Abstract

For spline regressions, it is well known that the choice of knots is crucial for the performance of the estimator. As a general learning framework covering the smoothing splines, learning in a Reproducing Kernel Hilbert Space (RKHS) has a similar issue. However, the selection of training data points for kernel functions in the RKHS representation has not been carefully studied in the literature. In this paper we study quantile regression as an example of learning in a RKHS. In this case, the regular squared norm penalty does not perform training data selection. We propose a data sparsity constraint that imposes thresholding on the kernel function coefficients to achieve a sparse kernel function representation. We demonstrate that the proposed data sparsity method can have competitive prediction performance for certain situations, and have comparable performance in other cases compared to that of the traditional squared norm penalty. Therefore, the data sparsity method can serve as a competitive alternative to the squared norm penalty method. Some theoretical properties of our proposed method using the data sparsity constraint are obtained. Both simulated and real data sets are used to demonstrate the usefulness of our data sparsity constraint.

Keywords: kernel learning, Rademacher complexity, regression, smoothing, sparsity

1. Introduction

Regression is one of the most important and commonly used statistical tools. Given a set of data points whose predictors and responses are both available, one builds a regression model to predict the response variable for any new instance with only predictors observed. When solving a regression problem, linear regression can be insufficient. In particular, when the response has highly nonlinear dependence on the predictors, linear models can be suboptimal. To overcome this difficulty, various nonlinear regression models such as kernel smoothers (see Hastie et al., 2009, for a review) and splines (De Boor, 1978) can be used. The main idea is to find a regression function in a nonlinear functional class that best fits the response variable.

In a typical spline regression problem with a univariate predictor, one can use a piecewise nonlinear function as the regression function. The function is smooth everywhere including at the knots, where the nonlinear pieces connect. The knots play a crucial role in spline regression. For the regular smoothing splines (see, for example, Wahba, 1990; Gu, 2002, and the references therein), the knots are located at the observed predictor values automatically. For some other types of spline regressions, one needs to determine the knots. For instance, B-splines (De Boor, 1978) commonly use a set of equally spaced knots, and certain types of P-splines (Eilers and Marx, 1996; Ruppert et al., 2003) take knots based on quantiles of the predictor variable.

For spline regression, it is known that too many knots may lead to overfitting and unnecessary fluctuation in the resulting estimator. For instance, based on Chappell (1989), Koenker et al. (1994) gave an example where the regular smoothing splines perform poorly because of too many change points, and the one-change-point method proposed by Chappell (1989) works much better. Extensive efforts have been devoted on how to choose the knots for B-spline and P-spline methods in the literature (see, for example, Friedman and Silverman, 1989; Eilers and Marx, 1996; Zhou et al., 1998; Ruppert, 2002; Hansen and Kooperberg, 2002; Mao and Zhao, 2003; Miyata and Shen, 2005; Gervini, 2006; Eilers and Marx, 2010, and the references therein).

In this paper, we consider multi-dimensional regression problems with the regression function in a Reproducing Kernel Hilbert Space (RKHS, Aronszajn, 1950; Schölkopf and Smola, 2002). This is a very general setting, which includes many well known regression techniques as special cases, for example penalized linear regressions, additive spline models with or without interactions, and the entire family of smoothing splines. Typically, the optimization of such a RKHS regression can be written in a *loss + penalty* form. Since the regression function is assumed to be in a RKHS, it is common to take the squared norm of the function as the penalty. By the well celebrated representer's theorem (Kimeldorf and Wahba, 1971), the resulting regression function can be represented as a linear combination of kernel functions determined by the training data.

Our motivation for this paper is based on the following observation. The kernel representation of the regression function is similar to the knot structure in smoothing splines, in the sense that each observation in the training data can be regarded as a "knot" in a multi-dimensional space. In particular, when we restrict the RKHS regression to the smoothing splines, the kernel function representation is equivalent to the piecewise nonlinear function representation. With the regular squared norm penalty, the resulting estimator involves all kernel functions on the training data. For large sample size problems, this estimator is known to be consistent with desirable theoretical properties. However, for problems with relatively smaller numbers of observations, using all kernel functions for the representation may introduce a similar issue as using too many knots in spline regressions. Hence it is desirable to have a regularization method that can select the kernel functions.

To this end, we propose a new penalty method to achieve a "data sparsity" model. Through simulation studies, we observe that for some cases, the data sparsity model can perform better than the regular squared norm penalty method, and for other cases, their performance is comparable. See Section 2 for more detailed discussions. Moreover, we provide some theoretical insights on the data sparsity method. In particular, we show that under very mild conditions, the asymptotic convergence rates of the estimation errors for the two methods are the same, and both are close to the "parametric rate". Furthermore, we give finite sample error bounds on the prediction errors for both

methods. We show that for a general RKHS and problems with small sample sizes, the bound for the squared norm penalty method can be large. On the other hand, the data sparsity method can enjoy a better bound because its corresponding functional space is smaller. Hence, we propose the data sparsity method as an alternative approach to the squared norm penalty for RKHS learning. Note that in the literature, Takeuchi et al. (2006) studied kernel based nonparametric quantile regression problems, and mentioned a similar method as a natural extension of their formulation. However, their work focused on nonparametric quantile regression, whereas the possible overfitting of the squared norm penalty wasn't brought to attention. Moreover, Takeuchi et al. (2006) didn't perform detailed theoretical or numerical studies on the data sparsity constraint. Our important contribution in this paper is to explore the similarity and (more importantly) differences between the data sparsity constraint and the regular squared norm penalty, through both numerical and theoretical studies.

In a regression problem, one needs to choose the loss function. The commonly used loss function is the squared error loss, which estimates the conditional mean of the response given the predictors. It is known that compared to the conditional mean estimation, the conditional median estimation is more robust against outliers. Therefore, in this paper, we consider quantile regression, and the loss function we use is the check function (Koenker and Bassett, 1978), although the idea of imposing data sparsity constraint is very general and can be applied to many other settings as well. Note that quantile regression with the check function provides the conditional median estimation as a special case. Another advantage is that it can provide more information on the conditional distribution of the response. Quantile regression has been widely used in many scientific fields, including survival analysis (Koenker and Geling, 2001), microarray study (Wang and He, 2007), economics (Koenker and Hallock, 2001), growth chart (Wei and He, 2006), and many others. Note that quantile regression in RKHS with the regular squared norm penalty was previously studied by Takeuchi et al. (2006) and Li et al. (2007).

In the machine learning literature, the Support Vector Machine (SVM, Boser et al., 1992; Cortes and Vapnik, 1995) and the Support Vector Regression (SVR, Drucker et al., 1997; Vapnik et al., 1997; Smola and Schölkopf, 1998; Stitson et al., 1999; Smola and Schölkopf, 2004) have been well studied and widely used as classification and regression tools. One attractive feature of the SVM and SVR is that even with the regular square norm penalty, due to the choice of the loss functions, the estimated classification function or regression function has a sparse representation in the dual space of the corresponding optimization problem. If the classification or regression function is in a RKHS, sparsity in the dual space representation is equivalent to sparsity in the kernel representation. However, with many other loss functions and the squared norm penalty, the advantage of a sparse representation is lost (Smola and Schölkopf, 2004). Our proposed data sparsity constraint is able to provide such a sparse representation for general loss functions. Note that in the Bayesian learning literature, Tipping (2001) proposed the relevance vector machines to obtain sparse solutions for regression and classification problems.

The rest of this article is organized as follows. In Section 2, we first discuss quantile regression problems under the RKHS learning, then introduce our data sparsity constraint. In Section 3, we derive theoretical results for both asymptotic and finite sample analysis of our data sparsity method. In Section 4, we discuss how to derive the solution path of the involved optimization problem with respect to the tuning parameter, and tackle the problem of tuning parameter selection. In Section 5, we demonstrate the performance of our data sparsity method, using both simulated and real data sets. Some discussions are provided in Section 6. All technical proofs are collected in the appendix.

2. Methodology

We are given the training data (x_i, y_i); $i = 1, \ldots, n$, which are observed according to the model $Y = f_0(X) + \varepsilon(X)$. Let D be the domain of f_0, and let the dimensionality of D be p. We assume that for any given X, $\varepsilon(X)$ has a finite mean. This assumption on ε is very general, in the sense that both the homoscedastic and heteroscedastic cases are covered, along with many commonly used distributions. To estimate the $100\tau\%$ quantile of the conditional distribution of Y given X for some quantile level $\tau \in (0,1)$, Koenker and Bassett (1978) proposed to use the check loss function, which can be written as

$$\rho_\tau(u) = \begin{cases} \tau u & \text{if } u > 0, \\ -(1-\tau)u & \text{if } u \le 0, \end{cases}$$

where $\tau \in (0,1)$ indicates the quantile we are interested in. It is known that for a given X, the population minimizer to the check function is the $100\tau\%$ conditional quantile. For a given τ, suppose that $f_{\text{true}}(X)$ is the population minimizer to the check function. Note that in general $f_0 \neq f_{\text{true}}$. A regular quantile regression problem can be typically formulated in terms of the following optimization

$$\min_{f \in \mathcal{F}} \frac{1}{n} \sum_{i=1}^{n} \rho_\tau\big(y_i - f(x_i)\big) + \lambda J(f), \tag{1}$$

where $\mathcal{F}$ is the functional class we are interested in, $J(\cdot)$ is a penalty on f to prevent overfitting, and λ is a tuning parameter that controls the magnitude of $J(\cdot)$. With $p = 1$, $J(f) = \int |\frac{d^2 f(x)}{dx^2}| dx$, and an appropriately chosen $\mathcal{F}$, Koenker et al. (1994) showed that the solution to (1) is a linear spline with knots at x_i; $i = 1, \ldots, n$.

In this article, we consider the case with $p \ge 1$ and the regression function in a RKHS, which is a more general setting than the regular smoothing splines. To begin with, we introduce some notations. A summary of important notations used in this paper can be found in Tables 11-14. Assume $\mathcal{F} = \{f = f' + b : f' \in \mathcal{H},\ b \in \mathbb{R}\}$, where $\mathcal{H}$ is a RKHS over X with the kernel function $K(\cdot,\cdot)$, and b is the intercept of the regression function. Throughout this paper, we use the notation f' for any function when it belongs to a RHKS without an extra intercept term. This definition of $\mathcal{F}$ allows a more flexible setting than $\mathcal{F} = \mathcal{H}$, because some RKHS's, for example the very popular Gaussian RKHS, do not include non-zero constant functions (Minh, 2010). In this paper, without loss of generality we assume each $f \in \mathcal{F}$ can be uniquely decomposed as $f' + b$. Let the norm in $\mathcal{H}$ be $\|\cdot\|_{\mathcal{H}}$. For more detailed discussions about $\mathcal{H}$ and $\|\cdot\|_{\mathcal{H}}$, we refer the readers to Aronszajn (1950), Wahba (1999), Schölkopf and Smola (2002), Steinwart et al. (2006), Hofmann et al. (2008), Minh (2010), and the references therein. Furthermore, we assume that the RKHS $\mathcal{H}$ is separable, and the kernel function $K(\cdot,\cdot)$ is upper bounded by 1. Our theory can be generalized to the case where $\sup_{X_1, X_2} K(X_1, X_2) < \infty$. Note that a similar assumption was previously used in Steinwart and Scovel (2007) and Blanchard et al. (2008). With a little abuse of notation, we define K to be the n by n matrix $\Big(K(x_i, x_j)\Big)$; $i, j = 1, \ldots, n$, which we call the gram matrix.

The quantile regression with the regular squared norm penalty (Takeuchi et al., 2006; Li et al., 2007) solves

$$\min_{f \in \mathcal{F}} \frac{1}{n} \sum_{i=1}^{n} \rho_\tau\big(y_i - f(x_i)\big) + \lambda \|f'\|_{\mathcal{H}}^2. \tag{2}$$

By the representer's theorem, the solution to (2) can be written as

$$\tilde{f}_n(x) = \tilde{f}_n'(x) + \tilde{b} = \sum_{i=1}^{n} \tilde{\alpha}_i K(x_i, x) + \tilde{b}, \tag{3}$$

where $K(x_i,\cdot)$ is the i^{th} kernel function from the training sample, and $\tilde{\alpha} = (\tilde{\alpha}_1, \ldots, \tilde{\alpha}_n)^T$ is the estimated kernel function coefficient vector. In this paper, to clarify notation, we denote the estimated function using the squared norm penalty by $\tilde{f}_n$, and the estimated function using our proposed data sparsity constraint by $\hat{f}_n$. Because $\tilde{f}_n$ possesses such a finite form, (2) can be equivalently written as

$$\min_{\alpha,b} \frac{1}{n} \sum_{i=1}^{n} \rho_\tau\{y_i - \big(\sum_{j=1}^{n} \alpha_j K(x_i, x_j) + b\big)\} + \lambda \alpha^T K \alpha. \tag{4}$$

Li et al. (2007) provided a solution path for (4), with respect to the tuning parameter λ.

For many commonly used kernel functions, we can assume that the gram matrix K is positive definite (Paulsen, 2009). Hence for any α_i; $i = 1, \ldots, n$, the penalty $\alpha^T K \alpha$ in (4) constrains α in an ellipsoid, which does not have any singularity at $\alpha_i = 0$. This is illustrated on the left panel of Figure 1. Note that in the linear learning literature, Fan and Li (2006) discussed the effect of singularity of penalties on variable selection. Similarly, in RKHS regression problems, because the regular squared norm penalty does not have any singularity at $\alpha_i = 0$, it does not perform "kernel function selection". As a result, the estimated $\tilde{\alpha}_i \neq 0$ for all $i = 1, \ldots, n$.

As discussed in Section 1, it is desirable to have a method that can deliver estimators with a sparse kernel function representation. To this end, we propose to penalize directly on the kernel function coefficients α such that some estimated α_i's will be set to 0. The details of our method are as follows. By the representer's theorem (Kimeldorf and Wahba, 1971), the estimated $\tilde{f}_n$ in (4) lies in a space linearly spanned by $K(x_i,\cdot)$; $i = 1, \ldots, n$, and $\tilde{\alpha}$ is constrained in an ellipsoid. To obtain a data-sparsely represented function, we propose to constrain α in an L_1 ball. In other words, we solve the following optimization problem with the data sparsity constraint

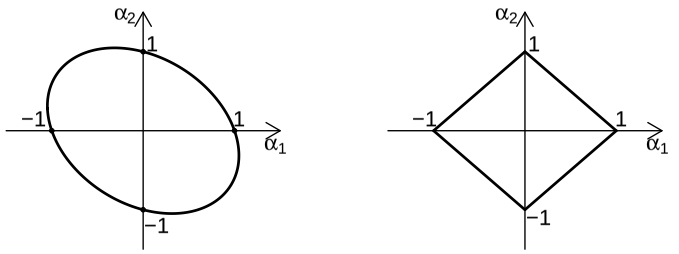
$$\min_{\alpha,b} \frac{1}{n} \sum_{i=1}^{n} \rho_\tau\big(y_i - f(x_i)\big), \text{ subject to } |b| + \sum_{i=1}^{n} |\alpha_i| \leq s, \tag{5}$$

where $s > 0$ is the tuning parameter. Note that Takeuchi et al. (2006) briefly mentioned a possible natural extension of their method that is similar to (5).

The constraint in (5) is an L_1 type regularization and imposes a soft thresholding (Tibshirani, 1996) on α. On the right panel of Figure 1, we illustrate the effect of the data sparsity constraint. For a small s, many of the estimated $\hat{\alpha}_i$ values will be set to 0. Consequently, the regression function $\hat{f}_n$ has a parsimonious representation in (3).

Through simulation studies, we demonstrate that for some settings, the data sparsity method can have a better performance, compared to the regular squared norm penalty method. For other cases, the performance difference between the two approaches is small. In particular,

- when n is small or moderate, and the underlying function can be well approximated by a sparse representation $\sum_{i=1}^{m} \gamma_i K(z_i,\cdot) + c$ for small m's, where z_i are fixed points in D and $c, \gamma_i \in \mathbb{R}$. The data sparsity can then provide a parsimonious model, and the corresponding prediction performance can be better. We demonstrate this issue using an example where $p = 1$ with the Laplacian kernel in Figure 2, and another example with $p = 2$ and the Gaussian kernel in Figure 3;



(a) The regular squared norm penalty. (b) The proposed data sparsity constraint.

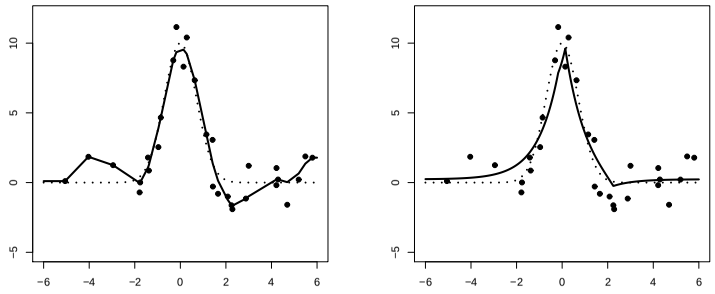
Figure 1: The left panel demonstrates the contour of the regular squared norm penalty $\alpha^T K \alpha = 1$ with $K = \big[(1, 0.3)^T \ (0.3, 1)^T\big]$. The right panel plots the contour of our data sparsity constraint $|\alpha_1| + |\alpha_2| = 1$. For the regular squared norm penalty, there is no singularity at the intersections of the contour and the axes ($\alpha_1 = 0$, $\alpha_2 = 0$), thus it does not encourage sparsity in the estimated kernel function coefficients. In contrast, the data sparsity penalty has singularity at the intersections and is able to achieve sparsity in the estimated kernel function coefficients.

- when n is small or moderate, and the underlying function does not possess such a sparse representation, the data sparsity method tends to choose a large s in (5). As a result, the fitted model is not sparsely represented. In this case, the prediction performance of the data sparsity method and the squared norm penalty method is often comparable. This is illustrated in Figure 4;

- and when n is large, there is enough information to estimate the underlying function accurately, and both methods can perform well in terms of prediction. In particular, we show in Section 3.1 that the estimation errors of (4) and (5) both converge at a rate very close to the "parametric rate" $O_P(n^{-1/2})$. In other words, asymptotically the data sparsity method can perform as well as the squared norm penalty. However, (5) can still provide a data sparse representation model. The advantages of such a parsimonious estimator is that the prediction for new observations can be much faster than the regular method, and a sparser model can be easier to interpret.

Therefore, the data sparsity method can be regarded as an alternative learning technique to the regular squared norm penalty method.

Notice that although we observe that the data sparsity constraint may work well under some settings when n is small or moderate, we still need a certain amount of information from the data

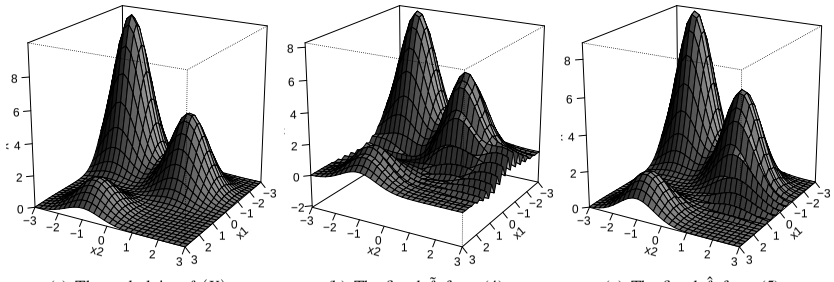


(a) The fitted $\tilde{f}_n$ from (4). (b) The fitted $\hat{f}_n$ from (5).

Figure 2: Plot of the fitted $\tilde{f}_n$ and $\hat{f}_n$ (solid lines) in a simulated example with $n = 30$ and $\tau = 0.5$, using the regular squared norm penalty (left panel) and the proposed data sparsity constraint (right panel). The kernel used is the Laplacian kernel. The error ε follows $U(-2,2)$. The best tuning parameters (λ, s and the kernel parameter) are selected by the GACV criterion (Yuan, 2006). The dotted line is the true regression function. Note that as the regular squared norm does not have sparsity in the estimated kernel function coefficients, the estimated regression function has quite a few wiggles which degrades the prediction performance. On the other hand, our data sparsity method performs remarkably well in this example.

to estimate the underlying function reasonably well. When the dimensionality p is high and the sample size n is small, without variable selection, the curse of dimensionality would prevent most of the kernel methods from working well. Therefore, we focus on the case when p is not large in this paper.

We would like to point out that besides the data sparsity constraint on α, we also impose regularization on b in (5). Although penalizing b may not be standard, some papers, for example Fan et al. (2008), also considered penalizing the intercept. The effect of penalizing on b is two fold. Firstly, it guarantees the uniqueness of the solution path with respect to s, which is discussed in Section 4. Secondly, it prevents b from diverging too fast as $n \to \infty$. This helps to bound the complexity of $\mathcal{F}$ and the functional space we consider in (5), and consequently helps to derive the theoretical properties in Section 3. If we remove b from the constraint, more conditions are needed for the corresponding theorems to be valid. In particular, in the RKHS learning literature, many theoretical results are derived with $f = f' \in \mathcal{H}$ without the intercept term. See, for example, Bousquet and Elisseeff (2002), Chen et al. (2004), and the discussion on Page 17 of Steinwart and Christmann (2008). Our data sparsity constraint can naturally incorporate the intercept in the regularization, and consequently provide desirable theoretical properties without additional assumptions. More discus-



(a) The underlying $f_0(X)$. (b) The fitted $\tilde{f}_n$ from (4). (c) The fitted $\hat{f}_n$ from (5).

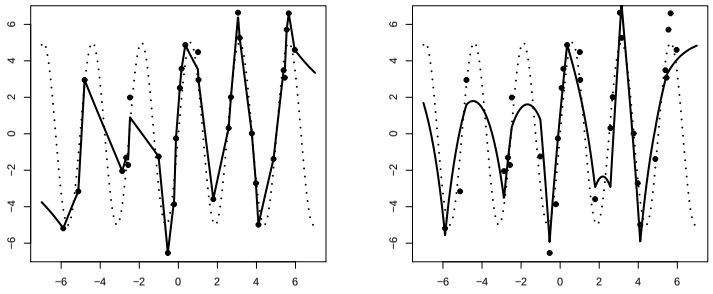
Figure 3: Panel (a) displays the underlying function $f_0(X)$, which has a sparse representation in the Gaussian RKHS. Panel (b) shows the estimated regression function $\tilde{f}_n$ from (4), using a simulated example of size 50 with the Gaussian RKHS and the regular square norm penalty. Panel (c) shows the estimated regression function $\hat{f}_n$ from the same example with our data sparsity constraint in (5). The error ε follows $N(0,1)$, and we use $\tau = 0.5$. We select the best tuning parameters (λ, s and the kernel parameter) over a grid of candidates by the GACV criterion (Yuan, 2006). On Panel (b), one can see that there are fluctuations in $\tilde{f}_n$ which degrade its prediction performance. On the other hand, $\hat{f}_n$ from our data sparsity method has less fluctuations.

sions on this issue are provided in Remark 4 and the proofs of the corresponding theorems in the appendix. In Section 5, we study the numerical performance of our method with and without $|b|$ penalized, respectively. The results demonstrate that the difference between the two settings is small, in terms of their empirical performance. In real data analysis, practitioners can choose whether to penalize b or not based on the nature of the problem and the model.

Next, we derive some theoretical properties of our data sparsity method, as well as the regular squared norm penalty method.

3. Statistical Theory

In this section, we investigate some statistical theory of our data sparsity method. In particular, we study the asymptotic behavior of our data sparsity method and the standard penalized quantile regression with the regular squared norm penalty as $n \to \infty$ in Section 3.1. An example is given in Section 3.2 to calculate the rate of convergence of the approximation error. We discuss the approximation ability of the RKHS in Section 3.3. We also derive some finite sample error bounds in Section 3.4. Note that our main results (Theorems 1-9) require only that the noise $\varepsilon(X)$ has finite mean for all X, therefore they hold in general for both homoscedastic and heteroscedastic cases.



(a) The fitted $\tilde{f}_n$ from (4). (b) The fitted $\hat{f}_n$ from (5).

Figure 4: The left panel shows the fitted $\tilde{f}_n$ from (4) with a simulated example of size 30 and the Laplacian kernel for $\tau = 0.5$. The right panel shows the fitted $\hat{f}_n$ from (5) using the same sample data and τ. The error follows $N(0,1)$. The best tuning parameters (λ, s and the kernel parameter) are selected by minimizing the GACV criterion (Yuan, 2006). Because the underlying function is quite wiggly, a sparse representation in this case cannot perform well. However, by allowing a large s, the data sparsity constraint yields a model that is not "sparse". Therefore one can see that the two methods give comparable performance.

3.1 Asymptotic Results

Before stating our main results, we introduce some additional notations. Let $\mathcal{F}_n(s) = \{f = f' + b : f'(x) = \sum_{i=1}^n \alpha_i K(x,x_i); |b| + \sum_{i=1}^n |\alpha_i| \le s\}$ be the functional space of the optimization problem (5). Note that we can define the functional space of the regular squared norm penalized method in a similar manner. Let $\mathcal{F}(\infty) = \lim_{s\to\infty} \lim_{n\to\infty} \mathcal{F}_n(s)$. Next, we define $f_n^{(s)} = \operatorname{arginf}_{f\in\mathcal{F}_n(s)} E\rho_\tau(Y - f(X))$ and $f^{(\infty)} = \operatorname{arginf}_{f\in\mathcal{F}(\infty)} E\rho_\tau(Y - f(X))$. Here the expectation is taken with respect to the joint distribution of X and the noise ε. Note that the conditional $100\tau\%$ quantile function f_{true} may not belong to $\mathcal{F}(\infty)$. Now let $e(f_1, f_2) = E\rho_\tau(Y - f_1(X)) - E\rho_\tau(Y - f_2(X))$. In the following theorem, we explore the convergence rate of $e(\hat{f}_n, f^{(\infty)})$ by decomposing it into the estimation error $e(\hat{f}_n, f_n^{(s)})$ and the approximation error $e(f_n^{(s)}, f^{(\infty)})$, where $\hat{f}_n = \operatorname{argmin}_{f\in\mathcal{F}_n(s)} \frac{1}{n}\sum_{i=1}^n \rho_\tau(y_i - f(x_i))$. We also study the convergence rate of $e(\tilde{f}_n, f^{(\infty)})$ for the regular method using the squared norm penalty.

Theorem 1 *For the data sparse L_1 method (5), we have $e(\hat{f}_n, f^{(\infty)}) = O_P(\max(sn^{-1/2}\log(n), d_{n,s}))$, where $d_{n,s} = e(f_n^{(s)}, f^{(\infty)})$ is the approximation error between $\mathcal{F}_n(s)$ and $\mathcal{F}(\infty)$.*

For the regular squared norm method with $|b|$ penalized, the estimation error of the solution $\tilde{f}_n$ to

$$\min_{f\in\mathcal{F}} \frac{1}{n}\sum_{i=1}^n \rho_\tau\big(y_i - f(x_i)\big), \text{ subject to } |b|^2 + \|f'\|_{\mathcal{H}_f}^2 \le s^2 \tag{6}$$

enjoys the same rate as above.

Remark 2 *In Theorem 1, the estimation error converges at the rate $O_P\big(sn^{-1/2}\log(n)\big)$, and $d_{n,s}$ approaches 0 as $s, n \to \infty$. Therefore the optimal value of the tuning parameter s is roughly determined by $sn^{-1/2}\log(n) \approx d_{n,s}$. It can be considered as the trade-off between the approximation error and the estimation error.*

Remark 3 *Theorem 1 is developed for a general separable RKHS such that the kernel function $K(\cdot,\cdot)$ is upper bounded. The results in Section 3 can be refined if one focuses on a smaller set of RKHS's that satisfies additional conditions. For example, the Gaussian RKHS is commonly used in the literature, and the corresponding theoretical properties are well studied (see, for example, Zhou, 2002; Keerthi and Lin, 2003; Steinwart et al., 2006; Steinwart and Scovel, 2007; Minh, 2010, and the references within). In Theorem 1, the width parameter σ of the Gaussian kernel and the dimensionality of X do not affect the convergence rate explicitly. They are both involved in the approximation error $d_{n,s}$. The choice of σ is often data dependent, as described in Section 5. The asymptotic effect of σ is studied in many papers, for example Keerthi and Lin (2003). If f is an element in a Banach space whose norm is defined to be $\|f_1 - f_2\| = |(E\rho_\tau(Y - f_1(X)) - E\rho_\tau(Y - f_2(X)))|$ with an appropriate definition of limits for Cauchy sequences, then the corresponding theory of $d_{n,s}$ can be derived as studied in Cucker and Smale (2002) and Smale and Zhou (2003). In Section 3.2, we give a simple example in which $d_{n,s}$ can be explicitly calculated and vanishes in a rate much faster than the estimation error.*

Remark 4 *The constraint on $|b|$ in (5) and (6) helps to bound the complexity of $\mathcal{F}_n(s)$ in terms of its L_2 entropy number. The definition of the L_2 entropy number is as follows. Let Q be a σ-finite measure on X. One can define the $L_2(Q)$ norm of a square integratable function f on X to be $\|f\|_{L_2(Q)} = (\int f^2 dQ)^{1/2}$. An $\eta-$net on $\mathcal{F}_n(s)$ is defined to be a set of functions $\mathcal{G} = \{g_1, g_2, \ldots\}$ such that for all $f \in \mathcal{F}_n(s)$, there exists a $g \in \mathcal{G}$ satisfying $\|f - g\|_{L_2(Q)} \le \eta$. For any fixed η, the $L_2(Q)$ entropy number of $\mathcal{F}_n(s)$ is defined as the logarithm of the cardinality of an $\eta-$net $\mathcal{G}$ on $\mathcal{F}_n(s)$ whose size is the smallest (Van der Vaart and Wellner, 2000). A bound on $|b|$ helps to control the L_2 entropy number of $\mathcal{F}_n(s)$. See Lemma 14 and its proof in the appendix for more details. Our theory can also be valid with some additional assumptions if $|b|$ is not penalized. The next corollary discusses a natural generalization of our asymptotic results without penalizing $|b|$, when we impose some assumptions on f_0 and ε. First, we define*

$$\mathcal{F}_n^*(s) = \{f = f' + b : f'(x) = \sum_{i=1}^n \alpha_i K(x,x_i); \sum_{i=1}^n |\alpha_i| \le s\},$$

and $f_n^{(*s)}$, $\mathcal{F}^*(\infty)$, and $f^{(*\infty)}$ are defined analogously as in Theorem 1. Note that if a random variable X is sub-Gaussian with the parameter S, then $pr(|X| > t) \le 2\exp(-t^2/S)$ for t large enough.

Corollary 5 *Suppose that f_0 is uniformly bounded, and the error $\varepsilon(X)$ follows a sub-Gaussian distribution with a common finite parameter for any X. Then the solution $\hat{f}_n^*$ to the following optimization*

$$\min_{\alpha,b} \frac{1}{n}\sum_{i=1}^{n} \rho_\tau\big(y_i - f(x_i)\big), \text{ subject to } \sum_{i=1}^{n} |\alpha_i| \le s,$$

satisfies that $e(\hat{f}_n^*, f^{(*\infty)}) = O_P(\max(sn^{-1/2}\log(n), d_{n,s}^*))$, where $d_{n,s}^* = e(f_n^{(*s)}, f^{(*\infty)})$ is the approximation error between $\mathcal{F}_n^*(s)$ and $\mathcal{F}^*(\infty)$.

In Corollary 5, we impose the assumption that the distributions of error terms ε_i; $i = 1,\ldots,n$, are all sub-Gaussian, which covers many commonly used distributions. Consequently, the probability that any observed y_i being significantly away from $f_0(x_i)$ can be well controlled. If the distribution of ε_i has a heavier tail than sub-Gaussian, and we do not penalize b, the convergence rate of the estimation error can be slower than that in Theorem 1. See the proof in the appendix for more discussions. Compared to Corollary 5, our asymptotic theory with $|b|$ in the constraint only requires the noise ε being integrable, hence is more general.

Remark 6 *Note that our results in Theorem 1 also apply to the regular squared norm penalty method. This suggests that asymptotically, the two methods can both perform well. However, for problems with a moderate or small n, asymptotic results may be less useful. In Section 3.4, we give bounds on the prediction errors $E\rho_\tau(Y - \hat{f}_n)$ and $E\rho_\tau(Y - \tilde{f}_n)$. In particular, we give two such bounds. The first bound works for both the regular method with the squared norm penalty and the proposed data sparsity method. The second bound is only for the data sparsity method. We show that for a small n, the second bound can be better than the first one. Therefore, when the true function can be well approximated by functions in $\mathcal{F}_m(s_0)$ for small m and s_0, the data sparsity method can enjoy a smaller prediction error bound.*

In the next section, we give an example where $f_0 \in \mathcal{F}_m(s_0)$ for some fixed s_0 and m, and the approximation error $d_{n,s}$ converges to 0 in a speed much faster than $O_P(n^{-1/2}\log(n))$. In that case, $e(\hat{f}_n, f^{(\infty)}) = O_P(n^{-1/2}\log(n))$.

In the literature, Takeuchi et al. (2006) derived finite sample bounds on the estimation error for general quantile regression problems, using the Rademacher complexity technique (Mohri et al., 2012). They showed that the estimation error can be upper bounded by the Rademacher complexity of the corresponding functional space (plus a small penalty which exists only in finite sample problems). Under various settings where the Rademacher complexity is well studied, one can obtain the asymptotic convergence rate of the estimation error accordingly. For example, when we perform learning with a radial basis function kernel such that $K(\cdot,\cdot)$ is upper bounded, or when the functional space has finite VC dimensions, one can verify that the corresponding Rademacher complexity converges to zero at a rate close or equal to $O_P(n^{-1/2})$. Li et al. (2007) also studied the asymptotic convergence rate of $e(\tilde{f}_n, f^{(\infty)})$ under some assumptions. For example, a bound on the complexity of $\mathcal{F}$ in terms of the L_2 metric entropy was assumed. Our asymptotic theory for quantile regression with the data sparsity constraint is more general, as we only use the assumption that the RKHS is separable and bounded. This is a very weak assumption and can be satisfied by most commonly used kernel spaces. Furthermore, in Section 3.4, we obtain finite sample error bounds on the prediction error for our proposed method with the data sparsity constraint. Our bounds can be directly calculated using the training data and the corresponding tuning parameter.

3.2 An Illustrative Example on the Approximation Error

In this section we give an example to calculate $d_{n,s}$, where we know f_0 and the distribution of X. The Gaussian RKHS is considered.

For simplicity, let $p = 1$, $\tau = 1/2$, $\sigma = 1$ and X be uniformly distributed on $[0,1]$. Moreover, assume that ε is symmetric with respect to 0 for all X. Suppose the underlying model is $f_{\text{true}} = f_0(x) = \exp(-x^2)$. One can verify that when s is fixed at 1, $d_{n,s} \le \frac{1}{2}E(|Y - f_0(X)|) - E(|Y - f_{(1)}(X)|)$, where $f_{(1)}(x) = \exp(-(1-x_{(1)})^2)$ with $x_{(1)}$ being the smallest order statistic of the sample $x = (x_1,\ldots,x_n)$. Note that the probability density function of $x_{(1)}$ is $n(1-x)^{n-1}I_{[0,1]}$ and $d_{n,s} \le \frac{1}{2}E(|f_0(X) - f_{(1)}(X)|)$. Since the largest difference between $f_0(x)$ and $f_{(1)}(x)$ occurs at $x = 0$, $d_{n,s} \le \frac{1}{2}\int_0^1 (1 - \exp(-x^2))n(1-x)^{n-1}dx$. By the Taylor's expansion, one can verify that $(1 - \exp(-x^2)) \le 2x^2$ for all $x \in [0,1]$. Thus, $d_{n,s} \le \frac{1}{2}\int_0^1 2nx^2(1-x)^{n-1}dx = \frac{2}{(n+1)(n+2)}$. Hence in this example, $d_{n,s} = O_P(n^{-2})$, which converges to 0 at a much faster rate than $O_P\big(n^{-1/2}\log(n)\big)$.

In general, when $f_0(x) = \sum_{j=1}^m \gamma_j K(x, z_j) + c$, where $c \in \mathbb{R}$, $\gamma_j \in \mathbb{R}$, and $z_j \in \mathbb{R}^p$ are fixed points (not the observed data points), we can have s fixed and the approximation error vanishes quickly as $n \to \infty$. This is because with growing n, there will be some observed x_i's that are close to z_j; $j = 1,\ldots,m$, and the approximation error $d_{n,s}$ may converge at a rate faster than $O_P(n^{-1/2}\log(n))$ with $s = |c| + \sum_{j=1}^m |\gamma_j|$.

3.3 Approximation Ability of $\mathcal{F}(\infty)$

We have explored the convergence rate of the estimation errors $e(\hat{f}_n, f_n^{(s)})$ and $e(\tilde{f}_n, f_n^{(s)})$ in Section 3.1, and in Section 3.2 we have given an example to illustrate the convergence rate of the approximation error $d_{n,s} = e(f_n^{(s)}, f^{(\infty)})$. For real applications, it is desirable to study the approximation ability of $\mathcal{F}(\infty)$. In other words, how well $f^{(\infty)}$ can approximate f_{true}. However, this approximation ability depends on the properties of f_{true} (i.e., the smoothness, etc.), the richness of the RKHS, and the underlying marginal distribution of X. In the literature of RKHS learning, Steinwart and Scovel (2007) studied the approximation ability of the Gaussian RKHS for support vector machines. In this section, we provide a discussion on this issue for quantile regression with a general RKHS. We measure such approximation ability by $A(\infty) := E\big(\rho_\tau(Y - f^{(\infty)})\big) - E\big(\rho_\tau(Y - f_{\text{true}})\big)$. We first show that if f_{true} is a bounded piecewise step function, an upper bound on $A(\infty)$ for the Gaussian kernel learning can be obtained. This upper bound depends on the marginal distribution of X. In particular, when the marginal distribution of X is absolutely continuous with respect to the Lebesgue measure, the Gaussian RKHS can approximate f_{true} arbitrary well. Then, we extend to the case where f_{true} is a Lipschitz function. Finally, we note that this upper bound can be generalized to other kernels satisfying certain conditions.

We begin with the description of f_{true} and some further notations. Recall the definition of D, and without loss of generality assume $D = \mathbb{R}^p$. As mentioned above, we assume that f_{true} is a bounded step function. In particular, assume $f_{\text{true}} = a_i$ on D_i, where a_i is a constant, D_i is a measurable set in D, and $D = \bigcup D_i$. Let $a > 0$ be the upper bound of $|f_{\text{true}}|$. Next, for any $x \in D_i$, define the distance of x to other D_j; $j \ne i$ as $\psi_x = \min_{j \ne i} \text{dis}(x, D_j)$, where $\text{dis}(x, D_j) = \inf_{x' \in D_j} \|x - x'\|$ and $\|\cdot\|$ is the usual Euclidean norm in D. By this definition of ψ_x, one can verify that $B(x, \psi_x) \in D_i$ for all x, where $B(x, \psi_x)$ is the ball centered at x with the radius ψ_x. Note that $B(x, \psi_x)$ is well defined for all $x \in D$. Recall that σ is the kernel parameter of the Gaussian RKHS.

The next theorem gives an upper bound on $A(\infty)$.

Theorem 7 *Suppose f_{true} is a piecewise step function with $|f_{true}| \le a$ for some $a > 0$. Define ψ_x and $A(\infty)$ as above. One has*

$$A(\infty) \le \max(\tau, 1-\tau) E_{P_X}\left\{8a \exp\left(-\psi_x^2/(2p\sigma^2)\right)\right\}, \tag{7}$$

where P_X is the marginal distribution of X, p is the dimensionality of X and σ is the kernel parameter of the Gaussian RKHS.

For a fixed p, the upper bound in Theorem 7 depends on ψ_x, σ and the distribution P_X. If P_X is absolutely continuous with respect to the Lebesgue measure, one can verify that $A(\infty) \to 0$ with $\sigma \to 0$. This means that $f^{(\infty)}$ can approximate f_{true} arbitrarily well almost everywhere.

Next we consider the case where f_{true} is a general bounded measurable function. All bounded measurable functions can be approximated arbitrarily well by step functions. However, if f_{true} is too wiggly or is discontinuous at too many points in D, it cannot be well approximated by the Gaussian RKHS functions. For example, when f_{true} is discontinuous on a dense subset of D, $\psi_x = 0$ for all x if the step function is close enough to f_{true}. This leads to the right hand side of (7) being large. Therefore, we need some smoothness condition on f_{true}. The next corollary shows that when f_{true} is Lipschitz, $A(\infty) \to 0$ as $\sigma \to 0$.

Corollary 8 *Assume that f_{true} is a bounded Lipschitz function, and P_X is absolutely continuous with respect to the Lebesgue measure on D. Then $A(\infty) \to 0$ as $\sigma \to 0$.*

The discussions above have focused on the Gaussian RKHS. We note that it is possible to generalize the obtained results to more general RKHS's. For example, using similar techniques, one can verify that similar results as in Theorem 7 and Corollary 8 still hold if we consider many other radial kernels such as the Laplacian kernel. Other kernels, for example the polynomial kernel, may not have such guarantee that functions in the kernel space can approximate the underlying function arbitrary well. See the proof of Theorem 7 in the appendix for more discussions.

3.4 Finite Sample Error Bounds

The theory in Section 3.1 gives the asymptotic convergence rate of the estimation error. It is useful when the sample size is large. In this section, we derive some finite sample bounds on the prediction errors $E\rho_\tau(Y - \hat{f}_n)$ and $E\rho_\tau(Y - \tilde{f}_n)$, which can be used to assess the goodness of fit of the resulting model, when n is not large. In this section, we focus on the comparison between $E\rho_\tau(Y - \hat{f}_n)$ and $E\rho_\tau(Y - \tilde{f}_n)$. In particular, we show that the Rademacher complexity for $\hat{f}_n$ can be smaller compared to that of $\tilde{f}_n$. Hence, the prediction error bound for the data sparsity method can be better, and this demonstrates the usefulness of our proposed method. Note that Takeuchi et al. (2006) also used the Rademacher complexity to bound the estimation error. In this paper, we further consider how to bound the Rademacher complexity, especially for the data sparsity method.

To begin with, we introduce the following assumption.

Assumption A: The noise ε is bounded such that $|\varepsilon| \le t$ for some positive t.

Theorem 9 *Suppose Assumption A holds. Then the solution $\hat{f}_n$ to (5) satisfies that, with probability at least $1-\delta$ with a small and positive δ,*

$$E\rho_\tau(Y - \hat{f}_n) \le \frac{1}{n}\sum_{i=1}^{n} \rho_\tau\big(y_i - \hat{f}_n(x_i)\big) + Z_n + \max(\tau, 1-\tau)\mu,$$

where $Z_n = 3\max(\tau, 1-\tau)\Big(n^{-1}(2s^2 + 2t^2)\log(2/\delta)\Big)^{1/2}$ and

$$\mu = s\sqrt{\frac{2\log(2n+2)}{n}}.$$

Moreover, the solution $\tilde{f}_n$ to (6) satisfies that, with probability at least $1-\delta$,

$$E\rho_\tau(Y - \tilde{f}_n) \le \frac{1}{n}\sum_{i=1}^{n} \rho_\tau\big(y_i - \tilde{f}_n(x_i)\big) + Z_n + \max(\tau, 1-\tau)\mu,$$

where Z_n is defined as above and

$$\mu = 2sn^{-1/4} + \sqrt{n^{-1}\big(2^{11}n^{1/4} + 2\log(5) + 0.5\log(n)\big)}.$$

One can see from Theorem 9 that μ for $\hat{f}_n$ is much smaller than $\tilde{f}_n$. This is because the functional space of (5) is smaller than that of (4) (see Lemma 13 in the appendix). The key to the proof for $\tilde{f}_n$ is to control the covering number of the functional space in (4), as in Lemma 14. In particular, we study the covering number of a unit ball in $\mathcal{H}$, i.e., $\{f' : \|f'\|_{\mathcal{H}} \le 1\}$. On the other hand, the key to the proof for $\hat{f}_n$ is that the Rademacher complexity of the functional space of (5) is equivalent to the Rademacher complexity of a convex hull of functions with $2n+2$ vertices, and the latter enjoys a much better bound compared to the Rademacher complexity in (4).

From Theorem 9, one can conclude that when the underlying function can be well approximated by a function that has a sparse representation (in other words, the term $\frac{1}{n}\sum_{i=1}^{n} \rho_\tau\big(y_i - \hat{f}_n(x_i)\big)$ and s are both small), the prediction error bound for the data sparsity method can be better. This observation provides some insight on the usefulness of the data sparsity method, which is illustrated by our numerical examples in Section 5, and discussed in Section 2.

Notice that our theory is for a general RKHS with very weak assumptions. Thus, the first choice of μ, $\mu = 2sn^{-1/4} + \sqrt{n^{-1}\big(2^{11}n^{1/4} + 2\log(5) + 0.5\log(n)\big)}$, can be refined if one considers specific kernels with additional assumptions, such as the decay rate of the eigenvalues of the corresponding Hilbert-Schmidt integral operator. See, for example, Zhou (2002) and Steinwart and Scovel (2007). This can lead to a better bound in Theorem 9. For example, with Gaussian kernel learning (including intercepts), an application of the result in Zhou (2002) gives $\mu = 2sn^{-1/3} + 2^{p+2}p^{1/2}n^{-1/3}\log^{p/2}(n)$, where p is the dimensionality of X. Hence for a small p, our μ on $\tilde{f}_n$ in Theorem 9 can be loose in this case. Nevertheless, one can verify that the bound on the data sparsity method is still better than $\mu = 2sn^{-1/3} + 2^{p+2}p^{1/2}n^{-1/3}\log^{p/2}(n)$. If we use the Gaussian kernel without an intercept, then one can verify that we have $\mu = O_P(n^{-1/2})$ for $\tilde{f}_n$ (Mendelson, 2003). However, without the intercept, the empirical prediction error term might be large for some problems, which can lead to suboptimal results.

As a remark, we note that Assumption A ensures that the response variable y is bounded if we restrict our consideration to the space $\mathcal{F}_n(s)$. Because we want to bound a finite sample error, any large noise in the response data, that is, an observed y_i being significantly away from its expected value given the predictors, can result in the failure of our bound derived in Theorem 9. Assumption A excludes the possibility that this large noise happens. This assumption can be removed if one assumes that the tail of the distribution of $|\varepsilon|$ satisfies certain properties, and similar results can

be obtained by modifying the proof of Theorem 9 accordingly. Corollary 10 gives one possible generalization of the bound in Theorem 9, where we make an assumption of the distribution of the error ε. Note that the results in Theorem 9 and Corollary 10 can be calculated directly from the data and the tuning parameter s we use.

Corollary 10 *Suppose that the errors ε_i; $i = 1,\ldots,n$ follow a common distribution with a continuous cumulative distribution function Φ_ε. For simplicity, assume that the distribution of ε is symmetric with respect to 0. Then $\hat{f}_n$ and $\tilde{f}_n$ are controlled by the same finite sample bounds as in Theorem 9 except that $Z_n = 3\max(\tau,1-\tau)\Big(n^{-1}(2s^2+2t^2)\log(4/\delta)\Big)^{1/2}$ and $t = \Phi_\varepsilon^{-1}\big(0.5+0.5(1-\delta/2)^{1/n}\big)$.*

If ε follows a Gaussian distribution, one can verify that for a fixed δ, $t = O_P\big(\log(n)^{1/2}\big)$ as $n \to \infty$. Hence, t diverges in a slow rate. For other error distributions, one can obtain similar results by studying the corresponding Φ_ε, and we omit the details here.

4. Optimization and Tuning Procedure

The numerical optimization of (5) for fixed s and τ can be done by a simple linear programming. However, it is often desirable to have the entire solution path of $\hat{\alpha}$ and $\hat{b}$ with respect to s. For example, when we need to perform a comprehensive tuning procedure for choosing the optimal s, the solution path can significantly reduce the computational cost. In the literature of penalized quantile regression, Li et al. (2007) developed the solution path for (4) with respect to λ, Li and Zhu (2008) derived the solution path for L_1 penalized quantile regression with linear learning, and Rosset (2009) studied the solution surface with respect to both λ and τ in (4). In this section, we first briefly discuss how to derive the corresponding solution path with respect to s, then consider how to select the tuning parameter s.

Let $\tilde{K}$ be the n by $(n+1)$ matrix $(1\ K)$, where 1 is a vector of 1 of length n, and let $\bar{\alpha} = (b,\alpha_1,\ldots,\alpha_n)$. With b penalized, one can verify that the optimization (5) is equivalent to

$$\min_{\bar{\alpha}} \frac{1}{n}\sum_{i=1}^{n} \rho_\tau\big(y_i - f(x_i)\big), \text{ subject to } |\bar{\alpha}| \le s,$$

where $\big(f(x_1),\ldots,f(x_n)\big) = \tilde{K}\bar{\alpha}$. We note that the solution path of this optimization problem can be obtained in a similar manner as in Li and Zhu (2008) without an intercept in their notation, despite that they only considered linear learning problems. We omit the details here.

To illustrate the algorithm, using the data considered in Figure 2, we plot the piecewise linear solution path $\{b(s),\alpha(s)\}$ in Figure 5. Because the entire set $\{b(s),\alpha(s)\}$ consists of 31 piecewise linear functions, we only report a subset of $\{b(s),\alpha(s)\}$ in Figure 5 to make the plot clear. Moreover, if we plot the solution path on $[0,s_1]$ for large s_1, the lines become less clear on $[0,s_2]$ with $s_2 \ll s_1$. Hence, we only plot the solution path on $[0,20]$ for a demonstration.

Remark 11 *As mentioned in Section 2, penalizing $|b|$ helps to guarantee the uniqueness of the solution path. In particular, if the intercept is not regularized, when s is large (or equivalently, the model is mildly penalized), there exist cases where b is not uniquely determined. See Li et al. (2007) and Li and Zhu (2008) for detailed discussions on this issue.*

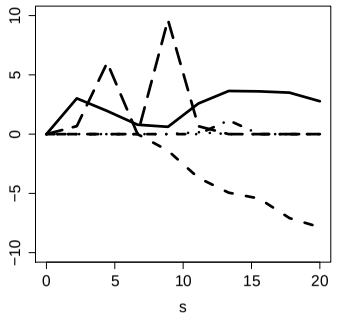


Figure 5: A subset of the solution path $\{b(s),\alpha(s)\}$ as a function of s. Notice that for brevity, we only plot five $\hat{\alpha}_i(s)$'s and the intercept b, and we restrict s such that $s \in [0,20]$ to illustrate the solution path. The solid line corresponds to $b(s)$.

Next, we briefly discuss how to select the optimal tuning parameter s in (5) for a given regression problem. Similar to many other penalized techniques, a proper choice of s is crucial in practice. In particular, s being too large can lead to an overfitted model, and s being too small can lead to an underfitted model. For either cases, the prediction accuracy can be low. Here we discuss two commonly used criteria for kernel quantile regression. The first criterion is the Schwarz Information Criterion (SIC, Schwarz, 1978; Koenker et al., 1994), which can be written as

$$\text{SIC}(s) = \log\left\{\frac{1}{n}\sum_{i=1}^{n}\rho_\tau\big(y_i - \hat{f}(x_i)\big)\right\} + \frac{\log(n)df}{n}.$$

Here df measures the dimensionality of the model, and $\frac{\log(n)df}{n}$ balances the model complexity and goodness-of-fit. The second criterion is the Generalized Approximate Cross-Validation criterion (GACV, Yuan, 2006), defined as

$$\text{GACV}(s) = \frac{1}{n-df}\left\{\frac{1}{n}\sum_{i=1}^{n}\rho_\tau\big(y_i - \hat{f}(x_i)\big)\right\}.$$

Note that GACV was originally proposed as a stable estimator of the generalized comparative Kullback-Leibler distance for the model.

To estimate df, it has been proposed to use the divergence (Nychka et al., 1995; Yuan, 2006)

$$\text{div}(\hat{f}) = \sum_{i=1}^{n}\frac{\partial\hat{f}(x_i)}{\partial y_i}.$$

Li et al. (2007) showed that for the kernel quantile regression with the regular squared norm penalty, $\mathrm{div}(\hat{f})$ coincides with the number of interpolated y_i's, and this makes the estimation of df convenient. The next proposition shows that for the proposed quantile regression with the data sparsity constraint, we have the same estimation formula, given the "one at a time" condition (Efron et al., 2004).

Proposition 12 *Assume the "one at a time" condition holds. For $(y_i;\ i=1,\ldots,n)\in\mathbb{R}^n$ except on a set of Lebesgue measure 0 and any fixed s, we have*

$$\sum_{i=1}^{n}\frac{\partial\hat{f}(x_i)}{\partial y_i}=|\mathcal{E}|,$$

where $\mathcal{E}$ is the set of interpolated y_i's.

5. Numerical Examples

In this section, we examine the performance of our proposed method with the data sparsity constraint using both simulated and real data sets. We demonstrate the effect of the SIC and GACV criteria. As a comparison, we also apply quantile regression using RKHS learning with the regular squared norm penalty, which was previously studied in Takeuchi et al. (2006) and Li et al. (2007).

5.1 Simulated Examples

We use three simulated examples to compare the performance of the proposed method with the data sparsity constraint and the standard method using the regular squared norm penalty. In particular, we study the three examples given in Section 2, which cover two cases. The first case (Examples 1 and 2) considers the situation when $f_0(x)$ can be well approximated by functions of the form $\sum_{j=1}^{m}\gamma_j K(x,z_j)$ for some fixed z_j and γ_j, where m is a small positive integer. For the second case (Example 3), f_0 is constructed to have many fluctuations. In this situation, f_0 cannot be well approximated by functions of the form $\sum_{j=1}^{m}\gamma_j K(x,z_j)$ with a small m.

For each example, we consider two choices of n: moderate ($n\in[30,50]$) and very large ($n=1000$). We show that for Examples 1-2 with moderate n's, the sparsely represented model from our method using the data sparsity constraint can have better prediction performance. On the other hand, for the case with a moderately large n but with the true function being quite wiggly (Example 3), or with a very large n, the performance of the two methods is comparable in terms of prediction accuracy. This is consistent with our theoretical insights.

We explore the performance under various settings of the noise. In particular, for the homoscedastic case, we let ε follow the standard normal distribution $N(0,1)$ (homoscedastic normal distribution, ho-norm. in Tables 2-7), and the t distribution with degrees of freedom 3 (t3). For the case when the noise is heteroscedastic, we let $\varepsilon(x)\sim U[-\|x\|_2/1.5,\|x\|_2/1.5]$ (heteroscedastic uniform distribution, unif. in Tables 2-7), and $\varepsilon(x)\sim N(0,\|x\|_2/3)$ (heteroscedastic normal distribution, he-norm. in Tables 2-7), where $\|\cdot\|_2$ is the usual Euclidian norm. Then we generate a training data set. Prediction models that correspond to different tuning parameters are built on the training data. We select the best tuning parameters by minimizing the SIC and GACV criteria on the training data respectively. The kernel parameters are also selected via the tuning procedure. We predict on a separate testing data set with the size 10000, to compare the performances of the two criteria. For

the choice of quantiles, since ε follows symmetric distributions with respect to 0, we choose $\tau=0.1$, 0.3 and 0.5.

As discussed in Section 3, in this section, we will demonstrate that empirically, the effect of whether to penalize the intercept b or not is not large. In particular, for all the examples, we fit the models of the two compared methods with or without $|b|$ penalized. Note that for the regular squared norm method, we include $|b|$ in the penalty as in (6).

To measure the goodness of fit of the model, we calculate the prediction error

$$\frac{1}{10000}\sum_{i\in\text{test set}}\rho_\tau(y_i-\hat{f}_n(x_i)),$$

and the L_1 norm of $\hat{f}_n-f_{\text{true}}$. This procedure is repeated 1000 times and we report the average prediction error, average L_1 norm and average model complexity in terms of df. For our data sparsity method, we also report the percentage of non-zero α_i's as a measurement of how sparse the model is. Note that this percentage for the regular squared norm method is always 100%.

The simulation results are reported in Tables 2-7. For brevity, we only report the results for certain settings listed in Table 1. The other results are omitted because the general pattern is similar. Notice that for the cases where we compare moderate to large n's, we penalize the intercept of the data sparsity method, but not the intercept of the regular squared norm method, because the numerical difference is small.

Example	τ	Comparison
Ex 1	$\tau=0.1$	Penalize b or not
	$\tau=0.3$	Moderate or large n
Ex 2	$\tau=0.3$	Penalize b or not
	$\tau=0.5$	Moderate or large n
Ex 3	$\tau=0.5$	Penalize b or not
	$\tau=0.1$	Moderate or large n

Table 1: Summary of the settings for the reported simulation results.

Example 1: We generate the data in the same way as in Figure 2. In particular, x is one dimensional and follows the uniform distribution between -6 and 6. The underlying $f_0(x)=10\exp(-x^2)$. We use $n=30$ for the training data. The Laplacian kernel is used.

Example 2: The data are generated in the same way as in Figure 3. In particular, we let x be uniformly distributed in $[-3,3]\times[-3,3]$. The underlying true model is given by $f_0(x)=10\exp(\|x-(-2,-2)^T\|_2^2)+5\exp(\|x-(-1,1)^T\|_2^2)+2\exp(\|x-(2,-1)^T\|_2^2)$. There are 50 observations in the training data set. We apply the Gaussian kernel for this example.

Example 3: The data are generated similarly as in Figure 4. To be specific, x is one dimensional, uniformly distributed in $[-7,7]$. We have the underlying function $f_0(x)=5\sin(2.5x)$. The training data consist of 30 observations, and the Laplacian kernel is employed.

We summarize our findings from the simulation results as follows.

- For Examples 1 and 2 with a moderate n, the data sparsity method tends to choose a simpler model than that of the square norm penalty, with either the GACV or the SIC criterion. Furthermore, the data sparsity constraint performs better than the regular squared norm penalty.

This implies that functions estimated by the squared norm penalty can have potential overfitting because of too many kernel functions, as indicated by Figures 2 and 3. For a large n, the prediction performance of the two methods is comparable, because asymptotically both methods can perform well.

- For Example 3 with a moderate n, the data sparsity method tends to choose a model with a large number of non-zero α_i's. In this case, the model from (5) is not sparse, and the two methods perform similarly.
- For a large n in all the examples, the data sparsity method can choose models with simpler representation than the regular method, while keeping similar prediction performance. Consequently, the data sparsity method yields a parsimonious model that has advantages in terms of computational efficiency and interpretability.
- The SIC always tends to choose a simpler model than the GACV criterion. In these examples, GACV overall works slightly better than SIC, for both the data sparsity constraint and the squared norm penalty.
- As τ gets closer to 0.5, the performances of the two penalties and the two criteria become better, in terms of the L_1 norm.

The standard errors of the percentage of non-zero α_i's for the data sparsity method range from 0.031 to 0.055.

5.2 Real Data Analysis

In this section, we apply our proposed method (5) to several real data sets. In particular, we consider 20 data sets studied in Section 5 of Takeuchi et al. (2006), and the well known annual salary of baseball players data studied in He et al. (1998), Yuan (2006) and Li et al. (2007). The description and a summary table of the first 20 data sets can be found in Takeuchi et al. (2006), and we do not repeat it here. For the baseball data, it consists of statistics for 263 North American major league baseball players in the year 1986. The original data set has 22 predictors and the players' 1987 annual salary as the response, and we use the whole data for our analysis reported in Tables 8-10. Furthermore, following He et al. (1998), Yuan (2006) and Li et al. (2007), we use two representative predictors from the baseball data to perform an illustrative analysis, which is reported in Figure 7. In particular, we measure players' performance by the number of home runs in the latest year, and measure player's seniority by the number of years played.

For all real data analysis, the Gaussian kernel is used. For the results reported in Tables 8-10, we first standardize the predictors and response to make the results comparable. We split each data set into 10 parts of roughly the same size. We choose 1 part as the testing data set, and the remaining as the training data. Then we select the best tuning parameter and kernel parameter on the training data, and predict on the testing data. We continue to the next random split once all the 10 parts have served as the testing data. This random split is repeated 100 times for each data set, and we

Table 4: Results of the simulation Example 2 with $\tau = 0.3$ and $|b|$ penalized (left) or not (right). The best mean prediction errors are 0.40 (ho-norm., homoscedastic normal distribution), 0.56 (t3), 0.59 (unif., heteroscedastic uniform distribution), and 0.60 (he-norm., heteroscedastic normal distribution). The standard errors of the prediction errors range from 0.0055 to 0.0068. The standard errors of the L_1 norms range from 0.0071 to 0.0133. The standard errors of df range from 0.066 to 0.072. The standard errors of the percentage of non-zero α_i's for the data sparsity method range from 0.044 to 0.057.

report the average prediction error (Pred) and its sample standard deviation (SSD) in Tables 8-10 for $\tau = 0.1, 0.5, 0.9$. We only report the results where the intercept is penalized for the data sparsity method, but not for the standard method with the squared norm penalty. Similar to the results in Section 5.1, the numerical difference of whether the intercept is penalized or not is not large. For the results reported in Figure 7, we train the model using the entire data set. We then plot the predicted values against the two dimensional input space.

Similar to Takeuchi et al. (2006), we perform a two-sided paired-sample t-test to compare the prediction performance of the two methods. In Tables 8-10, we can see that for the caution, sniffer, GAGurine, topo, CobarOre, and baseball data sets, the performance of the data sparsity method is overall better than that of the squared norm penalty method. For birthwt, engel, gilgais, and mcycle, the data sparsity method is slightly better. For BostonHousing and cpus, the squared norm penalty is slightly better. For the other data sets, their performance is comparable. This demonstrates the usefulness of the data sparsity method. Moreover, we plot the fitted functions $\hat{f}_n$ and $\tilde{f}_n$ with $\tau = 0.5$ for the mcycle data on the left panel of Figure 6. Compared to Figure 3 in Takeuchi et al. (2006), one can see that the data sparsity model has less wiggles, and yields a more interpretable result. We also plot the fitted functions with $\tau = 0.1$ on the right panel of Figure 6. In this case, one can see that $\tilde{f}_n$ is quite wiggly compared to $\hat{f}_n$.

For the results on the illustrative analysis of the baseball data, from the right panels of Figure 7 (our data sparsity constraint), we can see that for all players, the income increases with their perfor-

The standard errors of the percentage of non-zero α_i's for the data sparsity method range from 0.065 to 0.097.

mances. On the other hand, the salary does not necessarily increase with the seniority. For many players, especially the high income ones ($\tau = 0.75$), the salary increases with the seniority until a golden age, then it decreases. This is consistent with our intuition. For the results with the squared norm penalty (the left panels), we can see the same trend. However, for the very senior players, because the estimated salary function has fluctuations from kernel functions, the salary decreases if their performances increase from 20 to 30. This is against our intuition. Therefore, in this data set, our data sparsity constraint performs well and gives a good interpretation of the data.

6. Discussion

In this paper, we study the learning problem in a RKHS. In particular, we propose a data sparsity constraint that can achieve a parsimonious representation of the resulting learning function. Using quantile regression as an example, we numerically show that when the underlying function can be well approximated by functions that have a sparse representation in the corresponding RKHS and n is not large, the data sparsity method can perform better than the regular squared norm penalty method. For other cases, such as when the true function is relatively difficult to be approximated by

functions in the RKHS, or when n is large, the data sparsity method can have comparable performance as the regular method. Therefore, the data sparsity method can be regarded as an alternative penalization method to solve learning problems with RKHS learning. Moreover, because of the sparsity in the kernel representation, the prediction for new data sets can be computationally faster. Through theoretical comparisons, we demonstrate that the data sparsity method can achieve the same convergence rate of the estimation error, compared with the squared norm penalty method. Furthermore, we show that for certain cases, the data sparsity method can enjoy a smaller bound on the finite sample prediction error. This helps to shed some light on the usefulness of the data sparsity constraint. We also discuss how to obtain a solution path with respect to the tuning parameter s.

We would like to point out several open problems for the theory developed in Section 3. The technique used to prove Theorems 1 and 9 there does not take into account the fact that the "active functional space" of the estimated function is often smaller than the entire $\mathcal{F}_n(s)$. Therefore, one possible way to obtain better results is to consider the "localized" covering number of the active functional space of (5). See the discussion of localization idea in, for example, Bartlett et al. (2005). In that case, we can expect a faster convergence rate and a tighter bound on the prediction error. Another open problem is to consider a combination of the L_2 and L_1 penalties, which can be a more general form than the pure L_1 or L_2 penalty. In the literature of linear learning, Zou and Hastie (2005) proposed the elastic net penalty as a convex combination of the L_2 and L_1 penalties. In

kernel learning, how to perform such a generalization effectively can be an interesting problem to pursue.

Acknowledgments

The authors would like to thank the Action Editor Professor Saharon Rosset and three reviewers for their constructive comments and suggestions, which led to substantial improvements of the presentation of this paper. The authors are supported in part by National Science and Engineering Research Council of Canada (NSERC), National Natural Science Foundation of China (NSFC 61472475), NSF grant DMS-1407241, NSF DMS-1055210, NIH/NCI grant R01 CA-149569, and NIH/NCI P01 CA-142538.

Appendix A. Proof of Theorem 1

In the following proofs, when the technique can be applied to both the proposed data sparsity constraint and the regular squared norm penalty, we omit the difference between $\hat{f}_n$ and $\tilde{f}_n$ for brevity.

Before giving the proof of Theorem 1, we first introduce a lemma.

Table 8: Results of the real data analysis for $\tau = 0.1$. We reported $100 \times$ prediction error for Pred. Here $*$ means the difference of prediction error between the two methods, both GACV vs. GACV and SIC vs. SIC, is statistically significant at level 0.05 using two-sided paired-sample t-test.

Lemma 13 *Suppose the RKHS is separable and* $\sup_{X_1,X_2} K(X_1,X_2) = 1$. *Then* $\sum_{i=1}^n |\alpha_i| \le s$ *implies* $\|f'\|_{\mathcal{H}}^2 \le s^2$.

Lemma 13 indicates that a bound on $\sum_{i=1}^n |\alpha_i|$ is a stronger constraint than the usual squared norm constraint. Hence the effect of our data sparsity penalty is two fold: control the complexity of f and impose a soft threshold to gain data sparsity. Lemma 13 helps to bound the covering number of the functional class in Lemma 14.

Proof of Lemma 13: For any $f'(x) = \sum_{i=1}^n \alpha_i K(x_i,x)$ with $\sum_{i=1}^n |\alpha_i| \le s$, we have that $\|f'\|_{\mathcal{H}}^2 = \alpha^T K \alpha = \sum_{i=1}^n \sum_{j=1}^n K(x_i,x_j)\alpha_i\alpha_j \le \sum_{i=1}^n |\alpha_i| \cdot \sum_{j=1}^n |\alpha_j| \le s^2$, because $K(\cdot,\cdot) \le 1$. □

To prove Theorem 1, note that $\rho_\tau(y-f) \le |y-f|$. Hence in the following arguments, we can consider the loss $L(a,b) = |a-b|$ instead of the check function. Recall that the definition of $f_n^{(s)}$ is $f_n^{(s)} = \text{argmin}_{f \in \mathcal{F}_n(s)} L(Y,f)$. Define $g_f(\cdot) = (2s)^{-1}(L(\cdot,f) - L(\cdot,f_n^{(s)}))$, and $\mathcal{G} = \{g_f : f \in \mathcal{F}_n(s)\}$.

First we provide a lemma that controls the complexity of $\mathcal{G}$ in terms of its covering number. Notice that this technique can also be applied to the regular squared norm method, therefore, the result in Theorem 1 is also valid for the regular method that penalizes $|b|$ (or make additional assumptions to avoid this penalty on $|b|$). Before that we introduce some further notation. Let T_X be the empirical measure of a training set $((x_1,y_1),\ldots,(x_n,y_n))$, and the L_2 norm be defined as

Here $*$ means the difference of prediction error between the two methods, both GACV vs. GACV and SIC vs. SIC, is statistically significant at level 0.05 using two-sided paired-sample t-test.

$\|f\|_{L_2(T_X)} = \left(\frac{1}{n}\sum_{i=1}^n |f(x_i,y_i)|^2\right)^{1/2}$. For any $\eta > 0$, define $\mathcal{M}$ to be a η-net of a class of function $\mathcal{F}$ if, for any $f \in \mathcal{F}$, there exists $m \in \mathcal{M}$ such that $\|m-f\|_{L_2(T_X)} \le \eta$. Now let the $L_2(T_X)$ covering number $N(\eta,\mathcal{F},L_2(T_X))$ be the minimal size of all possible η-nets.

Lemma 14 *For* $\eta > 0$ *small enough and* $C_0 = 2^{10}$, *we have that*

$$\sup_{T_X} N\big(\eta,\mathcal{G},L_2(T_X)\big) \le \frac{5\exp(C_0\eta^{-2})}{\eta}.$$

Proof of Lemma 14: The proof consists of two steps. The first step is to bound the entropy number when there is no intercept in the regression function. The second step is to add the intercept into consideration, and bound the corresponding entropy based on the results obtained in the first step.

Here we focus on the covering number of $\mathcal{G}_{\mathcal{H},b} := \{(2s)^{-1}L(\cdot,f) : f \in \mathcal{F}_n(s)\}$, because $\mathcal{G}_{\mathcal{H},b}$ has the same covering number as $\mathcal{G}$. To that end, we first calculate the covering number of $\mathcal{G}_{\mathcal{H}} := \{(2s)^{-1}L(\cdot,f') : f' = \sum_{i=1}^n \alpha_i K(x_i,\cdot), \sum_{i=1}^n |\alpha_i| \le s\}$. Define

$$\mathcal{G}'_{\mathcal{H}} := \{(2s)^{-1}f' : f' = \sum_{i=1}^n \alpha_i K(x_i,\cdot), \sum_{i=1}^n |\alpha_i| \le s\}.$$

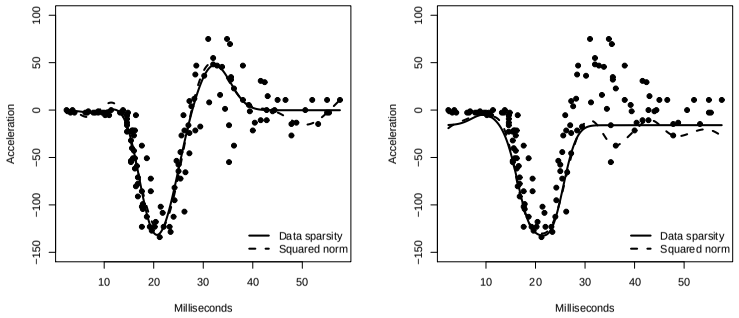
Table 10: Results of the real data analysis for $\tau = 0.9$. We reported $100\times$ prediction error for Pred. Here $*$ means the difference of prediction error between the two methods, both GACV vs. GACV and SIC vs. SIC, is statistically significant at level 0.05 using two-sided paired-sample t-test.

Define T'_X to be the empirical measure of the set $(x_1,\ldots,x_n)$. For any $g_1 := (2s)^{-1}L(\cdot,f'_1) \in \mathcal{G}_{\mathcal{H}}$, $g_2 := (2s)^{-1}L(\cdot,f'_2) \in \mathcal{G}_{\mathcal{H}}$, $|g_1-g_2| \le (2s)^{-1}|f'_1-f'_2|$. Hence, an $L_2(T'_X)$ net on $\mathcal{G}'_{\mathcal{H}}$ naturally introduces an $L_2(T_X)$ net on $\mathcal{G}_{\mathcal{H}}$, and furthermore the $L_2(T_X)$ covering number of $\mathcal{G}_{\mathcal{H}}$ is upper bounded by the $L_2(T'_X)$ covering number of $\mathcal{G}'_{\mathcal{H}}$. Moreover, by Lemma 13, $\|(2s)^{-1}f'\|_{\mathcal{H}} \le 1$. Thus, $\mathcal{G}'_{\mathcal{H}} \subset B_{\mathcal{H}}$, where $B_{\mathcal{H}}$ is the unit ball in $\mathcal{H}$. Hence, we only need to bound $N(\eta,B_{\mathcal{H}},L_2(T'_X))$. This can be done by a similar argument as in Theorem 2.1 of Steinwart and Scovel (2007). In particular, from analogous arguments as those that lead to (21) in Steinwart and Scovel (2007), we have that $\sup_{T'_X} N(\eta,B_{\mathcal{H}},L_2(T'_X)) \le \exp(\frac{C_0\eta^{-2}}{4})$, where one can choose $C_0 = 2^{10}$ (Carl and Stephani, 1990). In one words, we have that $\sup_{T_X} N(\eta,\mathcal{G}_{\mathcal{H}},L_2(T_X)) \le \sup_{T'_X} N(\eta,\mathcal{G}'_{\mathcal{H}},L_2(T'_X)) \le \sup_{T'_X} N(\eta,B_{\mathcal{H}},L_2(T'_X)) \le \exp(\frac{C_0\eta^{-2}}{4})$. Note that Theorem 2.1 of Steinwart and Scovel (2007) considered only the Gaussian RKHS, however the proof of the entropy bound for $p=2$ in their notation only requires that the RKHS is separable.

We proceed to bound the entropy number of $\mathcal{G}_{\mathcal{H},b}$. Define $\mathcal{G}'_{\mathcal{H},b} = \{(2s)^{-1}f : f \in \mathcal{F}_n(s)\}$. By similar arguments as above, $N(\eta,\mathcal{G}_{\mathcal{H},b},L_2(T_X)) \le N(\eta,\mathcal{G}'_{\mathcal{H},b},L_2(T'_X))$. Suppose $\mathcal{G}''$ is a minimal $\frac{\eta}{2}$-net of $\mathcal{G}'_{\mathcal{H}}$. One can verify that the union $\bigcup_{i=-S}^{S}\{\mathcal{G}''+is\frac{\eta}{2}\}$ is an η-net of $\mathcal{G}'_{\mathcal{H},b}$, where S is the smallest integer that is larger than $\frac{2}{\eta}$. To see this, let $g_1^b = (2s)^{-1}(f'_1+b_1)$ be an arbitrary point



(a) The fitted regression functions with $\tau = 0.5$ in the mcycle data.

(b) The fitted regression functions with $\tau = 0.1$ in the mcycle data.

Figure 6: The estimated functions for the mcycle data with $\tau = 0.5$ and $\tau = 0.1$. The dashed lines correspond to $\tilde{f}_n$ using the squared norm penalty method, and the solid lines correspond to $\hat{f}_n$ using the data sparsity method. Note that Takeuchi et al. (2006) also plotted the estimator for the squared norm penalty in their Figure 3. Compared to the dashed lines, the solid lines on both panels have less fluctuations especially when the predictor value is large, and are more interpretable.

in $\mathcal{G}'_{\mathcal{H},b}$, and $g_2^b = (2s)^{-1}(f'_2+b_2)$, with $(2s)^{-1}f'_2$ being the corresponding point in $\mathcal{G}''$ that has an $L_2(T'_X)$ distance to $(2s)^{-1}f'_1$ smaller than $\frac{\eta}{2}$, and $b_2 = is\frac{\eta}{2}$ for some integer $i \in [-S,S]$, such that $|b_2-b_1| \le s\frac{\eta}{2}$. Now the $L_2(T'_X)$ distance between g_1^b and g_2^b is

$$\begin{aligned}
&\Big(\int (g_1^b-g_2^b)^2\Big)^{1/2}\\
&\le (2s)^{-1}\Big(\int (2(f'_1-f'_2)^2+2(b_1-b_2)^2)^2\Big)^{1/2}\\
&\le \eta,
\end{aligned}$$

where the integral is taken with respect to the counting measure on T'_X. Therefore, the covering number of $\mathcal{G}'_{\mathcal{H},b}$ is less than $(\frac{4}{\eta}+2)\exp(C_0\eta^{-2})$. Consequently, the covering number of $\mathcal{G}_{\mathcal{H},b}$ is upper bounded by $(\frac{4}{\eta}+2)\exp(C_0\eta^{-2})$. The desired result follows when η is small enough. □

Proof of Theorem 1: The outline of the proof is as follows. First, we define $M = \sqrt{2}n^{-1/2}\log(n)$. Notice the difference between M (a number) and $\mathcal{M}$ (a functional space used for the definition of the entropy number introduced just before Lemma 14). Then we bound the probability $P(e(\hat{f}_n,f^{(\infty)}) \ge 8sM+d_{n,s})$. In particular, we show that $P(e(\hat{f}_n,f^{(\infty)}) \ge 8sM+d_{n,s}) \le 6(1-\frac{1}{16nM^2})^{-1}\exp(-nM^2)$, then apply the Borel-Cantelli Lemma to obtain the result.

For $M=\sqrt{2}n^{-1/2}\log(n)$, we first verify that for a large n, this M satisfies

$$(\log_2 \frac{16\sqrt{6}\eta_{n,0}}{M}+1)^2(\frac{256C_0}{n}) \le \frac{M^2}{256}, \tag{8}$$

where $\eta_{n,0}>0$ is chosen to satisfy

$$\frac{C_0}{\eta_{n,0}^2}+\log\frac{5}{\eta_{n,0}}=\frac{1}{4}nM^2, \tag{9}$$

and $C_0=2^{10}$ is a constant as in Lemma 14. From (9), one can verify that $\eta_{n,0}$ goes to 0. Now (8) is equivalent to $(\log_2 \frac{16\sqrt{6}\eta_{n,0}}{M}+1)^2 \le \frac{nM^2}{2^{16}C_0}$. Note that $\frac{nM^2}{2^{16}C_0}$ is of the order $O_P(\log(n))^2$. The order of $(\log_2 \frac{16\sqrt{6}\eta_{n,0}}{M}+1)^2$ is less than that of $(\log\frac{1}{M})^2$, which is $O_P(\log\frac{n^{1/2}}{\log(n)})^2$, and $O_P(\log\frac{n^{1/2}}{\log(n)})^2 < O_P(\log(n))^2$. Thus with n large enough, (8) holds.

Now we prove $P(e(\hat{f}_n,f^{(\infty)})\ge 8sM+d_{n,s}) \le 6(1-\frac{1}{16nM^2})^{-1}\exp(-nM^2)$. We have, by definition of $d_{n,s}$,

$$P(e(\hat{f}_n,f^{(\infty)})>8sM+d_{n,s}) \le P(e(\hat{f}_n,f_n^{(s)})(2s)^{-1}>4M).$$

Then because $\frac{1}{n}\sum_{i=1}^n(L(f_n^{(s)},y_i)-L(\hat{f},y_i))>0$, we have

$$\begin{aligned}
&P(e(\hat{f}_n,f^{(\infty)})>8sM+d_{n,s})\\
&\le P^*\Big(\sup_{f\in\mathcal{F}_n(s):e(f,f_n^{(s)})(2s)^{-1}>4M}\frac{1}{n}\sum_{i=1}^n(L(f_n^{(s)},y_i)-L(f,y_i))>0\Big)\\
&\le P^*\Big(\sup_{f\in\mathcal{F}_n(s):e(f,f_n^{(s)})(2s)^{-1}>4M}-\frac{1}{n}\sum_{i=1}^n[g_f(y_i)-Eg_f(y)]>(2s)^{-1}E(L(f,Y)-L(f_n^{(s)},Y))\Big)\\
&\le P^*(\sup_{g_f\in\mathcal{G}}|P_ng_f-Pg_f|>4M).
\end{aligned}$$

Here P^* denotes the outer probability, and the expectation is taken jointly with respect to the distribution of X and the noise. In the last inequality, for brevity we have the empirical process $g_f\to P_ng_f-Pg_f$, where $g_f\in\mathcal{G}$, $Pg_f=\int g_f$ and $P_ng_f=\frac{1}{n}\sum_{i=1}^n g_f(y_i)$.

Now we show that $P^*(\sup_{g_f\in\mathcal{G}}|P_ng_f-Pg_f|>4M)\le 6(1-\frac{1}{16nM^2})^{-1}\exp(-nM^2)$.

This part of proof follows a similar line as Theorem A.2 in Wang and Shen (2007). There are two steps involved. The first step is to sample n observations without replacement from $N=2n$ instances, which are $i.i.d.$ samples from P, and let $(W_1,\ldots,W_N)$ be uniformly distributed on the set of all permutations of $1,\ldots,N$. Define $\tilde{P}_{n,N}=\frac{1}{n}\sum_{i=1}^n\delta_{(X)_{W_i}}$, and $P_N=\frac{1}{N}\sum_{i=1}^N\delta_{(X)_i}$, where $\delta_{(X)_i}$ is the Dirac measure at the observation X_i. Then we can bound the LHS of the required inequality by Lemma 2.14.18 in Van der Vaart and Wellner (2000),

$$P^*(\sup_{g_f\in\mathcal{G}}|P_ng_f-Pg_f|>4M)\le(1-\frac{1}{16nM^2})^{-1}P^*_{|N}(\sup_{\mathcal{G}}|\tilde{P}_{n,N}g_f-P_Ng_f|>M), \tag{10}$$

where $P_{|N}$ is the conditional probability given N observations.

The second step is to bound $P^*_{|N}(\sup_{\mathcal{G}}|\tilde{P}_{n,N}g_f-P_Ng_f|>M)$. We apply the chaining technique here. Let $\eta_{n,0}>\eta_1>\cdots>\eta_T>0$ be a sequence of positive numbers to be determined later

on. Let $\mathcal{G}_q$ be the minimal η_q-net for $\mathcal{G}$ with respect to the $L_2(T_X)$ norm. For each q, let $\pi_qg=\text{argmin}_{h\in\mathcal{G}_q}\|g-h\|_{L_2(T_X)}$. That means, π_qg is the closest point to g within $\mathcal{G}_q$. By definition, $|\mathcal{G}_q|=N(\eta_q,\mathcal{G},L_2(T_X))$, and $\|\pi_qg-g\|_{L_2(T_X)}\le\eta_q$. Hence, decompose $P^*_{|N}(\sup_{\mathcal{G}}|\tilde{P}_{n,N}g_f-P_Ng_f|>M)$ into

$$\begin{aligned}
&P^*_{|N}(\sup_{\mathcal{G}}|\tilde{P}_{n,N}g_f-P_Ng_f|>M)\\
&\le P^*_{|N}(\sup_{\mathcal{G}}|(\tilde{P}_{n,N}-P_N)(\pi_0g_f)|>7M/8)\\
&\quad+P^*_{|N}(\sup_{\mathcal{G}}|(\tilde{P}_{n,N}-P_N)(\pi_0g_f-\pi_Tg_f)|>M/16)\\
&\quad+P^*_{|N}(\sup_{\mathcal{G}}|(\tilde{P}_{n,N}-P_N)(\pi_Tg_f-g_f)|>M/16)\\
&\le|\mathcal{G}_0|\sup_{\mathcal{G}}P^*_{|N}(|(\tilde{P}_{n,N}-P_N)(\pi_0g_f)|>7M/8)\\
&\quad+\sum_{q=1}^T|\mathcal{G}_q||\mathcal{G}_{q-1}|\sup_{\mathcal{G}}P^*_{|N}(|(\tilde{P}_{n,N}-P_N)(\pi_0g_f-\pi_Tg_f)|>\chi)\\
&\quad+P^*_{|N}(\sup_{\mathcal{G}}|(\tilde{P}_{n,N}-P_N)(\pi_Tg_f-g_f)|>M/16)\\
&:=P_1+P_2+P_3,
\end{aligned}$$

where $T\chi\le M/16$. Next, we bound P_1, P_2 and P_3 individually.

For P_3, one can verify that $\tilde{P}_{n,N}f\le 2P_Nf$ for any non-negative f. Note that we have $((\tilde{P}_{n,N}-P_N)z)^2\le 2(\tilde{P}_{n,N}z^2+P_Nz^2)$ for any z. Thus, $|(\tilde{P}_{n,N}-P_N)(\pi_Tg_f-g_f)|^2\le 2(\tilde{P}_{n,N}+P_N)(\pi_Tg_f-g_f)^2\le 6\eta_T^2$. This yields $P_3=0$ if we choose $\eta_T=\frac{M}{16\sqrt{6}}$.

For P_1, note that $0\le\pi_0g_f\le 1$ for any $g_f\in\mathcal{G}$ because $\mathcal{G}$ is scaled. By Hoeffding's inequalities for sums of bounded random variables (Hoeffding, 1963), $P^*_{|N}(|(\tilde{P}_{n,N}-P_N)(\pi_0g_f)|>7M/8)\le 2\exp(-2n(7/8)^2M^2)$. Thus by assumption (9) and Lemma 14,

$$P_1\le 2N(\eta_{n,0},\mathcal{G},L_2(T_X))\exp(-2n(7/8)^2M^2)\le 2\exp(-nM^2).$$

For P_2, if $\eta_{n,0}\le\frac{M}{16\sqrt{6}}$, then let $\eta_q=\eta_{n,0};q=1,\ldots,T$, and we have $P_2=0$ by a similar argument as in the P_3 part discussed above. So suppose $\eta_{n,0}>\frac{M}{16\sqrt{6}}>\eta_T$. Note that $P_N(\pi_qg_f-\pi_{q-1}g_f)^2\le 2(P_N(\pi_qg_f-g_f)^2+P_N(\pi_{q-1}g_f-g_f)^2)\le 4\eta_{q-1}^2$. By Massart's inequality from Lemma 2.14.19 in Van der Vaart and Wellner (2000), we have $P^*_{|N}(|(\tilde{P}_{n,N}-P_N)(\pi_0g_f-\pi_Tg_f)|>\chi)\le 2\exp(-\frac{n\chi^2}{2\sigma_N^2})$ with $\sigma_N^2=P_N(\pi_qg_f-\pi_{q-1}g_f)^2\le 4\eta_{q-1}^2$. So,

$$\begin{aligned}
P_2&\le 2\sum_{q=1}^T|\mathcal{G}_q|^2\exp(-\frac{n\chi^2}{2\sigma_N^2})\\
&\le 2\sum_{q=1}^T\exp(2C_0\eta_q^{-2}+2\log\frac{5}{\eta_q}-\frac{n\chi^2}{8\eta_{q-1}^2}).
\end{aligned}$$

Let $\eta_q=2^{-q}\eta;q=1,\ldots,T$, and let T be the greatest integer that does not exceed $\log_2\frac{16\sqrt{6}\eta_{n,0}}{M}$. Then let $\chi=(\frac{256C_0}{n})^{1/2}$. By assumption (8), we can verify that $T\chi\le M/16$ as satisfied. Because

when η is small enough, $\frac{C_0}{\eta^2} > \log\frac{5}{\eta}$, and this leads to

$$\begin{aligned} P_2 &\le 2\sum_{q=1}^{T}\exp(\frac{-4}{\eta_q^2}C_0) \\ &\le 2\sum_{q=1}^{T}\exp(-2^{2q-1}(nM^2)) \\ &\le 4\exp(-nM^2). \end{aligned}$$

Thus, $P^*_{|N}(\sup_{\mathcal{G}}|\tilde{P}_{n,N}g_f - P_N g_f| > M) < 6\exp(-nM^2)$. The desired result follows after we take expectation with respect to the distribution of N observations. We have proved $P^*(\sup_{g_f\in\mathcal{G}}|P_n g_f - Pg_f| > 4M) \le 6(1-\frac{1}{16nM^2})^{-1}\exp(-nM^2)$.

Finally, observe that $nM^2 = 2(\log(n))^2 > 2\log(n)$. We have $\exp(-nM^2) \le \exp(-2\log(n)) = \frac{1}{n^2}$. The desired result in Theorem 1 then follows from Borel-Cantelli Lemma. ■

Appendix B. Proof of Corollary 5

The key to the proof is to show that with a high probability, the estimated b would be bounded in a range. Then we can apply the same technique as that in the proof of Theorem 1 to prove the desired result.

Without loss of generality, assume $|f_0(X)| < \zeta$ for a fixed $\zeta > 0$. Moreover, for simplicity, we assume that $\varepsilon(X)$ follows a common sub-Gaussian distribution with c.d.f. Φ_ε. The generalization to heteroscedastic cases is straightforward, because we are only concerned with the tail probability $\mathrm{pr}(|\varepsilon(X)| > t)$. Next, for a small positive number δ, define $t^* = \Phi_\varepsilon^{-1}\big(0.5+0.5(1-\delta/2)^{1/n}\big)$. One can verify that with probability at least $1-\delta/2$, all the errors ε_i; $i = 1,\ldots,n$ are in $[-t^*,t^*]$. Therefore, for any τ, we have that with probability at least $1-\delta/2$, $|b| \le \zeta + t^*$. This is because the estimated function cannot be smaller (or larger) than all the observations. Hence, letting $s^* = s+\zeta+t^*$, $M^* = \sqrt{2}n^{-1/2}\log(n)/t^*$ and using similar techniques as that in the proof of Theorem 1, we have $P(e(\hat{f}_n^*, f^{(\infty)}) > 8s^*M^* + d_{n,s^*}) \le 6(1-\frac{1}{16nM^{*2}})^{-1}\exp(-nM^{*2}) + \delta/2$. Let δ converge to zero at the rate $O_P(n^{-2}\log(n))$. The last step is to check that (8) and (9) are both true with our new choice of M^*. Because we assume that Φ_ε is the c.d.f. of a sub-Gaussian distribution with a fixed parameter, one can verify that t^* diverges at a rate slower than $O_P(\log(n))$. Hence, (8) and (9) remain valid, and the Borel-Cantelli Lemma as in the final step of the proof of Theorem 1 holds. This completes the proof. ■

Appendix C. Proof of Theorem 7

The proof uses a similar technique as Theorem 2.7 in Steinwart and Scovel (2007). Consider the function

$$V(x) = C\int_D \exp(\frac{|x-x'|^2}{2\sigma^2})f_{\text{true}}(x')dx', \tag{11}$$

where C is a constant that depends only on σ and p and is to be determined later on. One can verify that $V(x) \in \mathcal{F}(\infty)$ (Steinwart et al., 2006). Hence,

$$\begin{aligned} A(\infty) &\le E\big(\rho_\tau(Y-V)\big) - E\big(\rho_\tau(Y-f_{\text{true}})\big) \\ &\le E_{P_X}\big(\rho_\tau(V-f_{\text{true}})\big). \end{aligned}$$

Therefore, one only needs to bound $E_{P_X}\big(\rho_\tau(V-f_{\text{true}})\big)$. We have

$$\begin{aligned} V(x) &= C\int_D \exp(\frac{|x-x'|^2}{2\sigma^2})\big(f_{\text{true}}(x')+a\big)dx' - a \\ &\ge C\int_{B(x,\psi_x)} \exp(\frac{|x-x'|^2}{2\sigma^2})\big(f_{\text{true}}(x')+a\big)dx' - a \\ &= a_i - (a_i+a)P'(|u| \ge \psi_x), \end{aligned}$$

where the first inequality is because $f_{\text{true}}(x')+a$ is lower bounded by 0, and on $B(x,\psi_x)$ the function f_{true} is constant. Here one chooses C such that P' is the measure of a spherical Gaussian in D (see the definition of spherical Gaussian in, for example, Steinwart, 2002). By the inequality (3.5) on page 59 of Ledoux and Talagrand (1991), $P'(|u| \ge \psi_x) \le 4\exp\big(-\psi_x^2/(2p\sigma^2)\big)$, and consequently we have that on D_i,

$$V - f_{\text{true}} \ge -8a\exp\big(-\psi_x^2/(2p\sigma^2)\big).$$

An analogous derivation on $-f_{\text{true}}$ and $-V$ gives

$$V - f_{\text{true}} \le 8a\exp\big(-\psi_x^2/(2p\sigma^2)\big).$$

Therefore

$$E\big(\rho_\tau(V-f_{\text{true}})\big) \le \max(\tau,1-\tau)E_{P_X}\big\{8a\exp\big(-\psi_x^2/(2p\sigma^2)\big)\big\}.$$

This completes the proof.

Notice that the core part of the proof is at the inequality (3.5) on page 59 of Ledoux and Talagrand (1991). For the Gaussian kernel (and other radial kernels), the probability $P'(|u| \ge \psi_x)$ vanishes as $\sigma \to 0$. However, for other kernels this may not be true. Take the polynomial kernel as an example. One can verify that when $|x_1 - x_2|$ is large, $K(x_1,x_2)$ is large, and this leads to $P'(|u| \ge \psi_x)$ being large. Therefore, the result here does not hold true for general RKHS's. ■

Appendix D. Proof of Corollary 8

Without loss of generality, let the Lipschitz constant of f_{true} be 1. In this proof, let ε be a small positive number, instead of the noise as $Y = f_0 + \varepsilon$. We first consider the approximation of V to f_{true} on $[0,1]^p$, where V is defined as in the proof of Theorem 7. Because $[0,1]^p$ is a compact set, there exists a finite set of $B(x_j,\varepsilon)$; $j = 1,\ldots,J$ that covers $[0,1]^p$. Here $B(x_j,\varepsilon)$ is a ball with center at x_j and radius ε, and J is a positive integer. Based on $B(x_j,\varepsilon)$; $j = 1,\ldots,J$, one can construct sets $S_{x_j} \subset B(x_j,\varepsilon)$; $j = 1,\ldots,J$ such that S_{x_i} and S_{x_j} are non-overlapping for $i \ne j$, and $\bigcup_{j=1}^J S_{x_j} = [0,1]^p$. On each S_{x_j}, one can verify that

$$f_{\text{true}}(x_j) - \varepsilon \le f_{\text{true}} \le f_{\text{true}}(x_j) + \varepsilon.$$

Now on S_{x_j}, define $\bar{f}_{\text{true}} = f_{\text{true}}(x_j)$. We have that

$$E_{[0,1]^p}\rho_\tau(V - f_{\text{true}}) \le E_{[0,1]^p}\rho_\tau(V - \bar{f}_{\text{true}}) + E_{[0,1]^p}\rho_\tau(\bar{f}_{\text{true}} - f_{\text{true}}). \tag{12}$$

By Theorem 7 and the discussion thereafter, the first part on the right hand side of (12) goes to 0 with $\sigma \to 0$, and the second part is upper bounded by ε. Let $\varepsilon \to 0$ and this proves that V can approximate f_{true} arbitrarily well on $[0,1]^p$. For the approximation on D, notice that D can be decomposed into countably many sets such as $[0,1]^p$, and a similar argument as above proves the corollary. ■

Appendix E. Proof of Theorem 9

To prove Theorem 9, we need to introduce the Rademacher variables (see, for example, Bartlett and Mendelson (2002), Koltchinskii and Panchenko (2002), Shawe-Taylor and Cristianini (2004), Bartlett et al. (2005), Koltchinskii (2006), Mohri et al. (2012) and the references therein). With a little abusing of notations, let σ_i; $i = 1,\dots,n$ be *i.i.d.* random variables that take 1 with probability $1/2$, and -1 with probability $1/2$. Denote by S a sample of (x_i, y_i); $i = 1,\dots,n$, *i.i.d.* from the joint distribution of X and Y. Recall the definition of $\mathcal{F}_n(s)$ in Section 3.1. With S fixed, we define the empirical Rademacher complexity of the function class $\mathcal{F}_n(s)$ as

$$\hat{R}_n(\mathcal{F}_n(s)) = E_\sigma[\sup_{f\in\mathcal{F}_n(s)} \frac{1}{n}\sum_{i=1}^n \sigma_i \rho_\tau\big(y_i - f(x_i)\big)],$$

where E_σ represents the expectation with respect to $\sigma = (\sigma_1,\dots,\sigma_n)$. Moreover, let the Rademacher complexity of $\mathcal{F}_n(s)$ be

$$R_n(\mathcal{F}_n(s)) = E_S \hat{R}_n(\mathcal{F}_n(s)),$$

where E_S is the expectation with respect to the distribution of S.

The proof of Theorem 9 follows directly from Lemmas 15, 17 and 18. Lemma 15 bounds $E\rho_\tau(Y - \hat{f}_n)$ or $E\rho_\tau(Y - \tilde{f}_n)$ in terms of the sum of its empirical measurement, the Rademacher complexity of the function class $\mathcal{F}_n(s)$, and a penalty term on δ, where δ is the small probability that the bound fails. Lemma 17 and Lemma 18 bound the Rademacher complexity. In particular, Lemma 17 provides the bound with $\mu = \sqrt{n^{-1}\big(2^{11}n^{1/4} + 2\log(5) + 0.5\log(n)\big)}$ that works for both the regular squared norm method and the data sparsity method. This is because the complexity bound of $\mathcal{F}_n(s)$ is from Lemma 14, which holds for both methods. As discussed in the main text, we provide another bound that only works for the data sparsity method in Lemma 18, which leads to $\mu = s\sqrt{\frac{2\log(2n+2)}{n}}$.

Lemma 15 *Define $R_n(\mathcal{F}_n(s))$ and $\hat{R}_n(\mathcal{F}_n(s))$ as above. Suppose Assumption A holds. With probability at least $1-\delta$,*

$$E\rho_\tau(Y - \hat{f}_n) \le \frac{1}{n}\sum_{i=1}^n \rho_\tau(y_i - \hat{f}_n(x_i)) + 2R_n(\mathcal{F}_n(s)) + T_n(\delta), \tag{13}$$

where $T_n(\delta) = \max(\tau, 1-\tau)\Big(n^{-1}(2s^2 + 2t^2)\log(1/\delta)\Big)^{1/2}$. In addition, with probability at least $1-\delta$,

$$E\rho_\tau(Y - \hat{f}_n) \le \frac{1}{n}\sum_{i=1}^n \rho_\tau(y_i - \hat{f}_n(x_i)) + 2\hat{R}_n(\mathcal{F}_n(s)) + 3T_n(\delta/2). \tag{14}$$

Moreover, (13) and (14) hold for $\tilde{f}_n$.

Proof of Lemma 15: We divide the proof into three parts. In the first part, we bound the left hand side of (13) in terms of its empirical estimation and the expectation of their supremum difference, by the McDiarmid inequality (McDiarmid, 1989). The second part bounds the expectation of the supremum difference from the first step by the previously defined Rademacher complexity with a symmetrization technique. In the third part, we bound the Rademacher complexity by its empirical version. In this proof, we focus on $\hat{f}_n$, as the proof for $\tilde{f}_n$ is the same.

We begin the proof by introducing some notation. For a given sample S, let

$$\phi(S) = \sup_{f\in\mathcal{F}_n(s)} [E\rho_\tau(Y - f(X)) - \frac{1}{n}\sum_{i=1}^n \rho_\tau(y_i - f(x_i))].$$

Define $S^{(i,x)} = \{(x_1,y_1),\dots,(x_i',y_i),\dots,(x_n,y_n)\}$ to be another sample from the joint distribution of X and Y. Notice that the difference between S and $S^{(i,x)}$ is only on the x value of their i^{th} pair. Similarly, define $S^{(i,y)} = \{(x_1,y_1),\dots,(x_i,y_i'),\dots,(x_n,y_n)\}$ with the y values in the i^{th} pair being different. Then we have

$$\begin{aligned}|\phi(S) - \phi(S^{(i,x)})| = |&\sup_{f\in\mathcal{F}_n(s)} [E\rho_\tau(Y - f(X)) - \frac{1}{n}\sum_{S} \rho_\tau(y_i - f(x_i))] \\ &- \sup_{f\in\mathcal{F}_n(s)} [E\rho_\tau(Y - f(X)) - \frac{1}{n}\sum_{S^{(i,x)}} \rho_\tau(y_i - f(x_i))]|.\end{aligned} \tag{15}$$

For simplicity, we consider only the case where there exists a measurable function $f^S \in \mathcal{F}_n(s)$ that achieves the supremum of $\phi(S)$. Note that the case of no function achieving the supremum can be treated similarly, with only minor modification on the proof, and the details are omitted. Substitute f^S in (15) and after some calculation, we have that

$$|\phi(S) - \phi(S^{(i,x)})| \le \frac{2}{n}\max(\tau, 1-\tau)s.$$

Similarly, one can verify that $|\phi(S) - \phi(S^{(i,y)})| \le \frac{2}{n}\max(\tau,1-\tau)t$. Hence, by the McDiarmid inequality, for any $z > 0$, $P(\phi(S) - E\phi(S) \ge z) \le \exp\Big(-\frac{2z^2}{\frac{1}{n}\left(\max(\tau,1-\tau)\right)^2(4s^2+4t^2)}\Big)$. Therefore, with probability at least $1-\delta$, $\phi(S) - E\phi(S) \le T_n(\delta)$. This proves the first part of the lemma.

In the second step, we bound $E\{\phi(S)\}$ by the Rademacher complexity $R_n(\mathcal{F}_n(s))$ using a symmetrization technique. To this end, define $S' = \{(x_i', y_i')\ (i = 1,\dots,n)\}$ as a duplicate sample of S with size n, and assume the distribution of S' is the same as S. Recall the definition of E_S. Moreover, notice that

$$E_{S'}[\frac{1}{n}\sum_{S}\{\rho_\tau(y_i' - \hat{f}_n(x_i')) \mid S\}] = \frac{1}{n}\sum_{S}\{\rho_\tau(y_i' - \hat{f}_n(x_i')),$$

and

$$E_{S'}[\frac{1}{n}\sum_{S'}\{\rho_\tau(y_i' - \hat{f}_n(x_i')) \mid S\}] = E\rho_\tau(Y - \hat{f}_n(X)).$$

Hence, with the Jensen's inequality and the definition of σ, we have

$$\begin{aligned}
E\{\phi(S)\} &= E_S\big(\sup_{f\in\mathcal{F}_n(s)} E_{S'}\big[\frac{1}{n}\sum_{S'}\{\rho_\tau(y_i'-\hat{f}_n(x_i'))\}-\frac{1}{n}\sum_{S}\{\rho_\tau(y_i-\hat{f}_n(x_i))\}\big]\mid S\big)\\
&\le E_{S,S'}\big[\frac{1}{n}\sum_{S'}\{\rho_\tau(y_i'-\hat{f}_n(x_i'))\}-\frac{1}{n}\sum_{S}\{\rho_\tau(y_i-\hat{f}_n(x_i))\}\big]\\
&= E_{S,S',\sigma}\big[\sup_{f\in\mathcal{F}_n(s)}\frac{1}{n}\sum_{S'}\{\rho_\tau(y_i'-\hat{f}_n(x_i'))\}-\frac{1}{n}\sum_{S}\{\rho_\tau(y_i-\hat{f}_n(x_i))\}\big]\\
&\le 2R_n(\mathcal{F}_n(s)).
\end{aligned}$$

This completes the proof of the second step.

The third step bounds $R_n(\mathcal{F}_n(s))$ by the empirical counterpart $\hat{R}_n(\mathcal{F}_n(s))$. This part of the proof is similar to that of the first part, in the sense that we apply the McDiarmid inequality on $\hat{R}_n(\mathcal{F}_n(s))$ and its expectation $R_n(\mathcal{F}_n(s))$. One can then verify that with probability at least $1-\delta$, $R_n(\mathcal{F}_n(s)) \le \hat{R}_n(\mathcal{F}_n(s))+T_n(\delta)$.

The proof of Lemma 15 is thus completed, after combining the results in Steps 1-3 and replacing δ by $\delta/2$. □

The next lemma, Lemma 17, bounds $\hat{R}_n(\mathcal{F}_n(s))$ with the data and tuning parameter that we use. It employs the result obtained in Lemma 14, and is a direct application of the "η-net" idea (Van der Vaart and Wellner, 2000). Because the result in Lemma 14 can be applied to both the regular squared norm method and the data sparsity method, the result in Lemma 17 holds for both methods as well. Before discussing Lemma 17 and its proof, we first introduce the Hoeffding's Inequality.

Proposition 16 *(Hoeffding's Inequality). Let X be a random variable with mean 0 and range in $[a,b]$. Then for any fixed $z>0$, $E(\exp(zX)) \le \exp(z^2(b-a)^2/8)$.*

Lemma 17 *The empirical Rademacher complexity $\hat{R}_n(\mathcal{F}_n(s))$ for $\tilde{f}_n$ satisfies that*

$$\hat{R}_n(\mathcal{F}_n(s)) \le 2sn^{-1/4}+\max(\tau,1-\tau)(s+t)\sqrt{2^{11}n^{-1/2}+(\log(5)/n)+(\log(n)/4n)}.$$

Proof of Lemma 17: Let $R=\frac{\hat{R}_n\mathcal{F}_n(s)}{2s}$. We consider the following function $h_f(\cdot)=(2s)^{-1}\rho_\tau(f-\cdot)$, and the corresponding class $\mathcal{H}_R=\{h_f : f\in\mathcal{F}_n(s)\}$. From the proof of Lemma 14, one can verify that the entropy number of $\mathcal{H}_R$ is bounded by that of $\mathcal{G}$, because the check function is upper bounded by $L(f,\cdot)$ defined after the proof of Lemma 13. Next, we construct the smallest η-net of $\mathcal{H}_R$, $\mathcal{Y}$, such that for all $f\in\mathcal{F}_n(s)$, there exists an element $g_\mathcal{Y}\in\mathcal{Y}$ with the $L_2(T_X)$ distance between f and $g_\mathcal{Y}$ smaller than η, for any arbitrary empirical measure T_X. Therefore, one can verify that

$$\begin{aligned}
R \le& \frac{1}{2s}E_\sigma[\sup_{g_\mathcal{Y}}\frac{1}{n}\sum_{i=1}^n\sigma_i\rho_\tau(g_\mathcal{Y}(x_i)-y_i)]\\
&+\frac{1}{2s}E_\sigma[\sup_{f,g_\mathcal{Y}\ \text{close}}\frac{1}{n}\sum_{i=1}^n\sigma_i(\rho_\tau(f(x_i)-y_i)-\rho_\tau(g_\mathcal{Y}(x_i)-y_i))]\\
:=&R_1+R_2.
\end{aligned}$$

Here "$f, g_\mathcal{Y}$ close" means that the $L_2(T_X)$ distance between f and $g_\mathcal{Y}$ is smaller than η. Consequently, we have that R_2 is bounded by η, by the Hölder's Inequality.

Now we bound R_1. To this end, let z be a positive number to be determined later. From the Jensen's Inequality, we have

$$\begin{aligned}
\exp(2sznR_1) \le& E_\sigma\exp[z\sup_{g_\mathcal{Y}}\sum_{i=1}^n\sigma_i\rho_\tau(g_\mathcal{Y}(x_i)-y_i)]\\
\le&\sum_{g_\mathcal{Y}}E_\sigma[\exp(z\sum_{i=1}^n\sigma_i\rho_\tau(g_\mathcal{Y}(x_i)-y_i))]\\
\le&\sum_{g_\mathcal{Y}}\prod_{i=1}^n E_{\sigma_i}[\exp(z\sigma_i\rho_\tau(g_\mathcal{Y}(x_i)-y_i)].
\end{aligned}$$

Observe that $E_{\sigma_i}[\sigma_i\rho_\tau(g_\mathcal{Y}(x_i)-y_i)]=0$, and

$$-\max(\tau,1-\tau)(s+t) \le \rho_\tau(g_\mathcal{Y}(x_i)-y_i) \le \max(\tau,1-\tau)(s+t).$$

Therefore, by the Hoeffding's Inequality, we have

$$\begin{aligned}
\exp(2sznR_1) \le&\sum_{g_\mathcal{Y}}\prod_{i=1}^n\exp(\frac{z^2(2\max(\tau,1-\tau)(s+t))^2}{8})\\
\le&|\mathcal{Y}|\exp(\frac{nz^2(\max(\tau,1-\tau)(s+t))^2}{2}).
\end{aligned}$$

Equivalently, we have $2snR_1 \le \frac{\log|\mathcal{Y}|}{z}+\frac{nz(\max(\tau,1-\tau)(s+t))^2}{2}$. Choose $z=\frac{\sqrt{2\log|\mathcal{Y}|}}{\max(\tau,1-\tau)(s+t)\sqrt{n}}$, and we have

$$2snR_1 \le \max(\tau,1-\tau)(s+t)\sqrt{2n\log|\mathcal{Y}|},$$

or equivalently,

$$R_1 \le \frac{\max(\tau,1-\tau)(s+t)\sqrt{2\log|\mathcal{Y}|}}{2s\sqrt{n}} \le \frac{\max(\tau,1-\tau)(s+t)}{2s\sqrt{n}}\sqrt{2(C_0\eta^{-2}+\log(5/\eta))}.$$

After we combine the bounds of R_1 and R_2, choose $\eta=n^{-1/4}$, the results then follows. □

Next, we focus on the data sparsity method. In Lemma 18 we would prove that the empirical Rademacher complexity of the functional space in (5) can be smaller than that of (4). As we will see, the technique we use only works for the data sparsity constraint. This bound then leads to another finite sample bound on the prediction error, namely, $\mu=s\sqrt{\frac{2\log(2n+2)}{n}}$. As discussed in the main text, when n is small or moderate, this bound can be much better than the one derived from Lemma 14.

Lemma 18 *The empirical Rademacher complexity $\hat{R}_n(\mathcal{F}_n(s))$ for $\hat{f}_n$ in (5) satisfies that*

$$\hat{R}_n(\mathcal{F}_n(s)) \le s\max(\tau,1-\tau)\sqrt{\frac{2\log(2n+2)}{n}}.$$

Proof of Lemma 18: We first consider the empirical Rademacher complexity of the functional space $\mathcal{F}_n(s)$ without taking the check loss function into consideration. To this end, let us define $\hat{R}_f(\mathcal{F}_n(s)) = E_\sigma[\sup_{f\in\mathcal{F}_n(s)} \frac{1}{n}\sum_{i=1}^n \sigma_i f(x_i)]$. Recall the definition of $\bar{\alpha}$ from Section 4, and define the augmented vector $\tilde{K}_i = (1, K_i)$ for $i = 1,\ldots,n$, where K_i is the i^{th} row of the gram matrix K. We can now rewrite $\hat{R}_f(\mathcal{F}_n(s))$ as

$$\begin{aligned}\hat{R}_f(\mathcal{F}_n(s)) &= E_\sigma[\sup_{\|\bar{\alpha}\|_1\le s} \frac{1}{n}\sum_{i=1}^n \sigma_i \bar{\alpha}^T \tilde{K}_i] \\ &= \frac{s}{n} E_\sigma \|\sum_{i=1}^n \sigma_i \tilde{K}_i\|_\infty \\ &= \frac{s}{n} E_\sigma[\max_{\sigma', j=1,\ldots,n+1} \sigma' \sum_{i=1}^n \sigma_i \tilde{K}_i(j)],\end{aligned}$$

where $\|\cdot\|_\infty$ is the L_∞ norm, $\tilde{K}_i(j)$ is the j^{th} element of $\tilde{K}_i$, and σ' is an independent Rademacher variable. Notice that the new functional space defined by

$$\{\sigma'(\tilde{K}_1(j), \tilde{K}_2(j), \ldots, \tilde{K}_n(j))^T;\ j = 1,\ldots,n+1, \sigma' \in \{\pm 1\}\}$$

consists of $2n+2$ elements.

Next, by applying the same technique as we used in the proof of Lemma 17 to bound R_1, we can show that

$$\hat{R}_f(\mathcal{F}_n(s)) \le s\sqrt{\frac{2\log(2n+2)}{n}}.$$

The rest of the proof is to apply the Talagrand's lemma (Lemma 4.2 on page 78 in Mohri et al., 2012). In particular, as the check loss function is $\max(\tau, 1-\tau)$-Lipschitz, we have

$$\hat{R}_n(\mathcal{F}_n(s)) \le \max(\tau, 1-\tau)\hat{R}_f(\mathcal{F}_n(s)) \le s\max(\tau, 1-\tau)\sqrt{\frac{2\log(2n+2)}{n}}.$$

This completes the proof. ■

Appendix F. Proof of Corollary 10

With the t defined in Corollary 10, one can verify that with probability at least $1-\delta/2$, all the errors ε_i; $i = 1,\ldots,n$ are in $[-t, t]$. Conditioning on this, the claim follows from Theorem 9. ■

Appendix G. Proof of Proposition 12

The proof follows directly from that of Theorem 1 in Li et al. (2007) and is omitted. ■

Section 2	**Methodology**
x, X	Predictor variable
y, Y	Response
n	Number of observation
p	Dimensionality of x
τ	Quantile level
$\varepsilon(\cdot)$	Noise, may depend on x
$f_0(\cdot)$	Defined as $Y = f_0 + \varepsilon$
D	Domain of f_0
$\rho_\tau(\cdot)$	The check function
f_{true}	The population minimizer of the check function
$J(\cdot)$	Penalty on the regression function
λ, s	Tuning parameters
$\mathcal{F}$	Functional class
$\mathbb{R}$	The real line
$\mathcal{H}$	A RKHS
$\|\cdot\|_{\mathcal{H}}$	The norm in the RKHS $\mathcal{H}$
b	Intercept
f'	Regression function in $\mathcal{H}$ without an explicit intercept
f	Regression function in $\mathcal{H}\oplus\mathbb{R}$
$K(\cdot,\cdot)$	The kernel function
K	The gram matrix
$\alpha = (\alpha_1,\ldots,\alpha_n)$	The kernel function coefficients
$\hat{f}_n$	The estimated regression function using the proposed data sparsity constraint
$\tilde{f}_n$	The estimated regression function using the squared norm penalty

BayesPy: Variational Bayesian Inference in Python

Jaakko Luttinen jaakko.luttinen@iki.fi
Department of Computer Science
Aalto University, Finland

Editor: Geoff Holmes

Abstract

BayesPy is an open-source Python software package for performing variational Bayesian inference. It is based on the variational message passing framework and supports conjugate exponential family models. By removing the tedious task of implementing the variational Bayesian update equations, the user can construct models faster and in a less error-prone way. Simple syntax, flexible model construction and efficient inference make BayesPy suitable for both average and expert Bayesian users. It also supports some advanced methods such as stochastic and collapsed variational inference.

Keywords: variational Bayes, probabilistic programming, Python

1. Introduction

Bayesian framework provides a theoretically solid and consistent way to construct models and perform inference. In practice, however, the inference is usually analytically intractable and is therefore based on approximation methods such as variational Bayes (VB), expectation propagation (EP) and Markov chain Monte Carlo (MCMC) (Bishop, 2006). Deriving and implementing the formulas for an approximation method is often straightforward but tedious, time consuming and error prone.

BayesPy is a Python 3 package providing tools for constructing conjugate exponential family models and performing VB inference easily and efficiently. It is based on the variational message passing (VMP) framework which defines a simple message passing protocol (Winn and Bishop, 2005). This enables implementation of small general nodes that can be used as building blocks for large complex models. BayesPy offers a comprehensive collection of built-in nodes that can be used to build a wide range of models and a simple interface for implementing custom nodes. The package is released under the MIT license.

Several other projects have similar goals for making Bayesian inference easier and faster to apply. VB inference is available in Bayes Blocks (Raiko et al., 2007), VIBES (Bishop et al., 2002) and Infer.NET (Minka et al., 2014). Bayes Blocks is an open-source C++/Python package but limited to scalar Gaussian nodes and a few deterministic functions, thus making it very limited. VIBES is an old software package for Java, released under the revised BSD license, but it is no longer actively developed. VIBES has been replaced by Infer.NET, which is partly closed source and licensed for non-commercial use only. Instead of VB inference, mainly MCMC is supported by other projects such as PyMC (Patil et al., 2010), OpenBUGS (Thomas et al., 2006), Dimple (Hershey et al., 2012) and Stan (Stan Development Team, 2014). Thus, there is a need for an open-source and maintained VB software package.

2. Features

BayesPy can be used to construct conjugate exponential family models. The documentation provides detailed examples of how to construct a variety of models, including principal component analysis models, linear state-space models, mixture models and hidden Markov models. BayesPy has also been used in two publications about parameter expansion and time-varying dynamics for linear state-space models (Luttinen, 2013; Luttinen et al., 2014).

Using BayesPy for Bayesian inference consists of four main steps: constructing the model, providing data, finding the posterior approximation and examining the results. The user constructs the model from small modular blocks called nodes. Roughly, each node corresponds to a latent variable, a set of observations or a deterministic function. The inference engine is used to run the message passing algorithm in order to obtain the posterior approximation. The resulting posterior can be examined, for instance, by using a few built-in plotting functions or printing the parameters of the posterior distributions.

Nodes are the primary building blocks for models in BayesPy. There are two types of nodes: stochastic and deterministic. Stochastic nodes correspond to probability distributions and deterministic nodes correspond to functions. Built-in stochastic nodes include all common exponential family distributions (e.g., Gaussian, gamma and Dirichlet distributions), a general mixture distribution and a few complex nodes for dynamic variables (e.g., discrete and Gaussian Markov chains). Built-in deterministic nodes include a gating node and a general sum-product node. In case a model cannot be constructed using the built-in nodes, the documentation provides instructions for implementing new nodes.

BayesPy is designed to be simple enough for non-expert users but flexible and efficient enough for expert users. One goal is to keep the syntax easy and intuitive to read and write by making it similar to the mathematical formulation of the model. Missing values are easy to handle and the variables can be monitored by plotting the posterior distributions during the learning. BayesPy has also preliminary support for some advanced VB methods such as stochastic variational inference (Hoffman et al., 2013), deterministic annealing (Katahira et al., 2008), collapsed inference (Hensman et al., 2012), Riemannian conjugate gradient learning (Honkela et al., 2010), parameter expansions (Qi and Jaakkola, 2007) and pattern searches (Honkela et al., 2003). For developers, the unit testing framework helps in finding bugs, making changes and implementing new features in a robust manner.

BayesPy can be installed similarly to other Python packages. It requires Python 3 and a few popular packages: NumPy, SciPy, matplotlib and h5py. The latest release can be installed from Python Package Index (PyPI) and detailed instructions can be found from the comprehensive online documentation[1]. The latest development version is available at GitHub[2], which is also the platform used for reporting bugs and making pull requests.

3. Example

This section demonstrates the key steps in using BayesPy. An artificial Gaussian mixture dataset is created by drawing 500 samples from two 2-dimensional Gaussian distributions. 200 samples have mean $[2, 2]$ and 300 samples have mean $[0, 0]$:

1. `http://bayespy.org`
2. `https://github.com/bayespy/bayespy`

```
import numpy as np
N = 500; D = 2
data = np.random.randn(N, D)
data[:200,:] += 2*np.ones(D)
```

We construct a mixture model for the data and assume that the parameters, the cluster assignments and the true number of clusters are unknown. The model uses a maximum number of five clusters but the effective number of clusters will be determined automatically:

```
K = 5
```

The unknown cluster means and precision matrices are given Gaussian and Wishart prior distributions:

```
from bayespy import nodes
mu = nodes.Gaussian(np.zeros(D), 0.01*np.identity(D), plates=(K,))
Lambda = nodes.Wishart(D, D*np.identity(D), plates=(K,))
```

The `plates` keyword argument is used to define repetitions similarly to the plate notation in graphical models. The cluster assignments are categorical variables, and the cluster probabilities are given a Dirichlet prior distribution:

```
alpha = nodes.Dirichlet(0.01*np.ones(K))
z = nodes.Categorical(alpha, plates=(N,))
```

The observations are from a Gaussian mixture distribution:

```
y = nodes.Mixture(z, nodes.Gaussian, mu, Lambda)
```

The second argument for the `Mixture` node defines the type of the mixture distribution, in this case Gaussian. The variable is marked as observed by providing the data:

```
y.observe(data)
```

Next, we want to find the posterior approximation for our latent variables. We create the variational Bayesian inference engine:

```
from bayespy.inference import VB
Q = VB(y, mu, z, Lambda, alpha)
```

Before running the VMP algorithm, the symmetry in the model is broken by a random initialization of the cluster assignments:

```
z.initialize_from_random()
```

Without the random initialization, the clusters would not be separated. The VMP algorithm updates the variables in turns and is run for 200 iterations or until convergence:

```
Q.update(repeat=200)
```

The results can be examined visually by using `bayespy.plot` module:

```
import bayespy.plot as bpplt
bpplt.gaussian_mixture_2d(y, alpha=alpha)
bpplt.pyplot.show()
```

It is also possible to print the parameters of the approximate posterior distributions:

```
print(alpha)
```

The `bayespy.plot` module contains also other functions for visually examining the distributions.

	Small GMM	Large GMM	Small PCA	Large PCA
BayesPy	6	90	7 (60)	400 (1 500)
Infer.NET	25	4 600	37 (350)	2 200 (210 000)

Table 1: The average CPU time in milliseconds per iteration for each dataset. The results in parentheses have the following meanings: a) BayesPy without using broadcasting. b) Infer.NET using the same factorization as BayesPy.

4. Comparison with Infer.NET

This section provides a brief comparison with Infer.NET because it is another active project implementing the variational message passing algorithm, whereas the other related active projects implement MCMC. The main advantages of Infer.NET over BayesPy are its support for non-conjugate models (e.g., logistic regression) and other inference engines (EP and Gibbs sampling). On the other hand, BayesPy is open-source software and supports several advanced VB methods (e.g., stochastic variational inference and collapsed inference).

The speed of the packages were compared by using two widely used models: a Gaussian mixture model (GMM) and principal component analysis (PCA).[3] Both models were run for small and large artificial datasets. For GMM, the small model used 10 clusters for 200 observations with 2 dimensions, and the large model used 40 clusters for 2000 observations with 10 dimensions. For PCA, the small model used 10-dimensional latent space for 500 observations with 20 dimensions, and the large model used 40-dimensional latent space for 2000 observations with 100 dimensions. For the PCA model, Infer.NET used both a fully factorizing approximation and also the same approximation as BayesPy which did not factorize with respect to the latent space dimensions. The experiments were run on a quad-core (i7-4702MQ) Linux computer. Because the packages run practically identical algorithms and thus converged to similar solutions in a similar number of iterations (50–100 iterations depending on the dataset), we compared the average CPU time per iteration.

The results are summarized in Table 1. For all datasets, BayesPy is faster probably because it uses highly optimized numerical libraries (BLAS and LAPACK). For PCA, BayesPy also automatically avoids redundant computations which arise because latent variables have equal posterior covariance matrices. However, such broadcasting is not always possible (e.g., if there are missing values in the PCA data). Thus, the table also presents the results when BayesPy is forced to not use broadcasting: BayesPy is slower than Infer.NET on the smaller PCA dataset but faster on the larger PCA dataset. If Infer.NET used the same factorization for PCA as BayesPy, Infer.NET may be orders of magnitude slower.

5. Conclusions

BayesPy provides a simple and efficient way to construct conjugate exponential family models and to find the variational Bayesian posterior approximation in Python. In addition to the standard variational message passing, it supports several advanced methods such

3. The scripts for running the experiments are available as supplementary material.

as stochastic and collapsed variational inference. Future plans include support for non-conjugate models and non-parametric models (e.g., Gaussian and Dirichlet processes).

Abstract

The Gaussian process latent variable model (GP-LVM) provides a flexible approach for non-linear dimensionality reduction that has been widely applied. However, the current approach for training GP-LVMs is based on maximum likelihood, where the latent projection variables are maximised over rather than integrated out. In this paper we present a Bayesian method for training GP-LVMs by introducing a non-standard variational inference framework that allows to approximately integrate out the latent variables and subsequently train a GP-LVM by maximising an analytic lower bound on the exact marginal likelihood. We apply this method for learning a GP-LVM from i.i.d. observations and for learning non-linear dynamical systems where the observations are temporally correlated. We show that a benefit of the variational Bayesian procedure is its robustness to overfitting and its ability to automatically select the dimensionality of the non-linear latent space. The resulting framework is generic, flexible and easy to extend for other purposes, such as Gaussian process regression with uncertain or partially missing inputs. We demonstrate our method on synthetic data and standard machine learning benchmarks, as well as challenging real world datasets, including high resolution video data.

Keywords: Gaussian processes, variational inference, latent variable models, dynamical systems, uncertain inputs

1. Introduction

Consider a non linear function, $f(x)$. A very general class of probability densities can be recovered by mapping a simpler density through the non linear function. For example, we might decide that x should be drawn from a Gaussian density

$$x \sim \mathcal{N}(0, 1)$$

and we observe y, which is given by passing samples from x through a non linear function, perhaps with some corrupting noise

$$y = f(x) + \epsilon, \tag{1}$$

where ϵ could also be drawn from a Gaussian density

$$\epsilon \sim \mathcal{N}\left(0, \sigma^2\right),$$

this time with variance σ^2. Whilst the resulting density for y, denoted by $p(y)$, can now have a very general form, these models present particular problems in terms of tractability.

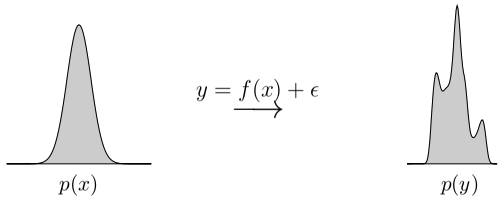

Figure 1: A Gaussian distribution propagated through a non-linear mapping. $y_i = f(x_i) + \epsilon_i$. $\epsilon \sim \mathcal{N}\left(0, 0.2^2\right)$ and $f(\cdot)$ uses RBF basis, 100 centres between -4 and 4 and $\ell = 0.1$. The new distribution over y (right) is multimodal and difficult to normalize.

Models of this form appear in several domains. They can be used for nonlinear dimensionality reduction (MacKay, 1995; Bishop et al., 1998) where several latent variables, $\mathbf{x} = \{x_j\}_{j=1}^q$ are used to represent a high dimensional vector $\mathbf{y} = \{y_j\}_{j=1}^p$ and we normally have $p > q$,

$$\mathbf{y} = \mathbf{f}(\mathbf{x}) + \boldsymbol{\epsilon}.$$

They can also be used for prediction of a regression model output when the input is uncertain (see e.g. Oakley and O'Hagan, 2002) or for autoregressive prediction in time series (see e.g. Girard et al., 2003). Further, by adding a dynamical autoregressive component to the non-linear dimensionality reduction approaches leads to non-linear state space models (Särkkä, 2013), where the states often have a physical interpretation and are propagated through time in an autoregressive manner:

$$\mathbf{x}_t = \mathbf{g}(\mathbf{x}_{t-1}),$$

where $\mathbf{g}(\cdot)$ is a vector valued function. The observations are then observed through a separate nonlinear vector valued function,

$$\mathbf{y}_t = \mathbf{f}(\mathbf{x}_t) + \boldsymbol{\epsilon}.$$

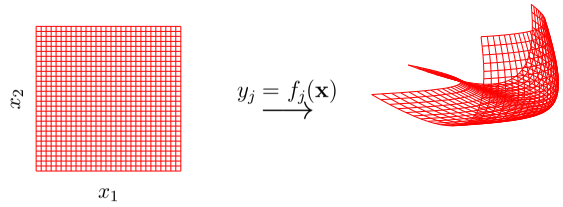

Figure 2: A three dimensional manifold formed by mapping from a two dimensional space to a three dimensional space.

The intractabilities of mapping a distribution through a non-linear function have resulted in a range of different approaches. In density networks sampling was proposed; in particular, in (MacKay, 1995) *importance sampling* was used. When extending importance samplers dynamically, the degeneracy in the weights needs to be avoided, thus leading to the resampling approach suggested for the bootstrap particle filter of Gordon et al. (1993). Other approaches in non-linear state space models include the Laplace approximation as used in extended Kalman filters and unscented and ensemble transforms (see Särkkä, 2013). In dimensionality reduction the generative topographic mapping (GTM Bishop et al., 1998) reinterpreted the importance sampling approach of MacKay (1995) as a mixture model, using a discrete representation of the latent space.

In this paper we suggest a variational approach to dealing with latent variables and input uncertainty that can be applied to Gaussian process models. Gaussian processes provide a probabilistic framework for performing inference over functions. A Gaussian process prior can be combined with a data set (through an appropriate likelihood) to obtain a posterior process that represents all functions that are consistent with the data and our prior.

Our initial focus will be application of Gaussian process models in the context of dimensionality reduction. In dimensionality reduction we assume that our high dimensional data set is really the result of some low dimensional control signals which are, perhaps, non-linearly related to our observed functions. In other words we assume that our data, $\mathbf{Y} \in \Re^{n\times p}$, can be generated by a lower dimensional matrix, $\mathbf{X} \in \Re^{n\times q}$ through a vector valued function where each row, $\mathbf{y}_{i,:}$ of $\mathbf{Y}$ represents an observed data point and is generated through

$$\mathbf{y}_{i,:} = \mathbf{f}(\mathbf{x}_{i,:}) + \boldsymbol{\epsilon}_{i,:},$$

so that the data is a lower dimensional subspace immersed in the original, high dimensional space. If the mapping is linear, e.g. $\mathbf{f}(\mathbf{x}_{i,:}) = \mathbf{W}\mathbf{x}_{i,:}$ with $\mathbf{W} \in \Re^{q\times p}$, methods like principal component analysis, factor analysis and (for non-Gaussian $p(\mathbf{x}_{i,:})$) independent component analysis (Hyvärinen et al., 2001) follow. For Gaussian $p(\mathbf{x}_{i,:})$ the marginalisation of the latent variable is tractable because placing a Gaussian density through an affine transformation retains the Gaussianity of the data density, $p(\mathbf{y}_{i,:})$. However, the linear assumption is very restrictive so it is natural to aim to go beyond it through a non linear mapping.

In the context of dimensionality reduction a range of approaches have been suggested that consider neighbourhood structures or the preservation of local distances to find a low dimensional representation. In the machine learning community, spectral methods such as isomap (Tenenbaum et al., 2000), locally linear embeddings (LLE, Roweis and Saul, 2000) and Laplacian eigenmaps (Belkin and Niyogi, 2003) have attracted a lot of attention. These spectral approaches are all closely related to kernel PCA (Schölkopf et al., 1998) and classical multi-dimensional scaling (MDS) (see e.g. Mardia et al., 1979). These methods do have a probabilistic interpretation as described by Lawrence (2012) which, however, does not explicitly include an assumption of underlying reduced data dimensionality. Other iterative methods such as metric and non-metric approaches to MDS (Mardia et al., 1979), Sammon mappings (Sammon, 1969) and t-SNE (van der Maaten and Hinton, 2008) also lack an underlying generative model.

Probabilistic approaches, such as the generative topographic mapping (GTM, Bishop et al., 1998) and density networks (MacKay, 1995), view the dimensionality reduction problem from a different perspective, since they seek a mapping from a low-dimensional latent space to the observed data space (as illustrated in Figure 2), and come with certain advantages. More precisely, their generative nature and the forward mapping that they define, allows them to be extended more easily in various ways (e.g. with additional dynamics modelling), to be incorporated into a Bayesian framework for parameter learning and to handle missing data. This approach to dimensionality reduction provides a useful archetype for the algorithmic solutions we are providing in this paper, as they require approximations that allow latent variables to be propagated through a non-linear function.

Our framework takes the generative approach prescribed by density networks and the non-linear variants of Kalman filters one step further. Because, rather than considering a specific function, $f(\cdot)$, to map from the latent variables to the data space, we will consider an entire family of functions. One that subsumes the more restricted class of either Gauss Markov processes (such as the *linear* Kalman filter/smoother) and Bayesian basis function models (such as the RBF network used in the GTM, with a Gaussian prior over the basis function weightings). These models can all be cast within the framework of Gaussian processes (Rasmussen and Williams, 2006). Gaussian processes are probabilistic kernel methods, where the kernel has an interpretation of a covariance associated with a prior density. This covariance specifies a distribution over functions that subsumes the special cases mentioned above.

The Gaussian process latent variable model (GP-LVM, Lawrence, 2005) is a more recent probabilistic dimensionality reduction method which has been proven to be very useful for high dimensional problems (Lawrence, 2007; Damianou et al., 2011). GP-LVM can be seen as a non-linear generalisation of probabilistic PCA (PPCA, Tipping and Bishop, 1999; Roweis, 1998), which also has a Bayesian interpretation (Bishop, 1999). In contrast to PPCA, the non-linear mapping of GP-LVM makes a Bayesian treatment much more challenging. Therefore, GP-LVM itself and all of its extensions, rely on a maximum a posteriori (MAP) training procedure. However, a principled Bayesian formulation is highly desirable, since it would allow for robust training of the model, automatic selection of the latent space's dimensionality as well as more intuitive exploration of the latent space's structure.

In this paper we formulate a variational inference framework which allows us to propagate uncertainty through a Gaussian process and obtain a rigorous lower bound on the marginal likelihood of the resulting model. The procedure followed here is non-standard, as computation of a closed-form Jensen's lower bound on the true log marginal likelihood of the data is infeasible with classical approaches to variational inference. Instead, we build on, and significantly extend, the variational GP method of Titsias (2009), where the GP prior is augmented to include auxiliary inducing variables so that the approximation is applied on an expanded probability model. The resulting framework defines a bound on the evidence of the GP-LVM which, when optimised, gives as a by-product an approximation to the true posterior distribution of the latent variables given the data.

Considering a posterior distribution rather than point estimates for the latent points means that our framework is generic and can be easily extended for multiple practical scenarios. For example, if we treat the latent points as noisy measurements of given inputs we obtain a method for Gaussian process regression with uncertain inputs (Girard et al., 2003) or, in the limit, with partially observed inputs. On the other hand, considering a latent space prior that depends on a time vector, allows us to obtain a Bayesian model for dynamical systems (Damianou et al., 2011) that significantly extends classical Kalman filter models with a non-linear relationship between the state space, $\mathbf{X}$, and the observed data $\mathbf{Y}$, along with non-Markov assumptions in the latent space which can be based on continuous time observations. This is achieved by placing a Gaussian process prior on the latent space, $\mathbf{X}$ which is itself a function of time, t. This approach can itself be trivially further extended by replacing the time dependency of the prior for the latent space with a spatial dependency, or a dependency over an arbitrary number of high dimensional inputs. As long as a valid *covariance function*[1] can be derived (this is also possible for strings and graphs). This leads to a Bayesian approach for warped Gaussian process regression (Snelson et al., 2004; Lázaro-Gredilla, 2012).

In the next subsection we summarise the notation and conventions used in this paper. In Section 2 we review the main prior work on dealing with latent variables in the context of Gaussian processes and describe how the model was extended with a dynamical component. We then introduce the variational framework and Bayesian training procedure in Section 3. In Section 4 we describe how the variational approach is applied to a range of predictive tasks and this is demonstrated with experiments conducted on simulated and real world datasets in Section 5. In Section 6 we discuss and experimentally demonstrate natural but important extensions of our model, motivated by situations where the inputs to the GP are not fully unobserved. These extensions give rise to an auto-regressive variant for performing iterative future predictions, as well as a GP regression variant which can handle missing inputs. Finally, based on the theoretical and experimental results of our work, we present our final conclusions in Section 7. This article builds on and extends the previously published conference papers in (Titsias and Lawrence, 2010; Damianou et al., 2011).

1. The constraints for a valid covariance function are the same as those for a Mercer kernel. It must be a positive (semi) definite function over the space of all possible input pairs.

1.1 Notation

Throughout this paper we use capital boldface letters to denote matrices, lower-case boldface letters to denote vectors and lower-case letters to denote scalar quantities. We denote the ith row of the matrix $\mathbf{Y}$ as $\mathbf{y}_{i,:}$ and its jth column as $\mathbf{y}_{:,j}$, whereas $y_{i,j}$ denotes the scalar element found in the ith row and jth column of $\mathbf{Y}$. We assume that data points are stored by rows, so that the $p-$dimensional vector $\mathbf{y}_{i,:}$ corresponds to the ith data point. The collection of test variables (i.e. quantities given at test time for making predictions) is denoted using an asterisk, e.g. $\mathbf{Y}_*$ which has columns $\{\mathbf{y}_{*,j}\}_{j=1}^{p}$.

Concerning variables of interest, $\mathbf{Y}$ is the collection of observed outputs, $\mathbf{F}$ is the collection of latent GP function instantiations and $\mathbf{X}$ is the collection of latent inputs. Further on we will introduce auxiliary inputs denoted by $\mathbf{X}_u$, auxiliary function instantiations denoted by $\mathbf{U}$, a time vector denoted by $\mathbf{t}$, and arbitrary (potentially partially) observed inputs denoted by $\mathbf{Z}$.

If a function f follows a Gaussian process, we use k_f to denote its covariance function and $\mathbf{K}_{ff}$ to denote the covariance matrix obtained by evaluating k_f on all available training inputs. The notation $\boldsymbol{\theta}_f$ then refers to the hyperparameters of k_f.

2. Gaussian Processes with Latent Variables as Inputs

This section provides background material on current approaches for learning using Gaussian process latent variable models (GP-LVMs). Specifically, Section 2.1 specifies the general structure of such models, Section 2.2 reviews the standard GP-LVM for i.i.d. data as well as dynamic extensions suitable for sequence data. Finally, Section 2.3 discusses the drawbacks of MAP estimation over the latent variables which is currently the standard way to train GP-LVMs.

2.1 Gaussian Processes for Latent Mappings

The unified characteristic of all GP-LVM algorithms, as they were first introduced by Lawrence (2005, 2004), is the consideration of a Gaussian Process as a prior distribution for the mapping function $\mathbf{f}(\mathbf{x}) = (f_1(\mathbf{x}), \dots, f_p(\mathbf{x}))$ so that

$$f_j(\mathbf{x}) \sim \mathcal{GP}(0, k_f(\mathbf{x}, \mathbf{x}')), \quad j = 1, \dots, p. \tag{2}$$

Here, the individual components of $\mathbf{f}(\mathbf{x})$ are taken to be independent draws from a Gaussian process with kernel or covariance function $k_f(\mathbf{x}, \mathbf{x}')$, which determines the properties of the latent mapping. As shown in (Lawrence, 2005) the use of a linear covariance function makes GP-LVM equivalent to traditional PPCA. On the the other hand, when non-linear covariance functions are considered the model is able to perfom non-linear dimensionality reduction. The non-linear covariance function considered in (Lawrence, 2005) is the exponentiated quadratic (RBF),

$$k_{f(\text{rbf})}(\mathbf{x}_{i,:}, \mathbf{x}_{k,:}) = \sigma^2_{\text{rbf}} \exp\left(-\frac{1}{2\ell^2}\sum_{j=1}^{q}(x_{i,j} - x_{k,j})^2\right), \tag{3}$$

which is infinitely many times differentiable and it uses a common lengthscale parameter for all latent dimensions. The above covariance function results in a non-linear but smooth

mapping from the latent to the data space. Parameters that appear in a covariance function, such as σ^2_{rbf} and ℓ^2, are often referred to as kernel hyperparameters and will be denoted by $\boldsymbol{\theta}_f$.

Given the independence assumption across dimensions in equation (2), the latent variables $\mathbf{F} \in \Re^{n\times p}$ (with columns $\{\mathbf{f}_{:,j}\}_{j=1}^p$), which have one-to-one correspondence with the data points $\mathbf{Y}$, follow the prior distribution $p(\mathbf{F}|\mathbf{X},\boldsymbol{\theta}_f) = \prod_{j=1}^p p(\mathbf{f}_{:,j}|\mathbf{X},\boldsymbol{\theta}_f)$, where $p(\mathbf{f}_{:,j}|\mathbf{X},\boldsymbol{\theta}_f)$ is given by

$$p(\mathbf{f}_{:,j}|\mathbf{X},\boldsymbol{\theta}_f) = \mathcal{N}\left(\mathbf{f}_{:,j}|\mathbf{0},\mathbf{K}_{ff}\right) = |2\pi\mathbf{K}_{ff}|^{-\frac{1}{2}} \exp\left(-\frac{1}{2}\mathbf{f}_{:,j}^\top \mathbf{K}_{ff}^{-1}\mathbf{f}_{:,j}\right), \tag{4}$$

and where $\mathbf{K}_{ff} = k_f(\mathbf{X},\mathbf{X})$ is the covariance matrix defined by the kernel function k_f. The inputs $\mathbf{X}$ in this kernel matrix are latent random variables following a prior distribution $p(\mathbf{X}|\boldsymbol{\theta}_x)$ with hyperparameters $\boldsymbol{\theta}_x$. The structure of this prior can depend on the application at hand, such as on whether the observed data are i.i.d. or have a sequential dependence. For the remaining of this section we shall leave $p(\mathbf{X}|\boldsymbol{\theta}_x)$ unspecified so that to keep our discussion general while specific forms for it will be given in the next section.

Given the construction outlined above, the joint probability density over the observed data and all latent variables is written as follows:

$$\begin{aligned} p(\mathbf{Y},\mathbf{F},\mathbf{X}|\boldsymbol{\theta}_f,\boldsymbol{\theta}_x,\sigma^2) &= p(\mathbf{Y}|\mathbf{F},\sigma^2)p(\mathbf{F}|\mathbf{X},\boldsymbol{\theta}_f)p(\mathbf{X}|\boldsymbol{\theta}_x) \\ &= \prod_{j=1}^p p(\mathbf{y}_{:,j}|\mathbf{f}_{:,j},\sigma^2)p(\mathbf{f}_{:,j}|\mathbf{X},\boldsymbol{\theta}_f)p(\mathbf{X}|\boldsymbol{\theta}_x), \end{aligned} \tag{5}$$

where the term

$$p(\mathbf{Y}|\mathbf{F},\sigma^2) = \prod_{j=1}^p \mathcal{N}\left(\mathbf{y}_{:,j}|\mathbf{f}_{:,j},\sigma^2\mathbf{I}_n\right) \tag{6}$$

comes directly from the assumed noise model of equation (1) while $p(\mathbf{F}|\mathbf{X},\boldsymbol{\theta}_f)$ and $p(\mathbf{X}|\boldsymbol{\theta}_x)$ come from the GP and the latent space. As discussed in detail in Section 3.1, the interplay of the latent variables (i.e. the latent matrix $\mathbf{X}$ that is passed as input in the latent matrix $\mathbf{F}$) makes inference very challenging. However, when fixing $\mathbf{X}$ we can treat $\mathbf{F}$ analytically and marginalise it out as follows:

$$p(\mathbf{Y}|\mathbf{X})p(\mathbf{X}) = \left(\int p\left(\mathbf{Y}|\mathbf{F}\right)p(\mathbf{F}|\mathbf{X})\mathrm{d}\mathbf{F}\right)p(\mathbf{X}),$$

where

$$p(\mathbf{Y}|\mathbf{X}) = \prod_{j=1}^p \mathcal{N}\left(\mathbf{y}_{:,j}|\mathbf{0},\mathbf{K}_{ff}+\sigma^2\mathbf{I}_n\right).$$

Here (and for the remaining of the paper), we omit reference to the parameters $\boldsymbol{\theta} = \{\boldsymbol{\theta}_f,\boldsymbol{\theta}_x,\sigma^2\}$ in order to simplify our notation. The above partial tractability of the model gives rise to a straightforward MAP training procedure where the latent inputs $\mathbf{X}$ are selected according to

$$\mathbf{X}_{\text{MAP}} = \arg\max_{\mathbf{X}} p(\mathbf{Y}|\mathbf{X})p(\mathbf{X}).$$

This is the approach suggested by Lawrence (2005, 2006) and subsequently followed by other authors (Urtasun and Darrell, 2007; Ek et al., 2008; Ferris et al., 2007; Wang et al., 2008; Ko and Fox, 2009c; Fusi et al., 2013; Lu and Tang, 2014). Finally, notice that point estimates over the hyperparameters $\boldsymbol{\theta}$ can also be found by maximising the same objective function.

2.2 Different Latent Space Priors and GP-LVM Variants

Different GP-LVM algorithms can result by varying the structure of the prior distribution $p(\mathbf{X})$ over the latent inputs. The simplest case, which is suitable for i.i.d. observations, is obtained by selecting a fully factorised (across data points and dimensions) latent space prior:

$$p(\mathbf{X}) = \prod_{i=1}^n \mathcal{N}\left(\mathbf{x}_{i,:}|\mathbf{0},\mathbf{I}_q\right) = \prod_{i=1}^n\prod_{j=1}^q \mathcal{N}\left(x_{i,j}|0,1\right). \tag{7}$$

More structured latent space priors can also be used that could incorporate available information about the problem at hand. For example, Urtasun and Darrell (2007) add discriminative properties to the GP-LVM by considering priors which encapsulate class-label information. Other existing approaches in the literature seek to constrain the latent space via a smooth dynamical prior $p(\mathbf{X})$ so as to obtain a model for dynamical systems. For example, Wang et al. (2006, 2008) extend GP-LVM with a temporal prior which encapsulates the Markov property, resulting in an auto-regressive model. Ko and Fox (2009b, 2011) further extend these models for Bayesian filtering in a robotics setting, whereas Urtasun et al. (2006) consider this idea for tracking. In a similar direction, Lawrence and Moore (2007) consider an additional temporal model which employs a GP prior that is able to generate smooth paths in the latent space.

In this paper we shall focus on dynamical variants where the dynamics are regressive, as in (Lawrence and Moore, 2007). In this setting, the data are assumed to be a multivariate timeseries $\{\mathbf{y}_{i,:},t_i\}_{i=1}^n$ where $t_i \in \Re_+$ is the time at which the datapoint $\mathbf{y}_{i,:}$ is observed. A GP-LVM dynamical model is obtained by defining a temporal latent function $\mathbf{x}(t) = (x_1(t),\ldots,x_q(t))$ where the individual components are taken to be independent draws from a Gaussian process,

$$x_j(t) \sim \mathcal{GP}(0,k_x(t,t')), \quad j=1,\ldots,q,$$

where $k_x(t,t')$ is the covariance function. The datapoint $\mathbf{y}_{i,:}$ is assumed to be produced via the latent vector $\mathbf{x}_{i,:} = \mathbf{x}(t_i)$, as shown in Figure 3(c). All these latent vectors can be stored in the matrix $\mathbf{X}$ (exactly as in the i.i.d. data case) which now follows the correlated prior distribution,

$$p(\mathbf{X}|\mathbf{t}) = \prod_{j=1}^q p(\mathbf{x}_{:,j}|\mathbf{t}) = \prod_{j=1}^q \mathcal{N}\left(\mathbf{x}_{:,j}|\mathbf{0},\mathbf{K}_x\right),$$

where $\mathbf{K}_x = k_x(\mathbf{t},\mathbf{t})$ is the covariance matrix obtained by evaluating the covariance function k_x on the observed times $\mathbf{t}$. In contrast to the fully factorised prior in (7), the above prior couples all elements in each column of $\mathbf{X}$. The covariance function k_x has parameters $\boldsymbol{\theta}_x$ and determines the properties of each temporal function $x_j(t)$. For instance, the use of

an Ornstein-Uhlenbeck covariance function (Uhlenbeck and Ornstein, 1930) yields a Gauss-Markov process for $x_j(t)$, while the exponentiated quadratic covariance function gives rise to very smooth and non-Markovian process. The specific choices and forms of the covariance functions used in our experiments are discussed in Section 5.1.

2.3 Drawbacks of the MAP Training Procedure

Current GP-LVM based models found in the literature rely on MAP training procedures, discussed in Section 2.1, for optimising the latent inputs and the hyperparameters. However, this approach has several drawbacks. Firstly, the fact that it does not marginalise out the latent inputs implies that it could be sensitive to overfitting. Further, the MAP objective function cannot provide any insight for selecting the optimal number of latent dimensions, since it typically increases when more dimensions are added. This is why most existing GP-LVM algorithms require the latent dimensionality to be either set by hand or selected with cross-validation. The latter case renders the whole training computationally slow and, in practice, only a very limited subset of models can be explored in a reasonable time.

As another consequence of the above, the current GP-LVMs employ simple covariance functions (typically having a common lengthscale over the latent input dimensions as the one in equation (3)) while more complex covariance functions, that could help to automatically select the latent dimensionality, are not popular. Such a latter covariance function can be an exponentiated quadratic, as in (3), but with different lengthscale per input dimension,

$$k_{f(\text{ard})}\left(\mathbf{x}_{i,:}, \mathbf{x}_{k,:}\right) = \sigma^2_{\text{ard}} \exp\left(-\frac{1}{2}\sum_{j=1}^{q}\frac{\left(x_{i,j}-x_{k,j}\right)^2}{l_j^2}\right), \tag{8}$$

where the squared inverse lengthscale per dimension can be seen as a weight, i.e. $\frac{1}{l_j^2} = w_j$. This covariance function could thus allow an automatic relevance determination (ARD) procedure to take place, during which unnecessary dimensions of the latent space $\mathbf{X}$ are assigned a weight w_j with value almost zero. However, with the standard MAP training approach the benefits of Bayesian shrinkage using the ARD covariance function cannot be realised, as typically overfitting will occur; this is later demonstrated in Figure 5. This is the reason why standard GP-LVM approaches in the literature avoid the ARD covariance function and are sensitive to the selection of q.

On the other hand, the fully Bayesian framework allows for a "soft" model selection mechanism (Tipping, 2000; Bishop, 1999), stemming from the different role played by q. Specifically, in such an approach q can be seen as an "initial conservative guess" for the effective dimensionality of the latent space; subsequent optimisation renders unnecessary dimensions almost irrelevant by driving the corresponding inverse lengthscales close to zero. Notice, however, that no threshold needs to be employed. Indeed, in the predictive equations all q latent dimensions are used, but the lengthscales automatically weight the contribution of each. In fact, typically the selection for q is not crucial, as long as it is large enough to capture the effective dimensionality of the data. That is, if $r > q$ is used instead, then the extra $r - q$ dimensions will only slightly affect any predictions, given that they will be assigned an almost zero weight. This was indeed observed in our initial experiments. An alternative to the ARD shrinkage principle employed in this paper is the spike and slab

principle (Mitchell and Beauchamp, 1988), which provides "hard" shrinkage so that unnecessary dimensions are assigned a weight exactly equal to zero. This alternative constitutes a promising direction for future research in the context of GP-LVMs.

Given the above, it is clear that the development of fully Bayesian approaches for training GP-LVMs could make these models more reliable and provide rigorous solutions to the limitations of MAP training. The variational method presented in the next section is such an approach that, as demonstrated in the experiments, shows great ability in avoiding overfitting and permits automatic soft selection of the latent dimensionality.

3. Variational Gaussian Process Latent Variable Models

In this section we describe in detail our proposed method which is based on a non-standard variational approximation that uses auxiliary variables. The resulting class of algorithms will be referred to as *Variational Gaussian Process Latent Variable Models*, or simply *variational GP-LVMs*.

We start with Section 3.1 where we explain the obstacles we need to overcome when applying variational methods to the GP-LVM and specifically why the standard mean field approach is not immediately tractable. In Section 3.2, we show how the use of auxiliary variables together with a certain variational distribution results in a tractable approximation. In Section 3.3 we give specific details about how to apply our framework to the two different GP-LVM variants that this paper is concerned with: the standard GP-LVM and the dynamical/warped one. Finally, we outline two extensions of our variational method that enable its application in more specific modelling scenarios. In the end of Section 3.3.2 we explain how multiple independent time-series can be accommodated within the same dynamical model and in Section 3.4 we describe a simple trick that makes the model (and, in fact, any GP-LVM model) applicable to vast dimensionalities.

3.1 Standard Mean Field is Challenging for GP-LVM

A Bayesian treatment of the GP-LVM requires the computation of the log marginal likelihood associated with the joint distribution of equation (5). Both sets of unknown random variables have to be marginalised out: the mapping values $\mathbf{F}$ (as in the standard model) and the latent space $\mathbf{X}$. Thus, the required integral is written as

$$\log p(\mathbf{Y}) = \log \int p(\mathbf{Y},\mathbf{F},\mathbf{X})\mathrm{d}\mathbf{X}\mathrm{d}\mathbf{F} = \log \int p(\mathbf{Y}|\mathbf{F})p(\mathbf{F}|\mathbf{X})p(\mathbf{X})\mathrm{d}\mathbf{X}\mathrm{d}\mathbf{F} \tag{9}$$

$$= \log \int p(\mathbf{Y}|\mathbf{F})\left(\int p(\mathbf{F}|\mathbf{X})p(\mathbf{X})\mathrm{d}\mathbf{X}\right)\mathrm{d}\mathbf{F}. \tag{10}$$

The key difficulty with this Bayesian approach is propagating the prior density $p(\mathbf{X})$ through the non-linear mapping. Indeed, the nested integral in equation (10) can be written as

$$\int p(\mathbf{X}) \prod_{j=1}^{p} p(\mathbf{f}_{:,j}|\mathbf{X})\mathrm{d}\mathbf{X}$$

where each term $p(\mathbf{f}_{:,j}|\mathbf{X})$, given by (4), is proportional to $|\mathbf{K}_{ff}|^{-\frac{1}{2}} \exp\left(-\frac{1}{2}\mathbf{f}_{:,j}^\top \mathbf{K}_{ff}^{-1}\mathbf{f}_{:,j}\right)$. Clearly, this term contains $\mathbf{X}$, which are the inputs of the kernel matrix $\mathbf{K}_{ff}$, in a complex, non-linear manner and therefore analytical integration over $\mathbf{X}$ is infeasible.

To make progress we can invoke the standard variational Bayesian methodology (Bishop, 2006) to approximate the marginal likelihood of equation (9) with a variational lower bound. We introduce a factorised variational distribution over the unknown random variables,

$$q(\mathbf{F}, \mathbf{X}) = q(\mathbf{F})q(\mathbf{X}),$$

which aims at approximating the true posterior $p(\mathbf{F}|\mathbf{Y}, \mathbf{X})p(\mathbf{X}|\mathbf{Y})$. Based on Jensen's inequality, we can obtain the standard variational lower bound on the log marginal likelihood

$$\log p(\mathbf{Y}) \geq \int q(\mathbf{F})q(\mathbf{X}) \log \frac{p(\mathbf{Y}|\mathbf{F})p(\mathbf{F}|\mathbf{X})p(\mathbf{X})}{q(\mathbf{F})q(\mathbf{X})} \mathrm{d}\mathbf{F}\mathrm{d}\mathbf{X}. \tag{11}$$

Nevertheless, this standard *mean field* approach remains problematic because the lower bound above is still intractable to compute. To isolate the intractable term, observe that (11) can be written as

$$\log p(\mathbf{Y}) \geq \int q(\mathbf{F})q(\mathbf{X}) \log p(\mathbf{F}|\mathbf{X}) \mathrm{d}\mathbf{F}\mathrm{d}\mathbf{X} + \int q(\mathbf{F})q(\mathbf{X}) \log \frac{p(\mathbf{Y}|\mathbf{F})p(\mathbf{X})}{q(\mathbf{F})q(\mathbf{X})} \mathrm{d}\mathbf{F}\mathrm{d}\mathbf{X},$$

where the first term of the above equation contains the expectation of $\log p(\mathbf{F}|\mathbf{X})$ under the distribution $q(\mathbf{X})$. This requires an integration over $\mathbf{X}$ which appears non-linearly in $\mathbf{K}_{ff}^{-1}$ and $\log|\mathbf{K}_{ff}|$ and cannot be done analytically. Therefore, standard mean field variational methodologies do not lead to an analytically tractable variational lower bound.

3.2 Tractable Lower Bound by Introducing Auxiliary Variables

In contrast, our framework allows us to compute a closed-form lower bound on the marginal likelihood by applying variational inference after expanding the GP prior so as to include auxiliary inducing variables. Originally, inducing variables were introduced for computational speed ups in GP regression models (Csató and Opper, 2002; Seeger et al., 2003; Csató, 2002; Snelson and Ghahramani, 2006; Quiñonero Candela and Rasmussen, 2005; Titsias, 2009). In our approach, these extra variables will be used within the variational sparse GP framework of Titsias (2009).

More specifically, we expand the joint probability model in (5) by including m extra samples (inducing points) of the GP latent mapping $\mathbf{f}(\mathbf{x})$, so that $\mathbf{u}_{i,:} \in \mathbb{R}^p$ is such a sample. The inducing points are collected in a matrix $\mathbf{U} \in \mathbb{R}^{m\times p}$ and constitute latent function evaluations at a set of pseudo-inputs $\mathbf{X}_u \in \mathbb{R}^{m\times q}$. The augmented joint probability density takes the form

$$\begin{aligned} p(\mathbf{Y}, \mathbf{F}, \mathbf{U}, \mathbf{X}|\mathbf{X}_u) =& p(\mathbf{Y}|\mathbf{F})p(\mathbf{F}|\mathbf{U}, \mathbf{X}, \mathbf{X}_u)p(\mathbf{U}|\mathbf{X}_u)p(\mathbf{X}) \\ =& \left(\prod_{j=1}^{p} p(\mathbf{y}_{:,j}|\mathbf{f}_{:,j})p(\mathbf{f}_{:,j}|\mathbf{u}_{:,j}, \mathbf{X}, \mathbf{X}_u)p(\mathbf{u}_{:,j}|\mathbf{X}_u)\right) p(\mathbf{X}), \end{aligned} \tag{12}$$

where

$$p(\mathbf{f}_{:,j}|\mathbf{u}_{:,j}, \mathbf{X}, \mathbf{X}_u) = \mathcal{N}\left(\mathbf{f}_{:,j}|\mathbf{a}_j, \mathbf{\Sigma}_f\right) \tag{13}$$

is the conditional GP prior (see e.g. Rasmussen and Williams (2006)), with

$$\mathbf{a}_j = \mathbf{K}_{fu}\mathbf{K}_{uu}^{-1}\mathbf{u}_{:,j} (\text{with } a_{i,j} = k_f(\mathbf{x}_{i,:}, \mathbf{X}_u)\mathbf{K}_{uu}^{-1}\mathbf{u}_{:,j}) \quad \text{and} \quad \mathbf{\Sigma}_f = \mathbf{K}_{ff} - \mathbf{K}_{fu}\mathbf{K}_{uu}^{-1}\mathbf{K}_{uf}. \tag{14}$$

Further,

$$p(\mathbf{u}_{:,j}|\mathbf{X}_u) = \mathcal{N}(\mathbf{u}_{:,j}|\mathbf{0}, \mathbf{K}_{uu}) \tag{15}$$

is the marginal GP prior over the inducing variables. In the above expressions, $\mathbf{K}_{uu}$ denotes the covariance matrix constructed by evaluating the covariance function on the inducing points, $\mathbf{K}_{uf}$ is the cross-covariance between the inducing and the latent points and $\mathbf{K}_{fu} = \mathbf{K}_{uf}^\top$. Figure 3(b) graphically illustrates the augmented probability model.

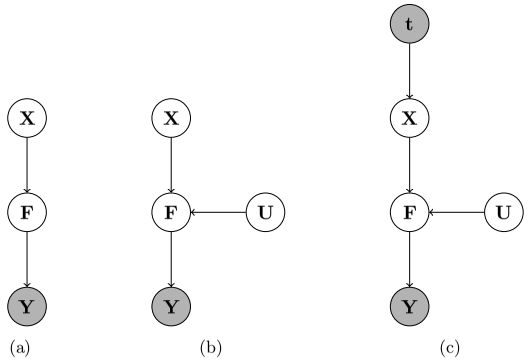

Figure 3: The graphical model for the GP-LVM (a) is augmented with auxiliary variables to obtain the variational GP-LVM model (b) and its dynamical version (c). Shaded nodes represent observed variables. In general, the top level input in (c) can be arbitrary, depending on the application.

Notice that the likelihood $p(\mathbf{Y}|\mathbf{X})$ can be equivalently computed from the above augmented model by marginalizing out $(\mathbf{F}, \mathbf{U})$ and crucially this is true for any value of the inducing inputs $\mathbf{X}_u$. This means that, unlike $\mathbf{X}$, the inducing inputs $\mathbf{X}_u$ are not random variables and neither are they model hyperparameters; they are variational parameters. This interpretation of the inducing inputs is key in developing our approximation and it arises from the variational approach of Titsias (2009). Taking advantage of this observation we now simplify our notation by dropping $\mathbf{X}_u$ from our expressions.

We can now apply variational inference to approximate the true posterior, $p(\mathbf{F}, \mathbf{U}, \mathbf{X}|\mathbf{Y}) = p(\mathbf{F}|\mathbf{U}, \mathbf{Y}, \mathbf{X})\ p(\mathbf{U}|\mathbf{Y}, \mathbf{X})p(\mathbf{X}|\mathbf{Y})$ with a variational distribution of the form

$$q(\mathbf{F}, \mathbf{U}, \mathbf{X}) = p(\mathbf{F}|\mathbf{U}, \mathbf{X})q(\mathbf{U})q(\mathbf{X}) = \left(\prod_{j=1}^{p} p(\mathbf{f}_{:,j}|\mathbf{u}_{:,j}, \mathbf{X})q(\mathbf{u}_{:,j})\right) q(\mathbf{X}), \tag{16}$$

where a key ingredient of this distribution is that the conditional GP prior term $p(\mathbf{F}|\mathbf{U},\mathbf{X})$ that appears in the joint density in (12) is also part of the variational distribution. As shown below this crucially leads to cancellation of difficult terms (involving inverses and determinants over kernel matrices on $\mathbf{X}$) and allows us to compute a closed-form variational lower bound. Furthermore, under this choice the conditional GP prior term $p(\mathbf{F}|\mathbf{U},\mathbf{X})$ attempts to approximate the corresponding exact posterior term $p(\mathbf{F}|\mathbf{U},\mathbf{Y},\mathbf{X})$. This promotes the inducing variables $\mathbf{U}$ to become *sufficient statistics* so that the optimisation of the variational distribution over the inducing inputs $\mathbf{X}_u$ attempts to construct $\mathbf{U}$ so that $\mathbf{F}$ approximately becomes conditionally independent from the data $\mathbf{Y}$ given $\mathbf{U}$. To achieve exact conditional independence we might need to use a large number of inducing variables so that $p(\mathbf{F}|\mathbf{U},\mathbf{X})$ becomes very sharply picked (a delta function). In practice, however, the number of inducing variables must be chosen so that to balance between computational complexity, which is cubic over the number m of inducing variables (see Section 3.4), and approximation accuracy where the latter deteriorates as m becomes smaller.

Moreover, the distribution $q(\mathbf{X})$ in (16) is constrained to be Gaussian,

$$q(\mathbf{X}) = \mathcal{N}\left(\mathbf{X}|\mathcal{M},\mathcal{S}\right), \tag{17}$$

while $q(\mathbf{U})$ is an arbitrary (i.e. unrestricted) variational distribution. We can choose the Gaussian $q(\mathbf{X})$ to factorise across latent dimensions or datapoints and, as will be discussed in Section 3.3, this choice will depend on the form of the prior distribution $p(\mathbf{X})$. For the time being, however, we shall proceed assuming a general form for this Gaussian.

The particular choice for the variational distribution allows us to analytically compute a lower bound. The key reason behind this is that the conditional GP prior term is part of the variational distribution which promotes the cancellation of the intractable $\log p(\mathbf{f}_{:,j}|\mathbf{u}_{:,j},\mathbf{X})$ term. Indeed, by making use of equations (12) and (16) the derivation of the lower bound is as follows:

$$\begin{aligned}
\mathcal{F}\left(q(\mathbf{X}),q(\mathbf{U})\right) &= \int q(\mathbf{F},\mathbf{U},\mathbf{X})\log\frac{p(\mathbf{Y},\mathbf{F},\mathbf{U},\mathbf{X})}{q(\mathbf{F},\mathbf{U},\mathbf{X})}\mathrm{d}\mathbf{X}\mathrm{d}\mathbf{F}\mathrm{d}\mathbf{U}\\
&= \int\prod_{j=1}^{p} p(\mathbf{f}_{:,j}|\mathbf{u}_{:,j},\mathbf{X})q(\mathbf{u}_{:,j})q(\mathbf{X})\log\frac{\prod_{j=1}^{p} p(\mathbf{y}_{:,j}|\mathbf{f}_{:,j})\cancel{p(\mathbf{f}_{:,j}|\mathbf{u}_{:,j},\mathbf{X})}p(\mathbf{u}_{:,j})p(\mathbf{X})}{\prod_{j=1}^{p}\cancel{p(\mathbf{f}_{:,j}|\mathbf{u}_{:,j},\mathbf{X})}q(\mathbf{u}_{:,j})q(\mathbf{X})}\mathrm{d}\mathbf{X}\mathrm{d}\mathbf{F}\mathrm{d}\mathbf{U}\\
&= \int\prod_{j=1}^{p} p(\mathbf{f}_{:,j}|\mathbf{u}_{:,j},\mathbf{X})q(\mathbf{u}_{:,j})q(\mathbf{X})\log\frac{\prod_{j=1}^{p} p(\mathbf{y}_{:,j}|\mathbf{f}_{:,j})p(\mathbf{u}_{:,j})}{\prod_{j=1}^{p} q(\mathbf{u}_{:,j})}\mathrm{d}\mathbf{X}\mathrm{d}\mathbf{F}\mathrm{d}\mathbf{U}\\
&- \int q(\mathbf{X})\log\frac{q(\mathbf{X})}{p(\mathbf{X})}\mathrm{d}\mathbf{X}\\
&= \hat{\mathcal{F}}\left(q(\mathbf{X}),q(\mathbf{U})\right) - \mathrm{KL}\left(q(\mathbf{X})\,\|\,p(\mathbf{X})\right),
\end{aligned} \tag{18}$$

with

$$\begin{aligned}
\hat{\mathcal{F}}\left(q(\mathbf{X}),q(\mathbf{U})\right) &= \sum_{j=1}^{p}\int q(\mathbf{u}_{:,j})\left(\left\langle\log p(\mathbf{y}_{:,j}|\mathbf{f}_{:,j})\right\rangle_{p(\mathbf{f}_{:,j}|\mathbf{u}_{:,j},\mathbf{X})q(\mathbf{X})} + \log\frac{p(\mathbf{u}_{:,j})}{q(\mathbf{u}_{:,j})}\right)\mathrm{d}\mathbf{u}_{:,j}\\
&= \sum_{j=1}^{p}\hat{\mathcal{F}}_j\left(q(\mathbf{X}),q(\mathbf{u}_{:,j})\right),
\end{aligned} \tag{19}$$

where $\langle\cdot\rangle$ is a shorthand for expectation. Clearly, the second KL term can be easily calculated since both $p(\mathbf{X})$ and $q(\mathbf{X})$ are Gaussians; explicit expressions are given in Section 3.3. To compute $\hat{\mathcal{F}}_j\left(q(\mathbf{X}),q(\mathbf{u}_{:,j})\right)$, first note that (see Appendix A for details)

$$\left\langle\log p(\mathbf{y}_{:,j}|\mathbf{f}_{:,j})\right\rangle_{p(\mathbf{f}_{:,j}|\mathbf{u}_{:,j},\mathbf{X})} = \log\mathcal{N}\left(\mathbf{y}_{:,j}|\mathbf{a}_j,\sigma^2\mathbf{I}_n\right) - \frac{1}{2\sigma^2}\mathrm{tr}\left(\mathbf{K}_{ff}\right) + \frac{1}{2\sigma^2}\mathrm{tr}\left(\mathbf{K}_{uu}^{-1}\mathbf{K}_{uf}\mathbf{K}_{fu}\right), \tag{20}$$

where $\mathbf{a}_j$ is given by equation (14), based on which we can write

$$\hat{\mathcal{F}}_j\left(q(\mathbf{X}),q(\mathbf{u}_{:,j})\right) = \int q(\mathbf{u}_{:,j})\log\frac{e^{\left\langle\log\mathcal{N}\left(\mathbf{y}_{:,j}|\mathbf{a}_j,\sigma^2\mathbf{I}_n\right)\right\rangle_{q(\mathbf{X})}}p(\mathbf{u}_{:,j})}{q(\mathbf{u}_{:,j})}\mathrm{d}\mathbf{u}_{:,j} - \mathcal{A}, \tag{21}$$

where $\mathcal{A} = \frac{1}{2\sigma^2}\mathrm{tr}\left(\left\langle\mathbf{K}_{ff}\right\rangle_{q(\mathbf{X})}\right) - \frac{1}{2\sigma^2}\mathrm{tr}\left(\mathbf{K}_{uu}^{-1}\left\langle\mathbf{K}_{uf}\mathbf{K}_{fu}\right\rangle_{q(\mathbf{X})}\right)$. The expression in (21) is a KL-like quantity and, therefore, $q(\mathbf{u}_{:,j})$ is optimally set to be proportional to the numerator inside the logarithm of the above equation, i.e.

$$q(\mathbf{u}_{:,j}) = \frac{e^{\left\langle\log\mathcal{N}\left(\mathbf{y}_{:,j}|\mathbf{a}_j,\sigma^2\mathbf{I}_n\right)\right\rangle_{q(\mathbf{X})}}p(\mathbf{u}_{:,j})}{\int e^{\left\langle\log\mathcal{N}\left(\mathbf{y}_{:,j}|\mathbf{a}_j,\sigma^2\mathbf{I}_n\right)\right\rangle_{q(\mathbf{X})}}p(\mathbf{u}_{:,j})\mathrm{d}\mathbf{u}_{:,j}}, \tag{22}$$

which is just a Gaussian distribution (see Appendix A for an explicit form). We can now re-insert the optimal value for $q(\mathbf{u}_{:,j})$ back into $\hat{\mathcal{F}}_j\left(q(\mathbf{X}),q(\mathbf{u}_{:,j})\right)$ in (21) to obtain:

$$\hat{\mathcal{F}}_j\left(q(\mathbf{X})\right) = \log\int e^{\left\langle\log\mathcal{N}\left(\mathbf{y}_{:,j}|\mathbf{a}_j,\sigma^2\mathbf{I}_n\right)\right\rangle_{q(\mathbf{X})}}p(\mathbf{u}_{:,j})\mathrm{d}\mathbf{u}_{:,j} - \mathcal{A}, \tag{23}$$

$$= \log\int\prod_{i=1}^{n} e^{\left\langle\log\mathcal{N}\left(y_{i,j}|a_{i,j},\sigma^2\right) - \frac{1}{2\sigma^2}\left(k_f(\mathbf{x}_{i,:},\mathbf{x}_{i,:}) - k_f(\mathbf{x}_{i,:},\mathbf{X}_u)\mathbf{K}_{uu}^{-1}k_f(\mathbf{X}_u,\mathbf{x}_{i,:})\right)\right\rangle_{q(\mathbf{x}_{i,:})}}p(\mathbf{u}_{:,j})\mathrm{d}\mathbf{u}_{:,j}, \tag{24}$$

where the second expression uses the factorisation of the Gaussian likelihood across data points and it implies that independently of how complex the overall variational distribution $q(\mathbf{X})$ could be, $\hat{\mathcal{F}}_j$ will depend only on the marginals $q(\mathbf{x}_{i,:})$ over the latent variables associated with different observations. Notice that the above trick of finding the optimal factor $q(\mathbf{u}_{:,j})$ and placing it back into the bound (firstly proposed in (King and Lawrence, 2006)) can be informally explained as *reversing Jensen's inequality* (i.e. moving the log outside of the integral) in the initial bound from (21) as pointed out by Titsias (2009).

Furthermore, by optimally eliminating $q(\mathbf{u}_{:,j})$ we obtain a tighter bound which no longer depends on this distribution, i.e. $\hat{\mathcal{F}}_j\left(q(\mathbf{X})\right) \geq \hat{\mathcal{F}}_j\left(q(\mathbf{X}),q(\mathbf{u}_{:,j})\right)$. Also notice that the expectation appearing in equation (23) is a standard Gaussian integral and (23) can be calculated in closed form, which turns out to be (see Appendix A.3 for details)

$$\hat{\mathcal{F}}_j\left(q(\mathbf{X})\right) = \log\left[\frac{\sigma^{-n}|\mathbf{K}_{uu}|^{\frac{1}{2}}}{(2\pi)^{\frac{n}{2}}|\sigma^{-2}\boldsymbol{\Psi}_2 + \mathbf{K}_{uu}|^{\frac{1}{2}}}e^{-\frac{1}{2}\mathbf{y}_{:,j}^{\top}\mathbf{W}\mathbf{y}_{:,j}}\right] - \frac{\psi_0}{2\sigma^2} + \frac{1}{2\sigma^2}\mathrm{tr}\left(\mathbf{K}_{uu}^{-1}\boldsymbol{\Psi}_2\right) \tag{25}$$

where the quantities

$$\psi_0 = \mathrm{tr}\left(\left\langle\mathbf{K}_{\tilde{f}\tilde{f}}\right\rangle_{q(\mathbf{X})}\right)\ ,\quad \boldsymbol{\Psi}_1 = \left\langle\mathbf{K}_{fu}\right\rangle_{q(\mathbf{X})}\ ,\quad \boldsymbol{\Psi}_2 = \left\langle\mathbf{K}_{uf}\mathbf{K}_{fu}\right\rangle_{q(\mathbf{X})} \tag{26}$$

are referred to as Ψ statistics and $\mathbf{W} = \sigma^{-2}\mathbf{I}_n - \sigma^{-4}\mathbf{\Psi}_1(\sigma^{-2}\mathbf{\Psi}_2 + \mathbf{K}_{uu})^{-1}\mathbf{\Psi}_1^\top$.

The computation of $\hat{\mathcal{F}}_j\left(q(\mathbf{X})\right)$ only requires us to compute matrix inverses and determinants which involve $\mathbf{K}_{uu}$ instead of $\mathbf{K}_{ff}$, something which is tractable since $\mathbf{K}_{uu}$ does not depend on $\mathbf{X}$. Therefore, this expression is straightforward to compute, as long as the covariance function k_f is selected so that the Ψ quantities of equation (26) can be computed analytically.

It is worth noticing that the Ψ statistics are computed in a decomposable way across the latent variables of different observations which is due to the factorisation in (24). In particular, the statistics ψ_0 and $\mathbf{\Psi}_2$ are written as sums of independent terms where each term is associated with a data point and similarly each column of the matrix $\mathbf{\Psi}_1$ is associated with only one data point. This decomposition is useful when a new data vector is inserted into the model and can also help to speed up computations during test time as discussed in Section 4. It can also allow for parallelisation in the computations as suggested firstly by Gal et al. (2014) and then by Dai et al. (2014). Therefore, the averages of the covariance matrices over $q(\mathbf{X})$ in equation (26) of the Ψ statistics can be computed separately for each marginal $q(\mathbf{x}_{i,:}) = \mathcal{N}\left(\mathbf{x}_{i,:}|\boldsymbol{\mu}_{i,:}, \mathbf{S}_i\right)$ taken from the full $q(\mathbf{X})$ of equation (17). We can, thus, write that $\psi_0 = \sum_{i=1}^n \psi_0^i$ where

$$\psi_0^i = \int k_f(\mathbf{x}_{i,:}, \mathbf{x}_{i,:})\mathcal{N}\left(\mathbf{x}_{i,:}|\boldsymbol{\mu}_{i,:}, \mathbf{S}_i\right) \mathrm{d}\mathbf{x}_{i,:}. \tag{27}$$

Further, $\mathbf{\Psi}_1$ is an $n \times m$ matrix such that

$$(\Psi_1)_{i,k} = \int k_f(\mathbf{x}_{i,:}, (\mathbf{x}_u)_{k,:})\mathcal{N}\left(\mathbf{x}_{i,:}|\boldsymbol{\mu}_{i,:}, \mathbf{S}_i\right) \mathrm{d}\mathbf{x}_{i,:}, \tag{28}$$

where $(\mathbf{x}_u)_{k,:}$ denotes the kth row of $\mathbf{X}_u$. Finally, $\mathbf{\Psi}_2$ is an $m \times m$ matrix which is written as $\mathbf{\Psi}_2 = \sum_{i=1}^n \Psi_2^i$ where Ψ_2^i is such that

$$(\Psi_2^i)_{k,k'} = \int k_f(\mathbf{x}_{i,:}, (\mathbf{x}_u)_{k,:})k_f((\mathbf{x}_u)_{k',:}, \mathbf{x}_{i,:})\mathcal{N}\left(\mathbf{x}_{i,:}|\boldsymbol{\mu}_{i,:}, \mathbf{S}_i\right) \mathrm{d}\mathbf{x}_{i,:}. \tag{29}$$

Notice that these statistics constitute convolutions of the covariance function k_f with Gaussian densities and are tractable for many standard covariance functions, such as the ARD exponentiated quadratic or the linear one. The analytic forms of the Ψ statistics for the aforementioned covariance functions are given in Appendix B.

To summarize, the final form of the variational lower bound on the marginal likelihood $p(\mathbf{Y})$ is written as

$$\mathcal{F}\left(q(\mathbf{X})\right) = \hat{\mathcal{F}}\left(q(\mathbf{X})\right) - \mathrm{KL}\left(q(\mathbf{X}) \,\|\, p(\mathbf{X})\right), \tag{30}$$

where $\hat{\mathcal{F}}\left(q(\mathbf{X})\right)$ can be obtained by summing both sides of (25) over the p outputs,

$$\hat{\mathcal{F}}\left(q(\mathbf{X})\right) = \sum_{j=1}^{p} \hat{\mathcal{F}}_j\left(q(\mathbf{X})\right).$$

We note that the above framework is, in essence, computing the following approximation analytically,

$$\hat{\mathcal{F}}\left(q(\mathbf{X})\right) \leq \int q(\mathbf{X}) \log p(\mathbf{Y}|\mathbf{X}) \mathrm{d}\mathbf{X}. \tag{31}$$

The lower bound (18) can be jointly maximised over the model parameters $\boldsymbol{\theta}$ and variational parameters $\{\mathcal{M}, \mathcal{S}, \mathbf{X}_u\}$ by applying a gradient-based optimisation algorithm. This approach is similar to the optimisation of the MAP objective function employed in the standard GP-LVM (Lawrence, 2005) with the main difference being that instead of optimising the random variables $\mathbf{X}$, we now optimise a set of *variational parameters* which govern the approximate posterior mean and variance for $\mathbf{X}$. Furthermore, the inducing inputs $\mathbf{X}_u$ are variational parameters and the optimisation over them simply improves the approximation similarly to variational sparse GP regression (Titsias, 2009).

