)$, where $t_a < t_c < t_b$, and cascade 2 is $(\infty, t_b, \infty, t_d, t_e, t_f)$, where $t_b < t_d < t_e < t_f$. Each cascade contains a source node (dark red), drawn from a source distribution $\mathbb{P}(s)$, as well as infected (light red) and uninfected (white) nodes, and it provides information on black and dark gray edges but does not on light gray edges.

in contrast to previous discrete-time models which associate each edge with a fixed infection probability (Kempe et al., 2003). Moreover, it also differs from discrete-time models in the sense that events in a cascade are not generated iteratively in rounds, but event timings are sampled directly from the transmission functions in the continuous-time model.

2.1 Cascade generative process

Given a *directed* contact network, $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ with N nodes, the process begins with an infected source node, s, initially adopting certain *contagion* (idea, meme or product) at time zero, which we draw from a source distribution $\mathbb{P}(s)$. The contagion is transmitted from the source along her out-going edges to her direct neighbors. Each transmission through an edge entails a *random* transmission time, τ, drawn from an associated pairwise transmission likelihood $f(\tau;\alpha_{ji})$. We assume transmission times are independent, possibly distributed differently across edges, and, in some cases, can be arbitrarily large, $\tau \to \infty$. Then, the infected neighbors transmit the contagion to their respective neighbors, and the process continues. We assume that an infected node remains infected for the entire diffusion process. Thus, if a node i is infected by multiple neighbors, only the neighbor that first infects node i will be the *true parent*. As a result, although the contact network can be an arbitrary directed network, each contagion induces a Directed Acyclic Graph (DAG). Figure 1 illustrates the process and Table 1 gives several examples of well-known parametric transmission likelihoods (Gomez-Rodriguez et al., 2011, 2013a, 2014).

2.2 Cascade data

Observations from the model are recorded as a set C^n of cascades $\{\mathbf{t}^1, \ldots, \mathbf{t}^n\}$. Each cascade $\mathbf{t}^c$ is an N-dimensional vector $\mathbf{t}^c := (t_1^c, \ldots, t_N^c)$ recording when nodes are infected, $t_k^c \in [0, T^c] \cup \{\infty\}$. Symbol ∞ labels nodes that are not infected during observation window $[0, T^c]$ – it does not imply they are never infected. The 'clock' is reset to 0 at the start of each

Model	Transmission functions $f(\tau;\alpha_{ji})$	Log survival $y(t+\tau\|t;\alpha_{ji}) = \log S(t+\tau\|t;\alpha_{ji})$	Hazard $H(t+\tau\|t;\alpha_{ji})$

Table 1: Pairwise transmission models

cascade. We assume $T^c = T$ for all cascades; the results generalize trivially. Contagions often propagate simultaneously (Myers and Leskovec, 2012; Prakash et al., 2012) over the same network but we assume each contagion to propagate independently of each other. Finally, we also assume that all activated nodes except the first one are activated by network diffusion, *i.e.*, by previously activated nodes, ignoring external influences (Myers et al., 2012). Refer to Figure 1 for an example.

2.3 Likelihood of a cascade

Gomez-Rodriguez et al. (2011) showed that the likelihood of a cascade $\mathbf{t}$ under the continuous-time independent cascade model is

$$f(\mathbf{t};\mathbf{A}) = \prod_{t_i \leq T}\prod_{t_m > T} S(T|t_i;\alpha_{im}) \times \prod_{k:t_k<t_i} S(t_i|t_k;\alpha_{ki}) \sum_{j:t_j<t_i} H(t_i|t_j;\alpha_{ji}), \tag{1}$$

where $\mathbf{A} = \{\alpha_{ji}\}$ denotes the collection of parameters, $S(t_i|t_j;\alpha_{ji}) = 1 - \int_{t_j}^{t_i} f(t-t_j;\alpha_{ji})\,dt$ is the survival function and $H(t_i|t_j;\alpha_{ji}) = f(t_i - t_j;\alpha_{ji})/S(t_i|t_j;\alpha_{ji})$ is the hazard function. The survival terms in the first line account for the probability that uninfected nodes survive to all infected nodes in the cascade up to T and the survival and hazard terms in the second line account for the likelihood of the infected nodes. The survival and hazard functions are simple for several well-known parametric transmission likelihoods, as shown in Table 1. Then, assuming cascades are sampled independently, the likelihood of a set of cascades is the product of the likelihoods of individual cascades given by Eq. 1. For notational simplicity, we define $y(t_i|t_k;\alpha_{ki}) := \log S(t_i|t_k;\alpha_{ki})$, and $h(\boldsymbol{t};\boldsymbol{\alpha}_i) := \sum_{k:t_k\leq t_i} H(t_i|t_k;\alpha_{ki})$ if $t_i \leq T$ and 0 otherwise.

3. Network Inference Problem

Consider an instance of the continuous-time diffusion model defined above with a contact network $\mathcal{G}^* = (\mathcal{V}^*, \mathcal{E}^*)$ and associated parameters $\left\{\alpha^*_{ji}\right\}$. We denote the set of parents of node i as $\mathcal{N}^-(i) = \{j \in \mathcal{V}^* : \alpha^*_{ji} > 0\}$ with cardinality $d_i = |\mathcal{N}^-(i)|$ and the minimum positive transmission rate as $\alpha^*_{\min,i} = \min_{j:\alpha^*_{ji}>0} \alpha^*_{ji}$. Let C^n be a set of n cascades sampled from the model, where the source $s \in \mathcal{V}^*$ of each cascade is drawn from a source distribution

Function	Infected node ($t_i < T$)	Uninfected node ($t_i > T$)
$g_i(\mathbf{t};\boldsymbol{\alpha})$	$\log h(\mathbf{t};\boldsymbol{\alpha}) + \sum_{j:t_j<t_i} y(t_i\|t_j;\alpha_j)$	$\sum_{j:t_j<T} y(T\|t_j;\alpha_j)$
$[\nabla y_i(\mathbf{t};\boldsymbol{\alpha})]_k$	$-y'(t_i\|t_k;\alpha_k)$	$-y'(T\|t_k;\alpha_k)$
$[D(\mathbf{t};\boldsymbol{\alpha})]_{kk}$	$-y''(t_i\|t_k;\alpha_k) - h(\mathbf{t};\boldsymbol{\alpha})^{-1}H''(t_i\|t_k;\alpha_k)$	$-y''(T\|t_k;\alpha_k)$

Table 2: Functions. $g_i(\mathbf{t};\boldsymbol{\alpha})$ is node i's log-likelihood in a cascade $\mathbf{t}$, $y_i(\mathbf{t};\boldsymbol{\alpha})$ is the logarithm of node i's survivals in a cascade $\mathbf{t}$, $D(\mathbf{t};\boldsymbol{\alpha})$ is a diagonal matrix defined in Eq. 5, $H(t_i|t_k;\alpha_k)$ is the hazard function, and $h(\mathbf{t};\boldsymbol{\alpha})$ denotes the sum of node i's hazard functions in a cascade $\mathbf{t}$.

$\mathbb{P}(s)$. Then, the network inference problem consists of finding the directed edges and the associated parameters using only the temporal information from the set of cascades C^n.

This problem has been cast as a maximum likelihood estimation problem (Gomez-Rodriguez et al., 2011)

$$\begin{array}{ll} \text{minimize}_{\mathbf{A}} & -\frac{1}{n}\sum_{c\in C^n} \log f(\mathbf{t}^c;\mathbf{A}) \\ \text{subject to} & \alpha_{ji} \geq 0,\ i,j = 1,\ldots,N, i \neq j, \end{array} \tag{2}$$

where the inferred edges in the network correspond to those pairs of nodes with non-zero parameters, *i.e.* $\hat{\alpha}_{ji} > 0$.

In fact, the problem in Eq. 2 decouples into a set of independent smaller subproblems, one per node, where we infer the parents of each node and the parameters associated with these incoming edges. Without loss of generality, for a particular node i, we solve the problem

$$\begin{array}{ll} \text{minimize}_{\boldsymbol{\alpha}_i} & \ell^n(\boldsymbol{\alpha}_i) \\ \text{subject to} & \alpha_{ji} \geq 0,\ j = 1,\ldots,N, i \neq j, \end{array} \tag{3}$$

where the parameters $\boldsymbol{\alpha}_i := \{\alpha_{ji} \,|\, j = 1,\ldots,N, i \neq j\}$ are the relevant variables, and $\ell^n(\boldsymbol{\alpha}_i) = -\frac{1}{n}\sum_{c\in C^n} g_i(\mathbf{t}^c;\boldsymbol{\alpha}_i)$ corresponds to the terms in Eq. 2 involving $\boldsymbol{\alpha}_i$. The function $g(\,\cdot\,;\boldsymbol{\alpha}_i)$ is simple for several well-known parametric transmission likelihoods, including those described in Table 1. For example, for an exponential transmission likelihood,

$$g_i(\mathbf{t};\boldsymbol{\alpha}_i) = \log\left(\sum_{j:t_j<t_i}\alpha_{ji}\right) - \sum_{j:t_j<t_i}\alpha_{ji}(t_i - t_j)$$

for an infected node and $g_i(\mathbf{t};\boldsymbol{\alpha}_i) = -\sum_{j:t_j<T}\alpha_{ji}(T-t_j)$ for an uninfected node. Refer to Table 2 for a general definition of $g(\,\cdot\,;\boldsymbol{\alpha}_i)$. Moreover, in this subproblem, we only need to consider a super-neighborhood $\mathcal{V}_i = \mathcal{R}_i \cup \mathcal{U}_i$ of i, with cardinality $p_i = |\mathcal{V}_i| \leq N$, where $\mathcal{R}_i$ is the set of upstream nodes from which i is reachable, $\mathcal{U}_i$ is the set of nodes which are reachable from at least one node $j \in \mathcal{R}_i$. Here, we consider a node i to be reachable from a node j if and only if there is a directed path from j to i. We can skip all nodes in $\mathcal{V}\backslash\mathcal{V}_i$ from our analysis because they will never be infected in a cascade before i, and thus, the maximum likelihood estimation of the associated transmission rates will always be zero (and correct).

Below, we show that, as $n \to \infty$, the solution, $\hat{\boldsymbol{\alpha}}_i$, of the problem in Eq. 3 is a consistent estimator of the true parameter $\boldsymbol{\alpha}^*_i$. However, it is not clear whether it is possible to

recover the true network structure with this approach given a finite amount of cascades and, if so, how many cascades are needed. We will show that by adding an ℓ_1-regularizer to the objective function and solving instead the following optimization problem

$$\begin{array}{ll} \text{minimize}_{\boldsymbol{\alpha}_i} & \ell^n(\boldsymbol{\alpha}_i) + \lambda_n ||\boldsymbol{\alpha}_i||_1 \\ \text{subject to} & \alpha_{ji} \geq 0,\, j = 1, \ldots, N, i \neq j, \end{array} \tag{4}$$

we can provide finite sample guarantees for recovering the network structure (and parameters). Our analysis also shows that by selecting an appropriate value for the regularization parameter λ_n, the solution of Eq. 4 successfully recovers the network structure with probability approaching 1 exponentially fast in n.

In the remainder of the paper, we will focus on estimating the parent nodes of a particular node i. For simplicity, we will use $\boldsymbol{\alpha} = \boldsymbol{\alpha}_i$, $\alpha_j = \alpha_{ji}$, $\mathcal{N}^- = \mathcal{N}^-(i)$, $\mathcal{R} = \mathcal{R}_i$, $\mathcal{U} = \mathcal{U}_i$, $d = d_i$, $p_i = p$ and $\alpha^*_{\min} = \alpha^*_{\min,i}$.

4. Consistency

Can we recover the hidden network structures from the observed cascades? The answer is yes. We will show this by proving that the estimator provided by Eq. 3 is consistent, meaning that as the number of cascades goes to **infinity**, we can always recover the true network structure.

More specifically, Gomez-Rodriguez et al. (2011) showed that the network inference problem defined in Eq. 3 is convex in $\boldsymbol{\alpha}$ if the survival functions are log-concave and the hazard functions are concave in $\boldsymbol{\alpha}$. Under these conditions, the Hessian matrix, $\mathcal{Q}^n = \nabla^2 \ell^n(\boldsymbol{\alpha})$, can be expressed as the sum of a nonnegative diagonal matrix $\boldsymbol{D}^n$ and the outer product of a matrix $\boldsymbol{X}^n(\boldsymbol{\alpha})$ with itself, *i.e.*,

$$\mathcal{Q}^n = \boldsymbol{D}^n(\boldsymbol{\alpha}) + \tfrac{1}{n} \boldsymbol{X}^n(\boldsymbol{\alpha}) [\boldsymbol{X}^n(\boldsymbol{\alpha})]^\top. \tag{5}$$

Here the diagonal matrix $\boldsymbol{D}^n(\boldsymbol{\alpha}) = \frac{1}{n} \sum_c \boldsymbol{D}(\mathbf{t}^c; \boldsymbol{\alpha})$ is a sum over a set of diagonal matrices $\boldsymbol{D}(\mathbf{t}^c; \boldsymbol{\alpha})$, one for each cascade c (see Table 2 for the definition of its entries); and $\boldsymbol{X}^n(\boldsymbol{\alpha})$ is the Hazard matrix

$$\boldsymbol{X}^n(\boldsymbol{\alpha}) = \left[\boldsymbol{X}(\mathbf{t}^1; \boldsymbol{\alpha}) \,|\, \boldsymbol{X}(\mathbf{t}^2; \boldsymbol{\alpha}) \,|\, \ldots \,|\, \boldsymbol{X}(\mathbf{t}^n; \boldsymbol{\alpha}) \right], \tag{6}$$

with each column $\boldsymbol{X}(\mathbf{t}^c; \boldsymbol{\alpha}) := h(\boldsymbol{t}^c; \boldsymbol{\alpha})^{-1} \nabla_{\boldsymbol{\alpha}} h(\boldsymbol{t}^c; \boldsymbol{\alpha})$. Intuitively, the Hessian matrix captures the co-occurrence information of nodes in cascades. Both $\boldsymbol{D}(\mathbf{t}^c; \boldsymbol{\alpha})$ and $\boldsymbol{X}^n(\boldsymbol{\alpha})$ are simple for several well-known transmission likelihoods, including those described in Table 1. For example, for an exponential transmission likelihood, $[\boldsymbol{D}(\mathbf{t}^c; \boldsymbol{\alpha})]_{kk} = 0$ and $[\boldsymbol{X}^n(\boldsymbol{\alpha})]_j = \left(\sum_{k:t_k<t_i} \alpha_{ki} \right)^{-1}$ if $t_j < t_i$ and 0 otherwise. Then, we can prove the following consistency result:

Theorem 1 *If the source probability $\mathbb{P}(s)$ is strictly positive for all $s \in \mathcal{R}$, then, the maximum likelihood estimator $\hat{\boldsymbol{\alpha}}$ given by the solution of Eq. 3 is consistent.*

Proof We check the three criteria for consistency: continuity, compactness and identification of the objective function (Newey and McFadden, 1994). Continuity is obvious. For compactness, since $L \to -\infty$ for both $\alpha_{ij} \to 0$ and $\alpha_{ij} \to \infty$ for all i, j so we lose nothing imposing upper and lower bounds thus restricting to a compact subset. For the identification condition, $\boldsymbol{\alpha} \neq \boldsymbol{\alpha}^* \Rightarrow \ell^n(\boldsymbol{\alpha}) \neq \ell^n(\boldsymbol{\alpha}^*)$, we use Lemma 9 and 10 (refer to

Appendices 12.1 and 12.2), which establish that $\boldsymbol{X}^n(\boldsymbol{\alpha})$ has full row rank as $n \to \infty$, and hence $\mathcal{Q}^n$ is positive definite. ■

5. Recovery Conditions

In this section, we will find a set of sufficient conditions on the diffusion model and the cascade sampling process under which we can recover the network structure from **finite samples**. These results allow us to address two questions:

- *Are there some network structures which are more difficult than others to recover?*
- *What kind of cascades are needed for the network structure recovery?*

The answers to these questions are intertwined. The difficulty of finite-sample recovery depends crucially on an irrepresentability condition which is a function of both network structure, parameters of the diffusion model and the cascade sampling process. Intuitively, the sources of the cascades in a diffusion network have to be chosen in such a way that nodes without parent-child relation should co-occur less often compared to nodes with such relation. Many commonly used diffusion models and network structures can be naturally made to satisfy this condition.

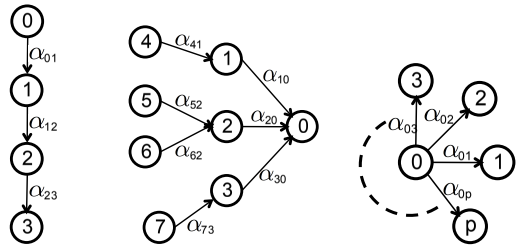
More specifically, we first place two conditions on the Hessian of the population log-likelihood, $\mathbb{E}_c \left[\ell^n(\boldsymbol{\alpha}) \right] = \mathbb{E}_c \left[\log g(\mathbf{t}^c; \boldsymbol{\alpha}) \right]$, where the expectation here is taken over the distribution $\mathbb{P}(s)$ of the source nodes, and the density $f(\mathbf{t}^c | s)$ of the cascades $\mathbf{t}^c$ given a source node s. In this case, we will further denote the Hessian of $\mathbb{E}_c \left[\log g(\mathbf{t}^c; \boldsymbol{\alpha}) \right]$ evaluated at the true model parameter $\boldsymbol{\alpha}^*$ as $\mathcal{Q}^*$. Then, we place two conditions on the Lipschitz continuity of $\boldsymbol{X}(\mathbf{t}^c; \boldsymbol{\alpha})$, and the boundedness of $\boldsymbol{X}(\mathbf{t}^c; \boldsymbol{\alpha}^*)$ and $\nabla g(\mathbf{t}^c; \boldsymbol{\alpha}^*)$ at the true model parameter $\boldsymbol{\alpha}^*$. For simplicity, we will denote the subset of indexes associated to node i's true parents as S, and its complement as S^c. Then, we use $\mathcal{Q}^*_{SS}$ to denote the sub-matrix of $\mathcal{Q}^*$ indexed by S and $\boldsymbol{\alpha}^*_S$ the set of parameters indexed by S. Note that $\boldsymbol{\alpha}^*_{S^c} = 0$.

Condition 1 (Dependency condition): There exists constants $C_{min} > 0$ and $C_{max} > 0$ such that $\Lambda_{min} \left(\mathcal{Q}^*_{SS} \right) \geq C_{min}$ and $\Lambda_{max} \left(\mathcal{Q}^*_{SS} \right) \leq C_{max}$ where $\Lambda_{min}(\cdot)$ and $\Lambda_{max}(\cdot)$ return the leading and the bottom eigenvalue of its argument respectively. This assumption ensures that two connected nodes co-occur reasonably frequently in the cascades but are not deterministically related.

Condition 2 (Irrepresentability condition): There exists a constant $\varepsilon \in (0, 1]$ such that $|||\mathcal{Q}^*_{S^cS} \left(\mathcal{Q}^*_{SS} \right)^{-1}|||_\infty \leq 1 - \varepsilon$, where $|||A|||_\infty = \max_j \sum_k |A_{jk}|$. This assumption captures the intuition that, node i and any of its neighbors should get infected together in a cascade more often than node i and any of its non-neighbors. A similar irrepresentability condition has been proposed on model selection consistency of Lasso (Zhao and Yu, 2006).

Condition 3 (Lipschitz Continuity): For any feasible cascade $\mathbf{t}^c$, the Hazard vector $\boldsymbol{X}(\mathbf{t}^c; \boldsymbol{\alpha})$ is Lipschitz continuous in the domain $\{\boldsymbol{\alpha} : \boldsymbol{\alpha}_S \geq \alpha^*_{\min}/2\}$,

$$\|\boldsymbol{X}(\mathbf{t}^c; \boldsymbol{\beta}) - \boldsymbol{X}(\mathbf{t}^c; \boldsymbol{\alpha})\|_2 \leq k_1 \|\boldsymbol{\beta} - \boldsymbol{\alpha}\|_2,$$



(a) Chain (b) Tree (c) Star

Figure 2: Example networks.

where k_1 is some positive constant. As a consequence, the spectral norm of the difference, $n^{-1/2}(\boldsymbol{X}^n(\boldsymbol{\beta}) - \boldsymbol{X}^n(\boldsymbol{\alpha}))$, is also bounded (refer to appendix 12.3), *i.e.*,

$$|||n^{-1/2}\big(\boldsymbol{X}^n(\boldsymbol{\beta}) - \boldsymbol{X}^n(\boldsymbol{\alpha})\big)|||_2 \leq k_1\|\boldsymbol{\beta} - \boldsymbol{\alpha}\|_2. \tag{7}$$

Furthermore, for any feasible cascade $\mathbf{t}^c$, $\boldsymbol{D}(\boldsymbol{\alpha})_{jj}$ is Lipschitz continuous for all $j \in \mathcal{V}$,

$$|\boldsymbol{D}(\mathbf{t}^c;\boldsymbol{\beta})_{jj} - \boldsymbol{D}(\mathbf{t}^c;\boldsymbol{\alpha})_{jj}| \leq k_2\|\boldsymbol{\beta} - \boldsymbol{\alpha}\|_2,$$

where k_2 is some positive constant.

Condition 4 (Boundedness): For any feasible cascade $\mathbf{t}^c$, the absolute value of each entry in the gradient of its log-likelihood and in the Hazard vector, as evaluated at the true model parameter $\boldsymbol{\alpha}^*$, is bounded,

$$\|\nabla g(\mathbf{t}^c;\boldsymbol{\alpha}^*)\|_\infty \leq k_3, \quad \|\boldsymbol{X}(\mathbf{t}^c;\boldsymbol{\alpha}^*)\|_\infty \leq k_4,$$

where k_3 and k_4 are positive constants. Then the absolute value of each entry in the Hessian matrix $\mathcal{Q}^*$, is also bounded $|||\mathcal{Q}^*|||_\infty \leq k_5$.

Remarks for condition 1 As stated in Theorem 1, as long as the source probability $\mathbb{P}(s)$ is strictly positive for all $s \in \mathcal{R}$, the maximum likelihood formulation is strictly convex and thus there exists $C_{min} > 0$ such that $\Lambda_{min}(\mathcal{Q}^*) \geq C_{min}$. Moreover, condition 4 implies that there exists $C_{max} > 0$ such that $\Lambda_{max}(\mathcal{Q}^*) \leq C_{max}$.

Remarks for condition 2 The irrepresentability condition depends, in a non-trivial way, on the network structure, diffusion parameters, observation window and source node distribution. Here, we give some intuition by studying three small canonical examples.

First, consider the chain graph in Fig. 2(a) and assume that we would like to find the incoming edges to node 3 when $T \to \infty$. Then, it is easy to show that the irrepresentability condition is satisfied if $(P_0+P_1)/(P_0+P_1+P_2) < 1-\varepsilon$ and $P_0/(P_0+P_1+P_2) < 1-\varepsilon$, where P_i denotes the probability of a node i to be the source of a cascade. Thus, for example, if the source of each cascade is chosen uniformly at random, the inequality is satisfied. Here, the irrepresentability condition depends on the source node distribution.

Second, consider the directed tree in Fig. 2(b) and assume that we would like to find the incoming edges to node 0 when $T \to \infty$. Then, it can be shown that the irrepresentability condition is satisfied as long as (1) $P_1 > 0$, (2) ($P_2 > 0$) or ($P_5 > 0$ and $P_6 > 0$), and (3) $P_3 > 0$. As in the chain, the condition depends on the source node distribution.

Finally, consider the star graph in Fig. 2(c), with exponential edge transmission functions, and assume that we would like to find the incoming edges to a leave node i when $T < \infty$. Then, as long as the root node has a nonzero probability $P_0 > 0$ of being the source of a cascade, it can be shown that the irrepresentability condition reduces to the inequalities $\left(1 - \frac{\alpha_{0j}}{\alpha_{0i}+\alpha_{0j}}\right) e^{-(\alpha_{0i}+\alpha_{0j})T} + \frac{\alpha_{0j}}{\alpha_{0i}+\alpha_{0j}} < 1 - \varepsilon(1 + e^{-\alpha_{0i}T})$, $j = 1, \ldots, p : j \neq i$, which always holds for some $\varepsilon > 0$. If $T \to \infty$, then the condition holds whenever $\varepsilon < \alpha_{0i}/(\alpha_{0i} + \max_{j:j\neq i}\alpha_{0j})$. Here, the larger the ratio $\max_{j:j\neq i}\alpha_{0j}/\alpha_{0i}$ is, the smaller the maximum value of ε for which the irrepresentability condition holds. To summarize, as long as $P_0 > 0$, there is always some $\varepsilon > 0$ for which the condition holds, and such ε value depends on the time window and the parameters α_{0j}.

Remarks for conditions 3 and 4 Well-known pairwise transmission likelihoods such as exponential, Rayleigh or Power-law, used in previous work Gomez-Rodriguez et al. (2011), satisfy conditions 3 and 4.

6. Sample Complexity

How many cascades do we need to recover the network structure? We will answer this question by providing a sample complexity analysis of the optimization in Eq. 4. Given the conditions spelled out in Section 5, we can show that the number of cascades needs to grow polynomially in the number of true parents of a node, and depends only logarithmically on the size of the network. This is a positive result, since the network size can be very large (millions or billions), but the number of parents of a node is usually small compared the network size. More specifically, for each individual node, we have the following result:

Theorem 2 *Consider an instance of the continuous-time diffusion model with parameters α^*_{ji} and associated edges $\mathcal{E}^*$ such that the model satisfies condition 1-4, and let C^n be a set of n cascades drawn from the model. Suppose that the regularization parameter λ_n is selected to satisfy*

$$\lambda_n \geq 8k_3\frac{2-\varepsilon}{\varepsilon}\sqrt{\frac{\log p}{n}}. \tag{8}$$

Then, there exist positive constants L and K, independent of (n, p, d), such that if

$$n > Ld^3 \log p, \tag{9}$$

then the following properties hold with probability at least $1 - 2\exp(-K\lambda_n^2 n)$:

1. *For each node $i \in \mathcal{V}$, the ℓ_1-regularized network inference problem defined in Eq. 4 has a unique solution, and so uniquely specifies a set of incoming edges of node i.*
2. *For each node $i \in \mathcal{V}$, the estimated set of incoming edges does not include any false edges and include all true edges.*

Furthermore, suppose that the finite sample Hessian matrix $\mathcal{Q}^n$ satisfies conditions 1 and 2. Then there exist positive constants L and K, independent of (n, p, d), such that the sample complexity can be improved to $n > Ld^2 \log p$ with other statements remain the same.

Remarks. The above sample complexity is proved for each node separately for recovering its parents. Using a union bound, we can provide the sample complexity for recovering the entire network structure by joining these parent-child relations together. The resulting sample complexity and the choice of regularization parameters will remain largely the same,

except that the dependency on d will change from d to d_{max} (the largest number of parents of a node), and the dependency on p will change from $\log p$ to $2\log N$ (N the number of nodes in the network).

6.1 Outline of Analysis

The proof of Theorem 2 uses a technique called primal-dual witness method, previously used in the proof of sparsistency of Lasso (Wainwright, 2009) and high-dimensional Ising model selection (Ravikumar et al., 2010). To the best of our knowledge, the present work is the first that uses this technique in the context of diffusion network inference. First, we show that the optimal solutions to Eq. 4 have shared sparsity pattern, and under a further condition, the solution is unique (proven in Appendix 12.4):

Lemma 3 *Suppose that there exists an optimal primal-dual solution $(\hat{\boldsymbol{\alpha}}, \hat{\boldsymbol{\mu}})$ to Eq. 4 with an associated subgradient vector $\hat{\mathbf{z}}$ such that $||\hat{\mathbf{z}}_{S^c}||_\infty < 1$. Then, any optimal primal solution $\tilde{\boldsymbol{\alpha}}$ must have $\tilde{\boldsymbol{\alpha}}_{S^c} = 0$. Moreover, if the Hessian sub-matrix $\mathcal{Q}^n_{SS}$ is strictly positive definite, then $\hat{\boldsymbol{\alpha}}$ is the unique optimal solution.*

Next, we will construct a primal-dual vector $(\hat{\boldsymbol{\alpha}}, \hat{\boldsymbol{\mu}})$ along with an associated subgradient vector $\hat{\mathbf{z}}$. Furthermore, we will show that, under the assumptions on (n, p, d) stated in Theorem 2, our constructed solution satisfies the KKT optimality conditions to Eq. 4, and the primal vector has the same sparsity pattern as the true parameter $\boldsymbol{\alpha}^*$, *i.e.*,

$$\hat{\alpha}_j > 0,\ \forall j : \alpha^*_j > 0, \tag{10}$$

$$\hat{\alpha}_j = 0,\ \forall j : \alpha^*_j = 0. \tag{11}$$

Then, based on Lemma 3, we can deduce that the optimal solution to Eq. 4 correctly recovers the sparsisty pattern of $\boldsymbol{\alpha}^*$, and thus the incoming edges to node i.

More specifically, we start by realizing that a primal-dual optimal solution $(\tilde{\boldsymbol{\alpha}}, \tilde{\boldsymbol{\mu}})$ to Eq. 4 must satisfy the generalized Karush-Kuhn-Tucker (KKT) conditions Boyd and Vandenberghe (2004):

$$0 \in \nabla \ell^n(\tilde{\boldsymbol{\alpha}}) + \lambda_n \tilde{\mathbf{z}} - \tilde{\boldsymbol{\mu}}, \tag{12}$$

$$\tilde{\mu}_j \tilde{\alpha}_j = 0, \tag{13}$$

$$\tilde{\mu}_j \geq 0, \tag{14}$$

$$\tilde{z}_j = 1,\ \forall \tilde{\alpha}_j > 0, \tag{15}$$

$$|\tilde{z}_j| \leq 1,\ \forall \tilde{\alpha}_j = 0, \tag{16}$$

where $\ell^n(\tilde{\boldsymbol{\alpha}}) = -\frac{1}{n}\sum_{c\in C^n} \log g(\mathbf{t}^c; \tilde{\boldsymbol{\alpha}})$ and $\tilde{\mathbf{z}}$ denotes the subgradient of the ℓ_1-norm.

Suppose the true set of parent of node i is S. We construct the primal-dual vector $(\hat{\boldsymbol{\alpha}}, \hat{\boldsymbol{\mu}})$ and the associated subgradient vector $\hat{\mathbf{z}}$ in the following way

1. We set $\hat{\boldsymbol{\alpha}}_S$ as the solution to the partial regularized maximum likelihood problem

$$\hat{\boldsymbol{\alpha}}_S = \underset{(\boldsymbol{\alpha}_S, 0), \boldsymbol{\alpha}_S \geq 0}{\operatorname{argmin}} \{\ell^n(\boldsymbol{\alpha}) + \lambda_n ||\boldsymbol{\alpha}_S||_1\}. \tag{17}$$

   Then, we set $\hat{\boldsymbol{\mu}}_S \geq 0$ as the dual solution associated to the primal solution $\hat{\boldsymbol{\alpha}}_S$.

2. We set $\hat{\boldsymbol{\alpha}}_{S^c} = 0$, so that condition (11) holds, and $\hat{\boldsymbol{\mu}}_{S^c} = \boldsymbol{\mu}^*_{S^c} \geq 0$, where $\boldsymbol{\mu}^*$ is the optimal dual solution to the following problem:

$$\begin{array}{ll} \text{minimize}_{\boldsymbol{\alpha}} & \mathbb{E}_c\left[\ell^n(\boldsymbol{\alpha})\right] \\ \text{subject to} & \alpha_j \geq 0,\ j = 1, \ldots, N, i \neq j. \end{array} \tag{18}$$

   Thus, our construction satisfies condition (14).

3. We obtain $\hat{\mathbf{z}}_{S^c}$ from (12) by substituting in the constructed $\hat{\boldsymbol{\alpha}}$, $\hat{\boldsymbol{\mu}}$ and $\hat{\mathbf{z}}_S$.

Then, we only need to prove that, under the stated scalings of (n, p, d), with high-probability, the remaining KKT conditions (10), (13), (15) and (16) hold.

For simplicity of exposition, we first assume that the dependency and irrepresentability conditions hold for the finite sample Hessian matrix $\mathcal{Q}^n$. Later we will lift this restriction and only place these conditions on the population Hessian matrix $\mathcal{Q}^*$. The following lemma (proven in Appendix 12.5) show that our constructed solution satisfies condition (10):

Lemma 4 *Under condition 3, if the regularization parameter is selected to satisfy*

$$\sqrt{d}\lambda_n \leq \frac{C^2_{\min}}{6(k_2 + 2k_1\sqrt{C_{\max}})},$$

and $\|\nabla_s \ell^n(\boldsymbol{\alpha}^*)\|_\infty \leq \frac{\lambda_n}{4}$, then,

$$\|\hat{\boldsymbol{\alpha}}_S - \boldsymbol{\alpha}^*_S\|_2 \leq \frac{3\sqrt{d}\lambda_n}{C_{\min}} \leq \frac{\alpha^*_{\min}}{2},$$

as long as $\alpha^*_{\min} \geq 6\sqrt{d}\lambda_n / C_{\min}$.

Based on this lemma, we can then further show that the KKT conditions (13) and (15) also hold for the constructed solution. This can be trivially deduced from condition (10) and (11), and our construction steps (a) and (b). Note that it also implies that $\hat{\boldsymbol{\mu}}_S = \boldsymbol{\mu}^*_S = 0$, and hence $\hat{\boldsymbol{\mu}} = \boldsymbol{\mu}^*$.

Proving condition (16) is more challenging. We first provide more details on how to construct $\hat{\mathbf{z}}_{S^c}$ mentioned in step (c). We start by using a Taylor expansion of Eq. 12,

$$\mathcal{Q}^n(\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}^*) = -\nabla \ell^n(\boldsymbol{\alpha}^*) - \lambda_n \hat{\boldsymbol{z}} + \hat{\boldsymbol{\mu}} - \mathbf{R}^n, \tag{19}$$

where $\mathbf{R}^n$ is a remainder term with its j-th entry

$$R^n_j = \left[\nabla^2 \ell^n(\bar{\boldsymbol{\alpha}}_j) - \nabla^2 \ell^n(\boldsymbol{\alpha}^*)\right]^T_j (\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}^*),$$

and $\bar{\boldsymbol{\alpha}}_j = \theta_j \hat{\boldsymbol{\alpha}} + (1-\theta_j)\boldsymbol{\alpha}^*$ with $\theta_j \in [0, 1]$ according to the mean value theorem. Rewriting Eq. 19 using block matrices

$$\begin{pmatrix} \mathcal{Q}^n_{SS} & \mathcal{Q}^n_{SS^c} \\ \mathcal{Q}^n_{S^cS} & \mathcal{Q}^n_{S^cS^c} \end{pmatrix} \begin{pmatrix} \hat{\boldsymbol{\alpha}}_S - \boldsymbol{\alpha}^*_S \\ \hat{\boldsymbol{\alpha}}_{S_c} - \boldsymbol{\alpha}^*_{S^c} \end{pmatrix} = -\begin{pmatrix} \nabla_S \ell^n(\boldsymbol{\alpha}^*) \\ \nabla_{S^c} \ell^n(\boldsymbol{\alpha}^*) \end{pmatrix} - \lambda_n \begin{pmatrix} \hat{\boldsymbol{z}}_S \\ \hat{\boldsymbol{z}}_{S^c} \end{pmatrix} + \begin{pmatrix} \hat{\mu}_S \\ \hat{\mu}_{S^c} \end{pmatrix} - \begin{pmatrix} \mathbf{R}^n_S \\ \mathbf{R}^n_{S^c} \end{pmatrix} \tag{20}$$

and, after some algebraic manipulation, we have

$$\lambda \hat{\mathbf{z}}_{S^c} = -\nabla_{S^c} \ell^n(\boldsymbol{\alpha}^*) + \hat{\boldsymbol{\mu}}_{S^c} - \mathbf{R}^n_{S^c} - \mathcal{Q}^n_{S^cS}(\mathcal{Q}^n_{SS})^{-1}\big(-\nabla_s \ell^n(\boldsymbol{\alpha}^*) - \lambda \hat{\boldsymbol{z}}_S + \hat{\boldsymbol{\mu}}_S - \mathbf{R}^n_S\big). \tag{21}$$

Next, we upper bound $\|\hat{\boldsymbol{z}}_{S^c}\|_\infty$ using the triangle inequality

$$\begin{aligned} \|\hat{\mathbf{z}}_{S^c}\|_\infty \quad & \leq \lambda_n^{-1}\|\boldsymbol{\mu}^*_{S^c} - \nabla_{S^c}\ell^n(\boldsymbol{\alpha}^*)\|_\infty + \lambda_n^{-1}\|\mathbf{R}^n_{S^c}\|_\infty + \|\mathcal{Q}^n_{S^cS}(\mathcal{Q}^n_{SS})^{-1}\|_\infty \times \left[1 + \lambda_n^{-1}\|\mathbf{R}^n_S\|_\infty\right. \\ & \left. + \lambda_n^{-1}\|\mu^*_S - \nabla_S \ell^n(\boldsymbol{\alpha}^*)\|_\infty\right], \end{aligned}$$

and we want to prove that this upper bound is smaller than 1. This can be done with the help of the following two lemmas (proven in Appendices 12.6 and 12.7):

Lemma 5 *Given $\varepsilon \in (0,1]$ from the irrepresentability condition, we have,*

$$P\left(\frac{2-\varepsilon}{\lambda_n}\|\nabla \ell^n(\boldsymbol{\alpha}^*) - \boldsymbol{\mu}^*\|_\infty \geq 4^{-1}\varepsilon\right) \leq 2p\exp\left(-\frac{n\lambda_n^2\varepsilon^2}{32k_3^2\left(2-\varepsilon\right)^2}\right), \tag{22}$$

which converges to zero at rate $\exp(-c\lambda_n^2 n)$ as long as $\lambda_n \geq 8k_3\frac{2-\varepsilon}{\varepsilon}\sqrt{\frac{\log p}{n}}$.

Lemma 6 *Given $\varepsilon \in (0,1]$ from the irrepresentability condition, if conditions 3 and 4 holds, λ_n is selected to satisfy*

$$\lambda_n d \leq C_{\min}^2 \frac{\varepsilon}{36K(2-\varepsilon)},$$

where $K = k_1 + k_4k_1 + k_1^2 + k_1\sqrt{C_{\max}}$, and $\|\nabla_s \ell^n(\boldsymbol{\alpha}^*)\|_\infty \leq \frac{\lambda_n}{4}$, then, $\frac{\|\mathbf{R}^n\|_\infty}{\lambda_n} \leq \frac{\varepsilon}{4(2-\varepsilon)}$, as long as $\alpha^*_{\min} \geq 6\sqrt{d}\lambda_n/C_{\min}$.

Now, applying both lemmas and the irrepresentability condition on the finite sample Hessian matrix $\mathcal{Q}^n$, we have

$$\begin{aligned}\|\hat{\boldsymbol{z}}_{S^c}\|_\infty &\leq (1-\varepsilon) + \lambda_n^{-1}(2-\varepsilon)\|\mathbf{R}^n\|_\infty + \lambda_n^{-1}(2-\varepsilon)\|\boldsymbol{\mu}^* - \nabla\ell^n(\boldsymbol{\alpha}^*)\|_\infty \\ &\leq (1-\varepsilon) + 0.25\varepsilon + 0.25\varepsilon = 1 - 0.5\varepsilon,\end{aligned}$$

and thus condition (16) holds.

A possible choice of the regularization parameter λ_n and cascade set size n such that the conditions of the Lemmas 4-6 are satisfied is $\lambda_n = 8k_3(2-\varepsilon)\varepsilon^{-1}\sqrt{n^{-1}\log p}$ and $n > 288^2k_3^2(2-\varepsilon)^4C_{min}^{-4}\varepsilon^{-4}d^2\log p + \left(48k_3(2-\varepsilon)C_{min}^{-1}(\alpha^*_{min})^{-1}\varepsilon^{-1}\right)^2 d\log p$.

Last, we lift the dependency and irrepresentability conditions imposed on the finite sample Hessian matrix $\mathcal{Q}^n$. We show that if we only impose these conditions in the corresponding population matrix $\mathcal{Q}^*$, then they will also hold for $\mathcal{Q}^n$ with high probability (proven in Appendices 12.8 and 12.9).

Lemma 7 *If condition 1 holds for $\mathcal{Q}^*$, then, for any $\delta > 0$,*

$$P\left(\Lambda_{min}\left(\mathcal{Q}^n_{SS}\right) \leq C_{min} - \delta\right) \leq 2d^{B_1}\exp\left(-A_1\frac{\delta^2 n}{d^2}\right),$$

$$P\left(\Lambda_{max}\left(\mathcal{Q}^n_{SS}\right) \geq C_{max} + \delta\right) \leq 2d^{B_2}\exp\left(-A_2\frac{\delta^2 n}{d^2}\right),$$

where A_1, A_2, B_1 and B_2 are constants independent of (n,p,d).

Lemma 8 *If $|||\mathcal{Q}^*_{S^cS}\left(\mathcal{Q}^*_{SS}\right)^{-1}|||_\infty \leq 1-\varepsilon$, then,*

$$P\left(\|\mathcal{Q}^n_{S^cS}(\mathcal{Q}^n_{SS})^{-1}\|_\infty \geq 1 - \varepsilon/2\right) \leq p\exp\left(-K\frac{n}{d^3}\right),$$

where K is a constant independent of (n,p,d).

Note in this case the cascade set size need to increase to $n > Ld^3\log p$, where L is a sufficiently large positive constant independent of (n,p,d), for the error probabilities on these last two lemmas to converge to zero.

7. Efficient soft-thresholding algorithm

Can we design efficient algorithms to solve Eq. (4) for network recovery? Here, we will design a proximal gradient algorithm which is well suited for solving non-smooth, constrained, large-scale or high-dimensional convex optimization problems Parikh and Boyd (2013). Moreover, they are easy to understand, derive, and implement. We first rewrite Eq. 4 as an unconstrained optimization problem:

$$\text{minimize}_{\boldsymbol{\alpha}} \quad \ell^n(\boldsymbol{\alpha}) + g(\boldsymbol{\alpha}),$$

where the non-smooth convex function $g(\boldsymbol{\alpha}) = \lambda_n||\boldsymbol{\alpha}||_1$ if $\boldsymbol{\alpha} \geq 0$ and $+\infty$ otherwise. By rewriting both problems as a sum of a smooth convex function $\ell^n(\boldsymbol{\alpha})$ and a non-smooth convex function $g(\boldsymbol{\alpha})$, the general recipe from Parikh and Boyd (2013) for designing proximal gradient algorithm can be applied directly.

Algorithm 1 summarizes the resulting algorithm. In each iteration of the algorithm, we need to compute $\nabla\ell^n$ (Table 2) and the proximal operator $\mathbf{prox}_{L^k g}(\mathbf{v})$, where L^k is a step size that we can set to a constant value L or find using a simple line search Beck and Teboulle (2009). Using Moreau's decomposition, we have

$$\mathbf{prox}_{L^k g}(\mathbf{v}) = \mathbf{v} - L^k\,\mathbf{prox}_{g^*/L^k}(\mathbf{v}/L^k), \tag{23}$$

where

$$g^*(\mathbf{y}) = \sup_{\mathbf{x}}\left((\mathbf{y} - \lambda_n\mathbf{1})^T x - \mathbf{1}(\mathbf{x} \geq 0)\right) = \begin{cases}\infty & \text{if } \exists i : y_i > \lambda_n \\ 0 & \text{otherwise}\end{cases}$$

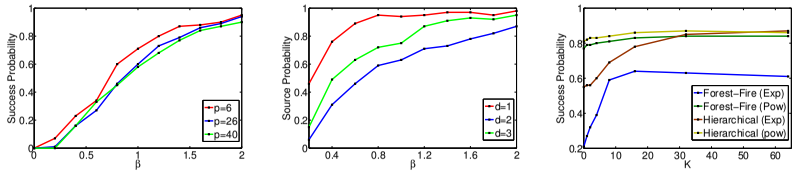
is the conjugate function of g. Then,

$$\mathbf{prox}_{g^*/L^k}(\mathbf{v}/L^k) = \operatorname*{argmin}_{\mathbf{y}}\{g^*(\mathbf{y}) + \frac{L^k}{2}\|y - \mathbf{v}/L^k\|_2^2\} = (\mathbf{v} - \lambda_n L^k)_+$$

In summary, the proximal operator for our particular function $g(\cdot)$ is a soft-thresholding operator, $(\mathbf{v} - \lambda_n L^k)_+$, which leads to a sparse optimal solution $\hat{\boldsymbol{\alpha}}$, as desired.

8. Experiments

In this section, we first illustrate some consequences of Th. 2 by applying our algorithm to several types of networks, parameters (n,p,d), and regularization parameter λ_n. Then, we compare our algorithm to two different state-of-the-art algorithms: NetRate Gomez-Rodriguez et al. (2011) and First-Edge Abrahao et al. (2013).



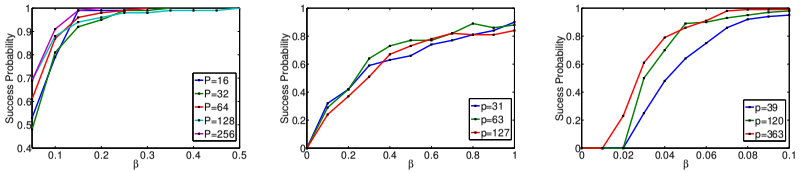
(a) Super-neighborhood p_i (b) In-degrees d_i (c) λ_n

Figure 3: Success probability vs. # of cascades.

Experimental Setup We focus on synthetic networks that mimic the structure of real-world diffusion networks – in particular, social networks. We consider two models of directed real-world social networks: the Forest Fire model (Barabási and Albert, 1999) and the Kronecker Graph model (Leskovec et al., 2010), and use simple pairwise transmission models such as exponential, power-law or Rayleigh. We use networks with 128 nodes and, for each edge, we draw its associated transmission rate from a uniform distribution $U(0.5, 1.5)$. In general, we proceed as follows: we generate a network $\mathcal{G}^*$ and transmission rates $\mathbf{A}^*$, simulate a set of cascades and, for each cascade, record the node infection times. Then, given the infection times, we infer a network $\hat{\mathcal{G}}$. Finally, when we illustrate the consequences of Th. 2, we evaluate the accuracy of the inferred neighborhood of a node $\hat{\mathcal{N}}^-(i)$ using probability of success $P(\hat{\mathcal{E}} = \mathcal{E}^*)$, estimated by running our method of 100 independent cascade sets. When we compare our algorithm to NetRate and First-Edge, we use the F_1 score, which is defined as $2PR/(P+R)$, where precision (P) is the fraction of edges in the inferred network $\hat{\mathcal{G}}$ present in the true network $\mathcal{G}^*$, and recall (R) is the fraction of edges of the true network $\mathcal{G}^*$ present in the inferred network $\hat{\mathcal{G}}$.

Parameters (n, p, d) According to Th. 2, the number of cascades that are necessary to successfully infer the incoming edges of a node will increase polynomially to the node's neighborhood size d_i and logarithmically to the super-neighborhood size p_i. Here, we first infer the incoming links of nodes on the same type of canonical networks as depicted in Fig. 2. We choose nodes the same in-degree but different super-neighboorhod set sizes p_i and experiment with different scalings β of the number of cascades $n = 10\beta d \log p$. We set the regularization parameter λ_n as a constant factor of $\sqrt{\log(p)/n}$ as suggested by Theorem 2 and, for each node, we used cascades which contained at least one node in the super-neighborhood of the node under study. We used an exponential transmission model and time window $T = 10$. As predicted by Theorem 2, very different p values lead to curves that line up with each other quite well.

Next, we infer the incoming links of nodes of a larger hierarchical Kronecker network. Again, we choose nodes with the same in-degree ($d_i = 3$) but different super-neighboorhod set sizes p_i under different scalings β of the number of cascades $n = 10\beta d \log p$. We used an exponential transmission model and $T = 5$. Fig. 3(a) summarizes the results, where, for each node, we used cascades which contained at least one node in the super-neighborhood of the node under study. Similarly as in the case of the canonical networks, very different p values lead to curves that line up with each other quite well.



(a) Chain ($d_i = 1$) (b) Stars ($d_i = 1$) (c) Tree ($d_i = 3$)

Figure 4: Success probability vs. # of cascades. Different super-neighborhood sizes p_i.

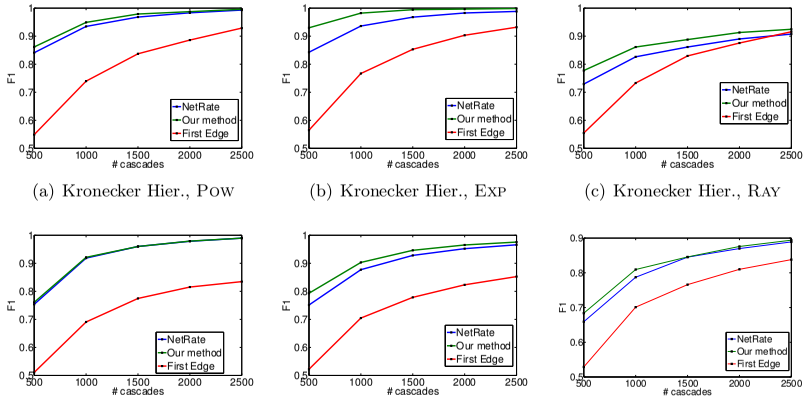
Finally, we infer the incoming links of nodes of a hierarchical Kronecker network with equal super neighborhood size ($p_i = 70$) but different in-degree (d_i) under different scalings β of the number of cascades $n = 10\beta d \log p$ and choose the regularization parameter λ_n as a constant factor of $\sqrt{\log(p)/n}$ as suggested by Theorem 2. We used an exponential transmission model and time window $T = 5$. Figure 3(b) summarizes the results, where we observe that, as predicted by Theorem 2, different d values lead to noticeably different curves.

Regularization parameter λ_n Our main result indicates that the regularization parameter λ_n should be a constant factor of $\sqrt{\log(p)/n}$. Fig. 3(c) shows the success probability of our algorithm against different scalings K of the regularization parameter $\lambda_n = K\sqrt{\log(p)/n}$ for different types of networks using 150 cascades and $T = 5$. We find that for sufficiently large λ_n, the success probability flattens, as expected from Th. 2. It flattens at values smaller than one because we used a fixed number of cascades n, which may not satisfy the conditions of Th. 2.

Comparison with NetRate and First-Edge Fig. 5 compares the accuracy of our algorithm, NetRate and First-Edge against number of cascades for three hierarchical Kronecker network and three Forest Fire networks, with power-law (Pow), exponential (Exp) and rayleigh (Ray) transmission models, and an observation window $T = 10$. Our method outperforms both competitive methods, finding especially striking the competitive advantage with respect to First-Edge, however, this may be explained by comparing the sample complexity results for both methods: First-Edge needs $O(Nd \log N)$ cascades to achieve a probability of success approaching 1 in a rate polynomial in the number of cascades while our method needs $O(d^3 \log N)$ to achieve a probability of success approaching 1 in a rate exponential in the number of cascades.

9. Discussion

Our results can be extended in multiple directions. First, our novel formulation of the diffusion network recovery problem as a ℓ_1-regularized convex optimization problem establishes a connection between the literature on information diffusion and a vast literature on high dimension sparse recovery problem from machine learning and statistics literature. This connection allows us to borrow analysis frameworks for graphical model structure estimation to analyze information diffusion. In terms of diffusion models, we can extend the current independent cascade model to deal with nonparametric transmission functions (Du



(a) Kronecker Hier., Pow (b) Kronecker Hier., Exp (c) Kronecker Hier., Ray

(d) Forest Fire, Pow (e) Forest Fire, Exp (f) Forest Fire, Ray

Figure 5: F_1-score vs. # of cascades.

et al., 2012a), transmission function conditioned on additional features (Du et al., 2013), diffusion models which allows for multiple events (Zhou et al., 2013). All three models will result in convex loss function; and for the former two models, we can employ grouped lasso regularization (Yuan and Lin, 2006), while for the latter model, we can employ a nuclear norm regularization (Recht et al., 2010). These models are more complicated than the independent cascade model we studied in the paper, but analysis for these models can be carried out using a general M-estimation analysis framework (Negahban et al., 2009), since these regularizers are decomposable and one needs to check the restricted strong convexity of the loss function. In terms of the estimation algorithms, we can employ proximal algorithms (Parikh and Boyd, 2013) or the conditional gradient algorithm (Jaggi, 2013) to deal with different type of diffusion models and regularizers. When the data is large, one can consider distributed (Boyd et al., 2011) and online estimation (Nemirovski et al., 2009) procedures.

Our results also bring out interesting further open problems on diffusion network estimations. For instance, the success of the network inference algorithm in Equation (2) relies on the fulfillment of the above mentioned irrepresentability condition on the Hessian, $\mathcal{Q}^*$, of the population log-likelihood $\mathbb{E}[\ell^n]$, where the expectation here is taken over the distribution $\mathbb{P}(s)$ of the source nodes and the random generative process of the diffusion model given a source node s. This condition captures the intuition that, node i and any of its neighbors should get infected together in a cascade more often than node i and any of its non-neighbors. Unfortunately, the irrepresentability condition depends, in a non-trivial way, on the network structure, diffusion parameters, and the source distribution $\mathbb{P}(s)$, which are all *unknown* during the network inference stage. Previous work has typically assumed the network structure, diffusion parameters, observation window and source distribution to be fixed, and source locations are sampled *passively* from the latter. However, in practice,

the source locations to sample from may be determined *actively* in a sequential manner, potentially based on the information gathered from previous source locations. Thus an interesting open question is:

> Suppose there exists an unknown $\mathbb{P}(s)$ where the irrepresentability conditions hold for the diffusion model. Under what conditions, can we design an "active" algorithm which samples the source location intelligently and achieves the sample complexity in Theorem 2, or even better sample complexity, *e.g.*, $o(d_i^3 \log N)$?

10. Conclusions

Our work contributes towards establishing a theoretical foundation of the network inference problem. Specifically, we proposed a ℓ_1-regularized maximum likelihood inference method for a well-known continuous-time diffusion model and an efficient proximal gradient implementation, and then show that, for general networks satisfying a natural irrepresentability condition, our method achieves an exponentially decreasing error with respect to the number of cascades as long as $O(d^3 \log N)$ cascades are recorded.

Our work also opens many interesting venues for future work. For example, given a fixed number of cascades, it would be useful to provide confidence intervals on the inferred edges. Further, a detailed theoretical analysis of the irrepresentability condition on large synthetic networks that mimic the structure of real-world diffusion networks, such as Kronecker or Forest-Fire networks, is still missing. Given a network with arbitrary pairwise likelihoods, it is an open question whether there always exists at least one source distribution and time window value such that the irrepresentability condition is satisfied, and, and if so, whether there is an efficient way of finding this distribution. Finally, our work assumes all activations occur due to network diffusion and are recorded. It would be interesting to allow for missing observations, as well as activations due to exogenous factors.

12. Appendix

12.1 Proof of Lemma 9

Lemma 9 *Given log-concave survival functions and concave hazard functions in the parameter(s) of the pairwise transmission likelihoods, then, a sufficient condition for the Hessian matrix $\mathcal{Q}^n$ to be positive definite is that the hazard matrix $X^n(\boldsymbol{\alpha})$ is non-singular.*

Proof Using Eq. 5, the Hessian matrix can be expressed as a sum of two matrices, $\mathbf{D}^n(\boldsymbol{\alpha})$ and $\mathbf{X}^n(\boldsymbol{\alpha})\mathbf{X}^n(\boldsymbol{\alpha})^\top$. The matrix $\mathbf{D}^n(\boldsymbol{\alpha})$ is trivially positive semidefinite by log-concavity of the survival functions and concavity of the hazard functions. The matrix $\mathbf{X}^n(\boldsymbol{\alpha})\mathbf{X}^n(\boldsymbol{\alpha})^\top$ is positive definite matrix since $\mathbf{X}^n(\boldsymbol{\alpha})$ is full rank by assumption. Then, the Hessian matrix is positive definite since it is a sum a positive semidefinite matrix and a positive definite matrix. ■

12.2 Proof of Lemma 10

Lemma 10 *If the source probability $\mathbb{P}(s)$ is strictly positive for all $s \in \mathcal{R}$, then, for an arbitrarily large number of cascades $n \to \infty$, there exists an ordering of the nodes and cascades within the cascade set such that the hazard matrix $\boldsymbol{X}^n(\boldsymbol{\alpha})$ is non-singular.*

Proof In this proof, we find a labeling of the nodes (row indices in $\mathbf{X}^n(\boldsymbol{\alpha})$) and ordering of the cascades (column indices in $\mathbf{X}^n(\boldsymbol{\alpha})$), such that, for an arbitrary large number of cascades, we can express the matrix $\mathbf{X}^n(\boldsymbol{\alpha})$ as $[T\ B]$, where $T \in \mathbb{R}^{p\times p}$ is an upper triangular with nonzero diagonal elements and $B \in \mathbb{R}^{p\times n-p}$. And, therefore, $\mathbf{X}^n(\boldsymbol{\alpha})$ has full rank (rank p). We proceed first by sorting nodes in $\mathcal{R}$ and then continue by sorting nodes in $\mathcal{U}$:

- **Nodes in $\mathcal{R}$**: For each node $u \in \mathcal{R}$, consider the set of cascades C_u in which u was a source and i got infected. Then, rank each node u according to the earliest position in which node i got infected across all cascades in C_u in decreasing order, breaking ties at random. For example, if a node u was, at least once, the source of a cascade in which node i got infected just after the source, but in contrast, node v was never the source of a cascade in which node i got infected the second, then node u will have a lower index than node v. Then, assign row k in the matrix $\mathbf{X}^n(\boldsymbol{\alpha})$ to node in position k and assign the first d columns to the corresponding cascades in which node i got infected earlier. In such ordering, $\mathbf{X}^n(\boldsymbol{\alpha})_{mk} = 0$ for all $m < k$ and $\mathbf{X}^n(\boldsymbol{\alpha})_{kk} \neq 0$.

- **Nodes in $\mathcal{U}$**: Similarly as in the first step, and assign them the rows $d+1$ to p. Moreover, we assign the columns $d+1$ to p to the corresponding cascades in which node i got infected earlier. Again, this ordering satisfies that $\mathbf{X}^n(\boldsymbol{\alpha})_{mk} = 0$ for all $m < k$ and $\mathbf{X}^n(\boldsymbol{\alpha})_{kk} \neq 0$. Finally, the remaining columns $n-p$ can be assigned to the remaining cascades at random.

This ordering leads to the desired structure $[T\ B]$, and thus it is non-singular. ■

12.3 Proof of Eq 7.

If the Hazard vector $\boldsymbol{X}(\mathbf{t}^c;\boldsymbol{\alpha})$ is Lipschitz continuous in the domain $\{\boldsymbol{\alpha} : \boldsymbol{\alpha}_S \geq \frac{\alpha^*_{\min}}{2}\}$,

$$\|\boldsymbol{X}(\mathbf{t}^c;\boldsymbol{\beta}) - \boldsymbol{X}(\mathbf{t}^c;\boldsymbol{\alpha})\|_2 \leq k_1\|\boldsymbol{\beta}-\boldsymbol{\alpha}\|_2,$$

where k_1 is some positive constant. Then, we can bound the spectral norm of the difference, $\frac{1}{\sqrt{n}}(\boldsymbol{X}^n(\boldsymbol{\beta}) - \boldsymbol{X}^n(\boldsymbol{\alpha}))$, in the domain $\{\boldsymbol{\alpha} : \boldsymbol{\alpha}_S \geq \frac{\alpha^*_{\min}}{2}\}$ as follows:

$$|||\frac{1}{\sqrt{n}}\big(\mathbf{X}^n(\boldsymbol{\beta}) - \mathbf{X}^n(\boldsymbol{\alpha})\big)|||_2 = \max_{\|\boldsymbol{u}\|_2=1}\frac{1}{\sqrt{n}}\|\boldsymbol{u}\big(\mathbf{X}^n(\boldsymbol{\beta}) - \mathbf{X}^n(\boldsymbol{\alpha})\big)\|_2$$

$$= \max_{\|\boldsymbol{u}\|_2=1}\frac{1}{\sqrt{n}}\sqrt{\sum_{c=1}^{n}\langle \boldsymbol{u}, \mathbf{X}(\mathbf{t}^c;\boldsymbol{\beta}) - \mathbf{X}(\mathbf{t}^c;\boldsymbol{\alpha})\rangle^2} \leq \frac{1}{\sqrt{n}}\sqrt{k_1^2 n\|\boldsymbol{u}\|_2^2\|\boldsymbol{\beta}-\boldsymbol{\alpha}\|_2^2} \leq k_1\|\boldsymbol{\beta}-\boldsymbol{\alpha}\|_2.$$

12.4 Proof of Lemma 3

By Lagrangian duality, the regularized network inference problem defined in Eq. 4 is equivalent to the following constrained optimization problem:

$$\begin{array}{ll}\text{minimize}_{\boldsymbol{\alpha}_i} & \ell^n(\boldsymbol{\alpha}_i) \\ \text{subject to} & \alpha_{ji} \geq 0,\ j = 1,\dots,N, i \neq j, \\ & ||\boldsymbol{\alpha}_i||_1 \leq C(\lambda_n)\end{array} \tag{24}$$

where $C(\lambda_n) < \infty$ is a positive constant. In this alternative formulation, λ_n is the Lagrange multiplier for the second constraint. Since λ_n is strictly positive, the constraint is active at any optimal solution, and thus $||\boldsymbol{\alpha}_i||_1$ is constant across all optimal solutions.

Using that $\ell^n(\boldsymbol{\alpha}_i)$ is a differentiable convex function by assumption and $\{\boldsymbol{\alpha} : \alpha_{ji} \geq 0, ||\boldsymbol{\alpha}_i||_1 \leq C(\lambda_n)\}$ is a convex set, we have that $\nabla\ell^n(\boldsymbol{\alpha}_i)$ is constant across optimal primal solutions Mangasarian (1988). Moreover, any optimal primal-dual solution in the original problem must satisfy the KKT conditions in the alternative formulation defined by Eq. 24, in particular,

$$\nabla\ell^n(\boldsymbol{\alpha}_i) = -\lambda_n\mathbf{z} + \boldsymbol{\mu},$$

where $\boldsymbol{\mu} \geq 0$ are the Lagrange multipliers associated to the non negativity constraints and $\mathbf{z}$ denotes the subgradient of the ℓ1-norm.

Consider the solution $\hat{\boldsymbol{\alpha}}$ such that $||\hat{\mathbf{z}}_{\mathbf{S}^c}||_\infty < 1$ and thus $\nabla_{\alpha_{S^c}}\ell^n(\hat{\boldsymbol{\alpha}}_i) = -\lambda_n\hat{\mathbf{z}}_{\mathbf{S}^c} + \hat{\boldsymbol{\mu}}_{S^c}$. Now, assume there is an optimal primal solution $\tilde{\boldsymbol{\alpha}}$ such that $\tilde{\alpha}_{ji} > 0$ for some $j \in S^c$, then, using that the gradient must be constant across optimal solutions, it should hold that $-\lambda_n\hat{z}_j + \hat{\mu}_j = -\lambda_n$, where $\tilde{\mu}_{ji} = 0$ by complementary slackness, which implies $\hat{\mu}_j = -\lambda_n(1-\hat{z}_j) < 0$. Since $\hat{\mu}_j \geq 0$ by assumption, this leads to a contradiction. Then, any primal solution $\tilde{\boldsymbol{\alpha}}$ must satisfy $\tilde{\boldsymbol{\alpha}}_{S^c} = 0$ for the gradient to be constant across optimal solutions.

Finally, since $\boldsymbol{\alpha}_{S^c} = 0$ for all optimal solutions, we can consider the restricted optimization problem defined in Eq. 17. If the Hessian sub-matrix $[\nabla^2 L(\hat{\boldsymbol{\alpha}})]_{SS}$ is strictly positive definite, then this restricted optimization problem is strictly convex and the optimal solution must be unique.

12.5 Proof of Lemma 4

To prove this lemma, we will first construct a function

$$G(\mathbf{u}_S) := \ell^n(\boldsymbol{\alpha}^*_S + \mathbf{u}_S) - \ell^n(\boldsymbol{\alpha}^*_S) + \lambda_n(\|\boldsymbol{\alpha}^*_S + \mathbf{u}_S\|_1 - \|\boldsymbol{\alpha}^*_S\|_1).$$

whose domain is restricted to the convex set $\mathcal{U} = \{\mathbf{u}_S : \boldsymbol{\alpha}^*_S + \mathbf{u}_S \geq \mathbf{0}\}$. By construction, $G(\mathbf{u}_S)$ has the following properties

1. It is convex with respect to $\mathbf{u}_S$.
2. Its minimum is obtained at $\hat{\boldsymbol{u}}_S := \hat{\boldsymbol{\alpha}}_S - \boldsymbol{\alpha}^*_S$. That is $G(\hat{\boldsymbol{u}}_S) \leq G(\mathbf{u}_S)$, $\forall \mathbf{u}_S \neq \hat{\boldsymbol{u}}_S$.
3. $G(\hat{\boldsymbol{u}}_S) \leq G(\mathbf{0}) = 0$.

Based on the properties 1 and 3 above, we deduce that any point in the segment, $\mathbb{L} := \{\tilde{\boldsymbol{u}}_S : \tilde{\boldsymbol{u}}_S = t\hat{\boldsymbol{u}}_S + (1-t)\mathbf{0}, t \in [0,1]\}$, connecting $\hat{\boldsymbol{u}}_S$ and $\mathbf{0}$ has $G(\tilde{\boldsymbol{u}}_S) \leq 0$. That is

$$G(\tilde{\boldsymbol{u}}_S) = G(t\hat{\boldsymbol{u}}_S + (1-t)\mathbf{0}) \leq tG(\hat{\boldsymbol{u}}_S) + (1-t)G(\mathbf{0}) \leq 0.$$

Next, we will find a sphere centered at $\mathbf{0}$ with strictly positive radius B, $\mathbb{S}(B) := \{\boldsymbol{u}_S : \|\boldsymbol{u}_S\|_2 = B\}$, such that function $G(\boldsymbol{u}_S) > 0$ (strictly positive) on $\mathbb{S}(B)$. We note that this sphere $\mathbb{S}(B)$ can not intersect with the segment $\mathbb{L}$ since the two sets have strictly different function values. Furthermore, the only possible configuration is that the segment is contained inside the sphere entirely, leading us to conclude that the end point $\hat{\boldsymbol{u}}_S := \hat{\boldsymbol{\alpha}}_S - \boldsymbol{\alpha}^*_S$ is also within the sphere. That is $\|\hat{\boldsymbol{\alpha}}_S - \boldsymbol{\alpha}^*_S\|_2 \leq B$.

In the following, we will provide details on finding such a suitable B which will be a function of the regularization parameter λ_n and the neighborhood size d. More specifically, we will start by applying a Taylor series expansion and the mean value theorem,

$$G(\mathbf{u}_S) = \nabla_S \ell^n(\boldsymbol{\alpha}^*_S)^\top \mathbf{u}_S + \mathbf{u}_S^\top \nabla^2_{SS} \ell^n(\boldsymbol{\alpha}^*_S + b\mathbf{u}_S)\mathbf{u}_S + \lambda_n(\|\boldsymbol{\alpha}^*_S + \mathbf{u}_S\|_1 - \|\boldsymbol{\alpha}^*_S\|_1), \quad (25)$$

where $b \in [0,1]$. We will show that $G(\mathbf{u}_S) > 0$ by bounding below each term of above equation separately.

We bound the absolute value of the first term using the assumption on the gradient, $\nabla_S \ell(\cdot)$,

$$|\nabla_S \ell^n(\boldsymbol{\alpha}^*_S)^\top \mathbf{u}_S| \leq \|\nabla_S \ell\|_\infty \|\mathbf{u}_S\|_1 \leq \|\nabla_S \ell\|_\infty \sqrt{d}\|\mathbf{u}_S\|_2 \leq 4^{-1}\lambda_n B\sqrt{d}. \quad (26)$$

We bound the absolute value of the last term using the reverse triangle inequality.

$$\lambda_n |\|\boldsymbol{\alpha}^*_S + \mathbf{u}_S\|_1 - \|\boldsymbol{\alpha}^*_S\|_1| \leq \lambda_n \|\mathbf{u}_S\|_1 \leq \lambda_n \sqrt{d}\|\mathbf{u}_S\|_2. \quad (27)$$

Bounding the remaining middle term is more challenging. We start by rewriting the Hessian as a sum of two matrices, using Eq. 5,

$$\begin{aligned} q &= \min_{\mathbf{u}_S} \mathbf{u}_S^\top \mathbf{D}^n_{SS}(\boldsymbol{\alpha}^*_S + b\mathbf{u}_S)\mathbf{u}_S + n^{-1}\mathbf{u}_S^\top \mathbf{X}^n_S(\boldsymbol{\alpha}^*_S + b\mathbf{u}_S)\mathbf{X}^n_S(\boldsymbol{\alpha}^*_S + b\mathbf{u}_S)^\top \mathbf{u}_S \\ &= \min_{\mathbf{u}_S} \mathbf{u}_S^\top \mathbf{D}^n_{SS}(\boldsymbol{\alpha}^*_S + b\mathbf{u}_S)\mathbf{u}_S + \|\mathbf{u}_S^\top \mathbf{X}^n_S(\boldsymbol{\alpha}^*_S + b\mathbf{u}_S)\|_2^2. \end{aligned}$$

Now, we introduce two additional quantities,

$$\Delta \mathbf{D}^n_{SS} = \mathbf{D}^n_{SS}(\boldsymbol{\alpha}^*_S + b\mathbf{u}_S) - \mathbf{D}^n_{SS}(\boldsymbol{\alpha}^*_S) \quad \text{and} \quad \Delta \mathbf{X}^n_S = \mathbf{X}^n_S(\boldsymbol{\alpha}^*_S + b\mathbf{u}_S) - \mathbf{X}^n_S(\boldsymbol{\alpha}^*_S),$$

and rewrite q as

$$\begin{aligned} q = \min_{\mathbf{u}_S} \big[&\mathbf{u}_S^\top \mathbf{D}^n_{SS}(\boldsymbol{\alpha}^*_S)\mathbf{u}_S + n^{-1}\|\mathbf{u}_S^\top \mathbf{X}^n_S(\boldsymbol{\alpha}^*_S)\|_2^2 + n^{-1}\|\mathbf{u}_S^\top \Delta \mathbf{X}^n_S\|_2^2 + \mathbf{u}_S^\top \Delta \mathbf{D}^n_{SS}\mathbf{u}_S \\ &+ 2n^{-1}\langle \mathbf{u}_S^\top \mathbf{X}^n_S(\boldsymbol{\alpha}^*_S), \mathbf{u}_S^\top \Delta \mathbf{X}^n_S \rangle \big]. \end{aligned}$$

Next, we use dependency condition,

$$q \geq C_{\min} B^2 - \max_{\mathbf{u}_S} |\underbrace{\mathbf{u}_S^\top \Delta \mathbf{D}^n_{SS}\mathbf{u}_S}_{T_1}| - \max_{\mathbf{u}_S} 2|\underbrace{n^{-1}\langle \mathbf{u}_S^\top \mathbf{X}^n_S(\boldsymbol{\alpha}^*_S), \mathbf{u}_S^\top \Delta \mathbf{X}^n_S \rangle}_{T_2}|,$$

and proceed to bound T_1 and T_2 separately. First, we bound T_1 using the Lipschitz condition,

$$|T_1| = |\sum_{k \in S} u_k^2 [\mathbf{D}^n_k(\boldsymbol{\alpha}^*_S + b\mathbf{u}_S) - \mathbf{D}^n_k(\boldsymbol{\alpha}^*_S)]| \leq \sum_{k \in S} u_k^2 k_2 \|b\mathbf{u}_S\|_2 \leq k_2 B^3.$$

Then, we use the dependency condition, the Lipschitz condition and the Cauchy-Schwartz inequality to bound T_2,

$$\begin{aligned} T_2 &\leq \frac{1}{\sqrt{n}}\|\mathbf{u}_S^\top \mathbf{X}^n_S(\boldsymbol{\alpha}^*_S)\|_2 \frac{1}{\sqrt{n}}\|\mathbf{u}_S^\top \Delta \mathbf{X}^n_S\|_2 \leq \sqrt{C_{\max}} B \frac{1}{\sqrt{n}}\|\mathbf{u}_S^\top \Delta \mathbf{X}^n_S\|_2 \\ &\leq \sqrt{C_{\max}} B \|\mathbf{u}_S\|_2 \frac{1}{\sqrt{n}}|\|\Delta \mathbf{X}^n_S\||_2 \leq \sqrt{C_{\max}} B^2 k_1 \|b\mathbf{u}_S\|_2 \\ &\leq k_1 \sqrt{C_{\max}} B^3, \end{aligned}$$

where we note that applying the Lipschitz condition implies assuming $B < \frac{\alpha_{min}}{2}$. Next, we incorporate the bounds of T_1 and T_2 to lower bound q,

$$q \geq C_{\min} B^2 - (k_2 + 2k_1\sqrt{C_{\max}})B^3. \quad (28)$$

Now, we set $B = K\lambda_n\sqrt{d}$, where K is a constant that we will set later in the proof, and select the regularization parameter λ_n to satisfy

$$\lambda_n \sqrt{d} \leq \frac{C_{\min}}{2K(k_2 + 2k_1\sqrt{C_{\max}})}. \quad (29)$$

Then,

$$\begin{aligned} G(\mathbf{u}_S) &\geq -4^{-1}\lambda_n\sqrt{d}B + 0.5C_{\min}B^2 - \lambda_n\sqrt{d}B \geq B(0.5C_{\min}B - 1.25\lambda_n\sqrt{d}) \\ &\geq B(0.5C_{\min}K\lambda_n\sqrt{d} - 1.25\lambda_n\sqrt{d}). \end{aligned}$$

In the last step, we set the constant $K = 3C^{-1}_{\min}$, and we have

$$G(\mathbf{u}_S) \geq 0.25\lambda_n\sqrt{d} > 0,$$

as long as

$$\begin{aligned} \sqrt{d}\lambda_n &\leq \frac{C^2_{\min}}{6(k_2 + 2k_1\sqrt{C_{\max}})} \\ \alpha^*_{\min} &\geq \frac{6\lambda_n\sqrt{d}}{C_{\min}}. \end{aligned}$$

Finally, convexity of $G(\mathbf{u}_S)$ yields

$$\|\hat{\boldsymbol{\alpha}}_S - \boldsymbol{\alpha}^*_S\|_2 \leq 3\lambda_n\sqrt{d}/C_{\min} \leq \frac{\alpha^*_{\min}}{2}.$$

12.6 Proof of Lemma 5

Define $z^c_j = [\nabla g(\mathbf{t}^c; \boldsymbol{\alpha}^*)]_j$ and $z_j = \frac{1}{n}\sum_c z^c_j$. Now, using the KKT conditions and condition 4 (Boundedness), we have that $\mu^*_j = \mathbb{E}_c\{z^c_j\}$ and $|z^c_j| \leq k_3$, respectively. Thus, Hoeffding's inequality yields

$$P\left(|z_j - \mu^*_j| > \frac{\lambda_n \varepsilon}{4(2-\varepsilon)}\right) \leq 2\exp\left(-\frac{n\lambda_n^2\varepsilon^2}{32k_3^2\,(2-\varepsilon)^2}\right),$$

and then,

$$P\left(\|\boldsymbol{z} - \boldsymbol{\mu}^*\|_\infty > \frac{\lambda_n \varepsilon}{4(2-\varepsilon)}\right) \leq 2\exp\left(-\frac{n\lambda_n^2\varepsilon^2}{32k_3^2\,(2-\varepsilon))^2} + \log p\right).$$

12.7 Proof of Lemma 6

We start by factorizing the Hessian matrix, using Eq. 5,

$$R_j^n = \left[\nabla^2 \ell^n(\bar{\boldsymbol{\alpha}}_j) - \nabla^2 \ell^n(\boldsymbol{\alpha}^*)\right]_j^\top (\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}^*) = \omega_j^n + \delta_j^n,$$

where,

$$\begin{aligned}
\omega_j^n &= \left[\mathbf{D}^n(\bar{\boldsymbol{\alpha}}_j) - \mathbf{D}^n(\boldsymbol{\alpha}^*)\right]_j^\top (\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}^*) \\
\delta_j^n &= \frac{1}{n} \boldsymbol{V}_j^n (\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}^*) \\
\boldsymbol{V}_j^n &= [\mathbf{X}^n(\bar{\boldsymbol{\alpha}}_j)]_j \mathbf{X}^n(\bar{\boldsymbol{\alpha}}_j)^\top - [\mathbf{X}^n(\boldsymbol{\alpha}^*)]_j \mathbf{X}^n(\boldsymbol{\alpha}^*)^\top.
\end{aligned}$$

Next, we proceed to bound each term separately. Since $[\bar{\boldsymbol{\alpha}}_j]_S = \theta_j \hat{\boldsymbol{\alpha}}_S + (1-\theta_j)\boldsymbol{\alpha}_S^*$ where $\theta_j \in [0,1]$, and $\|\hat{\boldsymbol{\alpha}}_S - \boldsymbol{\alpha}_S^*\|_\infty \leq \frac{\alpha_{\min}^*}{2}$ (Lemma 4), it holds that $[\bar{\boldsymbol{\alpha}}_j]_S \geq \frac{\alpha_{\min}^*}{2}$. Then, we can use condition 3 (Lipschitz Continuity) to bound ω_j^n.

$$|\omega_j^n| \leq k_1 \|\bar{\boldsymbol{\alpha}}_j - \boldsymbol{\alpha}^*\|_2 \|\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}^*\|_2 \leq k_1 \theta_j \|\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}^*\|_2^2 \leq k_1 \|\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}^*\|_2^2.$$

However, bounding term δ_j^n is more difficult. Let us start by rewriting δ_j^n as follows.

$$\delta_j^n = (\boldsymbol{\Lambda}_1 + \boldsymbol{\Lambda}_2 + \boldsymbol{\Lambda}_3)(\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}^*),$$

where,

$$\begin{aligned}
\boldsymbol{\Lambda}_1 &= [\mathbf{X}^n(\boldsymbol{\alpha}^*)]_j (\mathbf{X}^n(\bar{\boldsymbol{\alpha}}_j)^\top - \mathbf{X}^n(\boldsymbol{\alpha}^*)^\top) \\
\boldsymbol{\Lambda}_2 &= \{[\mathbf{X}^n(\bar{\boldsymbol{\alpha}}_j)]_j - [\mathbf{X}^n(\boldsymbol{\alpha}^*)]_j\} (\mathbf{X}^n(\bar{\boldsymbol{\alpha}}_j)^\top - \mathbf{X}^n(\boldsymbol{\alpha}^*)^\top) \\
\boldsymbol{\Lambda}_3 &= \left([\mathbf{X}^n(\bar{\boldsymbol{\alpha}}_j)]_j - [\mathbf{X}^n(\boldsymbol{\alpha}^*)]_j\right) \mathbf{X}^n(\boldsymbol{\alpha}^*)^\top.
\end{aligned}$$

Next, we bound each term separately. For the first term, we first apply Cauchy inequality,

$$|\boldsymbol{\Lambda}_1(\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}^*)| \leq \|[\mathbf{X}^n(\boldsymbol{\alpha}^*)]_j\|_2 \times \|\|\mathbf{X}^n(\bar{\boldsymbol{\alpha}}_j)^\top - \mathbf{X}^n(\boldsymbol{\alpha}^*)^\top\|\|_2 \|\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}^*\|_2,$$

and then use condition 3 (Lipschtiz Continuity) and 4 (Boundedness),

$$|\boldsymbol{\Lambda}_1(\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}^*)| \leq n k_4 k_1 \|\bar{\boldsymbol{\alpha}}_j - \boldsymbol{\alpha}^*\|_2 \|\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}^*\|_2 \leq n k_4 k_1 \|\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}^*\|_2^2.$$

For the second term, we also start by applying Cauchy inequality,

$$|\boldsymbol{\Lambda}_2(\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}^*)| \leq \|[\mathbf{X}^n(\bar{\boldsymbol{\alpha}}_j)]_j - [\mathbf{X}^n(\boldsymbol{\alpha}^*)]_j\|_2 \times \|\|\mathbf{X}^n(\bar{\boldsymbol{\alpha}}_j)^\top - \mathbf{X}^n(\boldsymbol{\alpha}^*)^\top\|\|_2 \|\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}^*\|_2,$$

and then use condition 3 (Lipschtiz Continuity),

$$|\boldsymbol{\Lambda}_2(\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}^*)| \leq n k_1^2 \|\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}^*\|_2^2.$$

Last, for third term, once more we start by applying Cauchy inequality,

$$|\boldsymbol{\Lambda}_3(\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}^*)| \leq \|[\mathbf{X}^n(\bar{\boldsymbol{\alpha}}_j)]_j - [\mathbf{X}^n(\boldsymbol{\alpha}^*)]_j\|_2 \times \|\|\mathbf{X}^n(\boldsymbol{\alpha}^*)^\top\|\|_2 \|\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}^*\|_2,$$

and then apply condition 1 (Dependency Condition) and condition 3 (Lipschitz Continuity),

$$|\boldsymbol{\Lambda}_3(\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}^*)| \leq n k_1 \sqrt{C_{\max}} \|\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}^*\|_2^2$$

Now, we combine the bounds,

$$\|\boldsymbol{R}^n\|_\infty \leq K \|\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}^*\|_2^2,$$

where

$$K = k_1 + k_4 k_1 + k_1^2 + k_1 \sqrt{C_{\max}}.$$

Finally, using Lemma 4 and selecting the regularization parameter λ_n to satisfy $\lambda_n d \leq C_{\min}^2 \frac{\varepsilon}{36K(2-\varepsilon)}$ yields:

$$\frac{\|\boldsymbol{R}^n\|_\infty}{\lambda_n} \leq \frac{3K\lambda_n d}{C_{\min}^2} \leq \frac{\varepsilon}{4(2-\varepsilon)}$$

12.8 Proof of Lemma 7

We will first bound the difference in terms of nuclear norm between the population Fisher information matrix $\mathcal{Q}_{SS}$ and the sample mean cascade log-likelihood $\mathcal{Q}_{SS}^n$. Define $z_{jk}^c = [\nabla^2 g(\mathbf{t}^c; \boldsymbol{\alpha}^*) - \nabla^2 \ell^n(\boldsymbol{\alpha}^*)]_{jk}$ and $z_{jk} = \frac{1}{n}\sum_{c=1}^n z_{jk}^c$. Then, we can express the difference between the population Fisher information matrix $\mathcal{Q}_{SS}$ and the sample mean cascade log-likelihood $\mathcal{Q}_{SS}^n$ as:

$$|\|\mathcal{Q}_{SS}^n(\boldsymbol{\alpha}^*) - \mathcal{Q}_{SS}^*(\boldsymbol{\alpha}^*)\|\|_2 \leq |\|\mathcal{Q}_{SS}^n(\boldsymbol{\alpha}^*) - \mathcal{Q}_{SS}^*(\boldsymbol{\alpha}^*)\|\|_F = \sqrt{\sum_{j=1}^d \sum_{k=1}^d (z_{ik})^2}.$$

Since $|z_{jk}^{(c)}| \leq 2k_5$ by condition 4, we can apply Hoeffding's inequality to each z_{jk},

$$P(|z_{jk}| \geq \beta) \leq 2\exp\left(-\frac{\beta^2 n}{8k_5^2}\right), \tag{30}$$

and further,

$$P(|\|\mathcal{Q}_{SS}^n(\boldsymbol{\alpha}^*) - \mathcal{Q}_{SS}^*(\boldsymbol{\alpha}^*)\|\|_2 \geq \delta) \leq 2\exp\big(-K\frac{\delta^2 n}{d^2} + 2\log d\big) \tag{31}$$

where $\beta^2 = \delta^2/d^2$. Now, we bound the maximum eigenvalue of $\mathcal{Q}_{SS}^n$ as follows:

$$\begin{aligned}
\Lambda_{\max}(\mathcal{Q}_{SS}^n) &= \max_{\|x\|_2=1} x^\top \mathcal{Q}_{SS}^n x = \max_{\|x\|_2=1} \{x^\top \mathcal{Q}_{SS}^* x + x^\top (\mathcal{Q}_{SS}^n - \mathcal{Q}_{SS}^*) x\} \\
&\leq y^\top \mathcal{Q}_{SS}^* y + y^\top (\mathcal{Q}_{SS}^n - \mathcal{Q}_{SS}^*) y,
\end{aligned}$$

where y is unit-norm maximal eigenvector of $\mathcal{Q}_{SS}^*$. Therefore,

$$\Lambda_{\max}(\mathcal{Q}_{SS}^n) \leq \Lambda_{\max}(\mathcal{Q}_{SS}^*) + |\|\mathcal{Q}_{SS}^n - \mathcal{Q}_{SS}^*\|\|_2,$$

and thus,

$$P\big(\Lambda_{\max}(\mathcal{Q}_{SS}^n) \geq C_{\max} + \delta\big) \leq \exp\left(-K\frac{\delta^2 n}{d^2} + 2\log d\right).$$

Reasoning in a similar way, we bound the minimum eigenvalue of $\mathcal{Q}_{SS}^n$:

$$P\big(\Lambda_{\min}(\mathcal{Q}_{SS}^n) \leq C_{\min} - \delta\big) \leq \exp\left(-K\frac{\delta^2 n}{d^2} + 2\log d\right)$$

12.9 Proof of Lemma 8

We start by decomposing $\mathcal{Q}_{S^cS}^n(\boldsymbol{\alpha}^*)(\mathcal{Q}_{S^cS}^n(\boldsymbol{\alpha}^*))^{-1}$ as follows:

$$\mathcal{Q}_{S^cS}^n(\boldsymbol{\alpha}^*)(\mathcal{Q}_{S^cS}^n(\boldsymbol{\alpha}^*))^{-1} = A_1 + A_2 + A_3 + A_4,$$

where,

$$A_1 = \mathcal{Q}^*_{S^cS}[(\mathcal{Q}^n_{S^cS})^{-1} - (\mathcal{Q}^*_{S^cS})^{-1}],$$
$$A_2 = [\mathcal{Q}^n_{S^cS} - \mathcal{Q}^*_{S^cS}][(\mathcal{Q}^n_{S^cS})^{-1} - (\mathcal{Q}^*_{S^cS})^{-1}]$$
$$A_3 = [\mathcal{Q}^n_{S^cS} - \mathcal{Q}^*_{S^cS}](\mathcal{Q}^*_{SS})^{-1},$$
$$A_4 = \mathcal{Q}^*_{S^cS}(\mathcal{Q}^*_{SS})^{-1},$$

$\mathcal{Q}^* = \mathcal{Q}^*(\boldsymbol{\alpha}^*)$ and $\mathcal{Q}^n = \mathcal{Q}^n(\boldsymbol{\alpha}^*)$. Now, we bound each term separately. The fourth term, A_4, is the easiest to bound, using simply the incoherence condition:

$$|||A_4|||_\infty \leq 1 - \varepsilon.$$

To bound the other terms, we need the following lemma:

Lemma 11 *For any $\delta \geq 0$ and constants K and K', the following bounds hold:*

$$P[|||\mathcal{Q}^n_{S^cS} - \mathcal{Q}^*_{S^cS}|||_\infty \geq \delta] \leq 2\exp\left(-K\frac{n\delta^2}{d^2} + \log d + log(p-d)\right) \tag{32}$$

$$P[|||\mathcal{Q}^n_{SS} - \mathcal{Q}^*_{SS}|||_\infty \geq \delta] \leq 2\exp\left(-K\frac{n\delta^2}{d^2} + 2\log d\right) \tag{33}$$

$$P[|||(\mathcal{Q}^n_{SS})^{-1} - (\mathcal{Q}^*_{SS})^{-1}|||_\infty \geq \delta] \leq 4\exp\left(-K\frac{n\delta}{d^3} - K'\log d\right) \tag{34}$$

Proof We start by proving the first confidence interval. By definition of infinity norm of a matrix, we have:

$$P[|||\mathcal{Q}^n_{S^cS} - \mathcal{Q}^*_{S^cS}|||_\infty \geq \delta] = P\big[\max_{j\in S^c}\sum_{k\in S}|z_{jk}| \geq \delta\big] \leq (p-d)P\big[\sum_{k\in S}|z_{jk}| \geq \delta\big],$$

where $z_{jk} = [\mathcal{Q}^n - \mathcal{Q}^*]_{jk}$ and, for the last inequality, we used the union bound and the fact that $|S^c| \leq p - d$. Furthermore,

$$P\big[\sum_{k\in S}|z_{jk}| \geq \delta\big] \leq P[\exists k \in S||z_{jk}| \geq \delta/d] \leq dP[|z_{jk}| \geq \delta/d].$$

Thus,

$$P[|||\mathcal{Q}^n_{S^cS} - \mathcal{Q}^*_{S^cS}|||_\infty \geq \delta] \leq (p-d)dP[|z_{jk}| \geq \delta/d].$$

At this point, we can obtain the first confidence bound by using Eq. 30 with $\beta = \delta/d$ in the above equation. The proof of the second confidence bound is very similar and we omit it for brevity. To prove the last confidence bound, we proceed as follows:

$$\begin{aligned}
|||(\mathcal{Q}^n_{SS})^{-1} - (\mathcal{Q}^*_{SS})^{-1}|||_\infty &= |||(\mathcal{Q}^n_{SS})^{-1}[\mathcal{Q}^n_{SS} - \mathcal{Q}^*_{SS}](\mathcal{Q}^*_{SS})^{-1}|||_\infty \\
&\leq \sqrt{d}|||(\mathcal{Q}^n_{SS})^{-1}[\mathcal{Q}^n_{SS} - \mathcal{Q}^*_{SS}](\mathcal{Q}^*_{SS})^{-1}|||_2 \\
&\leq \sqrt{d}|||(\mathcal{Q}^n_{SS})^{-1}|||_2|||\mathcal{Q}^n_{SS} - \mathcal{Q}^*_{SS}|||_2|||(\mathcal{Q}^*_{SS})^{-1}|||_2 \\
&\leq \frac{\sqrt{d}}{C_{\min}}|||\mathcal{Q}^n_{SS} - \mathcal{Q}^*_{SS}|||_2|||(\mathcal{Q}^n_{SS})^{-1}|||_2.
\end{aligned}$$

Next, we bound each term of the final expression in the above equation separately. The first term can be bounded using Eq. 31:

$$P\left[|||\mathcal{Q}^n_{SS} - \mathcal{Q}^*_{SS}|||_2 \geq \frac{C^2_{min}\delta}{2\sqrt{d}}\right] \leq 2\exp\left(-K\frac{n\delta^2}{d^3} + 2\log d\right),$$

The second term can be bounded using Lemma 6:

$$P\left[|||(\mathcal{Q}^n_{SS})^{-1}|||_2 \geq \frac{2}{C_{\min}}\right] = P\left[\Lambda_{\min}(\mathcal{Q}^n_{SS}) \leq \frac{C_{\min}}{2}\right] \leq \exp\left(-K\frac{n}{d^2} + B\log d\right).$$

Then, the third confidence bound follows. ■

Control of A_1. We start by rewriting the term A_1 as

$$A_1 = \mathcal{Q}^*_{S^cS}(\mathcal{Q}^*_{SS})^{-1}[(\mathcal{Q}^*_{SS}) - (\mathcal{Q}^n_{SS})](\mathcal{Q}^n_{SS})^{-1},$$

and further,

$$|||A_1|||_\infty \leq |||\mathcal{Q}^*_{S^cS}(\mathcal{Q}^*_{SS})^{-1}|||_\infty \times |||(\mathcal{Q}^*_{SS}) - (\mathcal{Q}^n_{SS})|||_\infty|||(\mathcal{Q}^n_{SS})^{-1}|||_\infty.$$

Next, using the incoherence condition easily yields:

$$|||A_1|||_\infty \leq (1-\varepsilon)|||(\mathcal{Q}^*_{SS}) - (\mathcal{Q}^n_{SS})|||_\infty \times \sqrt{d}|||(\mathcal{Q}^n_{SS})^{-1}|||_2$$

Now, we apply Lemma 6 with $\delta = C_{\min}/2$ to have that $|||(\mathcal{Q}^n_{SS})^{-1}|||_2 \leq \frac{2}{C_{\min}}$ with probability greater than $1 - \exp(-Kn/d^2 + K'\log d)$, and then use Eq. 34 with $\delta = \frac{\varepsilon C_{\min}}{12\sqrt{d}}$ to conclude that

$$P\left[|||A_1|||_\infty \geq \frac{\varepsilon}{6}\right] \leq 2\exp\left(-K\frac{n}{d^3} + K'\log d\right).$$

Control of A_2. We rewrite the term A_2 as

$$|||A_2|||_\infty \leq |||\mathcal{Q}^n_{S^cS} - \mathcal{Q}^*_{S^cS}|||_\infty|||(\mathcal{Q}^n_{SS})^{-1} - (\mathcal{Q}^*_{SS})^{-1}|||_\infty,$$

and then use Eqs. 32 and 33 with $\delta = \sqrt{\varepsilon/6}$ to conclude that

$$P\left[|||A_2|||_\infty \geq \frac{\varepsilon}{6}\right] \leq 4\exp\left(-K\frac{n}{d^3} + \log(p-d) + K'\log p\right).$$

Control of A_3. We rewrite the term A_3 as

$$|||A_3|||_\infty = \sqrt{d}|||(\mathcal{Q}^*_{SS})^{-1}|||_2|||\mathcal{Q}^n_{S^cS} - \mathcal{Q}^*_{S^cS}|||_\infty \leq \frac{\sqrt{d}}{C_{\min}}|||\mathcal{Q}^n_{S^cS} - \mathcal{Q}^*_{S^cS}|||_\infty.$$

We then apply Eq. 32 with $\delta = \frac{\varepsilon C_{\min}}{6\sqrt{d}}$ to conclude that

$$P\left[|||A_3|||_\infty \geq \frac{\varepsilon}{6}\right] \leq \exp\left(-K\frac{n}{d^3} + \log(p-d)\right),$$

and thus,

$$P\left[|||\mathcal{Q}^n_{S^cS}(\mathcal{Q}^n_{SS})^{-1}|||_\infty \geq 1 - \frac{\varepsilon}{2}\right] = \mathcal{O}\left(\exp(-K\frac{n}{d^3} + \log p)\right).$$

Abstract

Semi-metric labeling is a special case of energy minimization for pairwise Markov random fields. The energy function consists of arbitrary unary potentials, and pairwise potentials that are proportional to a given semi-metric distance function over the label set. Popular methods for solving semi-metric labeling include (i) move-making algorithms, which iteratively solve a minimum st-cut problem; and (ii) the linear programming (LP) relaxation based approach. In order to convert the fractional solution of the LP relaxation to an integer solution, several randomized rounding procedures have been developed in the literature. We consider a large class of parallel rounding procedures, and design move-making algorithms that closely mimic them. We prove that the multiplicative bound of a move-making algorithm exactly matches the approximation factor of the corresponding rounding procedure for any arbitrary distance function. Our analysis includes all known results for move-making algorithms as special cases.

Keywords: semi-metric labeling, move-making algorithms, linear programming relaxation, multiplicative bounds

1. Introduction

A Markov random field (MRF) is a graph whose vertices are random variables, and whose edges specify a neighborhood over the random variables. Each random variable can be assigned a value from a set of labels, resulting in a labeling of the MRF. The putative labelings of an MRF are quantitatively distinguished from each other by an energy function, which is the sum of potential functions that depend on the cliques of the graph. An important optimization problem associate with the MRF framework is energy minimization, that is, finding a labeling with the minimum energy.

Semi-metric labeling is a special case of energy minimization, which models several useful low-level vision tasks (Boykov et al., 1998, 1999; Szeliski et al., 2008). It is characterized by a finite, discrete label set and a semi-metric distance function over the labels. The energy function in semi-metric labeling consists of arbitrary unary potentials and pairwise potentials that are proportional to the distance between the labels assigned to them. The problem is known to be NP-hard (Veksler, 1999). Two popular approaches for semi-metric labeling are: (i) move-making algorithms (Boykov et al., 1999; Gupta and Tardos, 2000; Kumar and Koller, 2009; Kumar and Torr, 2008; Veksler, 2007), which iteratively improve the labeling by solving a minimum st-cut problem; and (ii) linear programming (LP) relaxation (Chekuri et al., 2001; Koster et al., 1998; Schlesinger, 1976; Wainwright et al., 2005), which is obtained by dropping the integral constraints in the corresponding integer programming formulation. Move-making algorithms are very efficient due to the availability of fast minimum st-cut solvers (Boykov and Kolmogorov, 2004) and are very popular in the computer vision community. In contrast, the LP relaxation is significantly slower, despite the development of several specialized solvers (Globerson and Jaakkola, 2007; Hazan and Shashua, 2008; Kolmogorov, 2006; Komodakis et al., 2007; Ravikumar et al., 2008; Tarlow et al., 2011; Wainwright et al., 2005; Weiss et al., 2007; Werner, 2007, 2010). However, when used in conjunction with randomized rounding algorithms, the LP relaxation provides the best known polynomial-time theoretical guarantees for semi-metric labeling (Archer et al., 2004; Chekuri et al., 2001; Kleinberg and Tardos, 1999).

At first sight, the difference between move-making algorithms and the LP relaxation appears to be the standard accuracy vs. speed trade-off. However, we prove that, for any arbitrary semi-metric distance function, it is possible to design move-making algorithms that match the theoretical guarantees of a large class of randomized rounding procedures, which we call parallel rounding. Our proofs are constructive, which allows us to test the rounding-based move-making algorithms empirically. Our experimental results confirm that rounding-based moves provide similar accuracy to the LP relaxation while being significantly faster.

2. Related Work

As our work is concerned with only semi-metric labeling, we will focus on the related work for this special case of energy minimization. For a more general survey, we refer the reader to (Wang et al., 2013), and for a thorough empirical comparison of the various algorithms we refer the reader to (Kappes et al., 2015; Szeliski et al., 2008).

The earliest known theoretical guarantee of a move-making algorithm was provided by Veksler (1999), who presented an analysis of the popular expansion move-making algorithm. The analysis showed that the expansion algorithm and the parallel rounding procedure of Kleinberg and Tardos (1999) provide matching guarantees for the uniform distance function. Komodakis et al. (2008) also proposed a move-making algorithm based on the primal-dual scheme of optimizing the LP relaxation. The resulting algorithm is similar to the expansion algorithm in terms of its theoretical guarantees, but provides a principled formulation for improving its efficiency in dynamic settings. Despite the existing analysis of expansion-like algorithms, parallel rounding procedures (Chekuri et al., 2001; Kleinberg and Tardos, 1999) are known to perform better for several distance functions of interest such as the truncated linear distance, the truncated quadratic distance, and the hierarchically well-separated tree (HST) metric.

Kumar and Torr (2008) proposed the range expansion move-making algorithm that matches the guarantees of the rounding procedure of Chekuri et al. (2001) for the truncated linear and quadratic distance. Kumar and Koller (2009) proposed a hierarchical move-making algorithm that matches the guarantees of the rounding procedure of Kleinberg and Tardos (1999) for the HST metric. However, their analysis is restricted to special cases of semi-metric labeling, whereas our work does not make

any assumptions on the form of the semi-metric distance function. We note that, recently, a more general algorithm has also been proposed for non-convex priors (Ajanthan et al., 2014). However, this generalized algorithm does not provide any strong theoretical gurantees on the quality of the solution, which is the key focus of our work.

While our analysis focuses on parallel rounding, it is also worth noting that Archer et al. (2004) have proposed a serial rounding procedure for metric labeling (which is a special case of semi-metric labeling where the distance function also satisfies the triangular inequality property). The theoretical guarantee of serial rounding depends on the *tree decomposibility* of a distance function. Given an MRF with n random variables, the tree decomposibility for any metric distance function is guaranteed to be less than or equal to $O(\log n)$. This worst-case theoretical guarantee of $O(\log n)$ over all metric distance functions can be matched by a mixture-of-tree algorithm that can be derived form the work of Andrew et al. (2011). Specifically, Andrew et al. (2011) describe an approximate algorithm for capacitated metric labeling that builds on the cut-based decomposition method of Racke (2008). Ignoring the capacity constraints, which are not present in the standard metric labeling problem, results in an approximation of the original MRF using an $O(m \log n)$ mixture of tree-structured MRFs. Here, m is the number of edges in the MRF, and n is the number of random variables. Solving the metric labeling problem over each tree-structured MRF optimally using belief propagation (Pearl, 1998), and choosing the best labeling in terms of the original problem, provides the $O(\log n)$ guarantee. We refer the reader to (Andrew et al., 2011) for details.

Note that while the mixture-of-tree algorithm provides matching worst-case guarantees to serial rounding, it does not provide a matching guarantee for a given distance function. In other words, the guarantee of the mixture-of-tree algorithm does not depend on the tree decomposibility of the distance function. The existence or the impossibility of a matching combinatorial algorithm for serial rounding remains an open question.

3. Our Contributions

Our paper can be thought of as a generalization of (Kumar and Koller, 2009; Kumar and Torr, 2008; Veksler, 1999). Indeed, the move-making algorithms proposed in this paper are simple extensions of the expansion, the range expansion and the hierarchical move-making algorithms. The novelty of our work lies in our analysis, which improves on the state of the art in two significant aspects. First, we do not place any assumptions on the form of the distance function except that it is a semi-metric distance. This is in contrast to previous works that only focus on special cases such as the uniform metric, the truncated convex models or the HST metric. Second, we show that the matching guarantees provided by our move-making algorithms and the parallel rounding procedures are *tight*, that is, they cannot be improved through a more careful analysis.

A preliminary version of this article has appeared as (Kumar, 2014). There are two significant differences between the preliminary version and the current paper. First, we provide detailed proofs of all the theorems, which were omitted from the preliminary version due to a lack of space. Second, we provide an experimental comparison of the rounding-based move-making algorithms with the state of the art methods for semi-metric labeling, including those that are directly related to the LP relaxation such as TRW-S (Kolmogorov, 2006), and those that are indirectly related to the LP relaxation such as (Andrew et al., 2011).

Finally, we note that since the publication of the preliminary version, we have also extended rounding-based move-making algorithms to special cases of high-order potentials. This includes the

interval move-making algorithm for truncated max-of-convex potentials (Pansari and Kumar, 2015) and the hierarchical move-making algorithm for parsimonious labeling (Dokania and Kumar, 2015).

4. Preliminaries

4.1 Semi-metric Labeling

The problem of semi-metric labeling is defined over an undirected graph $\mathbf{G} = (\mathbf{X}, \mathbf{E})$. The vertices $\mathbf{X} = \{X_1, X_2, \cdots, X_n\}$ are random variables, and the edges $\mathbf{E}$ specify a neighborhood relationship over the random variables. Each random variable can be assigned a value from the label set $\mathbf{L} = \{l_1, l_2, \cdots, l_h\}$. We assume that we are also provided with a semi-metric distance function $d : \mathbf{L} \times \mathbf{L} \rightarrow \mathbb{R}^+$ over the labels. Recall that a semi-metric distance function satisfies the following properties: $d(l_i, l_j) \geq 0$ for all $l_i, l_j \in \mathbf{L}$, and $d(l_i, l_j) = 0$ if and only if $i = j$. Furthermore, a distance function is said to be metric if, in addition to the above condition, it also satisfies the triangular inequality, that is, $d(l_i, l_j) + d(l_j, l_k) \geq d(l_i, l_k)$ for all $l_i, l_j, l_k \in \mathbf{L}$.

We refer to an assignment of values to all the random variables as a labeling. In other words, a labeling is a vector $\mathbf{x} \in \mathbf{L}^n$, which specifies the label x_a assigned to each random variable X_a. The h^n different labelings are quantitatively distinguished from each other by an energy function $Q(\mathbf{x})$, which is defined as follows:

$$Q(\mathbf{x}) = \sum_{X_a \in \mathbf{X}} \theta_a(x_a) + \sum_{(X_a, X_b) \in \mathbf{E}} w_{ab} d(x_a, x_b).$$

Here, the unary potentials $\theta_a(\cdot)$ are arbitrary, and the edge weights w_{ab} are non-negative. Semi-metric labeling requires us to find a labeling with the minimum energy. It is known to be NP-hard.

4.2 Multiplicative Bound

As semi-metric labeling plays a central role in low-level vision, several approximate algorithms have been proposed in the literature. A common theoretical measure of accuracy for an approximate algorithm is the multiplicative bound. In this work, we are interested in the multiplicative bound of an algorithm with respect to a distance function. Formally, given a distance function d, the multiplicative bound of an algorithm is said to be B if the following condition is satisfied for all possible values of unary potentials $\theta_a(\cdot)$ and non-negative edge weights w_{ab}:

$$\sum_{X_a \in \mathbf{X}} \theta_a(\hat{x}_a) + \sum_{(X_a, X_b) \in \mathbf{E}} w_{ab} d(\hat{x}_a, \hat{x}_b) \leq \sum_{X_a \in \mathbf{X}} \theta_a(x^*_a) + B \sum_{(X_a, X_b) \in \mathbf{E}} w_{ab} d(x^*_a, x^*_b). \quad (1)$$

Here, $\hat{\mathbf{x}}$ is the labeling estimated by the algorithm for the given values of unary potentials and edge weights, and $\mathbf{x}^*$ is an optimal labeling. Multiplicative bounds are greater than or equal to 1, and are invariant to reparameterizations of the unary potentials. A multiplicative bound B is said to be tight if the above inequality holds as an equality for some value of unary potentials and edge weights.

4.3 Linear Programming Relaxation

An overcomplete representation of a labeling can be specified using the following variables: (i) unary variables $y_a(i) \in \{0, 1\}$ for all $X_a \in \mathbf{X}$ and $l_i \in \mathbf{L}$ such that $y_a(i) = 1$ if and only if X_a is assigned the label l_i; and (ii) pairwise variables $y_{ab}(i, j) \in \{0, 1\}$ for all $(X_a, X_b) \in \mathbf{E}$ and $l_i, l_j \in \mathbf{L}$ such

that $y_{ab}(i,j) = 1$ if and only if X_a and X_b are assigned labels l_i and l_j respectively. This allows us to formulate semi-metric labeling as follows:

$$\begin{aligned}
\min_{\mathbf{y}} \quad & \sum_{X_a \in \mathbf{X}} \sum_{l_i \in \mathbf{L}} \theta_a(l_i) y_a(i) + \sum_{(X_a,X_b) \in \mathbf{E}} \sum_{l_i,l_j \in \mathbf{L}} w_{ab} d(l_i,l_j) y_{ab}(i,j), \\
\text{s.t.} \quad & \sum_{l_i \in \mathbf{L}} y_a(i) = 1, \forall X_a \in \mathbf{X}, \\
& \sum_{l_j \in \mathbf{L}} y_{ab}(i,j) = y_a(i), \forall (X_a,X_b) \in \mathbf{E}, l_i \in \mathbf{L}, \\
& \sum_{l_i \in \mathbf{L}} y_{ab}(i,j) = y_b(j), \forall (X_a,X_b) \in \mathbf{E}, l_j \in \mathbf{L}, \\
& y_a(i) \in \{0,1\}, y_{ab}(i,j) \in \{0,1\}, \forall X_a \in \mathbf{X}, (X_a,X_b) \in \mathbf{E}, l_i, l_j \in \mathbf{L}.
\end{aligned}$$

The first set of constraints ensures that each random variables is assigned exactly one label. The second and third sets of constraints ensure that, for binary optimization variables, $y_{ab}(i,j) = y_a(i) y_b(j)$. By relaxing the final set of constraints such that the optimization variables can take any value between 0 and 1 inclusive, we obtain a linear program (LP). The computational complexity of solving the LP relaxation is polynomial in the size of the problem.

4.4 Rounding Procedure

In order to prove theoretical guarantees of the LP relaxation, it is common to use a rounding procedure that can covert a feasible fractional solution $\mathbf{y}$ of the LP relaxation to a feasible integer solution $\hat{\mathbf{y}}$ of the integer linear program. Several rounding procedures have been proposed in the literature. In this work, we focus on the randomized parallel rounding procedures proposed by Chekuri et al. (2001) and Kleinberg and Tardos (1999). These procedures have the property that, given a fractional solution $\mathbf{y}$, the probability of assigning a label $l_i \in \mathbf{L}$ to a random variable $X_a \in \mathbf{X}$ is equal to $y_a(i)$, that is,

$$\Pr(\hat{y}_a(i) = 1) = y_a(i). \tag{2}$$

We will describe the various rounding procedures in detail in Sections 5-7. For now, we would like to note that our reason for focusing on the parallel rounding of Chekuri et al. (2001) and Kleinberg and Tardos (1999) is that they provide the best known polynomial-time theoretical guarantees for semi-metric labeling. Specifically, we are interested in their approximation factor, which is defined next.

4.5 Approximation Factor

Given a distance function d, the approximation factor for a rounding procedure is said to be F if the following condition is satisfied for all feasible fractional solutions $\mathbf{y}$:

$$\mathbb{E}\left(\sum_{l_i,l_j \in \mathbf{L}} d(l_i,l_j) \hat{y}_a(i) \hat{y}_b(j) \right) \leq F \sum_{l_i,l_j \in \mathbf{L}} d(l_i,l_j) y_{ab}(i,j). \tag{3}$$

Here, $\hat{\mathbf{y}}$ refers to the integer solution, and the expectation is taken with respect to the randomized rounding procedure applied to the feasible solution $\mathbf{y}$.

Given a rounding procedure with an approximation factor of F, an optimal fractional solution $\mathbf{y}^*$ of the LP relaxation can be rounded to a labeling $\hat{\mathbf{y}}$ that satisfies the following condition:

$$\begin{aligned}
& \mathbb{E}\left(\sum_{X_a \in \mathbf{X}} \sum_{l_i \in \mathbf{L}} \theta_a(l_i) \hat{y}_a(i) + \sum_{(X_a,X_b) \in \mathbf{E}} \sum_{l_i,l_j \in \mathbf{L}} w_{ab} d(l_i,l_j) \hat{y}_a(i) \hat{y}_b(j) \right) \\
\leq & \sum_{X_a \in \mathbf{X}} \sum_{l_i \in \mathbf{L}} \theta_a(l_i) y^*_a(i) + F \sum_{(X_a,X_b) \in \mathbf{E}} \sum_{l_i,l_j \in \mathbf{L}} w_{ab} d(l_i,l_j) y^*_{ab}(i,j).
\end{aligned}$$

The above inequality follows directly from properties (2) and (3). Similar to multiplicative bounds, approximation factors are always greater than or equal to 1, and are invariant to reparameterizations of the unary potentials. An approximation factor F is said to be tight if the above inequality holds as an equality for some value of unary potentials and edge weights.

Approximation factors are closely linked to the integrality gap of the LP relaxation (roughly speaking, the ratio of the optimal value of the integer linear program to the optimal value of the relaxation), which in turn is related to the computational hardness of the semi-metric labeling problem (Manokaran et al., 2008). However, establishing the integrality gap of the LP relaxation for a given distance function is beyond the scope of this work. We are only interested in designing move-making algorithms whose multiplicative bounds match the approximation factors of the parallel rounding procedures.

4.6 Submodular Energy Function

We will use the following important fact throughout this paper. Given an energy function defined using arbitrary unary potentials, non-negative edge weights and a submodular distance function, an optimal labeling can be computed in polynomial time by solving an equivalent minimum st-cut problem (Flach and Schlesinger, 2006). Recall that a submodular distance function d' over a label set $\mathbf{L} = \{l_1, l_2, \cdots, l_h\}$ satisfies the following properties: (i) $d'(l_i,l_j) \geq 0$ for all $l_i, l_j \in \mathbf{L}$, and $d'(l_i,l_j) = 0$ if and only if $i = j$; and (ii) $d'(l_i,l_j) + d'(l_{i+1},l_{j+1}) \leq d'(l_i,l_{j+1}) + d'(l_{i+1},l_j)$ for all $l_i, l_j \in \mathbf{L} \backslash \{l_h\}$ (where $\backslash$ refers to set difference).

5. Complete Rounding and Complete Move

We start with a simple rounding scheme, which we call complete rounding. While complete rounding is not very accurate, it would help illustrate the flavor of our results. We will subsequently consider its generalizations, which have been useful in obtaining the best-known approximation factors for various special cases of semi-metric labeling.

The complete rounding procedure consists of a single stage where we use the set of all unary variables to obtain a labeling (as opposed to other rounding procedures discussed subsequently). Algorithm 1 describes its main steps. Intuitively, it treats the value of the unary variable $y_a(i)$ as the probability of assigning the label l_i to the random variable X_a. It obtains a labeling by sampling from all the distributions $\mathbf{y}_a = [y_a(i), \forall l_i \in \mathbf{L}]$ simultaneously using the same random number $r \in [0,1]$.

It can be shown that using a different random number to sample the distributions $\mathbf{y}_a$ and $\mathbf{y}_b$ of two neighboring random variables $(X_a, X_b) \in \mathbf{E}$ results in an infinite approximation factor. For example, let $\overline{y}_a(i) = \overline{y}_b(i) = 1/h$ for all $l_i \in \mathbf{L}$, where h is the number of labels. The pairwise variables $\overline{\mathbf{y}}_{ab}$ that minimize the energy function are $\overline{y}_{ab}(i,i) = 1/h$ and $\overline{y}_{ab}(i,j) = 0$ when $i \neq j$.

For the above feasible solution of the LP relaxation, the RHS of inequality (3) is 0 for any finite F, while the LHS of inequality (3) is strictly greater than 0 if $h > 1$. However, we will shortly show that using the same random number r for all random variables provides a finite approximation factor.

Algorithm 1 The complete rounding procedure.

input A feasible solution $\mathbf{y}$ of the LP relaxation.

1: Pick a real number r uniformly from $[0, 1]$.
2: **for all** $X_a \in \mathbf{X}$ **do**
3: Define $Y_a(0) = 0$ and $Y_a(i) = \sum_{j=1}^{i} y_a(j)$ for all $l_i \in \mathbf{L}$.
4: Assign the label $l_i \in \mathbf{L}$ to the random variable X_a if $Y_a(i-1) < r \leq Y_a(i)$.
5: **end for**

We now turn our attention to designing a move-making algorithm whose multiplicative bound matches the approximation factor of the complete rounding procedure. To this end, we modify the range expansion algorithm proposed by Kumar and Torr (2008) for truncated convex pairwise potentials to a general semi-metric distance function. Our method, which we refer to as the complete move-making algorithm, considers all putative labels of all random variables, and provides an approximate solution in a single iteration. Algorithm 2 describes its two main steps. First, it computes a submodular overestimation of the given semi-metric distance function by solving the following optimization problem:

$$\begin{aligned} \overline{d} = \quad & \operatorname*{argmin}_{d'} t \\ \text{s.t.} \quad & d'(l_i, l_j) \leq t d(l_i, l_j), \forall l_i, l_j \in \mathbf{L}, \\ & d'(l_i, l_j) \geq d(l_i, l_j), \forall l_i, l_j \in \mathbf{L}, \\ & d'(l_i, l_j) + d'(l_{i+1}, l_{j+1}) \leq d'(l_i, l_{j+1}) + d'(l_{i+1}, l_j), \forall l_i, l_j \in \mathbf{L} \backslash \{l_h\}. \end{aligned} \tag{4}$$

The above problem minimizes the maximum ratio of the estimated distance to the original distance over all pairs of labels, that is,

$$\max_{i \neq j} \frac{d'(l_i, l_j)}{d(l_i, l_j)}.$$

We will refer to the optimal value of problem (4) as the submodular distortion of the distance function d. Second, it replaces the original distance function by the submodular overestimation and computes an approximate solution to the original semi-metric labeling problem by solving a single minimum st-cut problem. Note that, unlike the range expansion algorithm (Kumar and Torr, 2008) that uses the readily available submodular overestimation of a truncated convex distance (namely, the corresponding convex distance function), our approach estimates the submodular overestimation via the LP (4). Since the LP (4) can be solved for any arbitrary distance function, it makes complete move-making more generally applicable.