By investigating more carefully the resulting expression of the bound allows us to observe that each term $\hat{\mathcal{F}}_j\left(q(\mathbf{X})\right)$ from (25), that depends on the single column of data $\mathbf{y}_{:,j}$, closely resembles the corresponding variational lower bound obtained by applying the method of Titsias (2009) in standard sparse GP regression. The difference in variational GP-LVM is that now $\mathbf{X}$ is marginalized out so that the terms containing $\mathbf{X}$, i.e. the kernel quantities $\mathrm{tr}\left(\mathbf{K}_{ff}\right)$, $\mathbf{K}_{fu}$ and $\mathbf{K}_{fu}\mathbf{K}_{uf}$, are transformed into averages (i.e. the Ψ quantities in (26)) with respect to the variational distribution $q(\mathbf{X})$.

Similarly to the standard GP-LVM, the non-convexity of the optimisation surface means that local optima can pose a problem and, therefore, sensible initialisations have to be made. In contrast to the standard GP-LVM, in the *variational* GP-LVM the choice of a covariance function is limited to the class of kernels that render the Ψ statistics tractable. Throughout this paper we employ the ARD exponentiated quadratic covariance function. Improving on these areas (non-convex optimisation and choice of covariance function) is, thus, an interesting direction for future research.

Finally, notice that the application of the variational method developed in this paper is not restricted to the set of latent points. As in (Titsias and Lázaro-Gredilla, 2013), a fully Bayesian approach can be obtained by additionally placing priors on the kernel parameters and, subsequently, integrating them out variationally with the methodology that we described in this section.

3.3 Applying the Variational Framework to Different GP-LVM Variants

Different variational GP-LVM algorithms can be obtained by varying the form of the latent space prior $p(\mathbf{X})$ which so far has been left unspecified. One useful property of the variational lower bound is that $p(\mathbf{X})$ appears only in the separate KL divergence term, as can be seen by equation (18), which can be computed analytically when $p(\mathbf{X})$ is Gaussian. This allows our framework to easily accommodate different Gaussian forms for the latent space prior which give rise to different GP-LVM variants. In particular, incorporating a specific prior mainly requires us to specify a suitable factorisation for $q(\mathbf{X})$ and compute the corresponding KL term. In contrast, the general structure of the more complicated $\hat{\mathcal{F}}\left(q(\mathbf{X})\right)$ term remains unaffected. Next we demonstrate these ideas by giving further details about how to apply the variational method to the two GP-LVM variants discussed in Section 2.2. For both cases we follow the recipe that the factorisation of the variational distribution $q(\mathbf{X})$ resembles the factorisation of the prior $p(\mathbf{X})$.

3.3.1 The Standard Variational GP-LVM for I.i.d. Data

In the simplest case, the latent space prior is just a standard normal density, fully factorised across datapoints and latent dimensions, as shown in (7). This is the typical assumption in latent variable models, such as factor analysis and PPCA (Bartholomew, 1987; Basilevsky, 1994; Tipping and Bishop, 1999). We choose a variational distribution $q(\mathbf{X})$ that follows the factorisation of the prior,

$$q(\mathbf{X}) = \prod_{i=1}^{n} \mathcal{N}\left(\mathbf{x}_{i,:} | \boldsymbol{\mu}_{i,:}, \mathbf{S}_i\right), \tag{32}$$

where each covariance matrix $\mathbf{S}_i$ is diagonal. Notice that this variational distribution depends on $2nq$ free parameters. The corresponding KL quantity appearing in (30) takes the explicit form

$$\mathrm{KL}\left(q(\mathbf{X}) \,\|\, p(\mathbf{X})\right) = \frac{1}{2}\sum_{i=1}^{n} \mathrm{tr}\left(\boldsymbol{\mu}_{i,:}\boldsymbol{\mu}_{i,:}^{\top} + \mathbf{S}_i - \log \mathbf{S}_i\right) - \frac{nq}{2},$$

where $\log \mathbf{S}_i$ denotes the diagonal matrix resulting from $\mathbf{S}_i$ by taking the logarithm of its diagonal elements. To train the model we simply need to substitute the above term in the final form of the variational lower bound in equation (30) and follow the gradient-based optimisation procedure.

The resulting variational GP-LVM can be seen as a non-linear version of Bayesian probabilistic PCA (Bishop, 1999; Minka, 2001). In the experiments, we consider this model for non-linear dimensionality reduction and demonstrate its ability to automatically estimate the effective latent dimensionality.

3.3.2 The Dynamical Variational GP-LVM for Sequence Data

We now turn into the second model discussed in Section 2.2, which is suitable for sequence data. Again we define a variational distribution $q(\mathbf{X})$ so that it resembles fully the factorisation of the prior, i.e.

$$q(\mathbf{X}) = \prod_{j=1}^{q} \mathcal{N}\left(\mathbf{x}_{:,j} | \boldsymbol{\mu}_{:,j}, \mathbf{S}_j\right),$$

where $\mathbf{S}_j$ is a $n \times n$ full covariance matrix. The corresponding KL term takes the form

$$\mathrm{KL}\left(q(\mathbf{X}) \,\|\, p(\mathbf{X}|\mathbf{t})\right) = \frac{1}{2}\sum_{j=1}^{q}\left[\mathrm{tr}\left(\mathbf{K}_x^{-1}\mathbf{S}_j + \mathbf{K}_x^{-1}\boldsymbol{\mu}_{:,j}\boldsymbol{\mu}_{:,j}^{\top}\right) + \log|\mathbf{K}_x| - \log|\mathbf{S}_j|\right] - \frac{nq}{2}.$$

This term can be substituted into the final form of the variational lower bound in (30) and allow training using a gradient-based optimisation procedure. If implemented naively, such a procedure, will require too many parameters to tune since the variational distribution depends on $nq + \frac{n(n+1)}{2}q$ free parameters. However, by applying the reparametrisation trick suggested by Opper and Archambeau (2009) we can reduce the number of parameters in the variational distribution to just $2nq$. Specifically, the stationary conditions obtained by setting to zero the first derivatives of the variational bound w.r.t. $\mathbf{S}_j$ and $\boldsymbol{\mu}_{:,j}$ take the form

$$\mathbf{S}_j = \left(\mathbf{K}_x^{-1} + \boldsymbol{\Lambda}_j\right)^{-1} \quad \text{and} \quad \boldsymbol{\mu}_{:,j} = \mathbf{K}_x\bar{\boldsymbol{\mu}}_{:,j}, \tag{33}$$

where

$$\boldsymbol{\Lambda}_j = -2\frac{\partial \hat{\mathcal{F}}\left(q(\mathbf{X})\right)}{\partial \mathbf{S}_j} \quad \text{and} \quad \bar{\boldsymbol{\mu}}_{:,j} = \frac{\partial \hat{\mathcal{F}}\left(q(\mathbf{X})\right)}{\partial \boldsymbol{\mu}_{:,j}}. \tag{34}$$

Here, $\boldsymbol{\Lambda}_j$ is a $n \times n$ diagonal positive definite matrix and $\bar{\boldsymbol{\mu}}_{:,j}$ is a $n-$dimensional vector. Notice that the fact that the gradients of $\hat{\mathcal{F}}\left(q(\mathbf{X})\right)$ with respect to a full (coupled across data points) matrix $\mathbf{S}_j$ reduce to a diagonal matrix is because only the diagonal elements of $\mathbf{S}_j$ appear in $\hat{\mathcal{F}}\left(q(\mathbf{X})\right)$. This fact is a consequence of the factorisation of the likelihood across data points, which makes the term $\hat{\mathcal{F}}\left(q(\mathbf{X})\right)$ to depend only on marginals of the full variational distribution, as it was pointed by the general expression in equation (24).

The above stationary conditions tell us that, since $\mathbf{S}_j$ depends on a diagonal matrix $\boldsymbol{\Lambda}_j$, we can re-parametrise it using only the diagonal elements of that matrix, denoted by the $n-$dimensional vector $\boldsymbol{\lambda}_j$ where all elements of $\boldsymbol{\lambda}_j$ are restricted to be non-negative. Notice that with this re-parameterisation, and if we consider the pair $(\boldsymbol{\lambda}_j,\ \bar{\boldsymbol{\mu}}_{:,j})$ as the set of free parameters, the bound property is retained because any such pair defines a valid Gaussian distribution $q(\mathbf{X})$ based on which the corresponding (always valid) lower bound is computed. Therefore, if we optimise the $2qn$ parameters $(\boldsymbol{\lambda}_j,\ \bar{\boldsymbol{\mu}}_{:,j})$ and find some final values for those parameters, then we can obtain the mean and covariance of $q(\mathbf{X})$ using the transformation in equation (33).

There are two optimisation strategies, depending on the way we choose to treat the newly introduced parameters $\boldsymbol{\lambda}_j$ and $\bar{\boldsymbol{\mu}}_{:,j}$. Firstly, inspired by Opper and Archambeau (2009) we can construct an iterative optimisation scheme. More precisely, the variational bound $\mathcal{F}$ in equation (30) depends on the *actual* variational parameters $\boldsymbol{\mu}_{:,j}$ and $\mathbf{S}_j$ of $q(\mathbf{X})$, which through equation (33) depend on the newly introduced quantities $\bar{\boldsymbol{\mu}}_{:,j}$ and $\boldsymbol{\lambda}_j$ which, in turn, are associated with $\mathcal{F}$ through equation (34). These observations can lead to an EM-style algorithm which alternates between estimating one of the parameter sets $\{\boldsymbol{\theta}, \mathbf{X}_u\}$ and $\{\mathcal{M}, \mathcal{S}\}$ by keeping the other set fixed. An alternative approach, which is the one we use in our implementation, is to treat the new parameters $\boldsymbol{\lambda}_j$ and $\bar{\boldsymbol{\mu}}_{:,j}$ as completely free ones so that equation (34) is never used. In this case, the variational parameters are optimised directly with a gradient based optimiser, jointly with the model hyperparameters and the inducing inputs.

Overall, the above reparameterisation is appealing not only because of improved complexity, but also because of optimisation robustness. Indeed, equation (33) confirms that the original variational parameters are coupled via $\mathbf{K}_x$, which is a full-rank covariance matrix. By reparametrising according to equation (33) and treating the new parameters as free ones, we manage to approximately break this coupling and apply our optimisation algorithm on a set of less correlated parameters.

Furthermore, the methodology described above can be readily applied to model dependencies of a different nature (e.g. spatial rather than temporal), as any kind of high dimensional input variable can replace the temporal inputs of the graphical model in figure 3(c). Therefore, by simply replacing the input $\mathbf{t}$ with any other kind of observed input $\mathbf{Z}$ we trivially obtain a Bayesian framework for warped GP regression (Snelson et al., 2004; Lázaro-Gredilla, 2012) for which we can predict the latent function values in new inputs $\mathbf{Z}_*$ through a non-linear, latent warping layer, using exactly the same architecture and equations described in this section and in Section 4.2. Similarly, if the observed inputs of the top

layer are taken to be the outputs themselves, then we obtain a probabilistic auto-encoder (e.g. Kingma and Welling (2013)) which is non-parametric and based on Gaussian processes.

Finally, the above dynamical variational GP-LVM algorithm can be easily extended to deal with datasets consisting of multiple independent sequences (probably of different length) such as those arising in human motion capture applications. Let, for example, the dataset be a group of s independent sequences $\left(\mathbf{Y}^{(1)}, ..., \mathbf{Y}^{(s)}\right)$. We would like the dynamical version of our model to capture the underlying commonality of these data. We handle this by allowing a different *temporal* latent function for each of the independent sequences, so that $\mathbf{X}^{(i)}$ is the set of latent variables corresponding to the sequence i. These sets are a priori assumed to be independent since they correspond to separate sequences, i.e. $p\left(\mathbf{X}^{(1)}, \mathbf{X}^{(2)}, ..., \mathbf{X}^{(s)}\right) = \prod_{i=1}^{s} p(\mathbf{X}^{(i)})$. This factorisation leads to a block-diagonal structure for the time covariance matrix $\mathbf{K}_x$, where each block corresponds to one sequence. In this setting, each block of observations $\mathbf{Y}^{(i)}$ is generated from its corresponding $\mathbf{X}^{(i)}$ according to $\mathbf{Y}^{(i)} = \mathbf{F}^{(i)} + \boldsymbol{\epsilon}$, where the latent function which governs this mapping is shared across all sequences and $\boldsymbol{\epsilon}$ is Gaussian noise.

3.4 Time Complexity and Handling Very High Dimensional Datasets

Our variational framework makes use of inducing point representations which provide low-rank approximations to the covariance $\mathbf{K}_{ff}$. For the standard variational GP-LVM, this allows us to avoid the typical cubic complexity of Gaussian processes. Specifically, the computational cost is $O(m^3 + nm^2)$ which reduces to $O(nm^2)$, since we typically select a small set of inducing points $m \ll n$, which allows the variational GP-LVM to handle relatively large training sets (thousands of points, n). The *dynamical* variational GP-LVM, however, still requires the inversion of the covariance matrix $\mathbf{K}_x$ of size $n \times n$, as can be seen in equation (33), thereby inducing a computational cost of $O(n^3)$. Further, the models scale only linearly with the number of dimensions p, since the variational lower bound is a sum of p terms (see equation (19)). Specifically, the number of dimensions only matters when performing calculations involving the data matrix $\mathbf{Y}$. In the final form of the lower bound (and consequently in all of the derived quantities, such as gradients) this matrix only appears in the form $\mathbf{Y}\mathbf{Y}^\top$ which can be precomputed. This means that, when $n \ll p$, we can calculate $\mathbf{Y}\mathbf{Y}^\top$ only once and then substitute $\mathbf{Y}$ with the SVD (or Cholesky decomposition) of $\mathbf{Y}\mathbf{Y}^\top$. In this way, we can work with an $n \times n$ instead of an $n \times p$ matrix. Practically speaking, this allows us to work with data sets involving millions of features. In our experiments we model directly the pixels of HD quality video, exploiting this trick.

4. Predictions with the Variational GP-LVM

In this section, we explain how the proposed Bayesian models can accomplish various kinds of prediction tasks. We will use a star ($*$) to denote test quantities, e.g. a test data matrix will be denoted by $\mathbf{Y}_* \in \Re^{n_* \times p}$ while test row and column vectors of such a matrix will be denoted by $\mathbf{y}_{i,*}$ and $\mathbf{y}_{*,j}$ respectively.

The first type of inference we are interested in is the calculation of the probability density $p(\mathbf{Y}_*|\mathbf{Y})$. The computation of this quantity can allow us to use the model as a density estimator which, for instance, can represent the class conditional distribution in a generative based classification system. We will exploit such a use in Section 5.5. Secondly,

we discuss how from a test data matrix $\mathbf{Y}_* = (\mathbf{Y}_*^u, \mathbf{Y}_*^o)$, we can probabilistically reconstruct the unobserved part $\mathbf{Y}_*^u$ based on the observed part $\mathbf{Y}_*^o$ and where u and o denote non-overlapping sets of indices such that their union is $\{1, \ldots, p\}$. For this second problem the missing dimensions are reconstructed by approximating the mean and the covariance of the Bayesian predictive density $p(\mathbf{Y}_*^u|\mathbf{Y}_*^o, \mathbf{Y})$.

Section 4.1 discusses how to solve the above tasks in the standard variational GP-LVM case while Section 4.2 discusses the dynamical case. Furthermore, for the dynamical case the test points $\mathbf{Y}_*$ are accompanied by their corresponding timestamps $\mathbf{t}_*$ based on which we can perform an additional *forecasting* prediction task, where we are given only a test time vector $\mathbf{t}_*$ and we wish to predict the corresponding outputs.

4.1 Predictions with the Standard Variational GP-LVM

We first discuss how to approximate the density $p(\mathbf{Y}_*|\mathbf{Y})$. By introducing the latent variables $\mathbf{X}$ (corresponding to the training outputs $\mathbf{Y}$) and the new test latent variables $\mathbf{X}_* \in \Re^{n_* \times q}$, we can write the density of interest as the ratio of two marginal likelihoods,

$$p(\mathbf{Y}_*|\mathbf{Y}) = \frac{p(\mathbf{Y}_*, \mathbf{Y})}{p(\mathbf{Y})} = \frac{\int p(\mathbf{Y}_*, \mathbf{Y}|\mathbf{X}, \mathbf{X}_*) p(\mathbf{X}, \mathbf{X}_*) \mathrm{d}\mathbf{X} \mathrm{d}\mathbf{X}_*}{\int p(\mathbf{Y}|\mathbf{X}) p(\mathbf{X}) \mathrm{d}\mathbf{X}}. \tag{35}$$

In the denominator we have the marginal likelihood of the GP-LVM for which we have already computed a variational lower bound. The numerator is another marginal likelihood that is obtained by augmenting the training data $\mathbf{Y}$ with the test points $\mathbf{Y}_*$ and integrating out both $\mathbf{X}$ and the newly inserted latent variable $\mathbf{X}_*$. In the following, we explain in more detail how to approximate the density $p(\mathbf{Y}_*|\mathbf{Y})$ of equation (35) through constructing a ratio of lower bounds.

The quantity $\int p(\mathbf{Y}|\mathbf{X}) p(\mathbf{X}) \mathrm{d}\mathbf{X}$ appearing in the denominator of equation (35) is approximated by the lower bound $e^{\mathcal{F}(q(\mathbf{X}))}$ where $\mathcal{F}(q(\mathbf{X}))$ is the variational lower bound as computed in Section 3.2 and is given in equation (30). The maximisation of this lower bound specifies the variational distribution $q(\mathbf{X})$ over the latent variables in the training data. Then, this distribution remains fixed during test time. The quantity $\int p(\mathbf{Y}_*, \mathbf{Y}|\mathbf{X}, \mathbf{X}_*) p(\mathbf{X}, \mathbf{X}_*) \mathrm{d}\mathbf{X} \mathrm{d}\mathbf{X}_*$ appearing in the numerator of equation (35) is approximated by the lower bound $e^{\mathcal{F}(q(\mathbf{X}, \mathbf{X}_*))}$ which has exactly analogous form to (30). This optimisation is fast, because the factorisation imposed for the variational distribution in equation (32) means that $q(\mathbf{X}, \mathbf{X}_*)$ is also a fully factorised distribution so that we can write $q(\mathbf{X}, \mathbf{X}_*) = q(\mathbf{X}) q(\mathbf{X}_*)$. Then, if $q(\mathbf{X})$ is held fixed[2] during test time, we only need to optimise with respect to the $2n_*q$ parameters of the variational Gaussian distribution $q(\mathbf{X}_*) = \prod_{i=1}^{n_*} q(\mathbf{x}_{i,*}) = \prod_{i=1}^{n_*} \mathcal{N}(\boldsymbol{\mu}_{i,*}, \mathbf{S}_{i,*})$ (where $\mathbf{S}_{i,*}$ is a diagonal matrix). Further, since the Ψ statistics decompose across data, during test time we can re-use the already estimated Ψ statistics corresponding to the averages over $q(\mathbf{X})$ and only need to compute the extra average terms associated with $q(\mathbf{X}_*)$. Note that optimisation of the parameters $(\boldsymbol{\mu}_{i,*}, \mathbf{S}_{i,*})$ of $q(\mathbf{x}_{i,*})$ are subject to local minima. However, sensible initialisations of $\boldsymbol{\mu}_*$ can be employed based on the mean of the variational distributions associated with the nearest neighbours of each test point $\mathbf{y}_{i,*}$ in the training data $\mathbf{Y}$. Given the above, the approximation of $p(\mathbf{Y}_*|\mathbf{Y})$

2. Ideally $q(\mathbf{X})$ would be optimised during test time as well.

is given by rewriting equation (35) as

$$p(\mathbf{Y}_*|\mathbf{Y}) \approx e^{\mathcal{F}(q(\mathbf{X},\mathbf{X}_*))-\mathcal{F}(q(\mathbf{X}))}. \tag{36}$$

Notice that the above quantity does not constitute a bound, but only an approximation to the predictive density.

We now discuss the second prediction problem where a set of partially observed test points $\mathbf{Y}_* = (\mathbf{Y}_*^u, \mathbf{Y}_*^o)$ are given and we wish to reconstruct the missing part $\mathbf{Y}_*^u$. The predictive density is, thus, $p(\mathbf{Y}_*^u|\mathbf{Y}_*^o, \mathbf{Y})$. Notice that $\mathbf{Y}_*^u$ is totally unobserved and, therefore, we cannot apply the methodology described previously. Instead, our objective now is to just approximate the moments of the predictive density. To achieve this, we will first need to introduce the underlying latent function values $\mathbf{F}_*^u$ (the noise-free version of $\mathbf{Y}_*^u$) and the latent variables $\mathbf{X}_*$ so that we can decompose the exact predictive density as follows:

$$p(\mathbf{Y}_*^u|\mathbf{Y}_*^o, \mathbf{Y}) = \int p(\mathbf{Y}_*^u|\mathbf{F}_*^u)p(\mathbf{F}_*^u|\mathbf{X}_*, \mathbf{Y}_*^o, \mathbf{Y})p(\mathbf{X}_*|\mathbf{Y}_*^o, \mathbf{Y})\mathrm{d}\mathbf{F}_*^u\mathrm{d}\mathbf{X}_*.$$

Then, we can introduce the approximation coming from the variational distribution so that

$$p(\mathbf{Y}_*^u|\mathbf{Y}_*^o, \mathbf{Y}) \approx q(\mathbf{Y}_*^u|\mathbf{Y}_*^o, \mathbf{Y}) = \int p(\mathbf{Y}_*^u|\mathbf{F}_*^u)q(\mathbf{F}_*^u|\mathbf{X}_*)q(\mathbf{X}_*)\mathrm{d}\mathbf{F}_*^u\mathrm{d}\mathbf{X}_*, \tag{37}$$

based on which we wish to predict $\mathbf{Y}_*^u$ by estimating its mean $\mathbb{E}(\mathbf{Y}_*^u)$ and covariance $\mathrm{Cov}(\mathbf{Y}_*^u)$. This problem takes the form of GP prediction with uncertain inputs similar to (Oakley and O'Hagan, 2002; Quiñonero-Candela et al., 2003; Girard et al., 2003), where the distribution $q(\mathbf{X}_*)$ expresses the uncertainty over these inputs. The first term of the above integral comes from the Gaussian likelihood so $\mathbf{Y}_*^u$ is just a noisy version of $\mathbf{F}_*^u$, as shown in equation (6). The remaining two terms together $q(\mathbf{F}_*^u|\mathbf{X}_*)q(\mathbf{X}_*)$ are obtained by applying the variational methodology in order to optimise a variational lower bound on the following log marginal likelihood

$$\log p(\mathbf{Y}_*^o, \mathbf{Y}) = \log \int p(\mathbf{Y}_*^o, \mathbf{Y}|\mathbf{X}_*, \mathbf{X})p(\mathbf{X}_*, \mathbf{X})\mathrm{d}\mathbf{X}_*\mathrm{d}\mathbf{X} \tag{38}$$

which is associated with the total set of observations $(\mathbf{Y}_*^o, \mathbf{Y})$. By following exactly Section 3, we can construct and optimise a lower bound $\mathcal{F}(q(\mathbf{X}, \mathbf{X}_*))$ on the above quantity, which along the way it allows us to compute a Gaussian variational distribution $q(\mathbf{F}, \mathbf{F}_*^u, \mathbf{X}, \mathbf{X}_*)$ from which $q(\mathbf{F}_*^u|\mathbf{X}_*)q(\mathbf{X}_*)$ is just a marginal. Further details about the form of the variational lower bound and how $q(\mathbf{F}_*^u|\mathbf{X}_*)$ is computed are given in the Appendix D. In fact, the explicit form of $q(\mathbf{F}_*^u|\mathbf{X}_*)$ takes the form of the projected process predictive distribution from sparse GPs (Csató and Opper, 2002; Smola and Bartlett, 2001; Seeger et al., 2003; Rasmussen and Williams, 2006):

$$q(\mathbf{F}_*^u|\mathbf{X}_*) = \mathcal{N}\left(\mathbf{F}_*^u|\mathbf{K}_{*u}\mathbf{B}, \mathbf{K}_{**} - \mathbf{K}_{*u}\left[\mathbf{K}_{uu}^{-1} - (\mathbf{K}_{uu} + \sigma^{-2}\mathbf{\Psi}_2)^{-1}\right]\mathbf{K}_{*u}^\top\right), \tag{39}$$

where $\mathbf{B} = \sigma^{-2}\left(\mathbf{K}_{uu} + \sigma^{-2}\mathbf{\Psi}_2\right)^{-1}\mathbf{\Psi}_1^\top\mathbf{Y}$, $\mathbf{K}_{**} = k_f(\mathbf{X}_*, \mathbf{X}_*)$ and $\mathbf{K}_{*u} = k_f(\mathbf{X}_*, \mathbf{X}_u)$. By substituting now the above Gaussian $q(\mathbf{F}_*^u|\mathbf{X}_*)$ in equation (37) and using the fact that

$q(\mathbf{X}_*)$ is also a Gaussian, we can analytically compute the mean and covariance of the predictive density which, based on the results of Girard et al. (2003), take the form

$$\mathbb{E}(\mathbf{F}_*^u) = \mathbf{B}^\top\mathbf{\Psi}_1^* \tag{40}$$

$$\mathrm{Cov}(\mathbf{F}_*^u) = \mathbf{B}^\top\left(\mathbf{\Psi}_2^* - \mathbf{\Psi}_1^*(\mathbf{\Psi}_1^*)^\top\right)\mathbf{B} + \psi_0^*\mathbf{I} - \mathrm{tr}\left(\left(\mathbf{K}_{uu}^{-1} - \left(\mathbf{K}_{uu} + \sigma^{-2}\mathbf{\Psi}_2\right)^{-1}\right)\mathbf{\Psi}_2^*\right)\mathbf{I}, \tag{41}$$

where $\psi_0^* = \mathrm{tr}\left(\langle\mathbf{K}_{**}\rangle\right)$, $\mathbf{\Psi}_1^* = \langle\mathbf{K}_{u*}\rangle$ and $\mathbf{\Psi}_2^* = \left\langle\mathbf{K}_{u*}\mathbf{K}_{u*}^\top\right\rangle$. All expectations are taken w.r.t. $q(\mathbf{X}_*)$ and can be calculated analytically for several kernel functions as explained in Section 3.2 and Appendix B. Using the above expressions and the Gaussian noise model of equation (6), the predicted mean of $\mathbf{Y}_*^u$ is equal to $\mathbb{E}\left[\mathbf{F}_*^u\right]$ and the predicted covariance (for each column of $\mathbf{Y}_*^u$) is equal to $\mathrm{Cov}(\mathbf{F}_*^u) + \sigma^2\mathbf{I}_{n_*}$.

4.2 Predictions in the Dynamical Model

The two prediction tasks described in the previous section for the standard variational GP-LVM can also be solved for the dynamical variant in a very similar fashion. Specifically, the two predictive approximate densities take exactly the same form as those in equations (36) and (37) while again the whole approximation relies on the maximisation of a variational lower bound $\mathcal{F}(q(\mathbf{X}, \mathbf{X}_*))$. However, in the dynamical case where the inputs $(\mathbf{X}, \mathbf{X}_*)$ are a priori correlated, the variational distribution $q(\mathbf{X}, \mathbf{X}_*)$ does not factorise across $\mathbf{X}$ and $\mathbf{X}_*$. This makes the optimisation of this distribution computationally more challenging, as it has to be optimised with respect to its all $2(n + n_*)q$ parameters. This issue is further explained in Appendix D.1.

Finally, we shall discuss how to solve the forecasting problem with our dynamical model. This problem is similar to the second predictive task described in Section 4.1, but now the observed set is empty. We can therefore write the predictive density similarly to equation (37) as follows:

$$p(\mathbf{Y}_*|\mathbf{Y}) \approx \int p(\mathbf{Y}_*|\mathbf{F}_*)q(\mathbf{F}_*|\mathbf{X}_*)q(\mathbf{X}_*)\mathrm{d}\mathbf{X}_*\mathrm{d}\mathbf{F}_*.$$

The inference procedure then follows exactly as before, using equations (37), (40) and (41). The only difference is that the computation of $q(\mathbf{X}_*)$ (associated with a fully unobserved $\mathbf{Y}_*$) is obtained from standard GP prediction and does not require optimisation, i.e.

$$q(\mathbf{X}_*) = \int p(\mathbf{X}_*|\mathbf{X})q(\mathbf{X})\mathrm{d}\mathbf{X} = \prod_{j=1}^{q}\int p(\mathbf{x}_{*,j}|\mathbf{x}_{:,j})q(\mathbf{x}_{:,j})\mathrm{d}\mathbf{x}_{:,j},$$

where $p(\mathbf{x}_{*,j}|\mathbf{x}_{:,j})$ is a Gaussian found from the conditional GP prior (see Rasmussen and Williams (2006)). Since $q(\mathbf{X})$ is Gaussian, the above is also a Gaussian with mean and variance given by

$$\boldsymbol{\mu}_{x_{*,j}} = \mathbf{K}_{*n}\bar{\boldsymbol{\mu}}_{:,j}$$
$$\mathrm{var}(\mathbf{x}_{*,j}) = \mathbf{K}_{**} - \mathbf{K}_{*n}(\mathbf{K}_x + \mathbf{\Lambda}_j^{-1})^{-1}\mathbf{K}_{n*},$$

where $\mathbf{K}_{*n} = k_x(\mathbf{t}_*, \mathbf{t})$, $\mathbf{K}_{*n} = \mathbf{K}_{n*}^\top$ and $\mathbf{K}_{**} = k_x(\mathbf{t}_*, \mathbf{t}_*)$. Notice that these equations have exactly the same form as found in standard GP regression problems.

5. Demonstration of the Variational Framework

In this section we investigate the performance of the variational GP-LVM and its dynamical extension. The variational GP-LVM allows us to handle very high dimensional data and, using ARD, to automatically infer the importance of each latent dimension. The generative construction allows us to impute missing values when presented with only a partial observation.

In the experiments, a latent space variational distribution is required as initialisation. We use PCA to initialise the $q-$dimensional means. The variances are initialised to values around 0.5, which are considered neutral given that the prior is a standard normal. The selection of q can be almost arbitrary and does not affect critically the end result, since the inverse lengthscales then switch off unnecessary dimensions. The only requirement is for q to be reasonably large in the first place, but an upper bound is $q = n$. In practice, in ad-hoc experiments we never observed any advantage in using $q > 40$, considering the dataset sizes employed. Inducing points are initialised as a random subset of the initial latent space. ARD inverse lengthscales are initialised based on a heuristic that takes into account the scale of each dimension. Specifically, the inverse squared lengthscale w_j is set as the inverse of the squared difference between the maximum and the minimum value of the initial latent mean in direction j. Following initialisation, the model is trained by optimising jointly all (hyper)parameters using the scaled conjugate gradients method. The optimisation is stopped until the change in the objective (variational lower bound) is very small.

We evaluate the models' performance in a variety of tasks, namely visualisation, prediction, reconstruction, generation of data or timeseries and class-conditional density estimation. Matlab source code for repeating the following experiments is available on-line from: `http://git.io/A3TN` and supplementary videos from: `http://git.io/A3t5`.

The experiments section is structured as follows; in Section 5.1 we outline the covariance functions used for the experiments. In Section 5.2 we demonstrate our method in a standard visualisation benchmark. In Section 5.3 we test both, the standard and dynamical variant of our method in a real-world motion capture dataset. In Section 5.4 we illustrate how our proposed model is able to handle a very large number of dimensions by working directly with the raw pixel values of high resolution videos. Additionally, we show how the dynamical model can interpolate but also extrapolate in certain scenarios. In Section 5.5 we consider a classification task on a standard benchmark, exploiting the fact that our framework gives access to the model evidence, thus enabling Bayesian classification.

5.1 Covariance Functions

Before proceeding to the actual evaluation of our method, we first review and give the forms of the covariance functions that will be used for our experiments. The mapping between the input and output spaces $\mathbf{X}$ and $\mathbf{Y}$ is nonlinear and, thus, we use the covariance function of equation (8) which also allows simultaneous model selection within our framework. In experiments where we use our method to also model dynamics, apart from the infinitely differentiable exponentiated quadratic covariance function defined in equation (3), we will also consider for the dynamical component the Matérn 3/2 covariance function which is only once differentiable, and a periodic one (Rasmussen and Williams, 2006; MacKay, 1998) which can be used when data exhibit strong periodicity. These covariance functions take

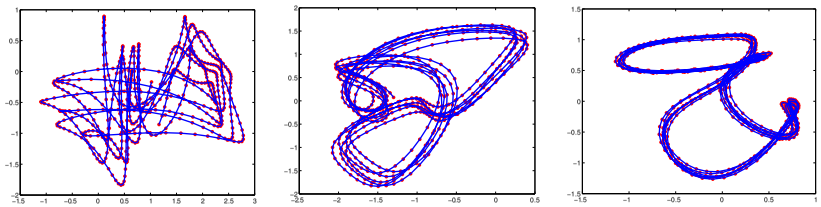
the form

$$k_{x(\text{mat})}\left(t_i, t_j\right) = \sigma^2_{\text{mat}}\left(1 + \frac{\sqrt{3}|t_i - t_j|}{\ell}\right)\exp\left(\frac{-\sqrt{3}|t_i - t_j|}{\ell}\right),$$

$$k_{x(\text{per})}\left(t_i, t_j\right) = \sigma^2_{\text{per}}\exp\left(-\frac{1}{2}\frac{\sin^2\left(\frac{2\pi}{T}\left(t_i - t_j\right)\right)}{\ell}\right),$$

where ℓ denotes the characteristic lengthscale and T denotes the period of the periodic covariance function.

Introducing a separate GP model for the dynamics is a very convenient way of incorporating any prior information we may have about the nature of the data in a nonparametric and flexible manner. In particular, more sophisticated covariance functions can be constructed by combining or modifying existing ones. For example, in our experiments we consider a compound covariance function, $k_{x(\text{per})} + k_{x(\text{rbf})}$ which is suitable for dynamical systems that are known to be only approximately periodic. The first term captures the periodicity of the dynamics whereas the second one corrects for the divergence from the periodic pattern by enforcing the datapoints to form smooth trajectories in time. By fixing the two variances, σ^2_{per} and σ^2_{rbf} to particular ratios, we are able to control the relative effect of each kernel. Example sample paths drawn from this compound covariance function are shown in Figure 4.



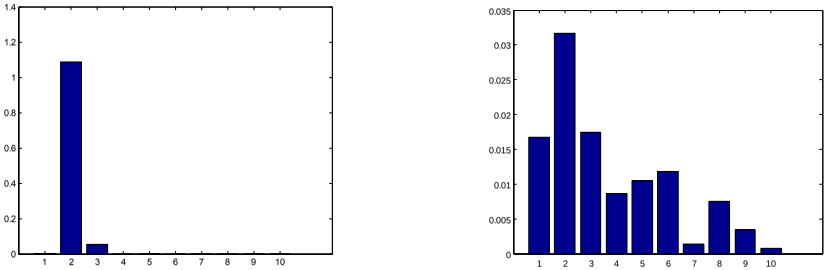
(a) (b) (c)

Figure 4: Typical sample paths drawn from the $k_{x(\text{per})} + k_{x(\text{rbf})}$ covariance function. The variances are fixed for the two terms, controlling their relative effect. In Figures (a), (b) and (c), the ratio $\sigma^2_{\text{rbf}}/\sigma^2_{\text{per}}$ of the two variances was large, intermediate and small respectively, causing the periodic pattern to be shifted accordingly each period.

For our experiments we additionally include a noise covariance function

$$k_{\text{white}}(\mathbf{x}_{i,:}, \mathbf{x}_{k,:}) = \theta_{\text{white}}\delta_{i,k},$$

where $\delta_{i,k}$ is the Kronecker delta. We can then define a compound kernel $k + k_{\text{white}}$, so that the noise level θ_{white} is jointly optimised along with the rest of the kernel hyperparameters. Similarly, we also include a bias term $\theta_{\text{bias}}\mathbf{1}$, where $\mathbf{1}$ denotes a vector of 1s.



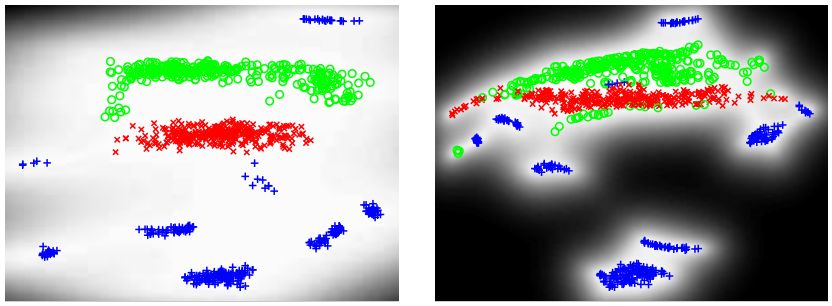
(a) Variational GP-LVM (b) GP-LVM

Figure 5: Left: The squared inverse lengthscales found by applying the variational GP-LVM with ARD EQ kernel on the oil flow data. Right: Results obtained for the standard GP-LVM with $q = 10$. These results demonstrate the ability of the variational GP-LVM to perform a "soft" automatic dimensionality selection. The inverse lengthscale for each dimension is associated with the expected number of the function's upcrossings in that particular direction; small values denote a more linear behaviour, whereas values close to zero denote an irrelevant dimension. For the variational GP-LVM, plot (a) suggests that the non-linearity is captured by dimension 2, as also confirmed by plot 6(a). On the other hand, plot (b) demonstrates the overfitting problem of the GP-LVM which is trained with MAP.

5.2 Visualisation Tasks

Given a dataset with known structure, we can apply our algorithm and evaluate its performance in a simple and intuitive way, by checking if the form of the discovered low dimensional manifold agrees with our prior knowledge.

We illustrate the method in the multi-phase oil flow data (Bishop and James, 1993) that consists of 1000, 12 dimensional observations belonging to three known classes corresponding to different phases of oil flow. This dataset is generated through simulation, and we know that the intrinsic dimensionality is 2 and the number of classes is 3. Figure 6 shows the results for these data obtained by applying the variational GP-LVM with 10 latent dimensions using the exponentiated quadratic ARD kernel. As shown in Figure 5(a), the algorithm switches off 8 out of 10 latent dimensions by making their inverse lengthscales almost zero. Therefore, the two-dimensional nature of this dataset is automatically revealed. Figure 6(a) shows the visualisation obtained by keeping only the dominant latent directions which are the dimensions 2 and 3. This is a remarkably high quality two dimensional visualisation of this data; to the best of our knowledge, our method is the only one that correctly picks up the true dimensionality and class separation at the same time, in a completely unsupervised manner. For comparison, Figure 6(b) shows the visualisation provided by the standard sparse GP-LVM that runs by a priori assuming only 2 latent dimensions. Both models use 50 inducing variables, while the latent variables $\mathbf{X}$ optimised in the standard



(a) Variational GP-LVM, $q = 10$ (2D projection) (b) GP-LVM, $q = 2$

Figure 6: Panel 6(a) shows the means of the variational posterior $q(\mathbf{X})$ for the variational GP-LVM, projected on the two dominant latent dimensions: dimension 2, plotted on the y-axis, and dimension 3 plotted on the x-axis. The plotted projection of a latent point $\mathbf{x}_{i,:}$ is assigned a colour according to the label of the corresponding output vector $\mathbf{x}_{i,:}$. The greyscale background intensities are proportional to the predicted variance of the GP mapping, if the corresponding locations were given as inputs. Plot 6(b) shows the visualisation found by standard sparse GP-LVM initialised with a two dimensional latent space.

GP-LVM are initialised based on PCA. Note that if we were to run the standard GP-LVM with 10 latent dimensions, the model would overfit the data and it would not reduce the dimensionality in the manner achieved by the variational GP-LVM, as illustrated in Figure 5(b). The quality of the class separation in the two-dimensional space can also be quantified in terms of the nearest neighbour error; the total error equals the number of training points whose closest neighbour in the latent space corresponds to a data point of a different class (phase of oil flow). The number of nearest neighbour errors made when finding the latent embedding for the variational GP-LVM is one. For the standard sparse GP-LVM it is 26, for the full GP-LVM with ARD kernel it is 8 and for the full GP-LVM with EQ kernel it is 2. Notice that all standard GP-LVMs were given the true dimensionality ($q = 2$) a priori.

5.3 Human Motion Capture Data

In this section we consider a data set associated with temporal information, as the primary focus of this experiment is on evaluating the dynamical version of the variational GP-LVM. We followed Taylor et al. (2007); Lawrence (2007) in considering motion capture data of walks and runs taken from subject 35 in the CMU motion capture database. We used the dynamical version of our model and treated each motion as an independent sequence. The data set was constructed and preprocessed as described in (Lawrence, 2007). This results in 2613 separate 59-dimensional frames split into 31 training sequences with an average length

of 84 frames each. Our model does not require explicit timestamp information, since we know a priori that there is a constant time delay between poses and the model can construct equivalent covariance matrices given any vector of equidistant time points.

The model is jointly trained, as explained in the last paragraph of Section 3.3.2, on both walks and runs, i.e. the algorithm learns a common latent space for these motions. As in (Lawrence, 2007), we used 100 inducing points. At test time we investigate the ability of the model to reconstruct test data from a previously unseen sequence given partial information for the test targets. This is tested once by providing only the dimensions which correspond to the body of the subject and once by providing those that correspond to the legs. We compare with results in (Lawrence, 2007), which used MAP approximations for the dynamical models, and against nearest neighbour. We can also indirectly compare with the binary latent variable model (BLV) of Taylor et al. (2007) which used a slightly different data preprocessing. Furthermore, we additionally tested the non-dynamical version of our model, in order to explore the structure of the distribution found for the latent space. In this case, the notion of sequences or sub-motions is not modelled explicitly, as the non-dynamical approach does not model correlations between datapoints. However, as will be shown below, the model manages to discover the dynamical nature of the data and this is reflected in both, the structure of the latent space and the results obtained on test data.

The performance of each method is assessed by using the cumulative error per joint in the scaled space defined in (Taylor et al., 2007) and by the root mean square error in the angle space suggested by Lawrence (2007). Our models were initialised with nine latent dimensions. For the dynamical version, we performed two runs, once using the Matérn covariance function for the dynamical prior and once using the exponentiated quadratic.

The appropriate latent space dimensionality for the data was automatically inferred by our models. The non-dynamical model selected a 5-dimensional latent space. The model which employed the Matérn covariance to govern the dynamics retained four dimensions, whereas the model that used the exponentiated quadratic kept only three. The other latent dimensions were completely switched off by the ARD parameters.

From Table 1 we see that the dynamical variational GP-LVM considerably outperforms the other approaches. The best performance for the legs and the body reconstruction was achieved by our dynamical model that used the Matérn and the exponentiated quadratic covariance function respectively. This is an intuitive result, since the smoother body movements are expected to be better modelled using the infinitely differentiable exponentiated quadratic covariance function, whereas the Matérn one can easier fit the rougher leg motion. Although it is not always obvious how to choose the best covariance function (without expensive cross-validation), the fact that both models outperform significantly other approaches shows that the Bayesian training manages successfully to fit the covariance function parameters to the data in any case. Furthermore, the non-dynamical variational GP-LVM, not only manages to discover a latent space with a dynamical structure, as can be seen in Figure 7(a), but is also proven to be quite robust when making predictions. Indeed, Table 1 shows that the non-dynamical variational GP-LVM performs comparably to nearest neighbor. However, the standard GP-LVM which explicitly models dynamics using MAP approximations performs slightly better than the non-dynamical variational GP-LVM; this suggests that temporal information is crucial in this dataset. Finally, it is worth highlighting the intuition gained by investigating Figure 7. As can be seen, all models split the

Data	CL	CB	L	L	B	B
Error Type	SC	SC	SC	RA	SC	RA

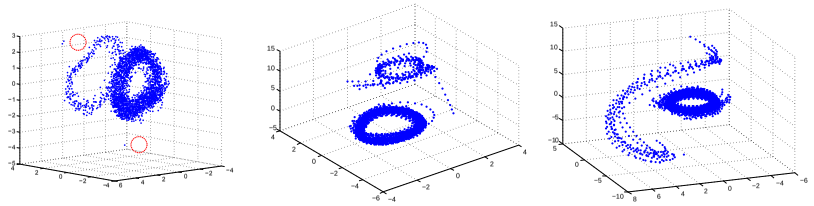
Table 1: Errors obtained for the motion capture dataset. The format of this table follows Lawrence (2007), where differently processed datasets were used for the first two columns, as opposed to the last four columns. Specifically, CL / CB are the leg and body data sets as preprocessed in (Taylor et al., 2007), L and B the corresponding datasets from Lawrence. Taylor et al. also used a different scaling for the data, which can be applied to the predictions of the models trained in the L/B datasets to obtain indirect comparisons with the models which were trained in the CL/CB datasets. Specifically, SC corresponds to the error in the scaled space, as in Taylor et al. while RA is the error in the angle space. The methods shown in the table are: nearest neighbour in the angle space (NN) and in the scaled space (NN sc.), GP-LVM (with different pre-selected latent dimensionality q), binary latent variable model (BLV), variational GP-LVM (VGP-LVM) and Dynamical variational GP-LVM (Dyn. VGP-LVM). Notice that NN was run once in the CL/CB dataset and once in the L/B dataset, so as to provide a "link" between the two first and the four last columns. The best error per column is in bold.



(a) (b) (c)

Figure 7: The latent space discovered by our models for the human motion capture data, projected into its three principal dimensions. The latent space found by the non-dynamical variational GP-LVM is shown in (a), by the dynamical model which uses the Matérn in (b) and by the dynamical model which uses the exponentiated quadratic in (c). The red, dotted circles highlight three "outliers".

encoding for the "walk" and "run" regimes into two subspaces. Further, we notice that the smoother the latent space is constrained to be, the less "circular" is the shape of the "run" regime latent space encoding. This can be explained by noticing the "outliers" in the top left and bottom positions of plot (a), highlighted with a red, dotted circle. These latent points correspond to training positions that are very dissimilar to the rest of the training set but, nevertheless, a temporally constrained model is forced to accommodate them in a smooth path. The above intuitions can be confirmed by interacting with the model in real time graphically, as is presented in the supplementary video.

5.4 Modeling Raw High Dimensional Video Sequences

For this set of experiments we considered video sequences (which are included in the supplementary videos available on-line). Such sequences are typically preprocessed before modelling to extract informative features and reduce the dimensionality of the problem. Here we work directly with the raw pixel values to demonstrate the ability of the dynamical variational GP-LVM to model data with a vast number of features. This also allows us to directly sample video from the learned model.

Firstly, we used the model to reconstruct partially observed frames from test video sequences.[3] For the first video discussed here we gave as partial information approximately 50% of the pixels while for the other two we gave approximately 40% of the pixels on each frame. The mean squared error per pixel was measured to compare with the $k-$nearest neighbour (NN) method, for $k \in (1, .., 5)$ (we only present the error achieved for the best choice of k in each case). The datasets considered are the following: firstly, the 'Missa' dataset, a standard benchmark used in image processing. This is a 103680-dimensional

3. 'Missa' dataset: cipr.rpi.edu. 'Ocean': cogfilms.com. 'Dog': fitfurlife.com. See details in supplementary on-line videos. The logo appearing in the 'dog' images in the experiments that follow, has been added with post-processing.

video, showing a woman talking for 150 frames. The data is challenging as there are translations in the pixel space. We also considered an HD video of dimensionality 9×10^5 that shows an artificially created scene of ocean waves as well as a $230400-$dimensional video showing a dog running for 60 frames. The latter is approximately periodic in nature, containing several paces from the dog. For all video datasets, the GPs were trained with $m = n$. For the first two videos we used the Matérn and exponentiated quadratic covariance functions respectively to model the dynamics and interpolated to reconstruct blocks of frames chosen from the whole sequence. For the 'dog' dataset we constructed a compound kernel $k_x = k_{x(\text{rbf})} + k_{x(\text{per})}$ presented in Section 5.1, where the exponentiated quadratic (RBF) term is employed to capture any divergence from the approximately periodic pattern. The variance of the periodic component was fixed to 1 and the variance of the RBF component to 1/150. This is to make sure that the RBF does not dominate before learning some periodicity (in this case periodicity is more difficult to discover as a pattern). The selection of the variances' ratio does not need to be exact and here was made in an ad-hoc manner, aiming at getting samples like the one shown in Figure 4(b). We then used our model to reconstruct the last 7 frames extrapolating beyond the original video. As can be seen in Table 2, our method outperformed NN in all cases. The results are also demonstrated visually in Figures 8, 9, 10 and 11 and the reconstructed videos are available in the supplementary on-line videos.

	Missa	Ocean	Dog
Dyn. VGP-LVM	2.52	9.36	4.01
NN	2.63	9.53	4.15

Table 2: The mean squared error per pixel for Dyn. VGP-LVM and NN for the three datasets (measured only in the missing inputs).

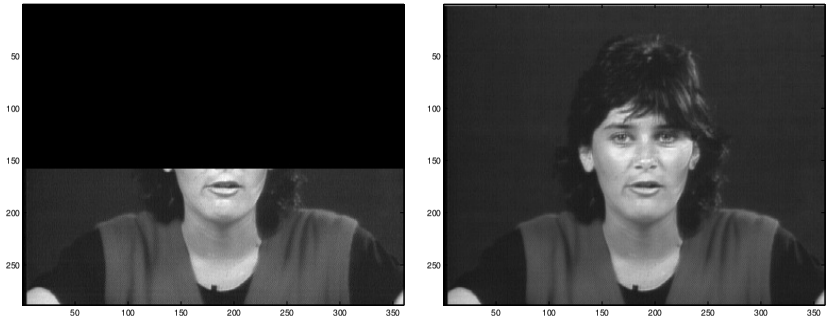
As can be seen in Figures 8, 9 and 10, the dynamical variational GP-LVM predicts pixels which are smoothly connected with the observed part of the image, whereas the NN method cannot fit the predicted pixels in the overall context. Figure 8(c) focuses on this specific problem with NN, but it can be seen more evidently in the corresponding video files.

As a second task, we used our generative model to create new samples and generate a new video sequence. This is most effective for the 'dog' video as the training examples were approximately periodic in nature. The model was trained on 60 frames (time-stamps $[t_1, t_{60}]$) and we generated new frames which correspond to the next 40 time points in the future. The only input given for this generation of future frames was the time-stamp vector, $[t_{61}, t_{100}]$. The results show a smooth transition from training to test and amongst the test video frames. The resulting video of the dog continuing to run is sharp and high quality. This experiment demonstrates the ability of the model to reconstruct massively high dimensional images without blurring. Frames from the result are shown in Figure 13. The full sequence is available in the supplementary on-line videos.

(a) (b)

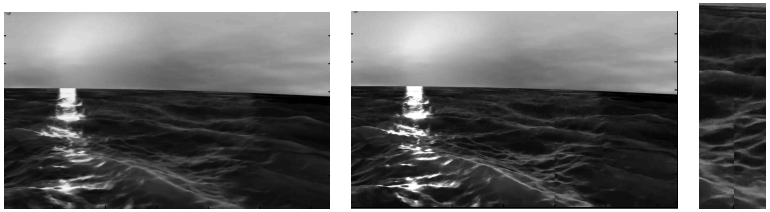
(c)

Figure 8: (a) and (c) demonstrate the reconstruction achieved by dynamical variational GP-LVM and NN respectively for one of the most challenging frames (b) of the 'missa' video, i.e. when translation occurs. In contrast to the NN method, which works in the whole high dimensional pixel space, our method reconstructed the images using a "compressed" latent space. The ARD scales for this example revealed an effectively 12−dimensional latent space.



(a) (b)

Figure 9: Another example of the reconstruction achieved by the dynamical variational GP-LVM given the partially observed image.



(a) (b) (c)

Figure 10: (a) (Dynamical variational GP-LVM) and (b) (NN) depict the reconstruction achieved for a frame of the 'ocean' dataset. Notice that in both of the aforementioned datasets, our method recovers a smooth image, in contrast to the simple NN (a close up of this problem with NN for the 'ocean' video is shown in Figure (c)). The dynamical var. GP-LVM reconstructed the ocean images using a latent space compression of the video defined by 9 effective dimensions (the rest of the inverse lengthscales approached zero).

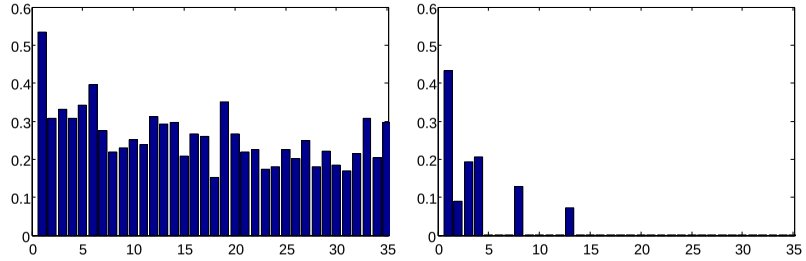
5.5 Class Conditional Density Estimation

In this experiment we use the variational GP-LVM to build a generative classifier for handwritten digit recognition. We consider the well known USPS digits dataset. This dataset consists of 16×16 images for all 10 digits and it is divided into 7291 training examples and 2007 test examples. We ran 10 variational GP-LVMs, one for each digit, on the USPS data base. We used 10 latent dimensions and 50 inducing variables for each model. This allowed us to build a probabilistic generative model for each digit so that we can compute

(a)

(b)

Figure 11: An example for the reconstruction achieved for the 'dog' dataset. 40% of the test image's pixels (Figure (a)) were presented to the model, which was able to successfully reconstruct them, as can be seen in (b).



(a) Initialised squared inverse lengthscales (b) Optimised squared inverse lengthscales

Figure 12: The figure demonstrates the ability of the model to automatically estimate an effective latent dimensionality by showing the initial squared inverse lengthscales (fig: (a)) of the ARD covariance function and the values obtained after training (fig: (b)) on the 'dog' data set.

Bayesian class conditional densities in the test data having the form $p(\mathbf{Y}_*|\mathbf{Y}, \text{digit})$. These class conditional densities are approximated through the ratio of lower bounds in equation (36) as described in Section 4. The whole approach allows us to classify new digits by determining the class labels for test data based on the highest class conditional density value and using a uniform prior over class labels. We used the following comparisons: firstly, a logistic classification approach. Secondly, a vanilla SVM from scikit-learn (Pedregosa et al., 2011), for which the error parameter C was selected with $5-$fold cross validation. Thirdly, a GP classification approach with EP approximation from GPy (authors, 2014). Lastly, the recent variational inference based GP classification approach of Hensman et al. (2014), referred to as "GP classification with VI" and taken from the GPy (authors, 2014) implementation. All of these methods operated in a 1-vs-all setting. The results of our experiments are shown in Table 3. In addition to the standard baselines reported here, more sophisticated schemes (many of which result in better performance) have been tried in this dataset by other researchers; a summary of previously published results can be found in (Keysers et al., 2002).

6. Extensions for Different Kinds of Inputs

So far we considered the typical dimensionality reduction scenario where, given high-dimensional output data we seek to find a low-dimensional latent representation in a completely unsupervised manner. For the dynamical variational GP-LVM we have additional temporal information, but the input space $\mathbf{X}$ from where we wish to propagate the uncertainty is still treated as fully unobserved. However, our framework for propagating the input uncertainty through the GP mapping is applicable to the full spectrum of cases, ranging from fully unobserved to fully observed inputs with known or unknown amount of uncertainty per input. In this section we discuss these cases and, further, show how they give

rise to an auto-regressive model (Section 6.1) and a GP regression variant which can handle missing inputs (Section 6.2).

6.1 Gaussian Process Inference with Uncertain Inputs

Gaussian processes have been used extensively and with great success in a variety of regression tasks. In the most common setting, we are given a dataset of observed input-output pairs, denoted as $\mathbf{Z} \in \Re^{n\times q}$ and $\mathbf{Y} \in \Re^{n\times p}$ respectively, and we wish to infer the unknown outputs $\mathbf{Y}^* \in \Re^{n^*\times p}$ corresponding to some novel given inputs $\mathbf{Z}^* \in \Re^{n^*\times q}$. However, in many real-world applications the inputs are uncertain, for example when measurements come from noisy sensors. In this case, the GP methodology cannot be trivially extended to account for the variance associated with the input space (Girard et al., 2003; McHutchon and Rasmussen, 2011). The aforementioned problem is also closely related to the field of heteroscedastic Gaussian process regression, where the uncertainty in the noise levels is modelled in the output space as a function of the inputs (Kersting et al., 2007; Goldberg et al., 1998; Lázaro-Gredilla and Titsias, 2011).

In this section we show that our variational framework can be used to explicitly model the input uncertainty in the GP regression setting. The assumption made is that the inputs $\mathbf{X}$ are not observed directly but, rather, we only have access to their noisy versions $\{\mathbf{z}_{i,:}\}_{i=1}^n = \mathbf{Z} \in \Re^{n\times q}$. The relationship between the noisy and true inputs is given by assuming the noise to be Gaussian,

$$\mathbf{x}_{i,:} = \mathbf{z}_{i,:} + (\boldsymbol{\epsilon}_x)_{i,:},$$

where $\boldsymbol{\epsilon}_x \sim \mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma}_x)$, as in (McHutchon and Rasmussen, 2011). Since $\mathbf{Z}$ is observed and $\mathbf{X}$ unobserved the above equation essentially induces a Gaussian prior distribution over $\mathbf{X}$ that has the form

$$p(\mathbf{X}|\mathbf{Z}) = \prod_{i=1}^{n} \mathcal{N}(\mathbf{x}_{i,:}|\mathbf{z}_{i,:}, \boldsymbol{\Sigma}_x),$$

where $\mathbf{\Sigma}_x$ is typically an unknown parameter. Given that $\mathbf{X}$ are really the inputs that eventually are passed through the GP latent function (to subsequently generate the outputs) the whole probabilistic model becomes a GP-LVM with the above special form for the prior distribution over the latent inputs, making thus our variational framework easily applicable. More precisely, using the above prior, we can define a variational bound on $p(\mathbf{Y})$ as well as an associated approximation $q(\mathbf{X})$ to the true posterior $p(\mathbf{X}|\mathbf{Y},\mathbf{Z})$. This variational distribution $q(\mathbf{X})$ can be used as a probability estimate of the noisy input locations $\mathbf{X}$. During optimisation of the lower bound we can also learn the parameter $\mathbf{\Sigma}_x$. Furthermore, if we wish to reduce the number of parameters in the variational distribution $q(\mathbf{X}) = \mathcal{N}(\mathcal{M},\mathcal{S})$ a sensible choice would be to set $\mathcal{M} = \mathbf{Z}$, although such a choice may not be optimal. However, this choice also allows us to incorporate $\mathbf{Z}$ directly in the approximate posterior and, hence, we may also remove the coupling in the prior (coming from $\mathbf{\Sigma}_x$) by instead considering a standard normal for $p(\mathbf{X})$. This is the approach taken in this paper.

Having a method which implicitly models the uncertainty in the inputs also allows for doing predictions in an autoregressive manner while propagating the uncertainty through the predictive sequence (Girard et al., 2003). To demonstrate this in the context of our framework, we will take the simple case where the process of interest is a multivariate time-series given as pairs of time points $\mathbf{t} = \{t\}_{i=1}^n$ and corresponding output locations $\mathbf{Y} = \{\mathbf{y}_{i,:}\}_{i=1}^n$, $\mathbf{y}_{i,:} \in \Re^p$. Here, we take the time locations to be deterministic and equally spaced, so that they can be simply denoted by the subscript of the output points $\mathbf{y}_{i,:}$; we thus simply denote with $\mathbf{y}_k$ the output point $\mathbf{y}_{k,:}$ which corresponds to t_k.

We can now reformat the given data $\mathbf{Y}$ into input-output pairs $\hat{\mathbf{Z}}$ and $\hat{\mathbf{Y}}$, where

$$[\hat{\mathbf{z}}_1, \hat{\mathbf{z}}_2, ..., \hat{\mathbf{z}}_{n-\tau}] = [[\mathbf{y}_1, \mathbf{y}_2, ..., \mathbf{y}_\tau], [\mathbf{y}_2, \mathbf{y}_3, ..., \mathbf{y}_{\tau+1}], ..., [\mathbf{y}_{n-\tau}, \mathbf{y}_{n-\tau+1}, ..., \mathbf{y}_{n-1}]],$$
$$[\hat{\mathbf{y}}_1, \hat{\mathbf{y}}_2, ..., \hat{\mathbf{y}}_{n-\tau}] = [\mathbf{y}_{\tau+1}, \mathbf{y}_{\tau+2}, ..., \mathbf{y}_n]$$

and τ is the size of the dynamics' "memory". In other words, we define a window of size τ which shifts in time so that the output in time t becomes an input in time $t+1$. Therefore, the uncertain inputs method described earlier in this section can be applied to the new dataset $[\hat{\mathbf{Z}}, \hat{\mathbf{Y}}]$. In particular, although the *training* inputs $\hat{\mathbf{Z}}$ are not necessarily uncertain in this case, the aforementioned way of performing inference is particularly advantageous when the task is extrapolation.

In more detail, consider the simplest case described in this section where the posterior $q(\mathbf{X})$ is centered in the given noisy inputs and we allow for variable noise around the centers. To perform extrapolation one firstly needs to train the model on the dataset $[\hat{\mathbf{Z}}, \hat{\mathbf{Y}}]$. Then, we can perform iterative $k-$step ahead prediction in order to find a future sequence $[\mathbf{y}_{n+1}, \mathbf{y}_{n+2}, ...]$ where, similarly to the approach taken by Girard et al. (2003), the predictive variance in each step is accounted for and propagated in the subsequent predictions. For example, if $k = 1$ the algorithm will make iterative 1-step predictions in the future; in the beginning, the output $\mathbf{y}_{n+1}$ will be predicted given the training set. In the next step, the training set will be augmented to include the previously predicted $\mathbf{y}_{n+1}$ as part of the input set, where the predictive variance is now encoded as the uncertainty of this point.

The advantage of the above method, which resembles a state-space model, is that the future predictions do not almost immediately revert to the mean, as in standard station-

ary GP regression, neither do they underestimate the uncertainty, as would happen if the predictive variance was not propagated through the inputs in a principled way.

6.1.1 Demonstration: iterative $k-$step ahead forecasting

Here we demonstrate our framework in the simulation of a state space model, as was described previously. More specifically, we consider the Mackey-Glass chaotic time series, a standard benchmark which was also considered in (Girard et al., 2003). The data is one-dimensional so that the timeseries can be represented as pairs of values $\{\mathbf{y}, \mathbf{t}\}, t = 1, 2, \cdots, n$ and simulates:

$$\frac{\mathrm{d}\zeta(t)}{dt} = -b\zeta(t) + \alpha\frac{\zeta(t-T)}{1+\zeta(t-T)^{10}}, \quad \text{with} \quad \alpha = 0.2, b = 0.1, T = 17.$$

As can be seen, the generating process is very non-linear, something which makes this dataset particularly challenging. The created dataset is in uniform time-steps.

The model trained on this dataset was the one described previously, where the modified dataset $\{\hat{\mathbf{y}}, \hat{\mathbf{z}}\}$ was created with $\tau = 18$ and we used the first $4\tau = 72$ points for training and predicted the subsequent 1110 points in the future. 30 inducing points were used. We firstly compared to a standard GP model where the input - output pairs were given by the modified dataset $\{\hat{\mathbf{z}}, \hat{\mathbf{y}}\}$ that was mentioned previously; this model is here referred to as the "naive autoregressive GP" model $\mathcal{GP}_{\hat{\mathbf{z}},\hat{\mathbf{y}}}$. For this model, the predictions are made in the $k-$step ahead manner, according to which the predicted values for iteration k are added to the training set. However, this standard GP model has no straight forward way of propagating the uncertainty, and therefore the input uncertainty is zero for every step of the iterative predictions. We also compared against a special case of the variational GP-LVM which implements the functionality developed by Girard et al. (2003). In this version, predictions at every step are performed on a noisy location, i.e. by incorporating the predictive variance of the previous step. In contrast to our algorithm, however, the predictive point is not incorporated as noisy input after the prediction but, rather, discarded. This method is here referred to as $\mathcal{GP}_{\text{uncert}}$. Although we use $\mathcal{GP}_{\text{uncert}}$ as an informative baseline, we note that in the original paper of Girard et al. (2003), additional approximations were implemented, by performing Taylor expansion around the predictive mean and variance in each step. The predictions obtained for all competing methods can be seen in Figure 14.

As shown in the last plot, both the variational GP-LVM and $\mathcal{GP}_{\text{uncert}}$ are robust in handling the uncertainty throughout the predictions; $\mathcal{GP}_{\hat{\mathbf{z}},\hat{\mathbf{y}}}$ underestimates the uncertainty. Consequently, as can be seen from the top three plots, in the first few predictions all methods give the same answer. However, once the predictions of $\mathcal{GP}_{\hat{\mathbf{z}},\hat{\mathbf{y}}}$ diverge a little by the true values, the error is carried on and amplified due to underestimating the uncertainty. On the other hand, $\mathcal{GP}_{\text{uncert}}$ perhaps overestimates the uncertainty and, therefore, is more conservative in its predictions, resulting in higher errors. Quantification of the error is shown in Table 4 and further validates the above discussion. The negative log. probability density for the predicted sequence was also computed for each method. The obtained values were then divided by the length of the predicted sequence to obtain an average per point. The result is 22447 for our method, 30013 for that of Girard et al. (2003) and 36583 for the "naive" GP method.

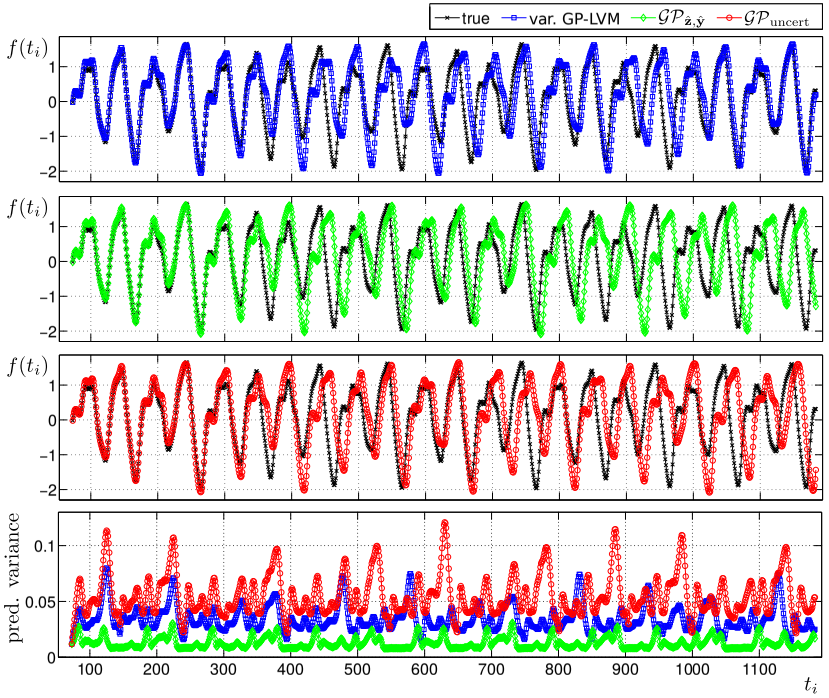

Figure 14: Iterative 1−step ahead prediction for a chaotic timeseries. From top to bottom, the following methods are compared: the variational GP-LVM, a "naive" autoregressive GP approach which does not propagate uncertainties ($\mathcal{GP}_{\hat{\mathbf{z}},\hat{\mathbf{y}}}$) and the approach of Girard et al. (2003) ($\mathcal{GP}_{\text{uncert}}$) implemented as a specific case of the variational GP-LVM. The plot at the bottom shows the predictive variances. The $x-$axis is common for all plots, representing the extrapolation step.

6.2 GP Regression with Missing Inputs and Data Imputation

In standard GP regression we assume that the inputs and the outputs are fully observed. However, in many realistic scenarios missing values can occur. The case where the missing values occur in the outputs (known as semi-supervised learning) has been addressed in the past in the context of GPs, e.g. by Lawrence and Jordan (2005); Sindhwani et al. (2007). However, handling partially observed *input* data in a fully probabilistic way is challenging, since propagating the uncertainty from the input to the output space is intractable. Girard et al. (2003); Quiñonero-Candela et al. (2003) provide an approximation, but their solution does not support uncertain *training* inputs.

Method	MAE	MSE
var. GP-LVM	**0.529**	**0.550**
$\mathcal{GP}_{\text{uncert}}$	0.700	0.914
$\mathcal{GP}_{\hat{\mathbf{z}},\hat{\mathbf{y}}}$	0.799	1.157

Table 4: Mean squared and mean absolute error obtained when extrapolating in the chaotic time-series data. $\mathcal{GP}_{\text{uncert}}$ refers to the method of Girard et al. (2003) implemented as a specific case of our framework and $\mathcal{GP}_{\hat{\mathbf{z}},\hat{\mathbf{y}}}$ refers to the "naive" autoregressive GP approach which does not propagate uncertainties. The lowest errors (achieved by our method) are in bold.

In this section, we describe how our proposed model can be used in a data imputation problem where part of the training inputs are missing. This scenario is here treated as a special case of the uncertain input modelling discussed above. Although a more general setting can be defined, here we consider the case where we have a fully and a partially observed set of inputs, i.e. $\mathbf{Z} = (\mathbf{Z}^o, \mathbf{Z}^u)$, where o and u denote set of rows of $(\mathbf{Z}, \mathbf{Y})$ that contain fully and partially observed inputs respectively[4]. This is a realistic scenario; it is often the case that certain input features are more difficult to obtain (e.g. human specified tags) than others, but we would nevertheless wish to model all available information within the same model. The features missing in $\mathbf{Z}^u$ can be different in number / location for each individual point $\mathbf{z}^u_{i,:}$.

A standard GP regression model cannot straightforwardly model jointly $\mathbf{Z}^o$ and $\mathbf{Z}^u$. In contrast, in our framework the inputs are replaced by distributions $q(\mathbf{X}^o)$ and $q(\mathbf{X}^u)$, so that $\mathbf{Z}^u$ can be taken into account naturally by simply initialising the uncertainty of $q(\mathbf{X}^u)$ in the missing locations to 1 (assuming normalized inputs) and the mean to the empirical mean and then, optionally, optimising $q(\mathbf{X}^u)$. In our experiments we use a slightly more sophisticated approach which resulted in better results. Specifically, we can use the fully observed data subset $(\mathbf{Z}^o, \mathbf{Y}^o)$ to train an initial model for which we fix $q(\mathbf{X}^o) = \mathcal{N}(\mathbf{X}^o|\mathbf{Z}^o, \varepsilon \rightarrow \mathbf{0})$. Given this model, we can then use $\mathbf{Y}^u$ to estimate the predictive posterior $q(\mathbf{X}^u)$ in the missing locations of $\mathbf{Z}^u$ (for the observed locations we match the mean with the observations, as for $\mathbf{Z}^o$). After initialising $q(\mathbf{X}) = q(\mathbf{X}^o, \mathbf{X}^u)$ in this way, we can proceed by training our model on the full (extended) training set $((\mathbf{Z}^o, \mathbf{Z}^u), (\mathbf{Y}^o, \mathbf{Y}^u))$, which contains fully and partially observed inputs. During this training phase, the variational distribution $q(\mathbf{X})$ is held fixed in the locations corresponding to observed values and is optimised in the locations of missing inputs. Considering a distribution $q(\mathbf{X})$ factorised w.r.t data points and constrained with $\mathbf{Z}$ as explained above might not be an optimal choice with respect to the true posterior. However, this approach allows us to incorporate knowledge of the observed locations without adding extra computational cost to the framework.

Given the above formulation, we define a new type of GP model referred to as "*missing inputs GP*". This model naturally incorporates fully and partially observed examples by

4. In section 4, the superscript u denoted the set of missing *columns from test outputs*. Here it refers to *rows of training inputs* that are *partially* observed, i.e. the union of o and u is now $\{1, \cdots, n\}$.

communicating the uncertainty throughout the relevant parts of the model in a principled way. Specifically, the predictive uncertainty obtained by the initial model trained on the fully observed data is incorporated as input uncertainty via $q(\mathbf{X}^u)$ in the model trained on the extended dataset, similarly to how extrapolation was achieved for our auto-regressive approach in Section 6.1. In extreme cases resulting in very non-confident predictions, for example presence of outliers, the corresponding locations will simply be ignored automatically due to the large uncertainty. This mechanism, together with the subsequent optimisation of $q(\mathbf{X}^u)$, guards against reinforcing bad predictions when imputing missing values after learning from small training sets. Details of the algorithm for this approach are given in Appendix E.

Although the focus of this section was on handling missing inputs, the algorithm developed above has conceptual similarities with procedures followed to solve the missing outputs (semi-supervised learning) problem. Specifically, our generative method treats the missing values task as a data imputation problem, similarly to (Kingma et al., 2014). Furthermore, to perform data imputation our algorithm trains an initial model on the fully observed portion of the data, used to predict the missing values. This draws inspiration from self-training methods used for incorporating unlabelled examples in classification tasks (Rosenberg et al., 2005). In a *bootstrap*-based self-training approach this incorporation is achieved by predicting the missing labels using the initial model and, subsequently, augmenting the training set using only the confident predictions subset. However, our approach differs from bootstrap-based self-training methods in two key points: firstly, the partially unobserved set is in the input rather than the output space; secondly, the predictions obtained from the "self-training" step of our method only constitute initialisations which are later optimised along with model parameters. Therefore, we refer to this step of our algorithm as *partial* self-training. Further, in our framework the predictive uncertainty is not used as a hard measure of discarding unconfident predictions but, instead, we allow all values to contribute according to an optimised uncertainty measure. Therefore, the way in which uncertainty is handled makes the "self-training" part of our algorithm principled compared to many bootstrap-based approaches.

6.2.1 Demonstration

In this section we consider simulated and real-world data to demonstrate our missing inputs GP algorithm, which was discussed in Section 6.2. The simulated data were created by sampling inputs $\mathbf{Z}$ from an unknown to the competing models GP and gave this as input to another (again, unknown) GP to obtain the corresponding outputs $\mathbf{Y}$. For the real-world data demonstration we considered a subset of the same motion capture dataset discussed in Section 5.3, which corresponds to a walking motion of a human body represented as a set of 59 joint locations. We formulated a regression problem where the first 20 dimensions of the original data are used as targets and the rest 39 as inputs. In other words, given a partial joint representation of the human body, the task is to infer the rest of the representation; that is, given fully observed test inputs $\mathbf{Z}_*$ we wish to reconstruct test outputs $\mathbf{Y}_*$. For both datasets, simulated and motion capture, we selected a portion of the training inputs, denoted as $\mathbf{Z}^u$, to have randomly missing features. The extended dataset $((\mathbf{Z}^o, \mathbf{Z}^u), (\mathbf{Y}^o, \mathbf{Y}^u))$ was used to train our method as well as a nearest neighbour (NN) method. The NN method

compares a test instance $\mathbf{z}_*$ to each training instance by only taking into account the dimensions that are observed in the training point. This gives a noisy similarity measure in the input space. The predicted output $\mathbf{y}_*$ is then taken to be the training output for which the corresponding input has the largest similarity (according to the above noisy measure). We further compared to a standard GP, which was trained using only the observed data $(\mathbf{Z}^o, \mathbf{Y}^o)$, since it cannot handle missing inputs straightforwardly.

For the simulated data we used the following sizes: $|\mathbf{Z}^o| = 40$, $|\mathbf{Z}^u| = 60$, $|\mathbf{Z}_*| = 100$ and $m = 30$. The dimensionality of the inputs is 15 and of the outputs is 5. For the motion capture data we used $|\mathbf{Z}^o| = 50$, $|\mathbf{Z}^u| = 80$, $|\mathbf{Z}_*| = 200$ and $m = 35$. In Figure 15 we plot the MSE obtained by the competing methods for a varying percentage of missing features in $\mathbf{Z}^u$. For the simulated data experiment, each of the points in the plot is an average of 4 runs which considered different random seeds. As can be seen, the missing inputs GP is able to handle the extra data and make better predictions, even if a very large portion is missing. Indeed, its performance starts to converge to that of a standard GP when there are 90% missing values in $\mathbf{Z}^u$ and performs identically to the standard GP when 100% of the values are missing. In Appendix F.2 we also provide a comparison to multiple linear regression (MLR) (Chatterjee and Hadi, 1986) and to the mean predictor. These methods gave very bad results, and for clarity they were not included in the main Figure 15.

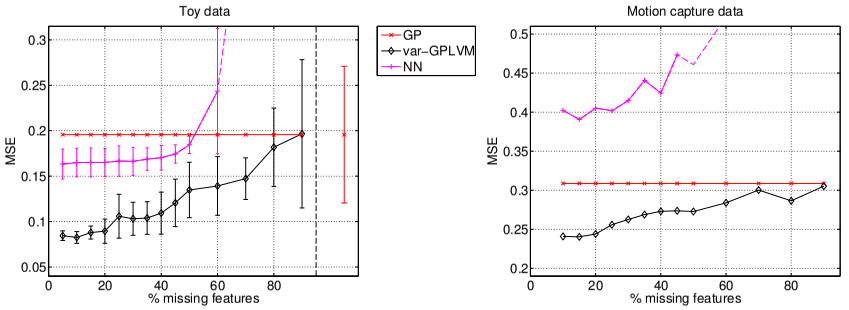

Figure 15: Mean squared error for predictions obtained by different methods in simulated (left) and motion capture data (right). The results for simulated data are obtained from 4 trials and, hence, errorbars are also plotted. For the GP, errorbars do not change with x-axis and, for clarity, they are plotted separately on the right of the dashed vertical line (for nonsensical x values). For clarity, the error for NN is not plotted when it grows too large; the full figure and comparison with other methods can be seen in Figure 20 of the Appendix.

7. Conclusion

We have introduced an approximation to the marginal likelihood of the Gaussian process latent variable model in the form of a variational lower bound. This provides a Bayesian

training procedure which is robust to overfitting and allows for the appropriate dimensionality of the latent space to be automatically determined. Our framework is extended for the case where the observed data constitute multivariate timeseries and, therefore, we obtain a very generic method for dynamical systems modelling able to capture complex, non-linear correlations. We demonstrated the advantages of the rigorous lower bound defined in our framework on a range of disparate real world data sets. This also emphasised the ability of the model to handle vast dimensionalities.

Our approach was easily extended to be applied to training Gaussian processes with uncertain inputs where these inputs have Gaussian prior densities. This further gave rise to two variants of our model: an auto-regressive GP as well as a GP regression model which can handle partially missing inputs. For future research, we envisage several other extensions that become computationally feasible using the same set of methodologies we espouse. In particular, propagation of uncertain inputs through the Gaussian process allows Bayes filtering (Ko and Fox, 2009a; Deisenroth et al., 2012; Frigola et al., 2014) applications to be carried out through variational bounds. Bayes filters are non-linear dynamical systems where time is discrete and the observed data $\mathbf{y}_t$ at time point t is non-linearly related to some unobserved latent state $\mathbf{x}_t$ via

$$\mathbf{y}_t = f(\mathbf{x}_t),$$

which itself has a non-linear autoregressive relationship with past latent states,

$$\mathbf{x}_t = g(\mathbf{x}_{t-1}),$$

where both $g(\cdot)$ and $f(\cdot)$ are assumed to be Gaussian processes. Propagation of the uncertainty through both processes can be achieved through our variational lower bound allowing fast efficient approximations to Gaussian process dynamical models.

The bound also allows for a promising new direction of research, that of *deep Gaussian processes*. In a deep Gaussian process (Lawrence and Moore, 2007; Damianou and Lawrence, 2013) the idea of placing a temporal prior over the inputs to a GP is further extended by hierarchical application. This formalism leads to a powerful class of models where Gaussian process priors are placed over function compositions (Damianou, 2015). For example, in a five layer model we have

$$f(\mathbf{X}) = g_5(g_4(g_3(g_2(g_1(\mathbf{X}))))),$$

where each $g_i(\cdot)$ is a draw from a Gaussian process. By combining such models with structure learning (Damianou et al., 2012) we can develop the potential to learn very complex non linear interactions between data. In contrast to other deep models *all* the uncertainty in parameters and latent variables is marginalised out.

Acknowledgments

This research was partially funded by the European research project EU FP7-ICT (Project Ref 612139 "WYSIWYD"), the Greek State Scholarships Foundation (IKY) and the University of Sheffield Moody endowment fund. We also thank Colin Litster and "Fit Fur Life" for allowing us to use their video files as datasets.

Appendix A. Further Details About the Variational Bound

This appendix contains supplementary details for deriving some mathematical formulae related to the calculation of the final expression of the variational lower bound for the training phase.

Since many derivations require completing the square to recognize a Gaussian, we will use the following notation throughout the Appendix:

$$\mathcal{Z} = \text{the collection of all constants for the specific line in equation,}$$

where the definition of a constant depends on the derivation at hand.

A.1 Calculation of: $\langle \log p(\mathbf{y}_{:,j}|\mathbf{f}_{:,j})\rangle_{p(\mathbf{f}_{:,j}|\mathbf{u}_{:,j},\mathbf{X})}$

First, we show in detail how to obtain the r.h.s of equation (20) for the following quantity: $\langle \log p(\mathbf{y}_{:,j}|\mathbf{f}_{:,j})\rangle_{p(\mathbf{f}_{:,j}|\mathbf{u}_{:,j},\mathbf{X})}$ which appears in the variational bound of equation (19). We now compute the above quantity analytically while temporarily using the notation $\langle\cdot\rangle = \langle\cdot\rangle_{p(\mathbf{f}_{:,j}|\mathbf{u}_{:,j},\mathbf{X})}$:

$$\begin{aligned}
\langle \log p(\mathbf{y}_{:,j}|\mathbf{f}_{:,j})\rangle &\overset{\text{eq. (6)}}{=} \left\langle \log \mathcal{N}\left(\mathbf{y}_{:,j}|\mathbf{f}_{:,j}, \sigma^2\mathbf{I}_n\right)\right\rangle \\
&= -\frac{n}{2}\log(2\pi) - \frac{1}{2}\log|\sigma^2\mathbf{I}_n| \\
&\quad -\frac{1}{2}\mathrm{tr}\left(\sigma^{-2}\mathbf{I}_n\left(\mathbf{y}_{:,j}\mathbf{y}_{:,j}^\top - 2\mathbf{y}_{:,j}\left\langle \mathbf{f}_{:,j}^\top\right\rangle + \left\langle \mathbf{f}_{:,j}\mathbf{f}_{:,j}^\top\right\rangle\right)\right) \\
&\overset{\text{eq. (13)}}{=} \mathcal{Z} - \frac{1}{2}\mathrm{tr}\left(\sigma^{-2}\mathbf{I}_n\left(\mathbf{y}_{:,j}\mathbf{y}_{:,j}^\top - 2\mathbf{y}_{:,j}\mathbf{a}_j^\top + \mathbf{a}_j\mathbf{a}_j^\top + \boldsymbol{\Sigma}_f\right)\right).
\end{aligned}$$

By completing the square we find:

$$\begin{aligned}
\langle \log p(\mathbf{y}_{:,j}|\mathbf{f}_{:,j})\rangle_{p(\mathbf{f}_{:,j}|\mathbf{u}_{:,j},\mathbf{X})} &= \log\mathcal{N}\left(\mathbf{y}_{:,j}|\mathbf{a}_j, \sigma^2\mathbf{I}_n\right) - \frac{1}{2}\mathrm{tr}\left(\sigma^{-2}\boldsymbol{\Sigma}_f\right) \\
&\overset{\text{eq. (14)}}{=} \log\mathcal{N}\left(\mathbf{y}_{:,j}|\mathbf{a}_j, \sigma^2\mathbf{I}_n\right) - \frac{1}{2\sigma^2}\mathrm{tr}\left(\mathbf{K}_{ff} - \mathbf{K}_{fu}\mathbf{K}_{uu}^{-1}\mathbf{K}_{uf}\right).
\end{aligned}$$

A.2 Calculating the Explicit Form of $q(\mathbf{u}_{:,j})$

From equation (22), we have:

$$\log q(\mathbf{u}_{:,j}) \propto \left\langle \log\mathcal{N}\left(\mathbf{y}_{:,j}|\mathbf{a}_j, \sigma^2\mathbf{I}_n\right)\right\rangle_{q(\mathbf{X})} + \log p(\mathbf{u}_{:,j}). \tag{42}$$

All the involved distributions are Gaussian and, hence, we only need to compute the r.h.s of the above equation and complete the square in order to get the posterior Gaussian distribution for $q(\mathbf{u}_{:,j})$. The expectation appearing in the above equation is easily computed

as:

$$\begin{aligned}\left\langle \log \mathcal{N}\left(\mathbf{y}_{:,j}|\mathbf{a}_j,\sigma^2\mathbf{I}_n\right)\right\rangle_{q(\mathbf{X})} =& \mathcal{Z} - \frac{1}{2\sigma^2}\mathrm{tr}\left(\mathbf{y}_{:,j}\mathbf{y}_{:,j}^\top - 2\mathbf{y}_{:,j}\left\langle \mathbf{a}_j^\top\right\rangle_{q(\mathbf{X})} + \left\langle \mathbf{a}_j\mathbf{a}_j^\top\right\rangle_{q(\mathbf{X})}\right)\\ \overset{\text{eq. (14)}}{=}& \mathcal{Z} - \frac{1}{2\sigma^2}\mathrm{tr}\Big(\mathbf{y}_{:,j}\mathbf{y}_{:,j}^\top - 2\mathbf{y}_{:,j}\mathbf{u}_{:,j}^\top\mathbf{K}_{uu}^{-1}\left\langle \mathbf{K}_{fu}^\top\right\rangle_{q(\mathbf{X})}\\ &+ \mathbf{u}_{:,j}^\top\mathbf{K}_{uu}^{-1}\left\langle \mathbf{K}_{fu}\mathbf{K}_{fu}\right\rangle_{q(\mathbf{X})}\mathbf{K}_{uu}^{-1}\mathbf{u}_{:,j}\Big)\\ \overset{\text{eq. (26)}}{=}& \mathcal{Z} - \frac{1}{2\sigma^2}\mathrm{tr}\Big(\mathbf{y}_{:,j}\mathbf{y}_{:,j}^\top - 2\mathbf{y}_{:,j}\mathbf{u}_{:,j}^\top\mathbf{K}_{uu}^{-1}\mathbf{\Psi}_1^\top\\ &+ \mathbf{u}_{:,j}^\top\mathbf{K}_{uu}^{-1}\mathbf{\Psi}_2\mathbf{K}_{uu}^{-1}\mathbf{u}_{:,j}\Big). \end{aligned} \tag{43}$$

We can now easily find equation (42) by combining equations (43) and (15):

$$\begin{aligned}\log q(\mathbf{u}_{:,j}) &\propto \left\langle \log \mathcal{N}\left(\mathbf{y}_{:,j}|\mathbf{a}_j,\sigma^2\mathbf{I}_n\right)\right\rangle_{q(\mathbf{X})} + \log p(\mathbf{u}_{:,j})\\ &= \mathcal{Z} - \frac{1}{2\sigma^2}\mathrm{tr}\Big(\mathbf{y}_{:,j}\mathbf{y}_{:,j}^\top - 2\mathbf{y}_{:,j}\mathbf{u}_{:,j}^\top\mathbf{K}_{uu}^{-1}\mathbf{\Psi}_1^\top + \mathbf{u}_{:,j}^\top\mathbf{K}_{uu}^{-1}\mathbf{\Psi}_2\mathbf{K}_{uu}^{-1}\mathbf{u}_{:,j}\Big)\\ &\quad - \frac{1}{2}\mathrm{tr}\Big(\mathbf{K}_{uu}^{-1}\mathbf{u}_{:,j}\mathbf{u}_{:,j}^\top\Big)\\ &= \mathcal{Z} - \frac{1}{2}\mathrm{tr}\Big(\mathbf{u}_{:,j}^\top\left(\sigma^{-2}\mathbf{K}_{uu}^{-1}\mathbf{\Psi}_2\mathbf{K}_{uu}^{-1} + \mathbf{K}_{uu}^{-1}\right)\mathbf{u}_{:,j} + \sigma^{-2}\mathbf{y}_{:,j}\mathbf{y}_{:,j}^\top - 2\sigma^{-2}\mathbf{K}_{uu}^{-1}\mathbf{\Psi}_1^\top\mathbf{y}_{:,j}\mathbf{u}_{:,j}^\top\Big).\end{aligned} \tag{44}$$

We can now complete the square again and recognize that $q(\mathbf{u}_{:,j}) = \mathcal{N}\left(\mathbf{u}_{:,j}|\boldsymbol{\mu}_u,\mathbf{\Sigma}_u\right)$, where:

$$\begin{aligned}\mathbf{\Sigma}_u &= \left(\sigma^{-2}\mathbf{K}_{uu}^{-1}\mathbf{\Psi}_2\mathbf{K}_{uu}^{-1} + \mathbf{K}_{uu}^{-1}\right)^{-1} \quad \text{and}\\ \boldsymbol{\mu}_u &= \sigma^{-2}\mathbf{\Sigma}_u\mathbf{K}_{uu}^{-1}\mathbf{\Psi}_1^\top\mathbf{y}_{:,j}.\end{aligned}$$

By "pulling" the $\mathbf{K}_{uu}$ matrices out of the inverse and after simple manipulations we get the final form of $q(\mathbf{u}_{:,j})$:

$$\begin{aligned}q(\mathbf{u}_{:,j}) &= \mathcal{N}\left(\mathbf{u}_{:,j}|\boldsymbol{\mu}_u,\mathbf{\Sigma}_u\right) \quad \text{where}\\ \boldsymbol{\mu}_u &= \mathbf{K}_{uu}\left(\sigma^2\mathbf{K}_{uu} + \mathbf{\Psi}_2\right)^{-1}\mathbf{\Psi}_1^\top\mathbf{y}_{:,j}\\ \mathbf{\Sigma}_u &= \sigma^2\mathbf{K}_{uu}\left(\sigma^2\mathbf{K}_{uu} + \mathbf{\Psi}_2\right)^{-1}\mathbf{K}_{uu}.\end{aligned} \tag{45}$$

A.3 Detailed Derivation of $\hat{\mathcal{F}}_j(q(\mathbf{X}))$

The quantity $\hat{\mathcal{F}}_j(q(\mathbf{X}))$ appears in equation (23). Based on the derivations of the previous section, we can rewrite equation (44) as a function of the optimal $q(\mathbf{u}_{:,j})$ found in equation (45) by completing the constant terms:

$$\left\langle \log \mathcal{N}\left(\mathbf{y}_{:,j}|\mathbf{a}_j,\sigma^2\mathbf{I}_n\right)\right\rangle_{q(\mathbf{X})} + \log p(\mathbf{u}_{:,j}) = \mathcal{B} + \log \mathcal{N}\left(\mathbf{u}_{:,j}|\boldsymbol{\mu}_u,\mathbf{\Sigma}_u\right) \tag{46}$$

where we have defined:

$$\mathcal{B} = -\frac{n}{2}\log(2\pi) - \frac{1}{2}\log|\sigma^2\mathbf{I}_n| - \frac{1}{2}\log|\mathbf{K}_{uu}| - \frac{1}{2\sigma^2}\mathbf{y}_{:,j}^\top\mathbf{y}_{:,j} + \frac{1}{2}\boldsymbol{\mu}_u^\top\mathbf{\Sigma}_u^{-1}\boldsymbol{\mu}_u + \frac{1}{2}\log|\mathbf{\Sigma}_u|. \tag{47}$$

We can now obtain the final expression for (23) by simply putting the quantity of (46) on the exponent and integrating. By doing so, we get:

$$\begin{aligned}&\int e^{\left\langle \log \mathcal{N}\left(\mathbf{y}_{:,j}|\mathbf{a}_d,\sigma^2 I_d\right)\right\rangle_{q(\mathbf{X})}}p(\mathbf{u}_{:,j})\mathrm{d}\mathbf{u}_{:,j} = \int e^{\mathcal{B}}e^{\log \mathcal{N}\left(\mathbf{u}_{:,j}|\boldsymbol{\mu}_u,\mathbf{\Sigma}_u\right)}\mathrm{d}\mathbf{u}_{:,j} = e^{\mathcal{B}}\\ \overset{\text{eq. (47)}}{=}& (2\pi)^{-\frac{N}{2}}\sigma^{-n}|\mathbf{K}_{uu}|^{-\frac{1}{2}}e^{-\frac{1}{2\sigma^2}\mathbf{y}_{:,j}^\top\mathbf{y}_{:,j}}|\mathbf{\Sigma}_u|^{\frac{1}{2}}e^{\frac{1}{2}\boldsymbol{\mu}_u^\top\mathbf{\Sigma}_u^{-1}\boldsymbol{\mu}_u}.\end{aligned} \tag{48}$$

By using equation (45) and some straightforward algebraic manipulations, we can replace in the above $\boldsymbol{\mu}_u^\top\mathbf{\Sigma}_u^{-1}\boldsymbol{\mu}_u$ with:

$$\boldsymbol{\mu}_u^\top\mathbf{\Sigma}_u^{-1}\boldsymbol{\mu}_u = \mathbf{y}_{:,j}^\top\underbrace{\sigma^{-4}\mathbf{\Psi}_1(\sigma^{-2}\mathbf{\Psi}_2 + \mathbf{K}_{uu})^{-1}\mathbf{\Psi}_1^\top}_{\mathbf{W}'}\mathbf{y}_{:,j}. \tag{49}$$

Finally, using equation (45) to replace $\mathbf{\Sigma}_u$ with its equal, as well as equation (49), we can write the integral of equation (48) as:

$$\int e^{\left\langle \log \mathcal{N}\left(\mathbf{y}_{:,j}|\mathbf{a}_d,\sigma^2 I_d\right)\right\rangle_{q(\mathbf{X})}}p(\mathbf{u}_{:,j})\mathrm{d}\mathbf{u}_{:,j} = \frac{\sigma^{-n}|\mathbf{K}_{uu}|^{-\frac{1}{2}}|\mathbf{K}_{uu}|e^{-\frac{1}{2\sigma^2}\mathbf{y}_{:,j}^\top\mathbf{y}_{:,j}}}{(2\pi)^{N/2}|\sigma^{-2}\mathbf{\Psi}_2 + \mathbf{K}_{uu}|^{\frac{1}{2}}}e^{\frac{1}{2}\mathbf{y}_{:,j}^\top\mathbf{W}'\mathbf{y}_{:,j}}. \tag{50}$$

We can now obtain the final form for the variational bound by replacing equation (50) in equation (23), as well as replacing the term $\mathcal{A}$ with its equal and defining $\mathbf{W} = \sigma^{-2}\mathbf{I}_n - \mathbf{W}'$. By doing the above, we get exactly the final form of the bound of equation (25).

Appendix B. Calculating the Ψ Quantities

Here we explain how one can compute the Ψ quantities (introduced in Section 3.2) for two standard choices for the GP prior covariance. For completeness, we start by rewriting the equations (27), (28) and (29):

$$\psi_0 = \sum_{i=1}^{n}\psi_0^i, \;\; \text{with} \;\; \psi_0^i = \int k(\mathbf{x}_{i,:},\mathbf{x}_{i,:})\mathcal{N}(\mathbf{x}_{i,:}|\boldsymbol{\mu}_{i,:},\mathbf{S}_i)\mathrm{d}\mathbf{x}_{i,:}.$$

$$(\mathbf{\Psi}_1)_{i,k} = \int k\left(\mathbf{x}_{i,:},(\mathbf{x}_u)_{k,:}\right)\mathcal{N}(\mathbf{x}_{i,:}|\boldsymbol{\mu}_{i,:},\mathbf{S}_i)\mathrm{d}\mathbf{x}_{i,:}.$$

$$\mathbf{\Psi}_2 = \sum_{i=1}^{n}\mathbf{\Psi}_2^i \;\; \text{where} \;\; (\Psi_2^i)_{k,k'} = \int k(\mathbf{x}_{i,:},(\mathbf{x}_u)_{k,:})k((\mathbf{x}_u)_{k',:},\mathbf{x}_{i,:})\mathcal{N}(\mathbf{x}_{i,:}|\boldsymbol{\mu}_{i,:},\mathbf{S}_i)\mathrm{d}\mathbf{x}_{i,:}.$$

The above computations involve convolutions of the covariance function with a Gaussian density. For some standard kernels such the ARD exponentiated quadratic (RBF) covariance and the linear covariance function these statistics are obtained analytically. In particular for the ARD exponentiated quadratic kernel of equation (8) we have:

$$\begin{aligned}\psi_0 &= n\sigma_f^2\\ (\mathbf{\Psi}_1)_{i,k} &= \sigma_f^2\prod_{j=1}^{q}\frac{\exp\left(-\frac{1}{2}\frac{w_j(\mu_{i,j}-(x_u)_{k,j})^2}{w_jS_{i,j}+1}\right)}{(w_jS_{i,j}+1)^{\frac{1}{2}}}\\ (\Psi_2^i)_{k,k'} &= \sigma_f^4\prod_{j=1}^{q}\frac{\exp\left(-\frac{w_j((x_u)_{k,j}-(x_u)_{k',j})^2}{4} - \frac{w_j(\mu_{i,j}-\bar{x}_{:,j})^2}{2w_jS_{i,j}+1}\right)}{(2w_jS_{i,j}+1)^{\frac{1}{2}}},\end{aligned}$$

where $\bar{x}_{:,j} = \frac{((x_u)_{k,j}+(x_u)_{k',j})}{2}$. This gives us all the components we need to compute the variational lower bound for the ARD exponentiated quadratic kernel.

The linear ARD covariance function $k_{f(\text{lin})}(\mathbf{x}_{i,:}, \mathbf{x}_{k,:}) = \sigma^2_{\text{lin}}\mathbf{x}_{i,:}^\top \mathbf{C}\mathbf{x}_{k,:}$ depends on a diagonal matrix $\mathbf{C}$ containing the ARD weights. For this covariance function, the integrals required for the Ψ statistics are also tractable, such that

$$\begin{aligned}\psi_0^i &= \text{tr}\left(\mathbf{C}(\boldsymbol{\mu}_{i,:}\boldsymbol{\mu}_{i,:}^\top + \mathbf{S}_i)\right)\\ (\boldsymbol{\Psi}_1)_{i,k} &= \boldsymbol{\mu}_{i,:}^\top \mathbf{C}(\mathbf{x}_u)_{k,:}\\ (\boldsymbol{\Psi}_2^i)_{k,k'} &= (\mathbf{x}_u)_{k,:}^\top \mathbf{C}\left(\boldsymbol{\mu}_{i,:}\boldsymbol{\mu}_{i,:}^\top + \mathbf{S}_i\right)\mathbf{C}(\mathbf{x}_u)_{k',:}.\end{aligned}$$

Appendix C. Derivatives of the Variational Bound for the Dynamical Version

Before giving the expressions for the derivatives of the variational bound (11), it should be recalled that the variational parameters $\boldsymbol{\mu}_j$ and $\mathbf{S}_j$ (for all qs) have been reparametrised as

$$\mathbf{S}_j = \left(\mathbf{K}_x^{-1} + \text{diag}(\boldsymbol{\lambda}_j)\right)^{-1} \text{ and } \boldsymbol{\mu}_{:,j} = \mathbf{K}_x\bar{\boldsymbol{\mu}}_{:,j},$$

where the function diag$(\cdot)$ transforms a vector into a square diagonal matrix and vice versa. Given the above, the set of the parameters to be optimised is $(\boldsymbol{\theta}_f, \boldsymbol{\theta}_x, \{\bar{\boldsymbol{\mu}}_{:,j}, \boldsymbol{\lambda}_j\}_{j=1}^q, \tilde{\mathbf{X}})$. The gradient w.r.t the inducing points $\tilde{\mathbf{X}}$, however, has exactly the same form as for $\boldsymbol{\theta}_f$ and, therefore, is not presented here.

Some more notation:

1. λ_j is a scalar, an element of the vector $\boldsymbol{\lambda}_j$ which, in turn, is the main diagonal of the diagonal matrix $\boldsymbol{\Lambda}_j$.
2. $(S_j)_{k,l} \triangleq S_{j;kl}$ the element of $\mathbf{S}_j$ found in the k-th row and l-th column.
3. $\mathbf{s}_j \triangleq \{(S_j)_{i,i}\}_{i=1}^n$, i.e. it is a vector with the diagonal of $\mathbf{S}_j$.

C.1 Derivatives w.r.t the Variational Parameters

$$\frac{\partial \mathcal{F}}{\partial \bar{\boldsymbol{\mu}}_j} = \mathbf{K}_x\left(\frac{\partial \hat{\mathcal{F}}}{\partial \boldsymbol{\mu}_{:,j}} - \bar{\boldsymbol{\mu}}_{:,j}\right) \text{ and } \frac{\partial \mathcal{F}}{\partial \boldsymbol{\lambda}_j} = -(\mathbf{S}_j \circ \mathbf{S}_j)\left(\frac{\partial \hat{\mathcal{F}}}{\partial \mathbf{s}_j} + \frac{1}{2}\boldsymbol{\lambda}_j\right).$$

where for each single dimensional element we have:

$$\begin{aligned}\frac{\partial \hat{\mathcal{F}}}{\partial \mu_j} &= -\frac{p}{2\sigma^2}\frac{\partial \psi_0}{\partial \mu_j} + \sigma^{-2}\text{tr}\left(\frac{\partial \boldsymbol{\Psi}_1^\top}{\partial \mu_j}\mathbf{Y}\mathbf{Y}^\top\boldsymbol{\Psi}_1\mathbf{A}^{-1}\right)\\ &\quad + \frac{1}{2\sigma^2}\text{tr}\left(\frac{\partial \boldsymbol{\Psi}_2}{\partial \mu_j}\left(p\mathbf{K}_{uu}^{-1} - \sigma^2 p\mathbf{A}^{-1} - \mathbf{A}^{-1}\boldsymbol{\Psi}_1^\top\mathbf{Y}\mathbf{Y}^\top\boldsymbol{\Psi}_1\mathbf{A}^{-1}\right)\right)\\ \frac{\partial \hat{\mathcal{F}}}{\partial (S_j)_{k,l}} &= -\frac{p}{2\sigma^2}\frac{\partial \Psi_0}{\partial (S_j)_{k,l}} + \sigma^{-2}\text{tr}\left(\frac{\partial \boldsymbol{\Psi}_1^\top}{\partial (S_j)_{k,l}}\mathbf{Y}\mathbf{Y}^\top\boldsymbol{\Psi}_1\mathbf{A}^{-1}\right)\\ &\quad + \frac{1}{2\sigma^2}\text{tr}\left(\frac{\partial \boldsymbol{\Psi}_2}{\partial (S_j)_{k,l}}\left(p\mathbf{K}_{uu}^{-1} - \sigma^2 p\mathbf{A}^{-1} - \mathbf{A}^{-1}\boldsymbol{\Psi}_1^\top\mathbf{Y}\mathbf{Y}^\top\boldsymbol{\Psi}_1\mathbf{A}^{-1}\right)\right)\end{aligned}$$

with $\mathbf{A} = \sigma^2\mathbf{K}_{uu} + \boldsymbol{\Psi}_2$.

C.2 Derivatives w.r.t $\boldsymbol{\theta} = (\boldsymbol{\theta}_f, \boldsymbol{\theta}_x)$ and $\beta = \sigma^{-2}$

In our implementation, we prefer to parametrise the software with the data precision β, rather than the data variance, σ^2. Therefore, here we will give directly the derivatives for the precision. Obviously, through the use of the chain rule and the relationship $\sigma^2 = \beta^{-1}$ one can obtain the derivatives for the variance. Further, when it comes to model parameters, we will write the gradients with respect to each single element θ_f or θ_x.

Given that the KL term involves only the temporal prior, its gradient w.r.t the parameters $\boldsymbol{\theta}_f$ is zero. Therefore:

$$\frac{\partial \mathcal{F}}{\partial \theta_f} = \frac{\partial \hat{\mathcal{F}}}{\partial \theta_f}$$

with:

$$\begin{aligned}\frac{\partial \hat{\mathcal{F}}}{\partial \theta_f} &= \text{const} - \frac{\beta p}{2}\frac{\partial \psi_0}{\partial \theta_f} + \beta\text{tr}\left(\frac{\partial \boldsymbol{\Psi}_1^\top}{\partial \theta_f}\mathbf{Y}\mathbf{Y}^\top\boldsymbol{\Psi}_1\mathbf{A}^{-1}\right)\\ &\quad + \frac{1}{2}\text{tr}\left(\frac{\partial \mathbf{K}_{uu}}{\partial \theta_f}\left(p\mathbf{K}_{uu}^{-1} - \beta^{-1}p\mathbf{A}^{-1} - \mathbf{A}^{-1}\boldsymbol{\Psi}_1^\top\mathbf{Y}\mathbf{Y}^\top\boldsymbol{\Psi}_1\mathbf{A}^{-1} - \beta p\mathbf{K}_{uu}^{-1}\boldsymbol{\Psi}_2\mathbf{K}_{uu}^{-1}\right)\right)\\ &\quad + \frac{\beta}{2}\text{tr}\left(\frac{\partial \boldsymbol{\Psi}_2}{\partial \theta_f}\quad\left(p\mathbf{K}_{uu}^{-1} - \beta^{-1}p\mathbf{A}^{-1} - \mathbf{A}^{-1}\boldsymbol{\Psi}_1^\top\mathbf{Y}\mathbf{Y}^\top\boldsymbol{\Psi}_1\mathbf{A}^{-1}\right)\right)\end{aligned}$$

The expression above is identical for the derivatives w.r.t the inducing points. For the gradients w.r.t the β term, we have a similar expression:

$$\begin{aligned}\frac{\partial \hat{\mathcal{F}}}{\partial \beta} &= \frac{1}{2}\Big[p\left(\text{tr}\left(\mathbf{K}_{uu}^{-1}\boldsymbol{\Psi}_2\right) + (n-m)\beta^{-1} - \psi_0\right) - \text{tr}\left(\mathbf{Y}\mathbf{Y}^\top\right) + \text{tr}\left(\mathbf{A}^{-1}\boldsymbol{\Psi}_1^\top\mathbf{Y}\mathbf{Y}^\top\boldsymbol{\Psi}_1\right)\\ &\quad + \beta^{-2}p\ \text{tr}\left(\mathbf{K}_{uu}\mathbf{A}^{-1}\right) + \beta^{-1}\text{tr}\left(\mathbf{K}_{uu}\mathbf{A}^{-1}\boldsymbol{\Psi}_1^\top\mathbf{Y}\mathbf{Y}^\top\boldsymbol{\Psi}_1\mathbf{A}^{-1}\right)\Big].\end{aligned}$$

In contrast to the above, the term $\hat{\mathcal{F}}$ does involve parameters $\boldsymbol{\theta}_x$, because it involves the variational parameters that are now reparametrised with $\mathbf{K}_x$, which in turn depends on $\boldsymbol{\theta}_x$. To demonstrate that, we will forget for a moment the reparametrisation of $\mathbf{S}_j$ and we will express the bound as $\mathcal{F}(\boldsymbol{\theta}_x, \mu_j(\boldsymbol{\theta}_x))$ (where $\mu_j(\boldsymbol{\theta}_x) = K_t\bar{\boldsymbol{\mu}}_{:,j}$) so as to show explicitly the dependency on the variational mean which is now a function of $\boldsymbol{\theta}_x$. Our calculations must now take into account the term $\left(\frac{\partial \hat{\mathcal{F}}(\boldsymbol{\mu}_{:,j})}{\partial \boldsymbol{\mu}_{:,j}}\right)^\top \frac{\partial \mu_j(\boldsymbol{\theta}_x)}{\partial \boldsymbol{\theta}_x}$ that is what we "miss" when we consider $\mu_j(\boldsymbol{\theta}_x) = \boldsymbol{\mu}_{:,j}$:

$$\begin{aligned}\frac{\partial \mathcal{F}(\boldsymbol{\theta}_x, \mu_j(\boldsymbol{\theta}_x))}{\partial \theta_x} &= \frac{\partial \mathcal{F}(\boldsymbol{\theta}_x, \boldsymbol{\mu}_{:,j})}{\partial \theta_x} + \left(\frac{\partial \hat{\mathcal{F}}(\boldsymbol{\mu}_{:,j})}{\partial \boldsymbol{\mu}_{:,j}}\right)^\top \frac{\partial \mu_j(\boldsymbol{\theta}_x)}{\partial \theta_x}\\ &= \cancel{\frac{\partial \hat{\mathcal{F}}(\boldsymbol{\mu}_{:,j})}{\partial \theta_x}} + \frac{\partial(-\text{KL})(\boldsymbol{\theta}_x, \mu_j(\boldsymbol{\theta}_x))}{\partial \theta_x} + \left(\frac{\partial \hat{\mathcal{F}}(\boldsymbol{\mu}_{:,j})}{\partial \boldsymbol{\mu}_{:,j}}\right)^\top \frac{\partial \mu_j(\boldsymbol{\theta}_x)}{\partial \theta_x}.\end{aligned}$$

We do the same for $\mathbf{S}_j$ and then we can take the resulting equations and replace $\boldsymbol{\mu}_j$ and $\mathbf{S}_j$ with their equals so as to take the final expression which only contains $\bar{\boldsymbol{\mu}}_{:,j}$ and $\boldsymbol{\lambda}_j$:

$$\frac{\partial \mathcal{F}(\boldsymbol{\theta}_x, \mu_j(\boldsymbol{\theta}_x), \mathbf{S}_j(\boldsymbol{\theta}_x))}{\partial \theta_x} = \text{tr}\Bigg[\Big[-\frac{1}{2}\left(\hat{\mathbf{B}}_j \mathbf{K}_x \hat{\mathbf{B}}_j + \bar{\boldsymbol{\mu}}_{:,j}\bar{\boldsymbol{\mu}}_{:,j}^\top\right) + \left(\mathbf{I} - \hat{\mathbf{B}}_j \mathbf{K}_x\right) \text{diag}\left(\frac{\partial \hat{\mathcal{F}}}{\partial \mathbf{s}_j}\right)\left(\mathbf{I} - \hat{\mathbf{B}}_j \mathbf{K}_x\right)^\top \Big] \frac{\partial \mathbf{K}_x}{\partial \theta_x}\Bigg] + \left(\frac{\partial \hat{\mathcal{F}}(\boldsymbol{\mu}_{:,j})}{\partial \boldsymbol{\mu}_{:,j}}\right)^\top \frac{\partial \mathbf{K}_x}{\partial \theta_x}\bar{\boldsymbol{\mu}}_{:,j}$$

where $\hat{\mathbf{B}}_j = \boldsymbol{\Lambda}_j^{\frac{1}{2}} \widetilde{\mathbf{B}}_j^{-1} \boldsymbol{\Lambda}_j^{\frac{1}{2}}$. and $\tilde{\mathbf{B}}_j = \mathbf{I} + \boldsymbol{\Lambda}_j^{\frac{1}{2}} \mathbf{K}_x \boldsymbol{\Lambda}_j^{\frac{1}{2}}$. Note that by using this $\tilde{\mathbf{B}}_j$ matrix (which has eigenvalues bounded below by one) we have an expression which, when implemented, leads to more numerically stable computations, as explained in Rasmussen and Williams (2006) page 45-46.

Appendix D. Variational Lower Bound for Partially Observed Test Data

This section provides some more details related to the task of doing predictions based on partially observed test data $\mathbf{Y}_*^u$. Specifically, section D.1 explains in more detail the form of the variational lower bound for the aforementioned prediction scenario and illustrates how this gives rise to certain computational differences for the standard and the dynamical GP-LVM. Section D.2 gives some more details for the mathematical formulae associated with the above prediction task.

D.1 The Variational Bound in the Test Phase and Computational Issues

As discussed in Section 4.1, when doing predictions based on partially observed outputs with the variational GP-LVM, one needs to construct a variational lower bound as for the training phase. However, this now needs to be associated with the full set of observations $(\mathbf{Y}, \mathbf{Y}_*^o)$. Specifically, we need to lower bound the marginal likelihood given in equation (38). To achieve this, we start from equation (38) and then separate $\mathbf{Y}$ into $(\mathbf{Y}^o, \mathbf{Y}^u)$ while factorising the terms according to the conditional independencies, i.e. :

$$\begin{aligned}\log p(\mathbf{Y}_*^o, \mathbf{Y}) &= \log \int p(\mathbf{Y}_*^o, \mathbf{Y}|\mathbf{X}_*, \mathbf{X}) p(\mathbf{X}_*, \mathbf{X}) \mathrm{d}\mathbf{X}_* \mathrm{d}\mathbf{X} \\ &= \log \int p(\mathbf{Y}^u|\mathbf{X}) p(\mathbf{Y}_*^o, \mathbf{Y}^o|\mathbf{X}_*, \mathbf{X}) p(\mathbf{X}_*, \mathbf{X}) \mathrm{d}\mathbf{X}_* \mathrm{d}\mathbf{X}.\end{aligned}$$

Exactly analogously to the training phase, the variational bound to the above quantity takes the form:

$$\log p(\mathbf{Y}_*^o, \mathbf{Y}) \geq \int q(\mathbf{X}_*, \mathbf{X}) \log \frac{p(\mathbf{Y}^u|\mathbf{X}) p(\mathbf{Y}_*^o, \mathbf{Y}^o|\mathbf{X}_*, \mathbf{X}) p(\mathbf{X}_*, \mathbf{X})}{q(\mathbf{X}_*, \mathbf{X})} \mathrm{d}\mathbf{X}_* \mathrm{d}\mathbf{X}. \tag{51}$$

For the standard variational GP-LVM, we can further expand the above equation by noticing that the distributions $q(\mathbf{X}, \mathbf{X}_*)$ and $p(\mathbf{X}, \mathbf{X}_*)$ are fully factorised as $q(\mathbf{X}, \mathbf{X}_*) = \prod_{i=1}^n q(\mathbf{x}_{i,:}) \prod_{i=1}^{n_*} q(\mathbf{x}_{i,*})$. Therefore, equation (51) can be written as:

$$\begin{aligned}\log p(\mathbf{Y}_*^o, \mathbf{Y}) \geq &\int q(\mathbf{X}) \log p(\mathbf{Y}^u|\mathbf{X}) \mathrm{d}\mathbf{X} + \int q(\mathbf{X}_*, \mathbf{X}) \log p(\mathbf{Y}_*^o, \mathbf{Y}^o|\mathbf{X}_*, \mathbf{X}) \mathrm{d}\mathbf{X}_* \mathrm{d}\mathbf{X} \\ &- \mathrm{KL}\left(q(\mathbf{X}) \,\|\, p(\mathbf{X})\right) - \mathrm{KL}\left(q(\mathbf{X}_*) \,\|\, p(\mathbf{X}_*)\right).\end{aligned} \tag{52}$$

Recalling equation (31), we see the first term above can be obtained as the sum $\sum_{j \in u} \hat{\mathcal{F}}_j \left(q(\mathbf{X})\right)$ where each of the involved terms is given by equation (25) and is already computed during the training phase and, therefore, can be held fixed during test time. Similarly, the third term of equation (52) is also held fixed during test time. As for the second and fourth term, they can be optimised exactly as the bound computed for the training phase with the difference that now the data are augmented with test observations and only the observed dimensions are accounted for.

In contrast, the dynamical version of our model requires the full set of latent variables $(\mathbf{X}, \mathbf{X}_*)$ to be fully coupled in the variational distribution $q(\mathbf{X}, \mathbf{X}_*)$, as they together form a timeseries. Consequently, the expansion of equation (52) cannot be applied here, meaning that in this case no precomputations can be used from the training phase. However, one could apply the approximation $q(\mathbf{X}, \mathbf{X}_*) = q(\mathbf{X})q(\mathbf{X}_*)$ to speed up the test phase. In this case, each set of latent variables is still correlated, but the two sets are not. However, this approximation was not used in our implementation as it is only expected to speed up the predictions phase if the training set is very big, which is not the case for our experiments.

D.2 Calculation of the Posterior $q(\mathbf{F}_*^u|\mathbf{X})$

Optimisation based on the variational bound constructed for the test phase with partially observed outputs, as explained in Section 4.1, gives rise to the posterior $q(\mathbf{F}_*^u, \mathbf{U}, \mathbf{X}_*)$, as exactly happens in the training phase. Therefore, according to equation (16) we can write:

$$q(\mathbf{F}_*^u, \mathbf{U}, \mathbf{X}_*) = \left(\prod_{j=1}^p p(\mathbf{f}_{*,j}^u|\mathbf{u}_{:,j}, \mathbf{X}_*) q(\mathbf{u}_{:,j})\right) q(\mathbf{X}_*).$$

The marginal $q(\mathbf{F}_*^u|\mathbf{X}_*)$ (of equation (39)) is then simply found as:

$$\prod_{j \in u} \int p(\mathbf{f}_{*,j}^u|\mathbf{u}_{:,j}, \mathbf{X}_*) q(\mathbf{u}_{:,j}) \mathrm{d}\mathbf{u}_{:,j}.$$

The integrals inside the product are easy to compute since both types of densities appearing there are Gaussian, according to equations (13) and (45). In fact, each factor takes the form of a projected process predictive distribution from sparse GPs (Csató and Opper, 2002; Seeger et al., 2003; Rasmussen and Williams, 2006).

We will show the analytic derivation for the general case where we do not distinguish between training or test variables and all dimensions are observed. In specific, we want to compute:

$$p(\mathbf{f}_{:,j}|\mathbf{X}) = \int p(\mathbf{f}_{:,j}|\mathbf{u}_{:,j}, \mathbf{X}) q(\mathbf{u}_{:,j}) \mathrm{d}\mathbf{u}_{:,j}.$$

For this calculation we simply use the following identity for Gaussians:

$$\int \mathcal{N}\left(\mathbf{f}_{:,j}|\mathbf{M}\mathbf{u}_{:,j} + \mathbf{m}, \boldsymbol{\Sigma}_f\right) \mathcal{N}\left(\mathbf{u}_{:,j}|\boldsymbol{\mu}_u, \boldsymbol{\Sigma}_u\right) \mathrm{d}\mathbf{u}_{:,j} = \mathcal{N}\left(\mathbf{f}_{:,j}|\mathbf{M}\boldsymbol{\mu}_u + \mathbf{m}, \boldsymbol{\Sigma}_f + \mathbf{M}\boldsymbol{\Sigma}_u\mathbf{M}^\top\right).$$

From equations (14) and (45) we recognise:

$$\mathbf{M} = \mathbf{K}_{fu}\mathbf{K}_{uu}^{-1}\ ,\ \mathbf{m} = \mathbf{0} \qquad \boldsymbol{\mu}_u = \mathbf{K}_{uu}(\sigma^2\mathbf{K}_{uu} + \boldsymbol{\Psi}_2)^{-1}\boldsymbol{\Psi}_1^\top \mathbf{y}_{:,j}$$
$$\boldsymbol{\Sigma}_f = \mathbf{K}_{fu} - \mathbf{K}_{fu}\mathbf{K}_{uu}^{-1}\mathbf{K}_{uf} \quad \boldsymbol{\Sigma}_u = \sigma^2\mathbf{K}_{uu}(\sigma^2\mathbf{K}_{uu} + \boldsymbol{\Psi}_2)^{-1}\mathbf{K}_{uu}$$

from where we easily find:

$$p(\mathbf{f}_{:,j}|\mathbf{X}) = \mathcal{N}\left(\mathbf{f}_{:,j}|\mathbf{K}_{fu}\mathbf{B}, \mathbf{K}_{ff} - \mathbf{K}_{fu}\left(\mathbf{K}_{uu}^{-1} + \left(\mathbf{K}_{uu} + \sigma^{-2}\boldsymbol{\Psi}_2\right)^{-1}\mathbf{K}_{uf}\right)\right)$$

with $\mathbf{B} = \sigma^{-2}(\mathbf{K}_{uu} + \sigma^{-2}\boldsymbol{\Psi}_2)^{-1}\boldsymbol{\Psi}_1^\top \mathbf{y}_{:,j}$.

Appendix E. Algorithm for GP Regression with Missing Inputs

Consider a fully and a partially observed set of inputs, i.e. $\mathbf{Z} = (\mathbf{Z}^o, \mathbf{Z}^u)$, where o and u denote set of rows of $(\mathbf{Z}, \mathbf{Y})$ that contain fully and partially observed inputs respectively. The features missing in $\mathbf{Z}^u$ can be different in number / location for each individual point $\mathbf{z}^u_{i,:}$. We can train the model in all of these observations jointly, by replacing the inputs $\mathbf{Z}^o$ and $\mathbf{Z}^u$ with distributions $q(\mathbf{X}^o)$ and $q(\mathbf{X}^u)$ respectively, and using Algorithm 1. Since the posterior distribution is factorised, the algorithm constrains it to be close to a delta function in regions where we have observations, i.e. in areas corresponding to $\mathbf{Z}^o$ and in areas corresponding to non-missing locations of $\mathbf{Z}^u$. The rest of the posterior area's parameters (means and variances of Gaussian marginals) are initialised according to a prediction model $\mathcal{M}^o$ and are subsequently optimised (along with model parameters) in an augmented model $\mathcal{M}^{o,u}$. Notice that the initial model $\mathcal{M}^o$ is obtained by training a variational GP-LVM model with a posterior $q(\mathbf{X}^o)$ whose mean is fully constrained to match the observations $\mathbf{Z}^o$ with very small uncertainty and, thus, the model $\mathcal{M}^o$ behaves almost as a standard GP regression model.

Appendix F. Additional Results from the Experiments

In this section we present additional figures obtained from the experiments.

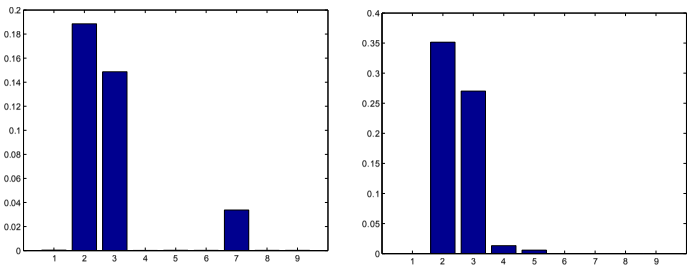
F.1 Motion Capture Data

We start by presenting additional results for the experiment described in Section 5.3 (motion capture data). Figure 16 depicts the optimised ARD weights (squared inverse lengthscales) for each of the dynamical models employed in the experiment. Figure 17 illustrates examples of the predictive performance of the models by plotting the true and predicted curves in the angle space.

As was explained in Section 5.3, all employed models encode the "walk" and "run" regime as two separate subspaces in the latent space. To illustrate this more clearly we sampled points from the learned latent space $\mathbf{X}$ of a trained dynamical variational GP-LVM model and generated the corresponding outputs, so as to investigate the kind of information that is encoded in each subspace of $\mathbf{X}$. Specifically, we considered the model that employed a Matérn $\frac{3}{2}$ covariance function to constrain the latent space and, based on the ARD weights of Figure 16(b), we projected the latent space on dimensions $(2, 3)$ and $(2, 4)$. Interacting with the model revealed that dimension 4 separates the "walk" from the "run" regime. This is an intuitive result, since the two kinds of motions are represented as separate clusters in the latent space. In other words, moving between two well separated

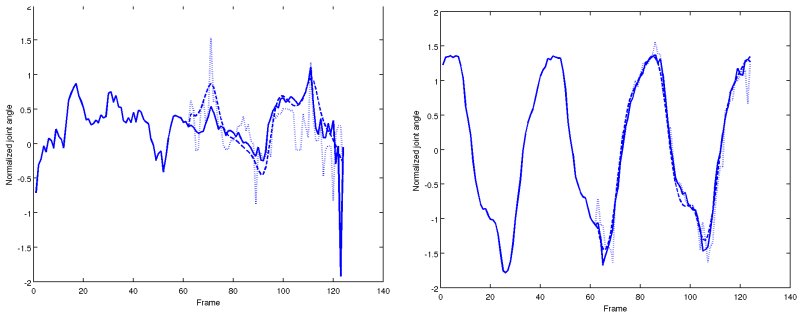
Algorithm 1 GP Regression with Missing Inputs Model: Training and predictions

Given: fully observed data $(\mathbf{Z}^o, \mathbf{Y}^o)$ and partially observed data $(\mathbf{Z}^u, \mathbf{Y}^u)$
Define a small value, e.g. $\varepsilon = 10^{-9}$
Initialize $q(\mathbf{X}^o) = \prod_{i=1}^n \mathcal{N}\left(\mathbf{x}^o_{i,:}|\mathbf{z}^o_{i,:}, \varepsilon\mathbf{I}\right)$
Fix $q(\mathbf{X}^o)$ in the optimiser *# (i.e. not be optimised)*
Train a variational GP-LVM model $\mathcal{M}^o$ given the above $q(\mathbf{X}^o)$ and $\mathbf{Y}^o$
for $i = 1, \cdots, |\mathbf{Y}^u|$ **do**
  Predict $p(\hat{\mathbf{x}}^u_{i,:}|\mathbf{y}^u_i, \mathcal{M}^o) \approx q(\hat{\mathbf{x}}^u_{i,:}) = \mathcal{N}\left(\hat{\mathbf{x}}^u_{i,:}|\hat{\boldsymbol{\mu}}^u_{i,:}, \hat{\mathbf{S}}^u_i\right)$
  Initialize $q(\mathbf{x}^u_{i,:}) = \mathcal{N}\left(\mathbf{x}^u_{i,:}|\boldsymbol{\mu}^u_{i,:}, \mathbf{S}^u_i\right)$ as follows:
  for $j = 1, \cdots, q$ **do**
    if $z^u_{i,j}$ is observed **then**
      $\mu^u_{i,j} = z^u_{i,j}$ and $(S^u_i)_{j,j} = \varepsilon$ *# $(S^u_i)_{j,j}$ denotes the j-th diagonal element of $\mathbf{S}^u_i$*
      Fix $\mu^u_{i,j}, (S^u_i)_{j,j}$ in the optimiser # *(i.e. will not be optimised)*
    else
      $\mu^u_{i,j} = \hat{\mu}^u_{i,j}$ and $(S^u_i)_{j,j} = (\hat{S}^u_i)_{j,j}$
Train a variational GP-LVM model $\mathcal{M}^{o,u}$ using the initial $q(\mathbf{X}^o)$ and $q(\mathbf{X}^u)$ defined above and data $\mathbf{Y}^o, \mathbf{Y}^u$ (the locations that were fixed for the variational distributions will not be optimised).
All subsequent predictions can be made using model $\mathcal{M}^{o,u}$.



(a) Model with exponentiated quadratic (b) Model with Matérn

Figure 16: The values of the weights (squared inverse lengthscales) of the ARD kernel after training on the motion capture dataset using the exponentiated quadratic (fig: (a)) and the Matérn (fig: (b)) kernel to model the dynamics for the dynamical variational GP-LVM. The weights that have zero value "switch off" the corresponding dimension of the latent space. The latent space is, therefore, 3-D for (a) and 4-D for (b). Note that the weights were initialised with very similar values.



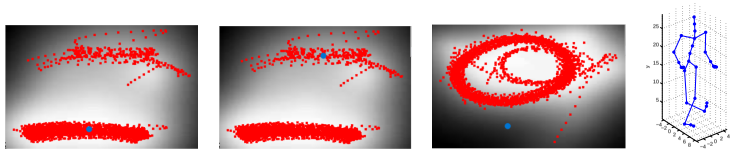
(a) (b)

Figure 17: The prediction for two of the test angles for the body (fig: 17(a)) and for the legs part (fig: 17(b)). Continuous line is the original test data, dotted line is nearest neighbour in scaled space, dashed line is dynamical variational GP-LVM (using the exponentiated quadratic kernel for the body reconstruction and the Matérn for the legs).

clusters needs to be encoded with a close to linear signal, which is in accordance with the small inverse lengthscale for dimension 4 (see also discussion in the caption of Figure 5). More specifically, to interact with the model we first fixed dimension 4 on a value belonging to the region encoding the walk, as can be seen in Figure 18(a), and then sampled multiple latent points by varying the other two dominant dimensions, namely 2 and 3, as can be seen in the top row of Figure 19. The corresponding outputs are shown in the second row of Figure 19. When dimension 4 was fixed on a value belonging to the region encoding the run (Figure 18(b)) the outputs obtained by varying dimensions 2 and 3 as before produced a smooth running motion, as can be seen in the third row of Figure 19. Finally, Figure 18(d) illustrates a motion which clearly is very different from the training set and was obtained by sampling a latent position far from the training data, as can be seen in Figure 18(c). This is indicative of a generative model's ability of producing novel data.

F.2 Gaussian Process Learning With Missing Inputs

In this section we present some more plots for the experiment presented in Section 6.2.1, where a set of fully observed outputs, $\mathbf{Y}$, corresponded to a set of fully observed inputs, $\mathbf{Z}^o$, and a set of inputs with randomly missing components, $\mathbf{Z}^u$. Even if $\mathbf{Y}$ is fully observed, it can be split according to the inputs, so that $\mathbf{Y} = (\mathbf{Y}^o, \mathbf{Y}^u)$. The variational GP-LVM, a nearest neighbour (NN) approach and multiple linear regression (MLR) (Chatterjee and Hadi, 1986) were trained on the full dataset $((\mathbf{Z}^o, \mathbf{Z}^u), (\mathbf{Y}^o, \mathbf{Y}^u))$. The standard GP model could only take into account the fully observed data, $(\mathbf{Z}^o, \mathbf{Y}^o)$. We also compared against predicting with the mean of $\mathbf{Y}$. The results are shown in Figure 20, which is an extension of the Figure 15 presented in the main paper.



(a) (b) (c) (d)

Figure 18: Plots (a) and (b) depict the projection of the latent space on dimensions 2 ($x-$axis) and 4 ($y-$axis), with the blue dot corresponding to the value on which these dimensions were fixed for the sampled latent points and red crosses represent latent points corresponding to training outputs. The intensity of the grayscale background represents the posterior uncertainty at each region (white corresponds to low predictive variance). Plot (c) depicts a latent space projection on dimensions 2 ($x-$axis) and 3 ($y-$axis), with the fixed latent positions corresponding to the generated output depicted in plot (d).

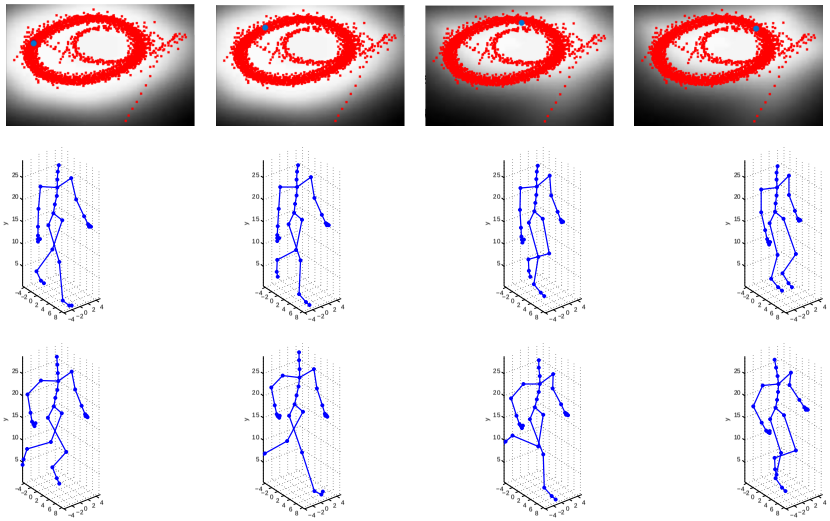


Figure 19: The first row depicts a projection of the latent space on dimensions 2 and 3 with the blue dot showing the value at which these dimensions were fixed for the sampled latent points. The corresponding outputs are depicted in the second row (for the walk regime) and third row (for the run regime).

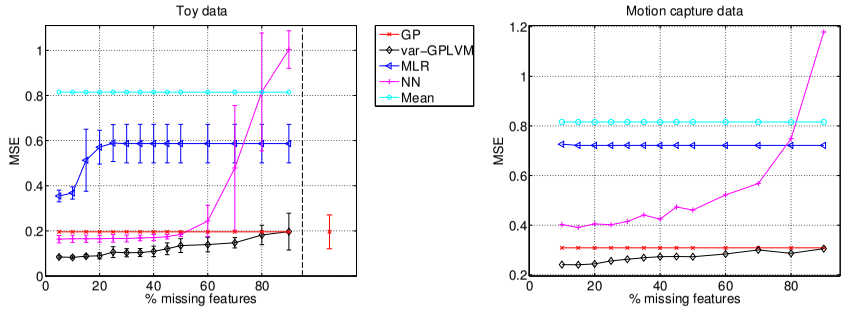

Figure 20: An augmented version of Figure 15. The above figure includes more results for the task of performing regression by learning from incomplete inputs. The results refer to the mean squared error for predictions obtained by different methods in simulated (left) and motion capture data (right). The results for simulated data are obtained from 4 trials and, hence, errorbars are also plotted. Lines without errorbars correspond to methods that cannot take into account partially observed inputs. For the GP, errorbars do not change with x-axis and, for clarity, they are plotted separately on the right of the dashed vertical line (for nonsensical x values).

Editor: Mikhail Belkin

Abstract

We consider the problem of estimating the gradient lines of a density, which can be used to cluster points sampled from that density, for example via the mean-shift algorithm of Fukunaga and Hostetler (1975). We prove general convergence bounds that we then specialize to kernel density estimation.

Keywords: mean-shift, gradient lines, density estimation, nonparametric clustering

1. Introduction

Fukunaga and Hostetler (1975) propose clustering points in space according to the gradient ascent flows of the underlying density. Let f be a differentiable density on $\mathbb{R}^d$. Assuming for now that f is known, consider the following scheme. Fix $a > 0$ and, starting at $x_0 \in \mathbb{R}^d$, iteratively define

$$x_\ell = x_{\ell-1} + a\frac{\nabla f(x_{\ell-1})}{f(x_{\ell-1})}, \quad \text{for } \ell \geq 1. \tag{1}$$

When it exists, define $x_\infty = \lim_{\ell\to\infty} x_\ell$. The rationale behind the iterative gradient ascent scheme (1) is to have the sequence $(x_\ell : t \geq 0)$ converge to a local mode of f — representing a cluster center, close in the spirit to Hartigan (1975) — without going through a valley. See Figure 1 and Figure 2 for simple illustrations involving the mixture of two Gaussians in dimensions $d = 1$ and $d = 2$. Now, a sample from f, say $X_1, \dots, X_n$, can be clustered by applying the iteration (1) to each X_i's, obtaining a sequence $(X_{i,\ell} : \ell \geq 0)$, and grouping according to the limit $X_{i,\infty}$, meaning that X_i and X_j are grouped together if $X_{i,\infty} = X_{j,\infty}$.

In the same spirit, Cheng et al. (2004) propose to use the gradient ascent lines of f, which form gradient trees, to perform a kind of hierarchical clustering of points on the plane. Clustering points according to the local maxima of the underlying density is also advocated

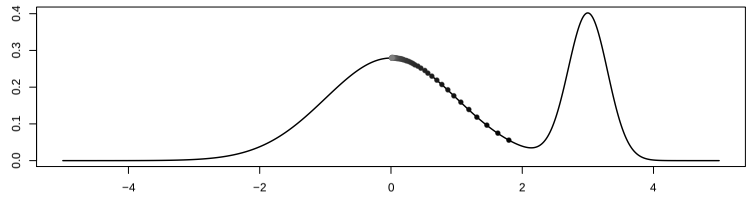

Figure 1: A mixture of two Gaussians in dimension $d = 1$: $f(x) = qg_{0,1}(x) + (1-q)g_{\mu,\sigma}(x)$ where $g_{\mu,\sigma}(x) := e^{-(x-\mu)^2/2\sigma^2}/\sqrt{2\pi}\sigma$, and $q = 0.7$, $\mu = 3$ and $\sigma = 0.3$. The starting point is at $x = 1.8$, and the 50 successive points in the iteration (1) are also plotted. Although the starting point is closer to the peak at $x = 3$, the sequence converges to the peak at $x = 0$.

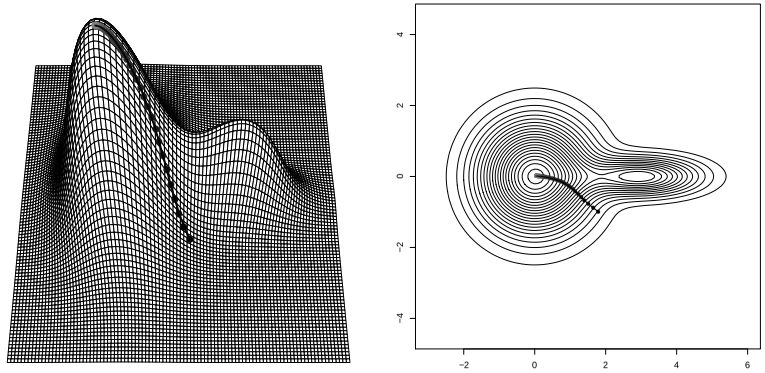

Figure 2: A mixture of two Gaussians in dimension $d = 2$: $f(x, y) = qg_{0,1}(x)g_{0,1}(y) + (1-q)g_{\mu_1,\sigma_1}(x)g_{0,\sigma_2}(y)$ with $q = 0.7$, $\mu_1 = 3$, $\sigma_1 = 1.5$ and $\sigma_2 = 0.5$. The starting point is at $(x, y) = (1.8, -1)$, and the 50 successive points in the iteration (1) are also plotted. Although the starting point is closer to the peak at $(x, y) = (3, 0)$, the sequence converges to the peak at $(x, y) = (0, 0)$.

by Comaniciu and Meer (2002), while an EM-type algorithm for finding the local maxima of the density f is suggested in Carreira-Perpinan and Williams (2003); Carreira-Perpinan (2007); Li et al. (2007).

In practice, the underlying density f is rarely known and has to be estimated. A kernel estimate is used in Fukunaga and Hostetler (1975); Cheng et al. (2004); Li et al.

(2007); Comaniciu and Meer (2002). Let $\Phi : \mathbb{R}^d \to \mathbb{R}$ be a kernel function — an integrable function with $\int_{\mathbb{R}^d} \Phi(x)\mathrm{d}x = 1$ — and for a bandwidth $h > 0$, let $\Phi_h(u) = h^{-d}\Phi(u/h)$. The corresponding kernel estimate for f based on a sample $X_1, \ldots, X_n$ is

$$f^{\phi}_{n,h}(x) := \frac{1}{n}\sum_{i=1}^{n} \Phi_h(x - X_i), \tag{2}$$

and if Φ is differentiable, then we may estimate the gradient of f by

$$\nabla f^{\phi}_{n,h}(x) := \frac{1}{nh}\sum_{i=1}^{n} \nabla\Phi_h(x - X_i).$$

Fukunaga and Hostetler (1975) introduce the term 'mean-shift' when describing the resulting estimate based on the Epanechnikov kernel $\Phi(u) \propto (1 - \|u\|^2)_+$, where $t_+ = \max(t, 0)$ is the positive part of $t \in \mathbb{R}$. Indeed, they show that, in that case,

$$\frac{\nabla f^{\phi}_{n,h}(x)}{f^{\phi}_{n,h}(x)} \propto \frac{1}{|I_{x,h}|}\sum_{i\in I_{x,h}} X_i - x, \quad I_{x,h} := \{i : \|X_i - x\| \le h\}.$$

Cheng (1995) further argues that the gradient ascent algorithm in (1) can be interpreted as a mean-shift when using a spherically symmetric kernel. Indeed, let Φ be a spherically symmetric kernel on $\mathbb{R}^d$, by which we mean a function $\Phi : \mathbb{R}^d \to \mathbb{R}$ of the form[1] $\Phi(u) = \phi(\|u\|)$, where $\phi : \mathbb{R}_+ \to \mathbb{R}_+$ is a non-negative function, called the *profile function* in Cheng (1995), that satisfies the following *unit integral* condition

$$\int_{\mathbb{R}^d} \Phi(u)\mathrm{d}u = \omega_d \int_0^{\infty} \phi(r) r^{d-1}\mathrm{d}r = 1, \tag{3}$$

where ω_d is the surface area of the unit sphere of $\mathbb{R}^d$, and

$$\int_{\mathbb{R}^d} u_i u_j \Phi(u)\mathrm{d}u = \begin{cases} 1 & \text{if } i = j; \\ 0 & \text{otherwise.} \end{cases} \tag{4}$$

The local average at x is

$$M_{n,h}(x) = \frac{\sum_{i=1}^n X_i \Phi_h(x - X_i)}{\sum_{i=1}^n \Phi_h(x - X_i)} = \frac{1}{n f^{\phi}_{n,h}(x)}\sum_{i=1}^{n} X_i \Phi_h(x - X_i).$$

The *mean shift* at x is defined by

$$T_{n,h}(x) = M_{n,h}(x) - x.$$

This is intimately related to the gradient of another kernel estimate of f. To see this, following Cheng (1995), we consider a *shadow kernel* Ψ of Φ, with profile function ψ defined by

$$\Psi(u) = \psi(\|u\|), \qquad \psi(r) = \int_r^{\infty} s\phi(s)\mathrm{d}s. \tag{5}$$

1. Note that Cheng (1995) uses a kernel of the form $\phi(\|u\|^2)$, so the presentation here is little different.

By construction and (3)-(4), Ψ integrates to 1, and is therefore a kernel function; it is also continuously differentiable. Let

$$f^{\psi}_{n,h}(x) = \frac{1}{n}\sum_{i=1}^{n} \Psi_h(x - X_i),$$

which is the kernel estimate of f with kernel Ψ and bandwidth h.

Lemma 1 *(Cheng, 1995) At any point x of $\mathbb{R}^d$, we have*

$$T_{n,h}(x) = h^2 \frac{\nabla f^{\psi}_{n,h}(x)}{f^{\phi}_{n,h}(x)}.$$

Assume that $\nabla\Psi$ is bounded in $\mathbb{R}^d$. Then by the Law of Large Numbers, for each fixed $x \in \mathbb{R}^d$, $f^{\phi}_{n,h}(x) \to f^{\phi}_h(x)$ and $\nabla f^{\psi}_{n,h}(x) \to \nabla f^{\psi}_h(x)$, almost surely as $n \to \infty$, where

$$f^{\phi}_h(x) = \int f(y)\Phi_h(x - y)\mathrm{d}y,$$

and f^{ψ}_h is defined similarly. Furthermore, if f is bounded and continuously differentiable on $\mathbb{R}^d$ with bounded gradient, then $f^{\phi}_h(x) \to f(x)$ and $\nabla f^{\psi}_h(x) \to \nabla f(x)$ as $h \to 0$. Hence, for any x fixed such that $f(x) > 0$,

$$T_{n,h}(x) \to T_h(x) \sim h^2 \nabla \log f(x),$$

as $n \to \infty$ first, followed by $h \to 0$. Following this line of thought, the mean-shift algorithm appears to approximate the gradient ascent scheme (1), with $a = h^2$. The convergence results in Cheng (1995) and Comaniciu and Meer (2002) provide only a very partial mathematical backing to this intuition.

Our contribution is a mathematical proof of consistency for the estimation of gradient ascent lines by the original mean-shift algorithm of Fukunaga and Hostetler (1975). We note that the same approach also applies to the more general mean-shift algorithm of Cheng (1995), and applies directly to the algorithm suggested by Cheng et al. (2004). In detail, let $f : \mathbb{R}^d \to \mathbb{R}$ be differentiable. Starting at $x_0 \in \mathbb{R}^d$, we study the convergence as $a \to 0$ of the sequence

$$x_\ell = x_{\ell-1} + a\nabla f(x_{\ell-1}), \quad \text{for } \ell \ge 1, \tag{6}$$

towards the gradient ascent line of f starting at x_0. In particular, we characterize the limit x_∞, providing a consistency result for the clustering algorithm based on the local maxima of f. Note that (6) includes (1) by replacing f with $\log f$. We note that such convergence results are available in the rich literature on dynamic systems — see, e.g., Stetter (1973, Sec 3.5), Beyn (1987) and Merlet and Pierre (2010, Sec 2) — and in the literature on convex optimization (where f is convex) — see, e.g., Boyd and Vandenberghe (2004, Sec. 9.3) and Bolte et al. (2010). However, for the general case, we could not find a specific rate of convergence as the one we obtain in (14). Although higher-order discretization schemes can be designed (Stetter, 1973), we focus entirely on the first-order scheme (6). We further elaborate on the literature after stating our main results in Section 2.

Then, given another differentiable function $\hat{f}$, meant to approximate f, we compare the sequence $(\hat{x}_\ell)$ to (x_ℓ), where

$$\hat{x}_\ell = \hat{x}_{\ell-1} + a\nabla\hat{f}(\hat{x}_{\ell-1}), \quad \text{for } \ell \geq 1, \tag{7}$$

starting at the same point $\hat{x}_0 = x_0$. In particular, when estimating the gradient ascent lines of a density f based on a sample $X_1, \ldots, X_n$, $\hat{f}$ can be taken to be some estimate of f, and the gradient ascent sequence defined by $\hat{f} = \log \hat{f}$ (starting at some x_0) is compared to that of $f = \log f$. Such approximation results are often called perturbation or stability results in the literature on dynamical systems. See, for example, Hirsch and Smale (1974, Chap 6) or Teschl (2012, Sec 2.5). Most of these results are qualitative (e.g., pertaining to the topology of the gradient flow lines), while the bound we obtain in (15) is quantitative.

Finally, we provide an explicit convergence rate for the case where the density is estimated by kernel convolution. This seems to be new in the literature on the mean-shift algorithm and, more generally, on the estimation of the gradient lines of a density.

The rest of the paper is organized as follows. In Section 2, we establish our main results, one on the convergence of the gradient ascent scheme (6), and another on the stability of smooth flows, relating the gradient flows of f and $\hat{f}$ when these functions are close as C^2 functions. In Section 3, we deduce convergence rates for the algorithm of Fukunaga and Hostetler (1975) defined in (1). The technical arguments are given in Section 4.

2. Main Results

Before stating our main results, we introduce some notations. For a function $f : \mathbb{R}^d \to \mathbb{R}$, we let $f^{(\ell)}(x)$ denote the differential form of f of order ℓ at a point $x \in \mathbb{R}^d$, and let $H_f(x)$ denote the Hessian matrix of f, when they exist. The differential form $f^{(\ell)}(x)$ of f at x is the multilinear map from $\mathbb{R}^d \times \cdots \times \mathbb{R}^d$ (ℓ times) to $\mathbb{R}$ defined by

$$f^{(\ell)}(x)[u_1, \ldots, u_\ell] = \sum_{i_1,\ldots,i_\ell=1}^{d} \frac{\partial^\ell f(x)}{\partial x_{i_1} \ldots \partial x_{i_\ell}} u_{1,i_1} \ldots u_{\ell,i_\ell},$$

where, for each $1 \leq i \leq \ell$, u_i has components $u_i = (u_{i,1}, \ldots, u_{i,d})$. Given a multilinear map L of order ℓ from $\mathbb{R}^d \times \cdots \times \mathbb{R}^d$ to $\mathbb{R}$, we denote by $\|L\|$ its operator norm defined by

$$\|L\| = \sup\left\{|L[u_1, \ldots, u_\ell]| : \|u_1\| = \cdots = \|u_\ell\| = 1\right\}, \tag{8}$$

and writing L as

$$L[u_1, \ldots, u_\ell] = \sum_{i_1,\ldots,i_\ell=1}^{d} L_{i_1,\ldots,i_\ell} u_{1,i_1} \ldots u_{\ell,i_\ell},$$

we denote by $\|L\|_{\max}$ the norm defined by

$$\|L\|_{\max} = \max\{|L_{i_1\ldots i_\ell}| : 1 \leq i_1, \ldots, i_\ell \leq d\}. \tag{9}$$

We note for future reference that

$$\|L\|_{\max} \leq \|L\| \leq d^{\frac{\ell}{2}} \|L\|_{\max}. \tag{10}$$

For a set $S \subset \mathbb{R}^d$, we also define

$$\kappa_\ell(f, S) = \sup_{x \in S} \|f^{(\ell)}(x)\|. \tag{11}$$

Note that $\kappa_\ell(f, S)$ is well-defined and is finite when f is of class C^ℓ and S is compact. The *upper level set* of a function $f : \mathbb{R}^d \to \mathbb{R}$ at $b \in \mathbb{R}$ is defined as

$$\mathcal{L}_f(b) = \{x \in \mathbb{R}^d : f(x) \geq b\}. \tag{12}$$

We suppress the dependence on f whenever no confusion is possible.

Recall that a *critical point* of f is a point x at which the gradient of f vanishes, that is, such that $\nabla f(x) = 0$. A *flow line* or *integral curve* of the positive gradient flow of f is a curve x such that $x'(t) = \nabla f(x(t))$. Note that, along any flow line, the value of f increases, that is, the function $t \mapsto f(x(t))$ is increasing with t. By the theory of ordinary differential equations, through any point $x_0 \in \mathbb{R}^d$ passes a unique flow line $x(t)$ defined for $t \in [0, t_0)$, where $t_0 > 0$, such that $x(0) = x_0$ (Hirsch et al., 2004, Section 7.2); we say that $x(t)$ is the flow line starting at x_0. Let $x^\star$ be a critical point of f. We say that x_0 is in the attraction basin of $x^\star$ if the flow line $x(t)$ starting at x_0 is defined for all $t \geq 0$ and $\lim_{t\to\infty} x(t) = x^\star$. An accumulation point of a sequence of points through an integral curve x, i.e., a sequence of the form $\{x(t_n) : t_1 < t_2 < \ldots\}$, is called a limit point of x. Any limit point of a gradient flow line of f is necessarily a critical point of f; see Hirsch et al. (2004, Section 9.3, Proposition, p. 206) and Hirsch et al. (2004, Section 9.3, Theorem, p. 205).

We start by establishing the convergence of the gradient ascent scheme (6) towards the flow lines of the underlying function f. Starting from a point x_0 in the attraction basin of the location of a stable local maximum $x^\star$, under some conditions stated below, the iteration (6) converges to $x^\star$. In fact, the polygonal line defined by the sequence (x_ℓ) is uniformly close to the flow line starting at x_0 and ending at $x^\star$. For the definition of a stable equilibrium of a dynamical system, we refer to Hirsch et al. (2004, Section 8.4).

Theorem 1 (Convergence of gradient ascent) *Let f be a function of class C^3. Let $(x(t) : t \geq 0)$ denote the flow line of f starting at x_0 and ending at a local maxima $x^\star$ of f. Let (x_ℓ) be the sequence defined in (6) starting at x_0. Then there exists $A = A(x_0, f) > 0$ such that, whenever $0 < a < A$,*

$$\lim_{\ell\to+\infty} x_\ell = x^\star. \tag{13}$$

Denote by $x_a(t)$ the following polygonal line

$$x_a(t) = x_{\ell-1} + (t/a - \ell + 1)(x_\ell - x_{\ell-1}), \quad \forall t \in [(\ell-1)a, \ell a).$$

Assume $H_f(x^\star)$ has all eigenvalues in $(-\overline{\nu}, -\underline{\nu})$ for some $0 < \underline{\nu} < \overline{\nu}$. Then, there exists a $C = C(x_0, f, \underline{\nu}, \overline{\nu}) > 0$ such that, for any $0 < a < A$,

$$\sup_{t\geq 0} \|x_a(t) - x(t)\| \leq Ca^\delta, \quad \delta := \frac{\underline{\nu}}{\underline{\nu} + \overline{\nu}}. \tag{14}$$

We mention the convergence result (Comaniciu and Meer, 2002, Th 1), which essentially says that, when f is a kernel density estimator with bandwidth h as in (2), the sequence (x_ℓ)

in (6) with choice $a = h^2$ converges and $(f(x_\ell))$ is monotone nondecreasing. In the literature on dynamical systems, the convergence result (13) is proved in (Merlet and Pierre, 2010, Sec 2), together with convergence rates, but under slightly different conditions; in particular, f is assumed to have compact upper level sets. Beyn (1987) compares the discrete and continuous trajectories under milder conditions, but only at a discrete grid of time points, and does so assuming that the starting point x_0 is sufficiently close to the corresponding stationary point $x^\star$. Moreover, the starting point of the discrete and continuous trajectories in Beyn (1987) are potentially different. In fact, Beyn (1987) refers the reader to (Stetter, 1973) — which we mentioned earlier — for the case where the starting points may be taken to be the same.

Next, we establish a stability result for flows of smooth functions. In words, under some conditions made precise below, when f and $\hat{f}$ are close as C^2 functions, then their flow lines are also close. Denote by $B(x, r)$ the open ball of radius r centered at x and by $\bar{B}(x, r)$ its closure.

Theorem 2 (Stability of smooth flows) *Suppose f and $\hat{f}$ are of class C^3. Let $(x(t) : t \geq 0)$ be a flow line of f starting at x_0 and ending at $x^\star$ where $H_f(x^\star)$ has all eigenvalues in $(-\overline{\nu}, -\underline{\nu})$ for some $0 < \underline{\nu} < \overline{\nu}$. Let $\hat{x}(t)$ be the flow line of $\hat{f}$ starting at x_0. Let $S = \mathcal{L}(f(x_0)/2) \cap \bar{B}(x_0, 3r_0)$ where $r_0 = \max_t \|x(t) - x_0\|$, and define*

$$\eta_m = \sup_{x \in S} \|f^{(m)}(x) - \hat{f}^{(m)}(x)\|.$$

Then there is a constant $C = C(f, x_0, \underline{\nu}, \overline{\nu}) \geq 1$ such that, when $\max(\eta_0, \eta_1, \eta_2) \leq 1/C$ and $\eta_3 \leq C$, $\hat{x}(t)$ is defined for all $t \geq 0$ and

$$\sup_{t \geq 0} \|x(t) - \hat{x}(t)\| \leq C \max\left\{\sqrt{\eta_0}, \eta_1^\delta\right\}, \tag{15}$$

where δ is defined in (14).

Stability results tend to be qualitative in the literature on dynamical systems. However, to establish the bound above, we do use a well-known quantitative result. See Lemma 7, which we took from Hirsch et al. (2004, Sec 17.5).

Combining Theorems 1 and 2, we arrive at the following bound for approximating the flow lines of a function f by the polygonal line obtained from the gradient ascent algorithm (7) based on an approximation $\hat{f}$ to f.

Corollary 1 *In the context of Theorem 2, for $a > 0$, define*

$$\hat{x}_a(t) = \hat{x}_{\ell-1} + (t/a - \ell + 1)(\hat{x}_\ell - \hat{x}_{\ell-1}), \quad \forall t \in [(\ell-1)a, \ell a), \tag{16}$$

where $(\hat{x}_\ell)$ is defined in (7). *Then there is a constant $C = C(f, x_0, \underline{\nu}, \overline{\nu}) \geq 1$ such that, when $\max(\eta_0, \eta_1, \eta_2) \leq 1/C$ and $\eta_3 \leq C$,*

$$\sup_{t \geq 0} \|\hat{x}_a(t) - x(t)\| \leq C \left[a^\delta + \max\left\{\sqrt{\eta_0}, \eta_1^\delta\right\}\right], \tag{17}$$

where δ is defined in (14).

Note that the exponent δ which appears in these results only depends on the ratio $\overline{\nu}/\underline{\nu}$ which is a lower bound on the condition number of $H_f(x^\star)$. But the constants in Theorems 1 and 2 depend on $\underline{\nu}$ and $\overline{\nu}$ not only through their ratio.

We note that Beyn (1987) establishes a result similar to Corollary 1 under milder assumptions. Indeed, just as we do here, he studies how the discrete system (7) approximates the continuous system

$$x'(t) = \nabla f(x(t)),$$

when the functions $\hat{f}$ and f may differ. He bounds the difference between the discrete and continuous trajectories, with possibly different starting points, over a discrete grid of time points, assuming the starting point x_0 is close enough to $x^\star$. He also assumes that $\nabla \hat{f}(x^\star) = 0$, which simplifies the analysis a fair amount. With these working assumptions, his bound is in $\kappa_2 a + \eta_1$ — see Equation (3.5) there. His method of proof is based on the theory of stable (solution) manifolds (Irwin, 1980, Chap 4). Our approach is more elementary and we do not know whether this more sophisticated approach has the potential to improve on ours.

We emphasize that Theorems 1 and 2, and their combined fruit in Corollary 1, are designed to establish our result on the uniform consistency of gradient line estimators based on kernel density estimators as stated in Theorem 3 in the next section.

3. The Estimation of Gradient Lines of a Density

Let $\hat{f}_{n,h}$ be the kernel density estimate of f in (2) with kernel Φ and bandwidth h. Sharp almost-sure convergence rates in the uniform norm of kernel density estimates have been obtained by several authors, for example Einmahl and Mason (2000); Giné and Guillou (2002); Einmahl and Mason (2005). Using the recent results of Mason and Swanepoel (2011) and Mason (2012), we derive strong uniform norm convergence rates for $\hat{f}_{n,k}$ and its derivatives.

We first control the bias component.

Lemma 2 *Assume Φ is nonnegative, C^3 on $\mathbb{R}^d$ with all partial derivatives up to order 3 vanishing at infinity, and satisfies*

$$\int_{\mathbb{R}^d} \Phi(x)\mathrm{d}x = 1, \quad \int_{\mathbb{R}^d} x\Phi(x)\mathrm{d}x = 0 \quad \text{and} \quad \int_{\mathbb{R}^d} \|x\|^2 \Phi(x)\mathrm{d}x < \infty. \tag{18}$$

Then for any C^3 density f on $\mathbb{R}^d$ with bounded derivatives up to order 3, there is a constant $C > 0$ such that

$$\sup_{x \in \mathbb{R}^d} \left\| \mathbb{E}\big[\hat{f}_{n,h}^{(\ell)}(x)\big] - f^{(\ell)}(x) \right\| \leq C h^{(3-\ell)\wedge 2}, \quad \forall 0 \leq \ell \leq 3. \tag{19}$$

Next, we control the variance component. For this, we apply the main result of Mason and Swanepoel (2011). See also Theorem 4.1 with Remark 4.2 in Mason (2012).

Lemma 3 *Suppose that Φ is of the form $\Phi : (x_1, \ldots, x_d) \mapsto \prod_{k=1}^d \phi_k(x_k)$, and that each ϕ_k is nonnegative, integrates to 1, and is C^3 on $\mathbb{R}$ with derivatives up to order 3 being of*

bounded variation and in $L_1(\mathbb{R}^d)$. *Then, for any bounded density* f *on* $\mathbb{R}^d$, *there exists a* $0 < b_0 < 1$ *such that*

$$\limsup_{n\to\infty} \sup_{\frac{\log n}{n} \le h^d \le b_0} \sup_{x\in\mathbb{R}^d} \sqrt{\frac{nh^{d+2\ell}}{\log n}} \left\| \hat{f}_{n,h}^{(\ell)}(x) - \mathbb{E}\big[\hat{f}_{n,h}^{(\ell)}(x)\big] \right\| < \infty, \quad \forall 0 \le \ell \le 3, \quad a.s. \quad (20)$$

It is straightforward to design a kernel that satisfies the conditions of Lemmas 2 and 3. In fact, the Gaussian kernel $\Phi(x) = (2\pi)^{-d/2} \exp(-\|x\|^2/2)$ is such a kernel.

Assuming that (20) holds and applying Corollary 1, we deduce a convergence result for the mean-shift algorithm of Fukunaga and Hostetler (1975). We note that a similar result holds for the simpler gradient ascent method of Cheng et al. (2004).

Theorem 3 *Consider a density* f *satisfying the conditions of Lemma 2. Suppose* $\hat{f}_{n,h}$ *is a kernel estimator of* f *of the form* (2), *where* Φ *satisfies the conditions of Lemmas 2 and 3. Let* $(x(t) : t \ge 0)$ *be the flow line of* f *starting at a point* x_0 *with* $f(x_0) > 0$, *ending at a point* $x^\star$ *where* $H_f(x^\star)$ *has all eigenvalues in* $(-\overline{\nu}, -\underline{\nu})$ *for some* $0 < \underline{\nu} < \overline{\nu}$. *For* $a > 0$, *define* $(\hat{x}_a(t) : t \ge 0)$ *by*

$$\hat{x}_a(t) = \hat{x}_{\ell-1} + (t/a - \ell + 1)(\hat{x}_\ell - \hat{x}_{\ell-1}), \quad \forall t \in [(\ell-1)a, \ell a),$$

where

$$\hat{x}_\ell = \hat{x}_{\ell-1} + a\frac{\nabla \hat{f}_{n,h}(\hat{x}_{\ell-1})}{\hat{f}_{n,h}(\hat{x}_{\ell-1})}, \quad for\ \ell \ge 1.$$

Suppose that $h \to 0$ *and* $\frac{nh^{d+6}}{\log n} \to \infty$. *Then there exists a constant* $C > 0$ *such that, with probability one, for all* n *large enough,*

$$\sup_{t\ge 0} \|\hat{x}_a(t) - x(t)\| \le C\left[a + h^2\right]^\delta, \quad \delta := \frac{\underline{\nu}}{\underline{\nu} + \overline{\nu}}. \quad (21)$$

The approximation error decreases as the discretization step a gets smaller, simply because it controls the precision of the (discrete) gradient ascent scheme (7). We made this precise in Theorem 1. However, as a gets smaller, the computational burden of running this gradient ascent scheme to its limit becomes heavier. So there is a compromise between (statistical and numerical) estimation and computational complexity. That said, choosing a smaller (in order of magnitude) than h^2 does not improve our bound (21). When a is that small, the main source of error comes from estimating the density, rather than the accuracy of the gradient ascent scheme, and the resulting rate is

$$\sup_{t\ge 0} \|\hat{x}_a(t) - x(t)\| \le C\gamma_n \left(\frac{\log n}{n}\right)^{2\delta/(d+6)},$$

for any choice of sequence (γ_n) with $\gamma_n \to \infty$. We note that faster rates are possible for densities that are C^k for $k > 3$, since they can be estimated more accurately by a higher order kernel (Devroye and Gyorfi, 1985). We also mention that the curse of dimensionality is at play here since we are estimating a nonparametric density.

4. Proofs

We start in Section 4.1 with some auxiliary results that will be used in the proofs of our main results. Theorem 1 and Theorem 2 are proved in Sections 4.2 and 4.3 respectively. We prove Lemma 2 and Lemma 3 in Sections 4.4 and 4.5, and then Theorem 3 in Section 4.6.

4.1 Preliminary Results

The following is a discrete version of Gronwall's lemma. The proof is straightforward and left to the reader.

Lemma 4 *Let* $(y_\ell : \ell \ge 0)$ *be a sequence of non-negative real numbers such that*

$$y_{\ell+1} \le Q_1 + (1 + Q_2)y_\ell.$$

Then

$$y_\ell \le y_0 e^{Q_2 \ell} + \frac{e^{Q_2\ell} - 1}{Q_2} Q_1.$$

The result below is on the behavior of the upper level set near a stable local maximum.

Lemma 5 *Suppose that* f *is of class* C^3. *Let* $x^\star$ *be the location of a stable local maxima of* f *where* $H_f(x^\star)$ *has all eigenvalues in* $(-\overline{\nu}, -\underline{\nu})$ *with* $\overline{\nu} > \underline{\nu} > 0$. *For* $\epsilon > 0$, *let* $\mathcal{C}(\epsilon)$ *be the connected component of* $\mathcal{L}_f(f(x^\star) - \epsilon)$ *that contains* $x^\star$. *Then there is a constant* $C_5 = C_5(f, x^\star)$ *such that*

$$\bar{B}(x^\star, \sqrt{2\epsilon/\overline{\nu}}) \subset \mathcal{C}(\epsilon) \subset \bar{B}(x^\star, \sqrt{2\epsilon/\underline{\nu}}), \quad for\ all\ \epsilon \le C_5, \quad (22)$$

and

$$f(x^\star) - f(x) \le \frac{\overline{\nu}}{2}\|x - x^\star\|^2, \quad for\ all\ x\ such\ that\ \|x - x^\star\| \le \sqrt{2C_5/\overline{\nu}}. \quad (23)$$

Proof Fix $r > 0$. Let $\mathbf{H}$ and κ_3 be short for $H_f(x^\star)$ and $\kappa_3(f, \bar{B}(x^\star, r))$, respectively. Let $\underline{\nu} < \underline{\nu}' < \overline{\nu}' < \overline{\nu}$ be such that $H_f(x^\star)$ has all eigenvalues in $[-\overline{\nu}', -\underline{\nu}']$. First, we prove (22). A Taylor development of f at $x \in \bar{B}(x^\star, r)$ gives

$$f(x) = f(x^\star) + \frac{1}{2}\mathbf{H}[x - x^\star, x - x^\star] + R(x, x^\star), \quad \text{with } |R(x, x^\star)| \le \frac{\kappa_3}{6}\|x - x^\star\|^3. \quad (24)$$

When $x \in \bar{B}(x^\star, r)$, using the Taylor expansion (24), we get that

$$\begin{aligned} f(x) &\le f(x^\star) - \frac{\underline{\nu}'}{2}\|x^\star - x\|^2 + \frac{\kappa_3}{6}\|x^\star - x\|^3 \\ &\le f(x^\star) - \frac{\underline{\nu}}{2}\|x^\star - x\|^2 \end{aligned}$$

when $\|x^\star - x\| \le \xi_1 := \frac{3(\underline{\nu}' - \underline{\nu})}{\kappa_3} \wedge r$. Fix $0 < \epsilon < \frac{\underline{\nu}\xi_1^2}{2}$ so that $\sqrt{\left(\frac{2\epsilon}{\underline{\nu}}\right)} < \xi_1$. We then have $f(x) < f(x^\star) - \epsilon$ when $\sqrt{\left(\frac{2\epsilon}{\underline{\nu}}\right)} < \|x^\star - x\| \le \xi_1$. This implies that

$$\mathcal{L}_f(f(x^\star) - \epsilon) \subset \bar{B}\big(x^\star, \sqrt{\left(\tfrac{2\epsilon}{\underline{\nu}}\right)}\big) \cup \bar{B}\big(x^\star, \xi_1\big)^{\mathsf{c}},$$

and since the two sets on the right-hand side are disconnected, while $\mathcal{C}(\epsilon)$ is connected and contains $x^\star$, necessarily, $\mathcal{C}(\epsilon) \subset B\big(x^\star, \sqrt{\big(\frac{2\epsilon}{\underline{\nu}}\big)}\big)$.

We also get using (24) that

$$\begin{aligned} f(x) &\geq f(x^\star) - \frac{\overline{\nu}'}{2}\|x^\star - x\|^2 - \frac{\kappa_3}{6}\|x^\star - x\|^3 \\ &\geq f(x^\star) - \frac{\overline{\nu}}{2}\|x^\star - x\|^2 \end{aligned}$$

when $\|x^\star - x\| \leq \xi_2 := \frac{3(\overline{\nu}-\overline{\nu}')}{\kappa_3} \wedge r$. Fix $0 < \epsilon < \frac{\overline{\nu}\xi_2^2}{2}$ so that $\sqrt{\big(\frac{2\epsilon}{\overline{\nu}}\big)} < \xi_2$. Then whenever $\|x^\star - x\| \leq \sqrt{\big(\frac{2\epsilon}{\overline{\nu}}\big)}$, we have $f(x) \geq f(x^\star) - \epsilon$. Reasoning as above, we obtain $B\big(x^\star, \sqrt{\big(\frac{2\epsilon}{\overline{\nu}}\big)}\big) \subset \mathcal{C}(\epsilon)$.

Therefore, by choosing $C_5 < \xi_1 \wedge \xi_2$, we see that (22) holds. Note that ξ_1 and ξ_2 depend on r. Since we do not need an explicit value for the constant C_5, we leave $r > 0$ arbitrarily fixed.

The bound (23) is a direct consequence of (22). ■

Next is a result establishing exponential convergence rates for the gradient flow of a smooth function ending at a stable local maximum.

Lemma 6 *Suppose that f is of class C^3. Let $\{\gamma(t) : t \geq 0\}$ be the flow line of f starting at x_0 and ending at $x^\star$ where $H_f(x^\star)$ has all its eigenvalues in $(-\infty, -\underline{\nu})$, with $\underline{\nu} > 0$. Then, there is $C_6 = C_6(f, x_0)$ such that, for all $t \geq 0$,*

$$\|\gamma(t) - x^\star\| \leq C_6 e^{-\underline{\nu}t}, \tag{25}$$

and

$$f(x^\star) - f(\gamma(t)) \leq C_6 e^{-2\underline{\nu}t}. \tag{26}$$

Proof Note that since γ has beginning and ending points, $\{\gamma(t) : t \geq 0\}$ is bounded. Let $r_0 > 0$ be such that $\{\gamma(t) : t \geq 0\}$ is contained in the ball $\bar{B}(x^\star, r_0)$. Let $\mathbf{H}$ and κ_3 be short for $H_f(x^\star)$ and $\kappa_3(f, \bar{B}(x^\star, r_0))$, respectively. A Taylor development of ∇f at $x \in \bar{B}(x^\star, r_0)$ gives

$$\nabla f(x) = \mathbf{H}(x - x^\star) + R(x, x^\star),$$

with

$$\|R(x, x^\star)\| \leq \kappa_3 \tfrac{\sqrt{d}}{2}\|x - x^\star\|^2.$$

Therefore, we have,

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\gamma(t) - x^\star\right) - \mathbf{H}\left(\gamma(t) - x^\star\right) = R\left(\gamma(t), x^\star\right),$$

and so, since $\gamma(0) = x_0$, γ satisfies the relation

$$\gamma(t) - x^\star = e^{t\mathbf{H}}(x_0 - x^\star) + \int_0^t e^{(t-s)\mathbf{H}} R\left(\gamma(s), x^\star\right) \mathrm{d}s.$$

Since all the eigenvalues of $\mathbf{H}$ are in $(-\infty, -\underline{\nu})$, there is $\nu > \underline{\nu}$ such that we have

$$\left\|e^{\alpha\mathbf{H}}\right\| \leq e^{-\nu\alpha}, \quad \text{for all } \alpha > 0.$$

Then,

$$\|\gamma(t) - x^\star\| \leq e^{-\nu t}\|x_0 - x^\star\| + \kappa_3 \tfrac{\sqrt{d}}{2}\int_0^t e^{-\nu(t-s)}\|\gamma(s) - x^\star\|^2 \mathrm{d}s.$$

Set $u(t) = e^{\nu t}\|\gamma(t) - x^\star\|$ and $U(t) = \|x_0 - x^\star\| + \kappa_3 \frac{\sqrt{d}}{2}\int_0^t e^{\nu s}\|\gamma(s) - x^\star\|^2 \mathrm{d}s$. Then $u(t) \leq U(t)$ and $U'(t) = \kappa_3 \frac{\sqrt{d}}{2} e^{-\nu t} u^2(t)$, so

$$\frac{U'(t)}{U(t)} = \kappa_3 \tfrac{\sqrt{d}}{2} e^{-\nu t} u(t) \frac{u(t)}{U(t)} \leq \kappa_3 \tfrac{\sqrt{d}}{2} e^{-\nu t} u(t) = \kappa_3 \tfrac{\sqrt{d}}{2}\|\gamma(t) - x^\star\|.$$

But since $\gamma(t) \to x^\star$ as $t \to \infty$, there exists $t_0 > 0$ such that $\|\gamma(t) - x^\star\| \leq \frac{2(\nu - \underline{\nu})}{\kappa_3\sqrt{d}}$ for all $t \geq t_0$. By integrating between t_0 and t, we deduce that

$$\log U(t) \leq \log U(t_0) + (\nu - \underline{\nu})(t - t_0),$$

and so

$$\|\gamma(t) - x^\star\| = e^{-\nu t} u(t) \leq e^{-\nu t} U(t) \leq Q_0 e^{-\underline{\nu}t}, \quad \text{for all } t \geq t_0,$$

with $Q_0 := U(t_0)e^{-(\nu - \underline{\nu})t_0}$. For $t < t_0$, we simply have $\|\gamma(t) - x^\star\| \leq Q_1 e^{-\underline{\nu}t}$, where $Q_1 = \max_{0 \leq t \leq t_0}\|\gamma(t) - x^\star\| e^{\underline{\nu}t}$. Therefore (25) holds with the constant $Q_2 = \max\{Q_0, Q_1\}$.

We now turn to proving (26). For any x in $\bar{B}(x^\star, r_0)$, we have

$$f(x) = f(x^\star) + \frac{1}{2}\mathbf{H}[x - x^\star, x - x^\star] + R(x, x^\star),$$

for all x in $\bar{B}(x^\star, r_0)$, where R is a different function (now real valued) satisfying

$$|R(x, x^\star)| \leq \tfrac{\kappa_3}{6}\|x - x^\star\|^3.$$

Then

$$\begin{aligned} f(x^\star) - f(\gamma(t)) &\leq \tfrac{1}{2}\|\mathbf{H}\|\,\|\gamma(t) - x^\star\|^2 + \tfrac{\kappa_3}{6}\|\gamma(t) - x^\star\|^3 \\ &\leq (\tfrac{1}{2}\|\mathbf{H}\| + Q_3)Q_2^2 e^{-2\underline{\nu}t}, \end{aligned}$$

where $Q_3 = \frac{\kappa_3}{6}\max_{t \geq 0}\|\gamma(t) - x^\star\|$ and we applied (25) in the second line with Q_2 defined above. Therefore, (26) holds with the constant $Q_4 := (\|\mathbf{H}\|/2 + Q_3)Q_2^2$.

We then take $C_6 = \max(Q_2, Q_4)$. ■

The following, adapted from Hirsch et al. (2004, Sec 17.5), is a stability result for autonomous gradient flows.

Lemma 7 *Suppose f and g are of class C^3. Let $x_0 \in \mathbb{R}^d$, and suppose that*

$$\|\nabla f(x) - \nabla g(x)\| < \eta, \quad \forall x \in \mathcal{S} := \mathcal{L}_f(f(x_0)) \cup \mathcal{L}_g(g(x_0)).$$

Let κ be a Lipschitz constant for ∇f on $\mathcal{S}$. Let $(x(t) : t \geq 0)$ and $(y(t) : t \geq 0)$ be the flow lines of f and g starting at x_0, supposed to be defined on $[0, \infty)$. Then,

$$\|x(t) - y(t)\| \leq \frac{\eta}{\kappa}\big[e^{\kappa t} - 1\big], \quad \forall t \geq 0.$$

Next is a result on the stability of local maxima.

Lemma 8 *Suppose f and g are of class C^3, and have local maxima at x and y, respectively, with $H_f(x)$ having all eigenvalues in $(-\infty,-\nu]$ for some $\nu>0$. Then for any $C_8 \geq \max\{1, \frac{2}{\sqrt{\nu}}, \frac{4\kappa}{3\nu}\}$, where $\kappa = \max\big(\kappa_3(f,\bar{B}(x,1)),\kappa_3(g,\bar{B}(y,1))\big)$,*

$$\|x-y\| \leq 1/C_8 \quad \Rightarrow \quad \|x-y\| \leq C_8\big(\|f(x)-g(x)\|+\|f(y)-g(y)\|\big)^{1/2}. \tag{27}$$

Proof Let $\mathbf{H}_f$ and $\mathbf{H}_g$ be short for $H_f(x)$ and $H_g(y)$, respectively. We develop f and g around x and y, respectively. Assuming $\|x-y\|\leq 1$, we have

$$\begin{aligned} f(y) &= f(x) + \tfrac{1}{2}\mathbf{H}_f[x-y,x-y] + R_f(x,y), \qquad \text{with} \quad |R_f(x,y)| \leq \tfrac{\kappa}{6}\|x-y\|^3; \\ g(x) &= g(y) + \tfrac{1}{2}\mathbf{H}_g[x-y,x-y] + R_g(x,y), \qquad \text{with} \quad |R_g(x,y)| \leq \tfrac{\kappa}{6}\|x-y\|^3. \end{aligned}$$

Summing these two equalities, we obtain

$$\frac{1}{2}(\mathbf{H}_f+\mathbf{H}_g)[x-y,x-y] = f(y)-g(y)+g(x)-f(x)-R_f(x,y)-R_g(x,y).$$

By the triangle inequality and the fact that $\mathbf{H}_g$ is negative semidefinite,

$$\nu\|x-y\|^2 \leq \|(\mathbf{H}_f+\mathbf{H}_g)[x-y,x-y]\| \leq 2\|f(x)-g(x)\|+2\|f(y)-g(y)\|+\tfrac{2\kappa}{3}\|x-y\|^3.$$

When $\|x-y\| \leq \min\big(\frac{3\nu}{4\kappa},1\big)$, we have $\nu\|x-y\|^2 - \frac{2\kappa}{3}\|x-y\|^3 \geq \frac{\nu}{2}\|x-y\|^2$, and therefore

$$\|x-y\|^2 \leq \tfrac{4}{\nu}\left(\|f(x)-g(x)\|+\|f(y)-g(y)\|\right),$$

and from this we conclude that (27) holds with $C_8 = \max(\sqrt{(\frac{4}{\nu})}, \frac{4\kappa}{3\nu}, 1)$. ■

4.2 Proof of Theorem 1

Below, C_m refers to the constant defined in Lemma m.