The following theorem establishes the theoretical guarantees of the complete move-making algorithm and the complete rounding procedure.

Theorem 1 *The tight multiplicative bound of the complete move-making algorithm is equal to the submodular distortion of the distance function. Furthermore, the tight approximation factor of the complete rounding procedure is also equal to the submodular distortion of the distance function.*

Algorithm 2 The complete move-making algorithm.

input Unary potentials $\theta_a(\cdot)$, edge weights w_{ab}, distance function d.

1: Compute a submodular overestimation of d by solving problem (4).
2: Using the approach of Flach and Schlesinger (2006), solve the following problem via an equivalent minimum st-cut problem:

$$\hat{\mathbf{x}} = \operatorname*{argmin}_{\mathbf{x} \in \mathbf{L}^n} \sum_{X_a \in \mathbf{X}} \theta_a(x_a) + \sum_{(X_a, X_b) \in \mathbf{E}} w_{ab} \overline{d}(x_a, x_b).$$

The proof of Theorem 1 is given in Appendix A. The following corollary of the above theorem was previously stated by Chekuri et al. (2001) without a formal proof.

Corollary 2 *The complete rounding procedure is tight for submodular distance functions, that is, its approximation factor is equal to 1.*

In terms of computational complexities, complete move-making is significantly faster than solving the LP relaxation. Specifically, given an MRF with n random variables and m edges, and a label set with h labels, the LP relaxation requires at least $O(m^3 h^3 \log(m^2 h^3))$ time, since it consists of $O(mh^2)$ optimization variables and $O(mh)$ constraints. In contrast, complete move-making requires $O(nmh^3 \log(m))$ time, since the graph constructed using the method of Flach and Schlesinger (2006) consists of $O(nh)$ nodes and $O(mh^2)$ arcs. Note that complete move-making also requires us to solve the linear program (4). However, since problem (4) is independent of the unary potentials and the edge weights, it only needs to be solved once beforehand in order to compute the approximate solution for any semi-metric labeling problem defined using the distance function d.

6. Interval Rounding and Interval Moves

Theorem 1 implies that the approximation factor of the complete rounding procedure is very large for distance functions that are highly non-submodular. For example, consider the truncated linear distance function defined as follows over a label set $\mathbf{L} = \{l_1, l_2, \cdots, l_h\}$:

$$d(l_i, l_j) = \min\{|i - j|, M\}.$$

Here, M is a user specified parameter that determines the maximum distance. The tightest submodular overestimation of the above distance function is the linear distance function, that is, $d(l_i, l_j) = |i - j|$. This implies that the submodular distortion of the truncated linear metric is $(h-1)/M$, and therefore, the approximation factor for the complete rounding procedure is also $(h-1)/M$. In order to avoid this large approximation factor, Chekuri et al. (2001) proposed an interval rounding procedure, which captures the intuition that it is beneficial to assign similar labels to as many random variables as possible.

Algorithm 3 provides a description of interval rounding. The rounding procedure chooses an interval of at most q consecutive labels (step 2). It generates a random number r (step 3), and uses it to attempt to assign labels to previously unlabeled random variables from the selected interval (steps 4-7). It can be shown that the overall procedure converges in a polynomial number of iterations with a probability of 1 (Chekuri et al., 2001). Note that if we fix $q = h$ and $z = 1$, interval

rounding becomes equivalent to complete rounding. However, the analyses of Chekuri et al. (2001) and Kleinberg and Tardos (1999) shows that other values of q provide better approximation factors for various special cases.

Algorithm 3 The interval rounding procedure.

input A feasible solution $\mathbf{y}$ of the LP relaxation.

1: **repeat**
2: Pick an integer z uniformly from $[-q+2, h]$. Define an interval of labels $\mathbf{I} = \{l_s, \cdots, l_e\}$, where $s = \max\{z, 1\}$ is the start index and $e = \min\{z+q-1, h\}$ is the end index.
3: Pick a real number r uniformly from $[0, 1]$.
4: **for all** Unlabeled random variables X_a **do**
5: Define $Y_a(0) = 0$ and $Y_a(i) = \sum_{j=s}^{s+i-1} y_a(j)$ for all $i \in \{1, \cdots, e-s+1\}$.
6: Assign the label $l_{s+i-1} \in \mathbf{I}$ to the X_a if $Y_a(i-1) < r \leq Y_a(i)$.
7: **end for**
8: **until** All random variables have been assigned a label.

Our goal is to design a move-making algorithm whose multiplicative bound matches the approximation factor of interval rounding for any choice of q. To this end, we propose the interval move-making algorithm that generalizes the range expansion algorithm (Kumar and Torr, 2008), originally proposed for truncated convex distances, to arbitrary distance functions. Algorithm 4 provides its main steps. The central idea of the method is to improve a given labeling $\hat{\mathbf{x}}$ by allowing each random variable X_a to either retain its current label $\hat{x}_a$ or to choose a new label from an interval of consecutive labels. In more detail, let $\mathbf{I} = \{l_s, \cdots, l_e\} \subseteq \mathbf{L}$ be an interval of labels of length at most q (step 4). For the sake of simplicity, let us assume that $\hat{x}_a \notin \mathbf{I}$ for any random variable X_a. We define $\mathbf{I}_a = \mathbf{I} \bigcup \{\hat{x}_a\}$ (step 5). For each pair of neighboring random variables $(X_a, X_b) \in \mathbf{E}$, we compute a submodular distance function $\overline{d}_{\hat{x}_a,\hat{x}_b} : \mathbf{I}_a \times \mathbf{I}_b \rightarrow \mathbb{R}^+$ by solving the following linear program (step 6):

$$\begin{aligned}
\overline{d}_{\hat{x}_a,\hat{x}_b} = \quad & \operatorname*{argmin}_{d'} t \qquad (5)\\
\text{s.t.} \quad & d'(l_i, l_j) \leq t d(l_i, l_j), \forall l_i \in \mathbf{I}_a, l_j \in \mathbf{I}_b,\\
& d'(l_i, l_j) \geq d(l_i, l_j), \forall l_i \in \mathbf{I}_a, l_j \in \mathbf{I}_b,\\
& d'(l_i, l_j) + d'(l_{i+1}, l_{j+1}) \leq d'(l_i, l_{j+1}) + d'(l_{i+1}, l_j), \forall l_i, l_j \in \mathbf{I} \backslash \{l_e\},\\
& d'(l_i, l_e) + d'(l_{i+1}, \hat{x}_b) \leq d'(l_i, \hat{x}_b) + d'(l_{i+1}, l_e), \forall l_i \in \mathbf{I} \backslash \{l_e\},\\
& d'(l_e, l_j) + d'(\hat{x}_a, l_{j+1}) \leq d'(l_e, l_{j+1}) + d'(\hat{x}_a, l_j), \forall l_j \in \mathbf{I} \backslash \{l_e\},\\
& d'(l_e, l_e) + d(\hat{x}_a, \hat{x}_b) \leq d'(l_e, \hat{x}_b) + d'(\hat{x}_a, l_e).
\end{aligned}$$

Similar to problem (4), the above problem minimizes the maximum ratio of the estimated distance to the original distance. However, instead of introducing constraints for all pairs of labels, it only considers pairs of labels l_i and l_j where $l_i \in \mathbf{I}_a$ and $l_j \in \mathbf{I}_b$. Furthermore, it does not modify the distance between the current labels $\hat{x}_a$ and $\hat{x}_b$ (as can be seen in the last constraint of problem (5)).

Given the submodular distance functions $\overline{d}_{\hat{x}_a,\hat{x}_b}$, we can compute a new labeling $\overline{\mathbf{x}}$ by solving the following optimization problem via minimum st-cut using the method of Flach and Schlesinger

(2006) (step 7):

$$\begin{aligned}
\overline{\mathbf{x}} = \quad & \operatorname*{argmin}_{\mathbf{x}} \sum_{X_a \in \mathbf{X}} \theta_a(x_a) + \sum_{(X_a, X_b) \in \mathbf{E}} w_{ab} \overline{d}_{\hat{x}_a,\hat{x}_b}(x_a, x_b)\\
\text{s.t.} \quad & x_a \in \mathbf{I}_a, \forall X_a \in \mathbf{X}. \qquad (6)
\end{aligned}$$

If the energy of the new labeling $\overline{\mathbf{x}}$ is less than that of the current labeling $\hat{\mathbf{x}}$, then we update our labeling to $\overline{\mathbf{x}}$ (steps 8-10). Otherwise, we retain the current estimate of the labeling and consider another interval. The algorithm converges when the energy does not decrease for any interval of length at most q. Note that, once again, the main difference between interval move-making and the range expansion algorithm is the use of an appropriate optimization problem, namely the LP (5), to obtain a submodular overestimation of the given distance function. This allows us to use the interval move-making algorithm for the general semi-metric labeling problem, instead of focusing on only truncated convex models.

Algorithm 4 The interval move-making algorithm.

input Unary potentials $\theta_a(\cdot)$, edge weights w_{ab}, distance function d, initial labeling $\mathbf{x}^0$.

1: Set current labeling to initial labeling, that is, $\hat{\mathbf{x}} = \mathbf{x}^0$.
2: **repeat**
3: **for all** $z \in [-q+2, h]$ **do**
4: Define an interval of labels $\mathbf{I} = \{l_s, \cdots, l_e\}$, where $s = \max\{z, 1\}$ is the start index and $e = \min\{z+q-1, h\}$ is the end index.
5: Define $\mathbf{I}_a = \mathbf{I} \bigcup \{\hat{x}_a\}$ for all random variables $X_a \in \mathbf{X}$.
6: Obtain submodular overestimates $\overline{d}_{\hat{x}_a,\hat{x}_b}$ for each pair of neighboring random variables $(X_a, X_b) \in \mathbf{E}$ by solving problem (5).
7: Obtain a new labeling $\overline{\mathbf{x}}$ by solving problem (6).
8: **if** Energy of $\overline{\mathbf{x}}$ is less than energy of $\hat{\mathbf{x}}$ **then**
9: Update $\hat{\mathbf{x}} = \overline{\mathbf{x}}$.
10: **end if**
11: **end for**
12: **until** Energy cannot be decreased further.

The following theorem establishes the theoretical guarantees of the interval move-making algorithm and the interval rounding procedure.

Theorem 3 *The tight multiplicative bound of the interval move-making algorithm is equal to the tight approximation factor of the interval rounding procedure.*

The proof of Theorem 3 is given in Appendix B. While Algorithms 3 and 4 use intervals of consecutive labels, they can easily be modified to use subsets of (potentially non-consecutive) labels. Our analysis could be extended to show that the multiplicative bound of the resulting subset move-making algorithm matches the approximation factor of the subset rounding procedure. However, our reason for focusing on intervals of consecutive labels is that several special cases of Theorem 3 have previously been considered separately in the literature (Gupta and Tardos, 2000; Kumar and Koller, 2009; Kumar and Torr, 2008; Veksler, 1999). Specifically, the following known results are corollaries of the above theorem. Note that, while the following corollaries have been previously proved in the literature, our work is the first to establish the tightness of the theoretical guarantees.

Corollary 4 *When $q = 1$, the multiplicative bound of the interval move-making algorithm (which is equivalent to the expansion algorithm) for the uniform metric distance is 2.*

The above corollary follows from the approximation factor of the interval rounding procedure proved by Kleinberg and Tardos (1999), but it was independently proved by Veksler (1999).

Corollary 5 *When $q = M$, the multiplicative bound of the interval move-making algorithm for the truncated linear distance function is 4.*

The above corollary follows from the approximation factor of the interval rounding procedure proved by Chekuri et al. (2001), but it was independently proved by Gupta and Tardos (2000).

Corollary 6 *When $q = \sqrt{2}M$, the multiplicative bound of the interval move-making algorithm for the truncated linear distance function is $2 + \sqrt{2}$.*

The above corollary follows from the approximation factor of the interval rounding procedure proved by Chekuri et al. (2001), but it was independently proved by Kumar and Torr (2008). Finally, since our analysis does not use the triangular inequality of metric distance functions, we can also state the following corollary for the truncated quadratic distance.

Corollary 7 *When $q = \sqrt{M}$, the multiplicative bound of the interval move-making algorithm for the truncated quadratic distance function is $O(\sqrt{M})$.*

The above corollary follows from the approximation factor of the interval rounding procedure proved by Chekuri et al. (2001), but it was independently proved by Kumar and Torr (2008).

An interval move-making algorithm that uses an interval length of q runs for at most $O(h/q)$ iterations. This follows from a simple modification of the result by Gupta and Tardos (2000) (specifically, theorem 3.7). Hence, the total time complexity of interval move-making is $O(nmhq^2 \log(m))$, since each iteration solves a minimum st-cut problem of a graph with $O(nq)$ nodes and $O(mq^2)$ arcs. In other words, interval move-making is at most as computationally complex as complete move-making, which in turn is significantly less complex than solving the LP relaxation. Note that problem (5), which is required for interval move-making, is independent of the unary potentials and the edge weights. Hence, it only needs to be solved once beforehand for all pairs of labels $(\hat{x}_a, \hat{x}_b) \in \mathbf{L} \times \mathbf{L}$ in order to obtain a solution for any semi-metric labeling problem defined using the distance function d.

7. Hierarchical Rounding and Hierarchical Moves

We now consider the most general form of parallel rounding that has been proposed in the literature, namely the hierarchical rounding procedure (Kleinberg and Tardos, 1999). The rounding relies on a hierarchical clustering of the labels. Formally, we denote a hierarchical clustering of m levels for the label set $\mathbf{L}$ by $\mathbf{C} = \{\mathbf{C}(i), i = 1, \cdots, m\}$. At each level i, the clustering $\mathbf{C}(i) = \{\mathbf{C}(i,j) \subseteq \mathbf{L}, j = 1, \cdots, h^i\}$ is mutually exclusive and collectively exhaustive, that is,

$$\bigcup_j \mathbf{C}(i,j) = \mathbf{L}, \mathbf{C}(i,j) \cap \mathbf{C}(i,j') = \emptyset, \forall j \neq j'.$$

Furthermore, for each cluster $\mathbf{C}(i,j)$ at the level $i > 2$, there exists a unique cluster $\mathbf{C}(i-1,j')$ in the level $i-1$ such that $\mathbf{C}(i,j) \subseteq \mathbf{C}(i-1,j')$. We call the cluster $\mathbf{C}(i-1,j')$ the parent of the

Algorithm 5 The hierarchical rounding procedure.

input A feasible solution $\mathbf{y}$ of the LP relaxation.

1: Define $f_a^1 = 1$ for all $X_a \in \mathbf{X}$.
2: **for all** $i \in \{2, \cdots, m\}$ **do**
3: **for all** $X_a \in \mathbf{X}$ **do**
4: Define $z_a^i(j)$ for all $j \in \{1, \cdots, h^i\}$ as follows:

$$z_a^i(j) = \begin{cases} \sum_k \text{ s.t. } l_k \in \mathbf{C}(i,j)\, y_a(k) & \text{if } p(i,j) = f_a^{i-1}, \\ 0 & \text{otherwise.} \end{cases}$$

5: Define $y_a^i(j)$ for all $j \in \{1, \cdots, h^i\}$ as follows:

$$y_a^i(j) = \frac{z_a^i(j)}{\sum_{j'=1}^{h^i} z_a^i(j')}$$

6: **end for**
7: Using a rounding procedure (complete or interval) on $\mathbf{y}^i = [y_a^i(j), \forall X_a \in \mathbf{X}, j \in \{1, \cdots, h^i\}]$, obtain an integer solution $\hat{\mathbf{y}}^i$.
8: **for all** $X_a \in \mathbf{X}$ **do**
9: Let $k_a \in \{1, \cdots, h^i\}$ such that $\hat{y}^i(k_a) = 1$. Define $f_a^i = k_a$.
10: **end for**
11: **end for**
12: **for all** $X_a \in \mathbf{X}$ **do**
13: Let l_k be the unique label present in the cluster $\mathbf{C}(m, f_a^m)$. Assign l_k to X_a.
14: **end for**

cluster $\mathbf{C}(i,j)$ and define $p(i,j) = j'$. Similarly, we call $\mathbf{C}(i,j)$ a child of $\mathbf{C}(i-1,j')$. Without loss of generality, we assume that there exists a single cluster at level 1 that contains all the labels, and that each cluster at level m contains a single label.

Algorithm 5 describes the hierarchical rounding procedure. Given a clustering $\mathbf{C}$, it proceeds in a top-down fashion through the hierarchy while assigning each random variable to a cluster in the current level. Let f_a^i be the index of the cluster assigned to the random variable X_a in the level i. In the first step, the rounding procedure assigns all the random variables to the unique cluster $\mathbf{C}(1,1)$ (step 1). At each step i, it assigns each random variable to a unique cluster in the level i by computing a conditional probability distribution as follows. The conditional probability $y_a^i(j)$ of assigning the random variable X_a to the cluster $\mathbf{C}(i,j)$ is proportional to $\sum_{l_k \in \mathbf{C}(i,j)} y_a(k)$ if $p(i,j) = f_a^{i-1}$ (steps 3-6). The conditional probability $y_a^i(j) = 0$ if $p(i,j) \neq f_a^{i-1}$, that is, a random variable cannot be assigned to a cluster $\mathbf{C}(i,j)$ if it wasn't assigned to its parent in the previous step. Using a rounding procedure (complete or interval) for $\mathbf{y}^i$, we obtain an assignment of random variables to the clusters at level i (step 7). Once such an assignment is obtained, the values f_a^i are computed for all random variables X_a (steps 8-10). At the end of step m, hierarchical rounding would have assigned each random variable to a unique cluster in the level m. Since each cluster at level m consists of a single label, this provides us with a labeling of the MRF (steps 12-14).

Algorithm 6 The hierarchical move-making algorithm.

input Unary potentials $\theta_a(\cdot)$, edge weights w_{ab}, distance function d.

1: **for all** $j \in \{1, \cdots, h\}$ **do**
2: Let l_k be the unique label in the cluster $\mathbf{C}(m,j)$. Define $x_a^{m,j} = l_k$ for all $X_a \in \mathbf{X}$.
3: **end for**
4: **for all** $i \in \{2, \cdots, m\}$ **do**
5: **for all** $j \in \{1, \cdots, h^{m-i+1}\}$ **do**
6: Define $\mathbf{L}_a^{m-i+1,j} = \{x_a^{m-i+2,j'}, p(m-i+2,j') = j, j' \in \{1, \cdots, h^{m-i+2}\}\}$.
7: Using a move-making algorithm (complete or interval), compute the labeling $\mathbf{x}^{m-i+1,j}$ under the constraint $x_a^{m-i+1,j} \in \mathbf{L}_a^{m-i+1,j}$.
8: **end for**
9: **end for**
10: The final solution is $\mathbf{x}^{1,1}$.

Our goal is to design a move-making algorithm whose multiplicative bound matches the approximation factor of the hierarchical rounding procedure for any choice of hierarchical clustering $\mathbf{C}$. To this end, we propose the hierarchical move-making algorithm, which extends the hierarchical graph cuts approach for hierarchically well-separated tree (HST) metrics proposed by Kumar and Koller (2009). Algorithm 6 provides its main steps. In contrast to hierarchical rounding, the move-making algorithm traverses the hierarchy in a bottom-up fashion while computing a labeling for each cluster in the current level. Let $\mathbf{x}^{i,j}$ be the labeling corresponding to the cluster $\mathbf{C}(i,j)$. At the first step, when considering the level m of the clustering, all the random variables are assigned the same label. Specifically, $x_a^{m,j}$ is equal to the unique label contained in the cluster $\mathbf{C}(m,j)$ (steps 1-3). At step i, it computes the labeling $\mathbf{x}^{m-i+1,j}$ for each cluster $\mathbf{C}(m-i+1,j)$ by using the labelings computed in the previous step. Specifically, it restricts the label assigned to a random variable X_a in the labeling $\mathbf{x}^{m-i+1,j}$ to the subset of labels that were assigned to it by the labelings corresponding to the children of $\mathbf{C}(m-i+1,j)$ (step 6). Under this restriction, the labeling $\mathbf{x}^{m-i+1,j}$ is computed

by approximately minimizing the energy using a move-making algorithm (step 7). Implicit in our description is the assumption that that we will use a move-making algorithm (complete or interval) in step 7 of Algorithm 6 whose multiplicative bound matches the approximation factor of the rounding procedure (complete or interval) used in step 7 of Algorithm 5. Note that, unlike the hierarchical graph cuts approach (Kumar and Koller, 2009), the hierarchical move-making algorithm can be used for any arbitrary clustering and not just the one specified by an HST metric.

The following theorem establishes the theoretical guarantees of the hierarchical move-making algorithm and the hierarchical rounding procedure.

Theorem 8 *The tight multiplicative bound of the hierarchical move-making algorithm is equal to the tight approximation factor of the hierarchical rounding procedure.*

The proof of the above theorem is given in Appendix C. The following known result is its corollary.

Corollary 9 *The multiplicative bound of the hierarchical move-making algorithm is $O(1)$ for an HST metric distance.*

The above corollary follows from the approximation factor of the hierarchical rounding procedure proved by Kleinberg and Tardos (1999), but it was independently proved by Kumar and Koller (2009). It is worth noting that the above result was also used to obtain an approximation factor of $O(\log h)$ for the general metric labeling problem by Kleinberg and Tardos (1999) and a matching multiplicative bound of $O(\log h)$ by Kumar and Koller (2009).

The time complexity of the hierarchical move-making algorithm depends on two factors: (i) the hierarchy, which defines the subproblems; and (ii) whether we use a complete or an interval move-making algorithm to solve the subproblems. In what follows, we analyze its worst case time complexity over all possible hierarchies. Clearly, since complete move-making is more expensive than interval move-making, the worst case complexity of hierarchical move-making will be achieved when we use complete move-making to solve each subproblem. We begin by noting that each problem is defined using a smaller label set. For simplicitly, let us assume that the clusters of the hierarchy are balanced, and that each subproblem is solved over $h' \leq h$ labels. It follows that the total number of subproblems that we would be required to solve is $O((h/h')^{(\log(h)/\log(h'))-1})$. Next, observe that the complexity of the complete move-making algorithms is cubic in the number of labels. Thus, it follows that in order to maximize the total time complexity of hierarchical move-making, we need to set $h' = h$. In other words, hierarchical move-making algorithm is at most as computationally complex as the complete move-making algorithm. Recall that the complete move-making complexity is $O(nmh^3 \log(m))$. Hence, hierarchical move-making is significantly faster than solving the LP relaxation.

8. Experiments

We demonstrate the efficacy of rounding-based moves by comparing them to several state of the art methods using both synthetic and real data.

8.1 Synthetic Experiments

8.1.1 DATA

We generated two synthetic data sets to conduct our experiments. The first data set consists of random grid MRFs of size 100×100, where each random variable can take one of 10 labels. The unary

potentials were sampled from a uniform distribution over $[0, 10]$. The edge weights were sampled from a uniform distribution over $[0, 3]$. We considered four types of pairwise potentials: (i) truncated linear metric, where the truncation is sampled from a uniform distribution over $[1, 5]$; (ii) truncated quadratic semi-metric, where the truncation is sampled from a uniform distribution over $[1, 25]$; (iii) random metrics, generated by computing the shortest path on graphs whose vertices correspond to the labels and whose edge lengths are uniformly distributed over $[1, 10]$; (iv) random semi-metrics, where the distance between two labels is sampled from a uniform distribution over $[1, 10]$. For each type of pairwise potentials, we generated 500 different MRFs.

The second data set is similar to the first one, except that it is defined on a smaller grid of size 20×20. The smaller grid size allows us to test the mixture-of-tree algorithm (Andrew et al., 2011) that is closely related to the serial rounding procedure of Archer et al. (2004). We generated 5 different grids by sampling their edge weights from a uniform distribution over $[5, 100]$. For each set of edge weights, we use the cut-based decomposition method of Racke (2008) to approximate the original grid graph using a mixture of tree-structured graphs. We generated three types of unary potentials by uniformly sampling from the range $[0, 100]$, $[100, 1000]$ and $[1000, 10000]$ respectively. Similar to the first data set, we considered four types of pairwise potentials. For each pair of unary potential type and pairwise potential type, we generated 100 different MRFs. This provided us with 1200 MRFs for each set of edge weights, and a total of 6000 MRFs to perform our experiments.

8.1.2 METHODS

We report results obtained by the following state of the art methods using the first data set: (i) belief propagation (BP) (Pearl, 1998); (ii) sequential tree-reweighted message passing (TRW) (Kolmogorov, 2006), which optimizes the dual of the LP relaxation, and provides comparable results to other LP relaxation based approaches; (iii) expansion algorithm (EXP) (Boykov et al., 1999); and (iv) swap algorithm (SWAP) (Boykov et al., 1998). We compare the above methods to a hierarchy move-making algorithm (HIER), where a set of hierarchies is obtained by approximating a given semi-metric as a mixture of r-HST metrics using the method proposed by Fakcharoenphol et al. (2003). We refer the reader to (Fakcharoenphol et al., 2003; Kumar and Koller, 2009) for details. Each subproblem of the hierarchical move-making algorithm is solved by interval move-making with interval length $q = 1$ (which corresponds to the expansion algorithm). In addition, for the truncated linear and truncated quadratic cases, we present results of interval move-making (INT) using the optimal interval length reported by Kumar and Torr (2008).

For the second data set, we report the results for all the above methods, as well as the mixture-of-tree (MOT) algorithm. The smaller size of the grid in the second data set allows us to obtain a mixture of tree-structured MRFs using the method of Racke (2008), which was not possible for the larger 100×100 grid used in the first data set.

8.1.3 RESULTS

Figure 1 shows the results for the first data set. In terms of the energy, TRW is the most accurate. However, it is slow as it optimizes the dual of the LP relaxation. The labelings obtained by BP have high energy values. The standard move-making algorithms, EXP and SWAP, are fast due to the use of efficient minimum st-cut solvers. However, they are not as accurate as TRW. For the truncated linear and quadratic pairwise potentials, INT provides labelings with comparable energy to those of TRW, and is also computationally efficient. However, for general metrics and semi-metrics,

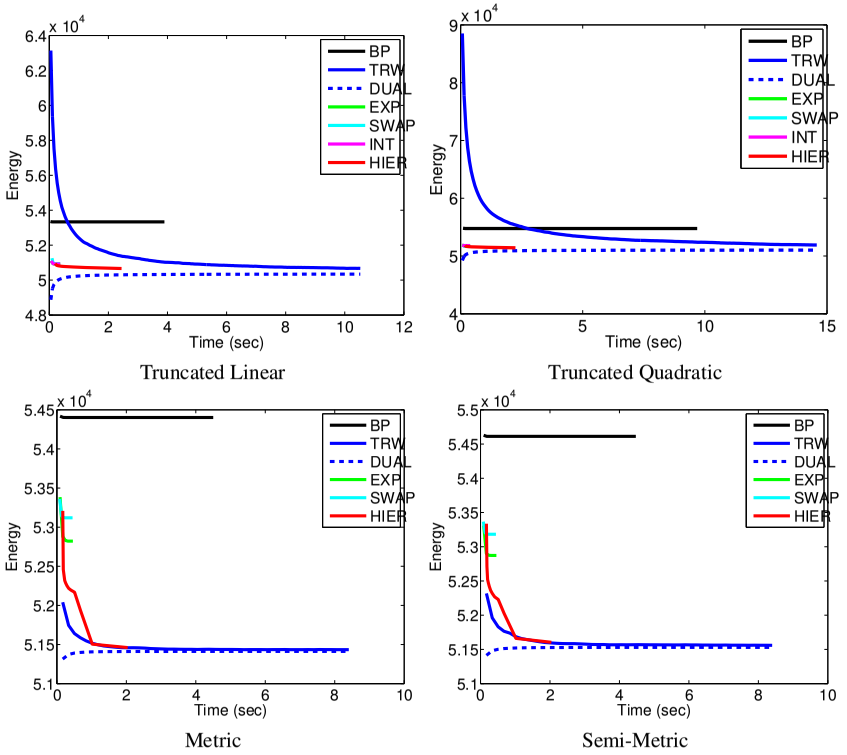

Figure 1: Results for the first synthetic data set. The x-axis shows the time in seconds, while the y-axis shows the energy value. The dashed line shows the value of the dual of the LP obtained by TRW. Best viewed in color.

it is not obvious how to obtain the optimal interval length. The HIER method is more generally applicable as there exist standard methods to approximate a semi-metric with a mixture of r-HST metrics (Fakcharoenphol et al., 2003). It provides very accurate labelings (comparable to TRW), and is efficient in practice as it relies on solving each subproblem using an iterative move-making algorithm.

Figure 2 shows the results for the second data set. The results of all the methods are similar to the first data set. However, the additional MOT algorithm performs very poorly compared to all other methods. This may be explained by the fact that, while MOT provides the same worst-case guarantees as serial rounding over all possible metric distance functions, it does not match the accuracy of serial rounding for a given distance function.

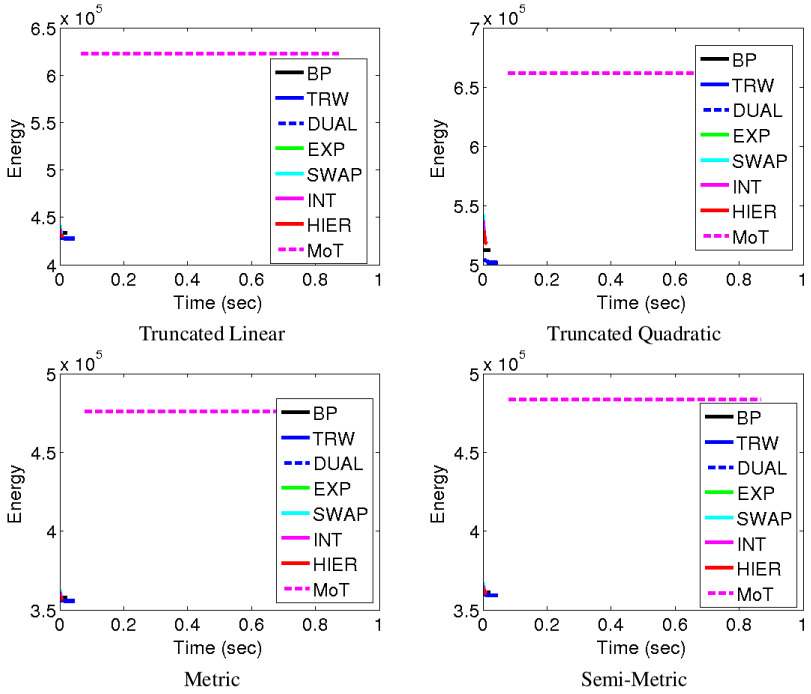

Figure 2: Results for the second synthetic data set. The x-axis shows the time in seconds, while the y-axis shows the energy value. The dashed line shows the value of the dual of the LP obtained by TRW. Best viewed in color.

8.2 Dense Stereo Correspondence

8.2.1 DATA

Given two epipolar rectified images of the same scene, the problem of dense stereo correspondence requires us to obtain a correspondence between the pixels of the images. This problem can be modeled as semi-metric labeling, where the random variables represent the pixels of one of the images, and the labels represent the disparity values. A disparity label l_i for a random variable X_a representing a pixel (u_a, v_a) of an image indicates that its corresponding pixel lies in location $(u_a + i, v_a)$. For the above problem, we use the unary potentials and edge weights that are specified by Szeliski et al. (2008). We use two types of pairwise potentials: (i) truncated linear with the truncation set at 4; and (ii) truncated quadratic with the truncation set at 16.

8.2.2 METHODS

We report results on all the baseline methods that were used in the synthetic experiments, namely, BP, TRW, EXP, and SWAP. Since the pairwise potentials are either truncated linear or truncated quadratic, we report results for the interval move-making algorithm INT, which uses the optimal value of the interval length. We also show the results obtained by the hierarchical move-making algorithm (HIER), where once again the hierarchies are obtained by approximating the semi-metric as a mixture of r-HST metrics.

8.2.3 RESULTS

Figure 3-Figure 8 shows the results for various standard pairs of images. Note that, similar to the synthetic experiments, TRW is the most accurate in terms of energy, but it is computationally inefficient. The results obtained by BP are not accurate. The standard move-making algorithms, EXP and SWAP, are fast but not as accurate as TRW. Among the rounding-based move-making algorithms INT is slower as it solves a minimum st-cut problem on a large graph at each iteration. In contrast, HIER uses an interval length of 1 for each subproblem and is therefore more efficient. The energy obtained by HIER is comparable to TRW.

9. Discussion

For any general distance function that can be used to specify the semi-metric labeling problem, we proved that the approximation factor of a large family of parallel rounding procedures is matched by the multiplicative bound of move-making algorithms. This generalizes previously known results on the guarantees of move-making algorithms in two ways: (i) in contrast to previous results (Kumar and Koller, 2009; Kumar and Torr, 2008; Veksler, 1999) that focused on special cases of distance functions, our results are applicable to arbitrary semi-metric distance functions; and (ii) the guarantees provided by our theorems are tight. Our experiments confirm that the rounding-based move-making algorithms provide similar accuracy to the LP relaxation, while being significantly faster due to the use of efficient minimum st-cut solvers.

Several natural questions arise. What is the exact characterization of the rounding procedures for which it is possible to design matching move-making algorithms? Can we design rounding-based move-making algorithms for other combinatorial optimization problems? Answering these questions

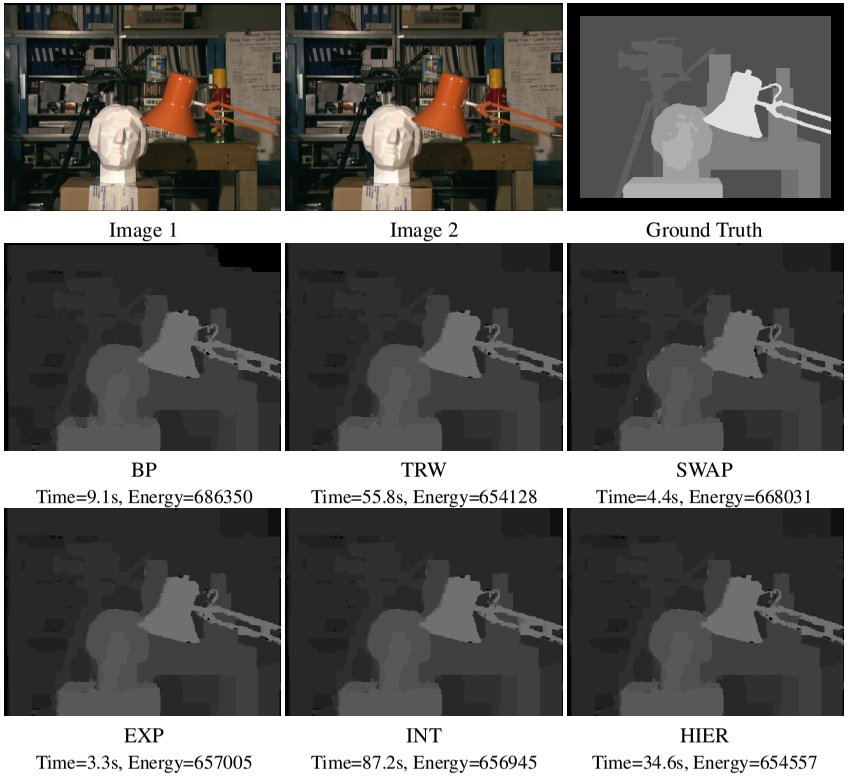

Figure 3: Results for the 'tsukuba' image pair with truncated linear pairwise potentials.

Appendix A. Proof of Theorem 1

We first establish the theoretical property of the complete move-making algorithm using the following lemma.

Lemma 10 *The tight multiplicative bound of the complete move-making algorithm is equal to the submodular distortion of the distance function.*

Proof The submodular distortion of a distance function d is obtained by computing its tightest submodular overestimation as follows:

$$\begin{aligned} \overline{d} = \quad & \operatorname*{argmin}_{d'} t \\ \text{s.t.} \quad & d'(l_i,l_j) \leq t d(l_i,l_j), \forall l_i,l_j \in \mathbf{L}, \\ & d'(l_i,l_j) \geq d(l_i,l_j), \forall l_i,l_j \in \mathbf{L}, \\ & d'(l_i,l_j) + d'(l_{i+1},l_{j+1}) \leq d'(l_i,l_{j+1}) + d'(l_{i+1},l_j), \forall l_i,l_j \in \mathbf{L}\backslash\{l_h\}. \end{aligned} \tag{7}$$

In order to prove the theorem, it is important to note that the definition of submodular distance function implies the following:

$$\overline{d}(l_i,l_j) + \overline{d}(l_{i'},l_{j'}) \leq \overline{d}(l_i,l_{j'}) + \overline{d}(l_{i'},l_j), \forall i' > i, j' > j.$$

A simple proof for the above claim can be found in (Flach and Schlesinger, 2006).

We denote the submodular distortion of d by B. By definition, it follows that

$$d(l_i,l_j) \leq \overline{d}(l_i,l_j) \leq B d(l_i,l_j), \forall l_i,l_j \in \mathbf{L}. \tag{8}$$

We denote an optimal labeling of the original semi-metric labeling problem as $\mathbf{x}^*$, that is,

$$\mathbf{x}^* = \operatorname*{argmin}_{\mathbf{x} \in \mathbf{L}^n} \sum_{X_a \in \mathbf{X}} \theta_a(x_a) + \sum_{(X_a,X_b) \in \mathbf{E}} w_{ab} d(x_a,x_b). \tag{9}$$

As the semi-metric labeling problem is NP-hard, an optimal labeling $\mathbf{x}^*$ cannot be computed efficiently using any known algorithm. In order to obtain an approximate solution $\hat{\mathbf{x}}$, the complete move-making algorithm replaces the original distance function d by its submodular overestimation $\overline{d}$, that is,

$$\hat{\mathbf{x}} = \operatorname*{argmin}_{\mathbf{x} \in \mathbf{L}^n} \sum_{X_a \in \mathbf{X}} \theta_a(x_a) + \sum_{(X_a,X_b) \in \mathbf{E}} w_{ab} \overline{d}(x_a,x_b). \tag{10}$$

Since the pairwise potentials in the above problem are submodular, the approximate solution $\hat{\mathbf{x}}$ can be obtained by solving a single minimum st-cut problem using the method of Flach and Schlesinger (2006). Using inequality (8), it follows that

$$\begin{aligned} & \sum_{X_a \in \mathbf{X}} \theta_a(\hat{x}_a) + \sum_{(X_a,X_b) \in \mathbf{E}} w_{ab} d(\hat{x}_a,\hat{x}_b) \\ \leq & \sum_{X_a \in \mathbf{X}} \theta_a(\hat{x}_a) + \sum_{(X_a,X_b) \in \mathbf{E}} w_{ab} \overline{d}(\hat{x}_a,\hat{x}_b) \\ \leq & \sum_{X_a \in \mathbf{X}} \theta_a(x^*_a) + \sum_{(X_a,X_b) \in \mathbf{E}} w_{ab} \overline{d}(x^*_a,x^*_b) \\ \leq & \sum_{X_a \in \mathbf{X}} \theta_a(x^*_a) + B \sum_{(X_a,X_b) \in \mathbf{E}} w_{ab} d(x^*_a,x^*_b). \end{aligned}$$

The above inequality proves that the multiplicative bound of the complete move-making algorithm is at most B. In order to prove that it is exactly equal to B, we need to construct an example for which the bound is tight. To this end, let l_k and $l_{k'}$ be two labels in the set $\mathbf{L}$ such that $k < k'$ and

$$\frac{\overline{d}(l_k,l_{k'})}{d(l_k,l_{k'})} = B.$$

Since B is the minimum possible value of the maximum ratio of the estimated distance $\overline{d}$ to the original distance d, such a pair of labels must exist (otherwise, the submodular distortion can be reduced further). Let us assume that there exists an $l_j \in \mathbf{L}$ such that $j < k$. Other cases (where $j > k'$ or $k < j < k'$) can be handled similarly. Note that since $\overline{d}$ is submodular, it follows that

$$\overline{d}(l_k,l_j) + \overline{d}(l_j,l_{k'}) \geq \overline{d}(l_k,l_{k'}). \tag{11}$$

We define a semi-metric labeling problem over two random variables X_a and X_b connected by an edge with weight $w_{ab} = 1$. The unary potentials are defined as follows:

$$\theta_a(i) = \begin{cases} 0, & \text{if } i = k, \\ \frac{\overline{d}(l_k,l_{k'}) + \overline{d}(l_k,l_j) - \overline{d}(l_j,l_{k'})}{2}, & \text{if } i = j, \\ \infty & \text{otherwise,} \end{cases}$$

$$\theta_b(i) = \begin{cases} 0, & \text{if } i = k', \\ \frac{\overline{d}(l_k,l_{k'}) - \overline{d}(l_k,l_j) + \overline{d}(l_j,l_{k'})}{2}, & \text{if } i = j, \\ \infty & \text{otherwise.} \end{cases}$$

For the above semi-metric labeling problem, it can be verified that an optimal solution $\mathbf{x}^*$ of problem (9) is the following: $x^*_a = l_k$ and $x^*_b = l_{k'}$. Furthermore, using inequality (11), it can be shown that the following is an optimal solution of problem (10): $\hat{x}_a = l_j$ and $\hat{x}_b = l_j$. In other words, $\hat{\mathbf{x}}$ is a valid approximate labeling provided by the complete move-making algorithm. The labelings $\mathbf{x}^*$ and $\hat{\mathbf{x}}$ satisfy the following equality:

$$\sum_{X_a \in \mathbf{X}} \theta_a(\hat{x}_a) + \sum_{(X_a,X_b) \in \mathbf{E}} w_{ab} d(\hat{x}_a,\hat{x}_b) = \sum_{X_a \in \mathbf{X}} \theta_a(x^*_a) + B \sum_{(X_a,X_b) \in \mathbf{E}} w_{ab} d(x^*_a,x^*_b).$$

Therefore, the tight multiplicative bound of the complete move-making algorithm is exactly equal to the submodular distortion of the distance function d. ■

We now turn our attention to the complete rounding procedure for the LP relaxation. Before we can establish its tight approximation factor, we need to compute the expected distance between the labels assigned to a pair of neighboring random variables. Recall that, in our notation, we denote a feasible solution of the LP relaxation by $\mathbf{y}$. For any feasible solution $\mathbf{y}$, we define $\mathbf{y}_a$ as the vector whose elements are the unary variables of $\mathbf{y}$ for the random variable $X_a \in \mathbf{X}$, that is,

$$\mathbf{y}_a = [y_a(i), \forall l_i \in \mathbf{L}]. \tag{12}$$

Similarly, we define $\mathbf{y}_{ab}$ as the vector whose elements are the pairwise variables of $\mathbf{y}$ for the neighboring random variables $(X_a, X_b) \in \mathbf{E}$, that is,

$$\mathbf{y}_{ab} = [y_{ab}(i,j), \forall l_i, l_j \in \mathbf{L}]. \tag{13}$$

Furthermore, using $\mathbf{y}_a$, we define $\mathbf{Y}_a$ as

$$Y_a(i) = \sum_{j=1}^{i} y_a(j).$$

In other words, if $\mathbf{y}_a$ is interpreted as the probability distribution over the labels of X_a, then $\mathbf{Y}_a$ is the corresponding cumulative distribution.

Given a feasible solution $\mathbf{y}$, we denote the integer solution obtained using the complete rounding procedure as $\hat{\mathbf{y}}$. The distance between the two labels encoded by vectors $\hat{\mathbf{y}}_a$ and $\hat{\mathbf{y}}_b$ will be denoted by $\hat{d}(\hat{\mathbf{y}}_a, \hat{\mathbf{y}}_b)$. In other words, if $\hat{f}_a$ and $\hat{f}_b$ are the indices of the labels assigned to X_a and X_b (that is, $\hat{y}_a(\hat{f}_a) = 1$ and $\hat{y}_b(\hat{f}_b) = 1$), then $\hat{d}(\hat{\mathbf{y}}_a, \hat{\mathbf{y}}_b) = d(l_{\hat{f}_a}, l_{\hat{f}_b})$.

The following shorthand notation would be useful for our analysis.

$$D_1(i) = \frac{1}{2}\left(d(l_i, l_1) + d(l_i, l_h) - d(l_{i+1}, l_1) - d(l_{i+1}, l_h)\right), \forall i \in \{1, \cdots, h-1\}, \tag{14}$$
$$D_2(i,j) = \frac{1}{2}\left(d(l_i, l_{j+1}) + d(l_{i+1}, l_j) - d(l_i, l_j) - d(l_{i+1}, l_{j+1})\right), \forall i, j \in \{1, \cdots, h-1\}.$$

Using the above notation, we can state the following lemma on the expected distance of the rounded solution for two neighboring random variables.

Lemma 11 *Let $\mathbf{y}$ be a feasible solution of the LP relaxation, $\mathbf{Y}_a$ and $\mathbf{Y}_b$ be cumulative distributions of $\mathbf{y}_a$ and $\mathbf{y}_b$, and $\hat{\mathbf{y}}$ be the integer solution obtained by the complete rounding procedure for $\mathbf{y}$. Then, the following equation holds true:*

$$\mathbb{E}(\hat{d}(\hat{\mathbf{y}}_a, \hat{\mathbf{y}}_b)) = \sum_{i=1}^{h-1} Y_a(i) D_1(i) + \sum_{j=1}^{h-1} Y_b(j) D_1(j) + \sum_{i=1}^{h-1}\sum_{j=1}^{h-1} |Y_a(i) - Y_b(j)| D_2(i,j).$$

Proof We define $\hat{f}_a$ and $\hat{f}_b$ to be the indices of the labels assigned to X_a and X_b by the rounded integer solution $\hat{\mathbf{y}}$. In other words, $\hat{y}_a(i) = 1$ if and only if $i = \hat{f}_a$ and $\hat{y}_b(j) = 1$ if and only if $j = \hat{f}_b$. We define binary variables $z_a(i)$ and $z_b(j)$ as follows:

$$z_a(i) = \begin{cases} 1 & \text{if } i \leq \hat{f}_a, \\ 0 & \text{otherwise,} \end{cases} \quad z_b(j) = \begin{cases} 1 & \text{if } j \leq \hat{f}_b, \\ 0 & \text{otherwise.} \end{cases}$$

For complete rounding, it can be verified that

$$\mathbb{E}(z_a(i)) = Y_a(i). \tag{15}$$

Furthermore, we also define binary variables $z_{ab}(i,j)$ that indicate whether i and j are contained within the interval defined by $\hat{f}_a$ and $\hat{f}_b$. Formally,

$$z_{ab}(i,j) = \begin{cases} 1 & \text{if } \min\{i,j\} \geq \min\{\hat{f}_a, \hat{f}_b\} \text{ and } \max\{i,j\} < \max\{\hat{f}_a, \hat{f}_b\}, \\ 0 & \text{otherwise.} \end{cases}$$

For complete rounding, it can be verified that

$$\mathbb{E}(z_{ab}(i,j)) = |Y_a(i) - Y_b(j)|. \tag{16}$$

Using the result of Flach and Schlesinger (2006), we know that

$$\hat{d}(\hat{\mathbf{y}}_a, \hat{\mathbf{y}}_b) = \sum_{i=1}^{h-1} z_a(i) D_1(i) + \sum_{j=1}^{h-1} z_b(j) D_1(j) + \sum_{i=1}^{h-1}\sum_{j=1}^{h-1} z_{ab}(i,j) D_2(i,j).$$

The proof of the lemma follows by taking the expectation of the LHS and the RHS of the above equation and simplifying the RHS using the linearity of expectation and equations (15) and (16). ■

In order to state the next lemma, we require the definition of uncrossing pairwise variables. Given unary variables $\mathbf{y}_a$ and $\mathbf{y}_b$, the pairwise variable vector $\mathbf{y}'_{ab}$ is called uncrossing with respect to $\mathbf{y}_a$ and $\mathbf{y}_b$ if it satisfies the following properties:

$$\begin{aligned}
&\sum_{j=1}^{h} y'_{ab}(i,j) = y_a(i), \forall i \in \{1, 2, \cdots, h\}, \\
&\sum_{i=1}^{h} y'_{ab}(i,j) = y_b(i), \forall j \in \{1, 2, \cdots, h\}, \\
&y'_{ab}(i,j) \geq 0, \forall i, j \in \{1, 2, \cdots, h\}, \\
&\min\{y'_{ab}(i,j'), y'_{ab}(i',j)\} = 0, \forall i, j, i', j' \in \{1, 2, \cdots, h\}, i < i', j < j'.
\end{aligned} \tag{17}$$

The following lemma establishes a connection between the expected distance between the labels assigned by complete rounding and the pairwise cost specified by uncrossing pairwise variables.

Lemma 12 *Let $\mathbf{y}$ be a feasible solution of the LP relaxation, and $\hat{\mathbf{y}}$ be the integer solution obtained by the complete rounding procedure for $\mathbf{y}$. Furthermore, let $\mathbf{y}'_{ab}$ be uncrossing pairwise variables with respect to $\mathbf{y}_a$ and $\mathbf{y}_b$. Then, the following equation holds true:*

$$\mathbb{E}(\hat{d}(\hat{\mathbf{y}}_a, \hat{\mathbf{y}}_b)) = \sum_{i=1}^{h}\sum_{j=1}^{h} d(l_i, l_j) y'_{ab}(i,j).$$

Proof We define $\mathbf{Y}_a$ and $\mathbf{Y}_b$ to be the cumulative distributions corresponding to $\mathbf{y}_a$ and $\mathbf{y}_b$ respectively. We claim that the uncrossing property (17) implies the following condition:

$$\sum_{i=1}^{i'}\sum_{j=1}^{j'} y'_{ab}(i,j) = \min\{Y_a(i'), Y_b(j')\}, \forall i', j' \in \{1, \cdots, h\}. \tag{18}$$

To prove this claim, assume that $Y_a(i') < Y_b(j')$. The other cases can be handled similarly. Since $\mathbf{y}'_{ab}$ satisfies the constraints of the LP relaxation, it follows that:

$$\begin{aligned}\sum_{i=1}^{h}\sum_{j=1}^{j'} y'_{ab}(i,j) &= Y_b(j'),\\ \sum_{i=1}^{i'}\sum_{j=1}^{h} y'_{ab}(i,j) &= Y_a(i').\end{aligned} \tag{19}$$

Since the LHS of equality (18) is less than or equal to the LHS of both the above equations, it follows that

$$\sum_{i=1}^{i'}\sum_{j=1}^{j'} y'_{ab}(i,j) \leq \min\{Y_a(i'), Y_b(j')\}. \tag{20}$$

Therefore, there must exist a $k > i'$ and $k' \leq j'$ such that $y'_{ab}(k,k') \neq 0$. Otherwise, the LHS in the above inequality will be exactly equal to $Y_b(j')$, which would result in a contradiction. By the uncrossing property (17), we know that $\min\{y'_{ab}(i,j), y'_{ab}(k,k')\} = 0$ if $i \leq i'$ and $j > j'$. Therefore, $y'_{ab}(i,j) = 0$ for all $i \leq i'$ and $j > j'$, which proves the claim.

Combining equations (19) and (20), we get the following:

$$\sum_{i=1}^{i'}\sum_{j=j'+1}^{h} y'_{ab}(i,j) + \sum_{i=i'+1}^{h}\sum_{j=1}^{j'} y'_{ab}(i,j) = |Y_a(i) - Y_b(j)|, \forall i', j' \in \{1, \cdots, h\}.$$

By solving for $\mathbf{y}'_{ab}$ using the above equations, we get

$$\sum_{i=1}^{h}\sum_{j=1}^{h} d(l_i, l_j) y'_{ab}(i,j) = \sum_{i=1}^{h-1} Y_a(i) D_1(i) + \sum_{j=1}^{h-1} Y_b(j) D_1(j) + \sum_{i=1}^{h-1}\sum_{j=1}^{h-1} |Y_a(i) - Y_b(j)| D_2(i,j).$$

Using the previous lemma, this proves that

$$\mathbb{E}(\hat{d}(\hat{\mathbf{y}}_a, \hat{\mathbf{y}}_b)) = \sum_{i=1}^{h}\sum_{j=1}^{h} d(l_i, l_j) y'_{ab}(i,j).$$

■

Our next lemma establishes that uncrossing pairwise variables are optimal for submodular distance functions.

Lemma 13 *Let $\mathbf{y}'_{ab}$ be the uncrossing pairwise variables with respect to the unary variables $\mathbf{y}_a$ and $\mathbf{y}_b$. Let $\overline{d} : \mathbf{L} \times \mathbf{L} \to \mathbb{R}^+$ be a submodular distance function. Then the following condition holds true:*

$$\begin{aligned}\mathbf{y}'_{ab} = \quad & \underset{\overline{\mathbf{y}}_{ab}}{\operatorname{argmin}} \sum_{i=1}^{h}\sum_{j=1}^{h} \overline{d}(i,j)\overline{y}_{ab}(i,j),\\ \textit{s.t.} \quad & \sum_{j=1}^{h} \overline{y}_{ab}(i,j) = y_a(i), \forall i \in \{1, \cdots, h\},\\ & \sum_{i=1}^{h} \overline{y}_{ab}(i,j) = y_b(j), \forall j \in \{1, \cdots, h\},\\ & \overline{y}_{ab}(i,j) \geq 0, \forall i, j \in \{1, \cdots, h\}.\end{aligned} \tag{21}$$

Proof We prove the lemma by contradiction. Suppose that the optimal solution to the above problem is $\mathbf{y}''_{ab}$, which is not uncrossing. Let

$$\min\{y''_{ab}(i,j'), y''_{ab}(i',j)\} = \lambda \neq 0,$$

where $i < i'$ and $j < j'$. Since $\overline{d}$ is submodular, it implies that

$$\overline{d}(l_i, l_j) + \overline{d}(l_{i'}, l_{j'}) \leq \overline{d}(l_i, l_{j'}) + \overline{d}(l_{i'}, l_j).$$

Therefore the objective function of problem (21) can be reduced further by the following modification:

$$\begin{aligned}y''_{ab}(i,j') &\leftarrow y''_{ab}(i,j') - \lambda, y''_{ab}(i',j) \leftarrow y''_{ab}(i',j) - \lambda,\\ y''_{ab}(i,j) &\leftarrow y''_{ab}(i,j) + \lambda, y''_{ab}(i',j') \leftarrow y''_{ab}(i',j') + \lambda.\end{aligned}$$

The resulting contradiction proves our claim that the uncrossing pairwise variables $\mathbf{y}'_{ab}$ are an optimal solution of problem (21). ■

Using the above lemmas, we will now obtain the tight approximation factor of the complete rounding procedure.

Lemma 14 *The tight approximation factor of the complete rounding procedure is equal to the submodular distortion of the distance function.*

Proof We denote a feasible fractional solution of the LP relaxation by $\mathbf{y}$ and the rounded solution by $\hat{\mathbf{y}}$. Consider a pair of neighboring random variables $(X_a, X_b) \in \mathbf{X}$. We define uncrossing pairwise variables $\mathbf{y}'_{ab}$ with respect to $\mathbf{y}_a$ and $\mathbf{y}_b$. Using Lemmas 12 and 13, the approximation factor of the

complete rounding procedure can be shown to be at most B as follows:

$$\begin{aligned}\mathbb{E}(\hat{d}(\hat{\mathbf{y}}_a,\hat{\mathbf{y}}_b)) = & \sum_{i=1}^{h}\sum_{j=1}^{h} d(l_i,l_j)y'_{ab}(i,j)\\ \leq & \sum_{i=1}^{h}\sum_{j=1}^{h} \overline{d}(l_i,l_j)y'_{ab}(i,j)\\ \leq & \sum_{i=1}^{h}\sum_{j=1}^{h} \overline{d}(l_i,l_j)y_{ab}(i,j)\\ \leq & B\sum_{i=1}^{h}\sum_{j=1}^{h} d(l_i,l_j)y_{ab}(i,j).\end{aligned}$$

In order to prove that the approximation factor of the complete rounding is exactly B, we need an example where the above inequality holds as an equality. The key to obtaining a tight example lies in the Lagrangian dual of problem (7). In order to specify its dual, we need three types of dual variables. The first type, denoted by $\alpha(i,j)$, corresponds to the constraint

$$d'(l_i,l_j) \leq t d(l_i,l_j).$$

The second type, denoted by $\beta(i,j)$, corresponds to the constraint

$$d'(l_i,l_j) \geq d(l_i,l_j).$$

The third type, denoted by $\gamma(i,j)$, corresponds to the constraint

$$d'(l_i,l_j) + d'(l_{i+1},l_{j+1}) \leq d'(l_i,l_{j+1}) + d'(l_{i+1},l_j).$$

Using the above variables, the dual of problem (7) is given by

$$\begin{aligned}\max \quad & \sum_{i=1}^{h}\sum_{j=1}^{h} d(l_i,l_j)\beta(i,j) \qquad (22)\\ \text{s.t.} \quad & \sum_{i=1}^{h}\sum_{j=1}^{h} d(l_i,l_j)\alpha(i,j) = 1,\\ & \beta(i,j) = \alpha(i,j) - \gamma(i,j-1) - \gamma(i-1,j) + \gamma(i-1,j-1) + \gamma(i,j),\\ & \forall i,j \in \{1,\cdots,h\},\\ & \alpha(i,j) \geq 0, \beta(i,j) \geq 0, \gamma(i,j) \geq 0, \forall i,j \in \{1,\cdots,h\}.\end{aligned}$$

We claim that the above dual problem has an optimal solution $(\boldsymbol{\alpha}^*,\boldsymbol{\beta}^*,\boldsymbol{\gamma}^*)$ that satisfies the following property:

$$\min\{\beta^*(i,j'),\beta^*(i',j)\} = 0, \forall i,i',j,j' \in \{1,\cdots,h\}, i<i', j<j'. \qquad (23)$$

We refer to the optimal dual solution $\boldsymbol{\beta}^*$ that satisfies the above property as uncrossing dual variables as it is analogous to uncrossing pairwise variables. The above claim, namely, the existence of an uncrossing optimal dual solution, can be proved by contradiction as follows. Suppose there exists no

optimal solution that satisfies the above property. Then consider the following problem, which is the dual of the problem of finding the tightest submodular overestimate of the submodular function $\overline{d}$:

$$\begin{aligned}\max \quad & \sum_{i=1}^{h}\sum_{j=1}^{h} \overline{d}(l_i,l_j)\beta(i,j) \qquad (24)\\ \text{s.t.} \quad & \sum_{i=1}^{h}\sum_{j=1}^{h} \overline{d}(l_i,l_j)\alpha(i,j) = 1,\\ & \beta(i,j) = \alpha(i,j) - \gamma(i,j-1) - \gamma(i-1,j) + \gamma(i-1,j-1) + \gamma(i,j),\\ & \forall i,j \in \{1,\cdots,h\},\\ & \alpha(i,j) \geq 0, \beta(i,j) \geq 0, \gamma(i,j) \geq 0, \forall i,j \in \{1,\cdots,h\}.\end{aligned}$$

By strong duality, problem (24) has an optimal value of 1. However, the optimal solution of problem (22), which is also a feasible solution for problem (24), provides a value strictly greater than 1. This results in a contradiction that proves our claim.

The optimal dual variables that satisfy property (23) allow us to construct an example that proves that the approximation factor B of the complete rounding procedure is tight. Specifically, we define

$$\begin{aligned}&\overline{y}_{ab}(i,j) = \frac{\alpha^*(i,j)}{\sum_{i'=1}^{h}\sum_{j'=1}^{h}\alpha^*(i',j')}, \forall i,j \in \{1,\cdots,h\},\\ &\overline{y}_a(i) = \sum_{j=1}^{h} \overline{y}_{ab}(i,j), \forall i \in \{1,\cdots,h\},\\ &\overline{y}_b(j) = \sum_{i=1}^{h} \overline{y}_{ab}(i,j), \forall j \in \{1,\cdots,h\}.\end{aligned}$$

Note that the pairwise variables $\overline{\mathbf{y}}_{ab}$ must minimize the pairwise potential corresponding to the unary variables $\mathbf{y}_a$ and $\mathbf{y}_b$, that is,

$$\begin{aligned}\overline{\mathbf{y}}_{ab} = & \operatorname*{argmin}_{\mathbf{y}_{ab}} \sum_{l_i,l_j \in \mathbf{L}} d(l_i,l_j)y_{ab}(i,j) \qquad (25)\\ \text{s.t.} \quad & \sum_{l_j \in \mathbf{L}} y_{ab}(i,j) = \overline{y}_a(i), \forall l_i \in \mathbf{L}\\ & \sum_{l_i \in \mathbf{L}} y_{ab}(i,j) = \overline{y}_b(j), \forall l_j \in \mathbf{L}\\ & y_{ab}(i,j) \geq 0, \forall l_i,l_j \in \mathbf{L}.\end{aligned}$$

If the above statement was not true, then the value of the dual problem (22) could be increased further.

We also define the following pairwise variables:

$$y'_{ab}(i,j) = \frac{\beta^*(i,j)}{\sum_{i'=1}^{h}\sum_{j'=1}^{h}\beta^*(i',j')}, \forall i,j \in \{1,\cdots,h\},$$
$$y'_a(i) = \sum_{j=1}^{h} y'_{ab}(i,j), \forall i \in \{1,\cdots,h\},$$
$$y'_b(j) = \sum_{i=1}^{h} y'_{ab}(i,j), \forall j \in \{1,\cdots,h\}.$$

It can be verified that

$$y'_a(i) = \overline{y}_a(i), y'_b(j) = \overline{y}_b(j), \forall i,j \in \{1,\cdots,h\}.$$

The above condition follows from the constraints of problem (22). Due to the uncrossing property of $\boldsymbol{\beta}^*$, the pairwise variables $\mathbf{y'_{ab}}$ are uncrossing with respect to $\overline{\mathbf{y}}_a$ and $\overline{\mathbf{y}}_b$. By Lemma 12, this implies that

$$\mathbb{E}(\hat{d}(\hat{\mathbf{y}}_a, \hat{\mathbf{y}}_b)) = \sum_{i=1}^{h}\sum_{j=1}^{h} d(l_i,l_j) y'_{ab}(i,j),$$

where $\hat{\mathbf{y}}_a$ and $\hat{\mathbf{y}}_b$ are integer solutions obtained by the complete rounding procedure. By strong duality, it follows that

$$\mathbb{E}(\hat{d}(\hat{\mathbf{y}}_a, \hat{\mathbf{y}}_b)) = B\sum_{i=1}^{h}\sum_{j=1}^{h} d(l_i,l_j)\overline{y}_{ab}(i,j). \tag{26}$$

The existence of an example that satisfies properties (25) and (26) implies that the tight approximation factor of the complete rounding procedure is B. ■

Lemmas 10 and 14 together prove Theorem 1.

Appendix B. Proof of Theorem 3

We begin by establishing the theoretical properties of the interval-move making algorithm. Recall that, given an interval of labels $\mathbf{I} = \{l_s, \cdots, l_e\}$ of at most q consecutive labels and a labeling $\hat{\mathbf{x}}$, we define $\mathbf{I}_a = \mathbf{I} \cup \{\hat{x}_a\}$ for all random variables $X_a \in \mathbf{X}$. In order to use the interval move-making algorithm, we compute a submodular distance function $\overline{d}_{\hat{x}_a,\hat{x}_b} : \mathbf{I}_a \times \mathbf{I}_b \rightarrow \mathbb{R}^+$ for all pairs of neighboring random variables $(X_a, X_b) \in \mathbf{E}$ as follows:

$$\begin{aligned}
\overline{d}_{\hat{x}_a,\hat{x}_b} = \quad & \operatorname*{argmin}_{d'} t \qquad (27)\\
\text{s.t.} \quad & d'(l_i,l_j) \leq t d(l_i,l_j), \forall l_i \in \mathbf{I}_a, l_j \in \mathbf{I}_b,\\
& d'(l_i,l_j) \geq d(l_i,l_j), \forall l_i \in \mathbf{I}_a, l_j \in \mathbf{I}_b,\\
& d'(l_i,l_j) + d'(l_{i+1},l_{j+1}) \leq d'(l_i,l_{j+1}) + d'(l_{i+1},l_j), \forall l_i,l_j \in \mathbf{I}\backslash\{l_e\},\\
& d'(l_i,l_e) + d'(l_{i+1},\hat{x}_b) \leq d'(l_i,\hat{x}_b) + d'(l_{i+1},l_e), \forall l_i \in \mathbf{I}\backslash\{l_e\},\\
& d'(l_e,l_j) + d'(\hat{x}_a,l_{j+1}) \leq d'(l_e,l_{j+1}) + d'(\hat{x}_a,l_j), \forall l_j \in \mathbf{I}\backslash\{l_e\},\\
& d'(l_e,l_e) + d(\hat{x}_a,\hat{x}_b) \leq d'(l_e,\hat{x}_b) + d'(\hat{x}_a,l_e).
\end{aligned}$$

For any interval $\mathbf{I}$ and labeling $\mathbf{x}$, we define the following sets:

$$\begin{aligned}
&\mathbf{V}(\mathbf{x},\mathbf{I}) = \{X_a | X_a \in \mathbf{X}, x_a \in \mathbf{I}\},\\
&\mathbf{A}(\mathbf{x},\mathbf{I}) = \{(X_a,X_b) | (X_a,X_b) \in \mathbf{E}, x_a \in \mathbf{I}, x_b \in \mathbf{I}\},\\
&\mathbf{B}_1(\mathbf{x},\mathbf{I}) = \{(X_a,X_b) | (X_a,X_b) \in \mathbf{E}, x_a \in \mathbf{I}, x_b \notin \mathbf{I}\},\\
&\mathbf{B}_2(\mathbf{x},\mathbf{I}) = \{(X_a,X_b) | (X_a,X_b) \in \mathbf{E}, x_a \notin \mathbf{I}, x_b \in \mathbf{I}\},\\
&\mathbf{B}(\mathbf{x},\mathbf{I}) = \mathbf{B}_1(\mathbf{x}) \cup \mathbf{B}_2(\mathbf{x}).
\end{aligned}$$

In other words, $\mathbf{V}(\mathbf{x},\mathbf{I})$ is the set of all random variables whose label belongs to the interval $\mathbf{I}$. Similarly, $\mathbf{A}(\mathbf{x},\mathbf{I})$ is the set of all neighboring random variables such that the labels assigned to both the random variables belong to the interval $\mathbf{I}$. The set $\mathbf{B}(\mathbf{x},\mathbf{I})$ contains the set of all neighboring random variables such that only one of the two labels assigned to the two random variables belongs to the interval $\mathbf{I}$. Given the set of all intervals $\mathcal{I}$ and a labeling $\hat{\mathbf{x}}$, we define the following for all $x_a, x_b \in \mathbf{L}$:

$$\begin{aligned}
D(x_a,x_b;\hat{x}_a,\hat{x}_b) = \quad & \sum_{\mathbf{I}\in\mathcal{I},\mathbf{A}(\mathbf{x},\mathbf{I})\ni(X_a,X_b)} d_{\hat{x}_a,\hat{x}_b}(x_a,x_b)\\
& + \sum_{\mathbf{I}\in\mathcal{I},\mathbf{B}_1(\mathbf{x},\mathbf{I})\ni(X_a,X_b)} d_{\hat{x}_a,\hat{x}_b}(x_a,\hat{x}_b)\\
& + \sum_{\mathbf{I}\in\mathcal{I},\mathbf{B}_2(\mathbf{x},\mathbf{I})\ni(X_a,X_b)} d_{\hat{x}_a,\hat{x}_b}(\hat{x}_a,x_b).
\end{aligned}$$

Using the above notation, we are ready to state the following lemma on the theoretical guarantee of the interval move-making algorithm.

Lemma 15 *The tight multiplicative bound of the interval move-making algorithm is equal to*

$$\frac{1}{q}\max_{x_a,x_b,\hat{x}_a,\hat{x}_b\in\mathbf{L},x_a\neq x_b}\frac{D(x_a,x_b;\hat{x}_a,\hat{x}_b)}{d(x_a,x_b)}.$$

Proof We denote an optimal labeling by $\mathbf{x}^*$ and the estimated labeling by $\hat{\mathbf{x}}$. Let $t \in [1,q]$ be a uniformly distributed random integer. Using t, we define the following set of non-overlapping intervals:

$$\mathcal{I}_t = \{[1,t],[t+1,t+q],\cdots,[.,h]\}.$$

For each interval $\mathbf{I} \in \mathcal{I}_t$, we define a labeling $\mathbf{x}^{\mathbf{I}}$ as follows:

$$x_a^{\mathbf{I}} = \begin{cases} x_a^* & \text{if } x_a^* \in \mathbf{I},\\ \hat{x}_a & \text{otherwise.}\end{cases}$$

Since $\hat{\mathbf{x}}$ is the labeling obtained after the interval move-making algorithm converges, it follows that

$$\sum_{X_a\in\mathbf{X}}\theta_a(\hat{x}_a) + \sum_{(X_a,X_b)\in\mathbf{E}} w_{ab}\overline{d}_{\hat{x}_a,\hat{x}_b}(\hat{x}_a,\hat{x}_b) \leq \sum_{X_a\in\mathbf{X}}\theta_a(x_a^{\mathbf{I}}) + \sum_{(X_a,X_b)\in\mathbf{E}} w_{ab}\overline{d}_{\hat{x}_a,\hat{x}_b}(x_a^{\mathbf{I}},x_b^{\mathbf{I}}).$$

By canceling out the common terms, we can simplify the above inequality as

$$\begin{aligned}
& \sum_{X_a \in \mathbf{V}(\mathbf{x}^*,\mathbf{I})} \theta_a(\hat{x}_a) \\
& + \sum_{(X_a,X_b)\in\mathbf{A}(\mathbf{x}^*,\mathbf{I})} w_{ab}\overline{d}_{\hat{x}_a,\hat{x}_b}(\hat{x}_a,\hat{x}_b) \\
& + \sum_{(X_a,X_b)\in\mathbf{B}_1(\mathbf{x}^*,\mathbf{I})} w_{ab}\overline{d}_{\hat{x}_a,\hat{x}_b}(\hat{x}_a,\hat{x}_b) \\
& + \sum_{(X_a,X_b)\in\mathbf{B}_2(\mathbf{x}^*,\mathbf{I})} w_{ab}\overline{d}_{\hat{x}_a,\hat{x}_b}(\hat{x}_a,\hat{x}_b) \\
\leq & \sum_{X_a \in \mathbf{V}(\mathbf{x}^*,\mathbf{I})} \theta_a(x^*_a) \\
& + \sum_{(X_a,X_b)\in\mathbf{A}(\mathbf{x}^*,\mathbf{I})} w_{ab}\overline{d}_{\hat{x}_a,\hat{x}_b}(x^*_a,x^*_b) \\
& + \sum_{(X_a,X_b)\in\mathbf{B}_1(\mathbf{x}^*,\mathbf{I})} w_{ab}\overline{d}_{\hat{x}_a,\hat{x}_b}(x^*_a,\hat{x}_b) \\
& + \sum_{(X_a,X_b)\in\mathbf{B}_2(\mathbf{x}^*,\mathbf{I})} w_{ab}\overline{d}_{\hat{x}_a,\hat{x}_b}(\hat{x}_a,x^*_b).
\end{aligned}$$

We now sum the above inequality over all the intervals $\mathbf{I} \in \mathcal{I}_t$. Note that the resulting LHS is at least equal to the energy of the labeling $\hat{\mathbf{x}}$ when the distance function between the random variables (X_a, X_b) is $\overline{d}_{\hat{x}_a,\hat{x}_b}$. This implies that

$$\begin{aligned}
& \sum_{X_a\in\mathbf{X}} \theta_a(\hat{x}_a) + \sum_{(X_a,X_b)\in\mathbf{E}} w_{ab}\overline{d}_{\hat{x}_a,\hat{x}_b}(\hat{x}_a,\hat{x}_b) \\
\leq & \sum_{X_a\in\mathbf{X}} \theta_a(x^*_a) \\
& + \sum_{\mathbf{I}\in\mathcal{I}_t} \sum_{(X_a,X_b)\in\mathbf{A}(\mathbf{x}^*,\mathbf{I})} w_{ab}\overline{d}_{\hat{x}_a,\hat{x}_b}(x^*_a,x^*_b) \\
& + \sum_{\mathbf{I}\in\mathcal{I}_t} \sum_{(X_a,X_b)\in\mathbf{B}_1(\mathbf{x}^*,\mathbf{I})} w_{ab}\overline{d}_{\hat{x}_a,\hat{x}_b}(x^*_a,\hat{x}_b) \\
& + \sum_{\mathbf{I}\in\mathcal{I}_t} \sum_{(X_a,X_b)\in\mathbf{B}_2(\mathbf{x}^*,\mathbf{I})} w_{ab}\overline{d}_{\hat{x}_a,\hat{x}_b}(\hat{x}_a,x^*_b).
\end{aligned}$$

Taking the expectation on both sides of the above inequality with respect to the uniformly distributed random integer $t \in [1, q]$ proves that the multiplicative bound of the interval move-making algorithm is at most equal to

$$\frac{1}{q} \max_{x_a,x_b,\hat{x}_a,\hat{x}_b\in\mathbf{L},x_a\neq x_b} \frac{D(x_a,x_b;\hat{x}_a,\hat{x}_b)}{d(x_a,x_b)}.$$

A tight example with two random variables X_a and X_b with $w_{ab} = 1$ can be constructed similar to the one shown in Lemma 10. ■

We now turn our attention to the interval rounding procedure. Let $\mathbf{y}$ be a feasible solution of the LP relaxation, and $\hat{\mathbf{y}}$ be the integer solution obtained using interval rounding. Once again, we define the unary variable vector $\mathbf{y}_a$ and the pairwise variable vector $\mathbf{y}_{ab}$ as specified in equations (12) and (13) respectively. Similar to the previous appendix, we denote the expected distance between $\hat{\mathbf{y}}_a$ and $\hat{\mathbf{y}}_b$ as $\hat{d}(\hat{\mathbf{y}}_a, \hat{\mathbf{y}}_b)$.

Given an interval $\mathbf{I} = \{l_s, \cdots, l_e\}$ of at most q consecutive labels, we define a vector $\mathbf{Y}^{\mathbf{I}}_a$ for each random variable X_a as follows:

$$Y^{\mathbf{I}}_a(i) = \sum_{j=s}^{s+i-1} y_a(j), \forall i \in \{1, \cdots, e-s+1\}.$$

In other words, $\mathbf{Y}^{\mathbf{I}}_a$ is the cumulative distribution of $\mathbf{y}_a$ within the interval $\mathbf{I}$. Furthermore, for each pair of neighboring random variables $(X_a, X_b) \in \mathbf{E}$ we define

$$\begin{aligned}
Z^{\mathbf{I}}_{ab} &= \max\{Y^{\mathbf{I}}_a(e-s+1), Y^{\mathbf{I}}_b(e-s+1)\} - \min\{Y^{\mathbf{I}}_a(e-s+1), Y^{\mathbf{I}}_b(e-s+1)\}, \\
Z^{\mathbf{I}}_a(i) &= \min\{Y^{\mathbf{I}}_a(i), Y^{\mathbf{I}}_b(e-s+1)\}, \forall i \in \{1, \cdots, e-s+1\}, \\
Z^{\mathbf{I}}_b(j) &= \min\{Y^{\mathbf{I}}_b(j), Y^{\mathbf{I}}_a(e-s+1)\}, \forall j \in \{1, \cdots, e-s+1\}.
\end{aligned}$$

The following shorthand notation would be useful to concisely specify the exact form of $\hat{d}(\hat{\mathbf{y}}_a, \hat{\mathbf{y}}_b)$.

$$\begin{aligned}
D^{\mathbf{I}}_0 = & \max_{l_i,l_j,|\{l_i,l_j\}\cap\mathbf{I}|=1} d(l_i,l_j), \\
D^{\mathbf{I}}_1(i) = & \frac{1}{2}\left(d(l_{s+i-1},l_s) + d(l_{s+i-1},l_e) - d(l_{s+i},l_s) - d(l_{s+i},l_e)\right), \forall i \in \{1,\cdots,e-s\}, \\
D^{\mathbf{I}}_2(i,j) = & \frac{1}{2}\left(d(l_{s+i-1},l_{s+j}) + d(l_{s+i},l_{s+j-1}) - d(l_{s+i-1},l_{s+j-1}) - d(l_{s+i},l_{s+j})\right), \\
& \forall i,j \in \{1,\cdots,e-s\}.
\end{aligned}$$

In other words, $\mathbf{D}^{\mathbf{I}}_0$ is the maximum distance between two labels such that only one of the two labels lies in the interval $\mathbf{I}$. The terms $\mathbf{D}^{\mathbf{I}}_1$ and $\mathbf{D}^{\mathbf{I}}_2$ are analogous to the terms defined in equation (14). Using the above notation, we can state the following lemma on the expected distance of the rounded solution for two neighboring random variables.

Lemma 16 *Let $\mathbf{y}$ be a feasible solution of the LP relaxation, and $\hat{\mathbf{y}}$ be the integer solution obtained by the interval rounding procedure for $\mathbf{y}$ using the set of intervals $\mathcal{I}$. Then, the following inequality holds true:*

$$\begin{aligned}
\mathbb{E}(\hat{d}(\hat{\mathbf{y}}_a,\hat{\mathbf{y}}_b)) \leq & \frac{1}{q}\left(\sum_{\mathbf{I}=\{l_s,\cdots,l_e\}\in\mathcal{I}} Z^{\mathbf{I}}_{ab}D^{\mathbf{I}}_0 + \sum_{i=1}^{e-s} Z^{\mathbf{I}}_a(i)D^{\mathbf{I}}_1(i) + \sum_{j=1}^{e-s} Z^{\mathbf{I}}_b(j)D^{\mathbf{I}}_1(j) + \right. \\
& \left. \sum_{i=1}^{e-s}\sum_{j=1}^{e-s} |Z^{\mathbf{I}}_a(i) - Z^{\mathbf{I}}_b(j)| D^{\mathbf{I}}_2(i,j)\right).
\end{aligned}$$

Proof We begin the proof by establishing the probability of a random variable X_a being assigned a label in an iteration of the interval rounding procedure. The total number of intervals in the set

$\mathcal{I}$ is $h+q-1$. Out of all the intervals, each label l_i is present in q intervals. Thus, the probability of choosing an interval that contains the label l_i is $q/(h+q-1)$. Once an interval containing l_i is chosen, the probability of assigning the label l_i to X_a is $y_a(i)$. Thus, the probability of assigning a label l_i to X_a is $y_a(i)q/(h+q-1)$. Summing over all labels l_i, we observe that the probability of assigning a label to X_a in an iteration of the interval rounding procedure is $q/(h+q-1)$.

Now we consider two neighboring random variables $(X_a, X_b) \in \mathbf{E}$. In the current iteration of interval rounding, given an interval $\mathbf{I}$, the probability of exactly one of the two random variables getting assigned a label in $\mathbf{I}$ is exactly equal to $Z^{\mathbf{I}}_{ab}$. In this case, we have to assume that the expected distance between the two variables will be the maximum possible, that is, $D^{\mathbf{I}}_0$. If both the variables are assigned a label in $\mathbf{I}$, then a slight modification of Lemma 11 gives us the expected distance as

$$\sum_{i=1}^{e-s} Z^{\mathbf{I}}_a(i) D^{\mathbf{I}}_1(i) + \sum_{j=1}^{e-s} Z^{\mathbf{I}}_b(j) D^{\mathbf{I}}_1(j) + \sum_{i=1}^{e-s}\sum_{j=1}^{e-s} |Z^{\mathbf{I}}_a(i) - Z^{\mathbf{I}}_b(j)| D^{\mathbf{I}}_2(i,j).$$

Thus, the expected distance between the labels of X_a and X_b conditioned on at least one of the two random variables getting assigned in an iteration is equal to

$$\frac{1}{(h+q-1)} \left(\sum_{\mathbf{I}=\{l_s,\cdots,l_e\}\in\mathcal{I}} Z^{\mathbf{I}}_{ab} D^{\mathbf{I}}_0 + \sum_{i=1}^{e-s} Z^{\mathbf{I}}_a(i) D^{\mathbf{I}}_1(i) + \sum_{j=1}^{e-s} Z^{\mathbf{I}}_b(j) D^{\mathbf{I}}_1(j) + \sum_{i=1}^{e-s}\sum_{j=1}^{e-s} |Z^{\mathbf{I}}_a(i) - Z^{\mathbf{I}}_b(j)| D^{\mathbf{I}}_2(i,j) \right),$$

where the term $1/(h+q-1)$ corresponds to the probability of choosing an interval from the set $\mathcal{I}$. In order to compute $\hat{d}(\hat{\mathbf{y}}_a, \hat{\mathbf{y}}_b)$, we need to divide the above term with the probability of at least one of the two random variables getting assigned a label in the current iteration. Since the two cumulative distributions $\mathbf{Y}^{\mathbf{I}}_a$ and $\mathbf{Y}^{\mathbf{I}}_b$ can be arbitrarily close to each other without being exactly equal, we can only lower bound the probability of at least one of X_a and X_b being assigned a label at the current iteration by the probability of X_a being assigned a label in the current iteration. Since the probability of X_a being assigned a label is $q/(h+q-1)$, it follows that

$$\mathbb{E}(\hat{d}(\hat{\mathbf{y}}_a, \hat{\mathbf{y}}_b)) \leq \frac{1}{q} \left(\sum_{\mathbf{I}=\{l_s,\cdots,l_e\}\in\mathcal{I}} Z^{\mathbf{I}}_{ab} D^{\mathbf{I}}_0 + \sum_{i=1}^{e-s} Z^{\mathbf{I}}_a(i) D^{\mathbf{I}}_1(i) + \sum_{j=1}^{e-s} Z^{\mathbf{I}}_b(j) D^{\mathbf{I}}_1(j) + \sum_{i=1}^{e-s}\sum_{j=1}^{e-s} |Z^{\mathbf{I}}_a(i) - Z^{\mathbf{I}}_b(j)| D^{\mathbf{I}}_2(i,j) \right).$$

■

Using the above lemma, we can now establish the theoretical property of the interval rounding procedure.

Lemma 17 *The tight approximation factor of the interval rounding procedure is equal to*

$$\frac{1}{q} \max_{x_a, x_b, \hat{x}_a, \hat{x}_b \in \mathbf{L}, x_a \neq x_b} \frac{D(x_a, x_b; \hat{x}_a, \hat{x}_b)}{d(x_a, x_b)}.$$

Proof Similar to Lemma 14, the key to proving the above lemma lies in the dual of problem (27). Given the current labels $\hat{x}_a$ and $\hat{x}_b$ of the random variables X_a and X_b respectively, as well as an interval $\mathbf{I} = \{l_s, \cdots, l_e\}$, problem (27) computes the tightest submodular overestimation $\overline{d}_{\hat{x}_a,\hat{x}_b} : \mathbf{I}_a \times \mathbf{I}_b \rightarrow \mathbb{R}^+$ where $\mathbf{I}_a = \mathbf{I} \cup \{\hat{x}_a\}$ and $\mathbf{I}_b = \mathbf{I} \cup \{\hat{x}_b\}$. Similar to problem (22), the dual of problem (27) consists of three types of dual variables. The first type, denoted by $\alpha(i,j;\hat{x}_a,\hat{x}_b,\mathbf{I})$ corresponds to the constraint

$$d'(l_i, l_j) \leq t d(l_i, l_j).$$

The second type, denoted by $\beta(i,j;\hat{x}_b,\hat{x}_b,\mathbf{I})$, corresponds to the constraint

$$d'(l_i, l_j) \geq d(l_i, l_j).$$

The third type, denoted by $\gamma(i,j;\hat{x}_a,\hat{x}_b,\mathbf{I})$, corresponds to the constraint

$$d'(l_i, l_j) + d'(l_{i+1}, l_{j+1}) \leq d'(l_i, l_{j+1}) + d'(l_{i+1}, l_j).$$

Let $(\boldsymbol{\alpha}^*(\hat{x}_a,\hat{x}_b,\mathbf{I}), \boldsymbol{\beta}^*(\hat{x}_a,\hat{x}_b,\mathbf{I}), \boldsymbol{\gamma}^*(\hat{x}_a,\hat{x}_b,\mathbf{I}))$ denote an optimal solution of the dual. A modification of Lemma 14 can be used to show that there must exist an optimal solution such that $\boldsymbol{\beta}^*(\hat{x}_a,\hat{x}_b,\mathbf{I})$ is uncrossing.

We consider the values of $\hat{x}_a$ and $\hat{x}_b$ for which we obtain the tight multiplicative bound of the interval move-making algorithm. For these values of $\hat{x}_a$ and $\hat{x}_b$, we define

$$\overline{y}_{ab}(i,j;\hat{x}_a,\hat{x}_b) = \frac{\sum_{\mathbf{I}\in\mathcal{I}} \alpha^*(i,j;\hat{x}_a,\hat{x}_b,\mathbf{I})}{\sum_{i',j'}\sum_{\mathbf{I}\in\mathcal{I}} \alpha^*(i',j';\hat{x}_a,\hat{x}_b,\mathbf{I})}, \forall i,j \in \{1,\cdots,h\},$$

$$\overline{y}_a(i;\hat{x}_a,\hat{x}_b) = \sum_{j=1}^{h} \overline{y}_{ab}(i,j;\hat{x}_a,\hat{x}_b), \forall i \in \{1,\cdots,h\},$$

$$\overline{y}_b(j;\hat{x}_a,\hat{x}_b) = \sum_{i=1}^{h} \overline{y}_{ab}(i,j;\hat{x}_a,\hat{x}_b), \forall j \in \{1,\cdots,h\},$$

$$y'_{ab}(i,j;\hat{x}_a,\hat{x}_b) = \frac{\sum_{\mathbf{I}\in\mathcal{I}} \beta^*(i,j;\hat{x}_a,\hat{x}_b,\mathbf{I})}{\sum_{i',j'}\sum_{\mathbf{I}\in\mathcal{I}} \beta^*(i',j';\hat{x}_a,\hat{x}_b,\mathbf{I})}, \forall i,j \in \{1,\cdots,h\},$$

$$y'_a(i;\hat{x}_a,\hat{x}_b) = \sum_{j=1}^{h} y'_{ab}(i,j;\hat{x}_a,\hat{x}_b), \forall i \in \{1,\cdots,h\},$$

$$y'_b(j;\hat{x}_a,\hat{x}_b) = \sum_{i=1}^{h} y'_{ab}(i,j;\hat{x}_a,\hat{x}_b), \forall j \in \{1,\cdots,h\}.$$

The constraints of the dual of problem (27) ensure that

$$\overline{y}_a(i;\hat{x}_a,\hat{x}_b) = y'_a(i;\hat{x}_a,\hat{x}_b), \forall i \in \{1,\cdots,h\},$$
$$\overline{y}_b(j;\hat{x}_a,\hat{x}_b) = y'_b(j;\hat{x}_a,\hat{x}_b), \forall j \in \{1,\cdots,h\}.$$

Given the distributions $\overline{\mathbf{y}}_a(\hat{x}_a, \hat{x}_b)$ and $\overline{\mathbf{y}}_b(\hat{x}_a, \hat{x}_b)$, we claim that the pairwise variables $\overline{\mathbf{y}}_{ab}(\hat{x}_a, \hat{x}_b)$ must minimize the pairwise potentials corresponding to these distributions, that is,

$$\begin{aligned}
\overline{\mathbf{y}}_{ab}(\hat{x}_a, \hat{x}_b) = \quad & \operatorname*{argmin}_{\mathbf{y}_{ab}} \sum_{l_i, l_j \in \mathbf{L}} d(l_i, l_j) y_{ab}(i, j) \\
\text{s.t.} \quad & \sum_{l_j \in \mathbf{L}} y_{ab}(i, j) = \overline{y}_a(i; \hat{x}_a, \hat{x}_b), \forall l_i \in \mathbf{L} \\
& \sum_{l_i \in \mathbf{L}} y_{ab}(i, j) = \overline{y}_b(j; \hat{x}_a, \hat{x}_b), \forall l_j \in \mathbf{L} \\
& y_{ab}(i, j) \geq 0, \forall l_i, l_j \in \mathbf{L}.
\end{aligned}$$

If the above claim was not true, then we could further increase the value of at least one of the duals of problem (27) corresponding to some interval $\mathbf{I}$. Furthermore, since $\mathbf{y}'_{ab}(\hat{x}_a, \hat{x}_b)$ is constructed using $\boldsymbol{\beta}^*(\hat{x}_a, \hat{x}_b, \mathbf{I})$, which is uncrossing, a modification of Lemma 12 can be used to show that

$$\hat{d}(\hat{\mathbf{y}}_a(\hat{x}_a, \hat{x}_b), \hat{\mathbf{y}}_b(\hat{x}_a, \hat{x}_b)) = \sum_{l_i, l_j \in \mathbf{L}} d(l_i, l_j) y'_{ab}(i, j; \hat{x}_a, \hat{x}_b).$$

Here $\hat{\mathbf{y}}_a(\hat{x}_a, \hat{x}_b)$ and $\hat{\mathbf{y}}_b(\hat{x}_a, \hat{x}_b)$ are the rounded solutions obtained by the interval rounding procedure applied to $\overline{\mathbf{y}}_a(\hat{x}_a, \hat{x}_b)$ and $\overline{\mathbf{y}}_b(\hat{x}_a, \hat{x}_b)$.

By duality, it follows that

$$\frac{\sum_{l_i, l_j \in \mathbf{L}} d(l_i, l_j) y'_{ab}(i, j; \hat{x}_a, \hat{x}_b)}{\sum_{l_i, l_j \in \mathbf{L}} d(l_i, l_j) \overline{y}_{ab}(i, j; \hat{x}_a, \hat{x}_b)} \leq \frac{1}{q} \max_{x_a, x_b, \hat{x}_a, \hat{x}_b \in \mathbf{L}, x_a \neq x_b} \frac{D(x_a, x_b; \hat{x}_a, \hat{x}_b)}{d(x_a, x_b)}.$$

Strong duality implies that there must exist a set of variables for which the above inequality holds as an equality. This proves the lemma. ■

Lemmas 15 and 17 together prove Theorem 3.

Appendix C. Proof of Theorem 8

Proof The proof of the above theorem proceeds in a similar fashion to the previous two theorems, namely, by computing the dual of the problems that are used to obtain the tightest submodular overestimation of the given distance function. In what follows, we provide a brief sketch of the proof and omit the details.

We start with the hierarchical move-making algorithm. Recall that this algorithm computes a labeling $\mathbf{x}^{i,j}$ for each cluster $\mathbf{C}(i, j) \subseteq \mathbf{L}$, where $\mathbf{C}(i, j)$ denotes the j-th cluster at the i-th level. In order to obtain a labeling $\mathbf{x}^{i,j}$ it makes use of the labelings computed at the $(i + 1)$-th level. Specifically, let $\mathbf{L}_a^{i,j} = \{x_a^{i+1,j'}, p(i + 1, j') = j, j' \in \{1, \cdots, h^{i+1}\}\}$. In other words, $\mathbf{L}_a^{i,j}$ is the set of labels that were assigned to the random variable X_a by the labelings corresponding to the children of the current cluster $\mathbf{C}(i, j)$. In order to compute the labeling $\mathbf{x}^{i,j}$, the algorithm has to choose one label from the set $\mathbf{L}_a^{i,j}$. This is achieved either using the complete move-making algorithm or the interval move-making algorithm. The algorithm is initialized by define $x_a^{m,j} = k$ for all $X_a \in \mathbf{X}$ where k is the unique label in the cluster $\mathbf{C}(m, j)$ The algorithm terminates by computing $\mathbf{x}^{1,1}$, which is the final labeling.

Let the multiplicative bound corresponding to the computation of $\mathbf{x}^{i,j}$ be denoted by $B^{i,j}$. From the arguments of Theorems 1 and 3, it follows that there must exist dual variables $(\boldsymbol{\alpha}^*(i, j), \boldsymbol{\beta}^*(i, j), \boldsymbol{\gamma}^*(i, j))$ that provide an approximation factor that is exactly equal to $B^{i,j}$ and $\boldsymbol{\beta}^*(i, j)$ is uncrossing. For each cluster $\mathbf{C}(i, j)$, we define variables $\delta_a(k; i, j)$ for $k \in \mathbf{L}_a^{i,j}$ as follows:

$$\delta_a(k; i, j) = \frac{\sum_{k' \in \mathbf{L}_b^{i,j}} \alpha^*(k, k'; i, j)}{\sum_{l \in \mathbf{L}_a^{i,j}} \sum_{l' \in \mathbf{L}_b^{i,j}} \alpha^*(l, l'; i, j)}.$$

Using the above variables we define unary variables $y_a(k; i, j)$ for each $k \in \mathbf{L}^{i,j}$ as follows:

$$\begin{aligned}
& y_a(k; 1, 1) = \delta_a(k; 1, 1), \\
& y_a(k; i, j) = y_a(x_a^{i-1, p(i,j)}; i - 1, p(i, j)) \delta_a(k; i, j).
\end{aligned}$$

Similarly, we define variables $\delta_b(k'; i, j)$ for each $k' \in \mathbf{L}_b^{i,j}$ as follows:

$$\delta_b(k'; i, j) = \frac{\sum_{k \in \mathbf{L}_a^{i,j}} \alpha^*(k, k'; i, j)}{\sum_{l \in \mathbf{L}_a^{i,j}} \sum_{l' \in \mathbf{L}_b^{i,j}} \alpha^*(l, l'; i, j)}.$$

Using the above variables, we define unary variables $y_b(k'; i, j)$ for each $k' \in \mathbf{L}_b^{i,j}$ as follows:

$$\begin{aligned}
& y_b(k'; 1, 1) = \delta_b(k'; 1, 1), \\
& y_b(k'; i, j) = y_a(x_a^{i-1, p(i,j)}; i - 1, p(i, j)) \delta_b(k'; i, j).
\end{aligned}$$

Since each cluster in the m-th level contains a single unique label, it follows that

$$\begin{aligned}
& \mathbf{y}_a = [y_a(x_a^{m,j}; m, j), \forall j = 1, \cdots, h], \\
& \mathbf{y}_b = [y_b(x_b^{m,j}; m, j), \forall j = 1, \cdots, h],
\end{aligned}$$

are valid unary variables for the LP relaxation. It can be shown that applying the hierarchical rounding procedure on the variables $\mathbf{y}_a$ and $\mathbf{y}_b$ provides an approximation factor that is exactly equal to the multiplicative bound of the hierarchical move-making algorithm. ■

Abstract

We study minimax rates for denoising simultaneously sparse and low rank matrices in high dimensions. We show that an iterative thresholding algorithm achieves (near) optimal rates adaptively under mild conditions for a large class of loss functions. Numerical experiments on synthetic datasets also demonstrate the competitive performance of the proposed method.

Keywords: Denoising, High dimensionality, Low rank matrices, Minimax rates, Simultaneously structured matrices, Sparse SVD, Sparsity.

1. Introduction

In recent years, there has been a surge of interest in estimating and denoising structured large matrices. Leading examples include denoising low rank matrices (Donoho and Gavish, 2014), recovering low rank matrices from a small number of entries, i.e., matrix completion (Candès and Recht, 2009; Candès and Plan, 2010; Keshavan et al., 2010; Koltchinskii et al., 2011; Negahban and Wainwright, 2011), reduced rank regression (Bunea et al., 2011), group sparse regression (Yuan and Lin, 2006; Lounici et al., 2011), among others.

In the present paper, we study the problem of denoising an $m \times n$ data matrix

$$\mathbf{X} = \mathbf{M} + \mathbf{Z}. \tag{1}$$

The primary interest lies in the matrix $\mathbf{M}$ that is sparse in the sense that nonzero entries are assumed to be confined on a $k \times l$ block, which is not necessarily consecutive. In addition to being sparse, the rank of $\mathbf{M}$, denoted by r, is assumed to be low. Thus, $\mathbf{M}$ can be regarded as *simultaneously structured* as opposed to those simply structured cases where $\mathbf{M}$ is assumed to be either only sparse or only of low rank. To be concrete, we assume that $\mathbf{Z}$ consists of i.i.d. additive Gaussian white noise with variance σ^2. In the literature, the problem has also been referred to as the sparse SVD (singular value decomposition) problem. See, for instance, Yang et al. (2014) and the references therein.

The interest in this problem is motivated by a number of related problems:

1. *Biclustering.* It provides an ideal model for studying biclustering of microarray data. Let the rows of $\mathbf{X}$ correspond to cancer patients and the columns correspond to gene expression levels measured with microarrays. A subset of k patients can be clustered together as a subtype of the same cancer, which in turn is determined by a subset of l genes. Moreover, the gene expression levels on such a bicluster can be captured by a low rank matrix. See, e.g., Shabalin et al. (2009); Lee et al. (2010); Butucea and Ingster (2013); Sun and Nobel (2013); Chen et al. (2013); Gao et al. (2015).

2. *Recovery of simultaneously structured matrices with compressive measurements.* There has been emerging interest in the signal processing community in recovering such simultaneously structured matrices based on compressive measurements, partly motivated by problems such as sparse vector recovery from quadratic measurements and sparse phase retrieval. See, e.g., Shechtman et al. (2011); Li and Voroninski (2013); Lee et al. (2013); Oymak et al. (2013); Cai et al. (2015) and the references therein. The connection between the recovery problem and the denoising problem considered here is partially explored in Oymak and Hassibi (2013). An interesting phenomenon in the recovery setting is that convex relaxation approach no longer works well (Oymak et al., 2015) as it does in the simply structured cases.

3. *Sparse reduced rank regression.* The denoising problem is also closely connected to prediction in reduced rank regression where the coefficient matrix is also sparse. Indeed, let $n = l$, then problem (1) reduces to sparse reduced rank regression with orthogonal design. See Bunea et al. (2012) and Ma and Sun (2014) for more discussion.

The main contribution of the present paper includes the following: i) We provide information-theoretic lower bounds for the estimation error of $\mathbf{M}$ under squared Schatten-q norm losses for all $q \in [1, 2]$; ii) We propose a computationally efficient estimator that, under mild conditions, attains high probability upper bounds that match the minimax lower bounds within a multiplicative log factor (and sometimes even within a constant factor) simultaneously for all $q \in [1, 2]$. The theoretical results are further validated and supported by numerical experiments on synthetic data.

The rest of the paper is organized as follows. In Section 2, we precisely formulate the denoising problem and propose a denoising algorithm based on the idea of iterative thresholding. Section 3 establishes minimax risk lower bounds and high probability upper bounds that match the lower bounds within a multiplicative log factor for all squared Schatten-q norm losses with $q \in [1, 2]$. Section 4 presents several numerical experiments which demonstrate the competitive finite sample performance of the proposed denoising algorithm. Section 5 discusses several additional issues related to the present paper. The proofs of the main results are presented in Section 6, with some technical details relegated to Appendix A.

2. Problem Formulation and Denoising Method

Notation For any $a, b \in \mathbb{R}$, let $a \wedge b = \min(a, b)$ and $a \vee b = \max(a, b)$. For any two sequences of positive numbers $\{a_n\}$ and $\{b_n\}$, we write $a_n = O(b_n)$ if $a_n \leq C b_n$ for some

absolute positive constant C and all n. For any matrix $\mathbf{A} \in \mathbb{R}^{m\times n}$, denote its successive singular values by $\sigma_1(\mathbf{A}) \geq \cdots \geq \sigma_{m\wedge n}(\mathbf{A}) \geq 0$. For any $q \in [1,\infty)$, the Schatten-q norm of $\mathbf{A}$ is defined as $\|\mathbf{A}\|_{\mathrm{S}_q} = (\sum_{i=1}^{m\wedge n} \sigma_i^q(\mathbf{A}))^{1/q}$. Thus, $\|\mathbf{A}\|_{\mathrm{S}_1}$ is the nuclear norm of $\mathbf{A}$ and $\|\mathbf{A}\|_{\mathrm{S}_2} = \|\mathbf{A}\|_{\mathrm{F}}$ is the Frobenius norm. In addition, the Schatten-∞ norm of $\mathbf{A}$ is $\|\mathbf{A}\|_{\mathrm{S}_\infty} = \sigma_1(\mathbf{A}) = \|\mathbf{A}\|_{\mathrm{op}}$, where $\|\cdot\|_{\mathrm{op}}$ stands for the operator norm. The rank of $\mathbf{A}$ is denoted by $\mathsf{rank}(\mathbf{A})$. For any vector $\mathbf{a}$, we denote its Euclidean norm by $\|\mathbf{a}\|$. For any integer m, $[m]$ stands for the set $\{1,\ldots,m\}$. For any subset $I \subset [m]$ and $J \subset [n]$, we use $\mathbf{A}_{IJ}$ to denote the submatrix of $\mathbf{A}$ with rows indexed by I and columns by J. When either I or J is the whole set, we replace it with $*$. For instance, $\mathbf{A}_{I*} = \mathbf{A}_{I[n]}$. Moreover, we use $\mathrm{supp}(\mathbf{A})$ to denote the set of nonzero rows of $\mathbf{A}$. For any set A, $|A|$ denotes its cardinality and A^c denotes its complement. A matrix $\mathbf{A}$ is called orthonormal, if the column vectors are of unit length and mutually orthogonal. For any event E, we use $\mathbf{1}_E$ to denote the indicator function on E, and E^c denotes its complement.

2.1 Problem Formulation

We now put the denoising problem in a decision-theoretic framework. Recall model (1). We are interested in estimating $\mathbf{M}$ based on the noisy observation $\mathbf{X}$, where $\mathbf{M}$ is simultaneously sparse and low rank. Let the singular value decomposition (SVD) of $\mathbf{M} = \mathbf{UDV}'$, where $\mathbf{U}$ is $m \times r$ orthonormal, $\mathbf{V}$ is $n \times r$ orthonormal and $\mathbf{D} = \mathrm{diag}(d_1,\ldots,d_r)$ is $r \times r$ diagonal with $d_1 \geq \cdots \geq d_r > 0$. In addition, since the nonzero entries on $\mathbf{M}$ concentrate on a $k \times l$ block, $\mathbf{U}$ has at most k nonzero rows and $\mathbf{V}$ at most l. Therefore, the parameter space of interest can be written as

$$\begin{aligned}\mathcal{F}(m,n,k,l,r,d,\kappa) = \{&\mathbf{M} = \mathbf{UDV}' \in \mathbb{R}^{m\times n} : \mathsf{rank}(\mathbf{M}) = r,\\ &|\mathrm{supp}(\mathbf{U})| \leq k, |\mathrm{supp}(\mathbf{V})| \leq l,\\ &d \leq d_r \leq \cdots \leq d_1 \leq \kappa d\}.\end{aligned} \tag{2}$$

We will focus on understanding the dependence of the minimax estimation error on the key model parameters (m,n,k,l,r,d), while $\kappa > 1$ is treated as an unknown universal constant. Without loss of generality, we assume $m \geq n$ here and after. Note that it is implicitly assumed in (2) that $m \geq k \geq r$ and $n \geq l \geq r$.

To measure the estimation accuracy, we use the following squared Schatten-q norm loss functions:

$$L_q(\mathbf{M},\widehat{\mathbf{M}}) = \|\widehat{\mathbf{M}} - \mathbf{M}\|_{\mathrm{s}_q}^2, \qquad q \in [1,2]. \tag{3}$$

The model (1), the parameter space (2) and the loss functions (3) give a precise formulation of the denoising problem.

2.2 Approach

From a matrix computation viewpoint, if one seeks a rank r approximation to a matrix $\mathbf{X}$, then one can first find its left and the right r leading singular vectors. If we organize these vectors as columns of the left and the right singular vector matrices $\mathbf{U}$ and $\mathbf{V}$, then the matrix $(\mathbf{UU}')\mathbf{X}(\mathbf{VV}')$ has the minimum Frobenius reconstruction error for $\mathbf{X}$ among all rank r matrices, since $\mathbf{U}'\mathbf{XV}$ will be a diagonal matrix consisting of the r leading singular values of $\mathbf{X}$. On the other hand, if one wants to enforce sparsity in the resulting matrix,

it is natural to utilize the idea of thresholding in the above calculation. Motivated by the above observation and also by an iterative thresholding idea previously used in solving sparse PCA problem (Ma, 2013; Yuan and Zhang, 2013), we propose the denoising scheme in Algorithm 1 via two-way iterative thresholding.

Algorithm 1: Matrix Denoising via Two-Way Iterative Thresholding

Input:
1. Observed data matrix $\mathbf{X}$.
2. Thresholding function η and thresholds γ_u and γ_v.
3. Rank r and noise standard deviation σ.
4. Initial orthonormal matrix $\mathbf{V}^{(0)} \in \mathbb{R}^{n\times r}$.

Output: Denoised matrix $\widehat{\mathbf{M}}$.

repeat

1 Right-to-Left Multiplication: $\mathbf{U}^{(t),\mathrm{mul}} = \mathbf{XV}^{(t-1)}$.

2 Left Thresholding: $\mathbf{U}^{(t),\mathrm{thr}} = (u_{ij}^{(t),\mathrm{thr}})$, with $\mathbf{U}_{i*}^{(t),\mathrm{thr}} = \frac{\mathbf{U}_{i*}^{(t),\mathrm{mul}}}{\|\mathbf{U}_{i*}^{(t),\mathrm{mul}}\|}\eta(\|\mathbf{U}_{i*}^{(t),\mathrm{mul}}\|,\gamma_u)$.

3 Left Orthonormalization with QR Decomposition: $\mathbf{U}^{(t)}\mathbf{R}_u^{(t)} = \mathbf{U}^{(t),\mathrm{thr}}$.

4 Left-to-Right Multiplication: $\mathbf{V}^{(t),\mathrm{mul}} = \mathbf{X}'\mathbf{U}^{(t)}$.

5 Right Thresholding: $\mathbf{V}^{(t),\mathrm{thr}} = (v_{ij}^{(t),\mathrm{thr}})$, with $\mathbf{V}_{i*}^{(t),\mathrm{thr}} = \frac{\mathbf{V}_{i*}^{(t),\mathrm{mul}}}{\|\mathbf{V}_{i*}^{(t),\mathrm{mul}}\|}\eta(\|\mathbf{V}_{i*}^{(t),\mathrm{mul}}\|,\gamma_v)$.

6 Right Orthonormalization with QR Decomposition: $\mathbf{V}^{(t)}\mathbf{R}_v^{(t)} = \mathbf{V}^{(t),\mathrm{thr}}$.

until *Convergence*;

7 Compute projection matrices $\widehat{\mathbf{P}}_u = \widehat{\mathbf{U}}\widehat{\mathbf{U}}'$ and $\widehat{\mathbf{P}}_v = \widehat{\mathbf{V}}\widehat{\mathbf{V}}'$, where $\widehat{\mathbf{U}}$ and $\widehat{\mathbf{V}}$ are $\mathbf{U}^{(t)}$ and $\mathbf{V}^{(t)}$ at convergence.

8 Compute denoised matrix $\widehat{\mathbf{M}} = \widehat{\mathbf{P}}_u\mathbf{X}\widehat{\mathbf{P}}_v$.

Without the two thresholding steps, the iterative part of the algorithm computes the leading singular vectors of any rectangular matrix, and can be viewed as a two-way generalization of the power iteration (Golub and Van Loan, 1996).

In the thresholding steps, we apply row-wise thresholding to the matrix $\mathbf{U}^{(t),\mathrm{mul}}$ (resp. $\mathbf{V}^{(t),\mathrm{mul}}$) obtained after the multiplication step. In the thresholding function $\eta(x,t)$, the second argument $t > 0$ is called the threshold level. In Algorithm 1, the first argument x is always non-negative. In order for the later theoretical results to work, we impose the following minimal assumption on the thresholding function η:

$$\begin{aligned}|\eta(x,t) - x| \leq t, &\quad \text{for any } x \geq 0,\ t > 0,\\ \eta(x,t) = 0, &\quad \text{for any } t > 0,\ x \in [0,t].\end{aligned} \tag{4}$$

Examples of such thresholding functions include the usual soft and hard thresholding, the SCAD (Fan and Li, 2001), the MCP (Zhang, 2010), etc. Thus, for instance, when thresholding $\mathbf{U}^{(t),\mathrm{mul}}$, if η is the hard thresholding function, then we are going to keep all the rows whose norms are greater than γ_u and kill all the rows whose norms are smaller than γ_u. For other thresholding function, we shrink the norms according to η while keeping the phases of the row vectors. Throughout the iterations, the threshold levels γ_u and γ_v are pre-specified

and remain unchanged. In order for the theorem to work, these levels can be chosen as in (10) below.

To determine the convergence of the iterative part, we could either run a pre-specified number of iterations or stop after the difference between successive iterates are sufficiently small, e.g.,

$$\|\mathbf{U}^{(t)}(\mathbf{U}^{(t)})' - \mathbf{U}^{(t-1)}(\mathbf{U}^{(t-1)})'\|_{\mathrm{F}}^2 \vee \|\mathbf{V}^{(t)}(\mathbf{V}^{(t)})' - \mathbf{V}^{(t-1)}(\mathbf{V}^{(t-1)})'\|_{\mathrm{F}}^2 \le \epsilon, \tag{5}$$

where ϵ is a pre-specified tolerance level.

Initialization To initialize Algorithm 1, we need to further specify the rank r, the noise standard deviation σ and a starting point $\mathbf{V}^{(0)}$ for the iteration. For the ease of exposition, we assume that r is known. Otherwise, it can be estimated by methods such as those described in Yang et al. (2014). When we have Gaussian noise and $kl < \frac{1}{2}mn$, the noise standard deviation can be estimated by

$$\widehat{\sigma} = 1.4826 \cdot \mathrm{MAD}(\{\mathbf{M}_{ij} : i \in [m], j \in [n]\}). \tag{6}$$

Finally, to obtain a reasonable initial orthonormal matrix $\mathbf{V}^{(0)}$, we propose to use Algorithm 2 for the case of Gaussian noise.

Algorithm 2: Initialization for Algorithm 1

Input:

1. Observed data matrix $\mathbf{X}$.
2. Tuning parameter α.
3. Rank r and noise standard deviation σ.

Output: Estimators $\widehat{\mathbf{U}} = \mathbf{U}^{(0)}$ and $\widehat{\mathbf{V}} = \mathbf{V}^{(0)}$.

1 Select the subset I_0 of rows and the subset J_0 of columns as

$$I^0 = \{i : \|\mathbf{X}_{i*}\|^2 \ge \sigma^2(n + \alpha\sqrt{n \log n})\}, \tag{7a}$$

$$J^0 = \{j : \|\mathbf{X}_{*j}\|^2 \ge \sigma^2(m + \alpha\sqrt{m \log m})\}. \tag{7b}$$

2 Compute $\mathbf{X}^{(0)} = (x_{ij}^{(0)})$, where $x_{ij}^{(0)} = x_{ij}\mathbf{1}_{i\in I^0}\mathbf{1}_{j\in J^0}$.

3 Compute $\mathbf{U}^{(0)} = [\mathbf{u}_1^{(0)}, \ldots, \mathbf{u}_r^{(0)}]$ and $\mathbf{V}^{(0)} = [\mathbf{v}_1^{(0)}, \ldots, \mathbf{v}_r^{(0)}]$, where $\mathbf{u}_\nu^{(0)}$ ($\mathbf{v}_\nu^{(0)}$) is the ν^{th} leading left (right) singular vector of $\mathbf{X}^{(0)}$.

Remark 1 *In practice, Algorithms 1 and 2 are not restricted to the denoising of matrices with Gaussian noise. With proper modification and robustification, they can be used together to deal with other noise distributions and/or outliers. See, e.g., Yang et al. (2014).*

3. Theoretical Results

In this section, we present a minimax theory underlying the denoising/estimation problem formulated in Section 2.1.

3.1 Minimax Lower Bounds

Theorem 2 *Let $\mathcal{F} = \mathcal{F}(m, n, k, l, r, d, \kappa)$ with $\kappa > 1$ and $k \wedge l \ge 2r$. There exists a positive constant c that depends only on κ, such that for any $q \in [1, 2]$, the minimax risk for estimating $\mathbf{M}$ under the squared Schatten-q error loss (3) satisfies*

$$\inf_{\widehat{\mathbf{M}}} \sup_{\mathcal{F}} \mathbb{E}L_q(\mathbf{M}, \widehat{\mathbf{M}}) \ge c\sigma^2 \left[\left(r^{\frac{2}{q}-1}\frac{d^2}{\sigma^2}\right) \wedge \Psi_q(m, n, k, l, r)\right] \tag{8}$$

where the rate function $\Psi_q(m, n, k, l, r) = r^{\frac{2}{q}}(k + l) + r^{\frac{2}{q}-1}\left(k \log \frac{em}{k} + l \log \frac{en}{l}\right)$.

A proof of the theorem is given in Section 6.1.

Remark 3 *Regardless of the value of q, the lower bounds reflect two different scenarios.*

The first scenario is the "low signal" case where

$$d^2 \le \sigma^2 \Psi_2(m, n, k, l, r). \tag{9}$$

In this case, the first term in the lower bound (8) dominates, and the rate is achieved by simply estimating $\mathbf{M}$ by $\mathbf{0} \in \mathbb{R}^{m\times n}$.

The second scenario is when (9) does not hold. In this case, the second term in (8) dominates. We note this term is expressed as the sum of two terms. As to be revealed by the proof, the first summand is an "oracle" error term which occurs even when the indices of the nonzero rows and columns of $\mathbf{M}$ are given by an oracle. In contrast, the second summand results from the combinatorial uncertainty about the locations of these nonzero rows and columns.

3.2 Minimax Upper Bounds

To state the upper bounds, we first specify the threshold levels used in Algorithm 1. In particular, for some sufficiently large constant $\beta > 0$, set

$$\gamma_u^2 = \gamma_v^2 = \gamma^2 = 1.01(r + 2\sqrt{r\beta \log m} + 2\beta \log m). \tag{10}$$

For Theorem 4 to hold, it suffices to choose any $\beta \ge 4$. In addition, we specify the stopping (convergence) rule for the loop in Algorithm 1. For $\mathbf{X}^{(0)}$ defined in Algorithm 2, let $d_r^{(0)}$ be its r^{th} largest singular value. Define

$$\widehat{T} = \frac{1.1}{2}\left[\frac{\log m}{\log 2} + \log \frac{(d_r^{(0)})^2}{\gamma^2}\right], \tag{11}$$

and

$$T = \frac{1.01}{2}\left[\frac{\log m}{\log 2} + \log \frac{d_r^2}{k\gamma_u^2 \vee l\gamma_v^2}\right]. \tag{12}$$

We propose to stop the iteration in Algorithm 1 after $\widehat{T}$ steps. Last but not least, we need the following technical condition.

Condition 1 *There exists a sufficiently small absolute constant c, such that $m \geq n$, $\log d \leq cm$, $c \leq \log m / \log n \leq 1/c$, $\log m \leq c[(m-k) \wedge (n-l)]$, $k \vee l \leq c(m \wedge n)$. In addition, there exists a sufficiently small constant c' that depends only on κ, such that $(\sigma/d)^2 r \left(k\sqrt{n \log m} + l\sqrt{m \log m}\right) \leq c'$.*

With the above definition, the following theorem establishes high probability upper bounds of the proposed estimator.

Theorem 4 *Let Condition 1 be satisfied. In Algorithm 1, let $\mathbf{V}^{(0)}$ be obtained by Algorithm 2 with $\alpha \geq 4$ in (7). Let γ_u and γ_v be defined as in (10) with $\beta \geq 4$. Moreover, we stop the iteration after $\widehat{T}$ steps with $\widehat{T}$ defined in (11), and use $\widehat{\mathbf{U}} = \mathbf{U}^{(\widehat{T})}$ and $\widehat{\mathbf{V}} = \mathbf{V}^{(\widehat{T})}$ in subsequent steps. For sufficiently large values of m and n, uniformly over $\mathcal{F}(m, n, k, l, r, d, \kappa)$, with probability at least $1 - O(m^{-2})$, $\widehat{T} \in [T, 3T]$ and*

$$\|\widehat{\mathbf{M}} - \mathbf{M}\|_{s_q}^2 \leq C\sigma^2 \left[r^{\frac{2}{q}} (k + l + \log m) + r^{\frac{2}{q}-1} (k+l) \log m \right]$$

where C is a positive constant that depends only on κ and β.

The proof of the theorem is given in Section 6.2.

Remark 5 *Under Condition 1, for sufficient large values of m and n, (9) cannot hold, and so the relevant lower bound is $c\sigma^2 \Psi_q(m, n, k, l, r)$. In comparison, when $k \wedge l \geq (1+\epsilon)r$ for any universal small constant $\epsilon > 0$, the upper bounds in Theorem 4 always matches the lower bounds for all $q \in [1, 2]$ up to a multiplicative log factor. If in addition, $\log m = O(k \vee l)$ and $k = O(m^a)$ and $l = O(n^a)$ for some constant $a \in (0, 1)$, then the rates in the lower and upper bounds match exactly for all $q \in [1, 2]$. We note that Condition 1 can essentially be interpreted as a minimum signal-to-noise ratio condition where we require $d^2/\sigma^2 \geq Cr(k\sqrt{n \log m} + l\sqrt{m \log m})$. The condition is needed in guaranteeing the success of the initialization method in Algorithm 2 and the rank selection method to be introduced below.*

Remark 6 *The proposed estimator is adaptive since it does not depend on the knowledge of k, l and q. Its dependence on r can also be removed, as we explain in the next subsection.*

3.3 Rank Selection

We now turn to data-based selection of the rank r. Recall the sets I^0 and J^0 defined in (7). We propose to use the following data-based choice of r:

$$\widehat{r} = \max\left\{ s : \sigma_s(\mathbf{X}_{I^0 J^0}) \geq \sigma\, \delta_{|I^0||J^0|} \right\}, \tag{13}$$

where for any $i \in [m]$ and $j \in [n]$, $\delta_{ij} = \sqrt{i} + \sqrt{j} + \sqrt{2i \log \frac{\mathrm{e}m}{i} + 2j \log \frac{\mathrm{e}n}{j} + 8 \log m}$. Here, the threshold $\sigma\delta_{|I^0||J^0|}$ used in rank selection (13) is motivated by the Davidson–Szarek bound (Davidson and Szarek, 2001) and the union bound. Basically, $\sigma\delta_{|I^0||J^0|}$ bounds the largest singular value of any submatrix of $\mathbf{Z}$ of size $|I^0|$ by $|J^0|$ and any singular value larger than the threshold has to come from the signal part. We note that it is straightforward to incorporate this rank selection step into Algorithm 2. Indeed, we can compute $\widehat{r}$ right after step 1 and replace all r in the subsequent steps by $\widehat{r}$. The following result justifies our proposal.

Proposition 7 *Under the condition of Theorem 4, $\widehat{r} = r$ holds with probability at least $1 - O(m^{-2})$.*

A proof of the proposition is given in Section 6.3. According to Proposition 7, we can use $\widehat{r}$ as the input for rank in Algorithm 1 and the conclusion of Theorem 4 continues to hold.

4. Simulation

In this section, we demonstrate the performance of the proposed denoising method on synthetic datasets.

In the first numerical experiment, we study the effect of the signal-to-noise ratio. To this end, we fix $m = 2000, n = 1000, k = l = 50$, $r = 10$, and set the singular values of $\mathbf{M}$ as $(d_1, \ldots, d_{10}) = (200, 190, \ldots, 120, 110)$. The signal-to-noise ratio is varied by varying noise standard deviation σ on ten equally spaced values between 0.2 and 2. The $\mathbf{U}$ matrix is obtained by orthonormalizing a $m \times r$ matrix the i^{th} row of which is filled i.i.d. $N(0, i^4)$ entries for any $i \in [k]$ and zeros otherwise. The $\mathbf{V}$ matrix is obtained in the same way with m and k replaced by n and l. Fig. 1 shows the boxplots of $L_q(\mathbf{M}, \widehat{\mathbf{M}})$ for $q = 1$ and 2 for the varying values of σ out of 100 repetitions for each of the ten values of σ. Throughout this section, we use (6) to estimate σ, Algorithm 2 with $\alpha = 4$ to compute $\mathbf{V}^{(0)}$ and (13) to select the rank. In Algorithm 1, we set $\beta = 3$ and we terminate the iteration once (5) holds with $\epsilon = 10^{-10}$. The thresholding function η is fixed to be hard thresholding $\eta(x, t) = x\mathbf{1}_{|x|>t}$. In all the repetitions, the proposed $\widehat{r}$ in (13) consistently yields the right rank $r = 10$. From Fig. 1, we conclude that the denoising error grows quadratically with the value of σ, which agrees well with the theoretical results in Theorem 4.

In the second experiment, we study the effect of the rank r on denoising error. To this end, we fix $m = 2000, n = 1000, k = l = 50$, $\sigma = 1$ and all the nonzero singular values of $\mathbf{M}$ as $d_1 = \cdots = d_r = 200$. We vary r between 1 and 10. For each value of r, the $\mathbf{U}$ and $\mathbf{V}$ matrices are generated in the same way as in the first experiment. Fig. 2 shows the boxplots of $L_q(\mathbf{M}, \widehat{\mathbf{M}})$ for $q = 1$ and 2 for the varying values of r out of 100 repetitions for each of the ten values of r. It is noticeable that for the L_1 loss, the denoising error grows quadratically as the rank r grows, while the trend is linear for the L_2 loss. Both cases agree with Theorem 4.

In the third experiment, we study the effect of the parameter q used in the loss function. To this end, we generated datasets in the same way as in the first experiment while fixing $\sigma = 1$. We take eleven different values of $q \in [1, 2]$ such that their reciprocals are equally spaced between 0.5 and 1. As Fig. 3 shows, the logarithm of the loss function scales linearly with $1/q$. Again, this is in accordance with the error bound in Theorem 4.

In the fourth experiment, we study the effect of sparsity levels. To this end, we fix $m = 2000, n = 1000, r = 10$ and the singular values of $\mathbf{M}$ are $(d_1, \ldots, d_{10}) = (200, 190, \ldots, 120, 110)$. On the other hand, we consider four different combinations of sparsity parameters: $(k, l) = (50, 50), (50, 200), (100, 200)$ and $(100, 50)$. For each (k, l) pair, the way we generate $\mathbf{U}$, $\mathbf{V}$ and $\mathbf{X}$ is the same as that in the first experiment. Moreover, the tuning parameter values used in denoising are also the same as before. In all the repetitions, $\widehat{r}$ in (13) consistently select $r = 10$. In Table 1, we report the average values of $L_q(\mathbf{M}, \widehat{\mathbf{M}})$ for $q = 2$ and 1 and

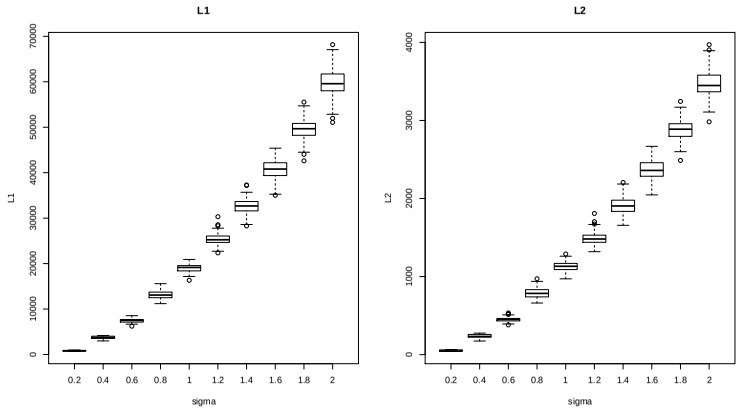

Figure 1: Loss vs. σ: boxplots of 100 repetitions. Left panel: L_1 loss. Right panel: L_2 loss.

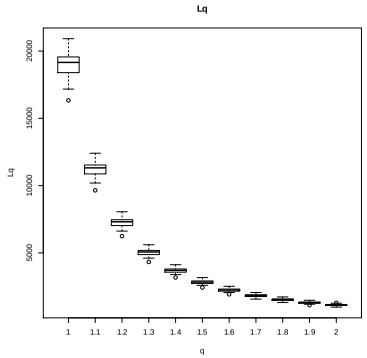

Figure 3: Loss vs. q: boxplots of 100 repetitions.

(k, l)	(50, 50)	(50, 200)	(100, 200)	(100, 50)
Average$(L_2(\mathbf{M}, \widehat{\mathbf{M}}))$	1133.03	2662.07	3598.69	1673.49
Standard error	(5.96)	(11.73)	(12.84)	(9.73)
Average$\left(\frac{L_2(\mathbf{M},\widehat{\mathbf{M}})}{(r+\log m)(k+l)}\right)$	0.64	0.60	0.68	0.63
Average$(L_1(\mathbf{M}, \widehat{\mathbf{M}}))$	19056.47	43035.95	65099.19	28347.12
Standard error	(88.42)	(172.39)	(231.98)	(146.07)
Average$\left(\frac{L_1(\mathbf{M},\widehat{\mathbf{M}})}{(r^2+r\log m)(k+l)}\right)$	1.08	0.98	1.23	1.07

Table 1: Average losses (with its standard error) and average rescaled losses of $\widehat{\mathbf{M}}$ out of 100 repetitions for different sparsity levels.

their standard errors over 100 repetitions. Moreover, we report the rescaled average loss where the rescaling constant is chosen to be $r^{\frac{2}{q}-1}(r+\log m)(k+l)$, the rate derived in Theorem 4. By the results reported in Table 1, we see that for either loss function, the rescaled average losses are stable with respect to different sparsity levels specified by different values of k and l. Again, this agrees well with the earlier theoretical results.

In the last experiment, we study the effect of "spikiness", i.e., how the concentration of energy of the nonzero entries in $\mathbf{M}$ affects denoising. To this end, we fix $m = 2000, n = 1000, k = l = 50$, $r = 1$, $d_1 = 200$ and $\sigma = 1$. In this case, $\mathbf{U}$ and $\mathbf{V}$ are both vectors. To vary the "spikiness", we set all nonzero entries of $\mathbf{V}$ to be equal and the nonzero entries of $\mathbf{U}$ as

$$\mathbf{U}_{i1} = C_s\, i^{-1/s}, \quad \text{for } i = 1, \ldots, k,$$

for a grid of twenty equally spaced s values in $\{0.1, 0.2, \ldots, 2\}$. Here, for any given s, C_s is the normalizing constant ensuring $\|\mathbf{U}\| = 1$. The smaller the s value, the faster the nonzero

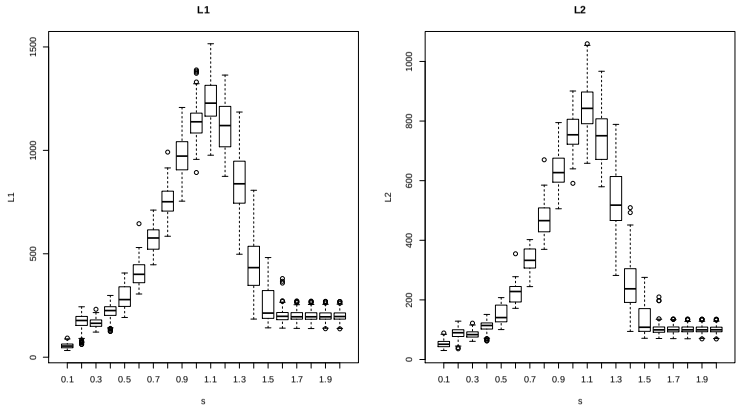

Figure 4: Loss vs. "spikiness": boxplots of 100 repetitions. Left panel: L_1 loss. Right panel: L_2 loss.

entries in $\mathbf{U}$ decay to zero and the more concentrated the energy of the nonzero entries in $\mathbf{U}$ and hence in $\mathbf{M}$. Fig. 4 shows the boxplots of $L_q(\mathbf{M}, \widehat{\mathbf{M}})$ for $q = 1$ and 2 for the varying values of s out of 100 repetitions for each of the twenty values of s. A somewhat surprising phenomenon is that the error is not monotone in "spikiness". For both L_1 and L_2 losses, the errors first increase as s increases until they reach the peak when $s = 1.1$ and then the errors decay as s further increases. Finally, they stabilize after s becomes 1.6 or larger. We feel that this intriguing phenomenon might be explained intuitively as the following. For small to medium values of s, both the bias and the variance in the estimator increases with s. However, due to the additional l_0 sparsity of $\mathbf{U}$, the bias starts to decrease after s grows larger than some critical value (1.1 in this simulation). Furthermore, when s grows larger than another critical value (1.6 in this simulation), the estimator essentially estimates the entire nonzero block in $\mathbf{M}$ and the bias term vanishes, which explains the stabilization near the end of the curves in Fig. 4.

5. Discussion

In this section, we discuss two additional issues related to the present work.

Sparse PCA The present paper is closely related to the sparse PCA problem where the interest is in estimating the sparse leading eigenvectors of the covariance matrix of the observed random vectors. Although the proposed algorithm in the present paper is partly motivated by the sparse PCA estimation schemes in Ma (2013) and Yuan and Zhang (2013), there are several important differences between the denoising model (1) and the sparse PCA model. First, we aim to recover the mean matrix in model (1) while sparse PCA is interested

in functionals (leading eigenvectors) of the covariance matrix. In addition, sparse PCA only deals with one set of sparse eigenvectors while the denoising problem studied here needs to deal with both left and right sparse singular vectors. In particular, even in the case of Schatten-2 (Frobenius) norm loss, the theoretical results of the present paper cannot be obtained directly from those for sparse PCA, such as those in Ma (2013), Cai et al. (2013a,b), etc.

Loss function In the present paper, we have considered the collection of squared Schatten-q norm for $q \in [1, 2]$ as possible loss functions. One of the referees raised the question whether it is possible to extend the results to the case of $q < 1$, where the loss function becomes a squared quasinorm[1]. This could serve as an interesting topic for future research. However, when $q < 1$, the quasinorm is no longer convex and so the technique for establishing estimation lower bounds which was first laid out in Ma and Wu (2015) no longer applies directly.

6. Proofs

6.1 Proof of Theorem 2

The proof of Theorem 2 relies on the following theorem, which is quoted without proof.

Theorem 8 (Theorem 2 in Ma and Sun (2014)) *Let the observed $\mathbf{X} \in \mathbb{R}^{n\times p}, \mathbf{Y} \in \mathbb{R}^{n\times m}$ be generated by the model $\mathbf{Y} = \mathbf{X}\mathbf{A}+\mathbf{Z}$ with $\mathbf{Z}$ having i.i.d. $N(0, \sigma^2)$ entries. Suppose for some absolute constant $\gamma > 1$, the coefficient matrix $\mathbf{A} \in \mathbb{R}^{p\times m}$ belongs to*

$$\Theta(s, r, d, \gamma) = \{\mathbf{A} : \mathrm{rank}(\mathbf{A}) = r, \gamma d \geq \sigma_1(\mathbf{A}) \geq \cdots \geq \sigma_r(\mathbf{A}) \geq d > 0, |\mathrm{supp}(\mathbf{A})| \leq s\}.$$

Moreover, suppose the $(2s)$-sparse Riesz constants of the design matrix $\mathbf{X}$ satisfy $K^{-1} \leq \kappa_-(2s) \leq \kappa_+(2s) \leq K$ for some absolute constant $K > 1$. Then there exists a positive constant c depending only on γ and $\kappa_+(2s)$ such that for all $q \in [1, 2]$,

$$\inf_{\widehat{\mathbf{A}}} \sup_{\Theta} \mathbb{E}L_q(\mathbf{A}, \widehat{\mathbf{A}}) \geq c\sigma^2 \left\{ \left(r^{2/q-1}\frac{d^2}{\sigma^2} \right) \wedge \left[r^{2/q}(s + m) + r^{2/q-1} s \log \frac{ep}{s} \right] \right\}.$$

Proof [Proof of Theorem 2] To establish the lower bound, first consider the subset $\mathcal{F}_1 \subset \mathcal{F}(m, n, k, l, r, d, \kappa)$ where we further require $\mathrm{supp}(\mathbf{V}) = [r]$. Thus, except for the first r columns, all columns of $\mathbf{M}$ are zeros. So, by a simple sufficiency argument, we may assume that $n = l = r$. In this case, the problem of estimating (the first r columns of) $\mathbf{M}$ under model (1) can be viewed as a special case of sparse reduced rank regression where the design matrix is the identity matrix $\mathbf{I}_m$. Note that the sparse Riesz constants for $\mathbf{I}_m$ are all equal to one. Therefore, Theorem 8 implies that

$$\inf_{\widehat{\mathbf{M}}} \sup_{\mathcal{F}} \mathbb{E}L_q(\mathbf{M}, \widehat{\mathbf{M}}) \geq \inf_{\widehat{\mathbf{M}}} \sup_{\mathcal{F}_1} \mathbb{E}L_q(\mathbf{M}, \widehat{\mathbf{M}}) \geq c \left[r^{\frac{2}{q}-1} d^2 \wedge \left(r^{\frac{2}{q}} k + r^{\frac{2}{q}-1} k \log \frac{em}{k} \right) \right].$$

By symmetry, we also have

$$\inf_{\widehat{\mathbf{M}}} \sup_{\mathcal{F}} \mathbb{E}L_q(\mathbf{M}, \widehat{\mathbf{M}}) \geq c \left[r^{\frac{2}{q}-1} d^2 \wedge \left(r^{\frac{2}{q}} l + r^{\frac{2}{q}-1} l \log \frac{en}{l} \right) \right].$$

1. A function satisfying all norm axioms except for the triangle inequality.

We complete the proof by noting that for any $a, b, c > 0$, $(a \wedge b) \vee (a \wedge c) = a \wedge (b \vee c) \asymp a \wedge (b+c)$. ■

6.2 Proof of Theorem 4

To prove Theorem 4, we follow the oracle sequence approach developed in Ma (2013). Throughout the proof, we assume that $\sigma = 1$ is known. The case of general $\sigma > 0$ comes from obvious scaling arguments. In what follows, we first define the oracle sequence and introduce some preliminaries. Then we give an overview of the proof, which is divided into three steps. After the overview, the three steps are carried out in order, which then leads to the final proof of the theorem. Due to the space limit, proofs of intermediate results are omitted.

Preliminaries We first introduce some notation. For any matrix $\mathbf{A}$, $\mathrm{span}(\mathbf{A})$ stands for the subspace spanned by the column vectors of $\mathbf{A}$. If we were given the oracle knowledge of $I = \mathrm{supp}(\mathbf{U})$ and $J = \mathrm{supp}(\mathbf{V})$, then we can define an oracle version of the observed matrix as

$$\widetilde{\mathbf{X}} = (x_{ij} \mathbf{1}_{i \in I} \mathbf{1}_{j \in J}) \in \mathbb{R}^{m \times n}. \tag{14}$$

With appropriate rearrangement of rows and columns, the $I \times J$ submatrix concentrates on the top-left corner. From now on, we assume that this is the case. We denote the singular value decomposition of $\mathbf{X}$ by

$$\widetilde{\mathbf{X}} = \begin{bmatrix} \widetilde{\mathbf{U}} & \widetilde{\mathbf{U}}_\perp \end{bmatrix} \begin{bmatrix} \widetilde{\mathbf{D}} & \mathbf{0} \\ \mathbf{0} & \widetilde{\mathbf{D}}_\perp \end{bmatrix} \begin{bmatrix} \widetilde{\mathbf{V}}' \\ (\widetilde{\mathbf{V}}_\perp)' \end{bmatrix}, \tag{15}$$

where $\widetilde{\mathbf{U}}, \widetilde{\mathbf{D}}, \widetilde{\mathbf{V}}$ consist of the first r singular triples of $\widetilde{\mathbf{X}}$, and $\widetilde{\mathbf{U}}_\perp, \widetilde{\mathbf{D}}_\perp, \widetilde{\mathbf{V}}_\perp$ contain the remaining $n - r$ triples (recall that we have assumed $m \geq n$). In particular, the successive singular values of $\widetilde{\mathbf{X}}$ are denoted by $\widetilde{d}_1 \geq \widetilde{d}_2 \geq \cdots \geq \widetilde{d}_n \geq 0$.

With the oracle knowledge of I and J, we can define oracle versions of Algorithm 2 and Algorithm 1. In the oracle version of Algorithm 2, we replace the subsets I^0 and J^0 by $\widetilde{I}^0 = I^0 \cap I$ and $\widetilde{J}^0 = J^0 \cap J$, and the output matrices are denoted by $\widetilde{\mathbf{U}}^{(0)}$ and $\widetilde{\mathbf{V}}^{(0)}$. In the oracle version of Algorithm 1, $\mathbf{X}$ is replaced by $\widetilde{\mathbf{X}}$ and $\mathbf{V}^{(0)}$ is replaced by $\widetilde{\mathbf{V}}^{(0)}$. The intermediate matrices obtained after each step within the loop are denoted by $\widetilde{\mathbf{U}}^{(t),\mathrm{mul}}$, $\widetilde{\mathbf{U}}^{(t),\mathrm{thr}}$, $\widetilde{\mathbf{U}}^{(t)}$ and $\widetilde{\mathbf{V}}^{(t),\mathrm{mul}}$, $\widetilde{\mathbf{V}}^{(t),\mathrm{thr}}$, $\widetilde{\mathbf{V}}^{(t)}$, respectively. We note that for any t, it is guaranteed that

$$\mathrm{supp}(\widetilde{\mathbf{U}}^{(t),\mathrm{thr}}) = \mathrm{supp}(\widetilde{\mathbf{U}}^{(t)}) \subset I,$$
$$\mathrm{supp}(\widetilde{\mathbf{V}}^{(t),\mathrm{thr}}) = \mathrm{supp}(\widetilde{\mathbf{V}}^{(t)}) \subset J.$$

To investigate the properties of the oracle sequence, we will trace the evolution of the columns subspaces of $\widetilde{\mathbf{U}}^{(t),\mathrm{mul}}$, $\widetilde{\mathbf{U}}^{(t)}$, $\widetilde{\mathbf{V}}^{(t),\mathrm{mul}}$ and $\widetilde{\mathbf{V}}^{(t)}$. To this end, denote the r canonical angles (Golub and Van Loan, 1996) between $\mathrm{span}(\widetilde{\mathbf{U}}^{(t),\mathrm{mul}})$ and $\mathrm{span}(\widetilde{\mathbf{U}})$ by $\pi/2 \geq \phi_{u,1}^{(t)} \geq \cdots \geq \phi_{u,r}^{(t)} \geq 0$, and define

$$\sin \Phi_u^{(t)} = \mathrm{diag}(\sin \phi_{u,1}^{(t)}, \ldots, \sin \phi_{u,r}^{(t)}). \tag{16}$$

Moreover, denote the canonical angles between $\mathrm{span}(\widetilde{\mathbf{U}}^{(t)})$ and $\mathrm{span}(\widetilde{\mathbf{U}})$ by $\pi/2 \geq \theta_{u,1}^{(t)} \geq \cdots \geq \theta_{u,r}^{(t)} \geq 0$, and let

$$\sin \Theta_u^{(t)} = \mathrm{diag}(\sin \theta_{u,1}^{(t)}, \ldots, \sin \theta_{u,r}^{(t)}). \tag{17}$$

The quantities $\phi_{v,i}^{(t)}$, $\sin \Phi_v^{(t)}$, $\theta_{v,i}^{(t)}$ and $\sin \Theta_v^{(t)}$ are defined analogously. For any pair of $m \times r$ orthonormal matrices $\mathbf{W}_1$ and $\mathbf{W}_2$, let the canonical angles between $\mathrm{span}(\mathbf{W}_1)$ and $\mathrm{span}(\mathbf{W}_2)$ be $\pi/2 \geq \theta_1 \geq \cdots \geq \theta_r \geq 0$ and $\sin \Theta = \mathrm{diag}(\sin \theta_1, \ldots, \sin \theta_r)$, then (Stewart and Sun, 1990)

$$\begin{aligned} \|\sin \Theta\|_{\mathrm{F}} &= \frac{1}{\sqrt{2}} \|\mathbf{W}_1 \mathbf{W}_1' - \mathbf{W}_2 \mathbf{W}_2'\|_{\mathrm{F}}, \\ \|\sin \Theta\|_{\mathrm{op}} &= \|\mathbf{W}_1 \mathbf{W}_1' - \mathbf{W}_2 \mathbf{W}_2'\|_{\mathrm{op}}. \end{aligned} \tag{18}$$

Overview Given the oracle sequence defined as above, we divide the proof into three steps. First, we show that the output of the oracle version of Algorithm 2 gives a good initial value for the oracle version of Algorithm 1. Next, we prove two recursive inequalities that characterize the evolution of the column subspaces of $\widetilde{\mathbf{U}}^{(t)}$ and $\widetilde{\mathbf{V}}^{(t)}$, and show that after T iterates, the output of the oracle version of Algorithm 1 estimates $\mathbf{M}$ well. Last but not least, we show that with high probability the oracle estimating sequence and the actual estimating sequence are identical up to $3T$ iterates and that $\widehat{T} \in [T, 3T]$. Therefore, the actual estimating sequence inherits all the nice properties that can be claimed for the oracle sequence.

In what follows, we carry out the three steps in order.

Initialization We first investigate the properties of $\widetilde{\mathbf{X}}$, $\widetilde{I}^0$, $\widetilde{J}^0$ and $\widetilde{\mathbf{V}}^{(0)}$.

Note that for any orthonormal matrix $\mathbf{W}$, $\mathbf{W}\mathbf{W}'$ gives the projection matrix onto $\mathrm{span}(\mathbf{W})$. The following lemma quantifies the difference between the leading singular structures of $\mathbf{X}$ and $\mathbf{M}$.

Lemma 9 *With probability at least* $1 - m^{-2}$,

$$\|\mathbf{U}\mathbf{U} - \widetilde{\mathbf{U}}\widetilde{\mathbf{U}}\|_{\mathrm{F}}, \|\mathbf{V}\mathbf{V} - \widetilde{\mathbf{V}}\widetilde{\mathbf{V}}\|_{\mathrm{F}} \leq \frac{\sqrt{2r}}{d_r} \left(\sqrt{k} + \sqrt{l} + 2\sqrt{\log m} \right), \tag{19}$$

and for any $i \in [n]$,

$$|\widetilde{d}_i - d_i| \leq \sqrt{k} + \sqrt{l} + 2\sqrt{\log m} = o(d_r), \tag{20}$$

where the last equality holds under Condition 1.

Proof By symmetry, we only need to spell out the arguments for $\mathbf{U}$ in (19). By definition, $\widetilde{\mathbf{X}} = \mathbf{U}\mathbf{D}\mathbf{V}' + \widetilde{\mathbf{Z}}$ where (after reordering of the rows and the columns) $\widetilde{\mathbf{Z}} = \begin{bmatrix} \mathbf{Z}_{IJ} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix}$. Thus, we have

$$\|\mathbf{U}\mathbf{U}' - \widetilde{\mathbf{U}}\widetilde{\mathbf{U}}'\|_{\mathrm{F}} \leq \sqrt{2r} \|\mathbf{U}\mathbf{U}' - \widetilde{\mathbf{U}}\widetilde{\mathbf{U}}'\|_{\mathrm{op}} \leq \frac{\sqrt{2r}}{d_r} \|\widetilde{\mathbf{Z}}\|_{\mathrm{op}}.$$

Here, the first inequality holds since $\mathsf{rank}(\mathbf{U}\mathbf{U}' - \widetilde{\mathbf{U}}\widetilde{\mathbf{U}}') \le 2r$ and the last inequality is due to Wedin's $\sin\theta$ theorem (Wedin, 1972). By the Davidson-Szarek bound (Davidson and Szarek, 2001), with probability at least $1 - m^{-2}$, $\|\widetilde{\mathbf{Z}}\|_{\mathrm{op}} = \|\mathbf{Z}_{IJ}\|_{\mathrm{op}} \le \sqrt{k} + \sqrt{l} + 2\sqrt{\log m}$. This completes the proof of (19).

On the other hand, Corollary 8.6.2 of Golub and Van Loan (1996) implies that $|\widetilde{d}_i - d_i| \le \|\mathbf{Z}_{IJ}\|_{\mathrm{op}}$. Together with the above discussion, we obtain the first inequality in (20). The second inequality is a direct consequence of Condition 1. This completes the proof. ■

Next, we investigate the properties of the sets selected in Algorithm 2. For some universal constants $0 < a_- < 1 < a_+$, define the following two deterministic sets

$$I^0_{\pm} = \left\{ i \in [m] : \|\mathbf{M}_{i*}\|^2 \ge a_{\mp}\alpha\sqrt{n\log m} \right\}, \quad J^0_{\pm} = \left\{ j \in [n] : \|\mathbf{M}_{*j}\|^2 \ge a_{\mp}\alpha\sqrt{m\log m} \right\}. \tag{21}$$

Lemma 10 *Let Condition 1 be satisfied, and let $\alpha \ge 4$, $a_- \le \frac{1}{20}$ and $a_+ \ge 2$ be fixed constants. For sufficiently large values of m and n, with probability at least $1 - O(m^{-2})$, we have $I_- \subseteq \widetilde{I}^0 \subseteq I_+$ and $J_- \subseteq \widetilde{J}^0 \subseteq J_+$, and so $I^0 = \widetilde{I}^0$ and $J^0 = \widetilde{J}^0$.*

Proof By symmetry, we only show the proof for $\widetilde{I}^0$ here. The arguments for $\widetilde{J}^0$ are similar. On the one hand, we have

$$\begin{aligned}
\mathbb{P}(I^0_- \nsubseteq \widetilde{I}^0) &\le \sum_{i \in I^0_-} \mathbb{P}\left(\|\mathbf{X}_{i*}\|^2 < n + \alpha\sqrt{n\log m} \right) \\
&\le m\,\mathbb{P}\left(\chi^2_n(a_+\alpha\sqrt{n\log m}) < n + \alpha\sqrt{n\log m} \right) \\
&\le m\,\exp\left(-\frac{(a_+ - 1)^2\alpha^2 n\log m}{4n + 8a_+\alpha\sqrt{n\log m}} \right) \\
&\le m\,\exp(-3\log m) = m^{-2}.
\end{aligned}$$

Here, the last inequality holds for fixed $a_+ \ge 2$, $\alpha \ge 4$ and all sufficiently large (m, n) such that $2a_+\alpha\sqrt{n\log m} \le n/3$, which is guaranteed by Condition 1.

On the other hand, for $x = \frac{(1-a_-)^2\alpha^2 n\log m}{(2.1)^2(n + 2a_-\sqrt{n\log m})}$, we have

$$\begin{aligned}
\mathbb{P}(\widetilde{I}^0 \nsubseteq I^0_+) &\le \sum_{i \in (I^0_+)^c} \mathbb{P}\left(\|\mathbf{X}_{i*}\|^2 > n + \alpha\sqrt{n\log m} \right) \\
&\le m\,\mathbb{P}\left(\chi^2_n(a_-\alpha\sqrt{n\log m}) > n + \alpha\sqrt{n\log m} \right) \\
&\le m\,\mathbb{P}\left(\chi^2_n(a_-\alpha\sqrt{n\log m}) > n + 2.1\sqrt{(n + 2\alpha_-\sqrt{n\log m})\,x} \right) \\
&\le m\,\mathbb{P}\left(\chi^2_n(a_-\alpha\sqrt{n\log m}) > n + 2\sqrt{(n + 2\alpha_-\sqrt{n\log m})x} + 2x \right) \\
&\le m\,\exp(-x) \\
&\le m\exp(-3\log m) = m^{-2}.
\end{aligned}$$

Here, the fourth inequality holds for fixed $\alpha \ge 4$, $a_- \le \frac{1}{20}$, and all sufficiently large (m, n) such that $n + 2a_-\sqrt{n\log m} \ge \frac{2}{0.21}(1 - a_-)^2\alpha\sqrt{n\log m}$. The last inequality holds when, in addition, $0.95^2 \cdot 16 \cdot n \ge 3 \cdot (2.1)^2 \cdot (n + 2a_-\sqrt{n\log m})$, which is again guaranteed by Condition 1.

Finally, when $I_- \subseteq \widetilde{I}^0 \subseteq I_+$, we have $I^0 = \widetilde{I}^0$ since $I_+ \subset I$. ■

The next lemma estimates the accuracy of the starting point $\widetilde{\mathbf{V}}^{(0)}$ for the oracle version of Algorithm 1.

Lemma 11 *Let Condition 1 be satisfied, and let $\alpha \ge 4$ and $a_+ \ge 2$ be fixed constants. For sufficiently large values of m and n, uniformly over $\mathcal{F}(m, n, k, l, r, d, \kappa)$, with probability at least $1 - O(m^{-2})$, for a positive constant C that depends only on κ, a_+ and α,*

$$\|\sin\widetilde{\Theta}^{(0)}_v\|_{\mathrm{F}} \le \frac{C}{d}\left[\left(r^2k^2 n\log m\right)^{1/4} + \left(r^2l^2 m\log m\right)^{1/4} \right] \le \frac{1}{6}.$$

Proof Let $\mathbf{X}^{(0)}$ be the matrix defined in Step 2 of Algorithm 2, but with I^0 and J^0 replaced by $\widetilde{I}^0$ and $\widetilde{J}^0$. Then we have

$$\|\sin\widetilde{\Theta}^{(0)}_v\|_{\mathrm{F}} = \frac{1}{\sqrt{2}}\|\widetilde{\mathbf{V}}^{(0)}\widetilde{\mathbf{V}}^{(0)} - \widetilde{\mathbf{V}}\widetilde{\mathbf{V}}'\|_{\mathrm{F}} \le \frac{\sqrt{2r}}{\sqrt{2}}\|\widetilde{\mathbf{V}}^{(0)}\widetilde{\mathbf{V}}^{(0)} - \widetilde{\mathbf{V}}\widetilde{\mathbf{V}}'\|_{\mathrm{op}} \le \frac{\sqrt{r}}{\widetilde{d}_r}\|\widetilde{\mathbf{X}} - \widetilde{\mathbf{X}}^{(0)}\|_{\mathrm{op}}.$$

Here, the first equality is from (18). The second inequality holds since $\mathsf{rank}(\widetilde{\mathbf{V}}^{(0)}\widetilde{\mathbf{V}}^{(0)} - \widetilde{\mathbf{V}}\widetilde{\mathbf{V}}') \le 2r$, and the last inequality is due to Wedin's $\sin\theta$ theorem (Wedin, 1972).

To further bound the rightmost side, we note that $\widetilde{\mathbf{X}}^{(0)}$ and $\widetilde{\mathbf{X}}$ are supported on $\widetilde{I}^0 \times \widetilde{J}^0$ and $I \times J$ respectively, with $\widetilde{I}^0 \times \widetilde{J}^0 \subset I \times J$. In addition, $(I \times J)\backslash(\widetilde{I}^0 \times \widetilde{J}^0)$ is the union of two disjoint subsets $(I\backslash\widetilde{I}^0) \times J$ and $\widetilde{I}^0 \times (J\backslash\widetilde{J}^0)$. Thus, the triangle inequality leads to

$$\begin{aligned}
\|\widetilde{\mathbf{X}} - \widetilde{\mathbf{X}}^{(0)}\|_{\mathrm{op}} &\le \|\widetilde{\mathbf{X}}_{I\backslash\widetilde{I}^0, J}\|_{\mathrm{op}} + \|\widetilde{\mathbf{X}}_{\widetilde{I}^0, J\backslash\widetilde{J}^0}\|_{\mathrm{op}} \\
&\le \|\mathbf{U}_{I\backslash\widetilde{I}^0,*}\mathbf{D}(\mathbf{V}_{J*})'\|_{\mathrm{op}} + \|\mathbf{U}_{\widetilde{I}^0*}\mathbf{D}(\mathbf{V}_{J\backslash\widetilde{J}^0*})'\|_{\mathrm{op}} + \|\mathbf{Z}_{I\backslash\widetilde{I}^0, J}\|_{\mathrm{op}} + \|\mathbf{Z}_{\widetilde{I}^0, J\backslash\widetilde{J}^0}\|_{\mathrm{op}}.
\end{aligned} \tag{22}$$

We now bound each of the four terms in (22) separately. For the first term, on the event such that the conclusion of Lemma 10 holds, we have

$$\|\mathbf{U}_{I\backslash\widetilde{I}^0,*}\mathbf{D}\mathbf{V}'_J\|_{\mathrm{op}} \le \|\mathbf{D}\|_{\mathrm{op}}\|\mathbf{V}_{J*}\|_{\mathrm{op}}\|\mathbf{U}_{I\backslash\widetilde{I}^0,*}\|_{\mathrm{op}} \le d_1\|\mathbf{U}_{I\backslash\widetilde{I}^0,*}\|_{\mathrm{F}} \le \frac{d_1}{d_r}(a_+\alpha)^{1/2}(k^2 n\log m)^{1/4}.$$

Here, the last inequality is due to $I^0_- \subset \widetilde{I}^0$, the definition of I^0_- in (21), and the facts that $\|\mathbf{M}_{i*}\| \ge d_r\|\mathbf{U}_{i*}\|$ for all $i \in [m]$ and that $|I\backslash\widetilde{I}^0| \le |I| \le k$. By similar argument, on the event such that the conclusion of Lemma 10 holds, we can bound the second term in (22) as

$$\begin{aligned}
\|\mathbf{U}_{\widetilde{I}^0*}\mathbf{D}(\mathbf{V}_{J\backslash\widetilde{J}^0*})'\|_{\mathrm{op}} &\le \|\mathbf{U}_{\widetilde{I}^0*}\|_{\mathrm{op}}\|\mathbf{D}\|_{\mathrm{op}}\|\mathbf{V}_{J\backslash\widetilde{J}^0*}\|_{\mathrm{op}} \le d_1\|\mathbf{U}\|_{\mathrm{op}}\|\mathbf{V}_{J\backslash\widetilde{J}^0*}\|_{\mathrm{F}} \\
&\le \frac{d_1}{d_r}(a_+\alpha)^{1/2}(l^2 m\log m)^{1/4}.
\end{aligned}$$

To bound the last two terms, we first note that on the event such that the conclusion of Lemma 10 holds, both terms are upper bounded by $\|\mathbf{Z}_{IJ}\|_{\mathrm{op}}$. Together with the Davidson–Szarek bound (Davidson and Szarek, 2001), this implies that with probability at least $1 - m^{-2}$,

$$\|\mathbf{Z}_{I\setminus\widetilde{I}^0,J}\|_{\mathrm{op}} + \|\mathbf{Z}_{\widetilde{I}^0,J\setminus\widetilde{J}^0}\|_{\mathrm{op}} \le 2\|\mathbf{Z}_{IJ}\|_{\mathrm{op}} \le 2\left(\sqrt{k} + \sqrt{l} + 2\sqrt{\log m}\right).$$

Assembling the last five displays and observe that $\widetilde{d}_r \ge 0.9 d_r$ for sufficiently large values of (m, n) on the event such that the conclusion of Lemma 9, we obtain the first inequality in the conclusion. The second inequality is a direct consequence of Condition 1. This completes the proof. ∎

Evolution We now study how the column subspaces of $\widetilde{\mathbf{U}}^{(t)}$ and $\widetilde{\mathbf{V}}^{(t)}$ evolve over iterations. To this end, let

$$\rho = \widetilde{d}_{r+1}/\widetilde{d}_r, \tag{23}$$

where $\widetilde{d}_i$ denotes the i^{th} singular value of $\widetilde{\mathbf{X}}$.

Proposition 12 *For any $t \ge 1$, let $x^t = \|\sin\Theta_u^{(t)}\|_{\mathrm{F}}$, $y^t = \|\sin\Theta_v^{(t)}\|_{\mathrm{F}}$. Moreover, define*

$$\omega_u = (2\widetilde{d}_r)^{-1}\sqrt{k\gamma_u^2}, \qquad \omega_v = (2\widetilde{d}_r)^{-1}\sqrt{l\gamma_v^2}, \qquad \omega = \omega_u \vee \omega_v. \tag{24}$$

Let Condition 1 be satisfied. Then for sufficiently large values of (m, n), on the event such that the conclusions of Lemmas 9–11 hold,

1) For any $t \ge 1$, if $y^{t-1} < 1$, then

$$x^t\sqrt{1-(y^{t-1})^2} \le \rho y^{t-1} + \omega_u, \qquad y^t\sqrt{1-(x^t)^2} \le \rho x^t + \omega_v. \tag{25}$$

2) For any $a \in (0, 1/2]$, if

$$y^{t-1} \le \frac{1.01\,\omega}{(1-a)(1-\rho)}, \tag{26}$$

then so is x^t. Otherwise,

$$x^t \le y^{t-1}[1 - a(1-\rho)]. \tag{27}$$

The same conclusions hold with the ordered pair (y^{t-1}, x^t) replaced by (x^t, y^t) in (26)–(27).

Proof 1) In what follows, we focus on showing the first inequality in (25). The second inequality follows from essentially the same argument.

Let $u^t = \|\sin\Phi_u^{(t)}\|_{\mathrm{F}}$. We first show that

$$u^t \le \frac{\rho y^{t-1}}{\sqrt{1-(y^{t-1})^2}}. \tag{28}$$

Recall the SVD of $\widetilde{\mathbf{X}}$ in (15). In addition, let the QR factorization of $\widetilde{\mathbf{U}}^{(t),\mathrm{mul}} = \widetilde{\mathbf{Q}}^{(t)}\widetilde{\mathbf{R}}^{(t),\mathrm{mul}}$. By definition, $\widetilde{\mathbf{U}}^{(t),\mathrm{mul}} = \widetilde{\mathbf{X}}\widetilde{\mathbf{V}}^{(t-1)}$. Premultiplying both sides by $\begin{bmatrix}\widetilde{\mathbf{U}} & \widetilde{\mathbf{U}}_\perp\end{bmatrix}'$, we obtain

$$\begin{bmatrix}\widetilde{\mathbf{D}} & \mathbf{0}\\ \mathbf{0} & \widetilde{\mathbf{D}}_\perp\end{bmatrix}\begin{bmatrix}\widetilde{\mathbf{V}}'\widetilde{\mathbf{V}}^{(t-1)}\\ (\widetilde{\mathbf{V}}_\perp)'\widetilde{\mathbf{V}}^{(t-1)}\end{bmatrix} = \begin{bmatrix}\widetilde{\mathbf{U}}'\widetilde{\mathbf{Q}}^{(t)}\\ (\widetilde{\mathbf{U}}_\perp)'\widetilde{\mathbf{Q}}^{(t)}\end{bmatrix}\widetilde{\mathbf{R}}^{(t),\mathrm{mul}}.$$

In addition, let

$$\begin{bmatrix}\widetilde{\mathbf{U}}'\widetilde{\mathbf{Q}}^{(t)}\\ (\widetilde{\mathbf{U}}_\perp)'\widetilde{\mathbf{Q}}^{(t)}\end{bmatrix} = \begin{bmatrix}\mathbf{O}^{(t)}\\ \mathbf{W}^{(t)}\end{bmatrix}.$$

By the last two displays, we have

$$\mathbf{W}^{(t)} = \widetilde{\mathbf{D}}_\perp(\widetilde{\mathbf{V}}_\perp)'\widetilde{\mathbf{V}}^{(t-1)}(\widetilde{\mathbf{R}}^{(t),\mathrm{mul}})^{-1} = \widetilde{\mathbf{D}}_\perp\left[(\widetilde{\mathbf{V}}_\perp)'\widetilde{\mathbf{V}}^{(t-1)}\right]\left[\widetilde{\mathbf{V}}'\widetilde{\mathbf{V}}^{(t-1)}\right]^{-1}\widetilde{\mathbf{D}}^{-1}\left[\widetilde{\mathbf{U}}'\widetilde{\mathbf{Q}}^{(t)}\right].$$

Thus,

$$\|\mathbf{W}^{(t)}\|_{\mathrm{F}} \le \|\widetilde{\mathbf{D}}_\perp\|_{\mathrm{op}}\|(\widetilde{\mathbf{V}}_\perp)'\widetilde{\mathbf{V}}^{(t-1)}\|_{\mathrm{F}}\|[\widetilde{\mathbf{V}}'\widetilde{\mathbf{V}}^{(t-1)}]^{-1}\|_{\mathrm{op}}\|\widetilde{\mathbf{D}}^{-1}\|_{\mathrm{op}}\|\widetilde{\mathbf{U}}\|_{\mathrm{op}}\|\widetilde{\mathbf{Q}}^{(t)}\|_{\mathrm{op}}.$$

By Corollary 5.5.4 of Stewart and Sun (1990), $\|\mathbf{W}^{(t)}\|_{\mathrm{F}} = u^t$, $\|(\widetilde{\mathbf{V}}_\perp)'\widetilde{\mathbf{V}}^{(t-1)}\|_{\mathrm{F}} = y^{t-1}$. Moreover, by Section 12.4.3 of Golub and Van Loan (1996), $\|[\widetilde{\mathbf{V}}'\widetilde{\mathbf{V}}^{(t-1)}]^{-1}\|_{\mathrm{op}} = 1/\cos\theta_{v,r}^{(t-1)} = 1/\sqrt{1-(\sin\theta_{v,r}^{(t-1)})^2} \le 1/\sqrt{1-(y^{t-1})^2}$. Here we have used the assumption that $y^{t-1} < 1$. Together with the facts that $\|\widetilde{\mathbf{D}}_\perp\|_{\mathrm{op}} = \widetilde{d}_{r+1}$, $\|\widetilde{\mathbf{D}}^{-1}\|_{\mathrm{op}} = \widetilde{d}_r^{-1}$, $\|\widetilde{\mathbf{U}}\|_{\mathrm{op}} = \|\widetilde{\mathbf{Q}}^{(t)}\|_{\mathrm{op}} = 1$, this leads to (28).

Next, we show that

$$x^t \le u^t + \frac{\omega_u}{\sqrt{1-(y^{t-1})^2}}. \tag{29}$$

To this end, let $w^t = \|\widetilde{\mathbf{Q}}^{(t)}(\widetilde{\mathbf{Q}}^{(t)})' - \widetilde{\mathbf{U}}^{(t)}(\widetilde{\mathbf{U}}^{(t)})'\|_{\mathrm{F}}$. Then, by (18) and the triangle inequality, we obtain

$$x^t \le u^t + \frac{1}{\sqrt{2}}w^t.$$

To bound w^t, note that Wedin's $\sin\theta$ theorem (Wedin, 1972) implies

$$w^t \le \frac{\|\widetilde{\mathbf{U}}^{(t),\mathrm{mul}} - \widetilde{\mathbf{U}}^{(t)}\|_{\mathrm{F}}}{\sigma_r(\widetilde{\mathbf{U}}^{(t),\mathrm{mul}})}.$$

In the oracle version, $\widetilde{\mathbf{U}}^{(t),\mathrm{mul}}$ has at most k nonzero rows, and so $\|\widetilde{\mathbf{U}}^{(t),\mathrm{mul}} - \widetilde{\mathbf{U}}^{(t)}\|_{\mathrm{F}} \le \sqrt{k\gamma_u^2}$. For any unit vector $\mathbf{y} \in \mathrm{span}(\widetilde{\mathbf{V}}^{(t-1)})$, decompose $\mathbf{y} = \mathbf{y}_0 + \mathbf{y}_1$ where $\mathbf{y}_0 \in \mathrm{span}(\widetilde{\mathbf{V}})$ and $\mathbf{y}_1 \in \mathrm{span}(\widetilde{\mathbf{V}}_\perp)$. Then by definition, $\|\mathbf{y}_0\| \ge \cos\theta_{v,1}^{(t-1)} \ge \sqrt{1-(y^{t-1})^2}$. Thus, for any unit vector $\mathbf{x}$, $\|\widetilde{\mathbf{U}}^{(t),\mathrm{mul}}\mathbf{x}\|^2 = \|\widetilde{\mathbf{X}}\mathbf{V}^{(t-1)}\mathbf{x}\|^2 = \|\widetilde{\mathbf{X}}\mathbf{y}\|^2 = \|\widetilde{\mathbf{X}}\mathbf{y}_0\|^2 + \|\widetilde{\mathbf{X}}\mathbf{y}_1\|^2 \ge \|\widetilde{\mathbf{X}}\mathbf{y}_0\|^2 = \|\widetilde{\mathbf{X}}\widetilde{\mathbf{V}}\widetilde{\mathbf{V}}'\mathbf{y}_0\|^2 \ge (\widetilde{d}_r)^2\|\mathbf{y}_0\|^2 \ge (\widetilde{d}_r)^2[1-(y^{t-1})^2]$. Hence,

$$\sigma_r(\widetilde{\mathbf{U}}^{(t),\mathrm{mul}}) \ge \inf_{\|\mathbf{x}\|=1}\|\widetilde{\mathbf{U}}^{(t),\mathrm{mul}}\mathbf{x}\| \ge \widetilde{d}_r\sqrt{1-(y^{t-1})^2}.$$

Assembling the last three display, we obtain (29). Finally, the first inequality in (25) comes from (28), (29) and the triangle inequality.

2) Given (25), we have

$$x^t \le \frac{\rho y^{t-1} + \omega}{\sqrt{1-(y^{t-1})^2}},$$

and that $y^0 \le \frac{1}{6} \le \frac{1}{5}(1-\rho)^2$ for sufficiently large values of (m,n) due to Condition 1 and Lemma 9. The proof of part (2) then follows from the same argument as in the proof of Proposition 6.1 in Ma (2013). ■

Convergence We say that the oracle sequence has *converged* if

$$x^t \vee y^t \le \frac{1.01\omega}{(1-m^{-1})(1-\rho)}. \tag{30}$$

This choice is motivated by the observation that $\frac{1.01\omega}{1-\rho}$ is the smallest possible value for x^t and y^t that Proposition 12 can lead to.

Proposition 13 *Let Condition 1 be satisfied and T be defined in (12). For sufficiently large values of (m,n), on the event such that the conclusions of Lemmas 9–11 hold, it takes at most T steps for the oracle sequence to converge in the sense of (30). For any t, let $\widetilde{\mathbf{P}}_u^{(t)} = \widetilde{\mathbf{U}}^{(t)}(\widetilde{\mathbf{U}}^{(t)})'$ and $\widetilde{\mathbf{P}}_v^{(t)} = \widetilde{\mathbf{V}}^{(t)}(\widetilde{\mathbf{V}}^{(t)})'$. Then there exists a constant C that depends only on κ, such that for all $t \ge T$,*

$$\|\widetilde{\mathbf{P}}_u^{(t)}\widetilde{\mathbf{X}}\widetilde{\mathbf{P}}_v^{(t)} - \widetilde{\mathbf{U}}\widetilde{\mathbf{D}}\widetilde{\mathbf{V}}\|_{\mathrm{F}}^2 \le C\left(k\gamma_u^2 + l\gamma_v^2\right).$$

Proof To prove the first claim, we rely on claim (2) of Proposition 12. Without loss of generality, assume that $m = 2^\nu$ for some integer $\nu \ge 1$. So $\nu = \log m/\log 2$. Let t_1 be the number of iterations needed to ensure that $x^t \vee y^t \le \frac{1.01\omega}{(1-\frac{1}{2})(1-\rho)}$. Note that when (26) does not hold, (27) ensures that

$$y^t \le y^{t-1}[1-a(1-\rho)]^2, \quad x^t \le x^{t-1}[1-a(1-\rho)]^2. \tag{31}$$

Thus, it suffices to have $\left[1-\frac{1}{2}(1-\rho)\right]^{2t_1} \ge \frac{1.01\omega}{(1-\frac{1}{2})(1-\rho)}$, i.e., $2t_1|\log(1-\frac{1}{2}(1-\rho))| \ge \log(1-\frac{1}{2})(1-\rho)/(1.01\omega)$. Since $|\log(1-x)| \ge x$ for all $x \in (0,1)$, it suffices to set

$$t_1 = \frac{1}{1-\rho}\log\frac{\frac{1}{2}(1-\rho)}{1.01\omega} = \frac{1+o(1)}{2}\log\left(\frac{d_r^2}{k\gamma_u^2 \vee l\gamma_v^2}\right).$$

Next, let $t_2 - t_1$ be the number of additional iterations needed to achieve $x^t \vee y^t \le 1.01\omega/[(1-\frac{1}{4})(1-\rho)]^2$. Before this is achieved, (31) is satisfied with $a = \frac{1}{4}$. So it suffices to have $[1-\frac{1}{4}(1-\rho)]^{2(t_2-t_1)} \le (1-\frac{1}{2})/(1-\frac{1}{4})$, which is guaranteed if $t_2 - t_1 \ge \frac{2}{1-\rho}[\log(1-\frac{1}{4}) - \log(1-\frac{1}{2})]$. Recursively, we define t_i for $i = 3,\dots,\nu$, such that $x^{t_i}, y^{t_i} \le 1.01\omega/[(1-2^{-i})(1-\rho)]$. Repeating the above argument shows that it suffices to have $t_i - t_{i-1} = \frac{2^{i-1}}{1-\rho}[\log(1-2^{-i}) - \log(1-2^{-(i-1)})]$ for $i = 3,\dots,\nu$. Therefore, if we let

$$t_\nu - t_1 = \frac{\nu+1/2}{2(1-\rho)} = \frac{(1+o(1))\log m}{2\log 2} \ge \sum_{i=1}^{\nu}\frac{2^{i-1}}{1-\rho}\left[\log(1-2^{-i}) - \log(1-2^{-(i-1)})\right],$$

then $x^t \vee y^t \le 1.01\omega/[(1-m^{-1})(1-\rho)]$ for all $t \ge t_\nu$. We complete the proof of the first claim by noting that $T \ge t_\nu$ for sufficiently large m, n under Condition 1.

To prove the second claim, let $\widetilde{\mathbf{P}}_u = \widetilde{\mathbf{U}}\widetilde{\mathbf{U}}'$ and $\widetilde{\mathbf{P}}_v = \widetilde{\mathbf{V}}\widetilde{\mathbf{V}}'$. Then we have

$$\begin{aligned}
\|\widetilde{\mathbf{P}}_u^{(t)}\widetilde{\mathbf{X}}\widetilde{\mathbf{P}}_v^{(t)} - \widetilde{\mathbf{U}}\widetilde{\mathbf{D}}\widetilde{\mathbf{V}}\|_{\mathrm{F}} &= \|\widetilde{\mathbf{P}}_u^{(t)}\widetilde{\mathbf{X}}\widetilde{\mathbf{P}}_v^{(t)} - \widetilde{\mathbf{P}}_u\widetilde{\mathbf{X}}\widetilde{\mathbf{P}}_v\|_{\mathrm{F}} && (32)\\
&\le \|(\widetilde{\mathbf{P}}_u^{(t)} - \widetilde{\mathbf{P}}_u)\widetilde{\mathbf{X}}\widetilde{\mathbf{P}}_v^{(t)}\|_{\mathrm{F}} + \|\widetilde{\mathbf{P}}_u\widetilde{\mathbf{X}}(\widetilde{\mathbf{P}}_v^{(t)} - \widetilde{\mathbf{P}}_v)\|_{\mathrm{F}}\\
&\le \|\widetilde{\mathbf{P}}_u^{(t)} - \widetilde{\mathbf{P}}_u\|_{\mathrm{F}}\|\widetilde{\mathbf{X}}\|_{\mathrm{op}}\|\widetilde{\mathbf{P}}_v^{(t)}\|_{\mathrm{op}} + \|\widetilde{\mathbf{P}}_v^{(t)} - \widetilde{\mathbf{P}}_v\|_{\mathrm{F}}\|\widetilde{\mathbf{X}}\|_{\mathrm{op}}\|\widetilde{\mathbf{P}}_u\|_{\mathrm{op}}\\
&= \widetilde{d}_1\left(\|\widetilde{\mathbf{P}}_u^{(t)} - \widetilde{\mathbf{P}}_u\|_{\mathrm{F}} + \|\widetilde{\mathbf{P}}_v^{(t)} - \widetilde{\mathbf{P}}_v\|_{\mathrm{F}}\right) && (33)\\
&\le C\left(\sqrt{k\gamma_u^2} + \sqrt{l\gamma_v^2}\right). && (34)
\end{aligned}$$

Here, the equality (32) is due to the definitions of $\widetilde{\mathbf{P}}_u$, $\widetilde{\mathbf{P}}_v$ and the fact that $\widetilde{\mathbf{U}}$, $\widetilde{\mathbf{D}}$ and $\widetilde{\mathbf{V}}$ consist of the first r singular values and vectors of $\widetilde{\mathbf{X}}$. The equality (33) holds since $\|\widetilde{\mathbf{X}}\|_{\mathrm{op}} = \widetilde{d}_1$ and $\|\widetilde{\mathbf{P}}_u\|_{\mathrm{op}} = \|\widetilde{\mathbf{P}}_v^{(t)}\|_{\mathrm{op}} = 1$ as both are projection matrices. Finally, the inequality (34) holds since $\|\widetilde{\mathbf{P}}_u^{(t)} - \widetilde{\mathbf{P}}_u\|_{\mathrm{F}} = \sqrt{2}x^t$ and $\|\widetilde{\mathbf{P}}_v^{(t)} - \widetilde{\mathbf{P}}_v\|_{\mathrm{F}} = \sqrt{2}y^t$ due to (18), the definitions in (24) and (30), and the fact that on the event such that (20) holds, $\widetilde{d}_1/\widetilde{d}_r \le 2\kappa$ when m and n are sufficiently large. This completes the proof. ■

Remark 14 *It is worth noting that the conclusions of Proposition 12 and Proposition 13 hold for any $\gamma_u > 0$ and $\gamma_v > 0$, though they will be used later with the specific choice of γ_u and γ_v in (10).*

Proof of Upper Bounds We are now in the position to prove Theorem 4. To this end, we need to establish the equivalence between the oracle and the actual estimating sequences. The following lemma shows that with high probability, the oracle sequence and the actual sequence are identical up to $3T$ iterates.

Lemma 15 *Let γ_u and γ_v be defined as in (10) with some fixed constant $\beta \ge 4$ and let Condition 1 be satisfied. For sufficiently large m and n, with probability at least $1-O(m^{-2})$, for all $1 \le t \le 3T$, $\mathbf{U}_{I^c*}^{(t)} = \mathbf{0}$, $\mathbf{V}_{J^c*}^{(t)} = \mathbf{0}$, and so $\mathbf{U}^{(t)} = \widetilde{\mathbf{U}}^{(t)}$ and $\mathbf{V}^{(t)} = \widetilde{\mathbf{V}}^{(t)}$.*

Proof First of all, by Lemma 10, with probability at least $1-O(m^{-2})$, $J^0 = \widetilde{J}^0 \subset J_+ \subset J$, and so $\widetilde{\mathbf{V}}^{(0)} = \mathbf{V}^{(0)}$. Define event $E^{(0)} = \{\mathbf{V}^{(0)} = \widetilde{\mathbf{V}}^{(0)}\}$.

We now focus on the first iteration. Define event

$$E_u^{(1)} = \left\{\|\mathbf{Z}_{i*}\widetilde{\mathbf{V}}^{(0)}\| < \gamma_u,\ \forall i \in I^c\right\}.$$

On $E^{(0)} \cap E_u^{(1)}$, for any $i \in I^c$, $\mathbf{U}_{i*}^{(1),\mathrm{mul}} = \mathbf{X}_{i*}\mathbf{V}^{(0)} = \mathbf{Z}_{i*}\widetilde{\mathbf{V}}^{(0)}$. Thus, $\|\mathbf{U}_{i*}^{(1),\mathrm{mul}}\| < \gamma_u$ and so $\mathbf{U}_{i*}^{(1),\mathrm{thr}} = \mathbf{0}$ for all $i \in I^c$. This further implies $\mathbf{U}_{I^c*}^{(1)} = \mathbf{0}$ and $\mathbf{U}^{(1)} = \widetilde{\mathbf{U}}^{(1)}$. Further define event

$$E_v^{(1)} = \left\{\|(\mathbf{Z}_{*j})'\widetilde{\mathbf{U}}^{(1)}\| < \gamma_v,\ \forall j \in J^c\right\}.$$

Then by similar argument, on the event $E^0 \cap E_u^{(1)} \cap E_v^{(1)}$, we have $\mathbf{V}_{J^c *}^{(1)} = \mathbf{0}$ and $\mathbf{V}^{(1)} = \widetilde{\mathbf{V}}^{(1)}$.

We now bound the probability of $(E_u^{(1)})^c$. Without loss of generality, let $J \subset [l]$. Note that for any $j \in J$, $i \in I^c$, $\widetilde{\mathbf{V}}^{(0)}$ depends on Z_{ij} only through $\|\mathbf{Z}_{I^c j}\|^2$ in the selection of $\widetilde{J}^0$ in the oracle version of Algorithm 2. Therefore, $\widetilde{\mathbf{V}}^{(0)}$ is independent of $\frac{Z_{ij}}{\|\mathbf{Z}_{I^c j}\|}$. Let $k' = |I^c|$ and $Y_1, \dots Y_l$ be i.i.d. $\chi_{k'}$ random variables independent of $\mathbf{Z}$. For any $i \in I^c$ and $j \in [l]$, let

$$\check{Z}_{ij} = Y_j \frac{Z_{ij}}{\|\mathbf{Z}_{I^c j}\|},$$

and $\check{\mathbf{Z}}_{i[l]} = (\check{Z}_{i1}, \dots, \check{Z}_{il}) \in \mathbb{R}^{1 \times l}$. Since $\mathrm{supp}(\widetilde{\mathbf{V}}^{(0)}) \subset J \subset [l]$ on the event $E^{(0)}$, we obtain that for any $i \in I^c$, $\mathbf{Z}_{i*}\widetilde{\mathbf{V}}^{(0)} = \mathbf{Z}_{i[l]}\widetilde{\mathbf{V}}^{(0)} = \check{\mathbf{Z}}_{i[l]}\widetilde{\mathbf{V}}^{(0)} + (\mathbf{Z}_{i[l]} - \check{\mathbf{Z}}_{i[l]})\widetilde{\mathbf{V}}^{(0)}$. Thus,

$$\|\mathbf{Z}_{i*}\widetilde{\mathbf{V}}^{(0)}\| \le \|\check{\mathbf{Z}}_{i[l]}\widetilde{\mathbf{V}}^{(0)}_{[l]*}\| + \|(\mathbf{Z}_{i[l]} - \check{\mathbf{Z}}_{i[l]})\widetilde{\mathbf{V}}^{(0)}_{[l]*}\| \le \|\check{\mathbf{Z}}_{i[l]}\widetilde{\mathbf{V}}^{(0)}_{[l]*}\| + \|\mathbf{Z}_{i[l]} - \check{\mathbf{Z}}_{i[l]}\|\|\widetilde{\mathbf{V}}^{(0)}_{[l]*}\|_{\mathrm{op}}.$$

For the first term on the rightmost side, since $\check{\mathbf{Z}}_{i[l]}$ is independent of $\widetilde{\mathbf{V}}^{(0)}$, $\|\check{\mathbf{Z}}_{i[l]}\widetilde{\mathbf{V}}^{(0)}_{[l]*}\|^2 \sim \chi_r^2$, and so by Lemma 17, with probability at least $1 - O(m^{-\beta})$,

$$\|\check{\mathbf{Z}}_{i[l]}\widetilde{\mathbf{V}}^{(0)}_{[l]*}\|^2 \le r + 2\sqrt{\beta r \log m} + 2\beta \log m.$$

For the second term, we first note that $\|\widetilde{\mathbf{V}}^{(0)}_{[l]*}\|_{\mathrm{op}} = 1$ since it has orthonormal columns. Moreover, $\check{\mathbf{Z}}_{i[l]} - \mathbf{Z}_{i[l]} = \mathbf{Z}_{i[l]} \,\mathrm{diag}\left(\frac{Y_1}{\|\mathbf{Z}_{I^c 1}\|} - 1, \dots, \frac{Y_l}{\|\mathbf{Z}_{I^c l}\|} - 1\right)$. Thus,

$$\|\check{\mathbf{Z}}_{i[l]} - \mathbf{Z}_{i[l]}\| \le \|\mathbf{Z}_{i[l]}\| \max_{j \in [l]} \left| \frac{Y_j}{\|\mathbf{Z}_{I^c j}\|} - 1 \right|.$$

By Lemma 17, with probability at least $1 - O(m^{-\beta})$,

$$\|\mathbf{Z}_{i[l]}\|^2 \le l + 2\sqrt{\beta l \log m} + 2\beta \log m.$$

By Lemma 18, for any $j \in [l]$, with probability at least $1 - O(m^{-(\beta+1)})$,

$$\left| \frac{Y_j}{\|\mathbf{Z}_{I^c j}\|} - 1 \right| \le \left| \frac{Y_j^2}{\|\mathbf{Z}_{I^c j}\|^2} - 1 \right| \le 4 \cdot 1.01 \cdot \sqrt{\frac{(\beta+1)\log m}{k'}}.$$

Here, the last inequality holds for sufficient large values of m and n, since Condition 1 implies that $(\log m)/k' = o(1)$. By the union bound, with probability at least $1 - O(m^{-\beta})$, for sufficient large values of m and n,

$$\|\check{\mathbf{Z}}_{i[l]} - \mathbf{Z}_{i[l]}\| \le 0.01\sqrt{\log m},$$

since Condition 1 ensures that $l/k' = o(1)$. Assembling the last six displays, we obtain that for any $\beta > 1$, with probability at least $1 - O(m^{-\beta})$,

$$\|\mathbf{Z}_{i*}\widetilde{\mathbf{V}}^{(0)}\| \le \sqrt{r + 2\sqrt{\beta r \log m} + 2\beta \log m} + 0.01\sqrt{\log m} \le \gamma_v.$$

Applying the union bound again, we obtain that when $\beta \ge 4$ in (10),

$$\mathbb{P}\left\{(E_u^{(1)})^c\right\} \le O(m^{-3}). \tag{35}$$

Similarly, for any $j \in J^c$, $\widetilde{\mathbf{U}}^{(1)}$ depends on Z_{ij} only through $\|\mathbf{Z}_{iJ^c}\|$. Therefore, by analogous arguments, we also obtain (35) for $(E_v^1)^c$ with any fixed $\beta \ge 4$.

Turn to subsequent iterations, we further define events

$$E_u^{(t)} = \left\{\|\mathbf{Z}_{i*}\widetilde{\mathbf{V}}^{(t-1)}\| < \gamma_u,\, \forall i \in I^c\right\}, \quad E_v^{(t)} = \left\{\|(\mathbf{Z}_{*j})'\widetilde{\mathbf{U}}^{(t)}\| < \gamma_v,\, \forall j \in J^c\right\}, \quad t = 2, \dots, 3T.$$

Iterating the above arguments, we obtain that on the event $E^{(0)} \cap (\cap_{t=1}^{3T} E_u^{(t)}) \cap (\cap_{t=1}^{3T} E_v^{(t)})$, $\mathbf{U}_{I^c *}^{(t)} = \mathbf{0}$, $\mathbf{V}_{J^c *}^{(t)} = \mathbf{0}$, and so $\mathbf{U}^{(t)} = \widetilde{\mathbf{U}}^{(t)}$ and $\mathbf{V}^{(t)} = \widetilde{\mathbf{V}}^{(t)}$. Moreover, by similar argument to that for (35), we can bound each $\mathbb{P}\{(E_u^{(t)})^c\}$ and $\mathbb{P}\{(E_v^{(t)})^c\}$ by $O(m^{-3})$ for all $t = 2, \dots, 3T$ with any fixed $\beta \ge 4$ in (10). Finally, under Condition 1, $T = O(m)$, and so

$$\mathbb{P}\left\{E^{(0)} \cap (\cap_{t=1}^{3T} E_u^{(t)}) \cap (\cap_{t=1}^{3T} E_v^{(t)})\right\} = 1 - O(m^{-2}).$$

This completes the proof. ■

Lemma 16 *Let $\widehat{T}$ be defined in (11). With probability at least $1 - O(m^{-2})$, $T \le \widehat{T} \le 3T$.*

Proof By definition (10) and (12), we have

$$T \le \frac{1.01}{2}\left(\frac{\log m}{\log 2} + \log \frac{d_r^2}{\gamma^2}\right).$$

On the other hand, note that $1/\log 2 \ge 1.44$ and that $\log(k \vee l) \le \log m$ under the assumption that $m \ge n$, and hence

$$T \ge \frac{1.01}{2}\left(\frac{\log m}{\log 2} - \log m + \log \frac{d_r^2}{\gamma^2}\right) \ge \frac{1.01}{2}\left(0.44 \log m + \log \frac{d_r^2}{\gamma^2}\right).$$

On the other hand, on the event such that the conclusions of Lemmas 9–11 hold, we have

$$\begin{aligned} |d_r^{(0)} - d_r| &\le |d_r^{(0)} - \widetilde{d}_r| + |\widetilde{d}_r - d_r| \\ &= |\widetilde{d}_r^{(0)} - \widetilde{d}_r| + |\widetilde{d}_r - d_r| \\ &\le \|\widetilde{\mathbf{X}}^{(0)} - \widetilde{\mathbf{X}}\|_{\mathrm{op}} + o(d_r) \\ &= o(d_r). \end{aligned}$$

Hence for sufficiently large values of m and n, $\log \gamma^2 > 1$ and with probability at least $1 - O(m^{-2})$, $|\log(d_r^{(0)})^2 / \log d_r^2 - 1| \le 0.01$. When the above inequalities all hold, we obtain $\widehat{T} \in [T, 3T]$. ■

We are now in the position to prove Theorem 4.

Proof [Proof of Theorem 4] Note that on the events such that the conclusions of Lemmas 9–16 hold, we have

$$\begin{aligned}
&\|\widehat{\mathbf{M}} - \mathbf{M}\|_{\mathrm{F}} \\
&\quad = \|\widehat{\mathbf{P}}_u^{(\widehat{T})}\mathbf{X}\widehat{\mathbf{P}}_v^{(\widehat{T})} - \mathbf{U}\mathbf{D}\mathbf{V}'\|_{\mathrm{F}} \\
&\quad \le \|\widehat{\mathbf{P}}_u^{(\widehat{T})}\mathbf{X}\widehat{\mathbf{P}}_v^{(\widehat{T})} - \widetilde{\mathbf{U}}\widetilde{\mathbf{D}}\widetilde{\mathbf{V}}'\|_{\mathrm{F}} + \|\widetilde{\mathbf{U}}\widetilde{\mathbf{D}}\widetilde{\mathbf{V}}' - \mathbf{U}\mathbf{D}\mathbf{V}'\|_{\mathrm{F}} \\
&\quad = \|\widetilde{\mathbf{P}}_u^{(\widehat{T})}\widetilde{\mathbf{X}}\widetilde{\mathbf{P}}_v^{(\widehat{T})} - \widetilde{\mathbf{P}}_u\widetilde{\mathbf{X}}\widetilde{\mathbf{P}}_v\|_{\mathrm{F}} + \|\widetilde{\mathbf{P}}_u\widetilde{\mathbf{X}}\widetilde{\mathbf{P}}_v - \mathbf{P}_u\mathbf{M}\mathbf{P}_v\|_{\mathrm{F}} \\
&\quad \le \|\widetilde{\mathbf{P}}_u^{(\widehat{T})}\widetilde{\mathbf{X}}\widetilde{\mathbf{P}}_v^{(\widehat{T})} - \widetilde{\mathbf{P}}_u\widetilde{\mathbf{X}}\widetilde{\mathbf{P}}_v\|_{\mathrm{F}} + \|\widetilde{\mathbf{P}}_u\widetilde{\mathbf{X}}\widetilde{\mathbf{P}}_v - \widetilde{\mathbf{P}}_u\mathbf{M}\widetilde{\mathbf{P}}_v\|_{\mathrm{F}} \\
&\qquad + \|\widetilde{\mathbf{P}}_u\mathbf{M}\widetilde{\mathbf{P}}_v - \mathbf{P}_u\mathbf{M}\mathbf{P}_v\|_{\mathrm{F}}.
\end{aligned}$$

Here, the first and the second inequalities are both due to the triangle inequality. The second equality is due to Lemma 16 and the facts that $\mathrm{supp}(\widetilde{\mathbf{U}}^{(t)}) \subset I$, $\mathrm{supp}(\widetilde{\mathbf{V}}^{(t)}) \subset J$ and that $\widetilde{\mathbf{U}}$ and $\widetilde{\mathbf{V}}$ collect the first r left and right singular vectors of $\widetilde{\mathbf{X}}$.

We now bound each of the three terms on the rightmost side of the last display. First, on the event such that the conclusions of Proposition 13 and Lemma 16 hold, we have

$$\|\widetilde{\mathbf{P}}_u^{(\widehat{T})}\widetilde{\mathbf{X}}\widetilde{\mathbf{P}}_v^{(\widehat{T})} - \widetilde{\mathbf{P}}_u\widetilde{\mathbf{X}}\widetilde{\mathbf{P}}_v\|_{\mathrm{F}} \le C\sqrt{k\gamma_u^2 + l\gamma_v^2}.$$

Next, by similar argument to that leading to the conclusion of Lemma 11, with probability at least $1 - O(m^{-2})$

$$\begin{aligned}
\|\widetilde{\mathbf{P}}_u\widetilde{\mathbf{X}}\widetilde{\mathbf{P}}_v - \widetilde{\mathbf{P}}_u\mathbf{M}\widetilde{\mathbf{P}}_v\|_{\mathrm{F}} &\le \|\widetilde{\mathbf{X}} - \mathbf{M}\|_{\mathrm{F}} = \|\mathbf{Z}_{IJ}\|_{\mathrm{F}} \\
&\le \sqrt{r}\|\mathbf{Z}_{IJ}\|_{\mathrm{op}} \\
&\le \sqrt{r}(\sqrt{k} + \sqrt{l} + 2\sqrt{\log m}).
\end{aligned}$$

Last but not least,

$$\begin{aligned}
&\|\widetilde{\mathbf{P}}_u\mathbf{M}\widetilde{\mathbf{P}}_v - \mathbf{P}_u\mathbf{M}\mathbf{P}_v\|_{\mathrm{F}} \\
&\quad \le \|(\widetilde{\mathbf{P}}_u - \mathbf{P}_u)\mathbf{M}\widetilde{\mathbf{P}}_v\|_{\mathrm{F}} + \|\mathbf{P}_u\mathbf{M}(\widetilde{\mathbf{P}}_v - \mathbf{P}_v)\|_{\mathrm{F}} \\
&\quad \le d_1(\|\widetilde{\mathbf{P}}_u - \mathbf{P}_u\|_{\mathrm{F}} + \|\widetilde{\mathbf{P}}_v - \mathbf{P}_v\|_{\mathrm{F}}) \\
&\quad \le \kappa\sqrt{r}(\sqrt{k} + \sqrt{l} + 2\sqrt{\log m}).
\end{aligned}$$

Assembling the last four displays, we complete the proof for the case of Frobenius norm, i.e., $q = 2$. To obtain the result for all $q \in [1, 2)$, simply note that for any matrix $\mathbf{A}$, $\|\mathbf{A}\|_{\mathbb{S}_q} \le (\mathsf{rank}(\mathbf{A}))^{\frac{1}{q}-\frac{1}{2}}\|\mathbf{A}\|_{\mathrm{F}}$ and that $\mathsf{rank}(\widetilde{\mathbf{M}} - \mathbf{M}) \le 2r$. This completes the proof. ■

6.3 Proof of Proposition 7

Proof [Proof of Proposition 7] Without loss of generality, assume that $\sigma = 1$. We first show that $\widehat{r} \le r$ with probability at least $1 - O(m^{-2})$. To this end, note that

$$\begin{aligned}
\mathbb{P}\{\widehat{r} > r\} &= \mathbb{P}\left\{\sigma_{r+1}(\mathbf{X}_{I^0J^0}) > \delta_{|I^0||J^0|}\right\} \\
&\le \mathbb{P}\left\{\max_{|A|=|I^0|,|B|=|J^0|} \sigma_{r+1}(\mathbf{X}_{AB}) > \delta_{|A||B|}\right\} \\
&\le \sum_{i=r+1}^{m}\sum_{j=r+1}^{n} \mathbb{P}\left\{\max_{|A|=i,|B|=j} \sigma_{r+1}(\mathbf{X}_{AB}) > \delta_{ij}\right\}.
\end{aligned}$$

By the interlacing property of singular values, we know that for $\mathbf{Z}$, a $m \times n$ standard Gaussian random matrix,

$$\max_{|A|=i,|B|=j} \sigma_{r+1}(\mathbf{X}_{AB}) \overset{st}{<} \max_{|A|=i-r,|B|=j-r} \sigma_1(\mathbf{Z}_{AB}) \overset{st}{<} \max_{|A|=i,|B|=j} \sigma_1(\mathbf{Z}_{AB}),$$

where $\overset{st}{<}$ means stochastically smaller. Together with the union bound, this implies

$$\begin{aligned}
\mathbb{P}\left\{\max_{|A|=i,|B|=j} \sigma_{r+1}(\mathbf{X}_{AB}) > \delta_{ij}\right\} &\le \binom{m}{i}\binom{n}{j}\mathbb{P}\{\sigma_1(\mathbf{Z}_{AB}) > \delta_{ij}\} \\
&\le \left(\frac{em}{i}\right)^i\left(\frac{en}{j}\right)^j \exp\left(-i\log\frac{em}{i} - j\log\frac{em}{j} - 4\log m\right) \\
&= m^{-4}.
\end{aligned}$$

Here, the second inequality is due to $\binom{p}{k} \le (ep/k)^k$ for any $k \in [p]$ and the Davidson-Szarek bound (Davidson and Szarek, 2001). As $n \le m$ under Condition 1, we obtain

$$\mathbb{P}\{\widehat{r} > r\} \le \sum_{i=r+1}^{m}\sum_{j=r+1}^{n} m^{-4} \le m^{-2}.$$

To show that $\widehat{r} \ge r$ with probability at least $1 - O(m^{-2})$, we note that on the event such that the conclusions of Lemmas 9–11 hold, $\sigma_r(\mathbf{X}_{I^0J^0}) = \sigma_r(\widetilde{\mathbf{X}}^0) = \widetilde{d}_r^{(0)}$. So by the triangle inequality, the conclusion of Lemma 9 and the proof of Lemma 11, we obtain that

$$\sigma_r(\mathbf{X}_{I^0J^0}) = \widetilde{d}_r^{(0)} \ge d_r - \|\mathbf{X} - \widetilde{\mathbf{X}}\|_{\mathrm{op}} - \|\widetilde{\mathbf{X}} - \widetilde{\mathbf{X}}^0\|_{\mathrm{op}} \ge d_r/4 > \delta_{kl},$$

where the second last and the last inequalities hold under Condition 1 for sufficiently large values of m and n. Note that on the event such that the conclusion of Lemma 10 holds, we have $|I^0| \le k$ and $|J^0| \le l$ and so $\delta_{|I^0||J^0|} \le \delta_{kl}$. This completes the proof. ■

Appendix A. Appendix

Lemma 17 (Lemma 8.1 in Birgé (2001)) *Let X follow the non-central chi square distribution $\chi^2_\nu(\delta)$ with degrees of freedom ν and non-centrality parameter $\delta \geq 0$. Then for any $x > 0$,*

$$\mathbb{P}\left\{X \geq \nu + \delta + 2\sqrt{(\nu+2\delta)x} + 2x\right\} \leq \mathrm{e}^{-x},$$
$$\mathbb{P}\left\{X \leq \nu + \delta - 2\sqrt{(\nu+2\delta)x}\right\} \leq \mathrm{e}^{-x}.$$

Lemma 18 *Let X and Y be two independent χ^2_ν random variables. Then for any $x > 0$,*

$$\mathbb{P}\left\{\left|\frac{X}{Y} - 1\right| \leq \frac{4\sqrt{x/\nu}(1+\sqrt{x/\nu})}{1 - 2\sqrt{x/\nu}}\right\} \geq 1 - 4\mathrm{e}^{-x}.$$

Proof By the triangle inequality,

$$\left|\frac{X}{Y} - 1\right| \leq \frac{1}{|Y|}\left(|X-\nu| + |Y-\nu|\right).$$

By Lemma 17, for any $x > 0$, each of the following holds with probability at least $1 - 2\mathrm{e}^{-x}$:

$$|X-\nu| \leq 2\sqrt{\nu x} + 2x,$$
$$|Y-\nu| \leq 2\sqrt{\nu x} + 2x, \quad \text{and} \quad |Y| \geq \nu - 2\sqrt{\nu x}.$$

Assembling the last two displays, we complete the proof. ■

Abstract

Many reinforcement learning (RL) tasks, especially in robotics, consist of multiple sub-tasks that are strongly structured. Such task structures can be exploited by incorporating hierarchical policies that consist of gating networks and sub-policies. However, this concept has only been partially explored for real world settings and complete methods, derived from first principles, are needed. Real world settings are challenging due to large and continuous state-action spaces that are prohibitive for exhaustive sampling methods. We define the problem of learning sub-policies in continuous state action spaces as finding a hierarchical policy that is composed of a high-level gating policy to select the low-level sub-policies for execution by the agent. In order to efficiently share experience with all sub-policies, also called inter-policy learning, we treat these sub-policies as latent variables which allows for distribution of the update information between the sub-policies. We present three different variants of our algorithm, designed to be suitable for a wide variety of real world robot learning tasks and evaluate our algorithms in two real robot learning scenarios as well as several simulations and comparisons.

Keywords: Reinforcement Learning, Policy Search, Hierarchical Learning, Robot Learning, Motor Skill Learning, Robust Learning, Structured Learning, Temporal Correlation, HiREPS, REPS

1. Introduction

Employing robots in unpredictable environments, such as in hospitals, disaster sites or households, requires robotic agents to autonomously learn new tasks and adapt to new environments. Such robots will need to acquire new skills through trial and error, also known as reinforcement learning (Sutton and Barto, 1998), as well as being able to generalize their skills to solve a large variety of tasks. However, successful implementation of reinforcement learning (RL) methods on real robot tasks is challenging for multiple reasons. Most importantly, real robots have high dimensional and continuous state-action spaces which is difficult to deal with for many RL methods. Furthermore, evaluations on real robots are resource intensive and, hence, the methods need to be sample efficient. Methods should also not fully explore the state-action space due to the risk of damaging the robot or its environment. Finally, real robot RL does not allow resetting of the state to arbitrary initial conditions as is required for many RL methods.

While presenting additional challenges, robot tasks also offer some advantages over traditional RL settings as many real world motor tasks are heavily structured. Exploiting the environment's structure can drastically simplify the learning problem. First, the solutions of many tasks lie within a tube of the solution space (Peters and Schaal, 2006), such that learning can be given a head start by demonstrating a sub-optimal solution. Local RL methods can, subsequently, be used to improve upon this demonstration. Second, the motor commands for many motor tasks exhibit strong temporal correlations. Such correlations allow for a hierarchical decomposition of the task into a sequence of elemental movements, often also referred to movement primitives (Schaal et al., 2003; Ijspeert and Schaal, 2003), options (Sutton et al., 1999b) or motor templates (Neumann and Peters, 2009). For example, a tennis game can be decomposed into a sequence of single strokes, e.g., a backhand strokes, forehand strokes, lobs, volleys and a serve. Finally, many motor tasks can be solved in multiple, often incompatible, ways. Identifying and representing such solutions as separate sub-policies to be used by the agent increases the versatility as well as the robustness of the learned policy. Additionally, it simplifies the use of local learning methods. In this paper, we extend our work on a robot learning framework (Daniel et al., 2012a,b), (Daniel et al., 2013) that can take advantage of such structured environments by identifying multiple sub-policies for a given task and learning to adapt, sequence and combine these sub-policies.

We base our learning algorithm on the Relative Entropy Policy Search (REPS) algorithm (Peters et al., 2010). In REPS, the exploitation-exploration trade-off is balanced by bounding the loss of information between policy updates. Such a bound results in a smoother and more stable learning process that avoids wild exploration of the state action space, as required by the robotics domain. We extend the REPS algorithm such that we can use sub-policies as building blocks of a hierarchical policy to exploit the temporal correlations inherent to many tasks. We formulate the problem of inferring such a hierarchical policy as a latent variable estimation problem, where the index of the sub-policy that has generated a given action is modeled as a latent variable. The policy update is now performed in two steps. In the Expectation step, we compute the responsibilities of the latent variables, i.e., the probabilities that the individual sub-policies have generated the observed state action pairs. The sub-policies are kept fixed in the E-step. Subsequently, the responsibilities are used to update the hierarchical policy containing the sub-policies with the REPS algorithm in the Maximization step. We show that such an Expectation-Maximization (EM) algorithm (Dempster et al., 1977) improves a lower bound of the original REPS optimization problem and that the lower bound is tight after each expectation step.

Our algorithm also allows for using prior knowledge to constrain the structure of the estimated hierarchical policy. For example, we often want the sub-policies to represent individual, distinct solutions. In many cases, these solutions may be incompatible, i.e., the solution space may not be convex. Therefore, the set of sub-policies should be separable in the solution space. Adding a constraint that avoids such an overlap ensures that the policy search algorithm does not average over multiple modes of the solution space, which may result in a poor performance of the resulting policy (Neumann, 2011).

We will discuss different variants of the Hierarchical REPS (HiREPS) approach with increasing complexity. We start our discussion with the contextual, continuous-armed bandit case where the episode ends after executing all actions belonging to one sub-policy. sub-policies are selected according to a gating policy $\pi(o|\boldsymbol{s})$ and define a distribution over the action given the state for a predetermined time horizon. Subsequently, we show how to extend this framework to the finite horizon setting, where the agent sequences multiple sub-policies to achieve his goal. Finally, we present the infinite horizon formulation of HiREPS, where the agent keeps executing sub-policies until either the task is fulfilled or a random reset occurs.

1.1 Related Work

Policy search (PS) is a class of RL methods which have been shown to fulfill the requirements of robot RL and is widely used in real robot learning. In applications, PS methods are often preferred over other traditional RL methods such as value-based methods, since they do not require the explicit estimation of a value function. Estimating a value function often requires the agent to fill the state and action space with samples, which is infeasible in robot RL. Therefore, most PS methods are commonly local methods and improve only locally on an initial, sub-optimal solution.

Particular properties of PS methods have been highlighted by several papers. Bagnell and Schneider (2003) show their strong convergence guarantees, Sutton et al. (1999a) discuss their application in combination with function approximators and Stone (2001) improved the possibilities of incorporating domain knowledge. Backing up the theoretical strength of policy search methods, several authors have demonstrated impressive application results. Bagnell and Schneider (2001) use policy search methods to autonomously control helicopters, Rosenstein (2001) learns robot weight-lifting, Kohl and Stone (2003) demonstrates learning of a quadrupedal walking behavior and Kober et al. (2008) successfully learn the ball in a cup (also known as Kendama) game. Endo et al. (2008) show the application of PS methods on a biped locomotion and Kormushev et al. (2010) PS to learn how to flip a pan-cake with a robot arm.

Important advances in the area of policy search methods have included pair-wise policy comparisons (Strens, 2003), policy gradient methods (Baxter and Bartlett, 2001; Sutton et al., 1999a) and natural policy gradient methods (Bagnell and Schneider, 2003; Peters and Schaal, 2006). More recently, Kober et al. (2008) presented probabilistic policy search approaches based on expectation maximization. Using EM like methods for reinforcement learning was initially pioneered by Dayan and Hinton (1997). Toussaint et al. (2006) showed how an EM like method can be used not only for MDPs but also partially observed MDPs. Deisenroth (2010) developed a model-based policy search method based on probabilistic modeling. Theodorou et al. (2010) showed a policy improvement algorithm inspired by path integrals and Peters et al. (2010) proposed a PS method that limits the loss of information between policy updates. Recently, Levine and Abbeel (2014) and Schulman et al. (2015) have shown how policy search methods can be combined with neural networks to learn complicated tasks in high dimensional domains. As these results show, current methods are well suited to learn single tasks in isolation. Nevertheless, they frequently fail to scale up to more complex motor tasks as they cannot exploit the hierarchical structure inherent to many tasks.

A common way of representing a hierarchical task structure is to use the concept of options. Options are temporally extended actions and were first introduced by Sutton et al. (1999a) as a way of reducing task complexity. They consist of three components, an action-selection policy, an initiation set that defines in which states an option can be initiated and a termination condition

which defines the probability of terminating an option in a given state. Typically, options extend the action space of the agent, i.e., the agent can still take the primitive actions which are active for one time step, and, in addition, the agent can choose the options as temporally extended actions. The use of options can significantly improve the learning speed as the options can be used to connect parts of the state space that are otherwise only reachable with a long action sequence (Sutton et al., 1999a). Consequently, the state space becomes easier to explore and, hence, the learning problem gets simplified. Formally, learning with options can be formulated as learning a Semi-Markov Decision Process (SMDP). SMDPs are not fully Markovian, as the selected option does not only depend on the current state, but also on the active option in the previous time step.

Unlike in the simplest setup where the set of options is given and fixed during learning, it is often also desirable to learn useful options for a given task. In this case, the data efficiency for learning the options can be significantly improved by leveraging all information collected during the execution of one option, also denoted as intra-option learning (Sutton et al., 1998). The state transitions generated by a certain option can also be used to update other options in an off-policy learning setup. Levy and Shimkin (2012) proposed a different view of intra-option learning by augmenting the state space with the option-termination probability. In that augmented state space, the option selection policy and termination condition may be represented by orthogonal basis functions and is optimized individually by standard policy gradient methods.

Options are also used in many hierarchical RL approaches where they are often extended to subtasks. A sub-task also contains an individual reward function such that we can learn the policy of the subtask. Dietterich (2000) proposed the MAXQ framework that uses several layers of subtasks. In contrast to the traditional option framework, the policies of the subtasks can also choose to execute a new subtask instead of just a primitive action. The subtasks are given by an individual reward function per subtask, a termination condition and a set of actions or other subtasks that can be executed. The policy of the subtasks is learned by the MAXQ-Q learning algorithm that learns the optimal value function for each subtask. However, the structure of the subtasks, i.e., the individual reward functions, must be specified by the user. How to define such subtasks for complex robot motor tasks or even learn the structure from data remains an open question. Additionally, value function methods are less applicable in continuous state action domains and not well suited for robotic tasks. Barto et al. (2004) used an 'intrinsic motivation' mechanism to define the reward signal of each subtask. A naturally curious agent is exploring its environment and whenever it discovers an unexpected change in its environment, it creates a new subtask in its internal representation that tries to reproduce this unexpected event. Hence, the agent incrementally builds up a set of skills that help the agent to explore its environment more efficiently. After this exploration phase, new tasks can be learned more efficiently by using the learned set of skills.

The notion of subtasks has also been used in continuous environments. Morimoto and Doya (2001) proposed a hierarchical RL setup where the subtask is defined by reaching a specific joint configuration of the robot. In this work, the set of subtasks, i.e., desired joint configurations, is given and the robot learns to reach the individual joint configurations as well as to choose a reachable next desired joint configuration. Ghavamzadeh and Mahadevan (2003) used a policy gradient approach to learn the policies for the individual subtasks while a value based method is used to select the next subtask. Policy gradient approaches work well in continuous environments but often converge slowly. In both approaches, the subtasks have been specified by the user and could not be modified by the learning algorithm. Hence, both approaches are limited to simpler robots where appropriate subtasks can be hand-tuned. In Konidaris and Barto (2009), the structure of the subtasks is also

learned by discovering the initiation set, the termination set and the option policy for new options. The options are then be chained together to solve the overall task. However, the option discovery algorithm is to date still limited to rather simple agents, such as a ball navigating in a maze.

The approach which is probably most closely related to ours is Bayesian policy search with hierarchical policy priors (Wingate et al., 2011). In this approach, the probabilistic formulation of policy search (Kober et al., 2008) is used and a hierarchical Bayesian prior is used for the policy parameters. Similarly to our approach, the activations of options are modeled as latent variables in their model that are estimated by MCMC sampling methods. While the use of hierarchical Bayesian priors is a promising idea, the approach is restricted to directly learn on the trajectory data instead of state actions pairs, which might lead to inefficient policy updates. In addition, the approach cannot be extended straightforwardly to complex high dimensional robots as the structure of the options is limited.

Another approach to simplifying the hierarchical RL problem in continuous action spaces is to restrict the space of possible trajectories by using parametrized policies, often also called movement primitives (Schaal et al., 2003), motion templates (Neumann and Peters, 2009) or parametrized skills (Da Silva et al., 2012). Learning the option policy now reduces to learning an appropriate parameter vector for the option. In Neumann and Peters (2009), the agent learned to sequence such parametrized policies, i.e., it learned the correct order of the parametrized policy as well as the single parameter vectors of the policy. In total, the agent has to learn fewer decisions as opposed to directly learning with primitive actions. However, learning is often also more difficult as the effect of an inaccurate decision can be much more costly than for primitive actions. While Neumann and Peters (2009) used value function approximation to evaluate the quality of the chosen parameter vectors of the options, Stulp and Schaal (2012) directly used the reward to come as evaluation. This reward to come was subsequently used by the Policy Improvement by Path Integrals (PI^2) algorithm (Theodorou et al., 2010) to learn the option policy.

Parametrized options or skills were also used for skill transfer, i.e., generalizing the parameters of the options to new tasks (Kupcsik et al., 2014). Thomas and Barto (2012) showed how the structure of motor primitives for continuous state action tasks can be learned and later be used to accelerate learning of a similar task. Da Silva et al. (2012) as well as Kober et al. (2010b) generalized parametrized skills for reasonably similar tasks drawn from a task distribution. They do not only use the concept of an option for a single policy, but instead allow each option to adapt to a subset of the task space by smoothly changing the parameter vector of the option. Hence, individual options are responsible for areas of the task space that are locally smooth. Multiple options together span discontinuous areas of the task space. The proposed framework consists of a pipeline of machine learning tools to identify the individual smooth lower dimensional manifolds as well as to generalize and improve the policy parameters. Alternative approaches for task generalization of parametrized options include learning a mixture of experts (Mülling et al., 2013) and Gaussian processes (Ude et al., 2010). The method presented in this paper is applicable to both primitive actions as well as movement primitives.

In the remainder of the paper we will explain how to obtain at a hierarchical formulation of the relative entropy policy search (REPS) method. We treat the problem of learning a hierarchical policy as a latent variable estimation problem. For the policy update, we assume that we can only observe the resulting actions of the old policy. The underlying hierarchy is unknown and, therefore, unobserved. The resulting algorithm is closely related to expectation maximization (EM) for latent variable models. We prove that such EM mechanisms can be incorporated in the information theo-

retic regularization of the REPS algorithm in order to get a lower bound of the original optimization problem which can, subsequently, be optimized in closed form. Furthermore, we introduce an additional constraint into the optimization problem that bounds the uncertainty of identifying a sub-policy given an action. As a consequence, the sub-policies are separated in the action space, which results in finding more versatile solutions and also alleviates the problem of averaging over several modes in the solution space, which is present in many current policy search algorithms as shown in Neumann (2011). In the evaluation section, we compare our algorithm to other state-of-the-art methods on benchmark problems and evaluate our algorithm on real world robotic applications.

2. Background on Information Theoretic Policy Search

As our algorithm is based on information theoretic policy search (Peters et al., 2010; Daniel et al., 2012a), we will quickly review the most relevant concepts of information theoretic policy search in the non-hierarchical learning setup. In policy search, an agent tries to maximize the expected return by adapting a parametrized policy. Formally, in a Markov decision process setting, the agent is in a state $\boldsymbol{s} \in \mathbb{S}$ and chooses an action $\boldsymbol{a} \in \mathbb{A}$ to execute. Given state $\boldsymbol{s}$ and action $\boldsymbol{a}$, the agent transfers to a next state $\boldsymbol{s}'$ in accordance with a transition probability distribution $p(\boldsymbol{s}'|\boldsymbol{s},\boldsymbol{a}) = \mathcal{P}^{\boldsymbol{a}}_{\boldsymbol{s}\boldsymbol{s}'}$. For each transition, the agent also receives a reward $r \in \mathbb{R}$ that depends on $\boldsymbol{s}$ and $\boldsymbol{a}$, which we also write as $\mathcal{R}_{\boldsymbol{s}\boldsymbol{a}}$. The agent chooses actions $\boldsymbol{a}$ in the current state $\boldsymbol{s}$ according to a policy $\pi(\boldsymbol{a}|\boldsymbol{s})$. We will consider an average reward setting where the goal of the agent is to find an optimal policy that will maximize the average reward

$$J(\pi) = \mathbb{E}[\mathcal{R}_{\boldsymbol{s}\boldsymbol{a}}] = \iint \mu^{\pi}(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s})\mathcal{R}_{\boldsymbol{s}\boldsymbol{a}}\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a}, \tag{1}$$

where $\mu^{\pi}(\boldsymbol{s})$ is the state visit distribution of policy π.

Information-theoretic policy search was introduced with the relative entropy policy search (REPS) algorithm (Peters et al., 2010). We will start by defining a constrained optimization problem for solving the discussed average reward reinforcement learning setting and, subsequently, add an information-theoretic constraint to make the optimization problem feasible.

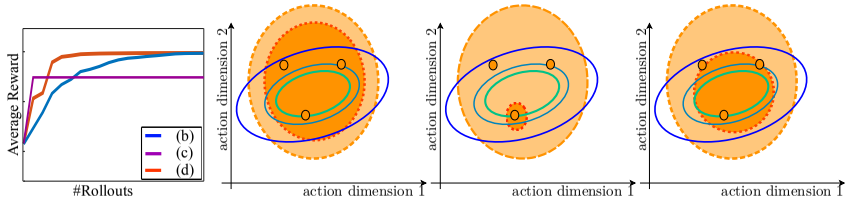
Constraints for the State Distribution. The objective of our optimization problem is given in Equation (1) which is supposed to be maximized with respect to $\mu^{\pi}(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s})$. The agent can not freely choose the state distribution $\mu^{\pi}(\boldsymbol{s})$ of the policy, since $\mu^{\pi}(\boldsymbol{s})$ needs to comply with the policy $\pi(\boldsymbol{a}|\boldsymbol{s})$ and the system dynamics $\mathcal{P}^{\boldsymbol{a}}_{\boldsymbol{s}\boldsymbol{s}'}$, i.e.,

$$\forall \boldsymbol{s}' : \mu^{\pi}(\boldsymbol{s}') = \int_{\boldsymbol{s},\boldsymbol{a}} \mu^{\pi}(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s})\mathcal{P}^{\boldsymbol{a}}_{\boldsymbol{s}\boldsymbol{s}'}\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a}.$$

However, direct matching of the state probabilities is not feasible in continuous state spaces. Instead, we introduce state features $\boldsymbol{\phi}(\boldsymbol{s})$ and only match the feature averages

$$\int \boldsymbol{\phi}(\boldsymbol{s}')\mu^{\pi}(\boldsymbol{s}')\,\mathrm{d}\boldsymbol{s}' = \iiint \mu^{\pi}(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s})\mathcal{P}^{\boldsymbol{a}}_{\boldsymbol{s}\boldsymbol{s}'}\boldsymbol{\phi}(\boldsymbol{s}')\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a}\,\mathrm{d}\boldsymbol{s}'. \tag{2}$$

For example, if we use all linear and squared terms of $\boldsymbol{s}$ in our feature vector $\boldsymbol{\phi}(\boldsymbol{s})$, we match the mean and the variance under both distributions. Additionally, we require the joint probability



(a) Learning Curves (b) Update not greedy enough (c) Update too greedy (d) Balanced Exploration

Figure 1: Schematic sketch of the behavior of policy updates. Solid lines show the contours of a quadratic reward function. The orange shaded area delimited by the dashed lines illustrates the area within two times the standard deviation of the sampling policy and the orange dots represent samples from the original policy. The darker shaded area delimited by the dotted line indicates the the possible policy update. The policy update needs to be balanced, such that it converges quickly to the local optimum, while not converging too fast to miss it. Such a balance is chosen by the user by specifying the relative entropy bound. Due to the relative entropy bound, the step size of the update is invariant to the task, the reward function or the parametrization of the policy. a) Learning curves corresponding to illustrations b-c. b) The update is not greedy enough, the policy will take too long to converge. c) The update is too greedy, the policy will not find the optimal solution. d) The update balances exploration and exploitation such that the policy quickly converges to a local optimum.

$p(\boldsymbol{s}, \boldsymbol{a}) = \mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s})$ to define a probability distribution, i.e., its integral has to evaluate to

$$1 = \iint \mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s}) \, \mathrm{d}\boldsymbol{s} \, \mathrm{d}\boldsymbol{a}. \tag{3}$$

While the optimization criterion given in Equation (1) with constraints in Equations (2,3) describes the general average reward reinforcement learning problem, it does not consider that we have typically estimated $\mathcal{R}_{\boldsymbol{sa}}$ and $\mathcal{P}^{\boldsymbol{a}}_{\boldsymbol{ss}'}$ from a limited amount of data. Hence, we do not want the agent to 'jump' to the optimum of this problem but instead balance exploitation versus exploration. In REPS (Peters et al., 2010), this exploitation-exploration trade off is balanced by the insight that the loss of information in the policy updates should be limited. Independently, such regularization was also suggested and motivated from different perspectives by other authors. Still and Precup (2011) showed that the policy update with maximum information gain results in a similar solution and Azar et al. (2012) motivated a similar update as punishing the distance between the controlled system and the uncontrolled one. Finally, Rawlik et al. (2012) showed that even previous probabilistic policy search approaches are closely related. All these arguments have lead to similar solutions despite their different motivations and the resulting algorithms work well on benchmark problems.

Staying Close to the Data by Information Theoretic Constraints. As motivated by Peters et al. (2010), one key feature of effective PS methods is to limit the loss of information between policy updates, i.e., while we want to maximize the average reward of the new policy, we also want to stay close to the 'data', i.e., the state action distribution $q(\boldsymbol{s}, \boldsymbol{a})$ of the old policy. Staying close to the

data can be achieved by limiting the Kullback-Leibler (KL) divergence between the observed data $q(\boldsymbol{s}, \boldsymbol{a})$ and the next policy, i.e.,

$$\epsilon \geq D_{\mathrm{KL}}\left(\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s}) \,||\, q(\boldsymbol{s}, \boldsymbol{a})\right) = \iint \mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s}) \log \frac{\mu(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s})}{q(\boldsymbol{s}, \boldsymbol{a})} \, \mathrm{d}\boldsymbol{s} \, \mathrm{d}\boldsymbol{a}. \tag{4}$$

Maximizing Equation (1) under the constraints of Equations (2, 3, 4) yields the optimization problem that defines the REPS method (Peters et al., 2010) which is the basis for our hierarchical policy search algorithm. The REPS optimization problem allows for a closed form solution for $\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s})$ that can be derived by the method of Lagrangian multipliers. It is given by

$$\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s}) \propto q(\boldsymbol{s}, \boldsymbol{a}) \exp\left(\frac{\mathcal{R}_{\boldsymbol{sa}} + \mathbb{E}\left[\boldsymbol{\theta}^T\boldsymbol{\phi}(\boldsymbol{s}')|\boldsymbol{s}, \boldsymbol{a}\right] - \boldsymbol{\theta}^T\boldsymbol{\phi}(\boldsymbol{s})}{\eta}\right), \tag{5}$$

where η and $\boldsymbol{\theta}$ are Lagrangian parameters that are obtained by optimizing the dual function

$$g(\eta, \boldsymbol{\theta}) = \eta \log \iint q(\boldsymbol{s}, \boldsymbol{a}) \exp\left(\frac{\mathcal{R}_{\boldsymbol{sa}} + \mathbb{E}[V(\boldsymbol{s}')] - V(\boldsymbol{s})}{\eta}\right) \mathrm{d}\boldsymbol{s} \, \mathrm{d}\boldsymbol{a} + \eta\epsilon, \tag{6}$$

of the original optimization problem. If we interpret the term $V(\boldsymbol{s}) = \boldsymbol{\theta}^T\boldsymbol{\phi}(\boldsymbol{s})$ as value function linear in the parameters $\boldsymbol{\theta}$, the term $\mathcal{R}_{\boldsymbol{sa}} + \mathbb{E}\left[V(\boldsymbol{s}')\right] - V(\boldsymbol{s})$ can be viewed as advantage function. The Lagrangian parameter η is a scaling factor for the advantage. It becomes the temperature of the soft-max distribution defined in Equation (5) such that the KL-bound from Equation (4) is met.

Sample-Based REPS. As the reward function and the old distribution $q(\boldsymbol{s}, \boldsymbol{a})$ can have an arbitrary structure, the integral contained in the dual function can typically not be obtained in closed form. However, the reward function can typically be evaluated on samples from $q(\boldsymbol{s}, \boldsymbol{a})$ and these samples can be used to approximate the dual function g. As a result, we can only evaluate the distribution $\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s})$ on a finite set of samples $\boldsymbol{s}_i$ and $\boldsymbol{a}_i$ with $i = 1 \ldots N$.

In order to sample new actions $\boldsymbol{a}$ in the next iteration of the algorithm, we need to find a parametric representation $\tilde{\pi}(\boldsymbol{a}|\boldsymbol{s}; \boldsymbol{\beta})$ of the policy that approximates the distribution $\pi(\boldsymbol{a}_i|\boldsymbol{s}_i)$, where $\boldsymbol{\beta}$ denotes the parameter vector of the policy. To do so, we aim to minimize the expected Kullback-Leibler divergence between $\pi(\boldsymbol{a}_i|\boldsymbol{s}_i)$ and the next parametric policy $\tilde{\pi}(\boldsymbol{a}|\boldsymbol{s}; \boldsymbol{\beta})$, i.e.,

$$\begin{aligned}
&\arg\min_{\boldsymbol{\beta}} \int p(\boldsymbol{s}) D_{\mathrm{KL}}\left(\pi(\boldsymbol{a}|\boldsymbol{s}) \,||\tilde{\pi}(\boldsymbol{a}|\boldsymbol{s}; \boldsymbol{\beta})\right) \, \mathrm{d}\boldsymbol{s} \\
&= \arg\min_{\boldsymbol{\beta}} \int p(\boldsymbol{s}) \int \pi(\boldsymbol{a}|\boldsymbol{s}) \log \frac{\pi(\boldsymbol{a}|\boldsymbol{s})}{\tilde{\pi}(\boldsymbol{a}|\boldsymbol{s}; \boldsymbol{\beta})} \, \mathrm{d}\boldsymbol{a} \, \mathrm{d}\boldsymbol{s} \\
&\approx \arg\max_{\boldsymbol{\beta}} \sum_i \frac{p(\boldsymbol{s}_i, \boldsymbol{a}_i)}{q(\boldsymbol{s}_i, \boldsymbol{a}_i)} \log \tilde{\pi}(\boldsymbol{a}_i|\boldsymbol{s}_i; \boldsymbol{\beta}) + \mathrm{const} \\
&= \arg\max_{\boldsymbol{\beta}} \sum_i w_i \log \tilde{\pi}(\boldsymbol{a}_i|\boldsymbol{s}_i; \boldsymbol{\beta}),
\end{aligned} \tag{7}$$

with

$$w_i = \exp\left(\frac{r(\boldsymbol{s}_i, \boldsymbol{a}_i) + \mathbb{E}\left[\boldsymbol{\theta}^T\boldsymbol{\phi}(\boldsymbol{s}')\middle|\, \boldsymbol{s}_i, \boldsymbol{a}_i\right] - \boldsymbol{\theta}^T\boldsymbol{\phi}(\boldsymbol{s}_i)}{\eta}\right). \tag{8}$$

Since the available samples are drawn from the distribution $q(\boldsymbol{s}, \boldsymbol{a})$, and not $p(\boldsymbol{s}, \boldsymbol{a})$, we need to perform importance sampling and divide by the sampling distribution $q(\boldsymbol{s}, \boldsymbol{a})$. Equation (7) is equivalent to computing the weighted maximum likelihood estimator for $\boldsymbol{\beta}$. In Section 4.3 we discuss how to compute the expectation over next states $\mathbb{E}\left[\boldsymbol{\theta}^T \boldsymbol{\phi}(\boldsymbol{s}') \middle| \boldsymbol{s}_i, \boldsymbol{a}_i\right]$.

Illustration of Information Theoretic Policy Search. We illustrate the concept of information theoretic policy search on a two-dimensional toy problem with a quadratic reward function in Figure 1(a). Here, the algorithm typically starts with a broad explorative policy. Given a set of samples generated using this policy, we update the policy such that the exploitation-exploration trade-off is well balanced. This trade-off is chosen by the relative entropy bound of the REPS algorithm. Due to the relative entropy bound, the step-size of the policy update is largely independent of the task, the reward function, or the representation of the policy. Changing the policy only by a small step leads to further exploration as we stay close to the old exploration policy as illustrated in Figure 1(b). In contrast, a large KL divergence for the policy update greedily jumps to the best observed samples with very little further exploration, see Figure 1(c). This trade-off has to be chosen by the user by specifying the bound ϵ for the KL-divergence. Typically, we want to achieve a moderate exploration-exploitation trade-off as illustrated in Figure 1(d).

3. Learning Hierarchical Policies for Real Robot Reinforcement Learning

In this section, we will extend the REPS optimization problem to the hierarchical case, where the agent learns a hierarchical policy that is based on both a gating network and sub-policies. In order to obtain an efficient update rule for the hierarchical policy, we will rely on several insights detailed below. We will use these insights to derive three different learning algorithms that can be employed in different scenarios.

Hierarchical Policies. More complex tasks often require multiple sub-policies, such as a forehand stroke, backhand stroke, smash or lob in tennis. Different sub-policies are appropriate in different states of the environment. In order to model a policy consisting of several sub-policies, we use a hierarchical policy $\pi(\boldsymbol{a}|\boldsymbol{s})$ which consists of a set of sub-policies $\pi(\boldsymbol{a}|\boldsymbol{s}, o)$ and a gating network $\pi(o|\boldsymbol{s})$ that selects the currently active sub-policy. Thus, the hierarchical policy can be represented as

$$\pi(\boldsymbol{a}|\boldsymbol{s}) = \sum_{o \in \mathcal{O}} \pi(o|\boldsymbol{s}) \pi(\boldsymbol{a}|\boldsymbol{s}, o). \tag{9}$$

In order to determine the action $\boldsymbol{a}$ in state $\boldsymbol{s}$, we first sample a sub-policy from the gating network $\pi(o|\boldsymbol{s})$ and, subsequently, sample the action $\boldsymbol{a}$ from the specific sub-policy $\pi(\boldsymbol{a}|\boldsymbol{s}, o)$. The benefit of representing multiple solutions has already been made evident in recent research results (Calinon et al., 2013; Daniel et al., 2012a).

Options as Latent Variables. Sharing of experience between sub-policies, known as inter-option learning, is an important property of a hierarchical learning algorithm for data-efficient learning. To realize inter-option learning, we treat the problem of learning sub-policies as a latent variable problem, i.e., we assume to observe only state-action samples $\{\boldsymbol{s}, \boldsymbol{a}\}$, but not the index of the generating sub-policy o. Instead, we infer the latent structure of the hierarchical policy that has generated the re-weighted samples. Expectation-maximization based methods can be used to iteratively estimate the responsibilities $p(o|\boldsymbol{s}, \boldsymbol{a})$ of the sub-policies for each sample $\{\boldsymbol{s}, \boldsymbol{a}\}$ and, subsequently, update

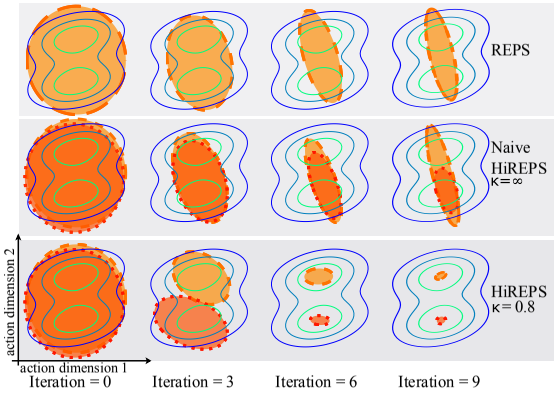


Figure 2: Schematic sketch of the behavior of REPS, and HiREPS with ($\tilde{\kappa} = 0.8$) and without ($\tilde{\kappa} = \infty$) bounding of the gating's entropy. A two-dimensional, bi-modal reward function is shown in the contour plot lines. Two sub-policies are shown in dashed and dotted outlines respectively (outlines show 95% confidence boundaries). REPS and naive HiREPS average over both modes. Constrained HiREPS separates the sub-policies and is therefore able to find both modes.

the sub-policies where the influence of each sample $\{\boldsymbol{s}, \boldsymbol{a}\}$ for the update of the sub-policy $\pi(\boldsymbol{a}|\boldsymbol{s}, o)$ is weighted by the responsibility $p(o_j|\boldsymbol{s}, \boldsymbol{a})$. Hence, the generated experience can be shared between the sub-policies. In Section 3.1, we integrate such an expectation-maximization mechanism into the REPS algorithm.

Learning Versatile Solutions. Being able to represent multiple solutions does not force the learning algorithm to find different solutions. Thus, without further constraints, we are likely to find multiple sub-policies that concentrate on the same mode of the solution space. Versatility of sub-policies can be achieved if the sub-policies are clearly separated in the state-action space. To enforce this separation of the sub-policies, we limit the expected change in the entropy H of the responsibilities of the sub-policies, i.e.,

$$\kappa \geq \frac{\mathbb{E}_{\boldsymbol{s},\boldsymbol{a}}[H\left(p(o|\boldsymbol{s}, \boldsymbol{a})\right)]}{\mathbb{E}_{q(\boldsymbol{s},\boldsymbol{a})}[H\left(q(o|\boldsymbol{s}, \boldsymbol{a})\right)]} = \frac{\iint \mu^{\pi}(\boldsymbol{s}) \pi(\boldsymbol{a}|\boldsymbol{s}) \sum_{o \in \mathcal{O}} p(o|\boldsymbol{s}, \boldsymbol{a}) \log p(o|\boldsymbol{s}, \boldsymbol{a}) \, \mathrm{d}\boldsymbol{s} \, \mathrm{d}\boldsymbol{a}}{\iint q(\boldsymbol{s}, \boldsymbol{a}) \sum_{o \in \mathcal{O}} q(o|\boldsymbol{s}, \boldsymbol{a}) \log q(o|\boldsymbol{s}, \boldsymbol{a}) \, \mathrm{d}\boldsymbol{s} \, \mathrm{d}\boldsymbol{a}}, \tag{10}$$

where $\mathbb{E}_{q(\boldsymbol{s},\boldsymbol{a})}[H\left(q(o|\boldsymbol{s}, \boldsymbol{a})\right)]$ is a constant and we write $\tilde{\kappa} = \mathbb{E}_{q(\boldsymbol{s},\boldsymbol{a})}[H\left(q(o|\boldsymbol{s}, \boldsymbol{a})\right)]\kappa$ to simplify the notation, such that the constraint reads

$$\tilde{\kappa} \geq \mathbb{E}_{\boldsymbol{s},\boldsymbol{a}}[H\left(p(o|\boldsymbol{s}, \boldsymbol{a})\right)] = -\iint \mu^{\pi}(\boldsymbol{s}) \pi(\boldsymbol{a}|\boldsymbol{s}) \sum_{o \in \mathcal{O}} p(o|\boldsymbol{s}, \boldsymbol{a}) \log p(o|\boldsymbol{s}, \boldsymbol{a}) \, \mathrm{d}\boldsymbol{s} \, \mathrm{d}\boldsymbol{a}. \tag{11}$$

A high entropy of the responsibility $p(o|\boldsymbol{s}, \boldsymbol{a})$ indicates a high uncertainty in deciding which sub-policy has generated the state action pair, which implies that several sub-policies do overlap in the parameter space. By limiting the entropy, such overlapping is avoided and we ensure that different sub-policies concentrate on different and separate solutions.