We assume that x_0 is not a critical point of f, for otherwise $x_0 = x^\star$ and there is nothing to prove. Let $t_\ell = a\ell$, which is the time at which the polygonal line $x_a(t)$ passes through x_ℓ. Let $\mathcal{L}_0$ be short for $\mathcal{L}_f(f(x_0))$. Note that $(x(t) : t \geq 0)$ is bounded since x is a continuous flow line with a beginning and ending points. Let r_0 be large enough that $(x(t) : t \geq 0) \subset \bar{B}(x_0, r_0)$.

Claim. *Without loss of generality, we may assume that $\mathcal{L}_0$ is bounded.* To see this, suppose the result is true when $\mathcal{L}_0 \subset \bar{B}(x_0, 3r_0)$. We shall prove that it remains true when $\mathcal{L}_0 \not\subseteq \bar{B}(x_0,3r_0)$. Given such a situation, build another function $\tilde{f}$ in such a way that $\tilde{f}$ is C^3 on $\mathbb{R}^d$ with $\tilde{f}(x) = f(x)$ for all $x \in \bar{B}(x_0,2r_0)$ and $\tilde{f}(x) < f(x_0)$ for $x \notin \bar{B}(x_0,3r_0)$, so that $\mathcal{L}_{\tilde{f}}(\tilde{f}(x_0)) \subset \bar{B}(x_0,3r_0)$. To verify that such a function exists, consider the smoothing function $s:\mathbb{R}^d \to \mathbb{R}$ defined by

$$s(x) = \frac{1}{\int_{\bar{B}(0,1)} e^{-1/(1-\|x\|^2)}\mathrm{d}x} e^{-1/(1-\|x\|^2)}\mathbf{1}_{B(0,1)}(x), \quad x \in \mathbb{R}^d,$$

and its dilated versions s_a defined by $s_a(x) = a^{-d}s(x/a)$ for $a>0$, where $\mathbf{1}_{\bar{B}(0,1)}(x) = 1$ if $x \in \bar{B}(0,1)$ and 0 otherwise. Define the function g by $g(x) = \mathbf{1}_{\bar{B}(0,5r_0/2)} \star s_{r_0/2}(x-x_0)$. Then g is of class C^∞, $g(x)=1$ for $x \in \bar{B}(x_0,2r_0)$, $g(x)=0$ if $x \notin \bar{B}(x_0,3r_0)$, and $0<g(x)<1$ when $2r_0 < \|x-x_0\| < 3r_0$. Then we may take $\tilde{f} = fg$.

Therefore, (13) and (14) hold for $\tilde{f}$, for constants $\tilde{A}$ and $\tilde{C}$, with the same exponent δ as given in (14). Denote by $\tilde{x}$ and $\tilde{x}_a$ the flow line and polygonal curve constructed from $\tilde{f}$ in the same way x and x_a are from f. Then, assuming $\tilde{C}a^\delta \leq r_0$, we see by the triangle inequality that $\tilde{x}(t)$ and $\tilde{x}_a(t)$ are determined by $\tilde{f}$ restricted to $\bar{B}(x_0,2r_0)$, and since $\tilde{f}$ coincides with f there, $x(t) = \tilde{x}(t)$ and $x_a(t) = \tilde{x}_a(t)$, so that (13) and (14) are valid for f if $a \leq \min\{\tilde{A}, (r_0/\tilde{C})^{1/\delta}\}$.

From now on, we assume that $\mathcal{L}_0$ is bounded. Note that $\mathcal{L}_0$ is also closed since f is continuous, so in fact $\mathcal{L}_0$ is compact. Let

$$S = \mathcal{L}_0 \oplus \bar{B}(0,\kappa_1(f,\mathcal{L}_0)) =: \{x \in \mathbb{R}^d : \operatorname{dist}(x,\mathcal{L}_0) \leq \kappa_1(f,\mathcal{L}_0)\}, \tag{28}$$

where $\operatorname{dist}(x,\mathcal{L}_0) = \inf\{\|x-y\| : y \in \mathcal{L}_0\}$. For any $0 \leq \ell \leq 3$, let $\kappa_\ell = \kappa_\ell(f,S)$, where S is defined in (28). For any $x \in \mathbb{R}^d$, let

$$\kappa_2(x) = \kappa_2(f,\bar{B}(x,\|\nabla f(x)\|)) = \sup\{\|f^{(2)}(y)\| : y \in \bar{B}(x,\|\nabla f(x)\|)\}. \tag{29}$$

Notice that $\mathcal{L}_0 \subset S$ and that, by construction, $\bar{B}(x,\|\nabla f(x)\|) \subset S$ for any $x \in \mathcal{L}_0$. Hence, $\kappa_2(x) \leq \kappa_2$ for all x in $\mathcal{L}_0$.

Claim. *For any $x \in \mathbb{R}^d$ with $\nabla f(x) \neq 0$ and any $0 \leq b \leq 1 \wedge (2\sqrt{d}\kappa_2(x))^{-1}$, we have $f(x+b\nabla f(x)) > f(x)$ and f is increasing along the line segment $[x, x+b\nabla f(x)]$.* Using a Taylor expansion of f at x, we have

$$f(x+b\nabla f(x)) = f(x) + b\|\nabla f(x)\|^2 + R(x,b),$$

where $|R(x,b)| \leq \frac{1}{2}b^2\kappa_2(x)\|\nabla f(x)\|^2 \leq \frac{b}{2}\|\nabla f(x)\|^2$, since $b \leq (2\sqrt{d}\kappa_2(x))^{-1} \leq \kappa_2^{-1}(x)$. Then

$$\zeta(b) := f(x+b\nabla f(x)) \geq f(x) + \frac{b}{2}\|\nabla f(x)\|^2 > f(x). \tag{30}$$

Now for any $0<\beta<b$,

$$\zeta'(\beta) = \nabla f\left(x+\beta\nabla f(x)\right)\cdot\nabla f(x),$$

and by a Taylor expansion of the components of ∇f

$$\nabla f\left(x+\beta\nabla f(x)\right) = \nabla f(x) + R_2(x,\beta),$$

where $\|R_2(x,\beta)\| \leq \beta\sqrt{d}\kappa_2(x)\|\nabla f(x)\|$. Hence, for any $0<\beta<b$

$$\zeta'(\beta) = \|\nabla f(x)\|^2 + R(x,\beta)\cdot\nabla f(x) \geq \frac{1}{2}\|\nabla f(x)\| > 0$$

since $\beta < b \leq (2\sqrt{d}\kappa_2(x))^{-1}$ and so f is increasing along the line segment $[x, x+b\nabla f(x)]$.

Claim. *For a sufficiently small, $x_a(t) \in \mathcal{L}_0$ for all $t \geq 0$.* Indeed, since $\kappa_2(x) \leq \kappa_2$ for all x in $\mathcal{L}_0$, we have $1 \wedge (2\sqrt{d}\kappa_2(x))^{-1} \geq 1 \wedge (2\sqrt{d}\kappa_2)^{-1}$ for all x in $\mathcal{L}_0$. Consequently, by the previous claim, for any x in $\mathcal{L}_0$ and $a \leq 1 \wedge (2\sqrt{d}\kappa_2)^{-1}$, we have $f(x+a\nabla f(x)) > f(x)$ and

the values of f are increasing along the line segment $[x, x + a\nabla f(x)]$. In particular, since x_a starts at $x_0 \in \mathcal{L}_0$, we have $f(x_1) = f(x_0 + \nabla f(x_0)) > f(x_0)$, and the segment $[x_0, x_1]$ belongs to $\mathcal{L}_0$. By recursion, we deduce that $x_a(t)$ belongs to $\mathcal{L}_0$ for all $t \geq 0$.

From now on, we assume that

$$a \leq A_1 := 1 \wedge (2\sqrt{d}\kappa_2)^{-1}. \tag{31}$$

Claim. *f is increasing along the polygonal curve x_a.* By the previous arguments, the values of f are increasing along the line segment $[x_\ell, x_{\ell+1}]$, for all $\ell \geq 0$.

Claim. *(x_ℓ) converges to a critical point of f.* We just showed that the sequence $(f(x_\ell) : \ell \geq 0)$ is increasing, and since it is bounded by κ_0, it converges. By the first inequality in (30) and the fact that $\|x_{\ell+1} - x_\ell\| = a\|\nabla f(x_\ell)\|$ by construction, we have

$$f(x_{\ell+1}) - f(x_\ell) \geq \frac{1}{2}a\|\nabla f(x_\ell)\|^2 = \frac{1}{2a}\|x_{\ell+1} - x_\ell\|^2, \tag{32}$$

for all $\ell \geq 1$. Hence, for all $\ell \geq 1$, and all $k \geq 1$, we have

$$f(x_{\ell+k}) - f(x_\ell) \geq \frac{1}{2a}\sum_{i=1}^{k}\|x_{\ell+i} - x_\ell\|^2 \geq \frac{1}{2a}\|x_{\ell+k} - x_\ell\|^2,$$

by the triangle inequality. Since $(f(x_\ell))$ is convergent, it is a Cauchy sequence, and consequently, so is (x_ℓ), so that $\tilde{x} := \lim_{\ell\to\infty} x_\ell$ exists. And by (32) and the fact that f is C^1, we have

$$\nabla f(\tilde{x}) = \lim_{\ell\to\infty} \nabla f(x_\ell) = 0,$$

so that $\tilde{x}$ is a critical point of f.

Claim. *We have*

$$\|x(t_\ell) - x_\ell\| \leq \left[e^{\ell a\kappa_2\sqrt{d}} - 1\right]\kappa_1 a, \quad \forall \ell \geq 0. \tag{33}$$

Indeed, let $e_\ell = x(t_\ell) - x_\ell$. Using (6), we have

$$\begin{aligned} e_{\ell+1} &= x(t_{\ell+1}) - x_{\ell+1} \\ &= e_\ell + [x(t_{\ell+1}) - x(t_\ell) - a\nabla f(x(t_\ell))] + a\left[\nabla f(x(t_\ell)) - \nabla f(x_\ell)\right]. \end{aligned} \tag{34}$$

By the definition of κ_2, and a Taylor expansion,

$$\|\nabla f(x(t_\ell)) - \nabla f(x_\ell)\| \leq \sqrt{d}\kappa_2\|x(t_\ell) - x_\ell\| = \sqrt{d}\kappa_2\|e_\ell\|. \tag{35}$$

We also have

$$\begin{aligned} x(t_{\ell+1}) - x(t_\ell) - a\nabla f(x(t_\ell)) &= \int_{t_\ell}^{t_{\ell+1}} x'(s)\mathrm{d}s - \frac{a}{t_{\ell+1} - t_\ell}\int_{t_\ell}^{t_{\ell+1}} x'(t_\ell)\mathrm{d}s \\ &= \int_{t_\ell}^{t_{\ell+1}} (x'(s) - x'(t_\ell))\mathrm{d}s, \end{aligned}$$

by the definitions of $x(t)$ and t_ℓ. Consequently,

$$\|x(t_{\ell+1}) - x(t_\ell) - a\nabla f(x(t_\ell))\| \leq \int_{t_\ell}^{t_{\ell+1}} \|x'(s) - x'(t_\ell)\|\mathrm{d}s.$$

For $s \in [t_\ell, t_{\ell+1}]$, we have

$$\|x'(s) - x'(t_\ell)\| = \|\nabla f(x(s)) - \nabla f(x(t_\ell))\| \leq \kappa_2\sqrt{d}\|x(s) - x(t_\ell)\|,$$

and

$$\|x(s) - x(t_\ell)\| = \left\|\int_{t_\ell}^{s} x'(t)\mathrm{d}t\right\| \leq \int_{t_\ell}^{s}\|x'(t)\|\mathrm{d}t = \int_{t_\ell}^{s}\|\nabla f(x(t))\|\mathrm{d}t \leq \kappa_1(s - t_\ell).$$

Hence

$$\|x'(s) - x'(t_\ell)\| \leq \sqrt{d}\kappa_2\kappa_1(s - t_\ell),$$

and, recalling that $t_\ell = a\ell$,

$$\|x(t_{\ell+1}) - x(t_\ell) - a\nabla f(x(t_\ell))\| \leq \sqrt{d}\kappa_2\kappa_1(t_{\ell+1} - t_\ell)^2 = \sqrt{d}\kappa_2\kappa_1 a^2. \tag{36}$$

Plugging (36) and (35) into (34), we deduce that

$$\|e_{\ell+1}\| \leq \sqrt{d}\kappa_2\kappa_1 a^2 + (1 + \sqrt{d}\kappa_2 a)\|e_\ell\|.$$

The inequality (33) is now a direct consequence of Lemma 4. (Recall that $x(t_0) = x_0$.)

Claim. *(x_ℓ) converges to $x^\star$.* By this we mean that $\tilde{x}$ coincides with $x^\star$. Indeed, for any $\eta > 0$, denote by $\mathcal{C}(\eta)$ the connected component of $\mathcal{L}_f(f(x^\star) - \eta)$ that contains $x^\star$. Let $\mathbf{H}$ be a shorthand for $H_f(x^\star)$. Suppose all the eigenvalues of $\mathbf{H}$ are in $(-\overline{\nu}, -\underline{\nu})$ for some $\overline{\nu} > \underline{\nu} > 0$. Because $\mathbf{H}$ is negative definite, when $\epsilon > 0$ is small enough $\bar{B}(x^\star, \epsilon)$ contains no critical point of f other than $x^\star$. Let ℓ_ϵ be such that $\|x_\ell - \tilde{x}\| \leq \epsilon/3$ when $\ell \geq \ell_\epsilon$, which is well-defined since (x_ℓ) converges to $\tilde{x}$. Using the triangle inequality, and then Lemma 6 and (33), for $\ell = \ell_{\epsilon,a} := \max\left\{\ell_\epsilon, \left\lceil \frac{1}{a\underline{\nu}}\log(3/(C_6\epsilon))\right\rceil\right\}$, we have

$$\begin{aligned} \|x^\star - \tilde{x}\| &\leq \|x^\star - x(t_\ell)\| + \|x(t_\ell) - x_\ell\| + \|x_\ell - \tilde{x}\| \\ &\leq \epsilon/3 + \left[e^{\sqrt{d}\kappa_2 a\ell_{\epsilon,a}} - 1\right]\kappa_1 a + \epsilon/3 \\ &\leq \epsilon, \end{aligned}$$

when $a \leq A_2$ for some $A_2 > 0$ (depending on $\epsilon > 0$) sufficiently small. Hence, $\tilde{x} \in \bar{B}(x^\star, \epsilon)$. Since $\tilde{x}$ is a critical point, and the only critical point in $\bar{B}(x^\star, \epsilon)$ is $x^\star$, necessarily $\tilde{x} = x^\star$. This proves (13) for $a \leq A := \min(1, A_1, A_2)$, where A_1 is defined in (31).

Henceforth, we assume that $a \leq A$, so that $x_\ell \to x^\star$ as $\ell \to \infty$, and focus on proving (14).

Bound for large t. A Taylor expansion gives

$$\nabla f(x) = \mathbf{H}(x - x^\star) + R(x, x^\star), \quad \text{where } \|R(x, x^\star)\| \leq \tfrac{\sqrt{d}}{2}\kappa_3\|x - x^\star\|^2.$$

We then have

$$\begin{aligned} x_{\ell+1} - x^\star &= x_\ell - x^\star + a\nabla f(x_\ell) \\ &= (\mathbf{I} + a\mathbf{H})(x_\ell - x^\star) + aR(x_\ell, x^\star), \end{aligned}$$

so that

$$\|x_{\ell+1} - x^\star\| \leq (1 - a\nu)\|x_\ell - x^\star\| + a\tfrac{\sqrt{d}}{2}\kappa_3\|x_\ell - x^\star\|^2,$$

for some $\nu > \underline{\nu}$. As $x_\ell \to x^\star$, there is ℓ_0 such that, for $\ell \geq \ell_0$, $\nu - \frac{\sqrt{d}}{2}\kappa_3\|x_\ell - x^\star\| > \underline{\nu}$, implying

$$\|x_{\ell+1} - x^\star\| \leq (1 - a\underline{\nu})\|x_\ell - x^\star\|, \quad \forall \ell \geq \ell_0.$$

By recursion, we deduce that there is a constant $Q_1 > 0$ such that

$$\|x_\ell - x^\star\| \leq Q_1(1 - a\underline{\nu})^\ell \leq Q_1 e^{-\underline{\nu}\ell a}, \quad \forall \ell \geq 0. \tag{37}$$

Fix $t \in [t_\ell, t_{\ell+1}]$. Starting with the triangle inequality, we have

$$\begin{aligned}\|x(t) - x_a(t)\| &\leq \|x(t) - x_\star\| + \|x_\star - x_\ell\| + \|x_\ell - x_a(t)\| \\ &\leq C_6 e^{-\underline{\nu}t} + Q_1 e^{-\underline{\nu}\ell a} + (t - t_\ell)\|\nabla f(x_\ell)\| \\ &\leq Q_2 e^{-\underline{\nu}t} + \kappa_1 a. \end{aligned} \tag{38}$$

In the first line, we applied (25), (37), and used the definition of x_a. In the second line, we let $Q_2 = C_6 + Q_1 e^{\underline{\nu}A}$ and used the definition of κ_1 in (11).

Bound for small t. On the other hand, we also have

$$\begin{aligned}\|x(t) - x_a(t)\| &\leq \|x(t) - x(t_\ell)\| + \|x(t_\ell) - x_\ell\| + \|x_\ell - x_a(t)\| \\ &\leq \kappa_1(t_{\ell+1} - t_\ell) + \|x(t_\ell) - x_\ell\| + \|x_\ell - x_{\ell+1}\| \\ &= \kappa_1 a + \|x(t_\ell) - x_\ell\| + a\|\nabla f(x_\ell)\| \\ &\leq 2\kappa_1 a + \|x(t_\ell) - x_\ell\|. \end{aligned}$$

Because f is C^3, there is $\epsilon > 0$ such that all the eigenvalues of $H_f(x)$ exceed $-\overline{\nu}$ when $x \in \bar{B}(x^\star, \epsilon)$. Let ℓ_ϵ be such that $x(t), x_\ell \in \bar{B}(x^\star, \epsilon)$ for all $t \geq a\ell_\epsilon$ and $\ell \geq \ell_\epsilon$, which implies

$$\|\nabla f(x(t)) - \nabla f(x_\ell)\| \leq \overline{\nu}\|x(t) - x_\ell\|.$$

Using this inequality instead of (35), we can refine (33) into

$$\|x(t_\ell) - x_\ell\| \leq \left[e^{\ell a\overline{\nu}} - 1\right]\kappa_1 a, \quad \forall \ell \geq \ell_\epsilon,$$

and since ϵ is fixed, we can combine this with (33) to get

$$\|x(t_\ell) - x_\ell\| \leq \left[e^{\ell a\overline{\nu}} - 1\right]\kappa_1 a + Q_3 a, \quad \forall \ell \geq 0, \tag{39}$$

for some constant Q_3. We thus have

$$\|x(t) - x_a(t)\| \leq \left[2\kappa_1 + (e^{\overline{\nu}t} - 1)\kappa_1 + Q_3\right] a, \tag{40}$$

using the fact that $t \geq t_\ell = a\ell$.

Combining (38) and (40), we have

$$\|x(t) - x_a(t)\| \leq (\kappa_1 + Q_3)a + \min\left\{\kappa_1 a e^{\overline{\nu}t}, Q_2 e^{-\underline{\nu}t}\right\}.$$

From this, we deduce (14) from elementary calculations.

4.3 Proof of Theorem 2

Below, C_m refers to the constant defined in Lemma m.

Arguing as in the proof of Theorem 1, we may assume, without any loss of generality, that $\mathcal{L}_f(f(x_0)/2) \subset \bar{B}(x_0, 3r_0)$. So from now on, we assume that $\mathcal{L}_f(f(x_0)/2)$ is compact and we set $S = \mathcal{L}_f(f(x_0)/2)$. For any $0 \leq \ell \leq 3$, we also let κ_ℓ be short for $\kappa_\ell(f, S)$.

Claim. *For η_0 sufficiently small, $\hat{x}(t) \in S$.* Indeed, suppose there is $t \geq 0$ such that $\hat{x}(t) \notin S$. Fix $\epsilon = f(x_0)/2$. Then, by continuity, there is $0 \leq t' < t$ such that $f(\hat{x}(t')) = f(x_0) - \epsilon$. Since $\hat{x}(t'), x_0 \in S$, we have

$$\begin{aligned}\hat{f}(\hat{x}(t')) &= \hat{f}(\hat{x}(t')) - f(\hat{x}(t')) + f(\hat{x}(t')) \\ &\leq \eta_0 + f(x_0) - \epsilon \\ &= \eta_0 + \hat{f}(x_0) + f(x_0) - \hat{f}(x_0) - \epsilon \\ &\leq \hat{f}(x_0) + 2\eta_0 - \epsilon, \end{aligned}$$

by the triangle inequality, applied twice. Since $\hat{f}(\hat{x}(t')) \geq \hat{f}(x_0)$, we see that this situation does not arise when $\eta_0 < \epsilon/2$.

Claim. *$\hat{x}^\star = \lim_{t\to\infty}\hat{x}(t)$ is well defined and is close to $x^\star$.* Since $\hat{f}$ is of class C^3 by assumption, the map $x \mapsto \nabla\hat{f}(x)$ is C^1, and since $\hat{x}(t)$ stays in S and S is compact, $\hat{x}(t)$ is defined for all $t \geq 0$ by the first corollary to the first theorem in (Hirsch et al., 2004, Sec. 17.4). For any $\epsilon \in (0, C_5)$, with $\epsilon < f(x^\star) - f(x_0)/2$, let t_ϵ be such that $x(t) \in \bar{B}(x^\star, \sqrt{(2\epsilon/\overline{\nu})})$ for all $t \geq t_\epsilon$, which is well-defined since $x(t) \to x^\star$ as $t \to \infty$. By Lemma 7, we have

$$\|\hat{x}(t) - x(t)\| \leq \frac{\eta_1}{\sqrt{d}\kappa_2}e^{\sqrt{d}\kappa_2 t}, \quad \forall t \geq 0. \tag{41}$$

Hence

$$\|\hat{x}(t_\epsilon) - x^\star\| \leq \|\hat{x}(t_\epsilon) - x(t_\epsilon)\| + \|x(t_\epsilon) - x^\star\| \leq \frac{\eta_1}{\sqrt{d}\kappa_2}e^{\sqrt{d}\kappa_2 t_\epsilon} + \sqrt{\frac{2\epsilon}{\overline{\nu}}} =: \delta_1. \tag{42}$$

Assume that η_1 and ϵ are small enough that $\delta_1 < \sqrt{(2C_5/\overline{\nu})}$. Letting $\mathcal{C}(\epsilon)$ be as in Lemma 5, by (22) we have

$$\bar{B}(x^\star, \delta_1) \subset \mathcal{C}(\epsilon_1),$$

with $\epsilon_1 := \frac{\overline{\nu}}{2}\delta_1^2$. Thus $\hat{x}(t_\epsilon)$ belongs to $\mathcal{C}(\epsilon_1)$ and in particular $f(\hat{x}(t_\epsilon)) \geq f(x^\star) - \epsilon_1$. Using this last inequality, we deduce by the triangle inequality and the fact that $t \mapsto \hat{f}(\hat{x}(t))$ is increasing that for all $t \geq t_\epsilon$,

$$f(\hat{x}(t)) \geq \hat{f}(\hat{x}(t)) - \eta_0 \geq \hat{f}(\hat{x}(t_\epsilon)) - \eta_0 \geq f(\hat{x}(t_\epsilon)) - 2\eta_0 \geq f(x^\star) - \epsilon_2,$$

where $\epsilon_2 := \epsilon_1 + 2\eta_0$. Since $\hat{x}(t_\epsilon) \in \mathcal{C}(\epsilon_1) \subset \mathcal{C}(\epsilon_2)$ and $\{\hat{x}(t) : t \geq t_\epsilon\}$ is connected and in $\mathcal{L}_f(f(x^\star) - \epsilon_2)$, we necessarily have $\{\hat{x}(t) : t \geq t_\epsilon\} \subset \mathcal{C}(\epsilon_2)$. Assume ϵ, η_0, η_1 are small enough that $\epsilon_2 \leq C_5$. Then, by Lemma 5, $\mathcal{C}(\epsilon_2) \subset \bar{B}(x^\star, \sqrt{2\epsilon_2/\underline{\nu}})$, and so

$$\|\hat{x}(t) - x^\star\| \leq \epsilon_3 := \sqrt{2\epsilon_2/\underline{\nu}}, \quad \text{for all } t \geq t_\epsilon. \tag{43}$$

Assume ϵ, η_0, η_1 are small enough that $\bar{B}(x^\star, \epsilon_3) \subset S$. For any x and y in $\bar{B}(x^\star, \epsilon_3)$, we then have

$$\|H_f(x) - H_f(y)\| \leq d\|H_f(x) - H_f(y)\|_{\max} \leq d^{\frac{3}{2}}\kappa_3\|x - y\|. \tag{44}$$

Using (44), for any x in $\bar{B}(x^\star, \epsilon_3)$

$$\begin{aligned}\|H_{\hat{f}}(x) - H_f(x^\star)\| &\leq \|H_{\hat{f}}(x) - H_f(x)\| + \|H_f(x) - H_f(x^\star)\| \\ &\leq \eta_2 + d^{\frac{3}{2}}\kappa_3\|x - x^\star\| \\ &\leq \eta_2 + d^{\frac{3}{2}}\kappa_3\epsilon_3. \end{aligned} \tag{45}$$

We then apply Weyl's inequality (Stewart and Sun, 1990, Cor. IV.4.9) to conclude that, when η_2 and ϵ_3 are small enough, for all x in $\bar{B}(x^\star, \epsilon_3)$, the eigenvalues of $H_{\hat{f}}(x)$ are all in $(-\infty, -\underline{\nu})$. We assume that $\epsilon, \eta_0, \eta_1, \eta_2$ are small enough that this is the case. This implies that any critical point of $\hat{f}$ in $\bar{B}(x^\star, \epsilon_3)$ is isolated and a local maximum of $\hat{f}$. Using (43) and the compactness of $\bar{B}(x^\star, \epsilon_3)$, by Cantor's intersection theorem $K := \cap_{t \geq t_\epsilon} \overline{\{\hat{x}(u) : u \geq t\}}$ is nonempty. In addition, K is composed of critical points of $\hat{f}$; see Hirsch et al. (2004, Section 9.3, Proposition, p. 206 and Theorem, p. 205) or Absil and Kurdyka (2006, Lemma 5). Therefore we conclude that K is a singleton, which we denote by $\hat{x}^\star$. This is a critical point of $\hat{f}$ in $\bar{B}(x^\star, \epsilon_3)$ and is the limit of $\hat{x}(t)$ as $t \to \infty$. Moreover, $\hat{x}^\star$ is a local maximum of $\hat{f}$.

Since our assumptions imply that $x^\star$ is also a local maximum, we can apply Lemma 8 to bound $\|\hat{x}^\star - x^\star\|$. In our setting, applying the triangle inequality, we may take $C_8 = \max\left\{1, \frac{2}{\sqrt{\underline{\nu}}}, \frac{4\kappa}{3\underline{\nu}}\right\}$, where $\kappa = \kappa_3 + \eta_3$. Assume ϵ, η_0, η_1 are small enough that $\epsilon_3 \leq 1/C_8$. Then, by (43) and Lemma 8, we conclude that $\|\hat{x}^\star - x^\star\| \leq C_8\sqrt{2\eta_0}$. Hence we have shown that there exists a constant $Q_0 := Q_0(f, \underline{\nu}) \geq 1$ such that, whenever $\max\{\eta_0, \eta_1, \eta_2\} \leq 1/Q_0$ and $\eta_3 \leq Q_0$,

$$\|\hat{x}^\star - x^\star\| \leq Q_0\sqrt{\eta_0}. \tag{46}$$

Let $\mathbf{H}$ and $\hat{\mathbf{H}}$ be short for $H_f(x^\star)$ and $H_{\hat{f}}(\hat{x}^\star)$, respectively. We now bound $\|\hat{x}(t) - x(t)\|$ in two ways.

Bound for large t. We proceed with a linearization of the flows near the critical points. Let $\nu > \underline{\nu}$, but close enough that all the eigenvalues of $\mathbf{H}$ are still in $(-\infty, -\nu)$. Note first that $x^\star$ is an interior point of S. Suppose that $\max\{\eta_0, \eta_1, \eta_2\} \leq 1/Q_0$ and $\eta_3 \leq Q_0$ so that (46) holds. By combining (45) and (46)

$$\|\hat{\mathbf{H}} - \mathbf{H}\| \leq \eta_2 + d^{\frac{3}{2}}\kappa_3 Q_0\sqrt{\eta_0}. \tag{47}$$

Suppose in addition that η_0 is small enough that $\hat{x}^\star$ is also an interior point to S, which is possible by (46), and that $\|\hat{\mathbf{H}} - \mathbf{H}\|$ is small enough that $\hat{\mathbf{H}}$ also has all its eigenvalues in $(-\infty, -\nu)$, which is possible by (47) and Weyl's inequality for η_0 and η_2 small enough. Then there exists $r_\ddagger > 0$ such that

$$\bar{B}(x^\star, r_\ddagger) \subset S \quad \text{and} \quad \bar{B}(\hat{x}^\star, r_\ddagger) \subset S,$$

and since $x(t) \to x^\star$ and $\hat{x}(t) \to \hat{x}^\star$ as $t \to \infty$, there exists a time $t_\ddagger > 0$ such that

$$x(t) \in \bar{B}(x^\star, r_\ddagger) \subset S \quad \text{and} \quad \hat{x}(t) \in \bar{B}(\hat{x}^\star, r_\ddagger), \quad \text{for any } t \geq t_\ddagger.$$

Letting $x_\ddagger(t) = x(t) - x^\star$ and $\hat{x}_\ddagger(t) = \hat{x}(t) - \hat{x}^\star$, by a Taylor expansion, for all $t \geq t_\ddagger$ we have

$$x'_\ddagger(t) = \nabla f(x(t)) = \mathbf{H}\, x_\ddagger(t) + R(t), \qquad \text{with} \quad \|R(t)\| \leq \tfrac{\sqrt{d}\kappa_3}{2}\|x_\ddagger(t)\|^2\,; \tag{48}$$

$$\hat{x}'_\ddagger(t) = \nabla \hat{f}(\hat{x}(t)) = \hat{\mathbf{H}}\,\hat{x}_\ddagger(t) + \hat{R}(t), \qquad \text{with} \quad \|\hat{R}(t)\| \leq \tfrac{\sqrt{d}(\kappa_3+\eta_3)}{2}\|\hat{x}_\ddagger(t)\|^2\,. \tag{49}$$

The difference gives

$$\begin{aligned} x'_\ddagger(t) - \hat{x}'_\ddagger(t) &= \mathbf{H}x_\ddagger(t) - \hat{\mathbf{H}}\hat{x}_\ddagger(t) + R(t) - \hat{R}(t) \\ &= \mathbf{H}(x_\ddagger(t) - \hat{x}_\ddagger(t)) + (\mathbf{H} - \hat{\mathbf{H}})\hat{x}_\ddagger(t) + R(t) - \hat{R}(t), \end{aligned} \tag{50}$$

and after integration between 0 and $t > 0$, we get

$$x_\ddagger(t) - \hat{x}_\ddagger(t) = -e^{t\mathbf{H}}(x^\star - \hat{x}^\star) + \int_0^t e^{(t-s)\mathbf{H}}\big[(\mathbf{H} - \hat{\mathbf{H}})\hat{x}_\ddagger(s) + R(s) - \hat{R}(s)\big]\mathrm{d}s. \tag{51}$$

To check that, note that $x_\ddagger(0) - \hat{x}_\ddagger(0) = x^\star - \hat{x}^\star$, and by differentiating (51), we get

$$\begin{aligned} x'_\ddagger(t) - \hat{x}'_\ddagger(t) = &-\mathbf{H}e^{t\mathbf{H}}(x^\star - \hat{x}^\star) + \mathbf{H}e^{t\mathbf{H}}\int_0^t e^{-s\mathbf{H}}\big[(\mathbf{H} - \hat{\mathbf{H}})\hat{x}_\ddagger(s) + R(s) - \hat{R}(s)\big]\mathrm{d}s \\ &+ (\mathbf{H} - \hat{\mathbf{H}})\hat{x}_\ddagger(t) + R(t) - \hat{R}(t). \end{aligned} \tag{52}$$

From (51), $e^{t\mathbf{H}}(x^\star - \hat{x}^\star)$ may be expressed as

$$e^{t\mathbf{H}}(x^\star - \hat{x}^\star) = -(x_\ddagger(t) - \hat{x}_\ddagger(t)) + \int_0^t e^{(t-s)\mathbf{H}}\big[(\mathbf{H} - \hat{\mathbf{H}})\hat{x}_\ddagger(s) + R(s) - \hat{R}(s)\big]\mathrm{d}s. \tag{53}$$

By reporting (53) in (52) we indeed obtain (50).

Using the triangle inequality in (51), and the fact that all the eigenvalues of $\mathbf{H}$ and $\hat{\mathbf{H}}$ are in $(-\infty, -\nu)$ we then get by (48) and (49) that

$$\begin{aligned} \|x_\ddagger(t) - \hat{x}_\ddagger(t)\| \leq\ & e^{-\nu t}\|x^\star - \hat{x}^\star\| \\ &+ \sqrt{d}\int_0^t e^{-\nu(t-s)}\left[\eta_2\|\hat{x}_\ddagger(s)\| + \tfrac{\kappa_3}{2}\|x_\ddagger(s)\|^2 + \tfrac{\kappa_3+\eta_3}{2}\|\hat{x}_\ddagger(s)\|^2\right]\mathrm{d}s. \end{aligned}$$

By Lemma 6, $\max(\|x_\ddagger(t)\|, \|\hat{x}_\ddagger(t)\|) \leq C_6 e^{-\nu t}$ for all $t \geq 0$. We use this to bound the integral above. We have

$$\begin{aligned} &\int_0^t e^{-\nu(t-s)}\left[\eta_2\|\hat{x}_\ddagger(s)\| + \tfrac{\kappa_3}{2}\|x_\ddagger(s)\|^2 + \tfrac{\kappa_3+\eta_3}{2}\|\hat{x}_\ddagger(s)\|^2\right]\mathrm{d}s \\ &\quad\leq \int_0^t e^{-\nu(t-s)}\left[\eta_2 C_6 e^{-\nu s} + \tfrac{\kappa_3}{2}C_6^2 e^{-2\nu s} + \tfrac{\kappa_3+\eta_3}{2}C_6^2 e^{-2\nu s}\right]\mathrm{d}s \\ &\quad\leq C_6 e^{-\nu t}\left[\eta_2 t + (\kappa_3 + \eta_3)C_6\frac{1 - e^{-\nu t}}{\nu}\right]. \end{aligned}$$

Hence

$$\|x_\ddagger(t) - \hat{x}_\ddagger(t)\| \leq e^{-\nu t}\|x^\star - \hat{x}^\star\| + \sqrt{d}C_6 e^{-\nu t}\left[\eta_2 t + (\kappa_3 + \eta_3)C_6\frac{1 - e^{-\nu t}}{\nu}\right]. \tag{54}$$

By the triangle inequality, $\|x(t)-\hat{x}(t)\| \le \|x^\star - \hat{x}^\star\| + \|x_\ddagger(t) - \hat{x}_\ddagger(t)\|$, and using (46) and (54), we deduce that

$$\|x(t)-\hat{x}(t)\| \le (1+e^{-\nu t})Q_0\sqrt{\eta_0} + \sqrt{d}C_6 e^{-\nu t}\left[\eta_2 t + (\kappa_3+\eta_3)C_6\frac{1-e^{-\nu t}}{\nu}\right], \quad \text{for all } t \ge t_\ddagger.$$

By increasing the constant factors as needed, we arrive at

$$\|x(t)-\hat{x}(t)\| \le Q_1\big(\sqrt{\eta_0} + e^{-\nu t}\left[\eta_2 t + \kappa_3 + \eta_3\right]\big), \quad \text{for all } t \ge 0, \tag{55}$$

for some constant $Q_1 > 0$.

Bound for small t. We also have the following refinement of (41). Since f is C^3, there exists $\epsilon > 0$ such that all the eigenvalues of $H_f(x)$ exceed $-\overline{\nu}$ when $x \in \bar{B}(x^\star, \epsilon)$. Note that this implies that ∇f is Lipschitz on $\bar{B}(x^\star,\epsilon)$ with constant $\overline{\nu}$.

Keeping $\epsilon > 0$ fixed, let t_ϵ be such that $x(t) \in \bar{B}(x^\star,\epsilon)$ and $\hat{x}(t) \in \bar{B}(\hat{x}^\star, \epsilon/2)$, for all $t \ge t_\epsilon$. Assume that η_0 is small enough that $\|\hat{x}^\star - x^\star\| \le \epsilon/2$, which is possible by (46). Then we also have $\hat{x}(t) \in \bar{B}(x^\star,\epsilon)$

We may now apply Lemma 7 to get

$$\|x(t)-\hat{x}(t)\| \le \frac{\eta_1}{\overline{\nu}}e^{\overline{\nu}t}, \quad \forall t \ge t_\epsilon. \tag{56}$$

Since ϵ is fixed, by (41), for any $0 \le t \le t_\epsilon$, we have

$$\|x(t)-\hat{x}(t)\| \le \frac{\eta_1}{\sqrt{d}\kappa_2}e^{\sqrt{d}\kappa_2 t} \le \frac{e^{|\sqrt{d}\kappa_2 - \overline{\nu}|t_\epsilon}}{\sqrt{d}\kappa_2}\eta_1 e^{\overline{\nu}t}. \tag{57}$$

Combining (56) and (57) we deduce that

$$\|x(t)-\hat{x}(t)\| \le Q_2\eta_1 e^{\overline{\nu}t}, \quad \forall t \ge 0, \tag{58}$$

for some constant Q_2.

We now combine (55) and (58), and use the fact that $te^{-\nu t} \le \frac{1}{\nu-\underline{\nu}}e^{-\underline{\nu}t}$ for all $t \ge 0$, to arrive at

$$\|x(t)-\hat{x}(t)\| \le Q_3 \min\left[\sqrt{\eta_0} + e^{-\underline{\nu}t}, \eta_1 e^{\overline{\nu}t}\right], \quad \forall t \ge 0, \tag{59}$$

for some constant Q_3. We shall show that the bound (15) follows from (59). To verify this, we start with

$$\min\left[\sqrt{\eta_0} + e^{-\underline{\nu}t}, \eta_1 e^{\overline{\nu}t}\right] \le 2B(t), \quad B(t) := \min\left[\max\{\sqrt{\eta_0}, e^{-\underline{\nu}t}\}, \eta_1 e^{\overline{\nu}t}\right].$$

Set $t_0 = \frac{1}{2\underline{\nu}}\log(1/\eta_0)$ and note that

$$\max\{\sqrt{\eta_0}, e^{-\underline{\nu}t}\} = \begin{cases} e^{-\underline{\nu}t} & \text{when } t \le t_0 \\ \sqrt{\eta_0} & \text{when } t \ge t_0. \end{cases}$$

- When $t \ge t_0$, then we simply observe that $B(t) \le \eta_0^{1/2}$.

- When $t \le t_0$, we have $B(t) = \min\left\{e^{-\underline{\nu}t}, \eta_1 e^{\overline{\nu}t}\right\}$. Let $t_1 = \frac{1}{\underline{\nu}+\overline{\nu}}\log(1/\eta_1)$. Note that the map defined on $[0,\infty)$ by $t \mapsto \min\left\{e^{-\underline{\nu}t}, \eta_1 e^{\overline{\nu}t}\right\}$ is increasing over $[0,t_1]$, decreasing over $[t_1,\infty)$, and that

$$\min\left\{e^{-\underline{\nu}t}, \eta_1 e^{\overline{\nu}t}\right\} = \begin{cases} \eta_1 e^{\overline{\nu}t} & \text{when } t \le t_1 \\ e^{-\underline{\nu}t} & \text{when } t \ge t_1. \end{cases}$$

  - When $t_1 \ge t_0$, $B(t) \le B(t_0) = \eta_1 e^{\overline{\nu}t_0} = \eta_1 \eta_0^{-\frac{\overline{\nu}}{2\underline{\nu}}}$.
  - When $t_1 < t_0$, then $B(t) \le B(t_1) = e^{-\underline{\nu}t_1} = \eta_1^{\frac{\underline{\nu}}{\underline{\nu}+\overline{\nu}}}$

  Since $t_0 \le t_1$ if, and only if, $\eta_1\eta_0^{-\frac{\overline{\nu}}{2\underline{\nu}}} \le \eta_1^{\frac{\underline{\nu}}{\underline{\nu}+\overline{\nu}}}$, we conclude that $B(t) \le \min\left\{\eta_1^{\frac{\underline{\nu}}{\underline{\nu}+\overline{\nu}}}, \eta_1\eta_0^{-\frac{\overline{\nu}}{2\underline{\nu}}}\right\}$ for all $t \le t_0$.

Hence, we worked (59) into

$$\sup_{t\ge 0}\|x(t)-\hat{x}(t)\| \le 2Q_3 \max\left\{\sqrt{\eta_0}, \min\left[\eta_1^\delta, \eta_0^{\frac{\delta-1}{2\delta}}\eta_1\right]\right\},$$

where $\delta = \frac{\underline{\nu}}{\underline{\nu}+\overline{\nu}}$. We note that

$$\sqrt{\eta_0} \le \eta_1^\delta \iff \eta_0^{\frac{1}{2\delta}} \le \eta_1 \iff \sqrt{\eta_0} \le \eta_1\eta_0^{\frac{1}{2}-\frac{1}{2\delta}} \iff \sqrt{\eta_0} \le \eta_0^{\frac{\delta-1}{2\delta}}\eta_1$$

and that

$$\eta_1^\delta \le \eta_0^{\frac{\delta-1}{2\delta}}\eta_1 \iff \eta_0^{\frac{1-\delta}{2\delta}} \le \eta_1^{1-\delta} \iff \sqrt{\eta_0} \le \eta_1^\delta.$$

Using these equivalences we deduce that

$$\max\left\{\sqrt{\eta_0}, \min\left[\eta_1^\delta, \eta_0^{\frac{\delta-1}{2\delta}}\eta_1\right]\right\} = \max\left\{\sqrt{\eta_0}, \eta_1^\delta\right\}.$$

4.4 Proof of Lemma 2

For any d-tuple $\beta = (\beta_1, \dots, \beta_d) \in \mathbb{N}^d$, let $|\beta| = \beta_1 + \cdots + \beta_d$, and let

$$\partial^\beta g(x) = \frac{\partial^{|\beta|}}{\partial x_1^{\beta_1}\dots\partial x_d^{\beta_d}}g(x) \tag{60}$$

denote the β-th partial derivative of a function $g : \mathbb{R}^d \to \mathbb{R}$. Let C be such that $|\partial^\beta f(x)| \le C$ for all $x \in \mathbb{R}^d$ and all β such that $|\beta| \le 3$.

Fix $\beta \in \mathbb{N}^d$ with $|\beta| = \ell \le 3$. Since the partial derivatives of Φ up to the order 3 vanish at infinity, and those of f are bounded, we obtain by integrating by parts

$$\begin{aligned}
\mathbb{E}\big[\partial^\beta \hat{f}(x)\big] &= \frac{1}{h^{d+\ell}}\mathbb{E}\left[\partial^\beta\Phi\left(\frac{x-X}{h}\right)\right] \\
&= \frac{1}{h^d}\int_{\mathbb{R}^d}\Phi\left(\frac{x-u}{h}\right)\partial^\beta f(u)\mathrm{d}u \\
&= \int_{\mathbb{R}^d}\Phi(u)\,\partial^\beta f(x-hu)\mathrm{d}u.
\end{aligned}$$

When $\ell = 3$, we simply deduce that

$$\left|\mathbb{E}\big[\partial^\beta \hat{f}(x)\big] - \partial^\beta f(x)\right| \le \left|\mathbb{E}\big[\partial^\beta \hat{f}(x)\big]\right| + C \le 2C,$$

using Jensen's inequality.

When $\ell = 2$, we use a Taylor expansion of order 1, to get

$$\left|\partial^\beta f(x - hu) - \partial^\beta f(x)\right| \le \sqrt{d}Ch\|u\|, \quad \forall x, u \in \mathbb{R}^d,$$

and deduce that

$$\left|\mathbb{E}\big[\partial^\beta \hat{f}(x)\big] - \partial^\beta f(x)\right| \le h\sqrt{d}C \int_{\mathbb{R}^d} \|u\|\Phi(u)\mathrm{d}u,$$

using the fact that Φ integrates to 1.

When $\ell \le 1$, we use a Taylor expansion of order 2, to get

$$\left|\partial^\beta f(x - hu) - \partial^\beta f(x) + h\big(\partial^\beta f\big)^{(1)}(x)[u]\right| \le dCh^2\|u\|^2, \quad \forall x, u \in \mathbb{R}^d,$$

and deduce that

$$\left|\mathbb{E}\big[\partial^\beta \hat{f}(x)\big] - \partial^\beta f(x)\right| \le h^2\, dC \int_{\mathbb{R}^d} \|u\|^2\Phi(u)\mathrm{d}u,$$

using the fact that Φ integrates to 1 and kills moments of order 1 by assumption (18).

4.5 Proof of Lemma 3

From Theorem 4.1 in Mason (2012), we immediately deduce the following. (Note that in the statement of condition (G.iii) of Theorem 4.1 in Mason (2012), $\mathcal{G}$ should be corrected to be $\mathcal{G}_0$).

Lemma 9 *Let f be a density on $\mathbb{R}^d$ and let $X \sim f$. Let $\mathcal{G}$ be a class of uniformly bounded measurable functions $\mathbb{R}^d \times (0,1] \to \mathbb{R}$, such that*

$$\sup_{g\in\mathcal{G}} \sup_{h\in(0,1]} \frac{1}{h^d}\mathbb{E}\left[g(X,h)^2\right] < \infty, \tag{61}$$

and such that the class

$$\mathcal{G}_0 = \{x \mapsto g(x,h) : g \in \mathcal{G}, h \in (0,1)\} \tag{62}$$

is pointwise measurable and of VC-type. Then there exists a $0 < b_0 < 1$ such that if $X_1, X_2, \ldots$ is an iid sequence from f,

$$\limsup_{n\to\infty} \sup_{g\in\mathcal{G}} \sup_{\frac{\log n}{n} \le h^d \le b_0} \sqrt{\frac{n}{h^d \log n}}\left|\frac{1}{n}\sum_{i=1}^n g(X_i,h) - \mathbb{E}[g(X,h)]\right| < \infty, \quad \textit{almost surely.} \tag{63}$$

For the definitions of VC-type and pointwise measurable, we refer to Mason (2012, Sec. 4.2) or van der Vaart and Wellner (1996).

Remark 1 *The assumption that the class $\mathcal{G}_0$ be pointwise measurable insures that the supremum of functionals defined on $\mathcal{G}_0$ be measurable. Another condition that is often imposed on a class of functions is image-Suslin measurable. For details see page 138 of de la Peña and Giné (1999).*

Let Φ be a kernel and f be a density as in Lemma 3, and let $X \sim f$. Fixing $\beta \in \mathbb{N}^d$ such that $|\beta| \le 3$, we apply this lemma to

$$\mathcal{G} = \big\{(x,h) \mapsto \partial^\beta\Phi(\tfrac{u-x}{h}) : u \in \mathbb{R}^d\big\}.$$

For any $x, u \in \mathbb{R}^d$ and $h \in (0,1]$,

$$\left|\partial^\beta\Phi(\tfrac{u-x}{h})\right| \le \|\partial^\beta\Phi\|_\infty,$$

so that $\mathcal{G}$ is uniformly bounded, and

$$\mathbb{E}\left[\partial^\beta\Phi\left(\frac{u-X}{h}\right)^2\right] = \int_{\mathbb{R}^d} \partial^\beta\Phi\left(\frac{u-x}{h}\right)^2 f(x)\mathrm{d}x,$$

which by the change of variables $v = \frac{u-x}{h}$ equals

$$h^d \int_{\mathbb{R}^d} \partial^\beta\Phi(v)^2 f(u-hv)\mathrm{d}v \le h^d\|f\|_\infty\|\partial^\beta\Phi\|_\infty \int_{\mathbb{R}^d}\left|\partial^\beta\Phi(v)\right|\mathrm{d}v, \tag{64}$$

where $\|f\|_\infty$, $\|\partial^\beta\Phi\|_\infty$, and $\int_{\mathbb{R}^d}\left|\partial^\beta\Phi(v)\right|\mathrm{d}v$ are finite by assumption. Hence $\mathcal{G}$ satisfies (61). In addition, $\mathcal{G}_0$ is seen to be pointwise measurable by consideration of the subclass

$$\big\{x \mapsto \partial^\beta\Phi(\tfrac{u-x}{h}) : u \in \mathbb{Q}^d, h \in (0,1] \cap \mathbb{Q}\big\}.$$

To see that $\mathcal{G}_0$ is of VC-type, notice that for any $x = (x_1, \ldots, x_d) \in \mathbb{R}^d$, $\partial^\beta\Phi(x) = \prod_{k=1}^d \phi_k^{(\beta_k)}(x_k)$. By assumption, $\phi_k^{(\beta_k)}$ is of bounded variation on $\mathbb{R}$, so that by Nolan and Pollard (1987, Lem 22) the class of functions given by

$$\mathrm{g}_{0,k} := \left\{s \in \mathbb{R} \mapsto \phi_k^{(\beta_k)}(\tfrac{s-t}{h}) : s \in \mathbb{R},\, 0 < h \le 1\right\}$$

is of VC-type. Then an application of Einmahl and Mason (2000, Lem A1) shows that the class of functions $\mathcal{G}_0$, which is equivalently expressed as

$$\mathcal{G}_0 := \{(u_1, \ldots, u_d) \mapsto g_1(u_1)\ldots g_d(u_d) : g_k \in \mathrm{g}_{0,k},\, k = 1, \ldots, d\},$$

is of VC-type.

Therefore, the conditions of Lemma 9 are met, so that we can assert that (63) holds. Noticing that

$$\frac{1}{n}\sum_{i=1}^n \partial^\beta\Phi(\tfrac{u-X_i}{h}) = h^{\ell+d}\partial^\beta f_{n,h}(u),$$

and consequently

$$\mathbb{E}\left[\partial^\beta\Phi(\tfrac{u-X}{h})\right] = h^{\ell+d}\,\mathbb{E}\left[\partial^\beta f_{n,h}(u)\right],$$

we see that (63) yields

$$\limsup_{n\to\infty} \sup_{u\in\mathbb{R}^d} \sup_{\frac{\log n}{n} \le h^d \le b_0} \sqrt{\frac{n}{h^d \log n}}h^{\ell+d}\left|\partial^\beta f_{n,h}(u) - \mathbb{E}\left[\partial^\beta f_{n,h}(u)\right]\right| < \infty, \quad \text{almost surely,}$$

which is exactly (20).

4.6 Proof of Theorem 3

As in the proofs of Theorems 1 and 2, we may assume without loss of generality that $\mathcal{L}_f(f(x_0/2)) \subset \bar{B}(x_0, 3r_0)$, with $r_0 = \sup_{t\geq 0} \|x(t) - x_0\|$, which implies that $\mathcal{L}_f(f(x_0/2)$ is compact. In this subsection,

$$S = \mathcal{L}_f(f(x_0)/2), \quad \kappa_\ell = \kappa_\ell(f, S), \quad \hat{f} = \hat{f}_{n,h}, \tag{65}$$

for short.

For any integer $0 \leq \ell \leq 2$, we let

$$\eta_\ell^\star = \sup_{x\in S} \left\| \hat{f}^{(\ell)}(x) - f^\ell(x) \right\|, \quad \eta_\ell = \sup_{x\in S} \left\| \left(\log \hat{f}\right)^{(\ell)}(x) - \left(\log f\right)^{(\ell)}(x) \right\|,$$

where the norm used is defined in (8). (Keep in mind that we are suppressing in the notation $\hat{f}^{(\ell)}$ and η_ℓ the dependence on n and h.) From (19) and (20), we see that, since $\frac{nh^{d+6}}{\log n} \to \infty$, for any $0 \leq \ell \leq 2$, $\eta_\ell^\star \to 0$ almost surely as $n \to \infty$ while $\eta_3^\star = O(1)$ almost surely. Since $f(x) \geq f(x_0)/2 > 0$ for all x in S, and since $\eta_0^\star \to 0$ almost surely, then almost surely, for all n large enough, $\log \hat{f}(x)$ is well-defined for all x in S. We have

$$\frac{\partial}{\partial x_i} \log f(x) = \frac{1}{f} \frac{\partial}{\partial x_i} f(x), \qquad \frac{\partial}{\partial x_i} f^{-k}(x) = -k f^{-(k+1)}(x) \frac{\partial}{\partial x_i} f(x), \tag{66}$$

and similarly for $\hat{f}$ almost surely for all n large enough, using the fact that $f(x) \geq f(x_0)/2$ for all x in S once again. We see using (66) that for each $0 \leq \ell \leq 3$ and $\beta \in \mathbb{N}^d$ with $|\beta| = \ell$ there is a continuously differentiable function $F_{\ell,\beta}$ defined on $(0,\infty) \times \mathbb{R}^d \times \cdots \times \mathbb{R}^{d\ell}$, where $\mathbb{R}^{d\ell}$ is suppressed if $\ell = 0$, such that for all $x \in S$

$$\partial^\beta \log f(x) = F_{\ell,\beta}\left(f(x), \partial^\alpha f(x),\, \alpha \in \mathbb{N}^d \text{ with } |\alpha| = k,\, k = 1, \ldots, \ell \right),$$

where with some abuse of notation, $\partial^\alpha f(x)$, $\alpha \in \mathbb{N}^d$ with $|\alpha| = k$, $k \geq 1$, represents a dk-vector in $\mathbb{R}^{dk}$, and, similarly, almost surely, for all large enough n

$$\partial^\beta \log \hat{f}(x) = F_{\ell,\beta}\left(\hat{f}(x), \partial^\alpha \hat{f}(x),\, \alpha \in \mathbb{N}^d \text{ with } |\alpha| = k,\, k = 1, \ldots, \ell \right).$$

Observe that the set of points

$$\left\{ \left(f(x), \partial^\alpha f(x),\, \alpha \in \mathbb{N}^d \text{ with } |\alpha| = k,\, k = 1, \ldots, \ell \right) : x \in S \right\} \tag{67}$$

lies in a compact subset of $(0,\infty) \times \mathbb{R}^d \times \cdots \times \mathbb{R}^{d\ell}$, and almost surely for all large enough n the same is true for the set of points formed as in (67) with f replaced by $\hat{f}$. Since a compact subset of $(0,\infty) \times \mathbb{R}^d \times \cdots \times \mathbb{R}^{d\ell}$ can be chosen to include both of these sets, using the mean value theorem we see that for some constant $C(\ell, \beta) > 0$

$$\sup_{x\in S} \left| \partial^\beta \log f(x) - \partial^\beta \log \hat{f}(x) \right|$$
$$\leq C(\ell,\beta) \max \left\{ \sup_{x\in S} \left| \partial^\alpha f(x) - \partial^\alpha \hat{f}(x) \right| : \alpha \in \mathbb{N}^d \text{ with } |\alpha| = k,\, k = 0, \ldots, \ell \right\}.$$

Using (10) this proves that there exists a constant $C > 0$ such that almost surely for all n large enough

$$\eta_\ell \leq C(\eta_0^\star + \cdots + \eta_\ell^\star), \quad 0 \leq \ell \leq 3. \tag{68}$$

Hence, almost surely, $\eta_\ell \to 0$ for all $\ell = 0, 1, 2$ and $\limsup \eta_3 < \infty$. We are then in a position to apply Corollary 1. Noting that $\sqrt{\left(\frac{\log n}{nh^{d+2}}\right)} = o(h^2)$ under the condition $\frac{nh^{d+6}}{\log n} \to \infty$, and using the inequalities in (68), almost surely for all n large enough, $\eta_0 \leq Ch^2$ and $\eta_1 \leq Ch^2$ for some constant $C > 1$, and since $\delta < 1/2$, almost surely, for all n large enough, $\max\{\sqrt{\eta_0}, \eta_1^\delta\} \leq Ch^{2\delta}$. We conclude by applying Corollary 1.

Acknowledgments

The authors are grateful to Jacob Sterbenz for pointers and stimulating discussions, and to three anonymous referees for comments and for bringing to their attention some important references that were missing, in particular, (Merlet and Pierre, 2010; Stetter, 1973; Comaniciu and Meer, 2002). Abstract

Ever increasing data quantity makes ever more urgent the need for highly scalable learners that have good classification performance. Therefore, an out-of-core learner with excellent time and space complexity, along with high expressivity (that is, capacity to learn very complex multivariate probability distributions) is extremely desirable. This paper presents such a learner. We propose an extension to the k-dependence Bayesian classifier (KDB) that discriminatively selects a sub-model of a full KDB classifier. It requires only one additional pass through the training data, making it a three-pass learner. Our extensive experimental evaluation on 16 large data sets reveals that this out-of-core algorithm achieves competitive classification performance, and substantially better training and classification time than state-of-the-art in-core learners such as random forest and linear and non-linear logistic regression.

Keywords: scalable Bayesian classification, feature selection, out-of-core learning, big data

1. Introduction

Until very recently most machine learning research has been conducted in the context of relatively small datasets, that is, no more than 50,000 instances and a few hundred attributes. It is only in the last five years that larger datasets have started to appear in the literature (Erhan et al., 2010; Sonnenburg and Franc, 2010; Agarwal et al., 2014; Sariyar et al., 2011) on a regular basis. We argue that larger data quantities do not simply call for scaling-up of existing learning algorithms. Rather, we believe, as first argued by Brain and Webb (1999), that the most accurate learners for large data will have much lower bias than the most accurate learners for small data. Thus we need a new generation of computationally efficient low bias learners. To achieve the necessary efficiency, a learning algorithm for very large data should ideally require only a few passes through the training data. Further, to remove memory size as a bottleneck, the algorithm should be able to process data out-of-core.

In this paper, we extend the KDB classifier. KDB is a form of restricted Bayesian network classifier (BNC). It has numerous desirable properties in the context of learning from large quantities of data. These include:

- the capacity to control its bias/variance trade-off with a single parameter, k,
- it does not require data to be held in-core,
- the capacity to learn in just two passes through the training data.

The contributions of this paper are as follows:

- We extend KDB to perform discriminative model selection in a single additional pass through the training data. In this single pass, our algorithm selects between both attribute subsets and network structures. The resulting highly scalable algorithm combines the computational efficiency of classical generative learning with the low bias of discriminative learning.
- We compare the performance of our algorithm with other state-of-the-art classifiers on several large datasets, ranging in size from 165 thousand to 54 million instances and 5 to 784 attributes. We show that our highly scalable algorithms achieve comparable or lower error on large data than a range of out-of-core and in-core state-of-the-art classification learning algorithms.

To illustrate our motivations, in Figure 1 we present learning curves for the poker-hand dataset (which is described in Table 7 in Appendix A). As can be seen, for lower quantities of data the lower variance delivered by low values of k results in lower error for KBD, while for larger quantities of data the lower bias of higher values of k results in lower error. While selective KDB sometimes selects a k that overfits this data with smaller training set sizes, when the training set size exceeds 550,000 it successfully selects the best k and by selecting a subset of the attributes it can substantially reduce error across the entire range of training set sizes relative to the KDB classifier using the same k.

Section 2 reviews the state-of-the-art in out-of-core BNCs and introduces our proposal: selective KDB (SKDB, Section 2.1). In Section 3 we present a set of comparisons for our proposed algorithm on 16 big datasets with *out-of-core* BNCs (Section 3.1), *out-of-core* linear classifiers using Stochastic Gradient Descent (Section 3.2), and with *in-core* (batch) learners BayesNet and Random Forest (Section 3.3). To finalize, Section 4 shows the main conclusions and outlines future work.

2. Scalable Bayesian Networks for Classification

We define the classification learning task as the assignment of a label $y \in \Omega_Y$, from a set of c labels of the class variable Y, to a given example $\mathbf{x} = (x_1, \ldots, x_d)$, with values for the d attributes $\mathcal{A} = \{X_1, \ldots, X_d\}$. Bayesian networks (BN) (Pearl, 1988) provide a framework for computing the joint probability of these d random variables. A BN is

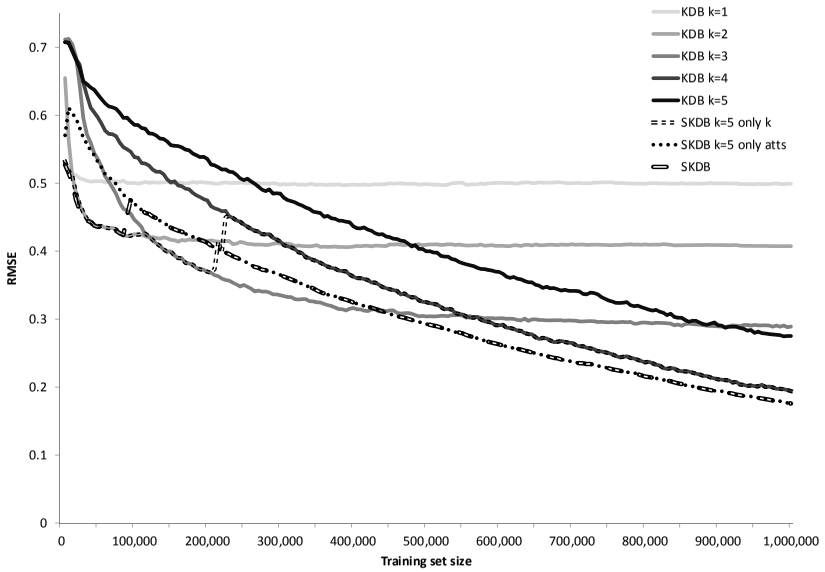

Figure 1: Learning curves for KDB and Selective KDB on the poker-hand dataset. *The values plotted are averages over 10 runs. For each run 1,000 examples are selected as a test set and samples of successive sizes are selected from the remaining data for training. As can be seen, for lower quantities of data the lower variance delivered by low values of k results in lower error for KBD, while for larger quantities of data the lower bias of higher values of k results in lower error, although there is not sufficient data for $k = 5$ to asymptote on this dataset. While only selecting a k (SKDB k=5 only k) causes selective KDB to overfit this data with smaller training set sizes (between 20,000 and 550,000), when the training set size is large enough it successfully selects the best k. Only selecting attributes (SKDB k=5 only atts) always reduces error (relative to KDB k=5). By selecting both k and attributes (SKDB k=5) selective KDB substantially reduces error relative to KDB with any value of k once there are more than approximately 450,000 training examples.*

a directed acyclic graph where the the joint probability of all attributes can be written as the product of the individual probabilities of all attributes given their parents, that is $p(y, \mathbf{x}) = p(y|\pi_y) \prod_{i=1}^{d} p(x_i|\pi_{x_i})$, where π_{x_i} denotes the parents of attribute X_i. If the structure is known, the likelihood of the BN given the data can be maximized by estimating $p(x_i|\pi_{x_i})$ using the empirical estimates from the training data $\mathcal{T}$, composed of t training instances.

While unrestricted BNs are the least biased, training such a model on even moderate size data sets can be extremely challenging, as the search-space that needs to be explored grows exponentially with the number of attributes. This has led to restricted BNCs, including naive Bayes (NB) (Duda and Hart, 1973; Minsky, 1961; Lewis, 1998), tree-augmented naive Bayes (TAN) (Friedman et al., 1997), averaged n-dependence estimators (ANDE) (Webb et al., 2012) and k-dependence estimators (KDB) (Sahami, 1996). These classifiers have in common either no structural learning or minimal structural learning that requires only one or two passes through the data. They have been referred to as semi-naive BNCs (Zheng and Webb, 2005). Even though highly biased due to their inherent conditional attribute independence assumption, they have been shown to be very effective classification methods.

NB is the simplest of the BNCs, assuming that all attributes are independent given the class. It estimates the joint probability using $\hat{p}(y) \prod_{i=1}^{d} \hat{p}(x_i|y)$, where $\hat{p}(\cdot)$ denotes an estimate of $p(\cdot)$. TAN is a structural augmentation of NB where every attribute has as parents the class and at most one other attribute. The structure is determined by using an extension of the Chow-Liu tree (Chow and Liu, 1968), that utilizes conditional mutual information to find a maximum spanning tree. This alleviates some of NB's independence assumption and therefore reduces its bias at the expense of increasing its variance. This results in better performance on larger data sets. TAN, provides an intermediate bias-variance trade-off, standing between NB on one hand and unrestricted BNCs on the other.

There has been a lot of prior work that has explored approaches to alleviate NB's independence assumption. One approach is to add a bounded number of additional interdependencies (Friedman et al., 1997; Zheng and Webb, 2000; Webb et al., 2005; Zhang et al., 2005; Yang et al., 2007; Flores et al., 2009a,b; Zheng et al., 2012; Zaidi et al., 2013). At the other extreme, Su and Zhang (2006) propose the use of a full Bayesian network. Of these algorithms, only two approaches allow the number of interdependencies to be adjusted to best accommodate the best trade-offs between bias and variance for differing data quantities. ANDE (Webb et al., 2012) averages many BNCs, where a parameter n controls the number of interdependencies to be modeled. KDB uses a parameter k to control the number of interdependencies modeled.

KDB relaxes NB's independence assumption by allowing every attribute to be conditioned on the class and, at most, k other attributes. Like TAN, KDB requires two passes over the training data for learning: the first pass collects the statistics to perform calculations of mutual information for structure learning, and the second performs the parameter learning based on the structure created in the former step (Algorithm 1). An advantage over the ANDE model is that KDB does not need to collect all statistics for all combinations of n or k attributes, allowing it to scale to higher order dependencies. It also has the capacity to select a model and hence more closely fit the data. This is a disadvantage for small data, which it may overfit, but KDB will often lead to higher accuracy than ANDE on large data which are more difficult to overfit.

Recently, some techniques have been proposed that address the classification problem with Bayesian networks from a relatively efficient discriminative perspective. Carvalho et al. (2011) propose a decomposable approximation to the conditional log-likelihood scoring criteria. Pernkopf and Bilmes (2010) propose a BNC learning algorithm with some resemblance to KDB but using discriminative evaluation for parent assignment. Neither

Algorithm 1: The KDB algorithm

Input: Training set $\mathcal{T}$ with attributes $\{X_1, \ldots, X_a, Y\}$ and k.
Output: KDB model.

Let $\mathcal{G}$ be a directed graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, in which $\mathcal{V}$ is a set of vertices and $\mathcal{E}$ is a set of links.
Let Θ be a Bayesian network with structure $\mathcal{G}$.
First pass begin
  $\mathcal{G}$ =**learnStructure**($\mathcal{T}$) ; `/* Algorithm 2 */`
end
Second pass begin
  Θ = **learnParameters**($\mathcal{T}$, $\mathcal{G}$) ; `/* Algorithm 3 */`
end
Let KDB be a BN with structure $\mathcal{G}$ and conditional probability distributions in Θ.
return *KDB*

Algorithm 2: learnStructure($\mathcal{T}$)

Input: Training set $\mathcal{T}$
Output: $\mathcal{G}$, network structure.

Calculate $MI(X_i; Y)$ from $\mathcal{T}$ for all attributes.
Calculate $MI(X_i; X_j|Y)$ from $\mathcal{T}$ for each pair of attributes $(i \neq j)$.
Let $\mathcal{L}$ be a list of all X_i in decreasing order of $MI(X_i; Y)$.
$\mathcal{V} = \{Y\}$; $\mathcal{E} = \emptyset$;
for $i = 1 \rightarrow \mathcal{L}.size$ **do**
  $\mathcal{V} = \mathcal{V} \cup \mathcal{L}_i$;
  $\mathcal{E} = \mathcal{E} \cup (Y, \mathcal{L}_i)$;
  $vk = min(i - 1, k)$;
  while *($vk > 0$)* **do**
    $m = \text{argmax}_j\{MI(\mathcal{L}_i; \mathcal{L}_j|Y) \mid 1 \leq j < i \wedge (\mathcal{L}_j, \mathcal{L}_i) \notin \mathcal{E}\}$;
    $\mathcal{E} = \mathcal{E} \cup (\mathcal{L}_j, \mathcal{L}_i)$;
    $vk = vk - 1$;
  end
end
return $\mathcal{G}$

Algorithm 3: learnParameters($\mathcal{T}$, $\mathcal{G}$)

Input: Training set $\mathcal{T}$ and $\mathcal{G}$.
Output: Θ.

Initialize Θ to structure $\mathcal{G}$.
Compute the CPTs for Θ from $\mathcal{T}$.
return Θ

algorithm is suited to learning a BNC in a limited number of passes through the training data.

There have also been some important refinements that improve KDB's performance. Bouckaert (2006) proposes averaging all possible network structures for a fixed value of k (including lower orders). Time complexity is significantly reduced by multiplying the sum of every attribute given all possible parents in the order. For $k = 2$ the authors propose a simplification that identifies one attribute as super parent and consider for every attribute of the class, possibly the super parent and possibly one other lower ordered attribute. The sum of class probabilities is taken as selecting criteria for the superparent. However they agree that this approach is not easy to implement incrementally for large datasets. Rubio and Gámez (2011) present a variant of KDB that employs a hill-climbing search to incrementally build a KDB classifier. This approach requires at least one pass through the data for each attribute.

2.1 Selective KDB

The parameter k controls KDB's bias-variance trade-off. Higher k results in higher variance and lower bias. Unfortunately there is no apriori means to preselect a value of k for which this trade-off will result in the lowest error for a given training set as this is a complex interplay between the data quantity and the complexity and strength of the interactions between the attributes. A further factor that can increase KDB's error is that attributes that carry no useful information about the class must be treated as if they do, which invariably introduces some noise into the estimates. Discarding these attributes can both reduce error and classification time. Our proposed algorithm, Selective KDB (SKDB), extends KDB to select between attribute subsets and values of k in a single additional pass through the training data.

In the general case, attribute selection is a complex combinatorial task. For d attributes there are 2^d alternative attribute subsets that could be explored. Many attribute selection algorithms utilize either forward selection or backwards elimination hill-climbing strategies (Langley and Sage, 1994; Koller and Sahami, 1996). These start with either no attributes or all attributes and then iteratively add or remove one attribute at a time. This requires that all attribute subsets resulting from adding/removing any one attribute are considered at each step. There are at most d such steps resulting in $\mathcal{O}(d^2)$ attribute subset evaluations. If all candidate modifications to a current subset are considered simultaneously in a single pass through the data, this implies up to d passes for the attribute selection stage.

We seek to perform both attribute and best-k selection in a single pass. For attribute selection, we take advantage of the attribute ordering selected by KDB based on mutual information with the class. Given that the attributes are sorted on this order, we consider only the attribute sets $\{x_1, \ldots x_i\}, 1 \leq i \leq d$, that is attribute sets that each contain the i attributes that have the greatest mutual information with the class. These d attribute subsets are evaluated simultaneously in a single pass through the data using leave-one-out cross validation (LOOCV). For big data, LOOCV can be expected to provide an unbiased low-variance estimate of the out-of-sample error. It is possible to efficiently evaluate all d subsets simultaneously, because a KDB classifier using subset $\{x_1, \ldots x_i\}$ is a minor addition to a KDB classifier using subset $\{x_1, \ldots x_{i-1}\}$. Calculating a KDB classifier for all attributes

already incorporates all the calculations for all the KDB classifiers using subsets that we consider.

We use incremental cross validation (Kohavi, 1995), which performs LOOCV on BNCs very efficiently. A naive approach to LOOCV will for each holdout example recalculate from scratch all of the joint frequency counts required by a BNC. Incremental cross-validation first gathers the counts for all training examples in a single pass through the data. Then, when classifying a holdout example, its counts are removed from the table. SKDB collects the complete counts in its second pass through the training data and performs LOOCV in a third pass.

Using the given order, the number of attributes with the best leave-one-out error is selected. In case of a draw, preference is given to the smallest number of attributes. Any loss function can be used that is a function, $\{\langle y^{\mathbf{x}}, \hat{p}(Y, \mathbf{x})\rangle \mid \mathbf{x} \in \mathcal{T}\} \rightarrow \mathbb{R}$ over all objects $\mathbf{x} \in \mathcal{T}$ of a predicted class distribution $\hat{p}(Y, \mathbf{x})$ and the true class for that object, $y^{\mathbf{x}}$. Such loss functions include 0-1 loss, root mean square error, log-loss, Matthews correlation coefficient (Matthews, 1975) or Brier score (Brier, 1950) to name a few. Because we believe it to be an effective measure of the calibration of a classifier's class probability estimates, we use root mean squared error (RMSE) as follows:

$$RMSE = \sqrt{\frac{1}{t}\sum_{\mathbf{x}\in\mathcal{T}} (1 - \hat{p}(y^{\mathbf{x}}|\mathbf{x}))^2} \tag{1}$$

where $\hat{p}(y^{\mathbf{x}}|\mathbf{x})$ is the estimated posterior probability of the true class given $\mathbf{x}$, $y^{\mathbf{x}}$ the class label for the example $\mathbf{x}$.

In order to make full use of available computational resources while reducing the risk of overfitting, we propose to select algorithmically the best value of k for a particular dataset. Just as the KDB classifiers built on successive attribute subsets are embedded one inside the other, a KDB classifier with $k = i$, can be evaluated with little additional computational effort during the process of evaluating a KDB classifier with $k = i + 1$. We leverage this capacity to simultaneously evaluate KDB classifiers with all attribute subsets $\{x_1, \ldots x_{i-1}\}$ and values of k up to the maximum capacity available, taking advantage of the above mentioned LOOCV. The combination of attribute subset and k with the best LOOCV error is selected. In case of a draw, the smaller attribute subset and smaller value of k are selected. The resulting SKDB algorithm is presented in Algorithm 4.

In the first pass our implementation of SKDB generates a three-dimensional table of co-occurrence counts for each pair of attribute values and each class value. This is required to calculate the mutual information of each attribute with the class and the conditional mutual information of every pair of attributes given the class. The resulting space complexity is $\mathcal{O}(c(dv)^2)$. The time complexity of forming the three dimensional probability table is $\mathcal{O}(td^2)$, as an entry must be updated for every training case and every combination of two attribute-values for that case. To calculate the conditional mutual informations, SKDB must consider every pairwise combination of their respective values in conjunction with each class value $\mathcal{O}(c(dv)^2)$. Attribute ordering and parent assignment are $\mathcal{O}(d \log d)$ and $\mathcal{O}(d^2 \log d)$ respectively.

The second pass requires d tables of $k+2$ dimensions (one for each of k parents, one for the child and one for the class), with $\mathcal{O}(cdv^{k+1})$. Updating the probability tables is $\mathcal{O}(tdk)$.

Algorithm 4: The SKDB algorithm

Input: Training set $\mathcal{T}$ with attributes $\{X_1, \ldots, X_a, Y\}$ and $k^{\max}$.
Output: SKDB model.

First pass begin
  $\mathcal{G}$ =**learnStructure**($\mathcal{T}$) ; /* Algorithm 2 */
end
Second pass begin
  Θ = **learnParameters**($\mathcal{T}$, $\mathcal{G}$) ; /* Algorithm 3 */

The algorithm to this stage is simply KDB, with time complexity $\mathcal{O}(td^2 + c(dv)^2 + tdk)$, where v is the maximum number of values per attribute, and space complexity $\mathcal{O}(cdv^{k+1})$.

SKDB then extends KDB with an extra pass through the training data to perform leave-one-out cross validation for the different (ordered) attributes $\mathcal{O}(tcdk)$.

At classification time, SKDB need only store the conditional probability distribution for the d_b selected attributes and the k_b selected, $\mathcal{O}(cd_bv_b^k)$. The time complexity of classifying a single example is $\mathcal{O}(cd_bk_b)$.

In summary, SKDB requires an extra pass over the data compared with KDB, and the complexity of this extra pass is linearly dependent on the number of training examples, classes, attributes and k so the order of the time complexity increases from $\mathcal{O}(td^2 + c(dv)^2 + tdk)$ to $\mathcal{O}(td^2 + c(dv)^2 + tcdk)$. This is not a great increase in practice, since the number of classes is generally small, and indeed for high dimensional data the complexity of the first

pass can dominate that of the subsequent passes. Classification time and space complexity are reduced compared to KDB if the number of selected attributes $d_b < d$ and/or $k_b < k_{\max}$.

For the cost of this modest increase in computation, KDB is extended so as to discriminatively choose between a large class of alternative BNC models. Note that while it is possible to use cross validation to select between any collection of alternative models, it is only possible to do so in the extremely efficient manner we have developed for a very restricted class of learners, those that can be evaluated using incremental cross-validation and can be decomposed into nested models. The only types of learners of which we are aware that belong to this class are KDB and ANDE. We leave applying the approach to ANDE and variants of KDB as a topic for future research.

It may be possible to gain further efficiencies through sampling. As discussed in Hulten and Domingos (2002), it is sometimes possible to obtain sufficiently accurate estimates of the parameters for a learning program from a subsample of the full data. For very large datasets we could potentially utilize a random sample for the first pass of our algorithm, which only needs to estimate the parameters for three-way interactions between each pair of attributes and the class. We believe that the best value of k will usually be the one for which there is only just enough data in the dataset to obtain sufficiently accurate estimates of the required parameters. Thus we do not believe that sampling will usually be useful for the second pass. A technique such as Racing (Maron and Moore, 1994) could be used to select the model in the final pass. However, we suspect that it will usually require extremely large samples to confidently distinguish between the large number of very similar models that are assessed in the third pass. Given that the computational overheads of scanning a large dataset in random order are considerable, we do not believe that sampling will often be useful. However, this also remains a potential direction for future research.

3. Experimental Methodology

We undertook an extensive online search to gather a group of large datasets, all of which have more than 100K instances. These datasets are described in Table 7 in Appendix A, in ascending order of number of samples. Those below the double line have more than 1 million instances. All datasets except for `poker-hand`, `uscensus1990` and `splice` contain one or more numeric attributes. 7 datasets contain only numeric attributes: `MITFaceSetA`, `MITFaceSetB`, `MITFaceSetC`, `Mnist`, `USPSExtended`, `MSDYearPrediction` and `satellite`. For the Bayesian network classifiers we discretize numeric attributes using 5-bin equal frequency discretization. To avoid loading the whole data into memory, only a random sample of 100K points is used to define the bins for discretization.

As described in Section 2.1, we use SKBD with RMSE as the objective function for the third pass that selects between structures because we believe it to be a good measure of the calibration of a classifier's class probability predictions. However, this raises the issue that we might be reporting the measure that best favors our approach. To guard against this, we also present in the Appendices 0-1 loss results of the relative performance of all algorithms, and discuss these results in the appropriate sections below. Table 9 shows that when evaluated on RMSE, SKDB trained to optimize RMSE and SKDB trained to optimize 0-1 loss (SKDB$^{0\text{-}1}$) attain identical 0-1 loss on 12 out of 16 datasets, suggesting that SKDB's performance is similar when selection uses different but closely related loss functions.

	Train		Test	
	time	space	time	space

Table 1: Orders of complexity for the different semi-naive BNCs where: t is the number of training examples, d is the number of attributes, v is the maximum number of values per attribute, c the number of classes, d_b (the best d) is the remaining attributes after applying SKDB, and k_b (the best k) is the k value selected in SKDB.

The structure of the experimental Section is as follows: Section 3.1 compares our proposed SKDB algorithm's results with different out-of-core semi-naive BNCs. Section 3.2 compares our SKDB algorithm with several *online* (out-of-core) linear classifiers. Section 3.3 includes comparisons with two state-of-the-art in-core machine learning algorithms, BayesNet (Augmented Bayesian network) and Random Forest. Section 3.4 presents a global comparison of all learners considered, along with empirical time comparisons for the different out-of-core classifiers. Each of these sections provides a summary of the relevant results. Detailed RMSE error outcomes are presented in Table 8 in Appendix A and a more detailed analysis of results is provided in in Appendix C.

All the experiments for the Bayesian out-of-core algorithms use C++ software specially designed to deal with out-of-core classification methods[1]. Appendix B specifies the implementation details.

Note that both RMSE and 0-1 Loss are assessed using 10-fold cross-validation. This should not be confused with the leave-one-out cross-validation used to select the number of attributes and parents in SKDB. For each fold of the 10-fold cross-validation, SKDB performs leave-one-out cross-validation on the training set to select the parameters of the model that is then tested on the holdout test fold.

3.1 SKDB vs Bayesian Out-of-core Algorithms

The first set of experiments compare SKDB with the out-of-core semi-naive BNCs described in Section 2: NB, TAN, AODE and KDB. We also consider a version of SKDB which fixes the value of k and just selects among the attributes, referred to as SKDB$_k$. Table 1 shows a summary of the orders of complexity for all these BNCs.

Tables 2 and 3 show win-draw-loss records summarizing the relative RMSE and 0-1 loss of the different approaches. Cell $[i, j]$ of each table contains the number of wins/draw/losses

1. A minimum functional part of the software containing SKDB can be found in the (two first) authors' academic web pages, for example `http://www.csse.monash.edu.au/~webb/`.

	KDB				
	$k=1$	$k=2$	$k=3$	$k=4$	$k=5$
TAN	6-3-7	0-0-16	-	-	-
AODE	3-0-13	0-0-16	-	-	-
SKDB$_k$	8-8-0	6-10-0	6-10-0	7-9-0	6-9-1
SKDB	16-0-0	16-0-0	14-2-0	14-2-0	8-8-0
SKDB $k_{\max}=5$	6-10-0 (vs best k)*				

* The result is 6-9-1 (shift in uscensus) if SKDB is optimized with 0-1 loss.

Table 2: Win-draw-loss records when comparing the RMSE of different out-of-core BNCs.

	KDB				
	$k=1$	$k=2$	$k=3$	$k=4$	$k=5$
TAN	7-2-7	0-0-16	-	-	-
AODE	4-1-11	0-0-16	-	-	-
SKDB$_k$	5-10-1	5-11-0	6-10-0	6-9-1	6-9-1
SKDB	16-0-0	14-2-0	13-3-0	10-5-1	6-9-1
SKDB $k_{\max}=5$	5-11-0 (vs best k)*				

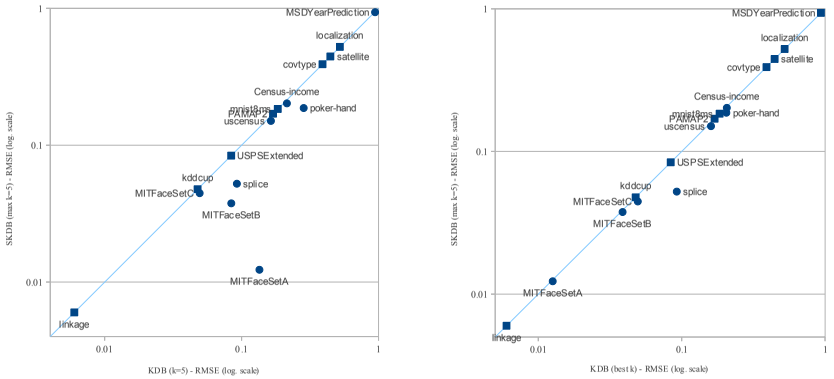
* The result is 6-10-0 if SKDB is optimized with 0-1 loss.

Table 3: Win-draw-loss records when comparing the 0-1 loss of different out-of-core BNCs.

for the classifier on row i against the classifier on column j. A win indicates that the algorithm has significantly lower error than the comparator. A draw indicates that the differences in error are not significant. Statistical significance has been assessed using Wilcoxon signed-rank tests to compare the 10-fold outputs. SKDB$_k$ and SKDB are compared against standard KDB with the same value of k. Additionally, SKDB with $k=5$ is compared against the lowest error of any standard KDB with k between 1 and 5 (which is a theoretical result, since the value of k that will minimize out of sample error can only be determined a posteriori).

The results indicate that TAN is competitive with KDB $k=1$, whereas AODE only achieves lower error on three or four of the datasets, depending on the loss function. We believe the reason AODE performs so poorly is that the advantage it gets in reduced variance from ensembling the d models is less useful for larger data. Both TAN and AODE consistently show higher error than higher orders of KDB on these large datasets. SKDB$_k$ only increases the RMSE of KDB relative to one value of k and only on one dataset, MITFaceSetB, and then only from 0.0841 to 0.0844. For many datasets it does not affect error (but nonetheless speeds up classification time). For many datasets it substantially reduces error, such as the reduction from 0.2048 to 0.1868 for poker-hand.

The average best k for SKDB across the 16 datasets is 4.08. On average, $78.46 \pm 29\%$ of the attributes are selected, which explains some of the ties, although in other cases SKDB



(a) KDB with $k=5$ and SKDB ($k_{\max}=5$).

(b) KDB with the best k for each dataset and SKDB ($k_{\max}=5$).

Figure 2: Scatter plot of RMSE comparisons for KDB and SKDB.

obtains the same results as KDB with the best value of k, but reducing the number of attributes. Indeed, reducing the number of attributes without affecting error is the worst case encountered by SKDB, because it never loses in terms of RMSE compared to the best KDB).

One could think that KDB with $k=5$ would be the fairest comparison with SKDB ($k_{\max}=5$). This comparison is shown in Figure 2a, where the X-axis represents the RMSE results with KDB with $k=5$ for the 16 datasets and the Y-axis the RMSE with SKDB. We have used a logarithmic scale because almost half of the points fall below the 0.1 range. Note that there is not a single point above the diagonal line, which indicates that SKDB is never worse than KDB $k=5$ or even KDB with the best k value considered, as shown in Figure 2b.

If only the best number of parents is selected by SKDB (best k) and no feature selection is performed, then the RMSE is always equivalent to the best RMSE obtained by KDB with any value of $k \in \{1,5\}$. That is, for all datasets SKDB without attribute selection is successful at selecting the best value of k with respect to the specified loss function. However, for five datasets the value of k that attains the best RMSE is different to that which attains the best 0-1 loss, demonstrating the value of optimizing with respect to the relevant loss function. These results are summarized on row SKDB$_{only_k}$ in Tables 8 and 9. The non-shaded cells on these rows correspond to those datasets for which feature selection contributes to further reduce the error of SKDB. There are 9 datasets in total for which the feature selection part of the algorithm does not reduce RMSE and 10 for which it does not reduce 0-1 loss. Note, however, that the extra computational complexity added by the feature selection evaluation is only related to the complexity of the loss function utilized. In the case of considering RMSE-like functions, this extra time is negligible, but if more

(a) Training Times (b) Classification Times

Figure 3: Training and classification time comparisons for KDB and SKDB$_k$.

complex evaluation functions were to be used in a highly time-constrained scenario, then only a random sample of instances could be considered at this step.

Figures 3a and 3b show the training and classification time comparisons for KDB and SKDB$_k$. Only the 11 smallest out of the 16 datasets have been considered for time measurement, since these experiments have been conducted on a desktop computer with an Intel(R) Core(TM) i5-2400 CPU @ 3.10 GHz, 3101 MHz, 64 bits and 7866 MiB of memory, whereas the remaining experiments have been conducted in a heterogeneous grid environment for which CPU times are not commensurable. Each bar represents the sum of all 11 datasets[2] in a 10-fold cross validation experiment. These graphs reinforce what the orders of complexity for the two algorithms indicated, that is, SKDB$_k$ requires a bit more time for training (extra pass on the data), while the classification time is less in practice, since the number of attributes selected is generally smaller than d.

Figures 4a and 4b show the training and classification empirical time comparisons of the different out-of-core BNCs relative to SKDB (with $k_{\max=5}$). The datasets are ordered at increasing time for SKDB. Note that SKDB always takes a bit more time for training, taking the largest time for `kddcup`, due to its large number of classes. Nevertheless, for the datasets with many attributes: `MITFaceSetA`, `MITFaceSetB`, `USPSExtended` and `MITFaceSetC`; the time differences with other BNCs become smaller. At classification time some gain can be appreciated for SKDB compared to KDB $k = 5$ if the selected k is less than 5. AODE's classification time is quadratic in the number of attributes, and hence much higher for all datasets.

3.2 SKDB vs Non-Bayesian Out-of-core Algorithms

In this section we compare SKDB with the state-of-the-art in online learning: Logistic Regression with Stochastic Gradient Descent (LRSGD). We use LRSGD's implementation in Vowpal Wabbit (VW) (Agarwal et al., 2014), an open source out-of-core linear learning system. VW provides a scalable implementation of LRSGD, which can be used in combination with several loss functions, different parameters for the learning rate and regularization, and quadratic or cubic combination of features.

(a) Training Times (b) Classification Times

Figure 4: Time comparisons per dataset for NB, TAN, AODE, KDB against SKDB.

We have performed experiments with varying numbers of passes for LRSGD, varying loss functions and combinations of features. We use the default advanced (step size) updates provided by VW, which are:

1. Importance weight invariance (Karampatziakis and Langford, 2011): this update is meant to be useful specially for cost-sensitive learning, that is, when the misclassification penalty varies for the different class labels. However, it is also claimed to reduce classification error even when no matrix of weights is provided. The following equation is used to compute the weights:

$$w_i \leftarrow w_i - s(\eta I)\frac{\partial L(\hat{y}_w(x), y)}{\partial w_i}, \tag{2}$$

where y is the true class; $\hat{y}_w(x)$ is the predicted value for example $x \in \mathbb{R}^d$ with parameters $w \in \mathbb{R}^d$; $L(\hat{y}_w(x), y)$ is the loss function; η is the learning rate; $I \in \mathbb{N}$ the number of times an example is more important than a typical example, in our case $I = 1$; and $s(\eta I)$ is a scaling factor, for which a closed form solution can be found for each loss function (Karampatziakis and Langford, 2011) .

2. Adaptive updates (Duchi et al., 2011; McMahan and Streeter, 2010): the learning rate must decay to converge. Instead of using $\eta_t = \frac{1}{\sqrt{t}}$ or $\eta_t = \frac{1}{t}$ at iteration t for all features, we use a per-feature learning rate decay:

$$w_i \leftarrow w_i - \eta\frac{g_{it}}{\sqrt{\sum_{t'=1}^{t} g_{it'}^2}}, g_{it} = \frac{\partial L(\hat{y}_w(x_t), y_t)}{\partial w_i}, \tag{3}$$

3. Normalized updates (Ross et al., 2013): instead of using Gaussian sphering standard solution, which would imply in-core processing and an increase in the size of the dataset, a scale-free update is used that renormalizes w_i at each timestep and keeps track of a global scale.

A fair comparison of LRSGD with SKDB should perform the same number of passes on the data. Since LRSGD requires data to be pre-shuffled, an n-pass LRSGD learner

		VWLF	VWSF
SKDB	RMSE	$7^{(+2)}$-0-7	14-0-2
	0-1 Loss	$8^{(+1)}$-1-$5^{(+1)}$	8-1-7

Table 4: Win-draw-loss records for VW and SKDB in terms of RMSE and 0-1 Loss

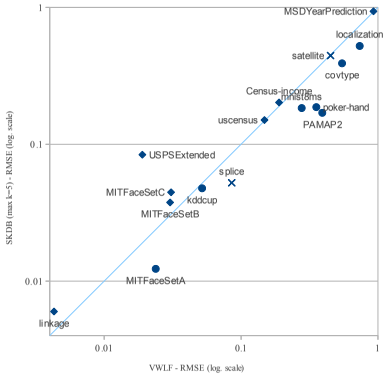
actually results in $n+1$ passes through the data. This is also true for SKDB on numeric data, as an extra pass is required for discretization. We have run experiments with 3, 10 and 20 passes for LRSGD. Each 10-fold cross validation experiment is repeated 10 times. Both the quadratic and logistic loss functions are considered. The one-against-all reduction from multiclass classification to binary classification has been used for the datasets with multiple class labels, which creates one binary problem for each of the classes. Table 10 in Appendix A shows the results for all of the different combinations for which we have conducted comprehensive experiments. The overall best results for LRSGD are obtained with 3 passes and using quadratic features. When the squared loss function is optimized we refer to it as VWSF, and VWLF if the logistic function is used. In all cases, SKDB is highly competitive compared to VW.

Note that while LRSGD has a number of parameters that could potentially be tuned using cross validation, doing so does not make a reasonable comparator to SKBD as such tuning would require multiple passes through the data for each cross-validation fold.

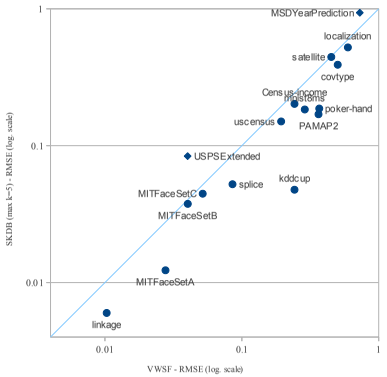
A win-draw-loss record summary is displayed on Table 4. The $^{(+1)}$ and $^{(+2)}$ for SKDB vs VWLF aim at distinguishing the results for `satellite` and `splice`, for which more than 400 hours are required to get the 10cv results using VWLF, and hence VWSF is considered instead. Irrespective of the fact that the SKDB model is optimized with respect to RMSE, the win-draw-loss records only vary for three datasets between evaluation with respect to RMSE or 0-1 loss. The win-draw-loss records remain exactly the same whichever loss function is optimized in VW (see Table 10 for more details).

Since the output of the VW algorithms is not probabilistic, we are using the class prediction, and hence computing 0-1 loss for comparisons with SKDB as well. By using, for example, the following sigmoid function $\frac{1}{1+e^{-\hat{y}w(x)}}$, probability estimates can be estimated from VW. Using this approach, the RMSE results for VWSF are only better than SKDB for two of the datasets (MSDYearPrediction and USPSExtended), both of them originally sparse and containing exclusively numeric attributes. These records improve when using a logistic function for optimization, that is VWLF (see Table 10 in Appendix A for more details). Nevertheless, computation time for VWLF is much larger than for VWSF as shown below.

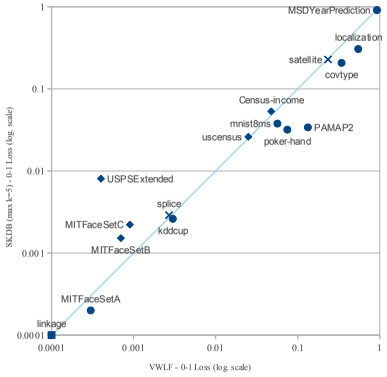
Figures 5a and 5b show the comparisons per dataset with SKDB in terms of RMSE, whereas Figures 5c and 5d show comparisons per dataset for 0-1 Loss. Figures on the left (5a and 5c) show VW optimizing a logistic function, while the two figures on the right (5b and 5d) show VW optimizing RMSE. A diamond symbol is used for those points above the diagonal line, indicating better results for SKDB, as opposed to the bullets. A squared symbol is used to show the ties. We can see that VW achieves lower error using a logistic function (VWLF), with the same number of datasets above and below the diagonal line, as opposed to only 2 wins for VW with the squared function (VWSF). Figures 5c and 5d shows



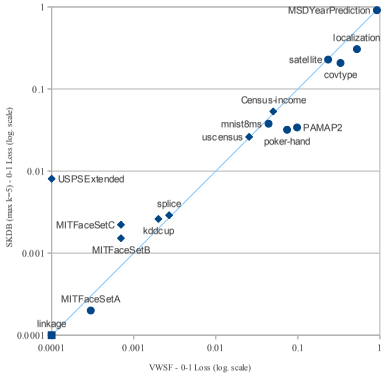
(a) RMSE for VWLF and SKDB.



(b) RMSE for VWSF and SKDB.



(c) 0-1 loss for VWLF and SKDB.



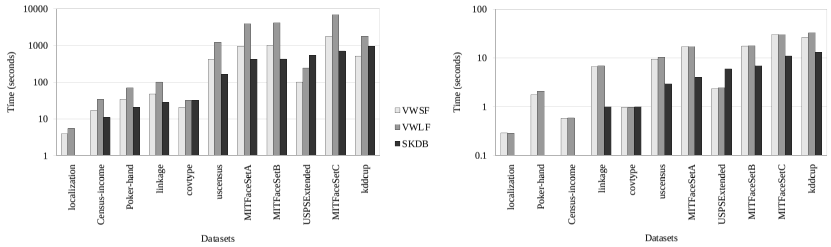
(d) 0-1 loss for VWSF and SKDB.

Figure 5: Scatter plot of RMSE and 0-1 loss comparisons for VW and SKDB ($k_{\max} = 5$).

the comparisons of VW with SKDB in terms of 0-1 Loss. In this case, VWSF performs slightly better than VWLF compared to SKDB.

Figure 5 shows the relative training and test times for VW and SKDB across all datasets. SKDB has substantially lower training and test time on most datasets. One exception is the sparse numeric USPSExtended dataset. Another is covtype, which has a large number of sparse boolean attributes.

While neither SKDB nor VW dominates the other in terms of error, SKDB is substantially more efficient, as shown in Figure 6a, where again training and classification times per dataset for VWLF, VWSF and SKDB are displayed. There is only one dataset for which



(a) Training Times (b) Classification Times

Figure 6: Time comparisons per dataset for VW with squared and logistic functions against SKDB.

SKDB takes more than the alternatives, which is `USPSExtended`. We believe that for this dataset VW is able to exploit the sparseness of the data while SKDB cannot. Some of the reasons why VW is taking in general more time than SKDB both for training and classifying is the consideration of quadratic features, the need to binarize discrete attributes (creating many binary attributes) and the need also to use one-against-all for multiclass classification.

3.3 SKDB vs In-core Algorithms

In order to understand how much predictive capacity, if any, is sacrificed by using our out-of-core classifiers, it is useful to compare them to the state-of-the-art in in-core classification. To this end, we have replicated our set of experiments with two in-core algorithms: a more general BNC and Random Forest, a powerful exemplar of the state-of-the-art. For some datasets it was infeasible to get results, even with high-performance computers, due either to time or memory limitations (indicated in Table 8 in Appendix A with $>$ 600h, when more than 600 CPU hours are required; or by >138G, when more than 138GB of RAM memory are required).

Note that while each of these algorithms has a number of parameters that could potentially be tuned using cross validation, doing so would not make reasonable comparators to SKBD. First, SKDB uses cross-validation to choose between multiple models rather than to choose between parameterizations. Cross validation could also be used to tune SKBD parameters such as the smoothing technique. Second, SKDB uses cross-validation in a constrained manner that requires only a single additional pass through the data while parameter tuning of these algorithms would increase compute time proportionally to the number of folds employed.

3.3.1 Augmented Bayesian Network

We compare performance against a state-of-the-art generic in-core Bayesian network classifier, that uses a hill-climbing algorithm for adding, deleting and reversing arcs (starting with a NB structure, this hill climber also considers arrows as part of the NB structure for

	BayesNet
SKDB	$6^{(+4)}$-3-3

Table 5: Win-draw-loss records for BayesNet and SKDB in terms of RMSE.

deletion, that is, arcs from the class to the attributes can be removed). It optimizes the K2 metric (Cooper and Herskovits, 1992). The maximum number of parents allowed for a node in the Bayes net is set to 5. The win-draw-loss comparison is presented in Table 5.

The detailed results can be found in Table 8 (Appendix A), row BayesNet. The darker grey background corresponds to those cases where BayesNet significantly outperforms SKDB. Note that there are only records for 12 out of the 16 datasets, because there are four cases for which results could not be computed for BayesNet due to memory constraints, since the network cannot be learned incrementally.

Even though BayesNet performs a more exhaustive search than SKDB of the model space of Bayesian networks with up to 5 parents, SKDB obtains lower error than BayesNet more often than the reverse. We hypothesize that this is due to SKDB's use of both generative and discriminative measures for model selection in contrast to BayesNet's use exclusively of generative measures.

3.3.2 Random Forest

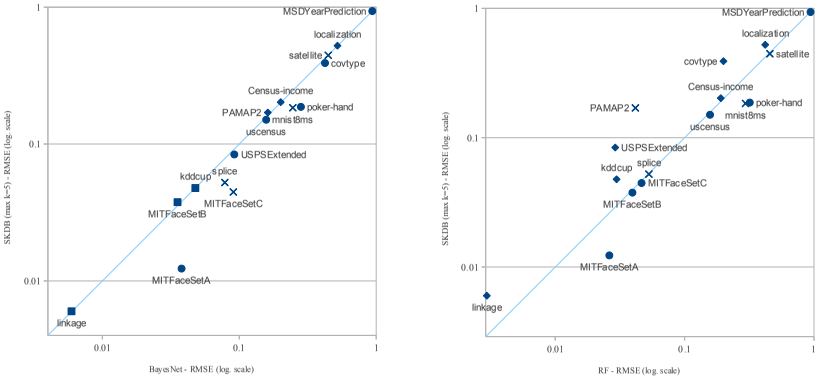
Random Forest (RF) is a state-of-the-art learning algorithm introduced in Breiman (2001). It uses bagging (Breiman, 1996) to aggregate an ensemble of trees that are each grown using a process that involves a stochastic element to increase diversity.

We have conducted experiments with RF selecting 100 trees. We present results both with pre-discretized data, to show relative performance on categorical data, and with undiscretized data. The detailed results can be found on the fifth and sixth from last rows in Table 8 in Appendix A. Table 6 shows the win-draw-loss records when compared with SKDB. The superscripts compute those datasets for which results cannot be obtained for RF due to main memory constrains ($>$ 138G are required). The results show that SKDB is competitive with RF in terms of RMSE, even when RF is performing its own discretization (5 wins for SKDB and 6 wins for RF), for which the computational cost in terms of memory and time is much higher than SKDB's. When 0-1 Loss is considered, out-of-core RF wins more frequently than SKDB, even when 0-1 Loss is used as the objective function during structure selection. When MDL discretization is used instead of 5EF for SKDB, then the results improve slightly for SKDB compared to RF performing its own discretization. When interpreting these results it is important to keep in mind that SKDB is a 3-pass out-of-core algorithm (4-pass with discretization) in contrast to the inherently computationally intensive in-core processing of RF.

Note that the sum of some cells is not exactly 16 but smaller, due to computational constraints for RF. RF is an in-core algorithm, and hence we have not been able to learn classification models for the largest datasets. Interestingly, RF is more negatively affected (in terms of computation) by a large number of classes than the BNCs, for example no 100 tree model can be learnt for `MSDYearPrediction`, which has 90 class labels. Precisely, there are three cases where RF with 10 trees cannot be run, and four in the case of RF with 100

		RF (5EF)	RF (Num)
RMSE	SKDB	$5^{(+4)}$-1-6	$5^{(+5)}$-0-6
0-1 Loss	SKDB	$2^{(+4)}$-3-7	$2^{(+5)}$-2-7
	SKDB$^{0-1}$	$3^{(+4)}$-2-7	$3^{(+5)}$-1-7
	SKDB^{MDL}	$8^{(+4)}$-2-2	$3^{(+5)}$-2-6

Table 6: Win-draw-loss records for RF and SKDB in terms of RMSE and 0-1 Loss.



(a) BayesNet and SKDB. (b) RF and SKDB.

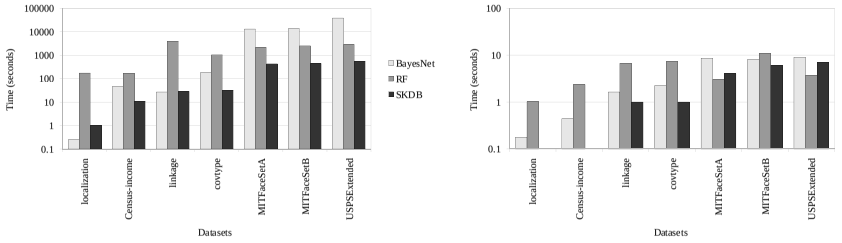
Figure 7: Scatter plot of RMSE comparisons for BayesNet, RF and SKDB.

trees. These four datasets are `MSDYearPrediction`, `satellite`, `mnist8ms` and `splice`, so the largest possible samples able to be computed have been considered.

RMSE comparisons for all datasets for BayesNet and RF when compared with SKDB are shown in Figures 7a and 7b, where the points with an X symbol indicate those datasets for which sampling is required. While BayesNet is not competitive with SKDB, RF provides competitive results for some datasets. `PAMAP2` provides a notable case for which only a sample of 2 millions out of 3.5 suffices for RF to provide better classification performance than SKDB using all the training data. This is however the only dataset for which RF learning from a sample can achieve lower RMSE than SKDB learning from all the data, the reverse being true for `splice`, `mnist` and `satellite`.

Figures 8a and 8b display the training and classification times per dataset for these classifiers compared to SKDB. For most datasets the in-core learners require substantially more time for learning and classifying[3].

3. RF requires more than 8GB of main memory to complete for poker-hand and uscensus1990 since these experiments to measure time has been conducted in a desktop computer no time measurements can be provided to compare with the rest of experiments. Weka's implementation has been considered.



(a) Training Times (b) Classification Times

Figure 8: Time comparisons per dataset for BayesNet and RF against SKDB.

3.4 Global Comparison of All Classifiers

In this section we analyze how all the classifiers explored in this paper perform when they are compared as a set. Figure 9 plots the average rankings across all datasets, along with the standard deviation for each learner. This ranking corresponds to the ranking obtained when a Friedman test is conducted. In this analysis we present the 0-1 Loss performance of SKDB when it is optimized for RMSE, its average rank on 0-1 Loss improves marginally from 2.94 to 2.84 when it is instead optimized for 0-1 Loss.

When assessing the calibration of the probability estimates using RMSE, SKDB obtains the lowest average rank of 2.53, followed by RF with 2.91 and KDB with 3.34 (very close to those for VW and BayesNet). When assessing performance using 0-1 Loss, RF using its own internal discretization of numeric attributes enjoys an average advantage of 1 in rank over SKDB, and SKDB enjoys an average advantage of almost one third over VWLF.

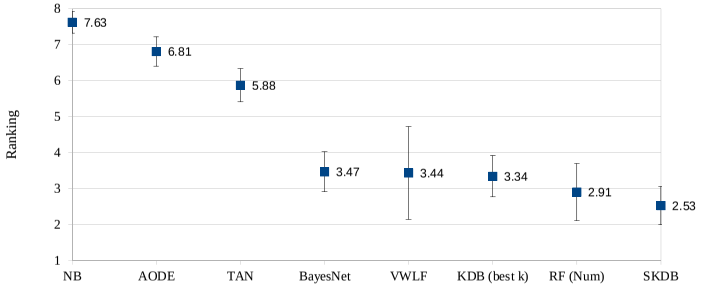
We find NB at the other extreme on both measures, with average ranks 7.63 and 7.72 out of a total of 8 classifiers.

SKDB obtains in the worst case the 4.5th position (this half is due to a tie with KDB-best-k) for the *linkage* dataset and the 4th position for *census-income* when ranked on RMSE and the 4th position for *MITFaceSetB* and *kddcup* when ranked on 0-1 Loss.

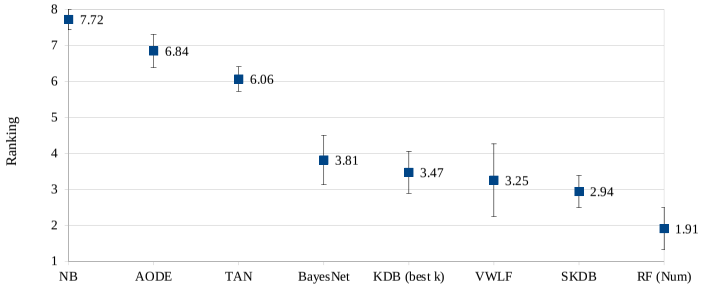
On both measures the largest standard deviation is observed for VW, which usually ranks either very well or rather poorly among the datasets. Still, VW obtains the largest number of top 1 datasets for RMSE, with a total number of 7, against 5 for RF and 4 for SKDB. On 0-1 Loss, RF ranks first 8 times, VW 4 times and SKDB twice (one of those times being a tie with KDB-best-k).

A Friedman test (Demšar, 2006) was performed for the set of 8 classifiers, yielding statistical difference for both measures. To identify where exactly these differences are found, we ran a set of posterior Nemenyi tests. These tests confirm the existence of two sets of algorithms in terms of performance on both RMSE and 0-1 Loss for these large datasets: on one hand NB, AODE and TAN; and on the other hand BayesNet, VW, KDB, RF and SKDB. The Nemenyi tests[4] showed significant differences for the second set of algorithms over NB and AODE, and only RF and SKDB over TAN.

4. Similarly for Holms and Shaffer post-hoc tests.



(a) RMSE

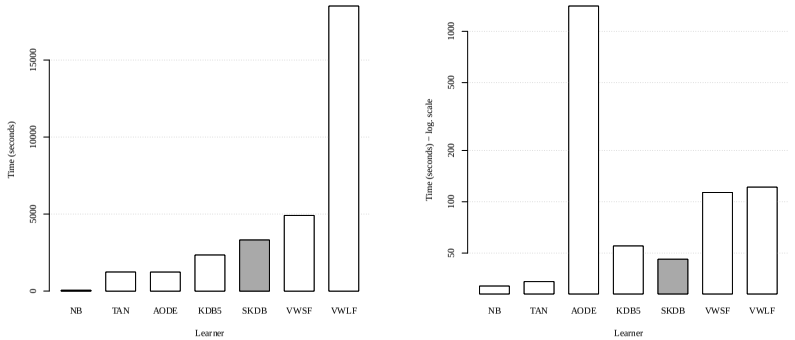


(b) 0-1 Loss

Figure 9: Ranking in terms of RMSE and 0-1 Loss for NB, TAN, AODE, KDB (with best k), SKDB, RF using numeric attributes, BayesNet and VW with a logistic function.

Even though the small number of datasets only allow tentative conclusions to be drawn, the following dataset characteristics appear to indicate a preference for one or another learning scheme.

- RF performs better on datasets with a small number of attributes.
- RF derives an advantage with respect to 0-1 Loss due to its internal discretization of numeric values. It does not achieve the lowest RMSE or 0-1 Loss on any of the three categorical only datasets *poker-hand*, *PAMAP2* or *splice*.
- SKDB seems to cope well with high-dimensional datasets and datasets with more than 1 million points. However its complexity is quadratic with respect to the number of attributes so, like most existing BNCs, it is not feasible for *very* high-dimensionality.



(a) Training Times

(b) Classification Times

Figure 10: Training and classification time comparisons for the out-of-core classifiers.

- VW appears to have an advantage for sparse numeric datasets.

A more detailed study of the domain of competence of these classifiers remains an important area for future work.

We can also analyze the performance of these classifiers with respect to the complexity of the decision function they provide. NB and linear regression, represented in this work by VW with linear features, are classifiers that learn linear decision boundaries. They have low variance and are particularly useful for small data quantity and sparse data. An extra level of expressiveness is offered by AODE, KDB ($k = 1$), TAN and VWSF/VWLF (with quadratic features); which produce quadratic decision functions. A2DE, KDB ($k = 2$) and VWSF/VWLF (with cubic features) produce cubic decision functions. More generally, AnDE and KDB can separate order-k(n) polynomially separable concepts (Jaeger, 2003). These two families of classifiers provide a set of a spectrum of models of increasing complexity, allowing a fine-tuned trade-off between expressivity on the one hand, and efficiency of learning and guarding against overfitting on the other hand, that is, the well-known bias-variance trade off (Brain and Webb, 1999).

Figures 10a and 10b show the time comparison for the out-of-core classifiers considered: namely NB, TAN, AODE, KDB with $k = 5$, SKDB and LRSGD with quadratic features in VW (using either a squared and a logistic function). The time required to pre-randomize the data for VW has not been included. No parallelization techniques have been used in any case, although most algorithms could be parallelized. The average of the 10-fold CV is shown. It is important to note that logarithmic scale has been used for classification times in order to appreciate the smaller differences in the faster learners. Again, only the 11 smallest out of the 16 datasets have been considered for time measurement, since these experiments have been conducted in a personal computer for a controlled environment.

Note that training SKDB with $k = 5$ (maximum) takes only a bit more time than training KDB with $k = 5$. The classification time for KDB is slightly higher than SKDB's (since all attributes are considered). Training time for LRSGD with quadratic features and 3 passes (VWSF and VWLF), which are those that obtain comparable results with SKDB, are also higher, presumably because they have to compute all pairs of quadratic features as indicated above. Similar reasoning holds for classification time. We believe that the extra time for VW is also due to the need to binarize discrete features, that is, since VW cannot deal with discrete attributes directly, v binary attributes are created for each originally discrete attribute with v values; and also because of the one-against-all approach required to handle classes with multiple labels. This overhead may be noticeable since we are using quadratic features. The time required for VWLF is much larger than VWSF, and in any case much larger both for training and testing than that for SKDB (specially note the logarithmic scale in Figure 10b).

4. Summary

We have developed an extension to KDB which performs discriminative attribute and best-k selection using leave-one-out cross validation.

SKDB only requires a single extra pass over the training data compared to KDB. In return for this extra pass during training, it often increases prediction accuracy relative to KDB with the best possible k, and always improves classification time (and space) by reducing the number of attributes considered, which can be quite significant for some datasets (for example for `MITFaceSetC` 60%, 215.8 out of 361, of the attributes are selected improving the classification performance at the same time). It is embarrassingly parallelizable. Furthermore, it can optimize any loss function that is a function over each training example $\mathbf{x}$ of $\hat{p}(Y, \mathbf{x})$ and $y^{\mathbf{x}}$, making it extremely flexible.

Due to its low bias, when datasets are large enough to avoid overfitting, SKDB attains lower error than the other in and out-of-core Bayesian network algorithms considered. It even provides competitive error compared to Random Forest, one of the most powerful in-core classification methods; and online linear and non-linear classifiers with stochastic gradient descent (that is, linear regression with quadratic and cubic features). Compared to the latter, it is in most cases substantially more efficient both at training and classification time. Further, it provides well-calibrated posterior class probability estimates.

Future directions for research include:

1. using only a sample of the data in the leave-one-out cross validation, in order to use more complex loss functions efficiently;

2. tackling SKDB's tendency to overfit small training sets;

3. studying a customized selection of the different links and attributes in a discriminative manner, that is, different numbers of parents for different attributes and also discarded in an order that does not follow the conditional mutual information rank;

4. consideration of other means of generating alternative classifiers to be selected in the final LOOCV pass; and

5. study of more appropriate loss functions for imbalanced datasets.

SKDB provides an efficient and effective solution to the problem of scalable low-bias learning. Its low bias allows it to capture and take advantage of the additional fine-detail that is inherent in very large data while its efficiency makes it feasible to deploy. SKDB thus sets new standards for classification learning from big data.

Acknowledgments

This research has been supported by the Australian Research Council grant DP140100087 and Asian Office of Aerospace Research and Development, Air Force Office of Scientific Research contract FA2386-15-1-4007. It has also been supported in part by the Monash eResearch Center and eSolutions-Research Support Services through the use of the Monash Campus HPC Cluster and the LIEF grant. This research was also undertaken on the NCI National Facility in Canberra, Australia, which is supported by the Australian Commonwealth Government. The authors would also like to thank the researchers from CESBIO (D. Ducrot, C. Marais-Sicre, O. Hagolle and M. Huc) for providing the land cover maps and the geometrically and radiometrically corrected FORMOSAT-2 images (satellite dataset). We also want to thank the anonymous reviewers for their insightful comments which have helped to greatly improve the revised version of the paper.

Appendix B. Implementation Details

All the experiments for the out-of-core algorithms have been carried out in a C++ software specially designed to deal with out-of-core classification methods. The following details in terms of implementation and configuration should be considered:

- 10-fold cross validation has been used.
- Equal frequency pre-discretization with 5 bins (EF5) has been utilized to discretize all numeric attributes (except if otherwise specified[5]). We have observed that EF5 and MDL (Minimum Description Length) (Fayyad and Irani, 1993) discretization provide the best results in approximately half of the datasets each, EF5 has been chosen because it is faster to perform than MDL, and also because it is not supervised and hence does not potentially provide the classifier with class information from the hold-out data when used for pre-discretization. Using a pre-fixed number of bins gives us the added advantage of not having to deal with a huge number of values per attribute created by MDL discretization in some cases.
- Missing values have been considered as a distinct value in all cases.
- The root mean square error is calculated exclusively on the true class label (different from Weka's implementation (Hall et al., 2009), where all class labels are considered).
- KDB's implementation benefits from a tree structure that resembles an ADTree (Moore and Lee, 1998), sparseness is achieved by storing a NULL instead of a node for any query that matches zero records. In our case, to save the probability distribution of the different attributes once the structure has been determined, we build a (distribution) tree for each attribute. Given, for example, attribute X_4 that has X_0 and X_3 as parents (in this order, and apart from the class), the counts (X_4, Y) are stored in the root node. The following level expands according to the number of values of X_0, which is the first parent, and store the counts for (X_4, Y, X_0). The following level expands as for the number of values of X_3, which is the second parent, and store the counts for (X_4, Y, X_0, X_2), and so forth if there were more parents. Note that as opposed to the ADTree, all the parameters are stored, that is, more than strictly required, since a branch is created for each attribute value, when strictly one less branch would be sufficient to represent the model parameters. The reason to do that is not to overload classification time by having to explore and combine branches.
- Two combined techniques are considered for smoothing. In the first place, we use m-estimates[6] (Mitchell, 1997) as follows:

$$\hat{p}(x_i|\pi_{x_i}) = \frac{counts(x_i, \pi_{x_i}) + \frac{m}{|X_i|}}{counts(\pi_{x_i}) + m} \tag{4}$$

5. Only for the experiments on the antepenultimate row on Table 8 as specified.
6. Also known as Schurmann-Grassberger's Law when $m = 1$, which is a particular case of Lidstone's Law (Lidstone, 1920; Hardy, 1920) with $\lambda = \frac{1}{|X_i|}$, also based on a Dirichlet prior.

Table 10: Results in terms of RMSE and 0-1 loss for SKDB and VW with different options: -p indicates the number of passes (3 or 20), -q indicates quadratic features (all possible combinations), -c refers to cubic features (all possible combinations), and -l the use of a logistic function for optimization. $SKDB_{0\text{-}1}$ is SKDB optimized for 0-1 loss.

* Results shown for 1 experiment only due to time limitations when using the logistic function in VW.

** Results shown for 1 fold only due to time limitations when using the logistic function in VW.

where π_{x_i} are the parent-values of X_i and $m = 1$. Secondly, if zero counts are found, we back off as many levels in the tree as necessary to find at least one count, that is, if $counts(x_4, x_0, x_3)$ is equal to zero, then $\hat{p}(x_4|x_0)$ is considered instead of $\hat{p}(x_4|x_0, x_3)$.

- In principle, any loss function that can be computed incrementally is suitable for SKDB. We have chosen RMSE (as defined above) for our first set of experiments.
- We use Averaged One Dependence Estimators (AODE) as a representative of the ANDE family of algorithms where $n = 1$.

  In order to avoid an extensive number of passes on each of the datasets, no dataset-tailored parameter tuning has been carried out for any of the algorithms considered. However as detailed in Sections 3.2, for logistic regression we have pre-conducted experiments with varying numbers of passes for stochastic gradient descent, varying loss functions and combinations of features; and used the default advanced (step size) updates provided by vowpal wabbit. In the case of random forest, we have made experiments with and without pre-discretising continuous attributes, as well as learning a variable number of trees (see Section 3.3.2 for more details).

Appendix C. Detailed Analysis of Results

The upper part of Table 8 (in the Appendix) shows the results in terms of RMSE ± standard deviation on the 16 datasets described above. We have decided to stop at $k = 5$, since some of the datasets already start to show worse results for $k = 5$ (due to variance increase), so increasing the complexity further is not productive. The results for NB, TAN and AODE are displayed as baseline orientations. The dark gray background on certain outputs for $SKDB_k$, corresponds to experiments that outperform KDB for the same value of k; the light grey background on others indicate a tie; whereas the absence of the two indicates that plain KDB outperforms $SKDB_k$. As for SKDB, the background coloring has the same meaning, but each entry is compared with the best KDB value for all possible k. Note that only the average of the 10 folds is shown for each experiment, and the background colors indicate statistical difference (Wilcoxon signed-rank tests), dark grey or white (in favor or against the algorithm in the row respectively); or lack of statistical difference, in light grey.

Table 8 also shows the number of selected attributes by $SKDB_k$. There are a few cases for which the number of selected attributes for all values of k is the total number of attributes in the datasets, such as `localization`, `PAMAP` and `linkage`. For some other datasets, for example `MSDYearPrediction`, `USPSExtended` or `mnist8ms`, the performance between selected KDB and KDB is similar, but fewer attributes are considered, so classification time (and space) will be reduced. In most of the cases the number of selected attributes is smaller than the original, sometimes even less than half, reducing the RMSE compared to KDB, for example `MITFaceSetC` with 215.8 attributes selected (out of 361) results in 0.0446 vs 0.0494 for KDB ($k = 5$), or `uscensus` with 22 attributes selected (out of 67) results in 0.1504 vs 0.1601 for KDB ($k = 4$), that in both cases results in statistical improvement.

The results for SKDB using MDL discretization are also shown in Table 8 (antepenultimate row). Note that there are some datasets, such as `linkage`, for which the discretization method used, in this case EF5, is not an adequate one; whereas a technique based on entropy minimization provides better results. Just the opposite situation occurs for datasets

such as MITFaceSetC. Apriori selection of the most appropriate discretization method is an open question, even more for very large datasets where we should consider the same bias/variance trade-off in terms of discretization bias and variance (Yang and Webb, 2009), that is, on the one hand we want that the number of intervals is sufficiently large to provide low discretization bias, but not too large to avoid an increase in discretization variance. The latter should not be a problem in large datasets, but considering a large number of intervals implies bigger datasets, which will have an impact on the classifier complexity.

Abstract

A unified view on multi-class support vector machines (SVMs) is presented, covering most prominent variants including the one-vs-all approach and the algorithms proposed by Weston & Watkins, Crammer & Singer, Lee, Lin, & Wahba, and Liu & Yuan. The unification leads to a template for the quadratic training problems and new multi-class SVM formulations. Within our framework, we provide a comparative analysis of the various notions of multi-class margin and margin-based loss. In particular, we demonstrate limitations of the loss function considered, for instance, in the Crammer & Singer machine.

We analyze Fisher consistency of multi-class loss functions and universal consistency of the various machines. On the one hand, we give examples of SVMs that are, in a particular hyperparameter regime, universally consistent without being based on a Fisher consistent loss. These include the canonical extension of SVMs to multiple classes as proposed by Weston & Watkins and Vapnik as well as the one-vs-all approach. On the other hand, it is demonstrated that machines based on Fisher consistent loss functions can fail to identify proper decision boundaries in low-dimensional feature spaces.

We compared the performance of nine different multi-class SVMs in a thorough empirical study. Our results suggest to use the Weston & Watkins SVM, which can be trained comparatively fast and gives good accuracies on benchmark functions. If training time is a major concern, the one-vs-all approach is the method of choice.

Keywords: support vector machines, multi-class classification, consistency

1. Introduction

Support vector machines (SVMs, Boser et al., 1992; Cortes and Vapnik, 1995) are founded on the intuitive geometric concepts of large margin separation and regularized risk minimization, and they are well embedded into statistical learning theory. However, there is no unique canonical extension to the case of multiple classes, neither from a geometric nor from a learning theoretical point of view. Instead, several variants relying on slightly different notions of margin and margin-based loss have been proposed. We present a unified view on multi-class SVMs. This view allows to identify similarities and differences between existing approaches. It provides a thorough framework for analyzing, designing, and efficiently training multi-class SVMs.

There exist generic ways of doing multi-category classification based on arbitrary binary learning machines by combining hypotheses from independently trained binary classifiers. In contrast, the focus of this study is on multi-class extensions of SVMs that aim at generalizing the notions of margin and large margin loss. These so-called all-in-one machines cast the learning problem into a single quadratic program, which allows them to take all class relationships into account simultaneously. The first of these all-in-one formulations was independently proposed by Weston and Watkins (1999), Vapnik (1998), and Bredensteiner and Bennett (1999). Crammer and Singer (2002) modified this machine, and their approach is frequently used, in particular when dealing with structured output. In addition to these popular methods, we consider the machine by Lee et al. (2004), a variant proposed by Liu and Yuan (2011), as well as multi-class maximum margin regression (Szedmak et al., 2006). The latter is equivalent to a multi-class SVM suggested by Zou et al. (2008). From a geometric point of view, the various approaches differ in the way they extend the concepts of margin and margin violation (or, to be more precise, margin-based loss) to multiple classes. Differentiating the machines form a learning-theoretical perspective is more difficult. Albeit there have been extensions of generalization bounds derived for binary SVMs to the multi-class case (e.g., Guermeur, 2007; Doğan et al., 2012), these do not allow to deduce relative advantages or disadvantages of certain multi-class SVM formulations. But there are hints from theoretical analyzes of consistency. In particular, the loss function proposed by Lee et al. was the first multi-class large margin loss known to be Fisher consistent (Lee et al., 2004; Tewari and Bartlett, 2007; Liu, 2007). The only other loss functions we are aware of sharing this property are those proposed in the work of Liu and Yuan (2011). In practice, however, the decision of which multi-class SVM to use is most often not governed by theoretical arguments, but by training-time considerations and the availability of efficient implementations. For instance, the canonical extension of binary SVMs to multiple classes proposed by Weston and Watkins and the machine by Lee et al. are rarely used. These approaches are theoretically sound and experiments indicate that they lead to well-generalizing hypotheses, but efficient training algorithms have been lacking so far.

Against this background, we analyze large-margin multi-category classification theoretically and derive fast training algorithms for established as well as for new learning machines, which we then evaluate empirically. Several researchers investigated multi-class SVM classification methods before, either experimentally (Hsu and Lin, 2002; Rifkin and Klautau, 2004) or conceptually (Allwein et al., 2001; Hill and Doucet, 2007; Liu, 2007; Guermeur, 2007). The experimental papers by Hsu and Lin (2002) and Rifkin and Klautau (2004) focus on the empirical comparison of methods. Some well established multi-class SVMs are missing in these studies. This also holds true for the conceptually oriented work by Allwein et al. (2001). The inspiring theoretical studies by Hill and Doucet (2007) and Liu (2007) completely lack any empirical comparison. The work most closely related to ours is perhaps the framework proposed by Hill and Doucet. They analyze several multi-class SVMs and present a solver for machine training, however, our study goes beyond their important achievements in several aspects. While Hill and Doucet's framework unifies already existing methods, one can neither easily develop new machines within the framework nor clearly identify the conceptual differences between machines. Further, their analysis

does not provide hints on how loss functions may affect the generalization performance of different machines. Finally, it is important to provide an extensive and unbiased empirical comparison.

This article is organized as follows. The next section presents our unifying framework, which categorizes multi-class SVMs according to their choice of multi-class loss function, margin function, and aggregation operator in subsections 2.1–2.3. Subsection 2.4 shows how the existing multi-class machines fit into our scheme. Then we derive new SVM variants suggested by the framework. Subsection 2.6 states a template for quadratic programs describing the learning problems induced by machines falling into our framework. Section 3 analyzes how different design choices affect the Fisher and universal consistency of the loss functions and the classifiers, respectively. The section closes with showcase experiments on synthetic test problems designed to highlight consequences of certain design choices. Section 4 presents an extensive experimental evaluation of various SVM variants, both with linear as well as Gaussian kernels. The theoretical as well as empirical findings finally lead us to conclusions including recommendations for the use of multi-class SVMs in practice.

2. A Framework for Multi-category SVM Classification

Multi-class SVMs construct hypotheses $h : X \to Y$ from training data $\big((x_1, y_1), \ldots, (x_\ell, y_\ell)\big) \in \big(X \times Y\big)^\ell$, where X and Y are the input and label space, respectively. The data points are assumed to be sampled i.i.d. from a distribution P on $X \times Y$. We restrict our considerations to the standard case of a finite label space and set $Y = \{1, \ldots, d\}$ (there exist extensions of multi-class SVMs to infinite label spaces, e.g., Bordes et al. e.g., 2008). The goal of training a multi-category SVM is to map the training data to a hypothesis minimizing the risk (generalization error) $\mathcal{R}(h) = \int\limits_{X \times Y} L(h(x), y) \ \mathrm{d}P(x, y)$, where the loss function L is typically the 0-1-loss, which is zero if both arguments are identical and one otherwise.

For multi-category classification the binary SVM concept of thresholding a real-valued decision function $f : X \to \mathbb{R}$ at zero is insufficient. The canonical extension to $d > 2$ classes is to employ a vector-valued linear decision function $f : X \to \mathbb{R}^d$, where the maximal component indicates the decision. Using a kernel-induced feature space, the corresponding hypothesis takes the form

$$h : X \to Y = \{1, \ldots, d\}\,; \quad x \mapsto \arg\max_{c \in Y} \big\{f_c(x)\big\} = \arg\max_{c \in Y} \big\{\langle w_c, \phi(x)\rangle + b_c\big\} \ , \qquad (1)$$

where $\phi : X \to \mathcal{H}$ is a feature map into an inner product space $\mathcal{H}$, $w_1, \ldots, w_d \in \mathcal{H}$ are class-wise weight vectors, and $b_1, \ldots, b_d \in \mathbb{R}$ are class-wise bias/offset values. The feature map is defined by a positive definite kernel function $k : X \times X \to \mathbb{R}$ with the property $k(x, x') = \langle \phi(x), \phi(x')\rangle$. We presume that the arg max operator in Equation (1) returns a single class index (ties may, for example, be broken at random). To ease the notation, we define the risk $\mathcal{R}(f)$ to be equal to the corresponding $\mathcal{R}(h)$.

Adding the same function $g : X \to \mathbb{R}$ to all components f_c of the decision function does not change the decision as $\arg\max_{c \in Y} \Big\{f_c(x)\Big\} = \arg\max_{c \in Y} \Big\{f_c(x) + g(x)\Big\}$. This is often undesired, for example, for the sake of uniqueness of a solution. This problem can be fixed

by enforcing the so-called *sum-to-zero* constraint

$$\sum_{c=1}^{d} f_c(x) = 0 \ . \qquad (2)$$

At least for universal kernels (Steinwart, 2002a) the constraint is equivalent to $\sum_{c=1}^{d} w_c = 0$ and $\sum_{c=1}^{d} b_c = 0$. With this constraint we have $f_2 = -f_1$ for the special case of binary classification, and the hypothesis $h(x) = \mathrm{sign}(f_1(x))$ maps the first class to $+1$ and the second to -1. Thus, the binary SVM can be recovered as a special case of the multi-class SVM, which is an important design criterion.

2.1 Multi-class Loss Functions

Support vector machines select a hypothesis by minimizing the regularized empirical risk functional

$$\frac{1}{2}\|f\|^2 + C \cdot \sum_{i=1}^{\ell} L(f(x_i), y_i) \ , \qquad (3)$$

where L is a large-margin loss function and $C > 0$ is a user-defined regularization constant. The squared norm is defined as $\|f\|^2 = \sum_{c \in Y} \|f_c\|^2 = \sum_{c \in Y} \|w_c\|^2$. Most existing approaches to multi-class large margin classification differ only in the type of loss function, which should typically be an upper bound on the 0-1-loss, lead to an optimization problem that can be solved efficiently, and vanish on an open set to allow for sparse solutions. The key observation for our unifying framework is that multi-class SVM loss functions can be decomposed into meaningful components, namely a set of margin functions for the different classes, a large-margin loss for binary problems, and an aggregation operator, combining the various target margin violations into a single loss value. This decomposition is found in all existing approaches to large margin multi-class classification. Given a labeled point $(x, y) \in X \times Y$ and the value $f(x) \in \mathbb{R}^d$ of the decision function, the general form of most multi-class loss functions is

$$L\big(f(x), y\big) = \Delta\Big(\widehat{L}^{\mathrm{bin}}\big(\mu(f(x), y), y\big)\Big) \ ,$$

or conceptually "$L = \Delta \circ \widehat{L}^{\mathrm{bin}} \circ \mu$". Here μ is a *margin function*, Δ is an *aggregation operator*, and L^{bin} is a loss function for binary classification, such as the hinge loss $L^{\mathrm{hinge}}(\mu) = \max\{0, 1 - \mu\}$, the squared hinge loss, or the Huber loss. With $\widehat{L}^{\mathrm{bin}}$ we denote the component-wise application of this loss function to the margin values.

In the next two subsections, we formalize the concepts of margin functions and aggregation operators and give examples of how existing machines can be expressed in our framework.

2.2 Margin Functions

The following definition extends the concept of a scalar margin of a training example to a vector-valued margin function.

Definition 1 (margin function) *A* margin function *is a non-constant function*

$$\mu : \mathbb{R}^d \times Y \to \mathbb{R}^d; \quad \mu = (\mu_1, \ldots, \mu_d)$$

of a prediction $f(x) \in \mathbb{R}^d$ *and a label* $y \in Y$ *that is linear in its first argument and fulfills the properties:*

1. $\forall y \in Y : \mu_y(f(x), y)$ *is non-decreasing in* $f_y(x)$,
2. $\forall c, y \in Y, c \neq y : \mu_c(f(x), y)$ *is non-increasing in* $f_c(x)$,
3. $\Big[\forall c \in Y : \mu_c(f(x), y) \geq 0$ *and* $\exists c \in Y : \mu_c(f(x), y) > 0\Big] \Rightarrow \big[\arg\max_{c \in Y} \big\{f_c(x)\big\} = y\big]$

Due to linearity in $f(x)$ margin functions are of the form

$$\mu_c\big(f(x), y\big) = \sum_{m=1}^{d} \nu_{y,c,m} \cdot f_m(x_i)$$

and can thus be expressed in terms of coefficients $\nu_{y,c,m}$. Property 3 in the above definition ensures that positive margins imply correct classification. Note that the reverse statement is not guaranteed, so, correct classification does not necessarily imply that all margin functions are non-negative. The definition is not as general as it may seem. If we assume an equal treatment of all classes, then the degrees of freedom in $\nu_{y,c,m}$ are drastically reduced.

The following types of margins are of primary interest:

Definition 2 (relative and absolute margins) *The* relative margin function *is given by*

$$\mu_c^{rel}(f(x), y) = \frac{1}{2}\big(f_y(x) - f_c(x)\big)$$

and the absolute margin function *by*

$$\mu_c^{abs}(f(x), y) = \begin{cases} +f_c(x) & \text{for } c = y \\ -f_c(x) & \text{for } c \in Y \setminus \{y\} \end{cases}.$$

The corresponding coefficients are

$$\nu_{y,c,m} = \frac{1}{2}\left(\delta_{y,m} - \delta_{c,m}\right) \qquad \text{(relative)}$$

and

$$\nu_{y,c,m} = \delta_{m,c} \cdot (2\delta_{c,y} - 1) = -(-1)^{\delta_{c,y}} \cdot \delta_{m,c} \qquad \text{(absolute)}$$

for the relative and the absolute margin, respectively, where $\delta_{a,b} = 1$ if $a = b$ and $\delta_{a,b} = 0$ otherwise denotes the Kronecker symbol. Both margin functions can be combined, as in the work of Liu and Yuan (2011). They have a number of interesting properties:

- The coefficients $\nu_{y,c,m}$ are sparse, so that the computation of a margin value μ_c from $f(x)$ is a constant time operation (independent of the number of classes).

- The "own-class-margin" component $\mu_y^{\text{rel}}(f(x), y)$ of relative margins is always zero. For a two-class problem, the other component coincides with the margin $y \cdot f(x)$ of the binary SVM (with labels $y \in \{\pm 1\}$ and real-valued decision function f).
- If the classification according to Equation (1) is correct, then no component of the relative margin function is negative. This implication does not necessarily hold for absolute margin functions regardless of whether the sum-to-zero constraint is enforced or not.
- It holds $\sum_m \nu_{y,c,m} = 0$ for relative but not for absolute margins. Adding the same function to all components f_c of the decision function does not change the decision (1). Hence it is reasonable to demand that adding the same value to all $\nu_{y,c,m}$ does not change the margins. This property is violated for absolute margins. This renders both the sign and the absolute value of a single margin (i.e., a component of the margin function) meaningless. This issue could be addressed by enforcing $\sum_m \nu_{y,c,m} = 0$ also for absolute margins.
- In principle, the sum-to-zero constraint (2) can be avoided at the level of the decision function by shifting the coefficients ν such that they fulfill $\sum_m \nu_{y,c,m} = 0$. However, this would destroy the sparsity of the coefficients. Thus, it can be argued that the sum-to-zero constraint $\sum_c f_c = 0$ is a preferable solution.
- A regularizer of the form $\sum_{c=1}^{d} \|w_c\|^2$ has the effect that the optimal solution of a relative margin SVM always fulfills the sum-to-zero constraint. This has been observed for particular machines by Guermeur (2007) and by Wu and Liu (2007), but can be shown to be true for all relative margin SVMs. Adding the same vector w to all weight vectors w_c (or the same function $g(x) = \langle w, \phi(x)\rangle$ to all components f_c) does not affect relative margins and thus the empirical error term in the primal problem. Thus, to find the optimal w we have to minimize the complexity term

$$\sum_{c=1}^{d} \langle w_c + w, w_c + w\rangle = \sum_{c=1}^{d} \langle w_c, w_c\rangle + 2 \cdot \sum_{c=1}^{d} \langle w_c, w\rangle + d \cdot \langle w, w\rangle$$

  w.r.t. w. Setting the derivative $2 \cdot \left(\sum_{c=1}^{d} w_c + d \cdot w\right)$ to zero gives $w = -\frac{1}{d}\sum_{c=1}^{d} w_c$, which results in $\sum_{c=1}^{d}(w_c + w) = 0$.
- Undesired situations can occur if the absolute margin function is applied without the sum-to-zero constraint. Consider, for instance, the case of all components of f being negative. In this case the "own class" margin μ_y is negative while all "other class" margins μ_c, $c \neq y$, are positive, and the example could still be classified correctly. This seems counter-intuitive, although formally allowed by Definition 1. Thus, we argue that the sum-to-zero constraint should be demanded for any multi-class SVM. The one-versus-all machine (OVA, see below) relies on absolute margins, but the sum-to-zero constraint is not enforced. However, in OVA it is not possible that all components of the margin function are negative.

2.3 Aggregation Operators

Definition 1 ensures that positive margins μ_c indicate correct classification. Therefore it is natural to construct a large margin loss from target margin violations, defined as

$$v_c(f(x), y) = \max\left\{0, \gamma_{y,c} - \mu_c\big(f(x), y\big)\right\} \ .$$

The target margins $\gamma_{y,c}$ are typically chosen to be $\gamma_{y,c} = 1$, which we assume in the following if not stated otherwise. The margin violations $v_c = L^{\text{hinge}}(\mu_c(f(x), y)$ correspond to the hinge loss applied to the different margin components. As indicated above, other binary SVM loss functions can be applied at this point. In this case the resulting multi-class SVMs will be compatible with the corresponding binary SVM based on that surrogate loss (e.g., the squared hinge loss is considered by Guermeur, 2012).

The d margin violations need to be combined into a single cost value:

Definition 3 (aggregation operator) *An* aggregation operator *is a non-constant function*

$$\Delta : (\mathbb{R}_0^+)^d \times Y \to \mathbb{R}_0^+$$

of margin violations $v = (v_1, \ldots, v_d)$ and a label $y \in Y$ with the properties

- $\Delta\big((0, \ldots, 0), y\big) = 0$, *and*
- $\Delta((v_1, \ldots, v_d), y)$ *is monotonically increasing in all components v_i of the first argument.*

The following aggregation operators are employed in machines that have been proposed in the literature:

Definition 4 *We define the following aggregation operators:*

$$\begin{aligned}
&\Delta^{\textit{self}}\big((v_1, \ldots, v_d), y\big) = v_y && (\textit{self} \text{ operator})\\
&\Delta^{\textit{t-max}}\big((v_1, \ldots, v_d), y\big) = \max_{c \in Y}\left\{v_c\right\} && (\textit{total-max} \text{ operator})\\
&\Delta^{\textit{o-max}}\big((v_1, \ldots, v_d), y\big) = \max_{c \in Y \setminus \{y\}}\left\{v_c\right\} && (\textit{max-over-others} \text{ operator})\\
&\Delta^{\textit{t-sum}}\big((v_1, \ldots, v_d), y\big) = \sum_{c \in Y} v_c \ , && (\textit{total-sum} \text{ operator})\\
&\Delta^{\textit{o-sum}}\big((v_1, \ldots, v_d), y\big) = \sum_{c \in Y \setminus \{y\}} v_c \ . && (\textit{sum-over-others} \text{ operator})
\end{aligned}$$

These operators can be understood as computing the value of a linear program, as outlined in the supplementary material (Section A).

2.4 Unification of Existing Machines

This study considers all-in-one approaches to SVM multi-class classification. These methods extend the SVM concept of large-margin classification to the multi-class case and cast the learning task as a single optimization problem. The first all-in-one methods proposed independently by Weston and Watkins (1999), Vapnik (1998, Section 10.10), and Bredensteiner and Bennett (1999) turned out to be equivalent, up to rescaling of the decision functions and the regularization parameter $C > 0$. We refer to this method as WW or as WW-SVM. It is expressed within our framework as the machine relying on the sum operator[1] applied to relative margins.

An alternative multi-class SVM was proposed by Crammer and Singer (2002). Like the WW-SVM, the CS machine takes all class relations into account simultaneously and solves a single optimization problem, however, with fewer slack variables in its primal optimization problem. It corresponds to combining relative margins with the max-over-others operator.

There are two key differences between the WW- and CS-SVMs. First, the aggregation operators are different. Second, the CS-SVM has originally been defined only for hypotheses without bias term. The machine can be extended to hypotheses with bias (Hsu and Lin, 2002), but efficient training algorithms have been missing for this extension. In our framework we do not distinguish between hypothesis classes with and without bias; all machines are defined for both classes.

Lee, Lin and Wahba (2004) proposed a distinct approach to multi-class SVM classification. We refer to this approach as the LLW-SVM. It was the first machine to use absolute margins in an all-in-one approach. The absolute margin violations are combined under the sum-to-zero constraint by means of the sum-over-others operator.

The LLW machine was the first multi-class SVM with a classification calibrated loss function, which guarantees its Fisher consistency (Lee et al., 2004; Tewari and Bartlett, 2007; Liu, 2007; Liu and Yuan, 2011). That is, in the limit of infinite data minimal risk in the LLW sense implies minimal 0-1-risk and thus a Bayes-optimal decision rule.

The multi-class maximum margin regression (MMR) method proposed by Szedmak et al. (2006) is driven by the observation that the quadratic term

$$\sum_{i=1}^{\ell}\sum_{j=1}^{\ell} \alpha_i \alpha_j y_i y_j k(x_i, x_j)$$

in the Wolfe dual of the binary SVM (Cortes and Vapnik, 1995; Bottou and Lin, 2007) can be interpreted as the squared norm with respect to the product kernel $k \otimes k_y$, where the "label kernel" $k_y : \{\pm 1\} \times \{\pm 1\} \to \mathbb{R}$ is defined as $k_y(y_i, y_j) = y_i y_j$. This is the standard inner product on the label space $Y = \{-1, +1\} \subset \mathbb{R}$. This idea is generalized to multiple classes by considering the standard inner product on $\mathbb{R}^d$ applied to label prototype vectors $\{\hat{y}_1, \ldots, \hat{y}_d\} = Y \subset \mathbb{R}^d$ representing the classes. This corresponds one-to-one to the definition of a positive definite kernel $k_y(c, c') = \langle \hat{y}_c, \hat{y}_{c'} \rangle$ on the standardized label space $Y = \{1, \ldots, d\}$. Two different sets of prototypes have been proposed, namely

$$\hat{y}_c = \sqrt{\frac{d-1}{d}}\left(\frac{-1}{d-1}, \ldots, 1, \ldots, \frac{-1}{d-1}\right)$$

1. For relative margins, the sum-over-others and the total-sum operator coincide.

and $\hat{y}_c = (0, \ldots, 1, \ldots, 0)$, where the c-th component equals 1. The first set corresponds to a symmetric setup of unit vectors with maximal angles between prototypes, while the second setup relies on an orthonormal basis. We refer to these variants as MMR and MMR$^\perp$, respectively. They correspond to the label kernels

$$k_y(y_i, y_j) = \begin{cases} 1 & \text{for } y_i = y_j \\ -\frac{1}{d-1} & \text{otherwise} \end{cases} \qquad \text{and} \qquad k_y^\perp(y_i, y_j) = \delta_{y_i, y_i} \ .$$

Both of these machines are obtained by applying the self aggregation operator to absolute margins, where the MMR machine enforces the sum-to-zero constraint, while the MMR$^\perp$ machine does not.

The MMR$^\perp$ method applied to a two-class problem does typically not give the same decision function as the standard binary SVM. With its orthogonal label kernel, it explicitly ignores all interactions between classes, so that the machine effectively trains d independent machines, similar to one-class SVMs for the different classes.

The unique selling proposition of the MMR and MMR$^\perp$ machines is their applicability to problems with large numbers of classes. By design, the optimization problem of the MMR machine has only ℓ dual variables. Even better, in case of the MMR$^\perp$ machine the problem decomposes into d independent sub-problems. However, this means that the MMR$^\perp$-SVM does not take any inter-class relationships in the data into account.

Our unification also captures the *reinforced multicategory SVM* (RM-SVM) recently proposed by Liu and Yuan (2011). This machine, or family of machines, weights two types of margin violations using a parameter $\gamma \in [0, 1]$. In our framework, it can be viewed as relying on a *reinforced margin function* defined as

$$\mu_c^{\mathrm{r}}(f(x), y) = \begin{cases} \gamma f_c(x) & \text{for } c = y \\ -(1-\gamma) f_c(x) & \text{for } c \in Y \setminus \{y\} \end{cases}$$

and using the total-sum operator and the coefficients

$$\gamma_{y,c} = \begin{cases} \gamma(d-1) & \text{for } c = y \\ (1-\gamma) & \text{for } c \in Y \setminus \{y\} \end{cases} \tag{4}$$

for combining the margin violations. The sum-to-zero constraint is enforced. For $\gamma = 0$, RM equals LLW and for $\gamma = 1$ it equals MMR with a scaled target margin.

There exist several general techniques to build a multi-category classifier based on some binary classifiers, which can be chosen to be binary SVMs. The most prominent of these so-called sequential approaches are the one-versus-one (OVO) and the one-versus-all (OVA) scheme. As an OVO approach inevitably requires some additional non-canonical decision making procedure different from (1) (e.g., Hastie and Tibshirani, 1998; Platt et al., 2000; Chang and Lin, 2011) and the optimal choice of this procedure is highly task-dependent, OVO-type approaches are out of the scope of this study (error-correcting-output-codes, ECOC, provide a general framework covering OVA and many OVO methods, see Dietterich and Bakiri, 1995; Allwein et al., 2001; Passerini et al., 2004).

However, the OVA scheme fits into our framework. It relies on only d different binary decision functions, each separating one class from all the rest (Vapnik, 1998, Section 10.10).

Usually this class is considered the "positive" class ($y = +1$) in the binary problem, and all other classes are mapped to the "negative" class ($y = -1$). The resulting decision function can be thought of as voting for the class under consideration. Let $y_i^c = +1$ if $c = y_i$ and $y_i^c = -1$ if $c \neq y_i$ denote the binary label of the i-th example when training the machine separating class c from the rest. Then OVA constructs decision functions f_c according to

$$\min_{f_c} \quad \frac{1}{2}\|f_c\|^2 + C \cdot \sum_{i=1}^{\ell} L^{\mathrm{hinge}}\big(y_i^c \cdot f_c(x_i)\big) \ .$$

and plugs them into Equation (1). Solving these d independent optimization problems at once results in a problem of type (3). This proceeding amounts to summing up the margin violations of all binary problems. Thus, OVA can be viewed as total-sum aggregation applied to absolute margins, without enforcing the sum-to-zero constraint.

Our framework highlights the conceptual similarities and differences of the above-mentioned machines, summarized in Table 1.

machine	margin μ	aggregation operator Δ	sum-to-zero constraint	bias term
WW	relative	sum-over-others	optional	yes
CS	relative	maximum-over-others	optional	no
LLW	absolute	sum-over-others	yes	yes
MMR	absolute	self	yes	yes
MMR$^\perp$	absolute	self	no	yes
RM	absolute	total-sum (affine combination of self and sum-over-others)	yes	yes
OVA	absolute	total-sum	no	yes

Table 1: Properties of the various multi-category SVMs in terms of the unifying framework. The last column indicates the presence of the bias or offset term in the original formulation found in the literature; all machines can be formulated with or without bias term.

2.5 Completing the Picture: New Multi-class SVMs

Our unification makes it easy to construct novel loss functions based on the principles extracted from existing approaches. From Table 1 it becomes obvious that some combinations of established margin functions and aggregation operators have not yet been explored. In the following, we define the corresponding machines and name them by a three-letter code, abbreviating the margin and loss types as indicated in bold in the following. The first of these new SVMs is the AMO machine, combining the **a**bsolute margin concept with the **m**ax-over-**o**thers operator. The machine can be understood as a combination of the LLW-SVM, from which it takes the margin concept, and the CS-SVM with its max-over-others aggregation.

The other two machines, ATM and ATS, use **a**bsolute margins with the **t**otal **m**aximum and the **t**otal **s**um operators. The ATS-SVM resembles the RM-SVM with $\gamma = 0.5$, however,

ATS uses target margins of $\gamma_{y,c} = 1$ for $y, c \in \{1, \ldots, d\}$, while RM-SVM uses the target margins defined by (4) which differ depending on whether c equals y or not. The only difference between the OVA scheme and the ATS machine is the presence of the sum-to-zero constraint in the latter. Still, the ATS machine is an all-in-one machine, because its training problem is not a composition of independent (binary) problems.

2.6 Unified Dual Problem

Training SVMs amounts to solving convex quadratic optimization problems. The traditional approach to solving these problems when using non-linear kernels is considering the corresponding dual formulations. In the following, we derive the Wolfe dual of the unified primal problem (3). The structure of the dual is often well-suited for the application of decomposition algorithms, which have proven to be a powerful choice for training SVMs with non-linear kernels.

For the case without sum-to-zero constraint, we arrive at the following dual problem (see supplement Section B for details):

$$\begin{aligned} \max_{\alpha} \quad & \sum_{i,p} \gamma_{y_i,p} \cdot \alpha_{i,p} - \frac{1}{2} \sum_{i,p} \sum_{j,q} M_{y_i,p,y_j,q} \cdot k(x_i, x_j) \cdot \alpha_{i,p} \cdot \alpha_{j,q} && (5) \\ \text{s.t.} \quad & \forall i, p: \quad 0 \leq \alpha_{i,p} \\ & \forall i, r: \quad \sum_{p \in P_y^r} \alpha_{i,p} \leq C \\ & \forall c: \sum_{i,p} \alpha_{i,p} \nu_{y_i,p,c} = 0 && (6) \end{aligned}$$

with

$$M_{y_i,p,y_j,q} = \sum_c \nu_{y_i,p,c} \nu_{y_j,q,c} \ .$$

The bias parameters b_c can be obtained from the KKT optimality conditions.

If the sum-to-zero constraint is enforced, we obtain the same structure of the dual problem, but this time with

$$M_{y_i,p,y_j,q} = \sum_{m,n} \left(\delta_{m,n} - \frac{1}{d} \right) \nu_{y_i,p,m} \nu_{y_j,q,n} \ .$$

We call these auxiliary constants $M_{y_i,p,y_j,q}$ used in the formulation of the dual problems *kernel modifiers*, because they appear as multipliers of the kernel in the dual problem. Let the map $I : \{1, \ldots, \ell\} \times P_y \to \{1, \ldots, \ell |P_y|\}$ assign a unique index to each pair of training pattern and constraint. We define $Q \in \mathbb{R}^{\ell |P_y| \times \ell |P_y|}$ by

$$Q_{I(i,p),I(j,q)} = M_{y_i,p,y_j,q} \cdot k(x_i, x_j) \ .$$

This matrix, together with the vector $V \in \mathbb{R}^{\ell |P_y|}$, $V_{I(i,p)} = \gamma_{y_i,p}$, defines the quadratic objective function

$$W(\alpha) = V^T \alpha - \frac{1}{2} \alpha^T Q \alpha \qquad (7)$$

of the dual problem, written in vector notation.

The weight vectors are given by

$$w_c = \sum_{i,p} \alpha_{i,p} \nu_{y_i,p,c} \phi(x_i) - \eta \qquad (8)$$

with $\eta = \sum_{i,p} \alpha_{i,p} \left(\frac{1}{d} \sum_c \nu_{y_i,p,c} \right) \phi(x_i)$ in case of a sum-to-zero constraint and zero otherwise.

For solving the problem with bias parameters, which lead to d equality constraints, we adopt the *iterative problem alternation* approach by Kienzle and Schölkopf (2005).

2.7 Training Complexity

Table 2 gives the asymptotic training times of various approaches. Under the assumption that the runtime bounds are tight, the table suggests that training MMR$^\perp$ is faster than training OVO, which is slightly faster than MMR, which is again faster than training OVA, which is finally followed by the various all-on-one SVMs with $O(d)$ dual variables per training example. The asymptotic nature of the runtime bounds hides factors considerably influencing training times in practice: Different machines often perform best for different hyper-parameters, and different concepts of separability (as discussed in Section 2 and Section 3) have an impact.

MMR$^\perp$	OVO	MMR	OVA	WW / CS / LLW AMO / ATM / ATS / RM
$\sum_{c=1}^{d} \mathcal{C}(\ell_c)$ $\widehat{=}\ d \cdot \mathcal{C}(\ell/d)$	$\sum_{1 \leq c < e \leq d} \mathcal{C}(\ell_c + \ell_e)$ $\widehat{=}\ d^2 \cdot \mathcal{C}(\ell/d)$	$\mathcal{C}(\ell)$	$d \cdot \mathcal{C}(\ell)$	$\mathcal{C}(d\ell)$

Table 2: Asymptotic runtime of the training algorithms under the assumption that solving the different n-dimensional quadratic programs is in the complexity class $\mathcal{C}(n)$. There are good arguments to assume $\mathcal{C}(n) = O(n^q)$ for some q between 2 and 3 (Joachims, 1998; Bottou and Lin, 2007). The number of training patterns is denoted by ℓ, the number of examples per class c by ℓ_c, and the number of different classes by d. In the second row the complexity is given under the assumption of (roughly) balanced classes, that is, $\ell_c \in \Theta(\ell/d)$.

3. A Closer Look at Aggregation Operators and Margin Concepts

In this section, we analyze the concepts underlying the various multi-class SVM variants.

First, we will consider the asymptotic behavior in the limit of infinite data by studying consistency. This analysis is closely related to two streams of research. First, we will focus on the Fisher consistency of the loss functions employed for SVM training. This type of consistency, also known as classification calibration, has already been studied for a number of multi-class losses (Lee et al., 2004; Tewari and Bartlett, 2007; Liu, 2007; Liu and Yuan, 2011). It is only indirectly concerned with the SVM itself, since the effect of the regularizer is ignored. Second, we will consider universal consistency building on the well-known result for binary SVMs by Steinwart (2002b). It states that with a suitable

dependency $C(\ell)$ of the regularization parameter C on the data set size ℓ, for any universal kernel, the SVM approaches the Bayes-optimal decision in the limit of infinite data. In addition to the theoretical analysis, we will empirically study the performance of the SVMs on artificial learning tasks that have been designed to highlight crucial differences between margin concepts and aggregation operators.

3.1 Fisher Consistency of Multi-class Loss Functions

In the following, we will analyze the Fisher consistency of the loss functions considered in this study. Let $L(f(x), y)$ denote the loss function applied by a multi-class SVM for training. Let $f^* : X \to \mathbb{R}^d$ denote a minimizer (among all measurable functions) of the risk under the data generating distribution P. A loss function is Fisher consistent if

$$\arg\max \left\{ f_c^*(x) \,\middle|\, c \in Y \right\} \subset \arg\max \left\{ P(y \,|\, x) \,\middle|\, y \in Y \right\} \ .$$

In the following, we use the statements that a multi-class SVM variant and its training loss are Fisher consistent interchangeably.

The consistency of the LLW loss was established by Lee et al. (2004), and it was confirmed by Liu (2007) that this is the only example of a Fisher consistent multi-class loss among the popular WW-, CS-, MMR-, and LLW-SVMs. The ATS machine can be viewed as belonging to the family of reinforced multicategory SVMs. Thus, the Fisher consistency of the ATS loss follows from the analysis by Liu and Yuan (2011).

We will investigate the consistency of the new machines AMO and ATM following the proceeding by Liu (2007). We adopt the short notation $P_y = P(y \,|\, x)$ for the probability of observing class y given x and define $[t]_+ = \max\{0, t\}$. It holds:

Theorem 5 *Let $L(f(x), y)$ denote either the loss function used by the AMO machine or the loss function used by the ATM machine, that is, the loss resulting from application of either the max-over-others or the total-max operator to absolute margins:*

$$L(f(x), y) = \max_{c \in Y \setminus \{y\}} \left\{ v_c^{abs}(f(x), y) \right\} = \left[1 + \max_{c \in Y \setminus \{y\}} \left\{ f_c(x) \right\} \right]_+ \qquad \text{(AMO)}$$

or

$$L(f(x), y) = \max_{c \in Y} \left\{ v_c^{abs}(f(x), y) \right\} = \max \left\{ \left[1 + \max_{c \in Y \setminus \{y\}} \left\{ f_c(x) \right\} \right]_+ , \left[1 - f_y(x) \right]_+ \right\} \ . \qquad \text{(ATM)}$$

Then the minimizer f^* of the corresponding risk $\mathcal{R} = \mathbb{E}[L(f(x), y)]$, subject to the sum-to-zero constraint $\sum_{c \in Y} f_c(x) = 0$, satisfies:

- *If there exists a* majority class *$y \in Y$ such that $P_y > (d-1)/d$, then $f_y^*(x) = d - 1$ and $f_c^*(x) = -1$ for all $c \in Y \setminus \{y\}$.*
- *If $P_y < (d-1)/d$ for all $y \in Y$, then $f^*(x) = 0$.*

The proof, which is given in the supplementary material (Section C), works by analyzing the point-wise risk $\mathcal{R}_x = \sum_{y \in Y} P(y \,|\, x) L(f(x), y)$ and computing the function values $f_c(x)$ minimizing $\mathcal{R}_x$. Thus, the Fisher consistency of the loss functions used in the all-in-one machines considering absolute margins can be summarized as follows:

Corollary 1 *It follows directly from the previous results that the AMO-loss and the ATM-loss are not Fisher consistent while the LLW-loss and the ATS-loss are Fisher consistent.*

In light of the conceptual similarity between the ATS machine and the LLW-SVM, it is not surprising that the ATS-loss is Fisher consistent. However, combining margin violations by means of the maximum-operator appears to be problematic, since neither the AMO nor the ATM machine (the two "max-loss siblings" of the Fisher consistent LLW and ATS machines) share this property.

The question arises how Fisher consistency is related to (a) the margin type, (b) the aggregation of margins in the loss, and (c) the sum-to-zero constraint. Part (a) is easy to answer, since Liu (2007) has proved inconsistency of the relative margin machines (WW and CS). Thus, we focus on absolute margins in the following. We investigate the impact of the sum-to-zero constraint on the maximum and the sum of margin violations. It turns out that dropping the constraint destroys Fisher consistency:

Theorem 6 *Let $L(f(x), y)$ denote the maximum or the sum over absolute margin violations, and assume $P_y < 1/2$ for all $y \in Y$. Then the unconstrained minimizer f^* of the corresponding risk $\mathcal{R} = \mathbb{E}[L(f(x), y)]$ satisfies $\forall c \in Y : f_c^*(x) = -1$ for the sum and $\forall c \in Y : f_c^*(x) = 0$ for the maximum.*

We do not prove this statement here; the proof is analog to the one of Theorem 5 using the techniques developed by Liu (2007). The optimal solution for the maximum operator is all zeros and satisfies the sum-to-zero constraint (cf. Theorem 5), and therefore dropping the constraint does not make any difference. However, the constraint is relevant when the sum operator is employed. The resulting solution does not sum to zero, and it is not Bayes-optimal. This result confirms the importance of the constraint for Fisher consistency.

The ATS machine can be interpreted as the OVA machine with sum-to-zero constraint, and Theorem 6 covers the OVA machine, which is inconsistent in the absence of a majority class. Thus, adding the sum-to-zero constraint makes the OVA machine consistent, at the cost that the different weight vectors w_c cannot be obtained independently anymore.

3.2 Universal Consistency

While Fisher consistency is just a property of the loss function, universal consistency considers the whole machine including the regularizer and its impact relative to the data set size. Steinwart's universal consistency analysis for binary SVMs builds on the fact that the hinge loss is classification calibrated for binary problems. It can be extended to multi-class SVMs with Fisher consistent losses under the assumption of the same training set size dependent choice $C(\ell)$ of the regularization parameter as assumed for the binary SVMs. Thus, from Corollary 1 we get:

Theorem 7 *The LLW-SVM and the ATS-SVM with universal kernel and regularization parameter chosen according to Theorem 2 by Steinwart (2002b) are universally consistent classifiers.*

We omit the proof of this statement, because is a straight-forward extension of the involved proof for binary machines.

It can be shown that using the same rule for $C(\ell)$ as in Theorem 2 from Steinwart (2002b) with a non-Fisher consistent loss does not yield a universally consistent classifier. However, this negative result does not exclude the existence of a different dependency of C on ℓ so that the resulting classifier is universally consistent. Thus, the question arises whether for an SVM surrogate loss function L there exists a dependency $C(\ell)$ of the regularization parameter on the training set size such that the resulting classifier is universally consistent. In the following, we answer the question for all SVM variants covered in this study—with the surprising result that also the MMR-, WW-, and OVA-SVMs can be made consistent when operated with a completely different trade-off $C(\ell)$:

Theorem 8 *For the Gaussian kernel $k(x,x') = \exp(-\gamma\|x-x'\|^2)$ on an input space $X \subset \mathbb{R}^p$, the machines MMR-SVM, WW-SVM, LLW-SVM, ATS-SVM, and OVA-SVM with regularization parameter $C(\ell) \le 1/(d\cdot\ell)$ and kernel parameter $\gamma(\ell)$ fulfilling $\lim_{\ell\to\infty}\gamma(\ell) = \infty$ and $\lim_{\ell\to\infty}\ell\cdot\gamma(\ell)^{-p/2} = \infty$ are universally consistent classifiers.*

Proof Let us first consider the all-in-one machines. The absolute values of all components of the quadratic matrix Q in the dual problem (7) are upper bounded by one. All components of the dual solution α are bounded by $C(\ell) = 1/(d\cdot\ell)$. The sum in the derivative

$$\frac{\partial W(\alpha)}{\partial \alpha_{i,p}} = 1 - \sum_{j,q} Q_{I(i,p),I(j,q)}\cdot\alpha_{j,q}$$

runs over at most $d\cdot\ell$ summands, each of which is bounded by $\frac{1}{d\cdot\ell}$. Thus all gradient components are non-negative in the whole box-shaped feasible region. It follows that all dual variables $\alpha_{i,p}$ end up at the upper bound C. From Equation (8) and the definition of the machines it can be seen that for the primal solution it holds $w_c = \tilde{w}_c - \tilde{\eta}$ with

- $\tilde{\eta} = \eta$ and $\tilde{w}_c = C\cdot\sum_{i|y_i=c}\phi(x_i)$ for the MMR machine,
- $\tilde{\eta} = \eta - C\cdot\sum_i\phi(x_i)$ and $\tilde{w}_c = C\cdot d/2\cdot\sum_{i|y_i=c}\phi(x_i)$ for the WW machine,
- $\tilde{\eta} = \eta - C\cdot\sum_i\phi(x_i)$ and $\tilde{w}_c = C\cdot\sum_{i|y_i=c}\phi(x_i)$ for the LLW machine,
- $\tilde{\eta} = \eta - C\cdot\sum_i\phi(x_i)$ and $\tilde{w}_c = 2C\cdot\sum_{i|y_i=c}\phi(x_i)$ for the ATS machine.

The weight vectors $\tilde{w}_c$ are a scaled version of the kernel density estimator (KDE), which is well known to be universally consistent. The above conditions on $\gamma(\ell)$ translate into the preconditions of Theorem 10.1 by Devroye et al. (1996, p. 150) for the kernel width $h = \sqrt{1/\gamma(\ell)}$. The KDE output fed into the arg max decision rule (1) ignores the additive constant $\tilde{\eta}$ and yields consistent classification predictions.

The OVA result can be proven in the same way. Again, all dual variables take the value C. It is easy to see that the primal SVM solution is then a scaled KDE plus a constant vector: $w_c = \tilde{w}_c - \tilde{\eta}$, with $\tilde{\eta} = \sum_i\phi(x_i)$ and $\tilde{w}_c = 2\cdot\sum_{i|y_i=c}\phi(x_i)$. Thus, the resulting classifier is universally consistent. ■

The above statement is a straight-forward reduction of the SVM to a simple kernel density estimator. The same result holds for binary SVMs. It is a much simpler statement with

a much simpler proof than the famous universal consistency result by Steinwart (2002b). The core idea of Steinwart's analysis is to carefully increase the modeling power of the SVM with growing number of training points so that the impact of regularizer decays to zero, while at the same time overfitting is avoided. In contrast, we keep the impact of the regularizer constantly high. When operating the SVM in this regime it loses its most important features, namely the large margin approach and the sparsity (Steinwart and Christmann, 2008). This may seem highly undesirable, but from the viewpoint of classification accuracy it does not matter much whether an SVM with a specific value of C works well because of a large margin or because of the consistency of KDE. Of course, KDE estimation is less sample and memory efficient than large-margin prediction. Sample efficiency is one of the primary arguments brought forward by Vapnik (1998) for preferring direct estimation of the decision boundary over a plug-in classifier based on KDE.

Theorem 8 establishes the consistency of the MMR, WW, and OVA machines, despite the Fisher inconsistency of their losses. This implies that an analysis of the loss function in isolation in terms of Fisher consistency is not sufficient for fully understanding the predictions made by these machines.

The simple trick of reverting to KDE-based prediction is not trivial, since it does not work for all large margin losses:

Theorem 9 *There exists no function $C(\ell)$ so that CS-SVM, AMO-SVM, or ATM-SVM become universally consistent.*

Proof Consider a single-point input space $X = \{x_0\}$ with any kernel $k(x_0,x_0) > 0$ (any positive kernel is universal on this space). Consider a problem with $d = 3$ classes. It is completely described by the class probabilities; w.l.o.g. they fulfill $p_1 \ge p_2 \ge p_3$. Lemma 4 by Liu (2007) for the CS machine, and Theorem 5 for the AMO-SVM and the ATM-SVM, respectively, offer choices of these probabilities so that the minimizer of the empirical risk is $f_1(x_0) = f_2(x_0) = f_3(x_0) = 0$, with corresponding weight vectors $w_1 = w_2 = w_3 = 0$. This inconsistent solution also minimizes the regularizer, and thus the regularized risk for all $C > 0$.[2] ■

The proof lifts results on Fisher-(in)consistency from the level of the loss function to inconsistency of the actual SVM, taking the regularizer into account. The case of the MMR, WW and OVA machines treated above makes clear that this extension is non-trivial, since for these machines the regularizer makes the difference between consistency and inconsistency. We regard this type of analysis as highly relevant, since SVMs do not actually minimize the empirical risk, but instead a combination of empirical risk and a specific regularizer.

The present analysis covers the three losses involving the max-aggregation completely, since for no C (or $C(\ell)$) they result in a universally consistent SVM. On the other hand, there is a gap in our analysis of machines employing sum-aggregation losses: For $\ell\cdot C(\ell)\to\infty$ Steinwart's analysis applies, while the trivial reduction to a KDE works only for $\ell\cdot C(\ell)$ (asymptotically) bounded by a rather small constant, so that all target margins are always

2. An alternative proof strategy is to construct a non-zero dual optimal solution that corresponds to the primal zero solution.

violated. The question whether an SVM can be consistent for parameters in the gap in between these regimes is left open.

3.3 Artificial Benchmark Problems

In the following, we will show experimental results on highly controlled problems with analytically defined distributions. This investigation complements and enriches the previous theoretical analysis. Some of the theoretical results on Fisher consistency of loss functions can be demonstrated in a non-asymptotic setting. The theoretical results on universal consistency require a universal kernel and thus an "arbitrarily rich" feature space. This is, however, not always the case in practice, where restricted and low-dimensional feature spaces can occur. We visualize the behavior of nine different multi-class SVMs over a range of values of the regularization parameter. The simple test problems serve as "counter examples" that help to understand when and why some of the machines deliver substantially sub-optimal solutions.

We define a basic test problem with two variants, one noise-free and one with label noise. The domain $X = S^1 = \{x \in \mathbb{R}^2 \,|\, \|x\| = 1\}$ of these test problems is the unit circle. The circle is parameterized by $t \in [0, 20[$ through the curve $\beta(t) = \big(\cos(t \cdot \pi/10), \sin(t \cdot \pi/10)\big)$. The problem involves three classes $Y = \{1, 2, 3\}$, see Figure 1 and Figure 2. For the noiseless problem data points $(x, y) \in X \times Y$ are generated as follows. First the label $y \in Y$ is drawn from the uniform distribution on Y. Then x is drawn uniformly at random from the sector X_y. The sectors have different sizes. They are defined as $X_1 = \beta([0, 5))$, $X_2 = \beta([5, 11))$, and $X_3 = \beta([11, 20))$. The only change for the noisy case is that 90% of the labels are reassigned uniformly at random. In other words the distribution of the x-component remains unchanged, and conditioned on $x \in X_z$ the event $y = z$ has probability 40%, while the other two cases have probabilities of 30%. In both variants of the problem it is Bayes-optimal to predict label y on sector X_y. This solution can be realized by a linear model without offset term.

These problems are rather elementary. They are low-dimensional and thus easy to visualize. Their only difficulty lies in the uneven sector sizes. This also results in different densities of the x-components in the different sectors. This design avoids the exploitation of artificial symmetries. The construction is so that in the noisy variant there is no majority class at any point.

We have conducted a parameter study with all nine machines (with linear kernel and without offset term). In the noise-free case we have drawn $\ell = 100$ samples. Since the problem is linearly separable and noise-free, we have tested rather large values of $C = 10^n$ with $n \in \{0, 1, 2, 3, 4\}$ (there are no interesting effects outside this range). The resulting classifiers are shown in Figure 1. The information content of noisy samples is significantly reduced, which is why we use $\ell = 500$ and $n \in \{-4, -3, -2, -1, 0\}$ here (again, results do not change outside this range). The classifier predictions are visualized in Figure 2.

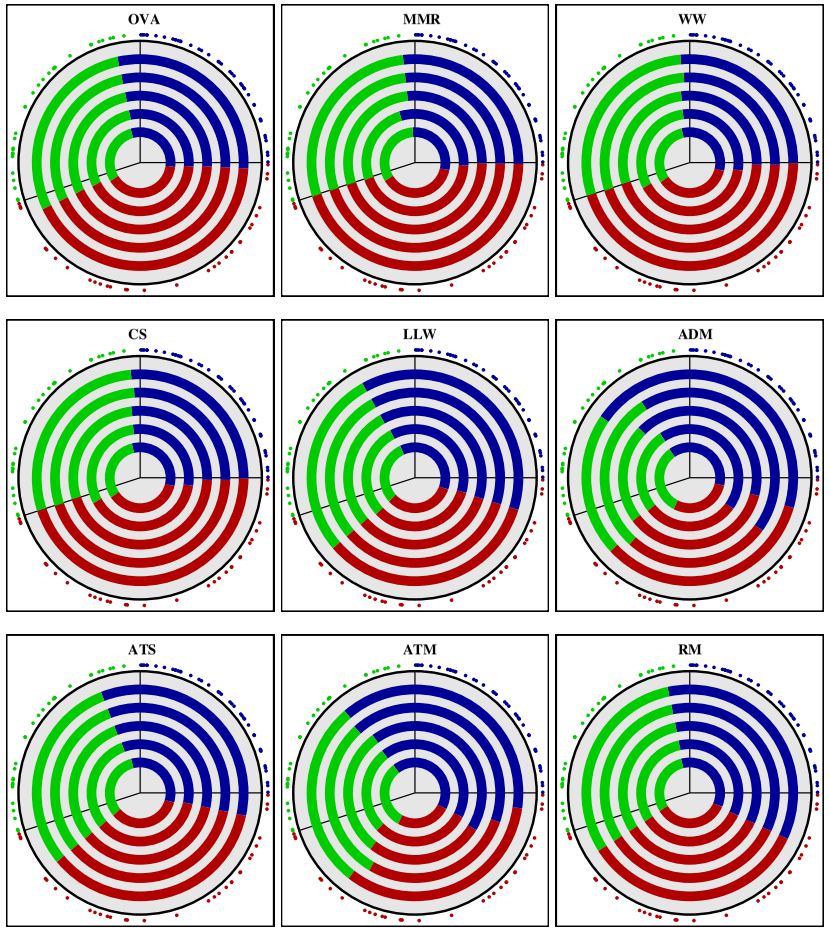

Figure 1: Noiseless circle problem. The sector separators are the decision boundaries of the Bayes-optimal predictor. Classes 1, 2, and 3 are indicated by colors blue, green, and red, respectively. The points on the outside of each graph are the 100 training samples. The colored circles indicate the classifier predictions for $C = 10^n$, $n \in \{0, 1, 2, 3, 4\}$, increasing from inner to outer circles.

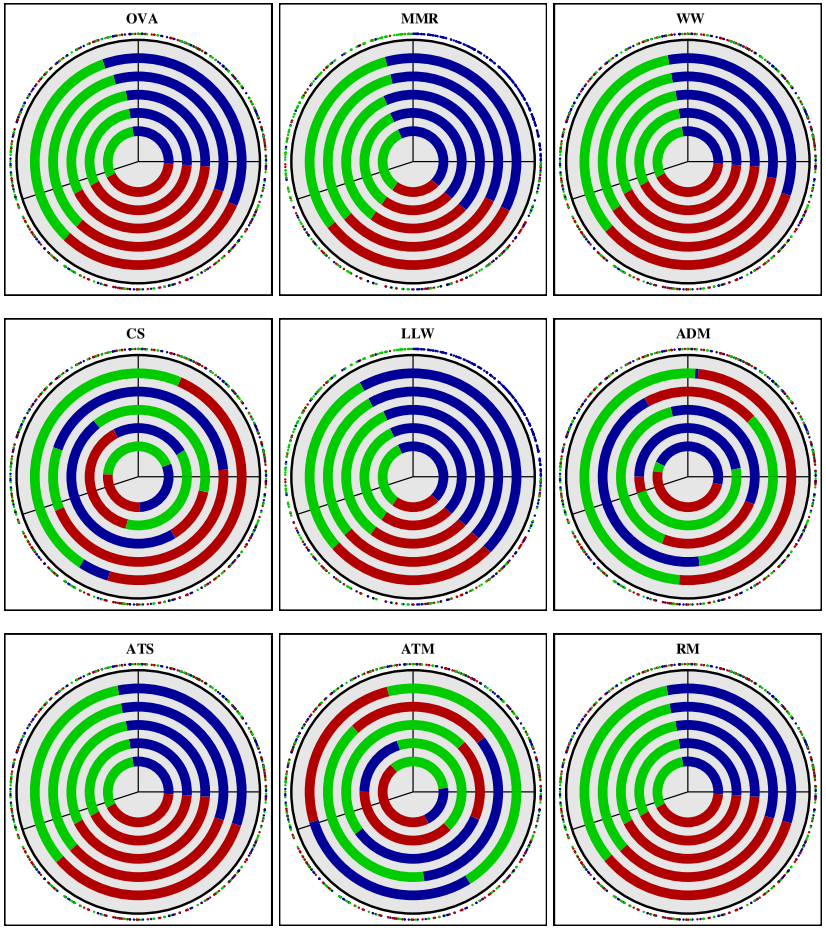

Figure 2: Noisy circle problem. The sector separators are the decision boundaries of the Bayes-optimal predictor. Classes 1, 2, and 3 are indicated by colors blue, green, and red, respectively. The points on the outside of each graph are the 500 training samples. The colored circles indicate the classifier predictions for $C = 10^n$, $n \in \{-4, -3, -2, -1, 0\}$, increasing from inner to outer circles.

Figure 1 shows that the relative margin machines WW and CS excel, in particular for high values of C. Also the MMR machine relying on the self-margin component performs well. In contrast, the absolute margin machines LLW, AMO, ATS, RM, and ATM all fail, over the whole range of parameters (despite the universal consistency of some of the approaches in rich enough feature spaces). The same defect can be observed for OVA, but in weaker form.

The reason for this failure is that the definition of absolute margins does not allow to solve the given problem without violation of the target margin. This holds even for the Bayes-optimal classifier. Thus, absolute margins are not compatible with the form of the decision function. This is obvious for the OVA approach on the circle problem, because one class cannot be separated from the others by a single linear hyperplane through the origin. It turns out that this effect is not a direct consequence of the OVA approach, but of absolute margins in general.

Figure 2 displays the performance in the presence of massive label noise. The performance of the WW machine remains good, but as expected it needs a much smaller value of C. The performance of MMR degrades a bit, while OVA does well in this case. The sub-optimal performance of the LLW machine is largely unchanged, while the closely related ATS and RM profit from the self-margin component (which by itself works well, as shown by the MMR results). Most strikingly, the CS machine with its relative margin as well as the AMO and ATM machines with their absolute margins give random predictions. All three approaches rely on maximum-based aggregation operators. This behavior is perfectly explained by the Fisher consistency results (also reflected in the proof of Theorem 5): Since there is no majority class, all losses favor the trivial solution $w_1 = w_2 = w_3 = 0$. This solution is also optimal for the regularizer. Thus, it is attained for all values of C, and the figures show nothing but numerical noise. In the noisy case the combination of loss components with maximum-based aggregation operators results in guessing performance. Notably this includes the well established CS machine.

In low dimensional feature spaces we see absolute margin machines fail in the noiseless case and maximum-based aggregation operators in the noisy case.[3] Despite the simplicity of the synthetic problems, only a single machine solves both cases, namely the WW approach. The simplistic OVA and MMR machines perform worse, but still satisfactory.

4. Empirical Comparison

This section empirically compares nine approaches to multi-category SVM learning, namely the sequential OVA scheme, the established all-in-one methods WW, CS, LLW, RM, and MMR, as well as the new methods called AMO, ATS, and ATM. All algorithms were implemented in the Shark open source machine learning library (Igel et al., 2008). Source code for reproducing the results can be found in the supplementary material. First, twelve standard benchmark data sets were considered for non-linear SVM learning, and careful model selection was conducted. This already makes our experiments the most extensive comparison of multi-class SVMs so far. Second, additional experiments for linear SVMs are presented later in this section.

3. This result does of course not exclude the existence of a similar problem where WW also fails. However, we did not manage to construct such an instance.

4.1 Multi-class Benchmark Problems

The descriptive statistics of the twelve data sets used to evaluate the non-linear multi-class SVM methods are given in Section D of the supplementary material. All features of all data sets were pre-processed by rescaling to unit variance. This rescaling was done for each split into training and test data individually based on the statistics of the particular training set.

4.2 Model Selection

In all non-linear SVM experiments, Gaussian kernels $k_\gamma(x_1, x_2) = \exp(-\gamma||x_1 - x_2||^2)$ were used. The bandwidth γ of the Gaussian kernel and the regularization parameter C of the machine were determined by nested grid search. Repeated cross-validation was employed as model selection criterion. Five-fold cross-validation was repeated ten times using ten independent random splits into five folds. This stabilizes the model selection procedure especially for small data sets. Candidate parameters were evaluated on the 5×10 validation subsets and the configuration yielding the best average performance was chosen. If any of the selected model parameters was at the grid boundary, then the grid was extended accordingly.

We set the initial grid to $\gamma \in \{2^{-12+3i} \,|\, i = 0, 1, \ldots, 4\}$ and $C \in \{2^{3i} \,|\, i = 0, 1, \ldots, 4\}$. Let (γ_0, C_0) denote the parameter configuration picked in the first stage. Then in the second stage the parameters were further refined on the grid $\gamma \in \{2^i \cdot \gamma_0 \,|\, i = -2, -1, 0, 1, 2\}$ and $C \in \{2^i \cdot C_0 \,|\, i = -2, -1, 0, 1, 2\}$. For linear SVMs we applied the same approach restricted to the complexity control parameter C. The hyperparameters as determined by the grid-searches are given in Section E of the supplementary material.

Table 3 provides a comparison reflecting the computational demand of parameter tuning. It lists the total training time for computing the 5-fold cross validation error on a 5×5 grid of the outer grid search loop, centered on the optimal parameters. Training times differ by several orders of magnitude depending on the SVM variant.

Data set	OVA	MMR	WW	CS	LLW	AMO	ATS	ADS	RM
Car	36.45	12.89	131.7	1027	6112	40231	2399	34046	4106
Glass	1.10	0.32	2.05	318.6	48.50	369.2	247.1	186.1	69.87
Iris	1.41	0.13	13.02	1.30	25.58	4.63	647.7	35.01	243.1

Table 3: Time in seconds for computing the 5-fold cross validation error on a single core over a 5×5 grid around the optimal parameter values.

4.3 Evaluation

The multi-class SVMs were evaluated as follows. Using the best parameters found during model selection, 100 machines were trained on 100 random splits into training and test data (preserving the original set sizes).[4] In this way properties of the test error distribution

4. Doing the full model selection 100 times would be the better setup, however, it was computationally too demanding.

can be estimated. We report empirical mean and standard deviation. Furthermore, the 100 repetitions allow to test results for significant differences. For each problem we have compared each machine to the best performing one with a paired U-test (at significance level $\alpha = 0.01$). We are not interested in the test results per se; instead, the tests provide thresholds for judging performance as competitive or inferior. It must be noted that the 100 repetitions share the same data and are thus not independent. This means that the confidence level needs adjustment. However, the U-test still provides a meaningful thresholding mechanism.

4.4 Stopping Condition

For a fair comparison of training times of different SVMs, it is of importance to choose comparable stopping criteria for the quadratic programming. Unfortunately, this is hardly possible in the experiments presented in this study, because the quadratic programs differ. However, in the case of just two classes all machines solve the same problem. Therefore the stopping condition was selected such that for a binary problem these machines would give the same solution. The common threshold of $\varepsilon = 10^{-3}$ on violations of the Karush-Kuhn-Tucker (KKT) conditions of optimality was used as stopping criterion (Bottou and Lin, 2007).

To rule out artifacts of this choice several experiments were repeated with an accuracy of $\varepsilon = 10^{-5}$. These experiments did not result in improved performance. Thus, the choice of the stopping criterion may in the worst case influence training times, but not the test accuracies reported in Section 4.5 and Section 4.6.

For all non-linear machines, the maximum number of SMO iterations was limited to 10.000 times the number of dual variables. The limit for linear machines was 10 times higher.[5] This was necessary to keep the grid searches computationally tractable. However, the few parameter configurations that had hit this limit corresponded to "degenerated" machines (i.e., bad solutions), typically with far too small γ and too large C. Thus, this proceeding did not influence the outcome of the model selection process.

4.5 Non-linear SVM Results

The test accuracies of all nine machines are listed in Table 4. The table also indicates whether a paired U-test judges the 100 test accuracies as significantly worse than the machine with the best performance. The relative accuracies of the 9 machines are represented graphically in Figure 3.

A similar plot in Figure 4 displays training times. The training times varied vastly with the choice of the hyper-parameters, that is, they were strongly dependent on the outcome of the model selection procedure. In some cases there exist configurations with similar prediction performance but different optimization times. Thus, the timing results were subject to non-negligible noise and should thus be interpreted with care.

5. The higher limit accounts for the fact that single iterations are less efficient, because in the algorithm proposed by Hsieh et al. (2008) and Fan et al. (2008) and refined by Glasmachers and Doğan (2013, 2014) the choice of the active variable does not take gradient and gain information into account, see Section 4.6.

Table 4: Classification accuracies in percent of correctly classified test examples. The table lists mean values and standard deviations. In each row bold numbers indicate that the result is not significantly worse than the best one (paired U-test, $\alpha = 0.01$).

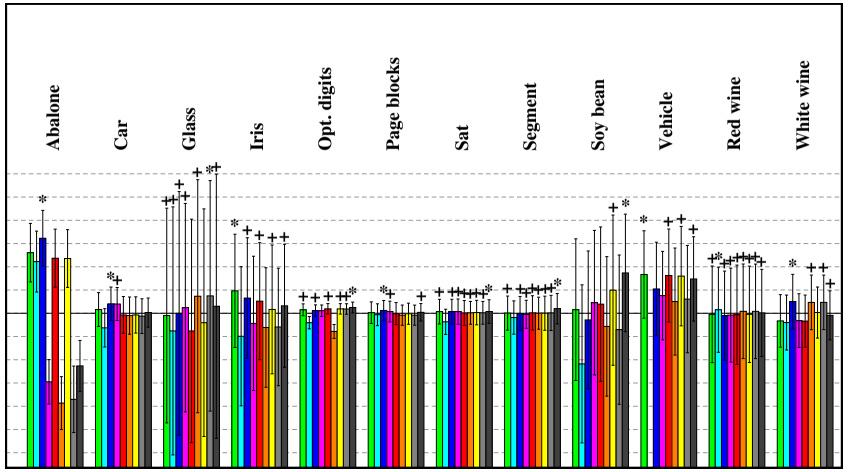

Figure 3: Relative accuracies of all nine machines. The average performance per data set defines the mid-line. Each dashed line marks 1% of deviation. The colored bars denote (relative) classification accuracy (higher is better). The error bars indicate the standard deviation across multiple training/test splits. The best result is indicated with a star (∗). Statistically insignificant differences to the best solution (U-test, $\alpha = 0.01$) are marked with a plus sign (+). Colors represent models as follows: green (OVA), cyan (MMR), blue (WW), pink (CS), red (LLW), orange (AMO), yellow (ATS), light gray (ATM), and dark gray (RM).

In many applications not only training times but also testing times are of relevance. The time it takes to compute the prediction of an SVM classifier is usually dominated by the kernel computations. In the multi-class case this means that sparsity in the dual variables is not enough: only variables that do not appear in any of the expansions of the weight vectors $w_1, \ldots, w_d$ can be dropped in the evaluation of the classifier. We count every training example that is used in the construction of any of the weight vectors as a support vector. The fraction of support vectors is reported in Figure 5.

4.6 Linear SVM Results

In recent years there has been increased interest in linear SVM classifiers. These are a viable alternative to non-linear SVMs in particular in high-dimensional input spaces commonly found, for instance, in text mining and bioinformatics problems. A powerful coordinate descent solver for the dual linear SVM problem was proposed by Hsieh et al. (2008) and Fan et al. (2008) and has been recently extended by Glasmachers and Doğan (2013, 2014). All linear SVM results reported in this section were obtained with an extension of the latter technique to the multi-class case.

For the linear kernel case we have extended the testbed beyond the twelve problems to data sets with different characteristics, which are typically used to evaluate linear multi-class models, see supplementary material (Section E). These data sets are available from the libsvm data collection.[6] We have included problems with rather low-dimenional as well as extremely high-dimensional input spaces. The test errors of the nine linear multi-class SVMs are summarized in Table 5.

6. http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/

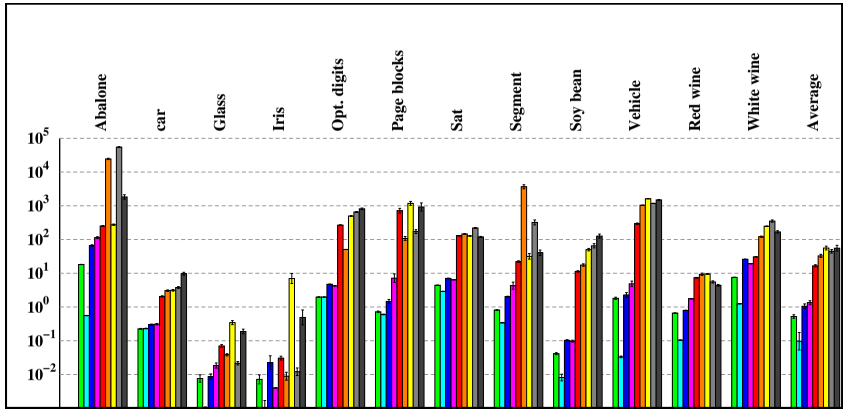

Figure 4: Average training times (logarithmic scale) of all nine machines, in seconds (lower is better). Colors represent models as follows: green (OVA), cyan (MMR), blue (WW), pink (CS), red (LLW), orange (AMO), yellow (ATS), light gray (ATM), and dark gray (RM). The (geometric) average training time across all 12 problems is found on the right.

4.7 Discussion

Our results allow to compare the nine different machines from different angles. We generally view accuracy as a primary goal and training speed and prediction speed (related to sparsity of the solution) as secondary criteria.

The accuracy results of the non-linear SVMs presented in Table 4 and Figure 3 were mixed. The prediction performances of most machines were rather close to each other. This is in accordance with the findings of Hsu and Lin (2002) and Rifkin and Klautau (2004). Larger deviations could be observed on the problems Abalone and Vehicle. The maximum combination operator absolute margin machines AMO and ATM fell behind on the Abalone problem, while the self-margin MMR machine did not give satisfactory performance on the Vehicle problem. Overall the WW and RM machines performed best, for example, when counting the number of data sets where the solution was either best or not significantly worse than the best result. The MMR machines showed the weakest performance. However, it appears than most machines give rather competitive results; OVA, CS, LLW and ATS are hard to put in a clear order, and they are only slightly worse than WW and RM (if at all).

This picture changes completely for linear SVMs. The results presented in Table 5 reveal drastic differences between machines, as already found by Hsu and Lin (2002). There were only two problems where all machines achieved roughly comparable performance, namely News-20 and Sector. These problems come with extremely high-dimensional feature spaces and are thus similar in character to the non-linear SVM problems. Here the classification

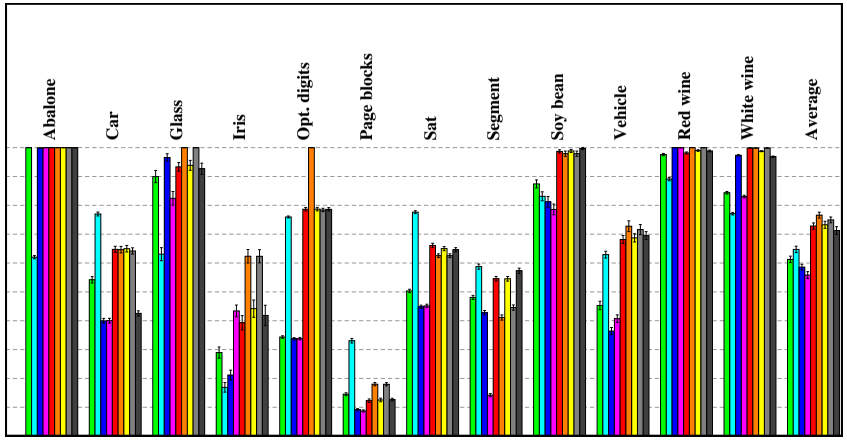

Figure 5: Average fraction of support vectors for all nine machines (lower is better). A bar hitting the top indicates that all points are support vectors, while a bar vanishing at the bottom indicates that no points were used as support vectors. Colors represent models as follows: green (OVA), cyan (MMR), blue (WW), pink (CS), red (LLW), orange (AMO), yellow (ATS), light gray (ATM), and dark gray (RM). The average fraction of support vectors across all 12 problems is found on the right.

calibrated LLW and RM approaches and the other absolute margin machines worked about as well as in the non-linear case. Most other problems have rather low-dimensional feature spaces. Thus, the setting comes conceptually closer to the synthetic circle problems presented in Section 3. This explains the complete breakdown of some methods on some of the problems, for example, all absolute margin machines on the letter data. In accordance with the findings in Section 3, WW and CS outperformed the classification calibrated LLW, ATS and RM machines. The linear SVM results also clearly display the problems of the OVA and MMR approaches. While OVA works well at least in some cases, we have to dismiss the MMR machine completely for its consistently inferior performance. The WW and CS machines clearly performed best, again with a slight but insignificant edge for WW.

The secondary goals of training and test times give a yet completely different picture. The rightmost column in Figure 4 summarizes the training times. The measurements are in accordance with the asymptotical results in Table 2. Not surprisingly, the MMR machine was clearly fastest to train. It is followed by OVA, which is, however, closely followed by WW and CS. It is clear from the asymptotical considerations that the differences between OVA and the all-in-one machines will get more pronounced with increasing number of classes. The WW machine was not slower to train than the popular CS approach, actually

it was slightly faster on average in our experiments.[7] Finally, the various absolute margin machines took at least an order of magnitude longer to train than WW and CS.

7. Here we only present our results for training without bias parameters. However, this statement also holds true for training with bias parameters.

At least for expensive kernel functions prediction speed is governed by the sparsity of the resulting model. Figure 5 reveals that sparsity is primarily a property of the problem, while the chosen loss function has only a minor impact. Overall, multi-class models are expected to be less sparse than, for instance, binary SVMs since a training point can be dropped only if it does not appear in any of the d weight vectors. We observed significant sparsity only for the page blocks data. In comparison relative margin machines gave slightly more sparse models than absolute margin machines. The MMR self-margin machine did not stand out in this category. However, only few problems had sparse solutions at all, and inter-problem spread was much higher than differences between methods. Hence we do not see good reasons to reject any machine based on these data.

In summary, the WW and CS machines showed robust performance across all disciplines, with WW slightly ahead of CS. The MMR machine performed worst in terms of accuracy, but was fastest to train. In most cases there are no good reasons for absolute margin machines.

The results have an interesting interpretation in the unified view presented in Section 2. Differences between self, relative and absolute machine machines were much more pronounced than differences between aggregation operators. Relying only on the single self-margin component (MMR) is computationally attractive but results in rather poor prediction accuracy. Relative margins give strong machines. Consistent absolute margin machines with sum-aggregation are a viable alternative in sufficiently high-dimensional feature spaces, although they are usually costly to train.

It is questionable whether a connection between asymptotic consistency and practical performance exists. This is partially observable in sum-aggregation absolute margin machines performing well only in high-dimensional feature spaces. However, this condition does not seem to be necessary, since the other absolute margin machines show the same trend and also the inconsistent CS machine performs well, except for the noisy circle problem (see Section 3.3). Overall, prediction performance seems to be more closely related to the applied margin concept than to uniform consistency.

Based on our empirical findings, we can recommend relative margin machines for almost all applications. We prefer the WW machine over the CS approach for its slightly more stable performance and its theoretical properties (consistency of WW with Gaussian kernel, see Theorem 8, and breakdown of CS on the noisy circle problem).

5. Conclusion

This article provides a novel unified view on multi-class SVMs, showing that the various approaches are not as different as they seem. All popular algorithms reduce to the standard SVM for binary classification problems, however, they differ along several dimensions when applied to more than two classes. The machines can be formulated based on a vector-valued decision function with as many components as classes. We have highlighted margin concepts, named relative and absolute margins (including the self-margin component), that describe whether the components of the decision function are optimized relative to each other or not. Independent of the margin concept, the machines can employ either sum- or maximum-based aggregation operators for combining margin violations into a scalar loss. A further distinction can be made based on whether a machine fulfills (or even enforces) that

the components of the decision function sum to zero or not. All machines can be formulated with and without bias term (i.e., for linear and affine hypotheses in feature space), and we derived a unified formulation of the corresponding dual optimization problems in terms of margin concepts and aggregation operators.

Our unifying view pointed at three combinations of these features that had not been investigated. These missing machines were derived and evaluated. The new classifiers, named AMO-, ATS- and ATM-SVM, all use the absolute margin concept but consider different aggregates of the margin violations. The ATS machine, which can be viewed as one-vs-all classification with imposed sum-to-zero constraint and is closely related to RM SVMs, turns out to be Fisher consistent.

The LLW, RM, and ATS SVMs rely on a classification calibrated loss function. However, we have shown that a non-classification calibrated training loss function does not need to be a principal problem for an SVM, since the overall *regularized* empirical risk minimizer can still be consistent. This is the case for the maximum margin regression (MMR), one-vs-all (OVA), and Weston & Watkins (WW) machines. One may argue that for large enough amounts of data one should prefer consistent models over inconsistent large margins. It is provably impossible to "repair" the inconsistency of the Crammer & Singer (CS) multi-class SVM, AMO and ATM losses by means of SVM-style regularization.[8] The MMR and WW machines, and even the OVA scheme (lacking the sum-to-zero property), turn out to be consistent classifiers when regularized properly. We argue that these results are best understood in the context of our unified view. All inconsistent machines apply the maximum operator for aggregation, while none of the consistent machines relies on this operator. Thus, our results hint at a fundamental difference between the sum and maximum aggregation operators.

Our unified learning problems lend themselves to efficient optimization algorithms. These allowed us to perform a thorough empirical comparison of the various multi-class SVMs and to draw conclusions about training times and generalization performance. We considered the LLW and RM machines in our experiments, which are typically omitted in comparison studies for training time reasons (e.g., Ding and Dubchak, 2001; Rifkin and Klautau, 2004; Statnikov et al., 2005), and we could perform proper model selection. We compared nine different multi-class SVM with Gaussian and linear kernel on a large collection of benchmark problems. The unified view enables a meaningful interpretation of the results by relating them to margin concepts and aggregation operators. We find that relative margin machines are superior for the linear kernel, and that sum-based aggregation generally outperforms the maximum approach. Our empirical and theoretical results support the following recommendations:

The standard all-in-one multi-class WW SVM should be used as the default since it gives robust performance at moderate training times. It can be trained at least as fast as the popular CS SVM while giving at least as good generalization results and having nicer theoretical properties (which can matter in practice as shown on artificial test problems and when using a linear kernel). The simplistic OVA method can be a viable alternative; it delivers slightly worse results on average while being a little faster to train. If training time is a major concern then the MMR machine may seem like the best option. However,

8. In practice, the performance of the CS machine is very similar to the WW machine. Thus, more often than not this effect does not seem to be dominant.

its performance can be so poor that even sub-sampling the data in combination with WW or OVA may be a better approach.

With universal kernels and in general in extremely high-dimensional feature spaces the LLW and RM machines with their classification calibrated losses are usually on par with WW and CS and thus promising candidates. However, training may be infeasible for large data sets, for its more than ten times longer training times compared to WW and CS.

Abstract

Q-learning (QL) is a popular reinforcement learning algorithm that is guaranteed to converge to optimal policies in Markov decision processes. However, QL exhibits an artifact: in expectation, the effective rate of updating the value of an action depends on the probability of choosing that action. In other words, there is a tight coupling between the learning dynamics and underlying execution policy. This coupling can cause performance degradation in noisy *non-stationary* environments.

Here, we introduce Repeated Update Q-learning (RUQL), a learning algorithm that resolves the undesirable artifact of Q-learning while maintaining simplicity. We analyze the similarities and differences between RUQL, QL, and the closest state-of-the-art algorithms theoretically. Our analysis shows that RUQL maintains the convergence guarantee of QL in stationary environments, while relaxing the coupling between the execution policy and the learning dynamics. Experimental results confirm the theoretical insights and show how RUQL outperforms both QL and the closest state-of-the-art algorithms in noisy non-stationary environments.

Keywords: reinforcement learning, Q-learning, multi-agent learning, non-stationary environments

1. Introduction

Q-Learning (Watkins and Dayan, 1992), QL, is one of the most widely-used and widely-studied learning algorithms due to its ease of implementation, intuitiveness, and effectiveness over a wide-range of problems (Sutton and Barto, 1999). Although QL was originally designed for single-agent domains, it has also been used in multi-agent settings with reasonable success (Claus and Boutilier, 1998). In addition, several gradient-based learning algorithms, which were invented specifically for multi-agent interactions, rely on Q-learning as an internal component to estimate the values of different actions (Abdallah and Lesser, 2008; Bowling, 2005; Zhang and Lesser, 2010). In this paper, we propose a novel algorithm that addresses important limitations of the Q-learning algorithm while retaining Q-learning's attractive simplicity. We show that our algorithm outperforms Q-learning and closely related state-of-the-art algorithms in several noisy and *non-stationary* environments.

*. An earlier version of this paper was presented at the International conference on Autonomous Agents and Multi-Agent Systems (Abdallah and Kaisers, 2013).

The main problem that our algorithm addresses is what we refer to as the *policy-bias* of the action value update. The policy-bias problem appears in Q-learning because the value of an action is only updated when the action is executed. Consequently, the *effective* rate of updating an action value directly depends on the probability of choosing the action for execution. If, hypothetically, the reward information for all actions (at every state) were available at every time step, then the update rule could be applied to all actions and the policy-bias would disappear. Let us refer to this hypothetical update as the *QL-ideal-update*.[1]

It is important to note that the policy-bias problem is different from the exploration-exploitation problem. To solve the exploration-exploitation problem, researchers optimize the execution policy in order to balance exploration vs. exploitation. However, the policy-bias refers to the dependency of the *rate of updating* an action's value on the *probability of selecting* the corresponding action; this dependency is not resolved by changing the policy. As previous research showed, the policy bias may cause a temporary decrease in the probability of choosing optimal actions with higher expected payoffs (Leslie and Collins, 2005; Kaisers and Tuyls, 2010; Wunder et al., 2010). This effect can be more severe, as we show later, in noisy non-stationary environments where the environment dynamics change over time.

Figure 1 illustrates the policy-bias problem using a very simple multi-armed-bandit domain. The domain is stateless with only two actions, one giving the reward of -1 and the other giving the reward of 1. For simplicity, let us assume the best value for the learning rate α, is 0.01 (as we highlight in our experiments later, the best value of the learning rate depends on how noisy the specific domain is). To measure the deviation between a learning algorithm and the QL-ideal-update, we use RMSE: the root mean square error of the Q values (for all actions) compared to the Q values of the QL-ideal-update over 1000 time steps. Figure 1 plots the RMSE of QL for different learning rates and over different execution policies (the probability of choosing the first action), which is fixed throughout the 1000 time steps.[2] We can observe from the figure that the RMSE of QL is minimal when the probability of choosing both actions are equal (pure exploration). However, as the execution policy deviates from the uniform distribution (toward exploitation), the RMSE of QL grows rapidly. It is also important to note that higher learning rate (α) will not lower the RMSE of QL across different execution policies. The RMSE of our proposed algorithm, RUQL, is lower across the different execution policies. In other words, even though our algorithm RUQL, similar to QL, updates only the selected action, the dynamics of learning are very similar to QL-ideal-update and therefore the Q values are close to the ideal values (as if all the actions are updated at every time step).

The algorithm we propose here addresses the policy bias problem. The main idea of the Repeated Update Q-learning (RUQL) is to repeat the update of an action inversely proportional to the probability of choosing that action. For example, if an action is to be chosen for execution only 10% of the time, then the update of that action (when finally chosen) shall be repeated 1/0.1 or 10 times. Consequently, every action will, in expectation, be updated an equal number of times. RUQL can be approximated by a closed-form expression that removes the need to actually repeat the updates,

1. In practice, QL-ideal-update may lead to horrible performance (since we are executing suboptimal actions every time step) and may be even impossible to achieve (in multi-state domains executing an action would change the state), but hypothetically QL-ideal-update would lead to ideal estimates of the action values (Q).
2. More specifically, QL-ideal-update was run for 1000 time steps. Then QL with each of the various execution policies was run for 1000 time steps. Then the squared error of Q-values were averaged over all actions, the root computed, and then averaged again over all time steps.

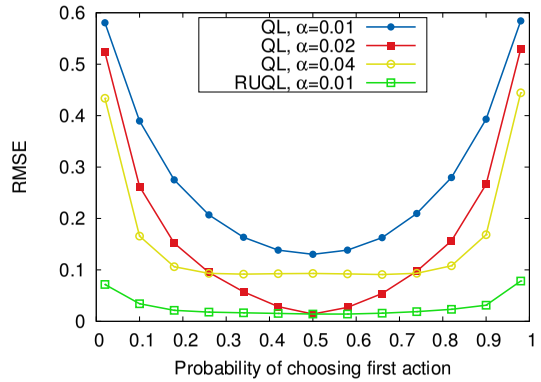

Figure 1: RMSE of QL for different values of α, and RUQL plotted against the probability of choosing the first action $\pi(1)$. RUQL, approximated as in Theorem 1, has the lowest RMSE across different policies.

as shown in Section 3. We show both theoretically and experimentally that the dynamics of RUQL approximate the dynamics of QL-ideal-update (as if all the actions were updated every time step). More importantly, RUQL outperforms both QL and the closest state-of-the-art, FAQL (Kaisers and Tuyls, 2010), in noisy non-stationary settings.

In summary, the main contributions of this paper are:

- A new reinforcement learning algorithm, RUQL, which builds on the Q-learning algorithm but does not suffer from the policy-bias problem.
- A mathematical derivation of a closed form of RUQL that makes the RUQL algorithm computationally feasible.
- Theoretical analysis that shows how RUQL maintains the convergence guarantee of QL (in stationary environments, and for tabular Q values), while having learning dynamics that are better suited for non-stationary environments.
- Theoretical analysis that shows the similarities and differences between RUQL and the closely-related state-of-the-art algorithm, FAQL (Kaisers and Tuyls, 2010).
- An extensive experimental study that confirms the theoretical analysis and compares the performance of RUQL to QL, FAQL, and two other learning algorithms.

The following section presents the required background concepts covering Q-learning and related algorithms. We then introduce the algorithm RUQL, followed by theoretical and experimental analysis. Finally, a summary and a discussion of the contributions conclude the article.

2. Background

The Q-learning algorithm (Watkins and Dayan, 1992) is a model-free[3] reinforcement learning algorithm that is guaranteed to find the optimal policy for a given Markov Decision Process (MDP). An MDP is defined by the tuple $\langle S, A, P, R \rangle$, where S is the set of states representing the system and $A(s)$ is the set of actions available to the agent at a given state s. The function $P(s, a, s')$ is the transition probability function and quantifies the probability of reaching state s' after executing action a at state s. Finally the reward function, $R(s, a, s')$, gives the average reward an agent acquires if the agent executes action a at state s and reaches state s'. The goal is then to find the optimal policy $\pi^*(s, a)$ which gives the probability of choosing every action a at every state s in order to maximize the expected total discounted rewards. In other words, $\pi^*(s, a) = \arg\max_{\pi(s,a)} E\{\sum_t \gamma^t r_t | s_{t=0} = s, a_{t=0} = a\}$, where the parameter γ denotes the discount factor that controls the relative value of future rewards. To solve the model, the action value function, Q, is introduced where $Q(s, a) = \sum_{s'} P(s, a, s') \left(R(s, a, s') + \gamma \max_{a'} Q(s', a')\right)$. The Q function represents the expected total discounted reward if the agent starts at state s, executes action a, and then follows the optimal policy thereafter. Intuitively, the function $Q^t(s, a)$ represents what the agent believes, at time t, to be the worth of action a at state s. The optimal policy can then be defined as $\pi^*(s) = \arg\max_a Q(s, a)$. The Q-learning algorithm incrementally improves the action-value function Q using the update equation

$$Q^{t+1}(s, a) \leftarrow Q^t(s, a) + \alpha \left(r + \gamma \max_{a'} Q^t(s', a') - Q^t(s, a) \right). \quad (1)$$

The parameter α is called the learning rate and controls the speed of learning. The variables r and s' refer to the immediate reward and the next state, both of which are observed after executing action a at state s. Algorithm 1 illustrates how the Q-learning update equation is typically used in combination with an exploration strategy that generates a policy from the Q-values.

Algorithm 1: Q-learning Algorithm

```
begin
    Initialize function Q arbitrarily.
    Observe the current state s.
    repeat
        Compute the policy π(s, a) from Q(s, a), balancing exploration and exploitation.
        Choose an action a according to agent policy π(s, a).
        Execute action a and observe the resulting reward r and the next state s'.
        Update Q(s, a) using Equation 1.
        Set s ← s'.
    until done
end
```

The agent needs to choose the next action considering that its current Q-values may still be erroneous. The belief of an action to be inferior may be based on a crude estimate, and there may be a chance that updating that estimate reveals the action's superiority. Therefore, the function Q^t

3. Q-learning does not require knowing the underlying stochastic reward or transition function of the MDP model.

in itself does not dictate which action an agent should choose in a given state (Step 5 in Algorithm 1). The policy $\pi(s,a)$ of an agent is a function that specifies the probability of choosing action a at state s. A greedy policy that only selects the action with the highest estimated expected value[4] can result in an arbitrarily bad policy, because if the optimal action initially has a low value of Q it might never be explored. To avoid such premature convergence on suboptimal actions, several definitions of π have been proposed that ensure all actions (including actions that may appear sub-optimal) are selected with non-zero probability. These definitions of π are often called *exploration* strategies (Sutton and Barto, 1999). The two most common exploration strategies are ϵ-greedy exploration and Boltzmann exploration. The ϵ-greedy exploration simply chooses a random action with probability ϵ and otherwise (with probability 1-ϵ) chooses the action with the highest Q-value greedily. The Boltzmann exploration strategy defines the policy $\pi(s,a)$ as a function of Q-values and τ

$$\pi^t(s,a) = \frac{e^{\frac{Q^t(s,a)}{\tau}}}{\sum_{a'} e^{\frac{Q^t(s,a')}{\tau}}}, \tag{2}$$

where the tunable parameter τ is called the temperature.

We use Boltzmann exploration in our experiments, but with an additional parameter π_{min}, which defines a threshold below which the probability of choosing an action can not fall. In a sense, this combines the nice continuity of the Boltzmann exploration with the exploration guarantee of ϵ-greedy exploration. This is implemented using a projection function (Zinkevich, 2003; Abdallah and Lesser, 2008), which projects the policy to the closest valid policy with minimum exploration.

Regardless of the exploration strategy, the agent needs to gain information about the value of each action at every state in order to become more certain over time that the action with the highest estimate truly is the optimal action. However, an agent can only execute one action at a time and the agent only receives feedback (reward) for the action that was actually executed. As a result, in Q-learning, the rate of updating an action relies on the probability of choosing that action. The theoretical comparison of updating one vs. all actions at each time step reveals that Q-learning counter-intuitively decreases the probability of optimal actions under some circumstances, which leads to drawbacks in non-stationary environments (Kaisers and Tuyls, 2010; Wunder et al., 2010).

Scaling the learning rate inversely proportional to the policy has been proposed to overcome this limitation, thereby approximating the simultaneous updating of all actions every time a state is visited. This concept has been initially studied to modify fictitious play (Fudenberg and Levine, 1998), and inspired two equivalent modifications of Q-learning named Individual Q-learning (Leslie and Collins, 2005) and Frequency Adjusted Q-learning (FAQL) (Kaisers and Tuyls, 2010). FAQL used the modified Q-learning update rule

$$Q^{t+1}(s,a) \leftarrow Q^t(s,a) + \frac{1}{\pi(s,a)}\alpha\Big(r + \gamma \max_{a'} Q^t(s',a') - Q^t(s,a)\Big).$$

Thus, FAQL scales the learning rate for an action a to be inversely proportional to the probability of choosing action a at a given state. This simple modification to the Q-learning update rule suffers from a practical concern: the update rate becomes unbounded (approaches ∞) as $\pi(s,a)$ approaches zero. Therefore, a safe-guard condition has to be added in practice (Kaisers and Tuyls, 2010)

$$Q^{t+1}(s,a) \leftarrow Q^t(s,a) + \min(1, \frac{\beta}{\pi(s,a)})\alpha\Big(r + \gamma \max_{a'} Q^t(s',a') - Q^t(s,a)\Big). \tag{3}$$

4. A greedy policy can be formally defined as $\pi^t(s,a) = 1$ iff $a = \arg\max_{a'} Q^t(s,a')$ and $\pi^t(s,a) = 0$ otherwise.

where β is a tuning parameter that safeguards against the cases where $\pi(s,a)$ is close to zero. The resulting algorithm is similar to Algorithm 1 but with Line 8 modified to use Equation 3 instead of Equation 1.

While introducing parameter β does make FAQL applicable in practical domains, the introduction of β also results in two undesirable properties. The first undesirable property is reducing the effective learning rate (instead of α it is now $\alpha\beta$) and therefore reducing the responsiveness of FAQL.[5] The second and more important undesirable property is what we refer to as the β-limitation: Once the probability of choosing an action, $\pi(s,a)$, goes below β, FAQL behaves identical to the original QL. In other words, FAQL suffers from the same policy-bias problem when the probability of choosing an action becomes lower than β. This is problematic because the lower the probability of choosing an action, the more important it is to adjust the learning rate (to account for the infrequency of choosing that action). Our proposed algorithm RUQL does not suffer from these limitations and we show in the experiments how this can improve performance in noisy and non-stationary settings.

3. Repeated-Update Q-learning, RUQL

Our proposed algorithm is based on a simple intuitive idea. If an action is chosen with low probability $\pi(s,a)$ then instead of updating the corresponding action value $Q(s,a)$ once, we repeat the update $\frac{1}{\pi(s,a)}$ times. Algorithm 2 shows the naive implementation of this idea. Line 8 is the only difference between Algorithm 2 and Algorithm 1.

Algorithm 2: RUQL (Impractical Implementation)

```
1  begin
2      Initialize function Q arbitrarily.
3      Observe the current state s.
4      for each time step do
5          Compute the policy π using Q.
6          Choose an action a according to agent policy π.
7          Execute action a and observe the resulting reward r and the next state s'.
8          for i : 1 ≤ i ≤ ⌊1/π(s,a)⌋ do
9              Update Q(s,a) using Equation 1.
10         end
11         Set s ← s'.
12     end
13 end
```

This simple modification to the QL algorithm addresses the policy-bias, but it has two limitations: (1) The repetition only works with $\frac{1}{\pi(s,a)}$ an integer, and (2) as $\pi(s,a)$ gets lower, the number of repetitions increases and quickly becomes unbounded as $\pi(s,a)$ approaches zero. Unlike FAQL, here the computation *time* (not the *value* of the update) is what becomes unbounded as $\pi(s,a)$ approaches zero. In the remainder of this section we will derive a closed-form expression for the

5. In our experiments we take the effective learning rate into account when comparing FAQL to our algorithm RUQL, setting $\alpha_{FAQL} = \beta_{FAQL} = \sqrt{\alpha_{RUQL}}$.

RUQL algorithm. The closed-form expression removes the need for actually repeating any update and therefore makes RUQL computationally feasible.

Theorem 1 *The RUQL update rule can be approximated with an error of $O(\alpha^2)$ as an instance of QL with learning rate (step size) z given by the equation*

$$z_{\pi^t(s,a)} = 1 - [1-\alpha]^{\lfloor \frac{1}{\pi(s,a)} \rfloor},$$

where α is a constant, denoting the learning rate of the underlying QL update equation being repeated.

Proof

For convenience, let $Q_i(s,a)$ refer to the intermediary value of the Q function after i iterations of the loop in Steps 8-10 in Algorithm 2. Before starting the loop, we have $Q_0(s,a) \leftarrow Q^t(s,a)$, i.e. before executing any iterations the value of $Q(s,a)$ is set to the value of the previous time step t. Upon finishing the loop we get $Q^{t+1}(s,a) = Q_{\lfloor \frac{1}{\pi(s,a)} \rfloor}(s,a)$, or the new value of $Q(s,a)$ at time step $t+1$. Let us now trace the computation of $Q^{t+1}(s,a) = Q_{\lfloor \frac{1}{\pi(s,a)} \rfloor}$. After one iteration we have

$$Q_1(s,a) \quad = \quad [1-\alpha]Q_0(s,a) + \alpha[r + \gamma \max_{a'} Q_0(s',a')].$$

The second iteration results in

$$\begin{aligned} Q_2(s,a) &= [1-\alpha]\left([1-\alpha]Q_0(s,a) + \alpha[r+\gamma \max_{a'} Q_0(s',a')]\right) + \alpha[r+\gamma \max_{a'} Q_1(s',a')] \\ &= [1-\alpha]^2 Q_0(s,a) + [1-\alpha]\alpha[r+\gamma \max_{a'} Q_0(s',a')] + \alpha[r+\gamma \max_{a'} Q_1(s',a')]. \end{aligned}$$

Similarly, after $\lfloor \frac{1}{\pi(s,a)} \rfloor$ iterations

$$\begin{aligned} Q_{\lfloor \frac{1}{\pi(s,a)} \rfloor}(s,a) \quad = \quad & [1-\alpha]^{\lfloor \frac{1}{\pi(s,a)} \rfloor} Q_0(s,a) + \\ & [1-\alpha]^{\lfloor \frac{1}{\pi(s,a)} \rfloor - 1} \alpha[r+\gamma \max_{a'} Q_0(s',a')] + \\ & [1-\alpha]^{\lfloor \frac{1}{\pi(s,a)} \rfloor - 2} \alpha[r+\gamma \max_{a'} Q_1(s',a')] + \\ & \ldots \\ & \alpha[r+\gamma \max_{a'} Q_{\lfloor \frac{1}{\pi(s,a)} \rfloor - 1}(s',a')]. \end{aligned}$$

It is important to keep in mind that all the above repeated updates occur at the *same time step*. It is also worth noting that the updates are monotonic (i.e., either increasing or decreasing) between t and $t+1$. In the following, the floor notation is dropped for notational convenience. There are four cases that we need to consider (derivations are given in the Appendix):

Case 1, $s' \neq s$, or $\left(s' = s$ and $a \neq \arg\max_{a'} Q^t(s,a')\right)$ throughout the $\frac{1}{\pi(s,a)}$ iterations:

$$Q^{t+1}(s,a) = [1-\alpha]^{\frac{1}{\pi(s,a)}} Q^t(s,a) + \left[1 - (1-\alpha)^{\frac{1}{\pi(s,a)}}\right][r + \gamma \max_{a'} Q^t(s',a')] \quad (4)$$

Case 2, $s' = s$ and $a = \arg\max_{a'} Q^t(s,a')$ throughout the $\frac{1}{\pi(s,a)}$ iterations:

$$Q^{t+1}(s,a) = [1-\alpha(1-\gamma)]^{\frac{1}{\pi(s,a)}} \left(Q^t(s,a) - \frac{r}{1-\gamma}\right) + \frac{r}{1-\gamma} \quad (5)$$

Case 3, $s' = s$ and $a \neq \arg\max_{a'} Q^t(s,a')$ until iteration $i_\top$: Since the update is monotonic, iteration $i_\top$ can be determined, at which $Q_i(s,a)$ becomes larger than $\max_{a'} Q^t(s,a')$. Subsequently, we can compute $Q^{t+1}(s,a)$ by applying the remaining updates $\frac{1}{\pi(s,a)} - i_\top$ to the value of $\max_{a'} Q^t(s,a')$ according to Equation 5, since the updated action bears the maximum value for the remaining updates, i.e.,

$$Q^{t+1}(s,a) = [1-\alpha+\alpha\gamma]^{\frac{1}{\pi(s,a)} - i_\top} \left(\max_{a'} Q^t(s,a') - \frac{r}{1-\gamma}\right) + \frac{r}{1-\gamma}.$$

Case 4, $s' = s$ and $a = \arg\max_{a'} Q^t(s,a')$ until iteration $i_\perp$: Similar to Case 3, let $i_\perp$ be the iteration at which $Q_{i_\perp}(s,a)$ drops below $\max_{a'} Q^t(s,a')$. As a result, we can compute $Q^{t+1}(s,a)$ by applying the remaining updates $\frac{1}{\pi(s,a)} - i_\perp$ to the value of $\max_{a'} Q^t(s,a')$ according to Equation 4, i.e.

$$Q^{t+1}(s,a) = [1-\alpha]^{\frac{1}{\pi(s,a)} - i_\perp} \max_{a'} Q^t(s,a') + \left[1 - (1-\alpha)^{\frac{1}{\pi(s,a)} - i_\perp}\right][r + \gamma \max_{a'} Q^t(s',a')].$$

The computation time complexity of $i_\top$, $i_\perp$ and the update rule of RUQ-Learning is $O(1)$, a significant improvement over the naive implementation in Algorithm 2 with unbounded time complexity. However, the four cases and the corresponding update equations are not as simple as the original Q-learning update equation (Equation 1) or even the FAQL update equation (Equation 3). The following derivation will elucidate the difference between Equation 4 and Equation 5 and show that it is insignificant for small learning rates, such that solely Equation 4 can be used as an approximation in all cases. Consider the Taylor series expansion of both equations at $\alpha = 0$, using $(1-\alpha)^c = 1 - c\alpha + O(\alpha^2)$. In Case 2, when $Q^t(s,a) = \max_{a'} Q(s,a')$, Equation 4 becomes

$$\begin{aligned} Q^{t+1}(s,a) &= \left(1 - \frac{\alpha}{\pi(s,a)}\right) Q^t(s,a) + \frac{\alpha}{\pi(s,a)}[r + \gamma Q^t(s,a)] + O(\alpha^2) \\ &= \left(1 - \frac{\alpha(1-\gamma)}{\pi(s,a)}\right) Q^t(s,a) + \frac{\alpha}{\pi(s,a)} r + O(\alpha^2), \end{aligned}$$

while Equation 5 becomes

$$\begin{aligned} Q^{t+1}(s,a) &= \left(1 - \frac{\alpha(1-\gamma)}{\pi(s,a)}\right)\left(Q^t(s,a) - \frac{r}{1-\gamma}\right) + \frac{r}{1-\gamma} + O(\alpha^2) \\ &= \left(1 - \frac{\alpha(1-\gamma)}{\pi(s,a)}\right) Q^t(s,a) + \frac{\alpha}{\pi(s,a)} r + O(\alpha^2). \end{aligned}$$

In brief, Case 1 requires to apply Equation 4 anyway, and other cases only require to change to Equation 5 if $Q^t(s,a) = \max_{a'} Q(s,a')$. However, given $Q^t(s,a) = \max_{a'} Q(s,a')$ the lines above show that the difference between the equations is $O(\alpha^2)$, and hence negligible for small α,

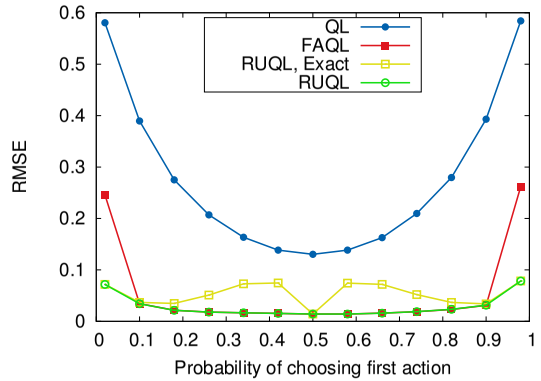

Figure 2: RMSE of QL, FAQL, RUQL (exact) and RUQL (approximate) plotted against the probability of choosing the first action $\pi(1)$. RUQL, approximated as in Theorem 1, has the lowest RMSE across different policies. The learning parameters are set as follows: $\alpha = 0.01$ for QL and RUQL and $\alpha_{FAQL} = \beta = \sqrt{\alpha} = 0.1$.

since higher order terms become insignificant. Therefore, Equation 4 can be applied in all four cases. In other words, RUQL can be approximated by

$$Q^{t+1}(s,a) = [1-\alpha]^{\frac{1}{\pi(s,a)}} Q^t(s,a) + \left[1-(1-\alpha)^{\frac{1}{\pi(s,a)}}\right][r + \gamma \max_{a'} Q^t(s',a')].$$

This equation can then replace Lines 8-10 in Algorithm 2 to produce a simple and efficient implementation of RUQL as an instance of QL with substitute learning rate $z_{\pi^t(s,a)} = 1-[1-\alpha]^{\frac{1}{\pi^t(s,a)}}$. ■

Algorithm 2 uses the floor notation, since fractional repetitions are not possible. However, the approximation alleviates this limitation, hence we adopt $z_{\pi^t(s,a)} = 1-[1-\alpha]^{\frac{1}{\pi(s,a)}}$ without flooring for both our experimental and theoretical analyses. The continuous and smooth definition of z_π will simplify the theoretical analysis we conduct later. More importantly, such smooth definition will handle fractions of $1/\pi$ more accurately. To illustrate this point we recall here the simple domain we used in the introduction section. The RUQL update equation is trying to imitate the QL update equation if (hypothetically) the agent can execute and update *every action at every time step*, or what we referred to as QL-ideal-update in the introduction. Figure 2 plots the RMSE of QL, FAQL, RUQL (exact) and RUQL (approximate) when compared to QL-ideal-update and using the same settings of the multi-armed bandit problem we explained in the introduction section.

It is clear from the figure that RUQL (approximate) has the lowest RMSE across different values of $\pi(1)$. In other words, independent of the underlying execution (exploration) strategy, RUQL results in action values that are the closest to the QL-ideal-update. Furthermore, as $\pi(1)$ goes beyond β in either direction the β limitation hits FAQL. Another interesting observation is that the RMSE of RUQL (exact) is higher than the RMSE of RUQL (approximate). The reason is the

inability of RUQL (exact) to handle partial iterations (i.e. if the ratio $\frac{1}{\pi}$ is not an integer). This is also why the performance of RUQL (exact) is best when $\pi(1) = 0.02, 0.1$, 0.5, 0.9, and 0.98 (with an almost perfect match with RUQL-approximate) in a clear verification of the validity of our approximation. At these points the boost in the learning rate that is given to the less probable action (with probability 0.02,0.1, and 0.5) is based on $\frac{1}{\pi}$ which is an integer in these cases. The further the probabilities are from these values, the further the RMSE of RUQL-exact from the RMSE of RUQL-approximate.

4. Theoretical Analysis

This section analyzes RUQ-Learning by comparing it with two closely-related algorithms: the original Q-learning and FAQL, the closest state of the art.

4.1 RUQL and QL

As stated by Theorem 1, RUQL can be approximated as an instance of QL with an effective learning rate $z_{\pi^t(s,a)} = 1-[1-\alpha]^{\frac{1}{\pi^t(s,a)}}$. However, while (traditionally) the learning rate of Q-learning, α, is independent of the policy, the *effective* learning rate of RUQL, z, is a function of the policy at the particular state s and action a at the given time t. For example, a common definition of the learning rate $\alpha(s,a,t) = \frac{1}{visits(s,a,t)}$, where $visits(s,a,t)$ is the number of times the learning agent visited state s and executed action a until time t. This is different from RUQL where the effective learning rate z includes the policy. The inclusion of the policy in z creates a feedback loop: the effective learning rate affects the learning which affects the policy which affects the effective learning rate.[6] As we show later in the experimental analysis, this results in significantly different learning dynamics (between RUQL and traditional QL) in non-stationary environments. In particular, we show that increasing the learning rate α even by 100 folds does not change the dynamics of QL significantly. On the other hand, using RUQL results in significantly different dynamics.

The dependence of the effective learning rate on the policy raises concerns of whether the convergence of Q-learning in stationary environments still holds for RUQL. We revisit here the main conditions for Q-learning convergence (Sutton and Barto, 1999), and consider whether the conditions still hold for RUQL and under what assumptions. For the original Q-learning two conditions concerning the learning rate need to be satisfied for convergence in MDPs: $\sum_t \alpha_t = \infty$ and $\sum_t (\alpha_t)^2 < \infty$. The second condition requires that the learning rate decays over time, while the first condition ensures that such decay is slow enough to allow the agent to learn the optimal Q values. One possible definition of α that satisfies both conditions is $\alpha_t = \frac{1}{t}$.

Extending the two conditions to RUQL, we substitute z for α_t in the learning rate conditions to get $\sum_t z_{\pi^t} = \infty$ and $\sum_t z_{\pi^t}^2 < \infty$. Expanding the first condition yields

$$\sum_t \left(1-[1-\alpha_t]^{\frac{1}{\pi^t(s,a)}}\right) = \infty.$$

Using polynomial expansion of z

$$z_{\pi^t} = 1-[1-\alpha_t]^{\frac{1}{\pi^t(s,a)}} = 1-\left(1+\frac{1}{\pi^t(s,a)}(-\alpha_t)+O(\alpha_t^2)\right) = \frac{\alpha_t}{\pi^t(s,a)} - O(\alpha_t^2).$$

6. In the case of a multi-agent system, this feedback loop is affected by other agents (because other agents affect the individually learned policy).

Subsequently, omitting the higher order terms[7] denoted by $O(\alpha_t^2)$ and substituting in the first condition leads to

$$\sum_t \left[\alpha_t \frac{1}{\pi^t(s,a)}\right] = \infty.$$

It is worth noting that $\pi^t(s,a)$ is bound away from zero since the sequence of updates proceeds over solely those actions that are selected with positive probability. This implies that for any sequence α_t for which $\sum_t \alpha_t = \infty$, the first condition also holds for the effective learning rate z_π of RUQL, since each summand is at least as large as before. We now move to the second condition:

$$\sum_t \left(1 - [1-\alpha_t]^{\frac{1}{\pi^t(s,a)}}\right)^2 < \infty.$$

Again using the polynomial expansion yields

$$\sum_t \left[\alpha_t \frac{1}{\pi^t(s,a)}\right]^2 < \infty.$$

Here we observe a clear distinction between RUQL and the original QL. Unlike the original Q-learning, we need to impose restrictions on the policy to ensure the above condition. Let us denote the minimum probability of choosing an action at a given time with $\epsilon^t = \min_{s,a} \pi^t(s,a)$ (which reflects the exploration rate). We then need to ensure that

$$\sum_t \left[\frac{\alpha_t}{\epsilon^t}\right]^2 < \infty.$$

To clarify how the above conditions can be used, consider the following example. Suppose we are using ϵ-greedy exploration strategy and $\alpha_t = \frac{1}{t}$, then one possible exploration rate that satisfies the second condition is $\epsilon^t = \frac{1}{\lg t}$.[8] Similarly, we can ensure minimum exploration using Boltzmann exploration through updating the temperature τ using the learned action values (Achbany et al., 2008).

It is worth noting that in practice, and particularly in non-stationary environments, the exploration rate parameter (which is ϵ in ϵ-greedy and τ in Boltzmann) is usually held to small constant values. In such cases, the second condition is trivially satisfied,[9] which means RUQL is guaranteed to converge to the optimal Q values. Our experiments confirm that RUQL works well in these environments.

4.2 RUQL and FAQL

Both RUQL and FAQL provide an algorithmic implementation to address the policy-bias of Q-learning. The two algorithms resolve this problem in different ways: FAQL normalizes the learning rate of the Q-learning update while RUQL repeats the Q-learning update rule. Despite their difference in implementation, RUQL learning dynamics are similar to FAQL learning dynamics when the

7. Omitting $O(\alpha_t^2)$ is justified because α_t is assumed to decay over time to establish convergence in stationary environments, and for small α_t the first order term dominates diminishing higher order terms.
8. The series $\sum_t \left[\frac{\lg t}{t}\right]^2$ is convergent using the Cauchy condensation test.
9. For constant exploration rates, ϵ^t is bound away from zero and can be replaced by a constant that represents the minimum positive value it assumes. RUQL thus satisfies the condition for the same α^t as QL.

probability of choosing actions are larger than β, otherwise FAQL learning dynamics deviate from RUQL learning dynamics. This can be shown through the following arguments.

Let $\Delta Q^t_{\text{algorithm}}(s,a) = Q^{t+1}(s,a) - Q^t(s,a)$ denote the update step for each of the algorithms FAQL and RUQL. Then the difference between the updates of FAQL and RUQL is $d_{\text{FAQL,RUQL}} = \Delta Q^t_{\text{FAQL}}(s,a) - \Delta Q^t_{\text{RUQL}}(s,a) = (w_{\pi^t(s,a)} - z_{\pi^t(s,a)})\mathbf{e}^t(s,a)$, where the Q-value error is denoted by $\mathbf{e}^t(s,a) = \left[r + \gamma Q^t(s', a_{\max}) - Q^t(s,a)\right]$, $w_{\pi^t(s,a)} = \min(1, \frac{\beta}{\pi(s,a)})\alpha_{FAQL}$ represents FAQL's effective learning rate, and $z_{\pi^t(s,a)} = 1 - [1-\alpha_{RUQL}]^{\frac{1}{\pi^t(s,a)}}$ represents RUQL's effective learning rate. Further working out the Taylor expansion at $\alpha = 0$ of the term $(1-\alpha_{RUQL})^{\frac{1}{\pi(s,a)}}$ from RUQL's update equation yields

$$[1-\alpha_{RUQL}]^{\frac{1}{\pi(s,a)}} = 1 - \frac{\alpha_{RUQL}}{\pi(s,a)} + O(\alpha^2_{RUQL}).$$

Therefore, the learning rate of RUQL can be simplified to.

$$\begin{aligned} z_{\pi^t(s,a)} &= 1 - \left(1 - \frac{\alpha_{RUQL}}{\pi(s,a)} + O(\alpha^2_{RUQL})\right) \\ &= \frac{\alpha_{RUQL}}{\pi(s,a)} + O(\alpha^2_{RUQL}). \end{aligned}$$

If $\mathbf{e}^t(s,a) = 0$, then both algorithms keep the Q-values unchanged, i.e.,

$$\Delta Q^t_{\text{FAQL}}(s,a) = \Delta Q^t_{\text{RUQL}}(s,a) = 0.$$

Otherwise, the difference in updates can be rewritten for small learning rates α_{RUQL} as

$$\frac{d_{\text{FAQL,RUQL}}}{\mathbf{e}^t(s,a)} = w_{\pi^t(s,a)} - z_{\pi^t(s,a)} = \min(1, \frac{\beta}{\pi(s,a)})\alpha_{FAQL} - \frac{\alpha_{RUQL}}{\pi(s,a)}.$$

For $\beta \cdot \alpha_{FAQL} = \alpha_{RUQL}$ the two algorithms yield equal updates if $\pi(s,a) \geq \beta$. However, when $\pi(s,a) < \beta$ the learning rates differ by $\frac{\alpha_{RUQL}}{\beta} - \frac{\alpha_{RUQL}}{\pi(s,a)}$, which is due to the β limitation of FAQL as we mentioned before.

5. Related Work

Several modifications and extensions to Q-learning were proposed, such as individual Q-learning (Leslie and Collins, 2005), the CoLF and CK heuristics (de Cote et al., 2006), and the utility-based Q-learning (Moriyama et al., 2011). Some of the proposed extensions aimed at improving the performance of Q-learning in specific domains (such as promoting cooperation in public good games (de Cote et al., 2006; Moriyama et al., 2011)), rather than addressing the policy-bias limitation of Q-learning. There also have been some works on modifying the learning rate α to speed up convergence (George and Powell, 2006; Dabney and Barto, 2012; Mahmood et al., 2012). Most of the proposed approaches defined different decaying functions for the learning rate (for example, as a function of time or the number of visits to a state) that are *independent* of the underlying policy (George and Powell, 2006). More recent approaches proposed more sophisticated methods for

adapting the learning rate based on the error (Dabney and Barto, 2012; Mahmood et al., 2012). None of the proposed approaches addressed the policy-bias problem.

Some learning algorithms specifically targeted non-stationary environments (da Silva et al., 2006; Noda, 2010; Kaisers and Tuyls, 2010). One technique devised a mechanism for updating the learning rate based on gradient descent (to minimize error) (Noda, 2010). Aside from being more complex than our simple update equation, the approach could only handle stateless domains. The RL-Context-Detection (RL-CD) algorithm (da Silva et al., 2006) was model-based and assumed finite set of stationary contexts that the environment switches among. For each stationary context a model was learned. This can be contrasted to our approach, which is model-free and tracks the non-stationarity of the environment without assuming a finite set of contexts. This is important when the non-stationarity is a result of an adaptive opponent (with potentially infinite contexts). The more recently proposed Frequency Adjusted Q-Learning (Kaisers and Tuyls, 2010) aimed to address the policy-bias limitation of Q-learning, but as we have shown, FAQL suffers from the β-limitation.

Q-learning was originally designed for single-agent environment, but yet performed adequately in multi-agent environments. HyperQ-learning was proposed as an extension to Q-learning in order to support multi-agent contexts (Tesauro, 2004). Unlike our approach, HyperQ attempts to learn the opponents' strategies without adapting the learning rate. We believe it is possible to integrate RUQL with HyperQ, but it is beyond the scope of this paper and remains an interesting future direction. Studying the dynamics of learning algorithms in multi-agent contexts has been an active area of research (Abdallah and Lesser, 2008; Babes et al., 2008; Bowling and Veloso, 2002; Claus and Boutilier, 1998; de Cote et al., 2006; Eduardo and Kowalczyk, 2009; Lazaric et al., 2007; Leslie and Collins, 2005; Moriyama, 2009; Tuyls et al., 2006; Vrancx et al., 2008; Wunder et al., 2010; Galstyan, 2013). The dynamics of Q-learning with Boltzmann exploration received attention earlier due to the continuous nature of the Boltzmann exploration. One of the earliest analyses of Q-learning assumed agents keep record of previous interactions and used Boltzmann exploration strategies (Sandholm and Crites, 1996). More recent analysis of Q-learning with Boltzmann exploration used evolutionary (replicator) dynamics (Kaisers and Tuyls, 2010; Lazaric et al., 2007; Tuyls et al., 2006). Similarly, Q-learning with ϵ-greedy exploration has been analyzed theoretically in stateless games (Eduardo and Kowalczyk, 2009; Wunder et al., 2010).

Another relevant and somewhat recent area of research is adversarial MDPs, where an oblivious adversary may choose a new reward function (and possibly the transition probability function as well) at each time step (Yu et al., 2009; Abbasi et al., 2013; Neu et al., 2010). A central assumption in that work is that the agent observes the full reward function (not only the current reward sample), and possibly the transition probability function once a change in the environment occurred. Furthermore, some of the approaches could not handle deterministic environments, as a mixed policy is assumed (Abbasi et al., 2013). Our approach (similar to Q-learning) does not make such strong assumptions.

Aside from Q-learning and its variations and extensions, several reinforcement learning algorithms have been proposed to optimize the exploration and achieve more efficient learning (Strehl et al., 2009; Jaksch et al., 2010). Aside from being more complex than Q-learning and RUQL, the algorithms that optimize exploration do not address the policy-bias problem. We view such algorithms as complementary to RUQL, which reduces the coupling between the learning dynamics and the underlying exploration strategy. Similar to the possible integration between RUQL and gradient-based multi-agent learning algorithms, RUQL can also be integrated with algorithms that optimize the exploration strategy.

The remainder of this section explains the two algorithms DynaQ and Double Q in more detail. These algorithms are more relevant to RUQL and serve as a benchmark comparison in our experiments.

5.1 Dyna-Q (DynaQ)

The Dyna-Q learning algorithm (Sutton, 1990) integrated the use of a model with the traditional Q-learning update. In its simplest form (which was used in the original paper experiments, as well as our experiments), Dyna-Q can be expressed as shown in Algorithm 3. Note that we intentionally framed DynaQ in such a way that highlights the similarities and differences with RUQL. From the algorithm, we note that similar to the original RUQL, DynaQ repeats the Q-learning update using the learned model. However, there are crucial differences. DynaQ repeats the updates *independent* of the underlying policy, in clear contrast to RUQL which repeats the update inversely proportional to the policy. Also there is no closed form equation that approximates DynaQ, and therefore it can be orders of magnitudes slower than QL (depending on the value of parameter k). Our intuition is that DynaQ is equivalent to uniformly increasing the effective learning rate, but we are not aware of any thorough theoretical analysis of DynaQ that established such connection (unlike our theoretical analysis of RUQL, which highlighted how RUQL affects the effective learning rate).

Algorithm 3: Dyna-Q

begin
  Initialize function Q arbitrarily and list L to empty.
  Observe the current state s.
  for *each time step* **do**
    Compute the policy π using Q.
    Choose an action a according to agent policy π.
    Execute action a and observe the resulting reward r and the next state s'.
    Update Q using Equation 1 and the information $\langle s, a, s', r\rangle$.
    Add the experience tuple $\langle s, a, s', r\rangle$ to L
    for $i : 1 \leq i \leq k$ **do**
      retrieve an experience tuple $\langle s, a, s', r\rangle$ uniformly at random from list L
      Update Q using Equation 1 and the information $\langle s, a, s', r\rangle$.
    end
    Set $s \leftarrow s'$.
  end
end

5.2 Double Q-Learning (DoubleQ)

An interesting recent variation of Q-learning is Double Q-learning (DQL) (Hasselt, 2010). DQL attempts to address how Q-learning may overestimate action values due to the max operator in the Q-learning equation. DQL counters overestimation of action values by maintaining two separate action values estimates, Q_A and Q_B, for each state-action pair. Whenever an action value is to be updated, either Q_A or Q_B is chosen uniformly at random to be updated. The update is done

using the traditional QL update equation, Equation 1, with only one difference: the max operator is applied to the action values of the other table. For example, suppose we chose Q_A is to be updated, then we apply Equation 6 as follows:

$$Q_A^{t+1}(s,a) \leftarrow Q_A^t(s,a) + \alpha \left(r + \gamma\, Q_B^t(s', a^*) - Q_A^t(s,a)\right), \tag{6}$$

where $a^* = \arg\max_{a'} Q_A^t(s', a')$. In other words, for the next state s', the best action is determined using the action value table to be updated. However, the *value* of the best action is determined using the action value in the other table. It is important to note that DoubleQ is *identical* to QL in stateless domains, where $\gamma = 0$. Therefore, the curve corresponding to DoubleQ in Figure 2 would be identical to the QL curve (DoubleQ suffers from the same policy bias as QL, at least for stateless domains).

6. Experimental Analysis

To ensure thorough evaluation of the RUQL algorithm, our analysis spans over several domains. The first two domains focus on verifying the theoretical arguments that we have made in Section 4 using simple, single-state, and non-stationary domains. The first domain (Section 6.1) uses a variation of the multi-armed-bandit problem to expose the effect of QL limitations in dynamic environments. The second domain (Section 6.2) aims at verifying the equivalence of RUQL and FAQL for sufficiently small values of the learning rate α. The subsequent three domains evaluate RUQL in multi-state, non-stationary, and noisy domains.

6.1 Multi-Armed Bandit With Switching Means

In order to tease out the differences between RUQL and FAQL, we propose a simple variation of the multi-armed bandit (MAB) problem (Robbins, 1952). Consider the basic MAB problem: an agent can choose between two actions. Each action i has a mean payoff $\mu_i \in \{0, 1\}$ with some random noise. Since the agent is not aware which action is the best (with expected payoff of 1), the agent needs to explore the two actions while learning the expected returns for each action.

We made two modifications to the traditional MAB problem. The first modification is *switching* the value of μ for the two actions every D time steps. In other words, having $D = 500$ means that from time 0 to time 499 $\mu_0 = 0$ and $\mu_1 = 1$ then from time 500 to time 999 $\mu_0 = 1$ and $\mu_1 = 0$ and so on. Allowing μ to switch models a non-stationary environment. The second modification is, instead of the usual Gaussian noise, we use an asymmetric noise signal. Let r_0 be the sample reward of the action with mean payoff of 0, and r_1 be the sample reward of the action with mean payoff of 1. The sample rewards r_0 and r_1 are defined as

$$r_0 = \begin{cases} \frac{-1}{1-p_0}, & \text{with probability } 1 - p_0. \\ \frac{1}{p_0}, & \text{otherwise (with probability } p_0), \end{cases}$$

$$r_1 = \begin{cases} \frac{2}{1-p_1}, & \text{with probability } 1 - p_1. \\ \frac{-1}{p_1}, & \text{otherwise (with probability } p_1), \end{cases}$$

where both p_0 and p_1 are parameters for controlling noise. The first thing to note here is that the expected payoffs remain 0 and 1, respectively. The value of p_1 determines how misleading the optimal action can be. For instance, with $p_1 = 0.01$ the optimal action provides (with very low probability) a payoff of -100, a payoff that is much lower than the expected payoff of the sub-optimal action. This type of noise targets the policy bias weakness of Q-learning. Once the optimal action receives such negative sample reward, and unless the learning rate is very small, the optimal action will not be tried for a long time. However, if the learning rate is very small, then Q-learning will respond poorly to changes in the environment. On the other hand, the value of p_0 determines how misleading the sub-optimal action can be. For example, with $p_0 = 0.01$ the sub-optimal action provides (with very low probability) a payoff of 100, which is much higher than the expected payoff of the actual optimal action. This type of noise targets the weakness of the RUQL algorithm, which gives a boost in the learning rate for infrequent actions.

The modified domain allows us to study two desired properties of learning algorithms: responding (quickly) to genuine change in the payoff *mean* of a particular action while resisting hasty response to stochastic payoff samples. Our definition of noise also resembles realistic situations. For example, the action of investing one's own money in gambling resembles a sub optimal action that has negative expected reward, while (very rarely) producing very high reward samples (very low p_0). Similarly, the action of investing money in stocks has positive expected reward with rare significant losses. It is worth noting that several techniques were proposed specifically to solve the non-stationary multi-armed bandit problem (Garivier and Moulines, 2011; Besbes et al., 2014). We are using the multi-armed bandit problem as a simple domain to understand the benefits and limitations of our approach. Our evaluation, therefore, include domains other than the multi-armed bandit problem (some of which are multi-state domains).

We conducted the experiments over a range of parameter values, including $D \in \{250, 500, \infty\}$, $p_0, p_1 \in \{0, 0.003, 0.01, 0.03, 0.1\}$, $\tau \in \{0.1, 0.3, 1\}$, $\alpha \in \{0.001, 0.01, 0.1, 1\}$,[10] and $\gamma = 0$. For each combination we collected the average payoff over 2000 consecutive time steps. The initial Q values are individually initialized randomly to either 0 or 1. Finally, statistical significance of the difference in the mean is computed over 100 independent simulation runs, using two-tail two-sample t-tests, where the null hypothesis is rejected at p-value 0.05.

In the absence of noise ($p_0 = p_1 = 0$), the only reason for change in a sampled payoff is the switch of μ. Therefore, setting $\alpha = 1$ achieves the best performance across the three algorithms, rendering all of them equivalent. Interestingly, increasing the value of p_0 (while the value of p_1 remains zero) does not cause the setting $\alpha = 1$ to be inferior. The reason is to be found in the QL policy bias. Increasing p_0 means that the suboptimal action will produce exceptionally high reward very rarely. With $\alpha = 1$, QL will naively, and from only one sample, think that the suboptimal action is the optimal one. As a result, QL will almost certainly choose the suboptimal action the following time step, which will most likely result in a disappointment. Therefore, QL will almost immediately correct its expectation. The same goes for RUQL and FAQL with $\alpha = 1$.

Table 1 shows the results for $p_1 = 0.01$ and $p_0 = 0.01$, for different values of D and α. For each algorithm, we report the best average payoff it achieved across the different values of the exploration parameter τ. Bold entries confirm the statistical significance of the outperforming algorithm(s). For example, if only RUQL is bold, then this means RUQL outperforms both QL and FAQL with statistical significance. If both RUQL and FAQL are bold, then this means both algorithms outperform QL with statistical significance but there is no statistical significance regarding the difference between FAQL and RUQL. Notice here the significant drop in performance for high α. The drop is more severe for stationary environments, which may appear counter intuitive.

10. Note that these values of α are for QL and RUQL. For FAQL, we used the square root of these α values for both α_{FAQ} and β_{FAQ}, so that FAQL has an effective learning rate $\alpha_{FAQ} \cdot \beta_{FAQ} = \alpha$.

D \ α	0.001	0.01	0.1	1
∞: QL	0.98	0.69	0.09	0.06
RUQL	0.97	**0.89**	0.09	0.06
FAQL	0.97	0.82	0.08	0.06
500: QL	0.51	0.58	0.37	0.53
RUQL	0.54	**0.72**	0.37	0.54
FAQL	0.53	**0.70**	0.37	0.53
250: QL	0.52	0.55	0.48	0.53
RUQL	0.52	**0.62**	0.48	0.53
FAQL	0.51	0.57	0.48	0.53

Table 1: The mean payoff for the MAB-switching game, with $p_0 = p_1 = 0.01$, and for different values of D and α. The reported value in each cell is the best value we obtained across the different values of the exploration rate τ. The first observation is the significant drop in performance when α increases beyond 0.01. The policy bias results in the optimal action being rarely tried after the optimal action receives a big penalty. For stationary environments ($D = \infty$), RUQL's performance is comparable to QL with no statistically significant difference for $\alpha = 0.001$. As alpha increases to 0.01, the policy bias affects QL significantly, even in stationary environments. RUQL is affected as well, but to a lesser degree. As alpha increases to 0.1 and above, the effect of noise becomes so significant that all algorithms perform poorly. Furthermore, RUQL achieves superior performance in non-stationary environments when $D < \infty$.

What happens here is that when the optimal action receives the rare negative reward, if α is high, then the corresponding Q value becomes much smaller than the Q-value of the suboptimal action, making it very unlikely that the optimal action will ever be tried. When the environment becomes non-stationary, QL's performance improves simply because the suboptimal action becomes optimal after the switch. RUQL reduces the severity of policy bias, which results in better performance in non-stationary cases ($D = 500$ and $D = 250$). It is important to note also that in the presence of noise, and for non-stationary environments, α should neither be too small nor too large. In this experiment, $\alpha = 0.01$ resulted in the most robust performance.

To have a closer look at the learning dynamics, Figure 3 illustrates a sample run with $\alpha = 0.01, D = 500, p_1 = p_0 = 0.01$ and $\tau = 0.3$. The figure compares the accumulated payoff for the three algorithms, using the same random seed (hence the synchronized noise). The three algorithms quickly learn to select Action 1, with payoff given by r_1 (hence the steady increase in the accumulated payoff). The first sudden drop in the accumulated payoff (around Time 50) is due to the noise defined by r_1. Notice slight gain of RUQL as a result of this noise. The reason is that the sudden drop reduces the probability of choosing the optimal action. The reduction in the probability results in subsequent small boost in the learning rate for RUQL (and FAQL), hence the quicker recovery of both RUQL and FAQL against QL. Now consider Time 500, when the first switch of the actions' expected payoff occurs and now Action 1 generates payoff according to r_0. We can see that both RUQL and FAQL initially continue to choose Action 1 (initial drop in the accumulated payoff). The probability of choosing Action 0, which is now the optimal action, is very low. RUQL quickly recovers while FAQL (due to the β-limitation) takes longer time to recover. This results in a bigger gain for RUQL.

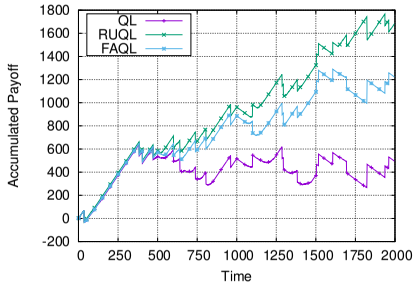

Figure 3: Comparison of the accumulated payoff for the three algorithms in a sample run (with the same random seed), using $\alpha = 0.01, D = 500, p_1 = p_0 = 0.01$ and $\tau = 0.3$.

D	$p_0 = p_1$ \ Alg.	0.003	0.01	0.03	0.1
∞	QL	0.96	0.98	0.95	1

	FAQL	**0.62**	**0.70**	**0.6**	0.71
250	QL	0.51	0.55	0.52	0.65
	RUQL	**0.58**	**0.62**	**0.56**	0.64
	FAQL	**0.57**	0.57	0.55	0.66

Table 2: The mean payoff for the MAB-switch game, for different values of D, p_0 and p_1. Each cell represents the average payoff, maximized over α and τ.

Table 2 compares the performance of the three algorithms for different levels of noise (p_i) and non-stationary environments (D). The performance reported for each algorithm is the maximum over α and τ.[11] We can observe here that for stationary environment, RUQL performs as well as QL, with no statistical significance for the difference between the three algorithms. As the environment becomes stationary and noisy, RUQL outperforms QL and FAQL with statistical significance for several settings. Even for the cases where RUQL does not outperform QL (or FAQL), RUQL has comparable performance with no-statistical significance of the difference.

6.2 Prisoner's Dilemma Game

This section compares the (experimental) dynamics of Q-learning, FAQL, and RUQL in the Prisoner's Dilemma game (PD). We are using the PD domain primarily for benchmarking, as it was

11. It is worth noting that for the majority of the cells, $\alpha = 0.01$ and $\tau = 0.3$ resulted in best performance for all three algorithms.

used before in evaluating FAQL (Kaisers and Tuyls, 2010). Each agent is oblivious to the existence of the other agent, therefore the domain can be viewed as a non-stationary environment from the perspective of each individual agent. For all the three algorithms (QL, FAQL, RUQL) the temperature for Boltzmann exploration was set to $\tau = 0.1$. The discount factor γ was set to 0. The learning rate α was set at 10^{-6} for both Q-learning and RUQL, while for FAQL both α and β were set to 10^{-3}. Table 3 shows the payoff values for the PD game. The above setting was used before in the literature (Kaisers and Tuyls, 2010) and we use the same setting here for comparability.

	c	d
c	3,3	0,5
d	5,0	1,1

Table 3: The prisoner's dilemma game with actions cooperate (c) and defect (d).

Figure 4 shows the dynamics of the three algorithms for three different initial value levels of Q. The dynamics of Q-learning and FAQL are consistent with the results reported before (Kaisers and Tuyls, 2010). It is worth noting that under pessimistic initial Q-values (centered around zero, top row), Q-learning approaches the Pareto optimal joint action, and hence a strictly dominated action, simply because it is initialized near this joint action, updates are self-reinforcing and low initial values lead to extremely low exploration probabilities. Given infinite time, the algorithms would converge to the Nash equilibrium, since the defection action would eventually catch up due to its factual higher value against cooperation. In contrast, the dynamics of both FAQL and RUQL show consistent behavior across different initializations, and they are very similar and close to the dynamical system of the infinitesimal limit (approximating that all actions were updated at every iteration), despite the conceptually different update equations. A plot of the infinitesimal limit is omitted since it would be indistinguishable from FAQL and RUQL, but illustrations can be found in related work (Kaisers and Tuyls, 2010).

To demonstrate that the effect of RUQL is not equivalent to simply scaling the learning rate of Q-learning, Figure 5 shows the behavior dynamics of Q-learning when increasing the learning rate up to 100 times. As we can see, the general gross features of the dynamics remain the same. Increasing the learning rate only increases the step size in policy space without changing the expected direction.

6.3 1-Row Domain

This section presents a simple multi-state domain to test RUQL's multi-state performance. The domain is depicted in Figure 6 [a]. There are 10 total states, which are organized in one row (hence the name). There are two actions: left and right. The agent starts at a random state (which is not goal) and uses the two actions to reach the goal state depicted by 'G'. Each step yields a reward of -1, and the expected reward for reaching the goal is

$$r_g = \begin{cases} \frac{11}{1-P}, & \text{with probability } 1-P \\ \frac{-1}{P}, & \text{otherwise (with probability } P\text{).} \end{cases}$$

The domain is episodic. An episode starts from any random state that is not a terminal state. A terminal state is either the goal, or the cell opposite from the goal. To study non-stationarity in the

Figure 4: The learning dynamics of Q-learning (left), FAQL (middle), and RUQL (right) for the PD game. Each figure plots the probability of defecting for Player 1 (x-axis) against the probability of defecting for Player 2 (y-axis). The rows show the dynamics when the initial Q-values are centered around 0, 2.5 and 5 (top, middle, bottom). For all figures, the algorithms were allowed to run for 5 million time steps. The learning rate α was set at 10^{-6} for both Q-learning and RUQL, while for FAQL both α and β were set to 10^{-3}. RUQL has dynamics very similar to FAQL, while Q-learning has erratic dynamics due to its policy bias.

(d) $\alpha = 0.000001$ (e) $\alpha = 0.00001$ (f) $\alpha = 0.0001$

(g) $\alpha = 0.000001$ (h) $\alpha = 0.00001$ (i) $\alpha = 0.0001$

Figure 5: The learning dynamics of Q-learning for different values of the learning rate α: 0.000001 (left), 0.00001 (middle), and 0.0001 (right) for the PD game. Each figure plots the probability of defecting for Player 1 (x-axis) against the probability of defecting for Player 2 (y-axis). The top row shows the dynamics when the initial Q-values are around 0, the middle row shows the dynamics when the initial Q-values are around 2.5, and the bottom row shows the dynamics when the initial Q-values are around 5. For all figures, the algorithms were allowed to run for $\frac{5}{\alpha}$ time steps.

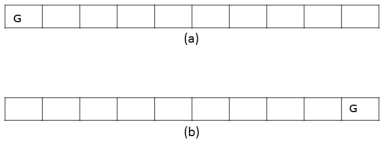

Figure 6: The two settings of the 1-row domain. G indicates the goal state.

domain, there are two settings (shown as [a] and [b] in Figure 6), where parameter D controls the duration before the environment switches from one setting to another.

We conducted the experiments over a range of parameter values, including $D \in \{5000, 10000, \infty\}$, $P \in \{0, 0.01, 0.1\}$, $\tau \in \{0.008, 0.04, 0.2, 1, 5\}$, $\pi_{min} \in \{0, 0.01, 0.001\}$, $\gamma = 1$, and $\alpha \in \{0.01, 0.04, 0.16, 0.64\}$.[12] For each combination we collected the average payoff over 20000 consecutive time steps. The initial Q values are initialized to 0. Finally, statistical significance of the difference in the mean is computed over 10 independent simulation runs, using two-tail two-sample t-test, where the null hypothesis is rejected at p-value 0.05.

Table 4 compares the performance of the three algorithms for different levels of noise (P) and non-stationary environments (D). The performance reported for each algorithm is the best over the different values of π_{min}, α and τ. We can observe similar results to the stateless domain. For noise-free and stationary environments, RUQL performs as well as the other algorithms, with no statistical significance for the difference. For noise-free non-stationary environments, DynaQ performs significantly better. The reason is that by repeating the updates, DynaQ is effectively increasing the learning rate for all actions, which is beneficial in noise-free environments. As the environment becomes non-stationary and noisy, RUQL consistently outperforms other algorithms, with FAQL and DoubleQ as close seconds. Dyna-Q fails in noisy environments because Dyna-Q effectively boosts the learning rate for *all* the actions (therefore, the Q-value of an optimal action may drop significantly upon receiving noisy negative reward).

6.4 Taxi Domain with Switching Stations

To investigate how RUQL works in multi-state environments we use a variation of the taxi domain (Dietterich, 2000). Figure 7 illustrates the domain. The world is a 5x5 grid that has 4 stations (represented by the letters) and walls (represented by the thick lines). A customer appears at a source station and is to be delivered to a destination station. Both the source and the destination stations are picked uniformly at random and can be the same. A taxi can pick a customer up, drop a customer, or navigate through the world, which results in a total of 6 actions: UP, DOWN, LEFT, RIGHT, PICK, and DROP. The state here is the taxi location (25 values) the customer location (5 values: 4 stations and in taxi) and destination (4 values) for a total of 500 states. Each navigation action receives a reward of -1. Hitting the wall results in no change in the state and the same reward of -1. Picking up or dropping off a customer receives a reward of 20 if at the right location, otherwise receives a reward of -10. We made two main modifications:

12. Note that these values of α are for QL, DoubleQ, DynaQ, and RUQL. For FAQL, we used the square root of these α values for both α_{FAQ} and β_{FAQ}, so that FAQL has an effective learning rate $\alpha_{FAQ}.\beta_{FAQ} = \alpha$.

D	Alg. \ P	0.0	0.01	0.1
5000	QL	0.77	0.74	0.83
	DynaQ	**1.31**	-0.01	0.02
	DoubleQ	0.85	0.75	0.80
	FAQL	0.81	**0.80**	**0.85**
	RUQL	0.84	**0.81**	**0.90**
10000	QL	0.81	0.74	0.84
	DynaQ	**1.34**	-0.16	0
	DoubleQ	0.95	0.74	**0.95**
	FAQL	0.88	**0.80**	0.86
	RUQL	0.90	**0.85**	**0.95**
∞	QL	1.18	**1.16**	**1.19**
	DynaQ	1.2	-0.17	0.36
	DoubleQ	1.20	**1.15**	**1.2**
	FAQL	1.18	**1.16**	**1.18**
	RUQL	1.18	**1.16**	**1.18**

Table 4: The mean payoff for the 1-Row Domain, for different values of D and P. Each cell represents the average payoff, maximized over α and τ.

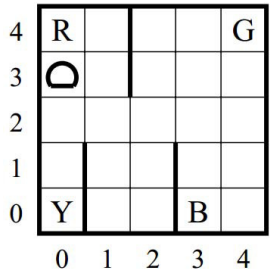

Figure 7: The Taxi domain (Dietterich, 2000).

- Rare but severe noise: PICK and DROP actions fail with probability p and result in penalty $\frac{R_p}{p}$.[13]
- Non-stationary domain: every duration D the stations (R,G,Y,B) rotate their locations (station R takes the location of station G which in turn takes the location of station Y, etc.).

We conducted the experiments over range of parameter values, including $D \in \{300000, 600000, \infty\}$, $\tau \in \{0.03, 0.1, 0.3, 1\}$, $\pi_{min} \in \{0, 0.001, 0.01\}$, $\alpha \in \{0.001, 0.01, 0.1\}$,[14] $p \in \{0, 0.01\}$, $R_p =$

13. For the navigation actions, the noise remains similar to the original Taxi domain: a navigation action fails with probability p and results in skidding to one of the sides with reward of -1.
14. Again the values of α are for QL and RUQL. For FAQL, we used the square root of these α values for both α_{FAQ} and β_{FAQ}, so that FAQL has an effective learning rate $\alpha_{FAQ}.\beta_{FAQ} = \alpha$.

D	Alg. \ p	0	0.01
8	QL	**2.35**	-0.61
	DynaQ	**2.34**	0.19
	DoubleQ	2.27	-1.23
	RUQL	**2.37**	**0.45**
	FAQL	**2.38**	0.29
600000	QL	**1.79**	-1.31
	DynaQ	**1.83**	**-0.42**
	DoubleQ	1.17	-1.91
	RUQL	**1.77**	**-0.47**
	FAQL	**1.80**	-0.58
300000	QL	0.64	-1.46
	DynaQ	**1.38**	-0.79
	DoubleQ	0.11	-1.92
	RUQL	1.19	**-0.70**
	FAQL	0.77	-0.94

Table 5: The mean payoff for the Taxi domain, for different values of p and D.

-6, and $\gamma = 1$. For each combination we collected the average payoff over 1200000 consecutive time steps. All Q-values are initialized to zeros. Finally, statistical significance of the difference in the mean is computed over 100 independent simulation runs, using two-tail two-sample t-test, where the null hypothesis is rejected at p-value 0.05.

Table 5 shows the results for different values of D and p. For each algorithm, we report the best average payoff it achieved across the different parameter values. Bold entries confirm the statistical significance of the outperforming algorithm, similar to the results shown in Section 6.1. We notice similarities to the previous domain. In noise-free environments, again DynaQ outperforms other algorithms. As the environment becomes noisy and non-stationary, the performance of DynaQ drops significantly, while RUQL outperforms all other algorithms. Interestingly, DoubleQ performs the worst in this domain, across the different settings. This is perhaps due to the reported underestimation of DoubleQ for the Q values (Hasselt, 2010). It is also worth noting that even in stationary but noisy setting, RUQL outperforms other algorithms in the taxi domain. The reason for this is that RUQL can boost the learning rate more effectively than Q-learning and other algorithms. For example, suppose the best action in a particular state is to drop the customer. However, due to noise, the payoff will be highly negative. This will result in sudden drop in the Q-value for the DROP action in this particular state, and consequently the probability of choosing DROP. However, RUQL will boost the learning rate for the DROP action once it is tried and succeeds, therefore recovering from the noise effect faster. This results in a cascading effect across states. Also because RUQL's boost diminishes as the action is chosen more frequently, the learning becomes stable in the face of the noise (which can not be achieved via simple increase of the learning rate for QL, or using DynaQ). This is consistent with previous work, which experimentally showed that converging to a policy is in some cases inferior to continuous learning (tracking) even in stationary environments (Sutton et al., 2007). As the environment becomes more dynamic ($D = 600000$ and $D = 300000$) the performance of all algorithms drop (as expected) but RUQL maintains the superior performance.

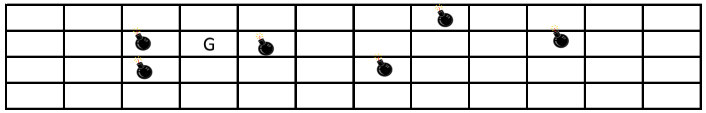

Figure 8: The Mines domain. The agent can navigate through the 4x16 grid, while avoiding the scattered mines and trying to reach the goal.

6.5 Mines Domain

The mines domain is illustrated by Figure 8 and is adopted from the RL-GLUE software (Tanner and White, 2009). The world consists of 4x16 grid, where the agent can navigate up, down, left and right (4 actions) and receives a reward of -1 unless it encounters a mine, in which case the reward is -100, or it reaches the goal state and receives the reward of 10. In this simple domain there are only 64 states. 6 mines in addition to the goal are scattered randomly in the grid. We modified the domain slightly from the original as follows:

- Rare but severe noise: reaching the goal state will fail with probability p and result in reward of $-1/p$, otherise will succeed and produce reward of $11/(1-p)$ (expected reward remains 10).
- Non-stationary domain: every duration D the goal state is randomly re-assigned.

We conducted the experiments over a range of parameter values, including $D \in \{25 \cdot 10^4, 50 \cdot 10^4, \infty\}$, $\tau \in \{0.008, 0.04, 0.2, 1, 5\}$, $p \in \{0, 10^{-2}\}$, $\alpha \in \{0.0025, 0.01, 0.04, 0.16\}$, $\pi_{min} \in \{0, 10^{-2}, 10^{-3}\}$, and $\gamma = 1$.[15] For each combination, we collected the average payoff over 10^6 consecutive time steps, and reported the best performance for each algorithm over the tested parameter values. All Q-values are initialized to zeros. Finally, statistical significance of the difference in the mean is computed over 20 independent simulation runs, using two-tail two-sample t-test, where the null hypothesis is rejected at p-value 0.05. Table 6 summarizes the results for different values of p and the duration D. We observe similar qualitative results to the previous domains. DynaQ is better in noise-free settings, with RUQL outperforming other algorithms as the environment becomes noisy and non-stationary. FAQL is close second in noisy and non-stationary environments as well, albeit RUQL is clearly superior in the most frequently changing benchmark environment with D=250,000.

7. Discussion of RUQL

Looking at the previous experimental results we can identify a few interesting observations. The main benefit of RUQL is reducing the policy-bias, which is reflected in better performance in non-stationary environments. In noise-free environments, however, the benefit of RUQL is diminishing, since for noise-free environments the learning rate can be as high as 1. As RUQL reduces the policy bias by boosting the learning rate for actions with low probability of being chosen, such

15. Again the values of α are for QL and RUQL. For FAQL, we used the square root of these α values for both α_{FAQ} and β_{FAQ}, so that FAQL has an effective learning rate $\alpha_{FAQ}.\beta_{FAQ} = \alpha$.

D	Alg. \ P	0	0.01
∞	QL	0.79	0.6
	DynaQ	0.78	0.35
	DoubleQ	0.78	0.54
	RUQL	0.79	**0.63**
	FAQL	0.79	**0.63**
500000	QL	0.70	0.43
	DynaQ	**0.77**	0.34
	DoubleQ	0.69	0.40
	RUQL	0.70	**0.49**
	FAQL	0.72	**0.48**
250000	QL	0.67	0.27
	DynaQ	**0.75**	0.29
	DoubleQ	0.63	0.39
	RUQL	0.65	**0.43**
	FAQL	0.66	0.33

Table 6: The mean payoff for the Mines domain, for different values of p and D.

benefit fades as the basic learning rate increases. In contrast, if the environment is noisier and changes more frequently, the benefits of RUQL become more apparent. This is consistent across the domains we have studied. Overall, RUQL retains the simplicity of QL, while showing robust performance across various experimental settings.

8. Conclusions

In this paper we proposed and evaluated the Repeated Update Q-learning algorithm, RUQL, which addresses the policy bias of Q-learning. Unlike the closest state-of-the-art algorithm, RUQL's behavior remains consistent even for policies with arbitrarily small probabilities of choosing actions. We show theoretically that our algorithm is guaranteed to converge to the optimal Q-values in single-agent stationary environments, while having better response to changes in non-stationary environments. We show experimentally how this results in superior performance in non-stationary and noisy environments, compared to 4 other algorithms.

Given its merits in non-stationary environments, RUQL may find interesting applications in multi-agent environments. There is a growing collection of algorithms that were designed specifically for multi-agent environments. The Win-or-Learn-Fast heuristic (Bowling and Veloso, 2002; Bowling, 2005) resulted in the first gradient-ascend-based (GAB) multi-agent learning algorithms that successfully converged to mixed Nash Equilibrium in small general-sum games with minimum knowledge of the underlying game (only the player's own payoff). This was followed by the more recent GAB algorithms (Abdallah and Lesser, 2008; Zhang and Lesser, 2010). Other multi-agent algorithms that assumed knowledge of the underlying game were also proposed and were able to converge in larger games (Hu and Wellman, 2003; Conitzer and Sandholm, 2007). All of these algorithms could benefit from improved value approximation techniques like the one presented in this paper. The integration of RUQL in specialized multi-agent learning algorithms is a promising avenue of future research.

Finally, it is important to note that RUQL is *not* intended as a replacement of Q-learning. In stationary environments with stochastic outcomes, QL may outperform RUQL, since the latter may slightly boost the learning rate of rarely chosen action. However, if the environment is actually changing over time (non-stationary and thus violating the core assumption of QL), then RUQL's boost may yield superior performance.

Appendix A. Theoretical Derivations of Exact RUQL

Here we derive the different quantities that are needed for each of the four cases of the exact RUQL.

Case 1:

$$\begin{aligned}
Q_{\lfloor\frac{1}{\pi(s,a)}\rfloor}(s,a) &= [1-\alpha]^{\lfloor\frac{1}{\pi(s,a)}\rfloor}Q_0(s,a)+\alpha[r+\gamma\max_{a'}Q_0(s',a')] \\
&\quad \left(1+(1-\alpha)+(1-\alpha)^2+...+(1-\alpha)^{\lfloor\frac{1}{\pi(s,a)}\rfloor-1}\right) \\
&= [1-\alpha]^{\lfloor\frac{1}{\pi(s,a)}\rfloor}Q_0(s,a)+\alpha[r+\gamma\max_{a'}Q_0(s',a')]\frac{[1-(1-\alpha)^{\lfloor\frac{1}{\pi(s,a)}\rfloor}]}{1-(1-\alpha)} \\
&= [1-\alpha]^{\lfloor\frac{1}{\pi(s,a)}\rfloor}Q_0(s,a)+[1-(1-\alpha)^{\lfloor\frac{1}{\pi(s,a)}\rfloor}][r+\gamma\max_{a'}Q_0(s',a')]
\end{aligned}$$

We can remove the floor notation for a better generalization, and using the equalities $Q_0(s,a) = Q^t(s,a)$ and $Q_{\lfloor\frac{1}{\pi(s,a)}\rfloor}(s,a) = Q^{t+1}(s,a)$ we get (RUQL's main update rule):

$$Q^{t+1}(s,a) = [1-\alpha]^{\frac{1}{\pi(s,a)}}Q^t(s,a)+\left[1-(1-\alpha)^{\frac{1}{\pi(s,a)}}\right][r+\gamma Q^t(s',a_{max})]$$

Case 2:

$$\begin{aligned}
Q_1(s,a) &= [1-\alpha]Q^t(s,a)+\alpha\left(r+\gamma Q^t(s,a)\right) \\
&= [1-\alpha+\alpha\gamma]Q^t(s,a)+\alpha r \\
Q_2(s,a) &= [1-\alpha+\alpha\gamma]Q_1(s,a)+\alpha r \\
&= [1-\alpha+\alpha\gamma]\left([1-\alpha+\alpha\gamma]Q^t(s,a)+\alpha r\right)+\alpha r \\
Q_n(s,a) &= [1-\alpha+\alpha\gamma]^nQ^t(s,a)+\alpha r\left(1+[1-\alpha+\alpha\gamma]+\ldots+[1-\alpha+\alpha\gamma]^{n-1}\right) \\
&= [1-\alpha+\alpha\gamma]^nQ^t(s,a)+\alpha r\frac{1-[1-\alpha+\alpha\gamma]^n}{1-[1-\alpha+\alpha\gamma]} \\
&= [1-\alpha+\alpha\gamma]^nQ^t(s,a)+r\frac{1-[1-\alpha+\alpha\gamma]^n}{1-\gamma} \\
&= [1-\alpha+\alpha\gamma]^nQ^t(s,a)+(1-[1-\alpha+\alpha\gamma]^n)\frac{r}{1-\gamma}
\end{aligned}$$

$$\begin{aligned}
&= [1-\alpha+\alpha\gamma]^n\left(Q^t(s,a)-\frac{r}{1-\gamma}\right)+\frac{r}{1-\gamma} \\
Q^{t+1}(s,a) &= [1-\alpha+\alpha\gamma]^{\frac{1}{\pi(s,a)}}\left(Q^t(s,a)-\frac{r}{1-\gamma}\right)+\frac{r}{1-\gamma}
\end{aligned}$$

Case 3 using $Q^t(s,a'') = Q^t(s,a)$, where $a'' = \arg\max_{a'\in A\setminus a}Q^t(s,a')$:

$$\begin{aligned}
Q^t(s,a'') &= [1-\alpha+\alpha\gamma]^{i_\top}\left(Q^t(s,a)-\frac{r}{1-\gamma}\right)+\frac{r}{1-\gamma} \\
Q^t(s,a'')-\frac{r}{1-\gamma} &= [1-\alpha+\alpha\gamma]^{i_\top}\left(Q^t(s,a)-\frac{r}{1-\gamma}\right) \\
\frac{Q^t(s,a'')-\frac{r}{1-\gamma}}{Q^t(s,a)-\frac{r}{1-\gamma}} &= [1-\alpha+\alpha\gamma]^{i_\top} \\
i_\top &= \frac{\log\left(\frac{Q^t(s,a'')-\frac{r}{1-\gamma}}{Q^t(s,a)-\frac{r}{1-\gamma}}\right)}{\log(1-\alpha+\alpha\gamma)}
\end{aligned}$$

Case 4 using $Q^t(s,a'') = Q^t(s,a)$, where $a'' = \arg\max_{a'\in A}Q^t(s,a')$:

$$\begin{aligned}
Q^t(s,a'') &= [1-\alpha]^{i_\perp}Q^t(s,a)+\left[1-(1-\alpha)^{i_\perp}\right][r+\gamma Q^t(s,a'')] \\
Q^t(s,a'')-r-\gamma Q^t(s,a'') &= [1-\alpha]^{i_\perp}Q^t(s,a)-(1-\alpha)^{i_\perp}[r+\gamma Q^t(s,a'')] \\
(1-\gamma)Q^t(s,a'')-r &= [1-\alpha]^{i_\perp}\left[Q^t(s,a)-r-\gamma Q^t(s,a'')\right] \\
\frac{(1-\gamma)Q^t(s,a'')-r}{Q^t(s,a)-r-\gamma Q^t(s,a'')} &= [1-\alpha]^{i_\perp} \\
\frac{(1-\gamma)Q^t(s,a'')-r}{Q^t(s,a)-\gamma Q^t(s,a'')-r} &= [1-\alpha]^{i_\perp} \\
i_\perp &= \frac{\log\left(\frac{(1-\gamma)Q^t(s,a'')-r}{Q^t(s,a)-\gamma Q^t(s,a'')-r}\right)}{\log(1-\alpha)}
\end{aligned}$$

Abstract

In this paper, we present a new framework for large scale online kernel learning, making kernel methods efficient and scalable for large-scale online learning applications. Unlike the regular budget online kernel learning scheme that usually uses some budget maintenance strategies to bound the number of support vectors, our framework explores a completely different approach of kernel functional approximation techniques to make the subsequent online learning task efficient and scalable. Specifically, we present two different online kernel machine learning algorithms: (i) Fourier Online Gradient Descent (FOGD) algorithm that applies the random Fourier features for approximating kernel functions; and (ii) Nyström Online Gradient Descent (NOGD) algorithm that applies the Nyström method to approximate large kernel matrices. We explore these two approaches to tackle three online learning tasks: binary classification, multi-class classification, and regression. The encouraging results of our experiments on large-scale datasets validate the effectiveness and efficiency of the proposed algorithms, making them potentially more practical than the family of existing budget online kernel learning approaches.

Keywords: online learning, kernel approximation, large scale machine learning

1. Introduction

In machine learning, *online learning* represents a family of efficient and scalable learning algorithms for building a predictive model incrementally from a sequence of data examples (Rosenblatt, 1958). Unlike regular batch machine learning methods (Shawe-Taylor and Cristianini, 2004; Vapnik, 1995) which usually suffer from a high re-training cost whenever new training data arrive, online learning algorithms are often very efficient and highly scalable, making them more suitable for large-scale online applications where data usually arrive sequentially and evolve dynamically and rapidly. Online learning techniques can be applied to many real-world applications, such as online spam detection (Ma et al., 2009), online advertising, multimedia retrieval (Xia et al., 2013), and computational finance (Li et al., 2012). In this paper, we first present an online learning methodology to tackle *online binary classification* tasks and then extend the technique to solve the tasks of *online multi-class classification* and *online regression* in the following sections.

Recently, a wide variety of online learning algorithms have been proposed to tackle online classification tasks. One popular family of online learning algorithms, which are referred to as the "linear online learning" (Rosenblatt, 1958; Crammer et al., 2006; Dredze et al., 2008), learn a linear predictive model on the input feature space. The key limitation of these algorithms lies in that the linear model sometimes is restricted to make effective classification if training data are linearly separable in the input feature space, which is not a common scenario for many real-world classification tasks especially when dealing with noisy training data in relatively low dimensional space. This has motivated the studies of "kernel based online learning" or referred to as "online kernel learning" (Kivinen et al., 2001; Freund and Schapire, 1999), which aims to learn kernel-based predictive models for resolving the challenging tasks of classifying instances that are non-separable in the input space.

One key challenge of conventional online kernel learning methods is that an online learner usually has to maintain a set of support vectors (SV's) in memory for representing the kernel-based predictive model. During the online learning process, whenever a new incoming training instance is misclassified, it typically will be added to the SV set, making the size of support vector set unbounded and potentially causing memory overflow for a large-scale online learning task. To address this challenge, a promising research direction is to explore "budget online kernel learning" (Crammer et al., 2003), which attempts to bound the number of SV's with a fixed budget size using different budget maintenance strategies whenever the budget overflows. Despite being studied actively, the existing budget online kernel methods have some limitations. Some efficient algorithms are too simple to achieve satisfactory approximation accuracy; some other algorithms are, despite more effective, too computationally intensive to run for large datasets, making them harm the crucial merit of high efficiency of online learning techniques for large-scale applications. In addition, when dealing with extremely large-scale databases in distributed machine learning environments (Low et al., 2012; Dean and Ghemawat, 2008), the growing large size of SV's would be a significant overhead for communication between different nodes. It is thus very important to investigate effective budget online kernel learning techniques to reduce the size of SV's so as to minimize the overall communication cost.

Unlike the existing budget online kernel learning methods, in this paper, we present a novel framework of large scale online kernel learning by exploring a completely different strategy. In particular, the key idea of our framework is to explore functional approximation techniques to approximate a kernel by transforming data from the input space to a new feature space, and then apply existing linear online learning algorithms on the new feature space. This allows to inherit the power of kernel learning while being able to take advantages of existing efficient linear online learning algorithms for large-scale online learning tasks. Specifically, we propose two different new algorithms: (i) Fourier Online Gradient

*. Corresponding Author

Descent (FOGD) algorithm which adopts the random Fourier features for approximating shift-invariant kernels and learns the subsequent model by online gradient descent; and (ii) Nyström Online Gradient Descent (NOGD) algorithm which employs the Nyström method for large kernel matrix approximation followed by online gradient descent learning. We explore the applications of the proposed algorithms for three different online learning tasks: binary classification, multi-class classification, and regression. We give theoretical analysis of our proposed algorithms, and conduct an extensive set of empirical studies to examine their efficacy.

The rest of the paper is organized as follows. Section 2 reviews the background and related work. Section 3 proposes the FOGD and NOGD algorithms for binary classification task and Section 4 analyze their theoretical properties. Section 5 and Section 6 further extends the two techniques for tackling online multi-class classification and online regression tasks, respectively. Section 7 presents our experimental results for three different tasks and Section 8 concludes our work.

2. Related Work

Our work is related to two major categories of machine learning research work: *online learning* and *kernel methods*. Below we briefly review some representative related work in each category.

First of all, our work is closely related to online learning methods for classification (Rosenblatt, 1958; Freund and Schapire, 1999; Crammer et al., 2006; Zhao and Hoi, 2010; Zhao et al., 2011; Wang et al., 2012a; Hoi et al., 2013), particularly for budget online kernel learning where various algorithms have been proposed to address the critical drawback of unbounded SV size and computational cost in online kernel learning. Most existing budget online kernel learning algorithms attempt to achieve a bounded number of SV's through the following major ways:

- *SV Removal*. Some well-known examples include Randomized Budget Perceptron (RBP) (Cavallanti et al., 2007) that randomly removes one existing SV when the number of SV's overflows the budget, Forgetron (Dekel et al., 2005) that simply discards the oldest SV, Budget Online Gradient Descent (BOGD) that basically also discards some old SV, and Budget Perceptron (Crammer et al., 2003) and Budgeted Passive Aggressive (BPA-S) algorithm (Wang and Vucetic, 2010) which attempt to discard the most redundant SV.

- *SV Projection*. By projecting the discarded SV's onto the remaining ones, these algorithms attempt to bound the SV size while reducing the loss due to budget maintenance. Examples include Projectron (Orabona et al., 2008), Budgeted Passive Aggressive Projectron (BPA-P), and Budgeted Passive Aggressive Nearest Neighbor (BPA-NN) (Wang and Vucetic, 2010). Despite achieving better accuracy, they often suffer extremely high computational costs.

- *SV Merging*. These methods attempt to maintain the budget by merging two existing SV's into a new one, such as the Twin Support Vector Machine (TVM) algorithm (Wang and Vucetic, 2009). The similar idea of SV merging was also explored to bound the number of SV's in Budget Stochastic Gradient Descent (BSGD-M) algorithm in (Wang et al., 2012b).

In contrast to the above approaches, our work explores a completely different approach, i.e., kernel functional approximation techniques, for resolving budget online kernel learning tasks. As a summary, Table 1 compares the properties of different budget online kernel learning algorithms, including the proposed FOGD and NOGD algorithms, where B is the budget on the desired SV size, D is the number of Fourier components, and k is the matrix approximation rank of Nyström.

Algorithms	Budget Strategy	Update Time	Space
Budget Perceptron	Removal	$O(B^2)$	$O(B)$
RBP	Removal	$O(B)$	$O(B)$
Forgetron	Removal	$O(B)$	$O(B)$
BOGD	Removal	$O(B)$	$O(B)$
BPA-S	Removal	$O(B)$	$O(B)$
Projectron	Projection	$O(B^2)$	$O(B^2)$
BPA-P	Projection	$O(B^3)$	$O(B^2)$
BPA-NN	Projection	$O(B)$	$O(B)$
TVM	Merging	$O(B^2)$	$O(B^2)$
FOGD	Functional Approximation	$O(D)$	$O(D)$
NOGD	Functional Approximation	$O(kB)$	$O(kB)$

Table 1: Comparison on different budget online kernel learning algorithms.

Moreover, our work is also related to kernel methods for classification tasks (Shawe-Taylor and Cristianini, 2004; Hoi et al., 2006, 2007), especially for some studies on large-scale kernel methods (Williams and Seeger, 2000; Rahimi and Recht, 2007). Our approach shares the similar idea with the Low-rank Linearization SVM (LLSVM) (Zhang et al., 2012), where the non-linear SVM is transformed into a linear problem via kernel approximation methods. Unlike their approach, we employ the technique of random Fourier features (Rahimi and Recht, 2007), which have been successfully explored for speeding up batch kernelized SVMs (Rahimi and Recht, 2007; Yang et al., 2012) and kernel-based clustering (Chitta et al., 2011, 2012) tasks. Besides, another kernel approximation technique used in our approach is the well-known Nyström method (Williams and Seeger, 2000), which has been widely applied in machine learning tasks, including Gaussian Processes (Williams and Seeger, 2000), Kernelized SVMs (Zhang et al., 2012), Kernel PCA, Spectral Clustering (Zhang and Kwok, 2009), and manifold learning (Talwalkar et al., 2008). Although these techniques have been applied for batch machine learning tasks, to the best of our knowledge, they have been seldom explored for online kernel learning tasks as studied in this paper. Finally, we note that the short version of this work had been published in the Proceedings of the Twenty-Third international joint conference on Artificial Intelligence (IJCAI2013) (Wang et al., 2013). The journal manuscript has made significant extension by including substantial amount of new contents and more extensive empirical studies.

3. Large Scale Online Kernel Learning for Binary Classification

In this section, we introduce the problem formulation of online kernel binary classification and the detailed steps of our proposed algorithms.

3.1 Problem Formulation

We consider the problem of online learning for binary classification by following online convex optimization settings. Our goal is to learn a function $f : \mathbb{R}^d \to \mathbb{R}$ from a sequence of training examples $\{(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_T, y_T)\}$, where instance $\mathbf{x}_t \in \mathbb{R}^d$ and class label $y_t \in \mathcal{Y} = \{+1, -1\}$. We refer to the output f of the learning algorithm as a *hypothesis* and denote the set of all possible hypotheses by $\mathcal{H} = \{f | f : \mathbb{R}^d \to \mathbb{R}\}$. We will use $\ell(f(\mathbf{x}); y) : \mathbb{R}^2 \to \mathbb{R}$ as the loss function that penalizes the deviation of estimating $f(\mathbf{x})$ from observed labels y. Further, we consider $\mathcal{H}$ a Reproducing Kernel Hilbert Space (**RKHS**) endowed with a kernel function $\kappa(\cdot, \cdot) : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}$ (Vapnik, 1998) implementing the inner product $\langle \cdot, \cdot \rangle$ such that: 1) κ has the reproducing property $\langle f, \kappa(\mathbf{x}, \cdot) \rangle = f(\mathbf{x})$ for $\mathbf{x} \in \mathbb{R}^d$; 2) $\mathcal{H}$ is the closure of the span of all $\kappa(\mathbf{x}, \cdot)$ with $\mathbf{x} \in \mathbb{R}^d$, that is, $\kappa(\mathbf{x}, \cdot) \in \mathcal{H}$ $\forall \mathbf{x} \in \mathcal{X}$. The inner product $\langle \cdot, \cdot \rangle$ induces a norm on $f \in \mathcal{H}$ in the usual way: $\|f\|_{\mathcal{H}} := \langle f, f \rangle^{\frac{1}{2}}$. To make it clear, we denote by $\mathcal{H}_\kappa$ an RKHS with explicit dependence on kernel κ. Throughout the analysis, we assume $\kappa(\mathbf{x}_i, \mathbf{x}_j) \leq 1$, $\forall \mathbf{x}_i, \mathbf{x}_j \in \mathbb{R}^d$.

Training an SVM classifier $f(\mathbf{x})$ can be formulated as the following optimization problem

$$\min_{f \in \mathcal{H}_\kappa} P(f) = \frac{\lambda}{2}\|f\|_{\mathcal{H}}^2 + \frac{1}{T}\sum_{t=1}^{T} \ell(f(\mathbf{x}_t); y_t),$$

where $\lambda > 0$ is a regularization parameter used to control model complexity. While in an pure online setting, the regularized loss in the t-th iteration is

$$\mathcal{L}_t(f) = \frac{\lambda}{2}\|f\|_{\mathcal{H}}^2 + \ell(f(\mathbf{x}_t); y_t).$$

The goal of an online learning algorithm is to find a sequence of functions f_t, $t \in [T]$ that achieve the minimum *Regret* along the whole learning process. The regret is defined as,

$$Regret = \sum_{t=1}^{T} \mathcal{L}_t(f_t) - \sum_{t=1}^{T} \mathcal{L}_t(f^*),$$

where $f^* = \arg\min_f \sum_{t=1}^{T} \mathcal{L}_t(f)$ is the optimal classifier assuming that we had foresight in all the training instances. In a typical online budgeted kernel learning algorithm, the algorithm learns the kernel-based predictive model $f(\mathbf{x})$ for classifying a new instance $\mathbf{x} \in \mathbb{R}^d$ as follows:

$$f(\mathbf{x}) = \sum_{i=1}^{B} \alpha_i \kappa(\mathbf{x}_i, \mathbf{x}),$$

where B is the number of Support Vectors (SV's), α_i denotes the coefficient of the i-th SV, and $\kappa(\cdot, \cdot)$ denotes the kernel function. The existing budget online kernel classification

approach aims to bound the number of SV's by a budget constant B using different budget maintenance strategies. Unlike the existing budget online kernel learning methods using the budget maintenance strategies, we propose to tackle the challenge by exploring a completely different strategy, i.e., the kernel functional approximation approach that construct a kernel-induced new representation $\mathbf{z}(\mathbf{x}) \in \mathbb{R}^D$ such that the inner product of instances in the new space is able to approximate the kernel function:

$$\kappa(\mathbf{x}_i, \mathbf{x}_j) \approx \mathbf{z}(\mathbf{x}_i)^\top \mathbf{z}(\mathbf{x}_j).$$

By the above approximation, the predictive model can be rewritten:

$$f(\mathbf{x}) = \sum_{i=1}^{B} \alpha_i \kappa(\mathbf{x}_i, \mathbf{x}) \approx \sum_{i=1}^{B} \alpha_i \mathbf{z}(\mathbf{x}_i)^\top \mathbf{z}(\mathbf{x}) = \mathbf{w}^\top \mathbf{z}(\mathbf{x}),$$

where $\mathbf{w} = \sum_{i=1}^{B} \alpha_i \mathbf{z}(\mathbf{x}_i)$ denotes the weight vector to be learned in the new feature space. As a consequence, solving the regular online kernel classification task can be turned into a problem of an linear online classification task on the new feature space derived from the kernel approximation. In the following, we will present two online kernel learning algorithms for classification by applying two different kernel approximation methods: (i) Fourier Online Gradient Descent (FOGD) and (ii) Nyström Online Gradient Descent (NOGD) methods.

3.2 Fourier Online Gradient Descent

Random Fourier features can be used in shift-invariant kernels (Rahimi and Recht, 2007). A shift-invariant kernel is the kernel that can be written as $\kappa(\mathbf{x}_1, \mathbf{x}_2) = k(\Delta\mathbf{x})$, where k is some function and $\Delta\mathbf{x} = \mathbf{x}_1 - \mathbf{x}_2$ is the shift between the two instances. Examples of shift-invariant kernels include some widely used kernels, such as Gaussian and Laplace kernels. By performing an inverse Fourier transform of the shift-invariant kernel function, one can obtain:

$$\kappa(\mathbf{x}_1, \mathbf{x}_2) = k(\mathbf{x}_1 - \mathbf{x}_2) = \int p(\mathbf{u}) e^{i\mathbf{u}^\top(\mathbf{x}_1 - \mathbf{x}_2)} d\mathbf{u}, \tag{1}$$

where $p(\mathbf{u})$ is a proper probability density function calculated from the Fourier transform of function $k(\Delta\mathbf{x})$,

$$p(\mathbf{u}) = (\frac{1}{2\pi})^d \int e^{-i\mathbf{u}^\top(\Delta\mathbf{x})} k(\Delta\mathbf{x}) d(\Delta\mathbf{x}). \tag{2}$$

More specifically, for a Gaussian kernel $\kappa(\mathbf{x}_1, \mathbf{x}_2) = \exp(-\frac{\|\mathbf{x}_1 - \mathbf{x}_2\|_2^2}{2\sigma^2})$, we have the corresponding random Fourier component $\mathbf{u}$ with the distribution $p(\mathbf{u}) = \mathcal{N}(0, \sigma^{-2}I)$. And for a Laplacian kernel $\kappa(\mathbf{x}_1, \mathbf{x}_2) = \exp(-\frac{\|\mathbf{x}_1 - \mathbf{x}_2\|_1}{\sigma})$, we have $p(\mathbf{u}) = \sigma\Pi_d \frac{1}{\pi(1+\sigma^2 u_d^2)}$. Given a kernel function that is continuous and positive-definite, according to the Bochner's theorem (Rudin, 1990), the kernel function can be expressed as an expectation of function with a random variable $\mathbf{u}$:

$$\begin{aligned} &\int p(\mathbf{u}) e^{i\mathbf{u}^\top(\mathbf{x}_1 - \mathbf{x}_2)} d\mathbf{u} = \mathrm{E}_{\mathbf{u}}[e^{i\mathbf{u}^\top\mathbf{x}_1} \cdot e^{-i\mathbf{u}^\top\mathbf{x}_2}] \\ &= \mathrm{E}_{\mathbf{u}}[\cos(\mathbf{u}^\top\mathbf{x}_1)\cos(\mathbf{u}^\top\mathbf{x}_2) + \sin(\mathbf{u}^\top\mathbf{x}_1)\sin(\mathbf{u}^\top\mathbf{x}_2)] \\ &= \mathrm{E}_{\mathbf{u}}[[\sin(\mathbf{u}^\top\mathbf{x}_1), \cos(\mathbf{u}^\top\mathbf{x}_1)] \cdot [\sin(\mathbf{u}^\top\mathbf{x}_2), \cos(\mathbf{u}^\top\mathbf{x}_2)]]. \end{aligned} \tag{3}$$

The equality (1) can be obtained by only keeping the real part of the complex function. From (3), we can see any shift-invariant kernel function can be expressed by the expectation of the inner product of the new representation of original data, where the new data representation is $\mathbf{z}(\mathbf{x}) = [\sin(\mathbf{u}^\top\mathbf{x}), \cos(\mathbf{u}^\top\mathbf{x})]^\top$. As a consequence, we can sample D number of random Fourier components $\mathbf{u}_1, ...\mathbf{u}_D$ independently for constructing the new representation as follows:

$$\mathbf{z}(\mathbf{x}) = (\sin(\mathbf{u}_1^\top\mathbf{x}), \cos(\mathbf{u}_1^\top\mathbf{x}), ..., \sin(\mathbf{u}_D^\top\mathbf{x}), \cos(\mathbf{u}_D^\top\mathbf{x}))^\top.$$

The online kernel learning task in the original input space can thus be approximated by solving a linear online learning task in the new feature space. For data arriving sequentially, we can construct the new representation of a data instance on-the-fly, and then perform online learning in the new feature space using the online gradient descent algorithm. We refer to the proposed algorithm as the Fourier Online Gradient Descent (FOGD), as summarized in Algorithm 1.

3.3 Nyström Online Gradient Descent

The above random Fourier feature based approach attempts to approximate the kernel function explicitly, which is in general data independent for the given dataset and thus may not fully exploit the potential of data distribution for kernel approximation. To address this, we propose to explore the Nyström method (Williams and Seeger, 2000) to approximate a large kernel matrix by a data-dependent approach.

Before presenting the method, we first introduce some notations. We denote a kernel matrix by $\mathbf{K} \in \mathbb{R}^{T\times T}$ with rank r, the Singular Value Decomposition (SVD) of $\mathbf{K}$ as $\mathbf{K} = \mathbf{V}\mathbf{D}\mathbf{V}^\top$, where the columns of $\mathbf{V}$ are orthogonal and $\mathbf{D} = \text{diag}(\sigma_1, \ldots, \sigma_r,)$ is diagonal. For $k < r$, $\mathbf{K}_k = \sum_{i=1}^k \sigma_i V_i V_i^\top = \mathbf{V}_k\mathbf{D}_k\mathbf{V}_k^\top$ is the best rank-k approximation of $\mathbf{K}$, where V_i is the i-th column of matrix $\mathbf{V}$.

Given a large kernel matrix $\mathbf{K} \in \mathbb{R}^{T\times T}$, the Nyström method randomly samples $B \ll T$ columns to form a matrix $\mathbf{C} \in \mathbb{R}^{T\times B}$, and then derive a much smaller kernel matrix $\mathbf{W} \in \mathbb{R}^{B\times B}$ based on the sampled B instances. We can in turn approximate the original large kernel matrix by

$$\hat{\mathbf{K}} = \mathbf{C}\mathbf{W}_k^+\mathbf{C}^\top \approx \mathbf{K}, \tag{4}$$

where $\mathbf{W}_k$ is the best rank-k approximation of $\mathbf{W}$, $\mathbf{W}^+$ denotes the pseudo inverse of matrix $\mathbf{W}$.

We now apply the above Nyström based kernel approximation to tackle large-scale online kernel classification task. Similar to the previous approach, the key idea is to construct the new representation for every newly arrived data instance based on the kernel approximation principle. In particular, we propose the following scheme: (i) at the very early stage of the online classification task, we simply run any existing online kernel learning methods (e.g., kernel-based online gradient descent in our approach) whenever the number of SV's is smaller than the predefined budget B; (ii) once the budget is reached, we then use the stored B SV's to approximate the kernel value of any new instances (which is equivalent to using the first B columns to approximate the whole kernel matrix). From the approximated kernel matrix in (4), we could see the kernel value between i-th instance $\mathbf{x}_i$ and j-th instance

Algorithm 1 FOGD — Fourier Online Gradient Descent for Binary Classification

Input: the number of Fourier components D, step size η, kernel function k;
Initialize $\mathbf{w}_1 = 0$.
Calculate $p(\mathbf{u})$ for kernel k as (2).
Generate random Fourier components: $\mathbf{u}_1, ..., \mathbf{u}_D$ sampled from distribution $p(\mathbf{u})$
for $t = 1, 2, \ldots, T$ **do**
  Receive $\mathbf{x}_t$;
  Construct new representation:
  $\mathbf{z}_t(\mathbf{x}_t) = (\sin(\mathbf{u}_1^\top\mathbf{x}_t), \cos(\mathbf{u}_1^\top\mathbf{x}_t), ..., \sin(\mathbf{u}_D^\top\mathbf{x}_t), \cos(\mathbf{u}_D^\top\mathbf{x}_t))^\top$
  Predict $\widehat{y}_t = \text{sgn}(\mathbf{w}_t^\top\mathbf{z}(\mathbf{x}_t))$;
  Receive y_t and suffer loss $\ell\big(\mathbf{w}_t^\top\mathbf{z}(\mathbf{x}_t); y_t\big)$;
  if $\ell\big(\mathbf{w}_t^\top\mathbf{z}(\mathbf{x}_t); y_t\big) > 0$ **then**
    $\mathbf{w}_{t+1} = \mathbf{w}_t - \eta\nabla\ell\big(\mathbf{w}_t^\top\mathbf{z}(\mathbf{x}_t); y_t\big)$.
  end if
end for

Algorithm 2 NOGD — Nyström Online Gradient Descent for Binary Classification

Input: the budget B, step size η, rank approximation k.
Initialize support vector set $\mathcal{S}_1 = \emptyset$, and model $f_1 = 0$.
while $|\mathcal{S}_t| < B$ **do**
  Receive new instance $\mathbf{x}_t$;
  Predict $\widehat{y}_t = \text{sgn}(f_t(\mathbf{x}_t))$;
  Update f_t by regular Online Gradient Descent (OGD);
  Update $\mathcal{S}_{t+1} = \mathcal{S}_t \cup \{t\}$ whenever loss is nonzero;
  $t = t + 1$;
end while
Construct the kernel matrix $\hat{\mathbf{K}}_t$ from $\mathcal{S}_t$.
$[\mathbf{V}_k, \mathbf{D}_k] = \mathsf{eigs}(\hat{\mathbf{K}}_t, k)$, where $\mathbf{V}_k$ and $\mathbf{D}_k$ are Eigenvectors and Eigenvalues of $\hat{\mathbf{K}}_t$.
Initialize $\mathbf{w}_t^\top = [\alpha_1, ..., \alpha_B](\mathbf{D}_k^{-0.5}\mathbf{V}_k^\top)^{-1}$.
Initialize the instance index $T_0 = t$;
for $t = T_0, \ldots, T$ **do**
  Receive new instance $\mathbf{x}_t$;
  Construct the new representation of $\mathbf{x}_t$:
  $\mathbf{z}(\mathbf{x}_t) = \mathbf{D}_k^{-0.5}\mathbf{V}_k^\top(\kappa(\mathbf{x}_t, \hat{\mathbf{x}}_1), ..., \kappa(\mathbf{x}_t, \hat{\mathbf{x}}_B))^\top$.
  Predict $\widehat{y}_t = \text{sgn}(\mathbf{w}_t^\top\mathbf{z}(\mathbf{x}_t))$;
  Update $\mathbf{w}_{t+1} = \mathbf{w}_t - \eta\nabla\ell\big(\mathbf{w}_t^\top\mathbf{z}(\mathbf{x}_t); y_t\big)$.
end for

$\mathbf{x}_j$ is approximated by the following

$$\begin{aligned}\hat{\kappa}(\mathbf{x}_i,\mathbf{x}_j) &= (\mathbf{C}_i\mathbf{V}_k\mathbf{D}_k^{-\frac{1}{2}})(\mathbf{C}_j\mathbf{V}_k\mathbf{D}_k^{-\frac{1}{2}})^\top \\ &= ([\kappa(\hat{\mathbf{x}}_1,\mathbf{x}_i),...,\kappa(\hat{\mathbf{x}}_B,\mathbf{x}_i)]\mathbf{V}_k\mathbf{D}_k^{-\frac{1}{2}})(\kappa(\hat{\mathbf{x}}_1,\mathbf{x}_j),...,\kappa(\hat{\mathbf{x}}_B,\mathbf{x}_j)\mathbf{V}_k\mathbf{D}_k^{-\frac{1}{2}})^\top,\end{aligned}$$

where $\hat{\mathbf{x}}_a, a \in \{1,...,B\}$ is the a-th support vector.

For a new instance, we construct the new representation as follows:

$$\mathbf{z}(\mathbf{x}) = ([\kappa(\hat{\mathbf{x}}_1,\mathbf{x}),...,\kappa(\hat{\mathbf{x}}_B,\mathbf{x})]\mathbf{V}_k\mathbf{D}_k^{-\frac{1}{2}})^\top.$$

Similarly, we can then apply the existing online gradient descent algorithm to learn the linear predictive model on the new feature space induced from the kernel. We denote the proposed algorithm the Nyström Online Gradient Descent (NOGD), as summarized in Algorithm 2. Different from the FOGD algorithm, the algorithm follows the kernelized online gradient descent until the number of SV's reaches B. To initialize the linear classifier $\mathbf{w}$, we aim to achieve

$$\mathbf{w}^\top\mathbf{z}(\mathbf{x}) = [\alpha_1,...,\alpha_B][\kappa(\hat{\mathbf{x}}_1,\mathbf{x}),...,\kappa(\hat{\mathbf{x}}_B,\mathbf{x})]^\top,$$

thus

$$\mathbf{w}^\top\mathbf{D}_k^{-\frac{1}{2}}\mathbf{V}_k^\top[\kappa(\hat{\mathbf{x}}_1,\mathbf{x}),...,\kappa(\hat{\mathbf{x}}_B,\mathbf{x})]^\top = [\alpha_1,...,\alpha_B][\kappa(\hat{\mathbf{x}}_1,\mathbf{x}),...,\kappa(\hat{\mathbf{x}}_B,\mathbf{x})]^\top.$$

The solution is

$$\mathbf{w}^\top\mathbf{D}_k^{-\frac{1}{2}}\mathbf{V}_k^\top = [\alpha_1,...,\alpha_B];$$

$$\mathbf{w}^\top = [\alpha_1,...,\alpha_B](\mathbf{D}_k^{-\frac{1}{2}}\mathbf{V}_k^\top)^{-1}.$$

4. Theoretical Analysis

In this section, we analyze the theoretical properties of the two proposed algorithms. We may use $\ell_t(f)$ instead of $\ell(f(\mathbf{x}_t);y_t)$ for simplicity.

Theorem 1 *Assume we have a shift-invariant kernel $\kappa(\mathbf{x}_1,\mathbf{x}_2) = k(\mathbf{x}_1-\mathbf{x}_2)$, where k is some function and the original data is contained by a ball $\mathbb{R}^d$ of diameter R. Let $\ell(f(\mathbf{x});y):\mathbb{R}^2\to\mathbb{R}$ be a convex loss function that is Lipschitz continuous with Lipschitz constant L. Let $\mathbf{w}_t, t\in[T]$ be the sequence of classifiers generated by FOGD in Algorithm 1. Then, for any $f^*(\mathbf{x}) = \sum_{t=1}^T \alpha_t^*\kappa(\mathbf{x},\mathbf{x}_t)$, we have the following with probability at least $1-2^8(\frac{\sigma_p R}{\epsilon})^2\exp(\frac{-D\epsilon^2}{4(d+2)})$,*

$$\sum_{t=1}^T \ell_t(\mathbf{w}_t) - \sum_{t=1}^T \ell_t(f^*) \le \frac{(1+\epsilon)\|f^*\|_1^2}{2\eta} + \frac{\eta}{2}L^2T + \epsilon LT\|f^*\|_1,$$

where $\|f^*\|_1 = \sum_{t=1}^T|\alpha_t^*|$, $\sigma_p^2 = E_p[\mathbf{u}^\top\mathbf{u}]$ is the second moment of the Fourier transform of the kernel function k given that $p(\mathbf{u})$ is the probability density function calculated by the Fourier transform of function k.

Proof Given $f^*(\mathbf{x}) = \sum_{t=1}^T \alpha_t^*\kappa(\mathbf{x},\mathbf{x}_t)$, according to the representer theorem (Schölkopf et al., 2001), we have a corresponding linear model: $\mathbf{w}^* = \sum_{t=1}^T \alpha_t^*\mathbf{z}(\mathbf{x}_t)$, where

$$\mathbf{z}(\mathbf{x}) = (\sin(\mathbf{u}_1^\top\mathbf{x}),\cos(\mathbf{u}_1^\top\mathbf{x}),...,\sin(\mathbf{u}_D^\top\mathbf{x}),\cos(\mathbf{u}_D^\top\mathbf{x}))^\top.$$

The first step to prove our theorem is to bound the regret of our sequence of linear model $\mathbf{w}_t$ learned by our online learner with respect to the linear model $\mathbf{w}^*$ in the new feature space. First of all, we have the following:

$$\begin{aligned}&\|\mathbf{w}_{t+1}-\mathbf{w}^*\|^2 = \|\mathbf{w}_t - \eta\nabla\ell_t(\mathbf{w}_t) - \mathbf{w}^*\|^2 \\ =&\|\mathbf{w}_t-\mathbf{w}^*\|^2 + \eta^2\|\nabla\ell_t(\mathbf{w}_t)\|^2 - 2\eta\nabla\ell_t(\mathbf{w}_t)(\mathbf{w}_t-\mathbf{w}^*).\end{aligned}$$

Combining the above and the convexity of the loss function, i.e.,

$$\ell_t(\mathbf{w}_t) - \ell_t(\mathbf{w}^*) \le \nabla\ell_t(\mathbf{w}_t)(\mathbf{w}_t-\mathbf{w}^*),$$

we then have the following

$$\ell_t(\mathbf{w}_t) - \ell_t(\mathbf{w}^*) \le \frac{\|\mathbf{w}_t-\mathbf{w}^*\|^2 - \|\mathbf{w}_{t+1}-\mathbf{w}^*\|^2}{2\eta} + \frac{\eta}{2}\|\nabla\ell_t(\mathbf{w}_t)\|^2.$$

Summing the above over $t=1,...,T$ leads to:

$$\begin{aligned}\sum_{t=1}^T(\ell_t(\mathbf{w}_t)-\ell_t(\mathbf{w}^*)) &\le \frac{\|\mathbf{w}_1-\mathbf{w}^*\|^2 - \|\mathbf{w}_{T+1}-\mathbf{w}^*\|^2}{2\eta} + \frac{\eta}{2}\sum_{t=1}^T\|\nabla\ell_t(\mathbf{w}_t)\|^2 \\ &\le \frac{\|\mathbf{w}^*\|^2}{2\eta} + \frac{\eta}{2}L^2T. \qquad (5)\end{aligned}$$

Next we further examine the relationship between $\sum_{t=1}^T\ell_t(\mathbf{w}^*)$ and $\sum_{t=1}^T\ell_t(f^*)$. According to the uniform convergence of Fourier features (Claim 1 in Rahimi and Recht (2007)), we have the high probability bound for the difference between the approximated kernel value and the true kernel value, i.e., with probability at least $1-2^8(\frac{\sigma_p R}{\epsilon})^2\exp(\frac{-D\epsilon^2}{4(d+2)})$, where $\sigma_p^2 = E_p[\mathbf{u}^\top\mathbf{u}]$ is the second moment of the Fourier transform of the kernel function k given that $p(\mathbf{u})$ is the probability density function calculated by the Fourier transform of function k. We have $\forall i,j$

$$|\mathbf{z}(\mathbf{x}_i)^\top\mathbf{z}(\mathbf{x}_j) - \kappa(\mathbf{x}_i,\mathbf{x}_j)| < \epsilon.$$

Since we assume $\kappa(\mathbf{x}_i,\mathbf{x}_j)\le 1$, we can assume $\mathbf{z}(\mathbf{x}_i)^\top\mathbf{z}(\mathbf{x}_j)\le 1+\epsilon$, which lead to:

$$\|\mathbf{w}^*\|^2 \le (1+\epsilon)\|f^*\|_1^2. \qquad (6)$$

When $|\mathbf{z}(\mathbf{x}_i)^\top\mathbf{z}(\mathbf{x}_j) - \kappa(\mathbf{x}_i,\mathbf{x}_j)| < \epsilon$, we have

$$\begin{aligned}|\sum_{t=1}^T\ell_t(\mathbf{w}^*) - \sum_{t=1}^T\ell_t(f^*)| &\le \sum_{t=1}^T|\ell_t(\mathbf{w}^*)-\ell_t(f^*)| \\ &\le \sum_{t=1}^T L\sum_{i=1}^T|\alpha_i^*||\mathbf{z}(\mathbf{x}_i)^\top\mathbf{z}(\mathbf{x}_t) - \kappa(\mathbf{x}_i,\mathbf{x}_t)| \\ &\le \sum_{t=1}^T L\epsilon\sum_{i=1}^T|\alpha_i^*| = \epsilon LT\|f^*\|_1. \qquad (7)\end{aligned}$$

Combining (5), (6) and (7) leads to complete the proof. ■

Remark 1. In general, the larger the dimensionality D, the higher the probability of the bound to be achieved. This means that by sampling more random Fourier components, one can approximate the kernel function more accurately and effectively. From the above theorem, it is not difficult to show that, by setting $\eta = \frac{1}{\sqrt{T}}$ and $\epsilon = \frac{1}{\sqrt{T}}$, we have

$$\sum_{t=1}^{T} \ell_t(\mathbf{w}_t) - \sum_{t=1}^{T} \ell_t(f^*) \quad \leq \quad (\frac{2\|f^*\|_1 + L^2}{2} + L\|f^*\|_1)\sqrt{T},$$

which leads to a sub-linear regret $O(\sqrt{T})$. However, setting $\epsilon = \frac{1}{\sqrt{T}}$ requires to sample $D = O(T)$ random components in order to achieve a high probability, which seems unsatisfactory since we will have to solve a very high-dimensional linear online learning problem. However, even in this case, for our FOGD algorithm, the learning time cost for each instance is $O(c_1 T)$, while the time cost for classifying an instance by regular online kernel classification is $O(c_2 T)$, here c_1 is the time for a scalar product by FOGD, while c_2 is the time for computing the kernel function. Since $c_2 \gg c_1$, our method is still much faster than the regular online kernel classification methods.

Remark 2. This theorem bounds the regret for any shift-invariant kernel. Specially, we can get the bound for a Gaussian kernel $k(\mathbf{x}_1 - \mathbf{x}_2) = \exp(-\gamma||\mathbf{x}_1 - \mathbf{x}_2||^2)$, by setting $\sigma_p^2 = 2d\gamma$ (Rahimi and Recht, 2007).

The theoretical analysis for the NOGD algorithm follows the similar procedure as used by the FOGD algorithm. We first introduce a lemma to facility our regret bound analysis.

Lemma 1 *$P(f) = \frac{\lambda}{2}\|f\|_{\mathcal{H}}^2 + \frac{1}{T}\sum_{t=1}^{T} \ell_t(f)$ is the objective function of an SVM problem, where $\ell_t(f)$ is the hinge loss function of the t-th iteration. Define f^* to be the optimal solution when using the exact kernel matrix $\mathbf{K}$ and f_N as the optimal when adopting the Nyström approximated kernel matrix $\hat{\mathbf{K}}$. We have*

$$P(f_N) - P(f^*) \leq \frac{1}{2T\lambda}||\mathbf{K} - \hat{\mathbf{K}}||_2,$$

where $\|\mathbf{K} - \hat{\mathbf{K}}\|_2$ is the spectral norm of the kernel approximation gap.

This lemma mainly follows the Lemma 1 in (Yang et al., 2012), we omit the proof for conciseness.

Theorem 2 *Assume we learn with kernel $\kappa(\mathbf{x}_i, \mathbf{x}_j) \leq 1$, $\forall i, j \in [T]$. Let $\ell(f(\mathbf{x}); y) : \mathbb{R}^2 \to \mathbb{R}$ be the hinge loss function. Let the sequence of T instances $\mathbf{x}_1, ..., \mathbf{x}_T$ form a kernel matrix $\mathbf{K} \in \mathbb{R}^{T \times T}$, and $\hat{\mathbf{K}}$ is the approximation of $\mathbf{K}$ using Nyström method. Let $f_t(\mathbf{x}) = \mathbf{w}_t^\top \mathbf{z}(\mathbf{x}), t \in [T]$ be the sequence of classifiers generated by NOGD in Algorithm 2. We assume the norm of the gradients in all iterations are always bounded by a constant L, which is easy to achieve by a few projection steps when necessary. In addition, define $f_N(\mathbf{x}) = \mathbf{w}_N^\top \mathbf{z}(\mathbf{x})$ be the optimal classifier when using Nyström kernel approximation and assuming we had foresight for all instances. By defining f^* as the optimal classifier in the original kernel space with the assumption of the foresight for all the instances, we have the following:*

$$\sum_{t=1}^{T} \mathcal{L}_t(\mathbf{w}_t) - \sum_{t=1}^{T} \mathcal{L}_t(f^*) \leq \frac{\|\mathbf{w}_N\|^2}{2\eta} + \frac{\eta}{2}L^2 T + \frac{1}{2\lambda}||\mathbf{K} - \hat{\mathbf{K}}||_2.$$

Proof Following the similar analysis as in Theorem 1, the regularized loss function in the t-th iteration, $\mathcal{L}_t(\mathbf{w}) = \frac{\lambda}{2}||\mathbf{w}||_2^2 + \ell_t(\mathbf{w})$ satisfies the following bound,

$$\sum_{t=1}^{T} (\mathcal{L}_t(\mathbf{w}_t) - \mathcal{L}_t(\mathbf{w}_N)) \leq \frac{\|\mathbf{w}_N\|^2}{2\eta} + \frac{\eta}{2}L^2 T.$$

As proven in (Yang et al., 2012), the linear optimization problem in $\mathbf{z}(\mathbf{x})$ space, i.e., $P(\mathbf{w}) = \frac{\lambda}{2}||\mathbf{w}||_2^2 + \frac{1}{T}\sum_{t=1}^{T} \ell_t(\mathbf{w})$ is equivalent to the approximated SVM $P(f) = \frac{\lambda}{2}||f||_{\mathcal{H}}^2 + \frac{1}{T}\sum_{t=1}^{T} \ell_t(f)$ when $f \in \mathcal{H}_N$ is the functional space of Nyström method. From Lemma 1, we have,

$$\sum_{t=1}^{T} \mathcal{L}_t(\mathbf{w}_N) = \sum_{t=1}^{T} \mathcal{L}_t(f_N) = TP(f_N) \leq TP(f^*) + \frac{1}{2\lambda}||\mathbf{K} - \hat{\mathbf{K}}||_2 = \sum_{t=1}^{T} \mathcal{L}(f^*) + \frac{1}{2\lambda}||\mathbf{K} - \hat{\mathbf{K}}||_2.$$

We complete the proof by combining the above two formulas. ■

Remark. As shown in Theorem 5 of (Yang et al., 2012), the kernel approximation gap $||\mathbf{K} - \hat{\mathbf{K}}||_2 \leq O(\frac{T}{B})$. Consequently when setting $B = \sqrt{T}$ and $\eta = \frac{1}{\sqrt{T}}$, we have

$$\sum_{t=1}^{T} \mathcal{L}_t(\mathbf{w}_t) - \sum_{t=1}^{T} \mathcal{L}(f^*) \leq O(\sqrt{T}).$$

This theorem bounds the regret of the NOGD algorithm when using all singular values of matrix $\mathbf{W}$ but only $O(\sqrt{T})$ support vectors. However, when the rank of the Nyström approximated matrix $\hat{\mathbf{K}}$ is only k, the bound should be slightly worse. As (Cortes et al., 2010)(Theorem 1) shows, the following holds with probability at least $1 - \epsilon$,

$$\|\hat{\mathbf{K}} - \mathbf{K}\|_2 \leq \|\mathbf{K} - \mathbf{K}_k\|_2 + \frac{T}{\sqrt{B}}\mathbf{K}_{\max}(2 + \log\frac{1}{\epsilon}),$$

where $\|\mathbf{K} - \mathbf{K}_k\|_2$ is the spectral norm of the best rank-k approximated gap and $\mathbf{K}_{\max}$ is the maximum diagonal entry of $\mathbf{K}$. This indicates that to get the $O(\sqrt{T})$ regret bound, we should set the budget size $B = T/c$, where c is some constant. This seems suboptimal, but we will demonstrate that only a small budget size is needed for satisfactory performance in our experimental results. In addition, the time cost of using k-rank approximation is only k/B times of that when using all singular values, which makes the algorithm extremely efficient.

5. Large Scale Online Kernel Learning for Multi-class Classification

In this section, we extend the proposed Fourier Online Gradient Descent and Nyström Online Gradient Descent methods, which are originally designed for binary classification, to online multi-class classification task. We also give theoretical analysis of the two approaches.

5.1 Problem Settings

Similar to online binary classification tasks, online multi-class classification is performed over a sequence of training examples $(\mathbf{x}_t, y_t)$, $t = 1, \ldots, T$, where $\mathbf{x}_t \in \mathbb{R}^d$ is the observed features of the t-th training instance. Unlike binary classification where class label $y_t \in \mathcal{Y} = \{+1, -1\}$, in a multi-class classification task, each label belongs to a finite set $\mathcal{Y}$ of size $m > 2$, i.e., $y_t \in \mathcal{Y} = \{1, \ldots, m\}$. The true class label y_t is only revealed after the prediction $\hat{y}_t \in \mathcal{Y}$ is made.

We follow the protocol of multi-prototype classification for deriving multi-class online learning algorithm (Crammer et al., 2006). Specifically, it learns a function $f^r : \mathbb{R}^d \to \mathbb{R}$ for each of the classes $r \in \mathcal{Y}$. During the t-th iteration, the algorithm predicts a sequence of scores for the classes:

$$\big(f_t^1(\mathbf{x}_t), \ldots, f_t^m(\mathbf{x}_t)\big).$$

The predicted class is set to be the class with the highest prediction score:

$$\hat{y}_t = \arg\max_{r \in \mathcal{Y}} f_t^r(\mathbf{x}_t). \tag{8}$$

We then define s_t as the irrelevant class with the highest prediction score:

$$s_t = \arg\max_{r \in \mathcal{Y}, r \neq y_t} f_t^r(\mathbf{x}_t).$$

The margin with respect to the hypothesis in the t-th iteration is defined to be the gap between the prediction score of class y_t and s_t:

$$\gamma_t = f_t^{y_t}(\mathbf{x}_t) - f_t^{s_t}(\mathbf{x}_t).$$

Obviously, in a correct prediction, the margin $\gamma_t > 0$. However, as stated in (Crammer et al., 2006), we are not satisfied by a positive margin value and thus we define a *hinge-loss* function:

$$\ell\big(\overline{f}_t, \mathbf{x}_t, y_t\big) = \max(0, 1 - \gamma_t),$$

where $\overline{f}_t$ denotes the set of all m functions for all classes.

5.2 Multi-class Fourier Online Gradient Descent

As introduced in the previous section for binary classification task, the online multi-class kernel classification task in the original input space can also be approximated by solving a linear online learning task in the new feature space. First, we use the same Fourier feature mapping approach as in the binary case to map each input instance $\mathbf{x}_t$ to $\mathbf{z}(\mathbf{x}_t)$. Then Online Gradient Descent method is applied to learn a linear classifier.

Following the multi-class problem setting, we learn a weight vector $\mathbf{w}^r \in \mathbb{R}^d$ for each of the classes $r \in \mathcal{Y}$. And use the linear classifier $f^r(\mathbf{x}_t) = \mathbf{w}^r \cdot \mathbf{z}(\mathbf{x}_t)$ to approximate to kernel prediction score. During the t-th iteration, the algorithm predicts a sequence of scores for the m classes:

$$\big(\mathbf{w}_t^1 \cdot \mathbf{z}(\mathbf{x}_t), \ldots, \mathbf{w}_t^m \cdot \mathbf{z}(\mathbf{x}_t)\big).$$

We define the *hinge-loss* function as following:

$$\ell\big(\overline{\mathbf{w}}_t, \mathbf{x}_t, y_t\big) = \max(0, 1 - \gamma_t) = \max(0, 1 - \mathbf{w}_t^{y_t} \cdot \mathbf{z}(\mathbf{x}_t) + \mathbf{w}_t^{s_t} \cdot \mathbf{z}(\mathbf{x}_t)), \tag{9}$$

where $\overline{\mathbf{w}}_t$ denotes the set of all m weight vectors.

Following the Online Gradient Descent approach, the update strategy of $\overline{\mathbf{w}_t}$ when $\ell > 0$ is:

$$\mathbf{w}_{t+1}^r = \mathbf{w}_t^r - \eta \nabla \ell\big(\overline{\mathbf{w}}_t, \mathbf{x}_t, y_t\big),$$

where η is a positive learning rate parameter and the gradient is taken with regards to $\mathbf{w}_t^r$. By rewriting the loss function explicitly, we can rewrite the above as follows:

$$\mathbf{w}_{t+1}^{y_t} = \mathbf{w}_t^{y_t} + \eta \mathbf{z}(\mathbf{x}_t); \tag{10}$$

$$\mathbf{w}_{t+1}^{s_t} = \mathbf{w}_t^{s_t} - \eta \mathbf{z}(\mathbf{x}_t). \tag{11}$$

Only two of the weight vectors are updated during each iteration. Thus, we can derive the FOGD algorithm for multi-class versions, as summarized in Algorithm 3.

5.3 Multi-class Nyström Online Gradient Descent

Similar to the binary task, in the first a few iterations of multi-class online Nyström algorithm (before the size of SV set reaches the predetermined budget size B), the algorithm performs a regular Online Gradient Descent update to the m kernel classifiers when $\ell > 0$:

$$f_{t+1}^r = f_t^r - \eta \nabla \ell\big(\overline{f}_t, \mathbf{x}_t, y_t\big),$$

where $\eta > 0$ is the gradient descent step size and the gradient is taken with regard to f_t^r. By rewriting the loss function explicitly, we have

$$f_{t+1}^{y_t} = f_t^{y_t} + \eta \kappa(\mathbf{x}_t, \cdot); \tag{12}$$

$$f_{t+1}^{s_t} = f_t^{s_t} - \eta \kappa(\mathbf{x}_t, \cdot). \tag{13}$$

Therefore, we need to store a SV set $\mathcal{S}$ and update it when necessary: $\mathcal{S}_{t+1} = \mathcal{S}_t \cup \{t\}$. Note that all the m classifiers share the same SV set, which is the same setting as that of binary case. However, the storage strategy for α_i, i.e., the coefficient of the i-th SV, is different from that of binary case. In multi-class task, a vector $\alpha_i \in \mathbb{R}^m$ is used to represent the coefficients of the i-th SV. Each of its element α_i^r is the coefficient of the i-th SV for the kernel classifier f^r. Obviously, $\alpha_i^r = 0$ if $r \neq y_t$ and $r \neq s_t$.

After the size of SV set reaches the budget B, we do a Nyström feature mapping as the approach discussed in the binary section to map each input instance $\mathbf{x}_t$ to $\mathbf{z}(\mathbf{x}_t)$. The following linear update steps follow that in the multi-class Fourier Gradient Descent algorithm, as equation (10) and (11).

We derive the NOGD algorithm for multi-class version, as summarized in Algorithm 4.

Algorithm 3 MFOGD — Multi-class Fourier Online Gradient Descent

Input: the number of Fourier components D, step size η, kernel function k;
Initialize $\mathbf{w}_1^r = 0$, $r = 1, ..., m$.
Calculate $p(\mathbf{u})$ for kernel k as (2).
Generate random Fourier components: $\mathbf{u}_1, ..., \mathbf{u}_D$ sampled from distribution $p(\mathbf{u})$.
for $t = 1, 2, \ldots, T$ **do**
  Receive $\mathbf{x}_t$;
  Construct new representation:
  $\mathbf{z}(\mathbf{x}_t) = (\sin(\mathbf{u}_1^\top \mathbf{x}_t), \cos(\mathbf{u}_1^\top \mathbf{x}_t), ..., \sin(\mathbf{u}_D^\top \mathbf{x}_t), \cos(\mathbf{u}_D^\top \mathbf{x}_t))^\top$
  Predict as in (8);
  Receive y_t and suffer loss $\ell\big(\overline{\mathbf{w}}_t, \mathbf{x}_t, y_t\big)$ (9);
  if $\ell\big(\overline{\mathbf{w}}_t, \mathbf{x}_t, y_t\big) > 0$ **then**

end for

Algorithm 4 MNOGD — Multi-class Nyström Online Gradient Descent

Input: the budget B, step size η, rank approximation k.
Initialize support vector set $\mathcal{S}_1 = \emptyset$, and model $f_1^r = 0$, $r = 1, ..., m$.
while $|\mathcal{S}_t| < B$ **do**
  Receive $\mathbf{x}_t$;
  Predict as in (8);
  Update $\overline{f}_t$ by regular Online Gradient Descent (OGD), as (12) and (13);
  Update $\mathcal{S}_{t+1} = \mathcal{S}_t \cup \{t\}$ whenever loss is nonzero;
  $t = t + 1$;
end while
Construct the kernel matrix $\hat{\mathbf{K}}_t$ from $\mathcal{S}_t$.
$[\mathbf{V}_k, \mathbf{D}_k] = \mathsf{eigs}(\hat{\mathbf{K}}_t, k)$, where $\mathbf{V}_k$ and $\mathbf{D}_k$ are Eigenvectors and Eigenvalues of $\hat{\mathbf{K}}_t$.
Initialize $\mathbf{w}_t^{r\top} = [\alpha_1^r, ..., \alpha_B^r](\mathbf{D}_k^{-0.5}\mathbf{V}_k^\top)^{-1}$, $r = 1, ..., m$.
Initialize the instance index $T_0 = t$;
for $t = T_0, \ldots, T$ **do**
  Receive $\mathbf{x}_t$;
  Construct the new representation of $\mathbf{x}_t$:
  $\mathbf{z}(\mathbf{x}_t) = \mathbf{D}_k^{-0.5}\mathbf{V}_k^\top(\kappa(\mathbf{x}_t, \hat{\mathbf{x}}_1), ..., \kappa(\mathbf{x}_t, \hat{\mathbf{x}}_B))^\top$.
  Predict as in (8);
  Update $\overline{\mathbf{w}}_t$ as (10) and (11)
end for

5.4 Theoretical Analysis

In this section, we analyze the theoretical properties of the two proposed multi-class algorithms. We may use $\ell_t(\overline{f})$ instead of $\ell(\overline{f}, \mathbf{x}_t, y_t)$ for simplicity.

Theorem 3 *Assume we have a shift-invariant kernel $\kappa(\mathbf{x}_1, \mathbf{x}_2) = k(\mathbf{x}_1 - \mathbf{x}_2)$, where k is some function and the original data is contained by a ball $\mathbb{R}^d$ of diameter R. Let $\ell\big(\overline{f}, \mathbf{x}, y\big)$ be the hinge-loss we talked above, where $\overline{f}$ denotes the set of m classifiers for the m classes and its output is a sequence of prediction scores. Let $\overline{\mathbf{w}}_t, t \in [T]$ be the sequence of classifiers generated by MFOGD in Algorithm 3. Then, for any $f_*^r(\mathbf{x}) = \sum_{t=1}^T \alpha_t^{r*}\kappa(\mathbf{x}, \mathbf{x}_t)$, $r \in \{1, ..., m\}$, we have the following with probability at least $1 - 2^8(\frac{\sigma_p R}{\epsilon})^2 \exp(\frac{-D\epsilon^2}{4(d+2)})$*

$$\sum_{t=1}^T \ell_t(\overline{\mathbf{w}}_t) - \sum_{t=1}^T \ell_t(\overline{f}_*) \le \frac{m(1+\epsilon)\|f_*\|_1^2}{2\eta} + \eta T D + 2T\epsilon\|f_*\|_1,$$

where $\|f_*\|_1 = \sum_{t=1}^T \max_{r\in\mathcal{Y}}|\alpha_t^{r*}|$, and $\sigma_p^2 = E_p[\mathbf{u}^\top\mathbf{u}]$ is the second moment of the Fourier transform of the kernel function k given that $p(\mathbf{u})$ is the probability density function calculated by the Fourier transform of function k.

Proof Given $f_*^r(\mathbf{x}) = \sum_{t=1}^T \alpha_t^{r*}\kappa(\mathbf{x}, \mathbf{x}_t)$, $r = 1, ...m$, according to the Representer Theorem (Schölkopf et al., 2001), we have a corresponding linear model: $\mathbf{w}_*^r = \sum_{t=1}^T \alpha_t^{r*}\mathbf{z}(\mathbf{x}_t)$, where

$$\mathbf{z}(\mathbf{x}) = (\sin(\mathbf{u}_1^\top\mathbf{x}), \cos(\mathbf{u}_1^\top\mathbf{x}), ..., \sin(\mathbf{u}_D^\top\mathbf{x}), \cos(\mathbf{u}_D^\top\mathbf{x}))^\top.$$

The first step to prove our theorem is to bound the regret of the sequence of linear models $\mathbf{w}_t$ learned by online learner with respect to the linear model $\mathbf{w}^*$ in the new feature space. We first have

$$\begin{aligned}\|\mathbf{w}_{t+1}^r - \mathbf{w}_*^r\|^2 - \|\mathbf{w}_t^r - \mathbf{w}_*^r\|^2 &= \|\mathbf{w}_t^r - \mathbf{w}_*^r + \beta_t^r\mathbf{z}(\mathbf{x}_t)\|^2 - \|\mathbf{w}_t^r - \mathbf{w}_*^r\|^2 \\ &= (\beta_t^r)^2\|\mathbf{z}(\mathbf{x}_t)\|^2 + 2\beta_t^r(\mathbf{w}_t^r \cdot \mathbf{z}(\mathbf{x}_t) - \mathbf{w}_*^r \cdot \mathbf{z}(\mathbf{x}_t)),\end{aligned}$$

where β_t^r is the parameter used to update $\mathbf{w}_t^r$ as (10) and (11). Thus, it may be η, $-\eta$, or 0. Obviously, $\|\mathbf{z}(\mathbf{x}_t)\|^2 = D$. We first assume that $\ell_t(\overline{\mathbf{w}}_t) > 0$ and there are updates in the t-th iteration. Summing the above over $r = 1, ..., m$, we have

$$\begin{aligned}&\sum_{r=1}^m \left(\|\mathbf{w}_{t+1}^r - \mathbf{w}_*^r\|^2 - \|\mathbf{w}_t^r - \mathbf{w}_*^r\|^2\right) \\ &= 2\eta^2 D + 2\eta(\mathbf{w}_t^{y_t} \cdot \mathbf{z}(\mathbf{x}_t) - \mathbf{w}_t^{s_t} \cdot \mathbf{z}(\mathbf{x}_t)) - 2\eta(\mathbf{w}_*^{y_t} \cdot \mathbf{z}(\mathbf{x}_t) - \mathbf{w}_*^{s_t} \cdot \mathbf{z}(\mathbf{x}_t)),\end{aligned}$$

where y_t is the true label in the t-th iteration and s_t is the label of the largest scored irrelevant label classified by the classifier set $\overline{\mathbf{w}}_t$, not by the classifier set $\overline{\mathbf{w}}_*$. Thus we have:

$$\mathbf{w}_t^{y_t} \cdot \mathbf{z}(\mathbf{x}_t) - \mathbf{w}_t^{s_t} \cdot \mathbf{z}(\mathbf{x}_t) = \gamma_{\mathbf{w},t} \qquad \mathbf{w}_*^{y_t} \cdot \mathbf{z}(\mathbf{x}_t) - \mathbf{w}_*^{s_t} \cdot \mathbf{z}(\mathbf{x}_t) \ge \gamma_{\mathbf{w}*,t}.$$

As we have assumed $\ell_t(\overline{\mathbf{w}}_t) > 0$, we have $\ell_t(\overline{\mathbf{w}}_t) = 1 - \gamma_{\mathbf{w},t}$. And from the fact that $\ell_t(\overline{\mathbf{w}}_*) \ge 1 - \gamma_{\mathbf{w}*,t}$, we have:

$$\gamma_{\mathbf{w},t} - \gamma_{\mathbf{w}*,t} \le 1 - \ell_t(\overline{\mathbf{w}}_t) - (1 - \ell_t(\overline{\mathbf{w}}_*)) = \ell_t(\overline{\mathbf{w}}_*) - \ell_t(\overline{\mathbf{w}}_t).$$

Combining the three formula above, we get

$$\ell_t(\overline{\mathbf{w}}_t) - \ell_t(\overline{\mathbf{w}}_*) \leq \eta D + \frac{\sum_{r=1}^m \|\mathbf{w}_t^r - \mathbf{w}_*^r\|^2 - \sum_{r=1}^m \|\mathbf{w}_{t+1}^r - \mathbf{w}_*^r\|^2}{2\eta}.$$

Note that in some iterations, $\ell_t(\overline{\mathbf{w}}_t) = 0$ and there is no update in the t-th iteration, i.e., $\mathbf{w}_t^r = \mathbf{w}_{t+1}^r$. The above formula still holds. Summing it over $t = 1, ...T$ and assuming $\mathbf{w}_1^r = 0$ for all $r = 1, ..., m$ leads to:

$$\sum_{t=1}^T \ell_t(\overline{\mathbf{w}}_t) - \sum_{t=1}^T \ell_t(\overline{\mathbf{w}}_*) \leq \eta T D + \frac{\sum_{r=1}^m \|\mathbf{w}_*^r\|^2}{2\eta}. \tag{14}$$

Next we further examine the relationship between $\sum_{t=1}^T \ell_t(\overline{\mathbf{w}}_*)$ and $\sum_{t=1}^T \ell_t(\overline{f_*})$. According to the uniform convergence of Fourier features (Claim 1 in Rahimi and Recht (2007)), we have the high probability bound for the difference between the approximated kernel value and the true kernel value, i.e., with probability at least $1 - 2^8(\frac{\sigma_p R}{\epsilon})^2 \exp(\frac{-D\epsilon^2}{4(d+2)})$, where $\sigma_p^2 = E_p[\mathbf{u}^\top \mathbf{u}]$ is the second moment of the Fourier transform of the kernel function k given that $p(\mathbf{u})$ is the probability density function calculated by the Fourier transform of function k. We have $\forall i, j$

$$|\mathbf{z}(\mathbf{x}_i)^\top \mathbf{z}(\mathbf{x}_j) - \kappa(\mathbf{x}_i, \mathbf{x}_j)| < \epsilon.$$

Similar to the binary case:

$$\sum_{r=1}^m \|\mathbf{w}_*^r\|^2 \leq m\|f_*\|_1^2(1+\epsilon). \tag{15}$$

When $|\mathbf{z}(\mathbf{x}_i)^\top \mathbf{z}(\mathbf{x}_j) - \kappa(\mathbf{x}_i, \mathbf{x}_j)| < \epsilon$, we have

$$\begin{aligned}
&|\sum_{t=1}^T \ell_t(\overline{\mathbf{w}}_*) - \sum_{t=1}^T \ell_t(\overline{f_*})| \leq \sum_{t=1}^T |\ell_t(\overline{\mathbf{w}}_*) - \ell_t(\overline{f_*})| \leq \sum_{t=1}^T L|\gamma_{\mathbf{w}^*,t} - \gamma_{\mathbf{f}^*,t}| \\
&= \sum_{t=1}^T |\sum_{i=1}^T (\alpha_i^{y_t *}\mathbf{z}(\mathbf{x}_i)^\top \mathbf{z}(\mathbf{x}_t) - \alpha_i^{s_t *}\mathbf{z}(\mathbf{x}_i)^\top \mathbf{z}(\mathbf{x}_t)) - \sum_{i=1}^T (\alpha_i^{y_t *}\kappa(\mathbf{x}_i, \mathbf{x}_t) - \alpha_i^{s_t' *}\kappa(\mathbf{x}_i, \mathbf{x}_t))| \\
&\leq \sum_{t=1}^T \big(\sum_{i=1}^T |\alpha_i^{y_t *}\mathbf{z}(\mathbf{x}_i)^\top \mathbf{z}(\mathbf{x}_t) - \alpha_i^{y_t *}\kappa(\mathbf{x}_i, \mathbf{x}_t)| + \sum_{i=1}^T |\alpha_i^{s_t *}\mathbf{z}(\mathbf{x}_i)^\top \mathbf{z}(\mathbf{x}_t) - \alpha_i^{s_t' *}\kappa(\mathbf{x}_i, \mathbf{x}_t)| \big),
\end{aligned}$$

where L in the first line is the Lipschitz constant and can be set to 1 in hinge loss case, and s_t is the largest scored irrelevant label with regards to $\overline{\mathbf{w}}_*$ and s_t' with regard to $\overline{f_*}$. Thus the bound of the first term is easy to find and we will focus on the second term. Without loss of generality, we assume $\alpha_i^{s_t *}\mathbf{z}(\mathbf{x}_i)^\top \mathbf{z}(\mathbf{x}_t) \geq \alpha_i^{s_t' *}\kappa(\mathbf{x}_i, \mathbf{x}_t)$. According to the definition of s_t and s_t', $\alpha_i^{s_t' *}\kappa(\mathbf{x}_i, \mathbf{x}_t) > \alpha_i^{s_t *}\kappa(\mathbf{x}_i, \mathbf{x}_t)$, leading to:

$$|\alpha_i^{s_t *}\mathbf{z}(\mathbf{x}_i)^\top \mathbf{z}(\mathbf{x}_t) - \alpha_i^{s_t' *}\kappa(\mathbf{x}_i, \mathbf{x}_t)| \leq |\alpha_i^{s_t *}\big(\mathbf{z}(\mathbf{x}_i)^\top \mathbf{z}(\mathbf{x}_t) - \kappa(\mathbf{x}_i, \mathbf{x}_t)\big)| \leq |\alpha_i^{s_t *}|\epsilon.$$

Consequently, we have

$$|\sum_{t=1}^T \ell_t(\overline{\mathbf{w}}_*) - \sum_{t=1}^T \ell_t(\overline{f_*})| \leq 2T\epsilon\|f_*\|_1. \tag{16}$$

Combining (14), (15) and (16) leads to complete the proof. ■

Similar to the analysis of the binary classification case, it is not difficult to observe that the proposed MFOGD algorithm also achieves sub-linear regret $O(\sqrt{T})$. We will continue the analysis of MNOGD method in the following. As in the binary analysis, we first propose a lemma that bounds the gap of averaged loss between the exact kernel SVM and approximated kernel SVM. Unlike the binary classification problem, there are many different problem settings for the multi-class SVM problem, as surveyed by Hsu and Lin (2002). For consistency, in the following analysis, we adopt the common slack variables for all classes setting (Crammer and Singer, 2001, 2002).

Lemma 2 *$P(\overline{f}) = \frac{\lambda}{2}\sum_{r=1}^m \|f^r\|_{\mathcal{H}}^2 + \frac{1}{T}\sum_{t=1}^T \ell_t(\overline{f})$ is the objective function of an multi-class SVM problem, where $\ell_t(\overline{f})$ is the multi-class hinge loss function of the t-th iteration. Define $\overline{f^*}$ as the optimal solution of $P(\overline{f})$ when using the exact kernel matrix $\mathbf{K}$ and $\overline{f_N}$ as the optimal solution of SVM algorithm when adopting the Nyström approximated kernel matrix $\hat{\mathbf{K}}$. We have*

$$P(\overline{f_N}) - P(\overline{f^*}) \leq \frac{m}{2T\lambda}||\mathbf{K} - \hat{\mathbf{K}}||_2,$$

where $\|\mathbf{K} - \hat{\mathbf{K}}\|_2$ is the spectral norm of the kernel approximation gap.

Proof The dual problem of multi-class SVM is

$$\begin{aligned}
\max P(\boldsymbol{\alpha}) &= -\frac{1}{2\lambda}\sum_{r=1}^m \boldsymbol{\alpha}_r^\top \mathbf{K}\boldsymbol{\alpha}_r - \sum_{r=1}^m \boldsymbol{\alpha}_r^\top \mathbf{e}_r, \\
s.t. \quad &\sum_{r=1}^m \alpha_{t,r} = 0, \ \forall t \in \{1, 2, ..., T\}; \\
\alpha_{t,r} \leq 0, \ &\text{if } y_t \neq r, \quad \alpha_{t,r} \leq \frac{1}{T}, \text{if } y_t = r, \quad \forall t \in \{1, 2, ..., T\}, \quad \forall r \in \{1, 2, ...m\}
\end{aligned}$$

where $\boldsymbol{\alpha}_r = [\alpha_{1,r}, \alpha_{2,r}, ..., \alpha_{T,r}]^\top$, $\mathbf{e}_r = [e_{1,r}, e_{2,r}, ..., e_{T,r}]^\top$ and $e_{t,r} = 0$ if $y_t = r$, otherwise $e_{t,r} = 1$.

We can get the dual problem of the Nyström approximated multi-class SVM by replacing the kernel matrix $\mathbf{K}$ with $\hat{\mathbf{K}}$.

$$\begin{aligned}
P(\overline{f_N}) &= \max\left[-\frac{1}{2\lambda}\sum_{r=1}^m \boldsymbol{\alpha}_r^\top \hat{\mathbf{K}}\boldsymbol{\alpha}_r - \sum_{r=1}^m \boldsymbol{\alpha}_r^\top \mathbf{e}_r\right] \\
&= \max\left[-\frac{1}{2\lambda}\sum_{r=1}^m \boldsymbol{\alpha}_r^\top (\hat{\mathbf{K}} - \mathbf{K} + \mathbf{K})\boldsymbol{\alpha}_r - \sum_{r=1}^m \boldsymbol{\alpha}_r^\top \mathbf{e}_r\right] \\
&= \max\left[\frac{1}{2\lambda}\sum_{r=1}^m \boldsymbol{\alpha}_r^\top (\mathbf{K} - \hat{\mathbf{K}})\boldsymbol{\alpha}_r\right] + \max\left[-\frac{1}{2\lambda}\sum_{r=1}^m \boldsymbol{\alpha}_r^\top \mathbf{K}\boldsymbol{\alpha}_r - \sum_{r=1}^m \boldsymbol{\alpha}_r^\top \mathbf{e}_r\right].
\end{aligned}$$

Consequently,

$$P(\overline{f_N}) - P(\overline{f^*}) \leq \max \frac{1}{2\lambda} \sum_{r=1}^{m} \boldsymbol{\alpha}_{\boldsymbol{r}}^{\top} (\mathbf{K} - \hat{\mathbf{K}}) \boldsymbol{\alpha}_{\boldsymbol{r}} \leq \max \sum_{r=1}^{m} \frac{1}{2\lambda} ||\boldsymbol{\alpha}_{\boldsymbol{r}}||_2^2 ||\mathbf{K} - \hat{\mathbf{K}}||_2.$$

We complete the proof by considering $|\alpha_{t,r}| \leq \frac{1}{T}$. ■

Theorem 4 *Assume we learn with kernel $\kappa(\mathbf{x}_i, \mathbf{x}_j) \leq 1, \forall i, j \in [T]$. Let $\ell(f(\mathbf{x}); y) : \mathbb{R}^2 \to \mathbb{R}$ be the multi-class hinge loss function. Let the sequence of T instances $\mathbf{x}_1, ..., \mathbf{x}_T$ form a kernel matrix $\mathbf{K} \in \mathbb{R}^{T \times T}$, and $\hat{\mathbf{K}}$ is the approximation of $\mathbf{K}$ using Nyström method . Let $f_t^r(\mathbf{x}) = \mathbf{w}_{t,r}^{\top} \mathbf{z}(\mathbf{x}), t \in [T], r \in \{1, 2, ..., m\}$ be the sequence of classifiers generated by NOGD in Algorithm 4. We assume the norm of the gradients in all iterations are always bounded by a constant L, which is easy to achieve by a few projection steps when necessary. In addition, define $f_N^r(\mathbf{x}) = \mathbf{w}_{N,r}^{\top} \mathbf{z}(\mathbf{x}), r \in \{1, 2, ..., m\}$ be the optimal classifier when using Nyström kernel approximation and assuming we had foresight for all instances. By defining $\overline{f^*}$ as the optimal classifier in the original kernel space with the assumption of the foresight for all the instances, we have the following:*

$$\sum_{t=1}^{T} \mathcal{L}_t(\overline{\mathbf{w}_t}) - \sum_{t=1}^{T} \mathcal{L}_t(\overline{f^*}) \leq \sum_{r=1}^{m} \frac{\|\mathbf{w}_{N,r}\|^2}{2\eta} + \frac{\eta}{2} L^2 T + \frac{m}{2\lambda} ||\mathbf{K} - \hat{\mathbf{K}}||_2.$$

This theorem is a combination of standard online gradient descent analysis and Lemma 2. The proof is omitted since it is similar to the binary analysis and straightforward. It's easy to find that the multi-class NOGD algorithm enjoys the similar regret bound as the binary algorithm.

6. Large Scale Online Kernel Learning for Regression

In this section, we extend the proposed FOGD and NOGD algorithms to tackle online regression tasks. Consider a typical online regression task with a sequence of instances $(\mathbf{x}_t, y_t), t = 1, ..., T$, where $\mathbf{x}_t \in \mathbb{R}^d$ is the feature vector of the t-th instance and $y_t \in \mathbb{R}$ is the real target value, which is only revealed after the prediction is made at each iteration. The goal of online kernel regression task is to learn a model $f(\mathbf{x})$ that maps a new input instance $\mathbf{x} \in \mathbb{R}^d$ to a real value prediction:

$$f(\mathbf{x}) = \sum_{i=1}^{B} \alpha_i \kappa(\mathbf{x}_i, \mathbf{x}).$$

We apply the squared loss as the evaluation metric of regression accuracy:

$$\ell(f(\mathbf{x}_t); y_t) = (f(\mathbf{x}_t) - y_t)^2.$$

As the same approximation strategy with the previous task, with a feature mapping function $\mathbf{z}(\mathbf{x})$, the kernel regression task can be tackled by solving its approximated problem: to find a linear model $f(\mathbf{x}) = \mathbf{w}^{\top} \mathbf{z}(\mathbf{x})$ that minimizes the accumulated squared loss of all the

training instances. We use online gradient descent algorithm in this new feature space. In order to reduce the frequency of update, we define ϵ as the threshold. Update is only performed when the loss exceeds threshold ϵ. We denote the proposed algorithms the FOGD for Regression (FOGD-R) and NOGD (NOGD-R) for regression tasks, as summarized in Algorithm 5 and Algorithm 6.

We omit the theoretical analysis of regression since it is similar to the binary case.

7. Experimental Results

In this section, we conduct an extensive set of experiments to examine the efficacy of the proposed algorithms for several kinds of learning tasks in varied settings. Specifically, our first experiment is to evaluate the empirical performance of the proposed FOGD and NOGD algorithms for regular binary classification tasks by following a standard batch learning setting where each dataset is divided into two parts: training set and test set. This experiment aims to make a direct comparison of the proposed algorithms with some state-of-the-art approaches for solving batch classification tasks.

Our second major set of experiments is to evaluate the effectiveness and efficiency of the proposed FOGD and NOGD algorithms for online learning tasks by following a purely online learning setting, where the performance measures are based on average mistake rate and time cost accumulated in the online learning process on the entire dataset (there is no split of training and test sets). In particular, we conduct such experiments for three different online learning tasks: binary classification, multi-class classification, and regression, by comparing the proposed algorithms with a variety of state-of-the-art budget online kernel learning algorithms.

All the source code and datasets for our experiments in this work can be downloaded from our project web page:`http://LSOKL.stevenhoi.org/`. We are planning to release our algorithms in the future release of the LIBOL library (Hoi et al., 2014).

7.1 Experiment for Binary Classification Task in Batch Setting

In this section, we compare our proposed algorithms with many state-of-the-art batch classification algorithms. Different from online learning, the aim of a batch learning task is to train a classifier on the training dataset so that it achieves the best generalized accuracy on the test dataset.

7.1.1 Experimental Test bed and Setups

Table 2 summarizes the details of the datasets used in this experiment. All of them can be downloaded from LIBSVM website [1] or KDDCUP competition site [2]. We follow the original splits of training and test sets in LIBSVM. For KDD datasets, a random split of 4/1 is used.

We compare the proposed algorithms with the following widely used algorithms for training kernel SVM for batch classification tasks:

1. `http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/`
2. `http://www.sigkdd.org/kddcup/`

Algorithm 5 FOGD-R — Fourier Online Gradient Descent for Regression

Input: the number of Fourier components D, step size η, threshold ϵ;
Initialize $\mathbf{w}_1 = 0$.
Calculate $p(\mathbf{u})$ as (2). Generate random Fourier components:$\mathbf{u}_1, ..., \mathbf{u}_D$ sampled from distribution $p(\mathbf{u})$.
for $t = 1, 2, \ldots, T$ **do**
  Receive $\mathbf{x}_t$;
  Construct new representation:
  $\mathbf{z}(\mathbf{x}_t) = (\sin(\mathbf{u}_1^\top \mathbf{x}_t), \cos(\mathbf{u}_1^\top \mathbf{x}_t), ..., \sin(\mathbf{u}_D^\top \mathbf{x}_t), \cos(\mathbf{u}_D^\top \mathbf{x}_t))^\top$
  Predict $\widehat{y}_t = \mathbf{w}_t^\top \mathbf{z}(\mathbf{x}_t)$;
  Receive y_t and suffer loss $\ell\big(\mathbf{w}_t^\top \mathbf{z}(\mathbf{x}_t); y_t\big)$;
  if $\ell\big(\mathbf{w}_t^\top \mathbf{z}(\mathbf{x}_t); y_t\big) > \epsilon$ **then**
    $\mathbf{w}_{t+1} = \mathbf{w}_t - \eta \nabla \ell\big(\mathbf{w}_t^\top \mathbf{z}(\mathbf{x}_t); y_t\big)$.
  end if
end for

Algorithm 6 NOGD-R — Nyström Online Gradient Descent for Regression

Input: the budget B, step size η, rank approximation k, threshold ϵ.
Initialize support vector set $\mathcal{S}_1 = \emptyset$, and model $f_1 = 0$.
while $|\mathcal{S}_t| < B$ **do**
  Receive new instance $\mathbf{x}_t$;
  Predict $\widehat{y}_t = f_t(\mathbf{x}_t)$;
  Update f_t by regular Online Gradient Descent (OGD);
  Update $\mathcal{S}_{t+1} = \mathcal{S}_t \cup \{t\}$ whenever loss exceeds threshold;
  $t = t + 1$;
end while
Construct the kernel matrix $\hat{\mathbf{K}}_t$ from $\mathcal{S}_t$.
$[\mathbf{V}_k, \mathbf{D}_k] = \mathsf{eigs}(\hat{\mathbf{K}}_t, k)$, where $\mathbf{V}_k$ and $\mathbf{D}_k$ are Eigenvectors and Eigenvalues of $\hat{\mathbf{K}}_t$, respectively.
Initialize $\mathbf{w}_t^\top = [\alpha_1, ..., \alpha_B](\mathbf{D}_k^{-0.5}\mathbf{V}_k^\top)^{-1}$.
Initialize the instance index $T_0 = t$;
for $t = T_0, \ldots, T$ **do**
  Receive new instance $\mathbf{x}_t$;
  Construct the new representation of $\mathbf{x}_t$:
  $\mathbf{z}(\mathbf{x}_t) = \mathbf{D}_k^{-0.5}\mathbf{V}_k^\top(\kappa(\mathbf{x}_t, \hat{\mathbf{x}}_1), ..., \kappa(\mathbf{x}_t, \hat{\mathbf{x}}_B))^\top$.
  Predict $\widehat{y}_t = \mathbf{w}_t^\top \mathbf{z}(\mathbf{x}_t)$;
  Update when loss exceeds ϵ: $\mathbf{w}_{t+1} = \mathbf{w}_t - \eta \nabla \ell\big(\mathbf{w}_t^\top \mathbf{z}(\mathbf{x}_t); y_t\big)$.
end for

Table 2: Details of Binary Classification Datasets.