We will discuss three settings for Hierarchical REPS (HiREPS). In the episodic setup, a single sub-policy is executed per episode, but the algorithm can choose between multiple sub-policies and adapt these to the current context. Subsequently, we will show how to sequence a fixed number of sub-policies with a finite horizon MDP formulation. Finally, we will use a infinite horizon MDP formulation to learn how to sequence a possibly infinite number of skills.

Illustration of Hierarchical Learning. We illustrate the advantage of learning with multiple sub-policies on a toy task with a two dimensional action space and a bi-modal reward function (see Figure 2). In this task, the reward function consists of two attractors $\boldsymbol{g}_1, \boldsymbol{g}_2$ and a reward scaling matrix Σ_r, such that the reward function is given by

$$r(\boldsymbol{a}) = -\min_i \left((\boldsymbol{a}-\boldsymbol{g}_i)\Sigma_r(\boldsymbol{a}-\boldsymbol{g}_i)^T\right),$$

and has two local optima at $\boldsymbol{g}_1$ and $\boldsymbol{g}_2$, respectively. The illustration in Figure 2 demonstrates two key insights into PS methods. First, many standard policy search methods such as Policy Improvement with Path Integrals (Theodorou et al., 2010) or EM-based policy search methods (Kober et al., 2008) will be attracted to multiple optima in a multi-modal solution space and, therefore, converge slowly due to averaging over several modes (Neumann, 2011). Second, we would like to represent a versatile solution space by learning all modes of the reward function. Figure 2 shows a qualitative comparison of HiREPS to the standard REPS algorithm which can only use one sub-policy and to the naive implementation of HiREPS that does not bound the sub-policies' entropy (i.e., $\tilde{\kappa} = \infty$). The single sub-policy algorithm tries to average over both modes and, takes a long time to converge. The naive HiREPS exhibits similar behavior. Both sub-policies are attracted by both modes. In most cases, both sub-policies will find the same mode and convergence will be slower. Thus, only introducing hierarchical policies without additional constraints cannot take full advantage of the increased flexibility. When limiting the entropy, however, the sub-policies quickly separate and concentrate on the two individual modes, allowing for a fast improvement of the policy without getting stuck between two modes.

3.1 Episodic Selection of Sub-Policies

We start our discussion of HiREPS with the continuous multi-armed contextual bandit setting. In this setting, the agent is presented with an initial state according to an initial state distribution $p^0(\boldsymbol{s})$ and has to select a sub-policy o as well as an action $\boldsymbol{a}$ according to this state. In this setting, an episode consists of executing exactly one sub-policy, afterwards the episode is terminated and the environment is reset. Thus, no state transition is modeled, as the whole episode consists of only one step, i.e., executing one sub-policy until it terminates.

Contextual Optimization of the Policy. While we do not need to use the state distribution constraint from REPS, as we do not have to incorporate state transitions, the agent can still not freely choose its state action distribution $p(\boldsymbol{s},\boldsymbol{a}) = \mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s})$ as the initial state distribution $p^0(\boldsymbol{s})$ is specified by the learning task. Hence, the estimated state distribution $\mu^\pi(\boldsymbol{s})$ has to satisfy $\mu^\pi(\boldsymbol{s}) = p^0(\boldsymbol{s})$ for all $\boldsymbol{s}$. As this requirement would result in an infinite number of constraints, we need to resort to matching feature averages, i.e.,

$$\hat{\boldsymbol{\phi}} = \sum_{o\in\mathcal{O}} \iint \mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})\boldsymbol{\phi}(\boldsymbol{s})\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a} \tag{12}$$

where $\hat{\boldsymbol{\phi}}$ denotes the average observed feature vector for the initial state

$$\hat{\boldsymbol{\phi}} = \iint q(\boldsymbol{s},\boldsymbol{a})\boldsymbol{\phi}(\boldsymbol{s})\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a}. \tag{13}$$

This constraint enforces that the learned state action distribution does not concentrate only on contexts where the task is easy to achieve, but considers all contexts sampled from the initial state distribution.

Resulting Optimization Problem. For the resulting optimization problem, we combine the insights from the previous section on hierarchical policies with the contextual episodic learning constraint in Eq. (12). The episodic learning problem of multiple sub-policies is then given as

$$\begin{aligned}
\max_{\pi,\mu} J(\pi) &= \max_{\pi,\mu} \sum \iint \mu^\pi(\boldsymbol{s})\pi(o|\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\mathcal{R}_{\boldsymbol{sa}}\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a},\\
\text{s.t.}\quad \epsilon &\geq D_{\mathrm{KL}}\left(\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})||\; q(\boldsymbol{s},\boldsymbol{a})p(o|\boldsymbol{s},\boldsymbol{a})\right),\\
\tilde{\kappa} &\geq \mathbb{E}_{\boldsymbol{s},\boldsymbol{a}}\left[H\big(p(o|\boldsymbol{s},\boldsymbol{a})\big)\right],\\
\hat{\boldsymbol{\phi}} &= \sum_{o\in\mathcal{O}} \iint \mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})\boldsymbol{\phi}(\boldsymbol{s})\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a},\\
1 &= \sum \iint \mu^\pi(\boldsymbol{s})\pi(o|\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)d\boldsymbol{s}d\boldsymbol{a}.
\end{aligned} \tag{14}$$

In this optimization problem, the responsibilities

$$p(o|\boldsymbol{s},\boldsymbol{a}) = \frac{\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})}{\sum_{o\in\mathcal{O}}\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})},$$

occur inside the log-term of the KL-divergence. As the responsibilities contain a sum in the denominator, we also obtain the sum inside the log-term, preventing us from solving for $\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})$ in closed form. However, we can resort to an iterative, expectation maximization (EM) update strategy shown in Daniel et al. (2012a). In the expectation step, we first fix the sub-policies and compute the responsibilities $\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})$. In the maximization step, we replace $p(o|\boldsymbol{s},\boldsymbol{a})$ in our optimization problem with the pre-computed responsibilities $\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})$ and, therefore, neglect that the responsibilities will change once we change the sub-policies. In Appendix A we show that the EM-step maximizes a lower bound of the original optimization problem. We use this iterative update strategy in all further algorithms. The adapted optimization problem reads as

$$\begin{aligned}
\max_{\pi,\mu} J(\pi) &= \max_{\pi,\mu} \mathbb{E}_{\boldsymbol{s},\boldsymbol{a},o}\left[\mathcal{R}_{\boldsymbol{sa}}\right],\\
\text{s.t.}\quad \epsilon &\geq D_{\mathrm{KL}}\left(\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})||\; q(\boldsymbol{s},\boldsymbol{a})\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})\right),\\
\tilde{\kappa} &\geq -\sum_{o\in\mathcal{O}} \iint \mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})\log\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a},\\
\hat{\boldsymbol{\phi}} &= \sum_{o\in\mathcal{O}} \iint \mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})\boldsymbol{\phi}(\boldsymbol{s})\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a},\\
1 &= \sum_{o\in\mathcal{O}} \iint \mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a}.
\end{aligned} \tag{15}$$

The above optimization problem can be solved by the method of Lagrange multipliers. The Lagrangian also allows for a closed form of $\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})$ which is given as

$$\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s}) \propto q(\boldsymbol{s},\boldsymbol{a})\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})^{1+\frac{\xi}{\eta}} \exp\left(\frac{\mathcal{R}_{\boldsymbol{sa}} - V(\boldsymbol{s})}{\eta}\right), \tag{16}$$

which depends on the Lagrangian parameters ξ, η and $\boldsymbol{\theta}$ with $V(\boldsymbol{s}) = \boldsymbol{\theta}^T \boldsymbol{\phi}(\boldsymbol{s})$. The Lagrangian parameter ξ is associated to the overlapping constraint in Eq. (11). In this update equation, the parameter ξ controls the spreading of the sub-policies. A higher value of ξ will force the sub-policies to spread further apart and reduce overlapping of sub-policies as the influence of state-action pairs with a high entropy of $p(o|\boldsymbol{s}, \boldsymbol{a})$ is weakened. The derivation of the dual formulation is given in the appendix.

In Table 3, we give the algorithmic form of episodic HiREPS. The new parametric policy $\tilde{\pi}(\boldsymbol{a}|\boldsymbol{s}, o; \boldsymbol{\beta}_o)$ has to be computed from the weighted samples by performing a weighted maximum likelihood estimate for the single sub-policy parameters $\boldsymbol{\beta}_o$ as well as the parameter vector for the gating policy. In HiREPS, we obtain a weight

$$w_{i,o} = \tilde{p}(o|\boldsymbol{s}_i, \boldsymbol{a}_i)^{1+\frac{\xi}{\eta}} \exp\left(\frac{\mathcal{R}_{\boldsymbol{s}\boldsymbol{a}} - V(\boldsymbol{s}_i)}{\eta}\right),$$

for each sample and each sub-policy. These weights can be used to update the policy. HiREPS does not make any assumptions on the form of the policy and many different representations could be considered. In Section 4, we show the details of the policy model we chose to implement for the evaluations, i.e., a soft-max gating policy and linear Gaussian sub-policies.

Since HiREPS does not assume knowledge of which sub-policy generated a sample, it can use all samples to update all sub-policies, also known as inter-option learning. The weights $w_{i,o}$ are then used to update the sub-policies $\pi(\boldsymbol{a}|\boldsymbol{s}, o)$ and the gating policy $\pi(o|\boldsymbol{s})$.

3.2 Sequencing of Skills

Many real world tasks require not only one, but multiple sequential interactions. For example, in a game of tennis, we need to perform several tennis strokes in sequence in order to win the game. Just learning to return a ball is insufficient to win a game. Instead, the ball has to returned in such a way that future strokes can lead to situations where the opponent is unable to return the ball. Hence, tasks like tennis can be learned more efficiently if we learn a sequence of tennis strokes against an opponent. We will model the skill sequencing case with a limited number K of sequential decisions. We will denote the individual action selection problems as stages of the decision problem. Our goal is to maximize the sum of the expected reward over all stages, i.e.,

$$\begin{aligned} J &= \mathbb{E}_{\boldsymbol{a}_{1:K}, \boldsymbol{s}_{1:K+1}}\left[r_{K+1}(\boldsymbol{s}_{K+1}) + \sum\nolimits_{k=1}^{K} r_k(\boldsymbol{s}_k, \boldsymbol{a}_k)\right] \\ &= \int \mu^{\pi}_{K+1}(\boldsymbol{s}) r_{K+1}(\boldsymbol{s}) d\boldsymbol{s} + \iint \sum_{k=1}^{K} \mu^{\pi}_k(\boldsymbol{s}) \pi_k(\boldsymbol{a}|\boldsymbol{s}) r_k(\boldsymbol{s}, \boldsymbol{a}) \, \mathrm{d}\boldsymbol{s} \, \mathrm{d}\boldsymbol{a}, \end{aligned} \tag{17}$$

where $\mu^{\pi}_k(\boldsymbol{s})$ are the state distributions at for each decision step. The function $r_{K+1}(\boldsymbol{s}_{K+1})$ denotes the final reward for reaching state $\boldsymbol{s}_{K+1}$ and $r_k(\boldsymbol{s}_k, \boldsymbol{a}_k)$ denotes the reward for executing an action $\boldsymbol{a}_k$ in state $\boldsymbol{s}_k$. In the tennis example, the individual rewards could, for example, describe the energy efficiency of the movements, while the overall reward signal carries information about winning or losing the point. The sub-policy is given by

$$\pi_k(\boldsymbol{a}|\boldsymbol{s}) = \sum_{o \in \mathcal{O}} \pi_k(o|\boldsymbol{s}) \pi_k(\boldsymbol{a}|\boldsymbol{s}, o). \tag{18}$$

Input: Information loss tolerance ϵ, Entropy tolerance $\tilde{\kappa}$, Number of sub-policies O, number of Iterations L, number of episodes per iteration M.
Initialize all $\pi(\boldsymbol{a}|\boldsymbol{s}, o)$ and $\pi(o|\boldsymbol{s})$.

for $l = 1$ to L ... # iterations

Collect samples

for $i = 1, \ldots, M$ (# episodes)

Sample initial state $\boldsymbol{s}_{1,i}$ from environment.

Sample action: $\boldsymbol{a}_i \sim q(\boldsymbol{a}|\boldsymbol{s}_i) = \sum_{o \in \mathcal{O}} \pi_{\text{old}}(o|\boldsymbol{s}_i) \pi_{\text{old}}(\boldsymbol{a}|\boldsymbol{s}_i, o)$.

Execute action $\boldsymbol{a}_i$ and observe reward $r(\boldsymbol{a}_i, \boldsymbol{s}_i)$.

Compute Responsibilities:

$\tilde{p}(o|\boldsymbol{s}_i, \boldsymbol{a}_i) = p_{\text{old}}(o|\boldsymbol{s}_i, \boldsymbol{a}_i) = \frac{\mu^{\pi}_{\text{old}}(\boldsymbol{s}_i) \pi_{\text{old}}(\boldsymbol{a}_i|\boldsymbol{s}_i o_i) \pi_{\text{old}}(o|\boldsymbol{s}_i)}{\sum_{o \in \mathcal{O}} \mu^{\pi}_{\text{old}}(\boldsymbol{s}_i) \pi_{\text{old}}(\boldsymbol{a}_i|\boldsymbol{s}_i o_i) \pi_{\text{old}}(o|\boldsymbol{s}_i)}$ for all i.

Minimize the dual function

$[\boldsymbol{\theta}^*, \eta^*, \xi^*] = \arg\min_{[\boldsymbol{\theta}, \eta, \xi]} g(\boldsymbol{\theta}, \eta, \xi)$.

Policy update:

Compute model distribution

$\mu^{\pi}(\boldsymbol{s}_i) \pi(\boldsymbol{a}_i|\boldsymbol{s}_i o_i) \pi(o|\boldsymbol{s}_i) \propto \tilde{p}(o|\boldsymbol{s}_i, \boldsymbol{a}_i)^{1+\xi^*/\eta^*} \exp\left(\frac{R_i - V^*(\boldsymbol{s}_i)}{\eta^*}\right)$.

Estimate policies

$\pi(o|\boldsymbol{s})$ and $\pi(\boldsymbol{a}|\boldsymbol{s}, o)$ for all $o = 1 \ldots O$ by weighted ML estimates.

Output: Policies $\pi(\boldsymbol{a}, o|\boldsymbol{s})$

Table 1: Episodic HiREPS. In each iteration the algorithm starts by sampling an sub-policy o from the gating policy $\pi(a|\boldsymbol{s})$ given the initial state $\boldsymbol{s}$ and an action $\boldsymbol{a}$ from $\pi(\boldsymbol{a}|\boldsymbol{s}, o)$ from the sub-policy. Subsequently, the action is executed to generate the reward $r(\boldsymbol{s}, \boldsymbol{a})$. The parameters η, ξ and $\boldsymbol{\theta}$ are determined by minimizing the dual-function g.

Alternatively, we can also share the sub-policies for all decision stages and only make the gating policy time dependent, i.e.,

$$\pi_k(\boldsymbol{a}|\boldsymbol{s}) = \sum_{o \in \mathcal{O}} \pi_k(o|\boldsymbol{s}) \pi(\boldsymbol{a}|\boldsymbol{s}, o).$$

This formulation allows for reusing experience between the stages. Whether this property is useful depends on the task at hand. For example in tennis, the strokes at the decision stages can taken from the same skill library[1]. In the case of skill sequencing, we have one latent variable $o_{i,k}$ per rollout i and per decision stage k.

Connecting the Decision Stages. The state distributions $\mu^{\pi}_k(\boldsymbol{s})$ are now connected through the transition dynamics $\mathcal{P}^{\boldsymbol{a}}_{\boldsymbol{s}\boldsymbol{s}'}$ yielding

$$\int \boldsymbol{\phi}(\boldsymbol{s}') \mu^{\pi}_{k+1}(\boldsymbol{s}') \, \mathrm{d}\boldsymbol{s}' = \sum_{o \in \mathcal{O}} \iiint \mathcal{P}^{\boldsymbol{a}}_{\boldsymbol{s}\boldsymbol{s}'} \mu^{\pi}_k(\boldsymbol{s}) \pi_k(\boldsymbol{a}|\boldsymbol{s}, o) \pi_k(o|\boldsymbol{s}) \boldsymbol{\phi}(\boldsymbol{s}') \, \mathrm{d}\boldsymbol{s} \, \mathrm{d}\boldsymbol{s}' \, \mathrm{d}\boldsymbol{a}. \tag{19}$$

1. Except for the first stroke, as it is supposed to be the serve.

In addition, the agent cannot freely choose the initial state distribution $\mu_1^\pi(\boldsymbol{s})$, but needs to match the given initial state distribution $p_1(\boldsymbol{s})$, which is implemented in the same way as for the episodic case. Typically the dynamics $\mathcal{P}_{\boldsymbol{ss}'}^{\boldsymbol{a}}$ of a task are not known and need to be estimated from data.

Skill Sequencing Optimization Problem. After including the overlapping constraints from the previous section, the optimization problem reads

$$\max_{\pi_k, \mu_k^\pi} \mathbb{E}_{\boldsymbol{a}_{1:K}, \boldsymbol{s}_{1:K+1}} \left[r_{K+1}(\boldsymbol{s}_{K+1}) + \sum\nolimits_{k=1}^{K} r_k(\boldsymbol{s}_k, \boldsymbol{a}_k) \right],$$

$$\text{s.t.} \quad \epsilon \geq D_{\text{KL}} \left(\mu_{K+1}^\pi(\boldsymbol{s}) || \, q_{K+1}(\boldsymbol{s}) \right),$$

$$\hat{\boldsymbol{\phi}}_1 = \int \boldsymbol{\phi}(\boldsymbol{s}') \mu_1^\pi(\boldsymbol{s}') \, \mathrm{d}\boldsymbol{s}',$$

$$\forall k \leq K : \epsilon \geq D_{\text{KL}} \left(\mu_k^\pi(\boldsymbol{s}) \pi_k(\boldsymbol{a}|\boldsymbol{s}, o) \pi_k(o|\boldsymbol{s}) || \, q_k(\boldsymbol{s}, \boldsymbol{a}) \tilde{p}_k(o|\boldsymbol{s}, \boldsymbol{a}) \right),$$

$$\tilde{\kappa} \geq - \sum_{o \in \mathcal{O}} \iint \mu_k^\pi(\boldsymbol{s}) \pi_k(\boldsymbol{a}|\boldsymbol{s}, o) \pi_k(o|\boldsymbol{s}) \log \tilde{p}_k(o|\boldsymbol{s}, \boldsymbol{a}) \, \mathrm{d}\boldsymbol{s} \, \mathrm{d}\boldsymbol{a},$$

$$\int \boldsymbol{\phi}(\boldsymbol{s}') \mu_{k+1}^\pi(\boldsymbol{s}') \, \mathrm{d}\boldsymbol{s}' = \sum_{o \in \mathcal{O}} \iiint \mathcal{P}_{\boldsymbol{ss}'}^{\boldsymbol{a}} \mu_k^\pi(\boldsymbol{s}) \pi_k(\boldsymbol{a}|\boldsymbol{s}, o) \pi_k(o|\boldsymbol{s}) \boldsymbol{\phi}(\boldsymbol{s}') \, \mathrm{d}\boldsymbol{s} \, \mathrm{d}\boldsymbol{s}' \, \mathrm{d}\boldsymbol{a},$$

$$1 = \sum\nolimits_{\boldsymbol{s}, \boldsymbol{a}, o} \mu_k^\pi(\boldsymbol{s}) \pi_k(\boldsymbol{a}|\boldsymbol{s}, o) \pi_k(o|\boldsymbol{s}). \tag{20}$$

The resulting policy update rules are given by

$$\mu_k^\pi(\boldsymbol{s}) \pi_k(\boldsymbol{a}|\boldsymbol{s}, o) \pi_k(o|\boldsymbol{s}) \propto$$
$$q_k(\boldsymbol{s}, \boldsymbol{a}) \tilde{p}_k(o|\boldsymbol{s}, \boldsymbol{a})^{1 + \frac{\xi_k}{\eta_k}} \exp\left(\frac{r_k(\boldsymbol{s}, \boldsymbol{a}) + \mathbb{E}[V_{k+1}(\boldsymbol{s}')|\boldsymbol{s}, \boldsymbol{a}] - V_k(\boldsymbol{s})}{\eta_k} \right), \tag{21}$$

where one set of Lagrangian parameters $\xi_k, \eta_t, \boldsymbol{\theta}_k$ is computed for each stage. As we observe, we now obtain an individual value function $V_k(\boldsymbol{s}_k)$ for each decision stage. As in the standard REPS algorithm, the value functions are connected by the advantage function term that occurs inside the exponent in the policy. The skill sequencing algorithm is given in Table 2. The derivations of the dual function and the update rules are given in Appendix A.2. In Section 4.3, we discuss how to compute the expectation over next states $\mathbb{E}[V_{k+1}(\boldsymbol{s}')|\boldsymbol{s}, \boldsymbol{a}]$.

3.3 Infinite Horizon

An infinite horizon setting is needed for all repetitive tasks where we sequence an unknown, possibly infinite amount of sub-policies to fulfill the task. For example, when bouncing a ball on a paddle, the repetitive paddling movements induce a clear structure in the motion that suggests the use of sub-policies. In addition, we want to bounce the ball on the paddle for an infinite amount of time. In this setting, the agent needs to consider the state of the environment before each stroke.

Input: Information loss tolerance ϵ, entropy tolerance $\tilde{\kappa}$, number of sub-policies n, number of time steps K, number of iterations L.
Initialize all $\pi_k(\boldsymbol{a}|\boldsymbol{s}, o)$ and $\pi_k(o|\boldsymbol{s})$.

for $l = 1$ to L ... # iterations
  Collect samples
    for $i = 1, \ldots, M$ (# episodes)
      Sample initial state $\boldsymbol{s}_{1,i}$ from environment.
      for $k = 1, \ldots, K$ (# motor primitives)
        Sample action: $\boldsymbol{a}_{k,i} \sim q_k(\boldsymbol{a}|\boldsymbol{s}_{k,i}) = \sum_{o \in \mathcal{O}} \pi_{k,\text{old}}(o|\boldsymbol{s}_{k,i}) \pi_{k,\text{old}}(\boldsymbol{a}|\boldsymbol{s}_{k,i}, o)$.
        Execute action $\boldsymbol{a}_{k,i}$, observe next state $\boldsymbol{s}_{k+1,i}$ and reward $r(\boldsymbol{a}_{k,i}, \boldsymbol{s}_{k,i})$.
      Observe Final Reward: $r(\boldsymbol{s}_{K+1,i})$.

  Compute Responsibilities:
    $\tilde{p}_k(o|\boldsymbol{s}_{k,i}, \boldsymbol{a}_{k,i}) = p_{k,\text{old}}(o|\boldsymbol{s}_{k,i}, \boldsymbol{a}_{k,i})$ for all k and i.

  Minimize the dual function
    $[\boldsymbol{\theta}_{1:K+1}{}^*, \eta_{1:K+1}{}^*, \xi_{1:K+1}{}^*] = \arg\min_{[\boldsymbol{\theta}_{1:K+1}, \eta_{1:K+1}, \xi_{1:K+1}]} g\left(\boldsymbol{\theta}_{1:K+1}, \eta_{1:K+1}, \xi_{1:K+1}\right)$.

  Policy update:
    for $k = 1, \ldots, K$
      Compute model distribution
        $\mu_k^\pi(\boldsymbol{s}_{k,i}) \pi_k(\boldsymbol{a}_{k,i}|\boldsymbol{s}_{k,i}, o) \pi_k(o|\boldsymbol{s}_{k,i}) \propto$
        $\tilde{p}_k(o|\boldsymbol{s}_{k,i}, \boldsymbol{a}_{k,i})^{1 + \xi_k{}^*/\eta_k{}^*} \exp\left(\frac{R_{k,i} + \mathbb{E}[V_{k+1}^*(\boldsymbol{s}')] - V_k^*(\boldsymbol{s}_{k,i})}{\eta_k{}^*} \right)$.
      Estimate policies
        $\pi_k(o|\boldsymbol{s})$ and $\pi_k(\boldsymbol{a}|\boldsymbol{s}, o)$ by weighted ML estimates.

Output: Policies $\pi_k(\boldsymbol{a}, o|\boldsymbol{s})$ for all $k = 1, \ldots, K$

Table 2: Time-indexed HiREPS. In each iteration the algorithm starts by sampling from the policy π_1 given the initial state $\boldsymbol{s}_1$ and executes the sampled action to generate the next state $\boldsymbol{s}_2$. From this state, the next action is sampled with policy π_2. This procedure is repeated until the final time-step is reached. The algorithm observes state transitions and rewards for each step k and the final reward signal $r(\boldsymbol{s})$. The parameters $\eta_{1:K+1}$, $\xi_{1:K+1}$ and $\boldsymbol{\theta}_{1:K+1}$ are determined by minimizing the dual-function g, where $\eta_{1:K+1}$ and $\xi_{1:K+1}$ are vectors containing the Lagrangian parameters η_k and ξ_k for each decision step.

The traditional objective in an infinite horizon MDP is to use the discounted accumulated future rewards, i.e.,

$$R = \sum_{t=0}^{\infty} \gamma^t r_t,$$

where $\gamma < 1$ is a discount factor. Such an objective can be easily transferred to the average reward setting by introducing a reset probability γ, where the agent jumps to a state sampled from the initial state distribution $\mu^0(\boldsymbol{s})$ with probability γ and transitions to the next state with probability $(1 - \gamma)$

(van Hoof et al., 2015). Thus, we obtain a transformed transition probability distribution given by

$$\tilde{p}(\boldsymbol{s}'|\boldsymbol{s},\boldsymbol{a}) = \gamma p(\boldsymbol{s}'|\boldsymbol{s},\boldsymbol{a}) + (1-\gamma)\mu^0(\boldsymbol{s}), \tag{22}$$

where γ is the reset probability. Thus, the discount factor is considered as a termination probability. The constraint ensuring the state transition probabilities are satisfied reads as

$$\int \boldsymbol{\phi}(\boldsymbol{s}')\mu^\pi(\boldsymbol{s}')\,\mathrm{d}\boldsymbol{s}' = \sum_{o\in\mathcal{O}} \iiint \tilde{\mathcal{P}}^{\boldsymbol{a}}_{\boldsymbol{s}\boldsymbol{s}'}\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})\boldsymbol{\phi}(\boldsymbol{s}')\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{s}'\,\mathrm{d}\boldsymbol{a}. \tag{23}$$

The optimization problem for the infinite horizon case reads as

$$\begin{aligned}
\max_{\pi,\mu^\pi} J(\pi) &= \max_{\pi,\mu^\pi} \mathbb{E}_{\boldsymbol{s},\boldsymbol{a},o}\left[\mathcal{R}_{\boldsymbol{s}\boldsymbol{a}}\right], \\
\text{s. t.} \quad \epsilon &\geq D_{\mathrm{KL}}\left(\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})||\, q(\boldsymbol{s},\boldsymbol{a})\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})\right), \\
\tilde{\kappa} &\geq -\sum_{o\in\mathcal{O}} \iint \mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})\log\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a}, \\
\int \boldsymbol{\phi}(\boldsymbol{s}')\mu^\pi(\boldsymbol{s}')\,\mathrm{d}\boldsymbol{s}' &= \sum_{o\in\mathcal{O}} \iiint \gamma\mathcal{P}^{\boldsymbol{a}}_{\boldsymbol{s}\boldsymbol{s}'}\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})\boldsymbol{\phi}(\boldsymbol{s}') + (1-\gamma)\mu^0(\boldsymbol{s})\boldsymbol{\phi}(\boldsymbol{s}')\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{s}'\,\mathrm{d}\boldsymbol{a}, \\
1 &= \sum_{o\in\mathcal{O}} \iint \mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a},
\end{aligned} \tag{24}$$

with the resulting policy update

$$\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s}) \propto q(\boldsymbol{s},\boldsymbol{a})\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})^{1+\xi/\eta}\exp\left(\frac{\mathcal{R}_{\boldsymbol{s}\boldsymbol{a}} + \mathbb{E}[V(\boldsymbol{s}')|\boldsymbol{s},\boldsymbol{a}] - V(\boldsymbol{s})}{\eta}\right), \tag{25}$$

where

$$\mathbb{E}[V(\boldsymbol{s}')|\boldsymbol{s},\boldsymbol{a}] = \boldsymbol{\theta}^T\left[\int \gamma\mathcal{P}^{\boldsymbol{a}}_{\boldsymbol{s}\boldsymbol{s}'}\boldsymbol{\phi}(\boldsymbol{s}')\,\mathrm{d}\boldsymbol{s}' + \int(1-\gamma)\mu^0(\boldsymbol{s})\boldsymbol{\phi}(\boldsymbol{s}')\,\mathrm{d}\boldsymbol{s}'\right].$$

In contrast to the finite horizon case, the value function, the policy and the state distributions are now stationary instead of time dependent.

4. Algorithmic Design Choices

Having shown the theoretical foundation of HiREPS, we use this Section to explain implementation details concerning the policy representation and parametrizations as well as feature representations and model learning. The choices detailed in this Section represent only some of the possible implementations and are design choices. The HiREPS framework as specified in the previous Section is independent of these design choices and can be used with arbitrary representations for the gating, the sub-policies as well as arbitrary feature representations. HiREPS only requires that the policy representation can be updated using weighted samples.

Input: Information loss tolerance ϵ, Entropy tolerance $\tilde{\kappa}$, Number of sub-policies O, number of Iterations L, number of rollouts per iteration M, reset probability γ.
Initialize all $\pi(\boldsymbol{a}|\boldsymbol{s},o)$ and $\pi(o|\boldsymbol{s})$.

for $l = 1$ to L ... # iterations

Collect samples

for $i = 1,\ldots,M$ (# rollouts)

t = 1; reset = 0;
Sample initial state $\boldsymbol{s}_{i,t}$ from environment.
while reset $< \gamma$
Sample action $\boldsymbol{a}_{i,t} \sim q(\boldsymbol{a}|\boldsymbol{s}_{i,t}) = \sum_{o\in\mathcal{O}} \pi_{\text{old}}(o|\boldsymbol{s}_{i,t})\pi_{\text{old}}(\boldsymbol{a}|\boldsymbol{s}_{i,t},o)$.
Execute action $\boldsymbol{a}_{i,t}$ and observe reward $r_{i,t}(\boldsymbol{a}_{i,t},\boldsymbol{s}_{i,t})$.
Observe reward $r_{i,t}(\boldsymbol{a}_{i,t},\boldsymbol{s}_{i,t})$ and next state $\boldsymbol{s}_{i,t+1}$.
Sample reset value.

Compute Responsibilities:

$\tilde{p}(o|\boldsymbol{s}_{i,t},\boldsymbol{a}_{i,t}) = p_{\text{old}}(o|\boldsymbol{s}_{i,t},\boldsymbol{a}_{i,t}) = \frac{p_{\text{old}}(\boldsymbol{s}_{i,t},\boldsymbol{a}_{i,t},o)}{\sum_{o\in\mathcal{O}} p_{\text{old}}(\boldsymbol{s}_{i,t},\boldsymbol{a}_{i,t},o)}$ for all i,t.

Minimize the dual function

$[\boldsymbol{\theta}^*,\eta^*,\xi^*] = \arg\min_{[\boldsymbol{\theta},\eta,\xi]} g\left(\boldsymbol{\theta},\eta,\xi\right)$.

Policy update:

Compute model distribution

$p(\boldsymbol{s}_{i,t},\boldsymbol{a}_{i,t},o) \propto \tilde{p}(o|\boldsymbol{s}_{i,t},\boldsymbol{a}_{i,t})^{1+\xi^*/\eta^*}\exp\left(\frac{R_{i,t}+\mathbb{E}[V(\boldsymbol{s}')]-V^*(\boldsymbol{s}_{i,t})}{\eta^*}\right)$.

Estimate policies

$\pi(o|\boldsymbol{s})$ and $\pi(\boldsymbol{a}|\boldsymbol{s},o)$ for all $o = 1\ldots O$ by weighted ML estimates.

Output: Policies $\pi(\boldsymbol{a},o|\boldsymbol{s})$

Table 3: Infinite Horizon HiREPS. The algorithm follows the form of the episodic implementation, however one iteration produces state, action, reward triples for each time step in each rollout of an iteration. In the infinite horizon case, a model $\mathcal{P}^{\boldsymbol{a}}_{\boldsymbol{s}\boldsymbol{s}'}$ is required to compute $\mathbb{E}[V(\boldsymbol{s}')]$.

4.1 Policy Representation

We implemented the hierarchical policy using a soft-max gating network $\pi(o|\boldsymbol{s})$ and linear Gaussian sub-policies $\pi(\boldsymbol{a}|\boldsymbol{s},o)$. The gating network $\pi(o|\boldsymbol{s})$ chooses which option to activate according to the model

$$\pi(o=k|\boldsymbol{s}) = \frac{\exp\left(\boldsymbol{\phi}_G(\boldsymbol{s})^T\boldsymbol{\beta}_{G,k}\right)}{\sum_i^O \exp\left(\boldsymbol{\phi}_G(\boldsymbol{s})^T\boldsymbol{\beta}_{G,i}\right)},$$

where $\boldsymbol{\beta}_{G,1\ldots O}$ are the parameter vectors defining the influence of the sub-policies and $\boldsymbol{\phi}_G$ are the feature representations of the state used for the gating network. While this model itself is relatively simple, the complexity and expressiveness of the resulting policy depends largely on the feature transformations employed for the individual components of the hierarchical policy. In HiREPS, we are free to choose different feature transformations for the sub-policies, the gating and the value

function, where the value function features are the features in the primal optimization problem. In the presented experiments, the sub-policies themselves are represented by linear Gaussian policies, i.e.,

$$\pi(\boldsymbol{a}|\boldsymbol{s}, o; \boldsymbol{\beta}_o) = \mathcal{N}\left(\boldsymbol{a}|\boldsymbol{\mu}_o + \boldsymbol{F}_o\boldsymbol{s}, \boldsymbol{\Sigma}_o\right),$$

where $\boldsymbol{\beta}_o = [\boldsymbol{\mu}_o, \boldsymbol{F}_o, \boldsymbol{\Sigma}_o]$ is the parameter tuple describing sub-policy o. The sub-policies could also be defined on a feature transformation of the state. Equally well, non-linear sub-policies instead of the linear Gaussians could be used. However, since HiREPS performs a piecewise linear approximation in the state space using multiple sub-policies, linear sub-policies are usually sufficient. Both, the gating policy as well as the sub-policies can easily be updated using the sample weights computed by HiREPS. The update equations, as shown in the appendix, yield a weight matrix with one row per sample and cone column per sub-policy. The gating requires the full weight matrix as well as the responsibilities to be updated whereas each sub-policy is updated independently using the respective column of the weight matrix to weigh all state-action samples.

Generally, HiREPS can be initialized with many more sub-policies than solutions are expected to be available for the problem at hand. The gating network $\pi(o|\boldsymbol{s})$ will reduce the probability of selecting options that are not concentrated on good solutions to zero and effectively ignore these unnecessary sub-policies. Options can also be pruned throughout the learning process as in the first series of experiments described in Section 5.1.2. There, we report the number of actual solutions found. In this case, whenever the prior $p(o) = \int \pi(o|\boldsymbol{s})\mu(\boldsymbol{s})d\boldsymbol{s}$ of sub-policy activation gets too small (i.e., $p(o) < 10^{-4}$) we delete the sub-policy. However, in order to avoid sub-policies getting deleted too quickly, we assure that each sub-policy gets a minimum amount of samples in the sampling process. We also bound the minimum variance of our Gaussian sub-policies to small values in order to avoid singularities. After the sampling process, we evaluate the quality of the exploration-free policy (i.e., without variance) found so far.

4.2 Feature Based State Representation

We use feature transformations for representing the value function as well as achieving a higher flexibility in the gating policy. Different feature representations can be used for the gating and the value function. In the presented experiments, the gating network $\pi(o|\boldsymbol{s})$ is constructed on squared expansion of the state space. Thus, the squared features are constructed as the vector of all linear and squared combinations of the state dimensions. For example, for a two-dimensional state space the feature vector would be given by

$$\boldsymbol{\phi}([s_1, s_2]) = [1, s_1, s_2, s_1^2, s_2^2, s_1 s_2].$$

While the squared expansion of the state space can also be used as feature representation for the value function, more complex tasks often benefit from a more flexible representation, such as a kernel based feature transformation. In our experiments we used either kernel based features or features based on a Fourier transformation as shown by (Konidaris et al., 2011). The kernel based features used a squared exponential kernel, i.e.,

$$[\boldsymbol{\phi}_V]_i(\mathbf{s}) = \exp\left(-\frac{1}{2}(\mathbf{s} - \mathbf{s}_i)^T \boldsymbol{\Lambda}^{-1}(\mathbf{s} - \mathbf{s}_i)\right),$$

where $\boldsymbol{\Lambda}$ is a diagonal matrix denoting the bandwidth of the kernel and the index i iterates over the reference set of observed states.

Choosing sufficiently expressive features for the representation of the value function is crucial to the success of the learning algorithm. As an example, we can consider a contextual bandit task, where the robot has to select the number of steps to take to walk to a goal position. The context in this task is given by the robot's initial distance to the goal. If the robot has access to insufficient features, e.g., only a constant feature, it cannot differentiate between the different starting positions, and, hence, cannot learn to adapt its policy to the initial position. This effect is compounded in the infinite horizon setting, were successful policies often depend on reaching intermediate states with potentially low rewards on the path to the goal states.

4.3 Model Learning

For the finite horizon, as well as the for the infinite horizon formulation, HiREPS requires a transition model $\mathcal{P}^{\boldsymbol{a}}_{\boldsymbol{s}\boldsymbol{s}'}$. In this paper, we use a sample based transition model, which reproduces previously observed state transitions and does not necessarily generalize. Using a sample based transition model effectively results in computing $V(\boldsymbol{s}')$ directly based on one single observed state transition instead of computing the expectation $\mathbb{E}[V(\boldsymbol{s}')|\boldsymbol{s}, \boldsymbol{a}]$ in the update, Equation (25), as well as in the corresponding dual function in Eq. (51) as given in Appendix A.3. Replacing the expectation in such a manner is only feasible if the controlled system has limited stochasticity. However, it is indeed still sufficiently robust to solve the real robot tasks as presented in the experimental Section. For systems with more stochasticity, van Hoof et al. (2015) show how to learn a better model that is able to generalize if sufficient data is available.

4.4 Sample Efficiency

One of the important trade-offs when using iterative policy update methods is the number of rollouts performed per iteration. More rollouts per iteration result in more stable policy updates but also increase the number of overall rollouts required to learn a task. When using sample based policy update techniques in high dimensional action spaces, the number of samples is crucial. Using fewer samples than action dimensions will lead to an underestimate of the variance or the variance might even collapse, as the new policy is just based on the available samples. In HiREPS, we are not restricted to using only samples from the previous iteration of rollouts when computing the sample weights. By considering samples from M multiple past iterations, we can stabilize the policy update while retaining a fast learning speed. As a general rule of thumb, keeping three times as many samples as used per rollout can stabilize the algorithm against aggressive choices in the number of rollouts per iteration (lower than number of parameters) or high ϵ (≥ 1.5). When keeping samples from previous iterations, we usually define our current state-action distribution $q(\boldsymbol{s}, \boldsymbol{a})$ to be given by the collection of these samples. Alternatively, importance weighting schemes can be employed to incorporate samples from previous iterations. However, in our experience, these importance weighting schemes are often prone to destabilizing the learning algorithm.

4.5 Parametrized Trajectories

For the results of this paper, we often rely on movement primitives that inherently encode temporal correlations, such that each sub-policy $\pi(\boldsymbol{a}|\boldsymbol{s}, o)$ describes the parametrization of one movement primitives. We are using the extended version of DMPs by Kober et al. (2010a), that parametrizes trajectories using a combination of weighted basis functions as well as the end point

g and final velocity $\dot{g}$ of the trajectory. DMPs are based on a simulated spring damper system $\ddot{x} = \alpha\left(\dot{g} - \dot{x}\right) + \beta\left(g - x\right)$ with damping factor α and spring stiffness β. The spring damper system will result in a trajectory that reaches the desired goal and goal velocity in a direct manner. However, the spring damper system alone is insufficient to encode arbitrary shapes along the trajectory. To represent arbitrary shapes, DMPs modulate the dynamical system with a forcing function $f(z, \boldsymbol{v}) = \boldsymbol{\Phi}(z)^T \boldsymbol{v}$ that depends on the phase z of the movement, the basis functions $\boldsymbol{\Phi}(z)$ and the basis functions weights $\boldsymbol{v}$. Using the forcing function to deviate from the direct path of the spring damper system allows DMPs to generate complicated trajectory shapes. To ensure that the desired final goal position and velocity constraints are met, the forcing function depends on the exponentially decaying phase variable z, such that the forcing function does not influence the system towards the end of the trajectory.

If a demonstration trajectory, for example from kinesthetic teach-in, exists, basis function weights $\boldsymbol{v}$ that reproduce the shape of that motion as well as the goal position and velocity can be computed to initialize the learning process. After initialization, the basis function weights as well as the desired goal position and velocity are the parameters that the reinforcement learner optimizes over. In the presented robot learning experiments we learn one DMP per degree of freedom. It is important to note that the output of the DMPs only represents the desired trajectories, which are then usually tracked by an internal controller of the robot itself. This distinction is important because even if the robot is unable to track trajectories, e.g., due to gain or torque limitations, the RL agent can adapt the DMP such that the resulting trajectory still solves the task. When using DMPs, each sub-policy lasts until the DMP has finished execution.

4.6 Computational Complexity

The presented algorithm depends on the three key computations: solving the dual function for HiREPS, fitting a gating policy and fitting the individual sub-policies. The optimization of the dual problem can be performed using existing optimizers such as, for example, the Broyden-Fletcher-Goldfarb-Shannon algorithm. The optimization can often be accelerated by providing the first and second derivative of the dual function. While the actual complexity depends on which algorithm is used, we can analyze the problem itself. The number of open parameters in this optimization problem stays constant with the number of options. However, the number of open parameters depends directly on the dimensionality of the features $\boldsymbol{\phi}_V(\boldsymbol{s})$ for the value function. Thus, the complexity of the optimization problem depends on the feature representation rather than on the number of options.

Fitting a gating policy based on the weights computed through the HiREPS optimization problem yields a multiclass classification problem. For example, multiclass logistic regression can be used. As before, a solution can be found through the use of third party optimization software. However, the number of open parameters scales multiplicative with the dimensionality of the gating feature representation and the number of options. Thus, for high dimensional gating features and a large number of options, the gating optimization problem can become computationally expensive.

Finally, the sub-policies have to be fitted. Given the gating, the sub-policies are independent and each sub-policy can be fitted individually using a weighted maximum-likelihood estimate. In the case of linear Gaussians, the complexity of this operation is governed by a linear regression operation which depends on the dimensionality of the sub-policy feature representation. However,

since these optimizations are performed individually per option, the computational effort for this last step is usually negligible.

4.7 Hyperparameter Tuning

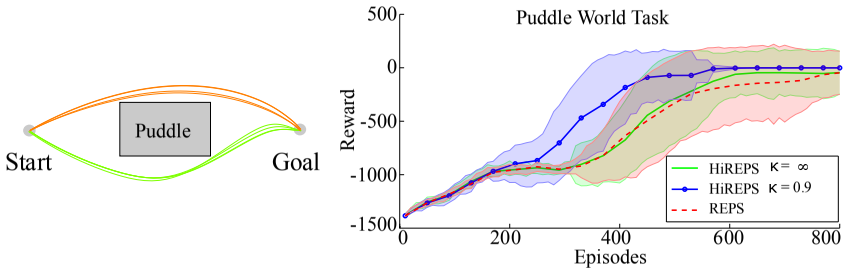
The presented method exposes three main hyperparameters to be set by the practitioner. These are the number of options O, the entropy bound κ as well as the relative entropy bound ϵ. The number of options can usually be chosen generously, i.e., around 20 seems to be reasonable for a wide range of problems. The algorithm will prioritize more promising options such that even if too many options are initialized, only options which yield high rewards will be sampled from after the first few iterations. The entropy bound κ is probably the most important parameter to consider since it does not have a clear equivalent in existing approaches. However, our experiments showed that a value of 0.9 seems to work well in almost all cases and no major tuning was necessary. The parameter ϵ is probably the parameter that is the most tuning-intensive in the proposed method, especially if the total number of episodes is crucial, e.g., in real robot experiments. In our experience values for ϵ between 0.5 and 1.5 are reasonable and, most often, we would start a new task with $\epsilon = 1$. Changing these parameters certainly influences the learning speed of the proposed method. However, while sub-optimal settings may lead to slower convergence, they usually do not prevent successful learning. Thus, in our experience, the algorithm is generally robust in that even sub-optimal settings will lead to convergence.

5. Experimental Validation

We validated the different presented formulations of HiREPS on both simulated and real robot tasks. We compare our algorithm to the non-hierarchical counterpart, REPS (Peters et al., 2010). Evaluating against REPS is interesting, as the two algorithms share the same basis. In effect, REPS is equivalent to our algorithm with just one sub-policy. This similarity allows us to directly investigate the influence of adding a hierarchical policy representation without additional confounders. The experimental section is structured analogously to the structure of Section 3, i.e., we first report results on the contextual episodic settings, subsequently the skill sequencing problem and finally the infinite horizon setting. For the contextual setting as well as for the skill sequencing, we report real robot results. In both cases, we start by presenting results on related simulated experiments to better investigate the properties of the presented algorithms as well as to compare to the REPS algorithm. For all presented results, we have optimized the parameters of the algorithms to deliver the best performance and both algorithms receive the same number of samples per iteration. For all experiments, if not noted otherwise, the experiments were repeated ten times to produce the errorbars reported in the results.

5.1 Episodic Skill Based Tasks

We start by presenting results for the episodic formulation of HiREPS. In the contextual setting, as well as for the skill sequencing setting in the next part, we start by presenting results of simpler experiments that allow a more in-depth analysis of the algorithms and then proceed to more complex tasks.



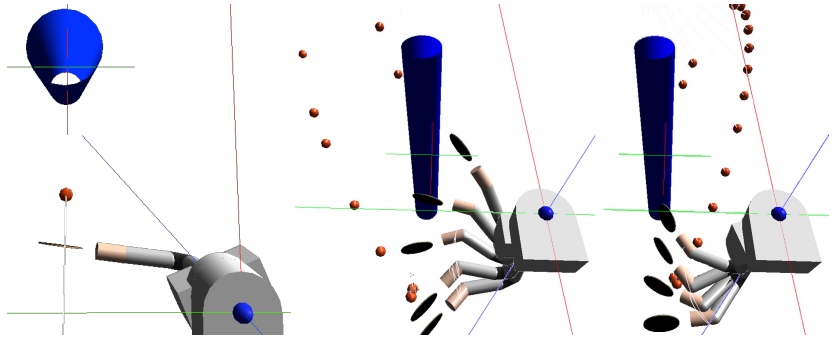
(a) Puddle World (b) Evaluation

Figure 3: (a) The puddle world task. Sub-policies are represented as two-dimensional DMPs with fixed end points. The DMPs have five basis functions per dimension and we learn the weights of the basis functions for the y dimension while leaving the weights for the x dimension fixed. The plot shows trajectories sampled from two sub-policies found after 80 iterations (using 10 samples per iteration) of HiREPS. Start and end points of the trajectory are pre-defined, the agent may choose the path in between those points. The puddle world has two solutions. The plot shows samples from both modes acquired by HiREPS after 30 iterations. (b) Performance of HiREPS and REPS on the puddle world task. As HiREPS can represent both solutions, it does not get stuck averaging over both modes. Note, that this effect is much more pronounced if we bound the entropy of the sub-policies.

5.1.1 PUDDLE WORLD EXPERIMENT

In a first toy task, we test HiREPS on a variation of the puddle world (Sutton, 1996). While this task is of limited difficulty it is interesting as it is a well known setting which exhibits the averaging problem of interest to us. Additionally, the simplicity of the problem allows us to thoroughly assess the quality of the solutions found by the RL agent, which is often difficult in real robot tasks. Our version differs from the standard version by having a continuous action space instead of a discrete one. While the agent proceeds with a constant velocity along the x-dimension of the environment, it has to learn the DMPs shape parameters such that the puddle is avoided. Thus, the actions $\mathbf{a}$ of our sub-policies are five-dimensional vectors. The reward of the task is given by the negative length of the line segments, which encourages shorter solutions. An additional punishment occurs for passing through the puddles. The arrangement of the puddles can be seen in Figure 3a. The presented puddle world has two solutions which are located close to each other. Still, the mean of both solutions leads through a puddle and, therefore, yields lower rewards.

In Figure 3b, we evaluate the performance of REPS and HiREPS with and without bounding the sub-policies' entropy. For HiREPS, just two sub-policies were used. REPS takes a longer time to reliably find good solutions, as the algorithm averages over both modes. HiREPS without bounded entropy performs slightly better than REPS. However, the advantage of HiREPS is much more pronounced when also bounding the expected entropy of the responsibilities. Furthermore, if we limit the entropy, the algorithm is able to reliably find both modes. The results also show that



(a) Top View (b) Left and right swings

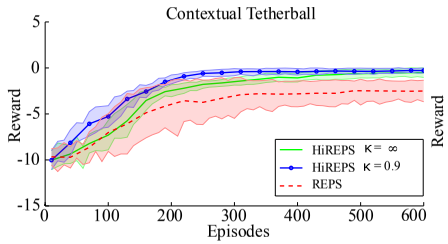
Figure 4: (a) Top view of the setup of robot tetherball. The ball is hung on a string from the ceiling in front of the pole. (b) Time series overlay of two swings in simulation, one left swing and one right swing. The two solutions use different sub-policies of the same hierarchical policy. HiREPS can also keep more sub-policies representing additional solutions to a task.

even after 80 iterations (using ten samples per iteration), the REPS learning curve still exhibits some variance, showing that the algorithm has not fully converged.

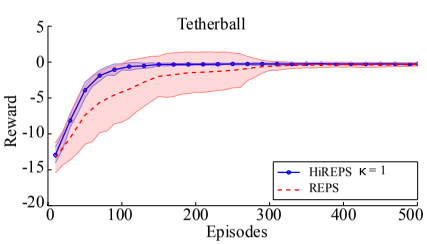
5.1.2 TETHERBALL

Our aim is to adapt the game 'Tetherball' for a robotic player, as shown in Figure 4b. Specifically, the task consists of a ball, a rope, an obstacle (i.e., a pole) and a target. The ball is hung in front of the pole, in a line with the robot, the pole and the target. This setup requires the robot to induce a circular trajectory to be able to wind the ball around the pole. In the planar simulation, the robot can induce this angular velocity through the elasticity of the rope. In the physically accurate simulation as well as on the real robot, a pre-strike is necessary to achieve similar results. This task presents a versatile solution space, as many different strategies successfully hit the target. Our goal is to model this versatile solution space with HiREPS. In order to thoroughly assess the proposed method, we split our investigation of the tetherball task into three parts of ascending difficulty. In a first evaluation, we implement a planar simulation of the task in which we abstract the robot into a force, i.e., we do not simulate a robotic arm but instead allow the agent to directly exert a force onto the ball. We use this simplified setup to compare HiREPS to its non-hierarchical counterpart as well as to investigate the effect of different settings. In a second evaluation, we use a detailed physical simulation of the task including the robot arm, in which we evaluate the benefits of a hierarchical policy in a more realistic setting. Finally, we present the results of the actual robotic task which show that HiREPS finds multiple solutions within one learning scenario.

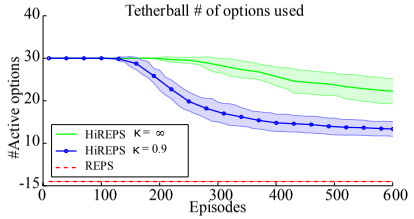
Planar Simulation. For the purpose of testing the HiREPS method, we use a strongly simplified setup where the tetherball task is implemented in a planar simulation. We initialize HiREPS with 30 randomly located sub-policies and use ten samples per iteration. The agent can accelerate the ball



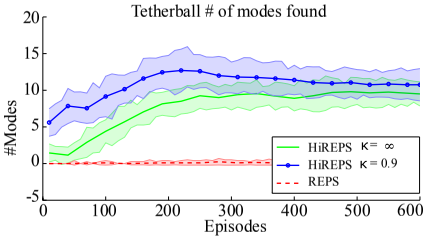
(a) Tetherball Average Reward



(b) Tetherball without States, Average Reward



(c) Tetherball Number of Sub-Policies Used



(d) Tetherball Number of Modes Found

Figure 5: (a) Average reward gathered by the REPS and the HiREPS with and without bounding the entropy of the sub-policies in the tetherball task including states. As REPS only uses a single sub-policy and thus a linear model as policy, it cannot represent the complicated structure of the solution. The HiREPS approach benefits from bounding the entropy of the sub-policies. (b) Average reward in the tetherball task without states. While REPS also finds one of the optimal solutions, HiREPS benefits from its structured policy representation and outperforms REPS in learning speed. At the same time, HiREPS finds both solutions. (c) Number of sub-policies used by the HiREPS approach with and without bounding the entropy. If the prior $p(o)$ of a sub-policy becomes too small it gets deleted. By bounding the overlap of the sub-policies, less sub-policies are used while the performance of the algorithm is increased. (d) Number of modes found by HiREPS with and without bounding the overlap of the sub-policies. We can see that, despite that HiREPS with bounding the overlap uses less sub-policies, it can find more modes. Without bounding the overlap of the sub-policies, many sub-policies concentrate on the same mode, which attenuates the advantages of the structured policy representation.

with a two dimensional impulse $\{F_x, F_y\}$. The reward is given by the negative minimum squared distance of the ball to the target throughout the ball's trajectory. The initial state of the agent is given by the initial position of the ball before hitting it. We only vary the x-position of the ball and learn different solutions to hit the target. As before, we compare HiREPS with and without bounding the overlap of the sub-policies to the standard REPS approach. In Figure 5a, we evaluate the average reward of all three approaches. The results show that HiREPS with the bound on the overlap outperforms the two other methods. The HiREPS approach already without the additional bound is better than the REPS approach, as REPS only uses one sub-policy to cover the whole

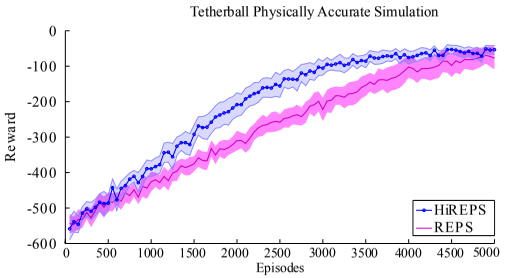


Figure 6: Results of the physically accurate tetherball simulation. Both REPS and HiREPS reach the same asymptotic reward. However, since HiREPS can differentiate between the multiple local optima and assign different options to these optima, it exhibits faster learning speed.

state space. Thus, REPS needs to approximate the optimal policy using a single linear model. Therefore, in order to have a fair comparison to REPS, we also compare HiREPS and REPS on the tetherball task without states, i.e., we always start from the same initial state in the middle. This comparison can be found in Figure 5b. We can observe that REPS is impaired by the multi-modality of the solution space as it tries to average over several modes, but finally learns a solution that is equally good as the solutions found by HiREPS. However, while REPS only learns one solutions, Figure 5d shows that HiREPS learns multiple solutions at the same time. In order to compute the number of modes, we divide each dimension of the state action space into 5 partitions and count the number of partitions which contain at least one sub-policy with an average reward larger than -1. The plot shows that, as the sub-policies distribute more uniformly in the state-action space due to the bounding, we can find more modes. Thus, the bound of the overlap also helps us to find more versatile solutions as it avoids situations where multiple sub-policies concentrate on the same solution. In Figure 5c, we show the number of sub-policies used for different bounds of the overlap $\tilde{\kappa}$. By bounding the overlap, the gating network can learn to select individual sub-policies more decisively, explaining the faster learning speed in the experiments when using the bound.

Physically Accurate Simulation. Having compared the properties of (Hi)REPS on the simpler simulation, we proceed to presenting the results of the physically accurate simulation as shown in Figure 4a, which also serves as a stepping stone to the real robot results. As described, the pole is placed on a line between the ball's resting position and the target location, such that it is impossible to hit the target with a single strike of the ball in direction of the target. In order to evoke a circular trajectory that arcs the ball around the ball, displacing the ball from its resting pose is necessary. Thus, we decompose our movement into a swing-in motion and a hitting motion. However, the parameters for both motions are combined into one parameter vector that is learned jointly. A more powerful approach would be to respect the natural separation of the successful trajectories and use the skill sequencing approach as presented in Section 3.2. The reward is determined by the speed of the ball when the ball winds around the pole. We define winding around the pole as the ball passing the pole on the opposite side of the pole. We run the algorithms with 50 samples per iteration and always keep the last 400 samples. We initialize our algorithm with 30 sub-policies and stop deleting sub-policies if only 5 sub-policies are left. The resulting learning curve in the simulation can is shown in Figure 6. After 100 iterations the robot has learned to wind the ball around the pole in 5/5 trials. In all trials, we were able to observe sub-policies for the left and for the right mode. The resulting movements are shown in Figure 4b and illustrate that the resulting movement of the two solutions are easily differentiated. The results show, that albeit HiREPS uses the same amount of

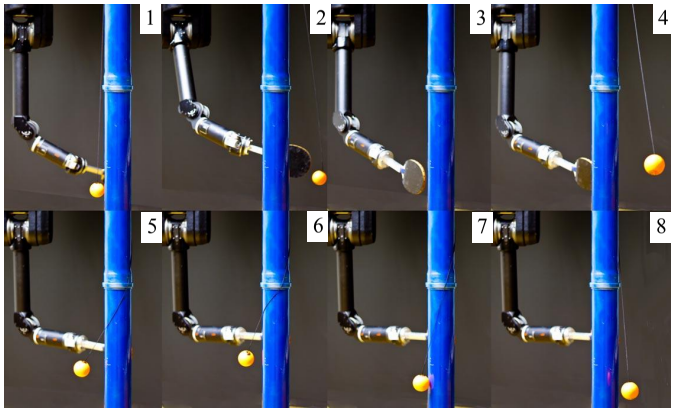

Figure 7: Time series of a successful swing of the robot. The robot first has to swing the ball to the pole and can, once the ball has swung backwards, arc the ball around the pole.

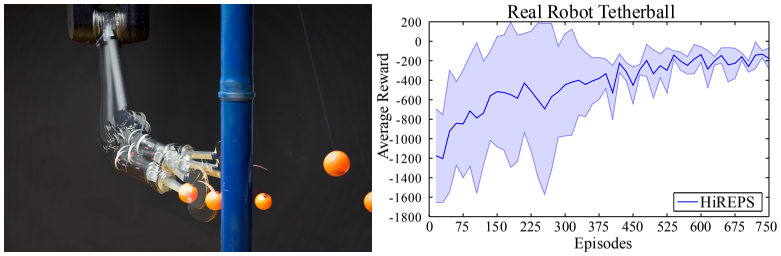
total samples per iteration as REPS, it can use those samples to learn multiple solutions while being faster than REPS can learn a single solution.

Real Robot Tetherball. After presenting the results on the two simulated tetherball settings, we proceed to show the results of the real robot experiment. For the robot experiment, we mounted a table-tennis paddle to the end-effector of the robot arm. The real-robot setup is depicted in Figure 8a and two successful hitting movements of the real robot are shown in Figure 7. In order to track the ball, a Kinect RGBD camera was setup to look at the robot from the opposite side of the pole. The vision data was used to compute the reward signal. As in the physically accurate simulation, the robot needed to perform a pre-swing as well as the actual swing. However, the real robot can easily be bootstrapped through imitation learning. Thus, we extract the shape parameters $\boldsymbol{v}$ by kinesthetic teach-in (Ijspeert and Schaal, 2003) for both motions. Subsequently, the robot learns the final positions and velocities of all seven joints through the presented approach. Additionally, we learn the waiting time between both movements. This task setup results in a $2 \times 2 \times 7 + 1 = 29$-dimensional action space. We initialized the algorithm with 15 sub-policies and sampled 15 trajectories per iteration. While this scheme amounts to considerably fewer samples than in simulation, it is sufficient to learn multiple solutions, given the initial demonstrations. We performed three trials to produce the errorbars reported in the results. The learning curve is shown in Figure 8b. The noisy reward signal is mostly due to the vision system and partly also due to real world effects such as friction which lead to a non-repeatability of rollouts. Two resulting movements of the robot are shown in Figures 7 and 4b.

5.2 Planar Reaching Task

To further evaluate the properties of the proposed algorithm, we present a series of experiments on a planar reaching task. In this simulated task, the agent controls the joint trajectories of a three-link



(a) Tetherball (b) Real robot results

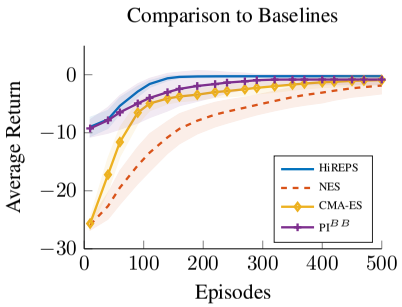
Figure 8: (a) The real robot tetherball setup. (b) Average rewards of HiREPS on the real robot Tetherball setup. Mean and standard deviation of three trials are shown. In all three trials, the robot has found solutions to wind the ball around the pole on either side after 50 iterations.

robotic arm using DMPs with two basis functions per joint. The robot starts from a fixed initial position and executes a trajectory for 100 time steps. At time steps 40 and 100 the robot is rewarded for passing through via points. While the robot is controlled in joint space, these via points are given in task space. Furthermore, for both time steps two possible via points exist.

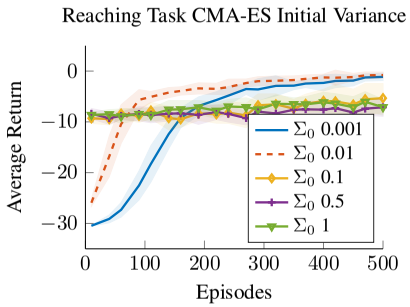
Comparison to Baseline Methods. Most of the presented experiments compare the performance of HiREPS to its natural competitor, REPS. To better analyze the performance levels of HiREPS, we also performed an experiment comparing HiREPS to other state of the art methods. Specifically, we compared to the PI^{BB} algorithm (Stulp and Sigaud, 2013), the CMA-ES algorithm (Hansen et al., 2003) as well as the NES algorithm (Wierstra et al., 2014). To compare HiREPS against these baselines we performed an empirical optimization of the open parameters these methods perform. For example, Fig. 9b shows the effects of the initial variance of CMA-ES. The results in Fig. 9a show that HiREPS converges faster than the alternative algorithms we compared to. Furthermore, the alternative algorithms are designed to represent a single solution. In this experiment, all algorithms used 10 samples per iteration. Both HiREPS and PI^{BB} used a higher initial variance than CMA-ES and NES in this experiment since the latter methods' performance decreases using higher initial variances as shown in Fig. 9b. Due to this higher initial variance, PI^{BB} and HiREPS start with a higher initial reward.

Initialization of the Algorithm. Since the presented algorithm is based on the availability of multiple sub-policies, these options have to be initialized to sensible values. In the presented experiments linear Gaussians were usually used as sub-policies, i.e., $\pi(\boldsymbol{a}|\boldsymbol{s}, o) = \mathcal{N}(\boldsymbol{a}|\boldsymbol{\mu}_o + \boldsymbol{F}_o\boldsymbol{s}, \Sigma_o)$. To initialize each linear Gaussian, we can keep $\boldsymbol{F}_o = \boldsymbol{0}$ and $\Sigma_o = c\boldsymbol{I}$, where the constant c is a task specific variable set by the experimenter. While F_o and Σ_o are initially identical for all sub-policies, the means $\boldsymbol{\mu}_o$ have to be different to allow for later separation of the sub-policies based on the responsibilities. To that effect, we usually sampled the individual sub-policy means $\boldsymbol{\mu}_o$ from a normal distribution, i.e., $\boldsymbol{\mu}_o \sim \mathcal{N}(\cdot|\boldsymbol{0}, \Sigma_\mu)$.

Figure 10a shows the results of varying Σ_μ relative to the admissible range of parameters. The results show that while a larger initial separation seems to help bootstrapping the learning process,



(a) Comparison To Baselines



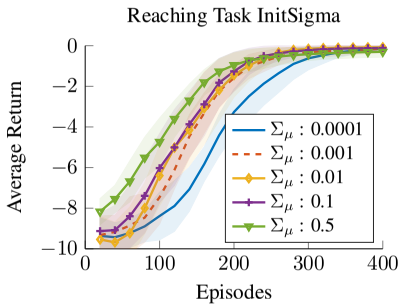
(b) Influence of Initial Variance in CMA-ES

Figure 9: (a) Comparison of HiREPS to popular baselines. HiREPS and PI^{BB} start at higher initial rewards because CMA-ES as well as NES have to be initiated with a much lower variance. While HiREPS and Pi^{BB} start with a high-variance initial policy (or sub-policies) and keep contracting it until convergence. CMA-ES and NES on the other hand work best with a smaller initial variance that is kept for longer. (b) Effects of different initial variances on CMA-ES. We chose the best initial variance for the comparative experiments.

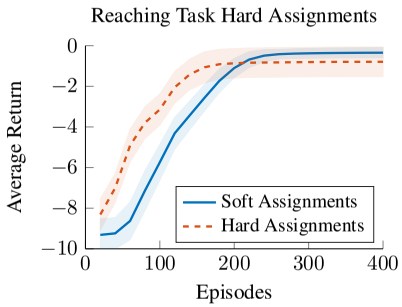
the overall effect of changing this parameter is negligible. In this experiment, a total of 20 options were available to the algorithm. While the comparison to the base-line methods was performed using ten samples per iteration, for the following experiments 20 samples per iteration were used. Using more samples per iteration allowed us to observe the effects under investigation more clearly, while the comparison to other baselines was optimized for the CMA-ES and NES algorithms.

The Influence of Probabilistic Option Assignments. The presented algorithm allows for inter-option learning, i.e., the sharing of information between options during learning which is expected to improve learning. To test this hypothesis, we performed an experiment comparing the proposed formulation of the algorithm to an alternative formulation based on hard assignments. In the alternative formulation, every option was effectively limited to using it's own samples to update its policy. This behavior was achieved by assigning a responsibility of 1 to the option that generated a sample while all other options had zero responsibility for the same sample. Using soft assignments allows the gating to shift responsibilities such that options can specialize on distinct sub-tasks. The results in Figure 10b show that using soft assignments did indeed improve asymptotic learning performance but was slower in the early stages. However, in our experiments we observed that the importance of this effect would diminish with an increasing number of options. As the number of options increases, HiREPS can implement a more effective divide and conquer strategy. Sharing of information can becomes less important after the division of the state-action space has been successfully performed.

Evaluation of the Entropy Bound. One of the main parameters to be considered in the proposed algorithm is the desired bound on the entropy of the responsibilities, $\tilde{\kappa}$. The lower the value for $\tilde{\kappa}$, the more aggressively the algorithm will separate the individual options. Figure 11a shows the



(a) Effect of Different Initializations



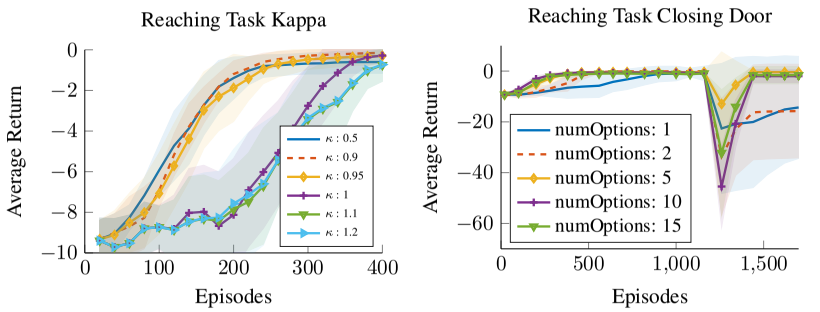
(b) Effect of Probabilistic Responsibilities

Figure 10: (a) Investigation of different initial distributions of sub-policies. Using a low initial variance of the distribution over option means, all options share similar responsibilities for all samples and the entropy bound forces a separation of the options. Using a higher initial variance for this distribution, the individual sub-policies will be responsible for different regions of the action space from the beginning. While the results show that such an initial separation can improve learning speed initially, it can also lead to sub-optimal asymptotic performance. (b) Using hard assignments, i.e., not sharing information between options, leads to high initial learning speed. However, using the hard assignments, the algorithm did not always find the optimal solution. In our experiments, the non-probabilistic (hard assignments) version of the algorithm would usually require more samples per iteration to consistently find equally good solutions as the proposed probabilistic approach. However, our experience shows that when using more samples per iteration, the learning speed of the hard assignment approach will actually decrease relative to the speed of the probabilistic approach. This effect can be explained by the fact that each option is drawn to all local optima more uniformly if more samples are used.

results of evaluating a wide range of possible parameter values for $\tilde{\kappa}$ in the reaching task. The results show that values for $\tilde{\kappa} \geq 1$ yield slower convergence speeds while the options still overlap and aim to explain multiple solutions. As in most other experiments presented in this paper, a value of $\tilde{\kappa} = 0.9$ seems to yield the best learning speeds. While even lower values of $\tilde{\kappa}$ do not noticeably decrease the learning speed in the presented experiment, our experience shows that lower values may prevent successfully learning multiple solutions. Since lower values of $\tilde{\kappa}$ force options apart, only few options may actually be fully developed while the probability of sampling from most other options will diminish.

The results reported for this experiment and the puddle world experiment regarding the entropy bound mirror our experience with the remaining experiments reported in this paper. In all experiments a bound of $\kappa = 0.9$ seems to give good results and much higher (> 0.95) or much lower (< 0.8) values usually deteriorate performance. Thus, for the remaining experiments, we chose $\kappa = 0.9$ and do not present further evaluations.

Robustness to Changing Environments. One main contribution of the proposed algorithm is to learn multiple solutions for the same task. Learning multiple solutions can be interesting if, for



(a) Influence of Entropy Bound

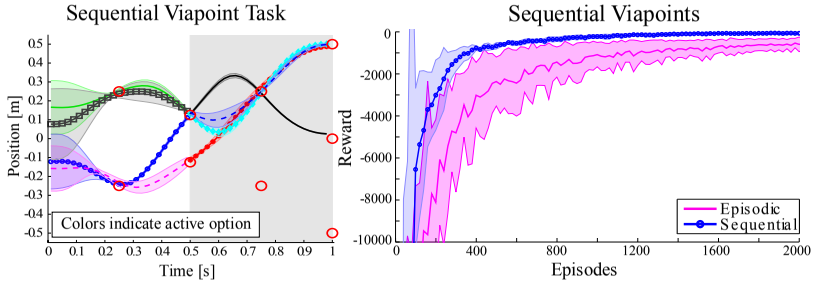
(b) Changing Environments

Figure 11: (a) Comparison of different relative values κ for the entropy bound. The results show that higher values for the entropy bound slow down learning, as the options are not forced to separate. Thus, multiple options will compete for the same local optimum for longer. Very low values for κ will also slow down learning and can potentially lead to sub-optimal asymptotic performance when the entropy bound 'overpowers' the reward maximization criterion. (b) Investigation of a task which requires multi-modal solutions. After learning a solution, some of the via points were randomly disabled and the agent had to rely on the availability of alternative solutions. The results show that increasing the number of options allowed for a robust policy which could recover from the change in the environment because the agent had previously learned multiple solutions.

example, the environment changes in a way that makes some solutions inaccessible. To evaluate the behavior of the proposed algorithm in such a scenario, we let the algorithm learn a solution for the reaching task as described above. After 30 iterations HiREPS typically converged to a good solution. At that point, the via points on either the lower or upper path were randomly disabled, which simulated blocking one of the paths. Figure 11b show the effects of learning multiple solutions. With only one option, the agent cannot recover in about half the trials. Using more options increases the likelihood that the agent has learned sufficiently versatile solutions to successfully perform the task even after cutting off of the paths.

5.3 Sequencing of Skills

As evident from the tetherball experiment, many real world tasks require multiple steps to be solved. To evaluate the skill sequencing implementation of HiREPS presented in Section 3.2, we present a second set of experiments. Before testing skill sequencing on a real robot task, we evaluated the time-indexed HiREPS algorithm on a via-point task in order to illustrate the properties of the approach. In this task, we modeled a second-order dynamical system. The state of the agent is given by its position x and velocity $\dot{x}$. The actions u control the accelerations $\ddot{x}$. The task of the agent is to reach specified via-points at four different points in time. For each of these time points, different via-points exist. The reward at the time points is given by the negative squared distance to the closest via-point. In addition to the deviation to the via-points at the four specified time



(a) Task Setup. Colors indicate active option.

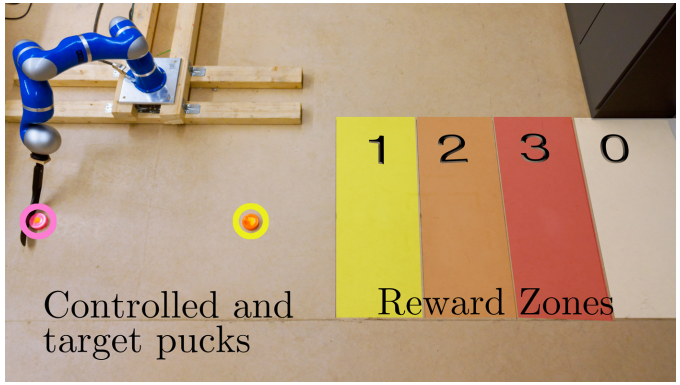
(b) Average Reward.

Figure 12: (a) We use this via-point task to illustrate our algorithm.The agent has to reach one of the via-points (denoted by red circles) at each of four specified times $[0.25, 0.5, 0.75, 1.0]$s. The reward is given by the negative squared distance to the closest via-point. The last via-point has to be reached with zero velocity. The initial positions and velocities are sampled from a Gaussian distribution with zero mean and a standard deviation of 0.25 for the position and 0.1 for the velocity. In this task, we learn to sequence two motor primitives, with the second primitive starting at $t = 0.5$s (shaded region in which the line colors change). This task is per construction multi-modal and illustrates how our algorithm learns distinct motor primitives. The mean and variance are indicated by shaded error bars. The agent learned several but not all possible solutions to solve the task. (b) The multi-modal via-point task learned with episodic and sequential motor primitive learning where the movement was decomposed into two primitives, see Figure 12a for a more detailed description. As we can see, our algorithm could exploit this decomposition resulting in increased learning speed and higher quality final policies.

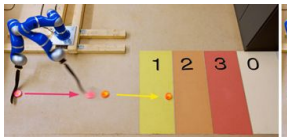
points, the reward function contains a squared punishment term for taking high accelerations. As we defined multiple via-points for each of the four time-points, this task has multiple solutions per construction. The agent used 20 samples per iteration for this task. The exact setting of the task including its via-points is depicted in Figure 12a.

In order to demonstrate sequencing of skills, we decomposed the task into two DMPs which were executed sequentially. We used five shape parameters for both DMPs. In addition, we also learn the goal-parameter of the DMP, resulting in 6 parameters per movement primitive. To compare our sequencing method to the commonly used episodic policy search setup, we also solve this task with the episodic version of HiREPS. In this case, we only used one DMP with ten shape parameters and the additional goal-parameter. For both scenarios, the agent could choose between four distinct sub-policies o_i at each decision time-point. As we can see from Figure 12a, the agent learned to select these primitives according to the state at the decision time-points as well as to adapt the primitives such the task can be solved. Our approach was able to learn multiple solutions for the task as can be seen from Figure 12a. However, only a subset of all possible solutions was found.

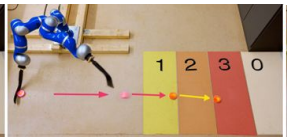
The comparison of the episodic and the sequential learning methods can be seen in Figure 12b and shows the advantage of the sequencing approach in learning speed as well as in the quality of the learned solution. Additionally, the episodic formulation will also require more options in total



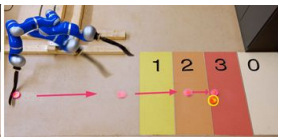
(a) Hockey Setup



(b) First strike



(c) Second strike



(d) Final strike

Figure 13: (a) The robot hockey task. The robot has two pucks, the pink control puck and the yellow target puck. The task is to shoot the yellow target puck into one of the colored reward zones. Since the best reward zone is too far away from the robot to be reached with only one shot, each episode consists of three strikes. After each strike the control puck is returned to the robot, but the target puck is only reset after one episode is concluded. Concluding an episode with the target puck in one of the reward zones yields rewards from one to three as indicated in the picture. However, if the robot shoots the target puck too far, the reward is zero. (b-d) One episode of the Hockey task, consisting of three strikes. Each picture shows the initial and final position of control and target puck. The movement of the pucks is indicated by arrows. The robot can shoot the pink control puck to move the target puck and tries to place the yellow target puck in one of the marked target zones while not overshooting. In the depicted episode the robot only needed two strikes to place the target puck into the highest reward zone. With the last strike the robot taps the target puck only slightly without actually moving it to avoid negative reward for missing it.

in order to find all possible solutions than the sequential formulation. However, in the presented experiment we only rewarded the agent for finding at least one solution such that this effect did not alter the resulting performance analysis.

5.3.1 EVALUATION ON THE ROBOT HOCKEY TASK

As before, after using a simpler task to investigate the properties of the proposed algorithm, we now present the results of a more sophisticated task. Similar to the structure of the tetherball experiments,

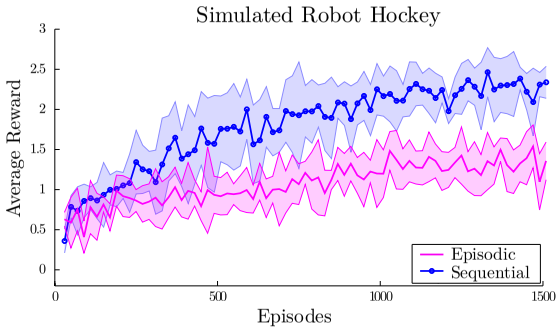


Figure 14: Comparison of sequential motor primitive learning to the episodic learning setup on the simulated robot hockey task. The sequential motor primitive learning framework was able to find a good strategy to place the puck in the third reward zone in most of the cases while the episodic learning scenario failed to learn such a strategy.

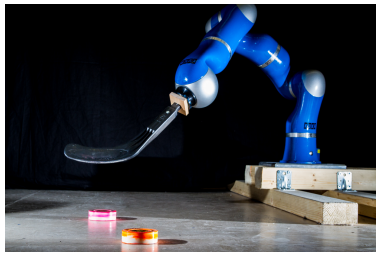
we first present a comparative analysis on a physically accurate simulation and then proceed to show the results of the real robot task. In the robot hockey task, the robot has to move a target puck into one of three target areas. This target puck can only be moved by shooting a control puck at it. The target areas are defined by a specified distance to the robot. The first zone is defined as distance from 1.4 to 1.8m, the second zone from 1.8 to 2.2m and the last zone from 2.2 to 2.6m. The robot gets rewards of 1, 2, and 3 for reaching zone 1, 2 or 3, respectively, with the target puck. If the robot overshoots the last target zone, the reward drops to zero. The reward is only given after each episode which consists of three shots of the control puck. After each shot, the control puck is returned to the robot. The target puck, however, is only reset after each episode. The setup of the robot hockey task is shown in Figure 13a.

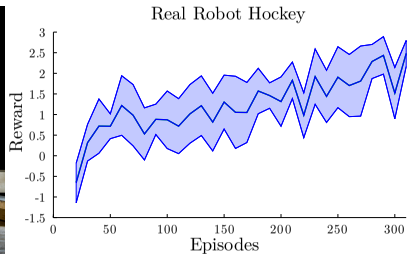
The 2-dimensional position of the target puck defines the state of the environment as perceived by the agent. After performing one shot, the agent observes the new position of the target puck to plan the subsequent shot. In order to give the agent an incentive to shoot at the target puck, we punished the agent with the negative minimum distance of the control puck to the target puck after each shot. While this reward was given after every step, the zone reward was only given at the end of the episode (every third step) as $r(\boldsymbol{s}_{K+1})$.

We used a DLR-Kuka lightweight arm with 7 degrees of freedom as depicted in Figure 15a. We used DMPs to represent single motor primitives where we only adapted the goal positions and velocities of the primitives. This setup resulted in 14 parameters per primitive per shot. Thus, the episodic version of HiREPS has to optimize one 42-dimensional parameter vector while the time indexed version of HiREPS that we use for skill sequencing has to optimize three policies with 14-dimensional parameter spaces each. Both, the episodic as well as the time-indexed version of HiREPS had access to five options. The shape parameters $\boldsymbol{v}$ of the single primitives were learned from imitation by collecting trajectory data via kinesthetic teach-in.

Simulation Results. We first implemented a realistic simulation of the robot hockey task. In simulation, we varied the initial position of the puck by sampling the position from a normal distribution with standard deviation of 10cm. The agent used 30 samples per iteration. We compared our sequential motor primitive learning method with its episodic variant. For the episodic variant, we encoded the policy-parameters of all three shots into one policy, resulting in 42 parameters. The episodic variant cannot use state-feedback except for the information of the initial position of the puck. To make the comparison as fair as possible we did not use any noise in our simulation



(a) Hockey Setup



(b) Real Robot Hockey Rewards

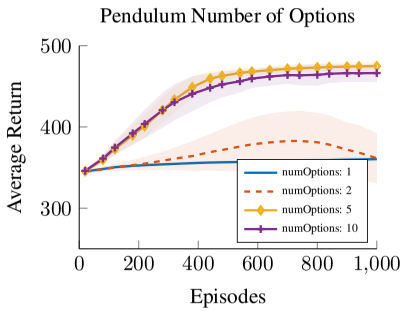
Figure 15: (a) The real robot Hockey setup. The robot first has to shoot the pink puck on the orange puck, to move the orange puck into a target zone. (b) One trial of of the real robot hockey tasks. The robot starts with a negative initial reward and learns to achieve an average reward of 2.5 after 300 episodes. The optimal theoretical reward of the presented task is 3.0. However, learning has not yet converged and had to be stopped prematurely due to time constraints.

and, hence, the initial position of the puck is sufficient to solve the task. The comparison of both methods can be seen in Figure 14. The episodic learning setup failed to learn a proper policy while our sequential motor primitive learning framework could steadily increase the average reward. Our method reached an average reward of 2.3 after learning for 1500 episodes. Note that an optimal strategy would have reached a reward value of 3, however, this is still a clear improvement in comparison to the episodic setup, which reached a final reward value of 1.4.

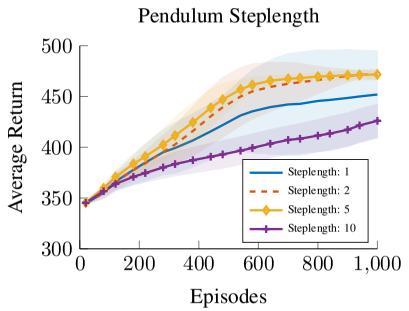
Real Robot Results We used a Kinect RGB-D camera to observe the state of target puck. For the real robot hockey task, the initial position was not varied. On the real robot, we could reproduce the simulation results. The robot learned a strategy which could move the target puck to the highest reward zone in most of the cases after 300 episodes, where the robot used ten samples per iteration. One episode of robot hockey is depicted in Figure 13. In the final trials, the robot tended to prefer using a soft hit in the first shot and to shoot the target puck to the last reward zone with the remaining two shots. This behavior yielded higher average reward, since it is easier to only tap the target puck without moving it too much while it is still closer to the robot. During learning the robot steadily adapted his strategy when it mastered the necessary motor skills to achieve higher rewards by placing the target puck in the highest reward zones.

5.4 Infinite Horizon Formulation for Sequencing Skills

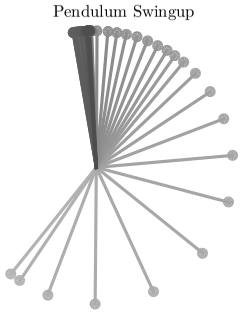
We evaluated the infinite horizon formulation of HiREPS on the pendulum swing-up task in simulation. In this task, the pendulum starts hanging down with a random perturbation. The goal of the robot is to find a solution that first swings up the pendulum and then stabilizes the pendulum at the top. Instead of directly choosing motor commands in each time step, the robot chooses a desired joint value which is tracked with a PD-controller that is active over multiple time steps d (in the standard setting $d = 5$). While using direct motor commands is generally feasible as well, using a PD-control scheme is often beneficial from a robotics point of view. Real systems are often



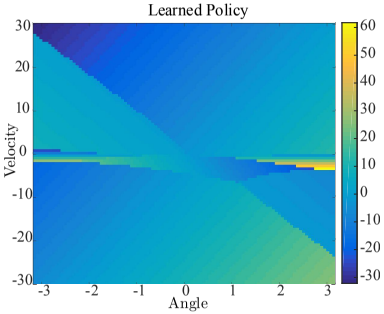
(a) Pendulum #Sub-Policies



(b) Pendulum #Steps per Decision



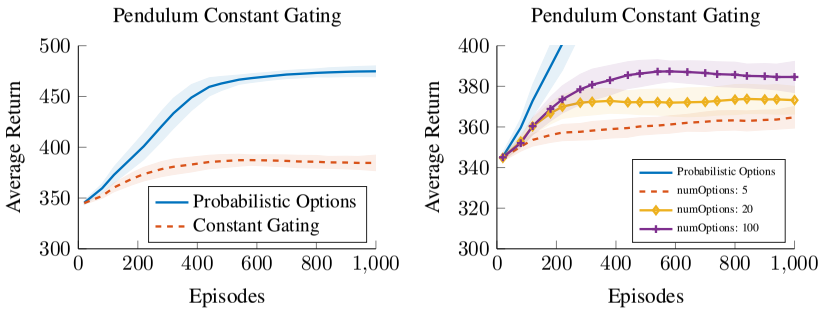
(c) Task Setup



(d) Policy

Figure 16: Evaluations of the pendulum swingup task. The task starts with the pendulum hanging down and the robot has to swing up and stabilize the pendulum. (a) The results show that one linear sub-policy is insufficient to learn this task. With five sub-policies the robot is able to learn the task, with ten sub-policies the asymptotic performance does not improve anymore. (b) The number of time steps d each sub-policy stays active. The results show that activating a sub-policy for multiple time steps increases the speed of learning. If a sub-policy stays active for more than five time steps, the performance decreases. (c) One rollout of the pendulum swingup task. The pendulum starts at the bottom and requires a pre-swing to be brought to the upright position. (d) Pendulum Swingup-Policy learned by HiREPS. Colors indicate the mean value of the policy.

controlled at very high frequencies internally, however, policy signals are usually only necessary at lower frequencies. Reducing the control frequency of the policy will increase the signal to noise ratio, especially in real systems. Furthermore, even in simulated systems, the temporal extension of the actions can benefit the learning process. Since this task is highly non-linear in nature, it cannot be solved with a single linear policy. However, since HiREPS is able to represent a piecewise linear policy, it can be used to solve the pendulum swing-up task with multiple linear sub-policies. In this



(a) Comparison to Constant Gating

(b) Number of Options in Constant Gating

Figure 17: (a) Evaluation of a pre-defined constant gating vs. a learned gating. In the constant gating approach, the gating was pre-determined by performing a K-Means clustering of the state space. The results show that the pre-defined constant gating does not allow the agent to successfully learn the task. (b) Effect of the number of options when using a constant gating. The results show that the constant gating depends strongly on the number of options used, which related directly to the resolution with which the state-action space is parceled. Even with 100 options the constant gating approach is outperformed by the learned approach which uses only five options.

task, the pendulum has a mass of 10kg, a length of 0.5m and a friction coefficient of 0.2. The robot can exert at most 30nm of torque and uses 20 samples per learning iteration. The internal robot control runs at 100Hz and the restart probability in the base setting is given as $(1-\gamma) = 0.02/d$, where d determines the control frequency of the learned policy. The primitive actions wich are chosen by the sub-policies are the desired joint angles of the pendulum. The robot can typically perform a swing-up within 1.5s. To represent the value function, we used the Fourier transform based feature transformation of the states using five Fourier bases, see Section 4. The gating uses a squared expansion of the states as feature representation. The reward function punishes deviation from the desired upright position with a factor of 500 and punishes velocities with a factor of 10. These punishments are subtracted from a base value of 500. The results of the experiments show that a single linear policy is insufficient for swinging up and stabilizing, however, HiREPS successfully combines multiple linear policies to solve the task, a resulting policy is shown in Fig 16.

Evaluation of a Constant Gating. In the pendulum swing-up task, a good gating policy is essential if the task is to be solved using simple sub-policies. To evaluate the effect of a learned gating versus a constant pre-determined gating, we compared the proposed approach to an alternative formulation where the individual action policies can be learned, but the gating stays constant. To find a such a constant gating, we divided the state space using K-Means clustering and kept the resulting gating constant afterwards. To perform K-Means clustering we sampled 1000 data points uniformly within $\pm[\pi, 50]$, where π in this case is the numerical value. The results show that the performance of such a constant gating strongly depended on the number of options available. However, even with 100 options the constant gating did not allow to learn this task successfully.

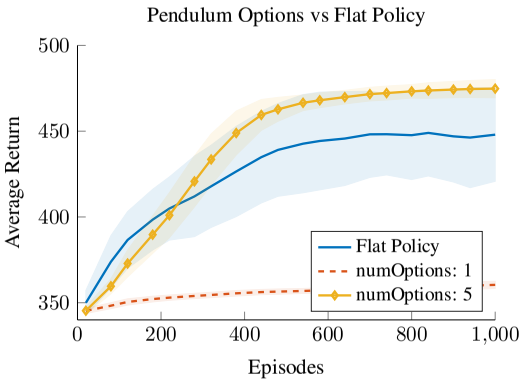


Figure 18: Comparison to flat but non-linear policy. The non-linear policy is given by a linear Gaussian based on a non-linear feature transformation of the states while the hierarchical policy uses only linear sub-policies. The results show that the non-linear flat policy is outperformed by the hierarchical policy. While the flat policy is able to learn the solution, the asymptotic performance varies over multiple runs and would require more samples per iteration to exhibit a robust learning performance.

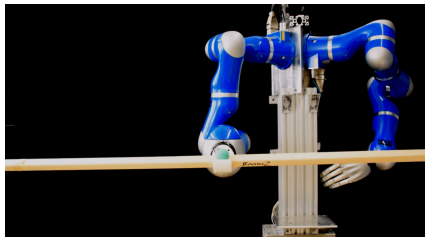
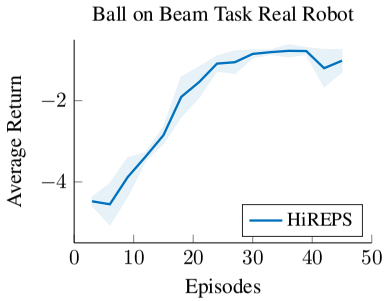
Comparison to a Non-linear Flat Policy. While the proposed approach can learn the pendulum swing-up task using a combination of linear sub-policies, the task can also be solved using a single non-linear policy. To evaluate the effects of the proposed approach, we compared to a non-linear flat policy which was based on the same features as the gating in HiREPS. The results in Figure 18 show that while the non-linear flat policy initially learned faster than the HiREPS, the average asymptotic performance of the HiREPS was higher. Initially, HiREPS requires some iterations to learn a good gating policy. However, once a good gating policy was available, having different options that specialize on sub-tasks such as high accelerations vs. stabilization yielded better policies.

5.5 Infinite Horizon Real Robot Experiment

To evaluate the practical applicability of the proposed infinite horizon approach, we performed a real robot evaluation on the 'ball on a beam' task as shown in Fig. 19a. In this task, the robot has to guide a ball to a prescribed position on a beam and balance it at this position. In our experiments, the robot had to choose between two possible goal positions, 10cm to the left or right of the beam center. To learn the task, the robot learned a policy which set a new desired end effector angle every 0.5s. Every policy was evaluated for 20s and in each iteration the agent collected three episodes before updating the policy. In this task, the state space was given by the ball's position and velocity as well as the current beam angle. The sub-policies were linear Gaussian policies. The gating operated on squared features of the state space and the value function was based on a Fourier feature transformation of the state space using five basis functions. The reward function in this task was given as the summed negative squared distance and velocity of the ball (to the closest goal position) in every control step. The ball's position and velocity were determined using a Microsoft Kinect which was mounted above the robot. The results in Fig. 19b show that the robot was able to learn this task within 30 episodes in all three trials performed.



(a) Ball On Beam Setup



(b) Ball On Beam Results

Figure 19: (a) The experimental setup for the 'ball on a beam' task. A beam of 1m length is attached as the robot's end effector. The robot has to balance a ball in one of two goal positions, $\pm$10cm from the center of the beam. The ball is initialized alternating on the right and left end of the beam. (b) Results of three trials on the real robot. In all trials the robot was able to learn the task within 30 episodes. In the second trial performance dropped slightly at the end of the trial before recovering again. This drop was most likely due to noise in the vision system.

6. Conclusion & Discussion

In this paper, we present a novel method, derived from first principles, to represent multiple solutions to a task. The representation of multiple versatile solutions is achieved though a hierarchical policy, which consists of a gating network and multiple sub-policies. We show that a naive implementation of a hierarchical policy is insufficient as it does not find distinct solutions. To address this problem, we introduce an entropy-based constraint which ensures that the agent finds distinct solutions with different sub-policies. Having a hierarchical policy based on multiple sub-policies additionally allows us to solve tasks that are non-linear using multiple linear sub-policies.

We evaluated the proposed method on two real robot tasks and several simulated tasks. The evaluations showed that our framework can be used to learn temporally extended sub-policies, also called options, and to sequence these sub-policies to learn complicated tasks on real systems.

The results show, that HiREPS is able to learn multiple solutions for complicated tasks and that HiREPS is able to learn piecewise linear solutions for non-linear tasks. The comparison to the non-hierarchical REPS method shows that HiREPS additionally often learns faster than REPS. This effect is especially intriguing as HiREPS does not only aim to learn one solution but multiple solutions at the same time and effectively uses fewer samples per sub-policy.

While the presented approach is able to learn a multi-modal policy using weights generated by solving one optimization problem, alternative solutions are possible. In the presented approach,

computing the lower bound and, subsequently, solving the optimization problem and fitting the sub-policies is equivalent to an EM approach with only one iteration. While EM approaches typically benefit from multiple iterations, we observed no further benefit from applying multiple passes in our experiments. The observation that one EM iteration is sufficient can be explained by the fact that we start with a distribution which is highly similar to the target distribution. Thus, using HiREPS with $\kappa \gg 1$ results in a version of the REPS algorithm which works on a mixture model. Furthermore, alternative mixture model fitting approaches could be used to incorporate the entropy bound which is integrated into the optimization problem in the proposed approach. For example, Graça et al. (2007, 2009) show how EM can be performed with additional constraints such as, for example, the entropy constraint presented in this paper.

In this paper we focus on learning multiple sub-policies and do not solve the temporal extension aspect of the options framework directly. Temporal extension is inherently achieved in many of the presented experiments through the use of movement primitives. Using movement primitives, the time horizon is usually pre-determined. However, this time horizon could be made adaptive by including the duration of the movement primitive into the set of parameters that is learned by the agent. Learning both when to terminate options as well as learning how to construct options from atomic state-action pairs in a unified framework is an important aspect for future work. Equally, extending the framework to not only allow pruning of sub-policies, but also generating new sub-policies during the learning process could be an important addition to the versatility of the presented framework. In the presented version, options might be separated in the state-action space in the beginning of learning when actually multi-modalities exist on a smaller scale than can initially be detected. In such cases, it would be helpful to split one sub-policy into two sub-policies that can adapt to the individual modes.

Appendix A. Derivation of the Lower Bound

Consider the optimization problem in Equation (14) with the real conditional $p(o|s,a)$ instead of the responsibilities $\tilde{p}(o|s,a)$. For simplicity, we do not introduce the steady-state distribution and the normalization constraint as, our results are not affected by these constraints. The Lagrangian of this problem is then given by

$$\begin{aligned} F(\pi,\eta,\xi) = &\sum_{o\in\mathcal{O}} \iint \mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})R_{\text{sa}}\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a} \\ &+\eta\left(\epsilon - \sum_{o\in\mathcal{O}} \iint \mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s}) \log \frac{\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})}{q(\boldsymbol{s},\boldsymbol{a})p(o|\boldsymbol{s},\boldsymbol{a})}\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a}\right) \\ &+\xi\left(\tilde{\kappa} + \iint p(\boldsymbol{s},\boldsymbol{a}) \sum_{o\in\mathcal{O}} p(o|\boldsymbol{s},\boldsymbol{a}) \log p(o|\boldsymbol{s},\boldsymbol{a})\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a}\right). \end{aligned} \tag{26}$$

Simplifying the terms, we obtain

$$F(\pi,\eta,\xi) = \sum_{o\in\mathcal{O}} \iint \mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})\left(R_{\text{sa}} - \eta \log \frac{p(\boldsymbol{s},\boldsymbol{a},o)}{q(\boldsymbol{s},\boldsymbol{a})p(o|\boldsymbol{s},\boldsymbol{a})^{1+\xi/\eta}}\right)\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a} + \eta\epsilon + \xi\tilde{\kappa}. \tag{27}$$

However, determining a closed form solution for $p(\boldsymbol{s},\boldsymbol{a},o)$ is infeasible as the conditional $p(o|\boldsymbol{s},\boldsymbol{a})$ is inside the $\log$. Yet, we can determine a lower bound $L(p,\eta,\xi,\tilde{p})$ by using a proposal distribution $\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})$ for $p(o|\boldsymbol{s},\boldsymbol{a})$ which we can iteratively maximize in an Expectation-Maximization like manner. We need to verify that L is a lower bound on F and that maximizing L w.r.t $\tilde{p}$ is equivalent to setting $\tilde{p}(o|\boldsymbol{s},\boldsymbol{a}) = p(o|\boldsymbol{s},\boldsymbol{a})$, both of which follows from the relation

$$L = F - (\eta+\xi) \iint p(\boldsymbol{s},\boldsymbol{a}) \underbrace{\sum_{o\in\mathcal{O}} p(o|\boldsymbol{s},\boldsymbol{a}) \log \frac{p(o|\boldsymbol{s},\boldsymbol{a})}{\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})}}_{D_{KL}\left(p(o|\boldsymbol{s},\boldsymbol{a})||\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})\right)\geq 0} \mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a}.$$

After the Expectation step, the lower bound is tight, i.e., $\max_{\tilde{p}} L(p,\eta,\xi,\tilde{p}) = F(p,\eta,\xi)$. In the Maximization step, we fix $\tilde{p}$ and maximize L w.r.t p, η and ξ. This combination defines our constraint optimization problem.

A.1 Derivation of Contextual HiREPS

We first reiterate the complete optimization problem, i.e.,

$$\begin{aligned} \max_{\pi,\mu^\pi} J(\pi) &= \max_{\pi,\mu^\pi} \sum_{o\in\mathcal{O}} \iint \mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})\mathcal{R}_{\boldsymbol{sa}}\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a}, \\ \text{s.t.} \quad \epsilon &\geq \sum_{o\in\mathcal{O}} \iint \mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s}) \log \frac{\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})}{q(\boldsymbol{s},\boldsymbol{a})\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})}\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a}, \\ \tilde{\kappa} &\geq -\sum_{o\in\mathcal{O}} \iint \mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)p(o|\boldsymbol{s},\boldsymbol{a}) \log \tilde{p}(o|\boldsymbol{s},\boldsymbol{a})\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a}, \\ \hat{\boldsymbol{\phi}} &= \sum_{o\in\mathcal{O}} \iint \mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})\boldsymbol{\phi}(\boldsymbol{s})\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a}, \\ 1 &= \sum_{o\in\mathcal{O}} \iint \mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a}, \end{aligned} \tag{28}$$

which includes an additional constraint to represent prior knowledge about the desired behavior of sub-policies, i.e., that sub-policies should spread out and not overlap. In the entropy constraint, we replace only the responsibility term inside the log with the approximation $\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})$, as we can combine the expectation over the entropy into $\mathbb{E}_{\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})} \log \tilde{p}(o|\boldsymbol{s},\boldsymbol{a})$.

The Lagrangian formulation reads

$$\begin{aligned} L = \sum_{o\in\mathcal{O}} \iint \mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s}) \Big[\mathcal{R}_{\boldsymbol{sa}} - \eta \log \frac{\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})}{q(\boldsymbol{s},\boldsymbol{a})\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})} \\ + \xi \log \tilde{p}(o|\boldsymbol{s},\boldsymbol{a}) - \boldsymbol{\theta}^T\boldsymbol{\phi}(\boldsymbol{s}) - \lambda\Big]\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a} + \eta\epsilon + \lambda + \boldsymbol{\theta}^T\hat{\boldsymbol{\phi}} + \xi\tilde{\kappa}, \end{aligned} \tag{29}$$

where η , $\boldsymbol{\theta}$, ξ and λ are Lagrangian parameters. To arrive at a closed form update rule for $\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})$, we differentiate L

$$\begin{aligned} \frac{\mathrm{d}L}{\mathrm{d}\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})} &= \mathcal{R}_{\boldsymbol{sa}} - \eta \log \frac{\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})}{q(\boldsymbol{s},\boldsymbol{a})\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})} + \xi \log \tilde{p}(o|\boldsymbol{s},\boldsymbol{a}) - \boldsymbol{\theta}^T\boldsymbol{\phi}(\boldsymbol{s}) - \lambda - \eta, \\ &= \mathcal{R}_{\boldsymbol{sa}} - \eta \log \frac{\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})}{q(\boldsymbol{s},\boldsymbol{a})\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})^{1+\xi/\eta}} - \boldsymbol{\theta}^T\boldsymbol{\phi}(\boldsymbol{s}) - \lambda - \eta, \end{aligned} \tag{30}$$

with

$$\xi \log \tilde{p}(o|\boldsymbol{s},\boldsymbol{a}) = \eta\frac{\xi}{\eta} \log \tilde{p}(o|\boldsymbol{s},\boldsymbol{a}) = \eta \log \tilde{p}(o|\boldsymbol{s},\boldsymbol{a})^{\frac{\xi}{\eta}} = -\eta \log \frac{1}{\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})^{\xi/\eta}}.$$

We set the derivative to zero and write $V(\boldsymbol{s}) = \boldsymbol{\theta}^T\boldsymbol{\phi}(\boldsymbol{s})$ to solve for the update rule

$$\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s}) = q(\boldsymbol{s},\boldsymbol{a})\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})^{1+\xi/\eta} \exp\left(\frac{\mathcal{R}_{\boldsymbol{sa}} - V(\boldsymbol{s})}{\eta}\right) \exp\left(-1 - \frac{\lambda}{\eta}\right). \tag{31}$$

Here, we use the fact that

$$\sum_{o\in\mathcal{O}} \iint \mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a} = 1, \tag{32}$$

and, thus,

$$\exp\left(-1-\frac{\lambda}{\eta}\right)^{-1} = \sum_{o\in\mathcal{O}} \iint q(\boldsymbol{s},\boldsymbol{a})\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})^{1+\xi/\eta} \exp\left(\frac{\mathcal{R}_{\boldsymbol{sa}} - V(\boldsymbol{s})}{\eta}\right) \mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a}. \tag{33}$$

Hence, the term $\exp(-1-\lambda/\eta)$ acts as a normalization constant and $\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})$ can be written as

$$\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s}) = \frac{q(\boldsymbol{s},\boldsymbol{a})\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})^{1+\xi/\eta}\exp\left(\frac{\mathcal{R}_{\boldsymbol{sa}}-V(\boldsymbol{s})}{\eta}\right)}{\sum_{o\in\mathcal{O}}\iint q(\boldsymbol{s},\boldsymbol{a})\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})^{1+\xi/\eta}\exp\left(\frac{\mathcal{R}_{\boldsymbol{sa}}-V(\boldsymbol{s})}{\eta}\right)\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a}}.$$

However, for improved clarity, we resort to writing the update equation in the proportional formulation

$$\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s}) \propto q(\boldsymbol{s},\boldsymbol{a})\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})^{1+\xi/\eta}\exp\left(\frac{\mathcal{R}_{\boldsymbol{sa}}-V(\boldsymbol{s})}{\eta}\right), \tag{34}$$

which depends only on the Lagrangian parameters ξ, η and $\boldsymbol{\theta}$ with $V(\boldsymbol{s}) = \boldsymbol{\theta}^T\boldsymbol{\phi}(\boldsymbol{s})$, but not on the parameter λ. The values for these Lagrangian parameters can be calculated by optimizing the dual problem. The dual formulation can be obtained by inserting Eq. (31) into the original Lagrangian formulation, i.e.,

$$\begin{aligned} g(\eta,\boldsymbol{\theta},\xi,\lambda) = \sum_{o\in\mathcal{O}}\iint \mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})\Big[\mathcal{R}_{\boldsymbol{sa}} \\ -\eta\log\frac{q(\boldsymbol{s},\boldsymbol{a})\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})^{1+\xi/\eta}\exp\left(\frac{\mathcal{R}_{\boldsymbol{sa}}-V(\boldsymbol{s})}{\eta}\right)\exp\left(-1-\frac{\lambda}{\eta}\right)}{q(\boldsymbol{s},\boldsymbol{a})\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})^{1+\xi/\eta}} \\ -\boldsymbol{\theta}^T\boldsymbol{\phi}(\boldsymbol{s})-\lambda\Big]\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a} + \eta\epsilon + \lambda + \boldsymbol{\theta}^T\hat{\boldsymbol{\phi}} + \xi\tilde{\kappa}, \end{aligned} \tag{35}$$

which can easily be simplified to

$$g(\eta,\boldsymbol{\theta},\xi,\lambda) = \eta\epsilon + \lambda + \boldsymbol{\theta}^T\hat{\boldsymbol{\phi}} + \xi\tilde{\kappa} + \sum_{o\in\mathcal{O}}\iint \mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})\eta\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a}, \tag{36}$$

where we again use Eq. (32) to simplify further to

$$g(\eta,\boldsymbol{\theta},\xi,\lambda) = \eta\epsilon + \lambda + \boldsymbol{\theta}^T\hat{\boldsymbol{\phi}} + \xi\tilde{\kappa} + \eta. \tag{37}$$

At this point we rewrite Eq. (33) as

$$\eta + \lambda = \eta\log\sum_{o\in\mathcal{O}}\iint q(\boldsymbol{s},\boldsymbol{a})\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})^{1+\xi/\eta}\exp\left(\frac{\mathcal{R}_{\boldsymbol{sa}}-V(\boldsymbol{s})}{\eta}\right)\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a}, \tag{38}$$

where we used $\log(a^{-1}) = -\log(a)$ and multiplied by η. We insert Eq. (38) back into Eq. (36) and get

$$\begin{aligned} g(\eta,\boldsymbol{\theta},\xi) =& \eta\log\sum_{o\in\mathcal{O}}\iint q(\boldsymbol{s},\boldsymbol{a})\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})^{1+\xi/\eta}\exp\left(\frac{\mathcal{R}_{\boldsymbol{sa}}-V(\boldsymbol{s})}{\eta}\right) \\ &+ \eta\epsilon + \boldsymbol{\theta}^T\hat{\boldsymbol{\phi}} + \xi\tilde{\kappa}. \end{aligned} \tag{39}$$

The dual function $g(\eta,\boldsymbol{\theta},\xi)$ is formulated in such a way that it does not depend on the Lagrangian parameter λ, which acts as a normalization factor.

If we work on samples $\{\boldsymbol{s},\boldsymbol{a}\}_i$ with $i = 1,2,\dots N$, we have to divide by the generating distribution $q(\boldsymbol{s},\boldsymbol{a})$ and obtain

$$\begin{aligned} g(\eta,\boldsymbol{\theta},\xi) =& \eta\log\frac{1}{N}\sum_{o\in\mathcal{O}}\sum_{i=1}^{N}\tilde{p}(o|\boldsymbol{s}_i,\boldsymbol{a}_i)^{1+\xi/\eta}\exp\left(\frac{R_i - V(\boldsymbol{s}_i)}{\eta}\right) \\ &+ \eta\epsilon + \boldsymbol{\theta}^T\hat{\boldsymbol{\phi}} + \xi\tilde{\kappa}, \end{aligned} \tag{40}$$

which we can optimize using standard optimization libraries.

A.2 Derivation of Skill Sequencing

As above, we first reiterate the complete optimization problem, i.e.,

$$\begin{aligned} \max_{\pi_k,\mu_k^\pi} J(\pi_{1:K}) &= \max_{\pi,\mu_k^\pi}\sum_{k=1}^{K}\sum_{o\in\mathcal{O}}\iint \mathcal{R}_{\boldsymbol{sa}}^k\pi_k(\boldsymbol{a}|\boldsymbol{s})\pi_k(o|\boldsymbol{s})\mu_k^\pi(\boldsymbol{s})\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a} + \int\mu_{K+1}^\pi(\boldsymbol{s})\mathcal{R}_{\boldsymbol{s}}^{K+1}\,\mathrm{d}\boldsymbol{s}, \\ \text{s. t. } : \epsilon &\geq \int\mu_{K+1}^\pi(\boldsymbol{s})\log\frac{\mu_{K+1}^\pi(\boldsymbol{s})}{q_{K+1}(\boldsymbol{s})}\,\mathrm{d}\boldsymbol{s}, \\ \hat{\boldsymbol{\phi}}_0 &= \int\boldsymbol{\phi}(\boldsymbol{s}')\mu_1^\pi(\boldsymbol{s}')\,\mathrm{d}\boldsymbol{s}', \\ \forall k\leq K : \epsilon &\geq \sum_{o\in\mathcal{O}}\iint\mu_k^\pi(\boldsymbol{s})\pi_k(\boldsymbol{a}|\boldsymbol{s},o)\pi_k(o|\boldsymbol{s})\log\frac{\mu_k^\pi(\boldsymbol{s})\pi_k(\boldsymbol{a}|\boldsymbol{s},o)\pi_k(o|\boldsymbol{s})}{q_k(\boldsymbol{s},\boldsymbol{a})\tilde{p}_k(o|\boldsymbol{s},\boldsymbol{a})}\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a}, \\ \tilde{\kappa} &\geq -\sum_{o\in\mathcal{O}}\iint\mu_k^\pi(\boldsymbol{s})\pi_k(\boldsymbol{a}|\boldsymbol{s},o)p_k(\boldsymbol{s},\boldsymbol{a})\pi_k(o|\boldsymbol{s})\log\tilde{p}_k(o|\boldsymbol{s},\boldsymbol{a})\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a}, \\ \int\boldsymbol{\phi}(\boldsymbol{s}')\mu_{k+1}^\pi(\boldsymbol{s}')\,\mathrm{d}\boldsymbol{s}' &= \sum_{o\in\mathcal{O}}\iiint\mathcal{P}_{\boldsymbol{ss}'}^{\boldsymbol{a}}\mu_k^\pi(\boldsymbol{s})\pi_k(\boldsymbol{a}|\boldsymbol{s},o)\pi_k(o|\boldsymbol{s})\boldsymbol{\phi}(\boldsymbol{s}')\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{s}'\,\mathrm{d}\boldsymbol{a}, \\ \forall k : 1 &= \sum\nolimits_{o\in\mathcal{O}}\iint\mu_k^\pi(\boldsymbol{s})\pi_k(\boldsymbol{a},o|\boldsymbol{s})\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a}. \end{aligned} \tag{41}$$

The Lagrangian formulation reads

$$\begin{aligned} L =& \boldsymbol{\theta}_1^T\hat{\boldsymbol{\phi}}_0 + \sum_{k=1}^{K}\eta_k\epsilon + \lambda_k + \int\boldsymbol{\theta}_{k+1}^T\boldsymbol{\phi}(\boldsymbol{s})\mu_k^\pi(\boldsymbol{s})\,\mathrm{d}\boldsymbol{s} + \xi_k\tilde{\kappa} + \sum_{o\in\mathcal{O}}\iint\mu_k^\pi(\boldsymbol{s})\pi_k(\boldsymbol{a}|\boldsymbol{s},o)\pi_k(o|\boldsymbol{s}) \\ &\left[\mathcal{R}_{\boldsymbol{sa}}^k - \eta_k\log\frac{\mu_k^\pi(\boldsymbol{s})\pi_k(\boldsymbol{a}|\boldsymbol{s},o)\pi_k(o|\boldsymbol{s})}{q_k(\boldsymbol{s},\boldsymbol{a})\tilde{p}_k(o|\boldsymbol{s},\boldsymbol{a})} + \xi_k\log\tilde{p}_k(o|\boldsymbol{s},\boldsymbol{a}) - \int\mathcal{P}_{\boldsymbol{ss}'}^{\boldsymbol{a}}\boldsymbol{\theta}_{k+1}^T\boldsymbol{\phi}(\boldsymbol{s}')\,\mathrm{d}\boldsymbol{s}' - \lambda_k\right]\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a} \\ &+ \int\mu_{K+1}^\pi(\boldsymbol{s})\Big[\mathcal{R}_{\boldsymbol{s}}^{K+1} - \eta_{K+1}\log\frac{\mu_{K+1}^\pi(\boldsymbol{s})}{q_{K+1}(\boldsymbol{s})} - \lambda_{K+1}\Big]\,\mathrm{d}\boldsymbol{s} + \eta_{K+1}\epsilon + \lambda_{K+1}, \end{aligned} \tag{42}$$

where η_k , $\boldsymbol{\theta}_k$, ξ_k and λ_k are Lagrangian parameters. To arrive at a closed form update rule for $\mu_k^\pi(\boldsymbol{s})\pi_k(\boldsymbol{a}|\boldsymbol{s},o)\pi_k(o|\boldsymbol{s})$, we differentiate L

$$\begin{aligned}\frac{\mathrm{d}L}{\mathrm{d}\mu_k^\pi(\boldsymbol{s})\pi_k(\boldsymbol{a}|\boldsymbol{s},o)\pi_k(o|\boldsymbol{s})} =&\mathcal{R}_{\boldsymbol{sa}}^k - \eta_k \log \frac{\mu_k^\pi(\boldsymbol{s})\pi_k(\boldsymbol{a}|\boldsymbol{s},o)\pi_k(o|\boldsymbol{s})}{q_k(\boldsymbol{s},\boldsymbol{a})\tilde{p}_k(o|\boldsymbol{s},\boldsymbol{a})} + \xi_k \log \tilde{p}_k(o|\boldsymbol{s},\boldsymbol{a}) \\ &+ \int \mathcal{P}_{\boldsymbol{ss'}}^{\boldsymbol{a}} \boldsymbol{\theta}_{k+1}^T \boldsymbol{\phi}(\boldsymbol{s'})\,\mathrm{d}\boldsymbol{s'} - \boldsymbol{\theta}_k^T\boldsymbol{\phi}(\boldsymbol{s}) - \lambda_k - \eta_k, \\ =&\mathcal{R}_{\boldsymbol{sa}}^k - \eta_k \log \frac{\mu_k^\pi(\boldsymbol{s})\pi_k(\boldsymbol{a}|\boldsymbol{s},o)\pi_k(o|\boldsymbol{s})}{q_k(\boldsymbol{s},\boldsymbol{a})\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})^{1+\xi_k/\eta_k}} \\ &+ \int \mathcal{P}_{\boldsymbol{ss'}}^{\boldsymbol{a}} \boldsymbol{\theta}_{k+1}^T \boldsymbol{\phi}(\boldsymbol{s'})\,\mathrm{d}\boldsymbol{s'} - \boldsymbol{\theta}_k^T\boldsymbol{\phi}(\boldsymbol{s}) - \lambda_k - \eta_k, \end{aligned} \tag{43}$$

with

$$\xi_k \log \tilde{p}_k(o|\boldsymbol{s},\boldsymbol{a}) = \eta_k \frac{\xi_k}{\eta_k} \log \tilde{p}_k(o|\boldsymbol{s},\boldsymbol{a}) = \eta_k \log \tilde{p}_k(o|\boldsymbol{s},\boldsymbol{a})^{\xi_k/\eta_k} = -\eta_k \log \frac{1}{\tilde{p}_k(o|\boldsymbol{s},\boldsymbol{a})^{\xi_k/\eta_k}}$$

and set the derivative to zero to solve for the update rule

$$\begin{aligned}\mu_k^\pi(\boldsymbol{s})\pi_k(\boldsymbol{a}|\boldsymbol{s},o)\pi_k(o|\boldsymbol{s}) =&q_k(\boldsymbol{s},\boldsymbol{a})\tilde{p}_k(o|\boldsymbol{s},\boldsymbol{a})^{1+\xi_k/\eta_k} \\ &\exp\left(\frac{\mathcal{R}_{\boldsymbol{sa}}^k + \int \mathcal{P}_{\boldsymbol{ss'}}^{\boldsymbol{a}} \boldsymbol{\theta}_{k+1}^T \boldsymbol{\phi}(\boldsymbol{s'})\,\mathrm{d}\boldsymbol{s'} - \boldsymbol{\theta}_k^T\boldsymbol{\phi}(\boldsymbol{s})}{\eta_k}\right) \exp\left(-1 - \frac{\lambda_k}{\eta_k}\right). \end{aligned} \tag{44}$$

For improved readability we write $\mathbb{E}[V_{k+1}(\boldsymbol{s'})] = \int \mathcal{P}_{\boldsymbol{ss'}}^{\boldsymbol{a}} \boldsymbol{\theta}_{k+1}^T \boldsymbol{\phi}(\boldsymbol{s'})\,\mathrm{d}\boldsymbol{s'}$ and $V_k(\boldsymbol{s}) = \boldsymbol{\theta}_k^T\boldsymbol{\phi}(\boldsymbol{s})$. As before, we use

$$\sum_{o\in\mathcal{O}} \iint \mu_k^\pi(\boldsymbol{s})\pi_k(\boldsymbol{a},o|\boldsymbol{s})\pi_k(o|\boldsymbol{s})\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a} = 1, \tag{45}$$

and, thus, obtain

$$\begin{aligned}\exp\left(-1 - \frac{\lambda_k}{\eta_k}\right)^{-1} =&\sum_{o\in\mathcal{O}} \iint q_k(\boldsymbol{s},\boldsymbol{a})\tilde{p}_k(o|\boldsymbol{s},\boldsymbol{a})^{1+\xi_k/\eta_k} \\ &\exp\left(\frac{\mathcal{R}_{\boldsymbol{sa}}^k + \mathbb{E}[V_{k+1}(\boldsymbol{s'})] - V_k(\boldsymbol{s})}{\eta_k}\right) \mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a}. \end{aligned} \tag{46}$$

Hence, the term $\exp\left(-1 - \frac{\lambda_k}{\eta_k}\right)$ acts as a normalization constant and $\mu_k^\pi(\boldsymbol{s})\pi_k(\boldsymbol{a}|\boldsymbol{s},o)\pi_k(o|\boldsymbol{s})$ can be written as

$$\mu_k^\pi(\boldsymbol{s})\pi_k(\boldsymbol{a}|\boldsymbol{s},o)\pi_k(o|\boldsymbol{s}) = \frac{q_k(\boldsymbol{s},\boldsymbol{a})\tilde{p}_k(o|\boldsymbol{s},\boldsymbol{a})^{1+\xi_k/\eta_k} \exp\left(\frac{\mathcal{R}_{\boldsymbol{sa}}^k + \mathbb{E}[V_{k+1}(\boldsymbol{s'})] - V_k(\boldsymbol{s})}{\eta_k}\right)}{\sum_{o\in\mathcal{O}} \iint q_k(\boldsymbol{s},\boldsymbol{a})\tilde{p}_k(o|\boldsymbol{s},\boldsymbol{a})^{1+\xi_k/\eta_k} \exp\left(\frac{\mathcal{R}_{\boldsymbol{sa}}^k + \mathbb{E}[V_{k+1}(\boldsymbol{s'})] - V_k(\boldsymbol{s})}{\eta_k}\right) \mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a}}.$$

For improved clarity, we resort to writing the update equation in the proportional formulation

$$\mu_k^\pi(\boldsymbol{s})\pi_k(\boldsymbol{a}|\boldsymbol{s},o)\pi_k(o|\boldsymbol{s}) \propto q_k(\boldsymbol{s},\boldsymbol{a})\tilde{p}_k(o|\boldsymbol{s},\boldsymbol{a})^{1+\xi_k/\eta_k} \exp\left(\frac{\mathcal{R}_{\boldsymbol{sa}}^k + \mathbb{E}[V_{k+1}(\boldsymbol{s'})] - V_k(\boldsymbol{s})}{\eta}\right), \tag{47}$$

which depends only on the Lagrangian parameters ξ, η and $\boldsymbol{\theta}$ with $V(\boldsymbol{s}) = \boldsymbol{\theta}^T\boldsymbol{\phi}(\boldsymbol{s})$, but not on the parameter λ. The values for these Lagrangian parameters can be calculated by optimizing the dual problem.