- "LIBSVM": one of state-of-the-art implementation for batch kernel SVM available at the LIBSVM website Chang and Lin (2011);
- "LLSVM": Low-rank Linearization SVM algorithm that transfers kernel classification to a linear problem using low-rank decomposition of the kernel matrix (Zhang et al., 2012);
- "BSGD-M": The Budgeted Stochastic Gradient Descent algorithm which extends the Pegasos algorithm (Shalev-Shwartz et al., 2011) by exploring the SV Merging strategy for budget maintenance (Wang et al., 2012b);
- "BSGD-R": The Budgeted Stochastic Gradient Descent algorithm which extends the Pegasos algorithm (Shalev-Shwartz et al., 2011) by exploring the SV Random Removal strategy for budget maintenance (Wang et al., 2012b).

To make a fair comparison of algorithms with different parameters, all the parameters, including regularization parameter (C in LIBSVM, λ in pegasos), the learning rate (η in FOGD and NOGD) and the RBF kernel width (σ) are optimized by following a standard 5-fold cross validation on the training datasets. The budget size B in NOGD and pegasos algorithms and the feature dimension D in FOGD are set individually for different datasets, as indicated in the tables of experimental results. In general, these parameters are chosen such that they are roughly proportional to the size of support vectors output by the batch SVM algorithm in LIBSVM, since we would expect a relatively larger budget size for tackling more challenging classification tasks in order to achieve competitive accuracy. The rank k in NOGD is set to $0.2B$ for all datasets. For the online learning algorithms, all models are trained by a single pass through the training sets and the reported accuracy and time cost are averaged over the five experiments conducted on different random permutations of the training instances. All the algorithms were implemented in C++, and conducted on a Windows machine with CPU of 3.0GHz. For the existing algorithms, all the codes can be downloaded from LIBSVM website and BudgetedSVM website [3].

7.1.2 Performance Evaluation Results

Table 3 shows the experimental results of batch binary classification tasks. We can drawn several observations from the results.

Table 3: Performance Evaluation Results on Batch Binary Classification Tasks.

First of all, by comparing the four online algorithms against the two batch algorithms, we found that the online algorithms in general enjoy significant advantage in terms of computational efficiency especially for large scale datasets. By further examining the learning accuracy, we found that some online algorithms, especially the proposed FOGD and NGOD algorithms, are able to achieve slightly lower but fairly competitive learning accuracy compared with the state-of-the-art batch SVM algorithm. This demonstrates that the proposed online kernel learning algorithms could be potentially a good alternative solution of the existing SVM solvers when solving large scale batch kernel classification tasks in real-world applications due to their significant advantage of much lower learning time and memory costs.

Further, by comparing the four different online algorithms, we found that, in terms of learning accuracy, despite running faster, the BSGD-R ("pegasos+remove") algorithm suffers from very high mistake rate in most of the datasets. This is due to its naive budget maintenance strategy that simply discards the oldest support vector that may contain important information. While for BSGD-M ("pegasos+merging") algorithm, the main drawback is its relatively high computational cost. This can be easily observed in some datasets

(e.g., a9a, w7a and codrna), in which the difference between the number of support vectors of LIBSVM and the budget size is relatively larger than that of the other datasets. Thus, we can conclude that the high time cost of the BSGD-M("pegasos+merging") is due to the complex computation in the merging steps. Compared with the other online learning algorithms, the proposed NOGD algorithm achieves the highest accuracy for most cases while spending almost the lowest learning time cost. Similarly, FOGD algorithm also obtains more accurate result than the two budget Pegasos algorithms on most of the datasets with comparable or sometimes ever lower learning time cost. These facts indicate that the two proposed budget online kernel learning algorithms are both efficient and effective in solving large scale kernel classification problems.

Finally, by comparing the two proposed algorithms, we found that the performance of NOGD is better than that of FOGD. This reflects that the Nyström kernel approximation tends to have a better approximation of the original RBF kernel than the Fourier feature based approximation.

7.2 Experiments for Online Binary Classification Tasks

In this section, we test the performance of our proposed algorithms on the online binary classification task.

7.2.1 Experimental Test beds and Setup

Table 4 shows the details of 9 publicly available datasets of diverse sizes for online binary classification tasks. All of them can be downloaded from LIBSVM website, UCI machine learning repository [4] and KDDCUP competition site. As a yardstick for evaluation, we

Dataset	# instances	# features
german	1,000	24
spambase	4,601	57
w7a	24,692	300
w8a	64,700	300
a9a	48,842	123
KDDCUP08	102,294	117
ijcnn1	141,691	22
codrna	271,617	8
KDDCUP99	1,131,571	127

Table 4: Details of Online Binary Classification Datasets.

include the following two popular algorithms for regular online kernel classification without concerning budget:

- "Perceptron": the kernelized Perceptron (Freund and Schapire, 1999) without budget;
- "OGD": the kernelized online gradient descent (Kivinen et al., 2001) without budget.

4. http://www.ics.uci.edu/~mlearn/

Further, we compare the proposed budget online kernel learning algorithms with the following state-of-the-art budget online kernel learning algorithms:

- "RBP": the random budget perceptron by random removal strategy (Cavallanti et al., 2007);
- "Forgetron": the Forgetron by discarding oldest support vectors (Dekel et al., 2005);
- "Projectron": the Projectron algorithm using the projection strategy (Orabona et al., 2009);
- "Projectron++": the aggressive version of Projectron algorithm (Orabona et al., 2008, 2009);
- "BPA-S": the Budget Passive-Aggressive algorithm with simple SV removal strategy in (Wang and Vucetic, 2010);
- "BOGD": the Budget Online Gradient Descent algorithm by SV removal strategy (Zhao et al., 2012);

To make fair comparisons, all the algorithms follow the same setups. We adopt the hinge loss as the loss function ℓ. Note that hinge loss is not a smooth function, whose gradient is undefined at the point that the classification confidence $yf(\mathbf{x}) = 1$. Following the sub-gradient definition, in our experiment, gradient is only computed under the condition that $yf(\mathbf{x}) < 1$, and set to 0 otherwise. The Gaussian kernel bandwidth is set to 8. The step size η in the all online gradient descent based algorithms is chosen through a random search in range {2, 0.2, ..., 0.0002}. We adopt the same budget size $B = 100$ for NOGD and other budget algorithms. In the setting of FOGD algorithm, $D = \rho_f B$, where $0 < \rho_f < \infty$ is a predefined parameter that controls the number of random Fourier components. For NOGD algorithm, $k = \rho_n B$, where $0 < \rho_n < 1$ is a predefined parameter that controls the accuracy of matrix approximation. We set $\rho_f = 4$ and $\rho_n = 0.2$ and will evaluate their influence on the algorithm performance in the following discussion. For each data set, all the experiments were repeated 20 times using different random permutation of instances in the dataset. All the results were obtained by averaging over these 20 runs. For performance metrics, we evaluate the online classification performance by standard mistake rates and running time (seconds). All algorithms are implemented in Matlab R2013b, on a Windows machine with 3.0 GHZ CPU,6 cores.

7.2.2 Performance Evaluation Results

Table 5 summarizes the empirical evaluation results on the nine diverse data sets. From the results, we can draw the following observations.

First of all, in terms of time efficiency, we found that the budget online classification algorithms in general run much faster than the regular online kernel classification algorithms (Perceptron and OGD) especially on the large datasets, validating the importance of studying scalable online kernel methods. By further examining their results of mistake rates, we found that the budget online classification algorithms are generally worse than the two non-budget algorithms, validating the motivation of exploring effective techniques for budget online kernel classification.

Table 5: Evaluation of Large-scale Online Kernel Learning on Binary Classification Task .

Second, by comparing the proposed algorithms (FOGD and NOGD) with the budget online classification algorithms, we found that they generally achieve the best classification performance for most cases using fairly comparable or even lower time cost. While other algorithms, are either too slow because of their extremely complex updating methods or of low accuracy because of their simply SV removal steps. Similarly to the batch setting, this demonstrates the effectiveness and efficiency of the proposed algorithms.

Third, it might seem surprising to find that the FOGD algorithm achieves extremely low mistake rate and even outperforms the OGD algorithm in some datasets ($w7a, w8a, ijcnn1$). Ideally, FOGD should perform nearly the same as the kernel-based OGD approach if the number of Fourier components D is extremely large. However, choosing a too large value of D will result in underfitting for a relatively small data set, meanwhile choosing a too small value of D will result in overfitting. In our experiments, we choose an appropriate value of D ($D = 4B$) , which not only could save computational cost, but also may prevent both underfitting and overfitting. In contrast, the kernel OGD always add a new support vector whenever the loss is nonzero. Thus, the predicted model learned by the kernel OGD will become more and more complicated as time goes, and thus would likely suffer from overfitting for noisy examples.

Finally, we note that there are several differences in this result compared with the previous section in batch setting. To begin with, FOGD achieves extremely low time cost in all datasets. While in batch setting using C++ implementation, its time cost is comparable with that of NOGD. This can be explained by the different settings of the two implementation methods. In C++ setting, the most time consuming step in FOGD is to compute the large number of random features, while in Matlab setting, it is automatic transformed to a matrix calculation and parallelized on all cores of CPU. In addition, FOGD tends to performance better than NOGD in terms of accuracy. This is the result of different budget size. For NOGD, it is difficult to approximate the whole kernel matrix with small number of support vectors (such as the setting in this section $B = 100$). But with larger budget size, as in the batch case, the approximation accuracy is better than that of FOGD.

7.3 Experiments for Multi-class Classification Tasks

This section tests the performance of our proposed algorithms on online multi-class classification task.

7.3.1 Experimental Test beds and Setup

In this section, we evaluate the multi-class versions of FOGD and NOGD algorithms on 9 real-world datasets for multi-class classification tasks from the LIBSVM website. Table 6 summarizes the details of these datasets.

We adopt the same set of compared algorithms and similar parameter settings in multi-class task as that of binary case. Larger the budget size parameter B is used for multiclass classification than binary case since we should ensure enough support vectors for each class label. We set $B = 200$ for the first 3 datasets and $B = 100$ for the last 6 large scale datasets. For time efficiency, we omit the experiments of non-budget algorithms on extremely large datasets.

Dataset	# instances	# features	# classes

acoustic	78,823	50	3
covtype	581,012	54	7
poker	1,000,000	10	10

Table 6: Details of Multi-class Classification Datasets.

7.3.2 Performance Evaluation Results

Table 7 summarizes the average performance evaluation results for the compared algorithms on multi-class classification task. To further inspect more details of online multi-class classification performance, Figure 1 and Figure 2 also show the online performance convergence of all the compared algorithms in the entire online learning process. From these results, we can draw some observations as follows.

First of all, similar to the binary case, budget online kernel learning algorithms are much more efficient than the regular online kernel learning algorithms without budget, which is more obvious for larger scale datasets. For the three largest datasets (*acoustic*, *covtype* and *poker*), some of which consists of nearly one million instances, we have to exclude the non-budget online learning algorithms due to their extremely expensive costs in both time and memory. This again demonstrates the importance of exploring budget online kernel learning algorithms. Among the two non-budget online kernel learning algorithms, we found that OGD often achieves the highest accuracy, which is much better than Perceptron. However, its high-accuracy performance is paid by spending significantly higher computational time cost in comparison to the Perceptron algorithm. This is because OGD performs much more aggressive updates than Perceptron in the online learning process, which thus results in a significantly larger number of support vectors.

Second, when comparing the performance of different existing budget online kernel learning algorithms, it is clear to observe that the algorithms based on support vector projection strategy (projectron and projectron++) achieve significantly higher accuracy than the algorithms using simple support vector removal strategy. However, the gain of accuracy is paid by the sacrifice of efficiency, as shown by the time cost results in the table. Furthermore, one might be surprised to observe that BPA-S, which is relatively efficient in binary case, is extremely slow in multi-class case. This is due to the different updating approach of BPA-S for multi-class classification. In particular, for other budget multi-class algorithms, their time complexity of each prediction is $O(2B)$, i.e., only 2 out of the m classes (y and s) are updated when adding a new support vector. By contrast, during the update of BPA-S at each iteration, every class has to be updated, leading to the overall time complexity of $O(mB)$. Consequently, the BPA-S is much more expensive than the other algorithms.

Furthermore, by comparing the two proposed algorithms, FOGD and NOGD, with the existing budget online kernel learning algorithms, we observe that the proposed algorithms achieve the highest accuracy for most cases, and meanwhile run significantly faster than the other algorithms, which again validates the effectiveness and efficiency of our proposed technique. Thus, we can conclude that the proposed functional approximation approach for budget online kernel learning is a promising technique for building scalable online kernel learning algorithms for large scale learning tasks. Finally, by comparing FOGD and NOGD, we found that their accuracy performance is nearly comparable while FOGD is relatively faster. As mentioned in the binary section, this indicates that FOGD is easier for parallelization.

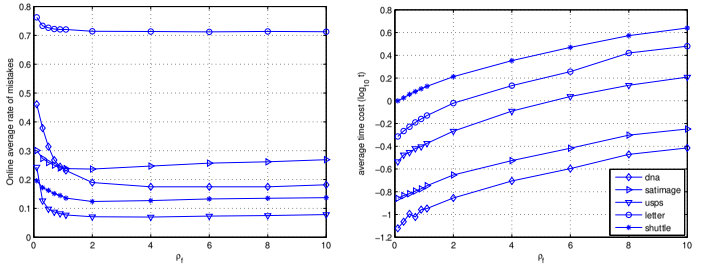
7.3.3 Evaluation for the ρ_f and ρ_n on Multi-class Tasks

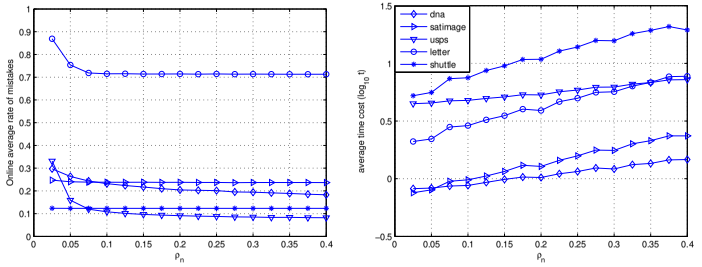
As mentioned in the previous experiments, we set the parameter for the number of Fourier components $D = \rho_f \times B$ and the rank of Nyström matrix approximation $k = \rho_n B$, where different choices of parameters ρ_f and ρ_n could affect the resulting performance of FOGD and NOGD, respectively. In this section, we evaluate the sensitivity of these two parameters and examine their influence to both learning accuracy and time cost of multi-class classification tasks.

Specifically, we fix the budget size B to 200 for all datasets, and set the other parameters (except B, ρ_f, and ρ_n) by following the same settings as the previous multi-class classification tasks. Figure 3 summarizes the performance evaluation results, including average mistake rates and average time costs. From the results, we can draw some observations as follows.

First of all, we observe that increasing the value of ρ_f or ρ_n leads to better classification accuracy but higher running time cost. This is not difficult to understand since increasing



(a) The effect of ρ_f on the mistake rate of FOGD (b) The effect of ρ_f on the time cost of FOGD



(c) The effect of ρ_n on the mistake rate of NOGD (d) The effect of ρ_n on the time cost of NOGD

Figure 3: Performance evaluation on different values of ρ_f and ρ_n.

the value ρ_f is essential to increasing the number of Fourier components, leading to a better approximation of lower variance and thus higher classification accuracy. Meanwhile the computational time cost of FOGD is proportional to the number of Fourier components, and thus is proportional to the value of ρ_f. Similarly, for NOGD, the large the value of ρ_n, the more accurate approximation achieved by the Nystrom kernel matrix approximation, and meanwhile the more computational cost required. Thus, the choice of parameter ρ_f or ρ_n for FOGD or NOGD is essentially a trade off between learning effectiveness and computational efficiency.

Second, we found there is some common tendency of the impact on the learning accuracy by the two parameters, although different datasets may have slightly different results. In particular, we observe that when the value of ρ_f or ρ_n is large enough (e.g., $\rho_f > 5$ or $\rho_n > 0.1$), increasing their value has limited impact on the improvement of the learning accuracy while the time cost keeps growing linearly. This gives an important guideline for one to choose the two parameters properly in order to gain computational efficiency without sacrificing learning accuracy. Specifically, as shown in the figure, by choosing the two parameters roughly in the ranges of $\rho_f \in (4, 6)$ and $\rho_n \in (0.2, 0.4)$, we are able to achieve satisfactory tradeoff for most cases.

7.3.4 Evaluation for the Selection of Budget Size on Multi-class Classification Task

For all the budget online kernel learning algorithms, the choice of budget size parameter B can have a considerable impact on the resulting performance. In our previous experiments, we simply fix the budget size parameter B to some constants for the compared budget online kernel learning algorithms to enable a fair and simplified comparison. In this section, we aim to evaluate the sensitivity of the budget size parameter B and examine if the proposed algorithms are consistently better than the other budget online kernel learning algorithms under varied settings of the budget size parameter. Specifically, in this experiment, we follow the same experimental setups as the previous experiments, except that we evaluate the influence of varied values of budget size parameter B.

Figure 4 shows the experimental results of both average mistake rates and average time costs of different algorithms during the online learning processes under different values of the budget size parameter B on four randomly chosen datasets, including two binary classification datasets and two multi-class classification datasets. From the experimental results, we can draw several observations on the impact of the budget size parameter to the performances as follows.

First of all, we observe that increasing the budget size generally results in better classification accuracy and higher learning time cost for all the budget online kernel learning algorithms. This is not difficult to understand since a larger budget size potentially leads to a more precise approximation to their non-budget original algorithm, and thus a better prediction accuracy. Second, similar to the previous experiments, we notice that when the budget size is large enough, further increasing the budget size has limited gain on the improvement of classification accuracy. This observation indicates that selecting a proper budget size parameter B is a tradeoff between classification accuracy and learning time cost. Moreover, by comparing different budget learning algorithms under varied values of B, we found that the projectron algorithms and the proposed two algorithms (FOGD and NOGD) tend to achieve the best classification accuracy results for most cases, particularly when the value of budget size B is small. By further examining the time costs, we found that the proposed algorithms (especially FOGD) are significantly more efficient than the Projectron for varied values of B. These encouraging results again validate that the proposed algorithms not only achieve consistently better accuracy results than the existing budget online kernel learning methods for most cases, but also have a significant advantage in computational efficiency for large-scale online kernel learning tasks.

7.4 Experiments for Online Regression Tasks

This section tests the performance of our proposed algorithms on online regression tasks.

7.4.1 Experimental Test beds and Setup

Table 8 summarizes the details of the 9 datasets of diverse sizes in our online regression experiments. All of them are publicly available at the LIBSVM and UCI websites.

For comparison schemes, we compare the proposed FOGD-R and NOGD-R algorithms with three non-budget online regression algorithms including OGD, Perceptron, and Norma

Dataset	# instances	# features
housing	506	13

slice	53,500	385
year	463,715	90

Table 8: Details of Regression Datasets.

(Kivinen et al., 2001), and four other existing budget online kernel learning algorithms including RBP, Forgetron, Projectron, and BOGD.

For parameter setting, we follow the same setup as the previous experiments for most of the parameters. For the Norma algorithm, the adaptable threshold parameter ϵ is learned and updated at each iteration. For all the other algorithms, this parameter ϵ is simply fixed to 0.1. We set $\rho_f = 15$ and $B = 30$ for all the regression datasets. According to our empirical experience on online regression tasks, the regular perceptron based algorithms that simply use the default step size 1 would perform extremely poor because of the inappropriate learning rate. In order to have a stronger baseline for comparison, we conduct a validation experiment by searching for the best learning rate parameter (about 0.1) for all the perceptron-based algorithms.

7.4.2 Performance Evaluation Results

Table 9 shows the summary of empirical evaluation results on the nine datasets, and Figures 6 and 6 show the detailed regressions results in terms of both regression errors and time cost in the online learning processes. From these results, we can draw several observations as follows.

First of all, by examining the running time costs of different algorithms, it is clear to see that the budget online kernel learning algorithms are more efficient than the non-budget algorithms, particularly on larger scale datasets. This observation is consistent to the previous classification experiments, again validating the importance of studying budget online kernel learning methods. By examining the non-budget algorithms, we found that NORMA runs faster than the other two algorithms (OGD and Perceptron) which is primarily because of it the adaptive threshold which reduces the frequency of update and thus obtains a relatively smaller support vector set size. Among all the budget algorithms, the proposed FOGD algorithm is able to achieve the smallest time cost for all cases.

Second, in terms of regression accuracy, among the existing budget algorithms, the projectron algorithm outperforms the other existing budget online learning algorithms due to its sophisticated projection strategy. By further comparing the proposed FOGD and NOGD algorithms with the existing ones, we found that our algorithms achieve the lowest squared

Table 9: Evaluation of Large-scale Online Kernel Learning on Regression Task (Time in Seconds).

loss for most cases while spending comparable or even lower time cost. This encouraging results again validate the advantages of the proposed technique for online kernel regression tasks.

Finally, by examining the two proposed algorithms, FOGD and NOGD, we found that they in general achieve fairly comparable regression accuracy, while FOGD tends to perform more efficiently than NOGD in terms of running time cost. This is primarily because NOGD has to involve the Nystrom matrix approximation which could be computationally intensive.

7.5 Comparison between FOGD and NOGD

In the previous experiments, we have made some comparisons of different budget online kernel learning algorithms for different learning tasks, in which the proposed algorithms

show promising performance. In this section, we conduct both quantitative comparison and in-depth qualitative analysis of the two proposed algorithms in order to better understand their strengths and weaknesses in different scenarios. Specifically, we summarize the comparison of the two algorithms as follows.

First of all, as observed in the previous experiments, the two proposed algorithms in general tends to achieve comparable learning accuracy for most cases. However, NOGD outperforms FOGD in batch setting while FOGD is more accurate in online setting. In terms of running time costs, the result seems relatively implementation dependent. Specifically, when comparing the Matlab implementations of both algorithms, FOGD is faster, while NOGD is faster when comparing their C++ implementations. We conjecture that the reason is primarily because the FOGD algorithm is naturally easier for parallelization than NOGD. When running the Matlab implementations, FOGD may take advantages of Matlab-embedded speedup with implicit multi-core parallelization. While running the C++ implementations, we do not explicitly engage any parallelization, and thus NOGD is faster than FOGD when no parallelization is exploited.

Second, the efficiency performance of the two proposed algorithms also depends on the dataset size. For small-sized datasets, FOGD tends to be more efficient, while NOGD tends to be more efficient on larger-sized datasets. The main reason is that a key step of

NOGD is the Nystrom approximation that involves the eigen-decomposition. The eigen-decomposition computation could be potentially very computationally intensive a small-scale dataset, but relatively small or even negligible for a large-scale dataset. By contrast, FOGD does not involve eigen-decomposition and thus does not suffer from such issue for small-scale datasets.

Third, FOGD suffers from high space complexity (high memory cost) when handling datasets with relatively high dimensionality. This is because FOGD has to maintain a $\rho_f B \times d$ matrix in memory for the random Fourier features computation, while NOGD only needs to keep $B \times \rho_n B$ matrix for storing the feature mapping matrix. For a large-scale high-dimensional learning task where $d \gg B$ and $\rho_f > 1$, FOGD will clearly suffer a much higher memory cost than NOGD.

Forth, FOGD has some restrictions in terms of applicable kernels, e.g., shift-invariant kernels as mentioned before. It may be difficult to be generalized for other divers kernels. By contrast, NOGD is based on the the Nyström approximation which only requires the computation of kernel matrix and does not have a restriction on the applicable kernel type as long as it is a valid kernel.

Finally, FOGD may suffer from some practical limitations and implementation challenges for novel feature extension in some real-world applications. For example, consider learning tasks with stream data where novel features may arrive at different time periods in the online learning process. At the beginning of the online learning task, it is impossible to know the full set of features. During the online learning process, whenever a novel feature appears, FOGD has to update the list of D random Fourier components by expanding their dimensionality. Such kind of updating process usually involves a series of memory operations, such as new memory space allocation, copying existing vectors, and freeing memory space of obsolete data, which could be quite expensive if novel feature appears frequently. By contrast, NOGD suffers less for the novel feature extension issue in that we can simply treat the value of a novel feature as zero when computing kernel value between an existing support vector and a new example with the novel feature.

8. Conclusions

This paper presented a novel framework of large-scale online kernel learning via functional approximation, going beyond conventional online kernel methods that often adopt the budget maintenance strategy for ensuring the size of support vector is bounded. The basic idea of our framework is to approximate a kernel function or kernel matrix by exploring functional approximation techniques, which transforms the online kernel learning task into an approximate linear online learning problem in a new kernel-inducing feature space that can be further resolved by applying existing efficient and scalable online algorithms. We presented two new algorithms for large-scale online kernel learning tasks: Fourier Online Gradient Descent (FOGD) and Nyström Online Gradient Descent (NOGD), and applied them to tackle different tasks, including binary classification, multi-class classification, and regression tasks. Our promising results on large-scale datasets show the proposed new algorithms are able to achieve the state-of-the-art performance in both learning efficacy and efficiency in comparison to a variety of existing techniques. By comparing the two proposed algorithms, we found that they in general achieve quite comparable learning performance

for most cases, while have different advantages and disadvantages under different scenarios. As the first comprehensive work of exploring functional approximation for large-scale online kernel learning, our framework is generic and can be extended to tackle different learning tasks in other settings (e.g., structured prediction). To facilitate other researchers to re-produce our results, we have released the source code of our implementations. In our future work, we plan to extend our work by exploring parallel computing techniques to make kernel methods practical for massive-scale data analytics tasks.

Abstract

A mean function in a reproducing kernel Hilbert space (RKHS), or a kernel mean, is central to kernel methods in that it is used by many classical algorithms such as kernel principal component analysis, and it also forms the core inference step of modern kernel methods that rely on embedding probability distributions in RKHSs. Given a finite sample, an empirical average has been used commonly as a standard estimator of the true kernel mean. Despite a widespread use of this estimator, we show that it can be improved thanks to the well-known Stein phenomenon. We propose a new family of estimators called kernel mean shrinkage estimators (KMSEs), which benefit from both theoretical justifications and good empirical performance. The results demonstrate that the proposed estimators outperform the standard one, especially in a "large d, small n" paradigm.

Keywords: covariance operator, James-Stein estimators, kernel methods, kernel mean, shrinkage estimators, Stein effect, Tikhonov regularization

1. Introduction

This paper aims to improve the estimation of the mean function in a reproducing kernel Hilbert space (RKHS), or a kernel mean, from a finite sample. A kernel mean is defined with respect to a probability distribution $\mathbb{P}$ over a measurable space $\mathcal{X}$ by

$$\mu_{\mathbb{P}} \triangleq \int_{\mathcal{X}} k(x,\cdot)\ \mathrm{d}\mathbb{P}(x) \in \mathcal{H}, \tag{1}$$

∗. Contributed equally

where $\mu_{\mathbb{P}}$ is a Bochner integral (see, *e.g.*, Diestel and Uhl (1977, Chapter 2) and Dinculeanu (2000, Chapter 1) for a definition of Bochner integral) and $\mathcal{H}$ is a separable RKHS endowed with a measurable reproducing kernel $k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ such that $\int_{\mathcal{X}} \sqrt{k(x,x)}\ \mathrm{d}\mathbb{P}(x) < \infty$.[1] Given an i.i.d sample $x_1, x_2, \ldots, x_n$ from $\mathbb{P}$, the most natural estimate of the true kernel mean is empirical average

$$\hat{\mu}_{\mathbb{P}} \triangleq \frac{1}{n}\sum_{i=1}^{n} k(x_i,\cdot)\,. \tag{2}$$

We refer to this estimator as a *kernel mean estimator* (KME). Though it is the most commonly used estimator of the true kernel mean, the key contribution of this work is to show that there exist estimators that can improve upon this standard estimator.

The kernel mean has recently gained attention in the machine learning community, thanks to the introduction of Hilbert space embedding for distributions (Berlinet and Thomas-Agnan, 2004; Smola et al., 2007). Representing the distribution as a mean function in the RKHS has several advantages. First, if the kernel k is *characteristic*, the map $\mathbb{P} \mapsto \mu_{\mathbb{P}}$ is injective.[2] That is, it preserves all information about the distribution (Fukumizu et al., 2004; Sriperumbudur et al., 2008). Second, basic operations on the distribution can be carried out by means of inner products in RKHS, *e.g.*, $\mathbb{E}_{\mathbb{P}}[f(x)] = \langle f, \mu_{\mathbb{P}}\rangle_{\mathcal{H}}$ for all $f \in \mathcal{H}$, which is an essential step in probabilistic inference (see, e.g., Song et al., 2011). Lastly, no intermediate density estimation is required, for example, when testing for homogeneity from finite samples. Thus, the algorithms become less susceptible to the curse of dimensionality; see, *e.g.*, Wasserman (2006, Section 6.5) and Sriperumbudur et al. (2012).

The aforementioned properties make Hilbert space embedding of distributions appealing to many algorithms in modern kernel methods, namely, two-sample testing via maximum mean discrepancy (MMD) (Gretton et al., 2007, 2012), kernel independence tests (Gretton et al., 2008), Hilbert space embedding of HMMs (Song et al., 2010), and kernel Bayes rule (Fukumizu et al., 2011). The performance of these algorithms relies directly on the quality of the empirical estimate $\hat{\mu}_{\mathbb{P}}$.

In addition, the kernel mean has played much more fundamental role as a basic building block of many kernel-based learning algorithms (Vapnik, 1998; Schölkopf et al., 1998). For instance, nonlinear component analyses, such as kernel principal component analysis (KPCA), kernel Fisher discriminant analysis (KFDA), and kernel canonical correlation analysis (KCCA), rely heavily on mean functions and covariance operators in RKHS (Schölkopf et al., 1998; Fukumizu et al., 2007). The kernel K-means algorithm performs clustering in feature space using mean functions as representatives of the clusters (Dhillon et al., 2004). Moreover, the kernel mean also served as a basis in early development of algorithms for classification, density estimation, and anomaly detection (Shawe-Taylor and Cristianini, 2004, Chapter 5). All of these employ the empirical average in (2) as an estimate of the true kernel mean.

1. The separability of $\mathcal{H}$ and measurability of k ensures that $k(\cdot, x)$ is a $\mathcal{H}$-valued measurable function for all $x \in \mathcal{X}$ (Steinwart and Christmann, 2008, Lemma A.5.18). The separability of $\mathcal{H}$ is guaranteed by choosing $\mathcal{X}$ to be a separable topological space and k to be continuous (Steinwart and Christmann, 2008, Lemma 4.33).
2. The notion of characteristic kernel is closely related to the notion of universal kernel. In brief, if the kernel is universal, it is also characteristic, but the reverse direction is not necessarily the case. See, *e.g.*, Sriperumbudur et al. (2011), for more detailed accounts on this topic.

We show in this work that the empirical estimator in (2) is, in a certain sense, not optimal, i.e., there exist "better" estimators (more below), and then propose simple estimators that outperform the empirical estimator. While it is reasonable to argue that $\hat{\mu}_{\mathbb{P}}$ is the "best" possible estimator of $\mu_{\mathbb{P}}$ if nothing is known about $\mathbb{P}$ (in fact $\hat{\mu}_{\mathbb{P}}$ is minimax in the sense of van der Vaart (1998, Theorem 25.21, Example 25.24)), in this paper we show that "better" estimators of $\mu_{\mathbb{P}}$ can be constructed if mild assumptions are made on $\mathbb{P}$. This work is to some extent inspired by Stein's seminal work in 1955, which showed that the maximum likelihood estimator (MLE) of the mean, θ of a multivariate Gaussian distribution $\mathcal{N}(\theta, \sigma^2\mathbf{I})$ is "inadmissible" (Stein, 1955)—i.e., there exists a better estimator—though it is minimax optimal. In particular, Stein showed that there exists an estimator that always achieves smaller total mean squared error regardless of the true $\theta \in \mathbb{R}^d$, when $d \geq 3$. Perhaps the best known estimator of such kind is James-Steins estimator (James and Stein, 1961). Formally, if $X \sim \mathcal{N}(\theta, \sigma^2\mathbf{I})$ with $d \geq 3$, the estimator $\delta(X) = X$ for θ is inadmissible in mean squared sense and is dominated by the following estimator

$$\delta_{\mathrm{JS}}(X) = \left(1 - \frac{(d-2)\sigma^2}{\|X\|^2}\right) X, \tag{3}$$

i.e., $\mathbb{E}\|\delta_{\mathrm{JS}}(X) - \theta\|^2 \leq \mathbb{E}\|\delta(X) - \theta\|^2$ for all θ and there exists at least one θ for which $\mathbb{E}\|\delta_{\mathrm{JS}}(X) - \theta\|^2 < \mathbb{E}\|\delta(X) - \theta\|^2$.

Interestingly, the James-Stein estimator is itself inadmissible, and there exists a wide class of estimators that outperform the MLE, see, *e.g.*, Berger (1976). Ultimately, Stein's result suggests that one can construct estimators better than the usual empirical estimator if the relevant parameters are estimated jointly and if the definition of risk ultimately looks at all of these parameters (or coordinates) together. This finding is quite remarkable as it is counter-intuitive as to why joint estimation should yield better estimators when all parameters are mutually independent (Efron and Morris, 1977). Although the Stein phenomenon has been extensively studied in the statistics community, it has not received much attention in the machine learning community.

The James-Stein estimator is a special case of a larger class of estimators known as *shrinkage estimators* (Gruber, 1998). In its most general form, the shrinkage estimator is a combination of a model with low bias and high variance, and a model with high bias but low variance. For example, one might consider the following estimator:

$$\hat{\theta}_{\mathrm{shrink}} \triangleq \lambda\tilde{\theta} + (1-\lambda)\hat{\theta}_{\mathrm{ML}},$$

where $\lambda \in [0,1]$, $\hat{\theta}_{\mathrm{ML}}$ denotes the usual maximum likelihood estimate of θ, and $\tilde{\theta}$ is an arbitrary point in the input space. In the case of James-Stein estimator, we have $\tilde{\theta} = 0$. Our proposal of shrinkage estimator to estimate $\mu_{\mathbb{P}}$ will rely on the same principle, but will differ fundamentally from the Stein's seminal works and those along this line in two aspects. First, our setting is "non-parametric" in the sense that we do not assume any parametric form for the distribution, whereas most of traditional works focus on some specific distributions, *e.g.*, the Gaussian distribution. The non-parametric setting is very important in most applications of kernel means because it allows us to perform statistical inference without making any assumption on the parametric form of the true distribution $\mathbb{P}$. Second, our setting involves a "non-linear feature map" into a high-dimensional space.

For example, if we use the Gaussian RBF kernel (see (6)), the mean function $\mu_{\mathbb{P}}$ lives in an infinite-dimensional space. As a result, higher moments of the distribution come into play and therefore one cannot adopt Stein's setting straightforwardly as it involves only the first moment. A direct generalization of James-Stein estimator to infinite-dimensional Hilbert space has been considered, for example, in Berger and Wolpert (1983); Mandelbaum and Shepp (1987); Privault and Rveillac (2008). In those works, the parameter to be estimated is assumed to be the mean of a Gaussian measure on the Hilbert space from which samples are drawn. In contrast, our setting involves samples that are drawn from $\mathbb{P}$ defined on an arbitrary measurable space, and not from a Gaussian measure defined on a Hilbert space.

1.1 Contributions

In the following, we present the main contributions of this work.

1. In Section 2.2, we propose kernel mean shrinkage estimators and show that these estimators can theoretically improve upon the standard empirical estimator, $\hat{\mu}_{\mathbb{P}}$ in terms of the mean squared error (see Theorem 1 and Proposition 4), however, requiring the knowledge of the true kernel mean. We relax this condition in Section 2.3 (see Theorem 5) where without requiring the knowledge of the true kernel mean, we construct shrinkage estimators that are *uniformly* better (in mean squared error) than the empirical estimator over a class of distributions $\mathcal{P}$. For bounded continuous translation invariant kernels, we show that $\mathcal{P}$ reduces to a class of distributions whose characteristic functions have an L^2-norm bounded by a given constant. Through concrete choices for $\mathcal{P}$ in Examples 1 and 2, we discuss the implications of the proposed estimator.

2. While the proposed estimators in Section 2.2 and 2.3 are theoretically interesting, they are not useful in practice as they require the knowledge of the true data generating distribution. In Section 2.4 (see Theorem 7), we present a completely data-dependent estimator (say $\check{\mu}_{\mathbb{P}}$)—referred to as B-KMSE—that is $\sqrt{n}$-consistent and satisfies

$$\mathbb{E}\|\check{\mu}_{\mathbb{P}} - \mu_{\mathbb{P}}\|^2_{\mathcal{H}} < \mathbb{E}\|\hat{\mu}_{\mathbb{P}} - \mu_{\mathbb{P}}\|^2_{\mathcal{H}} + O(n^{-3/2}) \text{ as } n \to \infty. \tag{4}$$

3. In Section 3, we present a regularization interpretation for the proposed shrinkage estimator, wherein the shrinkage parameter is shown to be directly related to the regularization parameter. Based on this relation, we present an alternative approach to choosing the shrinkage parameter (different from the one proposed in Section 2.4) through leave-one-out cross-validation, and show that the corresponding shrinkage estimator (we refer to it as R-KMSE) is also $\sqrt{n}$-consistent and satisfies (4).

4. The regularization perspective also sheds light on constructing new shrinkage estimators that incorporate specific information about the RKHS, based on which we present a new $\sqrt{n}$-consistent shrinkage estimator—referred to as S-KMSE—in Section 4 (see Theorem 13 and Remark 14) that takes into account spectral information of the covariance operator in RKHS. We establish the relation of S-KMSE to the problem of learning smooth operators (Grünewälder et al., 2013) on $\mathcal{H}$, and propose a leave-one-out cross-validation method to obtain a data-dependent shrinkage parameter. However, unlike B-KMSE and R-KMSE, it remains an open question as

to whether S-KMSE with a data-dependent shrinkage parameter is consistent and satisfies an inequality similar to (4). The difficulty in answering these questions lies with the complex form of the estimator, $\tilde{\mu}_{\mathbb{P}}$ which is constructed so as to capture the spectral information of the covariance operator.

5. In Section 6, we empirically evaluate the proposed shrinkage estimators of kernel mean on both synthetic data and several real-world scenarios including Parzen window classification, density estimation and discriminative learning on distributions. The experimental results demonstrate the benefits of our shrinkage estimators over the standard one.

While a shorter version of this work already appeared in Muandet et al. (2014a,b)—particularly, the ideas in Sections 2.2, 3 and 4—, this extended version provides a rigorous theoretical treatment (through Theorems 5, 7, 10, 13 and Proposition 15 which are new) for the proposed estimators and also contains additional experimental results.

2. Kernel Mean Shrinkage Estimators

In this section, we first provide some definitions and notation that are used throughout the paper, following which we present a shrinkage estimator of $\mu_{\mathbb{P}}$. The rest of the section presents various properties including the inadmissibility of the empirical estimator.

2.1 Definitions & Notation

For $a \triangleq (a_1, \ldots, a_d) \in \mathbb{R}^d$, $\|a\|_2 \triangleq \sqrt{\sum_{i=1}^d a_i^2}$. For a topological space $\mathcal{X}$, $C(\mathcal{X})$ (*resp.* $C_b(\mathcal{X})$) denotes the space of all continuous (*resp.* bounded continuous) functions on $\mathcal{X}$. For a locally compact Hausdorff space $\mathcal{X}$, $f \in C(\mathcal{X})$ is said to *vanish at infinity* if for every $\epsilon > 0$ the set $\{x : |f(x)| \geq \epsilon\}$ is compact. The class of all continuous f on $\mathcal{X}$ which vanish at infinity is denoted as $C_0(\mathcal{X})$. $M_b(\mathcal{X})$ (*resp.* $M_+^1(\mathcal{X})$) denotes the set of all finite Borel (*resp.* probability) measures defined on $\mathcal{X}$. For $\mathcal{X} \subset \mathbb{R}^d$, $L^r(\mathcal{X})$ denotes the Banach space of r-power ($r \geq 1$) Lebesgue integrable functions. For $f \in L^r(\mathcal{X})$, $\|f\|_{L^r} \triangleq \left(\int_{\mathcal{X}} |f(x)|^r \, \mathrm{d}x\right)^{1/r}$ denotes the L^r-norm of f for $1 \leq r < \infty$. The Fourier transform of $f \in L^1(\mathbb{R}^d)$ is defined as $f^\wedge(\omega) \triangleq (2\pi)^{-d/2} \int_{\mathbb{R}^d} f(x) e^{-\sqrt{-1}\omega^\top x} \, \mathrm{d}x$, $\omega \in \mathbb{R}^d$. The characteristic function of $\mathbb{P} \in M_+^1(\mathbb{R}^d)$ is defined as $\phi_{\mathbb{P}}(\omega) \triangleq \int e^{\sqrt{-1}\omega^\top x} \, \mathrm{d}\mathbb{P}(x)$, $\omega \in \mathbb{R}^d$.

An RKHS over a set $\mathcal{X}$ is a Hilbert space $\mathcal{H}$ consisting of functions on $\mathcal{X}$ such that for each $x \in \mathcal{X}$ there is a function $k_x \in \mathcal{H}$ with the property

$$\langle f, k_x \rangle_{\mathcal{H}} = f(x), \quad \forall f \in \mathcal{H}. \tag{5}$$

The function $k_x(\cdot) \triangleq k(x, \cdot)$ is called the *reproducing kernel* of $\mathcal{H}$ and the equality (5) is called the *reproducing property* of $\mathcal{H}$. The space $\mathcal{H}$ is endowed with inner product $\langle \cdot, \cdot \rangle_{\mathcal{H}}$ and norm $\|\cdot\|_{\mathcal{H}}$. Any symmetric and positive semi-definite kernel function $k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ uniquely determines an RKHS (Aronszajn, 1950). One of the most popular kernel functions is the Gaussian radial basis function (RBF) kernel on $\mathcal{X} = \mathbb{R}^d$,

$$k(x, y) = \exp\left(-\frac{\|x - y\|_2^2}{2\sigma^2}\right), \quad x, y \in \mathcal{X}, \tag{6}$$

where $\|\cdot\|_2$ denotes the Euclidean norm and $\sigma > 0$ is the bandwidth. For $x \in \mathcal{H}_1$ and $y \in \mathcal{H}_2$, $x \otimes y$ denotes the tensor product of x and y, and can be seen as an operator from $\mathcal{H}_2$ to $\mathcal{H}_1$ as $(x \otimes y)z = x\langle y, z \rangle_{\mathcal{H}_2}$ for any $z \in \mathcal{H}_2$, where $\mathcal{H}_1$ and $\mathcal{H}_2$ are Hilbert spaces.

We assume throughout the paper that we observe a sample $x_1, x_2, \ldots, x_n \in \mathcal{X}$ of size n drawn independently and identically (i.i.d.) from some unknown distribution $\mathbb{P}$ defined over a separable topological space $\mathcal{X}$. Denote by μ and $\hat{\mu}$ the true kernel mean (1) and its empirical estimate (2) respectively. We remove the subscript for ease of notation, but we will use $\mu_{\mathbb{P}}$ (resp. $\hat{\mu}_{\mathbb{P}}$) and μ (resp. $\hat{\mu}$) interchangeably. For the well-definedness of μ as a Bochner integral, throughout the paper we assume that k is continuous and $\int_{\mathcal{X}} k(x, x) \, \mathrm{d}\mathbb{P}(x) < \infty$ (see Footnote 1). We measure the quality of an estimator $\tilde{\mu} \in \mathcal{H}$ of μ by the risk function, $R : \mathcal{H} \times \mathcal{H} \to \mathbb{R}$, $R(\mu, \tilde{\mu}) = \mathbb{E}\|\mu - \tilde{\mu}\|_{\mathcal{H}}^2$, where $\mathbb{E}$ denotes the expectation over the choice of random sample of size n drawn i.i.d. from the distribution $\mathbb{P}$. When $\tilde{\mu} = \hat{\mu}$, for the ease of notation, we will use Δ to denote $R(\mu, \hat{\mu})$, which can be rewritten as

$$\begin{aligned}
\Delta = \mathbb{E}\|\hat{\mu} - \mu\|_{\mathcal{H}}^2 &= \mathbb{E}\|\hat{\mu}\|_{\mathcal{H}}^2 - \|\mu\|_{\mathcal{H}}^2 = \frac{1}{n^2} \sum_{i,j=1}^n \mathbb{E}_{x_i, x_j} k(x_i, x_j) - \|\mu\|_{\mathcal{H}}^2 \\
&= \frac{1}{n^2} \sum_{i=1}^n \mathbb{E}_{x_i} k(x_i, x_i) + \frac{1}{n^2} \sum_{i \neq j}^n \mathbb{E}_{x_i, x_j} k(x_i, x_j) - \|\mu\|_{\mathcal{H}}^2 \\
&= \frac{1}{n} \left(\mathbb{E}_x k(x, x) - \mathbb{E}_{x, \tilde{x}} k(x, \tilde{x}) \right),
\end{aligned} \tag{7}$$

where $\|\mu\|_{\mathcal{H}}^2 = \mathbb{E}_{x, \tilde{x}}[k(x, \tilde{x})] \triangleq \mathbb{E}_{x \sim \mathbb{P}}[\mathbb{E}_{\tilde{x} \sim \mathbb{P}}[k(x, \tilde{x})]]$ with x and $\tilde{x}$ being independent copies. An estimator $\hat{\mu}_1$ is said to be *as good as* $\hat{\mu}_2$ if $R(\mu, \hat{\mu}_1) \leq R(\mu, \hat{\mu}_2)$ for any $\mathbb{P}$, and is *better than* $\hat{\mu}_2$ if it is as good as $\hat{\mu}_2$ and $R(\mu, \hat{\mu}_1) < R(\mu, \hat{\mu}_2)$ for at least one $\mathbb{P}$. An estimator is said to be *inadmissible* if there exists a better estimator.

2.2 Shrinkage Estimation of $\mu_{\mathbb{P}}$

We propose the following kernel mean estimator

$$\hat{\mu}_\alpha \triangleq \alpha f^* + (1 - \alpha)\hat{\mu} \tag{8}$$

where $\alpha \geq 0$ and f^* is a fixed, but arbitrary function in $\mathcal{H}$. Basically, it is a shrinkage estimator that shrinks the empirical estimator toward a function f^* by an amount specified by α. The choice of f^* can be arbitrary, but we will assume that f^* is chosen independent of the sample. If $\alpha = 0$, the estimator $\hat{\mu}_\alpha$ reduces to the empirical estimator $\hat{\mu}$. We denote by Δ_α the risk of the shrinkage estimator in (8), *i.e.*, $\Delta_\alpha \triangleq R(\mu, \hat{\mu}_\alpha)$.

Our first theorem asserts that the shrinkage estimator $\hat{\mu}_\alpha$ achieves smaller risk than that of the empirical estimator $\hat{\mu}$ given an appropriate choice of α, regardless of the function f^*.

Theorem 1 *Let $\mathcal{X}$ be a separable topological space. Then for all distributions $\mathbb{P}$ and continuous kernel k satisfying $\int k(x, x) \, \mathrm{d}\mathbb{P}(x) < \infty$, $\Delta_\alpha < \Delta$ if and only if*

$$\alpha \in \left(0, \frac{2\Delta}{\Delta + \|f^* - \mu\|_{\mathcal{H}}^2}\right). \tag{9}$$

In particular, $\arg\min_{\alpha \in \mathbb{R}} (\Delta_\alpha - \Delta)$ *is unique and is given by* $\alpha_* \triangleq \frac{\Delta}{\Delta + \|f^* - \mu\|_{\mathcal{H}}^2}$.

Proof Note that

$$\Delta_\alpha = \mathbb{E}\|\hat{\mu}_\alpha - \mu\|_{\mathcal{H}}^2 = \|\mathbb{E}[\hat{\mu}_\alpha] - \mu\|_{\mathcal{H}}^2 + \mathbb{E}\,\|\hat{\mu}_\alpha - \mathbb{E}\hat{\mu}_\alpha\|_{\mathcal{H}}^2 = \|\mathrm{Bias}(\hat{\mu}_\alpha)\|_{\mathcal{H}}^2 + \mathrm{Var}(\hat{\mu}_\alpha),$$

where

$$\mathrm{Bias}(\hat{\mu}_\alpha) = \mathbb{E}[\hat{\mu}_\alpha] - \mu = \mathbb{E}[\alpha f^* + (1-\alpha)\hat{\mu}] - \mu = \alpha(f^* - \mu)$$

and

$$\mathrm{Var}(\hat{\mu}_\alpha) = (1-\alpha)^2 \mathbb{E}\,\|\hat{\mu} - \mu\|_{\mathcal{H}}^2 = (1-\alpha)^2 \Delta.$$

Therefore,

$$\Delta_\alpha = \alpha^2\,\|f^* - \mu\|_{\mathcal{H}}^2 + (1-\alpha)^2\Delta, \tag{10}$$

i.e., $\Delta_\alpha - \Delta = \alpha^2\left[\Delta + \|f^* - \mu\|_{\mathcal{H}}^2\right] - 2\alpha\Delta$. This is clearly negative if and only if (9) holds and is uniquely minimized at $\alpha_* \triangleq \frac{\Delta}{\Delta + \|f^* - \mu\|_{\mathcal{H}}^2}$. ■

Remark 2 *(i) The shrinkage estimator always improves upon the standard one regardless of the direction of shrinkage, as specified by the choice of f^*. In other words, there exists a wide class of kernel mean estimators that achieve smaller risk than the standard one.*

(ii) The range of α depends on the choice of f^*. The further f^* is from μ, the smaller the range of α becomes. Thus, the shrinkage gets smaller if f^* is chosen such that it is far from the true kernel mean. This effect is akin to James-Stein estimator.

(iii) From (9), since $0 < \alpha < 2$, i.e., *$0 < (1-\alpha)^2 < 1$, it follows that $\mathrm{Var}(\hat{\mu}_\alpha) < \mathrm{Var}(\hat{\mu}) = \Delta$,* i.e., *the shrinkage estimator always improves upon the empirical estimator in terms of the variance. Further improvement can be gained by reducing the bias by incorporating the prior knowledge about the location of μ via f^*. This implies that we can potentially gain "twice" by adopting the shrinkage estimator: by reducing variance of the estimator and by incorporating prior knowledge in choosing f^* such that it is close to the true kernel mean.*

While Theorem 1 shows $\hat{\mu}$ to be inadmissible by providing a family of estimators that are better than $\hat{\mu}$, the result is not useful as all these estimators require the knowledge of μ (which is the parameter of interest) through the range of α given in (9). In Section 2.3, we investigate Theorem 1 and show that $\hat{\mu}_\alpha$ can be constructed under some weak assumptions on $\mathbb{P}$, without requiring the knowledge of μ. From (9), the existence of positive α is guaranteed if and only if the risk of the empirical estimator is non-zero. Under some assumptions on k, the following result shows that $\Delta = 0$ if and only if the distribution $\mathbb{P}$ is a Dirac distribution, *i.e.*, the distribution $\mathbb{P}$ is a point mass. This result ensures, in many non-trivial cases, a non-empty range of α for which $\Delta_\alpha - \Delta < 0$.

Proposition 3 *Let $k(x,y) = \psi(x-y)$, $x, y \in \mathbb{R}^d$ be a characteristic kernel where $\psi \in C_b(\mathbb{R}^d)$ is positive definite. Then $\Delta = 0$ if and only if $\mathbb{P} = \delta_x$ for some $x \in \mathbb{R}^d$.*

Proof See Section 5.1. ■

2.2.1 Positive-part Shrinkage Estimator

Similar to James-Stein estimator, we can show that the positive-part version of $\hat{\mu}_\alpha$ also outperforms $\hat{\mu}$, where the positive-part estimator is defined by

$$\hat{\mu}_\alpha^+ \triangleq \alpha f^* + (1-\alpha)_+ \hat{\mu} \tag{11}$$

with $(a)_+ \triangleq a$ if $a > 0$ and zero otherwise. Equation (11) can be rewritten as

$$\hat{\mu}_\alpha^+ = \begin{cases} \alpha f^* + (1-\alpha)\hat{\mu}, & 0 \le \alpha \le 1 \\ \alpha f^* & 1 < \alpha < 2. \end{cases} \tag{12}$$

Let $\Delta_\alpha^+ \triangleq \mathbb{E}\|\hat{\mu}_\alpha^+ - \mu\|_{\mathcal{H}}^2$ be the risk of the positive-part estimator. Then, the following result shows that $\Delta_\alpha^+ \le \Delta_\alpha$, given that α satisfies (9).

Proposition 4 *For any α satisfying (9), we have that $\Delta_\alpha^+ \le \Delta_\alpha < \Delta$.*

Proof According to (12), we decompose the proof into two parts. First, if $0 \le \alpha \le 1$, $\hat{\mu}_\alpha$ and $\hat{\mu}_\alpha^+$ behave exactly the same. Thus, $\Delta_\alpha^+ = \Delta_\alpha$. On the other hand, when $1 < \alpha < 2$, the bias-variance decomposition of these estimators yields

$$\Delta_\alpha = \alpha^2\|f^* - \mu\|_{\mathcal{H}}^2 + (1-\alpha)^2\mathbb{E}\|\hat{\mu} - \mu\|_{\mathcal{H}}^2 \quad \text{and} \quad \Delta_\alpha^+ = \alpha^2\|f^* - \mu\|_{\mathcal{H}}^2.$$

It is easy to see that $\Delta_\alpha^+ < \Delta_\alpha$ when $1 < \alpha < 2$. This concludes the proof. ■

Proposition 4 implies that, when estimating α, it is better to restrict the value of α to be smaller than 1, although it can be greater than 1, as suggested by Theorem 1. The reason is that if $0 \le \alpha \le 1$, the bias is an increasing function of α, whereas the variance is a decreasing function of α. On the other hand, if $\alpha > 1$, both bias and variance become increasing functions of α. We will see later in Section 3 that $\hat{\mu}_\alpha$ and $\hat{\mu}_\alpha^+$ can be obtained naturally as a solution to a regularized regression problem.

2.3 Consequences of Theorem 1

As mentioned before, while Theorem 1 is interesting from the perspective of showing that the shrinkage estimator, $\hat{\mu}_\alpha$ performs better—in the mean squared sense—than the empirical estimator, it unfortunately relies on the fact that $\mu_{\mathbb{P}}$ (*i.e.*, the object of interest) is known, which makes $\hat{\mu}_\alpha$ uninteresting. Instead of knowing $\mu_{\mathbb{P}}$, which requires the knowledge of $\mathbb{P}$, in this section, we show that a shrinkage estimator can be constructed that performs better than the empirical estimator, uniformly over a class of probability distributions. To this end, we introduce the notion of an oracle upper bound.

Let $\mathcal{P}$ be a class of probability distributions $\mathbb{P}$ defined on a measurable space $\mathcal{X}$. We define an oracle upper bound as

$$U_{k,\mathcal{P}} \triangleq \inf_{\mathbb{P}\in\mathcal{P}} \frac{2\Delta}{\Delta + \|f^* - \mu\|_{\mathcal{H}}^2}.$$

It follows immediately from Theorem 1 and the definition of $U_{k,\mathcal{P}}$ that if $U_{k,\mathcal{P}} \neq 0$, then for any $\alpha \in (0, U_{k,\mathcal{P}})$, $\Delta_\alpha - \Delta < 0$ holds "uniformly" for all $\mathbb{P} \in \mathcal{P}$. Note that by virtue

of Proposition 3, the class $\mathcal{P}$ cannot contain the Dirac measure δ_x (for any $x \in \mathbb{R}^d$) if the kernel k is translation invariant and characteristic on $\mathbb{R}^d$. Below we give concrete examples of $\mathcal{P}$ for which $U_{k,\mathcal{P}} \neq 0$ so that the above uniformity statement holds. In particular, we show in Theorem 5 below that for $\mathcal{X} = \mathbb{R}^d$, if a non-trivial bound on the L^2-norm of the characteristic function of $\mathbb{P}$ is known, it is possible to construct shrinkage estimators that are better (in mean squared error) than the empirical average. In such a case, unlike in Theorem 1, α does not depend on the individual distribution $\mathbb{P}$, but only on an upper bound associated with a class $\mathcal{P}$.

Theorem 5 *Let $k(x,y) = \psi(x-y)$, $x, y \in \mathbb{R}^d$ with $\psi \in C_b(\mathbb{R}^d) \cap L^1(\mathbb{R}^d)$ and ψ is a positive definite function with $\psi(0) > 0$. For a given constant $A \in (0,1)$, let $A_\psi := \frac{A(2\pi)^{d/2}\psi(0)}{\|\psi\|_{L_1}}$ and*

$$\mathcal{P}_{k,A} \triangleq \left\{ \mathbb{P} \in M_+^1(\mathbb{R}^d) : \|\phi_{\mathbb{P}}\|_{L^2} \leq \sqrt{A_\psi} \right\},$$

where $\phi_{\mathbb{P}}$ denotes the characteristic function of $\mathbb{P}$. Then for all $\mathbb{P} \in \mathcal{P}_{k,A}$, $\Delta_\alpha < \Delta$ if

$$\alpha \in \left(0, \frac{2(1-A)}{1 + (n-1)A + \frac{n\|f^*\|_{\mathcal{H}}^2}{\psi(0)} + \frac{2n\sqrt{A}\|f^*\|_{\mathcal{H}}}{\sqrt{\psi(0)}}} \right].$$

Proof By Theorem 1, we have that

$$\Delta_\alpha < \Delta, \ \forall\ \alpha \in \left(0, \frac{2\Delta}{\Delta + \|f^* - \mu\|_{\mathcal{H}}^2} \right). \tag{13}$$

Consider

$$\begin{aligned} \frac{\Delta}{\Delta + \|f^* - \mu\|_{\mathcal{H}}^2} &= \frac{\mathbb{E}_x k(x,x) - \mathbb{E}_{x,\tilde{x}} k(x,\tilde{x})}{\mathbb{E}_x k(x,x) - \mathbb{E}_{x,\tilde{x}} k(x,\tilde{x}) + n\|f^* - \mu\|_{\mathcal{H}}^2} \\ &\overset{(\dagger)}{=} \frac{1 - \frac{\mathbb{E}_{x,\tilde{x}} k(x,\tilde{x})}{\mathbb{E}_x k(x,x)}}{1 + (n-1)\frac{\mathbb{E}_{x,\tilde{x}} k(x,\tilde{x})}{\mathbb{E}_x k(x,x)} + \frac{n\|f^*\|_{\mathcal{H}}^2}{\mathbb{E}_x k(x,x)} - \frac{2n\langle f^*, \mu\rangle_{\mathcal{H}}}{\mathbb{E}_x k(x,x)}} \\ &\geq \frac{1 - \frac{\mathbb{E}_{x,\tilde{x}} k(x,\tilde{x})}{\mathbb{E}_x k(x,x)}}{1 + (n-1)\frac{\mathbb{E}_{x,\tilde{x}} k(x,\tilde{x})}{\mathbb{E}_x k(x,x)} + \frac{n\|f^*\|_{\mathcal{H}}^2}{\mathbb{E}_x k(x,x)} + \frac{2n\|f^*\|_{\mathcal{H}}\sqrt{\mathbb{E}_{x,\tilde{x}} k(x,\tilde{x})}}{\mathbb{E}_x k(x,x)}}, \end{aligned} \tag{14}$$

where the division by $\mathbb{E}_x k(x,x)$ in $(\dagger)$ is valid since $\mathbb{E}_x k(x,x) = \psi(0) > 0$. Note that the numerator in the r.h.s. of (14) is non-negative since

$$\mathbb{E}_{x,\tilde{x}} k(x,\tilde{x}) \leq \mathbb{E}_x \sqrt{k(x,x)} \mathbb{E}_{\tilde{x}} \sqrt{k(\tilde{x},\tilde{x})} \leq \mathbb{E}_x k(x,x)$$

with equality holding if and only if $\mathbb{P} = \delta_y$ for some $y \in \mathbb{R}^d$ (see Proposition 3). However, for any $A \in (0,1)$ and $y \in \mathbb{R}^d$, it is easy to verify that $\delta_y \notin \mathcal{P}_{k,A}$, which implies the numerator in fact positive. The denominator is clearly positive since $\mathbb{E}_{x,\tilde{x}} k(x,\tilde{x}) \geq 0$ and therefore the r.h.s. of (14) is positive. Also note that

$$\mathbb{E}_{x,\tilde{x}} k(x,\tilde{x}) = \int\int \psi(x-y)\, \mathrm{d}\mathbb{P}(x)\, \mathrm{d}\mathbb{P}(y) \overset{(*)}{=} \int |\phi_{\mathbb{P}}(\omega)|^2 \psi^\wedge(\omega)\, \mathrm{d}\omega$$

$$\leq \sup_{\omega \in \mathbb{R}^d} \psi^\wedge(\omega) \|\phi_{\mathbb{P}}\|_{L_2}^2 \leq (2\pi)^{-d/2} \|\psi\|_{L_1} \|\phi_{\mathbb{P}}\|_{L_2}^2, \tag{15}$$

where $\psi^\wedge$ is the Fourier transform of ψ and $(*)$ follows—see (16) in the proof of Proposition 5 in Sriperumbudur et al. (2011)—by invoking Bochner's theorem (Wendland, 2005, Theorem 6.6), which states that ψ is Fourier transform of a non-negative finite Borel measure with density $(2\pi)^{-d/2}\psi^\wedge$, *i.e.*, $\psi(x) = (2\pi)^{-d/2} \int e^{-ix^\top \omega} \psi^\wedge(\omega)\, \mathrm{d}\omega$, $x \in \mathbb{R}^d$. As $\mathbb{E}_x k(x,x) = \psi(0)$, we have that

$$\frac{\mathbb{E}_{x,\tilde{x}} k(x,\tilde{x})}{\mathbb{E}_x k(x,x)} \leq \frac{A\|\phi_{\mathbb{P}}\|_{L^2}^2}{A_\psi}$$

and therefore for any $\mathbb{P} \in \mathcal{P}_{k,A}$, $\frac{\mathbb{E}_{x,\tilde{x}} k(x,\tilde{x})}{\mathbb{E}_x k(x,x)} \leq A$. Using this in (14) and combining it with (13) yields the result. ∎

Remark 6 *(i) Theorem 5 shows that for any $\mathbb{P} \in \mathcal{P}_{k,A}$, it is possible to construct a shrinkage estimator that dominates the empirical estimator,* i.e., *the shrinkage estimator has a strictly smaller risk than that of the empirical estimator.*

(ii) Suppose that $\mathbb{P}$ has a density, denoted by p, with respect to the Lebesgue measure and $\phi_{\mathbb{P}} \in L^2(\mathbb{R}^d)$. By Plancherel's theorem, $p \in L^2(\mathbb{R}^d)$ as $\|p\|_{L_2} = \|\phi_{\mathbb{P}}\|_{L_2}$, which means that $\mathcal{P}_{k,A}$ includes distributions with square integrable densities (note that in general not every p is square integrable). Since

$$\|\phi_{\mathbb{P}}\|_{L_2}^2 = \int |\phi_{\mathbb{P}}(\omega)|^2\, \mathrm{d}\omega \leq \sup_{\omega \in \mathbb{R}^d} |\phi_{\mathbb{P}}(\omega)| \int |\phi_{\mathbb{P}}(\omega)|\, \mathrm{d}\omega = \|\phi_{\mathbb{P}}\|_{L_1},$$

where we used the fact that $\sup_{\omega \in \mathbb{R}^d} |\phi_{\mathbb{P}}(\omega)| = 1$, it is easy to check that

$$\left\{ \mathbb{P} \in M_+^1(\mathbb{R}^d) : \|\phi_{\mathbb{P}}\|_{L^1} \leq \frac{A(2\pi)^{d/2}\psi(0)}{\|\psi\|_{L_1}} \right\} \subset \mathcal{P}_{k,A}.$$

This means bounded densities belong to $\mathcal{P}_{k,A}$ as $\phi_{\mathbb{P}} \in L^1(\mathbb{R}^d)$ implies that $\mathbb{P}$ has a density, $p \in C_0(\mathbb{R}^d)$. Moreover, it is easy to check that larger the value of A, larger is the class $\mathcal{P}_{k,A}$ and smaller is the range of α for which $\Delta_\alpha < \Delta$ and vice-versa.

In the following, we present some concrete examples to elucidate Theorem 5.

Example 1 (Gaussian kernel and Gaussian distribution) *Define*

$$\mathcal{N} \triangleq \left\{ \mathbb{P} \in M_+^1(\mathbb{R}^d) \,\middle|\, \mathrm{d}\mathbb{P}(x) = \frac{1}{(2\pi\sigma^2)^{d/2}} e^{-\frac{\|x-\theta\|_2^2}{2\sigma^2}}\, \mathrm{d}x,\ \theta \in \mathbb{R}^d, \sigma > 0 \right\},$$

where $\psi(x) = e^{-\|x\|_2^2/2\tau^2}$, $x \in \mathbb{R}^d$ and $\tau > 0$. For $\mathbb{P} \in \mathcal{N}$, it is easy to verify that

$$\phi_{\mathbb{P}}(\omega) = e^{\sqrt{-1}\theta^\top \omega - \frac{1}{2}\sigma^2\|\omega\|_2^2},\ \omega \in \mathbb{R}^d \ \text{ and } \ \|\phi_{\mathbb{P}}\|_{L_2}^2 = \int e^{-\sigma^2\|\omega\|_2^2}\, \mathrm{d}\omega = (\pi/\sigma^2)^{d/2}.$$

Also, $\|\psi\|_{L_1} = (2\pi\tau^2)^{d/2}$. Therefore, for $\mathcal{P}_{k,A} \triangleq \{\mathbb{P} \in \mathcal{N} : \sigma^2 \geq \pi\tau^2/A^{2/d}\}$, assuming $f^* = 0$, we obtain the result in Theorem 5, i.e., *the result in Theorem 5 holds for all Gaussian distributions that are smoother (having larger variance) than that of the kernel.*

Example 2 (Linear kernel) *Suppose $f^* = 0$ and $k(x,y) = x^\top y$. While the setting of Theorem 5 does not fit this choice of k, an inspection of its proof shows that it is possible to construct a shrinkage estimator that improves upon $\mu_{\mathbb{P}}$ for an appropriate class of distributions. To this end, let ϑ and Σ represent the mean vector and covariance matrix of a distribution $\mathbb{P}$ defined on $\mathbb{R}^d$. Then it is easy to check that $\frac{\mathbb{E}_{x,\tilde{x}} k(x,\tilde{x})}{\mathbb{E}_x k(x,x)} = \frac{\|\vartheta\|_2^2}{\mathrm{trace}(\Sigma)+\|\vartheta\|_2^2}$ and therefore for a given $A \in (0,1)$, define*

$$\mathcal{P}_{k,A} \triangleq \left\{ \mathbb{P} \in M_+^1(\mathbb{R}^d) \,\middle|\, \frac{\|\vartheta\|_2^2}{\mathrm{trace}(\Sigma)} \leq \frac{A}{1-A} \right\}.$$

*From (13) and (14), it is clear that for any $\mathbb{P} \in \mathcal{P}_{k,A}$, $\Delta_\alpha < \Delta$ if $\alpha \in \left(0, \frac{2(1-A)}{1+(n-1)A}\right]$. Note that this choice of kernel yields the setting similar to classical James-Stein estimation. In James-Stein estimation, $\mathbb{P} \in \mathcal{N}$ (see Example 1 for the definition of $\mathcal{N}$) and ϑ is estimated as $(1-\tilde{\alpha})\hat{\vartheta}$—which improves upon $\hat{\vartheta}$—where $\tilde{\alpha}$ depends on the sample $(x_i)_{i=1}^n$ and $\hat{\vartheta}$ is the sample mean. In our case, for all $\mathbb{P} \in \mathcal{P}_{k,A} = \left\{\mathbb{P} \in \mathcal{N} : \|\vartheta\|_2 \leq \sigma\sqrt{\frac{dA}{1-A}}\right\}$, $\Delta_\alpha < \Delta$ if $\alpha \in \left(0, \frac{2(1-A)}{1+(n-1)A}\right]$. In addition, in contrast to the James-stein estimator which improves upon the empirical estimator (*i.e.*, sample mean) for only $d \geq 3$, we note here that the proposed estimator improves for any d as long as $\mathbb{P} \in \mathcal{P}_{k,A}$. On the other hand, the proposed estimator requires some knowledge about the distribution (particularly a bound on $\|\vartheta\|_2$), which the James-Stein estimator does not (see Section 2.5 for more details).*

2.4 Data-Dependent Shrinkage Parameter

The discussion so far showed that the shrinkage estimator in (8) performs better than the empirical estimator if the data generating distribution satisfies a certain mild condition (see Theorem 5; Examples 1 and 2). However, since this condition is usually not checkable in practice, the shrinkage estimator lacks applicability. In this section, we present a completely data driven shrinkage estimator by estimating the shrinkage parameter α from data so that the estimator does not require any knowledge of the data generating distribution.

Since the maximal difference between Δ_α and Δ occurs at α_* (see Theorem 1), given an i.i.d. sample $X = \{x_1, x_2, \ldots, x_n\}$ from $\mathbb{P}$, we propose to estimate μ using $\hat{\mu}_{\tilde{\alpha}} = (1-\tilde{\alpha})\hat{\mu}$ (*i.e.*, assuming $f^* = 0$) where $\tilde{\alpha}$ is an estimator of $\alpha_* = \Delta/(\Delta + \|\mu\|_{\mathcal{H}}^2)$ given by

$$\tilde{\alpha} = \frac{\hat{\Delta}}{\hat{\Delta} + \|\hat{\mu}\|_{\mathcal{H}}^2}, \tag{16}$$

with $\hat{\Delta}$ and $\hat{\mu}$ being the empirical versions of Δ and μ, respectively (see Theorem 7 for precise definitions). The following result shows that $\tilde{\alpha}$ is a $n\sqrt{n}$-consistent estimator of α_* and $\|\hat{\mu}_{\tilde{\alpha}} - \mu\|_{\mathcal{H}}$ concentrates around $\|\hat{\mu}_{\alpha_*} - \mu\|_{\mathcal{H}}$. In addition, we show that

$$\Delta_{\alpha_*} \leq \Delta_{\tilde{\alpha}} \leq \Delta_{\alpha_*} + O(n^{-3/2}) \text{ as } n \to \infty,$$

which means the performance of $\hat{\mu}_{\tilde{\alpha}}$ is similar to that of the best estimator (in mean squared sense) of the form $\hat{\mu}_\alpha$. In what follows, we will call the estimator $\hat{\mu}_{\tilde{\alpha}}$ an *empirical-bound kernel mean shrinkage estimator (B-KMSE).*

Theorem 7 *Suppose $n \geq 2$ and $f^* = 0$. Let k be a continuous kernel on a separable topological space $\mathcal{X}$ satisfying $\int_{\mathcal{X}} k(x,x)\,\mathrm{d}\mathbb{P}(x) < \infty$. Define*

$$\hat{\Delta} \triangleq \frac{\hat{\mathbb{E}}k(x,x) - \hat{\mathbb{E}}k(x,\tilde{x})}{n} \quad \text{and} \quad \|\hat{\mu}\|_{\mathcal{H}}^2 \triangleq \frac{1}{n^2}\sum_{i,j=1}^n k(x_i,x_j)$$

where $\hat{\mathbb{E}}k(x,x) \triangleq \frac{1}{n}\sum_{i=1}^n k(x_i,x_i)$ and $\hat{\mathbb{E}}k(x,\tilde{x}) \triangleq \frac{1}{n(n-1)}\sum_{i\neq j}^n k(x_i,x_j)$ are the empirical estimators of $\mathbb{E}_x k(x,x)$ and $\mathbb{E}_{x,\tilde{x}} k(x,\tilde{x})$ respectively. Assume there exist finite constants $\kappa_1 > 0$, $\kappa_2 > 0$, $\sigma_1 > 0$ and $\sigma_2 > 0$ such that

$$\mathbb{E}\|k(\cdot,x) - \mu\|_{\mathcal{H}}^m \leq \frac{m!}{2}\sigma_1^2\kappa_1^{m-2}, \quad \forall\, m \geq 2. \tag{17}$$

and

$$\mathbb{E}|k(x,x) - \mathbb{E}_x k(x,x)|^m \leq \frac{m!}{2}\sigma_2^2\kappa_2^{m-2}, \quad \forall\, m \geq 2. \tag{18}$$

Then

$$|\tilde{\alpha} - \alpha_*| = O_{\mathbb{P}}(n^{-3/2}) \text{ and } \left|\|\hat{\mu}_{\tilde{\alpha}} - \mu\|_{\mathcal{H}} - \|\hat{\mu}_{\alpha_*} - \mu\|_{\mathcal{H}}\right| = O_{\mathbb{P}}(n^{-3/2})$$

as $n \to \infty$. In particular,

$$\min_\alpha \mathbb{E}\|\hat{\mu}_\alpha - \mu\|_{\mathcal{H}}^2 \leq \mathbb{E}\|\hat{\mu}_{\tilde{\alpha}} - \mu\|_{\mathcal{H}}^2 \leq \min_\alpha \mathbb{E}\|\hat{\mu}_\alpha - \mu\|_{\mathcal{H}}^2 + O(n^{-3/2}) \tag{19}$$

as $n \to \infty$.

Proof See Section 5.2. ∎

Remark 8 *(i) $\hat{\mu}_{\tilde{\alpha}}$ is a $\sqrt{n}$-consistent estimator of μ. This follows from*

$$\begin{aligned}\|\hat{\mu}_{\tilde{\alpha}} - \mu\|_{\mathcal{H}} &\leq \|\hat{\mu}_{\alpha_*} - \mu\|_{\mathcal{H}} + O_{\mathbb{P}}(n^{-3/2}) \\ &\leq (1-\alpha_*)\|\hat{\mu} - \mu\|_{\mathcal{H}} + \alpha_*\|\mu\|_{\mathcal{H}} + O_{\mathbb{P}}(n^{-3/2})\end{aligned}$$

with

$$\alpha_* = \frac{\Delta}{\Delta + \|\mu\|_{\mathcal{H}}^2} = \frac{\mathbb{E}_x k(x,x) - \mathbb{E}_{x,\tilde{x}} k(x,\tilde{x})}{\mathbb{E}_x k(x,x) + (n-1)\mathbb{E}_{x,\tilde{x}} k(x,\tilde{x})} = O(n^{-1})$$

as $n \to \infty$. Using (38), we obtain $\|\hat{\mu}_{\tilde{\alpha}} - \mu\|_{\mathcal{H}} = O_{\mathbb{P}}(n^{-1/2})$ as $n \to \infty$, which implies that $\hat{\mu}_{\tilde{\alpha}}$ is a $\sqrt{n}$-consistent estimator of μ.

(ii) Equation (19) shows that $\Delta_{\tilde{\alpha}} \leq \Delta_{\alpha_*} + O(n^{-3/2})$ where $\Delta_{\alpha_*} < \Delta$ (see Theorem 1) and therefore for any $\mathbb{P}$ satisfying (17) and (18), $\Delta_{\tilde{\alpha}} < \Delta + O(n^{-3/2})$ as $n \to \infty$.

(iii) Suppose the kernel is bounded, i.e., *$\sup_{x,y\in\mathcal{X}} |k(x,y)| \leq \kappa < \infty$. Then it is easy to verify that (17) and (18) hold with $\sigma_1 = \sqrt{\kappa}$, $\kappa_1 = 2\sqrt{\kappa}$, $\sigma_2 = \kappa$ and $\kappa_2 = 2\kappa$ and therefore the claims in Theorem 7 hold for bounded kernels.*

(iv) For $k(x,y) = x^\top y$, we have

$$\mathbb{E}\|k(\cdot,x) - \mu\|_{\mathcal{H}}^m = \mathbb{E}\left(\|k(\cdot,x) - \mu\|_{\mathcal{H}}^2\right)^{m/2} = \mathbb{E}\left(\|x - \mathbb{E}_x x\|_2^2\right)^{m/2} = \mathbb{E}\|x - \mathbb{E}_x x\|_2^m$$

and

$$\mathbb{E}|k(x,x) - \mathbb{E}_x k(x,x)|^m = \mathbb{E}|\|x\|_2^2 - \mathbb{E}_x\|x\|_2^2|^m.$$

The conditions in (17) *and* (18) *hold for* $\mathbb{P} \in \mathcal{N}$ *where* $\mathcal{N}$ *is defined in Example 1. With* $\mathbb{P} \in \mathcal{N}$ *and* $k(x,y) = x^\top y$*, the problem of estimating* μ *reduces to estimating* θ*, for which we have presented a James-Stein-like estimator,* $\hat{\mu}_{\tilde{\alpha}}$ *that satisfies the oracle inequality in* (19)*.*

(v) While the moment conditions in (17) *and* (18) *are obviously satisfied by bounded kernels, for unbounded kernels, these conditions are quite stringent as they require all the higher moments to exist. These conditions can be weakened and the proof of Theorem 7 can be carried out using Chebyshev inequality instead of Bernstein's inequality but at the cost of a slow rate in* (19)*.*

2.5 Connection to James-Stein Estimator

In this section, we explore the connection of our proposed estimator in (8) to the James-Stein estimator. Recall that Stein's setting deals with estimating the mean of the Gaussian distribution $\mathcal{N}(\theta, \sigma^2\mathbf{I}_d)$, which can be viewed as a special case of kernel mean estimation when we restrict to the class of distributions $\mathcal{P} \triangleq \{\mathcal{N}(\theta, \sigma^2\mathbf{I}_d) \,|\, \theta \in \mathbb{R}^d\}$ and a linear kernel $k(x,y) = x^\top y$, $x, y \in \mathbb{R}^d$ (see Example 2). In this case, it is easy to verify that $\Delta = d\sigma^2/n$ and $\Delta_\alpha < \Delta$ for

$$\alpha \in \left(0, \frac{2d\sigma^2}{d\sigma^2 + n\|\theta\|^2}\right).$$

Let us assume that $n = 1$, in which case, we obtain $\Delta_\alpha < \Delta$ for $\alpha \in \left(0, \frac{2d\sigma^2}{\mathbb{E}_x\|x\|^2}\right)$ as $\mathbb{E}_x\|x\|^2 = \|\theta\|^2 + d\sigma^2$. Note that the choice of α is dependent on $\mathbb{P}$ through $\mathbb{E}_x\|x\|^2$ which is not known in practice. To this end, we replace it with the empirical version $\|x\|^2$ that depends only on the sample x. For an arbitrary constant $c \in (0, 2d)$, the shrinkage estimator (assuming $f^* = 0$) can thus be written as

$$\hat{\mu}_\alpha = (1-\alpha)\hat{\mu} = \left(1 - \frac{c\sigma^2}{\|x\|^2}\right)x = x - \frac{c\sigma^2 x}{\|x\|^2},$$

which is exactly the James-Stein estimator in (3). This particular way of estimating the shrinkage parameter α has an intriguing consequence, as shown in Stein's seminal works (Stein, 1955; James and Stein, 1961), that the shrinkage estimator $\hat{\mu}_\alpha$ can be shown to dominate the maximum likelihood estimator $\hat{\mu}$ *uniformly* over all θ.

While it is compelling to see that there is seemingly a fundamental principle underlying both these settings, this connection also reveals crucial difference between our approach and classical setting of Stein—notably, original James-Stein estimator improves upon the sample mean even when α is data-dependent (see $\hat{\mu}_\alpha$ above), however, with the crucial assumption that x is normally distributed.

3. Kernel Mean Estimation as Regression Problem

In Section 2, we have shown that James-Stein-like shrinkage estimator, *i.e.*, Equation (8), improves upon the empirical estimator in estimating the kernel mean. In this section,

we provide a regression perspective to shrinkage estimation. The starting point of the connection between regression and shrinkage estimation is the observation that the kernel mean $\mu_{\mathbb{P}}$ and its empirical estimate $\hat{\mu}_{\mathbb{P}}$ can be obtained as minimizers of the following risk functionals,

$$\mathcal{E}(g) \triangleq \int_{\mathcal{X}} \|k(\cdot,x) - g\|_{\mathcal{H}}^2 \, \mathrm{d}\mathbb{P}(x) \;\text{ and }\; \widehat{\mathcal{E}}(g) \triangleq \frac{1}{n}\sum_{i=1}^n \|k(\cdot,x_i) - g\|_{\mathcal{H}}^2,$$

respectively (Kim and Scott, 2012). Given these formulations, it is natural to ask if minimizing the regularized version of $\widehat{\mathcal{E}}(g)$ will give a "better" estimator. While this question is interesting, it has to be noted that in principle, there is really no need to consider a regularized formulation as the problem of minimizing $\widehat{\mathcal{E}}$ is not ill-posed, unlike in function estimation or regression problems. To investigate this question, we consider the minimization of the following regularized empirical risk functional,

$$\widehat{\mathcal{E}}_\lambda(g) \triangleq \widehat{\mathcal{E}}(g) + \lambda\Omega(\|g\|_{\mathcal{H}}) = \frac{1}{n}\sum_{i=1}^n \|k(\cdot,x_i) - g\|_{\mathcal{H}}^2 + \lambda\Omega(\|g\|_{\mathcal{H}}), \tag{20}$$

where $\Omega : \mathbb{R}_+ \to \mathbb{R}_+$ denotes a monotonically increasing function and $\lambda > 0$ is the regularization parameter. By representer theorem (Schölkopf et al., 2001), any function $g \in \mathcal{H}$ that is a minimizer of (20) lies in a subspace spanned by $\{k(\cdot,x_1), \ldots, k(\cdot,x_n)\}$, *i.e.*, $g = \sum_{j=1}^n \beta_j k(\cdot,x_j)$ for some $\boldsymbol{\beta} \triangleq [\beta_1, \ldots, \beta_n]^\top \in \mathbb{R}^n$. Hence, by setting $\Omega(\|g\|_{\mathcal{H}}) = \|g\|_{\mathcal{H}}^2$, we can rewrite (20) in terms of $\boldsymbol{\beta}$ as

$$\widehat{\mathcal{E}}(g) + \lambda\Omega(\|g\|_{\mathcal{H}}) = \boldsymbol{\beta}^\top\mathbf{K}\boldsymbol{\beta} - 2\boldsymbol{\beta}^\top\mathbf{K}\mathbf{1}_n + \lambda\boldsymbol{\beta}^\top\mathbf{K}\boldsymbol{\beta} + c, \tag{21}$$

where $\mathbf{K}$ is an $n \times n$ Gram matrix such that $\mathbf{K}_{ij} = k(x_i,x_j)$, c is a constant that does not depend on $\boldsymbol{\beta}$, and $\mathbf{1}_n = [1/n, 1/n, \ldots, 1/n]^\top$. Differentiating (21) with respect to $\boldsymbol{\beta}$ and setting it to zero yields an optimal weight vector $\boldsymbol{\beta} = \left(\frac{1}{1+\lambda}\right)\mathbf{1}_n$ and so the minimizer of (20) is given by

$$\hat{\mu}_\lambda = \frac{1}{1+\lambda}\hat{\mu} = \left(1 - \frac{\lambda}{1+\lambda}\right)\hat{\mu} \triangleq (1-\alpha)\hat{\mu}, \tag{22}$$

which is nothing but the shrinkage estimator in (8) with $\alpha = \frac{\lambda}{1+\lambda}$ and $f^* = 0$. This provides a nice relation between shrinkage estimation and regularized risk minimization, wherein the regularization helps in shrinking the estimator $\hat{\mu}$ towards zero although it is not required from the point of view of ill-posedness. In particular, since $0 < 1 - \alpha < 1$, $\hat{\mu}_\lambda$ corresponds to a *positive-part* estimator proposed in Section 2.2.1 when $f^* = 0$.

Note that $\hat{\mu}_\lambda$ is a consistent estimator of μ as $\lambda \to 0$ and $n \to \infty$, which follows from

$$\|\hat{\mu}_\lambda - \mu\|_{\mathcal{H}} \leq \frac{1}{1+\lambda}\|\hat{\mu} - \mu\|_{\mathcal{H}} + \frac{\lambda}{1+\lambda}\|\mu\|_{\mathcal{H}} \leq O_{\mathbb{P}}(n^{-1/2}) + O(\lambda).$$

In particular $\lambda = \tau n^{-1/2}$ (for some constant $\tau > 0$) yields the slowest possible rate for $\lambda \to 0$ such that the best possible rate of $n^{-1/2}$ is obtained for $\|\hat{\mu}_\lambda - \mu\|_{\mathcal{H}} \to 0$ as $n \to \infty$. In addition, following the idea in Theorem 5, it is easy to show that $\mathbb{E}\|\hat{\mu}_\lambda - \mu\|_{\mathcal{H}}^2 < \Delta$ if

$\tau \in \left(0, \frac{2\sqrt{n}\Delta}{\|\mu\|^2_{\mathcal{H}} - \Delta}\right)$. Note that $\hat{\mu}_\lambda$ is not useful in practice as λ is not known *a priori*. However, by choosing

$$\lambda = \frac{\hat{\Delta}}{\|\hat{\mu}\|^2_{\mathcal{H}}},$$

it is easy to verify (see Theorem 7 and Remark 8) that

$$\mathbb{E}\|\hat{\mu}_\lambda - \mu\|^2_{\mathcal{H}} < \mathbb{E}\|\hat{\mu} - \mu\|^2_{\mathcal{H}} + O(n^{-3/2}) \tag{23}$$

as $n \to \infty$. Owing to the connection of $\hat{\mu}_\lambda$ to a regression problem, in the following, we present an alternate data-dependent choice of λ obtained from leave-one-out cross validation (LOOCV) that also satisfies (23), and we refer to the corresponding estimator as *regularized kernel mean shrinkage estimator (R-KMSE)*.

To this end, for a given shrinkage parameter λ, denote by $\hat{\mu}^{(-i)}_\lambda$ as the kernel mean estimated from $\{x_j\}_{j=1}^n \backslash \{x_i\}$. We will measure the quality of $\hat{\mu}^{(-i)}_\lambda$ by how well it approximates $k(\cdot, x_i)$ with the overall quality being quantified by the cross-validation score,

$$LOOCV(\lambda) = \frac{1}{n}\sum_{i=1}^n \left\| k(\cdot, x_i) - \hat{\mu}^{(-i)}_\lambda \right\|^2_{\mathcal{H}}. \tag{24}$$

The LOOCV formulation in (24) differs from the one used in regression, wherein instead of measuring the deviation of the prediction made by the function on the omitted observation, we measure the deviation between the feature map of the omitted observation and the function itself. The following result shows that the shrinkage parameter in $\hat{\mu}_\lambda$ (see (22)) can be obtained analytically by minimizing (24) and requires $O(n^2)$ operations to compute.

Proposition 9 *Let $n \geq 2$, $\rho := \frac{1}{n^2}\sum_{i,j=1}^n k(x_i, x_j)$ and $\varrho := \frac{1}{n}\sum_{i=1}^n k(x_i, x_i)$. Assuming $n\rho > \varrho$, the unique minimizer of $LOOCV(\lambda)$ is given by*

$$\lambda_r = \frac{n(\varrho - \rho)}{(n-1)(n\rho - \varrho)}. \tag{25}$$

Proof See Section 5.3. ∎

It is instructive to compare

$$\alpha_r = \frac{\lambda_r}{\lambda_r + 1} = \frac{\varrho - \rho}{(n-2)\rho + \varrho/n} \tag{26}$$

to the one in (16), where the latter can be shown to be $\frac{\varrho - \rho}{\varrho + (n-2)\rho}$, by noting that $\hat{\mathbb{E}}k(x,x) = \varrho$ and $\hat{\mathbb{E}}k(x,\tilde{x}) = \frac{n\rho - \varrho}{n-1}$ (in Theorem 7, we employ the U-statistic estimator of $\mathbb{E}_{x,\tilde{x}}k(x,\tilde{x})$, whereas ρ in Proposition 9 can be seen as a V-statistic counterpart). This means α_r obtained from LOOCV will be relatively larger than the one obtained from (16). Like in Theorem 7, the requirement that $n \geq 2$ in Theorem 9 stems from the fact that at least two data points are needed to evaluate the LOOCV score. Note that $n\rho > \varrho$ if and only if $\hat{\mathbb{E}}k(x,\tilde{x}) > 0$, which is guaranteed if the kernel is positive valued. We refer to $\hat{\mu}_{\lambda_r}$ as R-KMSE, whose $\sqrt{n}$-consistency is established by the following result, which also shows that $\hat{\mu}_{\lambda_r}$ satisfies (23).

Theorem 10 *Let $n \geq 2$, $n\rho > \varrho$ where ρ and ϱ are defined in Proposition 9 and k satisfies the assumptions in Theorem 7. Then $\|\hat{\mu}_{\lambda_r} - \mu\|_{\mathcal{H}} = O_{\mathbb{P}}(n^{-1/2})$,*

$$\min_\alpha \mathbb{E}\|\hat{\mu}_\alpha - \mu\|^2_{\mathcal{H}} \leq \mathbb{E}\|\hat{\mu}_{\lambda_r} - \mu\|^2_{\mathcal{H}} \leq \min_\alpha \mathbb{E}\|\hat{\mu}_\alpha - \mu\|^2_{\mathcal{H}} + O(n^{-3/2}) \tag{27}$$

where $\hat{\mu}_\alpha = (1-\alpha)\hat{\mu}$ and therefore

$$\mathbb{E}\|\hat{\mu}_{\lambda_r} - \mu\|^2_{\mathcal{H}} < \mathbb{E}\|\hat{\mu} - \mu\|^2_{\mathcal{H}} + O(n^{-3/2}) \tag{28}$$

as $n \to \infty$.

Proof See Section 5.4. ∎

4. Spectral Shrinkage Estimators

Consider the following regularized risk minimization problem

$$\arg\inf_{\mathbf{F} \in \mathcal{H}\otimes\mathcal{H}} \quad \mathbb{E}_{x\sim\mathbb{P}} \|k(x,\cdot) - \mathbf{F}[k(x,\cdot)]\|^2_{\mathcal{H}} + \lambda\|\mathbf{F}\|^2_{\mathrm{HS}}, \tag{29}$$

where the minimization is carried over the space of Hilbert-Schmidt operators, $\mathbf{F}$ on $\mathcal{H}$ with $\|\mathbf{F}\|_{\mathrm{HS}}$ being the Hilbert-Schmidt norm of $\mathbf{F}$. As an interpretation, we are finding a smooth operator $\mathbf{F}$ that maps $k(x,\cdot)$ to itself (see Grünewälder et al. (2013) for more details on this smooth operator framework). It is not difficult to show that the solution to (29) is given by $\mathbf{F} = \Sigma_{XX}(\Sigma_{XX} + \lambda I)^{-1}$ where $\Sigma_{XX} = \int k(\cdot.x) \otimes k(\cdot, x)\, \mathrm{d}\mathbb{P}(x)$ is a covariance operator defined on $\mathcal{H}$ (see, e.g., Grünewälder et al., 2012). Note that Σ_{XX} is a Bochner integral, which is well-defined as a Hilbert-Schmidt operator if $\mathcal{X}$ is a separable topological space and k is a continuous kernel satisfying $\int k(x,x)\, \mathrm{d}\mathbb{P}(x) < \infty$. Consequently, let us define

$$\mu_\lambda = \mathbf{F}\mu = \Sigma_{XX}(\Sigma_{XX} + \lambda I)^{-1}\mu,$$

which is an approximation to μ as it can be shown that $\|\mu_\lambda - \mu\|_{\mathcal{H}} \to 0$ as $\lambda \to 0$ (see the proof of Theorem 13). Given an i.i.d. sample $x_1, \ldots, x_n$ from $\mathbb{P}$, the empirical counterpart of (29) is given by

$$\arg\min_{\mathbf{F} \in \mathcal{H}\otimes\mathcal{H}} \quad \frac{1}{n}\sum_{i=1}^n \|k(x_i,\cdot) - \mathbf{F}[k(x_i,\cdot)]\|^2_{\mathcal{H}} + \lambda\|\mathbf{F}\|^2_{\mathrm{HS}} \tag{30}$$

resulting in

$$\check{\mu}_\lambda \triangleq \mathbf{F}\hat{\mu} = \hat{\Sigma}_{XX}(\hat{\Sigma}_{XX} + \lambda I)^{-1}\hat{\mu} \tag{31}$$

where $\hat{\Sigma}_{XX}$ is the empirical covariance operator on $\mathcal{H}$ given by

$$\hat{\Sigma}_{XX} = \frac{1}{n}\sum_{i=1}^n k(\cdot.x_i) \otimes k(\cdot, x_i).$$

Unlike $\hat{\mu}_\lambda$ in (22), $\check{\mu}_\lambda$ shrinks $\hat{\mu}$ differently in each coordinate by taking the eigenspectrum of $\hat{\Sigma}_{XX}$ into account (see Proposition 11) and so we refer to it as the *spectral kernel mean shrinkage estimator (S-KMSE)*.

Proposition 11 *Let $\{(\gamma_i, \phi_i)\}_{i=1}^n$ be eigenvalue and eigenfunction pairs of $\hat{\Sigma}_{XX}$. Then*

$$\check{\mu}_\lambda = \sum_{i=1}^{n} \frac{\gamma_i}{\gamma_i + \lambda} \langle \hat{\mu}, \phi_i \rangle_{\mathcal{H}} \phi_i.$$

Proof Since $\hat{\Sigma}_{XX}$ is a finite rank operator, it is compact. Since it is also a self-adjoint operator on $\mathcal{H}$, by Hilbert-Schmidt theorem (Reed and Simon, 1972, Theorems VI.16, VI.17), we have $\hat{\Sigma}_{XX} = \sum_{i=1}^n \gamma_i \langle \phi_i, \cdot \rangle_{\mathcal{H}} \phi_i$. The result follows by using this in (31). ■

As shown in Proposition 11, the effect of S-KMSE is to reduce the contribution of high frequency components of $\hat{\mu}$ (*i.e.*, contribution of $\hat{\mu}$ along the directions corresponding to smaller γ_i) when $\hat{\mu}$ is expanded in terms of the eigenfunctions of the empirical covariance operator, which are nothing but the kernel PCA basis (Rasmussen and Williams, 2006, Section 4.3). This means, similar to R-KMSE, S-KMSE also shrinks $\hat{\mu}$ towards zero, however, the difference being that while R-KMSE shrinks equally in all coordinates, S-KMSE controls the amount of shrinkage by the information contained in each coordinate. In particular, S-KMSE takes into account more information about the kernel by allowing for different amount of shrinkage in each coordinate direction according to the value of γ_i, wherein the shrinkage is small in the coordinates whose γ_i are large. Moreover, Proposition 11 reveals that the effect of shrinkage is akin to *spectral filtering* (Bauer et al., 2007)—which in our case corresponds to Tikhonov regularization—wherein S-KMSE filters out the high-frequency components of the spectral representation of the kernel mean. Muandet et al. (2014b) leverages this observation and generalizes S-KMSE to a family of shrinkage estimators via spectral filtering algorithms.

The following result presents an alternate representation for $\check{\mu}_\lambda$, using which we relate the smooth operator formulation in (30) to the regularization formulation in (20).

Proposition 12 *Let $\Phi : \mathbb{R}^n \to \mathcal{H}$, $\mathbf{a} \mapsto \sum_{i=1}^n a_i k(\cdot, x_i)$ where $\mathbf{a} \triangleq (a_1, \ldots, a_n)$. Then*

$$\check{\mu}_\lambda = \hat{\Sigma}_{XX} (\hat{\Sigma}_{XX} + \lambda I)^{-1} \hat{\mu} = \Phi (\mathbf{K} + n\lambda \mathbf{I})^{-1} \mathbf{K} \mathbf{1}_n,$$

where $\mathbf{K}$ is the Gram matrix, I is an identity operator on $\mathcal{H}$, $\mathbf{I}$ is an $n \times n$ identity matrix and $\mathbf{1}_n \triangleq [1/n, \ldots, 1/n]^\top$.

Proof See Section 5.5. ■

From Proposition 12, it is clear that

$$\check{\mu}_\lambda = \frac{1}{\sqrt{n}} \sum_{j=1}^{n} (\boldsymbol{\beta}_s)_j k(\cdot, x_j) \tag{32}$$

where $\boldsymbol{\beta}_s \triangleq \sqrt{n} (\mathbf{K} + n\lambda \mathbf{I})^{-1} \mathbf{K} \mathbf{1}_n$. Given the form of $\check{\mu}_\lambda$ in (32), it is easy to verify that $\boldsymbol{\beta}_s$ is the minimizer of (20) when $\widehat{\mathcal{E}}_\lambda$ is minimized over $\{g = \frac{1}{\sqrt{n}} \sum_{j=1}^n (\boldsymbol{\beta})_j k(\cdot, x_j) : \boldsymbol{\beta} \in \mathbb{R}^n\}$ with $\Omega(\|g\|_{\mathcal{H}}) \triangleq \|\boldsymbol{\beta}\|_2^2$.

The following result, discussed in Remark 14, establishes the consistency and convergence rate of S-KMSE, $\check{\mu}_\lambda$.

Theorem 13 *Suppose $\mathcal{X}$ is a separable topological space and k is a continuous, bounded kernel on $\mathcal{X}$. Then the following hold.*

(i) If $\mu \in \overline{\mathcal{R}(\Sigma_{XX})}$, then $\|\check{\mu}_\lambda - \mu\|_{\mathcal{H}} \to 0$ as $\lambda\sqrt{n} \to \infty$, $\lambda \to 0$ and $n \to \infty$.

(ii) If $\mu \in \mathcal{R}(\Sigma_{XX})$, then $\|\check{\mu}_\lambda - \mu\|_{\mathcal{H}} = O_{\mathbb{P}}(n^{-1/2})$ for $\lambda = cn^{-1/2}$ with $c > 0$ being a constant independent of n.

Proof See Section 5.6. ■

Remark 14 *While Theorem 13(i) shows that S-KMSE, $\check{\mu}_\lambda$ is not universally consistent,* i.e., *S-KMSE is not consistent for all $\mathbb{P}$ but only for those $\mathbb{P}$ that satisfies $\mu \in \overline{\mathcal{R}(\Sigma_{XX})}$, under some additional conditions on the kernel, the universal consistency of S-KMSE can be guaranteed. This is achieved by assuming that constant functions are included in $\mathcal{H}$,* i.e., *$1 \in \mathcal{H}$. Note that if $1 \in \mathcal{H}$, then it is easy to check that there exists $g \in \mathcal{H}$ (choose $g = 1$) such that $\mu = \Sigma_{XX} g = \int k(\cdot, x) g(x)\, \mathrm{d}\mathbb{P}(x)$,* i.e., *$\mu \in \mathcal{R}(\Sigma_{XX})$, and, therefore, by Theorem 13, $\check{\mu}_\lambda$ is not only universally consistent but also achieves a rate of $n^{-1/2}$. Choosing $k(x, y) = \tilde{k}(x, y) + b$, $x, y \in \mathcal{X}$, $b > 0$ where $\tilde{k}$ is any bounded, continuous positive definite kernel ensures that $1 \in \mathcal{H}$.*

Note that the estimator $\check{\mu}_\lambda$ requires the knowledge of the shrinkage or regularization parameter, λ. Similar to R-KMSE, below, we present a data dependent approach to select λ using leave-one-out cross validation. While the shrinkage parameter for R-KMSE can be obtained in a simple closed form (see Proposition 9), we will see below that finding the corresponding parameter for S-KMSE is more involved. Evaluating the score function (*i.e.*, (24)) naïvely requires one to solve for $\hat{\mu}_\lambda^{(-i)}$ explicitly for every i, which is computationally expensive. The following result provides an alternate expression for the score, which can be evaluated efficiently. We would like to point out that a variation of Proposition 15 already appeared in Muandet et al. (2014a, Theorem 4). However, Theorem 4 in Muandet et al. (2014a) uses an inappropriate choice of $\hat{\mu}_\lambda^{(-i)}$, which we fixed in the following result.

Proposition 15 *The LOOCV score of S-KMSE is given by*

$$LOOCV(\lambda) = \frac{1}{n} \mathrm{tr}\left((\mathbf{K} + \lambda_n \mathbf{I})^{-1} \mathbf{K} (\mathbf{K} + \lambda_n \mathbf{I})^{-1} \mathbf{A}_\lambda \right) - \frac{2}{n} \mathrm{tr}\left((\mathbf{K} + \lambda_n \mathbf{I})^{-1} \mathbf{B}_\lambda \right) + \frac{1}{n} \sum_{i=1}^{n} k(x_i, x_i),$$

where $\lambda_n \triangleq (n-1)\lambda$, $\mathbf{A}_\lambda \triangleq \frac{1}{(n-1)^2} \sum_{i=1}^n \mathbf{c}_{i,\lambda} \mathbf{c}_{i,\lambda}^\top$, $\mathbf{B}_\lambda \triangleq \frac{1}{n-1} \sum_{i=1}^n \mathbf{c}_{i,\lambda} \mathbf{k}_i^\top$, $d_{i,\lambda} \triangleq \mathbf{k}_i^\top (\mathbf{K} + \lambda_n \mathbf{I})^{-1} \mathbf{e}_i$,

$$\mathbf{c}_{i,\lambda} \triangleq \mathbf{K}\mathbf{1} - \mathbf{k}_i - \mathbf{e}_i \mathbf{k}_i^\top \mathbf{1} + \mathbf{e}_i k(x_i, x_i) + \frac{\mathbf{e}_i \mathbf{k}_i^\top (\mathbf{K} + \lambda_n \mathbf{I})^{-1} \mathbf{K}\mathbf{1}}{1 - d_{i,\lambda}} - \frac{\mathbf{e}_i \mathbf{k}_i^\top (\mathbf{K} + \lambda_n \mathbf{I})^{-1} \mathbf{k}_i}{1 - d_{i,\lambda}} - \frac{\mathbf{e}_i \mathbf{k}_i^\top (\mathbf{K} + \lambda_n \mathbf{I})^{-1} \mathbf{e}_i \mathbf{k}_i^\top \mathbf{1}}{1 - d_{i,\lambda}} + \frac{\mathbf{e}_i \mathbf{k}_i^\top (\mathbf{K} + \lambda_n \mathbf{I})^{-1} \mathbf{e}_i k(x_i, x_i)}{1 - d_{i,\lambda}},$$

$\mathbf{k}_i$ is the i^{th} column of $\mathbf{K}$, $\mathbf{1} \triangleq (1, \ldots, 1)^\top$ and $\mathbf{e}_i \triangleq (0, 0, \ldots, 1, \ldots, 0)^\top$ with 1 being in the i^{th} position. Here $\mathrm{tr}(\mathbf{A})$ denotes the trace of a square matrix $\mathbf{A}$.

Proof See Section 5.7. ■

Unlike R-KMSE, a closed form expression for the minimizer of $LOOCV(\lambda)$ in Proposition 15 is not possible and so proving the consistency of S-KMSE along with results similar to those in Theorem 10 are highly non-trivial. Hence, we are not able to provide any theoretical comparison of $\tilde{\mu}_\lambda$ (with λ being chosen as a minimizer of $LOOCV(\lambda)$ in Proposition 15) with $\hat{\mu}$. However, in the next section, we provide an empirical comparison through simulations where we show that the S-KMSE outperforms the empirical estimator.

5. Proofs

In this section, we present the missing proofs of the results of Sections 2–4.

5.1 Proof of Proposition 3

($\Rightarrow$) If $\mathbb{P} = \delta_x$ for some $x \in \mathcal{X}$, then $\hat{\mu} = \mu = k(\cdot, x)$ and thus $\Delta = 0$.
($\Leftarrow$) Suppose $\Delta = 0$. It follows from (7) that $\iint (k(x,x) - k(x,y))\, \mathrm{d}\mathbb{P}(x)\, \mathrm{d}\mathbb{P}(y) = 0$. Since k is translation invariant, this reduces to

$$\iint (\psi(0) - \psi(x-y))\, \mathrm{d}\mathbb{P}(x)\, \mathrm{d}\mathbb{P}(y) = 0.$$

By invoking Bochner's theorem (Wendland, 2005, Theorem 6.6), which states that ψ is the Fourier transform of a non-negative finite Borel measure Λ, *i.e.*, $\psi(x) = \int e^{-ix^\top \omega}\, \mathrm{d}\Lambda(\omega)$, $x \in \mathbb{R}^d$, we obtain (see (16) in the proof of Proposition 5 in Sriperumbudur et al. (2011))

$$\iint \psi(x-y)\, \mathrm{d}\mathbb{P}(x)\, \mathrm{d}\mathbb{P}(y) = \int |\phi_{\mathbb{P}}(\omega)|^2\, \mathrm{d}\Lambda(\omega),$$

thereby yielding

$$\int (|\phi_{\mathbb{P}}(\omega)|^2 - 1)\, \mathrm{d}\Lambda(\omega) = 0, \tag{33}$$

where $\phi_{\mathbb{P}}$ is the characteristic function of $\mathbb{P}$. Note that $\phi_{\mathbb{P}}$ is uniformly continuous and $|\phi_{\mathbb{P}}| \leq 1$. Since k is characteristic, Theorem 9 in Sriperumbudur et al. (2010) implies that $\mathrm{supp}(\Lambda) = \mathbb{R}^d$, using which in (33) yields $|\phi_{\mathbb{P}}(\omega)| = 1$ for all $\omega \in \mathbb{R}^d$. Since $\phi_{\mathbb{P}}$ is positive definite on $\mathbb{R}^d$, it follows from Sasvári (2013, Lemma 1.5.1) that $\phi_{\mathbb{P}}(\omega) = e^{\sqrt{-1}\omega^\top x}$ for some $x \in \mathbb{R}^d$ and thus $\mathbb{P} = \delta_x$.

5.2 Proof of Theorem 7

Before we prove Theorem 7, we present Bernstein's inequality in separable Hilbert spaces, quoted from Yurinsky (1995, Theorem 3.3.4), which will be used to prove Theorem 7.

Theorem 16 (Bernstein's inequality) *Let $(\Omega, \mathcal{A}, P)$ be a probability space, H be a separable Hilbert space, $B > 0$ and $\theta > 0$. Furthermore, let $\xi_1, \ldots, \xi_n : \Omega \to H$ be zero mean independent random variables satisfying*

$$\sum_{i=1}^n \mathbb{E}\|\xi_i\|_H^m \leq \frac{m!}{2}\theta^2 B^{m-2}. \tag{34}$$

Then for any $\tau > 0$,

$$P^n \left\{ (\xi_1, \ldots, \xi_n) : \left\| \sum_{i=1}^n \xi_i \right\|_H \geq 2B\tau + \sqrt{2\theta^2\tau} \right\} \leq 2e^{-\tau}.$$

Proof (of Theorem 7) Consider

$$\begin{aligned}
\tilde{\alpha} - \alpha_* &= \frac{\hat{\Delta}}{\hat{\Delta} + \|\hat{\mu}\|_{\mathcal{H}}^2} - \frac{\Delta}{\Delta + \|\mu\|_{\mathcal{H}}^2} = \frac{\hat{\Delta}\|\mu\|_{\mathcal{H}}^2 - \Delta\|\hat{\mu}\|_{\mathcal{H}}^2}{(\hat{\Delta} + \|\hat{\mu}\|_{\mathcal{H}}^2)(\Delta + \|\mu\|_{\mathcal{H}}^2)} \\
&= \frac{\hat{\Delta}(\|\mu\|_{\mathcal{H}}^2 - \|\hat{\mu}\|_{\mathcal{H}}^2)}{(\Delta + \|\mu\|_{\mathcal{H}}^2)(\hat{\Delta} + \|\hat{\mu}\|_{\mathcal{H}}^2)} + \frac{(\hat{\Delta} - \Delta)\|\hat{\mu}\|_{\mathcal{H}}^2}{(\Delta + \|\mu\|_{\mathcal{H}}^2)(\hat{\Delta} + \|\hat{\mu}\|_{\mathcal{H}}^2)} \\
&= \frac{\tilde{\alpha}(\|\mu\|_{\mathcal{H}}^2 - \|\hat{\mu}\|_{\mathcal{H}}^2)}{(\Delta + \|\mu\|_{\mathcal{H}}^2)} + \frac{(\hat{\Delta} - \Delta)(1 - \tilde{\alpha})}{(\Delta + \|\mu\|_{\mathcal{H}}^2)}.
\end{aligned}$$

Rearranging $\tilde{\alpha}$, we obtain

$$\tilde{\alpha} - \alpha_* = \frac{\alpha_*(\|\mu\|_{\mathcal{H}}^2 - \|\hat{\mu}\|_{\mathcal{H}}^2) + (1 - \alpha_*)(\hat{\Delta} - \Delta)}{\hat{\Delta} + \|\hat{\mu}\|_{\mathcal{H}}^2}.$$

Therefore,

$$|\tilde{\alpha} - \alpha_*| \leq \frac{\alpha_* |\|\mu\|_{\mathcal{H}}^2 - \|\hat{\mu}\|_{\mathcal{H}}^2| + (1 + \alpha_*)|\hat{\Delta} - \Delta|}{(\Delta + \|\mu\|_{\mathcal{H}}^2) - (\|\mu\|_{\mathcal{H}}^2 - \|\hat{\mu}\|_{\mathcal{H}}^2) + (\hat{\Delta} - \Delta)}, \tag{35}$$

where it is easy to verify that

$$|\hat{\Delta} - \Delta| \leq \frac{|\mathbb{E}_{x,\tilde{x}} k(x,\tilde{x}) - \hat{\mathbb{E}} k(x,\tilde{x})|}{n} + \frac{|\hat{\mathbb{E}} k(x,x) - \mathbb{E}_x k(x,x)|}{n}. \tag{36}$$

In the following we obtain bounds on $|\hat{\mathbb{E}} k(x,x) - \mathbb{E}_x k(x,x)|$, $|\mathbb{E}_{x,\tilde{x}} k(x,\tilde{x}) - \hat{\mathbb{E}} k(x,\tilde{x})|$ and $|\|\mu\|_{\mathcal{H}}^2 - \|\hat{\mu}\|_{\mathcal{H}}^2|$ when the kernel satisfies (17) and (18).

Bound on $|\hat{\mathbb{E}} k(x,x) - \mathbb{E}_x k(x,x)|$:

Since k is a continuous kernel on a separable topological space $\mathcal{X}$, it follows from Lemma 4.33 of Steinwart and Christmann (2008) that $\mathcal{H}$ is separable. By defining $\xi_i \triangleq k(x_i, x_i) - \mathbb{E}_x k(x.x)$, it follows from (18) that $\theta = \sqrt{n}\sigma_2$ and $B = \kappa_2$ and so by Theorem 16, for any $\tau > 0$, with probability at least $1 - 2e^{-\tau}$,

$$|\hat{\mathbb{E}} k(x,x) - \mathbb{E}_x k(x,x)| \leq \sqrt{\frac{2\sigma_2^2\tau}{n}} + \frac{2\kappa_2\tau}{n}. \tag{37}$$

Bound on $\|\hat{\mu} - \mu\|_{\mathcal{H}}$:

By defining $\xi_i \triangleq k(\cdot, x_i) - \mu$ and using (17), we have $\theta = \sqrt{n}\sigma_1$ and $B = \kappa_1$. Therefore, by Theorem 16, for any $\tau > 0$, with probability at least $1 - 2e^{-\tau}$,

$$\|\hat{\mu} - \mu\|_{\mathcal{H}} \leq \sqrt{\frac{2\sigma_1^2\tau}{n}} + \frac{2\kappa_1\tau}{n}. \tag{38}$$

Bound on $|\|\hat{\mu}\|_{\mathcal{H}}^2 - \|\mu\|_{\mathcal{H}}^2|$:

Since

$$\left|\|\hat{\mu}\|_{\mathcal{H}}^2 - \|\mu\|_{\mathcal{H}}^2\right| \leq (\|\hat{\mu}\|_{\mathcal{H}} + \|\mu\|_{\mathcal{H}})\|\hat{\mu} - \mu\|_{\mathcal{H}} \leq (\|\hat{\mu} - \mu\|_{\mathcal{H}} + 2\|\mu\|_{\mathcal{H}})\|\hat{\mu} - \mu\|_{\mathcal{H}},$$

it follows from (38) that for any $\tau > 0$, with probability at least $1 - 2e^{-\tau}$,

$$\left|\|\hat{\mu}\|_{\mathcal{H}}^2 - \|\mu\|_{\mathcal{H}}^2\right| \leq D_1\sqrt{\frac{\tau}{n}} + D_2\left(\frac{\tau}{n}\right) + D_3\left(\frac{\tau}{n}\right)^{3/2} + D_4\left(\frac{\tau}{n}\right)^2, \tag{39}$$

where $(D_i)_{i=1}^4$ are positive constants that depend only on σ_1^2, κ and $\|\mu\|_{\mathcal{H}}$, and not on n and τ.

Bound on $|\hat{\mathbb{E}}k(x,\tilde{x}) - \mathbb{E}_{x,\tilde{x}}k(x,\tilde{x})|$:
Since

$$\hat{\mathbb{E}}k(x,\tilde{x}) - \mathbb{E}_{x,\tilde{x}}k(x,\tilde{x}) = \frac{n^2(\|\hat{\mu}\|_{\mathcal{H}}^2 - \|\mu\|_{\mathcal{H}}^2) + n(\mathbb{E}_x k(x,x) - \hat{\mathbb{E}}k(x,x)) + n(\|\mu\|_{\mathcal{H}}^2 - \mathbb{E}_x k(x,x))}{n(n-1)},$$

it follows from (37) and (39) that for any $\tau > 0$, with probability at least $1 - 4e^{-\tau}$,

$$\begin{aligned}|\hat{\mathbb{E}}k(x,\tilde{x}) - \mathbb{E}_{x,\tilde{x}}k(x,\tilde{x})| &\leq F_1\sqrt{\frac{\tau}{n}} + F_2\left(\frac{\tau}{n}\right) + F_3\left(\frac{\tau}{n}\right)^{3/2} + F_4\left(\frac{\tau}{n}\right)^2 + \frac{F_5}{n} \\ &\leq F_1'\sqrt{\frac{1+\tau}{n}} + F_2'\left(\frac{1+\tau}{n}\right) + F_3'\left(\frac{1+\tau}{n}\right)^{3/2} + F_4'\left(\frac{1+\tau}{n}\right)^2 \end{aligned} \tag{40}$$

where $(F_i)_{i=1}^5$ and $(F_i')_{i=1}^4$ are positive constants that do not depend on n and τ.

Bound on $|\tilde{\alpha} - \alpha_*|$:
Using (37) and (40) in (36), for any $\tau > 0$, with probability at least $1 - 4e^{-\tau}$,

$$|\hat{\Delta} - \Delta| \leq \frac{F_1''}{n}\sqrt{\frac{1+\tau}{n}} + \frac{F_2''}{n}\left(\frac{1+\tau}{n}\right) + \frac{F_3''}{n}\left(\frac{1+\tau}{n}\right)^{3/2} + \frac{F_4''}{n}\left(\frac{1+\tau}{n}\right)^2,$$

using which in (35) along with (39), we obtain that for any $\tau > 0$, with probability at least $1 - 4e^{-\tau}$,

$$|\tilde{\alpha} - \alpha_*| \leq \frac{\sum_{i=1}^4 \left(G_{i1}\alpha_* + \frac{G_{i2}}{n}(1+\alpha_*)\right)\left(\frac{1+\tau}{n}\right)^{i/2}}{\left|\theta_n - \sum_{i=1}^4 \left(G_{i1} + \frac{G_{i2}}{n}\right)\left(\frac{1+\tau}{n}\right)^{i/2}\right|}, \tag{41}$$

where $\theta_n \triangleq \Delta + \|\mu\|_{\mathcal{H}}^2$ and $(G_{i1})_{i=1}^4$, $(G_{i2})_{i=1}^4$ are positive constants that do not depend on n and τ. Since $\alpha_* = \frac{\Delta}{\Delta + \|\mu\|_{\mathcal{H}}^2} = \frac{\mathbb{E}_x k(x,x) - \mathbb{E}_{x,\tilde{x}}k(x,\tilde{x})}{\mathbb{E}_x k(x,x) + (n-1)\mathbb{E}_{x,\tilde{x}}k(x,\tilde{x})} = O(n^{-1})$ and $\theta_n = \frac{\mathbb{E}_x k(x,x) + (n-1)\|\mu\|_{\mathcal{H}}^2}{n} = O(1)$ as $n \to \infty$, it follows from (41) that $|\tilde{\alpha} - \alpha_*| = O_{\mathbb{P}}(n^{-3/2})$ as $n \to \infty$.

Bound on $|\|\hat{\mu}_{\tilde{\alpha}} - \mu\|_{\mathcal{H}} - \|\hat{\mu}_{\alpha_*} - \mu\|_{\mathcal{H}}|$:
Using (38) and (41) in

$$|\|\hat{\mu}_{\tilde{\alpha}} - \mu\|_{\mathcal{H}} - \|\hat{\mu}_{\alpha_*} - \mu\|_{\mathcal{H}}| \leq \|\hat{\mu}_{\tilde{\alpha}} - \hat{\mu}_{\alpha_*}\|_{\mathcal{H}} \leq |\tilde{\alpha} - \alpha_*|\|\hat{\mu} - \mu\|_{\mathcal{H}} + |\tilde{\alpha} - \alpha_*|\|\mu\|_{\mathcal{H}},$$

for any $\tau > 0$, with probability at least $1 - 4e^{-\tau}$, we have

$$|\|\hat{\mu}_{\tilde{\alpha}} - \mu\|_{\mathcal{H}} - \|\hat{\mu}_{\alpha_*} - \mu\|_{\mathcal{H}}| \leq \frac{\sum_{i=1}^6 \left(G_{i1}'\alpha_* + \frac{G_{i2}'}{n}(1+\alpha_*)\right)\left(\frac{1+\tau}{n}\right)^{i/2}}{\left|\theta_n - \sum_{i=1}^4 \left(G_{i1} + \frac{G_{i2}}{n}\right)\left(\frac{1+\tau}{n}\right)^{i/2}\right|}, \tag{42}$$

where $(G_{i1}')_{i=1}^6$ and $(G_{i2}')_{i=1}^6$ are positive constants that do not depend on n and τ. From (42), it is easy to see that $|\|\hat{\mu}_{\tilde{\alpha}} - \mu\|_{\mathcal{H}} - \|\hat{\mu}_{\alpha_*} - \mu\|_{\mathcal{H}}| = O_{\mathbb{P}}(n^{-3/2})$ as $n \to \infty$.

Bound on $\mathbb{E}\|\hat{\mu}_{\tilde{\alpha}} - \mu\|_{\mathcal{H}}^2 - \mathbb{E}\|\hat{\mu}_{\alpha_*} - \mu\|_{\mathcal{H}}^2$:
Since

$$\begin{aligned}\|\hat{\mu}_{\tilde{\alpha}} - \mu\|_{\mathcal{H}}^2 - \|\hat{\mu}_{\alpha_*} - \mu\|_{\mathcal{H}}^2 &\leq (\|\hat{\mu}_{\tilde{\alpha}} - \mu\|_{\mathcal{H}} + \|\hat{\mu}_{\alpha_*} - \mu\|_{\mathcal{H}})\,|\|\hat{\mu}_{\tilde{\alpha}} - \mu\|_{\mathcal{H}} - \|\hat{\mu}_{\alpha_*} - \mu\|_{\mathcal{H}}| \\ &\leq 2(\|\hat{\mu}\|_{\mathcal{H}} + \|\mu\|_{\mathcal{H}})\,|\|\hat{\mu}_{\tilde{\alpha}} - \mu\|_{\mathcal{H}} - \|\hat{\mu}_{\alpha_*} - \mu\|_{\mathcal{H}}| \\ &\leq 2(\|\hat{\mu} - \mu\|_{\mathcal{H}} + 2\|\mu\|_{\mathcal{H}})\,|\|\hat{\mu}_{\tilde{\alpha}} - \mu\|_{\mathcal{H}} - \|\hat{\mu}_{\alpha_*} - \mu\|_{\mathcal{H}}|\,,\end{aligned}$$

for any $\tau > 0$, with probability at least $1 - 4e^{-\tau}$,

$$\begin{aligned}\|\hat{\mu}_{\tilde{\alpha}} - \mu\|_{\mathcal{H}}^2 - \|\hat{\mu}_{\alpha_*} - \mu\|_{\mathcal{H}}^2 &\leq \frac{\sum_{i=1}^8 \left(G_{i1}''\alpha_* + \frac{G_{i2}''}{n}(1+\alpha_*)\right)\left(\frac{1+\tau}{n}\right)^{i/2}}{\left|\theta_n - \sum_{i=1}^4 \left(G_{i1} + \frac{G_{i2}}{n}\right)\left(\frac{1+\tau}{n}\right)^{i/2}\right|}, \\ &\leq \frac{\sum_{i=1}^8 \left(G_{i1}''\alpha_* + \frac{G_{i2}''}{n}(1+\alpha_*)\right)\left(\frac{1+\tau}{n}\right)^{i/2}}{\left|\theta_n - \sum_{i=1}^4 \left(G_{i1} + \frac{G_{i2}}{n}\right)\left(\frac{1}{n}\right)^{i/2}\right|}, \\ &\leq \begin{cases} \frac{\gamma_n}{\phi_n}\sqrt{\frac{1+\tau}{n}}, & 0 < \tau \leq n-1 \\ \frac{\gamma_n}{\phi_n}\left(\frac{1+\tau}{n}\right)^4, & \tau \geq n-1 \end{cases},\end{aligned}$$

where $\gamma_n \triangleq H_1\alpha_* + \frac{H_2}{n}(1+\alpha_*)$, $\phi_n \triangleq \left|\theta_n - \sum_{i=1}^4 \left(G_{i1} + \frac{G_{i2}}{n}\right)\left(\frac{1}{n}\right)^{i/2}\right|$ and $(H_i)_{i=1}^2$ are positive constants that do not depend on n and τ. In other words,

$$\mathbb{P}\left(\|\hat{\mu}_{\tilde{\alpha}} - \mu\|_{\mathcal{H}}^2 - \|\hat{\mu}_{\alpha_*} - \mu\|_{\mathcal{H}}^2 > \epsilon\right) \leq \begin{cases} 4\exp\left(1 - n\left(\frac{\epsilon\phi_n}{\gamma_n}\right)^2\right), & \frac{\gamma_n}{\phi_n\sqrt{n}} \leq \epsilon \leq \frac{\gamma_n}{\phi_n} \\ 4\exp\left(1 - n\left(\frac{\epsilon\phi_n}{\gamma_n}\right)^{1/4}\right), & \epsilon \geq \frac{\gamma_n}{\phi_n} \end{cases}.$$

Therefore,

$$\begin{aligned}\mathbb{E}\|\hat{\mu}_{\tilde{\alpha}} - \mu\|_{\mathcal{H}}^2 - \mathbb{E}\|\hat{\mu}_{\alpha_*} - \mu\|_{\mathcal{H}}^2 &= \int_0^\infty \mathbb{P}\left(\|\hat{\mu}_{\tilde{\alpha}} - \mu\|_{\mathcal{H}}^2 - \|\hat{\mu}_{\alpha_*} - \mu\|_{\mathcal{H}}^2 > \epsilon\right)\,\mathrm{d}\epsilon \\ &\leq \frac{\gamma_n}{\phi_n\sqrt{n}} + 4\int_{\frac{\gamma_n}{\phi_n\sqrt{n}}}^{\frac{\gamma_n}{\phi_n}} \exp\left(1 - n\left(\frac{\epsilon\phi_n}{\gamma_n}\right)^2\right)\,\mathrm{d}\epsilon \\ &\quad + 4\int_{\frac{\gamma_n}{\phi_n}}^\infty \exp\left(1 - n\left(\frac{\epsilon\phi_n}{\gamma_n}\right)^{1/4}\right)\,\mathrm{d}\epsilon \\ &= \frac{\gamma_n}{\phi_n\sqrt{n}} + \frac{2\gamma_n}{\phi_n\sqrt{n}}\int_0^{n-1} \frac{e^{-t}}{\sqrt{t+1}}\,\mathrm{d}t + \frac{16e\gamma_n}{n^4\phi_n}\int_n^\infty t^3 e^{-t}\,\mathrm{d}t.\end{aligned}$$

Since $\int_0^{n-1} \frac{e^{-t}}{\sqrt{t+1}}\,\mathrm{d}t \leq \int_0^\infty e^{-t}\,\mathrm{d}t = 1$ and $\int_n^\infty t^3 e^{-t}\,\mathrm{d}t \leq \int_0^\infty t^3 e^{-t}\,\mathrm{d}t = 6$, we have

$$\mathbb{E}\|\hat{\mu}_{\tilde{\alpha}} - \mu\|_{\mathcal{H}}^2 - \mathbb{E}\|\hat{\mu}_{\alpha_*} - \mu\|_{\mathcal{H}}^2 \leq \frac{3\gamma_n}{\phi_n\sqrt{n}} + \frac{96e\gamma_n}{n^4\phi_n}.$$

The claim in (19) follows by noting that $\gamma_n = O(n^{-1})$ and $\phi_n = O(1)$ as $n \to \infty$. ■

5.3 Proof of Proposition 9

Define $\alpha \triangleq \frac{\lambda}{\lambda+1}$ and $\phi(x_i) \triangleq k(\cdot, x_i)$. Note that

$$\begin{aligned}
LOOCV(\lambda) &\triangleq \frac{1}{n}\sum_{i=1}^n \left\| \frac{(1-\alpha)}{n-1}\sum_{j\neq i}\phi(x_j) - \phi(x_i)\right\|_{\mathcal{H}}^2 \\
&= \frac{1}{n}\sum_{i=1}^n \left\| \frac{n(1-\alpha)}{n-1}\hat{\mu} - \frac{1-\alpha}{n-1}\phi(x_i) - \phi(x_i)\right\|_{\mathcal{H}}^2 \\
&= \left\|\frac{n(1-\alpha)}{n-1}\hat{\mu}\right\|_{\mathcal{H}}^2 - \frac{2}{n}\left\langle \sum_{i=1}^n \frac{n-\alpha}{n-1}\phi(x_i), \frac{n(1-\alpha)}{n-1}\hat{\mu}\right\rangle_{\mathcal{H}} + \frac{1}{n}\sum_{i=1}^n \left\|\frac{n-\alpha}{n-1}\phi(x_i)\right\|_{\mathcal{H}}^2 \\
&= \left(\frac{n^2(1-\alpha)^2}{(n-1)^2} - \frac{2n(n-\alpha)(1-\alpha)}{(n-1)^2}\right)\|\hat{\mu}\|_{\mathcal{H}}^2 + \frac{(n-\alpha)^2}{n(n-1)^2}\sum_{i=1}^n k(x_i,x_i) \\
&= \frac{1}{(n-1)^2}\left\{\alpha^2(n^2\rho - 2n\rho + \varrho) + 2n\alpha(\rho-\varrho) + n^2(\varrho-\rho)\right\} \triangleq \frac{F(\alpha)}{(n-1)^2}.
\end{aligned}$$

Since $\frac{d}{d\lambda}LOOCV(\lambda) = (n-1)^{-2}\frac{d}{d\alpha}F(\alpha)\frac{d\alpha}{d\lambda} = (n-1)^{-2}(1+\lambda)^{-2}\frac{d}{d\alpha}F(\alpha)$, equating it zero yields (25). It is easy to show that the second derivative of $LOOCV(\lambda)$ is positive implying that $LOOCV(\lambda)$ is strictly convex and so λ_r is unique.

5.4 Proof of Theorem 10

Since $\hat{\mu}_{\lambda_r} = \frac{\hat{\mu}}{1+\lambda_r} = (1-\alpha_r)\hat{\mu}$, we have $\|\hat{\mu}_{\lambda_r} - \mu\|_{\mathcal{H}} \leq \alpha_r\|\hat{\mu}\|_{\mathcal{H}} + \|\hat{\mu} - \mu\|_{\mathcal{H}}$. Note that

$$\alpha_r = \frac{n(\varrho-\rho)}{n(n-2)\rho + \varrho} = \frac{n\hat{\Delta}}{\hat{\Delta} + (n-1)\|\hat{\mu}\|_{\mathcal{H}}^2} = \frac{\hat{\mathbb{E}}k(x,x) - \hat{\mathbb{E}}k(x,\tilde{x})}{\hat{\mathbb{E}}k(x,x) + (n-2)\hat{\mathbb{E}}k(x,\tilde{x})},$$

where $\hat{\Delta}$, $\|\hat{\mu}\|_{\mathcal{H}}^2$, $\hat{\mathbb{E}}k(x,x)$ and $\hat{\mathbb{E}}k(x,\tilde{x})$ are defined in Theorem 7. Consider $|\alpha_r - \alpha_*| \leq |\alpha_r - \tilde{\alpha}| + |\tilde{\alpha} - \alpha_*|$ where $\tilde{\alpha}$ is defined in (16). From Theorem 7, we have $|\tilde{\alpha} - \alpha_*| = O_{\mathbb{P}}(n^{-3/2})$ as $n \to \infty$ and

$$\begin{aligned}
\alpha_r - \tilde{\alpha} &= \frac{\hat{\mathbb{E}}k(x,x) - \hat{\mathbb{E}}k(x,\tilde{x})}{\hat{\mathbb{E}}k(x,x) + (n-2)\hat{\mathbb{E}}k(x,\tilde{x})} - \frac{\hat{\mathbb{E}}k(x,x) - \hat{\mathbb{E}}k(x,\tilde{x})}{2\hat{\mathbb{E}}k(x,x) + (n-2)\hat{\mathbb{E}}k(x,\tilde{x})} \\
&= \frac{\tilde{\alpha}\hat{\mathbb{E}}k(x,x)}{\hat{\mathbb{E}}k(x,x) + (n-2)\hat{\mathbb{E}}k(x,\tilde{x})} = (\tilde{\alpha} - \alpha_*)\beta + \alpha_*\beta,
\end{aligned}$$

where $\beta \triangleq \frac{\hat{\mathbb{E}}k(x,x)}{\hat{\mathbb{E}}k(x,x) + (n-2)\hat{\mathbb{E}}k(x,\tilde{x})}$. Therefore, $|\alpha_r - \tilde{\alpha}| \leq |\tilde{\alpha} - \alpha_*||\beta| + \alpha_*|\beta|$, where $\alpha_* = O(n^{-1})$ as $n \to \infty$, which follows from Remark 8(i). Since $|\hat{\mathbb{E}}k(x,x) - \mathbb{E}_x k(x,x)| = O_{\mathbb{P}}(n^{-1/2})$ and

$|\hat{\mathbb{E}}k(x,\tilde{x}) - \mathbb{E}_{x,\tilde{x}}k(x,\tilde{x})| = O_{\mathbb{P}}(n^{-1/2})$, which follow from (37) and (40) respectively, we have $|\beta| = O_{\mathbb{P}}(n^{-1})$ as $n \to \infty$. Combining the above, we have $|\alpha_r - \tilde{\alpha}| = O_{\mathbb{P}}(n^{-2})$, thereby yielding $|\alpha_r - \alpha_*| = O_{\mathbb{P}}(n^{-3/2})$. Proceeding as in Theorem 7, we have

$$|\|\hat{\mu}_{\lambda_r} - \mu\|_{\mathcal{H}} - \|\hat{\mu}_{\alpha_*} - \mu\|_{\mathcal{H}}| \leq \|\hat{\mu}_{\lambda_r} - \mu_{\alpha_*}\|_{\mathcal{H}} \leq |\alpha_r - \alpha_*|\|\hat{\mu} - \mu\|_{\mathcal{H}} + |\alpha_r - \alpha_*|\|\mu\|_{\mathcal{H}},$$

which from the above follows that $|\|\hat{\mu}_{\lambda_r} - \mu\|_{\mathcal{H}} - \|\hat{\mu}_{\alpha_*} - \mu\|_{\mathcal{H}}| = O_{\mathbb{P}}(n^{-3/2})$ as $n \to \infty$. By arguing as in Remark 8(i), it is easy to show that $\hat{\mu}_{\lambda_r}$ is a $\sqrt{n}$-consistent estimator of μ. (27) follows by carrying out the analysis as in the proof of Theorem 7 verbatim by replacing $\tilde{\alpha}$ with α_r, while (28) follows by appealing to Remark 8(ii).

5.5 Proof of Proposition 12

First note that for any $i \in \{1, \ldots, n\}$,

$$\hat{\Sigma}_{XX}k(\cdot, x_i) = \frac{1}{n}\sum_{j=1}^n k(\cdot, x_j)k(x_i, x_j) = \frac{1}{n}\boldsymbol{\Phi}\mathbf{k}_i^\top$$

with $\mathbf{k}_i$ being the i^{th} row of $\mathbf{K}$. This implies for any $\mathbf{a} \in \mathbb{R}^n$,

$$\hat{\Sigma}_{XX}\boldsymbol{\Phi}\mathbf{a} = \hat{\Sigma}_{XX}\left(\sum_{i=1}^n a_i k(\cdot, x_i)\right) \overset{(*)}{=} \sum_{i=1}^n a_i \hat{\Sigma}_{XX}k(\cdot, x_i) = \frac{1}{n}\sum_{i=1}^n a_i \boldsymbol{\Phi}\mathbf{k}_i^\top,$$

where $(*)$ holds since $\hat{\Sigma}_{XX}$ is a linear operator. Also, since Φ is a linear operator, we obtain

$$\hat{\Sigma}_{XX}\boldsymbol{\Phi}\mathbf{a} = \frac{1}{n}\boldsymbol{\Phi}\left(\sum_{i=1}^n a_i \mathbf{k}_i^\top\right) = \frac{1}{n}\boldsymbol{\Phi}\mathbf{K}\mathbf{a}. \tag{43}$$

To prove the result, let us define $\mathbf{a} \triangleq (\mathbf{K} + n\lambda\mathbf{I})^{-1}\mathbf{K}\mathbf{1}_n$ and consider

$$(\hat{\Sigma}_{XX} + \lambda I)\boldsymbol{\Phi}\mathbf{a} \overset{(43)}{=} n^{-1}\boldsymbol{\Phi}\mathbf{K}\mathbf{a} + \lambda\boldsymbol{\Phi}\mathbf{a} = \boldsymbol{\Phi}(n^{-1}\mathbf{K} + \lambda\mathbf{I})\mathbf{a} = \frac{1}{n}\boldsymbol{\Phi}\mathbf{K}\mathbf{1}_n \overset{(43)}{=} \hat{\Sigma}_{XX}\boldsymbol{\Phi}\mathbf{1}_n = \hat{\Sigma}_{XX}\hat{\mu}.$$

Multiplying to the left on both sides of the above equation by $(\hat{\Sigma}_{XX} + \lambda I)^{-1}$, we obtain $\boldsymbol{\Phi}(\mathbf{K} + n\lambda\mathbf{I})^{-1}\mathbf{K}\mathbf{1}_n = (\hat{\Sigma}_{XX} + \lambda I)^{-1}\hat{\Sigma}_{XX}\hat{\mu}$ and the result follows by noting that $(\hat{\Sigma}_{XX} + \lambda I)^{-1}\hat{\Sigma}_{XX} = \hat{\Sigma}_{XX}(\hat{\Sigma}_{XX} + \lambda I)^{-1}$.

5.6 Proof of Theorem 13

By Proposition 12, we have $\check{\mu}_\lambda = (\hat{\Sigma}_{XX} + \lambda I)^{-1}\hat{\Sigma}_{XX}\hat{\mu}$. Define $\mu_\lambda \triangleq (\Sigma_{XX} + \lambda I)^{-1}\Sigma_{XX}\mu$. Let us consider the decomposition $\check{\mu}_\lambda - \mu = (\check{\mu}_\lambda - \mu_\lambda) + (\mu_\lambda - \mu)$ with

$$\begin{aligned}
\check{\mu}_\lambda - \mu_\lambda &= (\hat{\Sigma}_{XX} + \lambda I)^{-1}(\hat{\Sigma}_{XX}\hat{\mu} - \hat{\Sigma}_{XX}\mu_\lambda - \lambda\mu_\lambda) \\
&\overset{(*)}{=} (\hat{\Sigma}_{XX} + \lambda I)^{-1}(\hat{\Sigma}_{XX}\hat{\mu} - \hat{\Sigma}_{XX}\mu_\lambda - \Sigma_{XX}\mu + \Sigma_{XX}\mu_\lambda) \\
&= (\hat{\Sigma}_{XX} + \lambda I)^{-1}\hat{\Sigma}_{XX}(\hat{\mu} - \mu) - (\hat{\Sigma}_{XX} + \lambda I)^{-1}\hat{\Sigma}_{XX}(\mu_\lambda - \mu) \\
&\qquad + (\hat{\Sigma}_{XX} + \lambda I)^{-1}\Sigma_{XX}(\mu_\lambda - \mu),
\end{aligned}$$

where we used $\lambda\mu_\lambda = \Sigma_{XX}\mu - \Sigma_{XX}\mu_\lambda$ in $(*)$. By defining $\mathcal{A}(\lambda) \triangleq \|\mu_\lambda - \mu\|_{\mathcal{H}}$, we have

$$\begin{aligned}\|\check{\mu}_\lambda - \mu\|_{\mathcal{H}} &\leq \|(\hat{\Sigma}_{XX} + \lambda I)^{-1}\hat{\Sigma}_{XX}(\hat{\mu} - \mu)\|_{\mathcal{H}} + \|(\hat{\Sigma}_{XX} + \lambda I)^{-1}\hat{\Sigma}_{XX}(\mu_\lambda - \mu)\|_{\mathcal{H}} \\ &\quad + \|(\hat{\Sigma}_{XX} + \lambda I)^{-1}\Sigma_{XX}(\mu_\lambda - \mu)\|_{\mathcal{H}} + \mathcal{A}(\lambda) \\ &\leq \|(\hat{\Sigma}_{XX} + \lambda I)^{-1}\hat{\Sigma}_{XX}\| \left(\|\hat{\mu} - \mu\|_{\mathcal{H}} + \mathcal{A}(\lambda)\right) + \|(\hat{\Sigma}_{XX} + \lambda I)^{-1}\Sigma_{XX}\|\mathcal{A}(\lambda) \\ &\quad + \mathcal{A}(\lambda), \end{aligned} \tag{44}$$

where for any bounded linear operator B, $\|B\|$ denotes its operator norm. We now bound $\|(\hat{\Sigma}_{XX} + \lambda I)^{-1}\Sigma_{XX}\|$ as follows. It is easy to show that

$$\begin{aligned}(\hat{\Sigma}_{XX} + \lambda I)^{-1}\Sigma_{XX} &= \left(I - (\Sigma_{XX} + \lambda I)^{-1}(\Sigma_{XX} - \hat{\Sigma}_{XX})\right)^{-1}(\Sigma_{XX} + \lambda I)^{-1}\Sigma_{XX} \\ &= \left(\sum_{j=0}^{\infty}\left((\Sigma_{XX} + \lambda I)^{-1}(\Sigma_{XX} - \hat{\Sigma}_{XX})\right)^j\right)(\Sigma_{XX} + \lambda I)^{-1}\Sigma_{XX},\end{aligned}$$

where the last line denotes the Neumann series and therefore

$$\begin{aligned}\|(\hat{\Sigma}_{XX} + \lambda I)^{-1}\Sigma_{XX}\| &\leq \sum_{j=0}^{\infty}\left\|(\Sigma_{XX} + \lambda I)^{-1}(\Sigma_{XX} - \hat{\Sigma}_{XX})\right\|^j \|(\Sigma_{XX} + \lambda I)^{-1}\Sigma_{XX}\| \\ &\leq \sum_{j=0}^{\infty}\left\|(\Sigma_{XX} + \lambda I)^{-1}(\Sigma_{XX} - \hat{\Sigma}_{XX})\right\|_{\mathrm{HS}}^j,\end{aligned}$$

where we used $\|(\Sigma_{XX} + \lambda I)^{-1}\Sigma_{XX}\| \leq 1$ and the fact that Σ_{XX} and $\hat{\Sigma}_{XX}$ are Hilbert-Schmidt operators on $\mathcal{H}$ as $\|\Sigma_{XX}\|_{\mathrm{HS}} \leq \kappa < \infty$ and $\|\hat{\Sigma}_{XX}\|_{\mathrm{HS}} \leq \kappa < \infty$ with κ being the bound on the kernel. Define $\eta : \mathcal{X} \to \mathrm{HS}(\mathcal{H})$, $\eta(x) = (\Sigma_{XX} + \lambda I)^{-1}(\Sigma_{XX} - \Sigma_x)$, where $\mathrm{HS}(\mathcal{H})$ is the space of Hilbert-Schmidt operators on $\mathcal{H}$ and $\Sigma_x \triangleq k(\cdot, x) \otimes k(\cdot, x)$. Observe that $\mathbb{E}\frac{1}{n}\sum_{i=1}^n \eta(x_i) = 0$. Also, for all $i \in \{1, \ldots, n\}$, $\|\eta(x_i)\|_{\mathrm{HS}} \leq \|(\Sigma_{XX} + \lambda I)^{-1}\|\|\Sigma_{XX} - \Sigma_x\|_{\mathrm{HS}} \leq \frac{2\kappa}{\lambda}$ and $\mathbb{E}\|\eta(x_i)\|_{\mathrm{HS}}^2 \leq \frac{4\kappa^2}{\lambda^2}$. Therefore, by Bernstein's inequality (see Theorem 16), for any $\tau > 0$, with probability at least $1 - 2e^{-\tau}$ over the choice of $\{x_i\}_{i=1}^n$,

$$\|(\Sigma_{XX} + \lambda I)^{-1}(\Sigma_{XX} - \hat{\Sigma}_{XX})\|_{\mathrm{HS}} \leq \frac{\kappa\sqrt{2\tau}}{\lambda\sqrt{n}} + \frac{2\kappa\tau}{\lambda n} \leq \frac{\kappa\sqrt{2\tau}(\sqrt{2\tau} + 1)}{\lambda\sqrt{n}}.$$

For $\lambda \geq \frac{\kappa\sqrt{8\tau}(\sqrt{2\tau}+1)}{\sqrt{n}}$, we obtain that $\|(\Sigma_{XX} + \lambda I)^{-1}(\Sigma_{XX} - \hat{\Sigma}_{XX})\|_{\mathrm{HS}} \leq \frac{1}{2}$ and therefore $\|(\hat{\Sigma}_{XX} + \lambda I)^{-1}\Sigma_{XX}\| \leq 2$. Using this along with $\|(\hat{\Sigma}_{XX} + \lambda I)^{-1}\hat{\Sigma}_{XX}\| \leq 1$ and (38) in (44), we obtain that for any $\tau > 0$ and $\lambda \geq \frac{\kappa\sqrt{8\tau}(\sqrt{2\tau}+1)}{\sqrt{n}}$, with probability at least $1 - 2e^{-\tau}$ over the choice of $\{x_i\}_{i=1}^n$,

$$\|\check{\mu}_\lambda - \mu\|_{\mathcal{H}} \leq \frac{\sqrt{2\kappa\tau} + 4\tau\sqrt{\kappa}}{\sqrt{n}} + 4\mathcal{A}(\lambda). \tag{45}$$

We now analyze $\mathcal{A}(\lambda)$. Since k is continuous and $\mathcal{X}$ is separable, $\mathcal{H}$ is separable (Steinwart and Christmann, 2008, Lemma 4.33). Also Σ_{XX} is compact since it is Hilbert-Schmidt. The consistency result therefore follows from Sriperumbudur et al. (2013, Proposition A.2) which ensures $\mathcal{A}(\lambda) \to 0$ as $\lambda \to 0$. The rate also follows from Sriperumbudur et al. (2013, Proposition A.2) which yields $\mathcal{A}(\lambda) \leq \|\Sigma_{XX}^{-1}\mu\|_{\mathcal{H}}\lambda$, thereby obtaining $\|\check{\mu}_\lambda - \mu\|_{\mathcal{H}} = O_{\mathbb{P}}(n^{-1/2})$ for $\lambda = cn^{-1/2}$ with $c > 0$ being a constant independent of n.

5.7 Proof of Proposition 15

From Proposition 12, we have $\check{\mu}_\lambda^{(-i)} = (\hat{\Sigma}^{(-i)} + \lambda I)^{-1}\hat{\Sigma}^{(-i)}\hat{\mu}^{(-i)}$ where

$$\hat{\Sigma}^{(-i)} \triangleq \frac{1}{n-1}\sum_{j\neq i} k(\cdot, x_j) \otimes k(\cdot, x_j).$$

and $\hat{\mu}^{(-i)} \triangleq \frac{1}{n-1}\sum_{j\neq i} k(\cdot, x_j)$. Define $a \triangleq k(\cdot, x_i)$. It is easy to verify that

$$\hat{\Sigma}^{(-i)} = \frac{n}{n-1}\left(\hat{\Sigma} - \frac{a \otimes a}{n}\right) \text{ and } \hat{\mu}^{(-i)} = \frac{n}{n-1}\left(\hat{\mu} - \frac{a}{n}\right).$$

Therefore,

$$\check{\mu}_\lambda^{(-i)} = \frac{n}{n-1}\left((\hat{\Sigma} + \lambda_n' I) - \frac{a \otimes a}{n}\right)^{-1}\left(\hat{\Sigma} - \frac{a \otimes a}{n}\right)\left(\hat{\mu} - \frac{a}{n}\right),$$

which after using Sherman-Morrison formula[3] reduces to

$$\check{\mu}_\lambda^{(-i)} = \frac{n}{n-1}\left((\hat{\Sigma} + \lambda_n' I)^{-1} + \frac{(\hat{\Sigma} + \lambda_n' I)^{-1}(a \otimes a)(\hat{\Sigma} + \lambda_n' I)^{-1}}{n - \langle a, (\hat{\Sigma} + \lambda_n' I)^{-1}a\rangle_{\mathcal{H}}}\right)\left(\hat{\Sigma} - \frac{a \otimes a}{n}\right)\left(\hat{\mu} - \frac{a}{n}\right),$$

where $\lambda_n' \triangleq \frac{n-1}{n}\lambda$. Using the notation in the proof of Proposition 12, the following can be proved:

(i) $(\hat{\Sigma} + \lambda_n' I)^{-1}\hat{\Sigma}\hat{\mu} = n^{-1}\Phi(\mathbf{K} + \lambda_n\mathbf{I})^{-1}\mathbf{K}\mathbf{1}$.

(ii) $(\hat{\Sigma} + \lambda_n' I)^{-1}\hat{\Sigma}a = \Phi(\mathbf{K} + \lambda_n\mathbf{I})^{-1}\mathbf{k}_i$.

(iii) $(\hat{\Sigma} + \lambda_n' I)^{-1}a = n\Phi(\mathbf{K} + \lambda_n\mathbf{I})^{-1}\mathbf{e}_i$.

Based on the above, it is easy to show that

(iv) $(\hat{\Sigma} + \lambda_n' I)^{-1}(a \otimes a)\hat{\mu} = (\hat{\Sigma} + \lambda_n' I)^{-1}a\langle a, \hat{\mu}\rangle_{\mathcal{H}} = \Phi(\mathbf{K} + \lambda_n\mathbf{I})^{-1}\mathbf{e}_i\mathbf{k}_i^\top\mathbf{1}$.

(v) $(\hat{\Sigma} + \lambda_n' I)^{-1}(a \otimes a)a = (\hat{\Sigma} + \lambda_n' I)^{-1}a\langle a, a\rangle_{\mathcal{H}} = n\Phi(\mathbf{K} + \lambda_n\mathbf{I})^{-1}\mathbf{e}_i k(x_i, x_i)$.

(vi) $(\hat{\Sigma} + \lambda_n' I)^{-1}(a \otimes a)(\hat{\Sigma} + \lambda_n' I)^{-1}\hat{\Sigma}\hat{\mu} = \Phi(\mathbf{K} + \lambda_n\mathbf{I})^{-1}\mathbf{e}_i\mathbf{k}_i^\top(\mathbf{K} + \lambda_n\mathbf{I})^{-1}\mathbf{K}\mathbf{1}$.

(vii) $(\hat{\Sigma} + \lambda_n' I)^{-1}(a \otimes a)(\hat{\Sigma} + \lambda_n' I)^{-1}\hat{\Sigma}a = n\Phi(\mathbf{K} + \lambda_n\mathbf{I})^{-1}\mathbf{e}_i\mathbf{k}_i^\top(\mathbf{K} + \lambda_n\mathbf{I})^{-1}\mathbf{k}_i$.

(viii) $(\hat{\Sigma} + \lambda_n' I)^{-1}(a \otimes a)(\hat{\Sigma} + \lambda_n' I)^{-1}(a \otimes a)\hat{\mu} = n\Phi(\mathbf{K} + \lambda_n\mathbf{I})^{-1}\mathbf{e}_i\mathbf{k}_i^\top(\mathbf{K} + \lambda_n\mathbf{I})^{-1}\mathbf{e}_i\mathbf{k}_i^\top\mathbf{1}$.

(ix) $(\hat{\Sigma} + \lambda_n' I)^{-1}(a \otimes a)(\hat{\Sigma} + \lambda_n' I)^{-1}(a \otimes a)a = n^2\Phi(\mathbf{K} + \lambda_n\mathbf{I})^{-1}\mathbf{e}_i\mathbf{k}_i^\top(\mathbf{K} + \lambda_n\mathbf{I})^{-1}\mathbf{e}_i k(x_i, x_i)$.

(x) $\langle a, (\hat{\Sigma} + \lambda_n' I)^{-1}a\rangle_{\mathcal{H}} = n\mathbf{k}_i^\top(\mathbf{K} + \lambda_n\mathbf{I})^{-1}\mathbf{e}_i$.

Using the above in $\check{\mu}_\lambda^{(-i)}$, we obtain

$$\check{\mu}_\lambda^{(-i)} = \frac{1}{n-1}\Phi(\mathbf{K} + \lambda_n\mathbf{I})^{-1}\mathbf{c}_{i,\lambda}.$$

Substituting the above in (24) yields the result.

3. The Sherman-Morrison formula states that $(\mathbf{A} + \mathbf{u}\mathbf{v}^\top)^{-1} = \mathbf{A}^{-1} - \frac{\mathbf{A}^{-1}\mathbf{u}\mathbf{v}^\top\mathbf{A}^{-1}}{1+\mathbf{v}^\top\mathbf{A}^{-1}\mathbf{u}}$ where $\mathbf{A}$ is an invertible square matrix, $\mathbf{u}$ and $\mathbf{v}$ are column vectors such that $1 + \mathbf{v}^\top\mathbf{A}^{-1}\mathbf{u} \neq 0$.

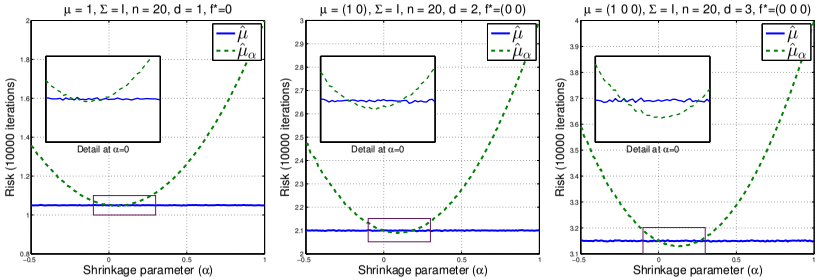

Figure 1: The comparison between standard estimator, $\hat{\mu}$ and shrinkage estimator, $\hat{\mu}_\alpha$ (with $f^* = 0$) of the mean of the Gaussian distribution $\mathcal{N}(\mu, \Sigma)$ on $\mathbb{R}^d$ where $d = 1, 2, 3$.

6. Experiments

In this section, we empirically compare the proposed shrinkage estimators to the standard estimator of the kernel mean on both synthetic and real-world datasets. Specifically, we consider the following estimators: *i*) empirical/standard kernel mean estimator (KME), *ii*) KMSE whose parameter is obtained via empirical bound (B-KMSE), *iii*) regularized KMSE whose parameter is obtained via Proposition 9 (R-KMSE), and *iv*) spectral KMSE whose parameter is obtained via Proposition 15 (S-KMSE).

6.1 Synthetic Data

Given the true data-generating distribution $\mathbb{P}$ and the i.i.d. sample $X = \{x_1, x_2, \ldots, x_n\}$ from $\mathbb{P}$, we evaluate different estimators using the loss function

$$L(\boldsymbol{\beta}, X, \mathbb{P}) \triangleq \left\| \sum_{i=1}^{n} \beta_i k(x_i, \cdot) - \mathbb{E}_{x\sim\mathbb{P}}[k(x, \cdot)] \right\|_{\mathcal{H}}^2,$$

where $\boldsymbol{\beta}$ is the weight vector associated with different estimators. Then, we can estimate the risk of the estimator by averaging over m independent copies of X, *i.e.*, $\widehat{R} = \frac{1}{m}\sum_{j=1}^{m} L(\boldsymbol{\beta}_j, X_j, \mathbb{P})$.

To allow for an exact calculation of $L(\boldsymbol{\beta}, X, \mathbb{P})$, we consider $\mathbb{P}$ to be a mixture-of-Gaussians distribution and k being one of the following kernel functions: *i*) linear kernel $k(x, x') = x^\top x'$, *ii*) polynomial degree-2 kernel $k(x, x') = (x^\top x' + 1)^2$, *iii*) polynomial degree-3 kernel $k(x, x') = (x^\top x' + 1)^3$ and *iv*) Gaussian RBF kernel $k(x, x') = \exp\left(-\|x - x'\|^2/2\sigma^2\right)$. We refer to them as LIN, POLY2, POLY3, and RBF, respectively. The analytic forms of $\mathbb{E}_{x\sim\mathbb{P}}[k(x, \cdot)]$ for Gaussian distribution are given in Song et al. (2008) and Muandet et al. (2012). Unless otherwise stated, we set the bandwidth parameter of the Gaussian kernel as $\sigma^2 = \text{median}\left\{\|x_i - x_j\|^2 : i, j = 1, \ldots, n\right\}$, *i.e.*, the median heuristic.

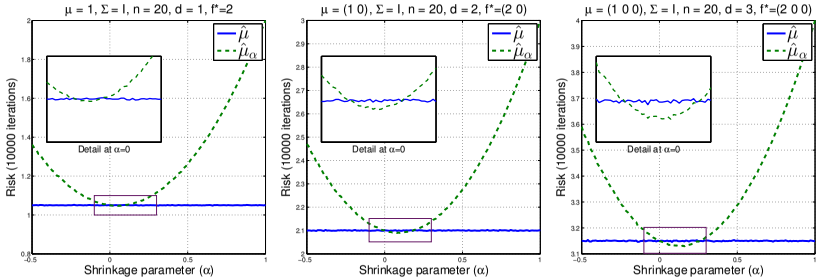

Figure 2: The risk comparison between standard estimator, $\hat{\mu}$ and shrinkage estimator, $\hat{\mu}_\alpha$ (with $f^* \in \{2, (2, 0)^\top, (2, 0, 0)^\top\}$) of the mean of the Gaussian distribution $\mathcal{N}(\mu, \Sigma)$ on $\mathbb{R}^d$ where $d = 1, 2, 3$.

6.1.1 Gaussian Distribution

We begin our empirical studies by considering the simplest case in which the distribution $\mathbb{P}$ is a Gaussian distribution $\mathcal{N}(\mu, \mathbf{I})$ on $\mathbb{R}^d$ where $d = 1, 2, 3$ and k is a linear kernel. In this case, the problem of kernel mean estimation reduces to just estimating the mean μ of the Gaussian distribution $\mathcal{N}(\mu, \mathbf{I})$. We consider only shrinkage estimators of form $\hat{\mu}_\alpha = \alpha f^* + (1-\alpha)\hat{\mu}$. The true mean μ of the distribution is chosen to be 1, $(1, 0)^\top$, and $(1, 0, 0)^\top$, respectively. Figure 1 depicts the comparison between the standard estimator and the shrinkage estimator, $\hat{\mu}_\alpha$ when the target f^* is the origin. We can clearly see that even in this simple case, an improvement can be gained by applying a small shrinkage. Furthermore, the improvement becomes more substantial as we increase the dimensionality of the underlying space. Figure 2 illustrates similar results when $f^* \neq 0$ but $f^* \in \{2, (2, 0)^\top, (2, 0, 0)^\top\}$. Interestingly, we can still observe similar improvement, which demonstrates that the choice of target f^* can be arbitrary when no prior knowledge about $\mu_\mathbb{P}$ is available.

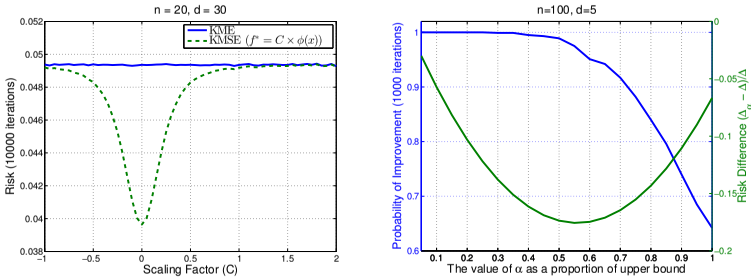
6.1.2 Mixture of Gaussians Distributions

To simulate a more realistic case, let y be a sample from $\mathbb{P} \triangleq \sum_{i=1}^{4} \pi_i \mathcal{N}(\boldsymbol{\theta}_i, \Sigma_i)$. In the following experiments, the sample x is generated from the following generative process:

$$x = y + \varepsilon, \quad \theta_{ij} \sim \mathcal{U}(-10, 10), \quad \Sigma_i \sim \mathcal{W}(2 \times \mathbf{I}_d, 7), \quad \varepsilon \sim \mathcal{N}(0, 0.2 \times \mathbf{I}_d),$$

where $\mathcal{U}(a, b)$ and $\mathcal{W}(\Sigma_0, df)$ represent the uniform distribution and Wishart distribution, respectively. We set $\boldsymbol{\pi} = (0.05, 0.3, 0.4, 0.25)^\top$. The choice of parameters here is quite arbitrary; we have experimented using various parameter settings and the results are similar to those presented here.

Figure 3(a) depicts the comparison between the standard kernel mean estimator and the shrinkage estimator, $\hat{\mu}_\alpha$ when the kernel k is the Gaussian RBF kernel. For shrinkage estimator $\hat{\mu}_\alpha$, we consider $f^* = C \times k(x, \cdot)$ where C is a scaling factor and each element of x is a realization of uniform random variable on $(0, 1)$. That is, we allow the target f^* to change



(a) (b)

Figure 3: (a) The risk comparison between $\hat{\mu}$ (KME) and $\hat{\mu}_{\tilde{\alpha}}$ (KMSE) where $\tilde{\alpha} = \hat{\Delta}/(\hat{\Delta} + \|f^* - \hat{\mu}\|^2_{\mathcal{H}})$. We consider when $f^* = C \times k(x, \cdot)$ where x is drawn uniformly from a pre-specified range and C is a scaling factor. (b) The probability of improvement and the risk difference as a function of shrinkage parameter α averaged over 1,000 iterations. As the value of α increases, we get more improvement in term of the risk, whereas the probability of improvement decreases as a function of α.

depending on the value of C. As the absolute value of C increases, the target function f^* will move further away from the origin. The shrinkage parameter α is determined using the empirical bound, *i.e.*, $\tilde{\alpha} = \hat{\Delta}/(\hat{\Delta} + \|f^* - \hat{\mu}\|^2_{\mathcal{H}})$. As we can see in Figure 3(a), the results reveal how important the choice of f^* is. That is, we may get substantial improvement over the empirical estimator if appropriate prior knowledge is incorporated through f^*, which in this case suggests that f^* should lie close to the origin. We intend to investigate the topic of prior knowledge in more detail in our future work.

Previous comparisons between standard estimator and shrinkage estimator is based entirely on the notion of a risk, which is in fact not useful in practice as we only observe a single copy of sample from the probability distribution. Instead, one should also look at the probability that, given a single copy of sample, the shrinkage estimator outperforms the standard one in term of a loss. To this end, we conduct an experiment comparing the standard estimator and shrinkage estimator using the Gaussian RBF kernel. In addition to the risk comparison, we also compare the probability that the shrinkage estimator gives smaller loss than that of the standard estimator. To be more precise, the probability is defined as a proportion of the samples drawn from the same distribution whose shrinkage loss is smaller than the loss of the standard estimator. Figure 3(b) illustrates the risk difference ($\Delta_\alpha - \Delta$) and the probability of improvement (*i.e.*, the fraction of times $\Delta_\alpha < \Delta$) as a function of shrinkage parameter α. In this case, the value of α is specified as a proportion of empirical upper bound $2\hat{\Delta}/(\hat{\Delta} + \|\hat{\mu}\|^2_{\mathcal{H}})$. The results suggest that the shrinkage parameter α controls the trade-off between the amount of improvement in terms of risk and the probability that the shrinkage estimator will improve upon the standard one. However, this trade-off only holds up to a certain value of α. As α becomes too large, both the probability of improvement and the amount of improvement itself decrease, which coincides with the intuition given for the positive-part shrinkage estimators (cf. Section 2.2.1).

6.1.3 Shrinkage Estimators via Leave-One-Out Cross-Validation

In addition to the empirical upper bound, one can alternatively compute the shrinkage parameter using leave-one-out cross-validation proposed in Section 3. Our goal here is to compare the B-KMSE, R-KMSE and S-KMSE on synthetic data when the shrinkage parameter λ is chosen via leave-one-out cross-validation procedure. Note that the only difference between B-KMSE and R-KMSE is the way we compute the shrinkage parameter.

Figure 4 shows the empirical risk of different estimators using different kernels as we increase the value of shrinkage parameter λ (note that R-KMSE and S-KMSE in Figure 4 refer to those in (22) and (31) respectively). Here we scale the shrinkage parameter by the smallest non-zero eigenvalue γ_0 of the kernel matrix $\mathbf{K}$. In general, we find that R-KMSE and S-KMSE outperforms KME. Nevertheless, as the shrinkage parameter λ becomes large, there is a tendency that the specific shrinkage estimate might actually perform worse than the KME, *e.g.*, see LIN kernel and outliers in Figure 4. The result also supports our previous observation regarding Figure 3(b), which suggests that it is very important to choose the parameter λ appropriately.

To demonstrate the leave-one-out cross-validation procedure, we conduct similar experiments in which the parameter λ is chosen by the proposed LOOCV procedure. Figure 5 depicts the percentage of improvement (with respect to the empirical risk of the KME[4]) as we vary the sample size and dimension of the data. Clearly, B-KMSE, R-KMSE and S-KMSE outperform the standard estimator. Moreover, both R-KMSE and S-KMSE tend to outperform the B-KMSE. We can also see that the performance of S-KMSE depends on the choice of kernel. This makes sense intuitively because S-KMSE also incorporates the eigen-spectrum of $\mathbf{K}$, whereas R-KMSE does not. The effects of both sample size and data dimensionality are also transparent from Figure 5. While it is intuitive to see that the improvement gets smaller with increase in sample size, it is a bit surprising to see that we can gain much more in high-dimensional input space, especially when the kernel function is non-linear, because the estimation happens in the feature space associated with the kernel function rather than in the input space. Lastly, we note that the improvement is more substantial in the "large d, small n" paradigm.

6.2 Real Data

To evaluate the proposed estimators on real-world data, we consider several benchmark applications, namely, classification via Parzen window classifier, density estimation via kernel mean matching (Song et al., 2008), and discriminative learning on distributions (Muandet et al., 2012; Muandet and Schölkopf, 2013). For some of these tasks we employ datasets from the UCI repositories. We use only real-valued features, each of which is normalized to have zero mean and unit variance.

6.2.1 Parzen Window Classifiers

One of the oldest and best-known classification algorithms is the *Parzen window classifier* (Duda et al., 2000). It is easy to implement and is one of the powerful non-linear supervised

4. If we denote the loss of KME and KMSE as ℓ_{KME} and ℓ_{KMSE}, respectively, the percentage of improvement is calculated as $100 \times (\ell_{KME} - \ell_{KMSE})/\ell_{KME}$.

(b) POLY2

(c) POLY3

(d) RBF

Figure 4: The average loss of KME (left), R-KMSE (middle) and S-KMSE (right) estimators with different values of shrinkage parameter. We repeat the experiments over 30 different distributions with $n = 10$ and $d = 30$.

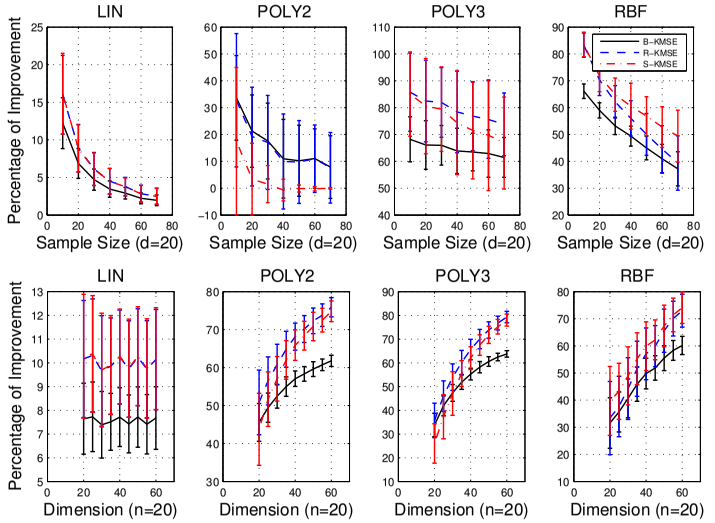

Figure 5: The percentage of improvement compared to KME over 30 different distributions of B-KMSE, R-KMSE and S-KMSE with varying sample size (n) and dimension (d). For B-KMSE, we calculate α using (16), whereas R-KMSE and S-KMSE use LOOCV to choose λ.

learning techniques. Suppose we have data points from two classes, namely, positive class and negative class. For positive class, we observe $\mathfrak{X} \triangleq \{x_1, x_2, \ldots, x_n\} \subset \mathcal{X}$, while for negative class we have $\mathfrak{Y} \triangleq \{y_1, y_2, \ldots, y_m\} \subset \mathcal{X}$. Following Shawe-Taylor and Cristianini (2004, Sec. 5.1.2), the Parzen window classifier is given by

$$f(z) = \operatorname{sgn}\left(\frac{1}{n}\sum_{i=1}^{n} k(z, x_i) - \frac{1}{m}\sum_{j=1}^{m} k(z, y_j) + b\right) = \operatorname{sgn}\left(\hat{\mu}_{\mathfrak{X}}(z) - \hat{\mu}_{\mathfrak{Y}}(z) + b\right), \tag{46}$$

where b is a bias term given by $b = \frac{1}{2}(\|\hat{\mu}_{\mathfrak{Y}}\|^2_{\mathcal{H}} - \|\hat{\mu}_{\mathfrak{X}}\|^2_{\mathcal{H}})$. Note that $f(z)$ is a threshold linear function in $\mathcal{H}$ with weight vector $\mathbf{w} = (1/n)\sum_{i=1}^{n}\phi(x_i) - (1/m)\sum_{j=1}^{m}\phi(y_j)$ (see Shawe-Taylor and Cristianini (2004, Sec. 5.1.2) for more detail). This algorithm is often referred to as the lazy algorithm as it does not require training.

In brief, the classifier (46) assigns the data point z to the class whose empirical kernel mean $\hat{\mu}$ is closer to the feature map $k(z, \cdot)$ of the data point in the RKHS. On the other hand, we may view the empirical kernel mean $\hat{\mu}_{\mathfrak{X}} \triangleq \frac{1}{n}\sum_{i=1}^{n} k(x_i, \cdot)$ (resp. $\hat{\mu}_{\mathfrak{Y}} \triangleq \frac{1}{m}\sum_{j=1}^{m} k(y_j, \cdot)$) as a standard empirical estimate, *i.e.*, KME, of the true kernel mean representation of the class-conditional distribution $\mathbb{P}(X|Y = +1)$ (resp. $\mathbb{P}(X|Y = -1)$). Given the improvement of shrinkage estimators over the empirical estimator of kernel mean, it is natural to expect

that the performance of Parzen window classifier can be improved by employing shrinkage estimators of the true mean representation.

Our goal in this experiment is to compare the performance of Parzen window classifier using different kernel mean estimators. That is, we replace $\hat{\mu}_{\mathcal{X}}$ and $\hat{\mu}_{\mathcal{Y}}$ by their shrinkage counterparts and evaluate the resulting classifiers across several datasets taken from the UCI machine learning repository. In this experiment, we only consider the Gaussian RBF kernel whose bandwidth parameter is chosen by cross-validation procedure over a uniform grid $\sigma \in [0.1, 2]$. We use 30% of each dataset as a test set and the rest as a training set. We employ a simple pairwise coupling and majority vote for multi-class classification. We repeat the experiments 100 times and perform the paired-sample t-test on the results at 5% significance level. Table 1 reports the classification error rates of the Parzen window classifiers with different kernel mean estimators. Although the improvement is not substantial, we can see that the shrinkage estimators consistently give better performance than the standard estimator.

6.2.2 Density Estimation

We perform density estimation via kernel mean matching (Song et al., 2008), wherein we fit the density $Q = \sum_{j=1}^{m} \pi_j \mathcal{N}(\boldsymbol{\theta}_j, \sigma_j^2 \mathbf{I})$ to each dataset by the following minimization problem:

$$\min_{\boldsymbol{\pi}, \boldsymbol{\theta}, \boldsymbol{\sigma}} \|\hat{\mu} - \mu_Q\|_{\mathcal{H}}^2 \quad \text{subject to} \quad \sum_{j=1}^{m} \pi_j = 1,\ \pi_j \geq 0\,. \tag{47}$$

The empirical mean map $\hat{\mu}$ is obtained from samples using different estimators, whereas μ_Q is the kernel mean embedding of the density Q. Unlike experiments in Song et al. (2008), our goal is to compare different estimators of $\mu_{\mathbb{P}}$ (where $\mathbb{P}$ is the true data distribution), by replacing $\hat{\mu}$ in (47) with different shrinkage estimators. A better estimate of $\mu_{\mathbb{P}}$ should lead to better density estimation, as measured by the negative log-likelihood of Q on the test set, which we choose to be 30% of the dataset. For each dataset, we set the number of mixture components m to be 10. The model is initialized by running 50 random initializations using

the k-means algorithm and returning the best. We repeat the experiments 30 times and perform the paired sign test on the results at 5% significance level.[5]

The average negative log-likelihood of the model Q, optimized via different estimators, is reported in Table 2. In most cases, both R-KMSE and S-KMSE consistently achieve smaller negative log-likelihood when compared to KME. B-KMSE also tends to outperform the KME. However, in few cases the KMSEs achieve larger negative log-likelihood, especially when we use linear and degree-2 polynomial kernels. This highlight the potential of our estimators in a non-linear setting.

6.2.3 Discriminative Learning on Probability Distributions

The last experiment involves the discriminative learning on a collection of probability distributions via the kernel mean representation. A positive semi-definite kernel between distributions can be defined via their kernel mean embeddings. That is, given a training sample $(\widehat{\mathbb{P}}_1, y_1), \ldots, (\widehat{\mathbb{P}}_m, y_m) \in \mathcal{P} \times \{-1, +1\}$ where $\widehat{\mathbb{P}}_i := \frac{1}{n_i} \sum_{p=1}^{n_i} \delta_{x_p^i}$ and $x_p^i \sim \mathbb{P}_i$, the linear kernel between two distributions is approximated by

$$\langle \hat{\mu}_{\mathbb{P}_i}, \hat{\mu}_{\mathbb{P}_j} \rangle_{\mathcal{H}} = \left\langle \sum_{p=1}^{n_i} \beta_p^i \phi(x_p^i), \sum_{q=1}^{n_j} \beta_q^j \phi(x_q^j) \right\rangle_{\mathcal{H}} = \sum_{p=1}^{n_i} \sum_{q=1}^{n_j} \beta_p^i \beta_q^j k(x_p^i, x_q^j),$$

where the weight vectors $\boldsymbol{\beta}^i$ and $\boldsymbol{\beta}^j$ come from the kernel mean estimates of $\mu_{\mathbb{P}_i}$ and $\mu_{\mathbb{P}_j}$, respectively. The non-linear kernel can then be defined accordingly, *e.g.*, $\kappa(\mathbb{P}_i, \mathbb{P}_j) = \exp(\|\hat{\mu}_{\mathbb{P}_i} - \hat{\mu}_{\mathbb{P}_j}\|_{\mathcal{H}}^2 / 2\sigma^2)$, see Christmann and Steinwart (2010). Our goal in this experiment is to investigate if the shrinkage estimators of the kernel mean improve the performance of discriminative learning on distributions. To this end, we conduct experiments on natural scene categorization using support measure machine (SMM) (Muandet et al., 2012) and group anomaly detection on a high-energy physics dataset using one-class SMM (OC-SMM) (Muandet and Schölkopf, 2013). We use both linear and non-linear kernels where the Gaussian RBF kernel is employed as an embedding kernel (Muandet et al., 2012). All hyper-parameters are chosen by 10-fold cross-validation.[6] For our unsupervised problem, we repeat the experiments using several parameter settings and report the best results. Table 3 reports the classification accuracy of SMM and the area under ROC curve (AUC) of OCSMM using different kernel mean estimators. All shrinkage estimators consistently lead to better performance on both SMM and OCSMM when compared to KME.

In summary, the proposed shrinkage estimators outperform the standard KME. While B-KMSE and R-KMSE are very competitive compared to KME, S-KMSE tends to outperform both B-KMSE and R-KMSE, however, sometimes leading to poor estimates depending on the dataset and the kernel function.

5. The paired sign test is a nonparametric test that can be used to examine whether two paired samples have the same distribution. In our case, we compare B-KMSE, R-KMSE and S-KMSE against KME.
6. In principle one can incorporate the shrinkage parameter into the cross-validation procedure. In this work we are only interested in the value of λ returned by the proposed LOOCV procedure.

7. Conclusion and Discussion

Motivated by the classical James-Stein phenomenon, in this paper, we proposed a shrinkage estimator for the kernel mean μ in a reproducing kernel Hilbert space $\mathcal{H}$ and showed they improve upon the empirical estimator $\hat{\mu}$ in the mean squared sense. We showed the proposed shrinkage estimator $\tilde{\mu}$ (with the shrinkage parameter being learned from data) to be $\sqrt{n}$-consistent and satisfies $\mathbb{E}\|\tilde{\mu} - \mu\|_{\mathcal{H}}^2 < \mathbb{E}\|\hat{\mu} - \mu\|_{\mathcal{H}}^2 + O(n^{-3/2})$ as $n \to \infty$. We also provided a regularization interpretation to shrinkage estimation, using which we also presented two shrinkage estimators, namely regularized shrinkage estimator and spectral shrinkage estimator, wherein the first one is closely related to $\hat{\mu}$ while the latter exploits the spectral decay of the covariance operator in $\mathcal{H}$. We showed through numerical experiments that the proposed estimators outperform the empirical estimator in various scenarios. Most importantly, the shrinkage estimators not only provide more accurate estimation, but also lead to superior performance on many real-world applications.

In this work, while we focused mainly on an estimation of the mean function in RKHS, it is quite straightforward to extend the shrinkage idea to estimate covariance (and cross-covariance) operators and tensors in RKHS (see Appendix A for a brief description). The key observation is that the covariance operator can be viewed as a mean function in a tensor RKHS. Covariance operators in RKHS are ubiquitous in many classical learning algorithms such as kernel PCA, kernel FDA, and kernel CCA. Recently, a preliminary investigation with some numerical results on shrinkage estimation of covariance operators is carried out in Muandet et al. (2014a) and Wehbe and Ramdas (2015). In the future, we intend to carry out a detailed study on the shrinkage estimation of covariance (and cross-covariance) operators.

Acknowledgments

The authors thanks the reviewers and the action editor for their detailed comments that significantly improved the manuscript. This work was partly done while Krikamol Muandet was visiting the Institute of Statistical Mathematics, Tokyo, and New York University, New York; and while Bharath Sriperumbudur was visiting the Max Planck Institute for Intelligent Systems, Germany. The authors wish to thank David Hogg and Ross Fedely for reading the first draft and giving valuable comments. We also thank Motonobu Kanagawa, Yu Nishiyama, and Ingo Steinwart for fruitful discussions. Kenji Fukumizu has been supported in part by MEXT Grant-in-Aid for Scientific Research on Innovative Areas 25120012.