As before, we set the solution for $\mu_k^\pi(\boldsymbol{s})\pi_k(\boldsymbol{a}|\boldsymbol{s},o)\pi_k(o|\boldsymbol{s})$ back into the Lagrangian and simplify to get a dual function that does not depend on the Lagrangian parameters λ_k, i.e.,

$$\begin{aligned}g(\eta_{1:K+1},\boldsymbol{\theta}_{1:K+1},\xi_{1:K+1}) =&\boldsymbol{\theta}_1^T\hat{\boldsymbol{\phi}}_0 + \sum_{k=1}^{K+1} \eta_k\epsilon + \xi_k\tilde{\kappa} + \eta_k \log \sum_{o\in\mathcal{O}} \iint q_k(\boldsymbol{s},\boldsymbol{a})\tilde{p}_k(o|\boldsymbol{s},\boldsymbol{a})^{1+\xi_k/\eta_k} \\ &\exp\left(\frac{\mathcal{R}_{\boldsymbol{sa}}^k + \mathbb{E}[V_{k+1}(\boldsymbol{s'})] - V_k(\boldsymbol{s})}{\eta_k}\right) \mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a}. \end{aligned} \tag{48}$$

Now, the dual function $g(\eta_{1:K+1},\boldsymbol{\theta}_{1:K+1},\xi_{1:K+1})$ is formulated in such a way that it does not depend on the Lagrangian parameters λ_k, which acts as a normalization factor.

A.3 Derivation of Infinite Horizon HiREPS

The derivation of the infinite horizon case follows the derivations given above, where the Lagrangian is given by

$$\begin{aligned}L =&\sum_{o\in\mathcal{O}} \iint \mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s}) \Big[\mathcal{R}_{\boldsymbol{sa}} - \eta\log\frac{\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s})}{q(\boldsymbol{s},\boldsymbol{a})\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})} \\ &+\xi\log\tilde{p}(o|\boldsymbol{s},\boldsymbol{a}) - \boldsymbol{\theta}^T\boldsymbol{\phi}(\boldsymbol{s}) - \lambda\Big]\,\mathrm{d}\boldsymbol{s}\,\mathrm{d}\boldsymbol{a} + \eta\epsilon + \lambda + \int \boldsymbol{\theta}^T\boldsymbol{\phi}(\boldsymbol{s'})\,\mathrm{d}\boldsymbol{s'} + \xi\tilde{\kappa}, \end{aligned} \tag{49}$$

and the resulting update rule and dual function are given as

$$\mu^\pi(\boldsymbol{s})\pi(\boldsymbol{a}|\boldsymbol{s},o)\pi(o|\boldsymbol{s}) \propto q(\boldsymbol{s},\boldsymbol{a})\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})^{1+\xi/\eta} \exp\left(\frac{\mathcal{R}_{\boldsymbol{sa}} + \mathbb{E}[V(\boldsymbol{s'})] - V(\boldsymbol{s})}{\eta}\right), \tag{50}$$

and

$$\begin{aligned}g(\eta,\boldsymbol{\theta},\xi) =&\eta\log\sum_{o\in\mathcal{O}} \iint q(\boldsymbol{s},\boldsymbol{a})\tilde{p}(o|\boldsymbol{s},\boldsymbol{a})^{1+\xi/\eta} \exp\left(\frac{\mathcal{R}_{\boldsymbol{sa}} + \mathbb{E}[V(\boldsymbol{s'})] - V(\boldsymbol{s})}{\eta}\right) \\ &+\eta\epsilon + \xi\tilde{\kappa}. \end{aligned} \tag{51}$$

As for the other cases we can find the minimum of the dual function using standard optimization libraries.

Abstract

We consider the problem of predicting an outcome variable on the basis of a small number of covariates, using an interpretable yet non-additive model. We propose *convex regression with interpretable sharp partitions* (CRISP) for this task. CRISP partitions the covariate space into blocks in a data-adaptive way, and fits a mean model within each block. Unlike other partitioning methods, CRISP is fit using a non-greedy approach by solving a convex optimization problem, resulting in low-variance fits. We explore the properties of CRISP, and evaluate its performance in a simulation study and on a housing price data set.

Keywords: convex optimization, interpretability, non-additivity, non-parametric regression, prediction

1. Introduction

Classification and regression trees (CART) are immensely popular for flexible and non-additive predictive modeling, despite the fact that they date back more than thirty years (Breiman et al., 1984). The trees are fit using a two-stage process in which the tree is first greedily "grown" to some maximum size, and then "pruned" to avoid overfitting. The final tree with K terminal nodes can be visually displayed as a decision tree with $K-1$ splits, or equivalently as K disjoint boxes that completely partition the covariate space. CART has stood the test of time, because its output is highly interpretable and it can easily incorporate complex non-additive relationships between features. However, it is a greedy procedure, and a small perturbation of the data can produce a very different tree. The high variability of the fitted values can compromise the scientific utility of the tree, as well as the tree's prediction accuracy on test data. While an ensemble approach, like random forests, can reduce CART's variability, this comes at the expense of interpretability (Breiman, 2001).

Two other well-known methods for flexible and non-additive predictive modeling are multivariate adaptive regression splines (MARS) (Friedman, 1991) and thin-plate splines (TPS) (Duchon, 1977). The MARS fit is a weighted sum of basis functions, which are greedily chosen and some of which involve pairs of features. TPS fits the observed data, regularized by smoothness penalties. In the case of two covariates x_1 and x_2 and a response y, the TPS fit is the solution to

$$\underset{f}{\text{minimize}} \quad \sum_{i=1}^{n}[y_i - f(x_{1i}, x_{2i})]^2 + \lambda \int\int_{\mathbb{R}^2} \|\nabla^2 f(x_1, x_2)\|_F^2 \, dx_1 \, dx_2.$$

The fits from MARS and TPS are incredibly flexible, but can be less interpretable than the fits from CART.

In recent years, the statistical community has been very interested in formulating predictive models as solutions to convex optimization problems. However, to the best of our knowledge, no proposals have been made for flexible, non-additive, and interpretable modeling via convex optimization. To close this gap, we propose a non-greedy procedure whose fits have a block structure reminiscent of CART. Our proposal, *convex regression with interpretable sharp partitions* (CRISP), is the solution to a convex optimization problem with predictions that are much less variable than those of CART. Also unlike CART, CRISP borrows information across the blocks, and is able to adequately model the data when the mean model is smooth. Thus our method provides a compromise between the interpretability of CART and the flexibility of MARS and TPS. In this paper, we consider the low-dimensional setting in which there are a small number of covariates of interest ($p \ll n$). We leave an extension to the $p > n$ setting to future work.

CRISP has a number of attractive properties:

- CRISP can accommodate interactions between pairs of covariates in a flexible way. This is useful when the impact of one covariate may depend on the value of another covariate, but there is not strong *a priori* knowledge about the form of the interaction.
- CRISP fits a piecewise constant model, which is easily interpreted by even those with limited statistical background.
- CRISP is formulated as a convex optimization problem. Thus we can solve for the global optimum, and can derive an expression for CRISP's degrees of freedom.

The remainder of this paper is organized as follows. In Section 2, we introduce our method and present an algorithm to implement it. We compare our method to existing approaches using simulated data in Section 3. In Section 4, we derive some properties of the method. In Section 5, we discuss connections between our method and other work. We illustrate our method on a housing price data set in Section 6. We consider a modification to our proposal in Section 7, and close with the discussion in Section 8. Proofs are in the Appendix.

2. Convex Regression with Interpretable Sharp Partitions

Throughout most of this paper, for ease of exposition, we focus on the case of $p = 2$ features. An extension to the case of $p > 2$ is given in Section 7.

We first present an overview of the CRISP approach. We wish to predict a random variable $y \in \mathbb{R}$ using $x_1, x_2 \in \mathbb{R}$. We assume that $y = f(x_1, x_2) + \epsilon$, where ϵ is a mean-zero

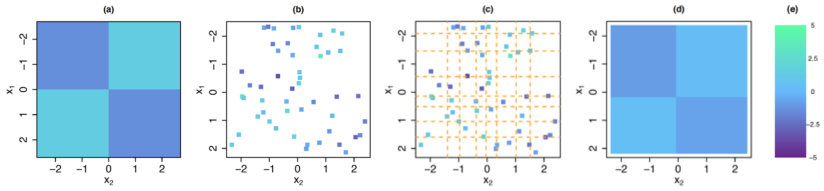

Figure 1: In *(a)*, the mean model $f(x_1, x_2)$ used to generate data. In *(b)*, each of the 50 squares represents an observation (x_1, x_2, y) with $y = f(x_1, x_2) + \epsilon$ with $\epsilon \sim N(0, 1)$. In *(c)*, there are $q^2 = 64$ bins of (x_1, x_2) values, whose boundaries coincide with the octiles (- - -) of $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$. In *(d)*, CRISP estimates $f(x_1, x_2)$ to be constant within each bin, and furthermore encourages adjacent bins to take on the same value. When applied to the data in *(b)* with $q = 8$, this leads to an estimated $f(x_1, x_2)$ with four *blocks*. In *(e)*, we show the heat scale legend.

error term, and f is an unknown function that we wish to estimate. An example of $f(x_1, x_2)$ is displayed in Figure 1(a). Figure 1(b) displays a training set of n i.i.d. observations of (x_1, x_2, y). We first partition the feature space into q^2 bins, as shown in Figure 1(c) with $q = 8$. The CRISP approach estimates $f(x_1, x_2)$ to be constant within each bin, and further encourages f to take on the same value at adjacent bins; this leads to constant-valued *blocks*. The CRISP output is shown in Figure 1(d); there are four estimated blocks. More details about this simulation set-up are provided in Section 3.

2.1 Notation and Goal of CRISP

We now introduce some new notation, and provide further intuition for CRISP, before presenting the optimization problem for CRISP in Section 2.2.

As is shown in Figure 1(c), we wish to estimate the mean model $f(x_1, x_2)$ for a $q \times q$ grid of bins, where $f(x_1, x_2)$ is estimated to be constant within each bin. Let $\boldsymbol{M} \in \mathbb{R}^{q \times q}$ denote a mean matrix whose element $M_{(i)(j)}$ contains the mean for pairs of covariate values within a *quantile range* of the observed predictors $\boldsymbol{x}_1, \boldsymbol{x}_2 \in \mathbb{R}^n$. For example, $M_{(1)(2)}$ represents the mean of the observations with x_1 less than the $\frac{1}{q}$-quantile of $\boldsymbol{x}_1$, and x_2 between the $\frac{1}{q}$- and $\frac{2}{q}$-quantiles of $\boldsymbol{x}_2$. In Figure 1(c), the corner grid bins correspond to $M_{(1)(1)}$, $M_{(8)(1)}$, $M_{(8)(8)}$, and $M_{(1)(8)}$, starting at the top-left corner of the grid and moving counter-clockwise. In CRISP, our goal is to estimate the $q \times q$ matrix $\boldsymbol{M}$ on the basis of $\boldsymbol{y} \in \mathbb{R}^n$, which contains n noisy observations from various bins of $\boldsymbol{M}$.

In the example shown in Figure 1, we partition the feature space into an 8×8 grid (shown in Figure 1(c)), which translates to estimating an 8×8 matrix $\boldsymbol{M}$. Therefore, instead of estimating $f(x_1, x_2)$ over the entire joint range of $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$, we need only estimate the 64 elements of $\boldsymbol{M}$. Furthermore, CRISP borrows information across bins of the grid by encouraging pairs of neighboring rows and columns of $\boldsymbol{M}^*$ to be equal, leading

to an estimated mean model with a *block structure*. For instance, in Figure 1(d), $\boldsymbol{M}$ is estimated to have four *blocks*, or regions of feature space over which $f(x_1, x_2)$ is constant. Consequently, the CRISP solution $\boldsymbol{M}^*$ shown in Figure 1(d) only has 4 unique elements, while $\boldsymbol{M}$ is an 8×8 matrix. If we examined the estimate $\boldsymbol{M}^*$, we would see that all pairs of neighboring rows and neighboring columns of $\boldsymbol{M}^*$ are identical, except for one pair of columns and one pair of rows.

While the true mean model in this example has a block structure (as seen in Figure 1(a)), we will show in Section 3 that CRISP can perform well even when the true mean model is smooth. The data in this example were uniformly distributed in the covariate space. CRISP is most suitable for data applications where observations are distributed throughout the covariate space. Highly correlated covariates will lead to an insufficient amount of data to estimate the mean model over the entire covariate space.

2.2 The Optimization Problem

The CRISP optimization problem balances the trade-off between fitting the data and encouraging a block structure. We estimate $\boldsymbol{M}$ by solving the convex optimization problem

$$\underset{\boldsymbol{M} \in \mathbb{R}^{q \times q}}{\text{minimize}} \quad \frac{1}{2} \sum_{i=1}^{n} (y_i - \Omega(\boldsymbol{M}, x_{1i}, x_{2i}))^2 + \lambda P(\boldsymbol{M}). \tag{1}$$

In (1), the function Ω extracts the element of $\boldsymbol{M}$ corresponding to the bin to which the observation (x_{1i}, x_{2i}) belongs. For instance, in Figure 1(c), $\Omega(\boldsymbol{M}, 0, -1) = M_{(4)(2)}$. Note that Ω is explicitly defined in Appendix A. Furthermore, $\lambda \geq 0$ is a tuning parameter, and the penalty P is defined as

$$P(\boldsymbol{M}) = \sum_{i=1}^{q-1} \left[\left\| \boldsymbol{M}_{i\cdot} - \boldsymbol{M}_{(i+1)\cdot} \right\|_2 + \left\| \boldsymbol{M}_{\cdot i} - \boldsymbol{M}_{\cdot(i+1)} \right\|_2 \right], \tag{2}$$

where $\boldsymbol{M}_{i\cdot}$ and $\boldsymbol{M}_{\cdot i}$ denote the ith row and column of $\boldsymbol{M}$, respectively. The sum of squared errors in (1) encourages the estimate of $\boldsymbol{M}$ to fit the data, while the group lasso penalty (Yuan and Lin, 2006) in (2) encourages pairs of neighboring rows (or columns) to be exactly identical. This leads to the formation of constant-valued blocks, which are comprised of multiple bins of the $q \times q$ grid. Appendix B discusses other possible penalties that could be used in (1).

We now rewrite (1) in a way that will be useful later. We introduce a vectorized form of $\boldsymbol{M}$, which is denoted by $\boldsymbol{m} = \text{vec}(\boldsymbol{M}) = \left((\boldsymbol{M}_{\cdot 1})^T, (\boldsymbol{M}_{\cdot 2})^T, \cdots, (\boldsymbol{M}_{\cdot q})^T\right)^T$ where $\boldsymbol{M}_{\cdot i}$ is the ith column of $\boldsymbol{M}$. The correspondence between $\boldsymbol{M}$ and $\boldsymbol{m}$ is shown in Figure 10 of Appendix A. In what follows, we will switch between using the matrix $\boldsymbol{M}$ and the vectorized $\boldsymbol{m}$. Then (1) can be rewritten as

$$\underset{\boldsymbol{m} \in \mathbb{R}^{q^2}}{\text{minimize}} \quad \frac{1}{2} \|\boldsymbol{y} - \boldsymbol{Q}\boldsymbol{m}\|_2^2 + \lambda \sum_{i=1}^{q-1} \left[\|\boldsymbol{R}_i \boldsymbol{m}\|_2 + \|\boldsymbol{C}_i \boldsymbol{m}\|_2 \right], \tag{3}$$

where each row of $\boldsymbol{Q} \in \mathbb{R}^{n \times q^2}$ contains $q^2 - 1$ elements that equal 0, and a single 1, such that $\boldsymbol{Q}_{i\cdot}\boldsymbol{m} = \Omega(\boldsymbol{M}, x_{1i}, x_{2i})$, where $\boldsymbol{Q}_{i\cdot}$ indicates the ith row of $\boldsymbol{Q}$. (Though $\boldsymbol{Q}$ is a function

of $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$, we suppress this to simplify the notation.) In (3), $\boldsymbol{R}_i, \boldsymbol{C}_i \in \mathbb{R}^{q \times q^2}$ extract differences between neighboring rows and columns of $\boldsymbol{M}$ (i.e., $\boldsymbol{R}_i\boldsymbol{m} = \boldsymbol{M}_{i\cdot} - \boldsymbol{M}_{(i+1)\cdot}$ and $\boldsymbol{C}_i\boldsymbol{m} = \boldsymbol{M}_{\cdot i} - \boldsymbol{M}_{\cdot(i+1)}$). An example of $\boldsymbol{Q}$ and explicit definitions of $\boldsymbol{Q}$, $\boldsymbol{R}_i$, and $\boldsymbol{C}_i$ are in Appendix A. We let $\boldsymbol{A} = \left(\boldsymbol{R}_1^T, \cdots, \boldsymbol{R}_{q-1}^T, \boldsymbol{C}_1^T, \cdots, \boldsymbol{C}_{q-1}^T\right)^T \in \mathbb{R}^{2q(q-1)\times q^2}$, and then rewrite (3) as

$$\underset{\boldsymbol{m}\in\mathbb{R}^{q^2}, \boldsymbol{z}\in\mathbb{R}^{2q(q-1)}}{\text{minimize}} \quad \frac{1}{2}\|\boldsymbol{y} - \boldsymbol{Q}\boldsymbol{m}\|_2^2 + \lambda \sum_{i=1}^{q-1} [\|\boldsymbol{z}_{1i}\|_2 + \|\boldsymbol{z}_{2i}\|_2] \quad \text{subject to } \boldsymbol{A}\boldsymbol{m} = \boldsymbol{z}, \tag{4}$$

where $\boldsymbol{z} = \left((\boldsymbol{z}_{11})^T, \cdots, (\boldsymbol{z}_{1(q-1)})^T, (\boldsymbol{z}_{21})^T, \cdots, (\boldsymbol{z}_{2(q-1)})^T\right)^T$ with $\boldsymbol{z}_{1i}, \boldsymbol{z}_{2i} \in \mathbb{R}^q$.

While (1), (3), and (4) have the same solution, it is most convenient to derive an algorithm to solve CRISP using the parameterization in (4). Throughout this paper, we will alternate between using the notation $\boldsymbol{M}^*$ and $\boldsymbol{m}^*$, where $\boldsymbol{m}^* = \text{vec}(\boldsymbol{M}^*)$, to represent the CRISP solution to (4). The training set predictions for CRISP are given by $\hat{\boldsymbol{y}} = \boldsymbol{Q}\boldsymbol{m}^*$.

2.3 An Algorithm for CRISP

We solve for the global optimum of the convex optimization problem (4) using the *alternating directions method of multipliers* (ADMM) algorithm (Boyd et al., 2011). This is summarized in Algorithm 1. Additional details are in Appendix C.

Algorithm 1 — Alternating Directions Method of Multipliers for Equation (4)

1. Let $\boldsymbol{u} = \left((\boldsymbol{u}_{11})^T, \ldots, (\boldsymbol{u}_{1(q-1)})^T, (\boldsymbol{u}_{21})^T, \ldots, (\boldsymbol{u}_{2(q-1)})^T\right)^T$ denote the scaled dual variables. Initialize $\boldsymbol{m}^{(0)} := \boldsymbol{0}, \boldsymbol{z}^{(0)} := \boldsymbol{0}$, and $\boldsymbol{u}^{(0)} := \boldsymbol{0}$.

2. For $k = 1, 2, \ldots$, until the primal and dual residuals satisfy a stopping criterion:

   (a) $\boldsymbol{m}^{(k)} := \left[\boldsymbol{Q}^T\boldsymbol{Q} + \rho\boldsymbol{A}^T\boldsymbol{A}\right]^{-1}\left[\boldsymbol{Q}^T\boldsymbol{y} + \rho\boldsymbol{A}^T(\boldsymbol{z}^{(k-1)} - \boldsymbol{u}^{(k-1)})\right]$

   (b) $\boldsymbol{z}_{1i}^{(k)} := (\boldsymbol{R}_i\boldsymbol{m}^{(k)} + \boldsymbol{u}_{1i}^{(k-1)})(1 - \lambda/(\rho\|\boldsymbol{R}_i\boldsymbol{m}^{(k)} + \boldsymbol{u}_{1i}^{(k-1)}\|_2))_+$,
   $\boldsymbol{z}_{2i}^{(k)} := (\boldsymbol{C}_i\boldsymbol{m}^{(k)} + \boldsymbol{u}_{2i}^{(k-1)})(1 - \lambda/(\rho\|\boldsymbol{C}_i\boldsymbol{m}^{(k)} + \boldsymbol{u}_{2i}^{(k-1)}\|_2))_+$ for $i = 1, \ldots, q-1$

   (c) $\boldsymbol{u}^{(k)} := \boldsymbol{u}^{(k-1)} + \boldsymbol{A}\boldsymbol{m}^{(k)} - \boldsymbol{z}^{(k)}$

In Algorithm 1, the computational bottleneck occurs in Step 2(a). Evaluating the q-banded matrix $\boldsymbol{Q}^T\boldsymbol{Q} + \rho\boldsymbol{A}^T\boldsymbol{A}$ has a one-time cost of $\mathcal{O}(n+q^4)$ operations, and computing its LU factorization requires an additional $\mathcal{O}(q^4)$ operations. Then Step 2(a) can be performed in $\mathcal{O}(q^3)$ operations (Boyd and Vandenberghe, 2004). Therefore, Algorithm 1 requires an initial step of $\mathcal{O}(n + q^4)$ operations, followed by a per-iteration complexity of $\mathcal{O}(q^3)$.

On a Macbook Pro with a 2.0 GHz Intel Sandy Bridge Core i7 processor, our `Python` implementation of CRISP with $n = q = 50$ takes 20.1 seconds for a sequence of 20 λ values. For $n = q = 100$ and $n = q = 200$, the run times are 84.7 and 383.6 seconds, respectively. Increasing n while holding q constant has little effect on the run times; this is consistent with the discussion in the previous paragraph. Thus even for very large n, the computational time is reasonable.

We chose to solve CRISP using an ADMM algorithm, as ADMM works well in related problems. For example, in the context of trend filtering, Ramdas and Tibshirani (forthcoming) found that their ADMM implementation converged more reliably across a variety of tuning parameter values and sample sizes than the primal-dual interior point method of Kim et al. (2009). In our setting, an interior point algorithm for CRISP involves solving a dense system of equations at each iteration, which has a computational complexity of $\mathcal{O}(q^6)$. Additionally, an interior point method would not recover the exact block structure (any strictly feasible solution would have no zero row or column differences). In contrast, we directly recover the block structure of our estimated mean model from the $\boldsymbol{z}$ variables of our ADMM algorithm. Furthermore, ADMM algorithms typically converge to moderate accuracy within only tens of iterations (Boyd et al., 2011), which is acceptable in our setting.

The value of λ can be chosen using K-fold cross-validation. Alternatively, λ can be selected using approaches based on Akaike's information criterion (AIC; Akaike, 1973) or Bayesian information criterion (BIC; Schwarz, 1978) using the degrees of freedom estimator proposed in Section 4.1. The roles of λ and q in controlling the granularity of the model are further characterized in Sections 4.2 and 4.3.

3. Simulations

In this section, we compare the performance of CRISP to CART, TPS, and competing methods. We consider a variety of mean models, as well as smaller ($n = 100$) and larger ($n = 10,000$) training set sample sizes.

3.1 Methods

We generate data with either $n = 100$ or $n = 10,000$, and $p = 2$. We independently sample each element of $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$ from a Unif$[-2.5, 2.5]$ distribution, and then take $\boldsymbol{y} = f(\boldsymbol{x}_1, \boldsymbol{x}_2) + \boldsymbol{\epsilon}$, where $\boldsymbol{\epsilon} \sim \text{MVN}(\boldsymbol{0}, \sigma^2\boldsymbol{I}_n)$ with $\sigma = 1$ for $n = 100$ and $\sigma = 10$ for $n = 10,000$. Note that we use the notation MVN to indicate a multivariate normal distribution.

We consider four mean models for $f(x_1, x_2)$; these are displayed in the top panel of Figure 2, and defined in detail in Appendix D. In Scenario 1, the mean model is additive in $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$. Scenario 2 is similar to Scenario 1, but the mean model is non-additive. The mean model in Scenario 3 is piecewise constant, with the cut points for $\boldsymbol{x}_2$ depending on $\boldsymbol{x}_1$. Finally, Scenario 4 is a smooth mean model.

For each scenario, we generate 200 data sets and estimate $\boldsymbol{M}$ using CRISP (with $q = 100$) and several competitors: FLAM (implemented with the `R` package `flam` (Petersen, 2014)); CART (implemented with the `R` package `rpart` (Therneau et al., 2014)); TPS (implemented with the `R` package `fields` (Nychka et al., 2014)); a linear model with predictors $\boldsymbol{x}_1$, $\boldsymbol{x}_2$, and their interaction; and an "oracle" linear model based on knowing *a priori* which regions of the mean model take on a constant value.

For each of the four scenarios, we plot mean squared prediction error[1] versus degrees of freedom (a notion that will be discussed extensively in Section 4.1). CRISP and FLAM are fit over a sequence of exponentially decreasing λ values, with the degrees of freedom estimated using (6) and a result from Petersen et al. (forthcoming), respectively. TPS is fit over a sequence of degrees of freedom. For CART, we vary the number of terminal nodes in the tree, and average the estimator (7) over the replicates in order to estimate the degrees of freedom for each number of terminal nodes. Note that the number of degrees of freedom of CART is non-monotonic for small numbers of terminal nodes (as seen in Figure 3).

3.2 Results for $n = 100$

Results are shown in Figure 3. We see that both CRISP and TPS perform reasonably well in terms of prediction error in all scenarios, regardless of the true mean model. FLAM outperforms the other methods in Scenario 1, which is unsurprising as the mean model is truly additive, and FLAM boils down to CRISP with an additivity constraint (Section 5.2). However, FLAM performs poorly for mean models with substantial non-additivity (Scenarios 2 and 4). Outside of Scenario 1, CART performs worse than TPS and CRISP. CRISP, TPS, and CART all perform better than a linear model with an interaction in Scenarios 1–3. However, in Scenario 4, the mean model is well-approximated using a linear model. We also fit MARS for all scenarios; however, performance was poor and the results are omitted.

While CRISP and TPS have comparable prediction error, their fits are quite different. In Figure 2, we show the estimated mean models for CRISP, TPS, and CART for a single replicate of data in each scenario. CRISP provides fits that reflect the true mean model well, even when the true mean model is smooth. While TPS has low prediction error, the smooth fits from TPS are not easily interpreted and are far from the true mean model in some scenarios. While the fits from CART reflect the mean model reasonably well in Scenarios 1 and 2, the fits from CART in all scenarios are highly variable. CART fits from different replicates of Scenario 4 are shown in Figure 4. The average variance of an element of $\boldsymbol{M}^*$ across the 200 replicates for Scenario 4 was 0.843 for CART, compared to 0.0935 for CRISP and 0.0653 for TPS. The variance of CART's fitted values is similarly inflated for the other scenarios. Small perturbations of the data can produce very different qualitative conclusions when examining CART's fits.

3.3 Results for $n = 10,000$

We compare CRISP to TPS and CART. Results are in Figures 2 and 5. Again, CRISP performs well in all scenarios, and the CART fits are much more variable than those of CRISP and TPS. The average variance of an element of $\boldsymbol{M}^*$ across the 200 replicates for Scenario 1 was 0.111 for CART, compared to 0.051 for CRISP and 0.083 for TPS. For Scenario 2, the average variance was 1.42 for CART, compared to 0.056 for CRISP and 0.083 for TPS. For Scenario 3, the average variance was 0.692 for CART, compared to 0.077 for CRISP and 0.129 for TPS. And finally, for Scenario 4, the average variance was 1.89 for

1. Mean squared prediction error is defined as $\frac{1}{q^2}\|\boldsymbol{M}-\boldsymbol{M}^*\|_F^2$, where $\boldsymbol{M} \in \mathbb{R}^{q\times q}$ is the true mean matrix and $\boldsymbol{M}^* \in \mathbb{R}^{q\times q}$ is the estimate from a given method. For methods other than CRISP, $\boldsymbol{M}^*$ was constructed using the mean model estimate at the midpoint of each bin of the $q \times q$ grid.

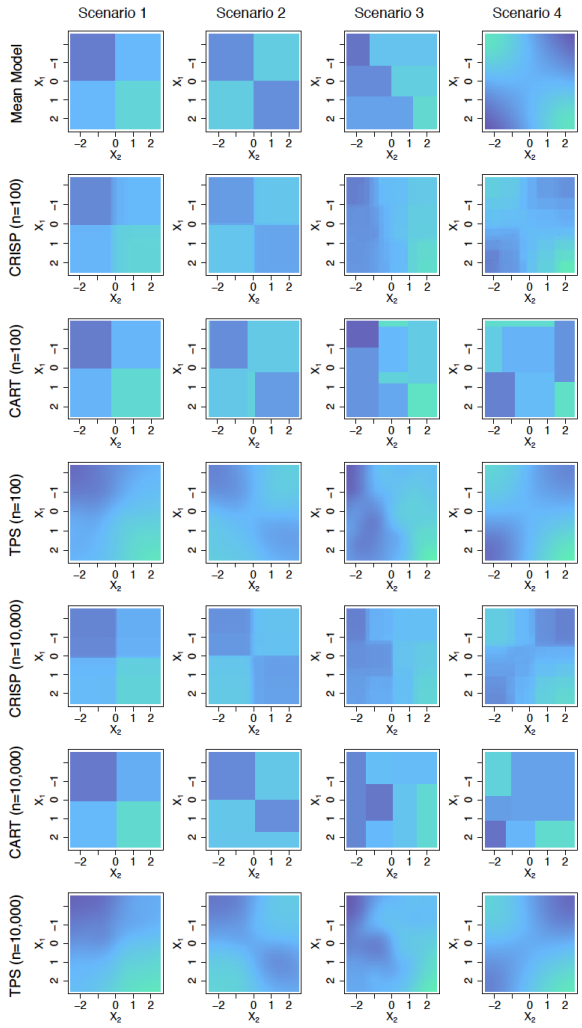

Figure 2: The mean models for Scenarios 1–4, as well as estimated mean models from CRISP, CART, and TPS for the simulations considered in Section 3. Each fit is from a single replicate of data, with the number of degrees of freedom indicated in Figures 3 and 5 for $n = 100$ and $n = 10,000$, respectively. The heat scale legend is in Figure 1(e).

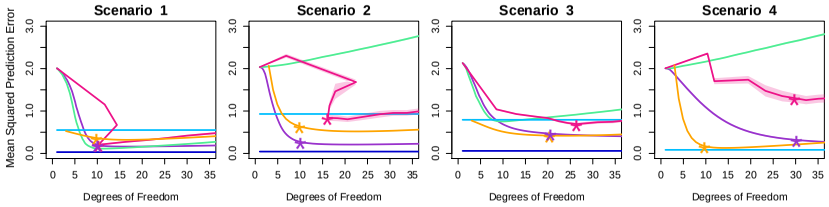

Figure 3: Mean squared prediction error, as a function of the degrees of freedom, for the four scenarios considered in the simulations of Section 3.2. The methods displayed are CRISP (—), FLAM (—), TPS (—), CART (—), linear model with an interaction (—), and the oracle linear model (—). The oracle linear model is only fit for Scenarios 1–3, for which the mean models have constant regions. Shaded bands (only visible for CART) indicate point-wise 95% confidence intervals over the 200 replicate data sets. The linear models have a fixed number of degrees of freedom, but are shown as horizontal lines. Asterisks indicate the degrees of freedom used for the fits shown in Figure 2.

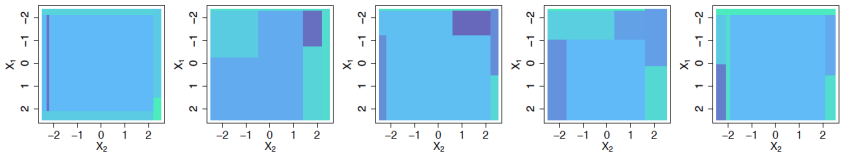

Figure 4: Fits for CART in Scenario 4 with $n = 100$ (as also shown in Figure 2) corresponding to five additional replicates of data. The heat scale legend is in Figure 1(e).

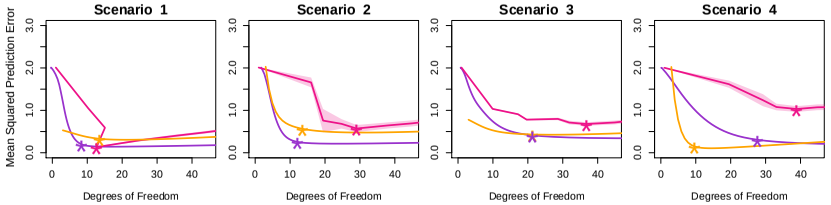

Figure 5: Results for $n = 10,000$ for CRISP (—), TPS (—), and CART (—) in the simulations of Section 3.3. Details are as given in Figure 3.

CART, compared to 0.096 for CRISP and 0.061 for TPS. Notably, a large sample size is not sufficient for producing stable CART fits, unless the signal-to-noise ratio is suitably large.

4. Properties of CRISP

In this section, we provide an unbiased estimator for CRISP's degrees of freedom. We also derive an analytical expression for the range of λ for which the solution to (4) takes a constant value, $\boldsymbol{m}^* = \left(\frac{1}{n}\mathbf{1}^T\boldsymbol{y}\right)\mathbf{1}$. Lastly, we discuss the role of q and λ in controlling the granularity of CRISP. Throughout this section, we use $\boldsymbol{A}^+$ to denote the Moore-Penrose pseudoinverse of a matrix $\boldsymbol{A}$.

4.1 Degrees of Freedom

Suppose that $\mathrm{Var}(\boldsymbol{y}) = \sigma^2\boldsymbol{I}$, and let $g(\boldsymbol{y}) = \hat{\boldsymbol{y}}$ denote the fit corresponding to some model-fitting procedure g. Then the degrees of freedom of g is defined as $\frac{1}{\sigma^2}\sum_{i=1}^n \mathrm{Cov}(y_i, \hat{y}_i)$ (Hastie and Tibshirani, 1990; Efron, 1986).

The concept of degrees of freedom provides a common framework for comparing the complexities of various models; this is particularly useful when the models under consideration are complex or unrelated. Ye (1998) proposed a computationally-burdensome Monte Carlo approach for estimating the degrees of freedom of a model-fitting procedure. In recent years, unbiased estimators for the degrees of freedom have been derived for the lasso and generalized lasso (Zou et al., 2007; Tibshirani and Taylor, 2012), among other methods. These estimators allow us to characterize a model's complexity, and also can be used in order to develop an approach for tuning parameter selection based on Akaike's information criterion (AIC; Akaike, 1973) or Bayesian information criterion (BIC; Schwarz, 1978).

Problem (3) is equivalent to the problem

$$\underset{\boldsymbol{m}}{\text{minimize}} \quad \frac{1}{2}\|\boldsymbol{y} - \boldsymbol{Q}\boldsymbol{m}\|_2^2 + \lambda\sum_{i=1}^{q-1}\left[\|\boldsymbol{R}_i\boldsymbol{m}\|_2 + \|\boldsymbol{C}_i\boldsymbol{m}\|_2\right] + \frac{\gamma}{2}\|\boldsymbol{m}\|_2^2 \tag{5}$$

with $\gamma = 0$. In the rest of this section, we take γ to be a small positive constant, which ensures strong convexity and enforces uniqueness of the solution.

We now introduce some notation. First, we define $\mathcal{C}$, the set of difference matrices corresponding to equal neighboring rows or columns in the solution $\boldsymbol{m}^*$ to (5). That is, $\mathcal{C} = \{\boldsymbol{A}_i : \|\boldsymbol{A}_i\boldsymbol{m}^*\|_2 = 0\}$ where $\boldsymbol{A}_1 = \boldsymbol{R}_1, \boldsymbol{A}_2 = \boldsymbol{R}_2, \ldots, \boldsymbol{A}_{q-1} = \boldsymbol{R}_{q-1}, \boldsymbol{A}_q = \boldsymbol{C}_1, \boldsymbol{A}_{q+1} = \boldsymbol{C}_2, \ldots, \boldsymbol{A}_{2q-2} = \boldsymbol{C}_{q-1}$. Then we define $\boldsymbol{A}_*$ to be the submatrix of $\boldsymbol{A}$ obtained by retaining only the rows of $\boldsymbol{A}$ corresponding to matrices $\boldsymbol{A}_i \in \mathcal{C}$. Note that $\boldsymbol{A}_* \in \mathbb{R}^{q|\mathcal{C}|\times q^2}$. We propose to estimate the degrees of freedom of CRISP as

$$\hat{df}_{CRISP} = \text{Tr}\left[\boldsymbol{Q}\left(\boldsymbol{D} + \lambda\boldsymbol{P}\sum_{i:\boldsymbol{A}_i\notin\mathcal{C}} S_2(\boldsymbol{A}_i, \boldsymbol{m}^*)\boldsymbol{P} + \gamma\boldsymbol{I}\right)^{-1}\boldsymbol{P}\boldsymbol{Q}^T\right], \tag{6}$$

where $\boldsymbol{P} = \boldsymbol{I}_{q^2} - \boldsymbol{A}_*^+\boldsymbol{A}_*$, $S_2(\boldsymbol{A}_i, \boldsymbol{m}^*) = \frac{\boldsymbol{A}_i^T\boldsymbol{A}_i}{\|\boldsymbol{A}_i\boldsymbol{m}^*\|_2} - \frac{\boldsymbol{A}_i^T\boldsymbol{A}_i\boldsymbol{m}^*\boldsymbol{m}^{*T}\boldsymbol{A}_i^T\boldsymbol{A}_i}{\|\boldsymbol{A}_i\boldsymbol{m}^*\|_2^3}$, and $\boldsymbol{Q}$ was defined in (3). Recall that $\boldsymbol{M}^*$ will tend to contain row-column blocks of constant value, as shown in Figure 1(d). We define $\boldsymbol{D} = \text{diag}\left(h(m_1^*), \cdots, h(m_{q^2}^*)\right)$, where $h(m_i^*)$ is the ratio of the number of observations in the block of $\boldsymbol{M}^*$ that contains m_i^* to the number of elements of $\boldsymbol{M}^*$ in the block of $\boldsymbol{M}^*$ that contains m_i^*. We use the notation MVN to indicate a multivariate normal distribution.

Proposition 1 *Assume $\boldsymbol{y} \sim MVN(\boldsymbol{\mu}, \sigma^2\boldsymbol{I})$. Then $\hat{df}_{CRISP}$ is an unbiased estimator of the degrees of freedom of CRISP.*

The following corollary indicates that the estimator (6) simplifies substantially when the CRISP solution takes a particular form.

Corollary 2 *Assume $\boldsymbol{y} \sim MVN(\boldsymbol{\mu}, \sigma^2\boldsymbol{I})$. If either all rows or all columns of $\boldsymbol{M}^*$ are equal, then the total number of blocks of $\boldsymbol{M}^*$ is an unbiased estimator of the degrees of freedom.*

In 100 replicate data sets with $y_i \sim N(\mu_i, \sigma^2)$, we compare the mean of (6) to the mean of

$$\frac{1}{\sigma^2}\sum_{i=1}^{n}(\hat{y}_i - \mu_i)(y_i - \mu_i), \tag{7}$$

which provides a Monte Carlo estimate of $\frac{1}{\sigma^2}\sum_{i=1}^{n}\text{Cov}(y_i, \hat{y}_i)$, the true degrees of freedom of CRISP. The results in Figure 6(a) empirically validate Proposition 1, showing that (6) is an unbiased estimator of CRISP's degrees of freedom. Note that the proofs of Proposition 1 and Corollary 2 can be found in Appendices E and F, respectively.

4.2 Range of λ that Yields a Constant Solution

CRISP has a single tuning parameter λ, which we typically will select via cross-validation or a related approach. Here, we derive the minimum value of λ such that $\boldsymbol{m}^* = \left(\frac{1}{n}\boldsymbol{1}^T\boldsymbol{y}\right)\boldsymbol{1}$, corresponding to a fit in which all elements of $\boldsymbol{m}^*$ are equal.

Lemma 3 *The solution to (4) is constant (i.e., $\boldsymbol{m}^* = \left(\frac{1}{n}\boldsymbol{1}^T\boldsymbol{y}\right)\boldsymbol{1}$) if and only if*

$$\lambda \geq \max_{1\leq i\leq q-1}\{\|\boldsymbol{d}_{1i}^*\|_2, \|\boldsymbol{d}_{2i}^*\|_2\},$$

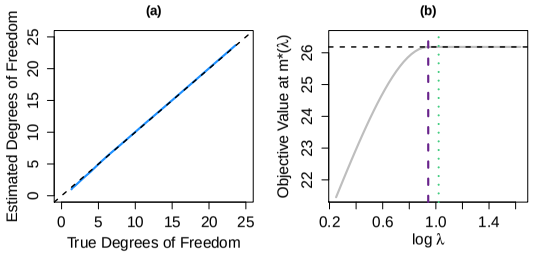

Figure 6: In *(a)*, we compare the degrees of freedom calculated using our estimator (7) (y-axis) from Section 4.1 to the unbiased, Monte Carlo estimator (6) (x-axis). Varying λ gives the solid line, and the dashed line indicates $y = x$. In *(b)*, we plot the value of the objective of (4) at $\boldsymbol{m}^*(\lambda)$, the minimizer of (4) at λ, for a replicate of data as λ varies. We compare two ways of finding a λ large enough such that $\boldsymbol{m}^*(\lambda) = \left(\frac{1}{n}\boldsymbol{1}^T\boldsymbol{y}\right)\boldsymbol{1}$, which results in the objective shown as - - -. We take $\lambda = \max_{1\leq i\leq q-1}\{\|\boldsymbol{d}_{1i}\|_2, \|\boldsymbol{d}_{2i}\|_2\}$ with either $\boldsymbol{d}$ being the solution to (8) (— —) or $\boldsymbol{d} = (\boldsymbol{A}^T)^+\boldsymbol{Q}^T\left(\boldsymbol{y} - \left(\frac{1}{n}\boldsymbol{1}^T\boldsymbol{y}\right)\boldsymbol{1}\right)$ (· - - ·). The former (— —) matches the result of Lemma 3 in Section 4.2.

where $\boldsymbol{d}^* = (\boldsymbol{d}_{11}^{*T} \cdots \boldsymbol{d}_{1(q-1)}^{*T}\ \boldsymbol{d}_{21}^{*T} \ldots \boldsymbol{d}_{2(q-1)}^{*T})^T$ is the solution to

$$\underset{\boldsymbol{d}}{\text{minimize}} \quad \max_{1\leq i\leq q-1}\{\|\boldsymbol{d}_{1i}\|_2, \|\boldsymbol{d}_{2i}\|_2\} \quad \textit{subject to} \quad \boldsymbol{Q}^T\left(\boldsymbol{y} - \left(\frac{1}{n}\boldsymbol{1}^T\boldsymbol{y}\right)\boldsymbol{1}\right) = \boldsymbol{A}^T\boldsymbol{d}. \tag{8}$$

Recall that the matrix $\boldsymbol{Q}$ was defined in (3). Taking $\lambda = \max_{1\leq i\leq q-1}\left\{\|\tilde{\boldsymbol{d}}_{1i}\|_2, \|\tilde{\boldsymbol{d}}_{2i}\|_2\right\}$ for any feasible vector $\tilde{\boldsymbol{d}}$ for (8) will give a value of λ sufficiently large so $\boldsymbol{m}^*$ is constant. For example, we can choose $\tilde{\boldsymbol{d}} = (\boldsymbol{A}^T)^+\boldsymbol{Q}^T\left(\boldsymbol{y} - \left(\frac{1}{n}\boldsymbol{1}^T\boldsymbol{y}\right)\boldsymbol{1}\right)$. However, choosing λ in accordance with Lemma 3 will give the minimum value of λ such that $\boldsymbol{m}^* = \left(\frac{1}{n}\boldsymbol{1}^T\boldsymbol{y}\right)\boldsymbol{1}$. The optimization problem (8) can be solved using a standard convex solver, such as SDPT3 via `CVX` in `MATLAB` (Grant and Boyd, 2008, 2014). An illustration of Lemma 3 is provided in Figure 6(b).

4.3 Controlling the Granularity of CRISP

Both q and λ control the granularity of the final CRISP model: q controls the size of the grid used to construct $\boldsymbol{M}$, and λ controls the number of blocks in the final fitted CRISP model. For a range of very small λ values, there will be q^2 blocks; for larger λ values, the CRISP solution will have a smaller number of blocks.

Given that q and λ both influence the number of blocks in the final fitted CRISP model, one might wonder whether it is necessary to have both q and λ. We illustrate the value of both q and λ through some simple examples.

4.3.1 Choice of q

In principle, q may be chosen to equal n. This means that each bin of the $q \times q$ grid would contain at most one observation. However, when n is large, choosing $q = n$ can lead to excessive computational time, memory burden, and variance in the fit. Instead, we aim to choose q to be large enough to allow for adequate granularity, but not excessively large. What constitutes adequate granularity will depend on the context of the problem.

In our analyses, we choose to treat q as a fixed parameter that is chosen prior to fitting CRISP. However, if desired, q could be chosen by K-fold cross validation.

4.3.2 Choice of λ

To illustrate the role of λ, consider taking $\lambda = 0$ in (3), and treating q as a tuning parameter rather than a fixed value. When $\lambda = 0$, (3) contains only a sum of squared errors term, so the estimate within each bin is the mean value of the observations in that bin. For bins without any observations, we estimate the corresponding element of $\boldsymbol{M}$ to be the overall mean of $\boldsymbol{y}$.

For the mean models shown in Figure 2, we compare CRISP to (3) with $\lambda = 0$ and q chosen adaptively. We focus on the general findings here, but detailed results are given in Appendix H. When the true mean model is piecewise constant with boundaries that are well-approximated by a grid of bins (as in Scenarios 1–3), CRISP and (3) with $\lambda = 0$ and variable q perform similarly. However, CRISP is clearly superior at estimating the smooth mean model of Scenario 4 (Figure 12), as it is able to borrow information across bins, instead of simply fitting the mean of observations within each bin. CRISP also allows the granularity of the fitted model to vary adaptively over the covariate space, as shown in Figure 13(a) of Appendix H. The blocks of this mean model perfectly align with a grid that has $q = 3$, but the mean model only has 4 blocks. While (3) with $\lambda = 0$ and $q = 3$ fits 9 blocks, CRISP correctly identifies 4 blocks (Figures 13(b) and 13(c) of Appendix H).

5. Connections to Other Methods

In this section, we establish connections between CRISP and two previous proposals.

5.1 Connection to One-Dimensional Fused Lasso

Suppose that for a given value of λ, the CRISP fit involves only one covariate: that is, $\boldsymbol{M}^* = \tilde{\boldsymbol{m}}\mathbf{1}_q^T$ or $\boldsymbol{M}^* = \mathbf{1}_q\tilde{\boldsymbol{m}}^T$ for some $\tilde{\boldsymbol{m}} \in \mathbb{R}^q$. We will now show that in this setting, the CRISP solution can be recovered by solving a one-dimensional fused lasso problem (Tibshirani et al., 2005).

Before presenting Lemma 4, we introduce some notation. Define $\boldsymbol{D} = [\boldsymbol{I}_{(q-1)\times(q-1)}\ \mathbf{0}_{(q-1)\times 1}] - [\mathbf{0}_{(q-1)\times 1}\ \boldsymbol{I}_{(q-1)\times(q-1)}]$ to be the first difference matrix. Define $\tilde{\boldsymbol{y}} \in \mathbb{R}^q$ such that $\tilde{y}_i$ is the mean outcome value of the observations in the ith row of the $q \times q$ grid used to construct $\boldsymbol{M}$. Let n_i denote the number of observations in the ith row of the $q \times q$ grid used to construct $\boldsymbol{M}$. Define $\boldsymbol{W} \in \mathbb{R}^{q\times q}$ to be the diagonal matrix with entries $\sqrt{n_1}, \sqrt{n_2}, \ldots, \sqrt{n_q}$.

Lemma 4 *Suppose that, for some value of λ, the CRISP solution is of the form $\boldsymbol{M}^* = \tilde{\boldsymbol{m}}\mathbf{1}_q^T$ for some $\tilde{\boldsymbol{m}} \in \mathbb{R}^q$. Then $\tilde{\boldsymbol{m}}$ is the solution to the problem*

$$\underset{\tilde{\boldsymbol{m}}\in\mathbb{R}^q}{\text{minimize}} \quad \frac{1}{2}\left\|\boldsymbol{W}(\tilde{\boldsymbol{y}} - \tilde{\boldsymbol{m}})\right\|_2^2 + \lambda\sqrt{q}\left\|\boldsymbol{D}\tilde{\boldsymbol{m}}\right\|_1. \tag{9}$$

If instead $\boldsymbol{M}^* = \mathbf{1}_q\tilde{\boldsymbol{m}}^T$, then a result similar to Lemma 4 holds, with modifications to the definitions of $\boldsymbol{W}$ and $\tilde{\boldsymbol{y}}$.

Equation 9 is a weighted fused lasso problem with response vector $\tilde{\boldsymbol{y}}$ and weights $\sqrt{n_1}, \sqrt{n_2}, \ldots, \sqrt{n_q}$. When $q = n$, (9) simplifies to a standard one-dimensional fused lasso problem.

Corollary 5 *If $q = n$ and $\boldsymbol{M}^* = \tilde{\boldsymbol{m}}\mathbf{1}_n^T$, then $\tilde{\boldsymbol{m}}$ is the solution to the one-dimensional fused lasso problem*

$$\underset{\tilde{\boldsymbol{m}}\in\mathbb{R}^n}{\text{minimize}} \quad \frac{1}{2}\left\|\boldsymbol{P}\boldsymbol{y} - \tilde{\boldsymbol{m}}\right\|_2^2 + \lambda\sqrt{n}\left\|\boldsymbol{D}\tilde{\boldsymbol{m}}\right\|_1, \tag{10}$$

where $\boldsymbol{P}$ is the permutation matrix that orders the elements of $\boldsymbol{x}_1$ from least to greatest.

If instead $\boldsymbol{M}^* = \mathbf{1}_n\tilde{\boldsymbol{m}}^T$, then Corollary 5 holds with $\boldsymbol{P}$ defined to be the permutation matrix that orders the elements of $\boldsymbol{x}_2$ from least to greatest.

5.2 Connection to Fused Lasso Additive Model

In this subsection, we will establish that CRISP is a generalization of the fused lasso additive model (FLAM) proposal of Petersen et al. (forthcoming). FLAM fits an additive model in which each covariate's fit is estimated to be piecewise constant with adaptively-chosen knots.

For simplicity, assume that $q = n$. Consider a modification of CRISP in which we impose additivity on the mean matrix $\boldsymbol{M}$. That is, we assume $f(x_1, x_2) = \theta_0 + f_1(x_1) + f_2(x_2)$, where θ_0 is an overall mean, and f_1 and f_2 are mean-zero over the training observations. We introduce the n-vectors $\boldsymbol{\theta}_1$ and $\boldsymbol{\theta}_2$, where $f_1(x_{i1}) = \theta_{1i}$ and $f_2(x_{i2}) = \theta_{2i}$ for all $i = 1, \ldots, n$. Thus the additivity constraint for the (i, j) element of $\boldsymbol{M}$, $M_{(i)(j)}$, can be expressed as

$$M_{(i)(j)} = \theta_0 + \theta_{1i} + \theta_{2j} \text{ for } i = 1, \ldots, n;\ j = 1, \ldots, n \quad \text{with} \quad \mathbf{1}^T\boldsymbol{\theta}_1 = \mathbf{1}^T\boldsymbol{\theta}_2 = 0. \tag{11}$$

Lemma 6 *CRISP (1)–(2) with $q = n$ and with the additional additivity constraint (11) is equivalent to FLAM with $p = 2$, which is the solution to the optimization problem*

$$\begin{aligned} &\underset{\theta_0\in\mathbb{R},\boldsymbol{\theta}_1,\boldsymbol{\theta}_2\in\mathbb{R}^n}{\text{minimize}} \quad \frac{1}{2}\left\|\boldsymbol{y} - (\theta_0\mathbf{1} + \boldsymbol{\theta}_1 + \boldsymbol{\theta}_2)\right\|_2^2 + \lambda\left(\left\|\boldsymbol{D}\boldsymbol{P}_1\boldsymbol{\theta}_1\right\|_1 + \left\|\boldsymbol{D}\boldsymbol{P}_2\boldsymbol{\theta}_2\right\|_1\right) \\ &\textit{subject to } \mathbf{1}^T\boldsymbol{\theta}_1 = \mathbf{1}^T\boldsymbol{\theta}_2 = \mathbf{0}, \end{aligned} \tag{12}$$

where $\lambda \geq 0$ is a tuning parameter, $\boldsymbol{P}_j$ is the permutation matrix that orders the elements of $\boldsymbol{x}_j$ from least to greatest, and $\boldsymbol{D} = [\boldsymbol{I}_{(n-1)\times(n-1)}\ \mathbf{0}_{(n-1)\times 1}] - [\mathbf{0}_{(n-1)\times 1}\ \boldsymbol{I}_{(n-1)\times(n-1)}]$ is the first difference matrix.

The proof of Lemma 6 follows from algebraic manipulation.

CRISP (1)–(2) with the additivity constraint (11) is also equivalent to FLAM when the ℓ_2 norms in the penalty (2) are changed to ℓ_1 or ℓ_∞ norms. These alternative penalties are discussed further in Appendix B.

Lemma 6 can be generalized in order to establish that CRISP with $q < n$ is equivalent to a version of FLAM that re-weights the loss function in (12) appropriately.

6. Data Application

We consider predicting median house value on the basis of median income and average occupancy, measured for 20,640 neighborhoods in California. The data set was originally considered in Pace and Barry (1997) and is publicly available from the Carnegie Mellon StatLib data repository (`lib.stat.cmu.edu`).

For this analysis, we focus on predicting median house value for the central area of the covariate space. In particular, we filter the neighborhoods to select those with median incomes and average occupancies that both fall within the central 95% of the covariate distribution, which results in 18,662 neighborhoods to be analyzed. Further details are provided in Appendix I. To illustrate the impact that the size of the data set may have on the preferred analysis approach, we consider five different training set sizes: 100, 500, 1000, 5000, and 11,198 (which corresponds to 60% of the observations). We use the observations not selected for the training set as the test set. For each training set size, we consider 10 different data samples. We compare the performance of CRISP (with $q = 100$) to CART and TPS.

Figure 7 shows that income is positively associated with house value. Occupancy is not strongly associated with house value in low-income neighborhoods. However, among neighborhoods with median incomes exceeding around \$50,000, neighborhoods with mostly single or double occupancy tend to have more expensive homes than those with higher occupancies and the same income. This is perhaps because single people and couples without children have more disposable income to spend on housing than families at the same income level.

In Figure 7, we show estimated mean models from CRISP for two different values of λ. The larger value of λ has slightly worse prediction performance, but has a simple block structure reminiscent of CART. The smaller value of λ gives better prediction performance with a more complex fit structure that resembles the fits from TPS. This illustrates how CRISP's tuning parameter, λ, balances the trade-off between interpretability and prediction performance.

While the fit from CART in Figure 7 is quite interpretable, CART gives highly-variable fits across different splits of the data. This is illustrated in Figure 8. The average variance of predictions from CART across the 10 splits of data is more than three times that of CRISP and TPS. For larger training sets, the variance decreases, though the variability of the CART predictions remains much larger than that of CRISP and TPS. In Figure 8, we also see that CART's performance in terms of test set mean squared error (MSE) is worse than CRISP and TPS, but becomes increasingly similar with larger sample sizes. For example, in Figure 9, we show the results for the largest training set sample considered ($n = 11,198$). We see that all three methods perform very similarly in terms of test set MSE, and provide qualitatively similar estimated mean models. As the available sample size increases, the differences between CRISP, TPS, and CART in terms of prediction performance and interpretability of fits become less pronounced.

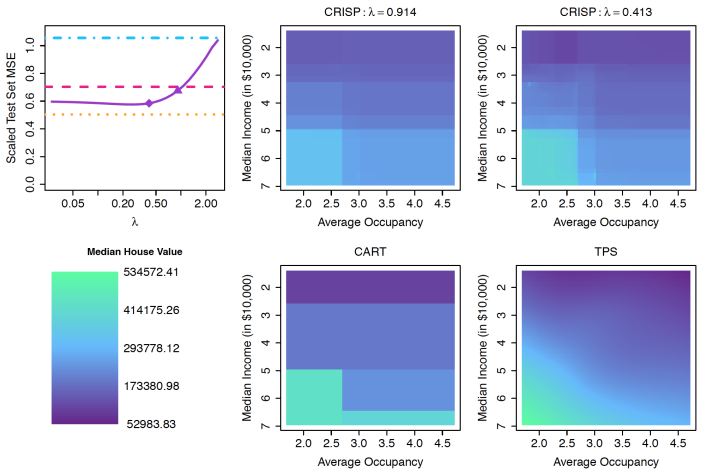

Figure 7: We consider predicting median house value on the basis of median income and average occupancy using a training set of size $n = 100$, as considered in Section 6. We plot the average value for 10 data samples of test set MSE divided by the variance of the training set outcome. We plot this scaled test set MSE versus λ for CRISP (▬), and show the minimum scaled test set MSE achieved by CART (▬ ▬), TPS (▬ ▬), and an intercept-only model (▬ ▬). Estimated mean models for CRISP are shown for a larger value of λ (indicated by ▲) and a smaller value (indicated by ◆). The estimated mean models shown for CART and TPS correspond to the tuning parameter with the minimum test set MSE. The heat scale legend for the median house value is shown.

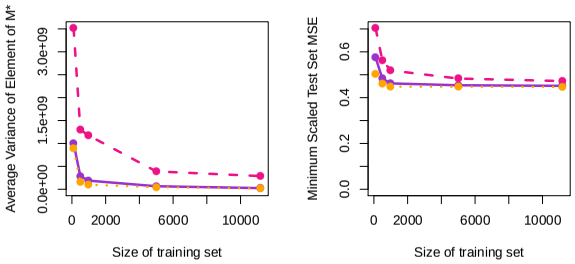

Figure 8: We plot the average variance of predictions and the minimum scaled test set MSE (as defined in Figure 7) as a function of training set sample size for CRISP (▬), CART (– – –), and TPS (- - -) applied to the housing data considered in Section 6.

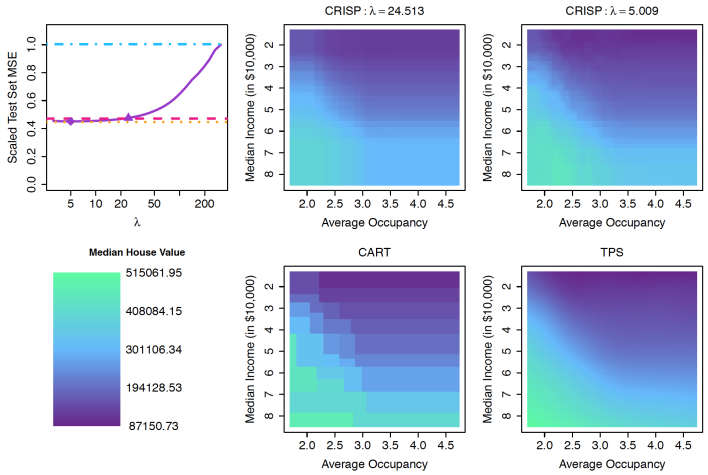

Figure 9: Results using median income and average occupancy as predictors of median house value using a training set of size $n = 11,198$, as considered in Section 6. Details are as in Figure 7.

7. Extension to $p > 2$

We have assumed thus far that $p = 2$. In this case, the estimated mean model for the entire covariate space can be summarized in a single plot, as in Figure 2.

We extend CRISP to the setting of $p > 2$ by constructing an *additive model of bivariate fits*. That is, we estimate the fit for each of the $\frac{p(p-1)}{2}$ *pairs* of features, giving a bivariate fit for each pair of covariates like those obtained in the setting of $p = 2$ and shown in Figure 2. We assume that the mean model is additive in these fits. We restrict the model to pairwise interactions between covariates for a couple of reasons. First, only considering pairwise interactions increases interpretability and reduces model complexity. Our model fit with pairwise interactions can be summarized using $\frac{p(p-1)}{2}$ plots, like those shown in Figure 2. There is no analogous way to easily summarize the model if we were to include higher-order interactions. Second, considering higher-order interactions would cause our model to suffer from the *curse of dimensionality*. That is, as the number of covariates increases, the data in any region of the p-dimensional space will become sparser and sparser: there would be an insufficient density of data throughout the covariate space to reasonably estimate a mean model with higher-order interactions.

We now present the details of our proposal for CRISP with $p > 2$. We consider interactions between each pair of features, $\{(j, j') : 1 \leq j < j' \leq p\}$. For ease of notation, we refer to the elements of this set using the index $k \in (1, \ldots, K)$ where $K = \frac{p(p-1)}{2}$. Recall that for $p = 2$, the mean model for CRISP is $\mathrm{E}[\boldsymbol{y} \mid \boldsymbol{x}_1, \boldsymbol{x}_2] = \boldsymbol{Q}\boldsymbol{m}$, where $\boldsymbol{m} \in \mathbb{R}^{q^2}$ is the vectorized mean matrix and $\boldsymbol{Q}$ selects the elements of $\boldsymbol{m}$ corresponding to the covariate bins of the elements of $\boldsymbol{y}$. Recall that $\boldsymbol{Q}$ is a function of $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$, though we suppress this to simplify the notation. For $p > 2$, we consider the mean model

$$\mathrm{E}[\boldsymbol{y} \mid \boldsymbol{x}_1, \ldots, \boldsymbol{x}_p] = m_0\mathbf{1} + \sum_{k=1}^{K} \boldsymbol{Q}_k \boldsymbol{m}_k,$$

where $m_0 \in \mathbb{R}$ is an intercept, $\boldsymbol{m}_k \in \mathbb{R}^{q^2}$ is the vectorized mean matrix for the pair of features indexed by k, and $\boldsymbol{Q}_k \in \mathbb{R}^{n \times q^2}$ selects the elements of $\boldsymbol{m}_k$ corresponding to the covariate bins for the pair of covariates indexed by k. We include the intercept $m_0 \in \mathbb{R}$ in our model, and assume that $\boldsymbol{m}_1, \ldots, \boldsymbol{m}_K$ are mean-zero, to ensure identifiability.

When $p > 2$, we extend the CRISP optimization problem (4) as follows:

$$\underset{m_0, \boldsymbol{m}_k, \boldsymbol{z}_k : k=1,\ldots,K}{\text{minimize}} \quad \frac{1}{2} \left\| \boldsymbol{y} - \left(m_0\mathbf{1} + \sum_{k=1}^{K} \boldsymbol{Q}_k \boldsymbol{m}_k \right) \right\|_2^2 + \lambda \sum_{k=1}^{K} \sum_{i=1}^{q-1} \left[\|\boldsymbol{z}_{k,1i}\|_2 + \|\boldsymbol{z}_{k,2i}\|_2 \right] \quad (13)$$
$$\text{subject to } \boldsymbol{A}\boldsymbol{m}_k = \boldsymbol{z}_k, \mathbf{1}^T \boldsymbol{m}_k = 0,$$

where $\boldsymbol{A}$ is as defined in Section 2.2. Thus $\hat{\boldsymbol{y}} = m_0^*\mathbf{1} + \sum_{k=1}^{K} \boldsymbol{Q}_k \boldsymbol{m}_k^*$, where $(m_0^*, \boldsymbol{m}_1^*, \ldots, \boldsymbol{m}_K^*)$ is the solution to (13).

Problem (13) can be solved using block coordinate descent (Tseng, 2001), which gives Algorithm 2. We iterate through the pairs of covariates, and perform a partial minimization (using Algorithm 1) for each $\boldsymbol{m}_k$, while keeping the others fixed. Using an argument similar to that in Section 2.3, the computational complexity of Algorithm 2 is $\mathcal{O}(K(n + q^4))$ for

an initial step and $\mathcal{O}(q^3)$ for each iteration of Step 2(b) of Algorithm 2. In practice, the number of iterations needed to achieve convergence in Step 2(b) of Algorithm 2 is relatively small.

We present a block coordinate descent algorithm, since it is a natural extension of Algorithm 1 to the $p > 2$ setting. However, CRISP with $p \gg 2$ can alternatively be fit using generalized gradient descent, which allows the updates for each bivariate fit to be run in parallel on a cluster.

Algorithm 2 — Block Coordinate Descent for CRISP with $p > 2$ (Equation (13))

1. Initialize $m_0^* = 0$ and $\boldsymbol{m}_k^* = \boldsymbol{0}$ for all $k = 1, \ldots, K$.
2. For $k = 1, \ldots, K, 1, \ldots, K, \ldots$, until convergence of the objective of (13):
   (a) Compute the residual $\boldsymbol{r}_k = \boldsymbol{y} - \left(m_0^* \boldsymbol{1} + \sum_{k' \neq k} \boldsymbol{Q}_{k'} \boldsymbol{m}_{k'}^*\right)$.
   (b) Using Algorithm 1, solve
   $$\underset{\boldsymbol{m}_k, \boldsymbol{z}_k}{\text{minimize}} \quad \frac{1}{2} \|\boldsymbol{r}_k - \boldsymbol{Q}_k \boldsymbol{m}_k\|_2^2 + \lambda \sum_{i=1}^{q-1} \left[\|\boldsymbol{z}_{k,1i}\|_2 + \|\boldsymbol{z}_{k,2i}\|_2\right] \quad \text{subject to } \boldsymbol{A}\boldsymbol{m}_k = \boldsymbol{z}_k.$$
   Let $\boldsymbol{m}_k^*$ denote the solution.
   (c) Compute the intercept, $m_0^* \leftarrow m_0^* + \text{mean}(\boldsymbol{m}_k^*)$, and center, $\boldsymbol{m}_k^* \leftarrow \boldsymbol{m}_k^* - \text{mean}(\boldsymbol{m}_k^*)$.

8. Discussion

We have presented CRISP, a method for fitting interpretable, flexible, and non-additive predictive models. CRISP fits have an easily-interpreted block structure, which is somewhat reminiscent of the fits from CART. But the fits from CRISP result from a non-greedy procedure, and are much less variable than those of CART. In our numerical studies, the prediction performance of CRISP is similar to TPS, and in many cases CRISP provides a simpler and more interpretable fit.

Future work could consider an alternative penalization scheme. Recall that CRISP first divides the covariate space into a $q \times q$ grid of bins. Our proposal only uses the information about the bin into which each of the n observations falls, which is used to construct $\boldsymbol{Q}$ in (4). Thus CRISP only makes use of the rankings of the observations for each covariate, rather than the actual values of the covariates. A modification to (4) could allow us to more heavily penalize the differences between pairs of neighboring rows or columns corresponding to observations with similar values in a given covariate. This modification is not very important when the covariate pairs are distributed uniformly over the covariate space, as in our simulation study in Section 3.

In this paper, we have only considered the setting of $p \ll n$. An extension of CRISP to larger p is left to future work.

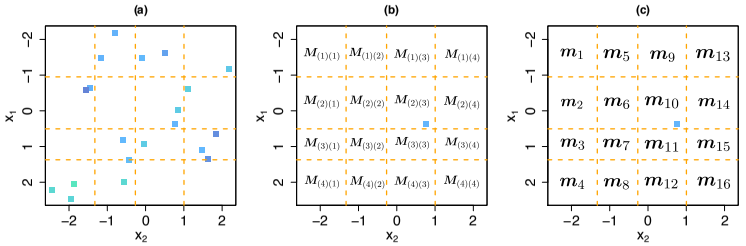

Figure 10: In *(a)*, each of the 20 squares represents an observation (x_1, x_2, y). There are $q^2 = 16$ bins of (x_1, x_2) values, whose boundaries coincide with the quartiles (- - -) of $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$. In *(b)* and *(c)*, we label the elements of $\boldsymbol{M}$ and $\boldsymbol{m}$, respectively, corresponding to each bin of (x_1, x_2) values. Additionally, in *(b)* and *(c)*, we show $(x_{1i}, x_{2i}) = (0.4, 0.8)$, which is used in Appendix A to describe the construction of $\boldsymbol{Q}$.

Appendix A. Notational Details

We first give an intuitive explanation of our vectorization scheme. Recall that each row of $\boldsymbol{Q} \in \mathbb{R}^{n \times q^2}$ contains $q^2 - 1$ elements that equal 0, and a single 1 that extracts an element of $\boldsymbol{m}$ according to the covariate values for that observation. For example, consider the ith row of $\boldsymbol{Q}$ for $(x_{1i}, x_{2i}) = (0.4, 0.8)$ in Figure 10(a). These covariate values fall within the 2nd row and 3rd column of the 4×4 grid, meaning that $\boldsymbol{M}_{(2)(3)}$ provides an estimate for y_i. After vectorizing $\boldsymbol{M}$, $\boldsymbol{M}_{(2)(3)}$ is $\boldsymbol{m}_{10}$, the 10th element of the mean vector. Note that we can convert between the matrix and vector notation by taking the column number minus one multiplied by q and adding the row number (e.g., $(3-1) \times 4 + 2$). The correspondence between $\boldsymbol{M}$ and $\boldsymbol{m}$ is illustrated in Figures 10(b) and 10(c). Thus the ith row of $\boldsymbol{Q}$ would contains all zeros, except a single 1 for the 10th element. Finally, $(\boldsymbol{Q}\boldsymbol{m})_i = m_{10}$.

Before formally defining the function Ω and matrices $\boldsymbol{Q}$, $\boldsymbol{R}_i$ for $i = 1, \ldots, q-1$, and $\boldsymbol{C}_i$ for $i = 1, \ldots, q-1$ introduced in Section 2.2, we define a quantile function. We use quantile$(\cdot)$ to denote the quantile range into which an element falls: quantile$(x_{1i}) = k$ if x_{1i} is between the $\frac{k-1}{q}$- and $\frac{k}{q}$-quantiles of $\boldsymbol{x}_1$. For example, if $n = q = 4$ and $\boldsymbol{x}_1 = (9\ 3\ 5\ 2)^T$, then quantile$(x_{11}) = 4$. Similarly, if $n = 6$, $q = 3$, and $\boldsymbol{x}_1 = (7\ 2\ 3\ 8\ 1\ 5)^T$, then quantile$(x_{16}) = 2$.

We define the function Ω as $\Omega(\boldsymbol{M}, x_{1i}, x_{2i}) = M_{(a)(b)}$ where $a = \text{quantile}(x_{1i})$ and $b = \text{quantile}(x_{2i})$.

We construct $\boldsymbol{Q} \in \mathbb{R}^{n \times q^2}$ such that

$$[\boldsymbol{Q}]_{jk} = \begin{cases} 1 & \text{if } k = \text{quantile}(x_{1j}) + q \times (\text{quantile}(x_{2j}) - 1) \\ 0 & \text{otherwise} \end{cases},$$

$\boldsymbol{R}_i \in \mathbb{R}^{q \times q^2}$ for $i = 1, \ldots, q-1$ such that

$$[\boldsymbol{R}_i]_{jk} = \begin{cases} 1 & \text{if } k = i + q \times (j-1) \\ -1 & \text{if } k = i + 1 + q \times (j-1) \\ 0 & \text{otherwise} \end{cases},$$

and $\boldsymbol{C}_i \in \mathbb{R}^{q \times q^2}$ for $i = 1, \ldots, q-1$ such that

$$[\boldsymbol{C}_i]_{jk} = \begin{cases} 1 & \text{if } k = j + q \times (i-1) \\ -1 & \text{if } k = j + q \times i \\ 0 & \text{otherwise} \end{cases}.$$

Appendix B. Alternative Penalties

A more general formulation of our proposal in (1) is

$$\underset{\boldsymbol{M} \in \mathbb{R}^{q \times q}}{\text{minimize}} \quad \frac{1}{2} \sum_{i=1}^{n} \left(y_i - \Omega(\boldsymbol{M}, x_{1i}, x_{2i})\right)^2 + \lambda \sum_{i=1}^{q-1} \left[\left\| \boldsymbol{M}_{i\cdot} - \boldsymbol{M}_{(i+1)\cdot} \right\|_t + \left\| \boldsymbol{M}_{\cdot i} - \boldsymbol{M}_{\cdot(i+1)} \right\|_t \right], \quad (14)$$

which is equivalent to (1) for $t = 2$. One might consider solving (14) for $t = \infty$, which (like $t = 2$) encourages pairs of neighboring rows or columns of $\boldsymbol{M}$ to be identical. We compare the fit for $t = 2$ to that for $t = \infty$ in Figure 11(a)–(b). While $t = \infty$ gives desirable fits similar to $t = 2$, the computational time required is much higher than that for $t = 2$. This is because when adapted to $t = \infty$, Step 2(b) of Algorithm 1 no longer has a closed-form solution (Duchi and Singer, 2009).

We also consider the use of $t = 1$ in (14); this encourages each element of $\boldsymbol{M}$ to equal its four adjacent elements. However, using $t = 1$ gives very poor results: the bins of $\boldsymbol{M}$ containing observations are estimated to be shrunken versions of their observed values, while the bins of $\boldsymbol{M}$ without observations are estimated to be a common value (Figure 11(c)). In a sense, the penalization for $t = 1$ is too local given the data sparsity (e.g., only q of q^2 elements observed when $q = n$).

The results for $t = 1$ improve if an additional penalty is added to the objective function. First, note that (14) can also be written as

$$\underset{\boldsymbol{M} \in \mathbb{R}^{q \times q}}{\text{minimize}} \quad \frac{1}{2} \sum_{i=1}^{n} \left(y_i - \Omega(\boldsymbol{M}, x_{1i}, x_{2i})\right)^2 + \lambda \left(\|\boldsymbol{M}^T \boldsymbol{D}^T\|_{t,1} + \|\boldsymbol{M} \boldsymbol{D}^T\|_{t,1} \right), \quad (15)$$

where $\boldsymbol{D} = [\boldsymbol{I}_{(q-1)\times(q-1)} \; \boldsymbol{0}_{(q-1)\times 1}] - [\boldsymbol{0}_{(q-1)\times 1} \; \boldsymbol{I}_{(q-1)\times(q-1)}]$. Motivated by a proposal from van de Geer (2000), we add an additional penalty to (15) with $t = 1$,

$$\underset{\boldsymbol{M} \in \mathbb{R}^{q \times q}}{\text{minimize}} \quad \frac{1}{2} \sum_{i=1}^{n} \left(y_i - \Omega(\boldsymbol{M}, x_{1i}, x_{2i})\right)^2 + \lambda \left(\|\boldsymbol{M}^T \boldsymbol{D}^T\|_{1,1} + \|\boldsymbol{M} \boldsymbol{D}^T\|_{1,1} + \|\boldsymbol{D}\boldsymbol{M}\boldsymbol{D}^T\|_{1,1} \right). \quad (16)$$

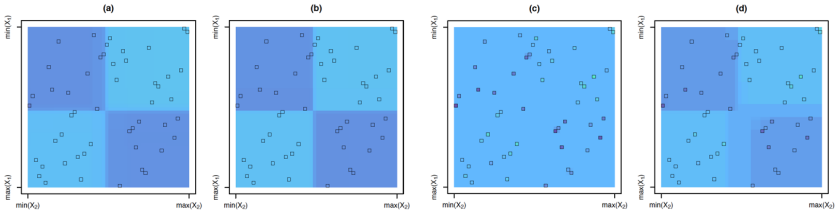

Figure 11: The estimated mean model from solving (14) for *(a)* $t = 2$ (CRISP), *(b)* $t = \infty$, and *(c)* $t = 1$, as well as *(d)* the estimated mean model from solving (16). The methods are described in detail in Appendix B. Note that $q = n$ was used for all methods. Data was generated for $n = 50$ from Scenario 2 (described in Section 3). The locations of the 50 observations are outlined in each plot. The heat scale legend is in Figure 1(e).

The penalty $\|\boldsymbol{D}\boldsymbol{M}\boldsymbol{D}^T\|_{1,1}$ encourages $|M_{(i)(j)} + M_{(i-1)(j-1)} - M_{(i-1)j} - M_{i(j-1)}|$ to equal zero, which results in a block structure as shown in Figure 11(d). While (16) outperforms (14) with $t = 1$, CRISP with $t = 2$ yields better results.

Appendix C. Details of Algorithm 1

C.1 Derivation of Algorithm 1

The scaled augmented Lagrangian of (4) is

$$L_\rho(\boldsymbol{m}, \boldsymbol{z}, \boldsymbol{u}) = \frac{1}{2} \|\boldsymbol{y} - \boldsymbol{Q}\boldsymbol{m}\|_2^2 + \lambda \sum_{i=1}^{q-1} \left[\|\boldsymbol{z}_{1i}\|_2 + \|\boldsymbol{z}_{2i}\|_2 \right] + \frac{\rho}{2} \sum_{i=1}^{q-1} \left[\|\boldsymbol{R}_i \boldsymbol{m} - \boldsymbol{z}_{1i} + \boldsymbol{u}_{1i}\|_2^2 + \|\boldsymbol{C}_i \boldsymbol{m} - \boldsymbol{z}_{2i} + \boldsymbol{u}_{2i}\|_2^2 \right] \quad (17)$$

where $\boldsymbol{u} = \left((\boldsymbol{u}_{11})^T \ldots (\boldsymbol{u}_{1(q-1)})^T (\boldsymbol{u}_{21})^T \ldots (\boldsymbol{u}_{2(q-1)})^T \right)^T$ is the scaled dual variable. Solving (4) using ADMM relies on initializing estimates $\boldsymbol{m}^{(0)} := \boldsymbol{0}, \boldsymbol{z}^{(0)} := \boldsymbol{0}$, and $\boldsymbol{u}^{(0)} := \boldsymbol{0}$ and then iterating over three steps until convergence. At iteration k, the updates are

Step 1. $\boldsymbol{m}^{(k)} := \underset{\boldsymbol{m}}{\text{argmin}} \quad L_\rho \left(\boldsymbol{m}^{(k-1)}, \boldsymbol{z}^{(k-1)}, \boldsymbol{u}^{(k-1)} \right)$

Step 2. $\boldsymbol{z}^{(k)} := \underset{\boldsymbol{z}}{\text{argmin}} \quad L_\rho \left(\boldsymbol{m}^{(k)}, \boldsymbol{z}^{(k-1)}, \boldsymbol{u}^{(k-1)} \right)$

Step 3. $\boldsymbol{u}_{1i}^{(k)} := \boldsymbol{u}_{1i}^{(k-1)} + \boldsymbol{R}_i \boldsymbol{m}^{(k)} - \boldsymbol{z}_{1i}^{(k)}$ for $i = 1, \ldots, q-1$
$\boldsymbol{u}_{2i}^{(k)} := \boldsymbol{u}_{2i}^{(k-1)} + \boldsymbol{C}_i \boldsymbol{m}^{(k)} - \boldsymbol{z}_{2i}^{(k)}$ for $i = 1, \ldots, q-1$

Note that Step 3 can equivalently be written as $\boldsymbol{u}^{(k)} := \boldsymbol{u}^{(k-1)} + \boldsymbol{A}\boldsymbol{m}^{(k)} - \boldsymbol{z}^{(k)}$. We provide details regarding Steps 1 and 2 below.

Details of Step 1

The optimality condition of (17) for $\boldsymbol{m}$ is

$$\frac{\partial L_\rho}{\partial \boldsymbol{m}} = -\boldsymbol{Q}^T(\boldsymbol{y} - \boldsymbol{Q}\boldsymbol{m}) + \rho \sum_{i=1}^{q-1} \left[\boldsymbol{R}_i^T(\boldsymbol{R}_i\boldsymbol{m} - \boldsymbol{z}_{1i} + \boldsymbol{u}_{1i}) + \boldsymbol{C}_i^T(\boldsymbol{C}_i\boldsymbol{m} - \boldsymbol{z}_{2i} + \boldsymbol{u}_{2i})\right] = \boldsymbol{0}$$

or equivalently, $-\boldsymbol{Q}^T(\boldsymbol{y} - \boldsymbol{Q}\boldsymbol{m}) + \rho\boldsymbol{A}^T(\boldsymbol{A}\boldsymbol{m} + \boldsymbol{u} - \boldsymbol{z}) = \boldsymbol{0}$. Therefore the update for Step 1 is $\boldsymbol{m}^{(k)} := \left[\boldsymbol{Q}^T\boldsymbol{Q} + \rho\boldsymbol{A}^T\boldsymbol{A}\right]^{-1}\left[\boldsymbol{Q}^T\boldsymbol{y} + \rho\boldsymbol{A}^T(\boldsymbol{z}^{(k-1)} - \boldsymbol{u}^{(k-1)})\right]$.

Details of Step 2

The *proximal operator* $\mathbf{prox}_{\lambda f}$ of λf is defined by $\mathbf{prox}_{\lambda f}(\boldsymbol{v}) = \underset{\boldsymbol{x}}{\operatorname{argmin}}\left(f(\boldsymbol{x}) + \frac{1}{2\lambda}\|\boldsymbol{x} - \boldsymbol{v}\|_2^2\right)$. The minimization for Step 2 is separable in the $\boldsymbol{z}_{1i}$ and $\boldsymbol{z}_{2i}$ for $i = 1, \ldots, q-1$. The minimization for $\boldsymbol{z}_{1i}$ is

$$\begin{aligned}
\boldsymbol{z}_{1i}^{(k)} &:= \underset{\boldsymbol{z}_{1i}}{\operatorname{argmin}} \left[\lambda\|\boldsymbol{z}_{1i}\|_2 + \frac{\rho}{2}\left\|\boldsymbol{R}_i\boldsymbol{m}^{(k)} - \boldsymbol{z}_{1i} + \boldsymbol{u}_{1i}^{(k-1)}\right\|_2^2\right] \\
&= \mathbf{prox}_{\frac{\lambda}{\rho}\|\cdot\|_2}\left(\boldsymbol{R}_i\boldsymbol{m}^{(k)} + \boldsymbol{u}_{1i}^{(k-1)}\right) \\
&= \left(\boldsymbol{R}_i\boldsymbol{m}^{(k)} + \boldsymbol{u}_{1i}^{(k-1)}\right)\left(1 - \frac{\lambda}{\rho\left\|\boldsymbol{R}_i\boldsymbol{m}^{(k)} + \boldsymbol{u}_{1i}^{(k-1)}\right\|_2}\right)_+ .
\end{aligned}$$

Similarly, the update for $\boldsymbol{z}_{2i}$ is $\boldsymbol{z}_{2i}^{(k)} := \left(\boldsymbol{C}_i\boldsymbol{m}^{(k)} + \boldsymbol{u}_{2i}^{(k-1)}\right)\left(1 - \frac{\lambda}{\rho\left\|\boldsymbol{C}_i\boldsymbol{m}^{(k)} + \boldsymbol{u}_{2i}^{(k-1)}\right\|_2}\right)_+$.

C.2 Stopping Criterion

We use the stopping criterion for Algorithm 1 suggested in Boyd et al. (2011), stopping when the primal residual $\boldsymbol{r}^{(k)} = \boldsymbol{A}\boldsymbol{m}^{(k)} - \boldsymbol{z}^{(k)}$ and dual residual $\boldsymbol{s}^{(k)} = \rho\boldsymbol{A}^T\left(\boldsymbol{z}^{(k-1)} - \boldsymbol{z}^{(k)}\right)$ are sufficiently small. Specifically, we check if

$$\|\boldsymbol{r}^{(k)}\|_2 \leq \sqrt{2q(q-1)}\epsilon^{abs} + \epsilon^{rel}\max\{\|\boldsymbol{A}\boldsymbol{m}^{(k)}\|_2, \|\boldsymbol{z}^{(k)}\|_2\} \quad \text{and} \quad \|\boldsymbol{s}^{(k)}\|_2 \leq q\epsilon^{abs} + \epsilon^{rel}\|\rho\boldsymbol{A}^T\boldsymbol{u}^{(k)}\|_2$$

with $\epsilon^{abs}, \epsilon^{rel} > 0$. We use $\epsilon^{abs} = 10^{-4}$ and $\epsilon^{rel} = 10^{-2}$ in order to obtain the results presented in Sections 3 and 6.

C.3 Varying Penalty Parameter

We can vary ρ from iteration to iteration in order to achieve better convergence and reduce the dependence of performance on the initially chosen ρ. We adopt the scheme for varying ρ that is reviewed in Boyd et al. (2011). Since we use the scaled dual variable, $\boldsymbol{u}$ must also

be updated in conjunction with the updating of ρ. At the end of each iteration, we apply the updates

$$(\rho^{(k+1)}, \boldsymbol{u}^{(k+1)}) := \begin{cases} (\tau^{incr}\rho^{(k)}, \boldsymbol{u}^{(k)}/\tau^{incr}) & \text{if } \|\boldsymbol{r}^{(k)}\|_2 > \delta\|\boldsymbol{s}^{(k)}\|_2 \\ (\rho^{(k)}/\tau^{decr}, \tau^{decr}\boldsymbol{u}^{(k)}) & \text{if } \|\boldsymbol{s}^{(k)}\|_2 > \delta\|\boldsymbol{r}^{(k)}\|_2 \\ (\rho^{(k)}, \boldsymbol{u}^{(k)}) & \text{otherwise} \end{cases}$$

where $\delta, \tau^{incr}, \tau^{decr} > 1$. We choose $\delta = 10$ and $\tau^{incr} = \tau^{decr} = 2$. Updating ρ keeps the norms of the residuals $\boldsymbol{r}^{(k)}$ and $\boldsymbol{s}^{(k)}$ within a factor of δ of one another. While convergence of ADMM has only been proven for fixed ρ, varying ρ has been shown to work well in practice (Boyd et al., 2011).

C.4 Modification to Provide Sparsity

Inspection of the updates for $\boldsymbol{z}_{1i}^*$ and $\boldsymbol{z}_{2i}^*$ in Algorithm 1 indicates that the ADMM algorithm yields sparsity in $\boldsymbol{z}_{1i}^*$ and $\boldsymbol{z}_{2i}^*$, but not necessarily exact equality of the rows and columns of $\boldsymbol{M}^*$. This is in effect a numerical issue: our algorithm might yield $\boldsymbol{z}_{1i} = \boldsymbol{0}$, but $\|\boldsymbol{M}_{i\cdot}^* - \boldsymbol{M}_{(i+1)\cdot}^*\|_2 = 1 \times 10^{-8}$. To resolve this issue, we first determine the "blocks" of $\boldsymbol{m}^*$ using an initial run of Algorithm 1, and then solve (4) once more with constraints on the rows and columns of $\boldsymbol{M}$ to enforce equality of the appropriate rows and columns. This second optimization is performed simply to yield an estimate of $\boldsymbol{M}$ for which elements are exactly equal within each block.

Appendix D. Details of Simulations in Section 3

The mean models $f(x_1, x_2)$ used to generate data for Scenarios 1–4 in Section 3 are defined as follows. Note that x_1 and x_2 are sampled uniformly from $[-2.5, 2.5]$. We define the indicator function $\mathbf{1}_{\mathcal{A}}(x) = \begin{cases} 1 & \text{if } x \in \mathcal{A} \\ 0 & \text{otherwise} \end{cases}$.

Scenario 1: $f(x_1, x_2) = \text{sign}(x_1) \times \mathbf{1}_{[0,\infty)}(x_1 \times x_2)$
Scenario 2: $f(x_1, x_2) = -\text{sign}(x_1 \times x_2)$
Scenario 3: $f(x_1, x_2) = -3 \times \mathbf{1}_{[-2.5,-0.83)}(x_1) \times \mathbf{1}_{[-2.5,-1.25)}(x_2) + \mathbf{1}_{[-2.5,-0.83)}(x_1) \times \mathbf{1}_{[-1.25,2.5]}(x_2) - 2\times\mathbf{1}_{[-0.83,0.83]}(x_1)\times\mathbf{1}_{[-2.5,0)}(x_2) + 2\times\mathbf{1}_{[-0.83,0.83]}(x_1)\times\mathbf{1}_{[0,2.5]}(x_2) - \mathbf{1}_{(0.83,2.5]}(x_1)\times\mathbf{1}_{[-2.5,1.25)}(x_2) + 3 \times \mathbf{1}_{(0.83,2.5]}(x_1) \times \mathbf{1}_{[1.25,2.5]}(x_2)$
Scenario 4: $f(x_1, x_2) = \frac{10}{\left(\frac{x_1-2.5}{3}\right)^2 + \left(\frac{x_2-2.5}{3}\right)^2 + 1} + \frac{10}{\left(\frac{x_1+2.5}{3}\right)^2 + \left(\frac{x_2+2.5}{3}\right)^2 + 1}$

Each of the mean models $f(x_1, x_2)$ defined above is centered and scaled such that $\int_{-2.5}^{2.5}\int_{-2.5}^{2.5} f(x_1, x_2)\, dx_1\, dx_2 = 0$ and $\frac{1}{25}\int_{-2.5}^{2.5}\int_{-2.5}^{2.5} f(x_1, x_2)^2\, dx_1\, dx_2 = 2$.

Appendix E. Proof Sketch of Proposition 1

Proof Using the dual problem of (5) and Lemma 1 of Tibshirani and Taylor (2012), it can be shown that $g : \mathbb{R}^n \to \mathbb{R}^n$ with $\hat{\boldsymbol{y}} = g(\boldsymbol{y}) = (g_1(\boldsymbol{y}), \ldots, g_n(\boldsymbol{y}))^T$ is continuous and almost differentiable. Thus, Stein's lemma implies that $\text{df}(\hat{\boldsymbol{y}}) = \text{E}\left[\text{Tr}\left(\frac{\partial g(\boldsymbol{y})}{\partial \boldsymbol{y}}\right)\right]$. At the optimum

of (5), we have

$$\boldsymbol{Q}^T(\boldsymbol{y}-\boldsymbol{Q}\boldsymbol{m}^*)=\lambda\sum_{i=1}^{q-1}[\boldsymbol{R}_i^T S_1(\boldsymbol{R}_i,\boldsymbol{m}^*)+\boldsymbol{C}_i^T S_1(\boldsymbol{C}_i,\boldsymbol{m}^*)]+\gamma\boldsymbol{m}^*, \tag{18}$$

where $S_1(\boldsymbol{A}_i,\boldsymbol{m}^*)=\begin{cases}\frac{\boldsymbol{A}_i\boldsymbol{m}^*}{\|\boldsymbol{A}_i\boldsymbol{m}^*\|_2} & \text{if } \|\boldsymbol{A}_i\boldsymbol{m}^*\|_2\neq 0\\ \in\{\boldsymbol{g}:\|\boldsymbol{g}\|_2\leq 1\} & \text{if } \|\boldsymbol{A}_i\boldsymbol{m}^*\|_2=0\end{cases}$.

We define $\mathcal{C}=\{\boldsymbol{A}_i:\|\boldsymbol{A}_i\boldsymbol{m}^*\|_2=0\}$ where $\boldsymbol{A}_1=\boldsymbol{R}_1,\boldsymbol{A}_2=\boldsymbol{R}_2,\ldots,\boldsymbol{A}_{q-1}=\boldsymbol{R}_{q-1},\boldsymbol{A}_q=\boldsymbol{C}_1,\boldsymbol{A}_{q+1}=\boldsymbol{C}_2,\ldots,\boldsymbol{A}_{2q-2}=\boldsymbol{C}_{q-1}$. We define $\boldsymbol{A}_*$ to be the submatrix of $\boldsymbol{A}$ with the rows corresponding to $\boldsymbol{A}_i\notin\mathcal{C}$ removed, and let $\boldsymbol{P}=\boldsymbol{I}_{q^2}-\boldsymbol{A}_*^+\boldsymbol{A}_*$, the projection onto the space orthogonal to the row space of $\boldsymbol{A}_*$. We left-multiply (18) by $\boldsymbol{P}$ to give

$$\boldsymbol{P}\boldsymbol{Q}^T(\boldsymbol{y}-\boldsymbol{Q}\boldsymbol{m}^*)=\lambda\boldsymbol{P}\sum_{i:\boldsymbol{A}_i\notin\mathcal{C}}\frac{\boldsymbol{A}_i^T\boldsymbol{A}_i\boldsymbol{m}^*}{\|\boldsymbol{A}_i\boldsymbol{m}^*\|_2}+\gamma\boldsymbol{P}\boldsymbol{m}^*, \tag{19}$$

since $\boldsymbol{P}\boldsymbol{A}_i^T S_1(\boldsymbol{A}_i,\boldsymbol{m}^*)=\boldsymbol{0}$ if $\boldsymbol{A}_i\in\mathcal{C}$ (i.e., $\|\boldsymbol{A}_i\boldsymbol{m}^*\|_2=0$). Because $\boldsymbol{P}\boldsymbol{m}^*=\boldsymbol{m}^*$, (19) can be rewritten as

$$\boldsymbol{P}\boldsymbol{Q}^T(\boldsymbol{y}-\boldsymbol{Q}\boldsymbol{P}\boldsymbol{m}^*)=\lambda\boldsymbol{P}\sum_{i:\boldsymbol{A}_i\notin\mathcal{C}}\frac{\boldsymbol{A}_i^T\boldsymbol{A}_i\boldsymbol{P}\boldsymbol{m}^*}{\|\boldsymbol{A}_i\boldsymbol{m}^*\|_2}+\gamma\boldsymbol{m}^*. \tag{20}$$

We let $\boldsymbol{D}=\operatorname{diag}\left(h(m_1^*),\cdots,h(m_{q^2}^*)\right)$, where $h(m_i^*)$ is defined to be the ratio of the number of observations in the block of $\boldsymbol{M}^*$ that contains m_i^* to the number of elements of $\boldsymbol{M}^*$ in the block of $\boldsymbol{M}^*$ that contains m_i^*. Note that $\boldsymbol{P}\boldsymbol{Q}^T\boldsymbol{Q}\boldsymbol{P}=\boldsymbol{D}\boldsymbol{P}$. Thus $\boldsymbol{P}\boldsymbol{Q}^T\boldsymbol{Q}\boldsymbol{P}\boldsymbol{m}^*=\boldsymbol{D}\boldsymbol{m}^*$, and (20) is equivalent to

$$\boldsymbol{P}\boldsymbol{Q}^T\boldsymbol{y}=\boldsymbol{D}\boldsymbol{m}^*+\lambda\boldsymbol{P}\sum_{i:\boldsymbol{A}_i\notin\mathcal{C}}\frac{\boldsymbol{A}_i^T\boldsymbol{A}_i\boldsymbol{P}\boldsymbol{m}^*}{\|\boldsymbol{A}_i\boldsymbol{m}^*\|_2}+\gamma\boldsymbol{m}^*. \tag{21}$$

We conjecture that there is a neighborhood around almost every $\boldsymbol{y}$ such that the blocks of $\boldsymbol{m}^*$ do not change. That is, $\mathcal{C}$ and $\boldsymbol{P}$ in (21) are constant with respect to $\boldsymbol{y}$, and the derivative of (21) with respect to $\boldsymbol{y}$ is

$$\boldsymbol{P}\boldsymbol{Q}^T=\left(\boldsymbol{D}+\lambda\boldsymbol{P}\sum_{i:\boldsymbol{A}_i\notin\mathcal{C}}S_2(\boldsymbol{A}_i,\boldsymbol{m}^*)\boldsymbol{P}+\gamma\boldsymbol{I}\right)\frac{\partial\boldsymbol{m}^*}{\partial\boldsymbol{y}}, \tag{22}$$

where $S_2(\boldsymbol{A}_i,\boldsymbol{m}^*)=\frac{\boldsymbol{A}_i^T\boldsymbol{A}_i}{\|\boldsymbol{A}_i\boldsymbol{m}^*\|_2}-\frac{\boldsymbol{A}_i^T\boldsymbol{A}_i\boldsymbol{m}^*\boldsymbol{m}^{*T}\boldsymbol{A}_i^T\boldsymbol{A}_i}{\|\boldsymbol{A}_i\boldsymbol{m}^*\|_2^3}$. Recall $\hat{\boldsymbol{y}}=\boldsymbol{Q}\boldsymbol{m}^*$, so solving (22) for $\frac{\partial\boldsymbol{m}^*}{\partial\boldsymbol{y}}$ and left-multiplying by $\boldsymbol{Q}$ gives

$$\frac{\partial\hat{\boldsymbol{y}}}{\partial\boldsymbol{y}}=\boldsymbol{Q}\left(\boldsymbol{D}+\lambda\boldsymbol{P}\sum_{i:\boldsymbol{A}_i\notin\mathcal{C}}S_2(\boldsymbol{A}_i,\boldsymbol{m}^*)\boldsymbol{P}+\gamma\boldsymbol{I}\right)^{-1}\boldsymbol{P}\boldsymbol{Q}^T,$$

where $\left(\boldsymbol{D}+\lambda\boldsymbol{P}\sum_{i:\boldsymbol{A}_i\notin\mathcal{C}}S_2(\boldsymbol{A}_i,\boldsymbol{m}^*)\boldsymbol{P}+\gamma\boldsymbol{I}\right)$ is invertible as both $\boldsymbol{D}$ and $\lambda\boldsymbol{P}\sum_{i:\boldsymbol{A}_i\notin\mathcal{C}}S_2(\boldsymbol{A}_i,\boldsymbol{m}^*)\boldsymbol{P}$ are positive semi-definite. Therefore, the degrees of freedom is

$$\mathrm{E}\left[\operatorname{Tr}\left(\boldsymbol{Q}\left(\boldsymbol{D}+\lambda\boldsymbol{P}\sum_{i:\boldsymbol{A}_i\notin\mathcal{C}}S_2(\boldsymbol{A}_i,\boldsymbol{m}^*)\boldsymbol{P}+\gamma\boldsymbol{I}\right)^{-1}\boldsymbol{P}\boldsymbol{Q}^T\right)\right].$$

This establishes the unbiasedness of the estimator (6). ■

Appendix F. Proof of Corollary 2

Proof This corollary pertains to the setting in which either all rows of $\boldsymbol{M}^*$ are equal (i.e., $\boldsymbol{R}_i\in\mathcal{C}$ for all i) or all columns of $\boldsymbol{M}^*$ are equal (i.e., $\boldsymbol{C}_i\in\mathcal{C}$ for all i). In this setting, we will show $\boldsymbol{P}S_2(\boldsymbol{A}_i,\boldsymbol{m}^*)=\boldsymbol{0}$ for any $\boldsymbol{A}_i\notin\mathcal{C}$ using two facts: (1) $\boldsymbol{A}_i\boldsymbol{m}^*=c_i\boldsymbol{1}_q$ for some $c_i\in\mathbb{R}$ and (2) $\boldsymbol{P}\boldsymbol{A}_i^T=\boldsymbol{v}_i\boldsymbol{1}_q^T$ for some $\boldsymbol{v}_i\in\mathbb{R}^{q^2}$. These facts follow from the assumption that either all rows or all columns of $\boldsymbol{M}^*$ are equal. Consider some $\boldsymbol{A}_i\notin\mathcal{C}$. We have

$$\begin{aligned}\boldsymbol{P}S_2(\boldsymbol{A}_i,\boldsymbol{m}^*)&=\frac{\boldsymbol{P}\boldsymbol{A}_i^T\boldsymbol{A}_i}{\|\boldsymbol{A}_i\boldsymbol{m}^*\|_2}-\frac{\boldsymbol{P}\boldsymbol{A}_i^T\boldsymbol{A}_i\boldsymbol{m}^*\boldsymbol{m}^{*T}\boldsymbol{A}_i^T\boldsymbol{A}_i}{\|\boldsymbol{A}_i\boldsymbol{m}^*\|_2^3}\\&=\frac{\boldsymbol{P}\boldsymbol{A}_i^T\boldsymbol{A}_i}{\|\boldsymbol{A}_i\boldsymbol{m}^*\|_2}-\frac{(\boldsymbol{v}_i\boldsymbol{1}_q^T)(c_i\boldsymbol{1}_q)(c_i\boldsymbol{1}_q^T)\boldsymbol{A}_i}{c_i^2q\|\boldsymbol{A}_i\boldsymbol{m}^*\|_2}\\&=\frac{\boldsymbol{P}\boldsymbol{A}_i^T\boldsymbol{A}_i}{\|\boldsymbol{A}_i\boldsymbol{m}^*\|_2}-\frac{\boldsymbol{v}_i\boldsymbol{1}_q^T\boldsymbol{A}_i}{\|\boldsymbol{A}_i\boldsymbol{m}^*\|_2}\\&=\frac{\boldsymbol{P}\boldsymbol{A}_i^T\boldsymbol{A}_i}{\|\boldsymbol{A}_i\boldsymbol{m}^*\|_2}-\frac{\boldsymbol{P}\boldsymbol{A}_i^T\boldsymbol{A}_i}{\|\boldsymbol{A}_i\boldsymbol{m}^*\|_2}\\&=\boldsymbol{0}.\end{aligned}$$

Therefore, the estimator (6) with $\gamma=0$ simplifies to $\operatorname{Tr}[\boldsymbol{Q}\boldsymbol{D}^{-1}\boldsymbol{P}\boldsymbol{Q}^T]=\operatorname{Tr}[\boldsymbol{D}^{-1}\boldsymbol{P}\boldsymbol{Q}^T\boldsymbol{Q}]$. Recall that $\boldsymbol{D}$ is a diagonal matrix with $D_{ii}=h(m_i^*)=N_i^0/N_i$, where N_i^0 and N_i are the number of observations and the number of elements, respectively, in the block of $\boldsymbol{M}^*$ containing m_i^*. Note that $(\boldsymbol{P}\boldsymbol{Q}^T\boldsymbol{Q})_{ii}$ equals n_i^0/N_i, where n_i^0 is the number of observations corresponding to m_i^*. Thus

$$\operatorname{Tr}[\boldsymbol{D}^{-1}\boldsymbol{P}\boldsymbol{Q}^T\boldsymbol{Q}]=\sum_{i=1}^{q^2}\frac{(\boldsymbol{P}\boldsymbol{Q}^T\boldsymbol{Q})_{ii}}{D_{ii}}=\sum_{i:m_i^*\text{ observed}}\frac{N_i}{N_i^0}\frac{n_i^0}{N_i}=\sum_{i:m_i^*\text{ observed}}\frac{n_i^0}{N_i^0},$$

which equals the total number of blocks of $\boldsymbol{M}^*$ since the n_i^0's for a block sum to N_i^0. ■

Appendix G. Proof of Lemma 3

Proof If $\boldsymbol{m}^* = \left(\frac{1}{n}\mathbf{1}_n^T\boldsymbol{y}\right)\mathbf{1}_{q^2}$ solves (3), then there exist q-vectors $\boldsymbol{d}_{1i}, \boldsymbol{d}_{2i}$ with $\|\boldsymbol{d}_{1i}\|_2 \leq \lambda$ and $\|\boldsymbol{d}_{2i}\|_2 \leq \lambda$ such that

$$\boldsymbol{Q}^T\left(\boldsymbol{y} - \left(\frac{1}{n}\mathbf{1}_n^T\boldsymbol{y}\right)\mathbf{1}_q\right) = \sum_{i=1}^{q-1}\left[\boldsymbol{R}_i^T\boldsymbol{d}_{1i} + \boldsymbol{C}_i^T\boldsymbol{d}_{2i}\right], \tag{23}$$

since $\boldsymbol{Q}\mathbf{1}_{q^2} = \mathbf{1}_q$. Let $\boldsymbol{d} = (\boldsymbol{d}_{11}^T \ \cdots \ \boldsymbol{d}_{1(q-1)}^T \ \boldsymbol{d}_{21}^T \ \ldots \ \boldsymbol{d}_{2(q-1)}^T)^T$. Then (23) can be rewritten as

$$\boldsymbol{Q}^T\left(\boldsymbol{y} - \left(\frac{1}{n}\mathbf{1}_n^T\boldsymbol{y}\right)\mathbf{1}_q\right) = \boldsymbol{A}^T\boldsymbol{d}. \tag{24}$$

Note that $\boldsymbol{m}^* = \left(\frac{1}{n}\mathbf{1}_n^T\boldsymbol{y}\right)\mathbf{1}_{q^2}$ for a certain λ if and only if (24) is satisfied for some $\boldsymbol{d}$ for which $\|\boldsymbol{d}_{1i}\|_2 \leq \lambda, \|\boldsymbol{d}_{2i}\|_2 \leq \lambda$ for $i = 1, \ldots, q-1$. We find the $\boldsymbol{d}^*$ corresponding to the minimum λ for which $\boldsymbol{m}^* = \left(\frac{1}{n}\mathbf{1}_n^T\boldsymbol{y}\right)\mathbf{1}_{q^2}$ by solving the convex optimization problem

$$\underset{\boldsymbol{d}}{\text{minimize}} \quad \max_{1\leq i\leq q-1}\left\{\|\boldsymbol{d}_{1i}\|_2, \|\boldsymbol{d}_{2i}\|_2\right\} \quad \text{subject to} \quad \boldsymbol{Q}^T\left(\boldsymbol{y} - \left(\frac{1}{n}\mathbf{1}_n^T\boldsymbol{y}\right)\mathbf{1}_q\right) = \boldsymbol{A}^T\boldsymbol{d}.$$

Thus $\boldsymbol{m}^* = \left(\frac{1}{n}\mathbf{1}_n^T\boldsymbol{y}\right)\mathbf{1}_{q^2}$ if and only if $\lambda \geq \max_{1\leq i\leq q-1}\left\{\|\boldsymbol{d}_{1i}^*\|_2, \|\boldsymbol{d}_{2i}^*\|_2\right\}$. ■

Appendix H. Simulations Illustrating Performance of (3) with $\lambda = 0$ and Variable q

We illustrate how (3) with $\lambda = 0$ over a range of q values performs compared to CRISP for a variety of scenarios. We generate data with $n = 100$ by independently sampling each element of $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$ from a Unif$[-2.5, 2.5]$ distribution, and then taking $\boldsymbol{y} = f(\boldsymbol{x}_1, \boldsymbol{x}_2) + \boldsymbol{\epsilon}$, where $\boldsymbol{\epsilon} \sim \text{MVN}(\mathbf{0}, \boldsymbol{I}_n)$. The four mean models $f(\boldsymbol{x}_1, \boldsymbol{x}_2)$ we consider are shown in Figure 12. Note that these are the same mean models we consider extensively in Section 3.

For each mean model, we generate 1000 replicates of data and estimate the mean model using (3) with $\lambda = 0$ and various q. We plot the MSE, squared bias, and variance of the mean model estimate as a function of q in Figure 12. In Scenarios 1 and 2, $q = 2$ has the best performance, which is unsurprising given the mean model structure. Using $q = 2$, there will be four bins whose boundaries roughly coincide with the true boundaries of the mean model. As q increases, the bias increases in an oscillating fashion where even values of q give better performance than odd ones. This is because odd values of q will not tend to have bins with boundaries that coincide with the true boundaries the mean model. As q increases, most of the q^2 bins will not have observations in them, and their estimates will be the mean of $\boldsymbol{y}$. Thus the variance decreases as many bins take on the same value, but the squared bias continues to increase. In Scenarios 3 and 4, the minimum MSE occurs at $q = 4$, not $q = 2$ as in Scenarios 1 and 2. This is because the mean models in Scenarios 3 and 4 are more complex and not well-estimated using only 2×2 grid of bins.

We also consider the performance for an additional mean model, shown in Figure 13(a). The same simulation set-up was used as for Scenarios 1–4 above. Though the blocks of the true mean model perfectly align with a grid that has $q = 3$, there are only 4 distinct blocks.

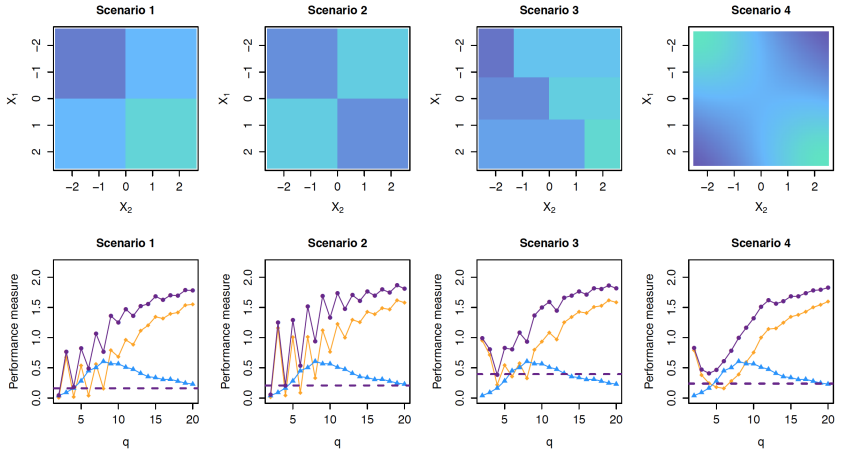

Figure 12: The top row of figures shows the mean models $f(x_1, x_2)$ used to generate data in each of the four scenarios in Appendix H. The bottom row of figures shows the performance of the method of (3) with $\lambda = 0$ as a function of q in terms of MSE (—●—), squared bias (—◆—), and variance (—▲—). The MSE for CRISP with $q = n$ and optimal λ is shown (- - -) for comparison.

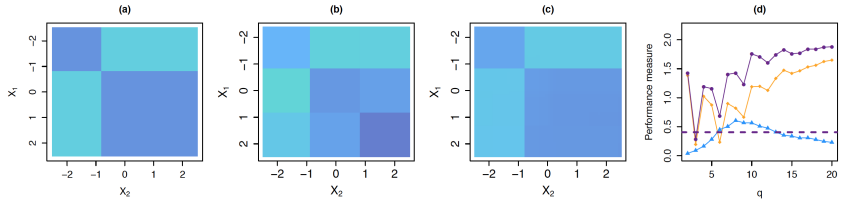

Figure 13: In *(a)*, we plot the mean model $f(x_1, x_2)$ used to generate data for the simulation described in Appendix H. In *(b)*, we show the estimated mean model from the method of (3) with $\lambda = 0$ and $q = 3$. In *(c)*, we show the estimated mean model from CRISP with $q = n$. In *(d)*, we show the performance of the method of (3) with $\lambda = 0$ as a function of q in terms of MSE (—●—), squared bias (—◆—), and variance (—▲—). The MSE for CRISP with $q = n$ and optimal λ is shown (- - -) for comparison.

The method of (3) with $\lambda = 0$ unsurprisingly has the best performance for $q = 3$, which is shown in Figure 13(d). The estimated mean model from using $q = 3$ and $\lambda = 0$ has $q^2 = 9$ blocks, as shown in Figure 13(b), since there is no adaptive shrinking together of blocks. However, CRISP is able to adaptively determine that only 4 blocks are needed, as shown in the estimated mean model in Figure 13(c). This example illustrates how CRISP is able to adaptively determine the amount of granularity over the covariate space. With $\lambda = 0$, the amount of granularity is constant across the covariate space.