Appendix A. Shrinkage Estimation of Covariance Operator

Let $(\mathcal{H}_X, k_X)$ and $(\mathcal{H}_Y, k_Y)$ be separable RKHSs of functions on measurable spaces $\mathcal{X}$ and $\mathcal{Y}$, with measurable reproducing kernels k_X and k_Y (with corresponding feature maps ϕ and φ), respectively. We consider a random vector $(X, Y) : \Omega \to \mathcal{X} \times \mathcal{Y}$ with distribution $\mathbb{P}_{XY}$. The marginal distributions of X and Y are denoted by $\mathbb{P}_X$ and $\mathbb{P}_Y$, respectively. If $\mathbb{E}_X k_X(X, X) < \infty$ and $\mathbb{E}_Y k_Y(Y, Y) < \infty$, then there exists a unique *cross-covariance*

operator $\Sigma_{YX} : \mathcal{H}_X \to \mathcal{H}_Y$ such that

$$\langle g, \Sigma_{YX} f \rangle_{\mathcal{H}_Y} = \mathbb{E}_{XY}[(f(X) - \mathbb{E}_X[f(X)])(g(Y) - \mathbb{E}_Y[g(Y)])] = Cov(f(X), g(Y))$$

holds for all $f \in \mathcal{H}_X$ and $g \in \mathcal{H}_Y$ (Baker, 1973; Fukumizu et al., 2004). If X is equal to Y, we obtain the self-adjoint operator Σ_{XX} called the *covariance operator*. Given i.i.d sample $\{(x_i, y_i)\}_{i=1}^n$ from $\mathbb{P}_{XY}$, we can write the empirical cross-covariance operator $\widehat{\Sigma}_{YX}$ as

$$\widehat{\Sigma}_{YX} \triangleq \frac{1}{n} \sum_{i=1}^{n} \phi(x_i) \otimes \varphi(y_i) - \hat{\mu}_X \otimes \hat{\mu}_Y \tag{48}$$

where $\hat{\mu}_X = \frac{1}{n} \sum_{i=1}^n \phi(x_i)$ and $\hat{\mu}_Y = \frac{1}{n} \sum_{i=1}^n \varphi(y_i)$.[7] Let $\tilde{\phi}$ and $\tilde{\varphi}$ be the centered version of the feature map ϕ and φ defined as $\tilde{\phi}(x) = \phi(x) - \hat{\mu}_X$ and $\tilde{\varphi}(y) = \varphi(y) - \hat{\mu}_Y$, respectively. Then, the empirical cross-covariance operator in (48) can be rewritten as

$$\widehat{\Sigma}_{YX} = \frac{1}{n} \sum_{i=1}^{n} \tilde{\phi}(x_i) \otimes \tilde{\varphi}(y_i),$$

and therefore a shrinkage estimator of Σ_{YX}, *e.g.*, an equivalent of B-KMSE, can be constructed based on the ideas presented in this paper. That is, by the inner product property in product space, we have

$$\begin{aligned} \langle \tilde{\phi}(x) \otimes \tilde{\varphi}(y), \tilde{\phi}(x') \otimes \tilde{\varphi}(y') \rangle_{\mathcal{H}_X \otimes \mathcal{H}_Y} &= \langle \tilde{\phi}(x), \tilde{\phi}(x') \rangle_{\mathcal{H}_X} \langle \tilde{\varphi}(y), \tilde{\varphi}(y') \rangle_{\mathcal{H}_Y} \\ &= \tilde{k}_X(x, x') \tilde{k}_Y(y, y'). \end{aligned}$$

where $\tilde{k}_X$ and $\tilde{k}_Y$ denote the centered kernel functions. As a result, we can obtain the shrinkage estimators for Σ_{YX} by plugging the above kernel into the KMSEs.

Abstract

Symmetric positive semidefinite (SPSD) matrix approximation is an important problem with applications in kernel methods. However, existing SPSD matrix approximation methods such as the Nyström method only have weak error bounds. In this paper we conduct in-depth studies of an SPSD matrix approximation model and establish strong relative-error bounds. We call it the prototype model for it has more efficient and effective extensions, and some of its extensions have high scalability. Though the prototype model itself is not suitable for large-scale data, it is still useful to study its properties, on which the analysis of its extensions relies.

This paper offers novel theoretical analysis, efficient algorithms, and a highly accurate extension. First, we establish a lower error bound for the prototype model and improve the error bound of an existing column selection algorithm to match the lower bound. In this way, we obtain the first optimal column selection algorithm for the prototype model. We also prove that the prototype model is exact under certain conditions. Second, we develop a simple column selection algorithm with a provable error bound. Third, we propose a so-called spectral shifting model to make the approximation more accurate when the eigenvalues of the matrix decay slowly, and the improvement is theoretically quantified. The spectral shifting method can also be applied to improve other SPSD matrix approximation models.

Keywords: Matrix approximation, matrix factorization, kernel methods, the Nyström method, spectral shifting

1. Introduction

The kernel methods are important tools in machine learning, computer vision, and data mining (Schölkopf and Smola, 2002; Shawe-Taylor and Cristianini, 2004). However, for two reasons, most kernel methods have scalability difficulties. First, given n data points of d dimension, generally we need $\mathcal{O}(n^2d)$ time to form the $n \times n$ kernel matrix $\mathbf{K}$. Second, most kernel methods require expensive matrix computations. For example, Gaussian process regression and classification require inverting some $n \times n$ matrices which costs $\mathcal{O}(n^3)$ time and $\mathcal{O}(n^2)$ memory; kernel PCA and spectral clustering perform the truncated eigenvalue decomposition which takes $\tilde{\mathcal{O}}(n^2k)$ time[1] and $\mathcal{O}(n^2)$ memory, where k is the target rank of the decomposition.

Besides high time complexities, these matrix operations also have high memory cost and are difficult to implement in distributed computing facilities. The matrix decomposition and (pseudo) inverse operations are generally solved by numerical iterative algorithms, which go many passes through the matrix until convergence. Thus, the whole matrix had better been placed in main memory, otherwise in each iteration there would be a swap between memory and disk, which incurs high I/O costs and can be more expensive than CPU time. Unless the algorithm is pass-efficient, that is, it goes constant passes through the data matrix, the main memory should be at least the size of the data matrix. For two reasons, such iterative algorithms are expensive even if they are performed in distributed computing facilities such as MapReduce. First, the memory cost is too expensive for each individual machine to stand. Second, communication and synchronization must be performed in each iteration of the numerical algorithms, so the cost of each iteration is high.

Many matrix approximation methods have been proposed to make kernel machines scalable. Among them the Nyström method (Nyström, 1930; Williams and Seeger, 2001) and random features (Rahimi and Recht, 2008) are the most efficient and widely applied. However, only weak results are known (Drineas and Mahoney, 2005; Gittens and Mahoney, 2013; Lopez-Paz et al., 2014). Yang et al. (2012) showed that the Nyström method is likely a better choice than random features, both theoretically and empirically. However, even the Nyström method cannot attain high accuracy. The lower bound in (Wang and Zhang, 2013) indicates that the Nyström method costs at least $\Omega(n^2k/\epsilon)$ time and $\Omega(n^{1.5}k^{0.5}\epsilon^{-0.5})$ memory to attain $1+\epsilon$ Frobenius norm error bound relative to the best rank k approximation.

In this paper we investigate a more accurate low-rank approximation model proposed by Halko et al. (2011); Wang and Zhang (2013), which we refer to as the prototype model. For any symmetric positive semidefinite (SPSD) matrix $\mathbf{K} \in \mathbb{R}^{n\times n}$, the prototype model first draws a random matrix $\mathbf{P} \in \mathbb{R}^{n\times c}$ and forms a sketch $\mathbf{C} = \mathbf{KP}$, and then computes the intersection matrix

$$\mathbf{U}^\star \;=\; \operatorname*{argmin}_{\mathbf{U}} \|\mathbf{K} - \mathbf{CUC}^T\|_F^2 \;=\; \mathbf{C}^\dagger\mathbf{K}(\mathbf{C}^\dagger)^T \;\in\; \mathbb{R}^{c\times c}. \tag{1}$$

Finally, the model approximates $\mathbf{K}$ by $\mathbf{CU}^\star\mathbf{C}^T$. With this low-rank approximation at hand, it takes time $\mathcal{O}(nc^2)$ to compute the approximate matrix inversion and eigenvalue decomposition. In the following we discuss how to form $\mathbf{C}$ and compute $\mathbf{U}^\star$.

Column Selection vs. Random Projection. Although the sketch $\mathbf{C} = \mathbf{KP}$ can be formed by either random projection or column selection, when applied to the kernel methods, column selection is preferable to random projection. As aforementioned, suppose we are given n data points of d dimension. It takes time $\mathcal{O}(n^2d)$ to compute the whole of the kernel matrix $\mathbf{K}$, which is prohibitive when n is in million scale. Unfortunately, whatever

∗. Corresponding author.

1. The $\tilde{\mathcal{O}}$ notation hides the logarithm terms and the data-dependent spectral gap parameter.

existing random projection technique is employed to form the sketch $\mathbf{C}$, every entry of $\mathbf{K}$ must be visited. In contrast, by applying data independent column selection algorithms such as uniform sampling, we can form $\mathbf{C}$ by observing only $\mathcal{O}(nc)$ entries of $\mathbf{K}$. At present all the existing column selection algorithms, including our proposed uniform+adaptive^2 algorithm, cannot avoid observing the whole of $\mathbf{K}$ while keeping constant-factor bound. Nevertheless, we conjecture that our uniform+adaptive^2 algorithm can be adapted to satisfy these two properties simultaneously (see Section 5.4 for discussions in detail).

The Intersection Matrix. With the sketch $\mathbf{C}$ at hand, it remains to compute the intersection matrix. The most straightforward way is (1), which minimizes the Frobenius norm approximation error. However, this approach has two drawbacks. First, it again requires the full observation of $\mathbf{K}$. Second, the matrix product $\mathbf{C}^\dagger\mathbf{K}$ costs $\mathcal{O}(n^2c)$ time. The prototype model is therefore time-inefficient. Fortunately, Wang et al. (2015) recently overcame the two drawbacks by solving (1) approximately rather than optimally. Wang et al. (2015) obtained the approximate intersection matrix $\tilde{\mathbf{U}}$ in $\mathcal{O}(nc^3/\epsilon)$ time while keeping

$$\|\mathbf{K}-\mathbf{C}\tilde{\mathbf{U}}\mathbf{C}^T\|_F^2 \;\le\; (1+\epsilon)\min_{\mathbf{U}}\|\mathbf{K}-\mathbf{C}\mathbf{U}\mathbf{C}^T\|_F^2 \tag{2}$$

with high probability.

With the more efficient solution, why is it useful to study the exact solution to the prototype model (1)? On the one hand, from (2) we can see that the quality of the approximation depends on the prototype model, thus improvement of the prototype model directly applies to the more efficient model. On the other hand, for medium-scale problems where $\mathbf{K}$ does not fit in memory, the prototype model can produce high quality approximation with reasonable time expense. The experiment on kernel PCA in Section 6.3 shows that the prototype model is far more accurate than the Nyström method. For the above two reasons, we believe the study of the prototype model is useful.

1.1 Contributions

Our contributions mainly include three aspects: theoretical analysis, column selection algorithms, and extensions. They are summarized as follows.

1.1.1 Contributions: Theories

Kumar et al. (2009); Talwalkar and Rostamizadeh (2010) previously showed that the Nyström method is exact when the original kernel matrix is low-rank. In Section 4.1 we show that the prototype model exactly recovers the original SPSD matrix under the same conditions.

The prototype model with the near-optimal+adaptive column sampling algorithm satisfies $1+\epsilon$ relative-error bound when $c=\mathcal{O}(k/\epsilon^2)$ (Wang and Zhang, 2013). It was unknown whether this upper bound is optimal. In Section 4.2 we establish a lower error bound for the prototype model. We show that at least $2k/\epsilon$ columns must be chosen to attain $1+\epsilon$ bound. In Theorem 3 we improve the upper error bound of the near-optimal+adaptive algorithm to $\mathcal{O}(k/\epsilon)$, which matches the lower bound up to a constant factor.

1.1.2 Contributions: Algorithms

In Section 5 we devise a simple column selection algorithm which we call *the uniform+adaptive^2 algorithm*. The uniform+adaptive^2 algorithm is more efficiently and more easily implemented than the near-optimal+adaptive algorithm of Wang and Zhang (2013), yet its error bound is comparable with the near-optimal+adaptive algorithm. It is worth mentioning that our uniform+adaptive^2 algorithm is the adaptive-full algorithm of (Figure 3, Kumar et al., 2012) with two rounds of adaptive sampling, and thus our results theoretically justify the adaptive-full algorithm.

1.1.3 Contributions: Extension

When the spectrum of a matrix decays slowly (that is, the $c+1$ to n largest eigenvalues are not small enough), all of the low-rank approximations are far from the original kernel matrix. Inspired by Zhang (2014), we propose a new method called *spectral shifting (SS)* to make the approximation still effective even when the spectrum decays slowly. Unlike the low-rank approximation $\mathbf{K}\approx\mathbf{C}\mathbf{U}\mathbf{C}^T$, the spectral shifting model approximates $\mathbf{K}$ by $\mathbf{K}\approx\tilde{\mathbf{C}}\mathbf{U}^{\mathrm{ss}}\tilde{\mathbf{C}}^T+\delta^{\mathrm{ss}}\mathbf{I}_n$, where $\mathbf{C},\tilde{\mathbf{C}}\in\mathbb{R}^{n\times c}$, $\mathbf{U},\mathbf{U}^{\mathrm{ss}}\in\mathbb{R}^{c\times c}$, and $\delta^{\mathrm{ss}}\ge 0$. When the spectrum of $\mathbf{K}$ decays slowly, the term $\delta^{\mathrm{ss}}\mathbf{I}_n$ helps to improve the approximation accuracy. In Section 7 we describe the spectral shifting method in detail.

We highlight that the spectral shifting method can naturally apply to improve other kernel approximation models such as the memory efficient kernel approximation (MEKA) model (Si et al., 2014). Experiments demonstrate that MEKA can be significantly improved by spectral shifting.

1.2 Paper Organization

The remainder of this paper is organized as follows. In Section 2 we define the notation. In Section 3 we introduce the motivations of SPSD matrix approximation and define the SPSD matrix approximation models. Then we present our work—theories, algorithms, and extension—respectively in Sections 4, 5, and 7. In Section 6 we conduct experiments to compare among the column sampling algorithms. In Section 8 we empirically evaluate the proposed spectral shifting model. All the proofs are deferred to the appendix.

2. Notation

Let $[n]=\{1,\dots,n\}$, and $\mathbf{I}_n$ be the $n\times n$ identity matrix. For an $m\times n$ matrix $\mathbf{A}=[a_{ij}]$, we let $\mathbf{a}_{i:}$ be its i-th row, $\mathbf{a}_{:i}$ be its i-th column, and use $\mathbf{a}_i$ to denote either row or column when there is no ambiguity. Let $\mathbf{A}_1\oplus\mathbf{A}_2\oplus\cdots\oplus\mathbf{A}_q$ be the block diagonal matrix whose the i-th diagonal block is $\mathbf{A}_i$. Let $\|\mathbf{A}\|_F=(\sum_{i,j}a_{ij}^2)^{1/2}$ be the Frobenius norm and $\|\mathbf{A}\|_2=\max_{\mathbf{x}\neq\mathbf{0}}\|\mathbf{A}\mathbf{x}\|_2/\|\mathbf{x}\|_2$ be the spectral norm.

Letting $\rho=\mathrm{rank}(\mathbf{A})$, we write the condensed singular value decomposition (SVD) of $\mathbf{A}$ as $\mathbf{A}=\mathbf{U}_\mathbf{A}\mathbf{\Sigma}_\mathbf{A}\mathbf{V}_\mathbf{A}^T$, where the (i,i)-th entry of $\mathbf{\Sigma}_\mathbf{A}\in\mathbb{R}^{\rho\times\rho}$ is the i-th largest singular value of $\mathbf{A}$ (denoted $\sigma_i(\mathbf{A})$). Unless otherwise specified, in this paper "SVD" means the condensed SVD. We also let $\mathbf{U}_{\mathbf{A},k}$ and $\mathbf{V}_{\mathbf{A},k}$ be the first k ($<\rho$) columns of $\mathbf{U}_\mathbf{A}$ and $\mathbf{V}_\mathbf{A}$, respectively, and $\mathbf{\Sigma}_{\mathbf{A},k}$ be the $k\times k$ top sub-block of $\mathbf{\Sigma}_\mathbf{A}$. Then the $m\times n$ matrix $\mathbf{A}_k=\mathbf{U}_{\mathbf{A},k}\mathbf{\Sigma}_{\mathbf{A},k}\mathbf{V}_{\mathbf{A},k}^T$ is the "closest" rank-k approximation to $\mathbf{A}$.

If $\mathbf{A}$ is normal, we let $\mathbf{A}=\mathbf{U}_\mathbf{A}\mathbf{\Lambda}_\mathbf{A}\mathbf{U}_\mathbf{A}^T$ be the eigenvalue decomposition, and denote the i-th diagonal entry of $\mathbf{\Lambda}_\mathbf{A}$ by $\lambda_i(\mathbf{A})$, where $|\lambda_1(\mathbf{A})|\ge\cdots\ge|\lambda_n(\mathbf{A})|$. When $\mathbf{A}$ is SPSD, the SVD and the eigenvalue decomposition of $\mathbf{A}$ are identical.

Table 1: Comparisons among the matrix approximation models in Section 3.2 and Section 3.3. Here "#Entries" denotes the number of entries of $\mathbf{K}$ required to observe. The costs of column selection is not counted; they are listed separately in Table 2.

	Time	Memory	#Entries	Theory
Prototype	$\mathcal{O}(n^2c)$	$\mathcal{O}(nc)$	n^2	$1+\epsilon$ relative-error
Faster	$\mathcal{O}(nc^3/\epsilon)$	$\mathcal{O}(nc)$	nc^2/ϵ	$1+\epsilon$ relative-error
Nyström	$\mathcal{O}(nc^2)$	$\mathcal{O}(nc)$	nc	weak
SS	the same to "prototype"			stronger than "prototype"
Faster SS	the same to "faster"			unknown

Based on SVD, the *matrix coherence* of the columns of $\mathbf{A}$ relative to the best rank-k approximation is defined as $\mu_k = \frac{n}{k}\max_j \left\|(\mathbf{V}_{\mathbf{A},k})_{j:}\right\|_2^2$. Let $\mathbf{A}^\dagger = \mathbf{V}_\mathbf{A}\mathbf{\Sigma}_\mathbf{A}^{-1}\mathbf{U}_\mathbf{A}^T$ be the *Moore-Penrose inverse* of $\mathbf{A}$. When $\mathbf{A}$ is nonsingular, the Moore-Penrose inverse is identical to the matrix inverse. Given another $n\times c$ matrix $\mathbf{C}$, we define $\mathcal{P}_\mathbf{C}(\mathbf{A}) = \mathbf{C}\mathbf{C}^\dagger\mathbf{A}$ as the projection of $\mathbf{A}$ onto the column space of $\mathbf{C}$ and $\mathcal{P}_{\mathbf{C},k}(\mathbf{A}) = \mathbf{C}\cdot\mathrm{argmin}_{\mathrm{rank}(\mathbf{X})\le k}\|\mathbf{A}-\mathbf{C}\mathbf{X}\|_F$ as the rank restricted projection. It is obvious that $\|\mathbf{A}-\mathcal{P}_\mathbf{C}(\mathbf{A})\|_F \le \|\mathbf{A}-\mathcal{P}_{\mathbf{C},k}(\mathbf{A})\|_F$.

3. SPSD Matrix Approximation Models

In Section 3.1 we provide motivating examples to show why SPSD matrix approximation is useful. In Section 3.2 we formally describe low-rank approximation models. In Section 3.3 we describe the spectral shifting model. In Table 1 we compare the matrix approximation models defined in Section 3.2 and Section 3.3.

3.1 Motivations

Let $\mathbf{K}$ be an $n\times n$ kernel matrix. Many kernel methods require the eigenvalue decomposition of $\mathbf{K}$ or solving certain linear systems involving $\mathbf{K}$.

- Spectral clustering, kernel PCA, and manifold learning need to perform the rank k eigenvalue decomposition which costs $\tilde{\mathcal{O}}(n^2k)$ time and $\mathcal{O}(n^2)$ memory.
- Gaussian process regression and classification both require solving this kind of linear systems:
$$(\mathbf{K}+\alpha\mathbf{I}_n)\mathbf{b} = \mathbf{y}, \tag{3}$$
whose solution is $\mathbf{b}^\star = (\mathbf{K}+\alpha\mathbf{I}_n)^{-1}\mathbf{y}$. Here α is a constant. This costs $\mathcal{O}(n^3)$ time and $\mathcal{O}(n^2)$ memory.

Fortunately, if we can efficiently find an approximation in the form
$$\tilde{\mathbf{K}} \;=\; \mathbf{L}\mathbf{L}^T+\delta\mathbf{I}_n \;\approx\; \mathbf{K},$$
where $\delta\ge 0$ and $\mathbf{L}\in\mathbb{R}^{n\times l}$ with $l\ll n$, then the eigenvalue decomposition and linear systems can be approximately solved in $\mathcal{O}(nl^2)$ time and $\mathcal{O}(nl)$ space in the following way.

Algorithm 1 Computing the Prototype Model in $\mathcal{O}(nc+nd)$ Memory.

Input: data points $\mathbf{x}_1,\cdots,\mathbf{x}_n\in\mathbb{R}^d$, kernel function $\kappa(\cdot,\cdot)$.
Compute $\mathbf{C}$ and $\mathbf{C}^\dagger$; *// In $\mathcal{O}(nc+nd)$ memory and $\mathcal{O}(ncd+nc^2)$ time*
Form a $c\times n$ all-zero matrix $\mathbf{D}$; *// In $\mathcal{O}(nc)$ memory and $\mathcal{O}(nc)$ time*
for $j=1$ to n **do**
    Form the j-th column of $\mathbf{K}$ by $\mathbf{k}_j=[\kappa(\mathbf{x}_1,\mathbf{x}_j),\cdots,\kappa(\mathbf{x}_n,\mathbf{x}_j)]^T$;
    Compute the j-th column of $\mathbf{D}$ by $\mathbf{d}_j=\mathbf{C}^\dagger\mathbf{k}_j$;
    Delete $\mathbf{k}_j$ from memory;
end for
// Now the matrix $\mathbf{D}$ is $\mathbf{C}^\dagger\mathbf{K}$
// The loop totaly costs $\mathcal{O}(nc+nd)$ memory and $\mathcal{O}(n^2d+n^2c)$ time
Compute $\mathbf{U}=\mathbf{D}(\mathbf{C}^\dagger)^T$; *// In $\mathcal{O}(nc)$ memory and $\mathcal{O}(nc^2)$ time*
return $\mathbf{C}$ and $\mathbf{U}$ $(=\mathbf{C}^\dagger\mathbf{K}(\mathbf{C}^\dagger)^T)$.

- Approximate Eigenvalue Decomposition. Let $\mathbf{L}=\mathbf{U}\mathbf{\Sigma}\mathbf{V}^T$ be the SVD and $\mathbf{U}_\perp$ be the orthogonal complement of $\mathbf{U}$. Then the full eigenvalue decomposition of $\tilde{\mathbf{K}}$ is
$$\tilde{\mathbf{K}} \;=\; \mathbf{U}(\mathbf{\Sigma}^2+\delta\mathbf{I}_l)\mathbf{U}^T+\mathbf{U}_\perp(\delta\mathbf{I}_{n-l})\mathbf{U}_\perp^T.$$
- Approximately Solving the Linear Systems. Here we use a more general form: $\tilde{\mathbf{K}}=\mathbf{L}\mathbf{L}^T+\mathbf{\Delta}$, where $\mathbf{\Delta}$ is a diagonal matrix with positive diagonal entries. Then
$$\begin{aligned}\mathbf{b}^\star &= (\mathbf{K}+\alpha\mathbf{I}_n)^{-1}\mathbf{y} \;\approx\; (\mathbf{L}\mathbf{L}^T+\mathbf{\Delta}+\alpha\mathbf{I}_n)^{-1}\mathbf{y} \;=\; (\mathbf{L}\mathbf{L}^T+\mathbf{\Delta}')^{-1}\mathbf{y}\\ &= \mathbf{\Delta}'^{-1}\mathbf{y}-\underbrace{\mathbf{\Delta}'^{-1}\mathbf{L}}_{n\times l}\underbrace{(\mathbf{I}_l+\mathbf{L}^T\mathbf{\Delta}'^{-1}\mathbf{L})^{-1}}_{l\times l}\underbrace{\mathbf{L}^T\mathbf{\Delta}'^{-1}}_{l\times n}\mathbf{y}.\end{aligned}$$
Here the second equality is obtained by letting $\mathbf{\Delta}'=\mathbf{\Delta}+\alpha\mathbf{I}_n$, and the third equality follows by the Sherman-Morrison-Woodbury matrix identity.

The remaining problem is to find such matrix approximation efficiently while keeping $\tilde{\mathbf{K}}$ close to $\mathbf{K}$.

3.2 Low-Rank Matrix Approximation Models

We first recall the prototype model introduced previously and then discuss its approximate solutions. In fact, the famous Nyström method (Nyström, 1930; Williams and Seeger, 2001) is an approximation to the prototype model. Throughout this paper, we let $\mathbf{P}\in\mathbb{R}^{n\times c}$ be random projection or column selection matrix and $\mathbf{C}=\mathbf{K}\mathbf{P}$ be a sketch of $\mathbf{K}$. The only difference among the discussed models is their intersection matrices.

The Prototype Model. Suppose we have $\mathbf{C}\in\mathbb{R}^{n\times c}$ at hand. It remains to find an intersection matrix $\mathbf{U}\in\mathbb{R}^{c\times c}$. Since our objective is to make $\mathbf{C}\mathbf{U}\mathbf{C}^T$ close to $\mathbf{K}$, it is straightforward to optimize their difference. The prototype model computes the intersection matrix by
$$\mathbf{U}^\star \;=\; \mathop{\mathrm{argmin}}_{\mathbf{U}}\|\mathbf{K}-\mathbf{C}\mathbf{U}\mathbf{C}^T\|_F^2 \;=\; \mathbf{C}^\dagger\mathbf{K}(\mathbf{C}^T)^\dagger \;\in\; \mathbb{R}^{c\times c}. \tag{4}$$

With $\mathbf{C}$ at hand, the prototype model still needs one pass through the data, and it costs $\mathcal{O}(n^2c)$ time. When applied to kernel methods, the memory cost is $\mathcal{O}(nc+nd)$ (see Algorithm 1), where n is the number of data points and d is the dimension. The prototype model has the same time complexity as the exact rank k eigenvalue decomposition, but it is more memory-efficient and pass-efficient.

Halko et al. (2011) showed that when $\mathbf{P}$ is a standard Gaussian matrix and $c=\mathcal{O}(k/\epsilon)$, the prototype model attains $2+\epsilon$ error relative to $\|\mathbf{K}-\mathbf{K}_k\|_F^2$. Wang and Zhang (2013) showed that when $\mathbf{C}$ contains $c=\mathcal{O}(k/\epsilon^2)$ columns selected by the near-optimal+adaptive sampling algorithm, the prototype model attains $1+\epsilon$ relative error. In Section 5.2 we improve the result to $c=\mathcal{O}(k/\epsilon)$, which is near optimal.

Faster SPSD matrix Approximation Model. Wang et al. (2015) noticed that (4) is a strongly over-determined linear system, and thus proposed to solve (4) by randomized approximations. They proposed to sample $s=\mathcal{O}(c\sqrt{n/\epsilon}) \ll n$ columns according to the row leverage scores of $\mathbf{C}$, which costs $\mathcal{O}(nc^2)$ time. Let $\mathbf{S}\in\mathbb{R}^{n\times s}$ be the corresponding column selection matrix. They proposed the faster SPSD matrix approximation model which computes the intersection matrix by

$$\tilde{\mathbf{U}} \;=\; \operatorname*{argmin}_{\mathbf{U}} \left\|\mathbf{S}^T(\mathbf{K}-\mathbf{C}\mathbf{U}\mathbf{C}^T)\mathbf{S}\right\|_F^2 \;=\; \underbrace{(\mathbf{S}^T\mathbf{C})^\dagger}_{c\times s}\underbrace{(\mathbf{S}^T\mathbf{K}\mathbf{S})}_{s\times s}\underbrace{(\mathbf{C}^T\mathbf{S})^\dagger}_{s\times c} \;\in\; \mathbb{R}^{c\times c}. \tag{5}$$

The faster model visits only $s^2=\mathcal{O}(nc^2/\epsilon)=o(n^2)$ entries of $\mathbf{K}$, and the time complexity is $\mathcal{O}(nc^2+s^2c)=\mathcal{O}(nc^3/\epsilon)$. The following error bound is satisfied with high probability:

$$\|\mathbf{K}-\mathbf{C}\tilde{\mathbf{U}}\mathbf{C}^T\|_F^2 \;\le\; (1+\epsilon)\min_{\mathbf{U}}\|\mathbf{K}-\mathbf{C}\mathbf{U}\mathbf{C}^T\|_F^2.$$

This implies that if $\mathbf{C}$ is such a high quality sketch that the prototype model satisfies $1+\epsilon$ relative-error bound, then the faster SPSD matrix approximation model also satisfies $1+\epsilon$ relative-error bound.

The Nyström Method. The Nyström method is a special case of the faster SPSD matrix approximation model, and therefore it is also an approximate solution to (4). If we let the two column selection matrices $\mathbf{S}$ and $\mathbf{P}$ be the same, then (5) becomes

$$\tilde{\mathbf{U}} \;=\; \operatorname*{argmin}_{\mathbf{U}} \left\|\mathbf{P}^T(\mathbf{K}-\mathbf{C}\mathbf{U}\mathbf{C}^T)\mathbf{P}\right\|_F^2 \;=\; \underbrace{(\mathbf{P}^T\mathbf{K}\mathbf{P})^\dagger}_{c\times c}\underbrace{(\mathbf{P}^T\mathbf{K}\mathbf{P})}_{c\times c}\underbrace{(\mathbf{P}^T\mathbf{K}\mathbf{P})^\dagger}_{c\times c} \;=\; \underbrace{(\mathbf{P}^T\mathbf{K}\mathbf{P})^\dagger}_{c\times c}.$$

The matrix $(\mathbf{P}^T\mathbf{K}\mathbf{P})^\dagger$ is exactly the intersection matrix of the Nyström method. The Nyström method costs only $\mathcal{O}(nc^2)$ time, and it can be applied to million-scale problems (Talwalkar et al., 2013). However, its accuracy is low. Much work in the literature has analyzed the error bound of the Nyström method, but only weak results are known (Drineas and Mahoney, 2005; Shawe-Taylor et al., 2005; Kumar et al., 2012; Jin et al., 2013; Gittens and Mahoney, 2013). Wang and Zhang (2013) even showed that the Nyström method cannot attain $1+\epsilon$ relative-error bound unless $c\ge\Omega(\sqrt{nk/\epsilon})$. Equivalently, to attain $1+\epsilon$ bound, the Nyström would take $\Omega(n^2k/\epsilon)$ time and $\Omega(n^{1.5}k^{0.5}\epsilon^{-0.5})$ memory.

3.3 Spectral Shifting Models

We propose a more accurate SPSD matrix approximation method called the spectral shifting model. Here we briefly describe the model and its fast solution. The theoretical analysis is left to Section 7.

The Spectral Shifting (SS) Model. As before, we let $\mathbf{P}\in\mathbb{R}^{n\times c}$ be a column selection matrix and $\bar{\mathbf{C}}=\bar{\mathbf{K}}\mathbf{P}$, where $\bar{\mathbf{K}}=\mathbf{K}$ or $\bar{\mathbf{K}}=\mathbf{K}-\bar{\delta}\mathbf{I}_n$ for some parameter $\bar{\delta}\ge 0$. We approximate $\mathbf{K}$ by $\bar{\mathbf{C}}\mathbf{U}^{\mathrm{ss}}\bar{\mathbf{C}}^T+\delta^{\mathrm{ss}}\mathbf{I}_n$, where

$$\left(\mathbf{U}^{\mathrm{ss}},\delta^{\mathrm{ss}}\right) \;=\; \operatorname*{argmin}_{\mathbf{U},\delta}\left\|\mathbf{K}-\bar{\mathbf{C}}\mathbf{U}\bar{\mathbf{C}}^T-\delta\mathbf{I}_n\right\|_F^2. \tag{6}$$

This optimization problem has closed-form solution (see Theorem 6)

$$\begin{aligned}\delta^{\mathrm{ss}} &= \frac{1}{n-\mathrm{rank}(\bar{\mathbf{C}})}\Big(\mathrm{tr}(\mathbf{K})-\mathrm{tr}\big(\bar{\mathbf{C}}^\dagger\mathbf{K}\bar{\mathbf{C}}\big)\Big),\\ \mathbf{U}^{\mathrm{ss}} &= \bar{\mathbf{C}}^\dagger\mathbf{K}(\bar{\mathbf{C}}^\dagger)^T-\delta^{\mathrm{ss}}(\bar{\mathbf{C}}^T\bar{\mathbf{C}})^\dagger,\end{aligned}$$

which can be computed in $\mathcal{O}(n^2c)$ time and $\mathcal{O}(nc)$ memory. Later we will show that the SS model is more accurate than the prototype model.

Faster Spectral Shifting Model. The same idea of Wang et al. (2015) also applies to the SS model (14). Specifically, we can draw another column selection matrix $\mathbf{S}\in\mathbb{R}^{n\times s}$ and solve

$$\begin{aligned}\left(\tilde{\mathbf{U}}^{\mathrm{ss}},\tilde{\delta}^{\mathrm{ss}}\right) &= \operatorname*{argmin}_{\mathbf{U},\delta}\left\|\mathbf{S}^T\big(\mathbf{K}-\bar{\mathbf{C}}\mathbf{U}\bar{\mathbf{C}}^T-\delta\mathbf{I}_n\big)\mathbf{S}\right\|_F^2\\ &= \operatorname*{argmin}_{\mathbf{U},\delta}\left\|\mathbf{S}^T\mathbf{K}\mathbf{S}-(\mathbf{S}^T\bar{\mathbf{C}})\mathbf{U}(\mathbf{S}^T\bar{\mathbf{C}})^T-\delta\mathbf{I}_s\right\|_F^2.\end{aligned}$$

Similarly, it has closed-form solution

$$\begin{aligned}\tilde{\delta}^{\mathrm{ss}} &= \frac{1}{s-\mathrm{rank}(\mathbf{S}^T\bar{\mathbf{C}})}\Big[\mathrm{tr}\big(\mathbf{S}^T\mathbf{K}\mathbf{S}\big)-\mathrm{tr}\Big((\mathbf{S}^T\bar{\mathbf{C}})^\dagger(\mathbf{S}^T\mathbf{K}\mathbf{S})(\mathbf{S}^T\bar{\mathbf{C}})\Big)\Big],\\ \tilde{\mathbf{U}}^{\mathrm{ss}} &= (\mathbf{S}^T\bar{\mathbf{C}})^\dagger(\mathbf{S}^T\mathbf{K}\mathbf{S})(\bar{\mathbf{C}}^T\mathbf{S})^\dagger-\tilde{\delta}^{\mathrm{ss}}(\bar{\mathbf{C}}^T\mathbf{S}\mathbf{S}^T\bar{\mathbf{C}})^\dagger.\end{aligned}$$

In this way, the time cost is merely $\mathcal{O}(s^2c)$. However, the theoretical properties of this model are yet unknown. We do not conduct theoretical or empirical study of this model; we leave it as a future work,

4. Theories

In Section 4.1 we show that the prototype model is exact when $\mathbf{K}$ is low-rank. In Section 4.2 we provide a lower error bound of the prototype model.

4.1 Theoretical Justifications

Let $\mathbf{P}$ be a column selection matrix, $\mathbf{C}=\mathbf{K}\mathbf{P}$ be a sketch, and $\mathbf{W}=\mathbf{P}^T\mathbf{K}\mathbf{P}$ be the corresponding submatrix. Kumar et al. (2009); Talwalkar and Rostamizadeh (2010) showed that the Nyström method is exact when $\mathrm{rank}(\mathbf{W})=\mathrm{rank}(\mathbf{K})$. We present a similar result in Theorem 1.

Theorem 1 *The following three statements are equivalent:* (i) $\mathrm{rank}(\mathbf{W})=\mathrm{rank}(\mathbf{K})$, (ii) $\mathbf{K}=\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T$, (iii) $\mathbf{K}=\mathbf{C}\mathbf{C}^\dagger\mathbf{K}(\mathbf{C}^\dagger)^T\mathbf{C}^T$.

Theorem 1 implies that the prototype model and the Nyström method are equivalent when $\mathrm{rank}(\mathbf{W})=\mathrm{rank}(\mathbf{K})$; that is, the kernel matrix $\mathbf{K}$ is low rank. However, it holds in general that $\mathrm{rank}(\mathbf{K})\gg c\ge\mathrm{rank}(\mathbf{W})$, where the two models are not equivalent.

4.2 Lower Bound

Wang and Zhang (2013) showed that with $c = \mathcal{O}(k/\epsilon^2)$ columns chosen by the near-optimal+adaptive sampling algorithm, the prototype model satisfies $1+\epsilon$ relative-error bound. We establish a lower error bound in Theorem 2, which shows that at least $c \geq 2k\epsilon^{-1}$ columns must be chosen to attain the $1+\epsilon$ bound. This indicates there exists a gap between the upper bound in (Wang and Zhang, 2013) and our lower bound, and thus there is room of improvement. The proof of Theorem 2 is left to Appendix B.

Theorem 2 (Lower Bound of the Prototype Model) *Whatever column sampling algorithm is used, there exists an $n \times n$ SPSD matrix $\mathbf{K}$ such that the error incurred by the prototype model obeys:*

$$\big\|\mathbf{K} - \mathbf{C}\mathbf{U}^\star\mathbf{C}^T\big\|_F^2 \;\geq\; \frac{n-c}{n-k}\Big(1+\frac{2k}{c}\Big)\|\mathbf{K}-\mathbf{K}_k\|_F^2.$$

Here k is an arbitrary target rank, c is the number of selected columns, and $\mathbf{U}^\star = \mathbf{C}^\dagger\mathbf{K}(\mathbf{C}^\dagger)^T$.

5. Column Sampling Algorithms

In Section 5.1 we introduce the column sampling algorithms in the literature. In Section 5.2 we improve the bound of the near-optimal+adaptive sampling algorithm (Wang and Zhang, 2013), and the obtained upper bound matches the lower bound up to a constant factor. In Section 5.3 we develop a more efficient column sampling algorithm which we call the uniform+adaptive^2 algorithm. In Section 5.4 we discuss the possibility of making uniform+adaptive^2 more scalable.

5.1 Related Work

Column selection is an important matrix sketching approach that enables expensive matrix computations to be performed on much a smaller matrix. The column selection problem has been widely studied in the theoretical computer science community (Boutsidis et al., 2014; Mahoney, 2011; Guruswami and Sinop, 2012; Woodruff, 2014) and the numerical linear algebra community (Gu and Eisenstat, 1996; Stewart, 1999), and numerous algorithms have been devised and analyzed. Here we focus on some provable algorithms studied in the theoretical computer science community.

The adaptive sampling algorithm devised by Deshpande et al. (2006) (see Algorithm 2) is the most relevant to this paper. The adaptive sampling algorithm has strong error bound (Deshpande et al., 2006; Wang and Zhang, 2013; Boutsidis et al., 2014) and good empirical performance (Kumar et al., 2012). Particularly, Wang and Zhang (2013) proposed an algorithm that combines the near-optimal column sampling algorithm (Boutsidis et al., 2014) and the adaptive sampling algorithm (Deshpande et al., 2006). They showed that by selecting $c = \mathcal{O}(k\epsilon^{-2})$ columns of $\mathbf{K}$ to form $\mathbf{C}$, it holds that

$$\mathbb{E}\big\|\mathbf{K} - \mathbf{C}\big(\mathbf{C}^\dagger\mathbf{K}(\mathbf{C}^\dagger)^T\big)\mathbf{C}^T\big\|_F \;\leq\; (1+\epsilon)\|\mathbf{K}-\mathbf{K}_k\|_F.$$

This error bound was the tightest among all the feasible algorithms for SPSD matrix approximation.

Algorithm 2 The Adaptive Sampling Algorithm.

1: **Input:** a residual matrix $\mathbf{B} \in \mathbb{R}^{n\times n}$ and number of selected columns c ($< n$).
2: Compute sampling probabilities $p_j = \|\mathbf{b}_{:j}\|_2^2/\|\mathbf{B}\|_F^2$ for $j = 1, \cdots, n$;
3: Select c indices in c i.i.d. trials, in each trial the index j is chosen with probability p_j;
4: **return** an index set containing the indices of the selected columns.

5.2 Near Optimal Column Selection for SPSD Matrix Approximation

The error bound of near-optimal+adaptive can be improved by a factor of ϵ by exploiting the latest results of Boutsidis and Woodruff (2014). Using the same algorithm except for different c_2 (i.e. the number of columns selected by adaptive sampling), we obtain the following stronger theorem. Recall from Theorem 2 that the lower bound is $c \geq \Omega\big(2k\epsilon^{-1}(1+o(1))\big)$. Thus the near-optimal+adaptive algorithm is optimal up to a constant factor. The proof of the theorem is left to Appendix 3.

Theorem 3 (Near-Optimal+Adaptive) *Given a symmetric matrix $\mathbf{K} \in \mathbb{R}^{n\times n}$ and a target rank k, the algorithm samples totally $c = 3k\epsilon^{-1}\big(1+o(1)\big)$ columns of $\mathbf{K}$ to construct the approximation. Then*

$$\mathbb{E}\big\|\mathbf{K} - \mathbf{C}\big(\mathbf{C}^\dagger\mathbf{K}(\mathbf{C}^\dagger)^T\big)\mathbf{C}^T\big\|_F \;\leq\; (1+\epsilon)\|\mathbf{K}-\mathbf{K}_k\|_F.$$

The algorithm costs $\mathcal{O}\big(n^2c + nk^3\epsilon^{-2/3}\big)$ time and $\mathcal{O}(nc)$ memory in computing $\mathbf{C}$.

Despite its optimal error bound, the near-optimal+adaptive algorithm lacks of practicality. The implementation is complicated and difficult. Its main component—the near-optimal algorithm (Boutsidis et al., 2014)—is highly iterative and therefore not suitable for parallel computing. Every step of the near-optimal algorithm requires the full observation of $\mathbf{K}$ and there is no hope to avoid this. Thus we propose to use uniform sampling to replace the near-optimal algorithm. Although the obtained uniform+adaptive^2 algorithm also has quadratic time complexity and requires the full observation of $\mathbf{K}$, there may be some way to making it more efficient. See the discussions in Section 5.4.

5.3 The Uniform+Adaptive^2 Column Sampling Algorithm

In this paper we propose a column sampling algorithm which is efficient, effective, and very easy to be implemented. The algorithm consists of a uniform sampling step and two adaptive sampling steps, so we call it *the uniform+adaptive^2 algorithm*. The algorithm is described in Algorithm 3 and analyzed in Theorem 4. The proof is left to Appendix D.

It is worth mentioning that our uniform+adaptive^2 algorithm is a special instance of the adaptive-full algorithm of (Kumar et al., 2012, Figure 3). The adaptive-full algorithm consists of random initialization and multiple adaptive sampling steps. Using multiple adaptive sampling steps can surely reduce the approximation error. However, the update of sampling probability in each step is expensive, so we choose to do only two steps. The adaptive-full algorithm of (Kumar et al., 2012, Figure 3) is merely a heuristic scheme without theoretical guarantee; our result provides theoretical justification for the adaptive-full algorithm.

Algorithm 3 The Uniform+Adaptive^2 Algorithm.

1: **Input:** an $n \times n$ symmetric matrix $\mathbf{K}$, target rank k, error parameter $\epsilon \in (0, 1]$, matrix coherence μ.
2: **Uniform Sampling.** Uniformly sample
$$c_1 = 20\mu k \log\big(20k\big)$$
columns of $\mathbf{K}$ without replacement to construct $\mathbf{C}_1$;
3: **Adaptive Sampling.** Sample
$$c_2 = 17.5k/\epsilon$$
columns of $\mathbf{K}$ to construct $\mathbf{C}_2$ using the adaptive sampling algorithm (Algorithm 2) according to the residual $\mathbf{K} - \mathcal{P}_{\mathbf{C}_1}(\mathbf{K})$;
4: **Adaptive Sampling.** Sample
$$c_3 = 10k/\epsilon$$
columns of $\mathbf{K}$ to construct $\mathbf{C}_3$ using the adaptive sampling algorithm (Algorithm 2) according to the residual $\mathbf{K} - \mathcal{P}_{[\mathbf{C}_1,\, \mathbf{C}_2]}(\mathbf{K})$;
5: **return** $\mathbf{C} = [\mathbf{C}_1, \mathbf{C}_2, \mathbf{C}_3]$.

Theorem 4 (Uniform+Adaptive^2) *Given an $n \times n$ symmetric matrix $\mathbf{K}$ and a target rank k, let μ_k denote the matrix coherence of $\mathbf{K}$. Algorithm 3 samples totally*

$$c = \mathcal{O}\big(k\epsilon^{-1} + \mu_k k \log k\big)$$

columns of $\mathbf{K}$ to construct the approximation. The error bound

$$\big\|\mathbf{K} - \mathbf{C}\big(\mathbf{C}^\dagger \mathbf{K} (\mathbf{C}^\dagger)^T\big)\mathbf{C}^T\big\|_F \;\leq\; \big(1+\epsilon\big)\big\|\mathbf{K} - \mathbf{K}_k\big\|_F$$

holds with probability at least 0.7. The algorithm costs $\mathcal{O}(n^2 c)$ time and $\mathcal{O}(nc)$ space in computing $\mathbf{C}$.

Remark 5 *Theoretically, Algorithm 3 requires computing the matrix coherence of $\mathbf{K}$ in order to determine c_1 and c_2. However, computing the matrix coherence is as hard as computing the truncated SVD; even the fast approximation approach of Drineas et al. (2012) is not feasible here because $\mathbf{K}$ is a square matrix. The use of the matrix coherence here is merely for theoretical analysis; setting the parameter μ in Algorithm 3 to be exactly the matrix coherence does not certainly result in the highest accuracy. Empirically, the resulting approximation accuracy is not sensitive to the value of μ. Thus we suggest setting μ in Algorithm 3 as a constant (e.g. 1), rather than actually computing the matrix coherence.*

Table 2 presents comparisons between the near-optimal+adaptive algorithm and our uniform+adaptive^2 algorithm over the time cost, memory cost, number of passes through $\mathbf{K}$, the number of columns required to attain $1+\epsilon$ relative-error bound, and the hardness of implementation. Our algorithm is more time-efficient and pass-efficient than the near-optimal+adaptive algorithm, and the memory costs of the two algorithms are the same. To attain the same error bound, our algorithm needs to select $c = \mathcal{O}\big(k\epsilon^{-1} + \mu_k k \log k\big)$ columns, which is a little larger than that of the near-optimal+adaptive algorithm.

Table 2: Comparisons between the two sampling algorithms.

	Uniform+Adaptive^2	Near-Optimal+Adaptive
Time	$\mathcal{O}(n^2 c)$	$\mathcal{O}(n^2 c + nk^3\epsilon^{-2/3})$
Memory	$\mathcal{O}(nc)$	$\mathcal{O}(nc)$
#Passes	2	4
#Columns	$\mathcal{O}\big(k\epsilon^{-1} + \mu_k k \log k\big)$	$\mathcal{O}\big(k\epsilon^{-1}\big)$
Implement	Easy to implement	Hard to implement

Algorithm 4 The Incomplete Uniform+Adaptive^2 Algorithm.

1: **Input:** part of an $n \times n$ symmetric matrix $\mathbf{K}$.
2: **Uniform Sampling.** Uniformly sample c_1 columns of $\mathbf{K}$ without replacement to construct $\mathbf{C}_1$;
3: **Adaptive Sampling.** Uniformly sample $o(n)$ columns of $\mathbf{K}$ to form $\mathbf{K}'$; then sample c_2 columns of $\mathbf{K}'$ to construct $\mathbf{C}_2$ using the adaptive sampling algorithm (Algorithm 2) according to the residual $\mathbf{K}' - \mathcal{P}_{\mathbf{C}_1}(\mathbf{K}')$;
4: **Adaptive Sampling.** Uniformly sample $o(n)$ columns of $\mathbf{K}$ to form $\mathbf{K}''$; then sample c_3 columns of $\mathbf{K}''$ to construct $\mathbf{C}_3$ using the adaptive sampling algorithm (Algorithm 2) according to the residual $\mathbf{K}'' - \mathcal{P}_{[\mathbf{C}_1,\, \mathbf{C}_2]}(\mathbf{K}'')$;
5: **return** $\mathbf{C} = [\mathbf{C}_1, \mathbf{C}_2, \mathbf{C}_3]$.

5.4 Discussions

The two algorithms discussed in the above have strong theoretical guarantees, but they are not efficient enough for large-scale applications. First, their time complexities are quadratic in n. Second, they require the full observation of $\mathbf{K}$. In fact, at present no existing column selection algorithm satisfies the three properties simultaneously:

1. the time and memory costs are $\mathcal{O}(n)$;
2. only $\mathcal{O}(n)$ entries of $\mathbf{K}$ need to be observed;
3. relative-error bound holds in expectation or with high probability.

It is interesting to find such an algorithm, and it remains an open problem.

Nevertheless, uniform+adaptive^2 is a promising column selection algorithm for it may be adapted to satisfy the above three properties. The drawback of uniform+adaptive^2 is that computing the adaptive sampling probability costs quadratic time and requires the full observation of $\mathbf{K}$. There may be remedies for this problem. The adaptive-partial algorithm in (Kumar et al., 2012) satisfies the first two properties, but it lacks theoretical analysis. Another possibility is to first uniformly sample $o(n)$ columns and then down-sample to $\mathcal{O}(k/\epsilon)$ columns by adaptive sampling, which we describe in Algorithm 4. In this way, the first two properties can be satisfied, and it may be theoretically explained under the incoherent matrix assumption. We do not implement such heuristics for their theoretical property is completely unknown and they are beyond the scope of this paper.

Table 3: A summary of the datasets for kernel approximation.

Dataset	MNIST	Letters	PenDigit	Cpusmall	Mushrooms
#Instance	60,000	15,000	10,992	8,192	8,124
#Attribute	780	16	16	12	112
γ ($\eta = 0.5$)	≈ 1.50	0.155	0.045	0.031	0.850
γ ($\eta = 0.9$)	≈ 2.30	0.290	0.073	0.057	1.140

6.1 Experiment Setting

We perform experiments on several datasets collected on the LIBSVM website[2] where the data are scaled to [0,1]. We summarize the datasets in Table 3.

For each dataset, we generate a radial basis function (RBF) kernel matrix $\mathbf{K}$ defined by $k_{ij} = \exp(-\frac{1}{2\gamma^2}\|\mathbf{x}_i - \mathbf{x}_j\|_2^2)$. Here $\gamma > 0$ is the scaling parameter; the larger the scaling parameter γ is, the faster the spectrum of the kernel matrix decays (Gittens and Mahoney, 2013). The previous work has shown that for the same dataset, with different settings of γ, the sampling algorithms have very different performances. Instead of setting γ arbitrarily, we set γ in the following way.

Letting $p = \lceil 0.05n \rceil$, we define

$$\eta \triangleq \frac{\sum_{i=1}^{p} \lambda_i^2(\mathbf{K})}{\sum_{i=1}^{n} \lambda_i^2(\mathbf{K})} = \frac{\|\mathbf{K}_p\|_F^2}{\|\mathbf{K}\|_F^2}, \tag{7}$$

which denotes the ratio of the top 5% eigenvalues of the kernel matrix $\mathbf{K}$ to the all eigenvalues. In general, a large γ results in a large η. For each dataset, we use two different settings of γ such that $\eta = 0.5$ or $\eta = 0.9$.

The models and algorithms are all implemented in MATLAB. We run the algorithms on a workstation with Intel Xeon 2.40GHz CPUs, 24GB memory, and 64bit Windows Server 2008 system. To compare the running time, we set MATLAB in single thread mode by the command "maxNumCompThreads(1)". In the experiments we do not keep $\mathbf{K}$ in memory. We use a variant of Algorithm 1—we compute and store one block, instead of one column, of $\mathbf{K}$ at a time. We keep at most 1,000 columns of $\mathbf{K}$ in memory at a time.

2. http://www.csie.ntu.edu.tw/∼cjlin/libsvmtools/datasets/

We set the target rank k to be $k = \lceil n/100 \rceil$ in all the experiments unless otherwise specified. We evaluate the performance by

$$\text{Approximation Error} \;=\; \|\mathbf{K} - \tilde{\mathbf{K}}\|_F / \|\mathbf{K}\|_F, \tag{8}$$

where $\tilde{\mathbf{K}}$ is the approximation generated by each method.

To evaluate the quality of the approximate rank-k eigenvalue decomposition, we use *misalignment* to indicate the distance between the true eigenvectors $\mathbf{U}_k$ $(n \times k)$ and the approximate eigenvectors $\tilde{\mathbf{V}}_k$ $(n \times k)$:

$$\text{Misalignment} \;=\; \frac{1}{k}\left\|\mathbf{U}_k - \tilde{\mathbf{V}}_k \tilde{\mathbf{V}}_k^T \mathbf{U}_k\right\|_F^2 \;\in\; [0,1]. \tag{9}$$

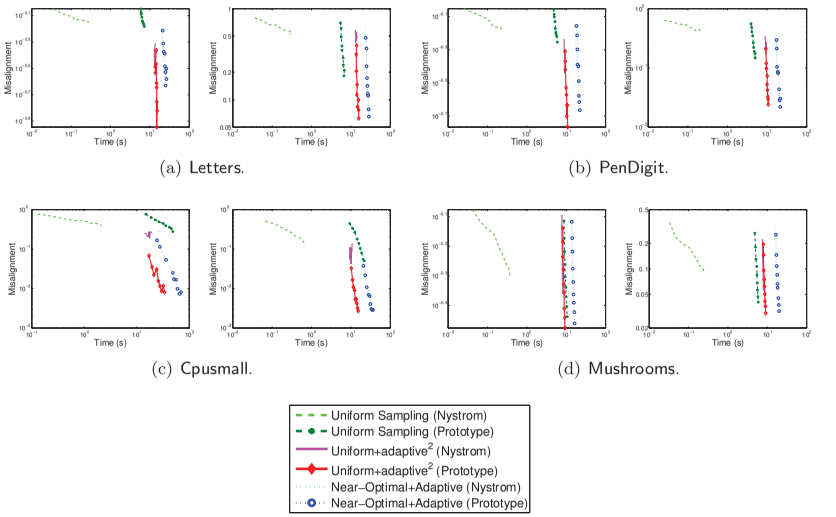
(e) Legend.

Figure 3: The number of selected columns c against the misalignment (log-scale) defined in (9). In each subfigure, the left corresponds to the RBF kernel matrix with $\eta = 0.5$, and the right corresponds to $\eta = 0.9$, where η is defined in (7).

6.2 Matrix Approximation Accuracy

In the first set of experiments, we compare the matrix approximation quality using the Frobenius norm approximation error defined in (8) as the metric.



(a) Letters. (b) PenDigit.

(c) Cpusmall. (d) Mushrooms.

(e) Legend.

Figure 4: The elapsed time (log-scale) against the misalignment (log-scale) defined in (9). In each subfigure, the left corresponds to the RBF kernel matrix with $\eta = 0.5$, and the right corresponds to $\eta = 0.9$, where η is defined in (7).

Every time when we do column sampling, we repeat each sampling algorithm 10 times and record the minimal approximation error of the 10 repeats. We report the average elapsed time of the 10 repeat rather than the total elapsed time because the 10 repeats can be done in parallel on 10 machines. We plot c against the approximation error in Figure 1. For the kernel matrices with $\eta = 0.9$, we plot c against the average elapsed time in Figure 2; for $\eta = 0.5$, the curve of the running time is very similar, so we do not show it.

The results show that our uniform+adaptive^2 algorithm achieves accuracy comparable with the near-optimal+adaptive algorithm. Especially, when c is large, these two algorithms have virtually the same accuracy, which agrees with our analysis: a large c implies a small error term ϵ, and the error bounds of the two algorithms coincide when ϵ is small. As for the running time, we can see that our uniform+adaptive^2 algorithm is much more efficient than the near-optimal+adaptive algorithm.

Particularly, the MNIST dataset has $60,000$ instances, and the $60,000 \times 60,000$ kernel matrix $\mathbf{K}$ does not fit in memory. The experiment shows that neither the prototype model nor the uniform+adaptive^2 algorithm require keeping $\mathbf{K}$ in memory.

6.3 Kernel Principal Component Analysis

In the second set of experiment, we apply the kernel approximation methods to approximately compute the rank $k = 3$ eigenvalue decomposition of the RBF kernel matrix. We use the *misalignment* defined in (9) as the metric, which reflects the distance between the true and the approximate eigenvectors. We report the average misalignment of the 20 repeats. We do not conduct experiments on the MNIST dataset because the true eigenvectors are too expensive to compute.

To evaluate the memory efficiency, we plot c against the misalignment in Figure 3. The results show that the two non-uniform sampling algorithms are significantly better than uniform sampling. The performance of our uniform+adaptive^2 algorithm is nearly the same to the near-optimal+adaptive algorithm.

To evaluate the time efficiency, we plot the elapsed time against the misalignment in Figure 4. Though the uniform sampling algorithm is the most efficient in most cases, its accuracy is unsatisfactory. In terms of time efficiency, the uniform+adaptive^2 algorithm is better than the near-optimal+adaptive algorithm.

The experiment on the kernel PCA shows that the prototype model with the uniform + adaptive^2 column sampling algorithm achieves the best performance. Though the Nyström method with uniform sampling is the most efficient, its resulting misalignment is worse by an order of magnitude. Therefore, when applied to speedup eigenvalue decomposition, the Nyström method may not be a good choice, especially when high accuracy is required.

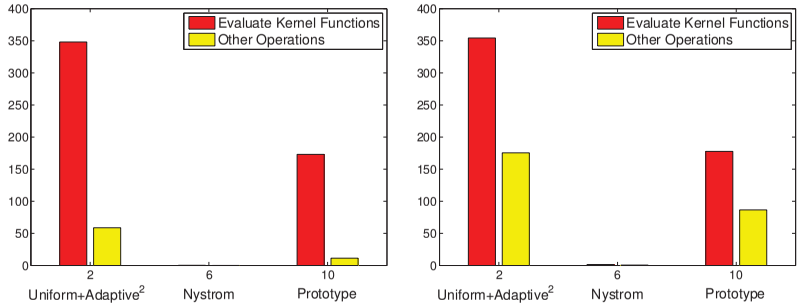
6.4 Separating the Time Costs

Besides the total elapsed time, the readers may be interested in the time cost of each step, especially when the data do no fit in memory. We run the Nyström method and the prototype model, each with uniform+adaptive^2 column sampling algorithm, on the MNIST dataset with $\gamma = 2.3$ (see Table 3). Notice that the $60,000 \times 60,000$ kernel matrix does not fit in memory, so we keep at most $1,000$ columns of the kernel matrix in memory at a time. We set $c = 50$ or 500 and repeat the procedure 20 times and record the average elapsed time. In Figure 5 we separately show the time costs of the uniform+adaptive^2 algorithm and the computation of the intersection matrices. In addition, we separate the time costs of evaluating the kernel functions and all the other computations (e.g. SVD of $\mathbf{C}$ and matrix multiplications).

We can see from Figure 5 that when $\mathbf{K}$ does not fit in memory, the computation of the kernel matrix contributes to the most of the computations. By comparing the two subfigures in Figure 5, we can see that as c increases, the costs of computing the kernel matrix barely change, but the costs of other matrix operations significantly increase.

7. The Spectral Shifting Model

All the low-rank approximation methods work well only when the bottom eigenvalues of $\mathbf{K}$ are near zero. In this section we develop extensions of the three SPSD matrix approximation models to tackle matrices with relatively big bottom eigenvalues. We call the proposed method the *spectral shifting (SS) model* and describe it in Algorithm 5. We show that the SS model has stronger error bound than the prototype model.



(a) $c = 50$ (b) $c = 500$

Figure 5: The time costs (s) of the uniform+adaptive^2 algorithm and the computation of the intersection matrices.

Algorithm 5 The Spectral Shifting Method.

Input: an $n \times n$ SPSD matrix $\mathbf{K}$, a target rank k, the number of sampled columns c, the oversampling parameter l.
// (optional) approximately do the initial spectral shifting
$\mathbf{\Omega} \longleftarrow n \times l$ standard Gaussian matrix;
$\mathbf{Q} \longleftarrow$ the l orthonormal basis of $\mathbf{K\Omega} \in \mathbb{R}^{n \times l}$;
$s \longleftarrow$ sum of the top k singular values of $\mathbf{Q}^T\mathbf{K} \in \mathbb{R}^{l \times n}$;
$\tilde{\delta} = \frac{1}{n-k}\big(\mathrm{tr}(\mathbf{K}) - s\big) \approx \bar{\delta}$;
$\bar{\mathbf{K}} \leftarrow \mathbf{K} - \tilde{\delta}\mathbf{I}_n \in \mathbb{R}^{n \times n}$;
// perform sketching, e.g. random projection or column selection
$\bar{\mathbf{C}} = \bar{\mathbf{K}}\mathbf{P}$, where $\mathbf{P}$ is an $n \times c$ random projection or selection matrix;
Optional: replace $\bar{\mathbf{C}}$ by its orthonormal bases;
// compute the spectral shifting parameter and the intersection matrix
$\delta^{\mathrm{ss}} \longleftarrow \frac{1}{n-\mathrm{rank}(\bar{\mathbf{C}})}\Big(\mathrm{tr}(\mathbf{K}) - \mathrm{tr}\big(\bar{\mathbf{C}}^\dagger\mathbf{K}\bar{\mathbf{C}}\big)\Big)$;
$\mathbf{U}^{\mathrm{ss}} \longleftarrow \bar{\mathbf{C}}^\dagger\mathbf{K}(\bar{\mathbf{C}}^\dagger)^T - \delta^{\mathrm{ss}}(\bar{\mathbf{C}}^T\bar{\mathbf{C}})^\dagger$;
return the approximation $\tilde{\mathbf{K}}_c^{\mathrm{ss}} = \bar{\mathbf{C}}\mathbf{U}^{\mathrm{ss}}\bar{\mathbf{C}}^T + \delta^{\mathrm{ss}}\mathbf{I}_n$.

In Section 7.1 we formulate the SS model. In Section 7.2 we study SS from an optimization perspective. In Section 7.3 we show that SS has better error bound than the prototype model. Especially, with the near-optimal+adaptive column sampling algorithm, SS demonstrates much stronger error bound than the existing matrix approximation methods. In Section 7.4 we provide an efficient algorithm for computing the initial spectral shifting term. In Section 7.5 we discuss how to combine spectral shifting with other kernel approximation methods.

7.1 Model Formulation

The spectral shifting (SS) model is defined by

$$\tilde{\mathbf{K}}_c^{\mathrm{ss}} \;=\; \bar{\mathbf{C}}\mathbf{U}^{\mathrm{ss}}\bar{\mathbf{C}}^T + \delta^{\mathrm{ss}}\mathbf{I}_n. \tag{10}$$

Here $\delta^{\mathrm{ss}} \geq 0$ is called the spectral shifting term. This approximation is computed in three steps. Firstly, (approximately) compute the initial spectral shifting term

$$\bar{\delta} \;=\; \frac{1}{n-k}\Big(\mathrm{tr}(\mathbf{K}) - \sum_{j=1}^{k}\sigma_j(\mathbf{K})\Big), \tag{11}$$

and then perform spectral shifting $\bar{\mathbf{K}} = \mathbf{K} - \bar{\delta}\mathbf{I}_n$, where $k \leq c$ is the target rank. This step is optional. Due to Theorem 6 and Remark 7, SS is better than the prototype model even if $\bar{\delta} = 0$; however, without this step, the quantity of the improvement contributed by SS is unknown. Secondly, draw a column selection matrix $\mathbf{P}$ and form the sketch $\bar{\mathbf{C}} = \bar{\mathbf{K}}\mathbf{P}$. Finally, with $\bar{\mathbf{C}}$ at hand, compute δ^{ss} and $\mathbf{U}^{\mathrm{ss}}$ by

$$\begin{aligned}\delta^{\mathrm{ss}} \;&=\; \frac{1}{n-\mathrm{rank}(\bar{\mathbf{C}})}\Big(\mathrm{tr}(\mathbf{K}) - \mathrm{tr}\big(\bar{\mathbf{C}}^\dagger\mathbf{K}\bar{\mathbf{C}}\big)\Big),\\ \mathbf{U}^{\mathrm{ss}} \;&=\; \bar{\mathbf{C}}^\dagger\mathbf{K}(\bar{\mathbf{C}}^\dagger)^T - \delta^{\mathrm{ss}}(\bar{\mathbf{C}}^T\bar{\mathbf{C}})^\dagger.\end{aligned} \tag{12}$$

We will show that $\tilde{\mathbf{K}}_c^{\mathrm{ss}}$ is positive (semi)definite if $\mathbf{K}$ is positive (semi)definite.

However, when the bottom eigenvalues of $\mathbf{K}$ are small, the computed spectral shifting term is small, where there is little difference between SS and the prototype model, and the spectral shifting operation is not advised.

7.2 Optimization Perspective

The SS model is an extension of the prototype model from the optimization perspective. Given an SPSD matrix $\mathbf{K}$, the prototype model computes the sketch $\mathbf{C} = \mathbf{K}\mathbf{P}$ and the intersection matrix

$$\mathbf{U}^\star \;=\; \mathbf{C}^\dagger\mathbf{K}(\mathbf{C}^\dagger)^T \;=\; \operatorname*{argmin}_{\mathbf{U}} \|\mathbf{K} - \mathbf{C}\mathbf{U}\mathbf{C}^T\|_F^2. \tag{13}$$

Analogously, with the sketch $\bar{\mathbf{C}} = \bar{\mathbf{K}}\mathbf{P} = \mathbf{K}\mathbf{P} - \bar{\delta}\mathbf{P}$ at hand, SS is obtained by solving

$$\big(\mathbf{U}^{\mathrm{ss}}, \delta^{\mathrm{ss}}\big) \;=\; \operatorname*{argmin}_{\mathbf{U},\delta} \big\|\mathbf{K} - \bar{\mathbf{C}}\mathbf{U}\bar{\mathbf{C}}^T - \delta\mathbf{I}_n\big\|_F^2, \tag{14}$$

obtaining the intersection matrix $\mathbf{U}^{\mathrm{ss}}$ and the spectral shifting term δ^{ss}. By analyzing the optimization problem (14), we obtain the following theorem. Its proof is in Appendix E.

Theorem 6 *The pair $(\delta^{ss}, \mathbf{U}^{ss})$ defined in (12) is the global minimizer of problem (14), which indicates that using any other $(\delta, \mathbf{U})$ to replace $(\delta^{ss}, \mathbf{U}^{ss})$ results in a larger approximation error. Furthermore, if $\mathbf{K}$ is positive (semi)definite, then the approximation $\bar{\mathbf{C}}\mathbf{U}^{ss}\bar{\mathbf{C}}^T + \delta^{ss}\mathbf{I}_n$ is also positive (semi)definite.*

Remark 7 *The optimization perspective indicates the superiority of SS. Suppose we skip the initial spectral shifting step and simply set $\bar{\delta} = 0$. Then $\bar{\mathbf{C}} = \mathbf{C}$. If the constraint $\delta = 0$ is to the optimization problem (14), then (14) will become identical to the prototype model (13). Obviously, adding this constraint will make the optimal objective function value get worse, so the optimal objective function value of (14) is always less than or equal to (13). Hence, without the initial spectral shifting step, SS is still more accurate than the prototype model.*

7.3 Error Analysis

The following theorem indicates that the SS model with any spectral shifting term $\delta \in (0, \bar{\delta}]$ has a stronger bound than the prototype model. The proof is in Appendix F.

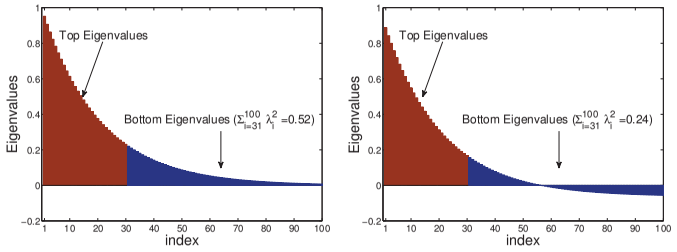
Theorem 8 *Suppose there is a sketching matrix $\mathbf{P} \in \mathbb{R}^{n\times c}$ such that for any $n \times n$ symmetric matrix $\mathbf{A}$ and target rank k ($\ll n$), by forming $\mathbf{C} = \mathbf{A}\mathbf{P}$, the prototype model satisfies the error bound*

$$\big\|\mathbf{A} - \mathbf{C}\mathbf{C}^\dagger\mathbf{A}(\mathbf{C}^\dagger)^T\mathbf{C}^T\big\|_F^2 \;\leq\; \eta\,\big\|\mathbf{A} - \mathbf{A}_k\big\|_F^2$$

for certain $\eta > 0$. Let $\mathbf{K}$ be any $n \times n$ SPSD matrix, $\tilde{\delta} \in (0, \bar{\delta}]$ be the initial spectral shifting term where $\bar{\delta}$ is defined in (11), $\bar{\mathbf{K}} = \mathbf{K} - \tilde{\delta}\mathbf{I}_n$, $\bar{\mathbf{C}} = \bar{\mathbf{K}}\mathbf{P}$, and $\tilde{\mathbf{K}}_c^{ss}$ be the SS model defined in (10). Then

$$\big\|\mathbf{K} - \tilde{\mathbf{K}}_c^{ss}\big\|_F^2 \;\leq\; \eta\,\big\|\bar{\mathbf{K}} - \bar{\mathbf{K}}_k\big\|_F^2 \;\leq\; \eta\,\big\|\mathbf{K} - \mathbf{K}_k\big\|_F^2.$$

We give an example in Figure 6 to illustrate the intuition of spectral shifting. We use the toy matrix $\mathbf{K}$: an $n\times n$ SPSD matrix whose the t-th eigenvalue is 1.05^{-t}. We set $n = 100$ and $k = 30$, and hence $\bar{\delta} = 0.064$. From the plot of the eigenvalues we can see that the "tail" of the eigenvalues becomes thinner after the spectral shifting. Specifically, $\|\mathbf{K} - \mathbf{K}_k\|_F^2 = 0.52$ and $\|\bar{\mathbf{K}} - \bar{\mathbf{K}}_k\|_F^2 \leq 0.24$. From Theorem 8 we can see that if $\|\mathbf{K} - \mathbf{C}\mathbf{C}^\dagger\mathbf{K}(\mathbf{C}^\dagger)^T\mathbf{C}^T\|_F \leq 0.52\eta$, then $\|\mathbf{K} - \tilde{\mathbf{K}}_c^{\mathrm{ss}}\|_F \leq 0.24\eta$. This indicates that SS has much stronger error bound than the prototype model.



(a) Before spectral shifting. (b) After spectral shifting.

Figure 6: We plot the eigenvalues of $\mathbf{K}$ in Figure 6(a) and $\bar{\mathbf{K}} = \mathbf{K} - \bar{\delta}\mathbf{I}_{100}$ in Figure 6(b).

The following theorem shows an error bound of the SS model, which is stronger than the prototype model, especially when the bottom $n-k$ eigenvalues of $\mathbf{K}$ are big. The proof is in Appendix F.

Theorem 9 *Suppose there is a sketching matrix $\mathbf{P} \in \mathbb{R}^{n\times c}$ such that for any $n \times n$ symmetric matrix $\mathbf{A}$ and target rank k ($\ll n$), by forming the sketch $\mathbf{C} = \mathbf{AP}$, the prototype model satisfies the error bound*

$$\left\|\mathbf{A} - \mathbf{C}\mathbf{C}^\dagger\mathbf{A}(\mathbf{C}^\dagger)^T\mathbf{C}^T\right\|_F^2 \;\le\; \eta\left\|\mathbf{A}-\mathbf{A}_k\right\|_F^2$$

for certain $\eta > 0$. Let $\mathbf{K}$ be any $n \times n$ SPSD matrix, $\bar{\delta}$ defined in (11) be the initial spectral shifting term, and $\tilde{\mathbf{K}}_c^{ss}$ be the SS model defined in (10). Then

$$\left\|\mathbf{K} - \tilde{\mathbf{K}}_c^{ss}\right\|_F^2 \;\le\; \eta\left(\left\|\mathbf{K}-\mathbf{K}_k\right\|_F^2 - \frac{\left[\sum_{i=k+1}^n \lambda_i(\mathbf{K})\right]^2}{n-k}\right).$$

If $\bar{\mathbf{C}}$ contains the columns of $\bar{\mathbf{K}}$ sampled by the near-optimal+adaptive algorithm in Theorem 3, which has the strongest bound, then the error bound incurred by SS is given in the following corollary.

Corollary 10 *Suppose we are given any SPSD matrix $\mathbf{K}$ and we sample $c = \mathcal{O}(k/\epsilon)$ columns of $\bar{\mathbf{K}}$ to form $\bar{\mathbf{C}}$ using the near-optimal+adaptive column sampling algorithm (Theorem 3). Then the inequality holds:*

$$\mathbb{E}\left\|\mathbf{K} - \tilde{\mathbf{K}}_c^{ss}\right\|_F^2 \le (1+\epsilon)\left(\left\|\mathbf{K}-\mathbf{K}_k\right\|_F^2 - \frac{\left[\sum_{i=k+1}^n \lambda_i(\mathbf{K})\right]^2}{n-k}\right).$$

Here we give an example to demonstrate the superiority of SS over the prototype model, the Nyström method, and even the truncated SVD of the same scale.

Example 1 *Let $\mathbf{K}$ be an $n \times n$ SPSD matrix such that $\lambda_1(\mathbf{K}) \ge \cdots \ge \lambda_k(\mathbf{K}) > \theta = \lambda_{k+1}(\mathbf{K}) = \cdots = \lambda_n(\mathbf{K}) > 0$. By sampling $c = \mathcal{O}(k)$ columns by the near-optimal+adaptive algorithm (Theorem 3), we have that*

$$\left\|\mathbf{K} - \tilde{\mathbf{K}}_c^{ss}\right\|_F^2 \;=\; 0$$

and that

$$(n-c)\theta^2 \;=\; \left\|\mathbf{K}-\mathbf{K}_c\right\|_F^2 \;\le\; \left\|\mathbf{K}-\tilde{\mathbf{K}}_c^{proto}\right\|_F^2 \;\le\; \left\|\mathbf{K}-\tilde{\mathbf{K}}_c^{nys}\right\|_F^2.$$

Here $\tilde{\mathbf{K}}_c^{proto}$ and $\tilde{\mathbf{K}}_c^{nys}$ respectively denote the approximation formed by the prototype model and the Nyström method. In this example the SS model is far better than the other models if we set θ as a large constant.

7.4 Approximately Computing $\bar{\delta}$

The SS model uses $\bar{\delta}$ as the initial spectral shifting term. However, computing $\bar{\delta}$ according to (11) requires the partial eigenvalue decomposition which costs $\mathcal{O}(n^2k)$ time and $\mathcal{O}(n^2)$ memory. For large-scale data, one can simply set $\bar{\delta} = 0$; Remark 7 shows that SS with this setting still works better than the prototype model. For medium-scale data, one can approximately compute $\bar{\delta}$ by the algorithm devised and analyzed in this subsection.

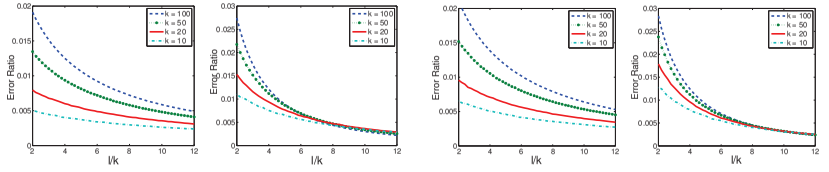
We depict the algorithm in Lines 2–6 of Algorithm 5. The performance of the approximation is analyzed in the following theorem.

Theorem 11 *Let $\bar{\delta}$ be defined in (11) and $\tilde{\delta}$, k, l, n be defined in Algorithm 5. The following inequality holds:*

$$\mathbb{E}\left[\left|\bar{\delta}-\tilde{\delta}\right| / \bar{\delta}\right] \;\le\; k/\sqrt{l},$$

where the expectation is taken w.r.t. the Gaussian random matrix $\mathbf{\Omega}$ in Algorithm 5. Lines 2–6 in Algorithm 5 compute $\tilde{\delta}$ in $\mathcal{O}(n^2l)$ time and $\mathcal{O}(nl)$ memory.

Here we empirically evaluate the accuracy of the approximation to $\bar{\delta}$ (Lines 2–6 in Algorithm 5) proposed in Theorem 11. We use the RBF kernel matrices with the scaling parameter γ listed Table 3. We use the error ratio $|\bar{\delta}-\tilde{\delta}|/\bar{\delta}$ to evaluate the approximation quality. We repeat the experiments 20 times and plot l/k against the average error ratio in Figure 7. Here $\tilde{\delta}$, l, and k are defined in Theorem 11. We can see that the approximation of $\bar{\delta}$ has high quality: when $l = 4k$, the error ratios are less than 0.03 in all cases, no matter whether the spectrum of $\mathbf{K}$ decays fast or slow.



(a) Letters (b) PenDigit

Figure 7: The ratio $\frac{l}{k}$ against the error $|\bar{\delta}-\tilde{\delta}|/\bar{\delta}$. In each subfigure, the left corresponds to the RBF kernel matrix with $\eta = 0.5$, and the right corresponds to $\eta = 0.9$, where η is defined in (7).

7.5 Combining with Other Matrix Approximation Methods

There are many other matrix approximation approaches such as the ensemble Nyström method (Kumar et al., 2012) and MEKA (Si et al., 2014). In fact, the key components of the ensemble Nyström method and MEKA are the Nyström method, which can be straightforwardly replaced by other matrix approximation methods such as the SS model.

The ensemble Nyström method improves the Nyström method by running the Nyström method t times and combine the samples to construct the kernel approximation:

$$\tilde{\mathbf{K}}^{\text{ens}}_{t,c} = \sum_{i=1}^{t} \mu^{(i)} \mathbf{C}^{(i)} \mathbf{W}^{(i)\dagger} \mathbf{C}^{(i)T},$$

where $\mu^{(1)}, \cdots, \mu^{(t)}$ are the weights of the samples, and a simple but effective strategy is to set the weights as $\mu^{(1)} = \cdots = \mu^{(t)} = \frac{1}{t}$. However, the time and memory costs of computing $\mathbf{C}$ and $\mathbf{U}$ are respectively t times as much as that of its base method (e.g. the Nyström method), and the ensemble Nyström method needs to use the Sherman-Morrison-Woodbury formula t times to combine the samples. When executed on a single machine, the accuracy gained by the ensemble may not worth the t times more time and memory costs.

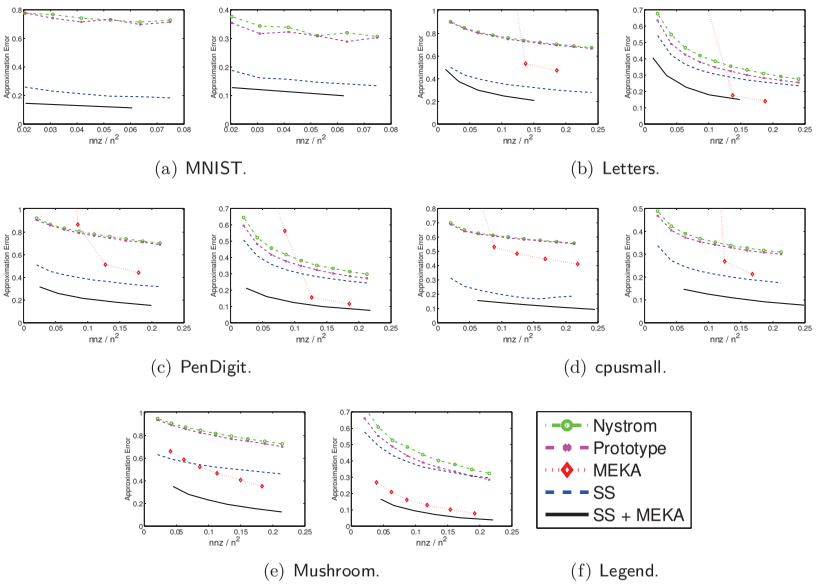
MEKA is reported to be the state-of-the-art kernel approximation method. It exploits the block-diagonal structure of kernel matrices, and outputs an $n \times c$ sparse matrix $\mathbf{C}$ and a $c \times c$ small matrix $\mathbf{U}$ such that $\mathbf{K} \approx \mathbf{C}\mathbf{U}\mathbf{C}^T$. MEKA first finds the blocks by clustering the data into b clusters and permutes the kernel matrix accordingly. It then approximates the diagonal blocks by the Nyström method, *which can be replaced by other methods.* It finally approximates the off-diagonal blocks using the diagonal blocks. If the kernel matrix is partitioned into b^2 blocks, only b blocks among the b^2 blocks of $\mathbf{C}$ are nonzero, and the number of nonzero entries of $\mathbf{C}$ is at most $\text{nnz}(\mathbf{C}) = nc/b$. MEKA is thus much more memory efficient than the Nyström method. If we use the SS model to approximate the diagonal blocks, then the resulting MEKA approximation will be in the form $\mathbf{K} \approx \mathbf{C}\mathbf{U}\mathbf{C}^T + \delta_1 \mathbf{I} \oplus \cdots \oplus \delta_b \mathbf{I}$, where δ_i corresponds to the i-th diagonal block.

8. Empirically Evaluating the Spectral Shifting Model

We empirically evaluate the spectral shifting method by comparing the following kernel approximation models in terms of approximation quality and the generalization performance on Gaussian process regression.

- The Nyström method with the uniform+adaptive^2 algorithm.
- The prototype model with the uniform+adaptive^2 algorithm.
- The memory efficient kernel approximation (MEKA) method (Si et al., 2014), which approximates the diagonal blocks of the kernel matrix by the Nyström method. We use the code released by the authors with default settings.
- The spectral shifting (SS) model with the uniform+adaptive^2 algorithm.
- SS+MEKA: the same to MEKA except for using SS, rather than the Nyström method, to approximate the diagonal blocks.

Since the experiments are all done on a single machine, the time and memory costs of the ensemble Nyström method (Kumar et al., 2012) are t times larger. It would be unfair to directly do comparison with the ensemble Nyström method.



(a) MNIST. (b) Letters. (c) PenDigit. (d) cpusmall. (e) Mushroom. (f) Legend.

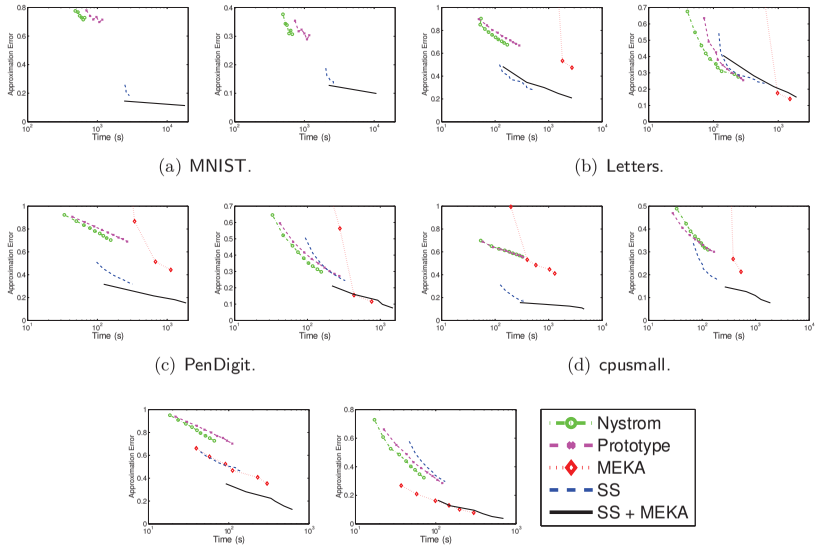
Figure 8: The memory cost against approximation error. Here "nnz" is number of nonzero entries in the sketch, namely, $\text{nnz}(\mathbf{C}) + \text{nnz}(\mathbf{U})$. In each subfigure, the left corresponds to the RBF kernel matrix with $\eta = 0.5$, and the right corresponds to $\eta = 0.9$, where η is defined in (7).

8.1 Experiments on Approximation Accuracy

We conduct experiments using the same setting as in Section 6.1. To demonstrate the effect of spectral shifting, we only consider a kernel matrix with slowly decaying spectrum. Thus we set η (defined in (7)) relatively small: $\eta = 0.5$ and $\eta = 0.9$. When η is near one, the spectral shifting term becomes near zero, and spectral shifting makes no difference.

We present the results in two ways: (1) Figure 8 plots the memory usage against the approximation error, where the memory usage is proportional to the number of nonzero entries of $\mathbf{C}$ and $\mathbf{U}$; (2) Figure 9 plots the elapsed time against the approximation error. The results have the following implications.

- Using the spectral shifting technique is better than without using it: SS and SS+MEKA are more accurate than the prototype model and MEKA, respectively. The advantage



(a) MNIST. (b) Letters.

(c) PenDigit. (d) cpusmall.

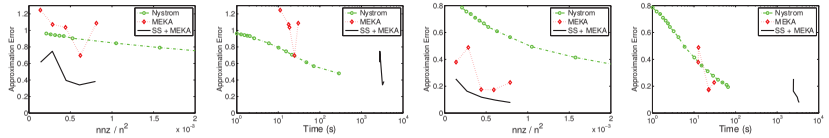
(e) Mushroom. (f) Legend.

Figure 9: The elapsed time (log-scale) against the approximation error. In each subfigure, the left corresponds to the RBF kernel matrix with $\eta = 0.5$, and the right corresponds to $\eta = 0.9$, where η is defined in (7).

of spectral shifting is particularly obvious when the spectrum of $\mathbf{K}$ decays slowly, i.e. when $\eta = 0.5$.

- SS and SS+MEKA are the best among the compared methods according to our experiments. Especially, if a high-quality approximation in limited memory is desired, SS+MEKA should be the best choice.
- The kernel matrix of the MNIST dataset is $60,000 \times 60,000$, which does not fit in the 24GB memory. This shows that the compared methods and sampling algorithm do not require keeping $\mathbf{K}$ in memory.

In addition, we conduct experiments on the large-scale dataset—covtype—which has 581,012 data instances. We compare among the Nyström method, MEKA, and MEKA+SS. The experiment setting is slightly different from the ones in the above. For each of the four methods, we use uniform sampling to select columns. As for the MEKA based methods, we set the number of clusters to be 30 (whereas the default is 10) to increase scalability. As



(a) $\eta \approx 0.5$ (b) $\eta \approx 0.9$

Figure 10: The experiments on the covtype dataset. We plot the memory cost against approximation error and plot the elapsed time (log-scale) against the approximation error.

Table 4: Summary of datasets for Gaussian process regression

	Plant	White Wine	Red Wine	Concrete	Energy (Heat)	Energy (Cool)	Housing
#Instance	9,568	4,898	1,599	1,030	768	768	506

γ	0.1	1	1	1	0.5	0.5	1
σ^2	0.1	0.01	0.01	0.0002	0.0005	0.001	0.005

for the spectral shifting method, we do not perform the initial spectral shifting. The results are plotted in Figure 10. The results show the effectiveness and scalability of the spectral shift method.

8.2 Experiments on Gaussian Process Regression

We apply the kernel approximation methods to Gaussian process regression (GPR). We assume that the training set is $\{(\mathbf{x}_1, y_1), ..., (\mathbf{x}_n, y_n)\}$, where $\mathbf{x}_i \in \mathbb{R}^d$ are input vectors and $y_i \in \mathbb{R}$ are the corresponding outputs. GPR is defined as

$$y = u + f(\mathbf{x}) + \epsilon, \quad \epsilon \sim \mathcal{N}(0, \sigma^2),$$

where $f(\mathbf{x})$ follows a Gaussian process with mean function 0 and kernel function $\kappa(\cdot, \cdot)$. Furthermore, we define the kernel matrix $\mathbf{K} \in \mathbb{R}^{n \times n}$, where the (i, j)-th entry of $\mathbf{K}$ is $\kappa(\mathbf{x}_i, \mathbf{x}_j)$.

For a test input $\mathbf{x}_*$, the prediction is given by

$$\hat{y}_* = \mathbf{k}^T(\mathbf{x}_*)(\mathbf{K} + \sigma^2\mathbf{I})^{-1}\mathbf{y},$$

where $\mathbf{y} = [y_1, \ldots, y_n]^T$ and $\mathbf{k}(\mathbf{x}_*) = [\kappa(\mathbf{x}_*, \mathbf{x}_1), \ldots, \kappa(\mathbf{x}_*, \mathbf{x}_n)]^T$. We apply different kernel approximation methods to approximate $\mathbf{K}$ and approximately compute $(\mathbf{K} + \sigma^2\mathbf{I})^{-1}\mathbf{y}$ according to Section 3.1. We evaluate the generalization performance using the mean squared error:

$$\text{MSE} = \frac{1}{m}\sum_{i=1}^{m}(y_{i*} - \hat{y}_{i*})^2,$$

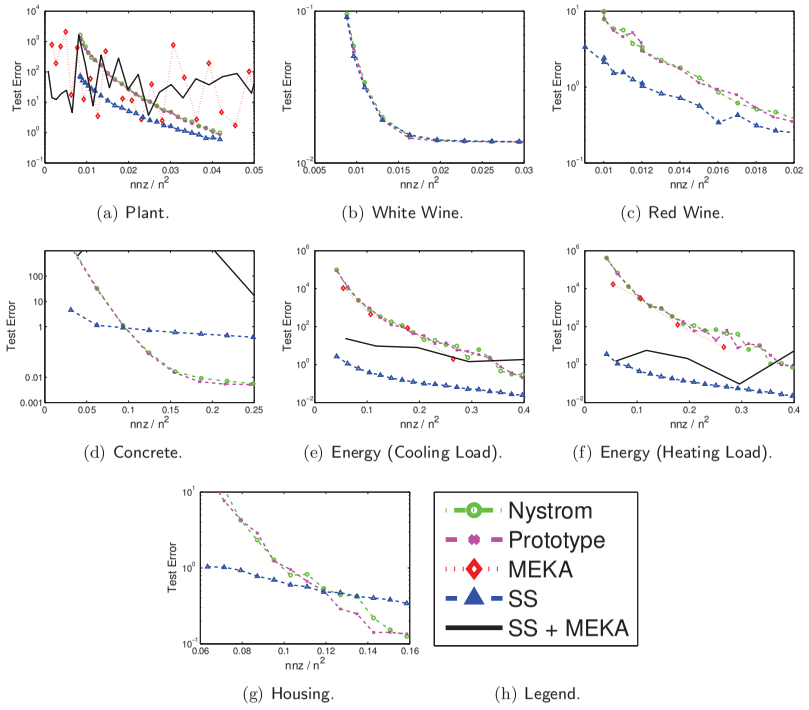

Figure 11: The results on Gaussian process regression. In the figures "nnz" is number of nonzero entries in the sketch, that is, $\mathrm{nnz}(\mathbf{C}) + \mathrm{nnz}(\mathbf{U})$.

where y_{i*} is the real output of the i-th test sample and m is the number of test samples.

We conduct experiment on seven datasets summarized in Table 4. We use the Gaussian RBF kernel and tune two parameters: the variance σ^2 and the kernel scaling parameter γ. Recall that there are seven compared methods and eight datasets, so the time cost would be daunting if we use cross-validation to find σ and γ for each method on each dataset. Thus we perform a five-fold cross-validation without using kernel approximation to predetermine the two parameters σ and γ, and the same parameters are used for all the kernel approximation methods. We list the obtained parameters in Table 4.

For each of the compared methods, we randomly hold 80% samples for training and the rest for test; we repeat this procedure 50 times and record the average MSE, the average

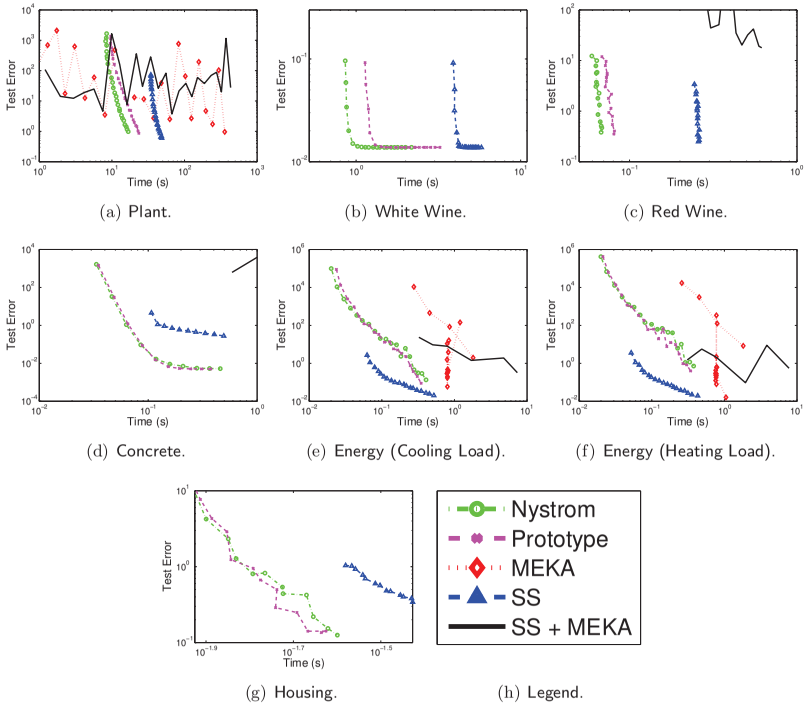

Figure 12: The results on Gaussian process regression.

elapsed time, and the average of the number of nonzero entries in the sketch. We plot $\frac{\mathrm{nnz}(\mathbf{C})+\mathrm{nnz}(\mathbf{U})}{n^2}$ against MSE in Figure 11 and the elapsed time against MSE in Figure 12.

Using the same amount of memory, our SS model achieves the best performance on the Plant, Red Wine, Energy (Cool), and Energy (Heat) datasets. On the Concrete and Housing datasets, using spectral shifting leads better results unless c is unreasonably large (e.g. $c > 0.1n$). However, using the same amount of time, the compared methods have competitive performance.

MEKA and SS+MEKA in general work very well, but they are numerically unstable on some of the randomly partitioned training data. On the White Wine, Housing, and Concrete datasets, MATLAB occasionally reports errors of numerical instability in approximating the off-diagonal blocks of $\mathbf{K}$ by solving some linear systems; when such happens, we do not report the corresponding test errors in the figures. MEKA and SS+MEKA are also sometimes unstable on the Plant and Red Wine datasets, though MATLAB does not report

error. Although MEKA and SS+MEKA have good performance in general, the numerical instability makes MEKA and SS+MEKA perform very poorly on a few among the 50 randomly partitioned training/test data, and consequently the average test errors become large. This problem can get avoided by repeating MEKA multiple times and choose the one that is stable. However, this will significantly increase the time cost.

9. Conclusions

We have provided an in-depth study of the prototype model for SPSD matrix approximation. First, we have shown that with $c = \mathcal{O}(k/\epsilon)$ columns sampled by the near-optimal+adaptive algorithm, the prototype model attains $1+\epsilon$ Frobenius norm relative-error bound. This upper bound matches the lower bound up to a constant factor. Second, we have devised a simple column selection algorithm called *uniform+adaptive*^{2}. The algorithm is efficient and very easy to implement, and it has near-optimal relative-error bound. Third, we have proposed an extension called the spectral shifting (SS) model. We have shown that SS has much stronger error bound than the low-rank approximation models, especially when the bottom eigenvalues are not sufficiently small.

Although the prototype model is not very time-efficient, we can resort to the approximate method provided by Wang et al. (2015) to obtain a faster solution to the prototype model. This faster solution requires only linear time and linear memory. The theoretical analysis of the fast solution heavily relies on that of the prototype model, so our established results are useful even if the prototype model itself is not the working horse in real-world applications. In addition, we have shown that the fast solution can also be naturally incorporated with the spectral shifting method.

Appendix A. Proof of Theorem 1

Proof Suppose that $\mathrm{rank}(\mathbf{W}) = \mathrm{rank}(\mathbf{K})$. We have that $\mathrm{rank}(\mathbf{W}) = \mathrm{rank}(\mathbf{C}) = \mathrm{rank}(\mathbf{K})$ because

$$\mathrm{rank}(\mathbf{K}) \;\geq\; \mathrm{rank}(\mathbf{C}) \;\geq\; \mathrm{rank}(\mathbf{W}). \tag{15}$$

Thus there exists a matrix $\mathbf{X}$ such that

$$\begin{bmatrix} \mathbf{K}_{21}^T \\ \mathbf{K}_{22} \end{bmatrix} \;=\; \mathbf{C}\mathbf{X}^T \;=\; \begin{bmatrix} \mathbf{W}\mathbf{X}^T \\ \mathbf{K}_{21}\mathbf{X}^T \end{bmatrix},$$

and it follows that $\mathbf{K}_{21} = \mathbf{X}\mathbf{W}$ and $\mathbf{K}_{22} = \mathbf{K}_{21}\mathbf{X}^T = \mathbf{X}\mathbf{W}\mathbf{X}^T$. Then we have that

$$\mathbf{K} \;=\; \begin{bmatrix} \mathbf{W} & (\mathbf{X}\mathbf{W})^T \\ \mathbf{X}\mathbf{W} & \mathbf{X}\mathbf{W}\mathbf{X}^T \end{bmatrix} \;=\; \begin{bmatrix} \mathbf{I} \\ \mathbf{X} \end{bmatrix} \mathbf{W} \begin{bmatrix} \mathbf{I} & \mathbf{X}^T \end{bmatrix}, \tag{16}$$

$$\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T \;=\; \begin{bmatrix} \mathbf{W} \\ \mathbf{X}\mathbf{W} \end{bmatrix} \mathbf{W}^\dagger \begin{bmatrix} \mathbf{W} & (\mathbf{X}\mathbf{W})^T \end{bmatrix} \;=\; \begin{bmatrix} \mathbf{I} \\ \mathbf{X} \end{bmatrix} \mathbf{W} \begin{bmatrix} \mathbf{I} & \mathbf{X}^T \end{bmatrix}. \tag{17}$$

Here the second equality in (17) follows from $\mathbf{W}\mathbf{W}^\dagger\mathbf{W} = \mathbf{W}$. We obtain that $\mathbf{K} = \mathbf{C}\mathbf{W}^\dagger\mathbf{C}$. Then we show that $\mathbf{K} = \mathbf{C}\mathbf{C}^\dagger\mathbf{K}(\mathbf{C}^\dagger)^T\mathbf{C}^T$.

Since $\mathbf{C}^\dagger = (\mathbf{C}^T\mathbf{C})^\dagger\mathbf{C}^T$, we have that

$$\mathbf{C}^\dagger \;=\; \big(\mathbf{W}(\mathbf{I}+\mathbf{X}^T\mathbf{X})\mathbf{W}\big)^\dagger\mathbf{W}\,[\mathbf{I},\,\mathbf{X}^T],$$

and thus

$$\begin{aligned} &\mathbf{C}^\dagger\mathbf{K}(\mathbf{C}^\dagger)^T\mathbf{W} \\ &= \big(\mathbf{W}(\mathbf{I}+\mathbf{X}^T\mathbf{X})\mathbf{W}\big)^\dagger\mathbf{W}(\mathbf{I}+\mathbf{X}^T\mathbf{X})\Big[\mathbf{W}(\mathbf{I}+\mathbf{X}^T\mathbf{X})\mathbf{W}\big(\mathbf{W}(\mathbf{I}+\mathbf{X}^T\mathbf{X})\mathbf{W}\big)^\dagger\mathbf{W}\Big] \\ &= \big(\mathbf{W}(\mathbf{I}+\mathbf{X}^T\mathbf{X})\mathbf{W}\big)^\dagger\mathbf{W}(\mathbf{I}+\mathbf{X}^T\mathbf{X})\mathbf{W}, \end{aligned}$$

where the second equality follows from Lemma 12 because $(\mathbf{I}+\mathbf{X}^T\mathbf{X})$ is positive definite. Similarly we have

$$\mathbf{W}\mathbf{C}^\dagger\mathbf{K}(\mathbf{C}^\dagger)^T\mathbf{W} \;=\; \mathbf{W}\big(\mathbf{W}(\mathbf{I}+\mathbf{X}^T\mathbf{X})\mathbf{W}\big)^\dagger\mathbf{W}(\mathbf{I}+\mathbf{X}^T\mathbf{X})\mathbf{W} \;=\; \mathbf{W}.$$

Thus we have

$$\mathbf{C}\mathbf{C}^\dagger\mathbf{K}(\mathbf{C}^\dagger)^T\mathbf{C} \;=\; \begin{bmatrix} \mathbf{I} \\ \mathbf{X} \end{bmatrix} \mathbf{W}\mathbf{C}^\dagger\mathbf{K}(\mathbf{C}^\dagger)^T\mathbf{W} \begin{bmatrix} \mathbf{I} & \mathbf{X}^T \end{bmatrix} \;=\; \begin{bmatrix} \mathbf{I} \\ \mathbf{X} \end{bmatrix} \mathbf{W} \begin{bmatrix} \mathbf{I} & \mathbf{X}^T \end{bmatrix}. \tag{18}$$

It follows from Equations (16) (17) (18) that $\mathbf{K} = \mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T = \mathbf{C}\mathbf{C}^\dagger\mathbf{K}(\mathbf{C}^\dagger)^T\mathbf{C}^T$.

Conversely, when $\mathbf{K} = \mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T$, it holds that $\mathrm{rank}(\mathbf{K}) \leq \mathrm{rank}(\mathbf{W}^\dagger) = \mathrm{rank}(\mathbf{W})$. It follows from (15) that $\mathrm{rank}(\mathbf{K}) = \mathrm{rank}(\mathbf{W})$.

When $\mathbf{K} = \mathbf{C}\mathbf{C}^\dagger\mathbf{K}(\mathbf{C}^\dagger)^T\mathbf{C}^T$, we have $\mathrm{rank}(\mathbf{K}) \leq \mathrm{rank}(\mathbf{C})$. Thus there exists a matrix $\mathbf{X}$ such that

$$\begin{bmatrix} \mathbf{K}_{21}^T \\ \mathbf{K}_{22} \end{bmatrix} \;=\; \mathbf{C}\mathbf{X}^T \;=\; \begin{bmatrix} \mathbf{W}\mathbf{X}^T \\ \mathbf{K}_{21}\mathbf{X}^T \end{bmatrix},$$

and therefore $\mathbf{K}_{21} = \mathbf{X}\mathbf{W}$. Then we have that

$$\mathbf{C} \;=\; \begin{bmatrix} \mathbf{W} \\ \mathbf{K}_{21} \end{bmatrix} \;=\; \begin{bmatrix} \mathbf{I} \\ \mathbf{X} \end{bmatrix} \mathbf{W},$$

so $\mathrm{rank}(\mathbf{C}) \leq \mathrm{rank}(\mathbf{W})$. Apply (15) again we have $\mathrm{rank}(\mathbf{K}) = \mathrm{rank}(\mathbf{W})$. ■

Lemma 12 $\mathbf{X}^T\mathbf{V}\mathbf{X}\big(\mathbf{X}^T\mathbf{V}\mathbf{X}\big)^\dagger\mathbf{X}^T = \mathbf{X}^T$ *for any positive definite matrix* $\mathbf{V}$.

Proof The positive definite matrix $\mathbf{V}$ have a decomposition $\mathbf{V} = \mathbf{B}^T\mathbf{B}$ for some nonsingular matrix $\mathbf{B}$. It follows that

$$\begin{aligned}\mathbf{X}^T\mathbf{V}\mathbf{X}\big(\mathbf{X}^T\mathbf{V}\mathbf{X}\big)^\dagger\mathbf{X}^T &= (\mathbf{B}\mathbf{X})^T\Big(\mathbf{B}\mathbf{X}\big((\mathbf{B}\mathbf{X})^T(\mathbf{B}\mathbf{X})\big)^\dagger\Big)(\mathbf{B}\mathbf{X})^T\mathbf{B}(\mathbf{B}^T\mathbf{B})^{-1}\\ &= (\mathbf{B}\mathbf{X})^T\big((\mathbf{B}\mathbf{X})^T\big)^\dagger(\mathbf{B}\mathbf{X})^T(\mathbf{B}^T)^{-1} = (\mathbf{B}\mathbf{X})^T(\mathbf{B}^T)^{-1} = \mathbf{X}^T.\end{aligned}$$

■

Appendix B. Proof of Theorem 2

In Section B.1 we provide several key lemmas, and then in Section B.2 we prove Theorem 2 using Lemmas 14 and 15.

B.1 Key Lemmas

Lemma 13 provides a useful tool for expanding the Moore-Penrose inverse of partitioned matrices, and the lemma will be used to prove Lemma 15 and Theorem 2.

Lemma 13 (see Ben-Israel and Greville, 2003, Page 179) *Given a matrix $\mathbf{X} \in \mathbb{R}^{m\times n}$ of rank c, let it have a nonsingular $c\times c$ submatrix $\mathbf{X}_{11}$. By rearrangement of columns and rows by permutation matrices $\mathbf{P}$ and $\mathbf{Q}$, the submatrix $\mathbf{X}_{11}$ can be bought to the top left corner of $\mathbf{X}$, that is,*

$$\mathbf{P}\mathbf{X}\mathbf{Q} = \begin{bmatrix}\mathbf{X}_{11} & \mathbf{X}_{12}\\ \mathbf{X}_{21} & \mathbf{X}_{22}\end{bmatrix}.$$

Then the Moore-Penrose inverse of $\mathbf{X}$ is

$$\mathbf{X}^\dagger = \mathbf{Q}\begin{bmatrix}\mathbf{I}_c\\ \mathbf{T}^T\end{bmatrix}\big(\mathbf{I}_c+\mathbf{T}\mathbf{T}^T\big)^{-1}\mathbf{X}_{11}^{-1}\big(\mathbf{I}_c+\mathbf{S}^T\mathbf{S}\big)^{-1}\begin{bmatrix}\mathbf{I}_c & \mathbf{S}^T\end{bmatrix}\mathbf{P},$$

where $\mathbf{T} = \mathbf{X}_{11}^{-1}\mathbf{X}_{12}$ and $\mathbf{S} = \mathbf{X}_{21}\mathbf{X}_{11}^{-1}$.

Lemmas 14 and 15 will be used to prove Theorem 2.

Lemma 14 (Wang and Zhang, 2013, Lemma 19) *Given n and k, we let $\mathbf{B}$ be an $\frac{n}{k}\times\frac{n}{k}$ matrix whose diagonal entries equal to one and off-diagonal entries equal to $\alpha\in[0,1)$. Let $\mathbf{A}$ be the $n\times n$ block-diagonal matrix*

$$\mathbf{A} = \underbrace{\mathbf{B}\oplus\mathbf{B}\oplus\cdots\oplus\mathbf{B}}_{k \text{ blocks}}. \tag{19}$$

Let $\mathbf{A}_k$ be the best rank-k approximation to $\mathbf{A}$. Then

$$\|\mathbf{A}-\mathbf{A}_k\|_F = (1-\alpha)\sqrt{n-k}.$$

Lemma 15 *Let $\mathbf{B}$ be the $n\times n$ matrix with diagonal entries equal to one and off-diagonal entries equal to α and $\tilde{\mathbf{B}}$ be its rank c approximation formed by the prototype model. Then*

$$\|\mathbf{B}-\tilde{\mathbf{B}}\|_F^2 \geq (1-\alpha)^2(n-c)\left(1+\frac{2}{c}-(1-\alpha)\frac{1+o(1)}{\alpha cn/2}\right).$$

Proof Without loss of generality, we assume the first c column of $\mathbf{B}$ are selected to construct $\mathbf{C}$. We partition $\mathbf{B}$ and $\mathbf{C}$ as:

$$\mathbf{B} = \begin{bmatrix}\mathbf{W} & \mathbf{B}_{21}^T\\ \mathbf{B}_{21} & \mathbf{B}_{22}\end{bmatrix} \quad \text{and} \quad \mathbf{C} = \begin{bmatrix}\mathbf{W}\\ \mathbf{B}_{21}\end{bmatrix}.$$

Here the matrix $\mathbf{W}$ can be expressed by $\mathbf{W} = (1-\alpha)\mathbf{I}_c + \alpha\mathbf{1}_c\mathbf{1}_c^T$. We apply the Sherman-Morrison-Woodbury matrix identity

$$(\mathbf{X}+\mathbf{Y}\mathbf{Z}\mathbf{R})^{-1} = \mathbf{X}^{-1} - \mathbf{X}^{-1}\mathbf{Y}(\mathbf{Z}^{-1}+\mathbf{R}\mathbf{X}^{-1}\mathbf{Y})^{-1}\mathbf{R}\mathbf{X}^{-1}$$

to compute $\mathbf{W}^{-1}$, and it follows that

$$\mathbf{W}^{-1} = \frac{1}{1-\alpha}\mathbf{I}_c - \frac{\alpha}{(1-\alpha)(1-\alpha+c\alpha)}\mathbf{1}_c\mathbf{1}_c^T. \tag{20}$$

We expand the Moore-Penrose inverse of $\mathbf{C}$ by Lemma 13 and obtain

$$\mathbf{C}^\dagger = \mathbf{W}^{-1}\big(\mathbf{I}_c+\mathbf{S}^T\mathbf{S}\big)^{-1}\begin{bmatrix}\mathbf{I}_c & \mathbf{S}^T\end{bmatrix}$$

where

$$\mathbf{S} = \mathbf{B}_{21}\mathbf{W}^{-1} = \frac{\alpha}{1-\alpha+c\alpha}\mathbf{1}_{n-c}\mathbf{1}_c^T.$$

It is easily verified that $\mathbf{S}^T\mathbf{S} = \big(\frac{\alpha}{1-\alpha+c\alpha}\big)^2(n-c)\mathbf{1}_c\mathbf{1}_c^T$.

Now we express the approximation by the prototype model in the partitioned form:

$$\begin{aligned}\tilde{\mathbf{B}} &= \mathbf{C}\mathbf{C}^\dagger\mathbf{B}\big(\mathbf{C}^\dagger\big)^T\mathbf{C}^T\\ &= \begin{bmatrix}\mathbf{W}\\ \mathbf{B}_{21}\end{bmatrix}\mathbf{W}^{-1}\big(\mathbf{I}_c+\mathbf{S}^T\mathbf{S}\big)^{-1}\begin{bmatrix}\mathbf{I}_c & \mathbf{S}^T\end{bmatrix}\mathbf{B}\begin{bmatrix}\mathbf{I}_c\\ \mathbf{S}\end{bmatrix}\big(\mathbf{I}_c+\mathbf{S}^T\mathbf{S}\big)^{-1}\mathbf{W}^{-1}\begin{bmatrix}\mathbf{W}\\ \mathbf{B}_{21}\end{bmatrix}^T\\ &= \begin{bmatrix}\big(\mathbf{I}_c+\mathbf{S}^T\mathbf{S}\big)^{-1}\\ \mathbf{B}_{21}\mathbf{W}^{-1}\big(\mathbf{I}_c+\mathbf{S}^T\mathbf{S}\big)^{-1}\end{bmatrix}\begin{bmatrix}\mathbf{I}_c & \mathbf{S}^T\end{bmatrix}\mathbf{B}\begin{bmatrix}\mathbf{I}_c\\ \mathbf{S}\end{bmatrix}\begin{bmatrix}\big(\mathbf{I}_c+\mathbf{S}^T\mathbf{S}\big)^{-1}\\ \mathbf{B}_{21}\mathbf{W}^{-1}\big(\mathbf{I}_c+\mathbf{S}^T\mathbf{S}\big)^{-1}\end{bmatrix}^T.\end{aligned} \tag{21}$$

We then compute the submatrices $\big(\mathbf{I}_c+\mathbf{S}^T\mathbf{S}\big)^{-1}$ and $\mathbf{B}_{21}\mathbf{W}^{-1}\big(\mathbf{I}_c+\mathbf{S}^T\mathbf{S}\big)^{-1}$ respectively as follows. We apply the Sherman-Morrison-Woodbury matrix identity to compute $\big(\mathbf{I}_c+\mathbf{S}^T\mathbf{S}\big)^{-1}$. We obtain

$$\big(\mathbf{I}_c+\mathbf{S}^T\mathbf{S}\big)^{-1} = \left(\mathbf{I}_c+\Big(\frac{\alpha}{1-\alpha+c\alpha}\Big)^2(n-c)\mathbf{1}_c\mathbf{1}_c^T\right)^{-1} = \mathbf{I}_c-\gamma_1\mathbf{1}_c\mathbf{1}_c^T, \tag{22}$$

where

$$\gamma_1 = \frac{n-c}{nc+\big(\frac{1-\alpha}{\alpha}\big)^2+\frac{2(1-\alpha)c}{\alpha}}.$$

It follows from (20) and (22) that

$$\mathbf{W}^{-1}\big(\mathbf{I}_c+\mathbf{S}^T\mathbf{S}\big)^{-1} = (\gamma_2\mathbf{I}_c-\gamma_3\mathbf{1}_c\mathbf{1}_c^T)(\mathbf{I}_c-\gamma_1\mathbf{1}_c\mathbf{1}_c^T) = \gamma_2\mathbf{I}_c+(\gamma_1\gamma_3c-\gamma_1\gamma_2-\gamma_3)\mathbf{1}_c\mathbf{1}_c^T,$$

where

$$\gamma_2 = \frac{1}{1-\alpha} \quad \text{and} \quad \gamma_3 = \frac{\alpha}{(1-\alpha)(1-\alpha+\alpha c)}.$$

It follows that

$$\mathbf{B}_{21}\mathbf{W}^{-1}\big(\mathbf{I}_c + \mathbf{S}^T\mathbf{S}\big)^{-1} = \alpha\big(\gamma_1\gamma_3 c^2 - \gamma_3 c - \gamma_1\gamma_2 c + \gamma_2\big)\mathbf{1}_{n-c}\mathbf{1}_c^T \triangleq \gamma\mathbf{1}_{n-c}\mathbf{1}_c^T, \tag{23}$$

where

$$\gamma = \alpha\big(\gamma_1\gamma_3 c^2 - \gamma_3 c - \gamma_1\gamma_2 c + \gamma_2\big) = \frac{\alpha(\alpha c - \alpha + 1)}{2\alpha c - 2\alpha - 2\alpha^2 c + \alpha^2 + \alpha^2 c n + 1}. \tag{24}$$

Since $\mathbf{B}_{21} = \alpha\mathbf{1}_{n-c}\mathbf{1}_c^T$ and $\mathbf{B}_{22} = (1-\alpha)\mathbf{I}_{n-c} + \alpha\mathbf{1}_{n-c}\mathbf{1}_{n-c}^T$, it is easily verified that

$$\begin{bmatrix} \mathbf{I}_c & \mathbf{S}^T \end{bmatrix}\mathbf{B}\begin{bmatrix} \mathbf{I}_c \\ \mathbf{S} \end{bmatrix} = \begin{bmatrix} \mathbf{I}_c & \mathbf{S}^T \end{bmatrix}\begin{bmatrix} \mathbf{W} & \mathbf{B}_{21}^T \\ \mathbf{B}_{21} & \mathbf{B}_{22} \end{bmatrix}\begin{bmatrix} \mathbf{I}_c \\ \mathbf{S} \end{bmatrix} = (1-\alpha)\mathbf{I}_c + \lambda\mathbf{1}_c\mathbf{1}_c^T, \tag{25}$$

where

$$\lambda = \frac{\alpha(3\alpha n - \alpha c - 2\alpha + \alpha^2 c - 3\alpha^2 n + \alpha^2 + \alpha^2 n^2 + 1)}{(\alpha c - \alpha + 1)^2}$$

It follows from (21), (22), (23), and (25) that

$$\tilde{\mathbf{B}} = \begin{bmatrix} \mathbf{I}_c - \gamma_1\mathbf{1}_c\mathbf{1}_c^T \\ \gamma\mathbf{1}_{n-c}\mathbf{1}_c^T \end{bmatrix}\Big((1-\alpha)\mathbf{I}_c + \lambda\mathbf{1}_c\mathbf{1}_c^T\Big)\begin{bmatrix} \mathbf{I}_c - \gamma_1\mathbf{1}_c\mathbf{1}_c^T \\ \gamma\mathbf{1}_{n-c}\mathbf{1}_c^T \end{bmatrix}^T \triangleq \begin{bmatrix} \tilde{\mathbf{B}}_{11} & \tilde{\mathbf{B}}_{21}^T \\ \tilde{\mathbf{B}}_{21} & \tilde{\mathbf{B}}_{22} \end{bmatrix},$$

where

$$\begin{aligned}
\tilde{\mathbf{B}}_{11} &= (1-\alpha)\mathbf{I}_c + \big[(1-\gamma_1 c)(\lambda - \lambda\gamma_1 c - (1-\alpha)\gamma_1) - (1-\alpha)\gamma_1\big]\mathbf{1}_c\mathbf{1}_c^T \\
&= (1-\alpha)\mathbf{I}_c + \eta_1\mathbf{1}_c\mathbf{1}_c^T, \\
\tilde{\mathbf{B}}_{21} &= \tilde{\mathbf{A}}_{12}^T = \gamma(1-\gamma_1 c)(1-\alpha+\lambda c)\mathbf{1}_{n-c}\mathbf{1}_c^T = \eta_2\mathbf{1}_{n-c}\mathbf{1}_c^T, \\
\tilde{\mathbf{B}}_{22} &= \gamma^2 c(1-\alpha+\lambda c)\mathbf{1}_{n-c}\mathbf{1}_{n-c}^T = \eta_3\mathbf{1}_{n-c}\mathbf{1}_{n-c}^T,
\end{aligned}$$

where

$$\begin{aligned}
\eta_1 &= (1-\gamma_1 c)(\lambda - \lambda\gamma_1 c - (1-\alpha)\gamma_1) - (1-\alpha)\gamma_1, \\
\eta_2 &= \gamma(1-\gamma_1 c)(1-\alpha+\lambda c), \\
\eta_3 &= \gamma^2 c(1-\alpha+\lambda c),
\end{aligned}$$

By dealing with the four blocks of $\tilde{\mathbf{B}}$ respectively, we finally obtain that

$$\begin{aligned}
\|\mathbf{B} - \tilde{\mathbf{B}}\|_F^2 &= \|\mathbf{W} - \tilde{\mathbf{B}}_{11}\|_F^2 + 2\|\mathbf{B}_{21} - \tilde{\mathbf{B}}_{21}\|_F^2 + \|\mathbf{B}_{22} - \tilde{\mathbf{B}}_{22}\|_F^2 \\
&= c^2(\alpha - \eta_1)^2 + 2c(n-c)(\alpha - \eta_2)^2 \\
&\quad + (n-c)(n-c-1)(\alpha - \eta_3)^2 + (n-c)(1-\eta_3)^2 \\
&= (n-c)(\alpha-1)^2\bigg(1 + \frac{2}{c} - \big(1+o(1)\big)\frac{1-\alpha}{\alpha c n/2}\bigg).
\end{aligned}$$

■

B.2 Proof of the Theorem

Now we prove Theorem 2 using Lemma 15 and Lemma 14. Let $\mathbf{C}$ consist of c columns sampled from $\mathbf{A}$ and $\hat{\mathbf{C}}_i$ consist of c_i columns sampled from the i-th block diagonal matrix in $\mathbf{A}$. Without loss of generality, we assume $\hat{\mathbf{C}}_i$ consists of the first c_i columns of $\mathbf{B}$. Then the intersection matrix $\mathbf{U}$ is computed by

$$\begin{aligned}
\mathbf{U} &= \mathbf{C}^\dagger\mathbf{A}(\mathbf{C}^T)^\dagger = \big[\hat{\mathbf{C}}_1 \oplus \cdots \oplus \hat{\mathbf{C}}_k\big]^\dagger\big[\mathbf{B} \oplus \cdots \oplus \mathbf{B}\big]\big[\hat{\mathbf{C}}_1^T \oplus \cdots \oplus \hat{\mathbf{C}}_k^T\big]^\dagger \\
&= \hat{\mathbf{C}}_1^\dagger\mathbf{B}(\hat{\mathbf{C}}_1^\dagger)^T \oplus \cdots \oplus \hat{\mathbf{C}}_k^\dagger\mathbf{B}(\hat{\mathbf{C}}_k^\dagger)^T.
\end{aligned}$$

Let $\tilde{\mathbf{A}}$ be the approximation formed by the prototype model. Then

$$\tilde{\mathbf{A}} = \mathbf{C}\mathbf{U}\mathbf{C}^T = \hat{\mathbf{C}}_1\hat{\mathbf{C}}_1^\dagger\mathbf{B}(\hat{\mathbf{C}}_1^\dagger)^T\hat{\mathbf{C}}_1^T \oplus \cdots \oplus \hat{\mathbf{C}}_k\hat{\mathbf{C}}_k^\dagger\mathbf{B}(\hat{\mathbf{C}}_k^\dagger)^T\hat{\mathbf{C}}_k^T,$$

and thus the approximation error is

$$\begin{aligned}
\|\mathbf{A} - \tilde{\mathbf{A}}\|_F^2 &= \sum_{i=1}^k \Big\|\mathbf{B} - \hat{\mathbf{C}}_i\hat{\mathbf{C}}_i^\dagger\mathbf{B}(\hat{\mathbf{C}}_i^\dagger)^T\hat{\mathbf{C}}_i^T\Big\|_F^2 \\
&\geq (1-\alpha)^2\sum_{i=1}^k(p-c_i)\bigg(1 + \frac{2}{c_i} - (1-\alpha)\Big(\frac{1+o(1)}{\alpha c_i p/2}\Big)\bigg) \\
&= (1-\alpha)^2\bigg(\sum_{i=1}^k(p-c_i) + \sum_{i=1}^k\frac{2(p-c_i)}{c_i}\Big(1 - \frac{(1-\alpha)(1+o(1))}{\alpha p}\Big)\bigg) \\
&\geq (1-\alpha)^2(n-c)\bigg(1 + \frac{2k}{c}\Big(1 - \frac{k(1-\alpha)(1+o(1))}{\alpha n}\Big)\bigg),
\end{aligned}$$

where the former inequality follows from Lemma 15, and the latter inequality follows by minimizing over $c_1, \cdots, c_k$. Finally the theorem follows by setting $\alpha \to 1$ and applying Lemma 14.

Appendix C. Proof of Theorem 3

Proof Sampling $c_1 = 2k\epsilon^{-1}\big(1+o(1)\big)$ columns of $\mathbf{K}$ by the near-optimal algorithm of Boutsidis et al. (2014) to form $\mathbf{C}_1 \in \mathbb{R}^{n\times c_1}$, we have that

$$\mathbb{E}\big\|\mathbf{K} - \mathcal{P}_{\mathbf{C}_1,k}(\mathbf{K})\big\|_F^2 \leq (1+\epsilon)\big\|\mathbf{K} - \mathbf{K}_k\big\|_F^2.$$

Applying Lemma 3.11 of Boutsidis and Woodruff (2014), we can find a much smaller matrix $\mathbf{U}_1 \in \mathbb{R}^{n\times k}$ with orthogonal columns in the column space of $\mathbf{C}_1$ such that

$$\big\|\mathbf{K} - \mathbf{U}_1\mathbf{U}_1^T\mathbf{K}\big\|_F^2 \leq \big\|\mathbf{K} - \mathcal{P}_{\mathbf{C}_1,k}(\mathbf{K})\big\|_F^2.$$

(We do not actually compute $\mathbf{U}_1$ because the adaptive sampling algorithm does not need to know $\mathbf{U}_1$.) Because the columns of $\mathbf{U}_1$ are all in the columns space of $\mathbf{C}_1$, we have that $\big\|\mathbf{K} - \mathbf{C}_1\mathbf{C}_1^\dagger\mathbf{K}\big\|_F^2 \leq \big\|\mathbf{K} - \mathbf{U}_1\mathbf{U}_1^T\mathbf{K}\big\|_F^2$. Combining the above inequalities we obtain

$$\mathbb{E}\big\|\mathbf{K} - \mathbf{C}_1\mathbf{C}_1^\dagger\mathbf{K}\big\|_F^2 \leq \mathbb{E}\big\|\mathbf{K} - \mathbf{U}_1\mathbf{U}_1^T\mathbf{K}\big\|_F^2 \leq \big\|\mathbf{K} - \mathcal{P}_{\mathbf{C}_1,k}(\mathbf{K})\big\|_F^2.$$

Given $\mathbf{C}_1$, we use adaptive sampling to select $c_2 = k\epsilon^{-1}$ rows of $\mathbf{K}$ to form $\mathbf{C}_2$ and denote $\mathbf{C} = [\mathbf{C}_1, \mathbf{C}_2]$. Since the columns of $\mathbf{U}_1$ are all in the columns space of $\mathbf{C}_1$, Lemma 17 of Wang and Zhang (2013) can be slightly modified to show

$$\big\|\mathbf{K} - \mathbf{C}_1\mathbf{C}_1^\dagger\mathbf{K}(\mathbf{C}^T)^\dagger\mathbf{C}^T\big\|_F^2 \;\leq\; \big\|\mathbf{K} - \mathbf{U}_1\mathbf{U}_1^T\mathbf{K}(\mathbf{C}^T)^\dagger\mathbf{C}^T\big\|_F^2.$$

By the adaptive sampling theorem of Wang and Zhang (2013) we have

$$\begin{aligned}
\mathbb{E}\big\|\mathbf{K} - \mathbf{C}_1\mathbf{C}_1^\dagger\mathbf{K}(\mathbf{C}^T)^\dagger\mathbf{C}^T\big\|_F^2 &\leq \mathbb{E}\big\|\mathbf{K} - \mathbf{U}_1\mathbf{U}_1^T\mathbf{K}(\mathbf{C}^T)^\dagger\mathbf{C}^T\big\|_F^2 \\
&\leq \big\|\mathbf{K} - \mathbf{U}_1\mathbf{U}_1^T\mathbf{K}\big\|_F^2 + \frac{k}{c_2}\big\|\mathbf{K} - \mathbf{K}(\mathbf{C}_1^T)^\dagger\mathbf{C}_1^T\big\|_F^2 \\
&\leq \Big(1 + \frac{k}{c_2}\Big)\big\|\mathbf{K} - \mathbf{U}_1\mathbf{U}_1^\dagger\mathbf{K}\big\|_F^2 \\
&\leq (1+\epsilon)\big\|\mathbf{K} - \mathcal{P}_{\mathbf{C}_1,k}(\mathbf{K})\big\|_F^2, \qquad (26)
\end{aligned}$$

where the expectation is taken w.r.t. $\mathbf{C}_2$, and the last inequality follows by setting $c_2 = k/\epsilon$. Here the trick is bounding $\mathbb{E}\big\|\mathbf{K} - \mathbf{U}_1\mathbf{U}_1^T\mathbf{K}(\mathbf{C}^T)^\dagger\mathbf{C}^T\big\|_F^2$ rather than directly bounding $\mathbb{E}\big\|\mathbf{K} - \mathbf{C}_1\mathbf{C}_1^\dagger\mathbf{K}(\mathbf{C}^T)^\dagger\mathbf{C}^T\big\|_F^2$; otherwise the factor $\frac{k}{c_2}$ would be $\frac{c_1}{c_2} = \frac{2k\epsilon^{-1}(1+o(1))}{c_2}$. This is the key to the improvement. It follows that

$$\begin{aligned}
\mathbb{E}\big\|\mathbf{K} - \mathbf{C}_1\mathbf{C}_1^\dagger\mathbf{K}(\mathbf{C}^T)^\dagger\mathbf{C}^T\big\|_F^2 &\leq (1+\epsilon)\mathbb{E}\big\|\mathbf{K} - \mathcal{P}_{\mathbf{C}_1,k}(\mathbf{K})\big\|_F^2 \\
&\leq (1+\epsilon)^2\big\|\mathbf{K} - \mathbf{K}_k\big\|_F^2,
\end{aligned}$$

where the first expectation is taken w.r.t. $\mathbf{C}_1$ and $\mathbf{C}_2$, and the second expectation is taken w.r.t. $\mathbf{C}_1$. Applying Lemma 17 of Wang and Zhang (2013) again, we obtain

$$\mathbb{E}\big\|\mathbf{K} - \mathbf{C}\mathbf{C}^\dagger\mathbf{K}(\mathbf{C}^T)^\dagger\mathbf{C}^T\big\|_F^2 \;\leq\; \mathbb{E}\big\|\mathbf{K} - \mathbf{C}_1\mathbf{C}_1^\dagger\mathbf{K}(\mathbf{C}^T)^\dagger\mathbf{C}^T\big\|_F^2 \;\leq\; (1+\epsilon)^2\big\|\mathbf{K} - \mathbf{K}_k\big\|_F^2.$$

Hence totally $c = c_1 + c_2 = 3k\epsilon^{-1}\big(1 + o(1)\big)$ columns suffice. ■

Appendix D. Proof of Theorem 4

In this section we first provide a constant factor bound of the uniform sampling, and then prove Theorem 4 in the subsequent subsections.

D.1 Tools for Analyzing Uniform Sampling

This subsection provides several useful tools for analyzing column sampling. The matrix $\mathbf{S} \in \mathbb{R}^{n\times s}$ is a column selection matrix if each column has exactly one nonzero entry; let (i_j, j) be the position of the nonzero entry in the j-th column. Let us add randomness to column selection. Suppose we are given the sampling probabilities $p_1, \cdots, p_n \in (0,1)$ and $\sum_i p_i = 1$. In each round we pick one element in $[n]$ such that the i-th element is sampled with probability p_i. We repeat the procedure s times, either with or without replacement, and let $i_1, \cdots, i_s$ be the selected indices. For $j = 1$ to s, we set

$$S_{i_j,j} = \frac{1}{\sqrt{sp_{i_j}}}. \qquad (27)$$

The following lemma shows an important property of arbitrary column sampling. The proof mirrors the leverage score sampling bound in (Woodruff, 2014).

Lemma 16 *Let $\mathbf{U} \in \mathbb{R}^{n\times k}$ be any fixed matrix with orthonormal columns. The column selection matrix $\mathbf{S} \in \mathbb{R}^{n\times s}$ samples s columns according to arbitrary probabilities $p_1, p_2, \cdots, p_n$. Assume that*

$$\max_{i\in[n]} \frac{\|\mathbf{u}_{i:}\|_2^2}{p_i} \;\leq\; \alpha$$

and $\alpha \geq 1$. When $s \geq \alpha\frac{6+2\eta}{3\eta^2}\log(k/\delta)$, it holds that

$$\mathbb{P}\Big\{\big\|\mathbf{I}_k - \mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}\big\|_2 \;\geq\; \eta\Big\} \;\leq\; \delta.$$

Proof We can express $\mathbf{I}_k = \mathbf{U}^T\mathbf{U}$ as the sum of size $k\times k$ and rank one matrices:

$$\mathbf{I}_k \;=\; \mathbf{U}^T\mathbf{U} \;=\; \sum_{i=1}^n \mathbf{u}_{i:}^T\mathbf{u}_{i:}$$

where $\mathbf{u}_{i:} \in \mathbb{R}^{1\times k}$ is the i-th row of $\mathbf{U}$. The approximate matrix product can be expressed as

$$\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U} \;=\; \sum_{j=1}^s S_{i_j,j}^2\mathbf{u}_{i_j:}^T\mathbf{u}_{i_j:} \;=\; \sum_{j=1}^s \frac{1}{sp_{i_j}}\mathbf{u}_{i_j:}^T\mathbf{u}_{i_j:}.$$

We define the symmetric random matrices

$$\mathbf{Z}_{i_j} \;=\; \frac{1}{sp_{i_j}}\mathbf{u}_{i_j:}^T\mathbf{u}_{i_j:} - \frac{1}{s}\mathbf{I}_k$$

for $j = 1$ to s. Whatever the sampling distribution is, it always holds that

$$\mathbb{E}\mathbf{Z}_{i_j} \;=\; \sum_{q=1}^n p_q\Big(\frac{1}{\sqrt{sp_q}}\Big)^2\mathbf{u}_{q:}^T\mathbf{u}_{q:} - \sum_{q=1}^n p_q\frac{1}{s}\mathbf{I}_k \;=\; \frac{1}{s}\mathbf{I}_k - \frac{1}{s}\mathbf{I}_k \;=\; \mathbf{0}. \qquad (28)$$

Thus $\mathbf{Z}_{i_j}$ has zero mean. Let $\mathcal{Z}$ be the set

$$\mathcal{Z} \;=\; \Big\{\frac{1}{s}\mathbf{I}_k - \frac{1}{sp_1}\mathbf{u}_{1:}^T\mathbf{u}_{1:},\; \cdots,\; \frac{1}{s}\mathbf{I}_k - \frac{1}{sp_n}\mathbf{u}_{n:}^T\mathbf{u}_{n:}\Big\}.$$

Clearly, $\mathbf{Z}_{i_1}, \cdots, \mathbf{Z}_{i_s}$ are sampled from $\mathcal{Z}$, and

$$\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U} - \mathbf{I}_k = \sum_{j=1}^s \mathbf{Z}_{i_j}.$$

Therefore we can bound its spectral norm using the matrix Bernstein. Elementary proof of the matrix Bernstein can be found in Tropp (2015).

Lemma 17 (Matrix Bernstein) *Consider a finite sequence $\{\mathbf{Z}_i\}$ of independent, random, Hermitian matrices with dimension k. Assume that*

$$\mathbb{E}\mathbf{Z}_i = \mathbf{0} \quad \text{and} \quad \max_i \|\mathbf{Z}_i\|_2 \le L$$

for each index i. Introduce the random matrix $\mathbf{Y} = \sum_i \mathbf{Z}_i$. Let $v(\mathbf{Y})$ be the matrix variance statistics of the sum:

$$v(\mathbf{Y}) \;=\; \left\|\mathbb{E}\mathbf{Y}^2\right\|_2 \;=\; \Big\|\sum_i \mathbb{E}\mathbf{Z}_i^2\Big\|_2.$$

Then

$$\mathbb{P}\{\lambda_{\max}(\mathbf{Y}) \ge \eta\} \;\le\; k \cdot \exp\left(\frac{-\eta^2/2}{v(\mathbf{Y}) + L\eta/3}\right).$$

To apply the matrix Bernstein, it remains to bound the variance of $\sum_{j=1}^s \mathbf{Z}_{i_j}$ and to bound $L = \max_{j\in[s]} \|\mathbf{Z}_{i_j}\|_2$. We have that

$$\begin{aligned}
\mathbb{E}\mathbf{Z}_{i_j}^2 &= \mathbb{E}\Big(\frac{1}{sp_{i_j}}\mathbf{u}_{i_j:}^T\mathbf{u}_{i_j:} - \frac{1}{s}\mathbf{I}_k\Big)^2 \\
&= \frac{1}{s^2}\left[\mathbb{E}\Big(\frac{1}{p_{i_j}}\mathbf{u}_{i_j:}^T\mathbf{u}_{i_j:}\Big)^2 - 2\mathbb{E}\Big(\frac{1}{p_{i_j}}\mathbf{u}_{i_j:}^T\mathbf{u}_{i_j:}\Big) + \mathbf{I}_k\right] \\
&= \frac{1}{s^2}\left[\sum_{q=1}^n \Big(p_q\Big(\frac{1}{p_q}\Big)^2\mathbf{u}_{q:}^T\mathbf{u}_{q:}\mathbf{u}_{q:}^T\mathbf{u}_{q:}\Big) - 2\mathbf{I}_k + \mathbf{I}_k\right] \\
&= -\frac{1}{s^2}\mathbf{I}_k + \frac{1}{s^2}\sum_{q=1}^n \frac{\|\mathbf{u}_{q:}\|_2^2}{p_q}\mathbf{u}_{q:}^T\mathbf{u}_{q:}.
\end{aligned}$$

The variance is defined by

$$v \;\triangleq\; \left\|\sum_{j=1}^s \mathbb{E}\mathbf{Z}_{i_j}^2\right\|_2 \;=\; \frac{1}{s}\left\| - \mathbf{I}_k + \sum_{q=1}^n \frac{\|\mathbf{u}_{q:}\|_2^2}{p_q}\mathbf{u}_{q:}^T\mathbf{u}_{q:}\right\|_2 \;\le\; \frac{1}{s}(\alpha - 1).$$

Here the inequality is due to the definition of α and

$$-\mathbf{I}_k + \sum_{q=1}^n \frac{\|\mathbf{u}_{q:}\|_2^2}{p_q}\mathbf{u}_{q:}^T\mathbf{u}_{q:} \;\preceq\; -\mathbf{I}_k + \sum_{q=1}^n \alpha\mathbf{u}_{q:}^T\mathbf{u}_{q:} \;=\; (-1+\alpha)\mathbf{I}_k.$$

In addition, $L = \max_{j\in[s]} \|\mathbf{Z}_{i_j}\|_2$ can be bounded by

$$\begin{aligned}
L \;&=\; \max_{j\in[s]} \|\mathbf{Z}_{i_j}\|_2 \;=\; \max_{j\in[s]} \left\|\frac{1}{s}\mathbf{I}_k - \frac{1}{sp_{i_j}}\mathbf{u}_{i_j:}^T\mathbf{u}_{i_j:}\right\|_2 \;\le\; \max_{i\in[n]} \left\|\frac{1}{s}\mathbf{I}_k - \frac{1}{sp_i}\mathbf{u}_{i:}^T\mathbf{u}_{i:}\right\|_2 \\
&\le\; \frac{1}{s} + \max_{i\in[n]} \left\|\frac{1}{sp_i}\mathbf{u}_{i:}^T\mathbf{u}_{i:}\right\|_2 \;=\; \frac{1}{s} + \max_{i\in[n]} \frac{\|\mathbf{u}_{i:}\|_2^2}{sp_i} \;\le\; \frac{1}{s}(\alpha+1).
\end{aligned}$$

Finally, the lemma follows by plugging v and L in the matrix Bernstein. ■

Theorem 18 shows an important property of uniform sampling. It shows that when the number of sampled columns is large enough, all the singular values of $\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U}$ are within $1 \pm \eta$ with high probability.

Theorem 18 *Let $\mathbf{U} \in \mathbb{R}^{n\times k}$ be any fixed matrix with orthonormal columns and $\mu(\mathbf{U})$ be its row coherence. Let $\mathbf{S} \in \mathbb{R}^{n\times s}$ be an uniformly sampling matrix. When $s \ge \mu(\mathbf{U})k\frac{6+2\eta}{3\eta^2}\log(k/\delta)$, it hold that*

$$\mathbb{P}\Big\{\big\|\mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{U} - \mathbf{I}_k\big\|_2 \;\ge\; \eta\Big\} \;\le\; \delta.$$

Proof Since $\frac{\|\mathbf{u}_{q:}\|_2^2}{p_q} = n\|\mathbf{u}_{q:}\|_2^2 \le k\mu(\mathbf{U})$ for all $q \in [n]$, the theorem follows from Lemma 16. ■

The following lemma was established by Drineas et al. (2008). It can be proved by writing the squared Frobenius norm as the sum of scalars and then taking expectation.

Lemma 19 *Let $\mathbf{A} \in \mathbb{R}^{n\times k}$ and $\mathbf{B} \in \mathbb{R}^{n\times d}$ be any fixed matrices and $\mathbf{S} \in \mathbb{R}^{n\times s}$ be the column sampling matrix defined in (27). Assume that the columns are selected randomly and pairwisely independently. Then*

$$\mathbb{E}\Big\|\mathbf{A}^T\mathbf{B} - \mathbf{A}^T\mathbf{S}\mathbf{S}^T\mathbf{B}\Big\|_F^2 \;\le\; \frac{1}{s}\sum_{i=1}^n \frac{1}{p_i}\big\|\mathbf{a}_{i:}\big\|_2^2\big\|\mathbf{b}_{i:}\big\|_2^2.$$

Theorem 20 follows from Lemma 19 and shows another important property of uniform sampling.

Theorem 20 *Let $\mathbf{U} \in \mathbb{R}^{n\times k}$ be any fixed matrix with orthonormal columns and $\mathbf{B} \in \mathbb{R}^{n\times d}$ be any fixed matrix. Use the uniform sampling matrix $\mathbf{S} \in \mathbb{R}^{n\times s}$ and set $s \ge \frac{k\mu(\mathbf{U})}{\epsilon\delta}$. Then it holds that*

$$\mathbb{P}\Big\{\big\|\mathbf{U}^T\mathbf{B} - \mathbf{U}^T\mathbf{S}^T\mathbf{S}\mathbf{B}\big\|_F^2 \;\ge\; \epsilon\|\mathbf{B}\|_F^2\Big\} \;\le\; \delta.$$

Proof We have shown that $\|\mathbf{u}_{q:}\|_2^2/p_q \le k\mu(\mathbf{U})$ for all $q = 1$ to n. It follows from Lemma 19 that

$$\mathbb{E}\Big\|\mathbf{U}^T\mathbf{B} - \mathbf{U}^T\mathbf{S}\mathbf{S}^T\mathbf{B}\Big\|_F^2 \;\le\; \frac{1}{s}\sum_{i=1}^n k\mu(\mathbf{U})\big\|\mathbf{b}_{i:}\big\|_2^2 \;=\; \frac{k\mu(\mathbf{U})}{s}\|\mathbf{B}\|_F^2.$$

The theorem follows from the setting of s and the Markov's inequality. ■

The following lemma is very useful in analyzing randomized SVD.

Lemma 21 *Let $\mathbf{M} \in \mathbb{R}^{m\times n}$ be any matrix. We decompose $\mathbf{M}$ by $\mathbf{M} = \mathbf{M}_1 + \mathbf{M}_2$ such that $\mathrm{rank}(\mathbf{M}_1) = k$. Let the right singular vectors of $\mathbf{M}_1$ be $\mathbf{V}_1 \in \mathbb{R}^{n\times k}$. Let $\mathbf{S} \in \mathbb{R}^{n\times c}$ be any matrix such that $\mathrm{rank}(\mathbf{V}_1^T\mathbf{S}) = k$ and let $\mathbf{C} = \mathbf{M}\mathbf{S} \in \mathbb{R}^{m\times c}$. Then*

$$\big\|\mathbf{M} - \mathbf{C}(\mathbf{V}_1^T\mathbf{S})^\dagger\mathbf{V}_1^T\big\|_\xi^2 \;\le\; \big\|\mathbf{M}_2\big\|_\xi^2 + \sigma_{\min}^{-2}(\mathbf{V}_1^T\mathbf{S}\mathbf{S}^T\mathbf{V}_1)\,\big\|\mathbf{M}_2\mathbf{S}\mathbf{S}^T\mathbf{V}_1\big\|_\xi^2$$

for $\xi = 2$ or F.

Proof Boutsidis et al. (2014) showed that

$$\big\|\mathbf{M}-\mathbf{C}(\mathbf{V}_1^T\mathbf{S})^\dagger\mathbf{V}_1^T\big\|_\xi^2 \;\le\; \big\|\mathbf{M}_2\big\|_\xi^2+\big\|\mathbf{M}_2\mathbf{S}(\mathbf{V}_1^T\mathbf{S})^\dagger\big\|_\xi^2.$$

Since $\mathbf{Y}^T(\mathbf{Y}\mathbf{Y}^T)^\dagger=\mathbf{Y}^\dagger$ for any matrix $\mathbf{Y}$, it follows that

$$\begin{aligned}&\big\|\mathbf{M}_2\mathbf{S}(\mathbf{V}_1^T\mathbf{S})^\dagger\big\|_\xi^2 \;=\; \big\|\mathbf{M}_2\mathbf{S}(\mathbf{V}_1^T\mathbf{S})^T(\mathbf{V}_1^T\mathbf{S}\mathbf{S}^T\mathbf{V}_1)^\dagger\big\|_\xi^2\\ &\le\; \big\|\mathbf{M}_2\mathbf{S}\mathbf{S}^T\mathbf{V}_1\big\|_\xi^2\,\big\|(\mathbf{V}_1^T\mathbf{S}\mathbf{S}^T\mathbf{V}_1)^\dagger\big\|_2^2 \;=\; \big\|\mathbf{M}_2\mathbf{S}\mathbf{S}^T\mathbf{V}_1^T\big\|_\xi^2\,\sigma_{\min}^{-2}(\mathbf{V}_1^T\mathbf{S}\mathbf{S}^T\mathbf{V}_1),\end{aligned}$$

by which the lemma follows. ■

D.2 Uniform Sampling Bound

Theorem 22 shows that uniform sampling can be applied to randomized SVD. Specifically, if $\mathbf{C}$ consists of $c=\mathcal{O}(k\mu_k/\epsilon+k\mu_k\log k)$ uniformly sampled columns of $\mathbf{A}$, then $\|\mathbf{A}-\mathcal{P}_{\mathbf{C},k}(\mathbf{A})\|_F^2\le(1+\epsilon)\|\mathbf{A}-\mathbf{A}_k\|_F^2$ holds with high probability, where μ_k is the column coherence of $\mathbf{A}_k$.

Theorem 22 *Let $\mathbf{A}\in\mathbb{R}^{m\times n}$ be any fixed matrix, k ($\ll m,n$) be the target rank, and μ_k be the column coherence of $\mathbf{A}_k$. Let $\mathbf{S}\in\mathbb{R}^{m\times c}$ be a uniform sampling matrix and $\mathbf{C}=\mathbf{A}\mathbf{S}\in\mathbb{R}^{m\times c}$. When $c\ge\mu_k k\cdot\max\{20\log(20k),\,45/\epsilon\}$,*

$$\min_{\mathrm{rank}(\mathbf{X})\le k}\big\|\mathbf{A}-\mathbf{C}\mathbf{X}\big\|_F^2 \;\le\; \big(1+\epsilon\big)\,\|\mathbf{A}-\mathbf{A}_k\|_F^2.$$

holds with probability at least 0.9.

Proof Let $\mathbf{V}_k\in\mathbb{R}^{n\times k}$ contain the top k right singular vectors of $\mathbf{A}$. Obviously μ_k is the row coherence of $\mathbf{V}_k$. We apply Theorem 18 with $\delta=0.05$, $\eta=1/3$, $s=20\mu_k k\log(20k)$ and obtain

$$\mathbb{P}\Big\{\sigma_{\min}(\mathbf{V}_k^T\mathbf{S}\mathbf{S}^T\mathbf{V}_k)\;\le\;2/3\Big\}\;\le\;0.05.$$

We then apply Theorem 20 with $\delta=0.05$ and $s=45\mu_k k/\epsilon$ and obtain

$$\mathbb{P}\Big\{\big\|\mathbf{U}^T\mathbf{S}^T\mathbf{S}(\mathbf{A}-\mathbf{A}_k)\big\|_F^2\;\ge\;\frac{4}{9}\epsilon\|\mathbf{A}-\mathbf{A}_k\|_F^2\Big\}\;\le\;0.05.$$

It follows from Lemma 21 that

$$\begin{aligned}\min_{\mathrm{rank}(\mathbf{X})\le k}\|\mathbf{A}-\mathbf{C}\mathbf{X}\|_F^2 \;&\le\; \|\mathbf{A}-\mathbf{A}_k\|_F^2+\sigma_{\min}^{-2}(\mathbf{V}_k^T\mathbf{S}\mathbf{S}^T\mathbf{V}_k)\big\|\mathbf{U}^T\mathbf{S}^T\mathbf{S}(\mathbf{A}-\mathbf{A}_k)\big\|_F^2\\ &\le\; (1+\epsilon)\|\mathbf{A}-\mathbf{A}_k\|_F^2,\end{aligned}$$

where the latter inequality holds with probability at least 0.9 (due to the union bound). ■

D.3 The Uniform+Adaptive Column Selection Algorithm

In fact, running adaptive sampling only once yields a column sampling algorithm with $1+\epsilon$ bound for any $m\times n$ matrix. We call it the uniform+adaptive column selection algorithm, which is a part of the uniform+adaptive^2 algorithm. Though the algorithm is irrelevant to this work, we describe it in the following for it is of independent interest.

Theorem 23 (The Uniform+Adaptive Algorithm) *Given an $m\times n$ matrix $\mathbf{A}$, we sample $c_1=20\mu_k k\log(20k)$ columns by uniform sampling to form $\mathbf{C}_1$ and sample additional $c_2=17.5k/\epsilon$ columns by adaptive sampling to form $\mathbf{C}_2$. Let $\mathbf{C}=[\mathbf{C}_1,\mathbf{C}_2]$. Then the inequality*

$$\min_{\mathrm{rank}(\mathbf{X})\le k}\big\|\mathbf{A}-\mathbf{C}\mathbf{X}\big\|_F^2\;\le\;(1+\epsilon)\big\|\mathbf{A}-\mathbf{A}_k\big\|_F^2$$

holds with probability at least 0.8.

Proof We apply Theorem 22 with $\epsilon=0.75$ and $c_1=20\mu_k k\log(20k)$ and obtain that

$$\|\mathbf{A}-\mathbf{C}_1\mathbf{C}_1^\dagger\mathbf{A}\|_F^2\;\le\;1.75\|\mathbf{A}-\mathbf{A}_k\|_F^2$$

holds with probability at least 0.9.

Deshpande et al. (2006) showed that

$$\mathbb{E}\Big[\min_{\mathrm{rank}(\mathbf{X})\le k}\big\|\mathbf{A}-\mathbf{C}\mathbf{X}\big\|_F^2-\|\mathbf{A}-\mathbf{A}_k\|_F^2\Big]\;\le\;\frac{k}{c_2}\|\mathbf{A}-\mathbf{C}_1\mathbf{C}_1^\dagger\mathbf{A}\|_F^2.$$

It follows from Markov's inequality that

$$\min_{\mathrm{rank}(\mathbf{X})\le k}\big\|\mathbf{A}-\mathbf{C}\mathbf{X}\big\|_F^2-\|\mathbf{A}-\mathbf{A}_k\|_F^2\;\le\;\frac{k}{\delta_2 c_2}\|\mathbf{A}-\mathbf{C}_1\mathbf{C}_1^\dagger\mathbf{A}\|_F^2$$

holds with probability at least $1-\delta_2$. We let $\delta_2=0.1$ and $c_2=17.5k/\epsilon$, and it follows that

$$\min_{\mathrm{rank}(\mathbf{X})\le k}\big\|\mathbf{A}-\mathbf{C}\mathbf{X}\big\|_F^2\;\le\;(1+\epsilon)\|\mathbf{A}-\mathbf{A}_k\|_F^2$$

holds with probability at least 0.8. ■

D.4 Proof of Theorem 4

We sample $c_1=20\mu_k k\log(20k)$ columns by uniform sampling to form $\mathbf{C}_1$ and sample additional $c_2=17.5k/\epsilon$ columns by adaptive sampling to form $\mathbf{C}_2$. Let $\hat{\mathbf{C}}=[\mathbf{C}_1,\mathbf{C}_2]$. It follows from Theorem 23 that

$$\big\|\mathbf{K}-\mathcal{P}_{\hat{\mathbf{C}},k}(\mathbf{K})\big\|_F^2\;\le\;(1+\epsilon)\big\|\mathbf{K}-\mathbf{K}_k\big\|_F^2$$

holds with probability at least 0.8.

Let $\mathbf{C} = [\hat{\mathbf{C}}, \mathbf{C}_3]$ where $\mathbf{C}_3$ consists of c_3 columns of $\mathbf{K}$ chosen by adaptive sampling. Then

$$\begin{aligned}\mathbb{E}\big\|\mathbf{K} - \mathbf{C}\mathbf{C}^\dagger\mathbf{K}(\mathbf{C}^T)^\dagger\mathbf{C}^T\big\|_F^2 &\leq \mathbb{E}\big\|\mathbf{K} - \hat{\mathbf{C}}\hat{\mathbf{C}}^\dagger\mathbf{K}(\mathbf{C}^T)^\dagger\mathbf{C}^T\big\|_F^2 \\ &\leq \Big(1+\frac{k}{c_3}\Big)\big\|\mathbf{K} - \mathcal{P}_{\hat{\mathbf{C}},k}(\mathbf{K})\big\|_F^2,\end{aligned}$$

where the former inequality follows from Lemma 17 of Wang and Zhang (2013), and the latter inequality follows from (26). It follows from Markov's inequality that

$$\big\|\mathbf{K} - \mathbf{C}\mathbf{C}^\dagger\mathbf{K}(\mathbf{C}^T)^\dagger\mathbf{C}^T\big\|_F^2 - \big\|\mathbf{K} - \mathcal{P}_{\hat{\mathbf{C}},k}(\mathbf{K})\big\|_F^2 \leq \frac{k}{\delta_3 c_3}\big\|\mathbf{K} - \mathcal{P}_{\hat{\mathbf{C}},k}(\mathbf{K})\big\|_F^2$$

holds with probability at least $1-\delta_3$. We set $\delta_3 = 0.1$ and $c_3 = 10k/\epsilon$, Then

$$\big\|\mathbf{K} - \mathbf{C}\mathbf{C}^\dagger\mathbf{K}(\mathbf{C}^T)^\dagger\mathbf{C}^T\big\|_F^2 \leq (1+\epsilon)\big\|\mathbf{K} - \mathcal{P}_{\hat{\mathbf{C}},k}(\mathbf{K})\big\|_F^2 \leq (1+\epsilon)^2\big\|\mathbf{K} - \mathbf{K}_k\big\|_F^2,$$

where the former inequality holds with probability $1-\delta_3$, and the latter inequality holds with probability $0.8 - \delta_3 = 0.7$.

Appendix E. Proof of Theorem 6

In Section E.1 we derive the solution to the optimization problem (14). In Section E.2 we prove that the solutions are global optimum. In Section E.3 we prove that the resulting solution is positive (semi)definite when $\mathbf{K}$ is positive (semi)definite.

E.1 Solution to the Optimization Problem (14)

We denote the objective function of the optimization problem (14) by

$$f(\mathbf{U},\delta) \;=\; \big\|\mathbf{K} - \bar{\mathbf{C}}\mathbf{U}\bar{\mathbf{C}}^T - \delta\mathbf{I}_n\big\|_F^2.$$

We take the derivative of $f(\mathbf{U},\delta)$ w.r.t. $\mathbf{U}$ to be zero

$$\begin{aligned}\frac{\partial f(\mathbf{U},\delta)}{\partial \mathbf{U}} &= \frac{\partial}{\partial \mathbf{U}}\mathrm{tr}(\bar{\mathbf{C}}\mathbf{U}\bar{\mathbf{C}}^T\bar{\mathbf{C}}\mathbf{U}\bar{\mathbf{C}}^T - 2\mathbf{K}\bar{\mathbf{C}}\mathbf{U}\bar{\mathbf{C}}^T + 2\delta\bar{\mathbf{C}}\mathbf{U}\bar{\mathbf{C}}^T) \\ &= 2\bar{\mathbf{C}}^T\bar{\mathbf{C}}\mathbf{U}\bar{\mathbf{C}}^T\bar{\mathbf{C}} - 2\bar{\mathbf{C}}^T\mathbf{K}\bar{\mathbf{C}} + 2\delta\bar{\mathbf{C}}^T\bar{\mathbf{C}} \;=\; \mathbf{0},\end{aligned}$$

and obtain the solution

$$\begin{aligned}\mathbf{U}^{\mathrm{ss}} &= (\bar{\mathbf{C}}^T\bar{\mathbf{C}})^\dagger(\bar{\mathbf{C}}^T\mathbf{K}\bar{\mathbf{C}} - \delta^{\mathrm{ss}}\bar{\mathbf{C}}^T\bar{\mathbf{C}})(\bar{\mathbf{C}}^T\bar{\mathbf{C}})^\dagger \\ &= (\bar{\mathbf{C}}^T\bar{\mathbf{C}})^\dagger\bar{\mathbf{C}}^T\mathbf{K}\bar{\mathbf{C}}(\bar{\mathbf{C}}^T\bar{\mathbf{C}})^\dagger - \delta^{\mathrm{ss}}(\bar{\mathbf{C}}^T\bar{\mathbf{C}})^\dagger\bar{\mathbf{C}}^T\bar{\mathbf{C}}(\bar{\mathbf{C}}^T\bar{\mathbf{C}})^\dagger \\ &= \bar{\mathbf{C}}^\dagger\mathbf{K}(\bar{\mathbf{C}}^\dagger)^T - \delta^{\mathrm{ss}}(\bar{\mathbf{C}}^T\bar{\mathbf{C}})^\dagger.\end{aligned}$$

Similarly, we take the derivative of $f(\mathbf{U},\delta)$ w.r.t. δ to be zero

$$\frac{\partial f(\mathbf{U},\delta)}{\partial \delta} \;=\; \frac{\partial}{\partial\delta}\mathrm{tr}(\delta^2\mathbf{I}_n - 2\delta\mathbf{K} + 2\delta\bar{\mathbf{C}}\mathbf{U}\bar{\mathbf{C}}^T) \;=\; 2n\delta - 2\mathrm{tr}(\mathbf{K}) + 2\mathrm{tr}(\bar{\mathbf{C}}\mathbf{U}\bar{\mathbf{C}}^T) = 0,$$

and it follows that

$$\begin{aligned}\delta^{\mathrm{ss}} &= \frac{1}{n}\Big(\mathrm{tr}(\mathbf{K}) - \mathrm{tr}(\bar{\mathbf{C}}\mathbf{U}^{\mathrm{ss}}\bar{\mathbf{C}}^T)\Big) \\ &= \frac{1}{n}\Big(\mathrm{tr}(\mathbf{K}) - \mathrm{tr}\Big(\bar{\mathbf{C}}\bar{\mathbf{C}}^\dagger\mathbf{K}(\bar{\mathbf{C}}^\dagger)^T\bar{\mathbf{C}}^T\Big) + \delta^{\mathrm{ss}}\mathrm{tr}\Big(\bar{\mathbf{C}}(\bar{\mathbf{C}}^T\bar{\mathbf{C}})^\dagger\bar{\mathbf{C}}^T\Big)\Big) \\ &= \frac{1}{n}\Big(\mathrm{tr}(\mathbf{K}) - \mathrm{tr}\Big(\bar{\mathbf{C}}^T\bar{\mathbf{C}}\bar{\mathbf{C}}^\dagger\mathbf{K}(\bar{\mathbf{C}}^\dagger)^T\Big) + \delta^{\mathrm{ss}}\mathrm{tr}\Big(\bar{\mathbf{C}}\bar{\mathbf{C}}^\dagger\Big)\Big) \\ &= \frac{1}{n}\Big(\mathrm{tr}(\mathbf{K}) - \mathrm{tr}\Big(\bar{\mathbf{C}}^T\mathbf{K}(\bar{\mathbf{C}}^\dagger)^T\Big) + \delta^{\mathrm{ss}}\mathrm{rank}(\bar{\mathbf{C}})\Big),\end{aligned}$$

and thus

$$\delta^{\mathrm{ss}} \;=\; \frac{1}{n-\mathrm{rank}(\bar{\mathbf{C}})}\Big(\mathrm{tr}(\mathbf{K}) - \mathrm{tr}\big(\bar{\mathbf{C}}^\dagger\mathbf{K}\bar{\mathbf{C}}\big)\Big).$$

E.2 Proof of Optimality

The Hessian matrix of $f(\mathbf{U},\delta)$ w.r.t. $(\mathbf{U},\delta)$ is

$$\mathbf{H} \;=\; \begin{bmatrix}\dfrac{\partial^2 f(\mathbf{U},\delta)}{\partial\mathsf{vec}(\mathbf{U})\partial\mathsf{vec}(\mathbf{U})^T} & \dfrac{\partial^2 f(\mathbf{U},\delta)}{\partial\mathsf{vec}(\mathbf{U})\partial\delta} \\ \dfrac{\partial^2 f(\mathbf{U},\delta)}{\partial\delta\partial\mathsf{vec}(\mathbf{U})^T} & \dfrac{\partial^2 f(\mathbf{U},\delta)}{\partial\delta^2}\end{bmatrix} \;=\; 2\begin{bmatrix}(\bar{\mathbf{C}}^T\bar{\mathbf{C}})\otimes(\bar{\mathbf{C}}^T\bar{\mathbf{C}}) & \mathsf{vec}(\bar{\mathbf{C}}^T\bar{\mathbf{C}}) \\ \mathsf{vec}(\bar{\mathbf{C}}^T\bar{\mathbf{C}})^T & n\end{bmatrix}.$$

Here $\otimes$ denotes the Kronecker product, and $\mathsf{vec}(\mathbf{A})$ denotes the vectorization of the matrix $\mathbf{A}$ formed by stacking the columns of $\mathbf{A}$ into a single column vector. For any $\mathbf{X}\in\mathbb{R}^{c\times c}$ and $b\in\mathbb{R}$, we let

$$\begin{aligned}q(\mathbf{X},b) &= \begin{bmatrix}\mathsf{vec}(\mathbf{X})^T & b\end{bmatrix}\mathbf{H}\begin{bmatrix}\mathsf{vec}(\mathbf{X}) \\ b\end{bmatrix} \\ &= \mathsf{vec}(\mathbf{X})^T\big((\bar{\mathbf{C}}^T\bar{\mathbf{C}})\otimes(\bar{\mathbf{C}}^T\bar{\mathbf{C}})\big)\mathsf{vec}(\mathbf{X}) + 2b\,\mathsf{vec}(\bar{\mathbf{C}}^T\bar{\mathbf{C}})^T\mathsf{vec}(\mathbf{X}) + nb^2 \\ &= \mathsf{vec}(\mathbf{X})^T\mathsf{vec}\big((\bar{\mathbf{C}}^T\bar{\mathbf{C}})\mathbf{X}(\bar{\mathbf{C}}^T\bar{\mathbf{C}})\big) + 2b\,\mathsf{vec}(\bar{\mathbf{C}}^T\bar{\mathbf{C}})^T\mathsf{vec}(\mathbf{X}) + nb^2 \\ &= \mathrm{tr}(\mathbf{X}^T\bar{\mathbf{C}}^T\bar{\mathbf{C}}\mathbf{X}\bar{\mathbf{C}}^T\bar{\mathbf{C}}) + 2b\,\mathrm{tr}(\bar{\mathbf{C}}^T\bar{\mathbf{C}}\mathbf{X}) + nb^2.\end{aligned}$$

Let $\bar{\mathbf{C}}\mathbf{X}\bar{\mathbf{C}}^T = \mathbf{Y}\in\mathbb{R}^{n\times n}$. Then

$$\begin{aligned}q(\mathbf{X},b) &= \mathrm{tr}(\bar{\mathbf{C}}\mathbf{X}^T\bar{\mathbf{C}}^T\bar{\mathbf{C}}\mathbf{X}\bar{\mathbf{C}}^T) + 2b\,\mathrm{tr}(\bar{\mathbf{C}}\mathbf{X}\bar{\mathbf{C}}^T) + nb^2 \\ &= \mathrm{tr}(\mathbf{Y}^T\mathbf{Y}) + 2b\,\mathrm{tr}(\mathbf{Y}) + nb^2 \\ &= \sum_{i=1}^n\sum_{j=1}^n y_{ij}^2 + 2b\sum_{l=1}^n y_{ll} + nb^2 \\ &= \sum_{i\neq j} y_{ij}^2 + \sum_{l=1}^n (y_{ll}+b)^2 \\ &\geq 0,\end{aligned}$$

which shows that the Hessian matrix $\mathbf{H}$ is SPSD. Hence $f(\mathbf{U}^{\mathrm{ss}},\delta^{\mathrm{ss}})$ is the global minimum of f.

E.3 Proof of Positive (Semi)Definite

We denote the thin SVD of $\bar{\mathbf{C}}$ by $\bar{\mathbf{C}} = \mathbf{U}_{\bar{\mathbf{C}}}\mathbf{\Sigma}_{\bar{\mathbf{C}}}\mathbf{V}_{\bar{\mathbf{C}}}^T$ and let $\mathbf{U}_{\bar{\mathbf{C}}}^\perp$ be the orthogonal complement of $\mathbf{U}_{\bar{\mathbf{C}}}$. The approximation is

$$\begin{aligned}\tilde{\mathbf{K}} &= \bar{\mathbf{C}}\mathbf{U}^{\text{ss}}\bar{\mathbf{C}}^T + \delta^{\text{ss}}\mathbf{I}_n = \bar{\mathbf{C}}\big(\bar{\mathbf{C}}^\dagger\mathbf{K}(\bar{\mathbf{C}}^\dagger)^T - \delta^{\text{ss}}(\bar{\mathbf{C}}^T\bar{\mathbf{C}})^\dagger\big)\bar{\mathbf{C}}^T + \delta^{\text{ss}}\mathbf{I}_n \\ &= \bar{\mathbf{C}}\big(\bar{\mathbf{C}}^\dagger\mathbf{K}(\bar{\mathbf{C}}^\dagger)^T\big)\bar{\mathbf{C}}^T + \delta^{\text{ss}}\big(\mathbf{I}_n - \bar{\mathbf{C}}(\bar{\mathbf{C}}^T\bar{\mathbf{C}})^\dagger\bar{\mathbf{C}}^T\big) \\ &= \mathbf{U}_{\bar{\mathbf{C}}}\mathbf{U}_{\bar{\mathbf{C}}}^T\mathbf{K}\mathbf{U}_{\bar{\mathbf{C}}}\mathbf{U}_{\bar{\mathbf{C}}}^T + \delta^{\text{ss}}\big(\mathbf{I}_n - \mathbf{U}_{\bar{\mathbf{C}}}\mathbf{U}_{\bar{\mathbf{C}}}^T\big) \\ &= \mathbf{U}_{\bar{\mathbf{C}}}\mathbf{U}_{\bar{\mathbf{C}}}^T\mathbf{K}\mathbf{U}_{\bar{\mathbf{C}}}\mathbf{U}_{\bar{\mathbf{C}}}^T + \delta^{\text{ss}}\mathbf{U}_{\bar{\mathbf{C}}}^\perp(\mathbf{U}_{\bar{\mathbf{C}}}^\perp)^T. \end{aligned} \tag{29}$$

The first term is SPSD because $\mathbf{K}$ is SPSD. The second term is SPSD if δ^{ss} is nonnegative. We have

$$\begin{aligned}\delta^{\text{ss}} &= \text{tr}(\mathbf{K}) - \text{tr}\big(\bar{\mathbf{C}}^\dagger\mathbf{K}\bar{\mathbf{C}}\big) = \text{tr}(\mathbf{K}) - \text{tr}\big(\bar{\mathbf{C}}\bar{\mathbf{C}}^\dagger\mathbf{K}\big) = \text{tr}\big(\mathbf{K} - \mathbf{U}_{\bar{\mathbf{C}}}\mathbf{U}_{\bar{\mathbf{C}}}^T\mathbf{K}\big) \\ &= \text{tr}\big[\mathbf{U}_{\bar{\mathbf{C}}}^\perp(\mathbf{U}_{\bar{\mathbf{C}}}^\perp)^T\mathbf{K}\big] = \text{tr}\big[\mathbf{U}_{\bar{\mathbf{C}}}^\perp(\mathbf{U}_{\bar{\mathbf{C}}}^\perp)^T\mathbf{U}_{\bar{\mathbf{C}}}^\perp(\mathbf{U}_{\bar{\mathbf{C}}}^\perp)^T\mathbf{K}\big] = \text{tr}\big[\mathbf{U}_{\bar{\mathbf{C}}}^\perp(\mathbf{U}_{\bar{\mathbf{C}}}^\perp)^T\mathbf{K}\mathbf{U}_{\bar{\mathbf{C}}}^\perp(\mathbf{U}_{\bar{\mathbf{C}}}^\perp)^T\big] \geq 0.\end{aligned}$$

To this end, we have shown SPSD.

Then we assume $\mathbf{K}$ is positive definite and prove that its approximation formed by SS is also positive definite. Since $\mathbf{U}_{\bar{\mathbf{C}}}^\perp(\mathbf{U}_{\bar{\mathbf{C}}}^\perp)^T\mathbf{K}\mathbf{U}_{\bar{\mathbf{C}}}^\perp(\mathbf{U}_{\bar{\mathbf{C}}}^\perp)^T$ is SPSD, its trace is zero only when it is all-zeros, which is equivalent to $\mathbf{K} = \mathbf{U}_{\bar{\mathbf{C}}}\mathbf{U}_{\bar{\mathbf{C}}}^T\mathbf{K}\mathbf{U}_{\bar{\mathbf{C}}}\mathbf{U}_{\bar{\mathbf{C}}}^T$. However, this cannot hold if $\mathbf{K}$ has full rank. Therefore $\delta^{\text{ss}} > 0$ holds when $\tilde{\mathbf{K}}$ is positive definite. When $\mathbf{K}$ is positive definite, the $c \times c$ matrix $\mathbf{U}_{\bar{\mathbf{C}}}^T\mathbf{K}\mathbf{U}_{\bar{\mathbf{C}}}$ is also positive definite. It follows from (29) that

$$\tilde{\mathbf{K}} = \bar{\mathbf{C}}\mathbf{U}^{\text{ss}}\bar{\mathbf{C}}^T + \delta^{\text{ss}}\mathbf{I}_n = \begin{bmatrix}\mathbf{U}_{\bar{\mathbf{C}}} & \mathbf{U}_{\bar{\mathbf{C}}}^\perp\end{bmatrix}\begin{bmatrix}\mathbf{U}_{\bar{\mathbf{C}}}^T\mathbf{K}\mathbf{U}_{\bar{\mathbf{C}}} & \mathbf{0} \\ \mathbf{0} & \delta^{\text{ss}}\mathbf{I}_{n-c}\end{bmatrix}\begin{bmatrix}\mathbf{U}_{\bar{\mathbf{C}}}^T \\ (\mathbf{U}_{\bar{\mathbf{C}}}^\perp)^T\end{bmatrix}.$$

Here the block diagonal matrix is positive definite, and thus $\tilde{\mathbf{K}}$ is positive definite.

Appendix F. Proof of Theorem 8 and Theorem 9

Directly analyzing the theoretical error bound of the SS model is not easy, so we formulate a variant of SS called the inexact spectral shifting (ISS) model and instead analyze the error bound of ISS. We define ISS in Section F.1 and prove Theorem 8 and Theorem 9 in Section F.2 and F.3, respectively. In the following we let $\tilde{\mathbf{K}}_c^{\text{ss}}$ and $\tilde{\mathbf{K}}_c^{\text{iss}}$ be respectively the approximation formed by the two models.

F.1 The ISS Model

ISS is defined by

$$\tilde{\mathbf{K}}_c^{\text{iss}} = \bar{\mathbf{C}}\bar{\mathbf{U}}\bar{\mathbf{C}}^T + \delta\mathbf{I}_n, \tag{30}$$

where $\delta > 0$ is the spectral shifting term, and $\bar{\mathbf{C}}\bar{\mathbf{U}}\bar{\mathbf{C}}^T$ is the prototype model of $\bar{\mathbf{K}} = \mathbf{K} - \delta\mathbf{I}_n$. It follows from Theorem 6 that ISS is less accurate than SS in that

$$\big\|\mathbf{K} - \tilde{\mathbf{K}}_c^{\text{ss}}\big\|_F \leq \big\|\mathbf{K} - \tilde{\mathbf{K}}_c^{\text{iss}}\big\|_F,$$

thus the error bounds of ISS still hold if $\tilde{\mathbf{K}}_c^{\text{iss}}$ is replaced by $\tilde{\mathbf{K}}_c^{\text{ss}}$.

We first show how to set the spectral shifting term δ. Since $\bar{\mathbf{C}}\bar{\mathbf{U}}\bar{\mathbf{C}}^T$ is the approximation to $\bar{\mathbf{K}}$ formed by the prototype model, it can holds with high probability that

$$\big\|\mathbf{K} - \tilde{\mathbf{K}}_c^{\text{iss}}\big\|_F = \big\|\mathbf{K} - \bar{\delta}\mathbf{I}_n - \bar{\mathbf{C}}\bar{\mathbf{U}}\bar{\mathbf{C}}^T\big\|_F = \big\|\bar{\mathbf{K}} - \bar{\mathbf{C}}\bar{\mathbf{U}}\bar{\mathbf{C}}^T\big\|_F \leq \eta\big\|\bar{\mathbf{K}} - \bar{\mathbf{K}}_k\big\|_F$$

for some error parameter η. Apparently, for fixed k, the smaller the error $\|\bar{\mathbf{K}} - \bar{\mathbf{K}}_k\|_F$ is, the tighter error bound the ISS has; if $\|\bar{\mathbf{K}} - \bar{\mathbf{K}}_k\|_F \leq \|\mathbf{K} - \mathbf{K}_k\|_F$, then ISS has a better error bound than the prototype model. Therefore, our goal is to make $\|\bar{\mathbf{K}} - \bar{\mathbf{K}}_k\|_F$ as small as possible, so we formulate the following optimization problem to compute δ:

$$\min_{\delta \geq 0} \big\|\bar{\mathbf{K}} - \bar{\mathbf{K}}_k\big\|_F^2; \qquad \text{s.t. } \bar{\mathbf{K}} = \mathbf{K} - \delta\mathbf{I}_n.$$

However, since $\bar{\mathbf{K}}$ is in general indefinite, it requires all of the eigenvalues of $\mathbf{K}$ to solve the problem exactly. Since computing the full eigenvalue decomposition is expensive, we attempt to relax the problem. Considering that

$$\big\|\bar{\mathbf{K}} - \bar{\mathbf{K}}_k\big\|_F^2 = \min_{|\mathcal{J}|=n-k}\sum_{j\in\mathcal{J}}\big(\sigma_j(\mathbf{K}) - \delta\big)^2 \leq \sum_{j=k+1}^{n}\big(\sigma_j(\mathbf{K}) - \delta\big)^2, \tag{31}$$

we seek to minimize the upper bound of $\|\bar{\mathbf{K}} - \bar{\mathbf{K}}_k\|_F^2$, which is the right-hand side of (31), to compute δ, leading to the solution

$$\bar{\delta} = \frac{1}{n-k}\sum_{j=k+1}^{n}\sigma_j(\mathbf{K}) = \frac{1}{n-k}\bigg(\text{tr}(\mathbf{K}) - \sum_{j=1}^{k}\sigma_j(\mathbf{K})\bigg). \tag{32}$$

If we choose $\delta = 0$, then ISS degenerates to the prototype model.

F.2 Proof of Theorem 8

Theorem 6 indicates that ISS is less accurate than SS, thus

$$\big\|\mathbf{K} - \tilde{\mathbf{K}}_c^{\text{ss}}\big\|_F \leq \big\|\mathbf{K} - \tilde{\mathbf{K}}_c^{\text{iss}}\big\|_F = \big\|\mathbf{K} - \bar{\delta}\mathbf{I}_n - \bar{\mathbf{C}}\bar{\mathbf{C}}^\dagger\bar{\mathbf{K}}(\bar{\mathbf{C}}^\dagger)^T\bar{\mathbf{C}}^T\big\|_F = \big\|\bar{\mathbf{K}} - \bar{\mathbf{C}}\bar{\mathbf{C}}^\dagger\bar{\mathbf{K}}(\bar{\mathbf{C}}^\dagger)^T\bar{\mathbf{C}}^T\big\|_F.$$

Theorem 8 follows from the above inequality and the following theorem.

Theorem 24 *Let $\mathbf{K}$ be any $n \times n$ SPSD matrix, $\bar{\delta}$ be defined in (32), and $\bar{\mathbf{K}} = \mathbf{K} - \delta\mathbf{I}_n$. Then for any $\delta \in (0, \bar{\delta}]$, the following inequality holds:*

$$\big\|\bar{\mathbf{K}} - \bar{\mathbf{K}}_k\big\|_F^2 \leq \big\|\mathbf{K} - \mathbf{K}_k\big\|_F^2.$$

Proof Since the righthand side of (31) is convex and $\bar{\delta}$ is the minimizer of the righthand of (31), for any $\delta \in (0, \bar{\delta}]$, it holds that

$$\sum_{j=k+1}^{n}\big(\sigma_j(\mathbf{K}) - \delta\big)^2 \leq \sum_{j=k+1}^{n}\big(\sigma_j(\mathbf{K}) - 0\big)^2 = \big\|\mathbf{K} - \mathbf{K}_k\big\|_F^2.$$

Then the theorem follows by the inequality in (31). ■

F.3 Proof of Theorem 9

Since $\|\mathbf{K}-\tilde{\mathbf{K}}_c^{\mathrm{ss}}\|_F \le \|\mathbf{K}-\tilde{\mathbf{K}}_c^{\mathrm{iss}}\|_F$, Theorem 9 follows from Theorem 25.

Theorem 25 *Suppose there is a sketching matrix $\mathbf{P}\in\mathbb{R}^{n\times c}$ such that for any $n\times n$ symmetric matrix $\mathbf{S}$ and target rank k ($\ll n$), by forming the sketch $\mathbf{C}=\mathbf{SP}$, the prototype model satisfies the error bound*

$$\left\|\mathbf{S}-\mathbf{CC}^{\dagger}\mathbf{S}(\mathbf{C}^{\dagger})^T\mathbf{C}^T\right\|_F^2 \le \eta\left\|\mathbf{S}-\mathbf{S}_k\right\|_F^2.$$

Let $\mathbf{K}$ be any $n\times n$ SPSD matrix, $\bar{\delta}$ defined in (32) be the initial spectral shifting term, and $\tilde{\mathbf{K}}_c^{iss}$ be the ISS approximation defined in (30). Then

$$\left\|\mathbf{K}-\tilde{\mathbf{K}}_c^{iss}\right\|_F^2 \le \eta\left(\left\|\mathbf{K}-\mathbf{K}_k\right\|_F^2-\frac{\left[\sum_{i=k+1}^n\lambda_i(\mathbf{K})\right]^2}{n-k}\right).$$

Proof The error incurred by SS is

$$\begin{aligned}\left\|\mathbf{K}-\tilde{\mathbf{K}}_c^{\mathrm{ss}}\right\|_F^2 &= \left\|\left(\bar{\mathbf{K}}+\bar{\delta}\mathbf{I}_n\right)-\left(\bar{\mathbf{C}}\bar{\mathbf{U}}\bar{\mathbf{C}}^T+\bar{\delta}\mathbf{I}_n\right)\right\|_F^2 = \left\|\bar{\mathbf{K}}-\bar{\mathbf{C}}\bar{\mathbf{U}}\bar{\mathbf{C}}^T\right\|_F^2\\ &\le \eta\left\|\bar{\mathbf{K}}-\bar{\mathbf{K}}_k\right\|_F^2 = \eta\sum_{i=k+1}^n\sigma_i^2\left(\bar{\mathbf{K}}\right) = \eta\sum_{i=k+1}^n\lambda_i(\bar{\mathbf{K}}^2).\end{aligned}$$

Here the inequality follows from the assumption. The i-th largest eigenvalue of $\bar{\mathbf{K}}$ is $\lambda_i(\mathbf{K})-\bar{\delta}$, so the n eigenvalues of $\bar{\mathbf{K}}^2$ are all in the set $\{(\lambda_i(\mathbf{K})-\bar{\delta})^2\}_{i=1}^n$. The sum of the smallest $n-k$ of the n eigenvalues of $\bar{\mathbf{K}}^2$ must be less than or equal to the sum of any $n-k$ of the eigenvalues, thus we have

$$\begin{aligned}\sum_{i=k+1}^n\lambda_i(\bar{\mathbf{K}}^2) &\le \sum_{i=k+1}^n\left(\lambda_i(\mathbf{K})-\bar{\delta}\right)^2\\ &= \sum_{i=k+1}^n\lambda_i^2(\mathbf{K})-2\sum_{i=k+1}^n\bar{\delta}\lambda_i(\mathbf{K})+(n-k)(\bar{\delta})^2\\ &= \left\|\mathbf{K}-\mathbf{K}_k\right\|_F^2-\frac{1}{n-k}\left[\sum_{i=k+1}^n\lambda_i(\mathbf{K})\right]^2,\end{aligned}$$

by which the theorem follows. ■

Appendix G. Proof of Theorem 11

Proof Let $\tilde{\mathbf{K}}=\mathbf{Q}(\mathbf{Q}^T\mathbf{K})_k$, where $\mathbf{Q}$ is defined in Line 4 in Algorithm 5. Boutsidis et al. (2014) showed that

$$\mathbb{E}\|\mathbf{K}-\tilde{\mathbf{K}}\|_F^2 \le (1+k/l)\left\|\mathbf{K}-\mathbf{K}_k\right\|_F^2, \tag{33}$$

where the expectation is taken w.r.t. the random Gaussian matrix $\mathbf{\Omega}$.

It follows from Lemma 26 that

$$\|\boldsymbol{\sigma}_{\mathbf{K}}-\boldsymbol{\sigma}_{\tilde{\mathbf{K}}}\|_2^2 \le \|\mathbf{K}-\tilde{\mathbf{K}}\|_F^2,$$

where $\boldsymbol{\sigma}_{\mathbf{K}}$ and $\boldsymbol{\sigma}_{\tilde{\mathbf{K}}}$ contain the singular values in a descending order. Since $\tilde{\mathbf{K}}$ has a rank at most k, the $k+1$ to n entries of $\boldsymbol{\sigma}_{\tilde{\mathbf{K}}}$ are zero. We split $\boldsymbol{\sigma}_{\mathbf{K}}$ and $\boldsymbol{\sigma}_{\tilde{\mathbf{K}}}$ into vectors of length k and $n-k$:

$$\boldsymbol{\sigma}_{\mathbf{K}} = \begin{bmatrix}\boldsymbol{\sigma}_{\mathbf{K},k}\\ \boldsymbol{\sigma}_{\mathbf{K},-k}\end{bmatrix} \quad\text{and}\quad \boldsymbol{\sigma}_{\tilde{\mathbf{K}}} = \begin{bmatrix}\boldsymbol{\sigma}_{\tilde{\mathbf{K}},k}\\ \mathbf{0}\end{bmatrix}$$

and thus

$$\|\boldsymbol{\sigma}_{\mathbf{K},k}-\boldsymbol{\sigma}_{\tilde{\mathbf{K}},k}\|_2^2+\|\boldsymbol{\sigma}_{\mathbf{K},-k}\|_2^2 \le \|\mathbf{K}-\tilde{\mathbf{K}}\|_F^2. \tag{34}$$

Since $\|\boldsymbol{\sigma}_{\mathbf{K},-k}\|_2^2=\|\mathbf{K}-\mathbf{K}_k\|_F^2$, it follows from (33) and (34) that

$$\mathbb{E}\|\boldsymbol{\sigma}_{\mathbf{K},k}-\boldsymbol{\sigma}_{\tilde{\mathbf{K}},k}\|_2^2 \le \frac{k}{l}\|\boldsymbol{\sigma}_{\mathbf{K},-k}\|_2^2.$$

Since $\|\mathbf{x}\|_2\le\|\mathbf{x}\|_1\le\sqrt{k}\|\mathbf{x}\|_2$ for any $\mathbf{x}\in\mathbb{R}^k$, we have that

$$\mathbb{E}\left\|\boldsymbol{\sigma}_{\mathbf{K},k}-\boldsymbol{\sigma}_{\tilde{\mathbf{K}},k}\right\|_1 \le \frac{k}{\sqrt{l}}\left\|\boldsymbol{\sigma}_{\mathbf{K},-k}\right\|_1.$$

Then it follows from (32) and Line 6 in Algorithm 5 that

$$\begin{aligned}\mathbb{E}\left|\bar{\delta}-\tilde{\delta}\right| &= \mathbb{E}\left[\frac{1}{n-k}\left|\sum_{i=1}^k\sigma_i(\mathbf{K})-\sum_{i=1}^k\sigma_i(\tilde{\mathbf{K}})\right|\right]\\ &\le \frac{1}{n-k}\mathbb{E}\left\|\boldsymbol{\sigma}_{\mathbf{K},k}-\boldsymbol{\sigma}_{\tilde{\mathbf{K}},k}\right\|_1 \le \frac{k}{\sqrt{l}}\frac{1}{n-k}\left\|\boldsymbol{\sigma}_{\mathbf{K},-k}\right\|_1 = \frac{k}{\sqrt{l}}\bar{\delta}.\end{aligned}$$

■

Lemma 26 *Let $\mathbf{A}$ and $\mathbf{B}$ be $n\times n$ matrices and $\boldsymbol{\sigma}_{\mathbf{A}}$ and $\boldsymbol{\sigma}_{\mathbf{B}}$ contain the singular values in a descending order. Then we have that*

$$\|\boldsymbol{\sigma}_{\mathbf{A}}-\boldsymbol{\sigma}_{\mathbf{B}}\|_2^2 \le \|\mathbf{A}-\mathbf{B}\|_F^2.$$

Proof It is easy to show that

$$\begin{aligned}\|\mathbf{A}-\mathbf{B}\|_F^2 &= \mathrm{tr}(\mathbf{A}^T\mathbf{A})+\mathrm{tr}(\mathbf{B}^T\mathbf{B})-2\mathrm{tr}(\mathbf{A}^T\mathbf{B})\\ &= \sum_{i=1}^n\sigma_i^2(\mathbf{A})+\sum_{i=1}^n\sigma_i^2(\mathbf{B})-2\mathrm{tr}(\mathbf{A}^T\mathbf{B}).\end{aligned} \tag{35}$$

We also have

$$\mathrm{tr}(\mathbf{A}^T\mathbf{B}) \le \sum_{i=1}^n\sigma_i(\mathbf{A}^T\mathbf{B}) \le \sum_{i=1}^n\sigma_i(\mathbf{A})\sigma_i(\mathbf{B}), \tag{36}$$

where the first inequality follows from Theorem 3.3.13 of Horn and Johnson and the second inequality follows from Theorem 3.3.14 of Horn and Johnson. Combining (35) and (36) we have that

$$\|\mathbf{A}-\mathbf{B}\|_F^2 \;\geq\; \sum_{i=1}^{n}\left(\sigma_i^2(\mathbf{A})+\sigma_i^2(\mathbf{B})-2\sigma_i(\mathbf{A})\sigma_i(\mathbf{B})\right) \;=\; \|\boldsymbol{\sigma}_{\mathbf{A}}-\boldsymbol{\sigma}_{\mathbf{B}}\|_2^2,$$

by which the theorem follows. ■

Abstract

We define a general framework for a large class of combinatorial multi-armed bandit (CMAB) problems, where subsets of base arms with unknown distributions form *super arms*. In each round, a super arm is played and the base arms contained in the super arm are played and their outcomes are observed. We further consider the extension in which more base arms could be probabilistically triggered based on the outcomes of already triggered arms. The reward of the super arm depends on the outcomes of all played arms, and it only needs to satisfy two mild assumptions, which allow a large class of nonlinear reward instances. We assume the availability of an offline (α, β)-approximation oracle that takes the means of the outcome distributions of arms and outputs a super arm that with probability β generates an α fraction of the optimal expected reward. The objective of an online learning algorithm for CMAB is to minimize (α, β)-*approximation regret*, which is the difference in total expected reward between the $\alpha\beta$ fraction of expected reward when always playing the optimal super arm, and the expected reward of playing super arms according to the algorithm. We provide CUCB algorithm that achieves $O(\log n)$ distribution-dependent regret, where n is the number of rounds played, and we further provide distribution-independent bounds for a large class of reward functions. Our regret analysis is tight in that it matches the bound of UCB1 algorithm (up to a constant factor) for the classical MAB problem, and it significantly improves the regret bound in an earlier paper on combinatorial bandits with linear rewards. We apply our CMAB framework to two new applications, probabilistic maximum coverage (PMC) for online advertising and social influence maximization for viral marketing, both having nonlinear reward structures. In particular, application to social influence maximization requires our extension on probabilistically triggered arms.

Keywords: combinatorial multi-armed bandit, online learning, upper confidence bound, social influence maximization, online advertising

*. A preliminary version of this paper has appeared in ICML'2013 (Chen et al., 2013). The current version contains the extension of CMAB to accommodate probabilistically triggered arms and its application to social influence maximization. The research is partially supported by the National Natural Science Foundation of China (Grant No. 61433014).

1. Introduction

Multi-armed bandit (MAB) is a problem extensively studied in statistics and machine learning. The classical version of the problem is formulated as a system of m arms (or machines), each having an unknown distribution of the reward with an unknown mean. The task is to repeatedly play these arms in multiple rounds so that the total expected reward is as close to the reward of the optimal arm as possible. An MAB algorithm needs to decide which arm to play in the next round given the outcomes of the arms played in the previous rounds. The metric for measuring the effectiveness of an MAB algorithm is its *regret*, which is the difference in the total expected reward between always playing the optimal arm (the arm with the largest expected reward) and playing arms according to the algorithm. The MAB problem and its solutions reflect the fundamental tradeoff between exploration and exploitation: whether one should try some arms that have not been played much (exploration) or one should stick to the arms that provide good reward so far (exploitation). Existing results show that one can achieve a regret of $O(\log n)$ when playing arms in n rounds, and this is asymptotically the best possible.

In many real-world applications, the setting is not the simple MAB one, but has a combinatorial nature among multiple arms and possibly non-linear reward functions. For example, consider the following online advertising scenario. A web site contains a set of web pages and has a set of users visiting the web site. An advertiser wants to place an advertisement on a set of selected web pages on the site, and due to his budget constraint, he can select at most k web pages. Each user visits a certain set of pages, and each visited page has one click-through probability for each user clicking the advertisement on the page, but the advertiser does not know these probabilities. The advertiser wants to repeatedly select sets of k web pages, observe the click-through data collected to learn the click-through probabilities, and maximize the number of users clicking his advertisement over time.

There are several new challenges raised by the above example. First, page-user pairs can be viewed as arms, but they are not played in isolation. Instead, these arms form certain combinatorial structures, namely bipartite graphs, and in each round, a set of arms (called a *super arm*) are played together. Second, the reward structure is not a simple linear function of the outcomes of all played arms but takes a more complicated form. In the above example, for all page-user pairs with the same user, the collective reward of these arms is either 1 if the user clicks the advertisement on at least one of the pages, or 0 if the user does not click the advertisement on any page. Third, even the offline optimization problem when the probabilities on all edges of the bipartite graph are known is still an NP-hard problem. Thus, the online learning algorithm needs to deal with combinatorial arm structures, nonlinear reward functions, and computational hardness of the offline optimization task.

Consider another example of viral marketing in online social networks. In an online social network such as Facebook, companies carry out viral marketing campaigns by engaging with

a certain set of seed users (e.g. providing free sample products to seed users), and hoping that these seed users could generate a cascade in the network promoting their products. The cascades follow certain stochastic diffusion model such as the independent cascade model (Kempe et al., 2003), but the influence probabilities on edges are not known in advance and have to be learned over time. Thus, the online learning task is to repeatedly select seed nodes in a social network, observe the cascading behavior of the viral information to learn influence probabilities between individuals in the social network, with the goal of maximizing the overall effectiveness of all viral cascades. Similar to the online advertising example given above, we can treat each edge in the social network as a base arm, and all outgoing edges from a seed set as a super arm, which is the unit of play. Besides sharing the same challenges such as the combinatorial arm structures, nonlinear reward functions, and computational hardness of the offline maximization task, this viral marketing task faces another challenge: in each round after some seed set is selected, the cascade from the seed set may probabilistically trigger more edges (or arms) in the network, and the reward of the cascade depends on all probabilistically or deterministically triggered arms.

A naive way to tackle both examples above is to treat every super arm as an arm and simply apply the classical MAB framework to solve the above combinatorial problems. However, such naive treatment has two issues. First, the number of super arms may be exponential to the problem instance size due to the combinatorial explosion, and thus classical MAB algorithms may need exponential number of steps just to go through all the super arms once. Second, after one super arm is played, in many cases, we can observe some information regarding the outcomes of the underlying arms, which may be shared by other super arms. However, this information is discarded in the classical MAB framework, making it less effective.

In this paper, we define a general framework for the *combinatorial multi-armed bandit (CMAB)* problem to address the above issues and cover a large class of combinatorial online learning problems in the stochastic setting, including the two examples given above. In the CMAB framework, we have a set of m base arms, whose outcomes follow certain unknown joint distribution. A super arm S is a subset of base arms. In each round, one super arm is played and all base arms contained in the super arm are played. To accommodate applications such as viral marketing, we allow that the play of a super arm S may further trigger more base arms probabilistically, and the triggering depends on the outcomes of the already played base arms in the current round. The reward of the round is determined by the outcomes of all triggered arms, which are observed as the feedback to the online learning algorithm. A CMAB algorithm needs to use these feedback information from the past rounds to decide the super arm to play in the next round.

The framework allows an arbitrary combination of arms into super arms. The reward function only needs to satisfy two mild assumptions (referred to as monotonicity and bounded smoothness), and thus covering a large class of nonlinear reward functions. We do not assume the direct knowledge on how super arms are formed from underlying arms or how the reward is computed. Instead, we assume the availability of an offline computation oracle that takes such knowledge as well as the expectations of outcomes of all arms as input and computes the optimal super arm with respect to the input.

Since many combinatorial problems are computationally hard, we further allow (randomized) approximation oracles with failure probabilities. In particular, we relax the oracle

to be an (α, β)-approximation oracle for some $\alpha, \beta \leq 1$, that is, with success probability β, the oracle could output a super arm whose expected reward is at least α fraction of the optimal expected reward. As a result, our regret metric is not comparing against the expected reward of playing the optimal super arm each time, but against the $\alpha\beta$ fraction of the optimal expected reward, since the offline oracle can only guarantee this fraction in expectation. We refer to this as the (α, β)-*approximation regret*.

For the general framework, we provide the CUCB (combinatorial upper confidence bound) algorithm, an extension to the UCB1 algorithm for the classical MAB problem (Auer et al., 2002a). We provide a rigorous analysis on the distribution-dependent regret of CUCB and show that it is still bounded by $O(\log n)$. Our analysis further allows us to provide a distribution-independent regret bound that works for arbitrary distributions of underlying arms, for a large class of CMAB instances. For the extension accommodating probabilistically triggered arms, we also provide distribution-dependent and -independent bounds with triggering probabilities as parameters.

We then apply our framework and provide solutions to two new bandit applications, the probabilistic maximum coverage problem for advertisement placement and social influence maximization for viral marketing. The offline versions of both problems are NP-hard, with constant approximation algorithms available. Both problems have nonlinear reward structures that cannot be handled by any existing work.

We also apply our result to combinatorial bandits with linear rewards, recently studied by Gai et al. (2012). We show that we significantly improve their distribution-dependent regret bound, even though we are covering a much larger class of combinatorial bandit instances. We also provide new distribution-independent bound not available in their paper (Gai et al., 2012).

This paper is an extension to our ICML'2013 paper (Chen et al., 2013), with explicit modeling of probabilistically triggered arms and their regret analysis for the CUCB algorithm. We correct an erroneous claim in that paper (Chen et al., 2013), which states that the original CMAB model and result without probabilistically triggered arms can be applied to the online learning task for social influence maximization. Our correction includes explicit modeling of probabilistically triggered arms in the CMAB framework, and significant reworking of the regret analysis to incorporate triggering probabilities in the analysis and the regret bounds.

In summary, our contributions include: (a) defining a general CMAB framework that encompasses a large class of nonlinear reward functions, (b) providing CUCB algorithm with a rigorous regret analysis as a general solution to this CMAB framework, (c) further generalizing our framework to accommodate probabilistically triggered base arms, and applying this framework to the social influence maximization problem, and (d) demonstrating that our general framework can be effectively applied to a number of practical combinatorial bandit problems, including ones with nonlinear rewards. Moreover, our framework provides a clean separation of the online learning task and the offline computation task: the oracle takes care of the offline computation task, which uses the domain knowledge of the problem instance, while our CMAB algorithm takes care of the online learning task, and is oblivious to the domain knowledge of the problem instance.

1.1 Related Work

Multi-armed bandit problem has been well studied in the literature, in particular in statistics and reinforcement learning (cf. Berry and Fristedt, 1985; Sutton and Barto, 1998). Our work follows the line of research on stochastic MAB problems, which is initiated by Lai and Robbins (1985), who show that under certain conditions on reward distributions, one can achieve a tight asymptotic regret of $\Theta(\log n)$, where n is the number of rounds played. Later, Auer et al. (2002a) demonstrate that $O(\log n)$ regret can be achieved uniformly over time rather than only asymptotically. They propose several MAB algorithms, including the UCB1 algorithm, which has been widely followed and adapted in MAB research.

For combinatorial multi-armed bandits, a few specific instances of the problem has been studied in the literature. A number of studies consider simultaneous plays of k arms among m arms (e.g. Anantharam et al., 1987; Caro and Gallien, 2007; Liu et al., 2011). Other instances include the matching bandit (Gai et al., 2010) and the online shortest path problem (Liu and Zhao, 2012).

The work closest to ours is a recent work by Gai et al. (2012), which also considers a combinatorial bandit framework with an approximation oracle. However, our work differs from theirs in several important aspects. Most importantly, their work only considers linear rewards while our CMAB framework includes a much larger class of linear and nonlinear rewards. Secondly, our regret analysis is much tighter, and as a result we significantly improve their distribution-dependent regret bound when applying our result to the linear reward case, and we are able to derive a distribution-independent regret bound close to the theoretical lower bound while they do not provide distribution-independent bounds. Moreover, we allow the approximation oracle to have a failure probability (i.e., $\beta < 1$), while they do not consider such failure probabilities.

In terms of types of feedbacks in combinatorial bandits (Audibert et al., 2011), our work belongs to the *semi-bandit* type, in which the player observes only the outcomes of played arms in one round of play. Other types include (a) *full information*, in which the player observes the outcomes of all arms, and (b) *bandit*, in which the player only observes the final reward but no outcome of any individual arm. More complicated feedback dependences are also considered by Mannor and Shamir (2011).

Bounded smoothness property in our paper is an extended form of Lipschitz condition, but our model and results differ from the Lipschitz bandit research (Kleinberg et al., 2008) in several aspects. First, Lipschitz bandit considers a continuous metric space where every point is an arm, and the Lipschitz condition is applied to two points (i.e., two arms). Under this assumption, if we know one arm pretty well, we will also know the nearby arms pretty well. In contrast, our bounded smoothness condition is applied to a vector of mean values of the base arms instead of one super arm, and by knowing one super arm well, we cannot directly know how good are the other super arms. Second, the feedback model is different: Lipschitz bandit assumes bandit feedback model while our CMAB assumes semi-bandit feedback. Third, using the Lipschitz condition, they designed a new algorithm called zooming algorithm, which maintains a confidence radius of arms, so that by knowing the center arm well, they are also pretty confident of the arms within the confidence radius of the center. In comparison, our algorithm is basically a direct extension of the classical UCB algorithm, in which the confidence radius is used to get confidence on the estimate of

every base arm. Kleinberg et al. (2008) generalize the setting of continuum bandits, which assumes the strategy set is a compact subset of $\mathbb{R}^d$ and the reward function satisfies the Lipschitz condition (see e.g. Agrawal, 1995; Kleinberg, 2004).

A different line of research considers *adversarial multi-armed bandit*, initiated by Auer et al. (2002b), in which no probabilistic assumptions are made about the rewards, and they can even be chosen by an adversary. In the context of adversarial bandits, several studies also consider combinatorial bandits (Cesa-Bianchi and Lugosi, 2009; Audibert et al., 2011; Bubeck et al., 2012). For linear rewards, Kakade et al. (2009) have shown how to convert an approximation oracle into an online algorithm with sublinear regret both in the full information setting and the bandit setting. For non-linear rewards, various online submodular optimization problems with bandit feedback are studied in the adversarial setting (Streeter and Golovin, 2008; Radlinski et al., 2008; Streeter et al., 2009; Hazan and Kale, 2009). Notice that our framework deals with stochastic instances and we can handle reward functions more general than the submodular ones.

This paper is the full version of our ICML'2013 paper (Chen et al., 2013) with the extension to include probabilistically triggered arms in the model and analysis. We made a mistake previously (Chen et al., 2013) by claiming that the online learning task for social influence maximization is an instance of the original CMAB model (Chen et al., 2013) without explicitly modeling probabilistically triggered arms. In this paper we correct this mistake by allowing probabilistically triggered arms in the CMAB model, and by significantly revising the analysis to include triggering probabilities in the analysis and the regret bounds.

Since our work of CMAB model (Chen et al., 2013), several studies are also related to combinatorial multi-armed bandits or in general combinatorial online learning. Qin et al. (2014) extend CMAB to contextual bandits and apply it to diversified online recommendations. Lin et al. (2014) address combinatorial actions with limited feedbacks. Gopalan et al. (2014) use Thompson sampling method to tackle combinatorial online learning problems. Comparing with our CMAB framework, they allow more feedback models than our semi-bandit feedback model, but they require finite number of actions and observations, their regret contains a large constant term, and it is unclear if their framework supports approximation oracles for hard combinatorial optimization problems. Kveton et al. (2014) study linear matroid bandits, which is a subclass of the linear combinatorial bandits we discussed in Section 4.2, and they provide better regret bounds than our general bounds given in Section 4.2, because their analysis utilizes the matroid combinatorial structure. In a latest paper, Kveton et al. (2015) improve the regret bounds of the linear combinatorial bandits via a more sophisticated non-uniform sufficient sampling condition than the one we used in our paper. However, it is unclear if this technique can be applied to non-linear reward functions satisfying the bounded smoothness condition (see discussions in Section 4.2 for more details).

1.2 Paper Organization

In Section 2 we formally define the CMAB framework. Section 3 provides the CUCB algorithm and the main results on its regret bounds and the proofs. Section 4 shows how to apply the CMAB framework and CUCB algorithm to the online advertising and viral

marketing applications, as well as the class of combinatorial bandits with linear reward functions. We conclude the paper in Section 5.

2. General CMAB Framework

A *combinatorial multi-armed bandit (CMAB)* problem consists of m *base arms* associated with a set of random variables $X_{i,t}$ for $1 \le i \le m$ and $t \ge 1$, with bounded support on $[0,1]$. Variable $X_{i,t}$ indicates the random outcome of the i-th base arm in its t-th trial. The set of random variables $\{X_{i,t} \mid t \ge 1\}$ associated with base arm i are independent and identically distributed according to some unknown distribution with unknown expectation μ_i. Let $\boldsymbol{\mu} = (\mu_1, \mu_2, \ldots, \mu_m)$ be the vector of expectations of all base arms. Random variables of different base arms may be dependent.

The unit of play in CMAB is a *super arm*, which is a set of base arms. Let $\mathcal{S}$ denote the set of all possible super arms that can be played in a CMAB problem instance. For example, $\mathcal{S}$ could be the set of all subsets of base arms containing at most k base arms. In each round, one of the super arms $S \in \mathcal{S}$ is selected and played, and every base arm $i \in S$ are triggered and played as a result. The outcomes of base arms in S may trigger other base arms not in S to be played, and the outcomes of these arms may further trigger more arms to be played, and so on. Therefore, when super arm S is played in round t, a superset of S is triggered and played, and the final reward of this round depends on the outcomes of all triggered base arms. The feedback in the round after playing super arm S is the outcomes of the triggered (played) base arms. The random outcomes of triggered base arms in one round are independent of random outcomes in other rounds, but they may depend on one another in the same round.

For each $i \in [m]$, let p_i^S denote the probability that base arm i is triggered when super arm S is played. Once super arm S is fixed, the event of triggering of base arm i is independent of the history of previous plays of super arms. It is clear that for all $i \in S$, $p_i^S = 1$. Note that probability p_i^S may not be known to the learning algorithm, since the event of triggering base arm i may depend on the random outcomes of other base arms, the distribution of which may be unknown. Moreover, the triggering of base arms may depend on certain combinatorial structure of the problem instance, and triggering of different base arms may not be independent from one another (for an example, see the social influence maximization application in Section 4.3).

Let $\tilde{S} = \{i \in [m] \mid p_i^S > 0\}$ denote the set of possibly triggered base arms by super arm S, also referred to as the *triggering set* of S. Let $p_i \triangleq \min_{S \in \mathcal{S}, i \in \tilde{S}} p_i^S$ denote the minimum nonzero triggering probability of base arm i under all super arms. When $p_i = 1$ for all $i \in [m]$, each super arm S deterministically triggers all base arms in $\tilde{S}$, in which case we treat S and $\tilde{S}$ as the same set. Let $p^* \triangleq \min_{i \in [m]} p_i$.

In our model, it is possible that a base arm i does not belong to any super arm, and thus i can only be probabilistically triggered. In fact, our model is flexible enough to allow that *all* based arms are probabilistically triggered. To do so, we can simply add a set of dummy base arms and dummy super arms for the purpose of probabilistically triggering real base arms. In particular, for each real base arm i, we can add a dummy base arm d_i, which is a Bernoulli random variable with 1 meaning i is triggered and 0 meaning i is not triggered. Then a dummy super arm containing a subset of these Bernoulli dummy base

arms can be used to probabilistically trigger a set of real base arms. If all super arms are such dummy super arms, then all real base arms are only probabilistically triggered.

For each arm $i \in [m]$, let $T_{i,t}$ denote the number of times arm i has been successfully triggered after the first t rounds in which t super arms are played. If an arm $i \in \tilde{S} \setminus S$ is not triggered in round t when super arm S is played, then $T_{i,t} = T_{i,t-1}$. Let $R_t(S)$ be a non-negative random variable denoting the reward of round t when super arm S is played. The reward depends on the actual problem instance definition, the super arm S played, and the outcomes of all triggered arms in round t. The reward $R_t(S)$ might be as simple as a summation of the outcomes of the triggered arms in S: $R_t(S) = \sum_{i \in \tilde{S}, i \text{ is triggered}} X_{i,T_{i,t}}$, but our framework allows more sophisticated nonlinear rewards, as explained below.

In this paper, we consider CMAB problems in which the expected reward of playing any super arm S in any round t, $\mathbb{E}[R_t(S)]$, is a function of S and the expectation vector $\boldsymbol{\mu}$ of all arms. For the linear reward case as given above together with no probabilistic triggering ($S = \tilde{S}$), this is true because linear addition is commutative with the expectation operator. For non-linear reward functions not commutative with the expectation operator, it is still true if we know the type of distributions and only the expectations of arm outcomes are unknown. For example, the distribution of $X_{i,t}$'s are known to be independent 0-1 Bernoulli random variables with unknown mean μ_i.[1] Henceforth, we denote the expected reward of playing S as $r_{\boldsymbol{\mu}}(S) \triangleq \mathbb{E}[R_t(S)]$.

Definition 1 (Assumptions on expected reward function)**.** *To carry out our analysis, we make the following two mild assumptions on the expected reward $r_{\boldsymbol{\mu}}(S)$:*

- **Monotonicity**. *The expected reward of playing any super arm $S \in \mathcal{S}$ is monotonically nondecreasing with respect to the expectation vector, i.e., if for all $i \in [m]$, $\mu_i \le \mu_i'$, we have $r_{\boldsymbol{\mu}}(S) \le r_{\boldsymbol{\mu}'}(S)$ for all $S \in \mathcal{S}$.*
- **Bounded smoothness.** *There exists a continuous, strictly increasing (and thus invertible) function $f(\cdot)$ with $f(0) = 0$, called* bounded smoothness function*, such that for any two expectation vectors $\boldsymbol{\mu}$ and $\boldsymbol{\mu}'$ and for any $\Lambda > 0$, we have $|r_{\boldsymbol{\mu}}(S) - r_{\boldsymbol{\mu}'}(S)| \le f(\Lambda)$ if $\max_{i \in \tilde{S}} |\mu_i - \mu_i'| \le \Lambda$, for all $S \in \mathcal{S}$.*

Both assumptions are natural. In particular, they hold true for all the applications we considered. We remark that bounded smoothness is an extended form of Lipschitz condition in that we use a general function f instead of linear or power-law functions typically used in Lipschitz condition definition, and we use infinity norm instead of typically used L_2 norm.

Definition 2 (CMAB algorithm)**.** *A CMAB algorithm A is one that selects the super arm of round t to play based on the outcomes of revealed arms of previous rounds, without knowing the expectation vector $\boldsymbol{\mu}$. Let $S_t^A \in \mathcal{S}$ be the super arm selected by A in round t. Note that S_t^A is a random super arm that depends on the outcomes of arms in previous rounds and potential randomness in the algorithm A itself. The objective of algorithm A is to maximize the expected reward of all rounds up to a round n, that is, $\mathbb{E}_{S,R}[\sum_{t=1}^n R_t(S_t^A)] = \mathbb{E}_S[\sum_{t=1}^n r_{\boldsymbol{\mu}}(S_t^A)]$, where $\mathbb{E}_{S,R}$ denotes taking expectation among all*

1. It is also possible that the Bernoulli random variables are not independent. For example, the joint distribution is determined by sampling a random value $\rho \in [0,1]$ uniformly at random, and then each base arm i takes value 1 if any only if $\rho \le \mu_i$.

random events generating the super arms S_t^A's and generating rewards $R_t(S_t^A)$'s, and $\mathbb{E}_S$ denotes taking expectation only among all random events generating the super arms S_t^A's.

We do not assume that the learning algorithm has the direct knowledge about the problem instance, e.g. how super arms are formed from the base arms, how base arms outside of a super arm are triggered, and how reward is defined. Instead, the algorithm has access to a computation oracle that takes the expectation vector $\boldsymbol{\mu}$ as the input, and together with the knowledge of the problem instance, computes the optimal or near-optimal super arm S. Let $\text{opt}_{\boldsymbol{\mu}} = \max_{S\in\mathcal{S}} r_{\boldsymbol{\mu}}(S)$ and $S^*_{\boldsymbol{\mu}} = \text{argmax}_{S\in\mathcal{S}} r_{\boldsymbol{\mu}}(S)$. We consider the case that exact computation of $S^*_{\boldsymbol{\mu}}$ may be computationally hard, and the algorithm may be randomized with a small failure probability. Thus, we resolve to the following (α,β)-*approximation oracle*:

Definition 3 ((α,β)-Approximation oracle)**.** *For some $\alpha,\beta \le 1$, (α,β)-approximation oracle is an oracle that takes an expectation vector $\boldsymbol{\mu}$ as input, and outputs a super arm $S \in \mathcal{S}$, such that $\Pr[r_{\boldsymbol{\mu}}(S) \ge \alpha \cdot \text{opt}_{\boldsymbol{\mu}}] \ge \beta$. Here β is the success probability of the oracle.*

Many computationally hard problems do admit efficient approximation oracles (Vazirani, 2004). With an (α,β)-approximation oracle, it is no longer fair to compare the performance of a CMAB algorithm against the optimal reward $\text{opt}_{\boldsymbol{\mu}}$ as the regret of the algorithm. Instead, we compare against the $\alpha\cdot\beta$ fraction of the optimal reward, because only a β fraction of oracle computations are successful, and when successful the reward is only an α-approximation of the optimal value.

Definition 4 ((α,β)-approximation regret)**.** *(α,β)-approximation regret of a CMAB algorithm A after n rounds of play using an (α,β)-approximation oracle under the expectation vector $\boldsymbol{\mu}$ is defined as*

$$Reg^A_{\boldsymbol{\mu},\alpha,\beta}(n) = n\cdot\alpha\cdot\beta\cdot\text{opt}_{\boldsymbol{\mu}} - \mathbb{E}_S\left[\sum_{t=1}^{n} r_{\boldsymbol{\mu}}(S_t^A)\right]. \tag{1}$$

Note that the classical MAB problem is a special case of our general CMAB problem, in which (a) the constraint $\mathcal{S} = \{\{i\} \mid i \in [m]\}$ so that each super arm is just a base arm; (b) $S = \tilde{S}$ for all super arm S, that is, playing of a base arm does not trigger any other arms; (c) the reward of a super arm $S = \{i\}$ in its t's trial is its outcome $X_{i,t}$; (d) the monotonicity and bounded smoothness hold trivially with function $f(\cdot)$ being the identity function; and (e) the (α,β)-approximation oracle is simply the argmax function among all expectation vectors, with $\alpha = \beta = 1$.

3. CUCB Algorithm for CMAB

We present our CUCB algorithm in Algorithm 1. We maintain an empirical mean $\hat{\mu}_i$ for each arm i. More precisely, if arm i has been played s times by the end of round n, then the value of $\hat{\mu}_i$ at the end of round n is $(\sum_{j=1}^{s} X_{i,j})/s$. The actual expectation vector $\bar{\boldsymbol{\mu}}$ given to the oracle contains an adjustment term $\sqrt{\frac{3\ln t}{2T_i}}$ for each $\hat{\mu}_i$, which depends on the round number t and the number of times arm i has been played (stored in variable T_i).

1: For each arm i, maintain: (1) variable T_i as the total number of times arm i is played so far, initially 0; (2) variable $\hat{\mu}_i$ as the mean of all outcomes $X_{i,*}$'s of arm i observed so far, initially 1.
2: $t \leftarrow 0$.
3: **while true do**
4: $\quad t \leftarrow t+1$.
5: $\quad$ For each arm i, set $\bar{\mu}_i = \min\left\{\hat{\mu}_i + \sqrt{\frac{3\ln t}{2T_i}}, 1\right\}$.
6: $\quad S = \text{Oracle}(\bar{\mu}_1, \bar{\mu}_2, \ldots, \bar{\mu}_m)$.
7: $\quad$ Play S, observe outcomes of played base arms i, and update all T_i's and $\hat{\mu}_i$'s.
8: **end while**

Algorithm 1: CUCB with computation oracle.

Then we simply play the super arm returned by the oracle and update variables T_i's and $\hat{\mu}_i$'s accordingly. Note that in our model all arms have bounded support on $[0,1]$, but with the adjustment the upper confidence bound $\hat{\mu}_i + \sqrt{\frac{3\ln t}{2T_i}}$ may exceed 1, in which case we simply trim it down to 1 and assign it to $\bar{\mu}_i$ (line 5).

Our algorithm does not have an initialization phase where all base arms are played at least once. This is to accommodate the case where some base arms may only be probabilistically triggered and there is no super arm that can trigger them deterministically. Instead, we simply initialize the counter T_i to 0 and $\hat{\mu}_i$ to 1 for every base arm i. Thus initially $\bar{\mu}_i = 1$ for all i, and the oracle will select a super arm given an all-one vector input. Intuitively, any base arm i that has not been played will have its $\bar{\mu}_i = 1$, which should let the oracle be biased toward playing a super arm that (likely) triggers i. It may be possible that a base arm i is never played, and this only means that i is not important for the optimization task and the oracle decides not to play it (deterministically or probabilistically). Our analysis works correctly without the initialization phase.

We now provide necessary definitions for the main theorems.

Definition 5 (Bad super arm)**.** *A super arm S is* bad *if $r_{\boldsymbol{\mu}}(S) < \alpha\cdot\text{opt}_{\boldsymbol{\mu}}$. The set of bad super arms is defined as $\mathcal{S}_{\text{B}} \triangleq \{S \mid r_{\boldsymbol{\mu}}(S) < \alpha\cdot\text{opt}_{\boldsymbol{\mu}}\}$. For a given base arm $i \in [m]$, let $\mathcal{S}_{i,\text{B}} = \{S \in \mathcal{S}_{\text{B}} \mid i \in \tilde{S}\}$ be the set of bad super arms whose triggering sets contain i. We sort all bad super arms in $\mathcal{S}_{i,\text{B}}$ as $S^1_{i,\text{B}}, S^2_{i,\text{B}}, \ldots, S^{K_i}_{i,\text{B}}$, in increasing order of their expected rewards, where $K_i = |\mathcal{S}_{i,\text{B}}|$. Note that when $K_i = 0$, there is no bad super arm that can trigger base arm i.*

Definition 6 (Δ of bad super arms)**.** *For a bad super arm $S \in \mathcal{S}_{\text{B}}$, we define $\Delta_S \triangleq \alpha\cdot\text{opt}_{\boldsymbol{\mu}} - r_{\boldsymbol{\mu}}(S)$. For a given base arm $i \in [m]$ with $K_i > 0$ and index $j \in [K_i]$, we define*

$$\Delta^{i,j} \triangleq \Delta_{S^j_{i,\text{B}}}.$$

We have special notations for the minimum and the maximum $\Delta^{i,j}$ for a fixed i with $K_i > 0$:

$$\Delta^i_{\max} \triangleq \Delta^{i,1},$$
$$\Delta^i_{\min} \triangleq \Delta^{i,K_i}.$$

Furthermore, define $\Delta_{\max} \triangleq \max_{i\in[m],K_i>0}\Delta^i_{\max}$, $\Delta_{\min} \triangleq \min_{i\in[m],K_i>0}\Delta^i_{\min}$.

Our main theorem below provides the distribution-dependent regret bound of the CUCB algorithm using the Δ notations. We use $\mathbb{I}\{\cdot\}$ to denote the indicator function, and $\mathbb{I}\{\mathcal{E}\} = 1$ if $\mathcal{E}$ is true, and 0 if $\mathcal{E}$ is false.

Theorem 1. *The (α, β)-approximation regret of the CUCB algorithm in n rounds using an (α, β)-approximation oracle is at most*

$$\sum_{i\in[m],K_i>0}\left(\ell_n(\Delta^i_{\min}, p_i)\Delta^i_{\min} + \int_{\Delta^i_{\min}}^{\Delta^i_{\max}} \ell_n(x, p_i)\mathrm{d}x\right) + \left(\frac{(2+\mathbb{I}\{p^*<1\})\pi^2}{6}+1\right)\cdot m\cdot\Delta_{\max}, \tag{2}$$

where $p^* = \min_{i\in[m]} p_i$, and

$$\ell_n(\Delta, p) = \begin{cases} \max\left(\frac{12\cdot\ln n}{(f^{-1}(\Delta))^2\cdot p}, \frac{24\cdot\ln n}{p}\right), & \text{if } 0<p<1,\\ \frac{6\ln n}{(f^{-1}(\Delta))^2}, & \text{if } p=1.\end{cases}$$

and $f(\cdot)$ is the bounded smoothness function.

Note that when $p_i = 1$ for all $i \in [m]$, each super arm S deterministically triggers base arms in S and no probabilistic triggering of other arms. In this case, the above theorem falls back to Theorem 1 of the original CMAB paper (Chen et al., 2013). When $p_i < 1$ for some $i \in [m]$, the regret bound is slightly more complicated, in particular, it has an extra factor of $1/p_i$ appearing in the leading $\ln n$ term.

In Theorem 1, when $\Delta^i_{\min}$ is extremely small, the regret would be approaching infinity. Below we prove a distribution-independent regret for arbitrary distributions with support in $[0, 1]$ on all arms, for a large class of problem instances with a polynomial bounded smoothness function $f(x) = \gamma x^\omega$ for $\gamma > 0$ and $0 < \omega \le 1$. The rough idea of the proof is, if $\Delta^i_{\min} \le 1/\sqrt{n}$, it can only contribute $\sqrt{n}$ regret at time horizon n. The proof of the following theorem relies on the tight regret bound of Theorem 1 on the leading $\ln n$ term.

Theorem 2. *Consider a CMAB problem with an (α, β)-approximation oracle. Let $p^* = \min_{i\in[m]} p_i$. If the bounded smoothness function $f(x) = \gamma\cdot x^\omega$ for some $\gamma > 0$ and $\omega \in (0, 1]$, the regret of CUCB is at most:*

$$\begin{cases} \frac{2\gamma}{2-\omega}\cdot(6m\ln n)^{\omega/2}\cdot n^{1-\omega/2} + \left(\frac{\pi^2}{3}+1\right)\cdot m\cdot\Delta_{\max}, & \text{if } p^*=1,\\ \frac{2\gamma}{2-\omega}\cdot\left(\frac{12m\ln n}{p^*}\right)^{\omega/2}\cdot n^{1-\omega/2} + \left(\frac{\pi^2}{2}+1\right)\cdot m\cdot\Delta_{\max} + \sum_{i\in[m]}\frac{24\ln n}{p_i}\cdot\Delta_{\max}, & \text{if } 0<p^*<1.\end{cases}$$

Note that for all applications discussed in Section 4, we have $\omega = 1$. For the classical MAB setting with $\omega = 1$ and $p^* = 1$, we obtain a distribution-independent bound of $O(\sqrt{mn\ln n})$, which matches (up to a logarithmic factor) the original UCB1 algorithm (Audibert et al., 2009). In the linear combinatorial bandit setting, i.e., semi-bandit with L_∞ assumption (Audibert et al., 2011), our regret is $O(\sqrt{m^3 n\log n})$, which is a factor $\sqrt{m}$ off the optimal bound in the adversarial setting, a more general setting than the stochastic setting (see the discussion in the end of Section 4.2 for a reason of this gap).

3.1 Proof of the Theorems

Below we prove Theorem 1 and Theorem 2.

3.1.1 Proof of Theorem 1

Before getting to the proof of our theorem, we need more definitions and lemmas. First, we have a convenient notation for the case when the oracle outputs non-α-approximation answers.

Definition 7 (Non-α-approximation output)**.** *In the t-th round, let F_t be the event that the oracle fails to produce an α-approximate answer with respect to its input $\bar{\boldsymbol{\mu}} = (\bar\mu_1, \bar\mu_2, \ldots, \bar\mu_m)$. We have $\Pr[F_t] = \mathbb{E}[\mathbb{I}\{F_t\}] \le 1-\beta$.*

Since the value of many variables are changing in different rounds, we also define notations for their value in round t. All of them are random variables.

Definition 8 (Variables in round t)**.** *For variable T_i, let $T_{i,t}$ be the value of T_i at the end of round t, that is, $T_{i,t}$ is the number of times arm i is played in the first t rounds. For variable $\hat\mu_i$, let $\hat\mu_{i,s}$ be the value of $\hat\mu_i$ after arm i is played s times, that is, $\hat\mu_{i,s} = (\sum_{j=1}^s X_{i,j})/s$, where $X_{i,j}$ is the outcome of base arm i in its j-th trial, as defined at the beginning of Section 2. Then, the value of variable $\hat\mu_i$ at the end of round t is $\hat\mu_{i,T_{i,t}}$. For variable $\bar\mu_i$, let $\bar\mu_{i,t}$ be the value of $\bar\mu_i$ at the end of round t.*

Next, we introduce an important parameter in our proof called sampling threshold.

Definition 9 (Sampling threshold)**.** *For a probability value $p \in (0, 1]$ and reward difference value $\Delta \in \mathbb{R}^+$, the value $\ell_n(\Delta, p)$ defined below is called the* sampling threshold *for round n:*

$$\ell_n(\Delta, p) = \begin{cases} \max\left(\frac{12\cdot\ln n}{(f^{-1}(\Delta))^2\cdot p}, \frac{24\cdot\ln n}{p}\right), & \text{if } 0<p<1,\\ \frac{6\ln n}{(f^{-1}(\Delta))^2}, & \text{if } p=1.\end{cases}$$

Informally, base arm $i \in [m]$ at round n is considered as sufficiently sampled if the number of times i has been played by round n, $T_{i,n}$, is above its sampling threshold $\ell_n(\Delta^i_{\min}, p_i)$. When all base arms are sufficiently sampled, with high probability we would obtain accurate estimates of their sample means and would be able to distinguish the α-approximate super arms from bad super arms.

We utilize the following well known tail bounds in our analysis.

Fact 1 (Hoeffding's Inequality (Hoeffding, 1963))**.** *Let $X_1, \cdots, X_n$ be independent and identically distributed random variables with common support $[0, 1]$ and mean μ. Let $Y = X_1 + \cdots + X_n$. Then for all $\delta \ge 0$,*

$$\Pr\{|Y - n\mu| \ge \delta\} \le 2e^{-2\delta^2/n}.$$

Fact 2 (Multiplicative Chernoff Bound (Mitzenmacher and Upfal, 2005)[2])**.** *Let $X_1, \cdots, X_n$ be Bernoulli random variables taking values from $\{0, 1\}$, and $\mathbb{E}[X_t|X_1, \cdots, X_{t-1}] \ge \mu$ for*

2. The result in the book by Mitzenmacher and Upfal (2005) (Theorem 4.5 together with Exercise 4.7) only covers the case where random variables X_i's are independent. However the result can be easily generalized to our case with an almost identical proof. The only main change is to replace $\mathbb{E}\left[e^{t(\sum_{j=1}^{i-1} X_j + X_i)}\right] = \mathbb{E}\left[e^{t\sum_{j=1}^{i-1} X_j}\right]\mathbb{E}\left[e^{tX_i}\right]$ with $\mathbb{E}\left[e^{t(\sum_{j=1}^{i-1} X_j + X_i)}\right] = \mathbb{E}\left[e^{t\sum_{j=1}^{i-1} X_j}\mathbb{E}\left[e^{tX_i} \mid X_1, \ldots, X_{i-1}\right]\right]$.

every $t \le n$. Let $Y = X_1 + \cdots + X_n$. Then for all $0 < \delta < 1$,

$$\Pr\{Y \le (1-\delta)n\mu\} \le e^{-\frac{\delta^2 n\mu}{2}}.$$

Using the above tail bounds, we can prove that with high probability, the empirical mean of a set of independently sampled variables is close to the actual mean. Below we give a definition on the standard difference between the empirical mean and the actual expectation.

Definition 10 (Standard difference). *For the random variable $T_{i,t-1}$, standard difference is defined as a random variable $\Lambda_{i,t} = \min\{\sqrt{\frac{3\ln t}{2T_{i,t-1}}}, 1\}$. The maximum standard difference is defined as a random variable $\Lambda_t = \max\{\Lambda_{i,t} \mid i \in \tilde{S}_t\}$ (be reminded that it is $\tilde{S}_t$, not S_t). The universal difference bound is defined as $\Lambda^{i,l} = \frac{f^{-1}(\Delta^{i,l})}{2}$, which is* not *a random variable.*

If in the round t, the difference between the empirical mean and the actual expectation is below the standard difference, we call the process a "nice process". See the formal definition below.

Definition 11 (Nice run). *The run of Algorithm 1 is* nice *at time t (denoted as the indicator $\mathcal{N}_t$) if:*

$$\forall i \in [m],\ |\hat{\mu}_{i,T_{i,t-1}} - \mu_i| \le \Lambda_{i,t}. \tag{3}$$

Lemma 1. *The probability that the run of Algorithm 1 is* nice *at time t is at least $1 - \frac{2m}{t^2}$.*

Proof. If $T_{i,t-1} = 0$, this is trivially true. If $T_{i,t-1} > 0$, by the Hoeffding's inequality in Fact 1, for any $i \in [m]$,

$$\begin{aligned}
&\Pr\left\{|\ \hat{\mu}_{i,T_{i,t-1}} - \mu_i\ | \ge \Lambda_{i,t}\right\} = \sum_{s=1}^{t-1} \Pr\left\{|\ \hat{\mu}_{i,s} - \mu_i\ | \ge \Lambda_{i,t}, T_{i,t-1} = s\right\} \\
\le &\sum_{s=1}^{t-1} \Pr\left\{|\ \hat{\mu}_{i,s} - \mu_i\ | \ge \sqrt{\frac{3\ln t}{2s}}\right\} \le t \cdot 2e^{-3\ln t} = \frac{2}{t^2}.
\end{aligned} \tag{4}$$

The lemma follows by taking union bound on i. □

Lemma 1 tells us that if at time t, $T_{i,t-1}$ is large, then we can get a good estimation of μ_i. Intuitively, if we estimate all μ_i's pretty well, it is unlikely that we will choose a bad super arm using the approximation oracle. On the other hand, in the case that for some i $T_{i,t-1}$ is small, although we may not have a good estimate of μ_i, it indicates that arm i has not been played for many times, which gives us an upper bound on the number of times that the algorithm plays a bad super arm containing arm i. Based on this idea, it is crucial to find a sampling threshold, which separates these two cases.

Now we need to define the way that we count the sampling times of each arm i.

Definition 12 (Counter for arm i). *We maintain a counter N_i for each arm i. Let $N_{i,t}$ be the value of N_i at the end of round t and $N_{i,0} = 0$. $\{N_i\}$ is updated in the following way.*

For a round $t > 0$, let S_t be the super arm selected in round t by the oracle (line 6 of Algorithm 1). Round t is bad *if the oracle selects a* bad *super arm $S_t \in \mathcal{S}_{\mathrm{B}}$. If round t is bad, let $i = \mathrm{argmin}_{j \in \tilde{S}_t} N_{j,t-1} \cdot p_j$. If the above i is not unique, we pick an arbitrary one. Then we increment the counter N_i, i.e., $N_{i,t} = N_{i,t-1} + 1$ while not changing other counters N_j with $j \ne i$. If round t is not bad, i.e., $S_t \notin \mathcal{S}_{\mathrm{B}}$, no counter N_i is incremented.*

Note that the counter N_i is for the purpose of analysis, and its maintenance is not part of the algorithm. Intuitively, for each round t where a bad super arm S_t is played, we increment exactly one counter N_i, where i is selected among all possibly triggered base arms $\tilde{S}_t$ such that the current value of $N_i \cdot p_i$ is the lowest. In the special case when $p_i = 1$ for some $i \in [m]$, we know that $i \notin \tilde{S} \setminus S$ for any super arm S. Therefore, whenever arm i is selected to increment its counter N_i in a round t, i must have been played in round t, and thus we have $T_{i,t} \ge N_{i,t}$ for any $i \in [m]$ with $p_i = 1$ and all time t. However, this may not holds for $i \in [m]$ with $p_i < 1$, that is, it is possible that in a round t a base arm i is not triggered but its counter N_i is incremented.

In every bad round, exactly one counter in $\{N_i\}$ is incremented, so the total number of bad rounds in the first n rounds is exactly $\sum_i N_{i,n}$. Below we give the definition of refined counters.

Definition 13 (Refined counters). *Each time N_i gets updated, one of the bad super arms that could trigger i is played. We further separate N_i into a set of counters as follows:*

$$\forall l \in [K_i],\ N^l_{i,n} = \sum_{t=1}^{n} \mathbb{I}\{S_t = S^l_{i,\mathrm{B}}, N_{i,t} > N_{i,t-1}\}.$$

That is, each time N_i is updated, we also record which bad super arm is played.

With these counters in hands, we shall define the two stages "sufficiently sampled" and "under-sampled" using the sampling threshold, which further split the counter $N^l_{i,n}$ into two counters.

Definition 14 (Sufficiently sampled and under-sampled). *Consider time horizon n and current time $t \le n$. For the refined counter $N^l_{i,n}$'s, we separate them into sufficiently sampled part and under-sampled part, as defined below. When counter $N^l_{i,t}$ is incremented at time t, i.e, $S_t = S^l_{i,\mathrm{B}}$, we inspect the counter $N_{i,t-1}$. If $N_{i,t-1} > \ell_n(\Delta^{i,l}, p_i)$, we say that the bad super arm $S^l_{i,\mathrm{B}}$ is* sufficiently sampled *(with respect to base arm i); otherwise, it is* under-sampled *(with respect to base arm i). Thus counter $N^l_{i,n}$ is separated into the following sufficiently sampled part and under-sampled part:*

$$\begin{aligned}
N^{l,suf}_{i,n} &= \sum_{t=1}^{n} \mathbb{I}\{S_t = S^l_{i,\mathrm{B}}, N_{i,t} > N_{i,t-1}, N_{i,t-1} > \ell_n(\Delta^{i,l}, p_i)\}, \\
N^{l,und}_{i,n} &= \sum_{t=1}^{n} \mathbb{I}\{S_t = S^l_{i,\mathrm{B}}, N_{i,t} > N_{i,t-1}, N_{i,t-1} \le \ell_n(\Delta^{i,l}, p_i)\}.
\end{aligned}$$

Following the definition, we have $N_{i,n}^{l,und} \le \ell_n(\Delta^{i,l}, p_i)$, and $N_{i,n} = \sum_{l\in[K_i]}(N_{i,n}^{l,suf} + N_{i,n}^{l,und})$. Using this notation, the total reward at time horizon n is at least

$$n \cdot \alpha \cdot \mathrm{opt}_{\boldsymbol{\mu}} - \sum_{i\in[m],K_i>0} \sum_{l\in[K_i]} (N_{i,n}^{l,suf} + N_{i,n}^{l,und}) \cdot \Delta^{i,l}. \tag{5}$$

To get an upper bound on the regret, we want to upper bound $N_{i,n}^{l,suf}$ and $N_{i,n}^{l,und}$ separately. Before doing that, we prove an important connection as follows.

Lemma 2 (Connection between $N_{i,t-1}$ and $T_{i,t-1}$)**.** *Let n be the time horizon. For every round t with $0 < t \le n$, every base arm $i \in [m]$, every $\Delta > 0$, and every integer $k > \ell_n(\Delta, p_i)$, we have,*

$$\Pr\left\{N_{i,t-1} = k, T_{i,t-1} \le \frac{6\cdot\ln t}{f^{-1}(\Delta)^2}\right\} \le \frac{1}{t^3}. \tag{6}$$

Moreover, if p_i=1, we have

$$\Pr\left\{N_{i,t-1} = k, T_{i,t-1} \le \frac{6\cdot\ln t}{f^{-1}(\Delta)^2}\right\} = 0.$$

Proof. Fix a base arm i. The case of $p_i = 1$ is trivial since in this case $T_{i,t-1} \ge N_{i,t-1}$ and $n \ge t$. Now we only consider the case of $0 < p_i < 1$.

In a run of CUCB algorithm (Algorithm 1), let $t^{(j)}$ be the round number at which counter N_i is incremented for the j-th time. Suppose that in round $t^{(j)}$, super arm $S^{(j)}$ is played. Note that both $t^{(j)}$ and $S^{(j)}$ are random, depending on the randomness of the outcomes of base arms and the triggering of base arms from super arms in all historical rounds.

Let $X^{(j)}$ be the Bernoulli random variable indicating whether arm i is triggered by the play of super arm $S^{(j)}$ in round $t^{(j)}$. If in a run of the CUCB algorithm counter N_i is only incremented a finite number of times, let $N_{i,\infty}$ denote the final value of the counter N_i in this run. In this case, we simply define $X^{(j)} = 1$ for all $j > N_{i,\infty}$. For convenience, when $j > N_{i,\infty}$, we denote the corresponding super arm $S^{(j)} = \perp$. Thus, for any $\ell \ge 1$, $\sum_{j=1}^{\ell} X^{(j)}$ is well defined. For all $0 < t \le n$, since $T_{i,t-1}$ is the number of times i is triggered by the end of round $t-1$, we have

$$\sum_{j=1}^{N_{i,t-1}} X^{(j)} \le T_{i,t-1}. \tag{7}$$

We now show that for any $j \ge 1$, $\mathbb{E}[X^{(j)} \mid X^{(1)}, \ldots, X^{(j-1)}] \ge p_i$. Fixing a super arm $A \in \mathcal{S}$, if super arm $S^{(j)}$ played in round $t^{(j)}$ is A, then conditioned on the event $S^{(j)} = A$, in this round whether arm i is triggered or not only depends on the randomness of triggering base arms after playing A, and is independent of randomness in previous rounds. In other words, we have

$$\Pr\left\{X^{(j)} = 1 \mid S^{(j)} = A, X^{(1)}, \ldots, X^{(j-1)}\right\} = \Pr\left\{X^{(j)} = 1 \mid S^{(j)} = A\right\} = p_i^A \ge p_i.$$

By the law of total probability, we have

$$\begin{aligned}
&\mathbb{E}[X^{(j)} \mid X^{(1)}, \ldots, X^{(j-1)}] \\
&= \Pr\left\{X^{(j)} = 1 \mid X^{(1)}, \ldots, X^{(j-1)}\right\} \\
&= \sum_{A\in\mathcal{S}} \Pr\left\{S^{(j)} = A\right\} \cdot \Pr\left\{X^{(j)} = 1 \mid S^{(j)} = A, X^{(1)}, \ldots, X^{(j-1)}\right\} \\
&\quad + \Pr\left\{S^{(j)} = \perp\right\} \cdot \Pr\left\{X^{(j)} = 1 \mid S^{(j)} = \perp, X^{(1)}, \ldots, X^{(j-1)}\right\} \\
&\ge p_i \sum_{A\in\mathcal{S}} \Pr\left\{S^{(j)} = A\right\} + \Pr\left\{S^{(j)} = \perp\right\} \cdot 1 \qquad (8) \\
&\ge p_i,
\end{aligned}$$

where the first part of the Inequality Eq. (8) comes from Eq. (3.1.1), and the second part comes from our definition that when $S^{(j)} = \perp$, it means that the counter N_i stops before reaching j and $X^{(j)} = 1$ in this case.

With the result that for any $j \ge 1$, $\mathbb{E}[X^{(j)} \mid X^{(1)}, \ldots, X^{(j-1)}] \ge p_i$, we apply the multiplicative Chernoff bound (Fact 2) to obtain that for any $\ell \ge 1$, $0 < \delta < 1$,

$$\Pr\left\{\sum_{j=1}^{\ell} X^{(j)} \le \ell \cdot p_i(1-\delta)\right\} \le e^{-\delta^2 \ell p_i/2}. \tag{9}$$

We are now ready to carry out the following derivation for any $0 < t \le n$, $i \in [m]$, $\Delta > 0$, and integer $k > \ell_n(\Delta, p_i)$:

$$\begin{aligned}
&\Pr\left\{N_{i,t-1} = k, T_{i,t-1} \le \frac{6\cdot\ln t}{f^{-1}(\Delta)^2}\right\} \\
&\le \Pr\left\{N_{i,t-1} = k, \sum_{j=1}^{N_{i,t-1}} X^{(j)} \le \frac{6\cdot\ln t}{f^{-1}(\Delta)^2}\right\} && \{\text{by Eq. (7)}\} \\
&\le \Pr\left\{\sum_{j=1}^{k} X^{(j)} \le \frac{6\cdot\ln t}{f^{-1}(\Delta)^2}\right\} \\
&\le \Pr\left\{\sum_{j=1}^{\lceil \ell_n(\Delta,p_i)\rceil} X^{(j)} \le \frac{6\cdot\ln t}{f^{-1}(\Delta)^2}\right\} \\
&\le \Pr\left\{\sum_{j=1}^{\lceil \ell_t(\Delta,p_i)\rceil} X^{(j)} \le \frac{6\cdot\ln t}{f^{-1}(\Delta)^2}\right\}. && \{n \ge t \Rightarrow \ell_n(\Delta,p_i) \ge \ell_t(\Delta,p_i)\} \qquad (10)
\end{aligned}$$

If $f^{-1}(\Delta)^2 \le \frac{1}{2}$, let $\delta = \frac{1}{2}$, we know $\ell_t(\Delta, p_i) = \frac{12 \cdot \ln t}{f^{-1}(\Delta)^2 \cdot p_i}$, so

$$\begin{aligned}
(10) &= \Pr\left\{\sum_{j=1}^{\lceil \ell_t(\Delta,p_i)\rceil} X^{(j)} \le \ell_t(\Delta,p_i)\cdot p_i \cdot \frac{1}{2}\right\} \\
&\le \Pr\left\{\sum_{j=1}^{\lceil \ell_t(\Delta,p_i)\rceil} X^{(j)} \le \lceil \ell_t(\Delta,p_i)\rceil \cdot p_i \cdot \frac{1}{2}\right\} \\
&\le e^{-\lceil \ell_t(\Delta,p_i)\rceil p_i/8} && \{\text{by Eq. (9)}\} \\
&\le e^{-\ell_t(\Delta,p_i)p_i/8} = e^{-\frac{3\ln t}{2f^{-1}(\Delta)^2}} \le e^{-3\ln t} = \frac{1}{t^3}.
\end{aligned}$$

If $f^{-1}(\Delta)^2 > \frac{1}{2}$, we know $\ell_t(\Delta, p_i) = \frac{24 \cdot \ln t}{p_i}$. Now let $\delta = 1 - \frac{1}{4f^{-1}(\Delta)^2} \ge \frac{1}{2}$, which means $1 - \delta = \frac{1}{4f^{-1}(\Delta)^2}$. So we have,

$$\begin{aligned}
(10) &= \Pr\left\{\sum_{j=1}^{\lceil \ell_t(\Delta,p_i)\rceil} X^{(j)} \le \frac{24\ln t}{4f^{-1}(\Delta)^2\cdot p_i}\cdot p_i\right\} \\
&= \Pr\left\{\sum_{j=1}^{\lceil \ell_t(\Delta,p_i)\rceil} X^{(j)} \le \ell_t(\Delta,p_i)\cdot p_i \cdot (1-\delta)\right\} \\
&\le e^{-\ell_t(\Delta,p_i)p_i/8} && \{\text{by Eq. (9)}\} \\
&= e^{-3\ln t} = \frac{1}{t^3}.
\end{aligned}$$

Therefore, Inequality (6) holds. □

Recall that a nice run at time t (Definition 11, denoted as $\mathcal{N}_t$) means that the difference between the empirical mean and the actual mean is bounded by the standard difference $\Lambda_{i,t}$ for every arm $i \in [m]$ ($\forall i \in [m]$, $|\hat{\mu}_{i,T_{i,t-1}} - \mu_i| \le \Lambda_{i,t}$). By Lemma 1, we know that with probability $1 - \frac{2m}{t^2}$, $\mathcal{N}_t$ holds. According to line 5 of Algorithm 1, we have $\bar{\mu}_{i,t} = \min\{\hat{\mu}_{i,T_{i,t-1}} + \Lambda_{i,t}, 1\}$. Thus, we have

$$\mathcal{N}_t \Rightarrow \forall i \in [m],\ \bar{\mu}_{i,t} - \mu_i \ge 0, \tag{11}$$

$$\mathcal{N}_t \Rightarrow \forall i \in \tilde{S}_t,\ \bar{\mu}_{i,t} - \mu_i \le 2\Lambda_t. \tag{12}$$

Meanwhile, by Definition 10, we know that for any $i \in [m]$, $l \in [K_i]$ and any time t:

$$\left\{S_t = S^l_{i,\mathrm{B}}, \forall s \in \tilde{S}_t, T_{s,t-1} > \frac{6\ln t}{f^{-1}(\Delta^{i,l})^2}\right\} \Rightarrow \Lambda^{i,l} > \Lambda_t. \tag{13}$$

With the previous observations, we have the following lemma. Informally, it says that in a nice run in round t, it is impossible that the algorithm would select a bad super arm S_t using the oracle, which outputs a correct α-approximation answer, while every arm in $\tilde{S}_t$ has been tested for enough times.

Lemma 3 (Impossible case)**.** *Let F_t be the indicator defined in Definition 7. For any $i \in [m]$, $l \in [K_i]$ and any time t, the event $\left\{\mathcal{N}_t, \neg F_t, S_t = S^l_{i,\mathrm{B}}, \forall s \in \tilde{S}_t, T_{s,t-1} > \frac{6\ln t}{f^{-1}(\Delta^{i,l})^2}\right\}$ is empty.*

Proof. Indeed, if all the conditions hold, we have:

$$\begin{aligned}
r_{\boldsymbol{\mu}}(S_t) + f(2\Lambda^{i,l}) &> r_{\boldsymbol{\mu}}(S_t) + f(2\Lambda_t) && \{\text{ strict monotonicity of } f(\cdot) \text{ and Eq.(13)}\} \\
&\ge r_{\bar{\boldsymbol{\mu}}_t}(S_t) && \{\text{bounded smoothness property and Eq.(12)}\} \\
&\ge \alpha \cdot \mathrm{opt}_{\bar{\boldsymbol{\mu}}_t} && \{\neg F_t \Rightarrow S_t \text{ is an } \alpha \text{ approximation w.r.t } \bar{\boldsymbol{\mu}}_t\ \} \\
&\ge \alpha \cdot r_{\bar{\boldsymbol{\mu}}_t}(S^*_{\boldsymbol{\mu}}) && \{\text{definition of } \mathrm{opt}_{\bar{\boldsymbol{\mu}}_t}\} \\
&\ge \alpha \cdot r_{\boldsymbol{\mu}}(S^*_{\boldsymbol{\mu}}) = \alpha \cdot \mathrm{opt}_{\boldsymbol{\mu}}. && \{\text{ monotonicity of } r_{\boldsymbol{\mu}}(S) \text{ and Eq.(11)}\}
\end{aligned}$$

So we have

$$r_{\boldsymbol{\mu}}(S^l_{i,\mathrm{B}}) + f(2\Lambda^{i,l}) > \alpha \cdot \mathrm{opt}_{\boldsymbol{\mu}}. \tag{14}$$

However, by Definition 10, $f(2\Lambda^{i,l}) = f(f^{-1}(\Delta^{i,l})) = \Delta^{i,l}$. Thus, Inequality (14) contradicts the definition of $\Delta^{i,l}$ in Definition 6. □

Now we are ready to prove the bound on sufficiently sampled part. Recall that $p^* = \min_{i\in[m]} p_i$.

Lemma 4. *[Bound on sufficiently sampled part] For any time horizon $n > m$,*

$$\mathbb{E}\left[\sum_{i\in[m],K_i>0}\sum_{l\in[K_i]} N^{l,suf}_{i,n}\right] \le (1-\beta)n + \frac{(2+\mathbb{I}\{p^*<1\})m\pi^2}{6}. \tag{15}$$

Proof. From Definition 14 on $N^{l,suf}_{i,n}$, we have

$$\begin{aligned}
&\mathbb{E}\left[\sum_{i\in[m],K_i>0}\sum_{l\in[K_i]} N^{l,suf}_{i,n}\right] \\
&= \mathbb{E}\left[\sum_{i\in[m],K_i>0}\sum_{l\in[K_i]}\sum_{t=1}^{n} \mathbb{I}\left\{S_t = S^l_{i,\mathrm{B}}, N_{i,t} > N_{i,t-1}, N_{i,t-1} > \ell_n\left(\Delta^{i,l}, p_i\right)\right\}\right] \\
&\le \sum_{i\in[m],K_i>0}\sum_{l\in[K_i]}\sum_{t=1}^{n} \Pr\left\{S_t = S^l_{i,\mathrm{B}}, N_{i,t} > N_{i,t-1}, \forall s \in \tilde{S}_t, N_{s,t-1} > \ell_n\left(\Delta^{i,l}, p_s\right)\right\},
\end{aligned}$$

where the last inequality is due to our way of updating counter N_i by Definition 12: When N_i is incremented in round t such that $N_{i,t} > N_{i,t-1}$, we know that $N_{i,t-1} \cdot p_i$ has the lowest value among all $N_{s,t-1} \cdot p_s$ for $s \in \tilde{S}_t$, and thus $N_{i,t-1} > \ell_n\left(\Delta^{i,l}, p_i\right)$ implies that for $s \in \tilde{S}_t$, $N_{s,t-1} \ge N_{i,t-1} \cdot p_i/p_s > \ell_n\left(\Delta^{i,l}, p_i\right) \cdot p_i/p_s = \ell_n\left(\Delta^{i,l}, p_s\right)$. To prove the lemma, it is sufficient to show that for any $0 < t \le n$,

$$\sum_{i\in[m],K_i>0}\sum_{l\in[K_i]} \Pr\left\{S_t = S^l_{i,\mathrm{B}}, N_{i,t} > N_{i,t-1}, \forall s \in \tilde{S}_t, N_{s,t-1} > \ell_n\left(\Delta^{i,l}, p_s\right)\right\} \tag{16}$$

$$\le (1-\beta) + \frac{(2+\mathbb{I}\{p^*<1\})m}{t^2}. \tag{17}$$

This is because we may then take the union bound on all t's, and get a bound of

$$\sum_{t=1}^{n}\left((1-\beta)+\frac{3m}{t^2}\right)\leq(1-\beta)n+\frac{(2+\mathbb{I}\{p^*<1\})m\pi^2}{6}.$$

Thus, in order to prove our claim, it suffices to prove Inequality (17).

We first split Eq.(16) into two parts:

$$\begin{aligned}
&\sum_{i\in[m],K_i>0}\sum_{l\in[K_i]}\Pr\left\{S_t=S_{i,\mathrm{B}}^l,N_{i,t}>N_{i,t-1},\forall s\in\tilde{S}_t,N_{s,t-1}>\ell_n\left(\Delta^{i,l},p_s\right)\right\}\\
=&\sum_{i\in[m],K_i>0}\sum_{l\in[K_i]}\Pr\Bigg\{S_t=S_{i,\mathrm{B}}^l,N_{i,t}>N_{i,t-1},\forall s\in\tilde{S}_t, &(18)\\
&N_{s,t-1}>\ell_n\left(\Delta^{i,l},p_s\right),T_{s,t-1}>\frac{6\cdot\ln t}{f^{-1}(\Delta^{i,l})^2}\Bigg\}\\
&+\sum_{i\in[m],K_i>0}\sum_{l\in[K_i]}\Pr\Bigg\{S_t=S_{i,\mathrm{B}}^l,N_{i,t}>N_{i,t-1},\forall s\in\tilde{S}_t, &(19)\\
&N_{s,t-1}>\ell_n\left(\Delta^{i,l},p_s\right),\exists s\in\tilde{S}_t,T_{s,t-1}\leq\frac{6\cdot\ln t}{f^{-1}(\Delta^{i,l})^2}\Bigg\}.\\
=&\Pr\Bigg\{\exists i\in[m],\exists l\in[K_i],S_t=S_{i,\mathrm{B}}^l,N_{i,t}>N_{i,t-1},\forall s\in\tilde{S}_t, &(20)\\
&N_{s,t-1}>\ell_n\left(\Delta^{i,l},p_s\right),T_{s,t-1}>\frac{6\cdot\ln t}{f^{-1}(\Delta^{i,l})^2}\Bigg\}\\
&+\Pr\Bigg\{\exists i\in[m],\exists l\in[K_i],S_t=S_{i,\mathrm{B}}^l,N_{i,t}>N_{i,t-1}, &(21)\\
&\forall s\in\tilde{S}_t,N_{s,t-1}>\ell_n\left(\Delta^{i,l},p_s\right),\exists s\in\tilde{S}_t,T_{s,t-1}\leq\frac{6\cdot\ln t}{f^{-1}(\Delta^{i,l})^2}\Bigg\}, &(22)
\end{aligned}$$

where the last equality is due to that the events $\{S_t=S_{i,\mathrm{B}}^l,N_{i,t}>N_{i,t-1}\}$ for all $i\in[m]$ and $l\in[K_i]$ are mutually exclusive, since $N_{i,t}>N_{i,t-1}$ determines the unique i (at most one N_i is incremented in each round by Definition 12) and then $S_t=S_{i,\mathrm{B}}^l$ determines the unique l.

For the first term in Eq.(22), we apply Lemma 3 and have:

$$\begin{aligned}
&\forall i\in[m]\forall l\in[K_i],\Pr\left\{\mathcal{N}_t,\neg F_t,S_t=S_{i,\mathrm{B}}^l,N_{i,t}>N_{i,t-1},\forall s\in\tilde{S}_t,\ T_{s,t-1}>\frac{6\cdot\ln t}{f^{-1}(\Delta^{i,l})^2}\right\}=0\Rightarrow\\
&\Pr\left\{\mathcal{N}_t,\neg F_t,\exists i\in[m],\exists l\in[K_i],S_t=S_{i,\mathrm{B}}^l,N_{i,t}>N_{i,t-1},\forall s\in\tilde{S}_t,\ T_{s,t-1}>\frac{6\cdot\ln t}{f^{-1}(\Delta^{i,l})^2}\right\}=0\Rightarrow\\
&\Pr\left\{\exists i\in[m],\exists l\in[K_i],S_t=S_{i,\mathrm{B}}^l,N_{i,t}>N_{i,t-1},\forall s\in\tilde{S}_t,\ T_{s,t-1}>\frac{6\cdot\ln t}{f^{-1}(\Delta^{i,l})^2}\right\}\\
&\quad\leq\Pr[F_t\vee\neg\mathcal{N}_t]\leq(1-\beta)+\frac{2m}{t^2}. \qquad (23)
\end{aligned}$$

The inequality in Eq.(23) uses the definition of F_t (Definition 7) and Lemma 1.

For the second term in Eq.(22), we have:

$$\begin{aligned}
&\Pr\Bigg\{\exists i\in[m],\exists l\in[K_i],S_t=S_{i,\mathrm{B}}^l,N_{i,t}>N_{i,t-1},\forall s\in\tilde{S}_t,N_{s,t-1}>\ell_n\left(\Delta^{i,l},p_s\right), &(24)\\
&\exists s\in\tilde{S}_t,T_{s,t-1}\leq\frac{6\cdot\ln t}{f^{-1}(\Delta^{i,l})^2}\Bigg\}\\
&\leq\Pr\left\{\exists i\in[m],\exists l\in[K_i],\exists s\in\tilde{S}_t,N_{s,t-1}>\ell_n\left(\Delta^{i,l},p_s\right),T_{s,t-1}\leq\frac{6\cdot\ln t}{f^{-1}(\Delta^{i,l})^2}\right\}\\
&\leq\sum_{s\in\tilde{S}_t}\sum_{k=1}^{t-1}\Pr\left\{\exists i\in[m],\exists l\in[K_i],N_{s,t-1}=k,N_{s,t-1}>\ell_n\left(\Delta^{i,l},p_s\right),T_{s,t-1}\leq\frac{6\cdot\ln t}{f^{-1}(\Delta^{i,l})^2}\right\}. \qquad (25)
\end{aligned}$$

Let $\Delta^*(s,k)=\min_{i\in[m],l\in[K_i],\ell_n(\Delta^{i,l},p_s)<k}\Delta^{i,l}$, and $\Delta^*(s,k)=\emptyset$ if the condition of min is not satisfied. Since $f^{-1}(\Delta)$ decreases when Δ decreases, we know that when the event $\{\exists i\in[m],\exists l\in[K_i],N_{s,t-1}=k,N_{s,t-1}>\ell_n\left(\Delta^{i,l},p_s\right),T_{s,t-1}\leq\frac{6\cdot\ln t}{f^{-1}(\Delta^{i,l})^2}\}$ is non-empty, it is included in the event $\{N_{s,t-1}=k,T_{s,t-1}\leq\frac{6\cdot\ln t}{f^{-1}(\Delta^*(s,k))^2}\}$. Therefore, we have

$$\begin{aligned}
(25)&\leq\sum_{s\in\tilde{S}_t}\sum_{k\in[t-1],\Delta^*(s,k)\neq\emptyset}\Pr\left\{N_{s,t-1}=k,T_{s,t-1}\leq\frac{6\cdot\ln t}{f^{-1}(\Delta^*(s,k))^2}\right\}\\
&\leq\sum_{s\in\tilde{S}_t}\sum_{k\in[t-1]}\frac{\mathbb{I}\{p_i<1\}}{t^3} &\{\text{by Lemma 2}\}\\
&\leq\frac{\mathbb{I}\{p^*<1\}m}{t^2}. &(26)
\end{aligned}$$

Combining Eq.(23) and Eq.(26), we obtain Eq.(17). □

Now we consider the bound on under-sampled part, i.e., the number of times that the played bad super arms are under-sampled. For a particular arm i, its counter N_i will increase from 0 to $\ell_n(\Delta^{i,K_i},p_i)$ before it is sufficiently sampled. Assume $N_{i,t-1}\in(\ell_n(\Delta^{i,j-1},p_i),\ell_n(\Delta^{i,j},p_i)]$ when N_i is incremented at time t with an *under-sampled* super arm $S_{i,B}^l$. We can conclude that $\Delta^{i,l}\leq\Delta^{i,j}$, which will be used as an upper bound for the regret. Otherwise, we must have $\Delta^{i,l}\geq\Delta^{i,j-1}$ and $S_{i,B}^l$ is already *sufficiently sampled*.

To simplify the notation, set $\ell_n(\Delta^{i,0},p_i)=0$. Notice that $N_{i,0}=0$ for all i. For each base arm i, the boundary case of $0=N_{i,t-1}<N_{i,t}$ occurs in only one round in a run, and we treat it separately by using $\Delta_{\max}^i$ as the regret for this case. For the rest, we break the range of the counter $N_{i,t-1}$ with $N_{i,t-1}>0$ into discrete segments, i.e., $(\ell_n(\Delta^{i,j-1},p_i),\ell_n(\Delta^{i,j},p_i)]$ for $j\in[K_i]$. Let us assume that the round t is bad and $N_{i,t}$ is incremented. Assume $N_{i,t-1}\in(\ell_n(\Delta^{i,j-1},p_i),\ell_n(\Delta^{i,j},p_i)]$ for some j. Notice that we are only interested in the case that S_t is under-sampled. In particular, if this is indeed the case, $S_t=S_{\mathrm{B}}^{i,l}$ for some $l\geq j$. (Otherwise, S_t is sufficiently sampled based on the counter $N_{i,t-1}$.) Therefore, we will suffer a regret of $\Delta^{i,l}\leq\Delta^{i,j}$ (See Definition 6). Consequently, for counter $N_{i,t}$ in range $(\ell_n(\Delta^{i,j-1},p_i),\ell_n(\Delta^{i,j},p_i)]$, we will suffer a total regret for those under-sampled arms at most $(\ell_n(\Delta^{i,j},p_i)-\ell_n(\Delta^{i,j-1},p_i))\cdot\Delta^{i,j}$ in rounds that $N_{i,t}$ is incremented.

Lemma 5 (Bound on under-sampled part). *For any time horizon $n > m$, we have,*

$$\sum_{i\in[m],K_i>0}\sum_{l\in[K_i]} N_{i,n}^{l,und}\cdot\Delta^{i,l} \le \sum_{i\in[m],K_i>0}\left(\ell_n(\Delta^i_{\min},p_i)\Delta^i_{\min}+\int_{\Delta^i_{\min}}^{\Delta^i_{\max}}\ell_n(x,p_i)\mathrm{d}x+\Delta^i_{\max}\right). \tag{27}$$

Proof. It suffices to show that for any arm $i\in[m]$ with $K_i>0$,

$$\sum_{l\in[K_i]} N_{i,n}^{l,und}\cdot\Delta^{i,l} \le \ell_n(\Delta^i_{\min},p_i)\Delta^i_{\min}+\int_{\Delta^i_{\min}}^{\Delta^i_{\max}}\ell_n(x,p_i)\mathrm{d}x+\Delta^i_{\max}.$$

Now, by definition and discussion on the interval that $N_{i,t-1}$ lies in, we have

$$\begin{aligned}
&\sum_{l\in[K_i]} N_{i,n}^{l,und}\cdot\Delta^{i,l}\\
=&\sum_{t=1}^{n}\sum_{l\in[K_i]}\mathbb{I}\{S_t=S^l_{i,\mathrm{B}},N_{i,t}>N_{i,t-1},N_{i,t-1}\le\ell_n(\Delta^{i,l},p_i)\}\cdot\Delta^{i,l}\\
=&\sum_{t=1}^{n}\sum_{l\in[K_i]}\mathbb{I}\{S_t=S^l_{i,\mathrm{B}},N_{i,t}>N_{i,t-1},0<N_{i,t-1}\le\ell_n(\Delta^{i,l},p_i)\}\cdot\Delta^{i,l}\\
&+\sum_{t=1}^{n}\sum_{l\in[K_i]}\mathbb{I}\{S_t=S^l_{i,\mathrm{B}},N_{i,t}>N_{i,t-1}=0\}\cdot\Delta^{i,l}\\
\le&\sum_{t=1}^{n}\sum_{l\in[K_i]}\mathbb{I}\{S_t=S^l_{i,\mathrm{B}},N_{i,t}>N_{i,t-1},0<N_{i,t-1}\le\ell_n(\Delta^{i,l},p_i)\}\cdot\Delta^{i,l}+\Delta^i_{\max}\\
=&\sum_{t=1}^{n}\sum_{l\in[K_i]}\sum_{j=1}^{l}\mathbb{I}\{S_t=S^l_{i,\mathrm{B}},N_{i,t}>N_{i,t-1},N_{i,t-1}\in(\ell_n(\Delta^{i,j-1},p_i),\ell_n(\Delta^{i,j},p_i))]\}\cdot\Delta^{i,l}+\Delta^i_{\max}\\
\le&\sum_{t=1}^{n}\sum_{l\in[K_i]}\sum_{j=1}^{l}\mathbb{I}\{S_t=S^l_{i,\mathrm{B}},N_{i,t}>N_{i,t-1},N_{i,t-1}\in(\ell_n(\Delta^{i,j-1},p_i),\ell_n(\Delta^{i,j},p_i))]\}\cdot\Delta^{i,\boldsymbol{j}}+\Delta^i_{\max}
\end{aligned}\tag{28}$$

$$\begin{aligned}
\le&\sum_{t=1}^{n}\sum_{l\in[K_i]}\sum_{j\in[K_i]}\mathbb{I}\{S_t=S^l_{i,\mathrm{B}},N_{i,t}>N_{i,t-1},N_{i,t-1}\in(\ell_n(\Delta^{i,j-1},p_i),\ell_n(\Delta^{i,j},p_i))]\}\cdot\Delta^{i,j}+\Delta^i_{\max}\\
=&\sum_{t=1}^{n}\sum_{j\in[K_i]}\mathbb{I}\{S_t\in\mathcal{S}_{i,\mathrm{B}},N_{i,t}>N_{i,t-1},N_{i,t-1}\in(\ell_n(\Delta^{i,j-1},p_i),\ell_n(\Delta^{i,j},p_i))]\}\cdot\Delta^{i,j}+\Delta^i_{\max}.
\end{aligned}\tag{29}$$

The Inequality (28) holds since $\Delta^{i,j}\ge\Delta^{i,l}$ for $j\le l$. Equality (29) is by first switching summations and then merging all $S^l_{i,\mathrm{B}}$ into $\mathcal{S}_{i,\mathrm{B}}$. We may now switch the summations again,

and get

$$\begin{aligned}
(29)=&\sum_{j\in[K_i]}\sum_{t=1}^{n}\mathbb{I}\{S_t\in\mathcal{S}_{i,\mathrm{B}},N_{i,t}>N_{i,t-1},N_{i,t-1}\in(\ell_n(\Delta^{i,j-1},p_i),\ell_n(\Delta^{i,j},p_i))]\}\cdot\Delta^{i,j}+\Delta^i_{\max}\\
\le&\sum_{j\in[K_i]}\left(\lfloor\ell_n(\Delta^{i,j},p_i)\rfloor-\lfloor\ell_n(\Delta^{i,j-1},p_i)\rfloor\right)\cdot\Delta^{i,j}+\Delta^i_{\max} &(30)\\
\le&\sum_{j\in[K_i]}\left(\ell_n(\Delta^{i,j},p_i)-\ell_n(\Delta^{i,j-1},p_i)\right)\cdot\Delta^{i,j}+\Delta^i_{\max}. &(31)
\end{aligned}$$

Inequality (30) uses a relaxation on the indicators. In Inequality (31), for every $j\ge2$, we relax the part of $(\ell_n(\Delta^{i,j-1},p_i)-\lfloor\ell_n(\Delta^{i,j-1},p_i)\rfloor)\cdot\Delta^{i,j}$ to $(\ell_n(\Delta^{i,j-1},p_i)-\lfloor\ell_n(\Delta^{i,j-1},p_i)\rfloor)\cdot\Delta^{i,j-1}$. Now we simply expand the summation, and some terms will be canceled Then, we upper bound the new summation using an integral:

$$\begin{aligned}
(31)=&\ell_n(\Delta^{i,K_i},p_i)\Delta^{i,K_i}+\sum_{j\in[K_i-1]}\ell_n(\Delta^{i,j},p_i)\cdot(\Delta^{i,j}-\Delta^{i,j+1})+\Delta^i_{\max}\\
\le&\ell_n(\Delta^{i,K_i},p_i)\Delta^{i,K_i}+\int_{\Delta^{i,K_i}}^{\Delta^{i,1}}\ell_n(x,p_i)\mathrm{d}x+\Delta^i_{\max} &(32)\\
=&\ell_n(\Delta^i_{\min},p_i)\Delta^i_{\min}+\int_{\Delta^i_{\min}}^{\Delta^i_{\max}}\ell_n(x,p_i)\mathrm{d}x+\Delta^i_{\max}. &(33)
\end{aligned}$$

Inequality (32) comes from the fact that $\ell_n(x,p_i)$ is decreasing in x. □

Finally we are ready to prove our main theorem. We just need to combine the upper bounds from the sufficiently sampled part and the under-sampled part together.

Proof of Theorem 1. Using the counters defined in Definition 13, we may get the expectation of the regret by computing the expectation of the value of the counters after the n-th round. More specifically, according to Definition 4, the expected regret is the difference between $n\cdot\alpha\cdot\beta\cdot\mathrm{opt}_{\boldsymbol{\mu}}$ and the expected reward, which is at least $\alpha\cdot n\cdot\mathrm{opt}_{\boldsymbol{\mu}}$ minus the expected loses from playing bad super arms.

Therefore, combining with Eq.(15) and Eq.(27), the overall regret of our algorithm is

$$
\begin{aligned}
&Reg^{A}_{\boldsymbol{\mu},\alpha,\beta}(n)\\
&\le \mathbb{E}\left[n\cdot\alpha\cdot\beta\cdot \mathrm{opt}_{\boldsymbol{\mu}} - \left(\alpha\cdot n\cdot \mathrm{opt}_{\boldsymbol{\mu}} - \sum_{i\in[m],K_i>0}\left(\sum_{l\in[K_i]}(N^{l,suf}_{i,n}+N^{l,und}_{i,n})\cdot\Delta^{i,l}\right)\right)\right] \quad (34)\\
&\le \Delta_{\max}\cdot\mathbb{E}\left[\sum_{i\in[m],K_i>0}\sum_{l\in[K_i]}N^{l,suf}_{i,n}\right]\\
&\quad+\sum_{i\in[m],K_i>0}\left(\ell_n(\Delta^i_{\min},p_i)\Delta^i_{\min}+\int_{\Delta^i_{\min}}^{\Delta^i_{\max}}\ell_n(x,p_i)\mathrm{d}x+\Delta^i_{\max}\right)-(1-\beta)\cdot n\cdot\alpha\cdot\mathrm{opt}_{\boldsymbol{\mu}}\\
&\le \sum_{i\in[m],K_i>0}\left(\ell_n(\Delta^i_{\min},p_i)\Delta^i_{\min}+\int_{\Delta^i_{\min}}^{\Delta^i_{\max}}\ell_n(x,p_i)\mathrm{d}x\right)+\left(\frac{(2+\mathbb{I}\{p^*<1\})\pi^2}{6}+1\right)\cdot m\cdot\Delta_{\max}\\
&\quad+(1-\beta)n\cdot\Delta_{\max}-(1-\beta)\cdot n\cdot\alpha\cdot\mathrm{opt}_{\boldsymbol{\mu}} \quad (35)\\
&\le \sum_{i\in[m],K_i>0}\left(\ell_n(\Delta^i_{\min},p_i)\Delta^i_{\min}+\int_{\Delta^i_{\min}}^{\Delta^i_{\max}}\ell_n(x,p_i)\mathrm{d}x\right)+\left(\frac{(2+\mathbb{I}\{p^*<1\})\pi^2}{6}+1\right)\cdot m\cdot\Delta_{\max}. \quad (36)
\end{aligned}
$$

The last step of derivation from Eq.(35) to Eq.(36) uses the fact that all rewards are nonnegative and thus $\Delta_{\max}\le\alpha\cdot\mathrm{opt}_{\boldsymbol{\mu}}$ by Definition 6. □

3.1.2 Proof of Theorem 2

The proof of Theorem 2 relies on the tight regret bound for the leading $\ln n$ term given by Theorem 1.

Proof of Theorem 2. We first prove the case of $p^*=1$. Following the proof of Theorem 1, we only need to consider the base arms that are played when they are under-sampled. Following the intuition, we need to quantify when Δ is too small. In particular, we measure the threshold for $\Delta^i_{\min}$ based on $N_{i,n}$, i.e., the counter of arm i at time horizon n. Let $\{n_j \mid j\in[m]\}$ be a set of possible counter values at time horizon n. Our analysis will then be conditioned on event $\mathcal{E}=\{\forall j\in[m], N_{j,n}=n_j\}$.

For an arm $i\in[m]$ with $K_i>0$, we have

$$
\begin{aligned}
&\sum_{l\in[K_i]}N^{l,und}_{i,n}\cdot\Delta^{i,l}\mid\mathcal{E}\\
=&\sum_{t=1}^{n}\sum_{l\in[K_i]}\mathbb{I}\{S_t=S^l_{i,\mathrm{B}},N_{i,t}>N_{i,t-1},N_{i,t-1}\le\ell_n(\Delta^{i,l},1)\mid\mathcal{E}\}\cdot\Delta^{i,l}
\end{aligned}
$$

With $f(x)=\gamma x^{\omega}$, we have $f^{-1}(x)=\left(\frac{x}{\gamma}\right)^{1/\omega}$. Define $\Delta^*(n_i)=\left(\frac{6\gamma^{2/\omega}\ln n}{n_i}\right)^{\omega/2}$, i.e., $\ell_n(\Delta^*(n_i),1)=n_i$. Now we consider two cases.

Case (1): $\Delta^i_{\min}>\Delta^*(n_i)$. Following the same derivation as in the proof of Lemma 5 (notice that the same derivation still works when conditioned on event $\mathcal{E}$), we have

$$
\begin{aligned}
\sum_{l\in[K_i]}N^{l,und}_{i,n}\cdot\Delta^{i,l}\mid\mathcal{E}&\le\ell_n(\Delta^i_{\min},1)\Delta^i_{\min}+\int_{\Delta^i_{\min}}^{\Delta^i_{\max}}\ell_n(x,1)\mathrm{d}x+\Delta^i_{\max} \quad (37)\\
&=\frac{6\gamma^{\frac{2}{\omega}}\ln n}{(\Delta^i_{\min})^{\frac{2}{\omega}-1}}+\frac{\omega}{2-\omega}6\gamma^{\frac{2}{\omega}}\ln n\left((\Delta^i_{\min})^{1-\frac{2}{\omega}}-(\Delta^i_{\max})^{1-\frac{2}{\omega}}\right)+\Delta^i_{\max}\\
&\le\frac{2}{2-\omega}\cdot\frac{6\cdot\gamma^{\frac{2}{\omega}}\ln n}{(\Delta^i_{\min})^{\frac{2}{\omega}-1}}\le\frac{2\gamma}{2-\omega}\cdot(6\ln n)^{\omega/2}n_i^{1-\omega/2}+\Delta^i_{\max}. \quad (38)
\end{aligned}
$$

The last inequality above is by replacing $\Delta^i_{\min}$ with $\Delta^*(n_i)$.

Case (2): $\Delta^i_{\min}\le\Delta^*(n_i)$. Let $l^*=\min\{l\in[K_i]\mid\Delta^{i,l}\le\Delta^*(n_i)\}$. Notice that $\Delta^{i,l^*}\le\left(\frac{6\gamma^{2/\omega}\ln n}{n_i}\right)^{\omega/2}$. We follow the same derivation as in the proof of Lemma 5, and then we critically use the fact that the counter N_i cannot go beyond n_i (in the first term in Inequality (40)):

$$
\begin{aligned}
&\sum_{l\in[K_i]}N^{l,und}_{i,n}\cdot\Delta^{i,l}\mid\mathcal{E}\\
&\le\sum_{j\in[K_i]}\sum_{t=1}^{n}\mathbb{I}\{S_t\in\mathcal{S}_{i,\mathrm{B}},N_{i,t}>N_{i,t-1},N_{i,t-1}\in(\ell_n(\Delta^{i,j-1},1),\ell_n(\Delta^{i,j},1)]\mid\mathcal{E}\}\cdot\Delta^{i,j}+\Delta^i_{\max} \quad (39)\\
&\le\sum_{j\ge l*}\sum_{t=1}^{n}\mathbb{I}\{S_t\in\mathcal{S}_{i,\mathrm{B}},N_{i,t}>N_{i,t-1},N_{i,t-1}\in(\ell_n(\Delta^{i,j-1},1),\ell_n(\Delta^{i,j},1)]\mid\mathcal{E}\}\cdot\Delta^*(n_i)+\Delta^i_{\max}\\
&\quad+\sum_{j\in[l*-1]}\sum_{t=1}^{n}\mathbb{I}\{S_t\in\mathcal{S}_{i,\mathrm{B}},N_{i,t}>N_{i,t-1},N_{i,t-1}\in(\ell_n(\Delta^{i,j-1},1),\ell_n(\Delta^{i,j},1)]\mid\mathcal{E}\}\cdot\Delta^{i,j}+\Delta^i_{\max}\\
&\le(n_i-\ell_n(\Delta^{i,l^*-1},1))\cdot\Delta^*(n_i)+\sum_{j\in[l^*-1]}(\ell_n(\Delta^{i,j},1)-\ell_n(\Delta^{i,j-1},1))\cdot\Delta^{i,j}+\Delta^i_{\max} \quad (40)\\
&\le n_i\cdot\Delta^*(n_i)+\int_{\Delta^*(n_i)}^{\Delta^{i,1}}\ell_n(x,1)\mathrm{d}x+\Delta^i_{\max}\le\frac{2\gamma}{2-\omega}\cdot(6\ln n)^{\omega/2}n_i^{1-\omega/2}+\Delta^i_{\max}. \quad (41)
\end{aligned}
$$

Therefore, Eq.(41) holds in both cases. We then have

$$
\begin{aligned}
\sum_{i\in[m],K_i>0}\sum_{l\in[K_i]}N^{l,und}_{i,n}\cdot\Delta^{i,l}\mid\mathcal{E}&\le\frac{2\gamma}{2-\omega}\cdot(6\ln n)^{\omega/2}\cdot\sum_{i\in[m],K_i>0}n_i^{1-\omega/2}+\Delta^i_{\max}\\
&\le\frac{2\gamma}{2-\omega}\cdot(6m\ln n)^{\omega/2}\cdot n^{1-\omega/2}+\Delta^i_{\max}. \quad (42)
\end{aligned}
$$

The last inequality comes from Jensen's inequality and $\sum_i n_i\le n$. Since the final inequality does not depend on n_i, we can drop the condition $\mathcal{E}$ above. With the bound on the under-sampled part given in Inequality (42), we combine it with the result on sufficiently

sampled part given in Lemma 4, then we can following the similar derivation as shown from Eq.(34) to Eq.(36) to derive the distribution-independent regret bound given in Theorem 2 for the case of $p^* = 1$.

We now prove the case of $p^* < 1$. The proof is essentially the same, but with a different definition of $\ell_n(\Delta, p)$. For convenience, we relax $\ell_n(\Delta, p) = \max\left(\frac{12\cdot\ln n}{(f^{-1}(\Delta))^2\cdot p}, \frac{24\cdot\ln n}{p}\right)$ to $\frac{12\cdot\ln n}{(f^{-1}(\Delta))^2\cdot p} + \frac{24\cdot\ln n}{p}$. In this case, we define $\Delta_i^*(n_i) = \left(\frac{12\gamma^{2/\omega}\ln n}{p_i n_i}\right)^{\omega/2}$.

For Case (1): $\Delta^i_{\min} > \Delta_i^*(n_i)$, following the same derivation as Eq.(37)—(38) except that we use $\ell_n(\cdot, p_i)$ instead of $\ell_n(\cdot, 1)$ (Definition 9), we have

$$\sum_{l\in[K_i]} N^{l,und}_{i,n}\cdot\Delta^{i,l} \mid \mathcal{E} \le \frac{2\gamma}{2-\omega}\cdot\left(\frac{12\ln n}{p_i}\right)^{\omega/2} n_i^{1-\omega/2} + \frac{24\ln n}{p_i}\cdot\Delta^i_{\max} + \Delta^i_{\max}.$$

For Case (2): $\Delta^i_{\min} \le \Delta_i^*(n_i)$, again following the same derivation Eq.(39)—(41) except that we use $\ell_n(\cdot, p_i)$ instead of $\ell_n(\cdot, 1)$,, we have

$$\sum_{l\in[K_i]} N^{l,und}_{i,n}\cdot\Delta^{i,l} \mid \mathcal{E} \le \frac{2\gamma}{2-\omega}\cdot\left(\frac{12\ln n}{p_i}\right)^{\omega/2} n_i^{1-\omega/2} + \frac{24\ln n}{p_i}\cdot\Delta^i_{\max} + \Delta^i_{\max}.$$

Together, we have

$$\begin{aligned}
&\sum_{i\in[m],K_i>0}\sum_{l\in[K_i]} N^{l,und}_{i,n}\cdot\Delta^{i,l} \mid \mathcal{E}\\
&\le \frac{2\gamma}{2-\omega}\cdot\left(\frac{12\ln n}{p^*}\right)^{\omega/2}\sum_{i\in[m],K_i>0} n_i^{1-\omega/2} + \sum_{i\in[m],K_i>0}\frac{24\ln n}{p_i}\cdot\Delta^i_{\max}\\
&\le \frac{2\gamma}{2-\omega}\cdot\left(\frac{12m\ln n}{p^*}\right)^{\omega/2} n^{1-\omega/2} + \sum_{i\in[m]}\frac{24\ln n}{p_i}\cdot\Delta_{\max} + \Delta^i_{\max}.
\end{aligned}$$

Finally, combining Lemma 4 and the derivation for the regret bound as shown from Eq.(34) to Eq.(36), we obtain the regret bound for the case of $p^* < 1$. □

3.2 Discussions

We may further improve the bound in Theorem 1 as follows, when all the triggering probabilities are 1.

Improving the coefficient of the leading term when $\forall i, p_i = 1$. In general, we can set $\bar{\mu}_i = \hat{\mu}_i + \sqrt{y/(2T_i)}$ for some y in line 6 in the CUCB algorithm. The corresponding regret bound obtained is

$$\sum_{i\in[m],K_i>0}\left(\frac{2\cdot y}{(f^{-1}(\Delta^i_{\min}))^2}\cdot\Delta^i_{\min} + \int_{\Delta^i_{\min}}^{\Delta^i_{\max}}\frac{2\cdot y}{(f^{-1}(x))^2}\mathrm{d}x\right) + \left(1+\sum_{t=1}^{n}\frac{2t}{e^{-y}}\right)\cdot m\cdot\Delta_{\max}.$$

What we need is to make sure the term $\sum_{t=1}^{n}\frac{2t}{e^{-y}}$ in the above regret bound converges. We can thus set y appropriately to guarantee convergence while improving the constant in the

leading term. One way is setting $y = (1+c)\ln t$ with a constant $c > 1$, or equivalently setting $\bar{\mu}_i = \hat{\mu}_i + \sqrt{(1+c)\ln t/(2T_i)}$, so that $\sum_{t=1}^{n}\frac{2t}{e^{-y}} = 2\sum_{t=1}^{n} t^{-c} \le 2\zeta(c)$, where $\zeta(c) = \sum_{t=1}^{\infty}\frac{1}{t^c}$ is the Riemann's zeta function, and has a finite value when $c > 1$. Then the regret bound is

$$\sum_{i\in[m],K_i>0}\left(\frac{2\cdot(1+c)\cdot\ln n}{(f^{-1}(\Delta^i_{\min}))^2}\cdot\Delta^i_{\min} + \int_{\Delta^i_{\min}}^{\Delta^i_{\max}}\frac{2\cdot(1+c)\cdot\ln n}{(f^{-1}(x))^2}\mathrm{d}x\right) + (2\cdot\zeta(c)+1)\cdot m\cdot\Delta_{\max}.$$

We can also further improve the constant factor from $2(1+c)$ to 4 by setting $\bar{\mu}_i = \hat{\mu}_i + \sqrt{\frac{2\ln t+\ln\ln t}{2T_i}}$ at the cost of a second order $\ln\ln n$ term (Garivier and Cappé, 2011), with regret at most

$$\sum_{i\in[m],K_i>0}\left(\frac{2\cdot(2\ln n+\ln\ln n)}{(f^{-1}(\Delta^i_{\min}))^2}\cdot\Delta^i_{\min} + \int_{\Delta^i_{\min}}^{\Delta^i_{\max}}\frac{2\cdot(2\ln n+\ln\ln n)}{(f^{-1}(x))^2}\mathrm{d}x\right) + (1+2\ln\ln n)\cdot m\cdot\Delta_{\max}.$$

This is because $\sum_{t=1}^{n}\frac{1}{t\ln t} \le \int_{m}^{n}\frac{1}{t\ln t}\mathrm{d}t \le \ln\ln n$ when $m > e$.

Comparing to classical MAB. As we discussed earlier, the classical MAB is a special instance of our CMAB framework in which each super arm is a simple arm, $p_i = 1$ for all $i \in [m]$, function $f(\cdot)$ is the identity function, and $\alpha = \beta = 1$. Notice that $\Delta^i_{\max} = \Delta^i_{\min}$. Thus, by Theorem 1, the regret bound of the classical MAB is

$$\sum_{i\in[m],\Delta^i>0}\frac{6\ln n}{\Delta^i} + \left(\frac{\pi^2}{3}+1\right)\cdot m\cdot\Delta_{\max}, \tag{43}$$

where $\Delta^i = \max_{j\in[m]}\mu_j - \mu_i$. Comparing with the regret bound in Theorem 1 of the paper by Auer et al. (2002a), we see that we even have a better coefficient $\sum_{i\in[m],\Delta^i>0} 6/\Delta^i$ in the leading $\ln n$ term than the one $\sum_{i\in[m],\Delta^i>0} 8/\Delta^i$ in the original analysis of UCB1.[3] The improvement is due to a tighter analysis, and is the reason that we obtained improved regret over the regret obtained by Gai et al. (2012). Thus, the regret upper bound of our CUCB algorithm when applying to the classical MAB problem is at the same level (up to a constant factor) as UCB1, which is designed specifically for the MAB problem.

4. Applications

In this section, we describe two applications with non-linear reward functions as well as the class of linear reward applications that fit our CMAB framework. Notice that, the probabilistic maximum coverage bandit and social influence maximization bandit are also instances of the online submodular maximization problem, which can be addressed in the adversarial setting by Streeter and Golovin (2008), but we are not aware of their counterpart in the stochastic setting.

4.1 Probabilistic Maximum Coverage Bandit

The online advertisement placement application discussed in the introduction can be modeled by the bandit version of the probabilistic maximum coverage (PMC) problem. PMC

3. We remark that the constant of UCB1 has been tightened to the optimum (Garivier and Cappé, 2011).

has as input a weighted bipartite graph $G = (L, R, E)$ where each edge (u, v) has a probability $p(u, v)$, and it needs to find a set $S \subseteq L$ of size k that maximizes the expected number of activated nodes in R, where a node $v \in R$ can be activated by a node $u \in S$ with an independent probability of $p(u, v)$. In the advertisement placement scenario, L is the set of web pages, R is the set of users, and $p(u, v)$ is the probability that user v clicks the advertisement on page u. PMC problem is NP-hard, since when all edge probabilities are 1, it becomes the NP-hard Maximum Coverage problem.

Using submodular set function maximization technique (Nemhauser et al., 1978), it can be easily shown that there exists a deterministic $(1 - 1/e)$ approximation algorithm for the PMC problem, which means that we have a $(1 - 1/e, 1)$-approximation oracle for PMC.

The PMC bandit problem is that edge probabilities are unknown, and one repeatedly selects k targets in L in multiple rounds, observes all edge activations and adjusts target selection accordingly in order to maximize the total number of activated nodes over all rounds.

We can formulate this problem as an instance in the CMAB framework. Each edge $(u, v) \in E$ represents an arm, and each play of the arm is a 0-1 Bernoulli random variable with parameter $p_{u,v}$. A super arm is the set of edges E_S incident to a set $S \subseteq L$ of size k. The reward of E_S is the number of activated nodes in R, which is the number of nodes in R that are incident to at least one edge in E_S with outcome 1. Since all arms are independent Bernoulli random variables, we know that the expected reward only depends on the probabilities on all edges. In particular we have that the expected reward $r_{\boldsymbol{\mu}}(E_S) = \sum_{v \in R}(1 - \prod_{u \in L,(u,v) \in E_S}(1 - p(u, v)))$. Note that this expected reward function is not linear in $\boldsymbol{\mu} = \{p(u, v)\}_{(u,v) \in E}$. For all arm $i \in E$, we have $p_i = 1$, that is, we do not have probabilistically triggered arms. The monotonicity property is straightforward. The bounded smoothness function is $f(x) = |E| \cdot x$, i.e., increasing all probabilities of all arms in a super arm by x can increase the expected number of activated nodes in V by at most $|E| \cdot x$. Since $f(\cdot)$ is a linear function, the integral in Eq.(2) has a closed form. In particular, by Theorem 1, we know that the distribution-dependent $(1 - 1/e, 1)$-approximation regret bound of our CUCB algorithm on PMC bandit is

$$\sum_{i \in E, K_i > 0} \frac{12 \cdot |E|^2 \cdot \ln n}{\Delta^i_{\min}} + \left(\frac{\pi^2}{3} + 1\right) \cdot |E| \cdot \Delta_{\max}.$$

Notice that all edges incident to a node $u \in L$ are always played together. In other words, these edges can share one counter. We call these arms (edges) as *clustered arms*. It is possible to exploit this property to improve the coefficient of the $\ln n$ term, so that the summation is not among all edges but only nodes in L. (See Section 4.1 and the supplementary material of Chen et al. (2013) for the regret bound and analysis for the case of clustered arms).

From Theorem 2, we also have the distribution-independent regret bound of

$$\sqrt{24|E|^3 n \ln n} + \left(\frac{\pi^2}{3} + 1\right) \cdot |E| \cdot \Delta_{\max}.$$

Note that for the PMC bandit, $\Delta_{\max}$ is at most the number of vertices covered in R, and thus $\Delta_{\max} \leq |R|$.

4.2 Combinatorial Bandits With Linear Rewards

Gai et al. (2012) studied the *Learning with Linear Reward* policy (LLR). Their formulation is close to ours except that their reward function must be linear. In their setting, there are m underlying arms. There are a finite number of super arms, each of which consists of a set of underlying arms S together with a set of coefficients $\{w_{i,S} \mid i \in S\}$. The reward of playing super arm S is $\sum_{i \in S} w_{i,S} \cdot X_i$, where X_i is the random outcome of arm i. The formulation can model a lot of bandit problems appeared in the literature, e.g., multiple plays, shortest path, minimum spanning tree and maximum weighted matching.

Our framework contains such linear reward problems as special cases.[4] In particular, let $L = \max_S |S|$ and $a_{\max} = \max_{i,S} w_{i,S}$, and we have the bounded smoothness function $f(x) = a_{\max} \cdot L \cdot x$. In this setting we have $p_i = 1$ for all $i \in [m]$. By applying Theorem 1, the regret bound is

$$\left(\sum_{i \in [m], K_i > 0} \frac{12 \cdot a^2_{\max} \cdot L^2 \cdot \ln n}{\Delta^i_{\min}}\right) + \left(\frac{\pi^2}{3} + 1\right) \cdot m \cdot \Delta_{\max}.$$

Our result significantly improves the coefficient of the leading $\ln n$ term comparing to Theorem 2 in the paper by Gai et al. (2012) in two aspects: (a) we remove a factor of $L+1$; and (b) the coefficient $\sum_{i \in [m], \Delta^i_{\min} > 0} 1/\Delta^i_{\min}$ is likely to be much smaller than $m \cdot \Delta_{\max}/(\Delta_{\min})^2$ used by Gai et al. (2012). This demonstrates that while our framework covers a much larger class of problems, we are still able to provide much tighter analysis than the one for linear reward bandits. Moreover, applying Theorem 2 we can obtain distribution-independent bound for combinatorial bandits with linear rewards, which is not provided by Gai et al. (2012):

$$a_{\max} L \sqrt{24 m n \ln n} + \left(\frac{\pi^2}{3} + 1\right) \cdot m \cdot \Delta_{\max}.$$

Note that, for the class of linear bandits, the reward is at most $a_{\max} \cdot L$, and thus $\Delta_{\max} \leq a_{\max} \cdot L$.

We remark that, in a latest paper, Kveton et al. (2015) show that the above regret bounds can be improved to $O(L \log n \sum_i 1/\Delta^i_{\min})$ for distribution-dependent regret and $O(\sqrt{Lmn \log n})$ for distribution-independent regret, respectively, which are tight (up to a factor of $\sqrt{\log n}$ for the distribution-independent bound). The improvement is achieved by a weaker and non-uniform sufficient sampling condition—in our analysis, we require all relevant base arms of a super arm S_t played in round t to be sufficiently sampled to ensure that S_t cannot be a bad super arm (Lemma 3), but Kveton et al. (2015) relax this and show that it is enough to have sufficiently many base arms to be sampled sufficiently many times, while the rest arms only need to satisfy some weaker sufficient sampling condition. The intuition is that due to linear reward summation, as long as many base arms are sufficiently sampled and the rest have a weaker sufficiently sampled condition, the sum of the errors would be still small enough to guarantee that a good super arm is selected by the oracle. However, it is unclear if this technique can be applied to non-linear reward functions

4. To include the linear reward case, we allow two super arms with the same set of underlying arms to have different sets of coefficients. This is fine as long as the oracle could output super arms with appropriate parameters.

satisfying our bounded smoothness assumption, since the estimate error of each base arm may not linearly affect the estimate error in the expected reward.

4.3 Application to Social Influence Maximization

In social influence maximization with the independent cascade model (Kempe et al., 2003), we are given a directed graph $G = (V, E)$, where every edge (u, v) is associated with an unknown *influence probability* $p_{u,v}$. Initially, a seed set $S \subseteq V$ are selected and activated. In each iteration of the diffusion process, each node u activated in the previous iteration has one chance of activating its inactive outgoing neighbor v independently with probability $p_{u,v}$. The reward of S after the diffusion process is the total number of activated nodes in the end. Influence maximization is to find a seed set S of at most k nodes that maximize the expected reward, also referred to as the *influence spread* of seed set S. Kempe et al. (2003) show that the problem is NP-hard and provide an algorithm with approximation ratio $1 - 1/e - \varepsilon$ with success probability $(1 - 1/|E|)$ for any fixed $\varepsilon > 0$. This means that we have a $(1 - 1/e - \varepsilon, 1 - 1/|E|)$-approximation oracle.

In the CMAB framework, we do not know the activation probabilities of edges and want to learn them during repeated seed selections while maximizing overall reward. Each edge in E is considered as a base arm, and a super arm in this setting is the set E_S of edges incident to the seed set S. Note that these edges will be deterministically triggered, but other edges not in E_S may also be triggered, and the reward is related to all the triggered arms. Therefore, this is an instance where arms may be probabilistically triggered, and thus $p_i < 1$ for some $i \in E$.

It is straightforward to see that the expected reward function is still a function of probabilities on all edges, and the monotonicity holds. However, bounded smoothness property is nontrivial to argue, as we will show in the following lemma.

Lemma 6. *The social influence maximization instance satisfies the bounded smoothness property with bounded smoothness function $f(x) = |E||V|x$.*

Proof. For the social influence maximization bandit, the expectation vector $\boldsymbol{\mu}$ is the vector of all probabilities on all edges. For a seed set $S \subseteq V$, the corresponding super arm is the set E_S of edges incident to vertices in S. Without loss of generality, we assume that for any edge $i \in E$, its probability $\mu_i > 0$. Then for super arm E_S, the set of base arms that can be triggered by E_S, denoted as $\tilde{E}_S$, is exactly the set of edges reachable from seed set S (an edge (u, v) reachable from a set S means its starting vertex u is reachable from S). By Definition 1, to show bounded smoothness with bounded smoothness function $f(x) = |E||V|x$, we need to show that for any two expectation vectors $\boldsymbol{\mu}$ and $\boldsymbol{\mu}'$ and for any $\Lambda > 0$, we have $|r_{\boldsymbol{\mu}}(E_S) - r_{\boldsymbol{\mu}'}(E_S)| \le f(\Lambda)$ if $\max_{i \in \tilde{E}_S} |\mu_i - \mu'_i| \le \Lambda$.

Since we know that monotonicity holds, it is sufficient to assume that for all $i \in \tilde{E}_S$, $\mu_i = \mu'_i + \Lambda$. This is because without loss of generality, we can assume $r_{\boldsymbol{\mu}}(E_S) \ge r_{\boldsymbol{\mu}'}(E_S)$, and if $\mu_i < \mu'_i + \Lambda$ we can increase μ_i and decrease μ'_i such that $\mu_i = \mu'_i + \Lambda$, and this only increase the gap between $r_{\boldsymbol{\mu}}(E_S)$ and $r_{\boldsymbol{\mu}'}(E_S)$. Thus, henceforth let us assume that $i \in \tilde{E}_S$, $\mu_i = \mu'_i + \Lambda$.

Starting from $\boldsymbol{\mu}'$, we take one edge i_1 in $\tilde{E}_S$, and increase μ'_{i_1} to $\mu'_{i_1} + \Lambda = \mu_{i_1}$ to get a new vector $\boldsymbol{\mu}^{(1)}$. Suppose the edge i_1 is (u_1, v_1). Comparing $\boldsymbol{\mu}'$ with $\boldsymbol{\mu}^{(1)}$, the only

difference is that the probability on edge (u_1, v_1) increases by Λ. For the influence spread of seed set S, the above change increases the activation probability of v_1 and every node reachable from v_1 by at most Λ. Thus the total increase of influence spread is at most $|V|\Lambda$. Then we select the second edge i_2 in $\tilde{E}_S$ and increases its probability by Λ. By the same argument, the influence spread increases at most $|V|\Lambda$. Repeating the above process, after selecting all edges in $\tilde{E}_S$, we obtain probability vector $\boldsymbol{\mu}^{(s)}$ where $s = |\tilde{E}_S|$, and the increase in influence spread is at most $s|V|\Lambda$. Comparing vector $\boldsymbol{\mu}^{(s)}$ with $\boldsymbol{\mu}$, they are the same on all edges in $\tilde{E}_S$, and may only differ in the rest of edges. However, since the rest of edges cannot be reachable from S, their difference will not affect the influence spread of S. Therefore, we know that the difference between influence spread $r_{\boldsymbol{\mu}}(E_S)$ and $r_{\boldsymbol{\mu}'}(E_S)$ is at most $s|V|\Lambda \le |E||V|\Lambda$. This concludes that if we use function $f(x) = |E||V|x$, the bounded smoothness property holds. □

Remark. In Section 4.2 of the original CMAB paper (Chen et al., 2013), we made a claim that social influence maximization bandit satisfies the bounded smoothness property (with function $f(x) = |E||V|x$) that does not consider probabilistically triggered arms, that is, it satisfies the property that for any two expectation vectors $\boldsymbol{\mu}$ and $\boldsymbol{\mu}'$ and for any $\Lambda > 0$, $|r_{\boldsymbol{\mu}}(E_S) - r_{\boldsymbol{\mu}'}(E_S)| \le f(\Lambda)$ if $\max_{i \in E_S} |\mu_i - \mu'_i| \le \Lambda$. This claim is incorrect. For example, all edges in E_S could have the same probability (and thus we could have Λ to be arbitrarily small), but other edges reachable from E_S have different probabilities, and thus the gap between $r_{\boldsymbol{\mu}}(E_S)$ and $r_{\boldsymbol{\mu}'}(E_S)$ will not be arbitrarily small and cannot be bounded by $f(\Lambda)$ for any continuous f tending to zero when Λ tends to zero.

With $f(x) = |E||V|x$, we have $\ell_n(\Delta, p) = \max\left(\frac{12 \cdot \ln n}{(f^{-1}(\Delta))^2 \cdot p}, \frac{24 \cdot \ln n}{p}\right) = \max\left(\frac{12|V|^2|E|^2 \ln n}{\Delta^2 \cdot p}, \frac{24 \cdot \ln n}{p}\right)$. Since Δ is at most $\Delta_{\max}$ in the regret bound and $\Delta_{\max} \le |V|$, it is clear that we have $\ell_n(\Delta, p) = \frac{12|V|^2|E|^2 \ln n}{\Delta^2 \cdot p}$. Then applying Theorem 1, we know that the distribution-dependent $(1 - 1/e - \varepsilon, 1 - 1/|E|)$-approximation regret bound of the CUCB algorithm on influence maximization is:

$$\sum_{i \in E, K_i > 0} \frac{24 \cdot |V|^2|E|^2 \cdot \ln n}{\Delta^i_{\min} \cdot p_i} + \left(\frac{\pi^2}{2} + 1\right) \cdot |E| \cdot \Delta_{\max}.$$

With Theorem 2 (and further using $\ell_n(\Delta, p) = \frac{12|V|^2|E|^2 \ln n}{\Delta^2 \cdot p}$ instead of the relaxed $\ell_n(\Delta, p) = \frac{12|V|^2|E|^2 \ln n}{\Delta^2 \cdot p} + \frac{24 \cdot \ln n}{p}$ as in the proof of Theorem 2), we obtain the distribution-independent bound:

$$|V|\sqrt{\frac{48|E|^3 n \ln n}{p^*}} + \left(\frac{\pi^2}{2} + 1\right) \cdot |E| \cdot \Delta_{\max}.$$

5. Conclusion

In this paper, we propose the first general stochastic CMAB framework that accommodates a large class of nonlinear reward functions among combinatorial and stochastic arms, and it even accommodates probabilistically triggered arms such as what occurs in the viral marketing application. We provide CUCB algorithm with tight analysis on its distribution-dependent and distribution-independent regret bounds and applications to new practical combinatorial bandit problems.

There are many possible future directions from this work. One may study the CMAB problems with Markovian outcome distributions on arms, or the restless version of CMAB, in which the states of arms continue to evolve even if they are not played. Another direction is to investigate if some of the results in this paper are tight or can be further improved. For example, for the nonlinear bounded smoothness function $f(x) = \gamma \cdot x^{\omega}$ with $\omega < 1$, if our bound in Theorem 2 is tight or can be improved; and for the case of probabilistic triggering, if the regret bound dependency on $1/p_i$ is necessary. For the latter case, one may also look into improvement specifically for the influence maximization application. For nonlinear reward functions, currently we assume that the expected reward is a function of the expectation vector of base arms. One may also look into the more general cases where the expected reward depends not only on the expected outcomes of base arms.

Abstract

In the past few years, differential privacy has become a standard concept in the area of privacy. One of the most important problems in this field is to answer queries while preserving differential privacy. In spite of extensive studies, most existing work on differentially private query answering assumes the data are *discrete* (i.e., in $\{0,1\}^d$) and focuses on queries induced by *Boolean* functions. In real applications however, *continuous* data are at least as common as binary data. Thus, in this work we explore a less studied topic, namely, differential privately query answering for continuous data with continuous function. As a first step towards the continuous case, we study a natural class of linear queries on continuous data which we refer to as *smooth* queries. A linear query is said to be K-smooth if it is specified by a function defined on $[-1,1]^d$ whose partial derivatives up to order K are all bounded. We develop two ϵ-differentially private mechanisms which are able to answer *all* smooth queries. The first mechanism outputs a summary of the database and can then give answers to the queries. The second mechanism is an improvement of the first one and it outputs a synthetic database. The two mechanisms both achieve an accuracy of $O(n^{-\frac{K}{2d+K}}/\epsilon)$. Here we assume that the dimension d is a constant. It turns out that even in this parameter setting (which is almost trivial in the discrete case), using existing discrete mechanisms to answer the smooth queries is difficult and requires more noise. Our mechanisms are based on L_∞-approximation of (transformed) smooth functions by low-degree even trigonometric polynomials with uniformly bounded coefficients. We also develop practically efficient variants of the mechanisms with promising experimental results.[1]

Keywords: differential privacy, smooth queries, synthetic dataset

1. Introduction

Statistical analysis and machine learning are often conducted on data sets containing sensitive information, such as medical records, commercial data, etc. The benefit of mining from such data is tremendous. But when releasing sensitive data, one must take privacy issue into consideration, and has to accept a tradeoff between the accuracy and the amount of privacy loss of the individuals in the database.

In this paper, we consider *differential privacy* (Dwork et al., 2006), which has become a standard concept in the area of privacy. Roughly speaking, a mechanism which releases information about some database is said to preserve differential privacy, if the change of a single database element does not affect the probability distribution of the output significantly. Differential privacy provides strong guarantees against attacks. It ensures that the risk of information leakage for any individual who submits her information to the database is very small, in the sense that an adversary can discover almost nothing new from the database that contains one individual's information compared with that from the database without that individual's information. Recently there have been extensive studies of machine learning, statistical estimation, and data mining under the differential privacy framework (Wasserman and Zhou, 2010; Chaudhuri et al., 2011; Lei, 2011; Kifer and Lin, 2010; Chaudhuri et al., 2012; Williams and McSherry, 2010; Jain et al., 2012; Chaudhuri and Hsu, 2011).

Accurately answering statistical queries is a well studied problem in differential privacy. A simple and efficient method is the Laplace mechanism (Dwork et al., 2006), which adds Laplace noise to the true answers. Laplace mechanism is especially useful for queries with low sensitivity, which is the maximal difference of the query values of two databases that are different in only one item. A typical class of queries that has low sensitivity is *linear* queries, whose sensitivity is $O(1/n)$, where n is the size of the database.

The Laplace mechanism has a limitation. It can answer at most $O(n^2)$ queries. If the number of queries is substantially larger than n^2, Laplace mechanism is not able to provide differentially private answers with nontrivial accuracy. Considering that potentially there are many users and each user may submit a set of queries, limiting the number of total

1. Part of this work has been appeared in (Wang et al., 2013).

1. Source codes available at `http://www.cis.pku.edu.cn/faculty/vision/wangliwei/software.html`

queries to be smaller than n^2 is too restricted in some situations. A remarkable result due to Blum, Ligett and Roth (Blum et al., 2008) (will be referred to as BLR in this paper) shows that: information theoretically it is possible for a mechanism to answer far more than n^2 linear queries while preserving differential privacy and nontrivial accuracy simultaneously.

There is a series of works (Dwork et al., 2009, 2010; Roth and Roughgarden, 2010; Hardt and Rothblum, 2010) improving the result of (Blum et al., 2008). All these mechanisms are very powerful in the sense that they can answer general and adversely chosen queries. On the other hand, even the fastest algorithms for query answering (Hardt and Rothblum, 2010; Hardt et al., 2012a) run in time linear in the size of the data universe. Often the size of the data universe is much larger than that of the database, so these mechanisms are inefficient. Recently, Ullman (2013) shows that there is no polynomial time algorithm that can answer $n^{2+o(1)}$ *general* linear queries while preserving privacy and accuracy (assuming the existence of one-way function).

Recently, there are growing interests in studying differentially private mechanisms for *restricted* classes of queries, in particular queries useful in applications. One class of queries that attracts a lot of attentions are the k-way conjunctions. The data universe for this problem is $\{0,1\}^d$. Thus each individual record has d binary attributes. A k-way conjunction query is specified by k features. The query asks what fraction of the individual records in the database has all these k features being 1. A series of works attack this problem using several different techniques (Barak et al., 2007; Gupta et al., 2011; Cheraghchi et al., 2012; Hardt et al., 2012b; Thaler et al., 2012) . They proposed elegant mechanisms which run in time $\text{poly}(n)$ when k is a constant. Another class of queries that yields efficient mechanisms is the class of sparse query. A query is m-sparse if it takes non-zero values on at most m elements in the data universe. Blum and Roth (2013) developed mechanisms which are efficient when $m = \text{poly}(n)$.

The above differentially private mechanisms can also be categorized into two classes according to the output of the algorithm. The first class of algorithms output answers to the queries. The second class of algorithms output synthetic databases instead; the answers of the queries can then be simply computed from the synthetic database. The Laplace mechanism belongs to the first class. BLR and the offline version of the Private Multiplicative Weight updating (PMW) mechanism (Hardt and Rothblum, 2010; Hardt et al., 2012a) output synthetic database. From a practical point of view, the synthetic dataset output is appealing. In fact, before the notion of differential privacy was proposed, almost all practical techniques developed to preserve privacy against certain types of attacks output a synthetic dataset by modifying the raw dataset (please see the survey Aggarwal and Yu 2008 and the references therein).

Among the studies of differentially private query answering, most existing works focus on binary data and queries induced by Boolean functions[2]. In real applications however, continuous data are at least as common as binary data; and one has to use continuous functions in this scenario instead of Boolean functions. In this paper, we explore this relatively less studied topic, i.e., differentially private query answering with continuous

2. On the other hand, there are many results (e.g., Chaudhuri et al. 2011, Williams and McSherry 2010, Jain et al. 2012, Chaudhuri and Hsu 2011) on differentially private learning that study continuous data and continuous function.

functions on continuous data. We assume that 1) the data universe is $\mathcal{X} = [-1,1]^d$; 2) a linear query q_f is induced by a continuous function $f : \mathcal{X} \to \mathbb{R}$.

As will be clear soon, answering general linear queries in the continuous setting is considerably more difficult than that in the binary case. Therefore we will focus our analysis on a restricted class of linear queries. The first question is: which subclass of linear queries is commonly used in practice? Let $D = \{x_1, \ldots, x_n\}$ ($x_i \in [-1,1]^d$) be a database consisting of continuous data. A linear query q_f on D is defined as $q_f(D) := \frac{1}{n}\sum_{x\in D} f(x)$, where $f : [-1,1]^d \to \mathbb{R}$ is a continuous function. Thus, to find out a natural class of linear queries, one only needs to find out a natural class of continuous functions.

The set of continuous functions considered in this paper is the set of smooth queries. We say a function $f : [-1,1]^d \to \mathbb{R}$ is K-smooth, if all the partial derivatives of f up to the Kth order are bounded. We say a linear query q_f is K-smooth if f is a K-smooth function. We believe smooth function is one of the most natural and useful classes of continuous functions; and therefore the set of smooth queries is a natural class of linear queries worth studying. Our aim is to answer *all* smooth queries while preserving differential privacy and accuracy. See also section 4.2 for an explanation of why answering all smooth queries is useful for differentially private machine learning. As a first step towards differential privacy for continuous query, we study in this work the case where the dimension d of the data universe $[-1,1]^d$ is a constant. It turns out that the smooth query problem is very challenging even for $d = O(1)$ which is almost trivial in the discrete case (see below).

We develop two mechanisms for the smooth query. The two mechanisms both achieve accuracy of $O\left(\left(\frac{1}{n}\right)^{\frac{K}{2d+K}}/\epsilon\right)$ for *all* K-smooth queries. If the order of smoothness K is large compared to the dimension d, then the errors of the mechanisms are close to n^{-1}.

To be more concrete, the former mechanism outputs a summary of the database. To obtain an answer of a smooth query, the user runs a public evaluation procedure which contains no information of the database. Outputting the summary has running time $O\left(n^{1+\frac{d}{2d+K}}\right)$, and the evaluation procedure for answering a query runs in time $\tilde{O}(n^{\frac{d+2+\frac{2d}{K}}{2d+K}})$. It can be seen that if K is large compared to d, then the mechanism runs in almost linear time. For our second mechanism which outputs synthetic database, the running time is $O(n^{\frac{3dK+5d}{4d+2K}})$, polynomial in the size of the database. Theoretically, the second mechanism is far less efficient as the first one. This is reasonable since outputting synthetic database is much harder than outputting answers. We then develop practically efficient variants of this mechanism.

As a comparison, we will consider how to apply existing mechanisms (e.g., PMW, BLR) to solve the smooth query problem. As our goal is to answer all smooth queries while preserving privacy and accuracy, and because there are infinitely many K-smooth functions, one has to discretize the set of smooth functions before using any existing mechanism. It is not clear how to efficiently discretize this set of queries. More importantly, we show that even if one can discretize this query set in an optimal way, there is a lower bound for the number of discretized queries of this set. The lower bound is exponential in $1/\alpha$, where α is the desired error of the query answering mechanism; and as a result, the best existing mechanism has significantly larger error than that of the algorithms proposed in this paper. (See Section 3.2.1 and Proposition 18 in Section 4.1 for details.)

The mechanisms proposed in this paper are based on L_∞-approximation and is motivated by Thaler et al. (2012), which considers approximation of k-way conjunctions by low degree polynomials. Our basic idea is to approximate the whole query class by linear combination of a small set of basis functions. The main technical difficulty lies in that in order that the approximation induces an efficient and differentially private mechanism, all the linear coefficients of the basis functions must be small. To guarantee this, we first transform the query function. Then by using even trigonometric polynomials as basis functions we prove a constant upper bound for the linear coefficients. It is worth pointing out that to guarantee accuracy, we must consider L_∞-approximation. It is completely different from L_2-approximation, which is simply Fourier analysis when using trigonometric polynomial as basis. Another difficulty for the first mechanism is how to efficiently compute the linear coefficients. It turns out that the smoothness of the functions allows us to use an efficient numerical method to compute the coefficients to a precision so that the accuracy of the mechanism is not affected significantly.

We also point out that the basis functions described above have some relation to conjunctions. In fact, conjunctions can also be viewed as smooth functions as they are multilinear polynomials. Conjunctions form a small subset of smooth functions. Moreover, the set of conjunctions is also a strict subset of the basis function used in our mechanism. If we restrict to conjunctions, our algorithm essentially reduces to Laplace mechanism (see Section 3.2.2 for details). But different to all existing works dealing with conjunctions, our aim here is to answer all smooth queries while preserving privacy and accuracy.

Finally we conduct experiments on the efficient variant of the mechanism which outputs synthetic database as it may be more useful in practice. Experimental results demonstrate that the algorithm achieves good accuracy and are practically efficient on datasets of various sizes and of a number of attributes.

This work is a small step towards an understanding of smooth queries. Our mechanisms have obvious limitations: The performances decrease exponentially with respect to the data dimension d. Thus the algorithms cannot handle the case in which d is a super constant. The experimental results also demonstrate that our mechanisms work well mostly when d is no more than a few hundred. Studying the general case $d = \omega(1)$ is our future work.

The rest of the paper is organized as follows. Section 2 gives the background and all the definitions. In Section 3, we propose the query-answering mechanism. In Section 4, we give the mechanism which is able to output synthetic database. In Section 5, we develop a practical variant of the second mechanism and conduct experiments to evaluate its performance. Finally, we conclude in Section 6.

2. Preliminaries

Let D be a database containing n data points in the data universe $\mathcal{X}$. In this paper, we consider the case that $\mathcal{X} \subset \mathbb{R}^d$ where d is a constant. Typically, we assume that the data universe $\mathcal{X} = [-1, 1]^d$. Two databases D and D' are called neighbors if $|D| = |D'| = n$ and they differ in exactly one data point. The following is the formal definition of differential privacy.

Definition 1 ((ϵ, δ)-differential privacy) *A randomized mechanism $\mathcal{M}$ whose output lies in some range $\mathcal{S}$ is said to preserve (ϵ, δ)-differential privacy if for all measurable $S \in \mathcal{S}$, for all pairs of neighbor databases D, D', the following holds:*

$$\mathbb{P}(\mathcal{M}(D) \in S) \leq \mathbb{P}(\mathcal{M}(D') \in S) \cdot e^\epsilon + \delta,$$

where the probability is taken over the randomness of the $\mathcal{M}$. If $\mathcal{M}$ preserves $(\epsilon, 0)$-differential privacy, we say $\mathcal{M}$ is ϵ-differentially private.

We consider *linear queries*. Each linear query q_f is specified by a function f which maps the data universe $[-1, 1]^d$ to $\mathbb{R}$. q_f is defined as

$$q_f(D) := \frac{1}{|D|} \sum_{\mathbf{x} \in D} f(\mathbf{x}).$$

Let Q be a set of queries. The accuracy of a mechanism with respect to Q is defined as follows.

Definition 2 ((α, β)-accuracy) *Let Q be a set of queries. A mechanism $\mathcal{M}$ is said to have (α, β)-accuracy for size n databases with respect to Q, if for every database D with $|D| = n$ the following holds*

$$\mathbb{P}(\exists q \in Q, \quad |\mathcal{M}(D, q) - q(D)| \geq \alpha) \leq \beta,$$

where $\mathcal{M}(D, q)$ is the answer to q given by $\mathcal{M}$, and the probability is over the internal randomness of the mechanism $\mathcal{M}$.

We will make use of the Laplace mechanism (Dwork et al., 2006) in our algorithm. Laplace mechanism adds Laplace noise to the output. We denote by $\mathrm{Lap}(\sigma)$ the random variable distributed according to the Laplace distribution with parameter σ, whose density function is $\frac{1}{2\sigma} \exp(-|x|/\sigma)$.

Next, we formally define smooth queries, which is a special class of linear queries. Since each linear query q_f is specified by a function f, a set of queries Q_F can be specified by a set of functions F. Remember that each $f \in F$ maps $[-1, 1]^d$ to $\mathbb{R}$. For any point $\mathbf{x} = (x_1, \ldots, x_d) \in [-1, 1]^d$, if $\mathbf{k} = (k_1, \ldots, k_d)$ is a d-tuple of nonnegative integers, then we define

$$D^{\mathbf{k}} := D_1^{k_1} \cdots D_d^{k_d} := \frac{\partial^{k_1}}{\partial x_1^{k_1}} \cdots \frac{\partial^{k_d}}{\partial x_d^{k_d}}.$$

Let $|\mathbf{k}| := k_1 + \ldots + k_d$. Define the K-norm as

$$\|f\|_K := \sup_{|\mathbf{k}| \leq K} \sup_{\mathbf{x} \in [-1,1]^d} |D^{\mathbf{k}} f(\mathbf{x})|.$$

We will study the set C_B^K which contains all *smooth* functions whose derivatives up to order K have ∞-norm upper bounded by a constant $B > 0$. Formally,

$$C_B^K := \{f : \quad \|f\|_K \leq B\}.$$

The set of queries specified by C_B^K, denoted as $Q_{C_B^K}$, is our focus. Smooth functions have been studied in depth in machine learning (van der Vart and Wellner, 1996; Wahba et al.,

1999; Smola et al., 1998; Wang, 2011). See Section 4.2 for examples of smooth functions and its relation to differentially private machine learning.

In this work we will frequently use *trigonometric polynomials*. For the univariate case, a function $p(\theta)$ is called a trigonometric polynomial of degree m if

$$p(\theta) = a_0 + \sum_{r=1}^{m} (a_r \cos r\theta + b_r \sin r\theta),$$

where a_r, b_r are constants. If $p(\theta)$ is an even function, we say that it is an even trigonometric polynomial, and

$$p(\theta) = a_0 + \sum_{r=1}^{m} a_r \cos r\theta.$$

For the multivariate case, if

$$p(\theta_1, \ldots, \theta_d) = \sum_{\mathbf{r}=(r_1,\ldots,r_d)} a_{\mathbf{r}} \cos(r_1\theta_1) \ldots \cos(r_d\theta_d),$$

then p is said to be an even trigonometric polynomial (with respect to each variable), and the degree of θ_i is $\max_{i\le d}\{r_i\}$.

3. The First Mechanism: Query Answering

In this section we propose our first mechanism which outputs answers to the queries. Our second mechanism which is able to output synthetic database will be given in the next section.

3.1 Mechanism and Main Results

The following theorem is our first main result. It says that if the query class is specified by smooth functions, then there is an efficient mechanism for query answering which preserves ϵ-differential privacy and good accuracy. The mechanism consists of two parts: One for outputting a summary of the database, the other for answering a query. The two parts are described in Algorithm 1 and Algorithm 2 respectively. The second part of the mechanism contains no private information of the database.

Theorem 3 *Let the query set be*

$$Q_{C_B^K} := \{q_f = \frac{1}{n}\sum_{\mathbf{x}\in D} f(\mathbf{x}) : \quad f \in C_B^K\},$$

where $K \in \mathbb{N}$ and $B > 0$ are constants. Let the data universe be $[-1,1]^d$, where $d \in \mathbb{N}$ is a constant. Then the mechanism $\mathcal{M}$ given in Algorithm 1 and Algorithm 2 satisfies that for any $\epsilon > 0$, the followings hold:

1) The mechanism is ϵ-differentially private.

Algorithm 1 Outputting the summary

Notations: $\mathcal{T}_t^d := \{0, 1, \ldots, t-1\}^d$, $\mathbf{x} := (x_1, \cdots, x_d)$, $\theta_i(\mathbf{x}) := \arccos(x_i)$.
Parameters: Privacy parameters $\epsilon, \delta > 0$, Failure probability $\beta > 0$,
Smoothness order $K \in \mathbb{N}$.
Input: Database $D \in \left([-1,1]^d\right)^n$
Output: A t^d-dimensional vector as the summary $\hat{\mathbf{b}}$.

1: Set $t = \lceil n^{\frac{1}{2d+K}} \rceil$.
2: **for all** $\mathbf{r} = (r_1, \ldots, r_d) \in \mathcal{T}_t^d$ **do**
3: $\quad b_{\mathbf{r}} \leftarrow \frac{1}{n}\sum_{\mathbf{x}\in D} \cos(r_1\theta_1(\mathbf{x})) \ldots \cos(r_d\theta_d(\mathbf{x}))$
4: $\quad \hat{b}_{\mathbf{r}} \leftarrow b_{\mathbf{r}} + \mathrm{Lap}\left(\frac{t^d}{n\epsilon}\right)$
5: **end for**
6: $\hat{\mathbf{b}} \leftarrow (\hat{b}_{\mathbf{r}})_{\|\mathbf{r}\|_\infty \le t-1}$ ($\hat{\mathbf{b}}$ is a t^d dimensional vector)

Algorithm 2 Answering a query

Input: A query q_f, where $f : [-1,1]^d \to \mathbb{R}$ and $f \in C_B^K$,
Summary $\hat{\mathbf{b}}$ returned by Algorithm 1
Output: Approximate answer to $q_f(D)$.

1: Set $t = \lceil n^{\frac{1}{2d+K}} \rceil$.
2: Let $g_f(\boldsymbol{\theta}) = f(\cos(\theta_1), \ldots, \cos(\theta_d))$, $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_d) \in [-\pi, \pi]^d$.
3: Compute the a trigonometric polynomial approximation $p_t(\boldsymbol{\theta})$ of $g_f(\boldsymbol{\theta})$, where $p_t(\boldsymbol{\theta}) = \sum_{\mathbf{r}=(r_1,\ldots,r_d), \|\mathbf{r}\|_\infty \le t-1} c_{\mathbf{r}} \cos(r_1\theta_1) \ldots \cos(r_d\theta_d)$. (see Section 3.3 for details)
4: $\mathbf{c} \leftarrow (c_{\mathbf{r}})_{\|\mathbf{r}\|_\infty \le t-1}$ ($\mathbf{c}$ is a t^d dimensional vector)
5: **return:** $\mathbf{c} \cdot \hat{\mathbf{b}}$

2) For any $\beta \ge 10 \cdot e^{-\frac{1}{5}(n^{\frac{d}{2d+K}})}$ the mechanism is (α, β)-accurate, where $\alpha = O\left(n^{-\frac{K}{2d+K}}/\epsilon\right)$, and the hidden constant depends only on d, K and B.

3) The running time for $\mathcal{M}$ to output the summary is $O(n^{\frac{3d+K}{2d+K}})$.

4) The running time for $\mathcal{M}$ to answer a query is $O(n^{\frac{d+2+\frac{2d}{K}}{2d+K}} \cdot \mathrm{polylog}(n))$.

The proof of Theorem 3 is essentially based on Theorem 4 given below. The detailed proof of Theorem 3 is given in the Section 3.4.

To have a better idea of how the performances depend on the order of smoothness, let us consider three cases. The first case is $K = 1$, i.e., the query functions only have the first order derivatives. Another extreme case is $K \gg d$, and we assume $d/K = \epsilon_0 \ll 1$. We also consider a case in the middle by assuming $K = 2d$. Table 1 gives simplified upper bounds for the error and running time in these cases. We have the following observations:

1) The accuracy α improves dramatically from roughly $O(n^{-\frac{1}{2d}})$ to nearly $O(n^{-1})$ as K increases. For $K > 2d$, the error is smaller than the sampling error $O(n^{-\frac{1}{2}})$.

Order of smoothness	Accuracy α	Running Time: Outputting summary	Running Time: Answering a query
$K=1$	$O(n^{-\frac{1}{2d+1}})$	$O(n^{\frac{3}{2}})$	$\tilde{O}(n^{\frac{3}{2}+\frac{1}{4d+2}})$
$K=2d$	$O(n^{-\frac{1}{2}})$	$O(n^{\frac{5}{4}})$	$\tilde{O}(n^{\frac{1}{4}+\frac{3/4}{d}})$
$\frac{d}{K}=\epsilon_0 \ll 1$	$O(n^{-(1-2\epsilon_0)})$	$O(n^{1+\epsilon_0})$	$\tilde{O}(n^{\epsilon_0(1+\frac{3}{d})})$

Table 1: Performance vs. Order of Smoothness for Query Answering

2) The running time for outputting the summary does not change too much, because reading through the database requires $\Omega(n)$ time.

3) The running time for answering a query reduces significantly from roughly $O(n^{3/2})$ to nearly $O(n^{\epsilon_0})$ as K getting large. When $K=2d$, it is approximately $n^{1/4}$ if d is not too small.

Conceptually our mechanism is simple. First, by change of variables we have

$$g_f(\theta_1,\ldots,\theta_d)=f(\cos\theta_1,\ldots,\cos\theta_d).$$

It also transforms the data universe from $[-1,1]^d$ to $[-\pi,\pi]^d$. Note that for each variable θ_i, g_f is an even function. To compute the summary, the mechanism just gives noisy answers to queries specified by *even trigonometric monomials* $\cos(r_1\theta_1)\ldots\cos(r_d\theta_d)$. For each trigonometric monomial, the highest degree of any variable is $\max_{1\le i\le d} r_i \le t = O(n^{\frac{1}{2d+K}})$. The summary is an $O(n^{\frac{d}{2d+K}})$-dimensional vector. To answer a query specified by a smooth function f, the mechanism computes a trigonometric polynomial approximation of g_f. The answer to the query q_f is a linear combination of the summary by the coefficients of the approximation trigonometric polynomial.

Our algorithm is an L_∞-approximation based mechanism, which is motivated by Thaler et al. (2012). An approximation based mechanism relies on three conditions:

1) There exists a small set of basis functions such that every query function can be well approximated by a linear combination of them.

2) All the linear coefficients are small.

3) The whole set of the linear coefficients can be computed efficiently.

If these conditions hold, then the mechanism just outputs noisy answers to the set of queries specified by the basis functions as the summary. When answering a query, the mechanism computes the coefficients with which the linear combination of the basis functions approximate the query function. The answer to the query is sidiscretizationmply the inner product of the coefficients and the summary vector.

The following theorem contains the main technical results based on which Theorem 3 holds. It guarantees that by change of variables and using even trigonometric polynomials as the basis functions, the class of smooth functions has all the three properties described above.

Theorem 4 *Let $\gamma>0$. For every $f\in C_B^K$ defined on $[-1,1]^d$, let*

$$g_f(\theta_1,\ldots,\theta_d)=f(\cos\theta_1,\ldots,\cos\theta_d),\qquad \theta_i\in[-\pi,\pi].$$

Then, there is an even trigonometric polynomial p whose degree of each variable is $t(\gamma)=\left(\frac{1}{\gamma}\right)^{1/K}$:

$$p(\theta_1,\ldots,\theta_d)=\sum_{0\le r_1,\ldots,r_d<t(\gamma)} c_{r_1,\ldots,r_d}\cos(r_1\theta_1)\ldots\cos(r_d\theta_d),$$

such that

1) $\|g_f-p\|_\infty\le\gamma$.

2) All the linear coefficients $c_{r_1,\ldots,r_d}$ can be uniformly upper bounded by a constant M independent of $t(\gamma)$ (i.e., M depends only on K, d, and B).

3) The whole set of the linear coefficients can be computed in time $O\left((\frac{1}{\gamma})^{\frac{d+2}{K}+\frac{2d}{K^2}}\cdot\mathrm{polylog}(\frac{1}{\gamma})\right)$.

Theorem 4 is proved in Section 3.3. Based on Theorem 4, the proof of Theorem 3 is mainly the argument for Laplace mechanism together with an optimization of the approximation error γ trading-off with the Laplace noise. (Please see Section 3.4 for more details.)

3.2 Discussions

In this section, we show that our algorithm is more effective than methods based on discretization.

3.2.1 Performance of Existing Mechanisms for Smooth Queries

As mentioned in Introduction, in order to apply existing mechanisms to smooth query problem, one has to conduct discretization, both to the data universe and the set of queries. Here, we show that even if one can discretize this function set and even if the it is implemented in an optimal way, the discretized set is exponentially large, and all existing mechanisms have accuracies significantly worse than that of our algorithm.

Proposition 5 *Let $0<\alpha<1$. Let $C_B^K(\alpha)$ be a subset of C_B^K so that for every $f,g\in C_B^K(\alpha)$, $\|f-g\|_{[-1,1]^d}\ge\alpha$. In other words, $|C_B^K(\alpha)|$ is the packing number of C_B^K. We have*

$$\log\left|C_B^K(\alpha)\right|\ge\Omega\left(\left(\frac{1}{\alpha}\right)^{d/K}\right).$$

If we further define $Q^\alpha_{C_B^K}$ as the corresponding discretization of $Q_{C_B^K}$ with precision α, then

$$\log\left|Q^\alpha_{C_B^K}\right|\ge\Omega\left(\left(\frac{1}{\alpha}\right)^{d/K}\right).$$

Corollary 6 *Suppose the query set $Q_{C_B^K}$ can be discretized in an optimal way. Then the accuracy guarantee of the PMW mechanism is at best $O(n^{-\frac{K}{2(d+K)}}/\epsilon)$, and the running time is $O(n^{\frac{Kd}{2(K+d)}})$ per query.*

Compare to the accuracy of our mechanism $O(n^{-\frac{K}{2d+K}}/\epsilon)$, our algorithm has significantly better accuracy especially when K is relatively large.

3.2.2 Connection with Conjunctions

In a sense, the well studied query class conjunctions defined on $\{0,1\}^d$ can be seen as smooth functions, by simply extending the domain from $\{0,1\}^d$ to $[-1,1]^d$ and extrapolating $x_{i_1} \wedge \ldots \wedge x_{i_J}$ to $x_{i_1} \cdots x_{i_J}$. Clearly $f(\mathbf{x}) := \prod_{j=1}^J x_{i_j}$ is multilinear and smooth.

Note that for multilinear function f induced query, our mechanism will transform it to $g_f(\theta_1, \ldots, \theta_d) := f(\cos\theta_1, \ldots, \cos\theta_d) = \prod_{j=1}^J \cos\theta_{i_j}$. Thus g_f is simply a multilinear trigonometric polynomial and is one of the basis functions used in our algorithm. Recall that the mechanism adds Laplace noise to the basis functions. Therefore, if we focus only on the conjunction queries, our algorithm simply reduces to Laplace mechanism.

3.3 L_∞-approximation of smooth functions: small and efficiently computable coefficients

In this section we prove Theorem 4. That is, for every $f \in C_B^K$ the corresponding g_f can be approximated by a low degree trigonometric polynomial in L_∞-norm. We also require that the linear coefficients of the trigonometric polynomial are all small and can be computed efficiently. These properties are crucial for the differentially private mechanism to be accurate and efficient.

In fact, L_∞-approximation of smooth functions in C_B^K by polynomial (and other basis functions) is an important topic in approximation theory. It is well-known that for every $f \in C_B^K$ there is a low degree polynomial with small approximation error. However, it is not clear whether there is an upper bound for the linear coefficients that is sufficiently good for our purpose. Instead we transform f to g_f and use trigonometric polynomials as the basis functions in the mechanism. Then we are able to give a constant upper bound for the linear coefficients. We also need to compute the coefficients efficiently. But results from approximation theory give the coefficients as complicated integrals. We adopt an algorithm which fully exploits the smoothness of the function and thus can efficiently compute approximations of the coefficients to certain precision so that the errors involved do not affect the accuracy of the differentially private mechanism too much.

Below, Section 3.3.1 describes the classical theory on trigonometric polynomial approximation of smooth functions. Section 3.3.2 shows that the coefficients have a small upper bound and can be efficiently computed. Theorem 4 then follows from these results.

3.3.1 Trigonometric Polynomial Approximation with Generalized Jackson Kernel

This section mainly contains known results of trigonometric polynomial approximation, stated in a way tailored to our problem. For a comprehensive description of univariate

approximation theory, please refer to the excellent book of DeVore and Lorentz (1993) and to Temlyakov (1994) for multivariate approximation theory.

Let g_f be the function obtained from $f \in C_B^K([-1,1]^d)$:

$$g_f(\theta_1, \ldots, \theta_d) = f(\cos\theta_1, \ldots, \cos\theta_d).$$

Note that $g_f \in C_{B'}^K([-\pi,\pi]^d)$ for some constant B' depending only on B, K, d, and g_f is even with respect to each variable. The key tool in trigonometric polynomial approximation of smooth functions is the generalized Jackson kernel.

Definition 7 *Define the generalized Jackson kernel as*

$$J_{t,r}(s) = \frac{1}{\lambda_{t,r}} \left(\frac{\sin(ts/2)}{\sin(s/2)} \right)^{2r},$$

where $\lambda_{t,r}$ is determined by $\int_{-\pi}^{\pi} J_{t,r}(s)\mathrm{d}s = 1$.

$J_{t,r}(s)$ is an even trigonometric polynomial of degree $r(t-1)$. Let $H_{t,r}(s) = J_{t',r}(s)$, where $t' = \lfloor t/r \rfloor + 1$. Then $H_{t,r}$ is an even trigonometric polynomial of degree at most t. We write

$$H_{t,r}(s) = a_0 + \sum_{l=1}^{t} a_l \cos ls. \tag{1}$$

Suppose that g is a univariate function defined on $[-\pi,\pi]$ which satisfies that $g(-\pi) = g(\pi)$. Define the approximation operator $I_{t,K}$ as

$$I_{t,K}(g)(x) = -\int_{-\pi}^{\pi} H_{t,r}(s) \sum_{l=1}^{K+1} (-1)^l \binom{K+1}{l} g(x+ls)\mathrm{d}s, \tag{2}$$

where $r = \lceil \frac{K+3}{2} \rceil$. It is not difficult to see that $I_{t,K}$ maps g to a trigonometric polynomial of degree at most t.

Next suppose that g is a d-variate function defined on $[-\pi,\pi]^d$, and is even with respect to each variable. Define an operator $I_{t,K}^d$ as sequential composition of $I_{t,K,1}, \ldots, I_{t,K,d}$, where $I_{t,K,j}$ is the approximation operator given in (2) with respect to the jth variable of g. Thus $I_{t,K}^d(g)$ is a trigonometric polynomial of d-variables and each variable has degree at most t.

Theorem 8 *Suppose that g is a d-variate function defined on $[-\pi,\pi]^d$, and is even with respect to each variable. Let $D_j^{(K)} g$ be the Kth order partial derivative of g respect to the j-th variable. If $\|D_j^{(K)} g\|_\infty \le M$ for some constant M for all $1 \le j \le d$, then there is a constant C such that*

$$\|g - I_{t,K}^d(g)\|_\infty \le \frac{C}{t^{K+1}},$$

where C depends only on M, d and K.

3.3.2 The Linear Coefficients

In this subsection we study the linear coefficients in the trigonometric polynomial $I^d_{t,K}(g_f)$. The previous subsection established that g_f can be approximated by $I^d_{t,K}(g_f)$ for a small t. Here we consider the upper bound and approximate computation of the coefficients. Since $I^d_{t,K}(g_f)(\theta_1,\ldots,\theta_d)$ is even with respect to each variable, we write

$$I^d_{t,K}(g_f)(\theta_1,\ldots,\theta_d) = \sum_{0\le n_1,\ldots,n_d\le t} c_{n_1,\ldots,n_d}\cos(n_1\theta_1)\ldots\cos(n_d\theta_d). \tag{3}$$

Fact 9 *The coefficients $c_{n_1,\ldots,n_d}$ of $I^d_{t,K}(g_f)$ can be written as*

$$c_{n_1,\ldots,n_d} = (-1)^d \sum_{\substack{1\le k_1,\ldots,k_d\le K+1\\ 0\le l_1,\ldots,l_d\le t\\ l_i=k_i\cdot n_i\,\forall i\in[d]}} m_{l_1,k_1,\ldots,l_d,k_d}, \tag{4}$$

where

$$m_{l_1,k_1,\ldots,l_d,k_d} = \prod_{i=1}^d (-1)^{k_i} a_{l_i}\binom{K+1}{k_i}\left(\int_{[-\pi,\pi]^d}\prod_{i=1}^d\cos\left(\frac{l_i}{k_i}\theta_i\right) g_f(\boldsymbol{\theta})\mathrm{d}\boldsymbol{\theta}\right), \tag{5}$$

and a_{l_i} is the linear coefficient of $\cos(l_i s)$ in $H_{t,r}(s)$ as given in (1).

The following lemma shows that the coefficients $c_{n_1,\ldots,n_d}$ of $I^d_{t,K}(g_f)$ can be uniformly upper bounded by a constant independent of t.

Lemma 10 *There exists a constant M which depends only on K, B, d but independent of t, such that for every $f\in C^K_B$, all the linear coefficients $c_{n_1,\ldots,n_d}$ of $I^d_{t,K}(g_f)$ satisfy*

$$|c_{n_1,\ldots,n_d}|\le M.$$

For clarity, we postpone the proof in Section 3.3.3.

Now we consider the computation of the coefficients $c_{n_1,\ldots,n_d}$ of $I^d_{t,K}(g_f)$. Note that each coefficient involves d-dimensional integrations of smooth functions, so we have to numerically compute approximations of them. For function class C^K_B defined on $[-1,1]^d$, traditional numerical integration methods run in time $O((\frac{1}{\tau})^{d/K})$ in order that the error is less than τ. Here we adopt the sparse grids algorithm due to Gerstner and Griebel (1998) which fully exploits the smoothness of the integrand. By choosing a particular quadrature rule as the algorithm's subroutine, we are able to prove that the running time of the sparse grids is bounded by $O((\frac{1}{\tau})^{2/K})$. The sparse grids algorithm, the theorem giving the bound for the running time and its proof are all given in the follow section 3.3.4 and 3.3.5. Based on these results, we establish the running time for computing the approximate coefficients of the trigonometric polynomial, which is stated in the following Lemma.

Lemma 11 *Let $\hat{c}_{n_1,\ldots,n_d}$ be an approximation of the coefficient $c_{n_1,\ldots,n_d}$ of $I^d_{t,K}(g_f)$ obtained by approximately computing the integral in* (5) *with a version of the sparse grids algorithm (Gerstner and Griebel, 1998) (given in the section 3.3.4). Let*

$$\hat{I}^d_{t,K}(g_f)(\theta_1,\ldots,\theta_d) = \sum_{0\le n_1,\ldots,n_d\le t}\hat{c}_{n_1,\ldots,n_d}\cos(n_1\theta_1)\ldots\cos(n_d\theta_d).$$

Then for every $f\in C^K_B$, in order that

$$\|\hat{I}^d_{t,K}(g_f) - I^d_{t,K}(g_f)\|_\infty \le O\left(t^{-K}\right),$$

it suffices that the computation of all the coefficients $\hat{c}_{n_1,\ldots,n_d}$ runs in time $O\left(t^{(1+\frac{2}{K})d+2}\cdot\mathrm{polylog}(t)\right)$. In addition, $\max_{n_1,\ldots,n_d}|\hat{c}_{n_1,\ldots,n_d} - c_{n_1,\ldots,n_d}| = o(1)$ as $t\to\infty$.

The proof of Lemma 11 is given in the Section 3.3.5. Theorem 4 then follows easily from Lemma 10 and Lemma 11.

Proof of Theorem 4

Setting $t = t(\gamma) = \left(\frac{1}{\gamma}\right)^{1/K}$. Let $p = \hat{I}^d_{m,K}(g_f)$. Combining Lemma 10 and Lemma 11, and note that the coefficients $\hat{c}_{n_1,\ldots,n_d}$ are upper bounded by a constant, the theorem follows. ■

3.3.3 Proof of Lemma 10

We first give a simple lemma.

Lemma 12 *Let*

$$H_{t,r}(s) = \sum_{l=0}^t a_l\cos ls. \tag{6}$$

Then for all $l = 0,1,\ldots,t$

$$|a_l|\le 1/\pi.$$

Proof For any $l\in\{0,1,\ldots,t\}$, multiplying $\cos ls$ on both sides of (6) and integrating from $-\pi$ to π, we obtain that for some $\xi\in[-\pi,\pi]$,

$$a_l = \frac{1}{\pi}\int_{-\pi}^{\pi} H_{t,r}(s)\cos ls\mathrm{d}s = \frac{\cos l\xi}{\pi}\int_{-\pi}^{\pi} H_{t,r}(s)\mathrm{d}s = \frac{\cos l\xi}{\pi}.$$

where in the last equation we use the identity

$$\int_{-\pi}^{\pi} H_{t,r}(s)\mathrm{d}s = 1.$$

This completes the proof. ■

Proof of Lemma 10

We first bound $m_{l_1,k_1,\ldots,l_d,k_d}$. Recall that (see also (5) in Fact 9)

$$m_{l_1,k_1,\ldots,l_d,k_d} = \prod_{i=1}^d (-1)^{k_i} a_{l_i}\binom{K+1}{k_i}\left(\int_{[-\pi,\pi]^d}\prod_{i=1}^d\cos\left(\frac{l_i}{k_i}\theta_i\right) g_f(\boldsymbol{\theta})\mathrm{d}\boldsymbol{\theta}\right).$$

It is not difficult to see that $|m_{l_1,k_1,\ldots,l_d,k_d}|$ can be upper bounded by a constant depending only on d, K and B, but independent of t. This is because that the previous lemma shows $|a_{l_i}| \leq \frac{1}{\pi}$ and g_f is upper bounded by a constant.

Now consider $c_{n_1,\ldots,n_d}$. Recall that

$$c_{n_1,\ldots,n_d} = (-1)^d \sum_{\substack{1\leq k_1,\ldots,k_d\leq K+1 \\ 0\leq l_1,\ldots,l_d\leq t \\ l_i=k_i\cdot n_i \forall i\in[d]}} m_{l_1,k_1,\ldots,l_d,k_d}.$$

We need to show that all $|c_{n_1,\ldots,n_d}|$ are upper bounded by a constant independent of t. Note that although each l_i takes $t+1$ values, l_i and k_i must satisfy the constraint $l_i/k_i = n_i$. Since k_i can take at most $K+1$ values, the number of $m_{l_1,k_1,\ldots,l_d,k_d}$ appeared in the summation is at most $(K+1)^d$. Therefore all $c_{n_1,\ldots,n_d}$ are bounded by a constant depending only on d, K and B, and is independent of t. ■

3.3.4 The Sparse Grids Algorithm

In this section we briefly describe the sparse grids numerical integration algorithm due to Gerstner and Griebel. (Please refer to Gerstner and Griebel 1998 for a complete introduction.) We also specify a subroutine used by this algorithm, which is important for proving the running time.

Numerical integration algorithms dicretize the space and use weighted sum to approximate the integration. Traditional methods for the multidimensional case usually discretize each dimension to the same precision level. In contrast, the sparse grids methods, first proposed by Smolyak (1963), discretize each dimension to carefully chosen and possibly different precision levels, and finally combine many such discretization results. When the integrand has bounded mixed derivatives, as in our case that the integrand is in C_B^K, one can use very few grids in most dimension and still achieve high accuracy.

The sparse grids method is based on one dimensional quadrature (i.e., numerical integration). There are many candidates for one dimensional quadrature. In order to prove an upper bound for the running time, we choose the Clenshaw-Curtis rule (Clenshaw and Curtis, 1960) as the subroutine. This also makes the analysis simpler.

Let $h : [-1,1]^d \to \mathbb{R}$ be the integrand. Let $SG(h)$ be the output of the sparse grids algorithm. Let l be the *level* parameter of the algorithm.

Let $\mathbf{k} = (k_1,\ldots,k_d)$ and $\mathbf{j} = (j_1,\ldots,j_d)$ be d-tuples of positive integers. Then $SG(h)$ is given as a combination of weighted sum:

$$SG(h) := \sum_{|\mathbf{k}|\leq l+d-1} \sum_{j_1=1}^{m(k_1)} \cdots \sum_{j_d=1}^{m(k_d)} u_{\mathbf{k},\mathbf{j}} f(\mathbf{x}_{\mathbf{k},\mathbf{j}}). \tag{7}$$

Below we describe $m(k_i)$, $\mathbf{x}_{\mathbf{k},\mathbf{j}}$ and $u_{\mathbf{k},\mathbf{j}}$ respectively.

1) For any $k \in \mathbb{N}$, $m(k) := 2^k$.

2) For each $\mathbf{k} = (k_1,\ldots,k_d)$ and $\mathbf{j} = (j_1,\ldots,j_d)$, define $\mathbf{x}_{\mathbf{k},\mathbf{j}} := (x_{k_1,j_1},\ldots,x_{k_d,j_d})$, and x_{k_i,j_i} is the j_ith zero of the Chebyshev polynomial with degree $m(k_i)$. Denote by $T_{m(k_i)}$ the

Chebyshev polynomial. Its zeros are given by the following formula.

$$x_{k_i,j_i} = \cos\left(\frac{(2j_i-1)\pi}{2m(k_i)}\right), \qquad j_i = 1,2,\ldots,m(k_i). \tag{8}$$

3) Now we define the weights $u_{\mathbf{k},\mathbf{j}}$. First let $w_{k,j}$ be the weight of $x_{k,j}$ in the one-dimensional Clenshaw-Curtis quadrature rule given by

$$\begin{aligned} w_{k,1} &= \frac{1}{(m(k)+1)(m(k)-1)}, \\ w_{k,j} &= \frac{2}{m(k)}\left(1 + 2\sum_{r=1}^{m(k)/2}{}' \frac{1}{1-4r^2}\cos\left(\frac{2\pi(j-1)r}{m(k)}\right)\right), \quad \text{for } 2\leq j\leq m(k), \end{aligned} \tag{9}$$

where $\sum'$ means that the last term of the summation is halved.

Next, for any fixed k and j, define

$$v_{(k+q),j} = \begin{cases} w_{k,j} & \text{if } q = 1, \\ w_{(k+q-1),r} - w_{(k+q-2),s} & \text{if } q > 1, \text{ and } r,s \text{ with } x_{k,j} = x_{(k+q-1),r} = x_{(k+q-2),s}\ , \end{cases}$$

where $x_{k,j}$ is the zero of Chebyshev polynomial defined above.

Finally, the weight $u_{\mathbf{k},\mathbf{j}}$ is given by

$$u_{\mathbf{k},\mathbf{j}} = \sum_{|\mathbf{k}+\mathbf{q}|\leq l+2d-1} v_{(k_1+q_1),j_1}\cdots v_{(k_d+q_d),j_d},$$

where $\mathbf{k} = (k_1,\ldots,k_d)$ and $\mathbf{q} = (q_1,\cdots,q_d)$. This completes the description of the sparse grids algorithm.

3.3.5 Proof of Lemma 11

We first give the result that characterizes the running time of the Gerstner-Griebel sparse grids algorithm in order to achieve a given accuracy.

Lemma 13 *Let $h \in C_B^K([-\pi,\pi]^d)$ for some constants K and B. Let $SG(h)$ be the numerical integration of h using the sparse grids algorithm described in the previous section. Given any desired accuracy parameter $\tau > 0$, the algorithm achieves*

$$\left|\int_{[\pi,\pi]^d} h(\theta)\mathrm{d}\theta - \mathrm{SG}(h)\right| \leq \tau,$$

with running time at most $O\left(\left(\frac{1}{\tau}\right)^{\frac{2}{K}}(\log\frac{1}{\tau})^{3d+\frac{2d}{K}+1}\right)$.

Proof

Let $L = 2^{l+1}-2$, where l is the level parameter of the sparse grids algorithm. l and L will be determined by the desired accuracy τ later. In fact, L is the maximum number of

grid points of one dimension. By (7) it is easy to see that the total number of grid points, denoted by N_l^d, is given by

$$\begin{aligned} N_l^d &= \sum_{|\mathbf{k}|\le l+d-1} m(k_1)\cdots m(k_d) \\ &= O(l^{d-1}L) \\ &= O(L(\log_2 L)^{d-1}). \end{aligned} \tag{10}$$

In Gerstner and Griebel (1998), it is shown that the approximation error τ can be bounded by the maximal number of grid points per dimension as follows.

$$\tau = O(L^{-K}(\log L)^{(K+1)(d-1)}). \tag{11}$$

Next, let us consider the computational cost per grid point. Since we assume that $h(\mathbf{x})$ can be computed in unit time, and the zeros of Chebyshev polynomials can be computed according to (8), then computing the weights $u_{\mathbf{kj}}$ dominates the running time. Fix $k \in \mathbb{N}$, consider $w_{k,j}$, $1 \le j \le m(k)$. From (9), it is not difficult to see that the set of $w_{k,j}$ can be computed by Fast Fourier Transform (FFT). Therefore the computation cost is $O(m(k)\log m(k))$. Some calculations yield that for a fixed $\mathbf{k},\mathbf{j}$, the computational cost for $u_{\mathbf{kj}}$ is $O(dL\log L)$. Combining this with (10) and (11) the lemma follows.

■

Next we turn to prove Lemma 11. First, we need the following famous result.

Lemma 14 *Let m be a positive integer, let $\sigma(m)$ denotes the number of divisors of m, then for large t*

$$\sum_{m=1}^{t}\sigma(m) = t\ln t + (2c-1)t + O(t^{1/2}),$$

where c is Euler's constant.

To analyze the running time, we also need a result about the normalizing constant of the generalized Jackson kernel (Vyazovskaya and Pupashenko, 2006).

Lemma 15 (Vyazovskaya and Pupashenko 2006) *Let*

$$J_{t,r} = \frac{1}{\lambda_{t,r}}\left(\frac{\sin(ts/2)}{\sin(s/2)}\right)^{2r},$$

be the generalized Jackson kernel as given in Definition 4.1, and the normalizing constant $\lambda_{t,r}$ is determined by

$$\int_{-\pi}^{\pi} J_{t,r}(s)\mathrm{d}s = 1.$$

Then the following identity of the normalizing constant $\lambda_{t,r}$ holds

$$\lambda_{t,r} = 2\pi\sum_{k=0}^{[r-r/t]}(-1)^k\binom{2r}{k}\binom{r(t+1)-tk-1}{r(t-1)-tk}. \tag{12}$$

Now we are ready to prove Lemma 11.

Proof of Lemma 11

Assume that the error induced by the sparse grids algorithm is at most τ per integration. That is, for every $\mathbf{k}=(k_1,\ldots,k_d)$, $\mathbf{l}=(l_1,\ldots,l_d)$

$$\left|\int_{[-\pi,\pi]^d}\prod_{i=1}^{d}\cos\left(\frac{l_i}{k_i}\theta_i\right)g(\boldsymbol{\theta})\mathrm{d}\boldsymbol{\theta} - SG\left(\prod_{i=1}^{d}\cos\left(\frac{l_i}{k_i}\theta_i\right)g(\boldsymbol{\theta})\right)\right| \le \tau.$$

Then

$$\sup_{n_1,\ldots,n_d}|c_{n_1,\ldots,n_d}-\hat{c}_{n_1,\ldots,n_d}| \le \sup_{n_1,\ldots,n_d}\left|\sum_{l_i/k_i=n_i}\prod_{i=1}^{d}(-1)^{k_i}\binom{K+1}{k_i}a_{l_i}\right|\cdot\tau.$$

By Lemma 12, $|a_{l_i}|\le\frac{1}{\pi}$. We obtain that

$$\sup_{n_1,\ldots,n_d}|c_{n_1,\ldots,n_d}-\hat{c}_{n_1,\ldots,n_d}| \le M\cdot\tau, \tag{13}$$

for some constant M independent of t.

Similarly, we have

$$\left\|I_{t,K}^d(g)-\hat{I}_{t,K}^d(g)\right\|_\infty \le O(t^d\tau). \tag{14}$$

Since in the statement of the lemma the desired approximation error is $O(t^{-K})$, we have

$$\tau = t^{-(K+d)}. \tag{15}$$

It is also clear that

$$\max_{n_1,\ldots,n_d}|\hat{c}_{n_1,\ldots,n_d}-c_{n_1,\ldots,n_d}| = o(1), \quad \text{as } t\to\infty.$$

Now let us consider the computation cost. Recall that the kernel $H_{t,r}$ is an even trigonometric of degree at most t:

$$H_{t,r}(s) = a_0 + \sum_{l=1}^{t}a_l\cos ls, \tag{16}$$

where $H_{t,r}(s)=J_{t',r}(s)$ and $J_{t',r}$ is the generalized Jackson kernel given in Definition 4.1. First we need to compute the value of the linear coefficient a_l of $H_{t,r}$. By Lemma 15, one can compute the linear coefficients a_l by solving a system of $t+1$ linear equations. That is, we choose arbitrary $t+1$ points in $[-\pi,\pi]$ and solve (16), since we can compute the value of $H_{t,r}(s)$ directly based on the value of $\lambda_{t,r}$. Clearly, the running time is $O(t^3)$.

Having a_{l_i}, let us consider the computational cost for calculating $\hat{c}_{n_1,\ldots,n_d}$. According to Lemma 13, the running time for the sparse grids algorithm to compute one integration is

$$O\left((\frac{1}{\tau})^{\frac{2}{K}}(\log(1/\tau))^{3d+\frac{2d}{K}+1}\right) = O\left(t^{\frac{2(K+d)}{K}}\mathrm{polylog}(t)\right).$$

Since we only need to compute the integration when $l_i|k_i$ for all $i \in [d]$, by Lemma 14 the number of integrations to compute is at most

$$(K+1+\sigma(1)+\ldots+\sigma(t))^d = O\left((t\log t)^d\right).$$

Thus the total time cost for all numerical integration is $O\left(t^{(1+\frac{2}{K})d+2}\text{polylog}(t)\right)$. Since

$$(1+\frac{2}{K})d+2 \geq 3,$$

the computation time for obtaining the coefficients a_l in $H_{t,r}$ is dominated by the running time of the sparse grids algorithm. It is also easy to see that all other computation costs are dominated by that of the numerical integration. The lemma follows. ■

3.4 Proof of Theorem 3

Here we provide the full proof of our first main theorem (Theorem 3).

Proof of Theorem 3

We prove the four results separately.

3.4.1 Differential Privacy

The summary is a t^d-dimensional vector with sensitivity $\frac{t^d}{n}$. By the standard argument for Laplace mechanism, adding t^d i.i.d. Laplace noise $\text{Lap}(\frac{t^d}{n\epsilon})$ preserves ϵ-differential privacy.

3.4.2 Accuracy

The error of the answer to each query consists of two parts: the approximation error and the noise error. Setting the approximation error γ in Theorem 4 as $\gamma = n^{-\frac{K}{2d+K}}$. Then the degree of each variable in $g(\boldsymbol{\theta})$ is

$$t(\gamma) = \left(\frac{1}{\gamma}\right)^{1/K} = n^{\frac{1}{2d+K}},$$

which is the same as t given in Algorithm 1. Now consider the error induced by the Laplace noise. The noise error is simply the inner product of the t^d linear coefficients $c_{l_1,\ldots,l_d}$ and t^d i.i.d. $\text{Lap}(\frac{t^d}{n\epsilon})$. Since the coefficients are uniformly bounded by a constant, the noise error is bounded by the sum of t^d independent and exponentially distributed random variables (i.e., $|\text{Lap}(\frac{t^d}{n\epsilon})|$). The following lemma gives it an upper bound.

Lemma 16 *Let $X_1,\ldots,X_N$ be i.i.d. random variables with p.d.f. $\mathbb{P}(X_i = x) = \frac{1}{\sigma}e^{-x/\sigma}$ for $x \geq 0$. Then*

$$\mathbb{P}(\sum_{i=1}^{N} X_i \geq 2N\sigma) \leq 10 \cdot e^{-\frac{N}{5}}.$$

Proof Let $Y = \sum_{i=1}^{N} X_i$. It is well-known that Y satisfies the gamma distribution, and for $\forall u > 0$

$$\mathbb{P}(Y \geq u) \leq e^{-\frac{u}{\sigma}} \sum_{n=0}^{N-1} \frac{1}{n!}\left(\frac{u}{\sigma}\right)^n.$$

Thus

$$\mathbb{P}(Y \geq 2N\sigma) \leq e^{-2N} \sum_{n=0}^{N-1} \frac{1}{n!}(2N)^n.$$

Note that for $n < N$

$$\frac{\frac{1}{n!}(2N)^n}{e^{2N}} \leq \frac{\frac{1}{N!}(2N)^N}{\frac{1}{(2N)!}(2N)^{2N}} \leq \prod_{n=1}^{N-1}(1-\frac{n}{2N}) \leq e^{-\frac{N-1}{4}}.$$

Thus

$$\mathbb{P}(Y \geq 2N\sigma) \leq e^{-2N}\left(e^{2N}Ne^{-\frac{N-1}{4}}\right) \leq 10 \cdot e^{-\frac{N}{5}}.$$

■

Part 2) of Theorem 3 then follows from Lemma 16.

3.4.3 Running Time for Outputing Summary

This is straightforward since the summary is a t^d-dimensional vector and for each item the running time is $O(n)$.

3.4.4 Running Time for Answering a Query

According to our setting of t, it is easy to check that the error induced by Laplace noise and that of approximation have the same order. Then by the third part of Theorem 4 we have the running time for computing the coefficients of the trigonometric polynomial is $O\left(n^{\frac{d+2+\frac{2d}{K}}{2d+K}} \cdot \text{polylog}(n)\right)$. The result follows since computing the inner product has running time $O(n^{\frac{d}{2d+K}})$, which is much less than computing the coefficients. ■

4. An Improved Mechanism: Output Synthetic Database

Although the mechanism given in the previous section achieves good accuracy for smooth queries and is efficient, it has a disadvantage: The mechanism can only output answers to given queries, and therefore is not convenient for most machine learning tasks which involve optimizations.

In this section we propose an improved mechanism. The mechanism has the advantage that it is able to output a synthetic database. From a practical point of view this is very appealing, because users can simply use this differentially private database to learn whatever they want. Of course, utility will be guaranteed only for restricted types of tasks

as described below. Also, the price for outputting synthetic database is that theoretically this mechanism is less efficient than the previous one, although it runs in polynomial time. Please see Section 5.2 for practically efficient variations.