Appendix I. Details of Data Application

In Section 6, we analyze housing data with the outcome of median house value and predictors of median income and average occupancy. We plot median income versus average occupancy in Figure 14. Note that 37 neighborhoods had an average occupancy larger than 10 and are omitted from the plot. The mean of average occupancy for these neighborhoods with an average occupancy greater than 10 was 88. In Figure 14, we outline the central 95% of the data in both covariates. That is, the 2.5% and 97.5% quantiles are shown for both covariates. We restrict our analysis to observations that fall in the central 95% of the data for both covariates. Of the original 20,640 neighborhoods, this excludes 1978 observations, leaving 18,662 observations for analysis.

Abstract

Active Learning has become an important area of research owing to the increasing number of real-world problems which contain labelled and unlabelled examples at the same time. JCLAL is a Java Class Library for Active Learning which has an architecture that follows strong principles of object-oriented design. It is easy to use, and it allows the developers to adapt, modify and extend the framework according to their needs. The library offers a variety of active learning methods that have been proposed in the literature. The software is available under the GPL license.

Keywords: active learning, framework, java language, object-oriented design

1. Introduction

In the last decade, the study of problems which contain a small number of labelled examples and a large number of unlabelled examples at the same time have received special attention. Currently, there are two main areas that research the learning of models from labelled and unlabelled data, namely Semi-Supervised Learning and Active Learning (AL). AL is concerned with learning accurate classifiers by choosing which instances will be labelled, reducing the labelling effort and the cost of training an accurate model (Settles, 2012).

Currently, there are several software tools which assist the experimentation process and development of new algorithms in the data mining and machine learning areas, such as Rapid Miner, WEKA, Scikit-learn, Orange and KEEL. However, these tools are focused to Supervised and Unsupervised Learning problems.

Some libraries and independent code that implement AL methods can be found on the Internet, such as Vowpal Wabbit, DUALIST, Active-Learning-Scala, TexNLP and LibAct. The Active-Learning-Scala and LibAct libraries are mainly focused to AL, they implement several AL strategies that have been proposed in the literature. On the other hand, Vowpal Wabbit, DUALIST and TexNLP have been designed for a different purpose, but they also include some AL methods.

To date, and in our opinion, there has been insufficient effort towards the creation of a computational tool mainly focused to AL. In our view, a good computational tool is not only a tool which includes the most relevant AL strategies, but also one that is extensible, user-friendly, interoperable, portable, etc.

The above situation motivated the development of the JCLAL framework. JCLAL is an open source software for researchers and end-users to develop AL methods. It includes the most relevant strategies that have been proposed in single-label and multi-label learning paradigms. It provides the necessary interfaces, classes and methods to develop any AL method.

This paper is arranged as follows: Section 2 provides a general description of the JCLAL framework. The Section 3 presents an example for using the software. Finally, the documentation and the requirements of this software are outlined in Section 4.

2. The JCLAL Framework

JCLAL is inspired by the architecture of JCLEC (Ventura et al., 2007; Cano et al., 2014) which is a framework for evolutionary computation. JCLAL provides a high-level software environment to perform any kind of AL method. It has an architecture that follows strong principles of object-oriented programming, where it is common and easy to reuse code. The main features of the library are the following:

- Generic. Through a flexible class structure, the library provides the possibility of including new AL methods, as well as the ability to adapt, modify or extend the framework according to developer's needs.
- User friendly. The library has several mechanisms that offer a user friendly programming interface. It allows users to execute an experiment through an XML configuration file.
- Portable. The library has been coded in the Java programming language. This ensures its portability between all platforms that implement a Java Virtual Machine.
- Elegant. The use of the XML file format provides a common ground for tools development and to integrate the framework with other systems.

- Open Source. The source code is free and available under the GNU General Public License (GPL). It is hosted at SourceForge, GitHub, OSSRH repository provided by Sonatype, and Maven Central Repository.

JCLAL aims to bring the benefits of machine learning open source software (Sönnenburg et al., 2007) to people working in the area of AL. The library offers several state-of-the-art AL strategies for single-label and multi-label learning paradigms. It uses the WEKA (Hall et al., 2009) and MULAN (Tsoumakas et al., 2011) libraries. WEKA is one of the most popular libraries which has several resources on supervised learning algorithms. On the other hand, MULAN is a Java library which includes several multi-label learning algorithms. For future versions, we hope to provide AL strategies related with multi-instance and multi-label-multi-instance learning paradigms.

Currently, the library provides the following single-label AL strategies: Entropy Sampling, Least Confident and Margin Sampling which belong to the Uncertainty Sampling category. Together with the Vote Entropy and Kullback Leibler Divergence strategies which belong to the Query By Committee category. In the Expected Error Reduction category, the Expected 0/1-loss and Expected Log-Loss strategies are included. One AL strategy belongs to the Variance Reduction family. The Information Density framework is also provided. More information about all of these single-label strategies can be found in (Settles, 2012). On the other hand, the following multi-label AL strategies are provided: Binary Minimum (Brinker, 2006), Max Loss (Li et al., 2004), Mean Max Loss (Li et al., 2004), Maximal Loss Reduction with Maximal Confidence (Yang et al., 2009), Confidence-Minimun-NonWeighted (Esuli and Sebastiani, 2009), Confidence-Average-NonWeighted (Esuli and Sebastiani, 2009), Max-Margin Prediction Uncertainty (Li and Guo, 2013) and Label Cardinality Inconsistency (Li and Guo, 2013).

The Stream-Based Selective Sampling and Pool-Based Sampling scenarios are supported. JCLAL provides the interfaces and abstract classes for implementing batch-mode AL methods and other types of oracle. Furthermore, the library has a simple manner of defining new stopping criteria which may change according to the problem. The library contains a structure which allows a set of listeners to simply define the events of an algorithm. The AL methods can be tested using the following evaluation methods: Hold-Out, k-fold cross validation, 5X2 cross validation and Leave-One Out. A method for actual deployment is also provided.

The library contains a set of utilities, e.g. algorithms for random number generation, sort algorithms, sampling methods and methods to compute, for example, AUC. A plug-in which permits the integration of the library with WEKA's explorer is also provided.

3. Using JCLAL

The library allows the users to execute an experiment through an XML configuration file as well as directly from Java code. A configuration file comprises a series of parameters required to run an algorithm. Below, an example of a configuration file is shown, which we call `MarginSampling.cfg`.

In this example, a 10-fold cross validation evaluation method is used on the data set `ecoli` located in the folder `datasets`. For each fold, 5% of the training set is selected to

construct the labelled set and the rest of the instances form the unlabelled set. A pool-based sampling scenario with the Margin Sampling strategy is used. The Naive Bayes algorithm is used as a base classifier.

```
<experiment>
 <process evaluation-method-type="net.sf.jclal.evaluation.method.kFoldCrossValidation">
  <rand-gen-factory seed="9871234" type="net.sf.jclal.util.random.RanecuFactory"/>
  <file-dataset>datasets/ecoli.arff</file-dataset>
  <stratify>true</stratify>
  <num-folds>10</num-folds>
  <sampling-method type="net.sf.jclal.sampling.unsupervised.Resample">
   <percentage-to-select>5.0</percentage-to-select>
  </sampling-method>
  <algorithm type="net.sf.jclal.activelearning.algorithm.ClassicalALAlgorithm">
   <stop-criterion type="net.sf.jclal.activelearning.stopcriteria.MaxIteration">
      <max-iteration>50</max-iteration>
   </stop-criterion>
   <stop-criterion type="net.sf.jclal.activelearning.stopcriteria.UnlabeledSetEmpty"/>
   <listener type="net.sf.jclal.listener.ClassicalReporterListener">
    <report-title>Margin-Sampling</report-title>
    <report-frequency>1</report-frequency>
    <report-directory>reports/ecoli</report-directory>
    <report-on-file>true</report-on-file>
   </listener>
   <scenario type="net.sf.jclal.activelearning.scenario.PoolBasedSamplingScenario">
    <batch-mode type="net.sf.jclal.activelearning.batchmode.QBestBatchMode">
     <batch-size>1</batch-size>
    </batch-mode>
    <oracle type="net.sf.jclal.activelearning.oracle.SimulatedOracle"/>
    <query-strategy type="net.sf.jclal.activelearning.singlelabel.querystrategy.
    MarginSamplingQueryStrategy">
     <wrapper-classifier type="net.sf.jclal.classifier.WekaClassifier">
       <classifier type="weka.classifiers.bayes.NaiveBayes"/>
     </wrapper-classifier>
    </query-strategy>
   </scenario>
  </algorithm>
 </process>
</experiment>
```

There are several ways to execute an experiment. One way is using the JAR file. For running the experiment just type:

```
java -jar jclal-1.0.jar -cfg "examples/MarginSampling.cfg"
```

After the experiment is run, a summary report which comprises information about the induced classifier and several performance measures is created.

4. Documentation, Requirements and Availability

The library is available under the GNU GPL license. A user manual and developer documentation which describes the software packages, examples, information to include new methods, API reference and running tests, is provided.

The software requires Java 1.7, Apache commons logging 1.1, Apache commons collections 3.2, Apache commons configuration 1.5, Apache commons lang 2.4, JFreeChart 1.0, WEKA 3.7, MULAN 1.4 and JUnit 4.10 (for running tests). There is also a mailing list and a discussion forum for requesting support on using or extending the framework.

Acknowledgments

This research was supported by the Spanish Ministry of Economy and Competitiveness, project TIN-2014-55252-P, and by FEDER funds.

Integrated Common Sense Learning and Planning in POMDPs

Brendan Juba* BJUBA@WUSTL.EDU
Washington University
1 Brookings Dr.
St. Louis, MO 63130 USA

Editor: John Langford

Abstract

We formulate a new variant of the problem of planning in an unknown environment, for which we can provide algorithms with reasonable theoretical guarantees in spite of large state spaces and time horizons, partial observability, and complex dynamics. In this variant, an agent is given a collection of example traces produced by a reference policy, which may, for example, capture the agent's past behavior. The agent is (only) asked to find policies that are supported by regularities in the dynamics that are observable on these example traces. We describe an efficient algorithm that uses such "common sense" knowledge reflected in the example traces to construct decision tree policies for goal-oriented factored POMDPs. More precisely, our algorithm (provably) succeeds at finding a policy for a given input goal when (1) there is a CNF that is almost always observed satisfied on the traces of the POMDP, capturing a sufficient *approximation* of its dynamics and (2) for a decision tree policy of bounded complexity, there exist small-space resolution proofs that the goal is achieved on each branch using the aforementioned CNF capturing the "common sense rules." Such a CNF always exists for noisy STRIPS domains, for example. Our results thus essentially establish that the possession of a suitable *exploration policy* for collecting the necessary examples is the fundamental obstacle to learning to act in such environments.

Keywords: Partially Observed Markov Decision Process, Decision Tree Policies, PAC-Semantics, Noisy STRIPS, Non-monontonic Reasoning

1. Introduction

A central problem in artificial intelligence, first considered by McCarthy (1959) concerns how to enable a machine to autonomously operate in an environment. The dominant approach to this problem has been to first build a *model* of the environment, and then use the model representation to generate *plans*. While these models were originally built by hand, modern advances across AI have been powered by the substitution of *learning* for hand-crafted knowledge representations, and we will likewise here consider the problem of learning an environment in order to support planning.

Although such separation of concerns is generally considered good engineering practice, such a decomposition of the problem mediated by an explicit intermediate representation may be intractable even when the overall problem has efficient algorithms: Khardon and Roth (1997) famously presented an efficient algorithm for an NP-hard reasoning task over a learned DNF representation, for example. And, *both* learning models of interactive environments *and* planning in them directly is indeed usually infeasible if, e.g., one is learning a model that can express DFAs (Kearns and Valiant, 1994), or one is attempting to plan in a model that captures propositional STRIPS domains with a bounded time horizon (Bylander, 1994; Erol et al., 1995). Although it is feasible to learn and plan in environments that are generated by extremely simple models, the problem becomes much harder when we are trying to utilize incomplete state information, when simple models do not perfectly capture the environment's dynamics, and when the state space is large—indeed, any one of these alone poses a challenge that current work seeks to address, but for most interesting applications, we must confront all three. In this work, we propose an approach to formulating plans using integrated learning and reasoning that provably simultaneously addresses all three challenges.

1.1 Formulation of the Integrated Learning and Planning Problem

Naturally, the task of developing algorithms to address the hard instances of intractable problems is inherently hopeless; as both learning and planning feature many hard instances, we can only hope to guarantee good performance by carefully formulating the theoretical problem to avoid these hopeless instances. Indeed, perhaps the main contribution of this work is the formulation of the integrated learning and planning problem that "factors out" the difficult task of *exploring* the environment: We avoid the exploration problem by assuming that an *exploration policy* has been fixed, and only seeking to plan using actions this reference policy explores with non-negligible probability. Naturally, we will also restrict the policies we consider—this is the analogue of the usual restrictions on the representations we consider in standard machine learning problems. For the concrete families of policies we consider, then, the polynomial-time algorithms we present for learning and planning thus establish that the only inherent difficulty in the task is exploring the environment.

Exploration often captures the essence of the kind of "needle in a haystack" search task that is necessarily slow: Even exploring environments described by very simple rules can force algorithms to suffer a complexity that is linear in the number of environment states, such as "combination lock" environments (Kakade, 2003, Section 8.6). And yet, the formulation of, for example, the standard reinforcement learning task combines the exploration task with the tasks of learning and planning, denying the possibility of any analysis establishing reasonable bounds on the time or number of samples required for most standard environment classes. By shifting our attention to settings where exploration is either solved for us or guaranteed to be possible, we will be able to obtain algorithms of polynomial complexity in the number of attributes describing the states, as opposed to the number of actual states (which is of course exponentially larger). This complexity bound is similar to what is achieved by the relaxation of Kakade and Langford (2002) for fully observed environments with a value function (as opposed to goal satisfaction), but using a different assumption.

We will aim to learn the dynamics (and observation model) of a *factored Partially Observed Markov Decision Process* (POMDP) with partial but noiseless observations. Pre-

*. Work originally performed while the author was affiliated with Harvard University and supported by ONR grant number N000141210358. Preparation of this article was supported by an AFOSR Young Investigator Award.

cisely, the state space we consider will be described by vectors of n Boolean attributes ("fluents" in the planning literature), and the agent's observations will be of the settings of a *subset* of these attributes. In our model, the agent may have access to some arbitrary *background knowledge* about the environment's dynamics. This knowledge is given to the agent as a collection of Boolean formulas over the state attributes that are assumed to be simultaneously true (with probability close to 1) on sequences of states generated by the environment. The agent also has access to a collection of observation histories that have been generated by the (arbitrary) exploration policy. The agent is then provided with a *goal*, represented by another Boolean formula over the attributes of the environment's state. The agent wishes to choose *actions* that guide the environment to a state satisfying this goal formula. We wish to use the background knowledge and example histories generated by the reference exploration policy to inform these choices of actions in the POMDP in order to achieve this new goal. That is, we are only seeking to learn the dynamics of the POMDP from this background knowledge and these example histories to the extent that it enables the agent to reach a goal state.

A naïve approach might directly estimate the dynamics of ("belief") distributions over the 2^n states produced by the model, but notice that the dynamics can require $2^{\Omega(2^n)}$ bits to represent. We note that unlike the full-information task, the history of past observations may provide additional information about the current state of a POMDP, and hence it is important to be able to construct a stateful policy. Following the spirit of McCarthy's approach, we propose to focus on cases where based on "common sense knowledge" that can be learned from the exploration policy's observations of the POMDP, there exists a *proof* that a given goal is satisfied on the actual, underlying trajectory generated by the policy and the POMDP.

Technically, the proofs serve to provide evaluations of the agent's performance under partial information: our "reward function" is given as an input formula that may refer to the unobserved portions of the state, separate from the domain examples. In order to determine that the reward function is satisfied when some information is missing, it is inherently necessary that we establish that none of the missing values could prevent the satisfaction of the goal—each setting of the missing data is either inconsistent with some background knowledge we have, or the goal condition is satisfied on it anyway. In particular, we do not assume that we have any model for the distribution for the missing values; these values are missing from the very data we use for learning. Addressing all of the possible values of such missing information is the essence of theorem-proving, and the existence of a simple proof gives us a potential means to efficiently consider all of these possible values for the missing data. In particular, we will assume that the goal is given as a DNF formula, and we will use treelike resolution proofs of bounded *Strahler numbers* (aka pebble number or clause space, cf. Section 2.2.1). This is a class of proofs that, even for Strahler number two, captures the kind of reasoning needed to verify the correctness of STRIPS plans, for example. Moreover, the reasoning problem for any constant Strahler number can furthermore be solved in polynomial time with the exponent depending on the Strahler number, cf. Kullmann (1999).

1.2 Techniques and Results

We propose here to use algorithms for reasoning over such common sense knowledge learned from partial information, as described by Juba (2013) for most known tractable proof systems, to encapsulate the learning of the POMDP's dynamics in planning. Indeed, we reduce the planning problem to answering such queries, establishing that such solutions to the integrated learning and reasoning problem are sufficient to solve our POMDP planning problem. This is analogous to Kautz and Selman's SATPLAN (Kautz and Selman, 1992), but for stochastic domains, with richer policy representations, and with the domain encoding *learned* from the partially observed traces; this learning is provided by the aforementioned algorithm from prior work by Juba, that stands in for the SAT-solver in this analogy.

Specifically, we will leverage the integrated learning and reasoning algorithm to find *decision tree policies of bounded Strahler number* for achieving the given goal in the POMDP (when they exist). A restriction to the space of decision tree policies was first considered for MDPs by Chapman and Kaelbling (1991) and essentially for POMDPs in the work of McCallum (1995, 1996); decision list policies (an example of *bounded* Strahler number decision tree policies) were considered by Khardon (1999). The restriction of the space of policies to more general bounded Strahler number trees is also natural: it encompasses bounded-fault tolerant policies (Jensen et al., 2004), for example. Such policy-space restrictions serve two relatively well-understood purposes: as with restrictions on the class of representations in learning theory, a restriction on the space of policies enables us to statistically distinguish good policies from bad policies (Kearns et al., 2002), and moreover enables us to design algorithms to *find* policies efficiently (e.g., as in the reduction of Mansour, 1999).

Our reduction adapts the algorithm of Ehrenfeucht and Haussler (1989) for supervised learning of decision tree classifiers of bounded Strahler number to search for policies. (Just like Ehrenfeucht and Haussler (1989), we can also search through all decision trees of a given size in *quasipolynomial* time, i.e., time $2^{\text{poly}\log n}$.) This algorithm proceeds by recursively building a tree below a candidate branch, using the ability to test when a branch is consistent with the input examples, terminating successfully when such a consistent branch is found. The key insight of Ehrenfeucht and Haussler was that a Strahler-number restriction enables the algorithm to control the amount of branching performed during this recursive search, by allowing us to search over the smaller (lower Strahler-number) subtrees first.

In our setting, deciding whether or not a branch is "consistent" means deciding whether or not the goal is achieved on the (example) traces that are consistent with the tests and actions selected on the branch. Such a test is thus naturally accomplished by a query to the integrated learning and reasoning algorithm of Juba (2013). The decision tree search algorithm also must be extended to search over *actions*, as opposed to just branches on settings of the observed attributes, which are all that the original decision trees use. We control this search indirectly, by partitioning the set of example traces according to the mutually exclusive choice of next action, and only passing the corresponding subset of the examples to the recursive call; the amount of work performed by the algorithm can be shown to be linear in the number of examples, so it is easy to bound the total work performed by these branches. We give an analysis of the overall algorithm showing in particular that only polynomially many traces are needed to learn the POMDP well enough to find policies.

This in turn crucially exploits the problem formulation: we only promise to find policies using actions that the reference exploration policy is likely to consider.

As promised, we note that this system finds plans even when the domain's dynamics are only partially, approximately captured by a small CNF formula (and hence, by the premises in a small resolution proof). For example, logical encodings of planning problems typically use "frame axioms" that assert that nothing changes unless it is the effect of an action. In a real world setting, these axioms are not strictly true, but such rules still provide a useful approximation. It is therefore crucial that we can learn to utilize such imperfect logical encodings. We will more generally be able to learn to plan in noisy versions of STRIPS instances (Fikes and Nilsson, 1971) (a standard test domain of interest) which are approximated well but imperfectly by their noiseless versions. Also, as a consequence of our adoption of *PAC-Semantics* (Valiant, 2000a) for our logic, we will also be able to soundly incorporate explicitly specified background knowledge into our algorithms, even when this knowledge may likewise only hold in an approximate sense.

In order to support some more interesting cases of planning under partial information, we also extend the PAC-Semantics slightly to non-monotonic logics using the Well-Founded Semantics (van Gelder et al., 1991) for negation-as-failure. The Well-Founded Semantics for propositional logics is a relatively clean semantics that features polynomial-time reasoning, and allows us to formulate, for example, "generic" frame axioms as explicit background knowledge; that is, frame axioms that do not depend on the unknown dynamics of the environment. These explicit frame axioms in turn allow the agent to reason about attributes of the environment that are unobserved in the traces collected by the exploration policy. The agent can then, for example, plan to achieve goals that refer to portions of the environment that cannot be simultaneously observed.

2. Preliminaries

Before stating the problem we address, we must describe the relevant models of environments, approximate reasoning, policies, and typical experiences.

2.1 Factored POMDPs

Informally, a POMDP is a state-based model of an environment for an agent that evolves probabilistically and only provides the agent with partial information about its states.

Definition 1 (POMDP) *A* Partially Observed Markov Decision Process (POMDP) *is given by collections of distributions on a* state space S *and an* observation space O *as follows: there is an* action set A *such that for each action* $a \in A$ *and* $s \in S$*, there is a distribution* $D_{(a,s)}$ *over* S*, and for each* $s \in S$ *there is a distribution* D_s *over* O*.*

For any fixed sequence of actions $a^{(1)}, a^{(2)}, \ldots$ from A, the distributions $\{D_{(a,s)}\}_{(a,s)\in A\times S}$ give rise to a (non-stationary) Markov process on S: given an initial state $s^{(1)}$, $s^{(2)}$ is drawn from $D_{(a^{(1)},s^{(1)})}$, and generally thereafter, $s^{(i+1)}$ is drawn from $D_{(a^{(i)},s^{(i)})}$. For a sequence of states so generated, the distributions $\{D_s\}_{s\in S}$ now give rise to the POMDP distribution over observations: the ith observation $o^{(i)}$ is drawn from $D_{s^{(i)}}$. We normally think of the agent choosing $a^{(i)}$ on the basis of the history of interaction with the environment somehow,

i.e., with knowledge of $o^{(1)}, \ldots, o^{(i)}$ and $a^{(1)}, \ldots, a^{(i-1)}$. We refer to the agent's strategy for choosing such actions as a *policy*. One normally also fixes some kind of a reward (or loss) function over the states S to quantify how "good" or "bad" an agent's policy for acting in the environment is (we will elaborate on this shortly). For a fixed policy, a sample from the joint distribution over the actions and observations generated by the interaction between the POMDP and the policy is called a *trace* or *history*; a sample from the distribution over the actual underlying states, actions, and observations is a *trajectory*. Naturally, a history can be obtained from a trajectory by dropping the actual states.

We will not use the most general definition of a POMDP; we will instead use the following natural special case featuring most of the key features of a POMDP. We will assume that the state space is *factored*, that is, described by n propositional variables (*"fluents,"* in the usual language of planning), taking $S = \{0,1\}^n$ (we will continue to denote the indices of these propositional variables in S by subscripts, hence our use of superscripts to denote the sequence of states). We choose to use propositional representations because they are sufficient to capture the only cases of first-order representations (to our knowledge) that have tractable learning and inference algorithms—note that Haussler (1989) shows that fitting first-order expressions even in very simple domains is intractable. By contrast, following Valiant (2000a) for example, we could consider relational representations of small arity and a polynomial size universe of objects, and take the atomic formulas obtained by various bindings of our relations over these objects as our propositional variables. But, as the propositional case is surely simpler and suffices for the current work, we will not consider first-order representations further. Thus, in particular, we will fix a (possibly polynomially related to n) horizon bound T, and for each tth step (of a candidate plan) and ith component of the state of the POMDP, we will have a separate propositional variable $s_i^{(t)}$.

The *observations* will then have the form of state vectors with some of their entries masked. More precisely:

Definition 2 (Partial states) *A* partial state ρ *is an element of* $\{0,1,*\}^n$*. We say that a partial state* ρ *is* consistent *with a state* $s \in \{0,1\}^n$ *if whenever* $\rho_i \neq *$*,* $\rho_i = s_i$*.*

The observations will consist of partial states produced by a fixed *masking process* applied to the current state of the POMDP (Michael, 2010):

Definition 3 (Masking process) *A* mask *is a function* $m : \{0,1\}^n \to \{0,1,*\}^n$*, with the property that for any* $s \in \{0,1\}^n$*,* $m(s)$ *is consistent with* s*. A* masking process M *is a mask-valued random variable (i.e., a random function).*

Notice, which attributes are hidden can depend arbitrarily on the underlying state. Masking leads to a kind of perceptual aliasing if the distinguishing attributes in two distinct states are masked; indeed, there may even be propositional variables that the masking process *never* reveals, that have an arbitrary effect on the dynamics (as they correspond to distinct states). In such a case, we cannot learn about the relationship of these missing variables to the larger dynamics of the POMDP using the observations alone. We may have *background knowledge* that mentions these variables though, thereby permitting us to reason about their contents. We shall discuss this further shortly.

In contrast to the most typical set-up, our reward function is *not* fixed with the POMDP, and in particular its value may not be determined by the partially observed example traces. It will be specified to the algorithm by a *goal predicate* G given by a DNF over the propositional state variables. Along these lines, an agent's policy is considered good if it manages to (quickly) reach a state in which G is satisfied (as opposed to demanding a policy that maintains a high average reward over time).

Noise. This model assumes that there is no noise in the observations themselves. Although as given this does not accurately reflect robotics problems (for example), it is a reasonable model for agents that interact with computer systems, for example a web-crawling agent.[1] In such applications, only a portion of the environment's state, such as a single web-page, single directory, etc. is visible at a time, but perception of this state is not at issue; the actions available to the agent then would correspond to the interface elements (e.g., links, buttons, etc.). In any case, it happens that noise in the observations will only affect our approach by possibly leading us to evaluate the goal predicate incorrectly, and therefore leading the policy to terminate prematurely. Otherwise there is not much difference between noise (stochasticity) in the dynamics—which we *do* consider, cf. Section 2.3.2 for an illustration—and noise in the observations.

2.1.1 Typical Actions

Our objective is to enable the agent to utilize knowledge that it may learn from its experiences. This means that the agent reasons about knowledge drawn from its particular experiences, which consist of a fixed collection of traces. We suppose that the agent's histories are generated by some arbitrary policy Π^*. In a fixed sample, we can only hope to evaluate actions that Π^* takes with probability polynomially related to the size of the sample, which are then explored reasonably well; conversely, we can also guarantee that all of the actions that Π^* takes with some minimum probability μ are well-explored in a sample of size polynomially related to $1/\mu$. So, the probability that Π^* explores a sequence of actions approximately characterizes the sequences that are well-represented in a sample of traces of a given size. In particular, since distinct sequences of actions refer to disjoint events, there are at most $1/\mu$ distinct sequences of actions that are taken with probability μ. A lower bound on this probability therefore bounds the number of sequences of actions we have to consider, and so the policy Π^* does all of the work in "exploring" the POMDP.

Conceptually, the policy Π^* will serve as a reference point that defines "typical" actions in the POMDP, and we will only expect the agent to understand the dynamics of the POMDP so far as it concerns traces that have some non-negligible weight under Π^*. Such settings reasonably capture everyday cases where the agent has been taught or has learned relevant sub-policies, or where the relevant plan is merely very simple. Some such guarantee seems to be necessary in order to obtain algorithms of reasonable complexity: Kakade (2003, Section 2.5) shows that even very simple fully-observed environments can be hard to learn, depending linearly on the number of possible states, which may be exponential in the number of fluents, or exponentially on the time horizon.

1. Indeed, the original motivation for considering this model arose from the desire to develop devices and distributed/networked software that featured "universal" (or at least broad) compatibility (Goldreich et al., 2012; Juba, 2011).

We further suppose that the agent's histories using Π^* are given together with the probabilities that Π^* chose its actions on each step in the history. These probabilities, although a somewhat nonstandard addition, are usually easy to generate (or at least estimate) while an algorithm computes a policy, and provide a convenient way to re-use the traces to estimate the quality of alternative policies via importance weighting, an observation due to Precup et al. (2000, 2001) for POMDPs. (The technique is discussed for full-information MDPs by Sutton and Barto, 1998, Chapter 5.)

Formally now, we will only hope for the agent to choose a policy consisting of sequences of actions $\alpha^{(1)}, \alpha^{(2)}, \ldots, \alpha^{(t)}$ such that Π^* takes the sequence of actions from the initial state of the POMDP with probability at least μ for some $\mu > 0$. For example, if Π^* is a random walk policy and the space of possible actions is small, then every short sequence of actions will be "typical" and we will expect the agent to be able to find any suitable short plan in such a case. But, Π^* may also describe some more sophisticated policy for exploring the relevant portions of the POMDP, or may be simply the time-average of the various policies used by the agent in the past (in which case such an estimator was considered by Shelton, 2001). We remark that the distribution over the initial states of the POMDP could be taken to be a "typical state" initial distribution such as the long-run state distribution under Π^*. Regardless of the details of this policy, we then reach the following definition of a typical sequence of actions:

Definition 4 (μ-typical) *If Π^* produces the sequence of actions $(\alpha^{(1)}, \ldots, \alpha^{(t)})$ with probability at least μ in a POMDP, then we say that the sequence of actions is* μ-typical *for Π^* in the POMDP.*

We stress that algorithms that achieve a sample complexity m for learning and planning in the POMDP under most conventional models can be used as an exploration policy for producing traces in which the (significant) actions of the plan are $1/\mathrm{poly}(m)$-typical. Otherwise, the algorithm would not have an adequate estimate of the quality of the traces to produce a reliable plan.

Another definition that similarly evaluates policies with respect to some fixed (reset) distribution was proposed previously by Kakade and Langford (2002) for learning in fully observed MDPs. The assumption is of course quite different, and their setting attempts to optimize a value function (with respect to this reset distribution) rather than achieving a goal. Nevertheless, much like in Kakade and Langford's work, we will be able to avoid an exponential dependence on the time horizon or number of attributes in the time and sample complexity of our algorithm as a result of our definition. A related assumption for POMDPs was introduced by Bagnell et al. (2004), which assumes that the fixed distribution is *close* to that induced by the target policy in statistical distance.

2.1.2 Knowledge Representations and STRIPS Domains

As we noted earlier, the special case of a factored POMDP that we consider here is naturally captured by a propositional logic in which there is a propositional variable for each ith fluent of the POMDP on each tth step of the trajectory. In this way, we can use propositional logic to reason about the actual, underlying state that the POMDP could be in on each step, and thus cope with our missing observations. In general, we will have a collection of propositional formulas (i.e., formed by the usual Boolean connectives over propositional

variables) capturing basic knowledge about our encoding of the POMDP, or specific to the actual POMDP under consideration. The entire collection is referred to as the *"background knowledge"* or *"knowledge base"* (abbreviated as "KB"). We will generally assume that the formulas in the knowledge base hold simultaneously with probability close to 1 over the distribution of sequences of states generated by the reference policy and POMDP.

It will be helpful for us to distinguish between the partial state as an observation and as a state of knowledge. In particular, looking ahead, our decision-tree policies will produce actions based on the three-valued observation vectors, not the actual state—so for example, it is meaningful for the policy to branch on whether or not an attribute's value is observed. Supposing we denote our observation in the tth step by $o^{(t)}$, we will encode $[o_i^{(t)} = b]$ for $b \in \{0, 1, *\}$ as variables $x_{i,b}^{(t)}$; we will add the clauses $x_{i,0}^{(t)} \vee x_{i,1}^{(t)} \vee x_{i,*}^{(t)}$ and $\neg x_{i_b}^{(t)} \vee \neg x_{i,b'}^{(t)}$ for all i and $b \neq b'$ to the background knowledge thus asserting that x_i takes exactly one of the three values.

When reasoning about plans for the POMDP, we will naturally likewise use a propositional representation: for each possible action α and action taken by the agent $a^{(t)}$, we will have a vector of propositional variables $a_\alpha^{(t)}$ encoding $[a^{(t)} = \alpha]$. Naturally, these propositional variables should be mutually exclusive. Typically, we will add a list of clauses to our background knowledge for every pair of actions $\alpha \neq \alpha'$ asserting that only one is taken, i.e., $\neg a_\alpha^{(t)} \vee \neg a_{\alpha'}^{(t)}$.

STRIPS domains. A class of simple domains that are sufficiently general to provide a variety of excellent examples of propositional domains were first introduced for the STRIPS planner of Fikes and Nilsson (1971). In a (propositionalized) STRIPS domain, the actions are described by lists of literals capturing the action's *preconditions* and *effects*. The intention is that the preconditions must be satisfied at time t in order for the action to be available to the agent. Once the action is taken, the state of the environment is updated so that at time $t + 1$, the literals capturing the effects are all satisfied. All other literals are unchanged. We will take the convention that if the preconditions of an action are not satisfied at time t but the agent tries to "take the action at time t," the action fails—as opposed to being unassertable, as traditionally required; this will be useful in partial information settings where the agent may not be certain whether or not the preconditions hold. Finally, the goals are given by a conjunction of literals.

The encoding of the action rules into clauses is then very natural. Supposing the action α has preconditions $p_1, \ldots, p_r$ and effects $e_1, \ldots, e_s$, for each time t, we have for each effect e_i a clause $[p_1^{(t)} \wedge \cdots \wedge p_r^{(t)} \wedge a_\alpha^{(t)}] \Rightarrow e_i^{(t+1)}$. The convention that the attributes of the state are only changed by actions is encoded by *"frame axioms"* like so. For each literal ℓ over some state of the environment and each action $\alpha_1 \ldots, \alpha_k$ that has an effect that falsifies ℓ, i.e., has some $e_i = \neg\ell$, we have a clause $[\ell^{(t)} \wedge \neg a_{\alpha_1}^{(t)} \wedge \cdots \wedge \neg a_{\alpha_k}^{(t)}] \Rightarrow \ell^{(t+1)}$.

Note that our DNF goals generalize the STRIPS-style "conjunctive goals." Likewise, although the actions are not necessarily captured by STRIPS actions, and the evolution of our environment is generally *not* deterministic (and our approach does *not* require it to be so, cf. Section 2.3.2), such examples are helpful to keep in mind as examples of POMDPs for which the dynamics can be concisely described by a CNF. We stress that in spite of our focus on STRIPS-like examples, our approach will extend to the kind of environments that can be expressed by, e.g., grounded PPDDL (Younes and Littman, 2004), provided

that there exists a sufficiently simple policy (for a given goal) that is "fault-tolerant" or otherwise reasonably reliable overall.

2.1.3 An Example

We can illustrate (STRIPS) rules, POMDPs, and their relationship with an example of a simple domain based on the Gripper problem from the first International Planning Competition (IPC 1998). Informally, the problem captures an environment consisting of two rooms, which may contain several balls. The agent is a robot that can pick up and put down the balls and carry then between rooms. The goal is usually to carry all of the balls to a given room.

The states. We can describe the environment (POMDP) with a vector of Boolean attributes as follows: We will index the rooms by $r \in \{1, 2\}$, and the balls by $b \in B$ (for some other set B). We will let the variables x_r indicate whether the agent is in room r, which are mutually exclusive; the variables $x_{r,b}$ indicate whether ball b is in room r, and for each fixed b the $x_{r,b}$ are mutually exclusive; and the variables x_b indicate whether the agent is holding ball b, and these are also mutually exclusive. The agent's actions are a_r, meaning "go to room r"; a_b, meaning "pick up ball b"; and a_0, meaning "drop."

The rules. The state variables and actions are related by the following clauses, and these are the STRIPS-style rules that will approximate the dynamics of the POMDP. First, if the agent executes action a_r, then the x_r is set to 1 and for $r' \neq r$, $x_{r'}$ is set to 0, that is for each time index t, we have rules $\neg a_r^{(t)} \vee x_r^{(t+1)}$ and $\neg a_r^{(t)} \vee \neg x_{r'}^{(t+1)}$. In the usual language of STRIPS, $x_r^{(t+1)}$ and $\neg x_{r'}^{(t+1)}$ are the *effects* of a_r at t. Furthermore, if the agent is holding ball b, then $x_{b,r}$ is also set to 1 and $x_{b,r'}$ is set to 0. These correspond to clauses $\neg x_b^{(t)} \vee \neg a_r^{(t)} \vee x_{b,r}^{(t+1)}$ and $\neg x_b^{(t)} \vee \neg a_r^{(t)} \vee \neg x_{b,r'}^{(t+1)}$ (for $r' \neq r$). These are *conditional effects* of $a_r^{(t)}$ with the *precondition* $x_b^{(t)}$.[2] Now, if the agent is in room r and ball b is also in room r, then the agent may pick up b with its gripper; when this happens, the agent also drops any other balls it was holding. This is captured by clauses $\neg x_{b,r}^{(t)} \vee \neg x_r^{(t)} \vee \neg a_b^{(t)} \vee x_b^{(t+1)}$ for each r and b, and clauses $\neg a_b^{(t)} \vee \neg x_{b'}^{(t+1)}$ for $b' \neq b$. Here $x_{b,r}^{(t)}$ and $x_r^{(t)}$ are again the preconditions for (conditional effects of) the action (they must jointly hold for *some* room r, or at the end the agent fails to hold b). Finally, if the agent executes a_0, it simply ceases to hold any balls at all, that is, $\neg a_0^{(t)} \vee \neg x_b^{(t+1)}$ for all b. Now, we also require *frame axioms* indicating that the state does not change unless it is the effect of one of these actions as described above. Actually, these are elegantly stated using negation-as-failure, as we describe in Section 4, so we will not list out the classical form of these rules here.

The actual POMDP and validity of the STRIPS-style rules. As we hinted at above, the deterministic STRIPS-style rules will only *approximate* the true environment, which is actually a Markov decision process. In this Markov decision process, we will model an agent whose actions are not flawlessly performed: suppose that the pick-up actions fail 1% of the time, and that when carrying a ball from one room to another, the agent has a 1% chance of dropping the ball in each of the rooms (for a 2% chance overall of ending up

2. Strictly speaking, conditional effects are not supported by STRIPS, so this is a (standard) extension.

in the destination without holding the ball). That is, in states where the pick-up action a_b should have set x_b to 1, the agent only enters such a state with probability .99, and enters a state where x_b is (still) 0 instead with probability .01. Likewise, in states where x_b is 1, x_r is 1, and the agent takes action $a_{r'}$, then with probability .98 the agent enters the state where x_b is still 1, $x_{r,b}$ and x_r are 0, and $x_{r',b}$ and $x_{r'}$ are 1; but, with probability .01, x_b switches to 0 (the agent drops the ball upon arrival in room r'), and with probability .01, not only does x_b become 0, but moreover $x_{r,b}$ is still 1 and $x_{r',b}$ is still 0 (that is, the ball didn't get carried). We could also further envision an environment in which the balls may switch rooms without our agent's intervention, because they were moved by some other agent, for example. We will assume that the other effects (in particular, the room-switching effect of a_r) occur with probability 1, and thus the corresponding rules are actually *"*1*-valid"* in the language of PAC-Semantics that we will discuss next; the rules for a_r described above turn out to be *".*99*-valid"* except for the frame axiom that asserts that x_b should remain 1 (unless a_0 or $a_{b'}$ are executed), which is only *".*98*-valid."*

In a POMDP, the agent does not observe the complete states of these underlying Markov decision processes in general. In our case, partial states are generated by the following simple masking process: when x_r is 1 and $x_{r,b}$ is not 1, the variables $x_{r',b}$ for $r' \neq r$ are masked (always set to $*$ in the partial states appearing in the example traces and the partial states provided to the agent's policy when it is executed). Intuitively, this means that the agent does not "see" the balls in room r', but may know that a ball b is in room r and not r'. In this simple environment, we will assume that all of the other attributes remain unmasked. Therefore, all of the rules that do not mention the $x_{r,b}$ variables are always *"witnessed true"* (i.e., they always have a satisfied literal—we will define this formally later); it turns out that the rules that *do* mention $x_{r,b}$—namely, the rules capturing the effects of a_r and a_b—also each have a satisfied literal and are therefore "witnessed true" with probability .99. Notice, $x_{r,b}$ (in the effects of a_r and $a_{r'}$) is only not "witnessed true" when both $\neg x_r$ and $\neg x_b$ are 0, and in this case, after a_r, $x_{r,b}$ and $\neg x_{r',b}$ are both guaranteed to be witnessed true unless the ball was dropped in room r', which occurs with probability .01. Similarly, in the rules describing the effect of a_b, either $\neg x_r$ or $\neg x_{r,b}$ is witnessed true (if the ball is absent), or else x_b is witnessed true unless the action fails, which occurs with probability .01. Since these STRIPS-style rules are all "witnessed true" with high probability, it will turn out that they are therefore guaranteed to be learnable in pursuit of policy construction, as we will see.

2.2 PAC-Semantics

Valiant (2000a) introduced PAC-Semantics in order to capture the property satisfied by the outputs of PAC-learning algorithms when formulated in a logic. For our purposes, PAC-Semantics will capture the extent to which a propositional formula holds on trajectories sampled according to the POMDP and some policy. We remark that Valiant's original motivation for formulating this semantics for a logic was to provide semantics for the representations created in the neuroidal cognitive model (Valiant, 2000b), and it is further proposed to capture certain kinds of learned "common sense" knowledge in general (Valiant, 2006). This roughly means that the agent possesses a large knowledge base without having been explicitly given most of its contents, as in the sense in which McCarthy (1959) used "common sense" when introducing the problem that we aim to address in this work. But, it also

so happens that this semantics features other hallmarks of "common sense" reasoning as identified in the AI literature, such as defaults and nonmonotonicity under conditioning, cf. Valiant (1995, 2000b) and Roth (1995). (We will not dwell on such aspects further in this work.) We note that systems using learning and logical reasoning based on PAC-Semantics have been successfully built and, for example, demonstrated to improve the accuracy with which a missing word in a sentence can be guessed (Michael and Valiant, 2008).

The key definition, capturing the notion of "approximation" in PAC-learning is:

Definition 5 ($(1-\epsilon)$-valid) *Given a distribution D, we say that a relation R is* $(1-\epsilon)$-valid *w.r.t. D if* $\Pr_{x\in D}[R(x)=1] \geq 1-\epsilon$.

Naturally, our relations will be given by formulas of propositional logic over the literals describing the observations over the n state attributes and the agent's actions for each time step $t = 1, \ldots, T$ over a trace of a policy in the POMDP. The distribution D we consider will generally be the distribution over actual states of the POMDP (and actions of the policy) given by the interaction between some policy and the POMDP, either the reference policy or else some (partial) policy under consideration by the algorithm.

Of course, since learning is impossible when *all* entries of our examples are hidden by a masking process, we must restrict our attention to settings where it is possible to learn something about D. We will consider formulas that can be evaluated in the straightforward way from the partial states with high probability:

Definition 6 (Witnessed and testable CNFs) *We say that a CNF φ is* witnessed to evaluate to true *on a partial state ρ if every clause of φ contains a literal ℓ such that $\ell(\rho) = 1$. If φ is witnessed true with probability at least p on partial states from some distribution over masked states $M(D)$ (usually given by a masking process M on a distribution D), we say that φ is* p-testable *with respect to $M(D)$.*

With respect to the individual clauses of the CNF, it is easy to see that only clauses that are witnessed to evaluate to true are known to be true in an example, and thus only clauses that are testable under D can possibly be learned from random examples.[3]

As we will only be able to learn the rules governing the POMDP's dynamics when they are witnessed true with high probability, it is important to note when rules are witnessed. In particular, consider the clause encoding a STRIPS action rule. In our model, the literals capturing the action are always observed. Thus, the rule is witnessed if either the effect of the action is observed *or* if some unsatisfied precondition is observed when the action fails. Likewise, a frame axiom expressing that the setting of a fluent ℓ persists at time t is witnessed when either an action is taken that changes the fluent ℓ, $\ell^{(t-1)}$ is observed to be false, or when $\ell^{(t)}$ is observed to be true.

2.2.1 Reasoning

We introduced the notions of propositional knowledge representations and PAC-Semantics in order to capture the process of reasoning about missing information. In this work, we

3. NB: these simple rules will only serve as the "base case" for reasoning, since our algorithms will further carry out reasoning based on them. Thus, in some sense, we also will "learn" knowledge that can be derived (easily enough) from these empirically observed rules.

are seeking algorithms for which we can provide theoretical guarantees of their performance. However, propositional reasoning was the original example of a (co-)NP-complete task (Cook, 1971). We will eventually recall a theorem due to Juba (2013) capturing a situation in which such reasoning is tractable. But, this theorem requires that we restrict the family of reasoning problems under consideration.

Although there are a variety of examples of families of reasoning problems for which algorithms exist, for our purposes the most natural family is described in terms of the *resolution* proof system. This is because resolution is one of the simplest propositional proof systems, and it simultaneously captures the capabilities of the most effective algorithms for reasoning in practice, cf. Beame et al. (2004). Recall, resolution is a proof system that operates on clauses. There is a single rule of inference in resolution called *cut* that allows one to derive new clauses: given a pair of clauses, $x \vee y \vee \cdots$ and $\neg x \vee z \vee \cdots$ that respectively contain an attribute x and its negation, cut allows one to derive the clause obained by taking the OR of the rest of the clauses, $(y \vee \cdots) \vee (z \vee \cdots)$.

Resolution is typically used to prove a DNF formula using a proof by contradiction: since the cut rule is sound, if we can derive the unsatisfiable, empty clause from an initial set of clauses, then the initial set must also have been unsatisfiable. If we are given that our background knowledge is true and we wish to prove that a DNF (say representing our goal) is satisfied, then by taking the negation of that DNF, we obtain a CNF via de Morgan's law; by showing that this CNF cannot be satisfied together with the background knowledge, we establish that the original DNF cannot be falsified, so it must be true.

For example, in our running example of the Gripper problem, suppose there are three rooms r, r', and r'', and two balls, b and b'. Suppose our goal for the moment is simply to not have the balls in the same room. This may be encoded by the DNF

$$[\neg x_{r,b} \wedge x_{r,b'}] \vee [\neg x_{r',b} \wedge x_{r',b'}] \vee [\neg x_{r',b} \wedge x_{r'',b'}].$$

Recall that we supposed that we had background knowledge capturing the fact that each ball is in exactly one room—in particular, for each of b and b', exactly one of $x_{r,b}$, $x_{r',b}$ and $x_{r'',b}$ is true. We would encode this by the clauses $x_{r,b} \vee x_{r',b} \vee x_{r'',b}$ (so at least one is true) and $\neg x_{r,b} \vee \neg x_{r',b}$, $\neg x_{r,b} \vee \neg x_{r'',b}$, and $\neg x_{r',b} \vee \neg x_{r'',b}$ (so at most one is true), and similarly for b'. Now, if we are in room r and we know that the ball b is in room r but the ball b' is not, then there is a resolution proof that the goal is satisfied as follows. We are now seeking to refute the negation of the goal,

$$[x_{r,b} \vee \neg x_{r,b'}] \wedge [x_{r',b} \vee \neg x_{r',b'}] \wedge [x_{r',b} \vee \neg x_{r'',b'}].$$

A resolution proof might proceed as follows: since we know $x_{r,b}$, our background knowledge that b is in at most one room, $\neg x_{r,b} \vee \neg x_{r',b}$ and $\neg x_{r,b} \vee \neg x_{r'',b}$ allows us to derive respectively $\neg x_{r',b}$ and $\neg x_{r'',b}$. In the second and third clauses of the negation of the goal, these allow us to derive $\neg x_{r',b'}$ and $\neg x_{r'',b'}$. But now, our background knowledge that b' is in some room, $x_{r,b'} \vee x_{r',b'} \vee x_{r'',b'}$ allows us to derive $x_{r,b'}$. But, we are given that b' is *not* in room r, i.e., $\neg x_{r,b'}$. So we can use this to arrive at the empty clause, a contradiction.

There is a natural graph associated with a proof: the clauses used in the proof appear as nodes of the graph, and for each derived clause in the proof, there is a directed edge from each of the clauses used in the derivation to the result. The sources of this graph are

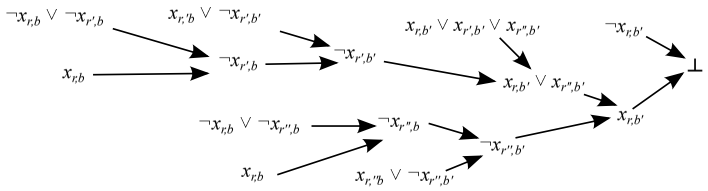

Figure 1: An example (treelike) resolution proof of $[\neg x_{r,b} \wedge x_{r,b'}] \vee [\neg x_{r',b} \wedge x_{r',b'}] \vee [\neg x_{r',b} \wedge x_{r'',b'}]$ from $x_{r,b}$, $\neg x_{r,b'}$, and the background knowledge.

labeled by premises of the proof, and the sink should be labeled by the empty clause. If this graph is a tree (we allow the same premise to label multiple leaves) then the proof is said to be *treelike*. Equivalently, a treelike proof is one that does not re-use intermediate derivations. The proof we just gave is treelike for example, cf. Figure 1. Any proof can be made treelike by simply repeating any intermediate steps; this comes at the price of increasing the number of steps, perhaps by up to a factor of two. Thus, the property of having a *small* treelike resolution proof (in terms of the number of steps) is a significant restriction. This restriction can be exploited to give efficient algorithms that guarantee that they find conclusions whenever such proofs exist. Again, we stress that without *some* such restriction, the problem of propositional reasoning is (co-)NP-complete.

A measure of tree complexity for proofs and policies. The main notion of "complexity" of a tree (either treelike resolution proof or decision tree) that we use is:

Definition 7 (Strahler number) *The* Strahler number *(aka* rank *or* pebble number*) of the nodes of a rooted binary tree are inductively defined as follows:*

- *all leaves have Strahler number one,*
- *nodes with two children of equal Strahler number s have Strahler number $s+1$, and*
- *nodes otherwise have Strahler number equal to the maximum of the Strahler numbers of their children.*

Finally, the Strahler number *of the tree is the Strahler number of its root.*

So, for example, our example treelike resolution proof given in Figure 1 has Strahler number three. Kullmann (1999) was the first to consider resolution proofs of bounded Strahler number, and showed that they can be found in polynomial time (where the polynomial depends on the Strahler number).

A significant property, noted by Ansótegui et al. (2008), is that derivations of Strahler number 2 correspond *precisely* to derivations using the well-known *unit propagation* rule, which in turn naturally simulates *chaining* with, e.g., Horn rules. In particular, our earlier example essentially followed from applications of the unit propagation rule, and the corresponding Strahler-2 derivation appears in Figure 2. (In general the Strahler-2 resolution proof follows the opposite derivation order from the unit propagation or chaining derivation.)

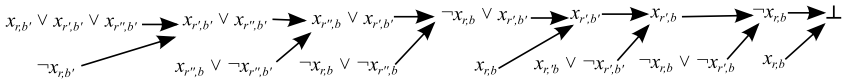

Figure 2: A Strahler-2 resolution proof of $[\neg x_{r,b} \wedge x_{r,b'}] \vee [\neg x_{r',b} \wedge x_{r',b'}] \vee [\neg x_{r',b} \wedge x_{r'',b'}]$ from $x_{r,b}$, $\neg x_{r,b'}$, and the background knowledge.

We also note that the Strahler number of a treelike resolution proof is always one less than the *clause space* of the proof, as defined by Esteban and Torán (2001): that is, the number of clauses that need to be remembered simultaneously to carry out the corresponding derivation. Indeed, if we consider derivations using a constant number of "registers" in which the registers' contents are deleted or overwritten upon their use in a derivation, then we obtain an alternative characterization of treelike proofs with bounded Strahler number.

These characterizations of bounded Strahler number proofs help clarify when such simple derivations exist. For example, plans (given by a set of action literals) in STRIPS domains can be proved to achieve their goals by chaining the action and initial state literals through the relevant clauses, and hence have derivations of Strahler number 2. Thus, it will be helpful to think of this work as giving a family of algorithms, parameterized by the Strahler numbers they use, as fixed Strahler numbers encompass natural syntactic classes of proofs and decision trees. (We will discuss the interpretation of bounded Strahler number decision trees later.)

We also briefly remark that Ansótegui et al. (2008) report experiments indicating that "industrial" instances of SAT that are easy in practice actually have (cf. the connection between modern SAT-solvers and resolution refutations from Beame et al., 2004) resolution (sub-)refutations with Strahler numbers that are significantly lower than those of random formulas of the same size and clause density. They propose that the property of having bounded Strahler number derivations might be what distinguishes instances that are easy in practice from those that are not.

Complex goals. We note that this environment model and class of proofs encompasses goals defined by arbitrary polynomial-size circuits, and not merely DNFs by a standard transformation: given a circuit defining a goal predicate, conceptually, we replace the POMDP we wish to solve with a new POMDP in which the states are extended with new propositional attributes that are always masked for each of the wires of the circuit, and the clausal (SAT) encoding of the constraints imposed by the circuit's gates is included as explicit background knowledge. Reasoning with resolution proofs of Strahler number two or greater will then use the background knowledge to evaluate the goal circuit: That is, once a setting for the inputs to a circuit has been guessed or fixed in some way, the unit propagation rule (which corresponds to a Strahler-2 proof) fills in the remaining, forced values of the circuit, much as it fills out the effects of a plan in an environment described by STRIPS rules. The propositional formula that we give to the algorithm then ultimately

consists only of the propositional variable encoding the output wire of the circuit, which then indeed indicates whether or not the goal is achieved.

2.2.2 Algorithms for Integrated Learning and Reasoning in PAC-Semantics

We now recall some efficient (but incomplete) algorithms for verifying the $(1-\epsilon)$-validity of a query DNF using a sample of partial assignments from our masked background distribution. Specifically, we recall an algorithm of Juba (2013) for verifying the $(1-\epsilon)$-validity of a formula when a Strahler-s treelike resolution proof of the formula from a $(1-\epsilon)$-testable CNF (and the KB, given as a CNF) exists.

Theorem 8 (cf. Theorem 13 of Juba 2013) *Let a KB CNF Φ and DNF query φ be given, and suppose that partial assignments are drawn from a masking process for an underlying distribution D' and are given together with weights w such that for the underlying example x, $w = D(x)/D'(x)$ with $w \leq W$; suppose further that for $\gamma > 0$ either*

1. *There exists some CNF ψ such that ψ is $(1-\epsilon+\gamma)$-testable under $M(D)$ and there is a Strahler-s treelike refutation of $\Phi \wedge \neg\varphi \wedge \psi$ or else*
2. *$[\Phi \Rightarrow \varphi]$ is at most $(1-\epsilon-\gamma)$-valid w.r.t. D*

Then, there is an algorithm running in time $O(\frac{W^2(|\Phi|+|\varphi|)}{\gamma^2} n^{2(s-1)} \log \frac{1}{\delta})$ (where $|\cdot|$ refers to the representation size in bits) that distinguishes these cases with probability $1-\delta$ when given φ, Φ, ϵ, γ, and a sample of $O(\frac{W^2}{\gamma^2} \log \frac{1}{\delta})$ partial assignments.

The cited result of Juba (2013) is for a sample of assignments from D directly without weights. Given that the algorithm simply computes an empirical estimate of an expectation over examples from $M(D)$, by reweighting each example from $M(D')$ by w, we obtain an unbiased estimate over $M(D)$ (at a cost of needing to scale γ by W to obtain our guarantee, yielding the quoted change to the sample complexity and running time).

As suggested earlier, works such as Precup et al. (2001) showed how such weights enable us to use importance weighting to use the traces produced by the exploration policy Π^* to estimate the probability with which a new, candidate policy Π achieves a goal. Since our goal predicate G will be given by a DNF, Theorem 8 allows us to check that a sequence of actions $\alpha^{(1)}, \ldots, \alpha^{(T)}$ results in the satisfaction of the goal predicate G in $s^{(T)}$, and hence test if a sequence of actions leads to the goal being achieved: the formula $[a^{(1)}_{\alpha^{(1)}} \wedge \cdots \wedge a^{(T)}_{\alpha^{(T)}}] \Rightarrow G(s^{(T)})$ is also a DNF, and hence Theorem 8 can be applied. Theorem 8 guarantees that if the algorithm reports that the formula is valid, then with probability $1-\delta$ over the examples, G will be satisfied on $s^{(T)}$ after these actions with probability $1-\epsilon-\gamma$ over the dynamics of the POMDP. At the same time, Theorem 8 guarantees that the algorithm reports that the formula is valid when some appropriate testable CNF exists, under which G can be proved from $a^{(1)}_{\alpha^{(1)}} \wedge \cdots \wedge a^{(T)}_{\alpha^{(T)}}$, e.g., a CNF encoding STRIPS rules for the environment if we are using Strahler-2 treelike resolution as our proof system.

2.3 Decision Tree Policies

The approach as described in the previous section—i.e., guaranteeing that the goal is satisfied given only the sequence of actions—is oblivious to the state of the environment, and hence only captures *"conformant"* planning (Goldman and Boddy, 1996). Such an approach

side-steps issues of partial information when it is possible, but of course such plans with high probability of success are unlikely to exist in most situations. On the other hand, introducing the *entire* sequence of observations (as a conjunction) is problematic as the space of possible observations is large, and under many natural environments it is unlikely that we would ever encounter a consistent sequence of observations even twice. It would then be infeasible to collect a large enough sample to learn the dynamics sufficiently well for such an approach to be effective. A natural alternative that incorporates some knowledge about the state of the environment at a "coarser" level is to use a policy that is computed by a (small) decision tree, as proposed by Chapman and Kaelbling (1991) in the context of fully observed MDPs, and essentially applied to POMDPs in McCallum (1995, 1996).

Definition 9 (Decision tree policy) *A* decision tree policy *is a rooted tree of degree* ≤ 2 *in which*

- *nodes of degree* 2 *are labeled by an attribute and an observed value for the attribute from the set of observable values* $\{0, 1, *\}$*, and one edge to a child node is labeled true, and the other false,*
- *other nodes (of degree zero or one) may be labeled with actions*

with the interpretation that given an observation $o \in \{0, 1, *\}^n$*, the agent takes the action (possibly, "no action") labeling the next such node on the branch starting from the previous action (or the root, if no such action exists) on which the true edge at each intermediate node is taken precisely when the attributes take the values on given node's label.*

If at most T *action nodes appear on any path, then we say that the policy is a* T-horizon decision tree.

A small decision tree policy is "coarser" in the sense that the actions of the policy only depend on the observed state (or lack of observation) of the attributes examined on a branch of the tree, which in general must contain far less than all of the attributes. We note that when the decision tree has some fixed polynomial size (in n), it has a polynomial number of leaves with polynomial length branches—and hence, if on each branch labeled by the literals $\ell_1, \ldots, \ell_k$, the formula $[\ell_1 \wedge \cdots \wedge \ell_k] \Rightarrow G$ is $(1-\epsilon)$-valid, then by a union bound, the policy will achieve G with probability at least $1 - \epsilon'$ for some ϵ' polynomially related to ϵ. Such a guarantee of $(1-\epsilon)$-validity can, in turn, be provided by the algorithm of Theorem 8 if a proof of $[\ell_1 \wedge \cdots \wedge \ell_k] \Rightarrow G$ (from some witnessed CNF) exists for each branch of the tree.

2.3.1 Strahler-s Decision Tree Policies

As hinted at in the previous section, we will also consider the Strahler number as a measure of decision tree complexity, specifying a restriction on the space of policies we consider. For a fixed Strahler number, the trees will indeed have a fixed polynomial bound on their size, and hence we can establish their quality leaf-by-leaf as discussed above. Moreover, a Strahler number bound will enable polynomial-time algorithms to *find* a policy when such "simple," provably good policies exist, and will guarantee the existence of quasipolynomial-time algorithms for general decision trees.

Much as with resolution proofs, the Strahler number of decision tree policies has a natural interpretation as follows. First, observe that "decision trees" of Strahler number 1 (i.e., a single branch) are precisely conformant plans. More generally, a policy of Strahler

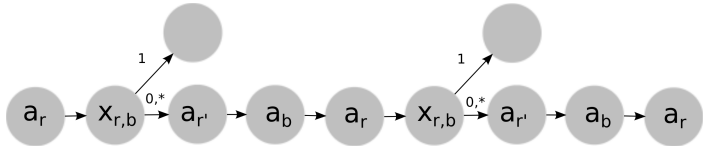

Figure 3: A Strahler-2 decision tree policy for the simple Gripper problem.

number s can be viewed as a decision list over Strahler number $s-1$ policies. That is, we have a hierarchically structured family of policies in which a sth level policy selects from among the members of level $s-1$ by testing a series of literals. (The policy may also take some actions amidst these tests, before selecting a lower-level policy to invoke.) We remark that, by testing the effects of each action after taking it, this captures a class of partial-information s-fault tolerant plans (cf. Jensen et al., 2004), where each fault is signaled by the first literal that did not end up satisfied. We note that Strahler-s policies can capture *all* such plans. We briefly remark that Strahler-s decision trees and the more popular OBDDs (Bryant, 1992) are of incomparable strength, depending on the variable ordering.

Alternatively, we can also characterize these policies in terms of the depth of nesting of the conditional branching: in a Strahler-s policy, at each conditional branch, there must be some sequence of branches such that the policy tests at most $s-1$ literals before terminating. Of course, this means that a policy that always tests k attributes to decide what action(s) to take has Strahler number k. Such a policy is a decision tree of size 2^k, and so may be very complex if k is even moderately large.

2.3.2 Example Decision Tree Policies

Returning to our running example based on the Gripper domain, we now describe a simple Strahler-2 decision tree policy for the goal $x_{r,b}$, i.e., carrying ball b to room r, that only fails on any given branch with probability at most .01. The policy is depicted in Figure 3. It first executes a_r, and branches on $x_{r,b}$; if $x_{r,b} = 1$, the agent terminates the execution (and the goal is satisfied w.p. 1 on this branch). Otherwise, the agent executes $a_{r'}$ for the other room r', and executes a_b. The agent then executes a_r, and branches on $x_{r,b}$. Again, if it is 1, the agent terminates and the goal is satisfied w.p. 1. Otherwise, the agent again executes $a_{r'}$, a_b, and a_r, and finally terminates. Notice, this final branch is only taken with probability $.01 + .01 \cdot .99 = .0199$, and conditioned on it having been taken, it only fails with probability .0199 again, so the overall probability of the branch ending in failure is $(.0199)^2 < .01$ (it is actually less than 0.04%), and it turns out that this is the total failure probability of this policy. The policy can be seen to have Strahler number 2 since at each test, (at least) one branch terminates with no further tests.

We note that a union bound over the failure probabilities of the two STRIPS-style rules only gives .98-validity for the conclusion that the ball should be in room r after the action sequence a_b, a_r, and the actual validity is .9801 since these failures are independent. This is (still) too high for the policy to safely terminate after executing it just once. The more

complex rule

$$[a_{r'}^{(t)} \wedge a_b^{(t+1)} \wedge a_r^{(t+2)} \wedge \neg x_{r,b}^{(t+3)} \wedge a_{r'}^{(t+3)} \wedge a_b^{(t+4)} \wedge a_r^{(t+5)}] \Rightarrow x_{r,b}^{(t+6)}$$

on the other hand, actually not only has validity $1-(.0199)^2$ (it is satisfied if either $x_{r,b}^{(t+3)}$ is 1 or $x_{r,b}^{(t+6)}$ is 1), but is also witnessed true with that probability in our environment (conditioned on that action sequence). Since this same conjunction of literals is asserted on the aforementioned branch of the policy, there is a Strahler-2 (chaining) derivation of the goal, $x_{r,b}$, using this witnessed rule.

Stochastic environments, iteration, and Strahler numbers. It should be evident that even if the failure probabilities were much higher than 1%—say it was p—by repeating the action sequence $a_{r'}, a_b, a_r$ k times, we can drive the probability of failure overall down to p^k; so, we can reach a desired ϵ failure probability in $3\log_p \frac{1}{\epsilon}$ steps (assuming the time horizon T is sufficiently large), and that such a policy still has Strahler number 2: it simply has a longer list of tests. In such a way, even if the environment is highly stochastic and is not well described by STRIPS rules, e.g., a more general PPDDL domain (Younes and Littman, 2004), there may still be rules referring to multiple states (e.g., repetitions of a faulty action) that are witnessed true with high probability and that guarantee that the goal is achieved. We stress that Theorem 8 (and hence our ultimate algorithm) only requires that such a rule exists to (implicitly) make use of it. We do not need to ever explicitly construct the rule, so it does not matter if the rule is complex, and it does not matter if all of the simple (STRIPS) rules are unreliable.

One change to the POMDP that would require a policy with a larger Strahler number would be if the number of rooms increased from 2 to R (since then it does not suffice from testing room r to determine that the ball is in the other room; more tests are needed). But, in this case there is a Strahler-3 decision tree policy: consider a decision list that iterates over the R rooms by invoking $a_{r'}$ for each room r', then branching on $x_{b,r'}$, moving on if $x_{b,r'}$ is not 1, but otherwise executing the Strahler-2 policy above for the room r' where $x_{b,r'}$ was 1. By our decision list characterization of the Strahler number, this is a Strahler-3 decision tree policy. By an essentially similar argument, it achieves the goal with similar reliability.

The role of reasoning. Back in the two-room environment, a more complicated goal is $x_{r,b} \wedge x_{r',b'}$ (where $r \neq r'$ and $b \neq b'$), that is, placing ball b in room r and ball r' in room b'. There is a natural Strahler-3 policy for this goal: the agent executes the Strahler-2 policy for $x_{r,b}$ until it would terminate, it then executes a_0 (dropping b in room r) and invokes the Strahler-2 policy for $x_{r',b'}$. (Since at every branch, at least one branch leads to a Strahler-2 policy, the overall policy is again guaranteed to have Strahler number 3.) It is easily verified that for this policy, we can bound the probability that each branch is taken and leads to failure by $2 \cdot (.0199)^2 - (.0199)^4$ which is less than 0.08%, and the overall probability of the policy failing is likewise less than 0.08%.

The verification of this goal is *not* trivial, however, since $x_{r,b}$ and $x_{r',b'}$ are never simultaneously unmasked. In the absence of any further knowledge about the environment, this would pose a problem. But, by providing the agent with explicit frame axioms as we describe in Section 4, we will see how the agent can still identify a successful policy. As

we noted above, for every branch of the initial policy for r and b, we have a proof that $x_{r,b}$ is satisfied. Now, after a_0 is executed, x_b is set to 0, and then none of the actions taken in the policy for r' and b' would ever falsify $x_{r,b}$. Therefore, the frame axioms for the literal $x_{r,b}$ can be invoked—and these are 1-valid here—and so by chaining $x_{r,b}$ across the subsequent steps, we obtain that $x_{r,b}$ is satisfied at the final step of the plan. Together with the derivation of $x_{r',b'}$ on the branch in question (variously described above for the simple one-ball policy) this allows us to *refute* $\neg x_{r,b} \vee \neg x_{r',b'}$ with a chaining proof, and hence we have a Strahler-2 derivation of $x_{r,b} \wedge x_{r',b'}$.

3. Learning and Planning

Algorithms for simultaneously learning and reasoning in PAC-Semantics (as captured in Theorem 8) turn out to provide a bridge between *learning* dynamics from examples and logic-based approaches to *planning*. Intuitively, Theorem 8 describes an algorithm that can verify when we have found a good branch of a policy by finding a proof (using knowledge learned from example traces) that the branch achieves the goal sufficiently well. Our algorithm is then based on the work of Ehrenfeucht and Haussler (1989) on learning decision trees with low Strahler number: once we can verify that individual branches are suitable, their analysis shows that the entire policy can be found efficiently via an algorithm that recursively searches for a decision tree policy that achieves the goal with high probability below a given, candidate branch.

Theorem 10 (Finding decision tree policies) *There is an algorithm that, when given a time horizon T, Strahler number bound s, $\mu, \gamma, \delta, \epsilon > 0$, KB CNF Φ, goal DNF G and action set A for an n attribute POMDP, runs in time $O(m|\Phi|(nT)^{4(s-1)})$ using at most $m = O(\frac{1}{\mu^2\gamma^2}(nT + \log\frac{|A|}{\mu} + \log\frac{1}{\delta}))$ weighted traces of an arbitrary policy Π^*. (Again, $|\Phi|$ refers to the representation size of Φ in bits, while $|A|$ refers to the cardinality of A.)*

Suppose there is a Strahler-s T-horizon decision tree policy Π taking μ-typical actions with respect to Π^* such that for each branch, there is a Strahler-s treelike resolution proof of "this branch is taken $\Rightarrow G$" from the KB and some CNF ψ that is $(1-\epsilon+\gamma)$-testable over traces of the POMDP with Π. Then with probability $1-\delta$, the algorithm finds a Strahler-s T-horizon decision tree policy that achieves G in the POMDP with probability $1-O((nT)^{s-1}(\epsilon+\gamma))$.

We stress that our focus is primarily on policies and proofs with small Strahler numbers, say $s = 2$, $s = 4$, etc., so that this algorithm is polynomial-time and obtains a polynomially bounded increase of the failure probability.

We require the following combinatorial lemma:

Lemma 11 *1. The number of branches k in a T-horizon decision tree policy over n fluents of Strahler number s with $n \geq s \geq 1$ is $2^{s-1} \leq k \leq (3enT/(s-1))^{(s-1)}$ where e is the base of the natural logarithm.*

2. At most $3^{3nT}\frac{T}{\mu}$ distinct sets of literals and actions label branches of any T-horizon decision tree policy over n fluents with μ-typical actions.

Proof Note that our T-horizon decision tree policy can be written as a decision tree over $3nT$ variables, $x_{i,b}^{(t)}$ for $i = 1, \ldots, n$, $b \in \{0, 1, *\}$, and $t = 1, \ldots, T$; therefore, the first part

Algorithm 1 Find-DT()

PAC-refute(φ, R) decides if $\varphi \wedge \psi$ is at most ϵ-valid given some testable ψ over weighted partial examples in R (taken out of m) (cf. Theorem 8).
Input: DNF goal G, CNF KB Φ, Strahler number s, policy branch Π taking $t-1$ actions, horizon bound T, sample of traces with stepwise weights R
Output: A Strahler-s decision tree or $\perp$
if Π takes more than T actions **then**
  return $\perp$
end if
$R^t \leftarrow \{(\times_{i=1}^{t-1}(o^{(i)}, a^{(i)}) \times o^{(t)}, \Pi_{i=1}^{t-1} w_i) : ((o^{(i)}, a^{(i)}, w_i)_{i=1}^{T}, o^{(T+1)}) \in R, \Pi_{i=1}^{t-1} w_i \leq \frac{4}{\mu}\}$
if PAC-Refute($\neg G^{(t)} \wedge \Phi \wedge \Pi$ taken, R^t) **then**
  return Π.
end if
if $s > 1$ **then**
  for all ℓ s.t. $\ell^{(t)}$ and $\neg\ell^{(t)}$ not in Π **do**
    $\Pi_\ell \leftarrow \Pi$ with a final test for $\ell^{(t)}$
    $\Pi_1 \leftarrow$Find-DT$(G, \Phi, s-1, \Pi_\ell, T, R)$
    if $\Pi_1 \neq \perp$ **then**
      $\Pi_0 \leftarrow$Find-DT$(G, \Phi, s, \Pi_{\neg\ell}, T, R)$
      if $\Pi_0 \neq \perp$ **then**
        return Policy following Π_b if $\ell^{(t)} = b$
      else
        return $\perp$
      end if
    end if
  end for
end if
for all α s.t. $\#\{\rho \in R : a^{(t)} = \alpha\} \geq (\mu/2)m$ **do**
  $\Pi_\alpha \leftarrow \Pi$ with $a^{(t)} = \alpha$
  $R_\alpha \leftarrow \{\rho \in R : a^{(t)} = \alpha\}$
  $\Pi' \leftarrow$Find-DT$(G, \Phi, s, \Pi_\alpha, T, R_\alpha)$
  if $\Pi' \neq \perp$ **then**
    return $a^{(t)} = \alpha$ followed by Π'
  end if
end for
return $\perp$

follows immediately from the first part of Lemma 1 of Ehrenfeucht and Haussler (1989). For the second part, we simply note that there are at most $\frac{1}{\mu}$ possible maximal sequences of μ-typical actions (i.e., that are not prefixes of one another). These sequences have at most T prefixes each, and for each of the $3nT$ variables, the branch may either omit the variable or check that the variable is true or false. The bound is now immediate. ■

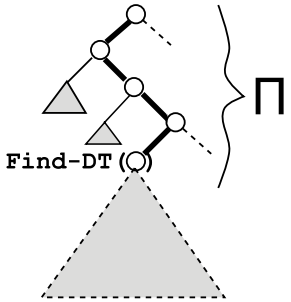

Figure 4: A snapshot of the execution of Algorithm 1: `Find-DT` is invoked at the indicated point at the end of the branch Π. `Find-DT` returns a subtree (shown in dashes) rooted at the end of Π such that the overall policy achieves the input goal G with high probability at all of the leaves of the subtree.

Proof (of Theorem 10) The algorithm, given as Algorithm 1, recursively searches for a sub-policy in which each leaf, with probability at least $(1 - \epsilon - \gamma)$, either achieves G or is not reached (see Figure 4). Intuitively, we are filtering our samples so that we obtain samples from a policy $\tilde{\Pi}^*$ that simulates Π^* until Π^* takes an action such that the action sequence would have overall probability less than $\mu/4$, and then takes a distinct "abort" action instead. Note that t-step traces in which $\tilde{\Pi}^*$ does not abort are precisely those with $\prod_{i=1}^{t} w_i \leq 4/\mu$. At each node, our learning and reasoning algorithm is invoked on the example traces to test if either G is satisfied or that branch is not taken with a $1-\epsilon$ fraction of the m examples (with examples off the branch removed from the sample since they are guaranteed to satisfy our target condition). If so, we have found a suitable leaf.

In $m \geq \frac{8}{\mu^2}(3nT \ln 3 + \ln \frac{4T|A|}{\mu} + \ln \frac{3}{\delta})$ example traces, the fraction of times a sequence of actions appears approximates its probability under $\tilde{\Pi}^*$ to within an additive $\mu/4$ with probability $1 - \delta/(3|A|M)$ where M is the number of distinct events corresponding to taking branches appearing in T-horizon decision tree policies labeled by $\mu/4$-typical actions, as given in part 2 of Lemma 11. In particular, since there are at most $|A|M$ action sequences that are either $\mu/4$-typical or not $\mu/4$-typical and minimally so, this guarantees that with probability $1 - \delta/3$, all of the action sequences which appear in a $\mu/2$-fraction of the traces are at least $\mu/4$-typical under $\tilde{\Pi}^*$, and that the $(3/4)\mu$-typical actions under $\tilde{\Pi}^*$ all appear in at least a $\mu/2$-fraction of the traces. In particular, since all of the μ-typical action sequences of Π^* are at least $(3/4)\mu$-typical under $\tilde{\Pi}^*$, all of these appear.

Soundness. We first note that as a consequence of our filtering the examples to be consistent with the branch Π, the weights we compute for our queries are

$$\prod_{i=1}^{t} w_i = \prod_{i=1}^{t} \frac{I[a^{(i)}_{\alpha^{(i)}} | \Pi \text{ followed for } 1,\ldots,i-1]}{\Pr_{\tilde{\Pi}^*}[a^{(i)}_{\alpha^{(i)}} | \Pi \text{ followed for } 1,\ldots,i-1]} = \frac{\Pr_{\Pi}[\Pi \text{ followed for } 1,\ldots,t]}{\Pr_{\tilde{\Pi}^*}[\Pi \text{ followed for } 1,\ldots,t]}$$

where these weights are bounded by $4/\mu$. Therefore m examples are sufficient to bound the probability of queries being satisfied over traces of Π by an additive γ with probability $1 - \frac{\delta}{3M}$. By a union bound over the M possible queries, every query is answered correctly w.p. $1 - \delta/3$.

As Theorem 8 guarantees that for each branch the formula asserting that either the leaf is not reached or the policy succeeds is $(1-\epsilon-\gamma)$-valid, the probability that the policy fails on each branch is at most $\epsilon+\gamma$. So, when a decision tree policy is returned, a union bound over the $O((nT)^{s-1})$ branches (by part 1 of Lemma 11) yields the claimed performance. So the algorithm only fails by returning a bad policy when some query is answered incorrectly, which occurs w.p. at most $\delta/3$.

Completeness. We already saw that the algorithm considers all sequences of μ-typical actions under Π^* with probability $1 - \delta/3$. Now, if the algorithm does not find a policy in which a branch with lower Strahler number takes no action, then if there is a policy with the given Strahler number bound, it must take *some* action at the next step, and otherwise, (i.e., if a sub-policy was found) there is no harm in asserting the opposite setting of $x^{(t)}_{i,b}$, since adding this literal to the formula for the branches of the target policy only increases the probability of the branch not being taken (and thus improves the success probability for that branch). In particular, the original Strahler-s tree is still a candidate. Theorem 8 also guarantees that for the quoted number of examples, all of the branches of the target policy will be accepted w.p. at least $1 - \delta/3$ as needed. Thus overall the algorithm succeeds at returning a good policy when it exists w.p. $1 - \delta$.

Time complexity. Finally, the work per recursive call of our algorithm involves partitioning the examples and running `PAC-refute` on the sample, which is linear in the sample size $|R|$. So, given $W \cdot m$ work per node with $|R| = m$, the running time bound for the algorithm of $O(W \cdot m(nT)^{2(s-1)})$ is easily established by considering the following recurrence with boundary conditions $f(0, m, s) = 0$, $f(n', m, 0) = W \cdot m$ over $n' = (3n+1)T$, counting the possible remaining literals plus one action for each time step: the bound is a solution to the recurrence

$$f(n', m, s) \leq f(n'-1, m, s) + 2n' f(n'-1, m, s-1) + W \cdot m.$$

The running time of the algorithm also satisfies this recurrence since for such an f linear in m, if we take $m_\alpha = |R_\alpha|$ in Algorithm 1, $\sum_{\alpha \in A} f(n'-1, m_\alpha, s) \leq f(n'-1, m, s)$, and indeed our algorithm only iterates over actions (in which it partitions the example set among the recursive calls) if it does not make a Strahler-s recursive call while searching for a branch over the literals. Thus the running time satisfies the given bound satisfying the recurrence.

We now merely observe that the work by the learning and reasoning algorithm per node is $W \cdot m = O(|\Phi|(nT)^{2(s-1)}m)$, giving the claimed time bound. ■

It follows from Theorem 10 that we can find *general* decision tree policies taking μ-typical actions in quasipolynomial time since if a policy has B branches, Lemma 11 guarantees it has Strahler number at most $s = \log B + 1$.

3.1 An Illustration of the Algorithm

We return once again to our running example of the simple goal in the Gripper domain to illustrate the behavior of our algorithm; recall that in Section 2.3.2 we described a Strahler-2 decision tree policy for the goal $x_{r,b}$ (carrying the ball b to room r in a two-room environment), that had a Strahler-2 proof from a witnessed CNF that the goal was achieved with probability greater than 99% on each branch (it actually had probability greater than 99.96%). The policy itself appeared in Figure 3.

There is actually a conformant (Strahler-1) policy that achieves the goal with similar probability. Indeed, the policy we discussed in Section 2.3.2 does not need to examine the state of the environment. Our analysis of the plan could be applied about as well to the plan that simply applies the sequence of actions "move to room r', try to pick up the ball, move to room r, drop the ball" twice. In this case, when the plan is successful, the goal $x_{r,b}$ is actually witnessed satisfied on the final step (the attribute is unmasked in room r), and hence is "proved" by a trivial, Strahler-1 proof. Let's suppose that this policy involves a μ-typical sequence of actions for the exploration policy Π^*, and first consider what Algorithm 1 does when invoked on Strahler number $s = 1$.

The algorithm first checks to see if the goal, $x_{r,b}$ can be proved satisfied in the initial environment configuration with probability 99% using `PAC-refute`. Let's suppose not. Then, since the algorithm is invoked on Strahler number $s = 1$, it skips the first loop that searches for literals to branch on, and moves directly to a search over actions. It partitions the examples according to the first action taken, invoking a recursive call along a branch taking each possible action that is empirically at least $\mu/2$-typical. Let us consider the recursive call on a branch that starts with the action, "move to room r'" that we know may lead to a successful policy. This branch consists of a literal asserting $a^{(1)}_{r'} = 1$, and the recursive call only receives the subset of traces in which this action was taken. Again, `PAC-refute` should determine that $x^{(2)}_{r,b}$ is not provable on these traces. Now, the algorithm searches over actions at $t = 2$; since we are only considering traces in which $a^{(1)}_{r'} = 1$, strictly fewer actions produce a sequence (following $a_{r'}$ at $t = 1$) that is empirically $\mu/2$-typical; perhaps few of these traces try to move to room r' again, or few traces try to move immediately back to room r. The algorithm then does not make a recursive call for those actions. Since we have supposed that the overall policy is μ-typical, the action "pick up ball b" in particular will still be considered, so we consider the recursive call on this branch that now asserts $a^{(1)}_{r'} = 1$ and $a^{(2)}_{b} = 1$, and only considers the traces satisfying these conditions. On this call, we should still not find that $x^{(3)}_{r,b}$ is provable, and so we will recursively consider the sequences that begin with $a^{(1)}_{r'}$ and $a^{(2)}_{b}$, and are empirically $\mu/2$-typical; a_r should be an option. Now, on this call, `PAC-refute` should find that $x^{(4)}_{r,b}$

is at least 98%-valid. Unfortunately, this is not high enough, so the algorithm continues; but, we know that on the branch $a^{(1)}_{r'}, a^{(2)}_{b}, a^{(3)}_{r}, a^{(4)}_{0}, a^{(5)}_{r'}, a^{(6)}_{b}, a^{(7)}_{r}$, then in more than 99% of the traces, $x^{(8)}_{r,b} = 1$, so this branch will be returned. Of course, there is no guarantee that this policy will be the one that is found. For example, if the sequence of actions that starts with dropping any balls, and then moving to room r, and then continuing with the above sequence is empirically $\mu/2$-typical under Π^* for some reason, then it may be that the algorithm returns a policy $a^{(1)}_{0}, a^{(2)}_{r}, a^{(3)}_{r'}, a^{(4)}_{b}, a^{(5)}_{r}, a^{(6)}_{0}, \ldots$.

It is also instructive to consider the behavior of Algorithm 1 in this example, when invoked with Strahler number $s = 2$. This may find a rather different policy than the one illustrated in Figure 3. As before, we suppose that $x^{(1)}_{r,b}$ is not provable with sufficiently high probability. The $s = 2$ case then searches for tests of a single literal such that Strahler-1 branches suffice to achieve the goal, given that the test is satisfied. Naturally, the goal itself, $x_{r,b}$ is such a test, the leaf of the branch on which $x^{(1)}_{r,b} = 1$ trivially satisfies the goal w.p. 1. So, the algorithm will generally construct such a branch when it considers the literal $x_{r,b}$, and continues recursively searching for a Straher-2 policy on the subtree where $x^{(1)}_{r,b} \in \{0, *\}$. But, on any other literal, we also know that there is a Strahler-1 policy that achieves the goal with probability greater than 99%. For such literals, depending on how many traces are consistent with the sequence of conditions on $x^{(1)}$ that have been imposed thus far, a branch featuring some appropriate Strahler-1 plan will be added. Relatedly, we may also find that some branches are added that use, e.g., the policy we discussed that only achieves the goal with probability 98%, as long as at least 1% of the traces that would end in failure do not reach that branch, so that overall only at most 1% of the traces actually fail on the branch. Finally, some conditions on $x^{(1)}$ may simply be satisfied by fewer than 1% of the traces. Since our algorithm tolerates branches with a 1% failure probability in general, the algorithm will also add such branches to the tree, terminating immediately with leaves.[4] In general, the algorithm continues until either (1) less than 1% of the traces remain consistent with all of the conditions on the traces imposed by the main, Strahler-2 branch, in which case the algorithm will consider the remaining leaf to be adequate or (2) the main, Strahler-2 branch adds a successful sequence of actions, allowing $x^{(t)}_{r,b}$ to be proved to hold with probability 99% (as in the Strahler-1 case described above). Actually, in this example, once the algorithm considers branches for each of the three possible observed settings of any single attribute, every example trace is consistent with one of these three branches, and hence less than 1% (actually, 0%) will remain consistent with the main branch. The algorithm will therefore terminate before moving on to consider a single action on the main, Strahler-2 branch. In any case, depending on the order in which the attributes are considered, the final decision tree policy that is returned may have up to $\sim n$ branches, each either containing some suitable conformant plan or reached by fewer than 1% of the traces (and may not achieve the goal). This possible inclusion of extra branches that are each allowed a 1% failure probability is the reason for the $\sim nT$ increase in the total failure probability in the guarantee provided by Theorem 10.

4. Intuitively, such branches that only lead to failure are undesirable. But, in general sometimes we may need to take a branch with a high conditional failure probability in order to capture a few traces where the policy succeeds.

3.2 Discussion

The complexity of Algorithm 1, as established by Theorem 10 is roughly what one would hope to achieve given the current state of knowledge in learning theory. Our task is very similar to supervised learning in the sense that we are using examples from a *fixed distribution* over trajectories generated by the reference policy Π^* to estimate the probability with which policies achieve the goal. Our sample complexity depends logarithmically on the number of possible branches (that is, linearly in their representation size), and quadratically on $\mu\gamma$. Note that a branch of a decision tree computes a conjunction, i.e., the AND of the literals that lead to that branch; the former quantity is the *VC-dimension* (Vapnik and Chervonenkis, 1971) of the class of conjunctions, which characterizes the number of examples needed to estimate their fit (Vapnik and Chervonenkis, 1971; Blumer et al., 1989; Ehrenfeucht et al., 1989). We are exploiting the fact that the VC-dimension actually characterizes the number of examples needed in order to obtain a *uniform bound* on the estimates of the error for *the entire class of conjunctions*—that is, the set of all possible branches, here. As we have seen (in the algorithm of Ehrenfeucht and Haussler, 1989), one only needs to know which branches have low error in order to identify a good tree. The latter, quadratic dependence on $\mu\gamma$ arises because we are trying to estimate the probability that a sequence of actions (that only is taken with probability μ) fails up to an accuracy of γ; since we are essentially conditioning on an event of probability $\sim \mu$, this means that we are essentially seeking to estimate the probability that the sequence of actions leads to failure up to an accuracy of $\mu\gamma$ in the original distribution. It is well-known that this latter task requires $\sim 1/(\mu\gamma)^2$ samples. In any case, we stress that if we had not separated out the task of exploration, a $\sim |A| \cdot 2^n$ or 2^T lower bound on the sample complexity holds for even very simple environments (Kakade, 2003, Section 2.5).

Likewise, the time complexity for finding a Strahler-s policy is comparable to the time taken by the algorithm of Ehrenfeucht and Haussler (1989) for finding decision tree classifiers, which remains the fastest known algorithm for this task. Our running time is slightly greater since we need to use theorem-proving techniques to determine whether or not a branch of our policies are suitable, and we test each branch individually. It is an interesting question whether or not, for example, some intermediate results can be cached across invocations of our theorem-proving algorithms, possibly leading to a reduced total running time.

The main quantitative downside of this algorithm is the potential $\sim (nT)^{s-1}$ increase of the failure probability of the policy found by the algorithm over the best-possible policy. Unfortunately, this is roughly in accordance with what we hope to achieve with the current state of the art. We again draw an analogy to supervised classification, in which even very simple tasks seem to lead to a similarly large increase in the error in the related "agnostic" noise model. The trouble is that the task of finding representations that optimize the error appears to be intractable under various plausible assumptions, even for very simple classes of representations such as halfspaces (Shalev-Shwartz et al., 2011) or even disjunctions (Kearns et al., 1994; Daniely et al., 2014; Daniely and Shalev-Shwartz, 2014). We still do not know how tight an approximation of the optimal error can be achieved, but an approximation factor that depends polynomially on the number of attributes reflects the current state of the art: consider for example, the relatively simple task of learning a disjunctive classifier (an

OR of the attributes). The best known algorithm for this task in the agnostic noise model suffers an increase of $\sim n^{1/3}$ in its error probability when there are n attributes (Awasthi et al., 2010).

Thus, in practice, this algorithm is only useful in situations when a highly fault-tolerant policy exists. As we noted in Section 2.3.2, such policies may exist, even if the environment is highly stochastic. Our algorithm is relatively tolerant of a long time horizon, and by repeating actions, it may be possible to decrease the failure probability of the overall plan exponentially with T (whereas the dependence of the overhead on T only grows linearly). This depends on repetitions of such actions being "typical" under Π^*, of course, but if Π^* is produced by (for example) solving other, smaller instances of planning problems, such sequences of repeated actions in a stochastic environment may well be typical.

4. Extension to Non-monotonic Reasoning

One weakness of the result of the previous section in learning STRIPS domains is that the frame axioms can only be learned under partial information when they are not needed: in order for them to be witnessed, the corresponding attributes of the POMDP must be observed. At the same time, we cannot supply generic frame axioms to the algorithm since the standard formulation of the frame axioms depends on the preconditions and effects of the actions, which are what we hope the agent to learn in each domain. Generic *non-monotonic* formulations of the frame axioms do exist, however: the clause $[\ell^{(t)} \wedge \sim(\neg\ell^{(t+1)})] \Rightarrow \ell^{(t+1)}$, where $\sim \ell$ roughly means "ℓ cannot be proved," nicely captures the frame axiom whenever we have learned the effects and preconditions of the actions. In this section, we will describe a semantics for $\sim\ell$ that is suitable for these purposes with respect to Strahler-s resolution and can be evaluated in polynomial time; we can then extend the algorithm of Theorem 8 to answer queries containing such literals, and thus we can add these generic frame axioms to the KB when invoking Algorithm 1.

We will use a variant of the *Well-Founded Semantics* (van Gelder et al., 1991) (WFS) for logic programs. More specifically, we will modify the iterated quotient definition of Przymusinski (1994) to obtain, for each s, an analogue of WFS for Strahler-s resolution. In particular, since Strahler-2 resolution corresponds precisely to chaining, our generalization for Strahler-2 resolution coincides with WFS over all (appropriate) directed versions of our original, undirected set of clauses.

Definition 12 (Quotient operator) *For any CNF φ over literals possibly using $\sim$ and any pair of sets of literals (L_+, L_-), the* quotient of φ modulo (L_+, L_-), *denoted $\varphi/(L_+, L_-)$, is the CNF obtained by substituting 1 for occurrences of $\sim\ell$ s.t. $\ell \in L_-$, substituting 0 for occurrences of $\sim\ell$ s.t. $\ell \in L_+$, substituting other occurrences of $\sim\ell$ with occurrences of a corresponding new variable $\tilde{\ell}$, and simplifying the resulting formula by deleting satisfied clauses and falsified literals.*

The intuition behind the quotient is that the sets L_+ and L_- consist of the literals that we know, respectively, can and can't be proved from φ. We will see how to obtain a pair (L_+, L_-) conservatively respecting this intuition for any formula.

Definition 13 (Least partial state) *The* Strahler-s least partial state *LPS_s of a CNF φ is a pair of sets of literals (L_+, L_-) (*not *over the $\tilde{\ell}$ variables) s.t. $\ell \in L_+$ iff ℓ has a Strahler-s proof from φ and $\ell \in L_-$ iff for the CNF φ' in which all occurrences of the $\tilde{\ell}$ variables have been deleted, there is no Strahler-s proof of ℓ from φ'.*

This definition is analogous to a construction of the (unique) "least partial models" for normal logic programs from Przymusinski (1991), in which the name has a more meaningful interpretation in terms of the partial models of logic programs. The name "least" partial state comes from considerations like the following. The pair of sets of literals (L_+, L_-) is a partial state in the sense that all literals $\ell \in L_+$ under a $\sim$ are set to 1, $\ell \in L_-$ under $\sim$ are set to 0, and otherwise $\sim\ell$ is set to 1/2. We suppose we are trying to (pointwise) minimize the truth values of the literals of φ while respecting the Strahler-s conclusions that can be derived from it, possibly given some further settings of the $\sim$ literals. That is, the existence of a Strahler-s derivation of ℓ requires that the ℓ be true in the partial state, and if for *some* substitution of the different occurrences of $\sim$ literals for truth values there exists a Strahler-s derivation of ℓ, then that prevents setting ℓ to false. Then we assign each literal the least possible value subject to these constraints.

We will finally obtain our "well-founded" Strahler-s semantics for negation-as-failure by taking the *least defined* fixed-point of the quotient and least partial state operators: the quotient incorporates the settings for $\sim$ literals that have been derived, and the least partial state operator obtains the consequences for Strahler-s provability. That is, it can be shown (moreover) that literals are only marked as "provable" (placed in L_+) or "unprovable" (placed in L_-) precisely when they are provable or unprovable, respectively, in *every* partial state that is a fixed-point under the composition of the quotient and least partial state operators. Much as in the original conception of the Well-Founded Semantics in van Gelder et al. (1991), this definition also conforms to the desirable intuition that literals are only marked as "provable" or "unprovable" if this can be ultimately derived from φ itself (with no additional knowledge or assumptions about what else is provable), ruling out consistent but circular negation-as-failure settings.

Proposition 14 (Semantics of Strahler-s NAF) *For any CNF φ over literals possibly using $\sim$, the sequence of pairs of sets of literals $(L_+^{(0)}, L_-^{(0)}) = (\varnothing, \varnothing)$, $(L_+^{(i+1)}, L_-^{(i+1)}) = LPS_s(\varphi/(L_+^{(i)}, L_-^{(i)}))$ converges to a pair of sets of literals (L_+^*, L_-^*) s.t. for every literal ℓ (without $\sim$),*

1. *if there is a Strahler-s proof of ℓ from $\varphi/(L_+^*, L_-^*)$, then $\ell \in L_+^*$*
2. *if $\ell \in L_-^*$ then there is no Strahler-s proof of ℓ from $\varphi/(L_+^*, L_-^*)$*

Furthermore, there is an algorithm that computes (L_+^*, L_-^*) given φ in time $O(|\varphi| n^{2s})$

Proof Convergence will follow from the observation that $L_+^{(i)} \subseteq L_+^{(i+1)}$ and $L_-^{(i)} \subseteq L_-^{(i+1)}$. For $i = 0$, the statement is trivial.

To see $L_+^{(i)} \subseteq L_+^{(i+1)}$ for $i \geq 1$, consider the proof of ℓ from $\varphi/(L_+^{(i-1)}, L_-^{(i-1)})$ witnessing $\ell \in L_+^{(i)}$. By induction on the structure of the proof of ℓ, we construct a new proof as follows: if this clause was obtained by a cut rule on one of the $\tilde{\ell}'$ variables and $\ell' \in L_+^{(i)} \cup L_-^{(i)}$, in which case, one of the clauses survives in $\varphi/(L_+^{(i)}, L_-^{(i)})$ with the occurrence of $\tilde{\ell}'$ eliminated, and hence the clause may be obtained by weakening the clause of $\varphi/(L_+^{(i)}, L_-^{(i)})$ from which $\tilde{\ell}'$ was eliminated; otherwise, by our induction hypothesis, we can derive subclauses of the two clauses involved in this final step from $\varphi/(L_+^{(i)}, L_-^{(i)})$. (The base case is trivial.)

As for $L_-^{(i)} \subseteq L_-^{(i+1)}$ for $i \geq 1$, we assume inductively that $L_+^{(i-1)} \subseteq L_+^{(i)}$ and $L_-^{(i-1)} \subseteq L_-^{(i)}$. We note that when $\ell \notin L_-^{(i+1)}$, there is a proof of ℓ from $(\varphi/(L_+^{(i)}, L_-^{(i)}))'$, which is constructed from φ ultimately by deleting clauses that either contain $\sim\ell'$ for $\ell' \in L_-^{(i)}$ or $\neg(\sim\ell')$ for $\ell' \in L_+^{(i)}$, and eliminating the rest of the $\tilde{\ell}'$ literals from the remaining clauses. Thus, $(\varphi/(L_+^{(i)}, L_-^{(i)}))'$ is a subformula of $(\varphi/(L_+^{(i-1)}, L_-^{(i-1)}))'$ since $L_+^{(i-1)} \subseteq L_+^{(i)}$ and $L_-^{(i-1)} \subseteq L_-^{(i)}$ by our inductive hypothesis. Therefore, the same proof establishes $\ell \notin L_-^{(i)}$, completing the inductive step.

Since we add at least one literal on each iteration until convergence, if we compute (L_+^*, L_-^*) using the iterative definition, the algorithm terminates in at most n iterations. Since each iteration can be computed by at most $2n$ applications of the Strahler-s proof search algorithm on a formula of size at most $|\varphi|$ (which runs in time $O(|\varphi| n^{2(s-1)})$, the running time bound follows.

For our fixed-point, we have a pair of sets of literals (L_+^*, L_-^*) such that $(L_+^*, L_-^*) = LPS_s(\varphi/(L_+^*, L_-^*))$, and hence the two claimed properties are immediate from the definition of the Strahler-s least partial state. ■

Naturally, the interpretation of φ is given by the classical propositional formula $\varphi/(L_+^*, L_-^*)$. In particular, we can now extend our PAC-Semantics to incorporate negation-as-failure like so:

Definition 15 *We say that a formula φ (possibly using $\sim$) is* $(1-\epsilon)$-valid *w.r.t. a distribution D and masking process M if, for m drawn from M, x drawn from D, and the formula ψ consisting of the conjunction of literals satisfied on $m(x)$, putting (L_+^*, L_-^*) equal to the fixed point obtained from $\varphi \wedge \psi$, the probability (over m and x) that x satisfies $\varphi/(L_+^*, L_-^*)$ is at least $1-\epsilon$.*

We can answer queries in this extended PAC-Semantics by an easy modification of the algorithm underlying Theorem 8 wherein, for each example, we first compute (L_+^*, L_-^*) for the KB Φ, and then for a query φ, check for a refutation of $\varphi \wedge (\Phi/(L_+^*, L_-^*))$. Such an algorithm simply replaces the existing subroutine in Algorithm 1. For $s \geq 2$, we can then verify that the generic frame axioms $[\ell^{(t)} \wedge \sim(\neg\ell^{(t+1)})] \Rightarrow \ell^{(t+1)}$ are $(1-\epsilon-\nu)$-valid under the Strahler-s NAF semantics in a noisy STRIPS instance with noise rate ν and $(1-\epsilon)$-testable actions. We are therefore free to include them in the KB at a small cost in validity. Crucially, it may also be verified that they allow the values of hidden state attributes to be propagated forward, at least when they are the only clauses in the KB containing the state attributes.

5. Relationship to Other Work

Our ability to learn descriptions of the dynamics that are simple but imperfect already distinguishes our work from some others that attempt to learn explicit descriptions of an environment's rules from examples, e.g., (Otero, 2005; Amir and Chang, 2008). Others attempt to construct a model that accounts for the imperfection (García-Martínez and Borrajo, 2000; Schmill et al., 2000; Pasula et al., 2007; Yoon and Kambhampati, 2007;

Lang and Toussaint, 2009; Mourão et al., 2012), but cannot provide a formal analysis. This lack of theoretical grounding seems inherent due to the difficulties posed by agnostic learning; moreover, the negative results of Michael (2011) speak to the advantages of attempting to answer queries without producing an explicit action model. Work on applying logic programming to learning for planning (Thon et al., 2009) features algorithms with theoretical grounding for several tasks, but similarly encounters the structure learning problem when learning rule sets, and indicates that it (together with dealing with hidden information) remains a frontier problem for that approach. Work on Predictive State Representations by Boots et al. (2011) only establishes consistency, not fast convergence under any clear conditions—some kind of assumption on the condition number of the matrices seems essential, but neither the details nor the significance of this requirement seem to be understood.

The use of a limited class of policies to approximate optimal behavior has a long history in the reinforcement learning literature, see Sutton and Barto (1998, Chapter 8) for a review; in particular, techniques that used neural nets or other kinds of linear approximators to choose a good action are examples of such techniques. Chapman and Kaelbling (1991) seem to be the first to limit their policies to decision trees. The Utile Suffix Memory of McCallum (1995) similarly builds a coarsened approximation of the state space itself by classifying histories in partial information environments. Both of these works viewed the decision trees as dynamically refined estimates of the environments in which (approximately) optimal actions may be selected directly, rather than simply as policy representations to optimize; this latter view emerged only somewhat later (Kearns et al., 2002; Meuleau et al., 1999). We note that McCallum (1995) did not consider factored state and observation spaces, and so Utile Suffix Memory differs from our decision trees in that it does not branch along the propositional factors of the observations as we use here; this was later considered in the U-Tree algorithm of McCallum (1996). In any case, both Utile Suffix Memory and U-Tree are still viewed as classifying a partial trace, indexed by offsets from the current observation (e.g., branching on the observation from t steps prior) by a choice of action. Conceptually, this is more like a reactive policy, but applied to a longer history; by contrast, "states" of our decision tree policies are captured by a node of the tree, so the behavior of the policy is "non-uniform" with respect to time. The representation is still thus not equivalent once complexity measures such as the size come into consideration; our objective is also different, in that we merely seek for our trees to reach a goal state, whereas McCallum's policies are in the usual utility-maximization framework in which one seeks a high discounted utility over time. The algorithm we use thus also ends up being rather different from those proposed by McCallum. Finally, McCallum focuses strictly on empirical evaluation of his strategies, whereas our focus is strictly on a theoretical evaluation.

Our setting is related to a setting considered previously by Khardon (1999), apprenticeship learning (Syed and Schapire, 2010) and reductions to classification (Langford and Zadrozny, 2005): These works aim to learn a policy using example traces, even for sophisticated policy representations. The distinction is that we don't assume that Π^* is our desired policy, just that there exists a good policy that Π^* agrees with at least a μ-fraction of the time. (If the number of actions is small, Π^* could even be a random walk.)

Reinforcement learning techniques such as Kearns et al. (2002) can learn from a poor initial policy such as a random walk. But, these works often face the exploration problem by using repeated experience with the environment model, in particular with an explicitly

provided reward function – i.e., goal – at hand to guide their search for a policy. Largely as a consequence of the inherent difficulties of exploration in general environments, the theoretical analyses provided by such works exhibit an undesirable dependence on either the size of the state space or, in the particular case of Kearns et al., on the time horizon. (We note that a discount factor of $1 - 1/T$ is roughly equivalent to a time horizon of T.) Along somewhat similar lines, work by Fern et al. (2006) and Lazaric et al. (2010) consider learning from a poor initial policy in a full-information model by using a reduction to classification; the full-information setting is quite different in that the history of observations is no longer relevant (and so there is no need to consider a stateful policy like our decision trees). Theoretically, Fern et al. showed how to solve the MDP if the best action at each state is substantially better than the second best, and if the resulting deterministic optimal policy for a fixed horizon is expressed by an efficiently learnable class. Naturally, these assumptions may easily be violated, in particular if the actions in a plan can be reordered. Lazaric et al. extended the analysis of Fern et al., but assume that a policy minimizing the (nonzero, in general) loss can be found somehow. It is not clear what kind of policies Lazaric et al. have in mind, but in Boolean classification, this is essentially the problem of agnostic learning (Kearns et al., 1994); recent evidence suggests that this is intractable for all but the simplest kinds of classifiers (Daniely et al., 2014; Daniely and Shalev-Shwartz, 2014).[5]

Work by Walsh (2010) touches on all of the above areas; he constructs complete relational domain models with a full theoretical analysis, but under the assumption of constant arity expressions and numbers of effects (and/or in an apprenticeship learning setup). The assumptions of bounded arity mean that these relational expressions can be expressed by moderate size propositional representations, so the main trade-off between Walsh's work and ours is that Walsh produces explicit rules unlike us, but at the cost of exponential scaling when these arities and numbers of possible effects is large.

Learning from exercises (Natarajan, 1989; Tadepalli, 2008) is similar, except that the learner is provided sequences of examples that gradually increase in difficulty. The difference with our work is that we don't assume that the current goal can be reduced to subproblems of "lower difficulty" (but nor do we guarantee success when this is the case). Later, Joshi et al. (2010) took a similar approach in which example policies (generated either by simple strategies or by other planning algorithms) were used to obtain a fast model-checking policy search algorithm for relational planning in a fully observed setting. Their setting was thus quite different from ours—we are seeking to cope with missing information, as opposed to gaining a speed-up in a full-information setting.

We noted that the use of importance sampling to enable off-policy learning in POMDPs was first considered by Precup et al. (2000, 2001), building on earlier work on off-policy learning in MDPs (Sutton and Barto, 1998, Chapter 5). Precup et al. used a second-moment bound in their analysis of importance sampling since in general, the likelihood ratios may be large. Indeed, the issue that generally plagues importance sampling is that this variance may be high (Shelton, 2001; Peshkin and Shelton, 2002), and a variety of techniques (e.g., Hachiya et al., 2009, 2011) have been proposed to control the variance in more general settings. This problem actually does not arise in our setting, as a consequence

5. And, *approximate* agnostic learning generally incurs an increase in the loss of a similar magnitude as we obtain in Theorem 10—cf., the best known polynomial time algorithm for learning disjunctive classifiers on n attributes increases the loss by a factor of $n^{1/3}$ (Awasthi et al., 2010).

of our exclusive focus on μ-typical sequences of actions under the sampling distribution, which thus translates into an absolute $1/\mu$ bound on the likelihood ratio. We note that some other works (Uchibe and Doya, 2004; Wawrzyński, 2009) have simply capped the likelihood ratios in an importance sampling computation; here, we achieve such a bound by *disregarding* policies that have a large likelihood ratio, instead of altering it. Our analysis of importance sampling then follows a standard learning theory paradigm, most similar to that of Peshkin and Mukherjee (2001), except that the bound on the likelihood ratios allows us to get away with the use of Hoeffding's inequality rather than Bernstein's inequality (which considers the variance).[6]

6. Future Directions

One natural direction concerns improving Theorem 10: One of the main insights underlying Theorem 8 is that the main barrier to agnostic learning is finding an explicit representation, and yet Algorithm 1 proceeds by constructing an explicit policy. It is conceivable that the $O((nT)^{s-1})$-factor blow-up in the policy failure probability ϵ could be eliminated if we could similarly identify a good action on-line, without going so far as to construct an entire policy.

Our set-up of learning policies that take typical actions with respect to a reference policy naturally suggests a bootstrapping approach to learning complex policies; another immediate direction is then to investigate what can be *proved* learnable by bootstrapping (in contrast to the empirical work of Fern et al., 2006). In a related direction, Ross and Bagnell (2012) essentially showed that a penalty for atypicality similar to what our algorithm suffers can be eliminated in the standard (discounted, fixed cost-function, full-information) MDP setting by iteratively constructing a policy, collecting new data, retraining the policy, and repeating. In this way, the training data is shaped so that the actions of the policy become highly "typical" and well-estimated. It is likely that a similar strategy will also work in our partial information setting, although it may rely on the goal remaining fixed during this process.

More generally, our work side-steps the entire problem of exploration of POMDPs; it can be viewed as finding a policy, given that the POMDP has been sufficiently well explored. So, one might try to address the exploration problem in the context of such planning algorithms by showing that a class of environments can be efficiently explored sufficiently well to permit good policies to be found.

Acknowledgments

I am grateful to Leslie Kaelbling for numerous detailed suggestions and criticisms of this work that improved it immensely. I likewise thank Mithun Chakraborty and my anonymous reviewers for their detailed comments and suggestions. This work was also heavily influenced by conversations with Leslie Valiant.

6. For off-policy evaluation in practice, it may be vastly preferable to apply a Bernstein-like inequality using an empirical estimate of the variance instead of Hoeffding's inequality (Thomas et al., 2015). I thank a reviewer for bringing this to my attention.

Abstract

The transcription of handwritten text on images is one task in machine learning and one solution to solve it is using multi-dimensional recurrent neural networks (MDRNN) with connectionist temporal classification (CTC). The RNNs can contain special units, the long short-term memory (LSTM) cells. They are able to learn long term dependencies but they get unstable when the dimension is chosen greater than one. We defined some useful and necessary properties for the one-dimensional LSTM cell and extend them in the multi-dimensional case. Thereby we introduce several new cells with better stability. We present a method to design cells using the theory of linear shift invariant systems. The new cells are compared to the LSTM cell on the IFN/ENIT and Rimes database, where we can improve the recognition rate compared to the LSTM cell. So each application where the LSTM cells in MDRNNs are used could be improved by substituting them by the new developed cells.

1. Introduction

Since the last decade, artificial neural networks (NN) became state-of-the-art in many fields of machine learning, for example they can be applied to pattern recognition. Typical NN are feedforward NN (FFNN) or recurrent NN (RNN), whereas the latter contain recurrent connections. When nearby inputs depend on each other, providing these inputs as additional information to the NN can improve its recognition result. FFNNs obtain these dependencies by making this nearby inputs accessible. If RNNs are used, the recurrent connections can be used to learn if the surrounding input is relevant, but these connections result in a vanishing dependency over time. In S. Hochreiter, J. Schmidhuber (1997) the authors develop the long short-term memory (LSTM) which is able to have a long term dependency. This LSTM is extended in A. Graves, S. Fernandez andJ. Schmidhuber (2007) to the multi-dimensional (MD) case and is used in a hierarchical multi-dimensional RNN (MDRNN) which performed best in three competitions at the International Conference on Document Analysis and Recognition (ICDAR) in 2009 without any feature extraction and knowledge of the recognized language model.
In this paper we analyse these MD LSTM regarding the ability to provide long term dependencies in MDRNNs and show that it can easily have an unwanted growing dependency for higher dimensions. We define a more general description of an LSTM—a cell—and change the LSTM architecture which leads to new MD cell types, which also can provide long term dependencies. In two experiments we show that substituting the LSTM in MDRNNs by these cells works well. Due to this we assume that substituting the LSTM cell by the best performing cell, the *LeakyLP cell*, will improve the performance of an MDRNN also in other scenarios. Furthermore the new cell types could also be used for the one-dimensional (1D) case, so using them in a bidirectional RNN with LSTMs (BLSTM) could lead to better recognition rates.
In Section 2 we introduce the reader to the development of the LSTM cells (S. Hochreiter, J. Schmidhuber, 1997) and its extension (F. A. Gers, J. Schmidhuber andF. Cummins, 1999). Based on that in Section 3 we define two properties that probably lead to the good performance of the 1D LSTM cells. Both together guarantee that the cell can have a long term dependency. A third property ensures that gradient cannot explode over time. In Section 4 we show that the MD version of the LSTM is still able to provide long term dependency whereas the gradient can explode easily for dimension greater than 1. In Section 5 we change the architecture of the MD LSTM cell and reduce it to the 1D LSTM cell so that the cell fulfills the two properties for any dimension. Nevertheless the internal cell state can linearly grow over time. This problem is solved in Section 6 using a trainable convex combination of the input and the previous internal cell states. The new cell type can provide long term dependencies and does not suffer from exploding gradients. Motivated by the last sections we introduce a more general way to define MD cells in Section 7. Using the theory of linear shift-invariant systems and their frequency analysis we are able to get a new interpretation of the cells and we create 5 new cell types. To test the performance of the cells in Section 8 we take two data sets from the ICDAR 2009 competitions, where the MDRNNs with LSTM cell won. On these data sets we compare the recognition results of the MDRNNs when we substitute the LSTM cells by the new developed cells. On both data sets, the IFN/ENIT data set and the RIMES data set we can improve the recognition rate using the new developed cells.

2. Previous Work

In this section we briefly want to introduce a recurrent neural network (RNN) and the development of the LSTM cell. In previous literature there are various notation to describe the update equations of RNNs an LSTMs. To unify the notations we will refer to their notation using "$\triangleq$" (F. A. Gers, J. Schmidhuber andF. Cummins, 1999; S. Hochreiter, J. Schmidhuber, 1997; A. Graves andJ. Schmidhuber, 2008). Therefore we concentrate on a simple hierarchical RNN with one input layer with the set of neurons I, one recurrent hidden layer with the set of neurons H and one output layer with the set of neurons O. For each time step $t \in \mathbb{N}$ the layers are updated asynchronously in the order I, H, O. In one specific layer all neurons can be updated synchronously. In the hidden layer for one neuron $c \in H$

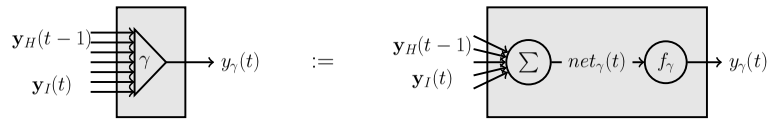

Figure 1: Schematic diagram of a unit: The unit $\gamma \in H$ is a simple neuron with the network's feed forward input $\mathbf{y}_I(t) = \left(y_i(t)\right)_{i\in I}$ and recurrent input $\mathbf{y}_H(t-1) = \left(y_h(t-1)\right)_{h\in H}$ and an output activation $y_\gamma(t)$. *Right:* A unit has an input activation $net_\gamma(t)$, which is a linear combination of the source activations $\mathbf{y}_I(t), \mathbf{y}_H(t-1)$. The output activation $y_\gamma(t)$ is computed by applying the activation function f_γ to the input activation. *Left:* The short notation of a unit.

at time $t \in \mathbb{N}$ we calculate the neuron's *input activation* net_c by

$$\left(a_c(t) \triangleq\right) \quad net_c(t) = \sum_{i\in I} w_{c,i} y_i(t) + \sum_{h\in H} w_{c,h} y_h(t-1). \tag{1}$$

with weights $w_{[\text{target neuron}],[\text{source neuron}]}$. A bias in (1) can be added by extending the set $I := I \cup \{bias\}$ with $y_{bias}(t) = 1 \forall t \in \mathbb{N}$ and hence we will not write the bias in the equations, but we use them in our RNNs in Section 8. The neuron's *output activation* is calculated by

$$\left(y^c(t), b_c(t) \triangleq\right) \quad y_c(t) = f_c\left(net_c(t)\right)$$

with a differentiable sigmoid *activation function* f_c. To make (1) suitable for $t \leq 0$ we define $\forall h \in H, \forall t \in \mathbb{Z} \setminus \mathbb{N} : y_h(t) = 0$. This simple neuron with a linear function of activations as input and one activation function we call *unit* (compare to Figure 1). In (1) the activation of the unit is dependent on the current activations of the layer below and the previous activations of the units from the same layer. When there are no recurrent connections ($\forall c, h \in H : w_{c,h} = 0$), the layer is called feed-forward layer, otherwise recurrent layer.

2.1 The Long Short-Term Memory

A *standard LSTM* cell c has one input with an input activation $y_{c_{in}}(t)$ a set of *gates*, one *internal state* s_c and one output(-activation) y_c ($\triangleq y^c$). The gates are also units and their task is to learn whether a signal should pass the gate or not. They almost always have the logistic activation function $f_{log}(x) := \frac{1}{1+\exp(-x)}$ ($\triangleq f_1(x)$). The input of the standard LSTM cell is calculated from a unit with an odd activation function with a slope of 1 at $x = 0$. We use $f_c(x) = \tanh(x)$ in this paper, another solution could be $f_c(x) = 2\tanh\left(\frac{x}{2}\right)$ (see S. Hochreiter, J. Schmidhuber, 1997). The standard LSTM has two gates: The *input gate* (IG or ι) and the *output gate* (OG or ω). These both gates are calculated like a unit, so that

$$net_\iota(t) = \sum_{i\in I} w_{\iota,i} y_i(t) + \sum_{h\in H} w_{\iota,h} y_h(t-1)$$
$$\left(y^{in_c}(t), b_\iota(t) \triangleq\right) \quad y_\iota(t) = f_{log}\left(net_\iota(t)\right)$$

and

$$net_\omega(t) = \sum_{i\in I} w_{\omega,i} y_i(t) + \sum_{h\in H} w_{\omega,h} y_h(t-1)$$
$$\left(y^{out_c}(t), b_\omega(t) \triangleq\right) \quad y_\omega(t) = f_{log}\left(net_\omega(t)\right).$$

The input of an LSTM is defined like in (1) by

$$\left(net_c(t) \triangleq\right) \quad net_{c_{in}}(t) = \sum_{i\in I} w_{c,i} y_i(t) + \sum_{h\in H} w_{c,h} y_h(t-1),$$
$$\left(g\left(net_c(t)\right), f_2\left(net_c(t)\right) \triangleq\right) \quad y_{c_{in}}(t) = f_c\left(net_{c_{in}}(t)\right).$$

The internal state $s_c(t)$ is calculated by

$$s_c(t) = y_{c_{in}}(t) \cdot y_\iota(t) + s_c(t-1), \tag{2}$$

the output activation $y_c(t)$ of the LSTM is calculated from

$$\left(y^c(t), b_c(t) \triangleq\right) \quad y_c(t) = h_c\left(s_c(t)\right) \cdot y_\omega(t) \tag{3}$$

with $h_c(x) := \tanh(x)$ ($\triangleq f_3(x)$). The LSTM can be interpreted as a kind of memory module where the internal state stores the information. For a given input $y_{c_{in}}(t) \in (-1, 1)$ the IG "decides" if the new input is relevant for the internal state. If so, the input is added to the internal state. The information of the input is now saved in the activation of the internal state. The OG determines whether or not the internal activation should be displayed to the rest of the network. So the information, stored in the LSTM is just "readable" when the OG is active. To sum up, an open IG can be seen as a "write"-operation into the memory and an open OG as a "read"-operation of the memory.

Another way to understand the LSTM is to take a look at the gradient propagated through it. To analyse the LSTM properly, we have to ignore gradients comming from recurrent weights. We define the *truncated gradient* similar to S. Hochreiter, J. Schmidhuber (1997) and F. A. Gers, J. Schmidhuber andF. Cummins (1999).

Definition 1 (truncated gradient) *Let $\gamma \in \{c_{in}, \iota, \omega\}$ be any input or gate unit and $y_c(t-1)$ any previous output activation. The* truncated gradient *differs from the exact gradient only by setting recurrent weighted gradient propagation $\frac{\partial net_\gamma(t)}{\partial y_c(t-1)}$ to zero. We write*

$$\frac{\partial net_\gamma(t)}{\partial y_c(t-1)}\Big(= w_{\gamma,c}\Big) \underset{tr}{=} 0.$$

Now, let E be an arbitrary error which is used to train the RNN and $\frac{\partial E(t)}{\partial y_c(t)}$ the resulting derivative at the output of the LSTM. The OG can eliminate the gradient coming from the output, because

$$\frac{\partial y_c(t)}{\partial s_c(t)} = \underbrace{h_c'\left(s_c(t)\right)}_{\in(0,1]} \cdot \underbrace{y_\omega(t)}_{\in(0,1)},$$

so the OG decides when the gradient should go into the internal state. Especially for $|s_c(t)| \ll 1$ we get

$$\frac{\partial y_c(t)}{\partial s_c(t)} \approx y_\omega(t).$$

The key idea of the LSTMs is that an error that occurs at the internal state neither explode nor vanish over time. Therefore, we take a look at the partial derivative $\frac{\partial s_c(t)}{\partial s_c(t-1)}$, which is also known as error carousel (for more details see S. Hochreiter, J. Schmidhuber, 1997). Using the truncated gradient of Definition 1 for this derivative, we get

$$\begin{aligned}
\frac{\partial s_c(t)}{\partial s_c(t-1)} =& y_{c_{in}}(t) \cdot \frac{\partial y_\iota(t)}{\partial s_c(t-1)} + y_\iota(t) \cdot \frac{\partial y_{c_{in}}(t)}{\partial s_c(t-1)} + 1 \\
=& y_{c_{in}}(t) \cdot \frac{\partial y_\iota(t)}{\partial y_c(t-1)} \frac{\partial y_c(t-1)}{\partial s_c(t-1)} + y_\iota(t) \cdot \frac{\partial y_{c_{in}}(t)}{\partial y_c(t-1)} \frac{\partial y_c(t-1)}{\partial s_c(t-1)} + 1 \\
=& y_{c_{in}}(t) \cdot \frac{\partial y_\iota(t)}{\partial net_\iota(t)} \underbrace{\frac{\partial net_\iota(t)}{\partial y_c(t-1)}}_{\underset{tr}{=}0} \frac{\partial y_c(t-1)}{\partial s_c(t-1)} \\
& + y_\iota(t) \cdot \frac{\partial y_{c_{in}}(t)}{\partial net_{c_{in}}(t)} \underbrace{\frac{\partial net_{c_{in}}(t)}{\partial y_c(t-1)}}_{\underset{tr}{=}0} \frac{\partial y_c(t-1)}{\partial s_c(t-1)} + 1 \\
\Rightarrow \frac{\partial s_c(t)}{\partial s_c(t-1)} \underset{tr}{=}& 1. \qquad (4)
\end{aligned}$$

So, once having a gradient at the internal state we can use the chain rule and get $\forall \tau \in \mathbb{N}$: $\frac{\partial s_c(t)}{\partial s_c(t-\tau)} \underset{tr}{=} 1$. This is called *constant error carousel*.
Like the OG can eliminate the gradient coming from the LSTM output, the IG can do the same with the gradient coming from the internal state, that means it decides when the gradient should be injected to the source activations. This can be seen by taking a look at the partial derivative

$$\frac{\partial s_c(t)}{\partial net_{c_{in}}(t)} = \frac{\partial s_c(t)}{\partial y_{c_{in}}(t)} \frac{\partial y_{c_{in}}(t)}{\partial net_{c_{in}}(t)} = y_\iota(t) f_c'\left(net_{c_{in}}(t)\right).$$

If there is a small input $|net_{c_{in}}(t)| \ll 1$, we get $f_c'(net_{c_{in}}(t)) \approx 1$ and can estimate

$$\frac{\partial s_c(t)}{\partial net_{c_{in}}(t)} \approx y_\iota(t).$$

All in all, this LSTM is able to store information and learn long-term dependencies, but it has one drawback which will be discussed in 2.2.

2.2 Learning to Forget

For long time series the internal state is unbounded (compare with F. A. Gers, J. Schmidhuber andF. Cummins, 1999, 2.1). Assuming a positive or negative input and a non zero

activation of the IG, the absolute activation of the internal state grows over time. Using the weight-space symmetries in a network with at least one hidden layer (Bishop, 2006, 5.1.1) we assume without loss of generality $y_{c_{in}}(t) \geq 0$, so $s_c(t) \xrightarrow{t\to\infty} \infty$. Hence, the activation function h_c saturates and (3) can be simplified to

$$y_c(t) = \underbrace{h_c\left(s_c(t)\right)}_{\to 1} y_\omega(t) \approx y_\omega(t).$$

Thus, for great activations of $s_c(t)$ the whole LSTM works like a unit with a logistic activation function. A similar problem can be observed for the gradient. The gradient coming from the output is multiplied by the activation of the OG and the derivative of h_c. For great values of $s_c(t)$ we get $h_c'\left(s_c(t)\right) \to 0$ and we can estimate the partial derivative

$$\frac{\partial y_c(t)}{\partial s_c(t)} = h_c'\left(\left(s_c(t)\right) \cdot y_\omega(t) \approx 0,\right.$$

which can be interpreted that the OG is not able to propagate back the gradient into the LSTM. Some solutions to solve the linear growing state problem are introduced in F. A. Gers, J. Schmidhuber andF. Cummins (1999). They tried to stabilize the LSTM with a "state decay" by multiplying the internal state in each time step with a value $\in (0, 1)$, which did not improve the performance. Another solution was to add an additional gate, the forget gate (FG or ϕ). The last state $s_c(t-1)$ is multiplied by the activation of the FG before it is added to the current state $s_c(t)$. So we can substitute (2) by

$$s_c(t) = y_{c_{in}}(t) \cdot y_\iota(t) + s_c(t-1) \cdot y_\phi(t),$$

so that the truncated gradient in (4) is changed to

$$\begin{aligned}
\frac{\partial s_c(t)}{\partial s_c(t-1)} &= y_{c_{in}}(t) \cdot \frac{\partial y_\iota(t)}{\partial s_c(t-1)} + y_\iota(t) \cdot \frac{\partial y_{c_{in}}(t)}{\partial s_c(t-1)} + y_\phi(t) \\
&\underset{tr}{=} y_\phi(t)
\end{aligned}$$

and for longer time series we get $\forall \tau \in \mathbb{N}$

$$\frac{\partial s_c(t)}{\partial s_c(t-\tau)} \underset{tr}{=} \prod_{t'=0}^{\tau-1} y_\phi(t-t').$$

Now, the *Extended LSTM* is able to learn to forget its previous state. However, an Extended LSTM is still able to work like an standard LSTM without FG by having an activation $y_\phi(t) \approx 1$. In this paper we denote the Extended LSTM as *LSTM*
Another point of view was introduce in Bengio et al. (1994): To learn long-term dependencies a system must have an architecture to that an input can be saved over long time and does not suffer from the "vanishing gradient" problem. On the other hand the system should avoid an "exploding gradient", which means that a small disturbance has a growing influence over time. In this paper we do not want to solve the problem of vanishing and exploding gradient for a whole system, we want to solve this problem only for one single cell. But we think that it is an necessary condition to provide long time dependencies of a system.

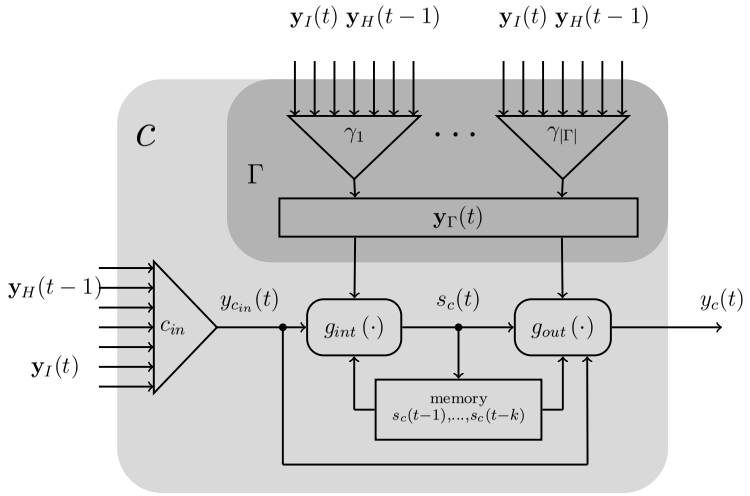

Figure 2: Schematic diagram of a cell: The function g_{int} calculates the internal state $s_c(t)$ from the previous internal states $s_c(t-1),\ldots,s_c(t-k)$ and the cell input $y_{c_{in}}(t)$ using the gate activations $\mathbf{y}_\Gamma(t)$. The function g_{out} calculates the output $y_c(t)$ of the cell from the actual and previous internal states $s_c(t),\ldots,s_c(t-k)$, the cell input $y_{c_{in}}(t)$ also using the gate activations $\mathbf{y}_\Gamma(t)$.

3. Cells and Their Properties

In this section we want to introduce a general cell and figure out properties for these cells which probably lead to the good performance observed by LSTM cells.

Definition 2 (Cell, cf. Fig. 2) *A* cell, c, of order k *consists of*

- *one designated* input *unit, c_{in}, with sigmoid activation function f_c (typically $f_c = \tanh$ unless specified otherwise);*
- *a set Γ (not containing c_{in}) of units called* gates $\gamma_1, \gamma_2, \ldots$ *with sigmoid activation functions f_{γ_i}, $i = 1, \ldots$ (typically logistic $f_{\gamma_i} = f_{log}$ unless specified otherwise);*
- *an arbitrary function, g_{int}, and a cell activation function, g_{out}, mapping into $[-1, 1]$.*

Each unit of $\Gamma \cup \{c_{in}\}$ receives the same set of input activations. The cell update in time step $t \in \mathbb{N}$ is performed in three subsequent phases:

1. *Following the classical update scheme of neurons (see Section 2), all units in $\Gamma \cup \{c_{in}\}$ calculate synchronously their activations, which will be denoted by $\boldsymbol{y}_\Gamma(t) := \left(y_\gamma(t)\right)_{\gamma\in\Gamma}$ and $y_{c_{in}}(t)$. Furthermore, we call $y_{c_{in}}(t)$ the* input activation *of the cell.*
2. *Then, the cell computes it's so-called* internal state
$$s_c(t) := g_{int}\left(\boldsymbol{y}_\Gamma(t), y_{c_{in}}(t), s_c(t-1), \ldots, s_c(t-k)\right) .$$
3. *Finally, the cell computes it's so-called* output activation
$$y_c(t) := g_{out}\left(\boldsymbol{y}_\Gamma(t), y_{c_{in}}(t), s_c(t), s_c(t-1), \ldots, s_c(t-k)\right) .$$

In this paper we concentrate on first order cells ($k = 1$). Now, we use Definition 2 to re-introduce the (Extended) LSTM cell.

Remark 3 (LSTM cell) *An* LSTM cell *is a cell of order* 1 *where $h_c = \tanh$ and*

- $\Gamma = \{\iota, \phi, \omega\}$
- $s_c(t) := g_{int}\left(\boldsymbol{y}_\Gamma(t), y_{c_{in}}(t), s_c(t-1)\right) := y_{c_{in}}(t)y_\iota(t) + s_c(t-1)y_\phi(t)$
- $y_c(t) := g_{out}\left(\boldsymbol{y}_\Gamma(t), s_c(t)\right) := h_c\left(s_c(t)\right) y_\omega(t)$

Properties of cells. Developing the 1D LSTM cells, the main idea is to save *exactly one piece of information* over a long time series and to propagate the gradient back over this long time, so that the system can learn precise storage of this piece of information. In instance a given input $y_{c_{in}}$ (which represent the information) at time t_{in} should be stored into the cell state s_c until the information is required at time t_{out}.
To be able to prove the following properties, we will assume the truncated gradient defined in Definition 1. Nevertheless we will use the full gradient in our Experiments, because it turned out that it works much better. The next two properties of a cell ensure the ability to work as such a memory.

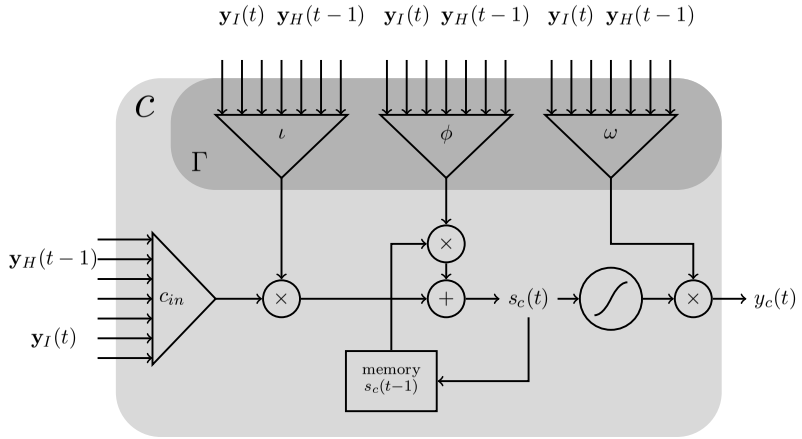

Figure 3: Schematic diagram of a one-dimensional LSTM cell: The input (c_{in}) is multiplied by the IG (ι). The previous state $s_c(t-1)$ is gated by the FG (ϕ) and added to the activation coming from the IG and input. The output of the cell is the squashed internal state (squashed by $h_c(x) = \tanh(x)$) and gated by the OG (ω).

The first property should ensure that an input $y_{c_{in}}$ at time t_{in} can be memorized (the cell input is open) in the internal activation s_c until t_{out} (the cell memorizes) and has a negligibly influence on the internal activation for $t > t_{out}$ (the cell forgets). In addition, the cell is able to prevent influence of other inputs at time steps $t \neq t_{in}$ (the cell input is closed).

Definition 4 (Not vanishing gradient (NVG)) *A cell c allows an NVG* $:\Leftrightarrow$
For arbitrary $t_{in}, t_{out} \in \mathbb{N}, t_{in} \leq t_{out}, \forall \delta > 0$ there exist gate activations $\boldsymbol{y}_\Gamma(t)$ such that for any $t_1, t_2 \in \mathbb{N}$

$$\frac{\partial s_c(t_2)}{\partial y_{c_{in}}(t_1)} \underset{tr}{\in} \begin{cases} [1-\delta, 1] & \text{for} \quad t_1 = t_{in} \text{ and } t_{in} \leq t_2 \leq t_{out} \\ [0, \delta] & \text{otherwise} \end{cases} \tag{5}$$

holds.

The next definition guaranties that at any time $t \in \mathbb{N}$ the gate activations can (the cell output is open) or not (the cell output is closed) distribute the piece of information saved in s_c to the network. This is an important property because the piece of information can be memorized in the cell without presenting it to the network. Note that the decision is just dependent on gate activations at time t and there are no constraints to previous gate activations. In Definition 2 we require $y_c(t) \in [-1, 1]$ whereas $s_c(t) \in \mathbb{R}$. So we cannot have arbitrarily small intervals of the derivative as in (5), but we can ensure two distinct intervals for open and closed cell output. When we take Definition 4 and 5 together, a cell is able to save an input over long term series, can decide at each time step whether or not it is presented to the network and can forget the saved input.

Definition 5 (Controllable output dependency (COD)) *A cell c of order k allows an COD* $:\Leftrightarrow$
There exist $\delta_1, \delta_2 \in (0, 1), \delta_2 < \delta_1$ so that for any time $t \in \mathbb{N}$ there exists a gate vector $\boldsymbol{y}_\Gamma(t)$ leading to open output dependency

$$\frac{\partial y_c(t)}{\partial s_c(t)} \in [\delta_1, 1] \tag{6}$$

and there exists another gate vector $\boldsymbol{y}_\Gamma(t)$ leading to a closed output dependency

$$\frac{\partial y_c(t)}{\partial s_c(t)} \in [0, \delta_2]\,. \tag{7}$$

The third property is a kind of stability criterion. An unwanted case is that a small change (caused by any noisy signal) at time step t_{in} has a growing influence at later time steps. This is equivalent to an exploding gradient over time. Controlling the gradient of the whole system and avoiding him not to explode is a hard problem. But we can at least avoid the exploding gradient in one cell. This should be prohibited for *any* gate activations.

Definition 6 (Not exploding gradient (NEG)) *A cell c has an NEG* $:\Leftrightarrow$
For any time steps $t_{in}, t \in \mathbb{N}, t_{in} < t$ and any gate activations $\boldsymbol{y}_\Gamma(t)$ the truncated gradient in bounded by

$$\frac{\partial s_c(t)}{\partial s_c(t_{in})} \underset{tr}{\in} [0, 1]\,.$$

We think that a cell fulfilling these three properties can work as stable memory. To be able to prove these properties for the LSTM cell we have to considerate the gate activations. In general, the activation function of the gates does not have to be the logistic activation function f_{log}, whereas for this paper we set $\forall\gamma \in \Gamma : f_\gamma := f_{log}$. So the activation of gates can never be exactly 0 or 1, because of a finite input activation $net_\gamma(t)$ to the gate activation function. But a gate can have an activation $y_\gamma(t) \in [1-\varepsilon, 1)$ if it is opened or $y_\gamma(t) \in (0, \varepsilon]$ if it is closed, because for a realistic large input activation $net_\gamma(t) \geq 7$ (low input activation $net_\gamma(t) < -7$) we get an activation within the interval $y_\gamma(t) \in [1-\varepsilon, 1)$ ($y_\gamma(t) \in (0, \varepsilon]$) with $\varepsilon < \frac{1}{1000}$. Handling with these activation intervals we can prove the definitions for the LSTM cell. Now we can prove whether or not the LSTM cell has these properties.

Theorem 7 (Properties of the LSTM cell) *The 1D LSTM cell allows NVG and has an NEG, but does not allow COD.*

Proof see A.1 in appendix. ■

4. Expanding to More Dimensions

In A. Graves, S. Fernandez andJ. Schmidhuber (2007) the 1D LSTM cell is extended to an arbitrary number of dimensions; this is solved by using one FG for each dimension. In many publications using the MD LSTM cell in MDRNNs outperform state-of-the-art recognition systems (for example see A. Graves andJ. Schmidhuber, 2008).
But by expanding the cell to the MD case, the absolute value of the internal state $|s_c|$ can grow faster than linear over time. When $\left|s_c^{\boldsymbol{p}}\right| \to \infty$ and there are peephole connections (for peephole connection details see F. A. Gers, N. Schraudolph andJ. Schmidhuber, 2002), the cells have an output activation of $y_c^{\boldsymbol{p}} \in \{-1, 0, 1\}$: The internal state multiplied by the peephole weight overlays the other activation-weight-products and this leads to an activation of the OG $y_\omega^{\boldsymbol{p}} \in \{0, 1\}$ and a squashed internal state $h_c\left(s_c^{\boldsymbol{p}}\right) \in \{-1, 1\}$. So the output of the cell is $y_\omega^{\boldsymbol{p}} h_c\left(s_c^{\boldsymbol{p}}\right) = y_c^{\boldsymbol{p}} \in \{-1, 0, 1\}$. But also without peephole connections the internal state can grow, which leads to $h_c\left(s_c^{\boldsymbol{p}}\right) \in \{-1, 1\}$ and the cell works like a conventional unit with a logistic activation function $y_c(t) \approx \pm y_\omega(t)$.
Our goal is to transfer the Definitions 4, 5 and 6 defined in Section 3 into the MD case and we will see that the MD LSTM cell has an exploding gradient. In the next sections we will provide alternative cell types, that fulfill two or all of these definitions.
In the 1D case it is clear, that there is just one way to come from date t_1 to date t_2, when $t_1 < t_2$, by incrementing t_1 as long as t_2 is reached. For the MD case the number of paths depends on the number of dimensions and the distance between these two dates. An MD path is defined as follows.

Definition 8 (MD path) *Let $\boldsymbol{p}, \boldsymbol{q} \in \mathbb{N}^D$ be two dates. A $\boldsymbol{p}$-$\boldsymbol{q}$-path π of length $k \geq 0$ is a sequence*

$$\pi := \{\boldsymbol{p} = \boldsymbol{p}_0, \boldsymbol{p}_1, \ldots, \boldsymbol{p}_k = \boldsymbol{q}\}$$

with $\forall i \in \{1, \ldots, k\} \exists! d \in \{1, \ldots, D\} : (\boldsymbol{p}_i)_d^- = \boldsymbol{p}_{i-1}$. Further, let $\pi_i := \boldsymbol{p}_i$.

We can define the distance vector

$$\overrightarrow{\boldsymbol{pq}} := \boldsymbol{q} - \boldsymbol{p} = \begin{pmatrix} \boldsymbol{q}_1 - \boldsymbol{p}_1 \\ \vdots \\ \boldsymbol{q}_D - \boldsymbol{p}_D \end{pmatrix} = \begin{pmatrix} \overrightarrow{\boldsymbol{pq}}_1 \\ \vdots \\ \overrightarrow{\boldsymbol{pq}}_D \end{pmatrix}$$

between the dates $\boldsymbol{p}$ and $\boldsymbol{q}$. When $\overrightarrow{\boldsymbol{pq}}$ has at least one negative component, there exists no $\boldsymbol{p}$-$\boldsymbol{q}$-path. Otherwise there exist exactly

$$\#\{\overrightarrow{\boldsymbol{pq}}\} := \binom{\sum_{i=1}^D \overrightarrow{\boldsymbol{pq}}_i}{\overrightarrow{\boldsymbol{pq}}_1, \ldots, \overrightarrow{\boldsymbol{pq}}_D} = \frac{\left(\sum_{i=1}^D \overrightarrow{\boldsymbol{pq}}_i\right)!}{\prod_{i=1}^D \overrightarrow{\boldsymbol{pq}}_i!}$$

$\boldsymbol{p}$-$\boldsymbol{q}$-paths (compare with the multinomial coefficient). We write $\boldsymbol{p} < \boldsymbol{q}$ when $\#\{\overrightarrow{\boldsymbol{pq}}\} \geq 1$ and $\boldsymbol{p} \leq \boldsymbol{q}$ when $\boldsymbol{p} = \boldsymbol{q} \vee \boldsymbol{p} < \boldsymbol{q}$. Now we can extend the definitions of the 1D case to the MD case, whereas we concentrate on the MD cells of order 1.

Definition 9 (MD cell) *An MD cell, c, of order 1 and dimension D consists of the same parts as a 1D cell of order 1. The cell update in date $\boldsymbol{p} \in \mathbb{N}^D$ is performed in three subsequent phases:*

1. *Following the classical update scheme of neurons (see Section 2), all units in $\Gamma \cup \{c_{in}\}$ synchronously calculate their activations, which will be denoted by $\boldsymbol{y}_\Gamma^{\boldsymbol{p}} = \left(y_\gamma^{\boldsymbol{p}}\right)_{\gamma \in \Gamma}$. Furthermore, we call $y_{c_{in}}^{\boldsymbol{p}}$ the* input activation *of the cell.*

2. *Then, the cell computes it's so-called* internal state

$$s_c^{\boldsymbol{p}} := g_{int}\left(\boldsymbol{y}_\Gamma^{\boldsymbol{p}}, y_{c_{in}}^{\boldsymbol{p}}, s_c^{\boldsymbol{p}_1^-}, \ldots, s_c^{\boldsymbol{p}_D^-}\right).$$

3. *Finally, the cell computes it's so-called* output activation

$$y_c^{\boldsymbol{p}} := g_{out}\left(\boldsymbol{y}_\Gamma^{\boldsymbol{p}}, y_{c_{in}}^{\boldsymbol{p}}, s_c^{\boldsymbol{p}}, s_c^{\boldsymbol{p}_1^-}, \ldots, s_c^{\boldsymbol{p}_D^-}\right).$$

Using this, we can reintroduce the LSTM cell as well as Definition 4, 5 and 6 for the MD case:

Definition 10 (MD LSTM cell) *An MD LSTM cell is a cell of dimension D and order 1 where $h_c = \tanh$ and*

- $\Gamma = \{\iota, (\phi, 1), \ldots, (\phi, D), \omega\}$
- $s_c^{\boldsymbol{p}} = g_{int}\left(\boldsymbol{y}_\Gamma^{\boldsymbol{p}}, y_{c_{in}}^{\boldsymbol{p}}, s_c^{\boldsymbol{p}_1^-}, \ldots, s_c^{\boldsymbol{p}_D^-}\right) = y_\iota^{\boldsymbol{p}} y_{c_{in}}^{\boldsymbol{p}} + \sum_{d=1}^D s_c^{\boldsymbol{p}_d^-} y_{\phi,d}^{\boldsymbol{p}}$
- $y_c^{\boldsymbol{p}} = g_{out}\left(\boldsymbol{y}_\Gamma^{\boldsymbol{p}}, s_c^{\boldsymbol{p}}\right) = h_c\left(s_c^{\boldsymbol{p}}\right) y_\omega^{\boldsymbol{p}}$

Definition 11 (MD Not vanishing gradient (NVG)) *An MD cell c allows an NVG* $:\Leftrightarrow$
For arbitrary $\boldsymbol{p}_{in}, \boldsymbol{p}_{out} \in \mathbb{N}^D, \boldsymbol{p}_{in} \leq \boldsymbol{p}_{out}, \forall \delta > 0$ there exist $\forall \boldsymbol{p} \in \mathbb{N}^D$ gate activations $\boldsymbol{y}_\Gamma^{\boldsymbol{p}}$ such that for any $\boldsymbol{p}_1, \boldsymbol{p}_2 \in \mathbb{N}^D$

$$\frac{\partial s_c^{\boldsymbol{p}_2}}{\partial y_{c_{in}}^{\boldsymbol{p}_1}} \underset{tr}{\in} \begin{cases} [1-\delta, 1] & \text{for} \quad \boldsymbol{p}_1 = \boldsymbol{p}_{in} \text{ and } \boldsymbol{p}_{in} \leq \boldsymbol{p}_2 \leq \boldsymbol{p}_{out} \\ [0, \delta] & \text{otherwise} \end{cases} \tag{8}$$

holds.

Definition 12 (MD Controllable output dependency (COD)) *An MD cell c allows an COD* $:\Leftrightarrow$
There exist $\delta_1, \delta_2 \in (0,1), \delta_2 < \delta_1$ so that for any time $t \in \mathbb{N}$ there exists a gate vector $\boldsymbol{y}_\Gamma^{\boldsymbol{p}}$ leading to open output dependency

$$\frac{\partial y_c^{\boldsymbol{p}}}{\partial s_c^{\boldsymbol{p}}} \in [\delta_1, 1] \tag{9}$$

and there exists another gate vector $\boldsymbol{y}_\Gamma^{\boldsymbol{p}}$ leading to a closed output dependency

$$\frac{\partial y_c^{\boldsymbol{p}}}{\partial s_c^{\boldsymbol{p}}} \in [0, \delta_2]\,. \tag{10}$$

Definition 13 (MD Not exploding gradient (NEG)) *An MD cell c has an NEG* $:\Leftrightarrow$
For any time steps $\boldsymbol{p}_{in}, \boldsymbol{p} \in \mathbb{N}^D, \boldsymbol{p}_{in} < \boldsymbol{p}$ and any gate activations $\boldsymbol{y}_\Gamma^{\boldsymbol{p}}$ the truncated gradient in bounded by

$$\frac{\partial s_c^{\boldsymbol{p}}}{\partial s_c^{\boldsymbol{p}_{in}}} \underset{tr}{\in} [0, 1]$$

We can now consider these definitions for the MD LSTM cell.

Theorem 14 (NVG of MD LSTM cells) *An MD LSTM cell allows an NVG.*

Proof see A.2 in appendix ■

For arbitrary activations of FGs the partial derivative $\frac{\partial s_c^{\boldsymbol{p}}}{\partial s_c^{\boldsymbol{p}_{in}}}$ can grow over time:

Theorem 15 (NEG of MD LSTM cells) *An MD LSTM cell can have an exploding gradient, when $D \geq 2$.*

Proof see A.3 in appendix. ■

The MD LSTM cell does not allow the COD, because the 1D case is a special case of the MD case.
Our idea for the next section is to change the MD LSTM layout, so that it has an NEG.

5. Reducing the MD LSTM Cell to One Dimension

In the last section, we showed that the MD LSTM cell can have an exploding gradient. We tried different ways to solve this problem. For example we divided the activation of the FG by the number of dimensions. Then the gradient cannot explode over time, but the gradient vanishes along some paths rapidly. Another approach was to give the cells the opportunity to learn to stabilize itself, when the internal state starts diverging. Therefore we add an additional peephole connection between the square value of the previous internal states $\left(s_c^{\boldsymbol{p}_d^-}\right)^2$ and the FGs so that the cell is able to learn that it has to close the FG for large internal states. This also does not make a significant difference. Also forcing the cell to learn to stabilize itself by adding an error

$$Loss_{state} = \varepsilon \left\| s_c^{\boldsymbol{p}} \right\|_p$$

with $p = \{1, 2, 3, 4\}$ and different learning rates ε does not work. So we tried to change the layout of the MD LSTM cell.

5.1 MD LSTM Stable Cell

In Section 3 we realized that 1D LSTM cells work good and the gradient does not explode, but in the MD case it does. Our idea is to combine the previous states $s_c^{\boldsymbol{p}_d^-}$ at date $\boldsymbol{p}$ to one previous state $s_c^{\boldsymbol{p}^-}$ and take the 1D form of the LSTM cell. For this reason we call this cell *LSTM Stable cell*.
Therefore, a function

$$s_c^{\boldsymbol{p}^-} = f\left(s_c^{\boldsymbol{p}_1^-}, \ldots, s_c^{\boldsymbol{p}_D^-}\right)$$

is needed, so that the following two benefits of the 1D LSTM cell remain:

1. The MD LSTM Stable cell has an NEG
2. The MD LSTM Stable cell allows NVG.

The convex combination

$$s_c^{\boldsymbol{p}^-} = f\left(s_c^{\boldsymbol{p}_1^-}, \ldots, s_c^{\boldsymbol{p}_D^-}\right) = \sum_{d=1}^{D} \lambda_d^{\boldsymbol{p}} s_c^{\boldsymbol{p}_d^-}, \forall d = 1, \ldots, D : \lambda_d^{\boldsymbol{p}} \geq 0, \sum_{d=1}^{D} \lambda_d^{\boldsymbol{p}} = 1 \tag{11}$$

of all states satisfies these both points (see Theorems 17 and 18). To calculate these D coefficients we want to use the activation of D gates and we call them lambda gates (LG or λ).

Definition 16 (MD LSTM Stable cell) *An MD LSTM Stable cell is a cell of dimension D and order 1 where $h_c = \tanh$ and*

- $\Gamma = \{\iota, (\lambda, 1), \ldots, (\lambda, D), \phi, \omega\}$

- $s_c^{\boldsymbol{p}^-} = g_{conv}\left(\boldsymbol{y}_\Gamma^{\boldsymbol{p}}, s_c^{\boldsymbol{p}_1^-}, \ldots, s_c^{\boldsymbol{p}_D^-}\right) = \sum_{d=1}^{D} s_c^{\boldsymbol{p}_d^-} \frac{y_{\lambda,d}^{\boldsymbol{p}}}{\sum_{d'=1}^{D} y_{\lambda,d'}^{\boldsymbol{p}}}$
- $s_c^{\boldsymbol{p}} = g_{int}\left(\boldsymbol{y}_\Gamma^{\boldsymbol{p}}, y_{c_{in}}^{\boldsymbol{p}}, s_c^{\boldsymbol{p}^-}\right) = y_t^{\boldsymbol{p}} y_{c_{in}}^{\boldsymbol{p}} + s_c^{\boldsymbol{p}^-} y_\phi^{\boldsymbol{p}}$
- $y_c^{\boldsymbol{p}} = g_{out}\left(\boldsymbol{y}_\Gamma^{\boldsymbol{p}}, s_c^{\boldsymbol{p}}\right) = y_\omega^{\boldsymbol{p}} h_c\left(s_c^{\boldsymbol{p}}\right)$

Using these equations we can test the cell for its properties. The MD LSTM Stable cell does not have the COD, because the 1D LSTM cell also does not have this property. For the other propertiese we get:

Theorem 17 (LTD of MD LSTM Stable cells) *An MD LSTM Stable cell allows NVG.*

Proof See A.4 in appendix. ■

Theorem 18 (NEG of MD LSTM Stable cells) *An MD LSTM Stable cell has an NEG.*

Proof See A.5 in appendix. ■

Reducing the number of gates by one. When $D \geq 2$ an MD LSTM Stable cell has one more gate than a classical MD LSTM (for $D = 1$ the both cells are equivalent). But it is possible to reduce the number of LGs by one. One solution is to choose one dimension $d' \in \{1, \ldots, D\}$ which does not get an LG. Its activation is calculated by

$$y_{\lambda,d'}^{\boldsymbol{p}} = \prod_{d \in \{1,..,D\} \setminus \{d'\}} \left(1 - y_{\lambda,d}^{\boldsymbol{p}}\right).$$

In the special case of $D = 2$ we can choose $d' = 2$ and we get $\sum_{d'=1}^{2} y_{\lambda,d'} = y_{\lambda,1} + (1 - y_{\lambda,1}) = 1$ and the update equation of the internal state can be simplified to

$$s_c^{\boldsymbol{p}} = g_{int}\left(y_t^{\boldsymbol{p}}, y_{\lambda,1}^{\boldsymbol{p}}, y_\phi^{\boldsymbol{p}}, s_c^{\boldsymbol{p}_1^-}, s_c^{\boldsymbol{p}_2^-}\right) = y_t^{\boldsymbol{p}} y_{c_{in}}^{\boldsymbol{p}} + y_{\lambda,1}^{\boldsymbol{p}} s_c^{\boldsymbol{p}_1^-} + \left(1 - y_{\lambda,1}^{\boldsymbol{p}}\right) s_c^{\boldsymbol{p}_2^-}.$$

6. Bounding the Internal State

In the last sections we discussed the growing of the EC over time and we found a solution to have a NGEC for higher dimensions. Nevertheless it is possible that the internal state grows linearly over time. When we take a look at Definition 10, we see that the partial derivative for $\boldsymbol{p} = \boldsymbol{p}_{out}$ depends on $h_c'\left(s_c^{\boldsymbol{p}}\right)$. So having the inequality

$$\frac{\partial y_c^{\boldsymbol{p}}}{\partial s_c^{\boldsymbol{p}}} \leq h_c'(s_c^{\boldsymbol{p}}) \quad \text{with} \quad h_c'\left(s_c^{\boldsymbol{p}}\right) \xrightarrow{|s_c^{\boldsymbol{p}}| \to \infty} 0$$

the cell allows NVG defined in Definition 11, but actually we have $\frac{\partial y_c^{\boldsymbol{p}_{out}}}{\partial y_{c_{in}}^{\boldsymbol{p}_{in}}} \xrightarrow{|s_c^{\boldsymbol{p}_{out}}| \to \infty} 0$ for arbitrary gate activations. Again, ideas like state decay, additional peephole connections or additional loss functions like mentioned in Section 4 either do not work or destroy the NVG of the LSTM and LSTM Stable cell. So, our solution is to change the architecture of the MD LSTM Stable cell, so that it fulfills has an NEG and allows NVG and COD. The key idea is to bound the internal state, so that for all inputs $\left|y_{c_{in}}^{\boldsymbol{p}}\right| \leq 1$, $\boldsymbol{p} \in \mathbb{N}^D$ the internal state is bounded by $\left|s_c^{\boldsymbol{p}}\right| \leq 1$.
Note that this is comparable with the well-known Bounded-Input-Bounded-Output-Stability (BIBO-Stability). To create an MD cell that has an NEG, allows NVG and has a bounded internal state, we take the MD LSTM Stable cell proposed in the last section and change its layout. Therefore we calculate the activation of the IG as function of the FG, so that we achieve $\left|s_c^{\boldsymbol{p}}\right| \leq 1$ by choosing $y_t^{\boldsymbol{p}} := 1 - y_\phi^{\boldsymbol{p}}$. So the activation of the FG controls how much leaks from the previous states. The activation of the FG can also be interpreted as switch, if the internal activation, the new activation or a convex combination of these both activations should be stored in the cell. So the s_c can be seen as *time-dependent exponential moving average* of $y_{c_{in}}$.

Definition 19 (MD Leaky cell) *An MD Leaky cell is a cell of dimension D and order 1 where $h_c = \tanh$ and*

- $\Gamma = \{(\lambda, 1), \ldots, (\lambda, D), \phi, \omega\}$
- $s_c^{\boldsymbol{p}^-} = g_{conv}\left(\boldsymbol{y}_\Gamma^{\boldsymbol{p}}, s_c^{\boldsymbol{p}_1^-}, \ldots, s_c^{\boldsymbol{p}_D^-}\right) = \sum_{d=1}^{D} s_c^{\boldsymbol{p}_d^-} \frac{y_{\lambda,d}^{\boldsymbol{p}}}{\sum_{d'=1}^{D} y_{\lambda,d'}^{\boldsymbol{p}}}$
- $s_c^{\boldsymbol{p}} = g_{int}\left(\boldsymbol{y}_\Gamma^{\boldsymbol{p}}, y_{c_{in}}^{\boldsymbol{p}}, s_c^{\boldsymbol{p}^-}\right) = \left(1 - y_\phi^{\boldsymbol{p}}\right) y_{c_{in}}^{\boldsymbol{p}} + s_c^{\boldsymbol{p}^-} y_\phi^{\boldsymbol{p}}$
- $y_c^{\boldsymbol{p}} = g_{out}\left(\boldsymbol{y}_\Gamma^{\boldsymbol{p}}, s_c^{\boldsymbol{p}}\right) = y_\omega^{\boldsymbol{p}} h_c\left(s_c^{\boldsymbol{p}}\right)$

Now we can prove that the resulting cell has all benefits.

Theorem 20 *The MD Leaky cell has an NEG and allows NVG and COD.*

Proof See A.6 in appendix. ■

The MD Leaky cell can have one gate less than the MD LSTM cell and the MD LSTM Stable cell and because of this, the update path requires less computations.

7. General Derivation of Leaky Cells

So far we proposed cells for the MD case, which are able to provide long term memory. But especially in MDRNNs with more than one MD layer it is hard to measure if and how much long term dependencies are used and even if it is useful. Another way to interpret the cell is to consider them as kind of MD feature extractor like "feature maps" in Convolutional Neural Networks (Bengio and LeCun, 1995). Then the aim is to construct an MD cell which is able to generate useful features. Having a hierarchical Neural Network like in Bengio and LeCun (1995) and A. Graves andJ. Schmidhuber (2008) over the hierarchies the number of

features increases with a simultaneously decreasing feature resolution. Features in a layer with low resolution can be seen as low frequency features in comparison to features in a layer with high resolution. So it would be useful to construct a cell as feature extractor which produces a low frequency output in comparison to its input. In appendix B we take a closer look at the theory of linear shift invariant (LSI)-systems and their frequency analysis and analyse a first order LSI-system regarding its free selectable parameters using the $\mathcal{F}$- and $\mathcal{Z}$-transform. There, we derive the *MD LeakyLP cell* (see Definition 21) and 5 additional first order MD cells, which we do not test in Section 8.

Definition 21 (MD LeakyLP cell) *An MD LeakyLP cell is a cell of dimension D and order 1 where $h_c = \tanh$ and*

- $\Gamma = \{(\lambda, 1), \ldots, (\lambda, D), \phi, \omega_0, \omega_1\}$
- $s_c^{\boldsymbol{p}^-} = g_{conv}\left(\boldsymbol{y}_\Gamma^{\boldsymbol{p}}, s_c^{\boldsymbol{p}_1^-}, \ldots, s_c^{\boldsymbol{p}_D^-}\right) = \sum_{d=1}^{D} s_c^{\boldsymbol{p}_d^-} \frac{y_{\lambda,d}^{\boldsymbol{p}}}{\sum_{d'=1}^{D} y_{\lambda,d'}^{\boldsymbol{p}}}$
- $s_c^{\boldsymbol{p}} = g_{int}\left(\boldsymbol{y}_\Gamma^{\boldsymbol{p}}, y_{c_{in}}^{\boldsymbol{p}}, s_c^{\boldsymbol{p}^-}\right) = \left(1 - y_\phi^{\boldsymbol{p}}\right) y_{c_{in}}^{\boldsymbol{p}} + s_c^{\boldsymbol{p}^-} y_\phi^{\boldsymbol{p}}$
- $y_c^{\boldsymbol{p}} = g_{out}\left(\boldsymbol{y}_\Gamma^{\boldsymbol{p}}, s_c^{\boldsymbol{p}}, s_c^{\boldsymbol{p}^-}\right) = h_c\left(s_c^{\boldsymbol{p}} y_{\omega_0}^{\boldsymbol{p}} + s_c^{\boldsymbol{p}^-} y_{\omega_1}^{\boldsymbol{p}}\right)$

Setting the second OG ($y_{\omega_1}^{\boldsymbol{p}}$) to zero, the LeakyLP cell corresponds to the Leaky cell, hence it fulfills all three properties, but has one more gate, which is as much gates as the LSTM cell.

8. Experiments

RNNs with 1D LSTM cells are well studied. In some experiments the activations of the gates and the internal state are observed and one can see that the cell can really learn, when to "forget" information and when the internal state should be accessible for the network (see F. A. Gers, N. Schraudolph andJ. Schmidhuber, 2002). However, we did not find experiments like these for the MD case and we do not want to transfer these experiments into the MD case. Instead we compare the different cell types with each other in two scenarios where the MD RNNs with LSTM cells perform very well. In both benchmarks the task is to transcribe a handwritten text on an image, so we have a 2D RNN. In this case we compare the cells on the IFN/ENIT (Pechwitz, M. and Maddouri, S. and Märgner, V. and Ellouze, N. and Amiri, H. and others, 2002) and the Rimes database (Augustin, E. and Brodin, J.-M and Carré, M. and Geoffrois, E. and Grosicki, E. and Prêteux, F., 2006). Both tasks are solved with the MD RNN layout described in A. Graves andJ. Schmidhuber (2008) and shown in Figure 4. All networks are trained with *Backpropagation through time (BPTT)* . To compare the different cell types in RNNs with each other we take 10 RNNs with different weight initializations of each cell type and calculate the minimum, the maximum and the median of the best label error rate (LER) on a validation set of these 10 RNNs. In all tables we present these three LERs to compare the cell types.
We think it is more important to have stable cells in the lower MD layers because of two reasons: First, when we have just a few cells in a layer, the saturation of one cell has a

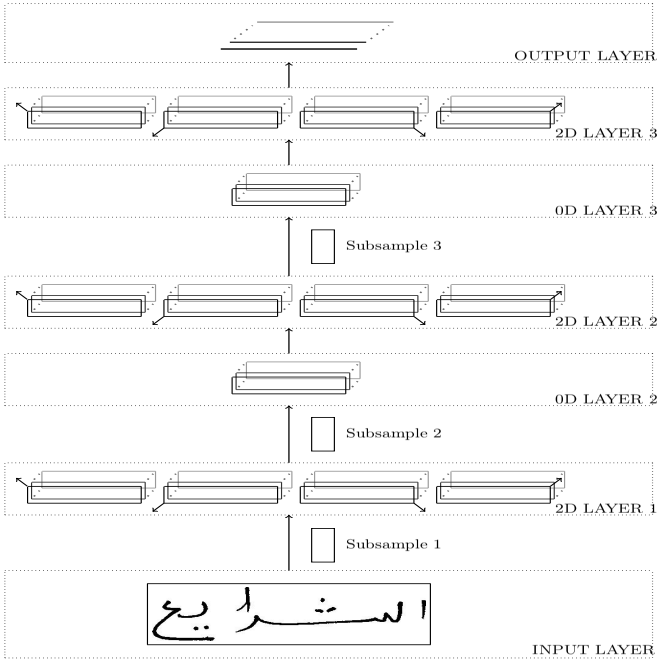

Figure 4: Architecture of the hierarchical MDRNN used for the experiments: It is equivalent to A. Graves andJ. Schmidhuber (2008, Figure 2). A 2D layer contains 2^2 distinct layers (for each combination of scanning direction left/right and up/down one layer). To reduce the number of weights between two 2D layers, a 0D layer is inserted, which contains units with tanh as activation function. They have dimension 0 because they have no recurrent connections. These layers can be seen as feed-forward or convolutional layer. Each 2D layer (or its allocated 0D layer) reduces its size in in x and y dimension using a two-dimensional subsampling. Simultaneously the number of feature maps (z-dimension) increases to have no bottleneck between input and output layer.

greater effect on the performance of the network. Second, in lower layers there are longer time series so having an unstable cell in such a layer, it has time to saturate. So our first experiment compares the recognition results when we substitute the LSTM cells in the lowest layer (which is "2D layer 1" in Figure 4) by the newly developed cells.
In the second experiment we compare the LSTM cell and the LeakyLP cell also in the higher MD layers ("2D layer 2 and 3 in Figure 4), to evaluate if the LeakyLP cell work better also

Celltype	Label-Error-Rate in Percent min	max	median
LSTM	8,58%	14,73%	10,58%
Stable	8,78%	11,75%	9,55%
Leaky	8,87%	10,47%	9,10%
LeakyLP	8,24%	9,40%	8,93%

Table 1: Different cell types in the lowest MD layer

in long time series.
In Bengio (2012, 3.1.1) it is mentioned, that an important hyper parameter for a training is the learning rate, so another experiment is to train all networks with stochastic gradient decent with different learning rates $\delta \in \{1 \cdot 10^{-3}, 5 \cdot 10^{-4}, 2 \cdot 10^{-4}, 1 \cdot 10^{-4}\}$ and compare the best LER according a fixed learning rate.

8.1 The IFN/ENIT Database

This database contains handwritten names of towns and villages of Tunisia. The set is divided into 7 (a-f,s) sets, where 5 (a-e) are available for training and validation (for details see Pechwitz, M. and Maddouri, S. and Märgner, V. and Ellouze, N. and Amiri, H. and others, 2002). With all information we got from A. Graves, we were able to get comparable results to A. Graves andJ. Schmidhuber (2008). Therefor we divide the sets a-e into 30000 training samples and 2493 validation samples. All network are trained 100 epochs with a fixed learning rate $\delta = 1 \cdot 10^{-4}$. The LER is calculated on the validation set.

8.1.1 Different Cells in the Lowest MD Layer

In our first experiment we substitute the LSTM cell in the lowest MD layer. We take some of the cells described in this paper. In Table 1 the results are shown. The first row is the same RNN layout used in A. Graves andJ. Schmidhuber (2008). We can see, that the LeakyLP cell performs the best. Nevertheless the worst RNN with LeakyLP cells in the lowest MD layer performs worth than the best RNN with LSTM cells. So we cannot say, that LeakyLP is always better. But it can be observed that the variance of the RNN performance is very high with LSTM cells in the lowest MD layer. Our interpretation is that LSTM cells have a comparable performance like the LeakyLP cells in the lowest layer, when they do not saturate. Note, that the Leaky cell has one gate less, so they are faster and have less trainable weights.

8.1.2 Different Cells in Other MD Layers

Now we want to compare the best new developed cell—the LeakyLP cell—with the LSTM cell in the other MD layers. So we also substitute the LSTM cell in the upper MD layers. We enumerate the 2D layers like shown in Figure 4. In Table 2 we can see that substituting the LSTM cells only in the lowest or in the both lowest layer perform slightly better. The best results can be achieved when we use LeakyLP cells in 2D layer 1 and LSTM cells in 2D layer 3. Using LSTM in the middle layer seems to work slightly better than using the LeakyLP

Celltype in 2D layer 1	2	3	Label-Error-Rate in Percent min	max	median
LSTM	LSTM	LSTM	8,58%	14,73%	10,58%
LeakyLP	LSTM	LSTM	8,24%	9,40%	8,93%
LeakyLP	LeakyLP	LSTM	8,35%	11,27%	8,91%
LeakyLP	LeakyLP	LeakyLP	8,92%	11,69%	9,74%

Table 2: Different cells in other layers

Celltype	BP-delta	Label-Error-Rate in Percent min	max	median
LSTM	$1 \cdot 10^{-4}$	8,58%	14,73%	10,58%
LSTM	$2 \cdot 10^{-4}$	9,15%	16,86%	10,51%
LSTM	$5 \cdot 10^{-4}$	9,03%	21,77%	11,44%
LSTM	$1 \cdot 10^{-3}$	10,21%	30,20%	11,44%
LeakyLP	$1 \cdot 10^{-4}$	8,92%	11,69%	9,74%
LeakyLP	$2 \cdot 10^{-4}$	8,38%	9,09%	8,81%
LeakyLP	$5 \cdot 10^{-4}$	8,25%	8,95%	8,78%
LeakyLP	$1 \cdot 10^{-3}$	8,29%	9,20%	8,88%
LeakyLP	$2 \cdot 10^{-3}$	8,95%	12,81%	9,55%

Table 3: Performance of cells regarding learning-rate

cells instead. This fits to our intuition mentioned before that the LSTM cells perform better when they do not have a too long time series and when there are enough cells in one layer which do not saturate.

8.1.3 Performance of Cells Regarding Learning-Rate

When we take a look at the update equations and the proofs of the NEG it can be assumed, that the gradient going through the cells is lower for LeakyLP cells in contrast to LSTM cells. So we think the learning rate have to be larger for LeakyLP cells. In Table 3 we compare the networks with either only LSTM or LeakyLP cells. There we can see that the learning rate have to be much higher for the LeakyLP cells. In addition, the RNNs with LeakyLP cells are more robust to the choice of the learning rate.

8.2 The Rimes Database

One task of the Rimes database is the handwritten word recognition (for more details see E. Grosicki, M. Carré, J.-M. Brodin andE. Geoffrois, 2008; E. Grosicki andH. El-Abed, 2011). It contains 59292 images of french single words. It is divided into distinct subsets; a training set of 44196 samples, a validation set of 7542 samples and a test set of 7464 samples. We train the MD RNNs by using the training set for training and calculate the LER over the validation set, so the network is trained on 44196 training samples each epoch. The network used in this section differs only in the subsampling rate between two layers from the network used in A. Graves andJ. Schmidhuber (2008). When there is a subsampling between layers,

Celltype	Label-Error-Rate in Percent min	max	median
LSTM	14,96%	17,63%	16,50%
Stable	14,45%	16,02%	15,11%
Leaky	14,77%	16,39%	15,85%
LeakyLP	14,63%	15,78%	15,30%

Table 4: Different cell types in the lowest MD layer

Celltype in 2D layer 1	2	3	Label-Error-Rate in Percent min	max	median
LSTM	LSTM	LSTM	14,96%	17,63%	16,50%
LeakyLP	LSTM	LSTM	14,63%	15,78%	15,30%
LeakyLP	LeakyLP	LSTM	14,21%	15,57%	14,92%
LeakyLP	LeakyLP	LeakyLP	14,94%	16,18%	15,52%

Table 5: Different cells in other layers

the factors are 3×2 instead of 4×3 or 4×2. The rest of the experiment is the same like described in Section 8.1.

8.2.1 Different Cells in the Lowest MD Layer

In Table 4 we can see that substituting the LSTM in the lowest layer by one of the three cells improves the performance of the network, even the Leaky cell with one gate less.

8.2.2 Different Cells in Other MD Layers

We want to see the effect of the substitution of the LSTM cell by the LeakyLP cell in the upper MD layers. In Table 5 we can see that using LeakyLP cells in both lowest layers perform very well. So we also take this setup to try different learning rates.

Performance of Cells Regarding Learning-Rate. Using different learning rates we can see that the RNN with LeakyLP cells in the both lowest layers and the LSTM cells in the top layer can significantly improve the performance . Even the maximal LER of this RNN works better than the best network with LSTM cells in each layer.

9. Conclusion

In this paper we took a look at the one-dimensional LSTM cell and discussed the benefits of this cell. We found two properties, that probably make these cells so powerful in the one dimensional case. Expanding these properties to the multi dimensional case, we saw that the LSTM does not fulfill one of these properties any more. We solved this problem by changing the architecture of the cell. In addition we presented a more general idea how to create one dimensional or multi dimensional cells. We compare some newly developed cells with the LSTM cell on two data sets and we can improve the performance using the

Celltype	BP-delta	Label-Error-Rate in Percent min	max	median
LSTM	$1 \cdot 10^{-4}$	14,96%	17,63%	16,50%
LSTM	$2 \cdot 10^{-4}$	14,41%	16,88%	15,61%
LSTM	$5 \cdot 10^{-4}$	15,05%	16,27%	15,47%
LeakyLP	$1 \cdot 10^{-4}$	14,94%	16,18%	15,52%
LeakyLP	$5 \cdot 10^{-4}$	12,68%	13,95%	13,57%
LeakyLP in 2D layer 1 & 2	$2 \cdot 10^{-4}$	13,26%	14,04%	13,65%
LeakyLP in 2D layer 1 & 2	$5 \cdot 10^{-4}$	12,08%	13,42%	12,87%

Table 6: Performance of cells regarding learning-rate

new cell types. Due to this we think that substituting the multi-dimensional LSTM cells by the multi-dimensional *LeakyLP cell* could improve the performance of many system working with a multi-dimensional space.

Appendix A. Proofs

A.1 Proof of 7

Proof Let c be a 1D LSTM cell. To get the derivative $\frac{\partial s_c(t_2)}{\partial s_c(t_1)}$ according the truncated gradient between two time steps $t_1, t_2 \in \mathbb{N}$ we have to take a look at g_{int}.

$$\begin{aligned}\frac{\partial s_c(t_2)}{\partial s_c(t_1)} &= \frac{\partial g_{int}\left(\boldsymbol{y}_\Gamma(t_2), y_{c_{in}}(t_2), s_c(t_2-1)\right)}{\partial s_c(t_1)} \\ &= \underbrace{\frac{\partial\left(y_{c_{in}}(t_2) y_\iota(t_2)\right)}{\partial s_c(t_1)}}_{\underset{tr}{=}0} + \frac{\partial s_c(t_2-1)}{\partial s_c(t_1)} y_\phi(t_2) + s_c(t_2-1) \underbrace{\frac{\partial y_\phi(t_2)}{\partial s_c(t_1)}}_{\underset{tr}{=}0} \\ &\underset{tr}{=} \frac{\partial s_c(t_2-1)}{\partial s_c(t_1)} y_\phi(t_2) \\ &\underset{tr}{=} \prod_{t=t_1+1}^{t_2} y_\phi(t)\end{aligned} \tag{12}$$

(13)

In addition, $\forall t \in \mathbb{N}$ we have

$$\frac{\partial s_c(t)}{\partial y_{c_{in}}(t)} = y_\iota(t) \qquad \text{and} \qquad \frac{\partial y_c(t)}{\partial s_c(t)} = h_c'\left(s_c(t)\right) y_\omega(t). \tag{14}$$

We will prove the properties successively.
NEG: For the LSTM cell the FG $f_\phi = f_{log}$ ensures $y_\phi(t) \in (0,1)$, so using these bounds in (13) with

$$\frac{\partial s_c(t)}{\partial s_c(t_{in})} \underset{tr}{=} \prod_{t'=t_{in}+1}^{t} y_\phi(t') \in (0,1)$$

the LSTM cell has an NEG.
NVG: Therefore, we choose

$$y_\iota(t) \in \begin{cases} [1-\varepsilon, 1) & \text{if} \quad t = t_{in} \\ (0, \varepsilon] & \text{otherwise} \end{cases},$$
$$y_\phi(t) \in \begin{cases} [1-\varepsilon, 1) & \text{if} \quad t_{in} < t \leq t_{out} \\ (0, \varepsilon] & \text{otherwise} \end{cases},$$

with a later chosen $\varepsilon > 0$. Let $t_1, t_2 \in \mathbb{N}, t_1 \leq t_2$ be two arbitrary dates, where we want to calculate the gradient $\frac{\partial s_c(t_2)}{\partial y_{c_{in}}(t_1)}$. First, we want to show that the LSTM cell allows NVG for $t_1 = t_{in}$ and $t_{in} \leq t_2 \leq t_{out}$:
We have $y_\iota(t_1) \in [1-\varepsilon, 1)$ and $\forall t = t_{in}+1, \ldots, t_{out} : y_\phi(t) \in [1-\varepsilon, 1)$. Then, we can estimate the derivative from (12) and (14) by

$$\begin{aligned} \frac{\partial s_c(t_2)}{\partial y_{c_{in}}(t_1)} = \frac{\partial s_c(t_2)}{\partial s_c(t_1)} \frac{\partial s_c(t_1)}{\partial y_{c_{in}}(t_1)} &\underset{tr}{=} y_\iota(t_1) \prod_{t=t_1+1}^{t_2} y_\phi(t) \\ &\underset{tr}{\in} \left[(1-\varepsilon) \prod_{t=t_1+1}^{t_2} (1-\varepsilon), 1 \right) \subseteq \left[(1-\varepsilon)^{t_{out}-t_{in}+1}, 1 \right). \end{aligned}$$

To fulfill the equation for NVG we choose ε depending on δ such that

$$\begin{aligned} & 1-\delta \leq (1-\varepsilon)^{t_{out}-t_{in}+1} \\ \Leftrightarrow \quad & \varepsilon \leq 1 - (1-\delta)^{\frac{1}{t_{out}-t_{in}+1}} \end{aligned}$$

holds. Second, we have to show, that the derivative is in $[0, \delta]$, when $t_1 = t_{in}$ and $t_{in} \leq t_2 \leq t_{out}$ is not fulfilled.
In the case of $t_1 \neq t_{in}$ when $\varepsilon \leq \delta$ we can use the NEG which leads to

$$\frac{\partial s_c(t_2)}{\partial y_{c_{in}}(t_1)} = \underbrace{\frac{\partial s_c(t_2)}{\partial s_c(t_1)}}_{\underset{tr}{\in}[0,1]} \underbrace{\frac{\partial s_c(t_1)}{\partial y_{c_{in}}(t_1)}}_{\in(0,\varepsilon]} \subseteq [0, \varepsilon] \subseteq [0, \delta].$$

When $t_1 = t_{in}$ we have two cases: $t_2 < t_{in}$ or $t_2 > t_{out}$. For the case $t_2 < t_{in}$ the derivative is zero ($\subset [0, \delta]$), because the cell is causal. For $t_2 > t_{out}$ we can split the derivative at t_{out} and get

$$\begin{aligned} \frac{\partial s_c(t_2)}{\partial y_{c_{in}}(t_1)} &\underset{tr}{=} \underbrace{y_\iota(t_1) \prod_{t=t_1+1}^{t_{out}} y_\phi(t)}_{\in(0,1)} \prod_{t=t_{out}+1}^{t_2} \underbrace{y_\phi(t)}_{\in(0,\varepsilon]} \\ &\underset{tr}{\in} \left(0, \varepsilon^{t_2-t_{out}}\right] \subset [0, \varepsilon] \subseteq [0, \delta]. \end{aligned}$$

For $\varepsilon \leq \min\left\{\delta, 1-(1-\delta)^{\frac{1}{t_{out}-t_{in}+1}}\right\}$ the LSTM cell allows NVG.
COD: To prove that the LSTM cell has no COD, we show that there are gate activations

such that in Definition 5 we get $\delta_2 > \delta_1$. Therefore, we assume that all gate activations are arbitrary ($y_\gamma(t) \in (0,1)$), closed ($y_\gamma(t) \in (0, \varepsilon]$) or opened ($y_\gamma(t) \in [1-\varepsilon, 1)$) with a later chosen $\varepsilon > 0$. We take a look at the right side of (14). For $s_c(t) = 0$ we get $h_c'(s_c(t)) = 1$. In Definition 5 we have to satisfy $\exists \boldsymbol{y}_\Gamma(t) : \frac{\partial y_c(t)}{\partial s_c(t)} \in [0, \delta_2]$ an choose the OG $y_\omega(t) \in (0, \varepsilon]$ with

$$\varepsilon \leq \delta_2. \tag{15}$$

But then for $t' = 1, \ldots, t-1$ we can choose the IG and FG open with the same ε so that

$$y_\phi(t'), y_\iota(t') \in [1-\varepsilon, 1).$$

When for all time steps $t' = 1, \ldots, t$ there is a positive input $y_{c_{in}}(t') \in [c, 1), c \in (0,1) \subset \mathbb{R}$ and an internal state $s_c(t'-1) < c\frac{(1-\varepsilon)}{\varepsilon}$, the internal state is growing over time, because

$$\begin{aligned} s_c(t') &= y_{c_{in}}(t') y_\iota(t') + s_c(t'-1) y_\phi(t') \\ &\geq c(1-\varepsilon) + s_c(t'-1)(1-\varepsilon) \\ &\geq s_c(t'-1) + c(1-\varepsilon) - s_c(t'-1)\varepsilon \\ &> s_c(t'-1) + c(1-\varepsilon) - c\frac{(1-\varepsilon)}{\varepsilon}\varepsilon \\ &> s_c(t'-1). \end{aligned}$$

For large $s_c(t) \geq c\frac{(1-\varepsilon)}{\varepsilon} \gg 1$ we can estimate

$$\underbrace{\tanh(s_c(t))}_{\approx \exp(-2s_c(t))} \leq \exp(-s_c(t)) \leq \exp\left(-c\frac{(1-\varepsilon)}{\varepsilon}\right).$$

This yields in (14) to the bound

$$\begin{aligned} \left|\frac{\partial y_c(t)}{\partial s_c(t)}\right| &= \left|h_c'(s_c(t))\, y_\omega(t)\right| && (16) \\ &\leq \exp\left(-c\frac{(1-\varepsilon)}{\varepsilon}\right) && (17) \end{aligned}$$

so in Definition 5 we get

$$\delta_1 \leq \exp\left(-c\frac{(1-\varepsilon)}{\varepsilon}\right). \tag{18}$$

But when we combine (15), (18) and the restriction in Definition 5, we have

$$\varepsilon \leq \delta_2 < \delta_1 \leq \exp\left(-c\frac{(1-\varepsilon)}{\varepsilon}\right),$$

but there exist ε, c, such that the inequality is not fulfilled, which is a contradiction.
Summarized, the 1D LSTM cell allows an NVG and has an NEG, but does not allow COD. ■

A.2 Proof of 14

Proof Let c be an MD LSTM cell of dimension D, $\boldsymbol{p},\boldsymbol{p}_1,\boldsymbol{p}_2,\boldsymbol{p}_{in},\boldsymbol{p}_{out} \in \mathbb{N}^D$,$\boldsymbol{p}_{in} \leq \boldsymbol{p}_{out}$ arbitrary dates and $h_c = \tanh$ the sigmoid function. Besides $\varepsilon > 0$ is a later chosen value. In the first step we want to show that there are activations of the forget gates, so that

$$\frac{\partial s_c^{\boldsymbol{p}}}{\partial s_c^{\boldsymbol{p}_{in}}} \underset{tr}{\in} \begin{cases} \left[(1-\varepsilon)^{\|\boldsymbol{p}-\boldsymbol{p}_{in}\|_1}, 1\right] & \text{for} \quad \boldsymbol{p}_{in} \leq \boldsymbol{p} \leq \boldsymbol{p}_{out} \\ [0, D\varepsilon] & \text{otherwise} \end{cases} \tag{19}$$

is fulfilled. The prove is done using induction over $k = \|\boldsymbol{p}-\boldsymbol{p}_{in}\|_1$ with $\boldsymbol{p} \geq \boldsymbol{p}_{in}$. The base $k = 0$ is clear. Let be $k \geq 1$. We define

$$P_{\boldsymbol{p}} := \left\{d \in \{1,\dots,D\} \mid \boldsymbol{p}_d^- \geq \boldsymbol{p}_{in}\right\}$$

the set of dimensions d, in which are $\boldsymbol{p}_{in}$-$\boldsymbol{p}_d^-$-paths. Note, that this set cannot be empty, because $\boldsymbol{p} > \boldsymbol{p}_{in}$ for $k \geq 1$. When we have a dimension $d \in P_{\boldsymbol{p}}$ then $\left\|\boldsymbol{p}_d^- - \boldsymbol{p}_{in}\right\|_1 = k-1$ and we assume

$$\frac{\partial s_c^{\boldsymbol{p}_d^-}}{\partial s_c^{\boldsymbol{p}_{in}}} \underset{tr}{\in} \left[(1-\varepsilon)^{\left\|\boldsymbol{p}_d^- - \boldsymbol{p}_{in}\right\|_1}, 1\right] = \left[(1-\varepsilon)^{k-1}, 1\right]. \tag{20}$$

Then we choose the activations of the FG to be

$$y_{\phi,d}^{\boldsymbol{p}} \in \begin{cases} \left[\frac{1-\varepsilon}{|P_{\boldsymbol{p}}|}, \frac{1}{|P_{\boldsymbol{p}}|}\right) & \text{for} \quad d \in P_{\boldsymbol{p}} \text{ and } \boldsymbol{p}_{in} < \boldsymbol{p} \leq \boldsymbol{p}_{out} \\ [0, \varepsilon] & \text{otherwise} \end{cases}. \tag{21}$$

Then we can estimate the derivative for $\boldsymbol{p}_{in} \leq \boldsymbol{p} \leq \boldsymbol{p}_{out}$ using (20) and (21) to

$$\begin{aligned} \frac{\partial s_c^{\boldsymbol{p}}}{\partial s_c^{\boldsymbol{p}_{in}}} &\underset{tr}{=} \sum_{d \in P_{\boldsymbol{p}}} \frac{\partial s_c^{\boldsymbol{p}_d^-}}{\partial s_c^{\boldsymbol{p}_{in}}} y_{\phi,d}^{\boldsymbol{p}} \in \left[\sum_{d \in P_{\boldsymbol{p}}} \frac{\partial s_c^{\boldsymbol{p}_d^-}}{\partial s_c^{\boldsymbol{p}_{in}}} \frac{1-\varepsilon}{|P_{\boldsymbol{p}}|}, \sum_{d \in P_{\boldsymbol{p}}} \frac{\partial s_c^{\boldsymbol{p}_d^-}}{\partial s_c^{\boldsymbol{p}_{in}}} \frac{1}{|P_{\boldsymbol{p}}|}\right) \\ \Rightarrow \frac{\partial s_c^{\boldsymbol{p}}}{\partial s_c^{\boldsymbol{p}_{in}}} &\underset{tr}{\in} \left[|P_{\boldsymbol{p}}|\,(1-\varepsilon)^{k-1}\,\frac{1-\varepsilon}{|P_{\boldsymbol{p}}|}, |P_{\boldsymbol{p}}|\,\frac{1}{|P_{\boldsymbol{p}}|}\right) \\ \Leftrightarrow \frac{\partial s_c^{\boldsymbol{p}}}{\partial s_c^{\boldsymbol{p}_{in}}} &\underset{tr}{\in} \left[(1-\varepsilon)^{\|\boldsymbol{p}-\boldsymbol{p}_{in}\|_1}, 1\right), \end{aligned} \tag{22}$$

so (19) is fulfilled for $\boldsymbol{p}_{in} \leq \boldsymbol{p} \leq \boldsymbol{p}_{out}$.
If we have $\boldsymbol{p} < \boldsymbol{p}_{in}$ in (19), the derivative is 0, because we have a causal system.
For $\boldsymbol{p} > \boldsymbol{p}_{out}$ in (19), we choose $\varepsilon \leq \frac{1}{D} \leq \frac{1}{|P_{\boldsymbol{p}}|}$ in (21) to ensure $\forall \boldsymbol{p} \in \mathbb{N}^D$:$\left|\frac{\partial s_c^{\boldsymbol{p}}}{\partial s_c^{\boldsymbol{p}_{in}}}\right| \leq 1$ (see (22)) and we get

$$\frac{\partial s_c^{\boldsymbol{p}}}{\partial s_c^{\boldsymbol{p}_{in}}} \underset{tr}{=} \sum_{d=1,\dots,D} \frac{\partial s_c^{\boldsymbol{p}_d^-}}{\partial s_c^{\boldsymbol{p}_{in}}} y_{\phi,d}^{\boldsymbol{p}} \in \left(0, D\varepsilon \max_{d=1,\dots,D} \frac{\partial s_c^{\boldsymbol{p}_d^-}}{\partial s_c^{\boldsymbol{p}_{in}}}\right] \subseteq (0, D\varepsilon], \tag{23}$$

and (19) is fulfilled.
In the second step let $\boldsymbol{p}_1 \leq \boldsymbol{p}_2$ be the date, for which we want to calculate the truncated gradient $\frac{\partial s_c^{\boldsymbol{p}_2}}{\partial y_{c_{in}}^{\boldsymbol{p}_1}}$. We choose the IG activation as

$$y_t^{\boldsymbol{p}} \in \begin{cases} [1-\varepsilon, 1) & \text{if} \quad \boldsymbol{p} = \boldsymbol{p}_{in} \\ (0, \varepsilon] & \text{otherwise} \end{cases} \tag{24}$$

and we get $\frac{\partial s_c^{\boldsymbol{p}}}{\partial y_{c_{in}}^{\boldsymbol{p}}} = y_t^{\boldsymbol{p}}$. Using (22), (23) and (24), we can estimate the partial derivative by

$$\begin{aligned} &\frac{\partial s_c^{\boldsymbol{p}_2}}{\partial y_{c_{in}}^{\boldsymbol{p}_1}} = \frac{\partial s_c^{\boldsymbol{p}_2}}{\partial s_c^{\boldsymbol{p}_1}} \frac{\partial s_c^{\boldsymbol{p}_1}}{\partial y_{c_{in}}^{\boldsymbol{p}_1}} \\ \Rightarrow &\frac{\partial s_c^{\boldsymbol{p}_2}}{\partial s_c^{\boldsymbol{p}_1}} \underset{tr}{\in} \begin{cases} \left[(1-\varepsilon)(1-\varepsilon)^{\|\boldsymbol{p}_2-\boldsymbol{p}_{in}\|_1}, 1\right] & \text{for} \quad \boldsymbol{p}_1 = \boldsymbol{p}_{in} \text{ and } \boldsymbol{p}_{in} \leq \boldsymbol{p}_2 \leq \boldsymbol{p}_{out} \\ [0, D\varepsilon] & \text{otherwise} \end{cases}. \end{aligned}$$

and setting

$$\varepsilon := \min\left\{\frac{\delta}{D}, 1-(1-\delta)^{\frac{1}{\|\boldsymbol{p}_{in}-\boldsymbol{p}_{out}\|_1+1}}\right\}$$

the conditions of Definition 11 are fulfilled. ■

A.3 Proof of 15

Proof Let c be an MD cell of dimension D with the internal state s_c and $\boldsymbol{p}_{in},\boldsymbol{p}_k \in \mathbb{N}^D$,$\boldsymbol{p}_{in} \leq \boldsymbol{p}_k$ two dates. Let $\boldsymbol{p}_k$ be a date k steps further in each dimension than a fixed date $\boldsymbol{p}_{in}$. So the distance between them is $\|\boldsymbol{p}_{in}-\boldsymbol{p}_k\|_1 = Dk$. Let Π be the set of all $\boldsymbol{p}_{in}$-$\boldsymbol{p}_k$-paths, then there exist $|\Pi| = \#\{\overrightarrow{\boldsymbol{p}_{in}\boldsymbol{p}_k}\}$ paths (see Definition 8). We assume

$$y_{\phi,d}^{\boldsymbol{p}} \in [\varepsilon, 1-\varepsilon]$$

with $\varepsilon \in (0, 0.5)$ and we can estimate the partial derivative, using the truncated gradient, with

$$\begin{aligned} \frac{\partial s_c^{\boldsymbol{p}_k}}{\partial s_c^{\boldsymbol{p}_{in}}} &\underset{tr}{=} \sum_{\pi \in \Pi} \prod_{i=1}^{k} y_{\phi,d}^{\pi_i} \\ &\underset{tr}{\in} \left[\varepsilon^k \#\{\overrightarrow{\boldsymbol{p}_{in}\boldsymbol{p}_k}\}, (1-\varepsilon)^k \#\{\overrightarrow{\boldsymbol{p}_{in}\boldsymbol{p}_k}\}\right]. \end{aligned}$$

For $D = 1$ we get $|\Pi| = 1$ and the cell has a NGEC. When $D \geq 2$ we can count the number of paths using the Stirling's approximation and we can estimate the number of paths with

$$\#\{\overrightarrow{\boldsymbol{p}_{in}\boldsymbol{p}_k}\} = \frac{\left(\sum_{i=1}^{D}\left(\overrightarrow{\boldsymbol{p}_{in}\boldsymbol{p}_k}\right)_i\right)!}{\prod_{i=1}^{D}\left(\overrightarrow{\boldsymbol{p}_{in}\boldsymbol{p}_k}\right)_i!} = \frac{(Dk)!}{(k!)^D} \xrightarrow{k \gg 1} \frac{\sqrt{2\pi Dk}\left(\frac{Dk}{e}\right)^{Dk}}{\left(\sqrt{2\pi k}\left(\frac{k}{e}\right)^k\right)^D} = \frac{\sqrt{D}D^{Dk}}{\sqrt{2\pi k}^{D-1}}.$$

When we combine it with the FG activations we can estimate the derivative for great k with the Stirling's approximation and get

$$\begin{aligned} \frac{\partial s_c^{\boldsymbol{p}_k}}{\partial s_c^{\boldsymbol{p}_{in}}} &\underset{tr}{\in} \left[\varepsilon^{Dk}\#\{\overrightarrow{\boldsymbol{p}_{in}\boldsymbol{p}_k}\}, (1-\varepsilon)^{Dk}\#\{\overrightarrow{\boldsymbol{p}_{in}\boldsymbol{p}_k}\}\right] \\ &\overset{k \gg 1}{\underset{tr}{\in}} \left[\frac{\sqrt{D}}{\sqrt{2\pi k}^{D-1}}(D\varepsilon)^{Dk}, \frac{\sqrt{D}}{\sqrt{2\pi k}^{D-1}}(D(1-\varepsilon))^{Dk}\right]. \end{aligned} \tag{25}$$

The upper bound of this interval can grow for great k, if $[D\,(1-\varepsilon)] > 1$ and this is the case for $D \geq 2$. So the MD LSTM cell can have an exploding gradient for $D \geq 2$. When the weights to the FGs are initialized with small values, we have $y^{\boldsymbol{p}}_{\phi,d} \approx 0.5$. Then we have an exploding gradient when $D \geq 3$, when the training is starting. In the worst case we have $y^{\boldsymbol{p}}_{\phi,d} \approx 1$ and the derivative in (25) goes for great k to

$$\frac{\partial s_c^{\boldsymbol{p}_k}}{\partial s_c^{\boldsymbol{p}_{in}}} \approx \frac{\sqrt{D}}{\sqrt{2\pi}^{D-1}} k^{\frac{1-D}{2}} (D)^{Dk}.$$

■

A.4 Proof of 17

Proof Let c be an MD LSTM Stable cell of dimension $D \geq 2$ (for $D = 1$ the proof is equivalent to the 1D case of the LSTM cell), $\boldsymbol{p}, \boldsymbol{p}_1, \boldsymbol{p}_2, \boldsymbol{p}_{in}, \boldsymbol{p}_{out} \in \mathbb{N}^D, \boldsymbol{p}_{in} \leq \boldsymbol{p}_{out}$ arbitrary dates and $h_c = \tanh$ the sigmoid function. Besides $\varepsilon > 0$ is a later chosen value.
In the first step we want to show that there are activations of the forget gates, so that

$$\frac{\partial s_c^{\boldsymbol{p}}}{\partial s_c^{\boldsymbol{p}_{in}}} \underset{tr}{\in} \begin{cases} \left[(1-(D-1)\varepsilon)^{2\|\boldsymbol{p}-\boldsymbol{p}_{in}\|_1}, 1\right] & \text{for} \quad \boldsymbol{p}_{in} \leq \boldsymbol{p} \leq \boldsymbol{p}_{out} \\ [0, \varepsilon] & \text{otherwise} \end{cases} \tag{26}$$

is fulfilled. The prove is done using induction over $k = \|\boldsymbol{p}\_\boldsymbol{p}_{in}\|_1$. The base $k = 0$ is clear. Let be $k \geq 1$. We define

$$P_{\boldsymbol{p}} := \left\{ d \in \{1, \ldots, D\} \mid \boldsymbol{p}_d^- \geq \boldsymbol{p}_{in} \right\}$$

the set of dimensions d, in which are $\boldsymbol{p}_{in}$-$\boldsymbol{p}_d^-$-paths. Note, that this set cannot be empty, because $\boldsymbol{p} > \boldsymbol{p}_{in}$ for $k \geq 1$. When we have a dimension $d \in P_{\boldsymbol{p}}$ then $\left\|\boldsymbol{p}_d^- - \boldsymbol{p}_{in}\right\|_1 = k-1$ and we assume

$$\frac{\partial s_c^{\boldsymbol{p}_d^-}}{\partial s_c^{\boldsymbol{p}_{in}}} \underset{tr}{\in} \left[(1-(D-1)\varepsilon)^{2\left\|\boldsymbol{p}_d^- - \boldsymbol{p}_{in}\right\|_1}, 1\right] = \left[(1-(D-1)\varepsilon)^{2(k-1)}, 1\right]. \tag{27}$$

When we choose the activations of the LGs to be

$$y^{\boldsymbol{p}}_{\lambda,d} \in \begin{cases} [1-\varepsilon, 1) & \text{for} \quad d \in P_{\boldsymbol{p}} \text{ and } \boldsymbol{p}_{in} < \boldsymbol{p} \leq \boldsymbol{p}_{out} \\ (0, \varepsilon] & \text{otherwise} \end{cases},$$

we can estimate $\frac{\sum_{d\in P_{\boldsymbol{p}}} y^{\boldsymbol{p}}_{\lambda,d}}{\sum_{d'=1}^{D} y^{\boldsymbol{p}}_{\lambda,d'}} \in (1-(D-1)\varepsilon, 1]$, because

$$\begin{aligned} 1 \geq \frac{\sum_{d\in P_{\boldsymbol{p}}} y^{\boldsymbol{p}}_{\lambda,d}}{\sum_{d'=1}^{D} y^{\boldsymbol{p}}_{\lambda,d'}} &= \frac{\sum_{d\in P_{\boldsymbol{p}}} y^{\boldsymbol{p}}_{\lambda,d}}{\sum_{d\in P_{\boldsymbol{p}}} y^{\boldsymbol{p}}_{\lambda,d} + \sum_{d\in\{1,..,D\}\setminus P_{\boldsymbol{p}}} y^{\boldsymbol{p}}_{\lambda,d'}} \\ &\geq \frac{|P_{\boldsymbol{p}}|\,(1-\varepsilon)}{|P_{\boldsymbol{p}}|\,(1-\varepsilon) + \underbrace{(D-|P_{\boldsymbol{p}}|)}_{\leq D-1}\varepsilon} \\ &\geq \frac{|P_{\boldsymbol{p}}|\,(1-(D-1)\varepsilon)}{|P_{\boldsymbol{p}}|\,(1-(D-1)\varepsilon) + (D-1)\,\varepsilon} \\ &\geq (1-(D-1)\varepsilon)\frac{|P_{\boldsymbol{p}}|}{|P_{\boldsymbol{p}}| - \varepsilon(D-1)\,(|P_{\boldsymbol{p}}|-1)} \\ &\geq (1-(D-1)\varepsilon). \end{aligned} \tag{28}$$

Setting the FG to

$$y^{\boldsymbol{p}}_{\phi} \in \begin{cases} [1-\varepsilon, 1) & \text{for} \quad \boldsymbol{p}_{in} < \boldsymbol{p} \leq \boldsymbol{p}_{out} \\ (0, \varepsilon] & \text{otherwise} \end{cases} \tag{29}$$

we can estimate the derivative for $\boldsymbol{p}_{in} \leq \boldsymbol{p} \leq \boldsymbol{p}_{out}$ using (27),(28) and (29) to

$$\begin{aligned} \frac{\partial s_c^{\boldsymbol{p}}}{\partial s_c^{\boldsymbol{p}_{in}}} &\underset{tr}{=} y^{\boldsymbol{p}}_{\phi} \left(\sum_{d\in P_{\boldsymbol{p}}} \frac{\partial s_c^{\boldsymbol{p}_d^-}}{\partial s_c^{\boldsymbol{p}_{in}}} \frac{y^{\boldsymbol{p}}_{\lambda,d}}{\sum_{d'=1}^{D} y^{\boldsymbol{p}}_{\lambda,d'}} + \underbrace{\sum_{d\in\{1,..,D\}\setminus P_{\boldsymbol{p}}} \frac{\partial s_c^{\boldsymbol{p}_d^-}}{\partial s_c^{\boldsymbol{p}_{in}}} \frac{y^{\boldsymbol{p}}_{\lambda,d}}{\sum_{d'=1}^{D} y^{\boldsymbol{p}}_{\lambda,d'}}}_{=0} \right) \\ &\underset{tr}{\in} \left((1-\varepsilon)\,(1-(D-1)\varepsilon)^{2(k-1)}\,(1-(D-1)\varepsilon), 1 \right) \\ \Rightarrow \quad \frac{\partial s_c^{\boldsymbol{p}}}{\partial s_c^{\boldsymbol{p}_{in}}} &\underset{tr}{\in} \left((1-(D-1)\varepsilon)^{2k}, 1 \right) \end{aligned} \tag{30}$$

so (26) is fulfilled for $\boldsymbol{p}_{in} \leq \boldsymbol{p} \leq \boldsymbol{p}_{out}$.
If we have $\boldsymbol{p} < \boldsymbol{p}_{in}$ in (26), the derivative is 0, because we have a causal system.
For $\boldsymbol{p} > \boldsymbol{p}_{out}$ the FG is closed (see (29)), and using the upper bounds of (27) and (28) we get

$$\begin{aligned} \frac{\partial s_c^{\boldsymbol{p}}}{\partial s_c^{\boldsymbol{p}_{in}}} &\underset{tr}{=} y^{\boldsymbol{p}}_{\phi} \left(\sum_{d=1}^{D} \frac{\partial s_c^{\boldsymbol{p}_d^-}}{\partial s_c^{\boldsymbol{p}_{in}}} \frac{y^{\boldsymbol{p}}_{\lambda,d}}{\sum_{d'=1}^{D} y^{\boldsymbol{p}}_{\lambda,d'}} \right) \\ &\underset{tr}{\in} (0, \varepsilon] \end{aligned} \tag{31}$$

and (26) is fulfilled.
In the second step let $\boldsymbol{p}_1 \leq \boldsymbol{p}_2$ be the date, for which we want to calculate the truncated gradient $\frac{\partial s_c^{\boldsymbol{p}_2}}{\partial y^{\boldsymbol{p}_1}_{c_{in}}}$. We choose the IG activation as

$$y^{\boldsymbol{p}}_{\iota} \in \begin{cases} [1-\varepsilon, 1) & \text{if} \quad \boldsymbol{p} = \boldsymbol{p}_{in} \\ (0, \varepsilon] & \text{otherwise} \end{cases} \tag{32}$$

and we get $\frac{\partial s_c^{\boldsymbol{p}}}{\partial y_{c_{in}}^{\boldsymbol{p}}} = y_t^{\boldsymbol{p}}$. Using (30), (31) and (32), we can estimate the partial derivative by

$$\frac{\partial s_c^{\boldsymbol{p}_2}}{\partial y_{c_{in}}^{\boldsymbol{p}_1}} = \frac{\partial s_c^{\boldsymbol{p}_2}}{\partial s_c^{\boldsymbol{p}_1}} \frac{\partial s_c^{\boldsymbol{p}_1}}{\partial y_{c_{in}}^{\boldsymbol{p}_1}}$$
$$\Rightarrow \frac{\partial s_c^{\boldsymbol{p}_2}}{\partial s_c^{\boldsymbol{p}_1}} \underset{tr}{\in} \begin{cases} \left[(1-\varepsilon)(1-(D-1)\varepsilon)^{2\|\boldsymbol{p}_2-\boldsymbol{p}_{in}\|_1}, 1\right] & \text{for} \quad \boldsymbol{p}_1 = \boldsymbol{p}_{in} \text{ and } \boldsymbol{p}_{in} \leq \boldsymbol{p}_2 \leq \boldsymbol{p}_{out} \\ [0, \varepsilon] & \text{otherwise} \end{cases}.$$

and setting

$$\varepsilon := \min\left\{\delta, \left(1-(1-\delta)^{\frac{1}{2\|\boldsymbol{p}_{in}-\boldsymbol{p}_{out}\|_1+1}}\right)\frac{1}{D-1}\right\}$$

the conditions of Definition 11 are fulfilled. ■

A.5 Proof of 18

Proof Let c be a MD LSTM Stable cell of dimension D with the internal state s_c and $\boldsymbol{p}_{in}, \boldsymbol{p} \in \mathbb{N}^D, \boldsymbol{p}_{in} \leq \boldsymbol{p}$ two arbitrary dates and $\|\boldsymbol{p}_{in} - \boldsymbol{p}\|_1 = k$. Let all gate activations be arbitrary in $[0,1]$. We show that

$$\frac{\partial s_c^{\boldsymbol{p}}}{\partial s_c^{\boldsymbol{p}_{in}}} \underset{tr}{\in} [0,1] \tag{33}$$

is fulfilled $\forall k \in \mathbb{N}$ using induction over k. For the base case $k=0$ we get $\frac{\partial s_c^{\boldsymbol{p}}}{\partial s_c^{\boldsymbol{p}_{in}}} = \frac{\partial s_c^{\boldsymbol{p}_{in}}}{\partial s_c^{\boldsymbol{p}_{in}}} = 1$. Let (33) be fulfilled for $k-1$. That means if $\boldsymbol{p}_d^- \geq \boldsymbol{p}_{in}$ we have $\left\|\boldsymbol{p}_d^- - \boldsymbol{p}_{in}\right\|_1 = k-1$ and this leads to $\frac{\partial s_c^{\boldsymbol{p}_d^-}}{\partial s_c^{\boldsymbol{p}_{in}}} \underset{tr}{\in} [0,1]$. If $\boldsymbol{p}_d^- \not\geq \boldsymbol{p}_{in}$ then there is no $\boldsymbol{p}_{in}$-$\boldsymbol{p}_d^-$-path and we have $\frac{\partial s_c^{\boldsymbol{p}_d^-}}{\partial s_c^{\boldsymbol{p}_{in}}} = 0$ for this dimension. Then we can calculate the derivative

$$0\frac{\partial s_c^{\boldsymbol{p}}}{\partial s_c^{\boldsymbol{p}_{in}}} = y_\phi^{\boldsymbol{p}} \sum_{d=1}^{D} \frac{\partial s_c^{\boldsymbol{p}_d^-}}{\partial s_c^{\boldsymbol{p}_{in}}} \frac{y_{\lambda,d}^{\boldsymbol{p}}}{\sum_{d'=1}^{D} y_{\lambda,d'}^{\boldsymbol{p}}} \in \left[0, \max_{d \in P_{\boldsymbol{p}}}\left\{\frac{\partial s_c^{\boldsymbol{p}_d^-}}{\partial s_c^{\boldsymbol{p}_{in}}} \underbrace{\frac{y_{\lambda,d}^{\boldsymbol{p}}}{\sum_{d'=1}^{D} y_{\lambda,d'}^{\boldsymbol{p}}}}_{\leq 1}\right\}\right]$$
$$\underset{tr}{\in} [0,1],$$

which gives us the desired interval. ■

A.6 Proof of 20

Proof
NEG: The cell has an NEG, because all gates have the same bounds as the MD Stable cell.
NVG: To prove the NVG, we use the proof of Theorem 17. The difference between the MD Stable cell and the MD Leaky cell is that the activations of the FG and IG are dependent

on each other for the Leaky cell. Let $\boldsymbol{p}_{in}, \boldsymbol{p} \in \mathbb{N}^D, \boldsymbol{p}_{in} \leq \boldsymbol{p}$ be two arbitrary dates like in Theorem 17. The IG has just the a restriction that for $\boldsymbol{p} = \boldsymbol{p}_{in}$ it has to hold $y_t^{\boldsymbol{p}} \in [1-\varepsilon, 1)$. Here, the FG can have an arbitrary activation, so we chose $y_\phi^{\boldsymbol{p}} = 1 - y_t^{\boldsymbol{p}}$. For all $\boldsymbol{p} > \boldsymbol{p}_{in}$ the FG have to be in the ranges, shown in (29), while the IG has no restriction and we choose $y_t^{\boldsymbol{p}} = 1 - y_\phi^{\boldsymbol{p}}$, so the MD Leaky cell has the NVG.
COD: The proof that the MD Leaky cell allows COD can be done by estimating the bounds of $s_c^{\boldsymbol{p}}$. From the update equations of the cell we get

$$\left|s_c^{\boldsymbol{p}^-}\right| \leq \max_{i=1,\ldots,D}\left|s_c^{\boldsymbol{p}_d^-}\right|.$$

Now we can estimate the internal state using the ranges $y_{c_{in}}^{\boldsymbol{p}} \in [-1,1]$, recursion over $\boldsymbol{p}$

$$|s_c^{\boldsymbol{p}}| = \left|\left(1-y_\phi^{\boldsymbol{p}}\right) y_{c_{in}}^{\boldsymbol{p}} + y_\phi^{\boldsymbol{p}} s_c^{\boldsymbol{p}^-}\right| \leq \max\left\{\left|y_{c_{in}}^{\boldsymbol{p}}\right|, \left|s_c^{\boldsymbol{p}_1^-}\right|, \ldots, \left|s_c^{\boldsymbol{p}_D^-}\right|\right\} \leq \max_{\boldsymbol{q}<\boldsymbol{p}}\left\{\left|y_{c_{in}}^{\boldsymbol{q}}\right|\right\} \leq 1$$

and get $s_c^{\boldsymbol{p}} \in [-1,1]$. To fulfill the derivatives in Definition 12, for δ_1 we choose $y_\omega^{\boldsymbol{p}} \in [1-\varepsilon, 1)$ and get

$$\delta_1 \leq \min_{s_c^{\boldsymbol{p}}}\left\{h_c'\left(s_c^{\boldsymbol{p}}\right)\right\}(1-\varepsilon) = h_c'(1)(1-\varepsilon). \tag{34}$$

For δ_2 we choose $y_\omega^{\boldsymbol{p}} \in (0, \varepsilon]$ and get

$$\delta_2 \geq \max_{s_c^{\boldsymbol{p}}}\left\{h_c'\left(s_c^{\boldsymbol{p}}\right)\right\}\varepsilon = \varepsilon. \tag{35}$$

To fulfill the derivatives in Definition 12 we use (34), (35) and $h_c'(1) > \frac{1}{3}$ and with

$$\varepsilon \leq \delta_2 < \delta_1 \leq h_c'(1)(1-\varepsilon)$$
$$\Rightarrow \varepsilon \leq \frac{1}{4} < \frac{h_c'(1)}{h_c'(1)+1}$$

the COD is proven. ■

Appendix B. Theory to Create First Order MD Cells

If one wants to take a closer look at the theory of linear shift invariant (LSI)-systems and their frequency analysis and analyse a first order LSI-system regarding its free selectable parameters using the $\mathcal{F}$- and $\mathcal{Z}$-transform, it is highly recommended to be familar with these theories (for a good overview and more details see Poularikas, 2000; Schlichthärle, 2000). Adding the knowledge of reducing the MD case to the 1D case (see Section 5) we create new cell types for the MD case.

B.1 Analysing a First Order LSI-System

The update equations of a first order LSI-system with one input u, one internal state x and one output y can be written as

$$x[n] = h_1(u[n], x[n-1]) = \alpha_0 u[n] + \alpha_1 x[n-1], \tag{36}$$
$$y[n] = h_2(x[n], x[n-1]) = b_0 x[n] + b_1 x[n-1] \tag{37}$$

with the free selectable coefficients $\alpha_0, \alpha_1, b_0, b_1 \in \mathbb{R}$. Let $U(z) = \mathcal{Z}\{u[n]\}$ be the $\mathcal{Z}$-transformed signal of $u[n]$ and $X(z), Y(z)$ respectively. Then we can write the so called *transfer functions*

$$H_1(z) := \frac{X(z)}{U(z)} = \frac{\alpha_0}{1 - \alpha_1 z^{-1}},$$
$$H_2(z) := \frac{Y(z)}{X(z)} = b_0 + b_1 z^{-1},$$
$$H(z) := \frac{Y(z)}{U(z)} = H_2(z) H_1(z).$$

To analyse (36) and (37) according their *frequency response* we use the relationship between the $\mathcal{F}$-transform and the $\mathcal{Z}$-transform:

Remark 22 *Let $u[n] = e^{j\omega n}$ be a harmonic input sequence with the imaginary number $j^2 = -1$ and $H(z) = \frac{Y(z)}{U(z)}$ be a transfer functions of an LSI-system. When the poles of $H(z)$ are inside the circle $|z| = 1$, we can change from $\mathcal{Z}$- to $\mathcal{F}$-transform using the substitution*

$$H(\omega) = H(z)\Big|_{z=e^{j\omega}}$$

with the harmonic sequence $y[n] = H(\omega)u[n] = H(\omega)e^{j\omega n}$ with the same frequency ω but with a different amplitude and a different phase dependent on the frequency ω.

We only want to analyse the amplitude of this harmonic sequence

$$|y[n]| = \left|H(z)e^{j\omega n}\right| = |H(z)| = |H_2(z)|\,|H_1(z)|$$

and do that by analysing both transfer functions $H_1(z)$ and $H_2(z)$ separately.
The amplitude of $H_1(\omega) = H_1(z)|_{z=e^{j\omega}}$ is calculated by

$$|H_1(\omega)| = \frac{|\alpha_0|}{\sqrt{(1 - \alpha_1 \cos(\omega))^2 + \alpha_1^2 \sin^2(\omega)}}.$$

Like mentioned before, in many tasks, the information signal has a low frequency. To have the largest amplitude at $\omega = 0$ we have to choose $\alpha_1 \geq 0$. As mentioned in Remark 22 the poles of $H_1(z) = \frac{\alpha_0}{1-\alpha_1 z^{-1}} = \frac{z\alpha_0}{z-\alpha_1}$ have to be in the circle $|z| = 1$, so we have the additional constraint $|\alpha_1| < 1$. This leads to the bounds $\alpha_1 \in [0, 1)$. But for $\alpha_1 \to 1$ we

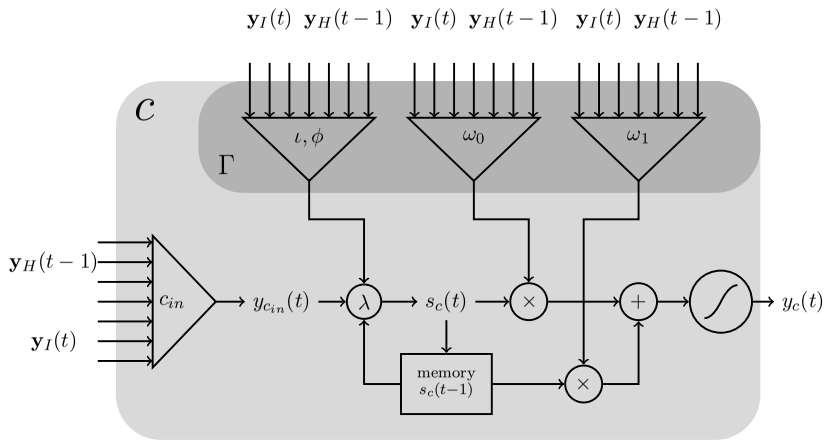

Figure 5: Schematic diagram of a one-dimensional LeakyLP cell: The internal state is a convex combination of the new input c_{in} and the previous state $s_c(t-1)$. The previous state $s_c(t-1)$ and the current state $s_c(t)$ are gated (ω_0 and ω_1) and accumulated afterwards. The output is squashed by tanh into the interval $[-1, 1]$.

have $H_1(0) \to \infty$, so we have to choose α_0 dependent on α_1. We set a maximum gain of $\max_\omega |H_1(\omega)| = |H_1(0)| = 1$, so we get the constraint

$$|\alpha_0| \leq 1 - \alpha_1. \tag{38}$$

In the same way we analyse $H_2(z)$:

$$|H_2(\omega)| = \left|b_0 + b_1 e^{-j\omega}\right| = \sqrt{(b_0 + b_1 \cos(\omega))^2 + b_1^2 \sin^2(\omega)}$$

To get the maximal gain at low frequency the parameters b_0 and b_1 must have the same sign.

B.2 Creating a First Order Cell

With these constraints for the parameters we now can define a new cell type. The parameters $\alpha_0, \alpha_1, b_0, b_1$ should be activations of gates like in LSTM cells. We have to find the right activation functions to fulfill the inequalities above. Using the weight-space symmetries in a network with at least one hidden layer (Bishop, 2006, 5.1.1), without loss of generality we set $\alpha_0, \alpha_1, b_0, b_1 \geq 0$. To fulfill the bounds for H_1, we set α_1 as activation of a gate with activation function f_{log}. So we have $\alpha_1 \in (0, 1)$. This is comparable with the FG in the previous sections. To select the α_0 we choose $\alpha_0 := 1 - \alpha_1$ (see (38)). So the value of α_0 is comparable with the activation of the IG. For H_2 we set both values b_0, b_1 as activations of

a gate with activation function f_{log} which leads to $\max_\omega |H_2(\omega)| = \max\{b_0 + b_1\} = 2$, so the amplitude response is bounded by 2.

With these bounds we can define a cell with a cell input $y^{\mathbf{p}}_{c_{in}} = u[n]$, a previous internal state $s^{\mathbf{p}^-}_c = x[n-1]$, an internal state $s^{\mathbf{p}}_c = x[n]$ and a cell output $y^{\mathbf{p}}_c = y[n]$. We substitute the coefficients by time dependent gate activations

$$\begin{array}{ll} \alpha_0 := 1 - y^{\mathbf{p}}_\phi = y^{\mathbf{p}}_\imath & \text{IG} \\ \alpha_1 := y^{\mathbf{p}}_\phi & \text{FG} \\ b_0 := y^{\mathbf{p}}_{\omega_0} & \text{OG} \\ b_1 := y^{\mathbf{p}}_{\omega_1} & \text{OG of the previous internal state} \end{array}$$

which leads to the transfer functions

$$\begin{aligned} H_1^{y^{\mathbf{p}}_\phi}(z) &= \frac{\alpha_0}{1 - \alpha_1 z^{-1}} = \frac{1 - y^{\mathbf{p}}_\phi}{1 - y^{\mathbf{p}}_\phi z^{-1}}, \\ H_2^{y^{\mathbf{p}}_{\omega_0}; y^{\mathbf{p}}_{\omega_1}}(z) &= b_0 + b_1 z^{-1} = y^{\mathbf{p}}_{\omega_0} + y^{\mathbf{p}}_{\omega_1} z^{-1}, \\ H(z) = H^{y^{\mathbf{p}}_\phi; y^{\mathbf{p}}_{\omega_0}; y^{\mathbf{p}}_{\omega_1}}(z) &= \frac{Y(z)}{U(z)} = \alpha_0 \frac{b_0 + b_1 z^{-1}}{1 - \alpha_1 z^{-1}} = \frac{1 - y^{\mathbf{p}}_\phi}{1 - y^{\mathbf{p}}_\phi z^{-1}} \left(y^{\mathbf{p}}_{\omega_0} + y^{\mathbf{p}}_{\omega_1} z^{-1}\right). \end{aligned} \tag{39}$$

and the update equations

$$\begin{aligned} x[n] =& \alpha_0 u[n] + \alpha_1 x[n-1] && \Leftrightarrow s^{\mathbf{p}}_c = (1 - y^{\mathbf{p}}_\phi) y^{\mathbf{p}}_{c_{in}} + y^{\mathbf{p}}_\phi s^{\mathbf{p}^-}_c, \\ y[n] =& b_0 x[n] + b_1 x[n-1] && \Leftrightarrow y^{\mathbf{p}}_c = y^{\mathbf{p}}_{\omega_0} s^{\mathbf{p}}_c + y^{\mathbf{p}}_{\omega_1} s^{\mathbf{p}^-}_c. \end{aligned} \tag{40}$$

The output of the cell is already bounded in $[-2, 2]$, but to fulfill Definition 9 we change (40) to

$$y^{\mathbf{p}}_c = h_c \left(y^{\mathbf{p}}_{\omega_0} s^{\mathbf{p}}_c + y^{\mathbf{p}}_{\omega_1} s^{\mathbf{p}^-}_c \right) \tag{41}$$

with $h_c = \tanh$ to ensure $y^{\mathbf{p}}_c \in [-1, 1]$. This additional non-linearity is not necessary but leads to a better performance. This new cell type called *MD Leaky lowpass (LeakyLP) cell* is defined in Definition 21. A block diagram of a 1D LeakyLP cell is shown in Figure 5 and different frequency responses in Figure 6.

B.3 General First Order MD Cells

With the theory of this section we can easily create new cell types. In general, a cell has a number of gates $\gamma_1, \gamma_2, \ldots \in \Gamma_c$. For $D = 1$ a previous state $s^{\mathbf{p}^-}_c$ is given directly. Otherwise the previous state is calculated as trainable convex combination of D previous states, like described in Section 5. In Table 7 cell layouts are depicted whereby type A is the cell developed in Section 7 (compare to (39)). For the other types we briefly want to describe the main ideas.

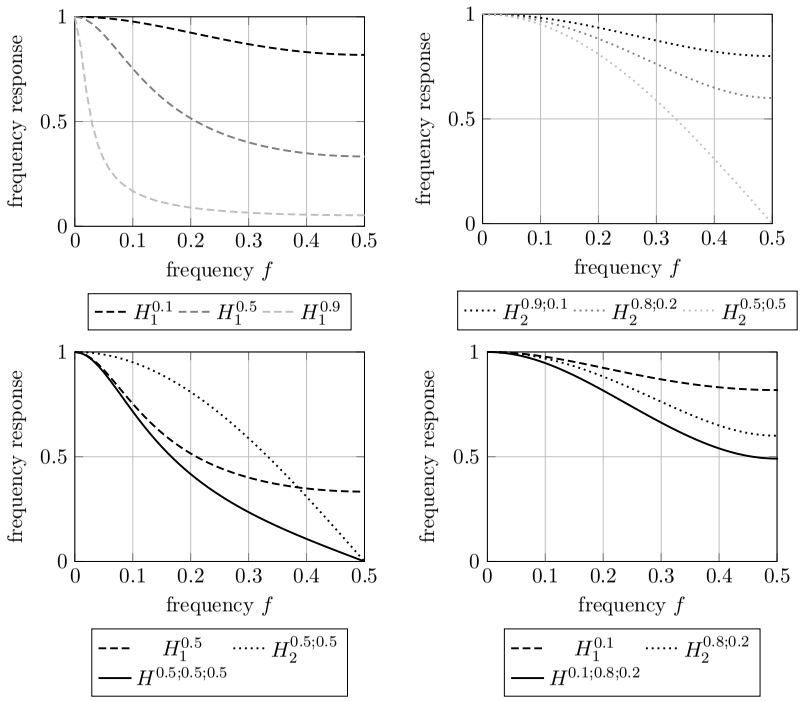

Figure 6: Frequency response of H_1 (dashed), H_2 (dotted) and H (solid) for special parameters. Top-left: The frequency response of an IIR filter is able to block even low frequency signals, but it cannot be zero at $f = 0.5$. Top-right: The frequency response of an FIR filter cannot be lower than the lightgray dotted line, but for $f = 0.5$ it can be zero. Bottom: When these both filters are concatenated, the resulting frequency response can combine the benefits of each filter.

B.3.1 The MD Butterworth Lowpass Filter

The cell of type B is a special case of the LeakyLP cell. When we set $y^{\mathbf{p}}_{\omega_0} = y^{\mathbf{p}}_{\omega_1} = 0.5$ there is a direct relation between the cutoff frequency of a discrete Butterworth lowpass filter and the activation of $y^{\mathbf{p}}_\phi$: Let f_{cutoff} be the frequency, where amplitude response is reduced to

$\frac{1}{\sqrt{2}}$ of the maximal gain. We can calculate f_{cutoff} by

$$f_{\text{cutoff}} = \frac{1}{\pi} \arctan\left(\frac{1-y_\phi^{\boldsymbol{p}}}{1+y_\phi^{\boldsymbol{p}}}\right) \tag{42}$$
$$\Leftrightarrow y_\phi^{\boldsymbol{p}} = \frac{1+\tan(\pi f_{\text{cutoff}})}{1-\tan(\pi f_{\text{cutoff}})}$$

with the bounds $f_{\text{cutoff}} \in (0, 0.5)$ and $y_\phi^{\boldsymbol{p}} \in (-1, 1)$ (for more details see Schlichthärle, 2000, 2.2;6.4.2). For $y_\phi^{\boldsymbol{p}} \in (0, 1)$ we get $f_{\text{cutoff}} \in (0, 0.25)$. In Figure 7 (left) we can see, that even for a negative value of $y_\phi^{\boldsymbol{p}}$ and a highpass characteristic of $H_1(z)$ the impulse response $H(z)$ has a lowpass characteristic.

B.3.2 Adding an Additional State Gate

In B.2 we fulfilled (38) for the MD LeakyLP cell by setting $\alpha_0 := 1 - \alpha_1$, so α_0 is directly connected with α_1. Another solution would be to add an additional value $\gamma \in (0, 1)$ and choose $\alpha_0 := \gamma(1 - \alpha_1)$. So we can extend the MD LeakyLP cell by adding an additional gate γ_4 for the previous state (see type C). Unfortunately this does not lead to a better performance and one more gate has to be calculated.

B.3.3 Another Solution for the Output

The cell of type D is another solution to choose b_0 and b_1 in Section B.2. For the LeakyLP cell we calculate the output as described in (41). Now we set $b_0 = \gamma_2^{\boldsymbol{p}} \gamma_3^{\boldsymbol{p}}$ and $b_1 = \left(1 - \gamma_2^{\boldsymbol{p}}\right) \gamma_3^{\boldsymbol{p}}$, and get

$$y_c^{\boldsymbol{p}} = \gamma_3^{\boldsymbol{p}} \left(\gamma_2^{\boldsymbol{p}} s_c^{\boldsymbol{p}} + \left(1 - \gamma_2^{\boldsymbol{p}}\right) s_c^{\boldsymbol{p}^-}\right).$$

This cell actually works as well as the MD LeakyLP cell and has the same number of gates. In this case we do not need a squashing function h_c, because we already have $y_c^{\boldsymbol{p}} \in [-1, 1]$.

B.3.4 An MD Cell as MD PID-Controller

Type E has a completely different interpretation: In controlling engineering a PID-controller gets an error as input. In our case the gate activations have to decide, if the proportional (P), the integral (I) or the derivative (D) term of the error is important for the output. When $\gamma_1^{\boldsymbol{p}} \approx 0$ we have $y_{c_{in}}^{\boldsymbol{p}} \approx s_c^{\boldsymbol{p}}$ so the internal state is proportional to the input. Then $\gamma_2^{\boldsymbol{p}}$ gates the proportional part (P) of the input. The second gate $\gamma_3^{\boldsymbol{p}}$ gates the difference between the last and the current input, which can be seen as a discrete derivative (D). If $\gamma_1^{\boldsymbol{p}} \approx 1$ the internal state is an exponential moving average of $y_{c_{in}}^{\boldsymbol{p}}$ which is an integral term. So $\gamma_2^{\boldsymbol{p}}$ gates a mainly integral part of the input (I), whereas $\gamma_3^{\boldsymbol{p}}$ gates a mainly proportional part of the input (P). Dependent on $\gamma_1^{\boldsymbol{p}}$ type E can be a PD-controller, a PI-controller or a mix of these both. In Figure 7(right) can be seen the frequency response of this cell for different gate activations.

Type	$g_{int}(\cdot)$	$g_{out}(\cdot)$	$H(z)$ for $h_c(x) = x$
A	$\left(1-\gamma_1^{\boldsymbol{p}}\right) y_{c_{in}}^{\boldsymbol{p}} + \gamma_1^{\boldsymbol{p}} s_c^{\boldsymbol{p}^-}$	$h_c\left(\gamma_2^{\boldsymbol{p}} s_c^{\boldsymbol{p}} + \gamma_3^{\boldsymbol{p}} s_c^{\boldsymbol{p}^-}\right)$	$\frac{(1-\gamma_1^{\boldsymbol{p}})}{1-\gamma_1^{\boldsymbol{p}} z^{-1}}\left(\gamma_2^{\boldsymbol{p}} + \gamma_3^{\boldsymbol{p}} z^{-1}\right)$
B	$\left(1-\gamma_1^{\boldsymbol{p}}\right) y_{c_{in}}^{\boldsymbol{p}} + \gamma_1^{\boldsymbol{p}} s_c^{\boldsymbol{p}^-}$	$\frac{s_c^{\boldsymbol{p}} + s_c^{\boldsymbol{p}^-}}{2}$	$\frac{(1-\gamma_1^{\boldsymbol{p}})}{1-\gamma_1^{\boldsymbol{p}} z^{-1}} \frac{1+z^{-1}}{2}$
C	$\left(1-\gamma_1^{\boldsymbol{p}}\right) y_{c_{in}}^{\boldsymbol{p}} + \gamma_1^{\boldsymbol{p}} \gamma_4^{\boldsymbol{p}} s_c^{\boldsymbol{p}^-}$	$h_c\left(\gamma_2^{\boldsymbol{p}} s_c^{\boldsymbol{p}} + \gamma_4^{\boldsymbol{p}} s_c^{\boldsymbol{p}^-}\right)$	$\frac{(1-\gamma_1^{\boldsymbol{p}})}{1-\gamma_1^{\boldsymbol{p}} \gamma_4^{\boldsymbol{p}} z^{-1}}\left(\gamma_2^{\boldsymbol{p}} + \gamma_3^{\boldsymbol{p}} z^{-1}\right)$
D	$\left(1-\gamma_1^{\boldsymbol{p}}\right) y_{c_{in}}^{\boldsymbol{p}} + \gamma_1^{\boldsymbol{p}} s_c^{\boldsymbol{p}^-}$	$\gamma_3^{\boldsymbol{p}}\left(\gamma_2^{\boldsymbol{p}} s_c^{\boldsymbol{p}} + \left(1-\gamma_2^{\boldsymbol{p}}\right) s_c^{\boldsymbol{p}^-}\right)$	$\frac{(1-\gamma_1^{\boldsymbol{p}})}{1-\gamma_1^{\boldsymbol{p}} z^{-1}} \gamma_3^{\boldsymbol{p}}\left(\gamma_2^{\boldsymbol{p}} + \left(1-\gamma_2^{\boldsymbol{p}}\right) z^{-1}\right)$
E	$\left(1-\gamma_1^{\boldsymbol{p}}\right) y_{c_{in}}^{\boldsymbol{p}} + \gamma_1^{\boldsymbol{p}} s_c^{\boldsymbol{p}^-}$	$h_c\left(\gamma_2^{\boldsymbol{p}} s_c^{\boldsymbol{p}} + \gamma_3^{\boldsymbol{p}}\left(s_c^{\boldsymbol{p}} - s_c^{\boldsymbol{p}^-}\right)\right)$	$\frac{(1-\gamma_1^{\boldsymbol{p}})}{1-\gamma_1^{\boldsymbol{p}} z^{-1}}\left(\gamma_2^{\boldsymbol{p}} + \gamma_3^{\boldsymbol{p}}\left(1-z^{-1}\right)\right)$

Table 7: Update equations and transfer function for different cell layouts. The column $s_c^{\boldsymbol{p}}$ contains the update equations to calculate the internal state and column $y_c^{\boldsymbol{p}}$ contains the update equation for the output. These equations lead to the transfer function $H(z) = H^{\gamma_1^{\boldsymbol{p}}, \gamma_2^{\boldsymbol{p}}, \cdots}(z)$.

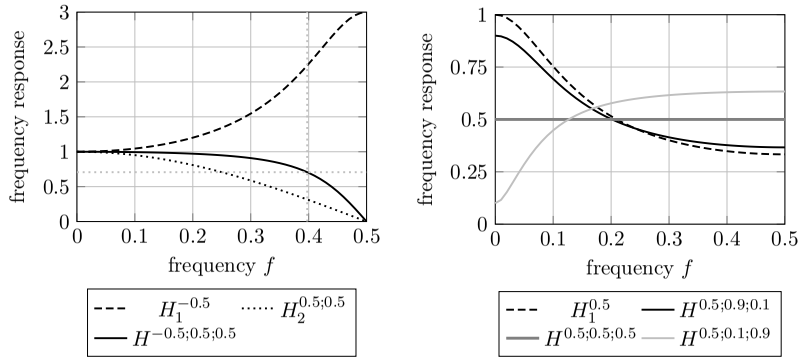

Figure 7: Frequency response of H_1 (dashed), H_2 (dotted) and H (solid) for special layouts and parameters of Table 7. Left (type B): A butterworth lowpass filter with a negative gate activation $\gamma_0^{\boldsymbol{p}} = -0.5$ leads to the cutoff frequency $f_{\text{cutoff}} = \frac{1}{\pi} \arctan\left(\frac{1+0.5}{1-0.5}\right) \approx 0.3976$. Right (type E): Different frequency responses of a PID controller. Having a fixed $\gamma_0^{\boldsymbol{p}} = 0.5$ the frequency response is dependent on the activations of $\gamma_1^{\boldsymbol{p}}$ and $\gamma_2^{\boldsymbol{p}}$ and can have lowpass (black), allpass (gray) and highpass (lightgray) characteristic.

Abstract

In this paper, we study flat and hierarchical classification strategies in the context of large-scale taxonomies. Addressing the problem from a learning-theoretic point of view, we first propose a multi-class, hierarchical data dependent bound on the generalization error of classifiers deployed in large-scale taxonomies. This bound provides an explanation to several empirical results reported in the literature, related to the performance of flat and hierarchical classifiers. Based on this bound, we also propose a technique for modifying a given taxonomy through pruning, that leads to a lower value of the upper bound as compared to the original taxonomy. We then present another method for hierarchy pruning by studying approximation error of a family of classifiers, and derive from it features used in a meta-classifier to decide which nodes to prune. We finally illustrate the theoretical developments through several experiments conducted on two widely used taxonomies.

Keywords: Large-scale classification, Hierarchical classification, Taxonomy adaptation, Rademacher complexity, Meta-learning

1. Introduction

With the rapid surge of digital data in the form of text and images, the scale of problems being addressed by machine learning practitioners is no longer restricted to the size of training and feature sets, but is also being quantified by the number of target classes. Classification of textual and visual data into a large number of target classes has attained significance particularly in the context of *Big Data*. This is due to the tremendous growth in data from various sources such as social networks, web-directories and digital encyclopedia. Directory Mozilla, DMOZ (`www.dmoz.org`), Wikipedia and Yahoo! Directory (`www.dir.yahoo.com`) are instances of such large scale textual datasets which consist of millions of documents that are distributed among hundreds of thousand target categories. Directory Mozilla, for instance, lists over 5 million websites distributed among close to 1 million categories, and is maintained by close to 100,000 editors. In the more commonly used Wikipedia, which consists of over 30 million pages, documents are typically assigned to multiple categories which are shown at the bottom of each page. The Medical Subject Heading (MESH) [1] hierarchy of the National Library of Medicine is another instance of a large-scale classification system in the domain of life sciences. The target classes in such large-scale scenarios typically have an inherent hierarchical structure among themselves. DMOZ is in the form of a rooted tree where a traversal of path from root-to-leaf depicts transformation of semantics from generalization to specialization. More generally parent-child relationship can exist in the form of directed acyclic graphs, as found in taxonomies such as Wikipedia. The tree and DAG relationship among categories is illustrated for DMOZ and Wikipedia taxonomies in Figure 1.

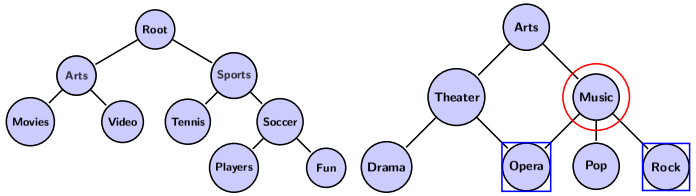

Figure 1: DMOZ and Wikipedia Taxonomies

Due to the sheer scale of the task of classifying data into target categories, there is a definite need to automate the process of classification of websites in DMOZ, encyclopedia pages in Wikipedia and medical abstracts in the MESH hierarchy. However, the scale of the data also poses challenges for the classical techniques that need to be adapted in order to tackle large-scale classification problems. In this context, one can exploit the taxonomy of classes as in the divide-and-conquer paradigm in order to partition the input space. Various classification techniques have been proposed for deploying classifiers in such large-scale scenarios, which differ in the way they exploit the given taxonomy. These can be broadly divided into four main categories :

- *Hierarchical top-down strategy* with independent classification problems at each node,
- Hierarchical top-down strategy on a *simplified hierarchy*, such as by partially flattening the hierarchy,
- Ignoring the hierarchy information altogether and using *flat classification* that is, training one classifier for each target class, and
- Using the taxonomy information for an *appropriate loss-function design* such as by considering the distance between the true and predicted target class label.

In large-scale classification involving tens of thousand of target categories, the goal of a machine learning practitioner is to achieve the best trade-off among the various metrics

1. `https://www.nlm.nih.gov/mesh/`

of interest. Flat and top-down hierarchical classification perform significantly differently on these metrics of interest which primarily include prediction accuracy, computational complexity of training, space complexity of the trained model and complexity of prediction.

1.1 Prediction Accuracy

Our focus in this work is primarily on the prediction accuracy when dealing with large-scale category systems. Hierarchical models for large scale classification, such as top-down Pachinko-machine based methods, suffer from the drawback that they have to make many decisions prior to reaching a final category, which leads to the error propagation phenomenon causing a decrease in accuracy. This is mainly due to the fact that the top level classes in large scale taxonomies are quite general. For example, *Business* and *Shopping* categories in DMOZ (not shown in Figure 1 above) are likely to be confused while classifying a new document. Moreover, since the classification is not recoverable, it leads to the phenomenon of error propagation and hence degrades accuracy at the leaf level. On the other hand, flat classifiers rely on a single decision including all the final categories, a single decision that is however difficult to make as it involves many categories, which are potentially unbalanced. It is thus very difficult to assess which strategy is better and there is no consensus, at the time being, on to which approach, flat or hierarchical, should be preferred on a particular category system. Furthermore, we explore the methods which learn to adapt the given hierarchy of categories such that the resulting hierarchy leads to better classification in the top-down Pachinko-machine based method. We also show that when dealing with large number of power-law distributed categories, taxonomy adaptation by pruning some nodes leads to better classification than building taxonomies from scratch.

1.2 Computational Complexity of Training and Prediction

When dealing with large-scale category systems, flat and hierarchical classification techniques exhibit significant difference in their performance when compared on the basis of computational complexity of training and prediction. In the pioneering work of Liu et al. (2005), an extensive comparison of training time complexity for flat and hierarchical classification has been studied. Using the power-law distribution of documents among categories, the authors analytically and empirically demonstrate that the training time of top-down Pachinko machine classification strategy is orders of magnitude better than that for flat classification.

In terms of complexity of prediction for flat classification when dealing with K target categories, for every test instance one needs to evaluate the inner-product with $O(K)$ weight vectors in . This is much higher than the logarithmic computational complexity of prediction in a top-down Pachinko-machine where only $O(\log(K))$ weight-vectors need to be evaluated. In view of this advantage for tree-based classifiers, there has been a surge in research works on the techniques for automatically building taxonomy of target categories (Bengio et al., 2010; Gao and Koller, 2011; Deng et al., 2011; Agrawal et al., 2013). The focus in these works is to show that by building such tree-based taxonomy of categories, one can reduce the complexity of prediction, while still maintaining good rates for accuracy of prediction.

Since the computational complexity of training and prediction has been studied in the above works, and it has been already shown that top-down methods are more favorable

as compared to flat method, we do not focus on these aspects explicitly in this paper. Furthermore, in our recent work Babbar et al. (2014a), we present a quantitative analysis of the fit to power-law distribution of documents among categories in large-scale category systems, and show that space complexity of top-down classification methods is lower than that of flat methods under conditions that typically hold in practice.

2. Contributions and Related Work

2.1 Contributions

One of the research challenges we address in this work is the study of flat versus hierarchical classification in large-scale taxonomies from a learning-theoretic point of view, and the consistency of the empirical risk minimization principle for the Pachinko-machine based methods. This theoretical analysis naturally leads to a model selection problem. We extend and elaborate further on our recent work Babbar et al. (2013a) to address the problem of choosing between the two strategies. We introduce bounds based on Rademacher complexity for the generalization errors of classifiers deployed in large-scale taxonomies. These bounds explicitly demonstrate the trade-off that both flat and hierarchical classifiers face in large-scale taxonomies.

Even though the given human-built taxonomies such as DMOZ and Yahoo! Directory provide a good starting point to capture the underlying semantics of the target categories, these may not be optimal, especially in the presence of large number of power-law distributed categories. In the second part of our contributions, we then propose a strategy for taxonomy adaptation which modifies the given taxonomy by pruning nodes in the tree to output a new taxonomy which is better suited for the classification problem. In this part, we exploit the generalization error bound developed earlier to build a criterion for Support Vector Machine classifier, so as to choose the nodes to prune in a computationally efficient manner. We also empirically show that adapting a given taxonomy leads to better generalization performance as compared to the original taxonomy and the ones obtained by taxonomy construction methods (Beygelzimer et al., 2009b; Choromanska and Langford, 2014). This difference is particularly magnified in category systems in which categories are power-law distributed. As discussed extensively in the work of Liu et al. (2005), power-law distribution of documents among categories is a common phenomenon in most naturally occurring category systems such as Yahoo! directory and Directory Mozilla.

In the third part, we present a more comprehensive approach for pruning the given hierarchy that is applicable to both discriminative and generative classifiers. Towards this end, we cover the Logistic Regression and Naive Bayes classifiers and present approximation error based bounds for their multi-class versions. Based on these bounds, we then propose a meta-learning strategy for hierarchy pruning applicable for both discriminative and generative classifiers. We perform a three-step procedure towards achieving hierarchy pruning, (i) we make classifier specific theoretical analysis to identify the key features which determine the variation in classification accuracy upon flattening, (ii) based on the features obtained in the step above, we train a meta-classifier on a validation set, and finally, (iii) the meta-classifier when presented with an unseen hierarchy and the corresponding training data modifies it to output the desired hierarchy which leads to better classification accuracy. Contrary to Dekel (2009) that reweighs the edges in a taxonomy through a cost sensitive

loss function to achieve this goal, our simple pruning strategy modifies the taxonomy in an explicit way.

Lastly, we empirically demonstrate and verify the theoretical findings for flat and hierarchical classification on several large-scale taxonomies extracted from DMOZ and the International Patent Classification (IPC) collections. The experimental results are in line with results reported in previous studies, as well as with our theoretical developments. Secondly, we also study the impact of the two methods proposed for taxonomy adaptation by pruning the hierarchy. Lastly, these strategies are also empirically compared against those that build taxonomies from scratch such as LOMTree (Choromanska and Langford, 2014) and FilterTree (Beygelzimer et al., 2009b).

2.2 Related Work

Large-scale classification, involving tens of thousand target categories, has assumed significance in the era of Big data. Many approaches for classification of data in large number of target categories have been proposed in the context of text and image classification. These approaches differ in the manner in which they exploit the semantic relationship among categories. In similar vein, open challenges such as Large-scale Hierarchical Text Classification (LSHTC) (Partalas et al., 2015) and Large Scale Visual Recognition Challenge (ILSVRC)[2] (Russakovsky et al., 2014) have been organized in recent years.

Some of the earlier works on exploiting hierarchy among target classes for the purpose of text classification has been studied by Koller and Sahami (1997) and Dumais and Chen (2000). These techniques use the taxonomy to train independent classifiers at each node in the top-down Pachinko Machine manner. Parameter smoothing for Naive Bayes classifier along the root to leaf path was explored by McCallum et al. (1998). The work by Liu et al. (2005) is one of first studies to apply hierarchical SVM to the scale with over 100,000 categories in Yahoo! directory. More recently, other techniques for large scale hierarchical text classification have been proposed. Prevention of error propagation by applying *Refined Experts* trained on a validation was proposed by Bennett and Nguyen (2009). In this approach, bottom-up information propagation is performed by utilizing the output of the lower level classifiers in order to improve the classification of top-level classifiers. Another approach to control the propagation of error in tree-based classifiers is to explore multiple root-to-leaf paths as in beam-search (Norvig, 1992). In this respect, Fleuret and Geman (2001); Sun et al. (2013) proposed such approaches. However, this increases the computationally complexity of prediction especially in the presence of large-number of target categories and hence these methods may not scale well for tens of thousand target categories. Deep Classification by Xue et al. (2008) proposes hierarchy pruning to first identify a much smaller subset of target classes. Prediction of a test instance is then performed by re-training a Naive Bayes classifier on the subset of target classes identified from the first step.

Using the taxonomy in the design of loss function for maximum-margin based approaches have been proposed by Cai and Hofmann (2004); Dekel et al. (2004), where the degree of penalization in mis-classification depends on the distance between the true and predicted class in the hierarchy tree. Another recent approach by Dekel (2009) which proposes to make the loss function design robust to class-imbalance and arbitrariness problems in taxonomy

2. http://www.image-net.org/challenges/LSVRC/

structure. However, these approaches were applied to the datasets in which the number of categories were limited to a few hundreds. Bayesian modeling of large scale hierarchical classification has been proposed by Gopal et al. (2012) in which hierarchical dependencies between the parent-child nodes are modeled by centering the prior of the child node at the parameter values of its parent. Recursive-regularization based strategy for large-scale classification has been proposed by Gopal and Yang (2013). The approaches presented in the two studies above attempt to solve the problem wherein the number of categories are in the range of tens of thousands. In both these works, the authors employ the intuition that the weight vectors of a parent-child pair of nodes should be close to each other. This can be enforced in the form of a prior in the Bayesian approach (Gopal et al., 2012) and as a regularizer in the recursive regularization approach (Gopal and Yang, 2013). However, on most of the large-scale datasets used in these papers, the accuracy performance (Micro-F1) of the proposed approaches is close to the flat classification scheme for which ready to use packages such as Liblinear are available. Another study related to our work is the one of Narasimhan et al. (2015) that studies the consistency of hierarchical classification algorithms with respect to the tree distance metric on the hierarchy tree of class labels.

Hierarchy simplification by flattening entire layer in the hierarchy has been studied from an empirical view-point by Wang and Lu (2010); Malik (2009). These strategies do not provide any theoretical justification for applying this procedure. Moreover, they offer no clear guidelines regarding which layer in the hierarchy one should flatten. In contrast, our strategy presented in this paper for taxonomy adaptation has the advantage that, (i) it is based on a well-founded theoretical criteria, and (ii) it is applied in a node-specific sense rather than to an entire layer. This strategy is also similar in spirit to the approach presented in our another recent study Babbar et al. (2013b) which is motivated from Perceptron Decision Trees (Bennett et al., 2000). The study by Weinberger and Chapelle (2008) introduces a slightly different simplification of the hierarchy of classes, and it achieves this by an embedding the classes and documents into a common space. Our recent work Babbar et al. (2013b) for hierarchy simplification by pruning nodes in a large-scale taxonomy is similar in spirit to the approach presented in this paper. Semi-supervised approach for hierarchical classification in incomplete hierarchies has been presented in the recent work of Dalvi and Cohen (2014). A post-processing approach for improving rare categories detection in large-scale power-law distributed category systems is discussed in the work by Babbar et al. (2014b).

Apart from accuracy, other important factors while evaluating the classification strategies for large scale classification are training and prediction speed. Learning the hierarchy tree from large number of classes in order to make faster prediction has also attained significance as explored in the recent works by Bengio et al. (2010); Beygelzimer et al. (2009a); Gao and Koller (2011); Choromanska and Langford (2014). The aim in these approaches is to achieve better prediction speed while maintaining the same classification accuracy as flat classification. On the other end of the spectrum are flat classification techniques such as employed by Perronnin et al. (2012) which ignore the hierarchy structure altogether. These strategies are likely to perform well for balanced hierarchies with sufficient training instances per target class and not so well in *truly* large-scale taxonomies which suffer from the problem of rare categories. In this respect, our work is unique in the sense that by performing selective hierarchy pruning we improve accuracy over the fully hierarchical

strategy. Furthermore, since the proposed pruning method maintains the overall hierarchical structure, it enjoys the computational advantages of better training and prediction speed.

The remainder of the paper is organized as follows: In Section 2.2 we review the recently proposed approaches in the context of large-scale hierarchical text classification. We introduce the notations used in Section 3 and then study flat versus hierarchical strategies by studying the generalization error bounds for classification in large-scale taxonomies. Taxonomy adaptation by pruning the hierarchy using the developed generalization error analyses is given in Section 4. Approximation error for multi-class versions of Naive Bayes and Logistic Regression classifiers are presented in Section 5.1 and Section 5.2 respectively, and the meta-learning based hierarchy pruning method is presented in Section 5.3. Section 6 illustrates these developments via experiments and finally, Section 7 concludes this study.

3. Flat versus Hierarchical Classification

In this section, we present the generalization error analysis for top-down hierarchical classification using the notion of Rademacher complexity for measuring the complexity of a function class. This will motivate a criterion for choosing between flat and hierarchical classification for a given category system. More importantly, the criterion will be based on quantities that can computed from the training data.

3.1 A hierarchical Rademacher data-dependent bound

Let $\mathcal{X} \subseteq \mathbb{R}^d$ be the input space and let V be a finite set of class labels. We further assume that examples are pairs $(\mathbf{x}, v)$ drawn according to a fixed but unknown distribution $\mathcal{D}$ over $\mathcal{X} \times V$. In the case of hierarchical classification, the hierarchy of classes $\mathcal{H} = (V, E)$ is defined in the form of a rooted tree, with a root $\perp$ and a parent relationship $\pi : V \setminus \{\perp\} \to V$ where $\pi(v)$ is the parent of node $v \in V \setminus \{\perp\}$, and E denotes the set of edges with parent to child orientation. For each node $v \in V \setminus \{\perp\}$, we further define the set of its siblings $\mathfrak{S}(v) = \{v' \in V \setminus \{\perp\}; v \neq v' \wedge \pi(v) = \pi(v')\}$ and its children $\mathfrak{D}(v) = \{v' \in V \setminus \{\perp\}; \pi(v') = v\}$. The nodes at the intermediary levels of the hierarchy define general class labels while the specialized nodes at the leaf level, denoted by $\mathcal{Y} = \{y \in V : \nexists v \in V, (y, v) \in E\} \subset V$, constitute the set of target classes. Finally for each class y in $\mathcal{Y}$ we define the set of its ancestors $\mathfrak{P}(y)$ defined as

$$\mathfrak{P}(y) = \{v_1^y, \ldots, v_{k_y}^y; v_1^y = \pi(y) \wedge \forall l \in \{1, \ldots, k_y - 1\}, v_{l+1}^y = \pi(v_l^y) \wedge \pi(v_{k_y}^y) = \perp\}$$

For classifying an example $\mathbf{x}$, we consider a top-down classifier making decisions at each level of the hierarchy, this process sometimes referred to as the *Pachinko* machine selects the best class at each level of the hierarchy and iteratively proceeds down the hierarchy. In the case of flat classification, the hierarchy $\mathcal{H}$ is ignored, $\mathcal{Y} = V$, and the problem reduces to the classical supervised multi-class classification problem.

Our main result is the following theorem which provides a data-dependent bound on the generalization error of a top-down multi-class hierarchical classifier. We consider here kernel-based hypotheses, with $K : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ a PDS (positive definite symmetric) kernel

and $\Phi : \mathcal{X} \to \mathbb{H}$ its associated feature mapping function, defined as :

$$\mathcal{F}_B = \{f : (\mathbf{x}, v) \in \mathcal{X} \times V \mapsto \langle \Phi(\mathbf{x}), \mathbf{w}_v \rangle \mid \mathbf{W} = (w_1 \ldots, w_{|V|}), ||\mathbf{W}||_{\mathbb{H}} \leq B\}$$

where $\mathbf{W} = (w_1 \ldots, w_{|V|})$ is the matrix formed by the $|V|$ weight vectors defining the kernel-based hypotheses, $\langle ., . \rangle$ denotes the dot product, and $||\mathbf{W}||_{\mathbb{H}} = \left(\sum_{v \in V} ||\mathbf{w}_v||^2\right)^{1/2}$ is the $L^2_{\mathbb{H}}$ group norm of $\mathbf{W}$. We further define the following associated function class:

$$\mathcal{G}_{\mathcal{F}_B} = \{g_f : (\mathbf{x}, y) \in \mathcal{X} \times \mathcal{Y} \mapsto \min_{v \in \mathfrak{P}(y)} (f(\mathbf{x}, v) - \max_{v' \in \mathfrak{S}(v)} f(\mathbf{x}, v')) \mid f \in \mathcal{F}_B\}$$

For a given hypothesis $f \in \mathcal{F}_B$, the sign of its associated function $g_f \in \mathcal{G}_{\mathcal{F}_B}$ directly defines a hierarchical classification rule for f as the top-down classification scheme outlined before simply amounts to: *assign* $\mathbf{x}$ *to* y *iff* $g_f(\mathbf{x}, y) > 0$. The learning problem we address is then to find a hypothesis f from $\mathcal{F}_B$ such that the generalization error of $g_f \in \mathcal{G}_{\mathcal{F}_B}$, $\mathcal{E}(g_f) = \mathbb{E}_{(\mathbf{x},y)\sim\mathcal{D}}\left[\mathbb{1}_{g_f(\mathbf{x},y)\leq 0}\right]$, is minimal ($\mathbb{1}_{g_f(\mathbf{x},y)\leq 0}$ is the 0/1 loss, equal to 1 if $g_f(\mathbf{x}, y) \leq 0$ and 0 otherwise).

The following theorem sheds light on the trade-off between flat versus hierarchical classification. The notion of function class capacity used here is the *empirical Rademacher complexity* (Bartlett and Mendelson, 2002; Meir and Zhang, 2003).

Theorem 1 *Let* $\mathcal{S} = ((\mathbf{x}^{(i)}, y^{(i)}))_{i=1}^m$ *be a dataset of* m *examples drawn i.i.d. according to a probability distribution* $\mathcal{D}$ *over* $\mathcal{X} \times \mathcal{Y}$*, and let* $\mathcal{A}$ *be a Lipschitz function with constant* L *dominating the* 0/1 *loss; further let* $K : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ *be a PSD (positive semi-definite) kernel and let* $\Phi : \mathcal{X} \to \mathbb{H}$ *be the associated feature mapping function. Assume that there exists* $R > 0$ *such that* $K(\mathbf{x}, \mathbf{x}) \leq R^2$ *for all* $\mathbf{x} \in \mathcal{X}$*. Then, for all* $1 > \delta > 0$*, with probability at least* $(1 - \delta)$ *the following hierarchical multi-class classification generalization bound holds for all* $g_f \in \mathcal{G}_{\mathcal{F}_B}$ *:*

$$\mathcal{E}(g_f) \leq \frac{1}{m} \sum_{i=1}^{m} \mathcal{A}(g_f(\mathbf{x}^{(i)}, y^{(i)})) + \frac{8BRL}{\sqrt{m}} \sum_{v \in V \setminus \mathcal{Y}} |\mathfrak{D}(v)|(|\mathfrak{D}(v)| - 1) + 3\sqrt{\frac{\ln(2/\delta)}{2m}} \quad (1)$$

where $|\mathfrak{D}(v)|$ *denotes the number of children of node* v*.*

Proof Exploiting the fact that $\mathcal{A}$ dominates the 0/1 loss and using the Rademacher data-dependent generalization bound presented in Theorem 4.9 of (Shawe-Taylor and Cristianini, 2004), one has:

$$\begin{aligned} \mathbb{E}_{(x,y)\sim\mathcal{D}}\left[\mathbb{1}_{g_f(\mathbf{x},y)\leq 0} - 1\right] &\leq \mathbb{E}_{(\mathbf{x},y)\sim\mathcal{D}}\left[\mathcal{A} \circ g_f(\mathbf{x}, y) - 1\right] \\ &\leq \frac{1}{m} \sum_{i=1}^{m} (\mathcal{A}(g_f(\mathbf{x}^{(i)}, y^{(i)})) - 1) + \hat{\mathcal{R}}_m((\mathcal{A} - 1) \circ \mathcal{G}_{\mathcal{F}_B}, \mathcal{S}) + 3\sqrt{\frac{\ln(2/\delta)}{2m}} \end{aligned}$$

where $\hat{\mathcal{R}}_m$ denotes the empirical Rademacher complexity of $(\mathcal{A}-1)\circ\mathcal{G}_{\mathcal{F}_B}$ on $\mathcal{S}$. As $x \mapsto \mathcal{A}(x)$ is a Lipschtiz function with constant L and $(\mathcal{A} - 1)(0) = 0$, we further have:

$$\hat{\mathcal{R}}_m((\mathcal{A} - 1) \circ \mathcal{G}_{\mathcal{F}_B}, \mathcal{S}) \leq 2L\hat{\mathcal{R}}_m(\mathcal{G}_{\mathcal{F}_B}, \mathcal{S})$$

with:

$$\begin{aligned}\hat{\mathcal{R}}_m(\mathcal{G}_{\mathcal{F}_B},\mathcal{S}) &= \mathbb{E}_\sigma\left[\sup_{g_f\in\mathcal{G}_{\mathcal{F}_B}}\left|\frac{2}{m}\sum_{i=1}^m \sigma_i\, g_f(\mathbf{x}^{(i)},y^{(i)})\right|\right]\\ &= \mathbb{E}_\sigma\left[\sup_{f\in\mathcal{F}_B}\left|\frac{2}{m}\sum_{i=1}^m \sigma_i \min_{v\in\mathfrak{P}(y^{(i)})}(f(\mathbf{x}^{(i)},v)-\max_{v'\in\mathfrak{S}(v)} f(\mathbf{x}^{(i)},v'))\right|\right]\end{aligned}$$

where σ_is are independent uniform random variables which take value in $\{-1,+1\}$ and are known as Rademacher variables.

Let us define the mapping c from $\mathcal{F}_B\times\mathcal{X}\times\mathcal{Y}$ into $V\times V$ as:

$$\begin{aligned}c(f,\mathbf{x},y)=(v,v') \;\Rightarrow\; & (f(\mathbf{x},v')=\max_{v''\in\mathfrak{S}(v)} f(\mathbf{x},v''))\\ & \wedge\,(f(\mathbf{x},v)-f(\mathbf{x},v')=\min_{u\in\mathfrak{P}(y)}(f(\mathbf{x},u)-\max_{u'\in\mathfrak{S}(u)} f(\mathbf{x},u')))\end{aligned}$$

This definition is similar to the one given by Guermeur (2010) for flat multi-class classification. Then, by construction of c:

$$\hat{\mathcal{R}}_m(\mathcal{G}_{\mathcal{F}_B},\mathcal{S})\le\frac{2}{m}\mathbb{E}_\sigma\left[\sup_{f\in\mathcal{F}_B}\sum_{(v,v')\in V^2,v'\in\mathfrak{S}(v)}\left|\sum_{i:c(f,\mathbf{x}^{(i)},y^{(i)})=(v,v')}\sigma_i(f(\mathbf{x}^{(i)},v)-f(\mathbf{x}^{(i)},v'))\right|\right]$$

By definition, $f(\mathbf{x}^{(i)},v)-f(\mathbf{x}^{(i)},v')=\langle\mathbf{w}_v-\mathbf{w}_{v'},\Phi(\mathbf{x}^{(i)})\rangle$ and using Cauchy-Schwartz inequality:

$$\begin{aligned}\hat{\mathcal{R}}_m(\mathcal{G}_{\mathcal{F}_B},\mathcal{S}) &\le \frac{2}{m}\mathbb{E}_\sigma\left[\sup_{\|\mathbf{W}\|_{\mathbb{H}}\le B}\sum_{(v,v')\in V^2,v'\in\mathfrak{S}(v)}\left|\left\langle\mathbf{w}_v-\mathbf{w}_{v'},\sum_{i:c(f,\mathbf{x}^{(i)},y^{(i)})=(v,v')}\sigma_i\Phi(\mathbf{x}^{(i)})\right\rangle\right|\right]\\ &\le \frac{2}{m}\mathbb{E}_\sigma\left[\sup_{\|\mathbf{W}\|_{\mathbb{H}}\le B}\sum_{(v,v')\in V^2,v'\in\mathfrak{S}(v)}\|\mathbf{w}_v-\mathbf{w}_{v'}\|_{\mathbb{H}}\left\|\sum_{i:c(f,\mathbf{x}^{(i)},y^{(i)})=(v,v')}\sigma_i\Phi(\mathbf{x}^{(i)})\right\|_{\mathbb{H}}\right]\\ &\le \frac{4B}{m}\sum_{(v,v')\in V^2,v'\in\mathfrak{S}(v)}\mathbb{E}_\sigma\left[\left\|\sum_{i:c(f,\mathbf{x}^{(i)},y^{(i)})=(v,v')}\sigma_i\Phi(\mathbf{x}^{(i)})\right\|_{\mathbb{H}}\right]\end{aligned}$$

Using Jensen's inequality, and as, $\forall i,j\in\{l|c(f,\mathbf{x}^{(l)},y^{(l)})=(v,v')\}^2, i\neq j, \mathbb{E}_\sigma[\sigma_i\sigma_j]=0$, we get:

$$\begin{aligned}\hat{\mathcal{R}}_m(\mathcal{G}_{\mathcal{F}_B},\mathcal{S}) &\le \frac{4B}{m}\sum_{(v,v')\in V^2,v'\in\mathfrak{S}(v)}\left(\mathbb{E}_\sigma\left[\left\|\sum_{i:c(f,\mathbf{x}^{(i)},y^{(i)})=(v,v')}\sigma_i\Phi(\mathbf{x}^{(i)})\right\|_{\mathbb{H}}^2\right]\right)^{1/2}\\ &= \frac{4B}{m}\sum_{(v,v')\in V^2,v'\in\mathfrak{S}(v)}\left(\sum_{i:c(f,\mathbf{x}^{(i)},y^{(i)})=(v,v')}\left\|\Phi(\mathbf{x}^{(i)})\right\|_{\mathbb{H}}^2\right)^{1/2}\\ &= \frac{4B}{m}\sum_{(v,v')\in V^2,v'\in\mathfrak{S}(v)}\left(\sum_{i:c(f,\mathbf{x}^{(i)},y^{(i)})=(v,v')}K\left(\mathbf{x}^{(i)},\mathbf{x}^{(i)}\right)\right)^{1/2}\\ &\le \frac{4B}{m}\sum_{(v,v')\in V^2,v'\in\mathfrak{S}(v)}\left(mR^2\right)^{1/2}\\ &= \frac{4BR}{\sqrt{m}}\sum_{v\in V\setminus\mathcal{Y}}|\mathfrak{D}(v)|(|\mathfrak{D}(v)|-1)\end{aligned}$$

Plugging this bound into the first inequality yields the desired result. □

This generalization bound proves the consistency of the ERM principle for the Pachinko-machine based method. Further, for flat multiclass classification, we recover the bounds by Guermeur (2010) by considering a hierarchy containing a root node with as many children as there are categories. Note that the definition of functions in $\mathcal{G}_{\mathcal{F}_B}$ subsumes the definition of the margin function used for the flat multiclass classification problems by Guermeur (2010), and that the factor $8L$ in the complexity term of the bound, instead of 4 by Guermeur (2010), is due to the fact that we are using an L-Lipschitz loss function dominating the 0/1 loss in the empirical Rademacher complexity. Krishnapuram et al. (2005) they provide PAC-Bayes bounds, different to ours, for Bayes Voting classifiers and Gibbs classifier under a PAC-Bayes setup (McAllester, 1998; Seeger, 2003). Lastly, Bartlett et al. (2005) have proposed tighter bounds using local Rademacher complexities. Using such bounds would lead to replace the term involving the complexity of the hierarchy in Theorem 1 by a term involving the fixed point of a sub-root function that upper bounds local Rademacher averages. Such a replacement, if it can lead to tighter bounds under some additional conditions, would however miss the explanation provided below on the behaviors of flat and hierarchical classifiers, an explanation that will be confirmed experimentally.

Flat vs hierarchical classification in large-scale taxonomies. The generalization error is controlled in inequality (1) by a trade-off between the empirical error and the Rademacher complexity of the class of classifiers. The Rademacher complexity term favors hierarchical classifiers over flat ones, as any split of a set of category of size K in p parts $K_1,\cdots,K_p$ ($\sum_{i=1}^p K_i=K$) is such that $\sum_{i=1}^p K_i^2\le K^2$. On the other hand, the empirical error term is likely to favor flat classifiers vs hierarchical ones, as the latter rely on a series of decisions (as many as the length of the path from the root to the chosen category in $\mathcal{Y}$) and are thus more likely to make mistakes. This fact is often referred to as the *propagation error* problem in hierarchical classification.

On the contrary, flat classifiers rely on a single decision and are not prone to this problem (even though the decision to be made is harder). When the classification problem in $\mathcal{Y}$ is highly unbalanced, then the decision that a flat classifier has to make is difficult; hierarchical classifiers still have to make several decisions, but the imbalance problem is less severe on each of them. So, in this case, even though the empirical error of hierarchical classifiers may be higher than the one of flat ones, the difference can be counterbalanced by the Rademacher complexity term, and the bound in Theorem 1 suggests that hierarchical classifiers should be preferred over flat ones.

On the other hand, when the data is well balanced, the Rademacher complexity term may not be sufficient to overcome the difference in empirical errors due to the propagation error in hierarchical classifiers; in this case, Theorem 1 suggests that flat classifiers should be preferred to hierarchical ones. These results have been empirically observed in different studies on classification in large-scale taxonomies and are further discussed in Section 6.

Similarly, one way to improve the accuracy of classifiers deployed in large-scale taxonomies is to modify the taxonomy by pruning (sets of) nodes (Wang and Lu, 2010). By doing so, one is flattening part of the taxonomy and is once again trading-off the two terms in inequality (1): pruning nodes leads to reduce the number of decisions made by the hierarchical classifier while maintaining a reasonable Rademacher complexity. Motivated from the Rademacher-based generalization error bound presented in Theorem 1, we now propose a method for pruning nodes of the given taxonomy. The output of this procedure is a new taxonomy which leads to improvement in classification accuracy when used for top-down classification.

4. Hierarchy Pruning

In this section, we present a strategy aiming at adapting the given hierarchy of classes by pruning some nodes in the hierarchy. An example of node pruning is shown in Figure 2. The rationale and motivation behind adapting the given hierarchy $\mathcal{H} = (V, E)$ to the set of input/output pair $(\mathbf{x}, y)$ is that

- Large-scale taxonomies, such as DMOZ and Yahoo! Directory, are designed with an intent of better user-experience and navigability, and not necessarily for the goal of classification,
- Taxonomy design is subject to certain degree of arbitrariness based on personal choices and preferences of the editors. Therefore, many competing taxonomies may exist, and
- The large-scale nature of such taxonomies poses difficulties in manually designing good taxonomies for classification.

The problem of pruning a hierarchy can be seen as a structure learning problem, where one wants to learn a simplified structure from a given one. The main difficulty in solving this problem is to identify the important features on which to base the decision to prune a node or not. We first present in this section a straightforward strategy that behaves well in practice but is nevertheless computationally expensive, prior to propose a "lighter" strategy based on the previous results. We will, in the next section (Section 5), introduce new theoretical results that will help us identify important features for node pruning, and

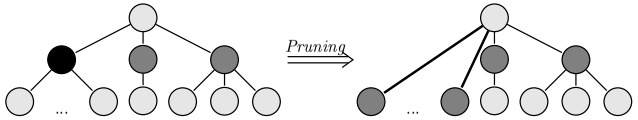

Figure 2: The pruning procedure; the node in black is replaced by its children. In the figure on the left, the gray nodes represent the siblings or sisters of node in black.

on which we will develop a greedy procedure to simplify a given hierarchy. The rationale for a greedy approach here is that optimal pruning would require evaluations of 2^k possible prunings for k siblings, which is infeasible in practice.

4.1 Hierarchy Pruning based on validation estimate

The challenge in the pruning procedure is to identify promising nodes which when pruned lead to improvement in classification accuracy. One of the simplest methods to identify such nodes is by using a validation set to check if pruning a node improves classification accuracy on that set by comparing it with accuracy obtained on the original taxonomy. This can also be interpreted as follows:

$$\text{Whether to prune a node } v? = \begin{cases} \text{Yes} & \text{If classification improves on the validation set} \\ \text{No} & \text{otherwise} \end{cases}$$

Algorithm 1 Hierarchy pruning based on validation estimate

Require: A hierarchy $\mathcal{G}$, Training set $\mathcal{S}$ and a validation set $\mathcal{S}'$
Train SVM classifier at each node of the tree $\mathcal{G}$ using the training set $\mathcal{S}$
Evaluate the accuracy of the classifier-cascade $\mathcal{G}$ on the validation set
for $v \in \mathcal{V}$ **do**
    Prune the node v and replace it by its children
    Re-train SVM classifier at the impacted node of the tree $\mathcal{G}'$
    Evaluate the accuracy of the classifier-cascade $\mathcal{G}'$ on the validation set
    if Cross-validation accuracy is higher on $\mathcal{G}'$ as compared to $\mathcal{G}$ **then**
        Prune the node v
    else
        Do not prune the node v
    end if
end for
return Pruned taxonomy $\mathcal{G}'$

This simple strategy is algorithmically presented in Algorithm 1. In terms of prediction accuracy, this method for pruning works reasonably well, however its main disadvantages are the computational complexity and lack of generalizability to new but somewhat related

taxonomies. In section 6, we also present experimental results obtained by this pruning strategy vis-à-vis other pruning methods presented later in this paper.

Computationally, this method requires (i) a trained cascade of top-down classifiers, (ii) for every pruned node, re-training the parent of the pruned node, and (iii) for every such node, evaluating the top-down performance on the validation set, which involves traversing the root-to-leaf path of classifier evaluation along the taxonomy. Furthermore, the steps (ii) and (iii) are to be repeated for every pruned node. Let C_{td-cas} denotes the computational complexity for training the cascade, C_v denotes the complexity for re-training of the parent node after pruning the node v, and C_{val} denotes the complexity of evaluating the validation set. Let $|V|_p$ denote the number of pruned nodes, then the complexity of the Algorithm 1 is $C_{td-cas} + |V|_p \times (C_v + C_{val})$. Due to the linear dependence on the number of pruned nodes, it becomes computationally expensive to prune a reasonably large number of nodes and check if this would result in improvement in classification accuracy of the top-down cascade. Furthermore, this process does not amount to a learning-based method for pruning and hence needs to be employed from scratch for newer taxonomies, even though these taxonomies may have similar characteristics to those encountered already.

To summarize, though quite simple, the above pruning method has the following disadvantages:

- This is a computationally expensive process to re-train the classifier at the pruned nodes and then test the performance on the validation set. As a result, this may not be applicable for large-scale taxonomies consisting of large number of internal nodes,
- This method does not amount to a learning-based strategy for pruning, and ignores data-dependent information available at the nodes of the taxonomy, and
- This process needs to be repeated for each taxonomy encountered, and information gained from taxonomy cannot be leveraged for newer taxonomies with similar characteristics.

We now turn to another method for taxonomy adaptation by pruning which is based on the generalization error analysis derived in Section 3.1. This method is computationally efficient compared to that presented in Algorithm 1 and only requires a cascade of top-down classifiers. Essentially, the criterion for pruning, which is related to the margin at each node, can be computed while training the top-down cascade. This corresponds to only the first step in Algorithm 1, and rest of the steps of evaluating on validation set are no longer required. Therefore, in terms of computational complexity, the method proposed in the next section has complexity of C_{td-cas}.

4.2 Hierarchy Pruning based on generalization-error

In this section, we present a strategy for pruning which is theoretically well motivated and is based on the generalization error bound for understanding the trade-off for flat and hierarchical classification. In view of the generalization error bound derived in Theorem 1, adapting the given taxonomy of classes aims at achieving a better trade-off between the empirical error and the error attributed to Rademacher complexity. In other words, adapting the given taxonomy $\mathcal{H}$ to the set of input output pairs $(\mathbf{x}, v)$ aims at achieving a lower value

of the bound as compared to that attained by using the original hierarchy. For a node v with parent $\pi(v)$, pruning v and replacing it by its children will increase the number of children of $\pi(v)$ and hence the associated Rademacher complexity but will decrease the empirical error along that path from root to leaf. Therefore, we need to identify those nodes in the taxonomy for which increase in the Rademacher complexity is among the lowest so that a better trade-off between the two error terms is achieved than in the original hierarchy. For this purpose, we turn to the bound on the empirical Rademacher complexity of the function class $\mathcal{G}_{\mathcal{F}_B}$.

In the derivation of Theorem 1, the empirical Rademacher complexity was upper bounded as follows:

$$\hat{\mathcal{R}}_m(\mathcal{G}_{\mathcal{F}_B}, \mathcal{S}) \leq \frac{2}{m}\mathbb{E}_\sigma \left[\sup_{\|\mathbf{W}\|_{\mathbb{H}} \leq B} \sum_{(v,v') \in V^2, v' \in \mathfrak{S}(v)} \|\mathbf{w}_v - \mathbf{w}_{v'}\|_{\mathbb{H}} \left\| \sum_{i:c(f,\mathbf{x}^{(i)},y^{(i)})=(v,v')} \sigma_i \Phi(\mathbf{x}^{(i)}) \right\|_{\mathbb{H}} \right] \quad (2)$$

From the above bound, we define a quantity $C(v)$ for each node v

$$C(v) = \sum_{(v,v') \in V^2, v' \in \mathfrak{S}(v)} \|\mathbf{w}_v - \mathbf{w}_{v'}\|_{\mathbb{H}} \quad (3)$$

As one can note, the right hand side of the inequality (2) above provides an upper bound on $\hat{\mathcal{R}}_m(\mathcal{G}_{\mathcal{F}_B}, \mathcal{S})$ and one can meaningfully compare only the sibling nodes since these nodes have the same training set. Thus, the explicit computation of expectation $\mathbb{E}_\sigma(.)$ with respect to the Rademacher random variables and the computation of the inner product in the feature space can be avoided. This motivates the definition of $C(v)$ in equation (3), that can be efficiently and effectively computed from the training data, and that represents a distance of node v to its sibling nodes. It must be noted that $C(v')$, for a set of siblings $\{v'\}$, as computed using equation 3 is different for each node v'.

$C(v)$ is higher when $\mathbf{w}_v$ is larger than $\mathbf{w}_{v'}$ (when measured in terms of L2-distance), for all siblings v' of v, or when $\mathbf{w}_v$ is far away from $\mathbf{w}_{v'}$ (implying that the L2-norm of the difference is large), or both. The first and last cases correspond to unbalanced classes, v being the dominant class. In such cases, pruning v by replacing it by its children leads to a more balanced problem, less prone to classification errors. Furthermore, as children of v are based on the features in v, most of them will likely be far away from the siblings of v, and the pruning, even though increasing the Rademacher complexity term, will decrease the empirical error term and, likely, the generalization error. In the second case, pruning v will lead to children that will again be, very likely, far away from the siblings of v. This pruning thus does not introduce confusion between categories and reduces the problem related to error propagations.

This suggests that an effective pruning algorithm must prune the nodes v in the taxonomy for which $C(v)$ is maximal. In practice, we focus on pruning the nodes in the top-two layers of the taxonomy. This is due to the following reasons:

- The categories in these levels represent generic concepts, such as Entertainment and Sports in Yahoo! Directory, which are typically over-lapping in nature, and
- This is also shown in the plot in Figure 3 for the average confusion of the nodes C_v^{avg} for the different levels for two of the taxonomies used in our experiments. It shows

that the confusion among the top-level nodes is much higher as compared to those in the lower levels.

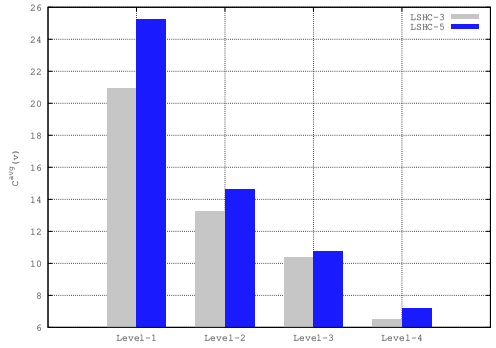

Figure 3: C_v^{avg} **plotted for various levels in the hierarchy Level 1 corresponds to the top-most level.**

Algorithm 2 The proposed method for hierarchy pruning based on Generalization Bound

Require: a hierarchy $\mathcal{G}$, Training set $\mathcal{S}$ consisting of $(\mathbf{x}, y)$ pairs, $\mathbf{x} \in \mathcal{X}$ and $y \in \mathcal{Y}$
  Train SVM classifier at each node of the tree
  $\Delta \leftarrow 0$
  for $v \in \mathcal{V}$ **do**
    Sort its child nodes $v' \in \mathfrak{D}(v)$ in decreasing order of $C(v')$
    Flatten 1st and 2nd ranked child nodes, say v'_1 and v'_2
    $\Delta = C(v'_1) - C(v'_2)$
    $v_{prev} \leftarrow v'_2$ ▷ Set the previous flattened node to v'_2
    for $v' \in \mathcal{V} - \{v'_1, v'_2\}, (v, v') \in \mathcal{E}$ **do**
      if $C(v_{prev}) - C(v') < \Delta$ **then**
        Flatten v'
        $\Delta \leftarrow C(v_{prev}) - C(v')$
        $v_{prev} \leftarrow v'$ ▷ Set the previous flattened node to v'
      else
        break
      end if
    end for
  end for
  return Pruned taxonomy $\mathcal{G}'$

The pruning process as an algorithmic procedure is shown in Algorithm 2, where the variable Δ is used to stop the pruning process in an inner iteration.

The above criterion for pruning the nodes in a large-scale taxonomy is also similar in spirit to the method introduced by Babbar et al. (2013b) which is motivated from the generalization error analysis of Perceptron Decision Trees. As shown in the experiments on large-scale datasets by using SVM and Logistic Regression classifiers, applying this strategy outputs a new taxonomy which leads to better classification accuracy as compared to the original taxonomy.

It may be noted that the pruning procedure adopts a conservative approach to avoid excessive flattening of the taxonomy. It can be modified to prune the nodes more aggressively by scaling the parameter Δ after pruning of every node, and hence allow more nodes to be pruned. However, irrespective of such design choice, this method based on the generalization bound for pruning the hierarchy has two following disadvantages :

- Higher computational complexity since one needs to learn the weight vector $\mathbf{w}_v$ for each node v in the given taxonomy. As a result, the process of identifying these nodes can be computationally expensive for large-scale taxonomies;
- It is restricted only to discriminative classifiers such as Support Vector Machines and Logistic Regression.

Therefore, we next present a meta-learning based pruning strategy for hierarchy pruning which avoids this initial training of the entire taxonomy, and is applicable to both discriminative and generative classifiers.

5. Meta-learning based pruning strategy

In this section, we present a meta-learning based generic pruning strategy which is applicable to both discriminative and generative classifiers. The meta-features for the instances are derived from the analysis of the approximation error for multi-class versions of the two well-known generative and discriminative classifiers: Naive Bayes and Logistic Regression. We then show how this generalization error analysis of the classifier at each node is combined when deployed in a typical top-down cascade of the hierarchy tree. Based on these analyses, we identify the important features that control the variation of the generalization error and determine whether a particular node should be flattened or not. We finally train a meta-classifier based on these meta-features, which predicts whether replacing a node in the hierarchy by its children (Figure 2) will improve the classification accuracy or not.

The remainder of this section is organized as follows:

1. In Section 5.1, we present asymptotic error bounds for Naive Bayes classifiers;
2. Asymptotic error bounds for Multinomial Logistic Regression classifiers are given in Section 5.2;
3. We then develop in Section 5.3:
   (a) A *pruning* bound for both types of classifiers;
   (b) A meta-classifier for pruning nodes of a taxonomy, based on features derived from both asymptotic error and pruning bounds.

Theorem 2 below is recalled by Ng and Jordan (2001). Theorems 3 and 4 provide multi-class versions of the bounds proposed by Ng and Jordan (2001) for the Naive Bayes and Logistic Regression classifiers respectively. Lastly, Theorem 5 provides a hierarchical generalization of these bounds for both classifiers. The features we are using to learn the meta-classifier are derived from Theorem 5.

5.1 Asymptotic approximation error bounds for Naive Bayes

Let us first consider a multinomial, multiclass Naive Bayes classifier in which the predicted class is the one with maximum posterior probability. The parameters of this model are estimated by maximum likelihood and we assume here that Laplace smoothing is used to avoid null probabilities. Our goal here is to derive a generalization error bound for this classifier. To do so, we recall the bound for the binomial version (directly based on the presence/absence of each feature in each document) of the Naive Bayes classifier for two target classes (Theorem 4 of (Ng and Jordan, 2001)).

Theorem 2 *For a two class classification problem in d dimensional feature space with m training examples $\{(\boldsymbol{x}_i, y_i)\}_{i=1}^m$ sampled from distribution $\mathcal{D}$, let h and h_∞ denote the classifiers learned from the training set of finite size m and its asymptotic version respectively. Then, with high probability, the bound on misclassification error of h is given by*

$$\mathcal{E}(h) \leq \mathcal{E}(h_\infty) + G\left(O\left(\sqrt{\frac{1}{m}\log d}\right)\right) \tag{4}$$

where $G(\tau)$ represents the probability that the asymptotic classifier predicts correctly and has scores lying in the interval $(-d\tau, d\tau)$.

We extend here this result to the multinomial, multiclass Naive Bayes classifier, for a K class classification problem with $\mathcal{Y} = \{y_1, \ldots y_K\}$. To do so, we first introduce the following lemma, that parallels Lemma 3 of (Ng and Jordan, 2001):

Lemma 1 *$\forall y_k \in \mathcal{Y}$, let $\widehat{P}(y_k)$ be the estimated class probability and $P(y_k)$ its asymptotic version obtained with a training set of infinite size. Similarly, $\forall y_k \in \mathcal{Y}$ and $\forall i$, $1 \leq i \leq d$, let $\widehat{P}(w_i|y_k)$ be the estimated class conditional feature probability and $P(w_i|y_k)$ its asymptotic version (w_i denotes the i^{th} word of the vocabulary). Then, $\forall \epsilon > 0$, with probability at least $(1-\delta)$ we have :*

$$|\widehat{P}(y_k) - P(y_k)| < \epsilon,\ |\widehat{P}(w_i|y_k) - P(w_i|y_k)| < \epsilon$$

with $\delta = K\delta_0 + d\sum_{k=1}^K \delta_k$, where $\delta_0 = 2\exp(-2m\epsilon^2)$ and $\delta_k = 2d\exp(-2d_k\epsilon^2)$. d_k represents the length of class y_k, that is the sum of lengths (in number of occurrences) of all the documents in class k.

The proof of this lemma directly derives from Hoeffding's inequality and the union bound, and is a direct extension of the proof of Lemma 3 given by Ng and Jordan (2001).

Let us now denote the joint log-likelihood of the vector representation of (a document) $\boldsymbol{x}$ in class y_k by $l(\boldsymbol{x}, y_k)$:

$$l(\boldsymbol{x}, y_k) = \log\left[\widehat{P}(y_k)\prod_{i=1}^d \widehat{P}(w_i|y_k)^{x_i}\right] \tag{5}$$

where x_i represents the number of times word w_i appears in $\boldsymbol{x}$. The decision of the Naive Bayes classifier for an instance $\boldsymbol{x}$ is given by:

$$h(\boldsymbol{x}) = \underset{y_k \in \mathcal{Y}}{\operatorname{argmax}}\, l(\boldsymbol{x}, y_k) \tag{6}$$

and the one for its asymptotic version by:

$$h_\infty(\boldsymbol{x}) = \underset{y_k \in \mathcal{Y}}{\operatorname{argmax}}\, l_\infty(\boldsymbol{x}, y_k) \tag{7}$$

Lemma 1 suggests that the predicted and asymptotic log-likelihoods are close to each other, as the quantities they are based on are close to each other. Thus, provided that the asymptotic log-likehoods between the best two classes, for any given $\boldsymbol{x}$, are not too close to each other, the generalization error of the Naive Bayes classifier and the one of its asymptotic version are close to each other. Theorem 3 below states such a relationship, using the following function that measures the confusion between the best two classes for the asymptotic Naive Bayes classifier.

Definition 1 *Let $l^1_\infty(\boldsymbol{x}) = \max_{y_k \in \mathcal{Y}} l_\infty(\boldsymbol{x}, y_k)$ be the best log-likelihood score obtained for $\boldsymbol{x}$ by the asymptotic Naive Bayes classifier, and let $l^2_\infty(\boldsymbol{x}) = \max_{y_k \in \mathcal{Y}\setminus h_\infty(\boldsymbol{x})} l_\infty(\boldsymbol{x}, y_k)$ be the second best log-likelihood score for $\boldsymbol{x}$. We define the confusion of the asymptotic Naive Bayes classifier for a category set $\mathcal{Y}$ as:*

$$G_{\mathcal{Y}}(\tau) = P_{(\boldsymbol{x},y)\sim D}(|l^1_\infty(\boldsymbol{x}) - l^2_\infty(\boldsymbol{x})| < 2\tau)$$

for $\tau > 0$.

We are now in position to formulate a relationship between the generalization error of the multinomial, multiclass Naive Bayes classifier and its asymptotic version.

Theorem 3 *For a K class classification problem in d dimensional feature space with a training set of size m, $\{\boldsymbol{x}^{(i)}, y^{(i)}\}_{i=1}^m$, $\boldsymbol{x}^{(i)} \in \mathcal{X}$, $y^{(i)} \in \mathcal{Y}$, sampled from distribution $\mathcal{D}$, let h and h_∞ denote the Naive Bayes classifiers learned from a training set of finite size m and its asymptotic version respectively, and let $\mathcal{E}(h)$ and $\mathcal{E}(h_\infty)$ be their generalization errors. Then, $\forall \epsilon > 0$, one has, with probability at least $(1-\delta_{\mathcal{Y}})$:*

$$\mathcal{E}(h) \leq \mathcal{E}(h_\infty) + G_{\mathcal{Y}}(\epsilon) \tag{8}$$

with:

$$\delta_{\mathcal{Y}} = 2K\exp\left(\frac{-2\epsilon^2 m}{C(d+d_{max})^2}\right) + 2d\exp\left(\frac{-2\epsilon^2 d_{min}}{C(d+d_{max})^2}\right)$$

where d_{max} (resp. d_{min}) represents the length (in number of occurrences) of the longest (resp. shortest) class in $\mathcal{Y}$, and C is a constant related to the longest document in $\mathcal{X}$.

Proof Using Lemma 1 and a Taylor expansion of the log function, one gets, $\forall \epsilon > 0$, $\forall \boldsymbol{x} \in \mathcal{X}$, $\forall k \in \mathcal{Y}$:

$$P\left(|l(\boldsymbol{x}, y_k) - l_\infty(\boldsymbol{x}, y_k)| < \sqrt{C}\frac{\epsilon}{\rho_0}\right) > 1 - \delta$$

where δ is the same as in Lemma 1, $\sqrt{C}$ equals to the maximum length of a document and $\rho_0 = \min_{i,k}\{P(y_k), P(w_i|y_k)\}$. The use of Laplace smoothing is important for the quantities $p(w_i|y_k)$, which may be null if word w_i is not observed in class y_k. The Laplace smoother in this case leads to $\rho_0 = \frac{1}{d+d_{max}}$. The log-likelihood functions of the multinomial, multiclass Naive Bayes classifier and the one of its asymptotic version are thus close to each other with high probability. The decision made by the trained Naive Bayes classifier and its asymptotic version on a given x only differ if the distance between the first two classes of the asymptotic classifier is less than two times the distance between the log-likelihood functions of the trained and asymptotic classifiers. Thus, using the union bound, one obtains, with probability at least $(1-\delta)$:

$$\mathcal{E}(h) \leq \mathcal{E}(h_\infty) + G_{\mathcal{Y}}\left(\epsilon\sqrt{C}(d+d_{max})\right)$$

Using a change of variable ($\epsilon' = \epsilon\sqrt{C}(d+d_{max})$) and approximating $\sum_{k=1}^{K}\exp(-2d_k\epsilon^2)$ by $\exp(-2d_{min}\epsilon^2)$, the dominating term in the sum, leads to the desired result. □

5.2 Asymptotic approximation error bounds for Multinomial Logistic Regression

We now propose an asymptotic approximation error bound for a multiclass logistic regression (`MLR`) classifier. We first consider the flat, multiclass case ($V = \mathcal{Y}$), and then show how the bounds can be combined in a typical top-down cascade, leading to the identification of important features that control the variation of these bounds.

Considering a pivot class $y^\star \in \mathcal{Y}$, a `MLR` classifier, with parameters $\boldsymbol{\beta} = \{\beta_0^y, \beta_j^y; y \in \mathcal{Y}\setminus\{y^\star\}, j \in \{1,\ldots,d\}\}$, models the class posterior probabilities via a linear function in $\mathbf{x} = (x_j)_{j=1}^d$ ((see for example Hastie et al., 2001, p. 96)) :

$$\begin{aligned} P(y|\mathbf{x};\boldsymbol{\beta})_{y\neq y^\star} &= \frac{\exp(\beta_0^y + \sum_{j=1}^d \beta_j^y x_j)}{1+\sum_{y'\in\mathcal{Y},y'\neq y^\star}\exp(\beta_0^{y'} + \sum_{j=1}^d \beta_j^{y'} x_j)} \\ P(y^\star|\mathbf{x};\boldsymbol{\beta}) &= \frac{1}{1+\sum_{y'\in\mathcal{Y},y'\neq y^\star}\exp(\beta_0^{y'} + \sum_{j=1}^d \beta_j^{y'} x_j)} \end{aligned}$$

The parameters $\boldsymbol{\beta}$ are usually fit by maximum likelihood over a training set $\mathcal{S}$ of size m (denoted by $\widehat{\boldsymbol{\beta}}_m$ in the following) and the decision rule for this classifier consists in choosing the class with the highest class posterior probability :

$$h_m(\mathbf{x}) = \operatorname*{argmax}_{y\in\mathcal{Y}} P(y|\mathbf{x}, \widehat{\boldsymbol{\beta}}_m) \tag{9}$$

The following lemma states to which extent the posterior probabilities with maximum likelihood estimates $\widehat{\boldsymbol{\beta}}_m$ may deviate from their asymptotic values obtained with maximum likelihood estimates when the training size m tends to infinity (denoted by $\widehat{\boldsymbol{\beta}}_\infty$).

Lemma 2 *Let $\mathcal{S}$ be a training set of size m and let $\widehat{\boldsymbol{\beta}}_m$ be the maximum likelihood estimates of the `MLR` classifier over $\mathcal{S}$. Further, let $\widehat{\boldsymbol{\beta}}_\infty$ be the maximum likelihood estimates of parameters of `MLR` when m tends to infinity. For all examples $\mathbf{x}$, let $R > 0$ be the bound such that $\forall y \in \mathcal{Y}\setminus\{y^\star\}, \exp(\beta_0^y + \sum_{j=1}^d \beta_j^y x_j) < \sqrt{R}$; then for all $1 > \delta > 0$, with probability at least $(1-\delta)$ we have:*

$$\forall y \in \mathcal{Y}, \left|P(y|\mathbf{x}, \widehat{\boldsymbol{\beta}}_m) - P(y|\mathbf{x}, \widehat{\boldsymbol{\beta}}_\infty)\right| < d\sqrt{\frac{R|\mathcal{Y}|\sigma_0}{\delta m}}$$

where $\sigma_0 = \max_{j,y}\sigma_j^y$ and $(\sigma_j^y)_{y,j}$ represent the components of the inverse (diagonal) Fisher information matrix at $\widehat{\boldsymbol{\beta}}_\infty$ and are different from σ_i used in Section 3 wherein these represented Rademacher random variables.

Proof By denoting the sets of parameters $\widehat{\boldsymbol{\beta}}_m = \{\hat{\beta}_j^y; j \in \{0,\ldots,d\}, y \in \mathcal{Y}\setminus\{y^\star\}\}$, and $\widehat{\boldsymbol{\beta}}_\infty = \{\beta_j^y; j \in \{0,\ldots,d\}, y \in \mathcal{Y}\setminus\{y^\star\}\}$, and using the independence assumption and the asymptotic normality of maximum likelihood estimates ((see for example Schervish, 1995, p. 421)), we have, for $0 \leq j \leq d$ and $\forall y \in \mathcal{Y}\setminus\{y^\star\}$: $\sqrt{m}(\widehat{\beta}_j^y - \beta_j^y) \sim N(0, \sigma_j^y)$ where the $(\sigma_j^y)_{y,i}$ represent the components of the inverse (diagonal) Fisher information matrix at $\widehat{\boldsymbol{\beta}}_\infty$. Let $\sigma_0 = \max_{j,y}\sigma_j^y$. Then using Chebyshev's inequality, for $0 \leq j \leq d$ and $\forall y \in \mathcal{Y}\setminus\{y^\star\}$ we have with probability at least $1 - \sigma_0/\epsilon^2$, $|\widehat{\beta}_j^y - \beta_j^y| < \frac{\epsilon}{\sqrt{m}}$. Further $\forall \mathbf{x}$ and $\forall y \in \mathcal{Y}\setminus\{y^\star\}, \exp(\beta_0^y + \sum_{j=1}^d \beta_j^y x_j) < \sqrt{R}$; using a Taylor development of the functions $\exp(x+\epsilon)$ and $(1+x+\epsilon x)^{-1}$ and the union bound, one obtains that, $\forall \epsilon > 0$ and $y \in \mathcal{Y}$ with probability at least $1 - \frac{|\mathcal{Y}|\sigma_0}{\epsilon^2}$: $\left|P(y|\mathbf{x}, \widehat{\boldsymbol{\beta}}_m) - P(y|\mathbf{x}, \widehat{\boldsymbol{\beta}}_\infty)\right| < d\sqrt{\frac{R}{m}}\epsilon$. Setting $\frac{|\mathcal{Y}|\sigma_0}{\epsilon^2}$ to δ, and solving for ϵ gives the result. □

Lemma 2 suggests that the predicted and asymptotic posterior probabilities are close to each other, as the quantities they are based on are close to each other. Thus, provided that the asymptotic posterior probabilities between the best two classes, for any given $\mathbf{x}$, are not too close to each other, the generalization error of the `MLR` classifier and the one of its asymptotic version should be similar. Theorem 4 below states such a relationship, using the following function that measures the confusion between the best two classes for the asymptotic `MLR` classifier defined as :

$$h_\infty(\mathbf{x}) = \operatorname*{argmax}_{y\in\mathcal{Y}} P(y|\mathbf{x}, \widehat{\boldsymbol{\beta}}_\infty) \tag{10}$$

For any given $\mathbf{x} \in \mathcal{X}$, the confusion between the best two classes is defined as follows.

Definition 2 *Let $f_\infty^1(\mathbf{x}) = \max_{y\in\mathcal{Y}} P(y|\mathbf{x}, \widehat{\boldsymbol{\beta}}_\infty)$ be the best class posterior probability for $\mathbf{x}$ by the asymptotic `MLR` classifier, and let $f_\infty^2(\mathbf{x}) = \max_{y\in\mathcal{Y}\setminus h_\infty(\mathbf{x})} P(y|\mathbf{x}, \widehat{\boldsymbol{\beta}}_\infty)$ be the second best class posterior probability for $\mathbf{x}$. We define the confusion of the asymptotic `MLR` classifier for a category set $\mathcal{Y}$ as:*

$$G_{\mathcal{Y}}(\tau) = P_{(\mathbf{x},y)\sim\mathcal{D}}(|f_\infty^1(\mathbf{x}) - f_\infty^2(\mathbf{x})| < 2\tau)$$

for a given $\tau > 0$.

The following theorem states a relationship between the generalization error of a trained `MLR` classifier and its asymptotic version.

Theorem 4 *For a multi-class classification problem in d dimensional feature space with a training set of size m, $\{\boldsymbol{x}^{(i)}, y^{(i)}\}_{i=1}^{m}$, $\boldsymbol{x}^{(i)} \in \mathcal{X}$, $y^{(i)} \in \mathcal{Y}$, sampled i.i.d. from a probability distribution $\mathcal{D}$, let h_m and h_∞ denote the multiclass logistic regression classifiers learned from a training set of finite size m and its asymptotic version respectively, and let $\mathcal{E}(h_m)$ and $\mathcal{E}(h_\infty)$ be their generalization errors. Then, for all $1 > \delta > 0$, with probability at least $(1-\delta)$ we have:*

$$\mathcal{E}(h_m) \leq \mathcal{E}(h_\infty) + G_{\mathcal{Y}}\left(d\sqrt{\frac{R|\mathcal{Y}|\sigma_0}{\delta m}}\right) \tag{11}$$

where $\sqrt{R}$ is a bound on the function $\exp(\beta_0^y + \sum_{j=1}^{d}\beta_j^y x_j)$, $\forall \boldsymbol{x} \in \mathcal{X}$ and $\forall y \in \mathcal{Y}$, and σ_0 is a constant.

Proof The difference $\mathcal{E}(h_m) - \mathcal{E}(h_\infty)$ is bounded by the probability that the asymptotic `MLR` classifier h_∞ correctly classifies an example $(\mathbf{x}, y) \in \mathcal{X} \times \mathcal{Y}$ randomly chosen from $\mathcal{D}$, while h_m misclassifies it. Using Lemma 2, for all $\delta \in (0,1), \forall \mathbf{x} \in \mathcal{X}, \forall y \in \mathcal{Y}$, with probability at least $1-\delta$, we have:

$$\left|P(y|\mathbf{x}, \widehat{\boldsymbol{\beta}}_m) - P(y|\mathbf{x}, \widehat{\boldsymbol{\beta}}_\infty)\right| < d\sqrt{\frac{R|\mathcal{Y}|\sigma_0}{\delta m}}$$

Thus, the decision made by the trained MLR and its asymptotic version on an example $(\mathbf{x}, y)$ differs only if the distance between the two predicted classes of the asymptotic classifier is less than two times the distance between the posterior probabilities obtained with $\widehat{\boldsymbol{\beta}}_m$ and $\widehat{\boldsymbol{\beta}}_\infty$ on that example; and the probability of this is exactly $G_{\mathcal{Y}}\left(d\sqrt{\frac{R|\mathcal{Y}|\sigma_0}{\delta m}}\right)$, which upper-bounds $\mathcal{E}(h_m) - \mathcal{E}(h_\infty)$. □

Note that the quantity σ_0 in Theorem 4 represents the largest value of the inverse (diagonal) Fisher information matrix ((Schervish, 1995)), and thus corresponds to the inverse of the smallest value of the (diagonal) Fisher information matrix, which corresponds to the smallest amount of information one has on the estimation of each parameter $\widehat{\beta}_j^k$. This smallest amount of information is in turn related to the length (in number of occurrences) of the longest (resp. shortest) class in $\mathcal{Y}$ denoted respectively by d_{max} and d_{min} as, the smaller they are, the larger σ_0 is likely to be.

5.3 A learning based node pruning strategy

Let us now consider a hierarchy of classes and a top-down classifier making decisions at each level of the hierarchy. A node-based pruning strategy can be easily derived from the approximation bounds above. Indeed, any node v in the hierarchy $\mathcal{H} = (V, E)$ is associated with three category sets: its sibling categories with the node itself $\mathfrak{S}'(v) = \mathfrak{S}(v) \cup \{v\}$, its children categories, $\mathfrak{D}(v)$, and the union of its siblings and children categories, denoted $\mathfrak{F}(v) = \mathfrak{S}(v) \cup \mathfrak{D}(v)$.

These three sets of categories are the ones involved before and after the pruning of node v. Let us now denote by $h_m^{\mathfrak{S}'_v}$ a classifier learned from a set of sibling categories of node v and the node itself, and by $h_m^{\mathfrak{D}_v}$ a classifier learned from the set of children categories of node v ($h_\infty^{\mathfrak{S}'_v}$ and $h_\infty^{\mathfrak{D}_v}$ respectively denote their asymptotic versions). The following theorem is a direct extension of Theorems 3 and 4 to this setting.

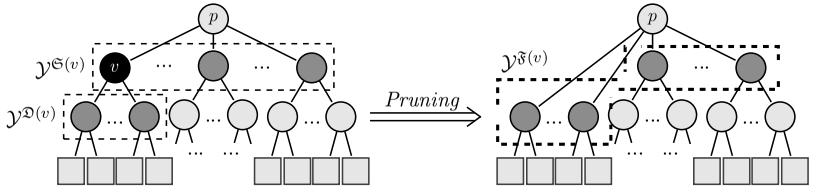

Figure 4: The pruning procedure for a candidate class node u (in black). After replacing the candidate node by its children, the new category set $\mathcal{Y}^{\mathfrak{F}(v)}$ contains the classes from both the daughter and the sister category sets of v.

Theorem 5 *Using notations from both Theorems 3 and 4, $\forall \epsilon > 0$, $v \in V \setminus \mathcal{Y}$, one has:*

$$\mathcal{E}(h_m^{\mathfrak{S}'_v}) + \mathcal{E}(h_m^{\mathfrak{D}_v}) \leq \mathcal{E}(h_\infty^{\mathfrak{S}'_v}) + \mathcal{E}(h_\infty^{\mathfrak{D}_v}) + G_{\mathfrak{S}'(v)}(\epsilon) + G_{\mathfrak{D}(v)}(\epsilon)$$

with probability at least $1 - \left(\frac{Rd^2|\mathfrak{S}'(v)|\sigma_0^{\mathfrak{S}'(v)}}{m_{\mathfrak{S}'(v)}\epsilon^2} + \frac{Rd^2|\mathfrak{D}(v)|\sigma_0^{\mathfrak{D}(v)}}{m_{\mathfrak{D}(v)}\epsilon^2}\right)$ for `MLR` classifiers and with probability at least $1 - \left(\delta_{\mathfrak{S}'(v)} + \delta_{\mathfrak{D}(v)}\right)$ for Naive Bayes classifiers, with $\delta_{\mathcal{Y}}$ defined in Theorem 3.

$\{|\mathcal{Y}^\ell|, m_{\mathcal{Y}^\ell}, \sigma_0^{\mathcal{Y}^\ell}, d_{max}^\ell, d_{min}^\ell; \mathcal{Y}^\ell \in \{\mathfrak{S}'(v), \mathfrak{D}(v)\};\}$ are constants related to the set of categories $\mathcal{Y}^\ell \in \{\mathfrak{S}'(v), \mathfrak{D}(v)\}$ and involved in the respective bounds stated in Theorem 3 and 4. Denoting by $h_m^{\mathfrak{F}_v}$ the classifier trained on the set $\mathfrak{F}(v)$ and by $h_\infty^{\mathfrak{F}_v}$ its asymptotic version, Theorem 5 suggests that one should prune node v if:

$$G_{\mathfrak{F}(v)}(\epsilon) \leq G_{\mathfrak{S}'(v)}(\epsilon) + G_{\mathfrak{D}(v)}(\epsilon) \tag{12a}$$

and, for `MLR` classifiers:

$$\frac{|\mathfrak{F}(v)|\sigma_0^{\mathfrak{F}(v)}}{m_{\mathfrak{F}(v)}} \leq \frac{|\mathfrak{S}'(v)|\sigma_0^{\mathfrak{S}'(v)}}{m_{\mathfrak{S}'(v)}} + \frac{|\mathfrak{D}(v)|\sigma_0^{\mathfrak{D}(v)}}{m_{\mathfrak{D}(v)}} \tag{12b}$$

or, for Naive Bayes classifiers:

$$\delta_{\mathfrak{F}(v)} \leq \delta_{\mathfrak{S}'(v)} + \delta_{\mathfrak{D}(v)} \tag{12c}$$

The above conditions for pruning a node v rely on the union bound and thus are not likely to be exploitable in practice. They nevertheless exhibit the factors that play an important role in assessing whether a particular trained classifier is close or not to its asymptotic version. Following Definitions 1 and 2, $G_{\mathcal{Y}}(\epsilon)$ is of the form:

$$G_{\mathcal{Y}}(\epsilon) = P_{(\mathbf{x},y)\sim\mathcal{D}}(|g_\infty(\mathbf{x}) - g_\infty(\mathbf{x})| < 2\epsilon)$$

where g corresponds to the best log-likelihood for Naive Bayes classifiers or the best class posterior for `MLR` classifiers. As it relies on the unknown distribution $\mathcal{D}$ and asymptotic log-likelihood $g_\infty()$, $G_{\mathcal{Y}}(.)$ cannot be computed directly. It however measures the confusion

Features for node $v \in V$	
1. # of classes in level ℓ, K^ℓ	2. Vocabulary size, d^ℓ
3. # of docs m^ℓ	4. d^ℓ_{min}
5. d^ℓ_{max}	6. $\frac{m^\ell}{(d^\ell+d^\ell_{max})^2}$
7. $\frac{d^\ell_{min}}{(d^\ell+d^\ell_{max})^2}$	8. $cos_{inter}(\ell)$
9. $\mathrm{KL}_{inter}(\ell)$	

Table 1: Features involved in the vector representation of a node $v \in \mathcal{H} = (V, E)$. As $\ell \in \{\mathfrak{F}(v), \mathfrak{D}(v), \mathfrak{S}(v)\}$, we have in total 27 features associated with the different category sets considered for flattening node u.

between categories and can thus be approximated by measures of the similarity between classes. We propose here to estimate this confusion with two simple quantities: the average cosine similarity of all the pairs of classes in $\mathcal{Y}$, and the average symmetric Kullback-Leibler divergences between all the pairs in $\mathcal{Y}$ according to class conditional multinomial distributions. Each node $v \in V$ when deployed with `MLR` and Naive Bayes classifiers can then be characterized by factors shown in Table 1, which are involved in the estimation of inequality (12) above.

The average cosine similarity and the average symmetric KL divergence are calculated as follows for each pair of nodes (u, v) in level l:

$$cos_{inter}(\ell) = \frac{1}{\sum_{k=1}^{K^\ell}\sum_{k'=1k'\neq k}^{K^\ell} m_{u_k^\ell} m_{v_{k'}^\ell}} \sum_{k=1}^{K^\ell}\sum_{k'=1k'\neq k}^{K^\ell} m_{u_k^\ell} m_{v_{k'}^\ell} cos(u_k^\ell, v_{k'}^\ell)$$

$$KL_{inter}(\ell) = \frac{1}{K^\ell(K^\ell-1)} \sum_{k=1}^{K^\ell}\sum_{k'=1k'\neq k}^{K^\ell} KL(Q_{u_k^\ell}||Q_{v_{k'}^\ell}) + KL(Q_{v_{k'}^\ell}||Q_{u_k^\ell}),$$

where $KL(Q_u||Q_v)$ denotes the Kullback-Leibler divergence between the class conditional probability distributions of the features present in the two classes u and v:

$$KL(Q_u||Q_v) = \sum_{w\in u,v} p(w|u) \log \frac{p(w|u)}{p(w|v)}$$

where $p(w|u)$ denotes the probability of word/feature w in class u, taking smoothing into account.

Algorithm 3 presents the process of learning the hierarchy pruning by learning a meta-classifier from the meta-features as mentioned above. The procedure for collecting training data associates a positive (resp. negative) class to a node if the pruning of that node leads to a final performance increase (resp. decrease). A meta-classifier is then trained on these features using a training set from a selected class hierarchy. After the learning phase, the meta-classifier is applied to each node of a new hierarchy of classes so as to identify which

17: end procedure
```

nodes should be pruned. A simple strategy to adopt is then to prune nodes in sequence: starting from the root node, the algorithm checks which children of a given node v should be pruned (lines 6-13) by creating the corresponding meta-instance and feeding the meta-classifier; the child that maximizes the probability of the positive class is then pruned; as the set of categories has changed, we recalculate which children of v can be pruned, prune the best one (as above) and iterate this process till no more children of v can be pruned; we then proceed to the children of v and repeat the process. The function MERGE takes as arguments the parent, the candidate children to be merged as well as the meta-classifier. It returns the index of the child that should be merged. In case where the meta-classifier does not identify any child eligible for merging then the pruning procedure continues with the next parent in the list. The meta-classifier tries to predict whether pruning a specific node will lead to an increase of the performance over 10%. That means that the classifier may identify several candidate nodes and one of them will be selected for pruning.

6. Experimental Analysis

We start our discussion by presenting results on different hierarchical datasets with different characteristics using `MLR` and `SVM` classifiers. The datasets we used in these experiments are two large datasets extracted from the International Patent Classification (**IPC**) dataset[3] and the publicly available DMOZ dataset from the second LSHTC challenge (**LSHTC2**)[4]. Both datasets are multi-class; **IPC** is single-label and **LSHTC2** multi-label with an average of 1.02 categories per class. We created 5 datasets from **LSHTC2** by splitting randomly the first layer nodes (11 in total) of the original hierarchy in disjoint subsets. The classes

Dataset	# Tr.	# Test	# Classes	# Feat.	Depth	CR	Error ratio
LSHTC2-1	25,310	6,441	1,789	145,859	6	0.008	1.24
LSHTC2-2	50,558	13,057	4,787	271,557	6	0.003	1.32
LSHTC2-3	38,725	10,102	3,956	145,354	6	0.004	2.65
LSHTC2-4	27,924	7,026	2,544	123,953	6	0.005	1.8
LSHTC2-5	68,367	17,561	7,212	192,259	6	0.002	2.12
IPC	46,324	28,926	451	1,123,497	4	0.02	12.27

Table 2: Datasets used in our experiments along with the properties: number of training examples, test examples, classes and the size of the feature space, the depth of the hierarchy and the complexity ratio of hierarchical over the flat case ($\sum_{v\in V\setminus\mathcal{Y}} |\mathfrak{D}(v)|(|\mathfrak{D}(v)|-1)/|\mathcal{Y}|(|\mathcal{Y}|-1)$), the ratio of empirical error for hierarchical and flat models.

for the **IPC** and **LSHTC2** datasets are organized in a hierarchy in which the documents are assigned to the leaf categories only. Table 2 presents the characteristics of the datasets.

CR denotes the complexity ratio between hierarchical and flat classification, given by the Rademacher complexity term in Theorem 1: $\left(\sum_{v\in V\setminus\mathcal{Y}} |\mathfrak{D}(v)|(|\mathfrak{D}(v)|-1)\right) / (|\mathcal{Y}|(|\mathcal{Y}|-1))$; the same constants B, R and L are used in the two cases. As one can note, this complexity ratio always goes in favor of the hierarchical strategy, although it is 2 to 10 times higher on the **IPC** dataset, compared to **LSHTC2-1,2,3,4,5**. On the other hand, the ratio of empirical errors (last column of Table 2) obtained with top-down hierarchical classification over flat classification when using `SVM` with a linear kernel is this time higher than 1, suggesting the opposite conclusion. The error ratio is furthermore really important on **IPC** compared to **LSHTC2-1,2,3,4,5**. The comparison of the complexity and error ratios on all the datasets thus suggests that the flat classification strategy may be preferred on **IPC**, whereas the hierarchical one is more likely to be efficient on the **LSHTC** datasets. This is indeed the case, as is shown below.

To test our simple node pruning strategy, we learned binary classifiers aiming at deciding whether to prune a node, based on the node features described in the previous section. The label associated to each node in this training set is defined as +1 if pruning the node increases the accuracy of the hierarchical classifier by at least 0.1, and -1 if pruning the node decreases the accuracy by more than 0.1. The threshold at 0.1 is used to avoid too much noise in the training set. The meta-classifier is then trained to learn a mapping from the vector representation of a node (based on the above features) and the labels $\{+1; -1\}$. We used the first two datasets of **LSHTC2** to extract the training data while **LSHTC2-3**, **4**, **5** and **IPC** were employed for testing.

The procedure for collecting training data is repeated for the `MNB`, `MLR` and `SVM` classifiers resulting in three meta-datasets of 119 (19 positive and 100 negative), 89 (34 positive and 55 negative) and 94 (32 positive and 62 negative) examples respectively. For the binary classifiers, we used AdaBoost with random forest as a base classifier, setting the number of trees to 20, 50 and 50 for the `MNB`, `MLR` and `SVM` classifiers respectively and leaving the other parameters at their default values. Several values have been tested for the number

of trees ({10, 20, 50, 100 and 200}), the depth of the trees ({unrestricted, 5, 10, 15, 30, 60}), as well as the number of iterations in AdaBoost ({10, 20, 30}). The final values were selected by cross-validation on the training set (**LSHTC2-1** and **LSHTC2-2**) as the ones that maximized accuracy and minimized false-positive rate in order to prevent degradation of accuracy. For example, Table 6 presents the true positive and false positive rates for the two classes for the meta-dataset of `MLR`.

Class	TP rate	FP rate
Prune (+1)	0.737	0.020
Do not prune (-1)	0.980	0.263

Table 3: True positive and false positive rates for the `MLR` meta-daset (119 examples).

We consider three different classifiers which include Multinomial Naive Bayes (`MNB`), Multi-class Logistic Regression (`MLR`) and Support Vector Machine (`SVM`) classifiers. The configurations of the taxonomy that we consider are fully flat classifier (FL), fully hierarchical (FH) top-down *Pachinko* machine, a random pruning (RN), and the two proposed pruning methods which include (i) Bound-based pruning strategy (PR-B) given in Section 4 and (ii) Meta-learning based pruning strategy (PR-M) proposed in Algorithm 3. For the PR-M pruning method, our experimental setup involves two scenarios: (i) The meta-classifier is trained over one kind of DMOZ hierarchy (LSHTC2-1, and LSHTC-2) and tested over another DMOZ hierarchy (LSHTC-3, LSHTC-4 and LSHTC-5), such that both sets have similar characteristics, and secondly, (ii) The meta-classifier is trained over one set of DMOZ hierarchy (LSHTC2-1, and LSHTC-2) and tested over IPC hierarchy which is derived from a different domain (patent classification) such that both sets have much less common characteristics. In this sense, our meta-classifier could learn to learn over one doamin and apply the learnt knowledge to another domain. For the random pruning we restrict the procedure to the first two levels and perform randomly prune 4 nodes (this is the average number of nodes that are pruned in the PR-M and PR-B strategies). We also present results for another pruning strategy proposed in our earlier work (Babbar et al., 2013b) which is based on error analysis of Perceptron Decision Trees (Bennett et al., 2000), and is referred to as PR-P. The results for the naive pruning method based on estimate on a validation set (as described in Section 4.1) are also presented, and referred to as PR-V. For each dataset we perform 5 independent runs for the random pruning and we record the best performance. For `MLR` and `SVM`, we use the LibLinear library (Fan et al., 2008) and use squared hinge-loss with $L2$-regularized versions, setting the penalty parameter C by cross-validation.

6.1 Flat versus Hierarchical classification

The classification error results on the test set of **LSHTC2-3,4,5** and **IPC** are reported in Table 4. On all **LSHTC** datasets flat classification performs worse than the fully hierarchy top-down classification, for all classifiers. These results are in line with complexity and empirical error ratios for `SVM` estimated on different collections and shown in table 2 as well as with the results obtained in Liu et al. (2005); Dumais and Chen (2000) over the same type

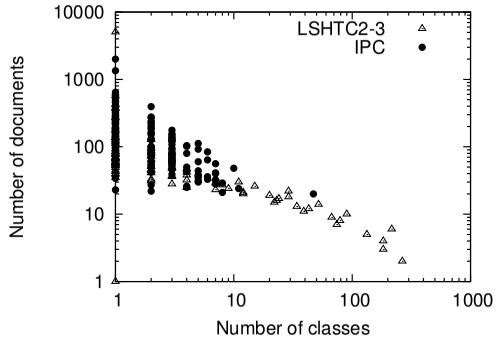

Figure 5: Number of classes (on X-axis) which have the specified number of documents (on Y-axis) for **LSHTC2-3** dataset and **IPC** dataset

of taxonomies. Further, the work by Liu et al. (2005) demonstrated that class hierarchies on **LSHTC** datasets suffer from *rare categories* problem, i.e., 80% of the target categories in such hierarchies have less than 5 documents assigned to them. The value for Macro-F1 measure which weighs all leaf-level classes equally (in contrast to Micro-F1 which weighs each example in the test set equally) is given in Table 5. Macro-F1 measure is particularly interesting when dealing with datasets consisting of rare-categories, which is typically the case in most naturally occurring category systems such as DMOZ and Wikipedia.

As a result, flat methods on such datasets face unbalanced classification problems which results in smaller error ratios; hierarchical classification should be preferred in this case. On the other hand, for hierarchies such as the one of **IPC**, which are relatively well balanced

and do not suffer from the rare categories phenomenon, flat classification performs at par or even better than hierarchical classification. The difference in the distribution of data among leaf-level categories for the **LSHTC** datasets and **IPC** dataset is illustrated in Figure 5 on log-log scale. As one can note, in most categories **IPC** have a lot (from tens to few hundreds) of documents which belong to them as denoted by the triangles. On the other hand, **LSHTC2-3** dataset has a lot of classes with a small number (1 or 2) of documents as shown by the high concentration of solid dots near the Y-axis. In this respect, the fit to power-law distribution of documents among categories in large-scale taxonomies has also been studied recently (Babbar et al., 2014a). The relative performance between the flat and top-down approaches on the two kinds of datasets is in agreement with the conclusions obtained in recent studies in which the datasets considered do not have *rare categories* and are more well-balanced (Bengio et al., 2010; Gao and Koller, 2011; Perronnin et al., 2012; Deng et al., 2011).

We would also like to mention that using the top-down classification for mono-label prediction, we obtained an accuracy of 36.6% on the original LSHTC2 dataset. On the other hand, the top approach was a neural network based approach which used the echo-state network, and achieved an accuracy of 38.8%. Unlike the participants in LSHTC whose goal was to maximize the accuracy by using techniques such as ensemble methods and feature engineering, our goal in this work is to theoretical analyze flat versus hierarchical classification and extend the framework for performing taxonomy adaptation. Furthermore, the original LSHTC2 dataset was mildly multi-label, and since our top-down prediction algorithm predicts only a single label, we would loose some performance as compared to algorithms which are aimed towards making multi-label predictions.

6.2 Effect of pruning

The proposed hierarchy pruning strategies aim to adapt the given taxonomy structure for better classification while maintaining the ancestor-descendant relationship between a given pair of nodes. We compare the four pruning strategies, (i) first, based on estimation

on a validation set (PR-V) as given in Section 4.1, (ii) second, based on minimizing the Rademacher-based generalization error bound (PR-B) as given in Section 4.2, (iii) third, based on meta-learning (PR-M) as described in Section 5, and (iv) fourth, based on a method presented by Babbar et al. (2013b) (PR-P) against the random pruning (RN) and fully hierarchical (FH) classification. As shown in Table 4, the proposed pruning strategies lead to statistically significant better results for all three classifiers compared to both the original taxonomy and a randomly pruned one. Since Rademacher-bound based pruning strategy, PR-B, is similar to PR-P proposed by Babbar et al. (2013b), they have almost similar performance on most datasets. A similar result is reported by Wang and Lu (2010) through a pruning of an entire layer of the hierarchy, which can be seen as a generalization, even though empirical in nature, of the pruning strategy retained here. Another interesting approach to modify the original taxonomy is presented by Zhang et al. (2006). In this study, three other elementary modification operations are considered, again with an increase of performance. It is also worth noticing that the pruning strategy based on estimation on a validation set also leads to improvement in classification accuracy. However, as discussed earlier, the method is computationally expensive and unlike the meta-learning based pruning method, this does not amount to a learning algorithm which can be applied to unseen but similar taxonomies.

For `MNB` classifier, one can notice that the proposed pruning method (PR-M) based on meta-learning has the best performance in all datasets achieving significantly better results compared to its rivals. This shows that flattening the hierarchy can boost the performance, even in situations where the fully hierarchical classifier is better than its flat version (this is the case for all the datasets considered for `MNB`). The random pruning achieves slightly better accuracies than FH in **LSHTC2-3** and **IPC** datasets, but is in general in between the performance of the flat classifier and its fully hierarchical version. Statistical significance tests report significant differences in favor of the proposed approach for pruning. We also observe that all hierarchical methods consistently outperform the flat case. This is an expected result as the flat `MNB` classifier suffers from the problem of unbalanced data. The difference between the performance of the flat `MNB` classifier and its hierarchical versions is less marked for the **IPC** dataset.

For `MLR` and `SVM` classifiers, both pruning approaches have better performance in all datasets compared to its rivals, the difference being significant in all cases but with the flat classifier on **IPC**. One can also notice that due to the balanced nature of the **IPC** dataset, the performance of the flat classifier is close to that of hierarchical methods. For the same reason, random pruning is also more effective in the **IPC** dataset as compared to other datasets. Comparing the respective behaviors of the `MLR` and `SVM` against `MNB`, one can note that `MLR` and `SVM` are more robust to variations in the taxonomy as compared to `MNB`. This is reflected in much lesser variation in the accuracy for these classifiers under different configurations of the hierarchy. Lastly, and not surprisingly, the performance of `MLR` and `SVM` are much better than that of `MNB` on all the datasets considered here.

Here we would like to stress that we follow a greedy strategy in both the pruning methods (PR-B and PR-M) which rank the sibling nodes in the order these should be pruned. In case of PR-B, this is measured using the confusion $C(v)$ for each node and for PR-M, this is given by the confidence of the meta-classifier which return this as a probability estimate. This is due to the fact that picking up the optimal subset of nodes to prune from

all possible subsets of children nodes (say K') would require considering all possible $2^{K'}$ subsets. Furthermore, considering all possible orders to pick the nodes one-by-one would require considering all possible permutations of ordering. Both of these have exponential computational complexity in the number of children nodes.

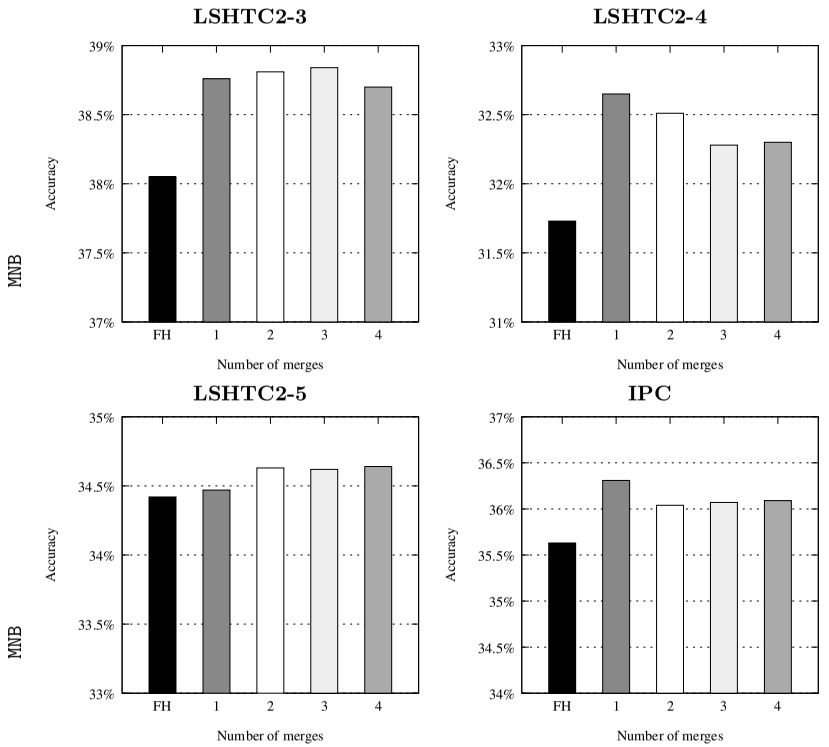

Figure 6: Accuracy performance with respect to the number of pruned nodes for `MNB` on different test sets.

6.3 Effect of number of pruned nodes for meta-learning based pruning strategy

For studying how the performance changes according to the number of pruned nodes, we record the accuracy of the proposed pruning method for 1 to 4 number of prunings. Note that pruning of nodes is done in sequence and is not independent. The results for both

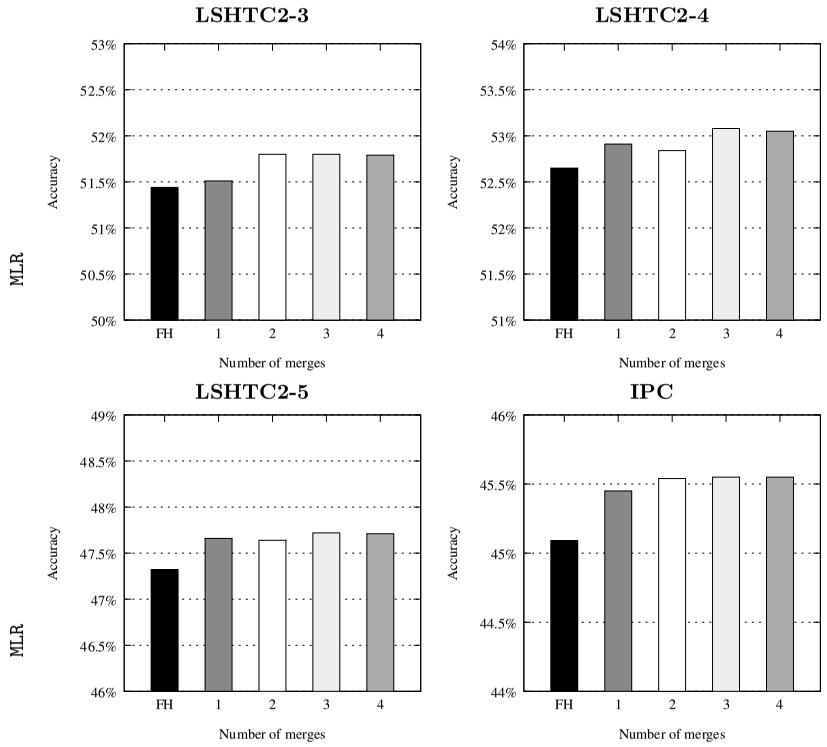

Figure 7: Accuracy performance with respect to the number of pruned nodes for MLR (down) on different test sets.

MNB and MLR are depicted in Figures 6 and 7, with a comparison to the FH method. The comparison with SVM is not explicitly shown as its behavior is similar to MLR classifier.

Interestingly, across all datasets, the proposed method has better performance than FH for all number of pruning nodes for both MNB and MLR. This shows that the proposed method is able to select appropriate nodes in the hierarchy for pruning. Additionally, we note that in the majority of cases the first pruned node provides a higher increase in accuracy than the following nodes. This is an expected behavior as the first prunings are typically performed at the upper level and thus tend to have a higher impact (as they will be used in more in the classification of more documents) than the nodes pruned done at lower levels. We want to stress here the fact that the performance with respect to the number of pruned nodes is affected by several factors, as the accuracy of the meta-classifier, the level of the hierarchy

Dataset	Logistic			Hinge		
	PR-M	LOMTree	FilterTree	PR-M	LOMTree	FilterTree

LSHTC2-4	46.9	72.7	73.6	47.2	72.7	72.6
LSHTC2-5	52.2	72.0	72.7	52.3	70.5	71.0
IPC	54.4	73.9	65.1	50.7	68.8	67.1

Table 6: Comparison of classification errors for the proposed pruning method (PR-M) with approaches that build the hierarchical structure.

where the nodes are pruned and their sequence. For example, in dataset **LSHTC2-4** (Figure 6), there is a drop of performance after the first flattening which we believe is due to false positives provided by the meta-classifier. As shown for MLR in Figure 7 and across all datasets that the behavior of the pruning method is more stable without decrease in the final performance.

6.4 Building Taxonomy

We also compare the proposed method with approaches that construct a hierarchy with logarithmic depth over the labels of the problem. Such methods are extremely useful in cases where there is no hierarchical structured information available. More specifically, we compare with LOMTree (Choromanska and Langford, 2014) and FilterTree (Beygelzimer et al., 2009b), both implemented in the Vowpal Wabbit open source system.[5] LOMTree creates binary trees assigning each time the examples to the two respective children of a parent node. When the algorithm decides to create a leaf node it assigns the target label from $\mathcal{Y}$ that corresponds to the most frequent one amongst the examples reaching that node. On the other hand FilterTree follows a bottom-up partition process. For both methods we experiment with hinge and logistic loss functions using different step sizes ($\{0.15, 0.25, 0.5, 0.75, 1, 2, 4, 8\}$) and up to 32 passes through the data. For the LOMTree we use different settings for final number of non-leaf nodes and for the swap resistance. Finally, for both methods we use bit precision of 30.

Table 6.4 presents the error rate for the pruning algorithm PR-M and the tree approaches LOMTree and FilterTree across all the datasets for logistic and hinge loss functions. In all cases PR-M which is based on the provided hierarchy outperforms the tree construction approaches having a large difference in their errors. The results strongly indicate that in the cases where the hierarchy is provided it is preferable to use in order to perform logarithmic prediction rather than constructing it as it leads to loss of accuracy.

7. Conclusion

We have studied in this paper flat and hierarchical classification strategies from a learning-theoretic view point in the context of large-scale taxonomies, through error generalization

5. http://hunch.net/vw

bounds of multiclass, hierarchical classifiers. The first theorem we have introduced provides an explanation to several empirical results related to the performance of such classifiers. We also introduced two methods to simplify a taxonomy by selectively pruning some of its nodes, (i) by exploiting the bound developed in the first theorem, and (ii) by designing a meta-learning technique which is based on the features derived from the approximation-error based generalization bounds proposed in Sections 5.1 and 5.2. The experimental results reported here (as well as in other papers) are in line with our theoretical developments and justify the pruning strategy adopted.

In addition to theoretically addressing the flat versus top-down classification for large-scale taxonomies, the focus of this work is also on the problem of aligning the taxonomy of classes to the set of input-output pairs. This can be useful in designing better taxonomies for large-scale classification problems. Lastly, this suggests that our theoretical development can also be exploited to grow a hierarchy of classes from a (large) set of categories, as has been done in several studies (like for example Bengio et al. (2010); Choromanska and Langford (2014)). We plan to explore this in future work.

Acknowledgments

This work was supported in part by the ANR project Class-Y, the Mastodons project Garguantua, the LabEx PERSYVAL-Lab ANR-11-LABX-0025 and the European project BioASQ (grant agreement no. 318652). The authors sincerely thank the anonymous reviewers for providing valuable feedback which has led to considerable improvement in the content of this paper.

Abstract

This work analyzes centered Restricted Boltzmann Machines (RBMs) and centered Deep Boltzmann Machines (DBMs), where centering is done by subtracting offset values from visible and hidden variables. We show analytically that (i) centered and normal Boltzmann Machines (BMs) and thus RBMs and DBMs are different parameterizations of the same model class, such that any normal BM/RBM/DBM can be transformed to an equivalent centered BM/RBM/DBM and *vice versa*, and that this equivalence generalizes to artificial neural networks in general, (ii) the expected performance of centered binary BMs/RBMs/DBMs is invariant under simultaneous flip of data and offsets, for any offset value in the range of zero to one, (iii) centering can be reformulated as a different update rule for normal BMs/RBMs/DBMs, and (iv) using the enhanced gradient is equivalent to setting the offset values to the average over model and data mean. Furthermore, we present numerical simulations suggesting that (i) optimal generative performance is achieved by subtracting mean values from visible as well as hidden variables, (ii) centered binary RBMs/DBMs reach significantly higher log-likelihood values than normal binary RBMs/DBMs, (iii) centering variants whose offsets depend on the model mean, like the enhanced gradient, suffer from severe divergence problems, (iv) learning is stabilized if an exponentially moving average over the batch means is used for the offset values instead of the current batch mean, which also prevents the enhanced gradient from severe divergence, (v) on a similar level of log-likelihood values centered binary RBMs/DBMs have smaller weights and bigger bias parameters than normal binary RBMs/DBMs, (vi) centering leads to an update direction that is closer to the natural gradient, which is extremely efficient for training as we show for small binary RBMs, (vii) centering eliminates the need for greedy layer-wise pre-training of DBMs, which often even deteriorates the results independently of whether centering is used or not, and (ix) centering is also beneficial for auto encoders.

Keywords: centering, restricted Boltzmann machine, deep Boltzmann machine, generative model, artificial neural network, auto encoder, enhanced gradient, natural gradient, stochastic maximum likelihood, contrastive divergence, parallel tempering

1. Introduction

In the last decade Restricted Boltzmann Machines (RBMs) got into the focus of attention because they can be considered as building blocks of deep neural networks (Hinton et al., 2006; Bengio, 2009). RBM training methods are usually based on gradient ascent on the Log-Likelihood (LL) of the model parameters given the training data. Since the gradient is intractable, it is often approximated using Gibbs sampling with only a few steps (Hinton et al., 2006; Tieleman, 2008; Tieleman and Hinton, 2009). Two major problems have been reported when training RBMs.

Firstly, the bias of the gradient approximation introduced by using only a few steps of Gibbs sampling may lead to a divergence of the LL during training (Fischer and Igel, 2010; Schulz et al., 2010; Fischer and Igel, 2011). To overcome the divergence problem Desjardins et al. (2010) and Cho et al. (2010) have proposed to use parallel tempering (Swendsen and Wang, 1986), which is an advanced sampling method that leads to a faster mixing Markov chain and thus to a better approximation of the LL gradient.

Secondly, the learning process is not invariant to the data representation. For example training an RBM on the *MNIST* data set leads to a better model than training it on *1-MNIST* (the data set generated by flipping each bit in *MNIST*). This is due to missing invariance properties of the gradient with respect to these flip transformations and not due to the model's capacity, since an RBM trained on *MNIST* can be transformed in such a way that it models *1-MNIST* with the same LL. Recently, two approaches have been introduced that address this invariance problem. The enhanced gradient (Cho et al., 2011, 2013b) has been designed as an invariant alternative to the true LL gradient of binary RBMs and has been derived by calculating a weighted average over the gradients one gets by applying any possible bit flip combination on the data set. Empirical results suggest that the enhanced gradient leads to more distinct features and thus to better classification results based on the learned hidden representation of the data. Furthermore, in combination with an adaptive learning rate the enhanced gradient leads to more stable training in the sense that good LL values are reached independently of the initial learning rate. Tang and Sutskever (2011) on the other hand have shown empirically that subtracting the data mean from the visible variables leads to a model that can reach similar LL values on the *MNIST* and the *1-MNIST* data set and comparable results to those of the enhanced gradient.[1] Removing the mean from all variables is known as the 'centering trick', which was originally proposed for feed forward neural networks (LeCun et al., 1998; Schraudolph, 1998). It has recently also been applied to the visible and hidden variables of Deep Boltzmann Machines (DBM) (Montavon and Müller, 2012) where it has been shown to lead to a better conditioned optimization problem. Furthermore, the learned features have shown better discriminative properties and centering has improved the generative properties of locally connected DBMs. A related approach applicable to multi-layer perceptrons where the activation functions of the neurons are transformed to have zero mean and zero slope on average has been proposed by Raiko et al. (2012). The authors could show that the gradient under this transformation gets closer to the natural gradient, which is desirable since the natural gradient follows the direction of steepest ascent in the manifold of probability distributions. Furthermore, the natural gradient is independent of the concrete parameterization of the distributions and is thus clearly the update direction of choice (Amari, 1998). Since the exact natural gradient is intractable already for rather small RBMs, Schwehn (2010) and Ollivier et al. (2011) have trained binary RBMs and Desjardins et al. (2013) binary DBMs using approximations of the natural gradient obtained by Markov chain Monte Carlo methods. However, due to

1. Note that changing the model such that the mean of the visible variables is removed is not equivalent to just removing the mean of the data.

the computational overhead the practical relevance of the natural gradient for RBM/DBM training remains questionable. Another approach related to the centering trick is batch normalization, which has recently been proposed by Ioffe and Szegedy (2015) and aims at removing first and second order statistics of the pre synaptic activation in a feed forward network.

In this article[2] we give a unified view on centering, revealing that the methods proposed by Cho et al. (2011), Tang and Sutskever (2011), and Montavon and Müller (2012) can all be considered as different ways of applying the centering trick to RBMs and DBMs. Furthermore, we analyze the properties and performance of different centering variants. In Section 2, we begin with a brief overview over binary RBMs, the standard learning algorithms, the natural gradient of the LL of RBMs, and the basic ideas used to construct the enhanced gradient. In Section 3, we discuss the theoretical properties of centered RBMs, show that centering can be reformulated as a different update rule for normal RBMs, that the enhanced gradient is a particular form of centering, and finally that centering and its properties naturally extend to DBMs and BMs. Furthermore, in Section 4, we show that centering is an alternative parameterization for arbitrary Artificial Neural Networks (ANNs) in general and we discuss how the parameters of centered and normal ANNs should be initialized. Our experimental setups are described in Section 5 before we empirically analyze the performance of centered RBMs with different initializations, offset parameters, sampling methods, and learning rates in Section 6. This empirical analysis includes a comparison of the centered gradient with the natural gradient and extensive experiments on 10 real world data sets. In addition we have also performed experiments with DBMs and Auto encoders (AEs) on the 10 real work data sets. Finally our work is concluded in Section 7.

2. Restricted Boltzmann Machines

An RBM (Smolensky, 1986) is a bipartite undirected graphical model with a set of N visible and M hidden variables taking values $\mathbf{x} = (x_1, ..., x_N)$ and $\mathbf{h} = (h_1, ..., h_M)$, respectively. Since an RBM is a Markov random field, its joint probability distribution is given by a Gibbs distribution

$$p(\mathbf{x}, \mathbf{h}) = \frac{1}{Z} \mathrm{e}^{-E(\mathbf{x},\mathbf{h})} ,$$

with partition function Z and energy $E(\mathbf{x}, \mathbf{h})$. For binary RBMs, $\mathbf{x} \in \{0,1\}^N$, $\mathbf{h} \in \{0,1\}^M$, the energy, which defines the bipartite structure, is given by

$$E(\mathbf{x}, \mathbf{h}) = -\mathbf{x}^T \mathbf{b} - \mathbf{c}^T \mathbf{h} - \mathbf{x}^T \mathbf{W} \mathbf{h} ,$$

where the weight matrix $\mathbf{W}$, the visible bias vector $\mathbf{b}$, and the hidden bias vector $\mathbf{c}$ are the parameters of the model, jointly denoted by $\boldsymbol{\theta}$. The partition function, which sums over all possible visible and hidden states, is given by

$$Z = \sum_{\mathbf{x}} \sum_{\mathbf{h}} \mathrm{e}^{-E(\mathbf{x},\mathbf{h})} .$$

2. Previous versions of this work have been published as an eprint (Melchior et al., 2013) and as part of the PhD thesis by Fischer (2014).

RBM training is usually based on gradient ascent using approximations of the LL gradient

$$\nabla \boldsymbol{\theta} = \frac{\partial \langle \log(p(\mathbf{x}|\boldsymbol{\theta})) \rangle_d}{\partial \boldsymbol{\theta}} = -\left\langle \frac{\partial E(\mathbf{x}, \mathbf{h})}{\partial \boldsymbol{\theta}} \right\rangle_d + \left\langle \frac{\partial E(\mathbf{x}, \mathbf{h})}{\partial \boldsymbol{\theta}} \right\rangle_m ,$$

where $\langle \cdot \rangle_m$ is the expectation under $p(\mathbf{x}, \mathbf{h})$ and $\langle \cdot \rangle_d$ is the expectation under $p(\mathbf{h}|\mathbf{x}) p_e(\mathbf{x})$ with empirical distribution p_e. We use the notation $\nabla \boldsymbol{\theta}$ for the derivative of the LL with respect to $\boldsymbol{\theta}$ in order to be consistent with the notation used by Cho et al. (2011). For binary RBMs the gradient becomes

$$\begin{aligned} \nabla \mathbf{W} &= \langle \mathbf{x}\mathbf{h}^T \rangle_d - \langle \mathbf{x}\mathbf{h}^T \rangle_m , \\ \nabla \mathbf{b} &= \langle \mathbf{x} \rangle_d - \langle \mathbf{x} \rangle_m , \\ \nabla \mathbf{c} &= \langle \mathbf{h} \rangle_d - \langle \mathbf{h} \rangle_m . \end{aligned}$$

Common RBM training methods approximate $\langle \cdot \rangle_m$ by samples gained by different Markov chain Monte Carlo methods. Sampling k (usually $k = 1$) steps from a Gibbs chain initialized with a data sample yields Contrastive Divergence (CD) (Hinton et al., 2006). In stochastic maximum likelihood (Younes, 1991), in the context of RBMs also known as Persistent Contrastive Divergence (PCD) (Tieleman, 2008), the chain is not reinitialized with a data sample after parameter updates. This has been reported to lead to better gradient approximations if the learning rate is chosen sufficiently small. Fast Persistent Contrastive Divergence (FPCD) (Tieleman and Hinton, 2009) tries to further speed up learning by introducing an additional set of parameters, that is only used for Gibbs sampling during learning. The advanced sampling method Parallel Tempering (PT) (Swendsen and Wang, 1986) introduces additional 'tempered' Gibbs chains corresponding to smoothed versions of $p(\mathbf{x}, \mathbf{h})$. The energy of these distributions is multiplied by $\frac{1}{T}$, where T is referred to as temperature. The higher the temperature of a chain, the 'smoother' the corresponding distribution and the faster the chain mixes. Samples may swap between chains with a probability given by the Metropolis Hastings ratio, which leads to better mixing of the original chain with temperature $T = 1$ (a first theoretical analysis of the mixing rate of PT for sampling in RBMs has been given by Fischer and Igel, 2015). We use PT_c to denote the RBM training algorithm that uses Parallel Tempering with c tempered chains as a sampling method. Usually only one step of Gibbs sampling is performed in each tempered chain before allowing samples to swap, and a deterministic even odd algorithm (Lingenheil et al., 2009) is used as a swapping schedule. PT_c increases the mixing rate and has been reported to achieve better gradient approximations than CD and (F)PCD (Desjardins et al., 2010; Cho et al., 2010) with the drawback of having a higher computational cost.

See the introductory paper of Fischer and Igel (2014) for a recent review of RBMs and their training algorithms.

2.1 Enhanced Gradient

Cho et al. (2011) have proposed a different way to update parameters during training of binary RBMs, which is invariant to the data representation.

When transforming the state $(\mathbf{x}, \mathbf{h})$ of a binary RBM by flipping some of its variables (that is $\tilde{x}_i = 1 - x_i$, and $\tilde{h_j} = 1 - h_j$ for some i, j), yielding a new state $(\tilde{\mathbf{x}}, \tilde{\mathbf{h}})$, one can

transform the parameters $\boldsymbol{\theta}$ of the RBM to $\tilde{\boldsymbol{\theta}}$ such that $E(\mathbf{x}, \mathbf{h}|\boldsymbol{\theta}) = E(\tilde{\mathbf{x}}, \tilde{\mathbf{h}}|\tilde{\boldsymbol{\theta}}) + const$ and thus $p(\mathbf{x}, \mathbf{h}|\boldsymbol{\theta}) = p(\tilde{\mathbf{x}}, \tilde{\mathbf{h}}|\tilde{\boldsymbol{\theta}})$. However, if we update the parameters of the transformed model based on the corresponding LL gradient to $\tilde{\boldsymbol{\theta}}' = \tilde{\boldsymbol{\theta}} + \eta \nabla \tilde{\boldsymbol{\theta}}$ and apply the inverse parameter transformation to $\tilde{\boldsymbol{\theta}}'$, the result differs from $\boldsymbol{\theta}' = \boldsymbol{\theta} + \eta \nabla \boldsymbol{\theta}$. The described procedure of transforming, updating, and transforming back can be regarded as a different way to update $\boldsymbol{\theta}$.

Following this line of thought there exist 2^{N+M} different parameter updates corresponding to the 2^{N+M} possible binary flips of $(\mathbf{x}, \mathbf{h})$. Cho et al. (2011) have proposed the enhanced gradient as a weighted sum of these 2^{N+M} parameter updates, which for their choice of weighting is given by

$$\nabla_e \mathbf{W} = \langle (\mathbf{x} - \langle \mathbf{x} \rangle_d)(\mathbf{h} - \langle \mathbf{h} \rangle_d)^T \rangle_d - \langle (\mathbf{x} - \langle \mathbf{x} \rangle_m)(\mathbf{h} - \langle \mathbf{h} \rangle_m)^T \rangle_m \ , \tag{1}$$

$$\nabla_e \mathbf{b} = \langle \mathbf{x} \rangle_d - \langle \mathbf{x} \rangle_m - \nabla_e \mathbf{W} \frac{1}{2} \left(\langle \mathbf{h} \rangle_d + \langle \mathbf{h} \rangle_m \right) \ , \tag{2}$$

$$\nabla_e \mathbf{c} = \langle \mathbf{h} \rangle_d - \langle \mathbf{h} \rangle_m - \nabla_e \mathbf{W}^T \frac{1}{2} \left(\langle \mathbf{x} \rangle_d + \langle \mathbf{x} \rangle_m \right) \ . \tag{3}$$

It has been shown that the enhanced gradient is invariant to arbitrary bit flips of the variables and therefore invariant under the data representation, which has been demonstrated on the *MNIST* and *1-MNIST* data set. Furthermore, the authors have reported more stable training under various settings in terms of the LL estimate and classification accuracy.

2.2 Natural Gradient

Following the direction of steepest ascent in the Euclidean parameter space (as given by the standard gradient) does not necessarily correspond to the direction of steepest ascent in the manifold of probability distributions $\{p(\mathbf{x}|\boldsymbol{\theta}), \boldsymbol{\theta} \in \Theta\}$, which we are actually interested in. To account for the local geometry of the manifold, the Euclidean metric should be replaced by the Fisher information metric defined by $||\boldsymbol{\theta}||_{\mathcal{I}(\boldsymbol{\theta})} = \sqrt{\sum \theta_k \mathcal{I}_{kl}(\boldsymbol{\theta}) \theta_l}$, where $\mathcal{I}(\boldsymbol{\theta})$ is the Fisher information matrix (Amari, 1998). The kl-th entry of the Fisher information matrix for a parameterized distribution $p(\mathbf{x}|\boldsymbol{\theta})$ is given by

$$\boldsymbol{\mathcal{I}}_{kl}(\theta) = \left\langle \left(\frac{\partial \log \left(p(\mathbf{x}|\boldsymbol{\theta}) \right)}{\partial \theta_k} \right) \left(\frac{\partial \log \left(p(\mathbf{x}|\boldsymbol{\theta}) \right)}{\partial \theta_l} \right) \right\rangle_m \ ,$$

where $\langle \cdot \rangle_m$ denotes the expectation under $p(\mathbf{x}|\boldsymbol{\theta})$. The gradient associated with the Fisher metric is called the natural gradient and is given by

$$\nabla_n \boldsymbol{\theta} = \boldsymbol{\mathcal{I}}(\theta)^{-1} \nabla \boldsymbol{\theta} \ .$$

The inverse Fisher information matrix corrects the direction and length of the standard gradient to achieve the largest change of the objective function (here the LL) for an infinitesimal small step $\delta\boldsymbol{\theta}$ from $p(\mathbf{x}|\boldsymbol{\theta})$ to $p(\mathbf{x}|\boldsymbol{\theta}+\boldsymbol{\delta\theta})$ in terms of the Kullback-Leibler divergence (Amari, 1998). This makes the natural gradient independent of the parameterization leading to an invariance to arbitrary coordinate transformations such as flipping variables, which makes it clearly the update direction of choice.

For binary RBMs the entries of the Fisher information matrix (Amari et al., 1992; Desjardins et al., 2013; Ollivier et al., 2011) are given by

$$\begin{aligned}
\boldsymbol{\mathcal{I}}_{w_{ij},w_{uv}}(\theta) = \boldsymbol{\mathcal{I}}_{,w_{uv},w_{ij}}(\theta) &= \langle x_i h_j x_u h_v \rangle_m - \langle x_u h_v \rangle_m \langle x_u h_v \rangle_m \\
&= Cov_m(x_i h_j, x_u h_v) \ , \\
\boldsymbol{\mathcal{I}}_{w_{ij},b_u}(\theta) = \boldsymbol{\mathcal{I}}_{b_u,w_{ij}}(\theta) &= Cov_m(x_i h_j, x_u) \ , \\
\boldsymbol{\mathcal{I}}_{w_{ij},c_v}(\theta) = \boldsymbol{\mathcal{I}}_{c_v,w_{ij}}(\theta) &= Cov_m(x_i h_j, h_v) \ , \\
\boldsymbol{\mathcal{I}}_{b_i,b_u}(\theta) = \boldsymbol{\mathcal{I}}_{b_u,b_i}(\theta) &= Cov_m(x_i, x_u) \ , \\
\boldsymbol{\mathcal{I}}_{c_j,c_v}(\theta) = \boldsymbol{\mathcal{I}}_{c_v,c_j}(\theta) &= Cov_m(h_j, h_v) \ ,
\end{aligned}$$

where $Cov_m(\cdot, \cdot)$ denotes the covariance under the model distribution. Since these expressions involve expectations under the model distribution they are not tractable in general, but can be approximated using MCMC methods (Ollivier et al., 2011; Desjardins et al., 2013). Furthermore, a diagonal approximation of the Fisher information matrix could be used. However, the approximation of the natural gradient for RBMs and DBMs is still computationally very expensive so that the practical usability remains questionable (Schwehn, 2010; Ollivier et al., 2011; Desjardins et al., 2013).

3. Centered Restricted Boltzmann Machines