4.1 The Mechanism and Theoretical Results

The following theorem is our second main result. It says that if the query class is specified by smooth functions, then there is a polynomial time mechanism which preserves ϵ-differential privacy and achieves good accuracy. The output of the mechanism is a synthetic dataset. A formal description of the mechanism is given in Algorithm 3.

Theorem 17 *Let the query set be*

$$Q_{C_B^K} := \{q_f(D) = \frac{1}{n}\sum_{\mathbf{x}\in D} f(\mathbf{x}) : \quad f \in C_B^K\},$$

where $K \in \mathbb{N}$ and $B > 0$ are constants. Let the data universe be $[-1,1]^d$, where d is a constant. Then the mechanism described in Algorithm 3 satisfies that for any $\epsilon > 0$, the followings hold:

1) *The mechanism preserves ϵ-differential privacy.*

2) *There is an absolute constant c such that for every $\beta \geq c \cdot e^{-n^{\frac{1}{2d+K}}}$ the mechanism is (α, β)-accurate, where $\alpha = O(n^{-\frac{K}{2d+K}}/\epsilon)$, and the hidden constant depends only on d, K and B.*

3) *The running time of the mechanism is $O(n^{\frac{3dK+5d}{4d+2K}})$. (This is dominated by solving the linear programming problem in step 20 of the algorithm.)*

4) *The size of the output synthetic database is $O(n^{1+\frac{K+1}{2d+K}})$.*

The proof of Theorem 17 is given in the Section 4.3. Note that the accuracy of this new mechanism is of the same order as that of our first mechanism.

In Table 2, we illustrate the results with typical parameters as we did in the previous section. From Table 2 we can see, as before, the same accuracy improvement as K/d increases. On the other hand, the running time of the mechanism increases if one wants better accuracy for highly smooth queries. Finally, the size of the output synthetic database also increases in order to have better accuracy: roughly, $O(n^{-1})$ accuracy requires an $O(n^2)$-size synthetic database.

Now we explain the mechanism in detail. Part of Algorithm 3 is the same as Algorithm 1. In particular, Algorithm 3 still employs L_∞ approximation with trigonometric polynomials as basis for transformed smooth functions

$$g_f(\theta_1, \ldots, \theta_d) = f(\cos\theta_1, \ldots, \cos\theta_d).$$

Here we view the trigonometric polynomial functions as a set of basis queries. As in Algorithm 1, we compute the answers to the basis queries and add Laplace noise. So far, if we

Algorithm 3 Private Synthetic DB for Smooth Queries

Notations: $\mathcal{T}_t^d := \{0, 1, \ldots, t-1\}^d$, $\mathbf{x} := (x_1, \cdots, x_d)$, $\theta_i(\mathbf{x}) := \arccos(x_i)$, $a_k := \frac{2k+1-N}{N}$, $\mathcal{A} := \{a_k | k = 0, 1, \ldots, N-1\}$, $\mathcal{L} := \{\frac{i}{L} | i = -L, -L+1, \ldots, L-1, L\}$.
Parameters: Privacy parameters $\epsilon, \delta > 0$, Failure probability $\beta > 0$, Smoothness order $K \in \mathbb{N}$.
Input: Database $D \in \left([-1,1]^d\right)^n$
Output: Synthetic database $\tilde{D} \in \left([-1,1]^d\right)^m$

1: Set $t = \lceil n^{\frac{1}{2d+K}} \rceil$, $N = \lceil n^{\frac{K}{2d+K}} \rceil$, $m = \lceil n^{1+\frac{K+1}{2d+K}} \rceil$, $L = \lceil n^{\frac{d+K}{2d+K}} \rceil$.
2: Initialize: $\underline{D} \leftarrow \emptyset$, $\tilde{D} \leftarrow \emptyset$, $\mathbf{u} \leftarrow \mathbf{0}_{N^d}$
3: **for all** $\mathbf{x} = (x_1, \ldots, x_d) \in D$ **do**
4: $\quad \underline{x_i} \leftarrow \arg\min_{a \in \mathcal{A}} |x_i - a|$, $i = 1, \ldots, d$
5: $\quad$ Add $\underline{\mathbf{x}} = (\underline{x_1}, \ldots, \underline{x_d})$ to $\underline{D}$
6: **end for**
7: **for all** $\mathbf{r} = (r_1, \ldots, r_d) \in \mathcal{T}_t^d$ **do**
8: $\quad b_{\mathbf{r}} \leftarrow \frac{1}{n}\sum_{\underline{\mathbf{x}} \in \underline{D}} \cos(r_1\theta_1(\underline{\mathbf{x}})) \ldots \cos(r_d\theta_d(\underline{\mathbf{x}}))$
9: $\quad \hat{b}_{\mathbf{r}} \leftarrow b_{\mathbf{r}} + \mathrm{Lap}\left(\frac{t^d}{n\epsilon}\right)$
10: $\quad \underline{\hat{b}_{\mathbf{r}}} \leftarrow \arg\min_{l \in \mathcal{L}} |\hat{b}_{\mathbf{r}} - l|$
11: **end for**
12: **for all** $\mathbf{k} = (k_1, \ldots, k_d) \in \mathcal{T}_N^d$ **do**
13: $\quad$ **for all** $\mathbf{r} = (r_1, \ldots, r_d) \in \mathcal{T}_t^d$ **do**
14: $\quad\quad W_{\mathbf{rk}} \leftarrow \cos(r_1 \arccos(a_{k_1})) \ldots \cos(r_d \arccos(a_{k_d}))$
15: $\quad\quad \underline{W_{\mathbf{rk}}} \leftarrow \arg\min_{l \in \mathcal{L}} |W_{\mathbf{rk}} - l|$
16: $\quad$ **end for**
17: **end for**
18: $\underline{\hat{\mathbf{b}}} \leftarrow (\underline{\hat{b}_{\mathbf{r}}})_{\|\mathbf{r}\|_\infty \leq t-1}$ ($\underline{\hat{\mathbf{b}}}$ is a t^d dimensional vector)
19: $\underline{\mathbf{W}} \leftarrow (\underline{W_{\mathbf{rk}}})_{\|\mathbf{r}\|_\infty \leq t-1, \|\mathbf{k}\|_\infty \leq N-1}$ (a $t^d \times N^d$ matrix)
20: Solve the following LP problem: $\min_{\mathbf{u}} \|\underline{\mathbf{W}}\mathbf{u} - \underline{\hat{\mathbf{b}}}\|_1$, subject to $\mathbf{u} \succeq 0$, $\|\mathbf{u}\|_1 = 1$. Obtain the optimal solution $\mathbf{u}^*$.
21: **repeat**
22: $\quad$ Sample $\mathbf{y}$ according to distribution $\mathbf{u}^*$
23: $\quad$ Add $\mathbf{y}$ to $\tilde{D}$
24: **until** $|\tilde{D}| = m$
25: **return:** $\tilde{D}$

ignore the discretization steps (step 3-6), Algorithm 3 is essentially the same as Algorithm 1.

Recall that the next step in our first mechanism is that, for any given smooth query function, we compute the linear coefficients with which the combination of the trigonometric polynomial basis functions is a good approximation of it. The key idea (and the main advantage) of Algorithm 3 is that we do not even need to know the linear coefficients. We merely need to know that there *exist* such coefficients which leads to a good approximation of the smooth function. Now, the goal of the algorithm is to generate a synthetic dataset so that if we evaluate all the basis queries on this synthetic database, all the answers will

Order of smoothness	Accuracy α	Running time	Size of synthetic DB
$K=1$	$O(n^{-\frac{1}{2d+1}})$	$O(n^2)$	$O(n^{1+\frac{2}{2d+1}})$
$K=2d$	$O(n^{-\frac{1}{2}})$	$O(n^{\frac{3}{4}d+\frac{5}{8}})$	$O(n^{\frac{3}{2}+\frac{1}{4d}})$
$\frac{d}{K}=\epsilon_0 \ll 1$	$O(n^{-(1-2\epsilon_0)})$	$O(n^{d(\frac{3}{2}-\frac{\epsilon_0}{2})})$	$O(n^{2-\frac{\epsilon_0}{2}})$

Table 2: Performance vs. Order of Smoothness for Outputing Synthetic Database

be close to the noisy answers obtained from the original dataset. The key observation is that if we have such a synthetic dataset, then the evaluation of any smooth query on this synthetic dataset is an answer both differentially private and accurate. To generate such a dataset, we first learn a probability distribution over $[-1,1]^d$ so that the answers of the basis queries with respect to this distribution are close to the noisy answers. Observe that such a distribution must exist, because the uniform distribution over the original dataset satisfies this requirement. However, learning a continuous distribution is computationally intractable. So we discretize the domain (as well as the original data (step 4)) and consider distributions over the discretized data universe. Because the queries are smooth, the error involved by discretization can be controlled. Learning the distribution can be formulated as a linear programming problem (step 20). Note that in the LP problem we minimize l_1 error instead of l_∞ error because it results in slightly better accuracy. Finally, we randomly draw sufficiently large number of data from this probability distribution, and these data form the output synthetic database.

The running time of the mechanism is dominated by the linear programming step. It is known that the worst-case time complexity of the interior point method is upper bounded in terms of the number of variables, number of constraints, and the number of bits to encode the problem. It is easy to see that there are only poly(n) variables and constraints. To control the number of bits, we round each number in the linear programming problem at a certain precision level (step 10 and 15). Because all the numbers after rounding are bounded uniformly by a constant, the total number of bits to encode the problem is not too large.

We can also analyze the performance of BLR for the smooth query problem and compare to our mechanism proposed in this section as both of them output synthetic database. The analysis is almost identical to that for PMW in Section 3.2.1. Even if one can discretize the query set $Q_{C_B^K}$ in an optimal way, the error of BLR is still considerably larger than that of our algorithm, as described in the following Proposition.

Proposition 18 *Suppose the query set $Q_{C_B^K}$ in an optimal way. The accuracy guarantee of the BLR is at best $O\left(n^{-\frac{K}{d+3K}}\right)$; and the running time is super-exponential in n.*

4.2 Examples of Smooth Queries and Application to Learning

Almost all widely used continuous functions are smooth up to a certain order. Here we list some simple examples. The smoothness of these functions are either obvious or are well known. (See Section 4.4 for proofs.)

1) Linear functions: $f(\mathbf{x}) = \mathbf{w}^T x$ is infinitely smooth if $\|\mathbf{w}\|$ is bounded.

2) Gaussian kernel functions: $f(\mathbf{x}) = \exp(\frac{\|\mathbf{x}-\mathbf{x}_0\|^2}{2\sigma^2})$ (for some $\mathbf{x}_0 \in \mathbb{R}^d$) is in $C_1^{\sigma^2}$, i.e., its derivatives up to order σ^2 is bounded by 1.

3) Logistic function: $f(\mathbf{x}) = \frac{1}{1+e^{-x/\sigma}}$ (for $\sigma > 2$) is K-smooth for any K such that $\max_{k\le K} B_k \le 1$, where B_k is the kth Bernoulli number.

We also point out that many loss functions used in machine learning, composed with smooth functions, are still smooth. Here we just give one example. Suppose the data record in the database are of the form $(\mathbf{x}, y)$. Then the square loss for a smooth regression function f defined as

$$l(f;\mathbf{x},y) = (y - f(x))^2,$$

is smooth.

Now let us discuss applications of our mechanisms to differentially private machine learning. Suppose people want to learn a regression function using the database, where for each data record the first $d-1$ features are independent variables and the dth feature is the dependent variable. In fact, there are excellent algorithms that can do this and guarantee differential privacy. However, consider the following setting: There are many users each wants to learn a regressor and each uses a different type of smooth functions (e.g., linear, polynomial, Ridge, kernel, etc.). Suppose there are totally M users. If we want to guarantee ϵ-differential privacy, we have to require each learner achieve ϵ/M-differential privacy; or equivalently an M-times accuracy decrease in accuracy. As the major goal of differential privacy is to safely release the data and allows everyone to use it, the number of learners M can be very large. Thus a differentially private regression algorithm is not sufficient for this aim. Recently, Ullman (2015) applied PMW to answering multiple convex optimization problems. Using their method, the accuracy decreases only $\log M$-times for M learning problems. However, their algorithm only works for convex loss of linear learning models, while ours work for all smooth functions.

On the other hand, our mechanism can achieve this goal easily: just run the mechanism and output the synthetic database. It is clear that the mechanism guarantees ϵ-differential privacy no matter how many learners use it. The mechanism also guarantees accuracy to *all* learners who use smooth regression functions and the least square criterion, because the accuracy provided by our mechanism hold for *all* smooth functions simultaneously. Therefore, there is no accuracy decrease or privacy loss increase as the number of users grow.

4.3 Proof of Theorem 17

In this section we prove Theorem 17.

Proof of Theorem 17

We first define some notations repeatedly used in this proof.Let the input database be $D = \{\mathbf{x}^{(1)}, \mathbf{x}^{(2)}, \cdots, \mathbf{x}^{(n)}\}$. Let the discretized dataset be (please see step 5 in Algorithm 3) $\underline{D} = \{\underline{\mathbf{x}}^{(1)}, \underline{\mathbf{x}}^{(2)}, \cdots, \underline{\mathbf{x}}^{(n)}\}$. Also let the output synthetic dataset be $\tilde{D} = \{\mathbf{y}^{(1)}, \mathbf{y}^{(2)}, \cdots, \mathbf{y}^{(m)}\}$.

Let

$$\mathbf{b} = (b_{\mathbf{r}})_{\|\mathbf{r}\|_\infty \le t-1}.$$

be a t^d dimensional vector, where $b_{\mathbf{r}}$ is defined in step 8 of the Algorithm 3. Similarly, Let

$$\hat{\mathbf{b}} = (\hat{b}_{\mathbf{r}})_{\|\mathbf{r}\|_\infty \le t-1}$$

and

$$\mathbf{W} = (W_{\mathbf{rk}})_{\|\mathbf{r}\|_\infty \le t-1, \|\mathbf{k}\|_\infty \le N-1},$$

where $\hat{b}_{\mathbf{r}}$ and $W_{\mathbf{rk}}$ are defined as in step 9 and 14 of the algorithm respectively. Let $\mathbf{\Delta} = \hat{\mathbf{b}} - \mathbf{b}$ be the t^d dimensional Laplace noise. Finally let

$$\tilde{\mathbf{b}} = (\tilde{b}_{\mathbf{r}})_{\|\mathbf{r}\|_\infty \le t-1},$$

where

$$\tilde{b}_{\mathbf{r}} = \frac{1}{m} \sum_{\mathbf{y} \in \tilde{D}} \cos(r_1 \theta_1(\mathbf{y})) \dots \cos(r_d \theta_d(\mathbf{y})).$$

(Recall that $\theta_i(\mathbf{y}) = \arccos(y_i)$. Please see also the Notations in Algorithm 3.)

Now we prove the four results in the theorem one by one.

4.3.1 Differential Privacy

That the mechanism preserves ϵ-differential privacy is straightforward. Note that the output synthetic database $\tilde{D}$ contains no private information other than that obtained from $\hat{\mathbf{b}}$. So we only need to show that $\hat{\mathbf{b}}$ is differentially private. But this is immediate from the privacy of Laplace mechanism.

4.3.2 Accuracy

Let $\boldsymbol{\theta} = (\theta_1, \dots, \theta_d)$. For any $f(\mathbf{x}) \in C_B^K$, where $\mathbf{x} \in [-1,1]^d$, let

$$g_f(\boldsymbol{\theta}) := f(\cos\theta_1, \dots, \cos\theta_d).$$

By Theorem 4, we know, there's an even trignometric polynomial:

$$h_f^{M,t}(\boldsymbol{\theta}) := \sum_{\mathbf{r}=(r_1,..,r_d), \|\mathbf{r}\|_\infty \le t-1} c_{\mathbf{r}}^* \cos(r_1\theta_1) \dots \cos(r_d\theta_d) \tag{17}$$

satisfy: (Denote $\mathbf{c}^* = (c_{\mathbf{r}}^*)_{\|\mathbf{r}\|_\infty \le t-1}$)

$$\|g_f - h_f^{M,t}\|_\infty \le O(\frac{1}{t^{K+1}}) \tag{18}$$

$$\|\mathbf{c}^*\|_\infty \le M \tag{19}$$

Where constant M only dependents on K, d, B.

Recall that $\boldsymbol{\theta}(\mathbf{x}) := (\arccos x_1, \dots, \arccos x_d)$. Now we are ready to decompose the error of the mechanism into several terms:

$$\begin{aligned}
&\left|q_f(\tilde{D}) - q_f(D)\right| = \left|\frac{1}{m}\sum_{\mathbf{y}\in\tilde{D}} f(\mathbf{y}) - \frac{1}{n}\sum_{\mathbf{x}\in D} f(\mathbf{x})\right| \\
\le &\left|\frac{1}{m}\sum_{\mathbf{y}\in\tilde{D}} f(\mathbf{y}) - \frac{1}{m}\sum_{\mathbf{y}\in\tilde{D}} h_f^{M,t}(\boldsymbol{\theta}(\mathbf{y}))\right| + \left|\frac{1}{m}\sum_{\mathbf{y}\in\tilde{D}} h_f^{M,t}(\boldsymbol{\theta}(\mathbf{y})) - \frac{1}{n}\sum_{\underline{\mathbf{x}}\in\underline{D}} h_f^{M,t}(\boldsymbol{\theta}(\underline{\mathbf{x}}))\right| \\
&+ \left|\frac{1}{n}\sum_{\underline{\mathbf{x}}\in\underline{D}} h_f^{M,t}(\boldsymbol{\theta}(\underline{\mathbf{x}})) - \frac{1}{n}\sum_{\underline{\mathbf{x}}\in\underline{D}} f(\underline{\mathbf{x}})\right| + \left|\frac{1}{n}\sum_{\underline{\mathbf{x}}\in\underline{D}} f(\underline{\mathbf{x}}) - \frac{1}{n}\sum_{\mathbf{x}\in D} f(\mathbf{x})\right|.
\end{aligned} \tag{20}$$

We further decompose the second term in the last row of the above inequality. We have

$$\begin{aligned}
&\left|\frac{1}{m}\sum_{\mathbf{y}\in\tilde{D}} h_f^{M,t}(\boldsymbol{\theta}(\mathbf{y})) - \frac{1}{n}\sum_{\underline{\mathbf{x}}\in\underline{D}} h_f^{M,t}(\boldsymbol{\theta}(\underline{\mathbf{x}}))\right| \\
= &\left|\mathbf{c}^* \cdot (\tilde{\mathbf{b}} - \mathbf{b})\right| \le \left(\|\tilde{\mathbf{b}} - \hat{\mathbf{b}}\|_1 + \|\mathbf{\Delta}\|_1\right)\|\mathbf{c}^*\|_\infty \\
\le &\left(\|\tilde{\mathbf{b}} - \mathbf{W}\mathbf{u}^*\|_1 + \|\mathbf{W}\mathbf{u}^* - \underline{\mathbf{W}}\mathbf{u}^*\|_1 + \|\underline{\mathbf{W}}\mathbf{u}^* - \underline{\hat{\mathbf{b}}}\|_1 + \|\underline{\hat{\mathbf{b}}} - \hat{\mathbf{b}}\|_1 + \|\mathbf{\Delta}\|_1\right)\|\mathbf{c}^*\|_\infty \\
\le &\Big(\|\tilde{\mathbf{b}} - \mathbf{W}\mathbf{u}^*\|_1 + \|(\mathbf{W} - \underline{\mathbf{W}})\mathbf{u}^*\|_1 + \|\mathbf{W}\underline{\mathbf{u}} - \hat{\mathbf{b}}\|_1 + \|(\mathbf{W} - \underline{\mathbf{W}})\underline{\mathbf{u}}\|_1 \\
&+ 2\|\underline{\hat{\mathbf{b}}} - \hat{\mathbf{b}}\|_1 + \|\mathbf{\Delta}\|_1\Big)\|\mathbf{c}^*\|_\infty \\
\le &\left(\|\tilde{\mathbf{b}} - \mathbf{W}\mathbf{u}^*\|_1 + \frac{4t^d}{L} + 4\|\mathbf{\Delta}\|_1\right)\|\mathbf{c}^*\|_\infty
\end{aligned} \tag{21}$$

where L is the number of grid points in each dimension for rounding, $\underline{\hat{\mathbf{b}}}$ is rounded version of $\hat{\mathbf{b}}$, $\underline{\mathbf{W}}$ is rounded version of $\mathbf{W}$, $\mathbf{u}^*$ is optimal distribution by solving LP in step 20 in Algorithm 3, and $\underline{\mathbf{u}}$ is the uniform distribution on $\underline{D}$. Note that the second last inequality holds because

$$\|\underline{\mathbf{W}}\mathbf{u}^* - \underline{\hat{\mathbf{b}}}\|_1 \le \|\underline{\mathbf{W}} \cdot \underline{\mathbf{u}} - \underline{\hat{\mathbf{b}}}\|_1.$$

Also, the last inequality in (21) follows from

$$\|\underline{\hat{\mathbf{b}}} - \hat{\mathbf{b}}\|_1 \le \frac{t^d}{L} + \|\mathbf{\Delta}\|_1,$$

and

$$\|\mathbf{W}\underline{\mathbf{u}} - \hat{\mathbf{b}}\|_1 \le \|\mathbf{W}\underline{\mathbf{u}} - \mathbf{b}\|_1 + \|\mathbf{\Delta}\|_1 = \|\mathbf{\Delta}\|_1,$$

where the last equality holds since $\mathbf{W}\underline{\mathbf{u}} = \mathbf{b}$.

Define

$$\begin{aligned}
\eta_d &= \left|\frac{1}{n}\sum_{\underline{\mathbf{x}}\in\underline{D}} f(\underline{\mathbf{x}}) - \frac{1}{n}\sum_{\mathbf{x}\in D} f(\mathbf{x})\right|, \\
\eta_n &= 4\|\mathbf{\Delta}\|_1\|\mathbf{c}^*\|_\infty, \\
\eta_a &= \left|\frac{1}{m}\sum_{\mathbf{y}\in\tilde{D}} f(\mathbf{y}) - \frac{1}{m}\sum_{\mathbf{y}\in\tilde{D}} h_f^{M,t}(\boldsymbol{\theta}(\mathbf{y}))\right| + \left|\frac{1}{n}\sum_{\underline{\mathbf{x}}\in\underline{D}} h_f^{M,t}(\boldsymbol{\theta}(\underline{\mathbf{x}})) - \frac{1}{n}\sum_{\underline{\mathbf{x}}\in\underline{D}} f(\underline{\mathbf{x}})\right|, \\
\eta_s &= \|\tilde{\mathbf{b}} - \mathbf{W}\mathbf{u}^*\|_1\|\mathbf{c}^*\|_\infty, \\
\eta_r &= \frac{4t^d}{L}\|\mathbf{c}^*\|_\infty,
\end{aligned}$$

where η_d, η_n, η_a, η_s, η_r correspond to the discretization error, noise error, approximation error, sampling error and rounding error, respectively. Combining (20), (21) and the equations above, we have the error of the mechanism bounded by the sum of these five types of errors:

$$\left|q_f(\tilde{D}) - q_f(D)\right| \le \eta_d + \eta_n + \eta_a + \eta_s + \eta_r.$$

We now bound the five errors separately.

Discretization error η_d: Since $f \in C_B^K$ ($K \geq 1$), the first order derivatives of f are all bounded by B. Also the discretization precision of $[-1,1]^d$ is $\frac{1}{N}$, so the distance between the data in D and the corresponding data in $\underline{D}$ is $O(\frac{1}{N})$. Recall that N is number of grid points in each dimension for discretization. Thus we have

$$\eta_d = \left| \frac{1}{n} \sum_{\underline{\mathbf{x}} \in \underline{D}} f(\underline{\mathbf{x}}) - \frac{1}{n} \sum_{\mathbf{x} \in D} f(\mathbf{x}) \right| \leq \frac{dB}{N} = O\left(n^{-\frac{K}{2d+K}}\right).$$

Noise error η_n: Since M in Equation (19) is a constant only depending on d, K, B, We know $\|\mathbf{c}^*\|_\infty = O(1)$. Thus to bound $\eta_n = \|\mathbf{\Delta}\|_1 \cdot \|\mathbf{c}^*\|_\infty$, we only need to bound the l_1 norm of the t^d-dimensional vector $\mathbf{\Delta}$ which contains i.i.d. random variables Lap $\left(\frac{t^d}{n\epsilon}\right)$; or equivalently bound the sum of t^d i.i.d. random variables with exponential distribution. It is well known that such a sum satisfies gamma distribution. Simple calculations yields

$$\mathbb{P}\left(\|\mathbf{\Delta}\|_1 \leq 2\frac{t^{2d}}{n\epsilon} \right) \geq 1 - 10e^{-\frac{t^d}{5}}.$$

Thus, with probability $1 - 10e^{-\frac{t^d}{5}}$, we have

$$\eta_n = \|\mathbf{\Delta}\|_1 \|\mathbf{c}^*\|_\infty \leq O\left(\frac{t^{2d}}{n\epsilon}\right).$$

Approximation error η_a: Recall that for any $\mathbf{x}$,

$$g_f(\boldsymbol{\theta}(\mathbf{x})) = f(\mathbf{x}).$$

Denote

$$\|g_f - h_f^{M,t}\|_{[-\pi,\pi]^d} := \sup_{\boldsymbol{\theta} \in [-\pi,\pi]^d} \left| g_f(\boldsymbol{\theta}) - h_f^{M,t}(\boldsymbol{\theta}) \right|.$$

We have

$$\begin{aligned}\eta_a &= \left| \frac{1}{m} \sum_{\mathbf{y} \in \tilde{D}} f(\mathbf{y}) - \frac{1}{m} \sum_{\mathbf{y} \in \tilde{D}} h_f^{M,t}(\boldsymbol{\theta}(\mathbf{y})) \right| + \left| \frac{1}{n} \sum_{\underline{\mathbf{x}} \in \underline{D}} h_f^{M,t}(\boldsymbol{\theta}(\underline{\mathbf{x}})) - \frac{1}{n} \sum_{\underline{\mathbf{x}} \in \underline{D}} f(\underline{\mathbf{x}}) \right| \\ &\leq 2\|g_f - h_f^{M,t}\|_\infty \leq O\left(\frac{1}{t^{K+1}}\right).\end{aligned}$$

Sampling error η_s: It is easy to bound sampling error. Let $\mathbf{W}_\mathbf{r}$. be the row vector of matrix $\mathbf{W}$ indexed by $\mathbf{r}$. Recall that $-1 \leq W_{\mathbf{rk}} \leq 1$. Thus for each $\mathbf{r}$, by Chernoff bound we have that for any $\tau > 0$:

$$\mathbb{P}\left(|\tilde{b}_\mathbf{r} - \mathbf{W}_\mathbf{r}.\mathbf{u}^*| \geq \tau \right) \leq 2e^{-\frac{m\tau^2}{2}},$$

since $\tilde{b}_\mathbf{r}$ is just the average of m i.i.d. samples and $\mathbf{W}\mathbf{u}^*$ is its expectation. Next by union bound

$$\mathbb{P}\left(\|\tilde{\mathbf{b}} - \mathbf{W}\mathbf{u}^*\|_\infty \geq \tau \right) \leq 2t^d e^{-\frac{m\tau^2}{2}},$$

and therefore

$$\mathbb{P}\left(\|\tilde{\mathbf{b}} - \mathbf{W}\mathbf{u}^*\|_1 \geq t^d\tau \right) \leq 2t^d e^{-\frac{m\tau^2}{2}}.$$

Setting τ such that $2t^d e^{-\frac{m\tau^2}{2}} = e^{-t}$, we have that with probability $1 - e^{-t}$,

$$\|\tilde{\mathbf{b}} - \mathbf{W}\mathbf{u}^*\|_1 \leq O\left(\frac{t^{d+1/2}}{\sqrt{m}}\right).$$

Rounding error η_r: Since $\|\mathbf{c}^*\|_\infty$ is upper bounded by a constant, we have

$$\eta_r \leq O\left(\frac{t^d}{L}\right).$$

Putting it together: Combining the five types of errors, we have that with probability $1 - e^{-t} - 10e^{-\frac{t^d}{5}}$, the error of the mechanism satisfies

$$\left| \frac{1}{m} \sum_{\mathbf{y} \in \tilde{D}} f(\mathbf{y}) - \frac{1}{n} \sum_{\mathbf{x} \in D} f(\mathbf{x}) \right| \leq O\left(\frac{1}{N} + \frac{1}{t^{K+1}} + \frac{t^{2d}}{n\epsilon} + \frac{t^{d+\frac{1}{2}}}{\sqrt{m}} + \frac{t^d}{L} \right). \tag{22}$$

Recall that the mechanism sets

$$\begin{aligned} t = \lceil n^{\frac{1}{2d+K}} \rceil,\ N = \lceil n^{\frac{K}{2d+K}} \rceil, \\ m = \lceil n^{1+\frac{K+1}{2d+K}} \rceil,\ L = \lceil n^{\frac{d+K}{2d+K}} \rceil. \end{aligned}$$

The theorem follows after some simple calculation.

4.3.3 Running Time

It is not difficult to see that in this case the running time of the mechanism is dominated by solving the Linear Programming problem in step 20. (Because the time complexity of linear programming is with respect to arithmetic operations, all running time discussed here should be understand in this way.) To analyze the running time of the LP problem, observe that it could be rewritten in following standard form:

$$\begin{aligned} \max_{\bar{\mathbf{x}}} \quad & \bar{\mathbf{c}}^T \bar{\mathbf{x}} \\ \text{s.t.} \quad & \bar{\mathbf{A}}\bar{\mathbf{x}} = \bar{\mathbf{b}} \\ & \bar{\mathbf{x}} \succeq \mathbf{0} \end{aligned} \tag{23}$$

where

$$\bar{\mathbf{A}} = \begin{pmatrix} L \cdot \underline{\mathbf{W}} & L \cdot \mathbf{I}_{t^d} & -L \cdot \mathbf{I}_{t^d} \\ \mathbf{1}_{N^d}^T & 0 & 0 \end{pmatrix},$$

$$\bar{\mathbf{b}} = \begin{pmatrix} L \cdot \hat{\underline{\mathbf{b}}} \\ 1 \end{pmatrix}, \quad \bar{\mathbf{c}} = \begin{pmatrix} \mathbf{0} \\ \mathbf{1}_{t^d} \\ \mathbf{1}_{t^d} \end{pmatrix}, \quad \bar{\mathbf{x}} = \begin{pmatrix} \mathbf{u} \\ \mathbf{v} \\ \mathbf{w} \end{pmatrix}.$$

$\bar{\mathbf{A}}$ is a $\bar{m} \times \bar{n}$ matrix where $\bar{m} = t^d + 1$ and $\bar{n} = N^d + 2t^d$. Note that 1) each element of $\underline{\mathbf{W}}$ is in $[-1, 1]$; 2) each element of $\underline{\hat{\mathbf{b}}}$ is in $[-1, 1]$; and 3) each element of $\underline{\mathbf{W}}$ and $\underline{\hat{b}}$ is rounded to precision $1/L$. So actually we have reduce to a LP problem (23), with elements of $\bar{\mathbf{A}}$, $\bar{b}$, $\bar{c}$ are all integers and bounded by L.

The most well-known worst-case complexity of the interior point algorithm for linear programming with integer parameters is $O(\bar{n}^3\tilde{L})$, where $\bar{n}$ is the number of variables and $\tilde{L}$ is the number of bits to encode the linear programming problem. Here we use a more refined bound given in Anstreicher (1999). By using this bound, we are able to prove a much better time complexity for our algorithm; because in the linear programming problem (23), the number of constraints is often much smaller than the number of variables. The bound we make use of for the complexity of linear programming is $O(\frac{\bar{n}^{1.5}\bar{m}^{1.5}}{\ln \bar{m}}\bar{L})$ (Anstreicher, 1999). Here, $\bar{L}$ is the size of LP problem in standard form defined as follows (Monteiro and Adler, 1989):

$$\begin{aligned}\bar{L} =& \lceil \log(1 + |\det(\bar{\mathbf{A}}_{max})|) \rceil + \lceil \log(1 + \|\bar{\mathbf{c}}\|_\infty) \rceil \\ &+ \lceil \log(1 + \|\bar{\mathbf{b}}\|_\infty) \rceil + \lceil \log(\bar{m} + \bar{n}) \rceil,\end{aligned}$$

where

$$\bar{\mathbf{A}}_{max} = \mathop{\arg\max}_{\mathbf{X} \text{is a square submatrix of} \bar{\mathbf{A}}} |\det(\mathbf{X})|.$$

Note that $\bar{m} < \bar{n}$, so the size of $\bar{\mathbf{A}}_{max}$ is at most $\bar{m} \times \bar{m}$. Therefore, we have

$$|\det(\bar{\mathbf{A}}_{max})| \leq \bar{m}! L^{\bar{m}},$$

and

$$\bar{L} = O(\bar{m}(\log \bar{m} + \log L) + \log \bar{n}).$$

Given $\bar{m} = O(t^d)$ and $\bar{n} = O(N^d)$, simple calculation shows that the total time complexity is

$$O\left(\frac{\bar{n}^{1.5}\bar{m}^{1.5}}{\ln \bar{m}}\bar{L}\right) = O\left(N^{1.5d}t^{2.5d}\right) = O\left(n^{\frac{3dK+5d}{4d+2K}}\right).$$

4.3.4 Size of the Output Synthetic Database

The size of synthetic dataset m is set in step 1 of the algorithm. ■

4.4 Proof of Smoothness

Here we prove the smoothness of the functions listed in Section 4.2. We only give the proof for Gaussian kernel function. The smoothness for logistic function follows directly from the derivative of hyperbolic tangent.

Proposition 19 *Let*

$$f(\mathbf{x}) = \sum_{j=1}^{J} \alpha_j \exp\left(-\frac{\|\mathbf{x} - \mathbf{x}_j\|^2}{2\sigma^2}\right),$$

where $\mathbf{x} \in \mathbb{R}^d$. *Let* $\boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_J)$. *Suppose* $\|\boldsymbol{\alpha}\|_1 \leq 1$. *Then for every* $K \leq \sigma^2$, $\|f\|_K \leq 1$.

Proof We first give a well-known inequality for Hermite polynomial. Proposition 19 follows immediately from this lemma.

Lemma 20 (Indritz 1961) *For Hermite polynomial of degree* k *defined as*

$$H_k(x) = (-1)^k e^{x^2} \frac{\mathrm{d}^k}{\mathrm{d}x^k} e^{-x^2},$$

where $k \in \mathbb{N}$ *and* $x \in (-\infty, \infty)$, *it satisfies following inequality:*

$$|H_k(x)| \leq (2^k k!)^{\frac{1}{2}} e^{\frac{1}{2}x^2}.$$

To prove Proposition 19, we only need to show that the K-norm of the Gaussian kernel function is bounded by 1 since $\|\boldsymbol{\alpha}\|_1 \leq 1$.

Let $g(x) = e^{-x^2}$. From Lemma 20 we directly have:

$$|\frac{\mathrm{d}^k}{\mathrm{d}x^k} g(x)| = |H_k(x) e^{-x^2}| \leq (2^k k!)^{\frac{1}{2}}.$$

Let $\mathbf{k} = (k_1, \ldots, k_d)$, and $|\mathbf{k}| = K$. Therefore, for $f(\mathbf{x})$ defined in Proposition 19, we have:

$$|D^{\mathbf{k}} f(\mathbf{x})| = \prod_{j=1}^{d} \frac{\mathrm{d}^{k_j}}{\mathrm{d}x_j^{k_j}} g\left(\frac{x_j - y_j}{\sqrt{2}\sigma}\right) \leq \left(\frac{1}{\sqrt{2}\sigma}\right)^K \left(\prod_{j=1}^{d} (2^{k_j} k_j!)\right)^{\frac{1}{2}} \leq \frac{(K!)^{\frac{1}{2}}}{\sigma^K}.$$

Obviously, when $K \leq \sigma^2$,

$$|D^{\mathbf{k}} f(\mathbf{x})| \leq \frac{K^{\frac{K}{2}}}{\sigma^K} \leq 1.$$

The proposition follows. ■

5. Additional Results

In this section we provide some additional results. In Section 5.1 we show that the two mechanisms described in Section 3 and Section 4 respectively can be modified to achieve slightly better accuracy and preserve (ϵ, δ)-differential privacy. In Section 5.2 we give a variant of our second mechanism which outputs synthetic database. The goal is to make the algorithm practically efficient, since as stated in Theorem 17 the running time of that mechanism is approximately $O(n^{3d/2})$, which is not acceptable in real applications.

5.1 (ϵ, δ)-Differentially Private Mechanisms

The two mechanisms given in Section 3 and Section 4 respectively preserve ϵ-differential privacy. It is easy to generalize them to preserve (ϵ, δ)-differential privacy and have slightly better accuracy.

For the first mechanism, simply setting

$$t = \lceil n^{\frac{2}{3d+2K}} (\log \frac{1}{\delta})^{-\frac{1}{3d+2K}} \rceil,$$

in step 1 of Algorithm 1 and Algorithm 2 respectively we have the following result.

Theorem 21 *Let the query set be*

$$Q_{C_B^K} = \{q_f = \frac{1}{n}\sum_{\mathbf{x}\in D} f(\mathbf{x}) : \quad f \in C_B^K\},$$

where $K \in \mathbb{N}$ and $B > 0$ are constants. Let the data universe be $[-1,1]^d$, where $d \in \mathbb{N}$ is a constant. Then the new mechanism related to Algorithm 1 and Algorithm 2 satisfies that for any $\epsilon > 0$, $\delta > 0$, the following hold:

1) *The mechanism is (ϵ, δ)-differentially private.*

2) *There is an absolute constant c such that for any $\beta \geq c \cdot e^{-n^{\frac{2}{3d+2K}}(\log\frac{1}{\delta})^{-\frac{1}{3d+2K}}}$, the mechanism is (α, β)-accurate, where $\alpha = O\left(n^{-\frac{2K}{3d+2K}}(\log\frac{1}{\delta})^{\frac{K}{3d+2K}}/\epsilon\right)$, and the hidden constant depends only on d, K and B.*

3) *The running time of the mechanism is $O\left(n^{\frac{5d+2K}{3d+2K}}(\log\frac{1}{\delta})^{-\frac{d}{3d+2K}}\right)$.*

4) *The running time for $\mathcal{S}$ to answer a query is $O\left(n^{\frac{2d+4+\frac{2d}{K}}{3d+2K}}(\log\frac{1}{\delta})^{-\frac{d+2+\frac{d}{K}}{3d+2K}}\log(n)\right)$.*

The proof of Theorem 21 is along the same line as the proof of Theorem 3 plus standard use of the composition theorem (Dwork et al., 2010). We omit the details.

For the second mechanism, replacing step 1 and step 9 of Algorithm 3 by the following we obtain an (ϵ, δ)-differentially private mechanism.

1) Step 1. Set $t = \lceil n^{\frac{2}{3d+2K}}(\log\frac{1}{\delta})^{-\frac{1}{3d+2K}}\rceil$, $N = \lceil n^{\frac{2K}{3d+2K}}(\log\frac{1}{\delta})^{-\frac{K}{3d+2K}}\rceil$,
$m = \lceil n^{\frac{4d+4K+2}{3d+2K}}(\log\frac{1}{\delta})^{-\frac{2d+2K+1}{3d+2K}}\rceil$, and $L = \lceil n^{\frac{2d+2K}{3d+2K}}(\log\frac{1}{\delta})^{-\frac{d+K}{3d+2K}}\rceil$.

2) Step 9. $\hat{b}_{\mathbf{r}} = b_{\mathbf{r}} + \text{Lap}\left(\frac{(t^d\log\frac{1}{\delta})^{\frac{1}{2}}}{n\epsilon}\right)$.

Theorem 22 *Let the query set $Q_{C_B^K}$ be defined as in Theorem 17. Let the data universe be $[-1,1]^d$, where $d \in \mathbb{N}$ is a constant. Then the new mechanism related to Algorithm 3 satisfies that for any $\epsilon > 0$, $\delta > 0$, the followings hold:*

1) *The mechanism is (ϵ, δ)-differentially private.*

2) *There is an absolute constant c such that for any $\beta \geq c \cdot e^{-n^{\frac{2}{3d+2K}}(\log\frac{1}{\delta})^{-\frac{1}{3d+2K}}}$, the mechanism is (α, β)-accurate, where $\alpha = O\left(n^{-\frac{2K}{3d+2K}}(\log\frac{1}{\delta})^{\frac{K}{3d+2K}}/\epsilon\right)$, and the hidden constant depends only on d, K and B.*

3) *The running time of the mechanism is $O\left(n^{\frac{3dK+5d}{3d+2K}}(\log\frac{1}{\delta})^{-\frac{3dK+5d}{6d+4K}}\right)$.*

4) *The size of synthetic database is $O\left(n^{\frac{4d+4K+2}{3d+2K}}(\log\frac{1}{\delta})^{-\frac{2d+2K+1}{3d+2K}}\right)$.*

The proof of Theorem 22 is omitted for the same reason as above.

5.2 A Practical Variant of the Synthetic-Database-Output Mechanism

The time complexity of our second mechanism, which outputs synthetic database, can be nearly $n^{\frac{3d}{2}}$ to achieve n^{-1} accuracy for highly smooth queries, where d is the dimension of the data. In real application such a running time is unacceptable. We thus consider a variant of Algorithm 3 which turns out to be very efficient and suffers only from minor loss in accuracy in our experiments. (On the other hand we do not have theoretical guarantee for the utility of this algorithm any more.) Note that the running time of Algorithm 3 is dominated by the linear programming step. This LP problem has $O(N^d)$ variables and $O(t^d)$ constraints, where N^d is the number of discretized grids in $[-1,1]^d$ and t^d is the number of trigonometric polynomial basis functions. To make our algorithm practical, we consider a subset $\mathcal{S}$ of the N^d grids with size $C := |\mathcal{S}| \ll N^d$ and restrict the probability distribution $\mathbf{u}$ on this subset of grids (see step 20 in Algorithm 3). Similarly, we may use a subset of size R of the t^d trigonometric polynomial basis functions preferred to lower degrees. By doing this, the LP problem has C variables and R constraints.

The simplest approach to obtain a small subset $\mathcal{S}$ is sampling from the N^d grids in $[-1,1]^d$ uniformly. However, this approach suffers from substantial loss in accuracy (see the supplementary material for experimental results of this method), because $|\mathcal{S}|$ is extremely small compared to N^d, the probability that $\mathcal{S}$ contains data points in D (or close to D) is very small. In order to reduce the size of the LP problem and preserve the accuracy, we need a better approach to obtain $\mathcal{S}$. Formally, the problem of choosing a subset $\mathcal{S}$ for our purpose can be formulated as follows: We want a subset $\mathcal{S}$ so that

1) $\mathcal{S}$ is differentially private;

2) $|\mathcal{S}|$ is small;

3) For almost every data point x in D, there is a point in $\mathcal{S}$ close to x.

Note that without the privacy concern, one can simply let $\mathcal{S} = D$. But under the requirement of privacy, this problem is non-trivial. Here we adopt private PCA to obtain a low dimensional ellipsoid. The ellipsoid is spanned by the (private) top eigenvectors of the data covariance matrix with the square root of the (private) eigenvalues as the radius. In particular, we use a slightly modified version of the Private Subspace Iteration (PSI) mechanism (Hardt, 2013) to compute the private eigenpairs. The mechanism is described in Algorithm 4. Finally, we uniformly sample C points from the ellipsoid to form $\mathcal{S}$.

In the following three results, we show that the PSI mechanism is differentially private and accurate for the top eigenvectors and eigenvalues respectively. Note that Hardt (2013) shows that the principal angle between the space spanned by the top-k leading eigenvectors of the true data covariance matrix and the the space spanned by the output column vectors of $\mathbf{X}^{(T)}$ is small. However, it does not directly imply that the output private ellipsoid converges to the true PCA ellipsoid. Our results slightly strengthen the results in Hardt (2013). We show each private top-k eigenvalue is close to the true eigenvalue and each private top-k eigenvector is close to the true eigenvector, provided the true eigenvalues are well separated.

Theorem 23 (Accuracy of the eigenvectors) *Given a database D with $|D| = n$, let*

$$\mathbf{A} = \frac{1}{n}\sum_{\mathbf{y}\in D}(\mathbf{y} - \bar{\mathbf{y}})(\mathbf{y} - \bar{\mathbf{y}})^T$$

Algorithm 4 Private Subspace Iteration (Hardt, 2013)

Input: Database $D \in ([-1,1]^d)^n$

Output: $\boldsymbol{\lambda}$ (as private top-k eigenvalues), $\mathbf{X}^{(T)}$ (columns as private top-k eigenvectors).

Parameters: Number of iterations $T \in \mathbb{N}$, dimension k, privacy parameters $\epsilon, \delta > 0$, Denote GS as the Gram-Schmidt orthonormalization algorithm.

1: Set $\sigma = \frac{5d\sqrt{4k(T+1)\log(1/\delta)}}{n\epsilon}$, $\mathbf{A} = \frac{1}{n}\sum_{\mathbf{y}\in D}(\mathbf{y}-\bar{\mathbf{y}})(\mathbf{y}-\bar{\mathbf{y}})^T$, where $\bar{\mathbf{y}} = \frac{1}{n}\sum_{\mathbf{y}\in D}\mathbf{y}$. Thus $\mathbf{A}$ is the data covariance matrix.
2: Initialize: $\mathbf{G}^{(0)} \sim N(0,1)^{d\times k}$ (i.i.d. Gaussian distribution), $\mathbf{X}^{(0)} \leftarrow \mathrm{GS}(\mathbf{G}^0)$
3: **for all** $l = 1, 2, \ldots, T$ **do**
4: Sample $\mathbf{G}^{(l)} \sim N(0,\sigma^2)^{n\times k}$.
5: $\mathbf{W}^{(l)} = \mathbf{A}\mathbf{X}^{(l-1)} + \mathbf{G}^{(l)}$
6: $\mathbf{X}^{(l)} \leftarrow \mathrm{GS}(\mathbf{W}^{(l)})$
7: **end for**
8: Set $\hat{\lambda}_s = \|\mathbf{w}_s^{(T)}\|_2$ for $s = [k]$, where $\mathbf{w}_s^{(T)}$ is the s-th column of $\mathbf{W}^{(T)}$. Set $\boldsymbol{\lambda} = (\hat{\lambda}_s)_{s\le k}$.

be the data covariance matrix. Also let $\lambda_1 \ge \cdots \ge \lambda_d$ be the eigenvalues of A and $\gamma_k = \lambda_k/\lambda_{k+1} - 1$. Let

$$\mathbf{U} = (\mathbf{u}_1, \ldots, \mathbf{u}_k) \in \mathbb{R}^{d\times k},$$

where $\mathbf{u}_1, \ldots, \mathbf{u}_k$ are the top k eigenvectors of $\mathbf{A}$. Denote $\theta(\mathbf{u},\mathbf{v})$ as the angle between two vectors $\mathbf{u}$ and $\mathbf{v}$. Then, with parameters $k \le d/2$ and $T \ge C(\min_{s\le k}\gamma_s)^{-1}\log d$ for some sufficiently large constant C, the matrix $\mathbf{X}^{(T)} = (\mathbf{x}_1^{(T)}, \ldots, \mathbf{x}_k^{(T)}) \in \mathbb{R}^{d\times k}$ returned by Algorithm 4 satisfies that: with probability $1 - o(1)$, for all $s \le k$

$$\sin\theta(\mathbf{u}_s, \mathbf{x}_s^{(T)}) \le O\Big(\frac{\omega_s d^{\frac{3}{2}}\sqrt{kT\log T\log\left(\frac{1}{\delta}\right)}}{n\epsilon}\Big),$$

where

$$\omega_s = \begin{cases} \frac{1}{\gamma_1\lambda_1} & s = 1, \\ \max\{\frac{1}{\gamma_s\lambda_s}, \frac{1}{\gamma_{s-1}\lambda_{s-1}}\} & 2 \le s \le k. \end{cases}$$

Theorem 24 (Accuracy of the eigenvalues) *Using the same notions as in Theorem 23, let $\hat{\lambda}_s = \|\mathbf{w}_s^{(T)}\|_2$ for $s \le k$, where $\mathbf{w}_s^{(T)}$ is the sth column of $\mathbf{W}^{(T)}$. Then with probability $1 - o(1)$, we have for all $s \le k$*

$$|\hat{\lambda}_s - \lambda_s| \le O\Big(\frac{d^3kT\log T\log\left(\frac{1}{\delta}\right)}{n^2\epsilon^2\gamma_s^2\lambda_s^2} + \frac{kd\sqrt{T\log T\log\left(\frac{1}{\delta}\right)}}{n\epsilon}\Big).$$

Theorem 25 (Privacy) *If Algorithm 4 is executed with each $\mathbf{G}^{(l)}$ independently sampled as*

$$\mathbf{G}^{(l)} \sim N(0,\sigma^2)^{d\times k},$$

with

$$\sigma = \frac{5d\sqrt{4kT\log(1/\delta)}}{n\epsilon},$$

then Algorithm 4 satisfies (ϵ,δ)-differential privacy.

If Algorithm 4 is executed with each $\mathbf{G}^{(l)}$ independently sampled as

$$\mathbf{G}^{(l)} \sim Lap(\sigma)^{d\times k},$$

with

$$\sigma = \frac{50d^{3/2}kT}{n\epsilon},$$

then Algorithm 4 satisfies ϵ-differential privacy.

The proof of Theorem 23, Theorem 24 and Theorem 25 are given below.

Before we state it formally, let us take a closer look at the Theorem 3.3 in Hardt (2013): With high probability, the tangent of the angle between the space spanned by the top-k leading eigenvectors, namely eigenspace, and the space spanned by the output columns, namely output-space, is *small*, given regularity conditions. Our goal is the column-wise convergence between eigenvectors and output columns, which can be concluded from the simultaneous convergence between the increasing sequence of eigenspaces and the increasing sequence of output-spaces, given that they shared the same dimension. This constraint leads us to utilize a weaker version of Theorem 3.3 by specifying $r = k$, but the favored column-wise convergence at least compensated for the loss of tuning parameter r. Note that simply applying Theorem 3.3 consecutively for the sequence will not assure the high convergence probability $1 - o(1)$ and our analysis can be extended to the case $k = O(d)$, where the dimension d can grow as the size of database given the aptitude of added noise is adequate.

Our results generalize Theorem 3.3 in Hardt (2013) which proves that the principal angle between the subspace spanned by the private top-k eigenvectors and the subspace spanned by the true eigenvectors is small. But what we need in this paper is that each private eigenvector (and eigenvalue) converges to the true eigenvector (and eigenvalue). It is worth pointing out that simply applying Theorem 3.3 in Hardt (2013) consecutively for each k does not obtain our result, although our proofs rely on some results in Hardt (2013).

We first give three lemmas. The proof of the first two lemmas are straightforward and are omitted. For simplicity, below we denote $\|\mathbf{X}\|$ the spectral norm of a matrix $\mathbf{X}$.

Lemma 26 *Assuming the data universe $\mathcal{X} = [-1,1]^d$, for all pairs of neighbor databases D, D' with $|D| = |D'| = n$, let*

$$\mathbf{A}(D) = \frac{1}{n}\sum_{\mathbf{y}\in D}(\mathbf{y}-\bar{\mathbf{y}})(\mathbf{y}-\bar{\mathbf{y}})^T,$$

be the data covariance matrix. It holds that

$$\|\mathbf{A}(D) - \mathbf{A}(D')\| \le \frac{5d}{n}.$$

Lemma 27 *Let $\mathbf{A} = (a_{ij}) \in \mathbb{R}^{n\times d}$, denote $\mathbf{A}_{kl} = (a_{ij})_{i\le k, j\le l}$ the (k,l)-sub matrix of $\mathbf{A}$ for any $k \le n$ and $l \le d$, then $\|\mathbf{A}_{kl}\| \le \|\mathbf{A}\|$.*

Lemma 28 *Let $\mathbf{U} \in \mathbb{R}^{d\times k}$ be a matrix with orthonormal columns. Let*

$$\mathbf{G}^{(1)}, ..., \mathbf{G}^{(T)} \sim N(0, \sigma^2)^{d\times k},$$

with $k \leq d$ and assume that $T \leq d$. Let $\mathbf{G}_s^{(l)}$ and $\mathbf{U}_s$ be the (d, s)-sub matrix of $\mathbf{G}^{(l)}$ and $\mathbf{U}$ respectively for $s \in [k]$. Then, with probability $1 - o(1)$,

$$\max_{l\in[T]} \|\mathbf{U}_s^T \mathbf{G}_s^{(l)}\| \leq O(\sigma\sqrt{k \log T}), \quad \forall\, s \in [k].$$

Proof

By Lemma A.3 in Hardt (2013),

$$\|\mathbf{U}_k^T \mathbf{G}_k^{(l)}\| \leq O(\sigma\sqrt{k \log T}).$$

The desired result follows from Lemma 27 since $\mathbf{U}_s^T \mathbf{G}_s^{(l)}$ is the (s, s)-sub matrix of $\mathbf{U}_k^T \mathbf{G}_k^{(l)}$. ■

Proof of Theorem 23 Consider the spectral decomposition $\mathbf{A} = \mathbf{Z}\mathbf{\Lambda}\mathbf{Z}^{-1}$, and denote $\mathbf{\Lambda} = \begin{pmatrix} \mathbf{\Lambda}_1 & \\ & \mathbf{\Lambda}_2 \end{pmatrix}$, and $\mathbf{Z} = \begin{pmatrix} \mathbf{Z}_1 & \mathbf{Z}_2 \end{pmatrix}$, where $\mathbf{\Lambda}_1 \in \mathbb{R}^{s\times s}$ and $\mathbf{Z}_1 \in \mathbb{R}^{d\times s}$. Next we denote $\mathbf{U}_s = \mathbf{Z}_1\mathbf{\Lambda}_1\mathbf{Z}_1^T$ and $\mathbf{V}_s = \mathbf{Z}_2\mathbf{\Lambda}_2\mathbf{Z}_2^T$. Obviously we have

$$\mathbf{A} = \mathbf{U}_s\mathbf{\Lambda}_1\mathbf{U}_s^T + \mathbf{V}_s\mathbf{\Lambda}_2\mathbf{V}_s^T.$$

Let

$$\Delta(\mathbf{U}_s) = \max_l \|\mathbf{U}_s^T \mathbf{G}_s^{(l)}\|,$$

and

$$\Delta(\mathbf{V}_s) = \max_l \|\mathbf{V}_s^T \mathbf{G}_s^{(l)}\|,$$

where $\mathbf{G}_s^{(l)}$ is the (d, s)-sub matrix of $\mathbf{G}^{(l)}$. By Lemma 28, we concludes that with probability $1 - o(1)$, the following events occur simultaneously:

1. $\forall\, s \in [k], \Delta(\mathbf{U}_s) \leq O(\sigma\sqrt{k \log T})$,
2. $\forall\, s \in [k], \Delta(\mathbf{V}_s) \leq O(\sigma\sqrt{d \log T})$.

Notice that for all $s \leq k$, we have with probability $1 - o(1)$ that $\Delta(\mathbf{U}_s) \leq \Delta(\mathbf{V}_s)$ as we set $s \leq k \leq d/2$. Since $\arccos\theta(\mathbf{U}_s, \mathbf{X}_s^{(0)})$ is bounded, where $\mathbf{X}_s^{(0)}$ is the (d, s)-sub matrix of $\mathbf{X}^{(0)}$, we have for all $s \leq k$

$$\Delta(\mathbf{U}_s) \arccos\theta(\mathbf{U}_s, \mathbf{X}_s^{(0)}) \leq O(\sigma\sqrt{k \log T}).$$

Applying Theorem 2.9 in Hardt (2013), we have with probability of $1 - o(1)$, for all $s \in [k]$

$$\tan\theta(\mathbf{U}_s, \mathbf{X}_s^{(T)}) \leq O\Big(\frac{\sigma}{\gamma_s\lambda_s}\sqrt{d \log T}\Big). \tag{24}$$

For the case $s = 1$, the theorem is proved. Now for any fixed $s \in [k]$, notice that $\mathbf{u}_s$ is in the space spanned by $(\mathbf{u}_1, \ldots, \mathbf{u}_s)$ as well as the orthogonal complement of the space spanned by $(\mathbf{u}_1, \ldots, \mathbf{u}_{s-1})$, we have

$$\begin{aligned}
&\sin^2\theta(\mathbf{u}_s, \mathbf{x}_s^{(T)}) \\
&= \|\mathbf{U}_{s-1}\mathbf{U}_{s-1}^T\mathbf{x}_s^{(T)} + (\mathbf{I} - \mathbf{U}_s\mathbf{U}_s^T)\mathbf{x}_s^{(T)}\|^2 \\
&= \|\mathbf{U}_{s-1}\mathbf{U}_{s-1}^T\mathbf{x}_s^{(T)}\|^2 + \|(\mathbf{I} - \mathbf{U}_s\mathbf{U}_s^T)\mathbf{x}_s^{(T)}\|^2 \\
&\leq \sin^2\theta(\mathbf{U}_{s-1}, \mathbf{X}_{s-1}^{(T)}) + \sin^2\theta(\mathbf{U}_s, \mathbf{X}_s^{(T)}) \\
&\leq 2(\max\{\sin^2\theta(\mathbf{U}_{s-1}, \mathbf{X}_{s-1}^{(T)}), \sin^2\theta(\mathbf{U}_s, \mathbf{X}_s^{(T)})\}) \\
&\leq 2(\max\{\tan^2\theta(\mathbf{U}_{s-1}, \mathbf{X}_{s-1}^{(T)}), \tan^2\theta(\mathbf{U}_s, \mathbf{X}_s^{(T)})\}).
\end{aligned} \tag{25}$$

The theorem, for the case $s \geq 2$, is proved by substituting (24) into (25). ■

Proof of Theorem 24 Denote $\mathbf{x}_s = \mathbf{x}_s^{(T-1)}$, $\mathbf{w}_s = \mathbf{w}_s^{(T)}$, $\mathbf{g}_s$ as the s-column of $\mathbf{G}^{(T)}$, and $\theta^{(T)} = \theta(\mathbf{U}_s, \mathbf{X}_s^{(T)})$ for short. Let $\mathbf{x}_s = \mathbf{u} + \mathbf{u}^\perp$, where $\mathbf{u}$ is the eigenvector corresponding to λ_s. Then, since $\mathbf{u} = \mathbf{x}_s\cos\phi$ and $\mathbf{u}^\perp = \mathbf{x}_s\sin\phi$ for a $\phi \leq \theta^{(T)}$, we have

$$\begin{aligned}
\hat{\lambda}_s^2 &= \mathbf{w}_s^T\mathbf{w}_s \\
&= (\mathbf{A}\mathbf{x}_s + \mathbf{g}_s)^T(\mathbf{A}\mathbf{x}_s + \mathbf{g}_s) \quad , \\
&= \mathbf{x}_s^T\mathbf{A}^2\mathbf{x}_s + 2\mathbf{x}_s^T\mathbf{A}\mathbf{g}_s + \mathbf{g}_s^T\mathbf{g}_s
\end{aligned}$$

Let $R = 2\mathbf{x}_s^T\mathbf{A}\mathbf{g}_s + \mathbf{g}_s^T\mathbf{g}_s$, then by Lemma 28, with probability $1 - o(1)$, $R \leq O(\sigma\sqrt{k \log T}) + O(d\sigma^2)$.

$$\begin{aligned}
\mathbf{x}_s^T\mathbf{A}^2\mathbf{x}_s &= \mathbf{u}^T\mathbf{A}^2\mathbf{u} + \mathbf{u}^{\perp T}\mathbf{A}^2\mathbf{u}^\perp \\
&= \lambda_s^2\mathbf{u}^T\mathbf{u} + \mathbf{u}^{\perp T}\mathbf{A}^2\mathbf{u}^\perp \\
&\leq \lambda_s^2\|\mathbf{u}\|^2 + \lambda_1^2\|\mathbf{u}^\perp\|^2 \\
&\leq \lambda_s^2\cos^2\theta^{(T)} + \lambda_1^2\sin^2\theta^{(T)} \\
&= \lambda_s^2(1 - \sin^2\theta^{(T)}) + \lambda_1^2\sin^2\theta^{(T)} \\
&= \lambda_s^2 + (\lambda_1^2 - \lambda_s^2)\sin^2\theta^{(T)}.
\end{aligned}$$

Thus,

$$\begin{aligned}
|\hat{\lambda}_s - \lambda_s| &\leq \frac{(\lambda_1^2 - \lambda_s^2)}{\hat{\lambda}_s + \lambda_s}\sin^2\theta^{(T)} + O(\sigma\sqrt{k \log T}) + O(d\sigma^2) \\
&= O(\frac{\sigma^2 d \log T}{\gamma_s^2\lambda_s^2}) + O(\sigma\sqrt{k \log T}).
\end{aligned}$$

Plug in the setting of σ the corollary follows. ■

Dataset	Size (n)	# Attributes (d)
NOM	20643	116
NUR	12958	28
CTG	2126	42

Table 3: Summary of the dataset

Remark 29 *The accuracy of both the private eigenvectors and the private eigenvalues can be improved by considering the matrix coherence of A, as analyzed in Hardt (2013). Typically, the accuracy can be improved by a factor of $O\left(\frac{1}{d}\cdot \text{polylog}(d)\right)$.*

Proof of Theorem 25 The theorem follows immediately from Lemma 26 and Lemma 3.6 in Hardt (2013). ■

5.2.1 Experimental Results

Here we provide experimental results for the practical variant mechanism described above. It turns out that this algorithm is also far more efficient than our first mechanism given in Section 3 as answering a query is still time consuming in practice.

We adopt three datasets all from the UCI repository. A summary of the size and the number of attributes of these datasets is given in Table 3. Since the data universe considered in this paper is $[-1,1]^d$, we normalize each attribute to $[-1,1]$.

We conduct two sets of experiments in order to have a relatively comprehensive understanding of the *utility* of the differentially private synthetic database generated by our mechanism. In both sets of experiments we first output the synthetic database. In one set of experiments, we test the accuracy of query answering, as described in the previous sections. In the other set of experiments, we consider a very different task. We learn a SVM classifier from the synthetic database, and evaluate its accuracy (on the original data). We think that this task may be more useful from a practical point of view. It is worth pointing out that in the scenario of classification, the classification error ($0-1$ loss) is not a smooth function. Therefore the second set of experiments might be viewed, in a sense, as a test of how well our mechanism generalize to non-smooth functions.

The queries employed in the first set of experiments are linear combinations of Gaussian kernel functions. We use this type of functions because 1) These functions possess good smoothness property as stated in Section 2, and 2) linear combinations of Gaussian are universal approximators.

Detailed parameter setting of the query functions is as follows. We consider

$$f(\mathbf{x}) = \sum_{j=1}^{J} \alpha_j \exp\left(-\frac{\|\mathbf{x}-\mathbf{x}_j\|^2}{2\sigma^2}\right).$$

In all experiments, we set $J = 10$; α_j is randomly chosen from $[0,1]$, and $\mathbf{x}_j$ is randomly chosen from $[-1,1]^d$. We test various values of σ and various ϵ to see how the smoothness

Table 4: Worst-case error for the variant of the database-outputting mechanism

of the query function and privacy parameter affect the performance of the algorithm (see below for detailed results).

We use different performance measures to evaluate the algorithm. The goal is to have a comprehensive understanding of the performance of the mechanism. We consider the worst-case error of the mechanism over the set of queries. Because our query set, i.e., linear combination of Gaussian Kernels, contains infinitely many functions, we randomly choose 10^4 queries in each experiment. The worst-case error is over these 10^4 queries.

We give both absolute error and relative error for all experiments. The absolute error of a query q_f is defined as $|q_f(D) - q_f(\tilde{D})|$; and relative error is defined as $|\frac{q_f(D)-q_f(\tilde{D})}{q_f(D)}|$. We present relative error because in certain cases (e.g. when σ is small) $f(\mathbf{x})$ is very small for most $\mathbf{x} \in D$. Therefore in this case a small absolute error does not necessarily imply good performance, and relative error is more informative[3].

We present the running time of the mechanism for outputting the synthetic database in each experiment. The computer used in all the experiments is a workstation with 2 Intel Xeon X5650 processors of 2.67GHz and 32GB RAM.

We present the performance of the ϵ-differentially private algorithm in Table 4. For each dataset, both absolute error and relative error, as average of 20 rounds, are reported

3. One also needs to be careful when using relative error. In our experiments, we deliberately set $\alpha_j \in [0,1]$. So $f(\mathbf{x}) \geq 0$ for all $\mathbf{x}$. If instead we set $\alpha_j \in [-1,1]$, then $f(\mathbf{x})$ can be either positive or negative, and it is possible that $q_f(D)$ is close to zero while $f(\mathbf{x})$ is not small for most $\mathbf{x} \in D$. In such a case, a large relative error does not necessarily imply a bad performance.

Dataset	Original	ϵ		
		0.1	1	10
NOM	0.9353	0.6328	0.7959	0.8491
NUR	0.9081	0.5361	0.7748	0.8164
CTG	0.9755	0.5309	0.5853	0.6116

Table 5: AUC for the variant of the database-outputting mechanism

sequentially. We make use of linear combination of Gaussian with different values of σ as the query functions. The last column of the table lists the running time with respect to the worst σ of the algorithm for outputting the synthetic database.

Now we analyze the experimental results in Table 4 in greater detail. First, the algorithm is quite efficient. On all datasets, the mechanism outputs the synthetic databases in a few seconds. Next consider the accuracy. As explained earlier, the relative error is more meaningful in our experiments. It can be seen that except for the case $\sigma = 2$ (recall that $K = \sigma^2$), the accuracy is reasonably good. The relative errors decrease monotonically as the the order of smoothness of the queries increases.

We then turn to describe the second set of experiments. We randomly partition each dataset into two subsets of equal size. One subset is used as *training* dataset, the other as *test* dataset. By running our mechanism, we generate a differentially private synthetic database using the training dataset as input. Since our task is classification, and the attribute values in the synthetic dataset are continuous ($[-1, 1]$), we round the label attribute to $\{-1, 1\}$. We then learn a SVM classifier from the synthetic dataset. Finally we test the classifier's performance on the *test* dataset. As a comparison, we also list the performance of the SVM classifier learned from the non-private training data, as shown in the second column of Table 5. Here, the performance measures are Area Under ROC Curve (AUC).

We test three values of ϵ, and the performances are given in Table 5. For each dataset, the AUC is an average of 10 rounds. It can be seen that when ϵ is small, there is usually a relatively big utility gap. But as ϵ getting large, the performances improve quickly.

6. Conclusion

In this paper, we study differentially private mechanisms with respect to the K-smooth queries. We first propose a differentially private mechanism for efficiently answering smooth queries. The running time for outputting the summary is $O(n^{1\sim1.5})$. For queries of high order smoothness, the running time for answering a query is sublinear, and nearly $O(n^{\epsilon_0})$. Furthermore, the mechanisms achieve an accuracy nearly $O(n^{-1})$ in highly smooth case, much better than the sampling error $O(n^{-1/2})$ which is inherent to differentially private mechanisms answering general queries.

From a practical viewpoint, outputting a synthetic database while preserving differential privacy is more appealing. In this paper, we also propose a differentially private mechanism which output synthetic database. The user can obtain accurate answers to all smooth queries from the synthetic database. Our mechanisms run in polynomial time, while existing

algorithms run in super-exponential time. This synthetic dataset outputing mechanism achieves almost the same level of accuracy as the query-answering mechanism.

There is a future direction we think worth exploring. As mentioned in Introduction, there exists an efficient and differentially private algorithm which outputs a synthetic database and is accurate to the class of rectangle queries defined on $[-1, 1]^d$ (Blum et al., 2008). Rectangle queries are not smooth. They are specified by indicator functions which are not even continuous. The mechanism proposed in Blum et al. (2008) is completely different to the mechanism for smooth queries given in this paper. Thus an immediate question is: can we develop efficient mechanisms which output synthetic database and preserve differential privacy for a natural class of queries containing both smooth and important non-smooth functions?

Abstract

The goal of subspace learning is to find a k-dimensional subspace of $\mathbb{R}^d$, such that the expected squared distance between instance vectors and the subspace is as small as possible. In this paper we study subspace learning in a *partial information* setting, in which the learner can only observe $r \leq d$ attributes from each instance vector. We propose several efficient algorithms for this task, and analyze their sample complexity.

Keywords: principal components analysis, budgeted learning, statistical learning, learning with partial information, learning theory

1. Introduction

Subspace learning is a dimensionality reduction technique in a variety of applications such as face recognition (Yang et al., 2004), image compression (Du and Fowler, 2007), and document classification (Papadimitriou et al., 1998). Recently, there has been growing interest in subspace learning from partially observed data (e.g., (Chen et al., 2013; Wang and Poor, 1998; Chi et al., 2013)). As motivation, consider the scenario of subspace learning from corrupted data. As discussed in Chen et al. (2013), data corruption may cause some (or even most) of the attributes to be missing. Another typical scenario is subspace learning from multiple sources. Many applications (e.g., wireless sensor networks (Chi et al., 2013)) rely on data which is collected from multiple sources (e.g., sensors). When the data dimension is high, it may be impossible or prohibitively expensive to collect every data entry from every source. Note that in the first scenario, we have no control over which attributes are missing, while in the second one a learner may actively choose which attributes to observe.

The subspace learning problem is formally defined as follows. Let $\mathcal{X}$ be a subset of the Euclidean unit ball in $\mathbb{R}^d$, and let P be some unknown distribution over $\mathcal{X}$. Our goal is to find a rank-k projection matrix $\Pi \in \mathbb{R}^{d\times d}$ such that the expected squared distance, $\mathbb{E}_{x\sim P}[\|x - \Pi x\|_2^2]$, is as small as possible.

When $\mathcal{X}$ is a finite set and P is the uniform distribution over $\mathcal{X}$, the optimal solution to the subspace learning problem is given by the Principal Component Analysis (PCA) algorithm, which returns the projection matrix that corresponds to the k leading eigenvectors of the matrix $\frac{1}{|\mathcal{X}|}\sum_{x\in\mathcal{X}} xx^\top$. In the more general stochastic optimization setting of subspace learning, $\mathcal{X}$ is not restricted to be a finite set, P is an arbitrary distribution over $\mathcal{X}$, and the information given to the learner has the form of an i.i.d. training sequence $(x_1, \ldots, x_m) \sim P^m$.

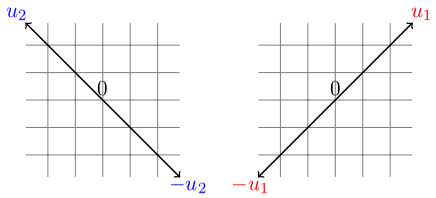
In the usual full information setting of subspace learning, the learner has access to all attributes of the sampled vectors. In this paper, we consider subspace learning in a partial information setting, in which only a subset of indices from each vector can be observed. Inspired by the two applications presented above, we study two variants of this problem, which will be named the *passive* setting, and the *active* setting, respectively. In the passive setting, we assume that each attribute is observed with probability $p = r/d$ ($r \leq d$). Therefore, the expected number of observed attributes from each vector is r. In the active setting, the learner can choose (possibly at random) r attributes to be revealed. The *sample complexity* of a subspace learning algorithm is defined as the number of samples that are needed by the algorithm in order to find a projection matrix Π with expected squared distance, $\mathbb{E}_{x\sim P}[\|x - \Pi x\|_2^2]$, of at most ϵ more than the optimal expected squared distance. The sample complexity for each of the models is defined as the minimal sample complexity attained by any algorithm. In this paper we propose efficient algorithms for both settings and analyze their sample complexity. We also provide several lower bounds on the sample complexity that can be attained by any algorithm.

1.1 Our Contribution

Our first observation is that subspace learning (in both the passive and active models) using $r = 1$ attributes is impossible. Consider the task of learning a 1-dimensional subspace (a line) in $\mathbb{R}^2$ (see Figure 1). Let $u_1 = (\alpha, \alpha)$, $u_2 = (-\alpha, \alpha)$. Denote by P_1 the uniform distribution over $\{u_1, -u_1\}$, and by P_2 be the uniform distribution over $\{u_2, -u_2\}$. Suppose that the actual distribution P is chosen uniformly at random from $\{P_1, P_2\}$. The task of subspace learning in this case amounts to distinguishing between P_1 and P_2. However, since each single coordinate is distributed uniformly over $\{-\alpha, \alpha\}$, the learner does not obtain any information from a single observation, and hence cannot identify the right subspace.

For the case $2 \leq r \leq d$ we propose two efficient algorithms, named Partially Observed PCA (Section 2.1) and Matrix Bandit Exponentiated Gradient (Section 3.1), which are designed for the passive and active models, respectively.

Partially Observed PCA (POPCA) is an extension of the PCA algorithm. Denote the population covariance matrix $\mathbb{E}[xx^\top]$ by C. The optimal projection matrix, denoted $\Pi^\star$, is the projection onto the subspace that is spanned by the k leading eigenvectors of C. An ERM (empirical risk minimizer, i.e., an algorithm that minimizes the empirical loss) for the full information setting is given by PCA which returns the projection matrix corresponding to the k leading eigenvectors of



(a) (b)

Figure 1: Impossibility of subspace learning using $r = 1$ observed attributes. The distribution of the observed attribute is identical for (a) and for (b), therefore they are indistinguishable.

the matrix $m^{-1}\sum_{i=1}^{m} x_i x_i^\top$ (whose expected value is C). Similarly, the POPCA algorithm uses the random observations in order to construct an estimate $\hat{C}$ of C, and approximates $\Pi^\star$ using the projection matrix onto the k leading eigenvectors of $\hat{C}$. We analyze the sample complexity of this algorithm, showing (see Corollary 3) that it is bounded from above by $(d/r)^2\frac{k}{\epsilon^2}$.

In the full information setting, the sample complexity is known to be $O(k/\epsilon^2)$ (This bounds coincides with our bound when $r = d$). Hence, the (multiplicative) price of partial information, that is, how many more examples we need in order to compensate for the lack of full information on each individual example, is $O((d/r)^2)$. It is interesting to understand whether a lower price can be achieved. In Theorem 4 we prove that the sample complexity of every algorithm in the passive model is $\Omega\left((d/r)^2\frac{k}{\epsilon^2}\right)$. The optimality of POPCA in the passive mode is thus established. Another appealing property of POPCA is that, in terms of computational complexity, the challenge of partial information does not incur any additional cost; While the sample complexity grows as r decreases, the runtime per iteration decreases by the same order.

Next, we investigate the active model and ask whether the price of partial information can be reduced due to the ability of the learner to actively choose the observed attributes. Intuitively, one may hope that the learning process would reveal some useful information that can be utilized while choosing which coordinates to observe. Our second algorithm, called Matrix Bandit Exponentiated Gradient (MBEG), exploits the active setting by maintaining a "weight matrix" which is updated with every observation, and induces a non-uniform attribute sampling distribution. For MBEG, we derive an upper bound of $\max\left\{8k\cdot\frac{d+r}{r}\cdot\frac{k}{\epsilon^2}\,,\,\frac{d^4 r}{2(d+r)}\right\}\cdot\log(d)$ (see Theorem 7) on the sample complexity. We note that if ϵ is small enough, then the right term in the bound becomes irrelevant, and thus a linear dependence on d/r is obtained (for a detailed comparison, see Section 3.2). The (almost trivial) fact that every subspace learner, even in the active model, must have a sample complexity that grows linearly with d/r is proved in Appendix C. Hence, the dependence of MBEG on d/r is optimal, in the regime where ϵ is small.

The results in the active model immediately lead to the following question: Can we attain a linear price for partial information in the active model, independently of the required accuracy? We discuss possible directions for tackling this question in Section 4.

1.2 Related Work

In the full information setting, it has been shown by Shawe-Taylor et al. (2005) and Blanchard et al. (2007) that the optimal sample complexity of subspace learning is at most $O(k/\epsilon^2)$, and this upper bound is achievable by applying PCA on i.i.d. samples according to the distribution P. A similar result is obtained by applying the Stochastic Gradient Descent algorithm (Arora et al., 2013).

Subspace learning in the partial information setting has been studied in Chi et al. (2013), where an algorithm named PETRELS is proposed. However, no formal guarantees are derived for this method. The setting in Mitliagkas et al. (2014) is similar to our passive setting, but they assume that the distribution that generates the instance vectors is Gaussian.

A closely related problem to the task of subspace learning (in the passive setting) is the approximation of the covariance matrix using partially observed attributes. We discusses this relation in Section 2.2.

One possible way to tackle the challenge of subspace learning with partial information is based on the matrix completion method. For example, we may think of the partially observed examples as a data matrix with unobserved entries. Then, one could first fill in the missing entries using a matrix completion technique (e.g., as described in Candès and Recht (2009)), and then apply PCA to the data matrix. We note that this approach may work[1] provided that the average number of observed attributes per example is sufficiently large. More precisely, according to the main result of Candès and Recht (2009), the number of observed attributes per example (column of the data matrix) should scale with the rank of the data matrix (which may be large as d). In contrast, our focus in this paper is on methods that work even when the number of observed attributes per example is much smaller (two attributes per instance suffice).

The active setting resembles the setting of the multi-armed bandit problem (Auer et al., 2002), in which the learner obtains limited feedback at each time, namely, it receives only the reward of the chosen arm. The challenge of learning linear predictors in $\mathbb{R}^d$ with partially observed attributes (e.g., as in Cesa-Bianchi et al. (2011)) may be seen as an extension of this problem. One of the most significant challenges in this work is to adapt the technique used in the vector setting (e.g., those employed by the Exp3 algorithm of Auer et al. (2002)) to the corresponding matrix setting. We already observed one difference: While a single arm suffices in the vector case, subspace learning with $r = 1$ attributes is impossible.

Our MBEG algorithm can be seen as an extension of the Online PCA algorithm of Warmuth and Kuzmin (2008) (see also Nie et al. (2013)) to the partial information setting. Similarly to their approach, MBEG maintains a weight matrix which induces a probability distribution over projection matrices. In MBEG, this weight matrix also induces a distribution over which attributes to observe.

2. The Passive Setting

We begin by investigating the passive setting. We start by describing an algorithm for this case. We then analyze its sample complexity, and discuss its implementation.

2.1 Partially Observed Principal Component Analysis (POPCA)

In this section we describe the POPCA algorithm. We start by reviewing the definition of the loss function and characterizing the minimizer of the loss.

1. Under some additional assumptions on the data such as the incoherence assumption made in Candès and Recht (2009)

Denote the set of projection matrices from $\mathbb{R}^d$ onto $\mathbb{R}^k$ by $\mathcal{P}_k^d$. Since $\Pi^2 = \Pi$ for any $\Pi \in \mathcal{P}_k^d$, the loss of a projection matrix $\Pi \in \mathcal{P}_k^d$ can be expressed as

$$L(\Pi) = \mathbb{E}\|x - \Pi x\|_2^2 = \mathbb{E}\left[\|x\|_2^2 - 2x^\top \Pi x + x^\top \Pi^\top \Pi x\right] = \mathbb{E}\left[\|x\|_2^2 - x^\top \Pi x\right] , \quad (1)$$

Define the inner product of matrices A, B by $\langle A, B\rangle = \mathrm{tr}(A^\top B)$. We can further rewrite the loss as

$$L(\Pi) = \mathbb{E}\left[\|x\|_2^2 - \langle \Pi, xx^\top\rangle\right] = \mathbb{E}\left[\|x\|_2^2\right] - \mathbb{E}\left[\langle \Pi, xx^\top\rangle\right] = \mathbb{E}\left[\|x\|_2^2\right] - \langle \Pi, \mathbb{E}[xx^\top]\rangle .$$

Denote the covariance matrix $\mathbb{E}[xx^\top]$ by C. Since $\|x\|_2^2$ does not depend on Π, the goal of subspace learning is equivalent to finding a projection matrix Π such that

$$\langle \Pi, -C\rangle \le \min_{\Pi' \in \mathcal{P}_k^d} \langle \Pi', -C\rangle + \epsilon . \quad (2)$$

It is well-known that the rank-k matrix which minimizes the expression $\langle \Pi', -C\rangle$ is the matrix $\sum_{i=1}^k v_i v_i^\top$, where $v_1, \ldots, v_k$ are the leading eigenvectors of C. The PCA approach for subspace learning in the full information setting replaces C with $C(S) = \frac{1}{m}\sum_{i=1}^m x_i x_i^\top$, where $S = (x_1, \ldots, x_m)$ is an i.i.d. training sequence drawn according to the distribution P. Clearly, $\mathbb{E}[C(S)] = C$. In our case, we will construct an unbiased estimate of C based on partially observed examples, as detailed below.

Consider an instance vector $x \sim P$ and let $\hat{x}$ be the observed vector. According to our assumptions, for each $i \in [d]$, the i-th coordinate of $\hat{x}$ satisfies

$$\hat{x}_i = \begin{cases} x_i & \text{w.p. } r/d \\ 0 & \text{w.p. } 1 - r/d . \end{cases} \quad (3)$$

Denote $p = r/d$. Similarly to Mitliagkas et al. (2014), we form the estimate

$$\hat{C}_{\hat{x}} = \frac{1}{p^2}\hat{x}\hat{x}^\top + \left(\frac{1}{p} - \frac{1}{p^2}\right)\mathrm{diag}(\hat{x}\hat{x}^\top) . \quad (4)$$

Indeed, it is easy to verify that $\hat{C}_{\hat{x}}$ forms an unbiased estimate of C:

$$\mathbb{E}\left[\left(\frac{1}{p^2}\hat{x}\hat{x}^\top\right)_{i,j}\right] = \begin{cases} \frac{1}{p}\mathbb{E}[x_i^2] & i = j \\ \mathbb{E}[x_i x_j] & i \ne j , \end{cases}$$

and

$$\mathbb{E}\left[\left(\frac{1}{p} - \frac{1}{p^2}\right)\mathrm{diag}(\hat{x}\hat{x}^\top)_{i,j}\right] = \begin{cases} \mathbb{E}[x_i^2] - \frac{1}{p}\mathbb{E}[x_i^2] & i = j \\ 0 & i \ne j . \end{cases}$$

Summing the corresponding entries, we see that $\mathbb{E}[(\hat{C}_{\hat{x}})_{i,j}] = \mathbb{E}_{x\sim P}[x_i x_j] = C_{i,j}$. Therefore, $\mathbb{E}[\hat{C}_{\hat{x}}] = C$.

The POPCA algorithm (see Algorithm 1) assumes access to m i.i.d. vectors sampled according to P. For each instance vector, it forms an estimate according to 4. By averaging these m estimates we obtain $\hat{C}$. The returned projection corresponds to the k leading eigenvectors of $\hat{C}$.

Algorithm 1 POPCA

Input: $r, k \le d$
$\hat{C} = 0 \in \mathbb{R}^{d\times d}$
for $i = 1$ **to** m **do**
  Let $x_i \sim P$ and let $\hat{x}_i$ be the observed vector
  $\hat{C}_{\hat{x}_i} = \frac{d^2}{r^2}\hat{x}_i\hat{x}_i^\top + \left(\frac{d}{r} - \frac{d^2}{r^2}\right)\mathrm{diag}(\hat{x}_i\hat{x}_i^\top)$
  $\hat{C} = \hat{C} + \frac{1}{m}\hat{C}_{\hat{x}_i}$
end for
Compute the eigendecomposition $\hat{C} = \sum_{j=1}^d \lambda_j v_j v_j^\top$
Assuming $\lambda_1 \ge \ldots \ge \lambda_d$, return $\hat{\Pi} = \sum_{j=1}^k v_j v_j^\top$

2.2 Analysis of POPCA

The following lemma relates the success of Algorithm 1 to the quality of the estimation $\hat{C}$ of the covariance matrix C.

Lemma 1 *Suppose that the final estimate $\hat{C}$ of POPCA satisfies*

$$\mathbb{E}[\|C - \hat{C}\|_F] \le \epsilon/\sqrt{k} . \quad (5)$$

Then, the resulting projection matrix $\hat{\Pi}$ satisfies the desired bound

$$\mathbb{E}[\langle \hat{\Pi}, -C\rangle] \le \min_{\Pi' \in \mathcal{P}_k^d} \langle \Pi', -C\rangle + \epsilon .$$

Proof Using the Cauchy-Schwarz inequality, we get

$$\begin{aligned} \mathbb{E}[\sup_{\Pi\in\mathcal{P}_k^d} \langle \Pi, -C\rangle - \langle \Pi, -\hat{C}\rangle] &\le \mathbb{E}[\sup_{\Pi\in\mathcal{P}_k^d} \|\Pi\|_F \|\hat{C} - C\|_F] \\ &\le \sup_{\Pi\in\mathcal{P}_k^d} \|\Pi\|_F \, \mathbb{E}[\|\hat{C} - C\|_F] \\ &\le \sqrt{k}\cdot\epsilon/\sqrt{k} \\ &= \epsilon . \end{aligned}$$

Consequently, since $\hat{\Pi} = \mathrm{argmin}_{\Pi\in\mathcal{P}_k^d}\langle \Pi, -\hat{C}\rangle$, we have

$$\begin{aligned} \mathbb{E}[\langle \hat{\Pi}, -C\rangle - \langle \Pi^\star, -C\rangle] &= \mathbb{E}[\langle \hat{\Pi}, -C\rangle - \langle \Pi^\star, -\hat{C}\rangle] \\ &\le \mathbb{E}[\langle \hat{\Pi}, -\hat{C}\rangle - \langle \Pi^\star, -\hat{C}\rangle] + \epsilon \\ &\le \epsilon , \end{aligned}$$

which completes the proof. ■

In view of Lemma 1, obtaining upper bound on the sample complexity of POPCA reduces to analyzing the quality of the covariance estimation. A fairly vast body of literature exists on the latter task in the full-information scenario, and several results are known in the case of missing entries. For example, Lounici (2014) considered a setting similar to our passive setting. Corollary 1 in Lounici

(2014) gives a bound on the Frobenius error that depends on the spectral decay of C. We will derive a slightly different (worst-case) bound under the assumption that the instances are bounded in the Euclidean unit ball. A comparison between the two bounds is given Appendix E.

Lemma 2 *Let $\epsilon \in (0,1)$. If $m \geq \left\lceil (d/r)^2 \cdot \frac{k}{\epsilon^2} \right\rceil$, then*

$$\mathbb{E}[\|C - \hat{C}\|_F] \leq \epsilon/\sqrt{k} \,.$$

Proof Using Jensen's inequality, we have

$$\mathbb{E}[\|\hat{C} - C\|_F] = \mathbb{E}[(\|\hat{C} - C\|_F^2)^{1/2}] \leq (\,\mathbb{E}[\|\hat{C} - C\|_F^2])^{1/2} \,.$$

Since the observations are i.i.d.,

$$\begin{aligned}\mathbb{E}[\|\hat{C} - C\|_F^2] &= \sum_{i,j} \mathrm{Var}[\hat{C}_{i,j}] = \sum_{i,j} \mathrm{Var}\left[(1/m)\sum_{q=1}^{m} \hat{C}_{\hat{x}_q,i,j}\right] \\ &= \frac{1}{m}\sum_{i,j} \mathrm{Var}[\hat{C}_{\hat{x}_1,i,j}] \leq \frac{1}{m}\sum_{i,j} \mathbb{E}[\hat{C}^2_{\hat{x}_1,i,j}] \,,\end{aligned}$$

where $\hat{C}_{\hat{x}_q,i,j}$ is the $[i,j]$-th entry of $\hat{C}_q$. Denote $\hat{x} = \hat{x}_1$ and $x = x_1$ (subscript indices will now correspond to the entries of these vectors). According to 4,

$$\mathbb{E}[\hat{C}^2_{\hat{x},i,j}|x] = \begin{cases} p^{-4}\,\mathbb{E}[\hat{x}_i^2\hat{x}_j^2|x] = p^{-2}x_i^2x_j^2 & i \neq j \\ p^{-2}\,\mathbb{E}[\hat{x}_i^4|x] = p^{-1}x_i^4 \leq p^{-2}x_i^4 & i = j \end{cases} .$$

Therefore, since the ℓ_2 norm of the instances is at most 1, we have

$$\sum_{i,j} \mathbb{E}[\hat{C}^2_{\hat{x}_1,i,j}|x] \leq p^{-2}\sum_{i,j} x_i^2x_j^2 = p^{-2}\|x\|^4 \leq p^{-2} = \frac{d^2}{r^2} \,,$$

and $\sum_{i,j} \mathbb{E}[\hat{C}^2_{\hat{x}_1,i,j}] \leq \frac{d^2}{r^2}$. Combining the above bounds, we obtain

$$\mathbb{E}[\|\hat{C} - C\|_F] \leq \frac{1}{\sqrt{m}} \cdot \frac{d}{r} \,.$$

For $m \geq \left\lceil \frac{d^2}{r^2} \cdot \frac{k}{\epsilon^2} \right\rceil$, we arrive at the claimed bound. ■

Let $m_p(d,k,r,\epsilon)$ be the sample complexity of subspace learning in the passive partial information model, namely, how many examples are needed (for the optimal learner) to guarantee that (2) holds. Based on Lemma 2 and Lemma 1, we now conclude the following bound on the sample complexity.

Corollary 3 *Using POPCA (Algorithm 1), we have the following bound on the sample complexity for any integer $r \geq 2$:*

$$m_p(d,k,r,\epsilon) \leq \left\lceil (d/r)^2 \cdot \frac{k}{\epsilon^2} \right\rceil \,.$$

2.3 Optimality of POPCA

In this section we prove the following lower bound on the sample complexity of subspace learning with partial information in the passive model.

Theorem 4 *Assume that $k \leq d/2$ and $\epsilon \in (0, 1/128)$. The sample complexity in the passive model is at least $\Omega\left((d/r)^2 \cdot \frac{k}{\epsilon^2}\right)$. Therefore, we have*

$$m_p(d,k,r,\epsilon) = \Theta\left((d/r)^2 \cdot \frac{k}{\epsilon^2}\right) \,.$$

Note that up to a constant factor, our lower bound coincides with the upper bound obtained by POPCA (Corollary 3). Therefore, Theorem 4 establishes the optimality of POPCA in the passive model.

The proof of Theorem 4 is divided into two parts. First, in Theorem 5 we prove that the sample complexity in the full-information setting is at least $\Omega(k/\epsilon^2)$. Then, we complete the proof of Theorem 4 by showing that the multiplicative price of partial information is at least $\Omega((d/r)^2)$.

Theorem 5 *Assume that $k \leq d/2$ and let $\epsilon \in (0, 1/128)$. The sample complexity of subspace learning with full information is bounded below by*

$$m(d,k,r=d,\epsilon) = \Omega(k/\epsilon^2) \,.$$

We now sketch the proof of Theorem 5. A detailed proof is provided in Appendix A.

Proof (sketch)
The idea is to reduce the problem of coin identification (see Section 5.2 in Anthony and Bartlett (2009)) to that of subspace learning. Assume that $k \leq d/2$ and $\epsilon \in (0, 1/128)$. Let $\mathcal{U} = \{u_j\}_{j=1}^{2k} \subseteq \mathbb{R}^d$ be a set of $2k$ orthonormal vectors. A distribution over $\mathcal{U}$ is defined as follows. First, we draw a sequence $b = (b_1, \ldots, b_k) \in \{-1,1\}^k$ uniformly at random. We associate the pair $\{u_i, u_{i+k}\}$ with a Bernoulli random variable B_i with parameter $p_i = \frac{1+b_i\alpha}{2}$, where $\alpha = 16\epsilon$. To define a distribution $P := P_b$, we now describe the process of drawing an instance $x \sim P$:

1. An integer $i \in [k]$ is chosen uniformly at random.
2. The i-th coin is flipped (according to p_i). Denote the corresponding random variable by Z.
3. If $Z = 1$, then x is chosen uniformly at random from the set $\{u_i, -u_i\}$. Otherwise ($Z = 0$), x is chosen uniformly at random from the set $\{u_{i+k}, -u_{i+k}\}$.

In Lemma 10 we show that a successful subspace learner must identify the bias of "most" of the coins. Thus, we can reduce k independent tasks of coin identification to the task of subspace learning. A well-known result in statistics (Anthony and Bartlett, 2009)[Lemma 5.1] tells us that $\Omega(1/\alpha^2)$ samples are needed to identify a coin with bias α. Hence, each of the pairs must be observed $\Omega(1/\epsilon^2)$ times. ■

Proof (of Theorem 4) Consider the construction presented in the proof (sketch) of Theorem 5. We next specify the set $\mathcal{U}$ and prove that the price of partial information in the passive model is $\Omega(d^2/r^2)$. Consequently, this will conclude the proof of Theorem 4.

For every $i \in [k]$, let $u_i = \frac{\sqrt{2}}{2}(e_i + e_{i+k})$, $u_{i+k} = \frac{\sqrt{2}}{2}(-e_i + e_{i+k})$. To specify a distribution P, fix a vector $b = (b_1, \ldots, b_k) \in \{-1, 1\}^k$. Consider now a single interaction between the learner and the environment. A vector x is drawn according to P as described in the proof (sketch) of Theorem 5. Let $i \in [k]$ denote the index of the coin which is associated with x. As we observed in Section 1, each of the coordinates i, $i + k$ is distributed uniformly over $\{-\frac{\sqrt{2}}{2}, \frac{\sqrt{2}}{2}\}$. Hence, to obtain any information, the learner must observe both of the coordinates i and $i + k$. The probability that both coordinates are observed is at most $O(r^2/d^2)$. Hence, in expectation, (only) a single "meaningful" observation is obtained every $\Omega(d^2/r^2)$ iterations. Therefore, the price of partial information is $\Omega(d^2/r^2)$. ■

2.4 Implementation of POPCA

As we discussed above, when the data is fully visible, the sample complexity of the PCA algorithm (which computes the k leading eigenvectors of the empirical covariance matrix, $m^{-1}\sum_{i=1}^m x_i x_i^\top$, and returns the corresponding projection matrix) is $m_f := O(k/\epsilon^2)$. When the number of samples, m_f, is larger than the dimension, a standard implementation of this algorithm costs $O(m_f d^2)$. We next show that POPCA has a similar runtime.

We established above that POPCA requires a training set of size $O((d/r)^2 m_f)$. Consider a single iteration of POPCA. Note that the construction of $\hat{C}_{\hat{x}_i}$ (see 4) costs $O(r^2)$. Therefore, it costs $O(m_f d^2)$ to obtain the average of the estimates, $\hat{C}$. The computation of the SVD of $\hat{C}$ costs $O(d^3)$. Therefore, when $m_f \geq d$, the overall runtime of POPCA is indeed $O(m_f d^2)$.

3. The Active Setting

We now consider the active model of subspace learning with partial information. In particular, we will present and analyze the Matrix Bandit Exponentiated Gradient (MBEG) algorithm.

Before describing MBEG, it should be noticed that POPCA (along with its analysis) can be modified to fit the active model; An active version of POPCA simply selects the r observed attributes uniformly at random (with replacement) and then proceeds similarly to POPCA[2]. It is not hard to verify that the sample complexity of this algorithm is asymptotically equivalent to the sample complexity of POPCA. In particular, the price of partial information is quadratic in d/r.

The main differences between MBEG and POPCA are as follows:

1. MBEG is designed for the active model. It employs a non-uniform sampling method which gives higher priority to "stronger" directions.

2. MBEG is an iterative algorithm which maintains a *weight matrix* that belongs to the convex hull of the set $\mathcal{P}_k^d$ of projection matrices. It can be thought of as a Bandit version of the extension of the Exponentiated Gradient (EG) algorithm to matrices. The EG algorithm, and its extension to matrices are due to Kivinen and Warmuth (1997), and Tsuda et al. (2005), respectively.

2. Note that here the attributes are no longer independent and therefore we should replace the weights in the definition of $\hat{C}_{\hat{x}}$.

3.1 Matrix Bandit Exponentiated Gradient (MBEG)

3.1.1 CONVEXIFICATION

In order to be able to apply the Matrix EG algorithm, we first need to formulate our task as a convex optimization problem. Recall that our problem is equivalent to approximately minimizing the objective $\operatorname{argmin}_{\Pi \in \mathcal{P}_k^d} \langle \Pi, -C \rangle$, where $C = \mathbb{E}[xx^\top]$. The objective is linear and thus convex. We will replace the non-convex set $\mathcal{P}_k^d$ with its convex hull, $\mathcal{C}_k^d := \text{conv}(\mathcal{P}_k^d)$. Note that for every W in $\mathcal{C}_k^d$, the gradient is given by $-C$. Therefore, the EG procedure would start with some $W_1 \in \mathcal{C}_k^d$, and, at iteration i, would update according to

$$\begin{aligned} &1.\quad U_{i+1} = \exp(\log(W_i) + \eta C) \\ &2.\quad W_{i+1} = \operatorname*{argmin}_{W \in \mathcal{C}_k^d} D_R(W, U_{i+1}) \,, \end{aligned} \tag{6}$$

where $D(R, U) = \text{tr}(W \log W - W \log U - W + U)$ is the Bregman divergence induced by the *quantum entropy* regularizer, $R(W) = \text{tr}(W \log W - W)$. Additional details regarding this regualarizer can be found in Tsuda et al. (2005) and Warmuth and Kuzmin (2008). As in POPCA, the gradient C is unknown but can be estimated. We would like to exploit the active setting, and therefore, we will employ a non-uniform sampling method which relies on the current weight matrix W_t (see Section 3.1.2).

Next, we recall that the output of the algorithm should be a projection matrix, while our algorithm maintains weight matrices, which may not belong to the set $\mathcal{P}_k^d$. Therefore, the final step of the algorithm is to construct an element from $\mathcal{P}_k^d$ that performs "similarly" to the average of the weight matrices maintained during the run of the algorithm. For this purpose, we rely on the following lemma, due to Warmuth and Kuzmin (2008):

Lemma 6 *Every matrix $W \in \mathcal{C}_k^d$ can be decomposed in time $O(d^3)$ into a convex combination of at most d elements from $\mathcal{P}_k^d$.*

For completeness, we recall the decomposition procedure of Warmuth and Kuzmin (2008) in Appendix D. Getting back to our algorithm, let $\hat{W} = \frac{1}{m}\sum_{i=1}^m W_i$ be the average weight matrix, and denote by $\hat{W} = \sum_{j=1}^d \beta_j \Pi_j$ a decomposition of $\hat{W}$ into a convex combination of elements from $\mathcal{P}_k^d$. The final step of MBEG sets the output matrix $\hat{\Pi}$ to be Π_j with probability β_j. This guarantees that the expected performance of $\hat{\Pi}$ is the same as the performance of $\hat{W}$.

3.1.2 PRIORITIZING "STRONGER" DIRECTIONS

In this part we present the non-uniform sampling mechanism which is employed by MBEG for attribute sampling. We first consider the case $r = 2$. Let $W := W_i$ be a weight matrix obtained during the run of MBEG. Recall[3] that $\sum_i W_{i,i} = k$, and for every $i \in [d]$, $W_{i,i} \in [0, 1]$. Therefore, a natural distribution for attribute sampling is to choose each pair $(s, q) \in [d]^2$ with probability $p_{s,q} = \frac{W_{s,s}}{k} \cdot \frac{W_{q,q}}{k}$. Unfortunately, we were not able to obtain a good bound using this sampling technique. Instead, we pick attributes according to

$$p_{s,q} = (1 - \alpha)\frac{W_{s,s} + W_{q,q}}{2dk} + \frac{\alpha}{d^2} \,, \tag{7}$$

3. These properties clearly hold for projection matrices, and thus hold for any convex combination of projection matrices.

for some parameter $\alpha \in (0, 1/2)$, which is tuned below. That is, we mix a uniform distribution over $[d]^2$, with a distribution which gives higher sampling probability to pairs for which $W_{s,s}, W_{q,q}$ are high, reflecting a bias toward sampling from "stronger" directions. Mixing with the uniform distribution guarantees that every pair has large enough probability to be sampled, which will later help us ensure that we perform enough "exploration".

Based on this probability distribution over pairs, we define an unbiased estimate of the matrix C by

$$\hat{C} = \frac{1}{2p_{s,q}} x_s x_q (E_{s,q} + E_{q,s}) \,, \tag{8}$$

where $E_{s,q}$ is the all zeros matrix except 1 in the i, j coordinate.

The extension of MBEG to any (even) $r > 2$ is straightforward. We simply pick $r/2$ independent estimates $\hat{C}_1, \ldots, \hat{C}_{r/2}$, each of which is constructed as in the case $r = 2$, and set $\hat{C} = \frac{2}{r} \sum_{j=1}^{r/2} \hat{C}_j$.

The algorithm is summarized in Algorithm 2. As explained in Tsuda et al. (2005), the projection step w.r.t. the Bregman divergence, $W_{i+1} = \operatorname{argmin}_{W \in \mathcal{C}_k^d} D_R(W, U_{i+1})$ can be performed in time $O(d^3)$. Overall, the running time per iteration is $O(d^3)$.

Algorithm 2 Matrix Bandit Exponentiated Gradient

Input: $r, k < d$ ($r \mod 2 = 0$)
$\eta = \sqrt{\frac{r \log(d)}{2m(d+r)}}$
$\alpha = \eta d^2$ (we assume that m is large enough so that $\alpha \leq 1/2$)
$W_1 = \frac{k}{d} I$
for $i = 1$ **to** m **do**
  denote $W = W_i$
  for $j = 1$ **to** $r/2$ **do**
    pick $(s, q) \in [d]^2$ with probability $p_{s,q} = (1 - \alpha) \frac{W_{s,s} + W_{q,q}}{2dk} + \frac{\alpha}{d^2}$
    for $x \sim P$, let (x_s, x_q) be the corresponding attributes
    $\hat{C}_{i,j} = \frac{1}{2p_{s,q}} x_s x_q (E_{s,q} + E_{q,s})$
  end for
  $\hat{C}_i = \frac{2}{r} \sum_{j=1}^{r/2} \hat{C}_{i,j}$
  $U_{i+1} = \exp(\log(W) + \eta \hat{C}_i)$
  $W_{i+1} = \operatorname{argmin}_{W \in \mathcal{C}_k^d} D_R(W, U_{i+1})$
end for
$\hat{W} = \frac{1}{m} \sum_{i=1}^{m} W_i$
decompose $\hat{W}$ into $\hat{W} = \sum_{j=1}^{d} \beta_j \Pi_j$ using Algorithm 3
return $\hat{\Pi} = \Pi_j$ with probability β_j

3.1.3 ANALYSIS OF MBEG

Let $m_a(d, k, r, \epsilon)$ be the sample complexity of subspace learning in the active partial information model. We denote the Frobenius norm, the spectral norm, and the trace norm by $\|\cdot\|_F$, $\|\cdot\|_{\mathrm{sp}}$, and $\|\cdot\|_{\mathrm{tr}}$, respectively. Throughout this section we prove the following result.

Theorem 7 *Using MBEG (Algorithm 2), we have the following bound on the sample complexity for any (even) integer $r \geq 2$:*

$$m_a(d, k, r, \epsilon) \leq \max \left\{ 8k \cdot \frac{d + r}{r} \cdot \frac{k}{\epsilon^2} \,,\ \frac{2d^4 r}{d + r} \right\} \cdot \log(d) \,.$$

In order to prove Theorem 7, we next apply the general analysis of Matrix EG (Hazan et al., 2012)[Theorem 13] to our case.

Theorem 8 *Assume that the sequence $\hat{C}_1, \ldots, \hat{C}_m$ obtained during the run of MBEG satisfies $\|\hat{C}_i\|_{\mathrm{sp}} \leq 1/\eta$ for every $i \in [m]$. Then, for every $\Pi^\star \in \mathcal{P}_k^d$,*

$$\sum_{i=1}^{m} \langle W_i - \Pi^\star, -\hat{C}_i \rangle \leq \frac{k \log(d)}{\eta} + \eta \sum_{i=1}^{m} \langle W_i, \hat{C}_i^2 \rangle \,. \tag{9}$$

The right-most term in 9 can be thought as the variance which is associated with the estimation process of MBEG. We now show that in contrast to POPCA, the variance scales only linearly with d/r.

Lemma 9 *For any matrix $W_i \in \mathcal{C}_k^d$ maintained by MBEG at time i, denote the conditional expectation given W_i by $\mathbb{E}_i$. Then,*

$$\mathbb{E}_i \langle W_i, \hat{C}_i^2 \rangle \leq \frac{2k(d + r)}{r} \,.$$

We now prove the lemma while assuming that $r = 2$. The extension to any $r > 2$ is detailed in Appendix B.

Proof Let $W = W_i, \hat{C} = \hat{C}_i$. Then,

$$\begin{aligned} \mathbb{E}_i \langle W, \hat{C}^2 \rangle &= \sum_{(s,q) \in [d]^2} p_{s,q} (W_{s,s} + W_{q,q}) \frac{1}{4p_{s,q}^2} x_s^2 x_q^2 \\ &= \sum_{(s,q) \in [d]^2} \frac{(W_{s,s} + W_{q,q})}{4p_{s,q}} x_s^2 x_q^2 \,. \end{aligned}$$

Since $\alpha \in (0, 1/2)$, we have

$$\frac{W_{s,s} + W_{q,q}}{p_{s,q}} = \frac{W_{s,s} + W_{q,q}}{(1 - \alpha) \frac{W_{s,s} + W_{q,q}}{2dk} + \alpha/d^2} \leq \frac{W_{s,s} + W_{q,q}}{(1 - \alpha) \frac{W_{s,s} + W_{q,q}}{2dk}} \leq 4dk \,.$$

Therefore, since $r = 2$, we obtain

$$\mathbb{E}_i \langle W, \hat{C}^2 \rangle \leq dk \sum_{(s,q) \in [d]^2} x_s^2 x_q^2 \leq dk < \frac{2k(d + r)}{r} \,,$$

completing the proof of the lemma. ■

Proof (of Theorem 7) By definition of $\hat{C}_{i,j}$ we have that $\hat{C}_{i,j}^2 = \hat{C}_{i,j}\hat{C}_{i,j}^\top$ is a diagonal matrix with all elements on the diagonal equal to zero except the (s,s) and (q,q) elements, which are both bounded above by $\frac{x_s^2 x_q^2}{p_{s,q}^2}$. It follows that

$$\|\hat{C}_{i,j}\|_{\mathrm{sp}} \leq \frac{|x_s x_q|}{p_{s,q}} \leq \frac{1}{p_{s,q}} \leq \frac{d^2}{\alpha} = \frac{1}{\eta} \,.$$

Hence,

$$\|\hat{C}_i\|_{\mathrm{sp}} \leq \frac{2}{r}\sum_{j=1}^{r/2} \|\hat{C}_{i,j}\|_{\mathrm{sp}} \leq \frac{2}{r}\frac{r}{2}\frac{1}{\eta} = \frac{1}{\eta} \,.$$

Therefore, the conditions of Theorem 8 hold. Taking expectation over 9, we obtain

$$\sum_{i=1}^{m} \mathbb{E}\left\langle W_i - \Pi^\star, -\hat{C}_i \right\rangle \leq \frac{k\log(d)}{\eta} + \eta \sum_{i=1}^{m} \mathbb{E}\left\langle W_i, \hat{C}_i^2 \right\rangle \,. \tag{10}$$

Let $\mathbb{E}_i$ denote the conditional expectation given W_i. Then, $\mathbb{E}_i[\hat{C}_i] = C$ and therefore, by the law of total expectation,

$$\mathbb{E}\left\langle W_i - \Pi^\star, -\hat{C}_i \right\rangle = \mathbb{E}\langle W_i - \Pi^\star, -C\rangle \,. \tag{11}$$

Combining 11 with Lemma 9, and plugging into 10, we obtain that

$$\mathbb{E}\sum_{i=1}^{m}\langle W_i - \Pi^\star, -C\rangle \leq \frac{k\log(d)}{\eta} + \eta m \frac{2k(d+r)}{r} \,.$$

Dividing by m, denoting $\hat{W} = \frac{1}{m}\sum_{i=1}^{m} W_i$, substituting $\eta = \sqrt{\frac{r\log(d)}{2(d+r)m}}$, rearranging terms, and observing that $\mathbb{E}[\hat{\Pi}|\hat{W}] = \hat{W}$, we have that

$$\mathbb{E}\left\langle \hat{\Pi} - \Pi^\star, -C\right\rangle = \left\langle \mathbb{E}\left[\hat{W}\right] - \Pi^\star, -C\right\rangle \leq \sqrt{\frac{8k^2(d+r)\log(d)}{rm}} \,.$$

The right-hand side of the above is smaller than ϵ if $m \geq 8k\log(d)\cdot\frac{d+r}{r}\cdot\frac{k}{\epsilon^2}$. Note, however, that we also require that m is large enough so that $\alpha \leq 1/2$. Since $\alpha = \eta d^2$, it follows that m should also satisfy $m \geq \frac{2d^4 r\log(d)}{d+r}$. ■

3.2 Comparison between the bounds in the passive and the active models

The left term in the bound of MBEG is smaller than the bound of POPCA if $\frac{d^2}{r^2} > 8k\log(d)\cdot\frac{d+r}{r}$. The right term in the bound of MBEG is smaller than the bound of POPCA if

$$\epsilon < \sqrt{\frac{(d+r)k}{2d^2 r^3\log(d)}} \,.$$

Hence, if both of the conditions hold, then the bound of MBEG is better than the bound of POPCA. Also, if $\epsilon < \frac{2(d+r)k}{d^2 r}$, then the dependence of the sample complexity of MBEG on d/r is linear.

A reasonable regime in which MBEG enjoys a linear price is when r and k are constants, and ϵ is proportional to $1/d$. Note that in this regime, the bound of POPCA scales with d^4, while the bound of MBEG scales only with d^3 (in the full-information setting, the sample complexity for this case scales with d^2). To summarize, ignoring the dependence on k (and logarithmic factors), MBEG attains the desired linear price when ϵ is 'small'.

4. Discussion

We introduced the problem of subspace learning with partial information, and considered both a passive and active model. Our first observation was that looking at a single coordinate does not give any information. Therefore, our algorithms look at the products of attribute pairs. Using the POPCA algorithm for the passive model, we showed that the sample complexity is tightly characterized by $\Theta((d/r)^2 k/\epsilon^2)$. Hence, the price of partial information in this case is quadratic. For the active model we introduced the MBEG algorithm which exploits the gathered information in order to make a better choice over which attributes to observe. We showed that if the desired accuracy ϵ is small, then MBEG achieves a linear price. Since the expected number of observed attributes from each vector is r, we can not hope for a better dependence on d/r. At this point, a natural question arises: can we attain a linear price of partial information in the active model, independently of the required accuracy? We conclude with an observation regarding MBEG that provides a partial answer to this question.

Assume that ϵ, r and k are constants. Examining the implementation of MBEG, we note that as long as the products, $x_s x_q$, between two consecutive observed attributes is zero, MBEG does not change the sampling distribution (which is initially uniform) nor its current estimation of the covariance matrix. Fix some attribute j and consider the distribution P_j which is concentrated on e_j. The probability that the product between two consecutive observed attributes is not zero is $(1/d)^2$. Since r is constant, only zero products are observed for at least $\Omega(d^2)$ iterations, implying the same bound on the sample complexity.

The implication of this result is that in order to achieve a linear price for any value of ϵ, it is necessary to extract more information from the partial observations (e.g., take into account both the products of attribute pairs and the single attributes). Developing such algorithms or alternatively, tightening the lower bounds, is left for future research.

Acknowledgments

We thank the anonymous reviewers for their helpful comments. We also thank Amit Daniely for helpful discussions. This research has been supported by ISF no 1673/14.

Appendix A. Proof of Theorem 5

In this section we prove Theorem 5.

A.1 The adversarial distribution

Let $\mathcal{U} = \{u_j\}_{j=1}^{2k} \subseteq \mathbb{R}^d$ be a set of $2k$ orthonormal vectors. In the proof sketch of Theorem 5 we described a family $\mathcal{F}$ of distributions over the set $\{u, -u : u \in \mathcal{U}\}$. Our lower bounds will be proved to hold in expectation when choosing $P \in \mathcal{F}$ at random. According to Yao's minimax principle, such a result implies that the lower bound holds for some distribution in $\mathcal{F}$.

A.2 A Successful Subspace Learner Is Also a Successful Coin identifier

In this part we formalize the reduction from coin identification to subspace learning. As we sketched before, a key ingredient of our analysis of the lower bounds is the relation between subspace learning and "coin identification". This relation is formalized next. We first need to introduce some additional notation. To specify the distribution $P \in \mathcal{F}$, fix a vector $(b_1, \ldots, b_k) \in \{-1, 1\}^k$. Let $\hat{\Pi} = \sum_{i=1}^k \hat{u}_i \hat{u}_i^\top \in \mathcal{P}_k^d$ (where $\hat{u}_1, \ldots, \hat{u}_k$ are orthonormal). For every $(i, j) \in [k] \times [2k]$, define $\theta_{i,j} = |\langle \hat{u}_i, u_j \rangle|$ to be the *covariance* between $\hat{u}_i$ and u_j. Next, for each $j \in [2k]$, define $\theta_j^2 = \sum_{i=1}^k \theta_{i,j}^2$. Also, define the set

$$J = \{j \in [k] : b_j = 1 \wedge \theta_j^2 > \theta_{j+k}^2\} \cup \{j \in [k] : b_j = -1 \wedge \theta_j^2 < \theta_{j+k}^2\} \,. \tag{12}$$

For reasons that will become apparent shortly, we name J the set of identified coins. The following lemma asserts that a successful subspace learner must identify most of the coins.

Lemma 10 *Let $\epsilon \in (0, 1)$. Assume that $L(\hat{\Pi}) - \min_{\Pi \in \mathcal{P}_k^d} L(\Pi) \leq \epsilon$. Let J be defined as in 12. Then, $|J|/k > 1 - \frac{2\epsilon}{\alpha}$.*

Proof Assume w.l.o.g. that $b_1 = \ldots = b_k = 1$. Note that

$$\mathbb{E}[xx^\top] = \frac{1}{k} \sum_{j=1}^k \left(\frac{1+\alpha}{2} u_j u_j^\top + \frac{1-\alpha}{2} u_{j+k} u_{j+k}^\top \right) \,.$$

The optimal projection is obtained by picking the largest eigenvectors of $\mathbb{E}[xx^\top]$. Precisely, the optimal projection matrix is $\Pi^\star = \sum_{i=1}^k u_i u_i^\top$. We assume the loss function as formulated in 1.

The loss of $\hat{\Pi}$ is calculated as follows:

$$\begin{aligned}
\mathbb{E}[\|x\|_2^2] - L(\hat{\Pi}) &= \langle \sum_{i=1}^k \hat{u}_i \hat{u}_i^\top \,,\, \mathbb{E}[xx^\top] \rangle \\
&= \frac{1}{k} \sum_{i=1}^k \sum_{j=1}^k \left(\frac{1+\alpha}{2} \langle \hat{u}_i \hat{u}_i^\top, u_j u_j^\top \rangle + \frac{1-\alpha}{2} \langle \hat{u}_i \hat{u}_i^\top, u_{j+k} u_{j+k}^\top \rangle \right) \\
&= \frac{1}{k} \sum_{i=1}^k \sum_{j=1}^k \left(\frac{(1+\alpha)\theta_{i,j}^2}{2} + \frac{(1-\alpha)\theta_{i,j+k}^2}{2} \right) \\
&= \frac{1}{k} \sum_{j=1}^k \left(\frac{(1+\alpha)\theta_j^2}{2} + \frac{(1-\alpha)\theta_{j+k}^2}{2} \right) \\
&= \frac{1}{2k} \sum_{j=1}^{2k} \theta_j^2 + \frac{\alpha}{2k} \sum_{j=1}^k (\theta_j^2 - \theta_{j+k}^2) \,.
\end{aligned} \tag{13}$$

Since $\{u_j\}_{j=1}^{2k}$ is orthonormal, for each $i \in [k]$ we have $\sum_{j=1}^{2k} \theta_{i,j}^2 \leq 1$. Hence, $\sum_{j=1}^{2k} \theta_j^2 \leq k$, so that the second-to-last term of 13 is at most $\frac{1}{2}$. This value is attained by $\Pi^\star$, and for simplicity, we will assume that is attained by $\hat{\Pi}$ as well. For the same reasons, for each $i \in [k]$, we have $\sum_{j=1}^k (\theta_{i,j}^2 - \theta_{i,j+k}^2) \leq 1$. Hence, $\sum_{j=1}^k (\theta_j^2 - \theta_{j+k}^2) \leq k$, so that the last term of 13 is at most $\alpha/2$. Once again, this value is attained by $\Pi^\star$. Our last observation is that if the j-th coin is not identified, i.e., $j \notin J$, then $\theta_j^2 - \theta_{j+k}^2 \leq 0$. Combining these observations, we obtain that

$$L(\hat{\Pi}) - L(\Pi^\star) \geq \alpha(1 - |J|/k)/2 \,.$$

The proof is completed by combining the assumption that $L(\hat{\Pi}) - L(\Pi^\star) \leq \epsilon$. ■

A.2.1 LOWER BOUND ON COIN IDENTIFICATION

We previously informally argued that $\Omega(1/\alpha^2)$ samples are needed to identify a coin with bias $\frac{1\pm\alpha}{2}$. If we have k such independent coins, then $\Omega(k/\alpha^2)$ are needed. Let us formalize this result.

A coin identification problem with parameter α is defined as follows. Consider a binary classification problem with a domain $[k]$ and label set $\{0, 1\}$. The hypothesis class is the set $\mathcal{H} = \{0, 1\}^{[k]}$. The underlying distribution over $[k] \times \{0, 1\}$ is chosen at random using the following mechanism. The marginal distribution over $[k]$ is uniform, and the conditional probability over the label (coin) is determined by $P(y = 1 | x = j) = \frac{1+b_j\alpha}{2}$, where each b_j is an independent Rademacher random variable (drawn in advance). We observe that this distribution is identical to the distribution defined (over a shattered set of size k) in (Anthony and Bartlett, 2009, Theorem 5.2).

As usual, an algorithm for coin identification obtains an i.i.d. training sequence S according to P, and has to return a hypothesis $h \in \mathcal{H}$. The generalization error of $h \in \mathcal{H}$, denoted $\text{err}(h)$, is defined to be the probability that it misclassifies a new generated point (x, y), i.e., $\text{err}(h) = P(h(x) \neq y)$. The next theorem follows from (Anthony and Bartlett, 2009, Theorem 5.2).

Theorem 11 *Let $\mathcal{B}$ be an algorithm for coin identification, and let $\tilde{\epsilon} \in (0, 1/64)$. Consider a coin identification problem with $\alpha = 8\tilde{\epsilon}$. If $m < \frac{k}{8\tilde{\epsilon}^2}$, then there exists a distribution P for which*

$$\mathbb{E}_{S\sim P^m} \mathit{err}(\mathcal{B}(S)) - \min_{h\in\mathcal{H}} \mathit{err}(h) > \tilde{\epsilon} \,.$$

A.3 Concluding the Theorem

We are now in position to complete the reduction from the task of coin identification to the task of subspace learning, and consequently conclude Theorem 5.

Let $\mathcal{A}$ be a subspace learner whose sample complexity is $m(d, k, r = d, \epsilon)$. We describe an algorithm $\mathcal{B}$ for coin identification (with parameter α) which uses $\mathcal{A}$ as a subroutine. To this end, we shall provide a (randomized) map between the input of $\mathcal{B}$ to the input of $\mathcal{A}$. These inputs have the form of training sequences, which will be denoted by S_{subspace} and S_{coins}, respectively. For each $j \in [k]$, the pair $(j, 1)$ is associated with u_j or $-u_j$ with equal probability. The pair $(j, 0)$ is associated with u_{j+k} of $-u_{j+k}$ with equal probability. Clearly, the sequence provided to $\mathcal{A}$ is generated according to the distribution discussed in the proof sketch of Theorem 5. Given an accuracy parameter $\tilde{\epsilon} \in (0, 1/64)$ for $\mathcal{B}$, we will require accuracy $\epsilon = \tilde{\epsilon}/2$ from $\mathcal{A}$. To complete the reduction, we will specify how the output of $\mathcal{B}$ is determined using the output of $\mathcal{A}$.

For each $j \in [k]$, the output hypothesis returned by $\mathcal{B}$ is defined by

$$h(j) = \begin{cases} 1 & \theta_j > \theta_{j+k} \\ 0 & \text{otherwise} \end{cases} \,.$$

Denote the set of identified coins by J (as in Lemma 10). Observe that each coin that is not identified, adds α/k to the relative error of $\mathcal{B}$. It follows from Lemma 10 that

$$\begin{aligned} \text{err}(\mathcal{B}(S_{\text{coins}})) - \min_{h\in\mathcal{H}} \text{err}(h) &= \alpha(1 - |J|/k) \\ &\leq 2\left(L(\mathcal{A}(S_{\text{subspace}})) - \min_{\Pi\in\mathcal{P}_k^d} L(\Pi)\right) \,. \end{aligned} \tag{14}$$

If $m \geq m(d, k, r = d, \epsilon)$, then the right-hand side of 14 is at most $2\epsilon = \tilde{\epsilon}$. The proof is completed by applying Theorem 11 (with $\alpha = 8\tilde{\epsilon}$).

Appendix B. Extending Lemma 9 to r > 2

We will now extend the proof of Lemma 9 to any (even) $r > 2$. Fix an iteration i, and denote $\hat{C} = \hat{C}_i, W = W_i$. We have

$$\mathbb{E}_i\langle W, \hat{C}^2\rangle = \frac{4}{r^2}\left[\sum_{j=1}^{r/2} \mathbb{E}_i\langle W, \hat{C}_j^2\rangle + \sum_{j\neq t} \mathbb{E}_i\langle W, \hat{C}_j\hat{C}_t\rangle\right] \,.$$

From the case $r = 2$, we already know that the term $\mathbb{E}_i\langle W, \hat{C}_j^2\rangle$ is at most dk. Fix some pair $j \neq t$. Note that $\hat{C}_j\hat{C}_t \neq 0$ if and only if (at least) one of the indices s_j, q_j is equal to one of the indices

s_t, q_t. Hence,

$$\begin{aligned} \mathbb{E}_i\langle W, \hat{C}_j\hat{C}_t\rangle \leq 2 &\sum_{(s,q)\in[d]^2} p_{s,q}^2(W_{s,s} + W_{q,q})\frac{x_s^2 x_q^2}{4p_{s,q}^2} \\ &+ 4 \sum_{\substack{(s,q,q')\in[d]^3: \\ q\neq q'}} p_{s,q}p_{s,q'}W_{q,q'}\frac{x_s^2|x_q||x'_q|}{4p_{s,q}p_{s,q'}} \,. \end{aligned}$$

The first term can be bounded as follows:

$$\begin{aligned} 2\sum_{(s,q)\in[d]^2} p_{s,q}^2(W_{s,s} + W_{q,q})\frac{x_s^2x_q^2}{4p_{s,q}^2} &= \frac{2}{4}\sum_{(s,q)\in[d]^2}(W_{s,s} + W_{q,q})x_s^2x_q^2 \\ &= \frac{2}{4}\left\langle (W_{s,s} + W_{q,q})_{(s,q)\in[d]^2}, (x_s^2x_q^2)_{(s,q)\in[d]^2}\right\rangle \\ &\leq \frac{2}{4}\|(W_{s,s} + W_{q,q})_{(s,q)\in[d]^2}\|_\infty \|(x_s^2x_q^2)_{(s,q)\in[d]^2}\|_1 \\ &\leq \frac{2}{4}\cdot 2 = 1 \,. \end{aligned}$$

The second term can be bounded as:

$$\begin{aligned} 4\sum_{\substack{(s,q,q')\in[d]^3: \\ q\neq q'}} p_{s,q}p_{s,q'}W_{q,q'}\frac{x_s^2|x_q||x_{q'}|}{4p_{s,q}p_{s,q'}} &\leq 4\cdot\frac{1}{4}\left(\sum_{s\in[d]} x_s^2\right)\left(\sum_{(q,q')\in[d]^2} |W_{q,q'}|\cdot|x_qx_{q'}|\right) \\ &\leq \|W\|_{\text{tr}}\|xx^\top\|_{\text{sp}} \\ &\leq k \,. \end{aligned}$$

Combining the above, we obtain

$$\begin{aligned} \mathbb{E}_i\langle W, \hat{C}^2\rangle &= \frac{4}{r^2}\left[\frac{r}{2}dk + \frac{r}{2}\left(\frac{r}{2} - 1\right)(k+1)\right] \\ &\leq \frac{2dk}{r} + k + 1 \\ &\leq \frac{2dk}{r} + 2k \\ &= \frac{2k(d+r)}{r} \,. \end{aligned}$$

Appendix C. The Price of Partial Information is at Least Linear

Theorem 12 *Let $k = 1$. Then, the sample complexity of subspace learning is bounded below by:*

$$m(d, k = 1, r, \epsilon) \geq \Omega\left(\frac{d}{r\epsilon}\right) \,.$$

Proof Let $\epsilon \in (0, 1/4)$, and let $\mathcal{A}$ be a bandit subspace learner. For each $s \in [d]$, we define a distribution P_s as follows. The zero vector is drawn with probability $1 - c\epsilon$ (where $c > 2$), and the

vector e_s is drawn with probability $c\epsilon$. Note that $\mathbb{E}[xx^\top] = c\epsilon\, e_s e_s^\top$, and thus the optimal projection is given by $\Pi^\star := e_s e_s^\top$.

We next show that a successful subspace learner must identify the distribution. Let P_s be a concrete distribution. Denote by $\hat{\Pi} = \hat{u}\hat{u}^\top$ the output of the learner. Define $\theta_s = u_s^2$. It can be easily seen that if $L(\hat{\Pi}) - L(\Pi^\star) < \epsilon < c\epsilon/2$, then $\theta_s > \theta_q$ for any $q \neq s$. That is, a successful subspace learner must identify the index s.

Next we observe that if the size of the sample is at most $o\left(\frac{d}{r\epsilon}\right)$, then with a non-negligible probability, all the observations made by the learner are equal to zero. It follows that there exists a distribution P_j for which, $\mathbb{E}[L(\hat{\Pi}) - L(\Pi^\star)] > c\epsilon/2 > \epsilon$. ■

Appendix D. Decomposing Elements in $\mathcal{C}_k^d$ into a Convex Combination of Elements From $\mathcal{P}_k^d$

In this part we detail the decomposition procedure mentioned in Lemma 6. For a symmetric $d \times d$ matrix A, we denote its eigenvalues by $\lambda(A)_1 \geq \ldots \geq \lambda(A)_d$. For convenience, we define two subroutines. The procedure $\mathrm{sort}(x, s)$ returns a set of s indices, corresponding to the s largest values of x. Given a vector $x \in \mathbb{R}^d$, the function $\mathrm{diag} : \mathbb{R}^d \to \mathbb{R}^{d\times d}$ returns a diagonal matrix X with $X_{j,j} = x_j$.

Algorithm 3 Decomposition Procedure

Input: $W \in \mathcal{C}_k^d = \mathrm{conv}(\mathcal{P}_k^d)$
perform eigendecomposition $W = U\mathrm{diag}(\lambda(A))U^\top$
$\lambda := k^{-1}(\lambda(A)_1, \ldots, \lambda(A)_d)$
$i := 1$
repeat
  $J := \mathrm{sort}(\lambda, k)$
  $c_i := k^{-1}\sum_{j\in J} e_j$
  $s := \min_{j\in J} \lambda_j$
  $l := \max_{j\in[d]\setminus J} \lambda_j$
  $\beta_i := \min\left\{sk, \sum_{j=1}^d \lambda_j - lk\right\}$
  $\lambda := \lambda - \beta_i c_i$
  $\Pi_i := U\mathrm{diag}(kc_i)U^\top$
  $i := i + 1$
until $\lambda = (0, \ldots, 0)$
For each $j \in [i-1]$ choose $A = \Pi_j$ with probability β_j

It has been proved by Warmuth and Kuzmin (2008) that the loop inside Algorithm 3 repeats at most d times, and decomposes W into a convex combination $\sum \beta_i \Pi_i$ of elements from $\mathcal{P}_k^d$.

Appendix E. Covariance Estimation with Missing Entries

Corollary 1 in Lounici (2014) provides bounds under the assumption that the instances are drawn from a sub-gaussian distribution (see assumption 1 in Lounici (2014)). This assumption is weaker than our boundedness assumption. Translating the results to our notation yields:

Lemma 13 *Given m partial observations, let $\hat{C}$ be the unbiased estimation constructed by POPCA. Let $\lambda > 0$ be a parameter.*

$$\tilde{C} := C(\tilde{\lambda}) = \operatorname*{argmin}_{S\in\mathbb{S}_+^d}\{\|S - \hat{C}\|_F^2 + \lambda\|S\|_1\}\,,$$

where $\mathbb{S}_+^d$ is the set of symmetric positive semi-definite $d \times d$ matrices. Then, for a suitable choice of λ, with probability at least $1 - 1/(2d)$, we have

$$\|\tilde{C} - C\|_F \leq \sqrt{\inf_{S\in\mathbb{S}_+^d}\{\|S - C\|_F^2 + c_1\lambda_1^2(C)\cdot\frac{\mathrm{tr}(C)}{\lambda_1(C)}\cdot\frac{d^2}{r^2 m}\cdot \mathit{rank}(S)\cdot\log(2d)\}}\,,$$

where c_1 is a constant and $\lambda_1(C)$ is the leading eigenvalue of C.

Substituting $m = \lceil (d/r)^2 \cdot \frac{k}{\epsilon^2}\rceil$ from Lemma 2 into the above bound, we obtain that the RHS is at most

$$\sqrt{\inf_{S\in\mathbb{S}_+^d}\{\|S - C\|_F^2 + c_1\lambda_1^2(C)\cdot\frac{\mathrm{tr}(C)}{\lambda_1(C)}\cdot\frac{\epsilon^2}{k}\cdot\mathrm{rank}(S)\cdot\log(2d))\}}\,.$$

This bound is always worse than our bound (i.e., larger than $\epsilon/\sqrt{k}$).

Abstract

We study randomized sketching methods for approximately solving least-squares problem with a general convex constraint. The quality of a least-squares approximation can be assessed in different ways: either in terms of the value of the quadratic objective function (cost approximation), or in terms of some distance measure between the approximate minimizer and the true minimizer (solution approximation). Focusing on the latter criterion, our first main result provides a general lower bound on any randomized method that sketches both the data matrix and vector in a least-squares problem; as a surprising consequence, the most widely used least-squares sketch is sub-optimal for solution approximation. We then present a new method known as the *iterative Hessian sketch*, and show that it can be used to obtain approximations to the original least-squares problem using a projection dimension proportional to the statistical complexity of the least-squares minimizer, and a logarithmic number of iterations. We illustrate our general theory with simulations for both unconstrained and constrained versions of least-squares, including ℓ_1-regularization and nuclear norm constraints. We also numerically demonstrate the practicality of our approach in a real face expression classification experiment.

Keywords: Convex optimization, Random Projection, Lasso, Low-rank Approximation, Information Theory

1. Introduction

Over the past decade, the explosion of data volume and complexity has led to a surge of interest in fast procedures for approximate forms of matrix multiplication, low-rank approximation, and convex optimization. One interesting class of problems that arise frequently in data analysis and scientific computing are constrained least-squares problems. More specifically, given a data vector $y \in \mathbb{R}^n$, a data matrix $A \in \mathbb{R}^{n \times d}$ and a convex constraint set $\mathcal{C}$, a constrained least-squares problem can be written as follows

$$x^{\mathrm{LS}} := \arg\min_{x \in \mathcal{C}} f(x) \qquad \text{where } f(x) := \tfrac{1}{2n}\|Ax - y\|_2^2. \tag{1}$$

The simplest case is the unconstrained form ($\mathcal{C} = \mathbb{R}^d$), but this class also includes other interesting constrained programs, including those based ℓ_1-norm balls, nuclear norm balls, interval constraints $[-1, 1]^d$ and other types of regularizers designed to enforce structure in the solution.

Randomized sketches are a well-established way of obtaining an approximate solutions to a variety of problems, and there is a long line of work on their uses (e.g., see the books and papers by Vempala (2004); Boutsidis and Drineas (2009); Mahoney (2011); Drineas et al. (2011); Kane and Nelson (2014), as well as references therein). In application to problem (1), sketching methods involving using a random matrix $S \in \mathbb{R}^{m \times n}$ to project the data matrix A and/or data vector y to a lower dimensional space ($m \ll n$), and then solving the approximated least-squares problem. There are many choices of random sketching matrices; see Section 2.1 for discussion of a few possibilities. Given some choice of random sketching matrix S, the most well-studied form of sketched least-squares is based on solving the problem

$$\widetilde{x} := \arg\min_{x \in \mathcal{C}} \Big\{ \frac{1}{2n}\|SAx - Sy\|_2^2 \Big\}, \tag{2}$$

in which the data matrix-vector pair (A, y) are approximated by their sketched versions (SA, Sy). Note that the sketched program is an m-dimensional least-squares problem, involving the new data matrix $SA \in \mathbb{R}^{m \times d}$. Thus, in the regime $n \gg d$, this approach can lead to substantial computational savings as long as the projection dimension m can be chosen substantially less than n. A number of authors (e.g., Sarlos (2006); Boutsidis and Drineas (2009); Drineas et al. (2011); Mahoney (2011); Pilanci and Wainwright (2015a)) have investigated the properties of this sketched solution (2), and accordingly, we refer to to it as the *classical least-squares sketch*.

There are various ways in which the quality of the approximate solution $\widetilde{x}$ can be assessed. One standard way is in terms of the minimizing value of the quadratic cost function f defining the original problem (1), which we refer to as *cost approximation*. In terms of f-cost, the approximate solution $\widetilde{x}$ is said to be ε-optimal if

$$f(x^{\mathrm{LS}}) \;\leq\; f(\widetilde{x}) \;\leq\; (1+\varepsilon)^2 f(x^{\mathrm{LS}}). \tag{3}$$

For example, in the case of unconstrained least-squares ($\mathcal{C} = \mathbb{R}^d$) with $n > d$, it is known that with Gaussian random sketches, a sketch size $m \gtrsim \frac{1}{\varepsilon^2} d$ suffices to guarantee that $\widetilde{x}$ is ε-optimal with high probability (for instance, see the papers by Sarlos (2006) and Mahoney (2011), as well as references therein). Similar guarantees can be established for sketches based on sampling according to the statistical leverage scores (Drineas and Mahoney, 2010; Drineas et al., 2012). Sketching can also be applied to problems with constraints: Boutsidis and Drineas (2009) prove analogous results for the case of non-negative least-squares considering

JMLR 17(53):1-38

the sketch in equation (2), whereas our own past work (Pilanci and Wainwright, 2015a) provides sufficient conditions for ε-accurate cost approximation of least-squares problems over arbitrary convex sets based also on the form in (2).

It should be noted, however, that other notions of "approximation goodness" are possible. In many applications, it is the least-squares minimizer x^{LS} itself—as opposed to the cost value $f(x^{\mathrm{LS}})$—that is of primary interest. In such settings, a more suitable measure of approximation quality would be the ℓ_2-norm $\|\widetilde{x} - x^{\mathrm{LS}}\|_2$, or the prediction (semi)-norm

$$\|\widetilde{x} - x^{\mathrm{LS}}\|_A := \frac{1}{\sqrt{n}}\|A(\widetilde{x} - x^{\mathrm{LS}})\|_2. \tag{4}$$

We refer to these measures as *solution approximation*.

Now of course, a cost approximation bound (3) can be used to derive guarantees on the solution approximation error. However, it is natural to wonder whether or not, for a reasonable sketch size, the resulting guarantees are "good". For instance, using arguments from Drineas et al. (2011), for the problem of unconstrained least-squares, it can be shown that the same conditions ensuring a ε-accurate cost approximation also ensure that

$$\|\widetilde{x} - x^{\mathrm{LS}}\|_A \leq \varepsilon \sqrt{f(x^{\mathrm{LS}})}. \tag{5}$$

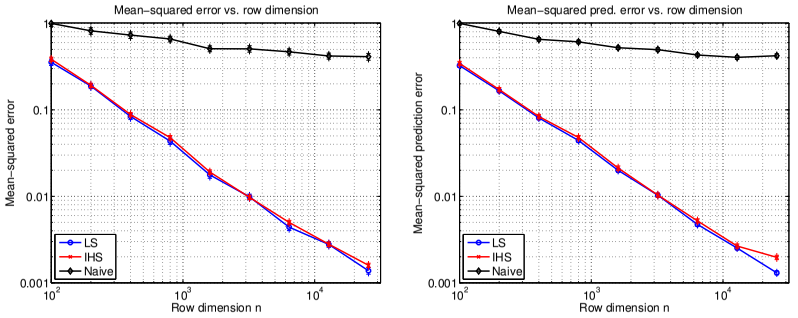
Given lower bounds on the singular values of the data matrix A, this bound also yields control of the ℓ_2-error.

In certain ways, the bound (5) is quite satisfactory: given our normalized definition (1) of the least-squares cost f, the quantity $f(x^{\mathrm{LS}})$ remains an order one quantity as the sample size n grows, and the multiplicative factor ε can be reduced by increasing the sketch dimension m. But how small should ε be chosen? In many applications of least-squares, each element of the response vector $y \in \mathbb{R}^n$ corresponds to an observation, and so as the sample size n increases, we expect that x^{LS} provides a more accurate approximation to some underlying population quantity, say $x^* \in \mathbb{R}^d$. As an illustrative example, in the special case of unconstrained least-squares, the accuracy of the least-squares solution x^{LS} as an estimate of x^* scales as $\|x^{\mathrm{LS}} - x^*\|_A \asymp \frac{\sigma^2 d}{n}$. Consequently, in order for our sketched solution to have an accuracy of the same order as the least-square estimate, we must set $\varepsilon^2 \asymp \frac{\sigma^2 d}{n}$. Combined with our earlier bound on the projection dimension, this calculation suggests that a projection dimension of the order

$$m \gtrsim \frac{d}{\varepsilon^2} \asymp \frac{n}{\sigma^2}$$

is required. This scaling is undesirable in the regime $n \gg d$, where the whole point of sketching is to have the sketch dimension m much lower than n.

Now the alert reader will have observed that the preceding argument was only rough and heuristic. However, the first result of this paper (Theorem 1) provides a rigorous confirmation of the conclusion: whenever $m \ll n$, the classical least-squares sketch (2) is sub-optimal as a method for solution approximation. Figure 1 provides an empirical demonstration of the poor behavior of the classical least-squares sketch for an unconstrained problem.



(a) (b)

Figure 1. Plots of mean-squared error versus the row dimension $n \in \{100, 200, 400, \ldots, 25600\}$ for unconstrained least-squares in dimension $d = 10$. The blue curves correspond to the error $x^{\mathrm{LS}} - x^*$ of the unsketched least-squares estimate. Red curves correspond to the IHS method applied for $N = 1 + \lceil \log(n) \rceil$ rounds using a sketch size $m = 7d$. Black curves correspond to the naive sketch applied using $M = Nm$ projections in total, corresponding to the same number used in all iterations of the IHS algorithm. (a) Error $\|\widetilde{x} - x^*\|_2^2$. (b) Prediction error $\|\widetilde{x} - x^*\|_A^2 = \frac{1}{n}\|A(\widetilde{x} - x^*)\|_2^2$. Each point corresponds to the mean taken over 300 trials with standard errors shown above and below in crosses.

This sub-optimality holds not only for unconstrained least-squares but also more generally for a broad class of constrained problems. Actually, Theorem 1 is a more general claim: *any estimator* based only on the pair (SA, Sy)—an infinite family of methods including the standard sketching algorithm as a particular case—is sub-optimal relative to the original least-squares estimator in the regime $m \ll n$. We are thus led to a natural question: can this sub-optimality be avoided by a different type of sketch that is nonetheless computationally efficient? Motivated by this question, our second main result (Theorem 2) is to propose an alternative method—known as the iterative Hessian sketch—and prove that it yields optimal approximations to the least-squares solution using a projection size that scales with the intrinsic dimension of the underlying problem, along with a logarithmic number of iterations. The main idea underlying iterative Hessian sketch is to obtain multiple sketches of the data $(S^1A, ..., S^NA)$ and iteratively refine the solution where N can be chosen logarithmic in n.

The remainder of this paper is organized as follows. In Section 2, we begin by introducing some background on classes of random sketching matrices, before turning to the statement of our lower bound (Theorem 1) on the classical least-squares sketch (2). We then introduce the Hessian sketch, and show that an iterative version of it can be used to compute ε-accurate solution approximations using $\log(1/\varepsilon)$-steps (Theorem 2). In Section 3, we illustrate the consequences of this general theorem for various specific classes of least-squares problems, and we conclude with a discussion in Section 4. The majority of our proofs are deferred to the appendices.

For the convenience of the reader, we summarize some standard notation used in this paper. For sequences $\{a_t\}_{t=0}^{\infty}$ and $\{b_t\}_{t=0}^{\infty}$, we use the notation $a_t \preceq b_t$ to mean that there is a constant (independent of t) such that $a_t \leq C\, b_t$ for all t. Equivalently, we write $b_t \succeq a_t$. We write $a_t \asymp b_t$ if $a_t \preceq b_t$ and $b_t \preceq a_t$.

2. Main results

In this section, we begin with background on different classes of randomized sketches, including those based on random matrices with sub-Gaussian entries, as well as those based on randomized orthonormal systems and random sampling. In Section 2.2, we prove a general lower bound on the solution approximation accuracy of any method that attempts to approximate the least-squares problem based on observing only the pair (SA, Sy). This negative result motivates the investigation of alternative sketching methods, and we begin this investigation by introducing the Hessian sketch in Section 2.3. It serves as the basic building block of the iterative Hessian sketch (IHS), which can be used to construct an iterative method that is optimal up to logarithmic factors.

2.1 Different types of randomized sketches

Various types of randomized sketches are possible, and we describe a few of them here. Given a sketching matrix S, we use $\{s_i\}_{i=1}^m$ to denote the collection of its n-dimensional rows. We restrict our attention to sketch matrices that are zero-mean, and that are normalized so that $\mathbb{E}[S^T S/m] = I_n$.

2.1.1 Sub-Gaussian sketches:

The most classical sketch is based on a random matrix $S \in \mathbb{R}^{m \times n}$ with i.i.d. standard Gaussian entries. A straightforward generalization is a random sketch with i.i.d. sub-Gaussian rows. In particular, a zero-mean random vector $s \in \mathbb{R}^n$ is 1-sub-Gaussian if for any $u \in \mathbb{R}^n$, we have

$$\mathbb{P}[\langle s,\, u\rangle \geq \varepsilon \|u\|_2] \leq e^{-\varepsilon^2/2} \qquad \text{for all } \varepsilon \geq 0. \tag{6}$$

For instance, a vector with i.i.d. $N(0,1)$ entries is 1-sub-Gaussian, as is a vector with i.i.d. Rademacher entries (uniformly distributed over $\{-1,+1\}$). Suppose that we generate a random matrix $S \in \mathbb{R}^{m \times n}$ with i.i.d. rows that are zero-mean, 1-sub-Gaussian, and with $\mathrm{cov}(s) = I_n$; we refer to any such matrix as a *sub-Gaussian sketch*. As will be clear, such sketches are the most straightforward to control from the probabilistic point of view. However, from a computational perspective, a disadvantage of sub-Gaussian sketches is that they require matrix-vector multiplications with unstructured random matrices. In particular, given an data matrix $A \in \mathbb{R}^{n \times d}$, computing its sketched version SA requires $\mathcal{O}(mnd)$ basic operations in general (using classical matrix multiplication).

2.1.2 Sketches based on randomized orthonormal systems (ROS):

The second type of randomized sketch we consider is *randomized orthonormal system* (ROS), for which matrix multiplication can be performed much more efficiently.

In order to define a ROS sketch, we first let $H \in \mathbb{R}^{n \times n}$ be an orthonormal matrix with entries $H_{ij} \in [-\frac{1}{\sqrt{n}}, \frac{1}{\sqrt{n}}]$. Standard classes of such matrices are the Hadamard or Fourier bases, for which matrix-vector multiplication can be performed in $\mathcal{O}(n \log n)$ time via the fast Hadamard or Fourier transforms, respectively. Based on any such matrix, a sketching matrix $S \in \mathbb{R}^{m \times n}$ from a ROS ensemble is obtained by sampling i.i.d. rows of the form

$$s^T = \sqrt{n} e_j^T H D \qquad \text{with probability } 1/n \text{ for } j = 1, \ldots, n,$$

where the random vector $e_j \in \mathbb{R}^n$ is chosen uniformly at random from the set of all n canonical basis vectors, and $D = \mathrm{diag}(\nu)$ is a diagonal matrix of i.i.d. Rademacher variables $\nu \in \{-1,+1\}^n$. A similar sketching matrix can also be obtained by sampling canonical basis vectors without replacement. Given a fast routine for matrix-vector multiplication, the sketched data (SA, Sy) can be formed in $\mathcal{O}(n\, d \log m)$ time (for instance, see Ailon and Chazelle (2006)).

2.1.3 Sketches based on random row sampling:

Given a probability distribution $\{p_j\}_{j=1}^n$ over $[n] = \{1, \ldots, n\}$, another choice of sketch is to randomly sample the rows of the extended data matrix $\begin{bmatrix} A & y \end{bmatrix}$ a total of m times with replacement from the given probability distribution. Thus, the rows of S are independent and take on the values

$$s^T = \frac{e_j}{\sqrt{p_j}} \qquad \text{with probability } p_j \text{ for } j = 1, \ldots, n$$

where $e_j \in \mathbb{R}^n$ is the j^{th} canonical basis vector. Different choices of the weights $\{p_j\}_{j=1}^n$ are possible, including those based on the leverage values of A—i.e., $p_j \propto \|u_j\|_2$ for $j = 1, \ldots, n$, where $U \in \mathbb{R}^{n \times d}$ is the matrix of left singular vectors of A (e.g., see Drineas and Mahoney (2010)). In our analysis of lower bounds to follow, we assume that the weights are α-balanced, meaning that

$$\max_{j=1,\ldots,n} p_j \leq \frac{\alpha}{n} \tag{7}$$

for some constant α independent of n.

In the following section, we present a lower bound that applies to all the three kinds of sketching matrices described above.

2.2 Sub-optimality of classical least-squares sketch

We begin by proving a lower bound on any estimator that is a function of the pair (SA, Sy). In order to do so, we consider an ensemble of least-squares problems, namely those generated by a noisy observation model of the form

$$y = Ax^* + w, \qquad \text{where } w \sim N(0, \sigma^2 I_n), \tag{8}$$

the data matrix $A \in \mathbb{R}^{n \times d}$ is fixed, and the unknown vector x^* belongs to some set $\mathcal{C}_0$ that is star-shaped around zero.[1] In this case, the constrained least-squares estimate x^{LS} from

1. Explicitly, this star-shaped condition means that for any $x \in \mathcal{C}_0$ and scalar $t \in [0,1]$, the point tx also belongs to $\mathcal{C}_0$.

equation (1) corresponds to a constrained form of maximum-likelihood for estimating the unknown regression vector x^*. In Appendix D, we provide a general upper bound on the error $\mathbb{E}[\|x^{\text{LS}} - x^*\|_A^2]$ in the least-squares solution as an estimate of x^*. This result provides a baseline against which to measure the performance of a sketching method: in particular, our goal is to characterize the minimal projection dimension m required in order to return an estimate $\widetilde{x}$ with an error guarantee $\|\widetilde{x} - x^{\text{LS}}\|_A \approx \|x^{\text{LS}} - x^*\|_A$. The result to follow shows that unless $m \geq n$, then *any method* based on observing *only* the pair (SA, Sy) necessarily has a substantially larger error than the least-squares estimate. In particular, our result applies to an arbitrary measurable function $(SA, Sy) \mapsto x^\dagger$, which we refer to as an *estimator*.

More precisely, our lower bound applies to any random matrix $S \in \mathbb{R}^{m \times n}$ for which

$$\|\mathbb{E}\Big[S^T(SS^T)^{-1}S\Big]\|_{\text{op}} \leq \eta \, \frac{m}{n}, \tag{9}$$

where η is a constant independent of n and m, and $\|A\|_{\text{op}}$ denotes the ℓ_2-operator norm (maximum eigenvalue for a symmetric matrix). In Appendix A.1, we show that these conditions hold for various standard choices, including most of those discussed in the previous section. Letting $\mathbb{B}_A(1)$ denote the unit ball defined by the semi-norm $\|\cdot\|_A$, our lower bound also involves the complexity of the set $\mathcal{C}_0 \cap \mathbb{B}_A(1)$, which we measure in terms of its metric entropy. In particular, for a given tolerance $\delta > 0$, the δ-packing number M_δ of the set $\mathcal{C}_0 \cap \mathbb{B}_A(1)$ with respect to $\|\cdot\|_A$ is the largest number of vectors $\{x^j\}_{j=1}^M \subset \mathcal{C}_0 \cap \mathbb{B}_A(1)$ such that $\|x^j - x^k\|_A > \delta$ for all distinct pairs $j \neq k$.

With this set-up, we have the following result:

Theorem 1 (Sub-optimality) *For any random sketching matrix $S \in \mathbb{R}^{m \times n}$ satisfying condition* (9)*, any estimator $(SA, Sy) \mapsto x^\dagger$ has MSE lower bounded as*

$$\sup_{x^* \in \mathcal{C}_0} \mathbb{E}_{S,w}\big[\|x^\dagger - x^*\|_A^2\big] \geq \frac{\sigma^2}{128\,\eta} \, \frac{\log(\frac{1}{2}M_{1/2})}{\min\{m,n\}} \tag{10}$$

where $M_{1/2}$ is the 1/2-packing number of $\mathcal{C}_0 \cap \mathbb{B}_A(1)$ in the semi-norm $\|\cdot\|_A$.

The proof, given in Appendix A, is based on a reduction from statistical minimax theory combined with information-theoretic bounds. The lower bound is best understood by considering some concrete examples:

Example 1 (Sub-optimality for ordinary least-squares) *We begin with the simplest case—namely, in which $\mathcal{C} = \mathbb{R}^d$. With this choice and for any data matrix A with $\text{rank}(A) = d$, it is straightforward to show that the least-squares solution x^{LS} has its prediction mean-squared error at most*

$$\mathbb{E}\big[\|x^{LS} - x^*\|_A^2\big] \precsim \frac{\sigma^2 d}{n}. \tag{11a}$$

On the other hand, with the choice $\mathcal{C}_0 = \mathbb{B}_2(1)$, we can construct a 1/2-packing with $M = 2^d$ elements, so that Theorem 1 implies that any estimator $x^\dagger$ based on (SA, Sy) has its prediction MSE lower bounded as

$$\mathbb{E}_{S,w}\big[\|\widehat{x} - x^*\|_A^2\big] \succsim \frac{\sigma^2\, d}{\min\{m,n\}}. \tag{11b}$$

Consequently, the sketch dimension m must grow proportionally to n in order for the sketched solution to have a mean-squared error comparable to the original least-squares estimate. This is highly undesirable for least-squares problems in which $n \gg d$, since it should be possible to sketch down to a dimension proportional to $\text{rank}(A) = d$. Thus, Theorem 1 this reveals a surprising gap between the classical least-squares sketch (2) *and the accuracy of the original least-squares estimate.*

In contrast, the sketching method of this paper, known as iterative Hessian sketching (IHS), matches the optimal mean-squared error using a sketch of size $d + \log(n)$ in each round, and a total of $\log(n)$ rounds; see Corollary 2 for a precise statement. The red curves in Figure 1 show that the mean-squared errors ($\|\widehat{x} - x^*\|_2^2$ in panel (a), and $\|\widehat{x} - x^*\|_A^2$ in panel (b)) of the IHS method using this sketch dimension closely track the associated errors of the full least-squares solution (blue curves). Consistent with our previous discussion, both curves drop off at the n^{-1} rate.

Since the IHS method with $\log(n)$ rounds uses a total of $T = \log(n)\big\{d + \log(n)\big\}$ sketches, a fair comparison is to implement the classical method with T sketches in total. The black curves show the MSE of the resulting sketch: as predicted by our theory, these curves are relatively flat as a function of sample size n. Indeed, in this particular case, the lower bound (10)

$$\mathbb{E}_{S,w}\big[\|\widetilde{x} - x^*\|_A^2\big] \succsim \frac{\sigma^2 d}{m} \succsim \frac{\sigma^2}{\log^2(n)},$$

showing we can expect (at best) an inverse logarithmic drop-off. ♢

This sub-optimality can be extended to other forms of constrained least-squares estimates as well, such as those involving sparsity constraints.

Example 2 (Sub-optimality for sparse linear models) *We now consider the sparse variant of the linear regression problem, which involves the ℓ_0-"ball"*

$$\mathbb{B}_0(s) := \big\{x \in \mathbb{R}^d \mid \sum_{j=1}^d \mathbb{I}[x_j \neq 0] \leq s\big\},$$

corresponding to the set of all vectors with at most s non-zero entries. Fixing some radius $R \geq \sqrt{s}$, consider a vector $x^* \in \mathcal{C}_0 := \mathbb{B}_0(s) \cap \{\|x\|_1 = R\}$, and suppose that we make noisy observations of the form $y = Ax^* + w$.

Given this set-up, one way in which to estimate x^* is by by computing the least-squares estimate x^{LS} constrained[2] *to the ℓ_1-ball $\mathcal{C} = \{x \in \mathbb{R}^n \mid \|x\|_1 \leq R\}$. This estimator is a*

2. This set-up is slightly unrealistic, since the estimator is assumed to know the radius $R = \|x^*\|_1$. In practice, one solves the least-squares problem with a Lagrangian constraint, but the underlying arguments are basically the same.

form of the Lasso (Tibshirani, 1996): as shown in Appendix D.2, when the design matrix A satisfies the restricted isometry property (see Candes and Tao (2005) for a definition), then it has MSE at most

$$\mathbb{E}\big[\|x^{LS} - x^*\|_A^2\big] \precsim \frac{\sigma^2 s \log\left(\frac{ed}{s}\right)}{n}. \tag{12a}$$

On the other hand, the $\frac{1}{2}$-packing number M of the set $\mathcal{C}_0$ can be lower bounded as $\log M \succsim s \log\left(\frac{ed}{s}\right)$; see Appendix D.2 for the details of this calculation. Consequently, in application to this particular problem, Theorem 1 implies that any estimator $x^\dagger$ based on the pair (SA, Sy) has mean-squared error lower bounded as

$$\mathbb{E}_{w,S}\big[\|x^\dagger - x^*\|_A^2\big] \succsim \frac{\sigma^2 s \log\left(\frac{ed}{s}\right)}{\min\{m, n\}}. \tag{12b}$$

Again, we see that the projection dimension m must be of the order of n in order to match the mean-squared error of the constrained least-squares estimate x^{LS} up to constant factors. By contrast, in this special case, the sketching method developed in this paper matches the error $\|x^{LS} - x^*\|_2$ using a sketch dimension that scales only as $s \log\left(\frac{ed}{s}\right) + \log(n)$; see Corollary 3 for the details of a more general result. ♢

Example 3 (Sub-optimality for low-rank matrix estimation) *In the problem of multivariate regression, the goal is to estimate a matrix $X^* \in \mathbb{R}^{d_1 \times d_2}$ model based on observations of the form*

$$Y = AX^* + W, \tag{13}$$

where $Y \in \mathbb{R}^{n \times d_1}$ is a matrix of observed responses, $A \in \mathbb{R}^{n \times d_1}$ is a data matrix, and $W \in \mathbb{R}^{n \times d_2}$ is a matrix of noise variables. One interpretation of this model is as a collection of d_2 regression problems, each involving a d_1-dimensional regression vector, namely a particular column of X^*. In many applications, among them reduced rank regression, multi-task learning and recommender systems (e.g., Srebro et al. (2005); Yuan and Lin (2006); Negahban and Wainwright (2011); Bunea et al. (2011)), it is reasonable to model the matrix X^* as having a low-rank. Note a rank constraint on matrix X be written as an ℓ_0-"norm" constraint on its singular values: in particular, we have

$$\operatorname{rank}(X) \leq r \quad \text{if and only if} \quad \sum_{j=1}^{\min\{d_1, d_2\}} \mathbb{I}[\gamma_j(X) > 0] \leq r,$$

where $\gamma_j(X)$ denotes the j^{th} singular value of X. This observation motivates a standard relaxation of the rank constraint using the nuclear norm $\|X\|_{nuc} := \sum_{j=1}^{\min\{d_1, d_2\}} \gamma_j(X)$.

Accordingly, let us consider the constrained least-squares problem

$$X^{LS} = \arg\min_{X \in \mathbb{R}^{d_1 \times d_2}} \Big\{ \frac{1}{2}\|Y - AX\|_{fro}^2 \Big\} \qquad \text{such that } \|X\|_{nuc} \leq R, \tag{14}$$

where $\|\cdot\|_{fro}$ denotes the Frobenius norm on matrices, or equivalently the Euclidean norm on its vectorized version. Let $\mathcal{C}_0$ denote the set of matrices with rank $r < \frac{1}{2}\min\{d_1, d_2\}$, and Frobenius norm at most one. In this case, we show in Appendix D that the constrained least-squares solution X^{LS} satisfies the bound

$$\mathbb{E}\Big[\|X^{LS} - X^*\|_A^2\Big] \precsim \frac{\sigma^2 r\,(d_1 + d_2)}{n}. \tag{15a}$$

On the other hand, the $\frac{1}{2}$-packing number of the set $\mathcal{C}_0$ is lower bounded as $\log M \succsim r\big(d_1 + d_2\big)$, so that Theorem 1 implies that any estimator $X^\dagger$ based on the pair (SA, SY) has MSE lower bounded as

$$\mathbb{E}_{w,S}\big[\|X^\dagger - X^*\|_A^2\big] \succsim \frac{\sigma^2 r\big(d_1 + d_2\big)}{\min\{m, n\}}. \tag{15b}$$

As with the previous examples, we see the sub-optimality of the sketched approach in the regime $m < n$. In contrast, for this class of problems, our sketching method matches the error $\|X^{LS} - X^*\|_A$ using a sketch dimension that scales only as $\{r(d_1 + d_2) + \log(n)\}\log(n)$. See Corollary 4 for further details.

♢

2.3 Introducing the Hessian sketch

As will be revealed during the proof of Theorem 1, the sub-optimality is in part due to sketching the response vector—i.e., observing Sy instead of y. It is thus natural to consider instead methods that sketch *only* the data matrix A, as opposed to both the data matrix and data vector y. In abstract terms, such methods are based on observing the pair $\big(SA, A^T y\big) \in \mathbb{R}^{m \times d} \times \mathbb{R}^d$. One such approach is what we refer to as the *Hessian sketch*—namely, the sketched least-squares problem

$$\widehat{x} := \arg\min_{x \in \mathcal{C}} \Big\{ \underbrace{\frac{1}{2}\|SAx\|_2^2 - \langle A^T y,\, x\rangle}_{g_S(x)} \Big\}. \tag{16}$$

As with the classical least-squares sketch (2), the quadratic form is defined by the matrix $SA \in \mathbb{R}^{m \times d}$, which leads to computational savings. Although the Hessian sketch on its own does not provide an optimal approximation to the least-squares solution, it serves as the building block for an iterative method that can obtain an ε-accurate solution approximation in $\log(1/\varepsilon)$ iterations.

In controlling the error with respect to the least-squares solution x^{LS} the set of possible descent directions $\{x - x^{\mathrm{LS}} \mid x \in \mathcal{C}\}$ plays an important role. In particular, we define the *transformed tangent cone*

$$\mathcal{K}^{\mathrm{LS}} = \big\{ v \in \mathbb{R}^d \mid v = t\,A(x - x^{\mathrm{LS}}) \quad \text{for some } t \geq 0 \text{ and } x \in \mathcal{C} \big\}. \tag{17}$$

Note that the error vector $\widehat{v} := A(\widehat{x} - x^{\mathrm{LS}})$ of interest belongs to this cone. Our approximation bound is a function of the quantities

$$Z_1(S) := \inf_{v \in \mathcal{K}^{\mathrm{LS}} \cap \mathcal{S}^{n-1}} \frac{1}{m}\|Sv\|_2^2 \quad \text{and} \tag{18a}$$

$$Z_2(S) := \sup_{v \in \mathcal{K}^{\mathrm{LS}} \cap \mathcal{S}^{n-1}} \left| \langle u, \, (\frac{S^T S}{m} - I_n)\, v \rangle \right|, \tag{18b}$$

where u is a fixed unit-norm vector. These variables played an important role in our previous analysis (Pilanci and Wainwright, 2015a) of the classical sketch (2). The following bound applies in a deterministic fashion to any sketching matrix.

Proposition 1 (Bounds on Hessian sketch) *For any convex set $\mathcal{C}$ and any sketching matrix $S \in \mathbb{R}^{m \times n}$, the Hessian sketch solution $\widehat{x}$ satisfies the bound*

$$\|\widehat{x} - x^{LS}\|_A \leq \frac{Z_2}{Z_1} \|x^{LS}\|_A. \tag{19}$$

For random sketching matrices, Proposition 1 can be combined with probabilistic analysis to obtain high probability error bounds. For a given tolerance parameter $\rho \in (0, \frac{1}{2}]$, consider the "good event"

$$\mathcal{E}(\rho) := \left\{ Z_1 \geq 1 - \rho, \text{ and } Z_2 \leq \frac{\rho}{2} \right\}. \tag{20a}$$

Conditioned on this event, Proposition 1 implies that

$$\|\widehat{x} - x^{\mathrm{LS}}\|_A \leq \frac{\rho}{2\,(1-\rho)} \|x^{\mathrm{LS}}\|_A \;\leq\; \rho \|x^{\mathrm{LS}}\|_A, \tag{20b}$$

where the final inequality holds for all $\rho \in (0, 1/2]$.

Thus, for a given family of random sketch matrices, we need to choose the projection dimension m so as to ensure the event $\mathcal{E}\rho$ holds for some ρ. For future reference, let us state some known results for the cases of sub-Gaussian and ROS sketching matrices. We use (c_0, c_1, c_2) to refer to numerical constants, and we let $D = \dim(\mathcal{C})$ denote the dimension of the space $\mathcal{C}$. In particular, we have $D = d$ for vector-valued estimation, and $D = d_1 d_2$ for matrix problems.

Our bounds involve the "size" of the cone $\mathcal{K}^{\mathrm{LS}}$ previously defined (17), as measured in terms of its *Gaussian width*

$$\mathcal{W}(\mathcal{K}^{\mathrm{LS}}) := \mathbb{E}_g\big[\sup_{v \in \mathcal{K}^{\mathrm{LS}} \cap \mathbb{B}_2(1)} |\langle g, \, v \rangle| \big], \tag{21}$$

where $g \sim N(0, I_n)$ is a standard Gaussian vector. With this notation, we have the following:

Lemma 1 (Sufficient conditions on sketch dimension (Pilanci and Wainwright, 2015a))

(a) For sub-Gaussian sketch matrices, given a sketch size $m > \frac{c_0}{\rho^2}\mathcal{W}^2(\mathcal{K}^{LS})$, we have

$$\mathbb{P}\big[\mathcal{E}(\rho)\big] \geq 1 - c_1 e^{-c_2 m \delta^2}. \tag{22a}$$

(b) For randomized orthogonal system (ROS) sketches (sampled with replacement) over the class of self-bounding cones, given a sketch size $m > \frac{c_0 \, \log^4(D)}{\rho^2}\mathcal{W}^2(\mathcal{K}^{LS})$, we have

$$\mathbb{P}\big[\mathcal{E}(\rho)\big] \geq 1 - c_1 e^{-c_2 \frac{m\rho^2}{\log^4(D)}}. \tag{22b}$$

The class of self-bounding cones is described more precisely in Lemma 8 of our earlier paper (Pilanci and Wainwright, 2015a). It includes among other special cases the cones generated by unconstrained least-squares (Example 1), ℓ_1-constrained least squares (Example 2), and least squares with nuclear norm constraints (Example 3). For these cones, given a sketch size $m > \frac{c_0 \, \log^4(D)}{\rho^2}\mathcal{W}^2(\mathcal{K}^{\mathrm{LS}})$, the Hessian sketch applied with ROS matrices is guaranteed to return an estimate $\widehat{x}$ such that

$$\|\widehat{x} - x^{\mathrm{LS}}\|_A \leq \rho \|x^{\mathrm{LS}}\|_A \tag{23}$$

with high probability. More recent work by Bourgain et al. (2015) has established sharp bounds for various forms of sparse Johnson-Lindenstrauss transforms (Kane and Nelson, 2014). As a corollary of their results, a form of the guarantee (23) also holds for such random projections.

Returning to the main thread, the bound (23) is an analogue of our earlier bound (5) for the classical sketch with $\sqrt{f(x^{\mathrm{LS}})}$ replaced by $\|x^{\mathrm{LS}}\|_A$. For this reason, we see that the Hessian sketch alone suffers from the same deficiency as the classical sketch: namely, it will require a sketch size $m \asymp n$ in order to mimic the $\mathcal{O}(n^{-1})$ accuracy of the least-squares solution.

2.4 Iterative Hessian sketch

Despite the deficiency of the Hessian sketch itself, it serves as the building block for an novel scheme—known as the iterative Hessian sketch—that can be used to match the accuracy of the least-squares solution using a reasonable sketch dimension. Let begin by describing the underlying intuition. As summarized by the bound (20b), conditioned on the good event $\mathcal{E}(\rho)$, the Hessian sketch returns an estimate with error within a ρ-factor of $\|x^{\mathrm{LS}}\|_A$, where x^{LS} is the solution to the original unsketched problem. As show by Lemma 1, as long as the projection dimension m is sufficiently large, we can ensure that $\mathcal{E}(\rho)$ holds for some $\rho \in (0, 1/2)$ with high probability. Accordingly, given the current iterate x^t, *suppose that we can construct a new least-squares problem* for which the optimal solution is $x^{\mathrm{LS}} - x^t$. Applying the Hessian sketch to this problem will then produce a new iterate x^{t+1} whose distance to x^{LS} has been reduced by a factor of ρ. Repeating this procedure N times will reduce the initial approximation error by a factor ρ^N.

With this intuition in place, we now turn a precise formulation of the *iterative Hessian sketch*. Consider the optimization problem

$$\widehat{u} = \arg\min_{u \in \mathcal{C} - x^t} \Big\{ \frac{1}{2}\|Au\|_2^2 - \langle A^T(y - Ax^t), u \rangle \Big\}, \tag{24}$$

where x^t is the iterate at step t. By construction, the optimum to this problem is given by $\widehat{u} = x^{\mathrm{LS}} - x^t$. We then apply to Hessian sketch to this optimization problem (24) in order to obtain an approximation $x^{t+1} = x^t + \widehat{u}$ to the original least-squares solution x^{LS} that is more accurate than x^t by a factor $\rho \in (0, 1/2)$. Recursing this procedure yields a sequence of iterates whose error decays geometrically in ρ.

Formally, the iterative Hessian sketch algorithm takes the following form:

Iterative Hessian sketch (IHS): Given an iteration number $N \geq 1$:

(1) Initialize at $x^0 = 0$.

(2) For iterations $t = 0, 1, 2, \ldots, N-1$, generate an independent sketch matrix $S^{t+1} \in \mathbb{R}^{m \times n}$, and perform the update

$$x^{t+1} = \arg\min_{x \in \mathcal{C}} \Big\{ \frac{1}{2m}\|S^{t+1}A(x - x^t)\|_2^2 - \langle A^T(y - Ax^t), x \rangle \Big\}. \tag{25}$$

(3) Return the estimate $\widehat{x} = x^N$.

The following theorem summarizes the key properties of this algorithm. It involves the sequence $\{Z_1(S^t), Z_2(S^t)\}_{t=1}^N$, where the quantities Z_1 and Z_2 were previously defined in equations (18a) and (18b). In addition, as a generalization of the event (20a), we define the sequence of "good" events

$$\mathcal{E}^t(\rho) := \left\{ Z_1(S^t) \geq 1 - \rho, \text{ and } Z_2(S^t) \leq \frac{\rho}{2} \right\} \qquad \text{for } t = 1, \ldots, N. \tag{26}$$

With this notation, we have the following guarantee:

Theorem 2 (Guarantees for iterative Hessian sketch) *The final solution $\widehat{x} = x^N$ satisfies the bound*

$$\|\widehat{x} - x^{LS}\|_A \leq \Big\{ \prod_{t=1}^N \frac{Z_2(S^t)}{Z_1(S^t)} \Big\} \|x^{LS}\|_A. \tag{27a}$$

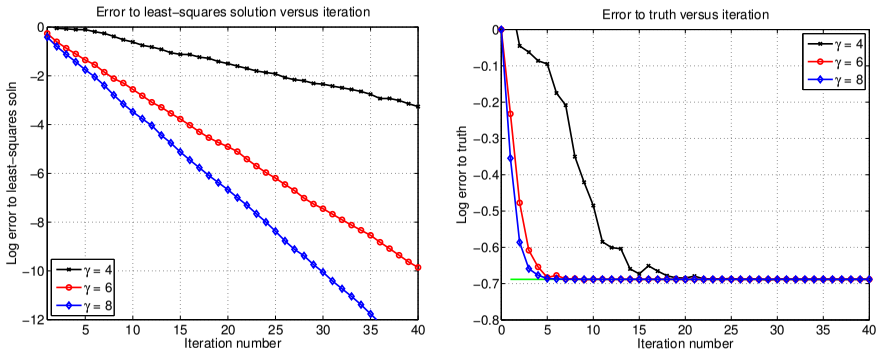
Consequently, conditioned on the event $\cap_{t=1}^N \mathcal{E}^t(\rho)$ for some $\rho \in (0, 1/2)$, we have

$$\|\widehat{x} - x^{LS}\|_A \leq \rho^N \, \|x^{LS}\|_A. \tag{27b}$$

Note that for any $\rho \in (0, 1/2)$, then event $\mathcal{E}^t(\rho)$ implies that $\frac{Z_2(S^t)}{Z_1(S^t)} \leq \rho$, so that the bound (27b) is an immediate consequence of the product bound (27a).

Lemma 1 can be combined with the union bound in order to ensure that the compound event $\cap_{t=1}^N \mathcal{E}^t(\rho)$ holds with high probability over a sequence of N iterates, as long as the sketch size is lower bounded as $m \geq \frac{c_0}{\rho^2}\mathcal{W}^2(\mathcal{K}^{\mathrm{LS}}) \log^4(D) + \log N$. Based on the bound (27b), we then expect to observe geometric convergence of the iterates.

In order to test this prediction, we implemented the IHS algorithm using Gaussian sketch matrices, and applied it to an unconstrained least-squares problem based on a data matrix with dimensions $(d, n) = (200, 6000)$ and noise variance $\sigma^2 = 1$. As shown in Appendix D.2, the Gaussian width of $\mathcal{K}^{\mathrm{LS}}$ is proportional to d, so that Lemma 1 shows that it suffices to choose a projection dimension $m \gtrsim \gamma d$ for a sufficiently large constant γ. Panel (a) of Figure 2 illustrates the resulting convergence rate of the IHS algorithm, measured in terms of the error $\|x^t - x^{\mathrm{LS}}\|_A$, for different values $\gamma \in \{4, 6, 8\}$. As predicted by Theorem 2, the convergence rate is geometric (linear on the log scale shown), with the rate increasing as the parameter γ is increased.



(a) (b)

Figure 2. Simulations of the IHS algorithm for an unconstrained least-squares problem with noise variance $\sigma^2 = 1$, and of dimensions $(d, n) = (200, 6000)$. Simulations based on sketch sizes $m = \gamma d$, for a parameter $\gamma > 0$ to be set. (a) Plots of the log error $\|x^t - x^{\mathrm{LS}}\|_A$ versus the iteration number t. Three different curves for $\gamma \in \{4, 6, 8\}$. Consistent with the theory, the convergence is geometric, with the rate increasing as the sampling factor γ is increased. (b) Plots of the log error $\|x^t - x^*\|_A$ versus the iteration number t. Three different curves for $\gamma \in \{4, 6, 8\}$. As expected, all three curves flatten out at the level of the least-squares error $\|x^{\mathrm{LS}} - x^*\|_A = 0.20 \approx \sqrt{\sigma^2 d/n}$.

Assuming that the sketch dimension has been chosen to ensure geometric convergence, Theorem 2 allows us to specify, for a given target accuracy $\varepsilon \in (0,1)$, the number of iterations required.

Corollary 1 *Fix some $\rho \in (0,1/2)$, and choose a sketch dimension $m > \frac{c_0 \log^4(D)}{\rho^2} \mathcal{W}^2(\mathcal{K}^{LS})$. If we apply the IHS algorithm for $N(\rho,\varepsilon) := 1 + \frac{\log(1/\varepsilon)}{\log(1/\rho)}$ steps, then the output $\widehat{x} = x^N$ satisfies the bound*

$$\frac{\|\widehat{x} - x^{LS}\|_A}{\|x^{LS}\|_A} \leq \varepsilon \tag{28}$$

with probability at least $1 - c_1 N(\rho,\varepsilon) e^{-c_2 \frac{m\rho^2}{\log^4(D)}}$.

This corollary is an immediate consequence of Theorem 2 combined with Lemma 1, and it holds for both ROS and sub-Gaussian sketches. (In the latter case, the additional $\log(D)$ terms may be omitted.) Combined with bounds on the width function $\mathcal{W}(\mathcal{K}^{\text{LS}})$, it leads to a number of concrete consequences for different statistical models, as we illustrate in the following section.

One way to understand the improvement of the IHS algorithm over the classical sketch is as follows. Fix some error tolerance $\varepsilon \in (0,1)$. Disregarding logarithmic factors, our previous results (Pilanci and Wainwright, 2015a) on the classical sketch then imply that a sketch size $m \gtrsim \varepsilon^{-2}\, \mathcal{W}^2(\mathcal{K}^{\text{LS}})$ is sufficient to produce a ε-accurate solution approximation. In contrast, Corollary 1 guarantees that a sketch size $m \gtrsim \log(1/\varepsilon)\, \mathcal{W}^2(\mathcal{K}^{\text{LS}})$ is sufficient. Thus, the benefit is the reduction from ε^{-2} to $\log(1/\varepsilon)$ scaling of the required sketch size.

It is worth noting that in the absence of constraints, the least-squares problem reduces to solving a linear system, so that alternative approaches are available. For instance, one can use a randomized sketch to obtain a preconditioner, which can then be used within the conjugate gradient method. As shown in past work (Rokhlin and Tygert, 2008; Avron et al., 2010), two-step methods of this type can lead to same reduction of ε^{-2} dependence to $\log(1/\varepsilon)$. However, a method of this type is very specific to unconstrained least-squares, whereas the procedure described in this paper is generally applicable to least-squares over any compact, convex constraint set.

2.5 Computational and space complexity

Let us now make a few comments about the computational and space complexity of implementing the IHS algorithm using the fast Johnson-Lindenstrauss (ROS) sketches, such as those based on the fast Hadamard transform. For a given sketch size m, the IHS algorithm requires $\mathcal{O}(nd\log(m))$ basic operations to compute the data sketch $S^{t+1}A$ at iteration t; in addition, it requires $\mathcal{O}(nd)$ operations to compute $A^T(y - Ax^t)$. Consequently, if we run the algorithm for N iterations, then the overall complexity scales as

$$\mathcal{O}\Big(N\,\big(nd\log(m) + C(m,d)\big)\Big), \tag{29}$$

where $C(m,d)$ is the complexity of solving the $m \times d$ dimensional problem in the update (25). Also note that, in problems where the data matrix A is sparse, $S^{t+1}A$ can be computed in time proportional to the number of non-zero elements in A using Gaussian sketching matrices. The space used by the sketches SA scales as $\mathcal{O}(md)$. To be clear, note that the IHS algorithm also requires access to the data via matrix-vector multiplies for forming $A^T(y - Ax^t)$. In limited memory environments, computing matrix-vector multiplies is considerably easier via distributed or interactive computation. For example, they can be efficiently implemented for multiple large datasets which can be loaded to memory only one at a time.

If we want to obtain estimates with accuracy ε, then we need to perform $N \asymp \log(1/\varepsilon)$ iterations in total. Moreover, for ROS sketches, we need to choose $m \gtrsim \mathcal{W}^2(\mathcal{K}^{\text{LS}})\log^4(d)$. Consequently, it only remains to bound the Gaussian width $\mathcal{W}$ in order to specify complexities that depend only on the pair (n,d), and properties of the solution x^{LS}.

For an unconstrained problem with $n > d$, the Gaussian width can be bounded as $\mathcal{W}^2(\mathcal{K}^{\text{LS}}) \precsim d$, and the complexity of the solving the sub-problem (25) can be bounded as d^3. Thus, the overall complexity of computing an ε-accurate solution scales as $\mathcal{O}(nd\log(d) + d^3)\log(1/\varepsilon)$, and the space required is $\mathcal{O}(d^2)$.

As will be shown in Section 3.2, in certain cases, the cone $\mathcal{K}^{\text{LS}}$ can have substantially lower complexity than the unconstrained case. For instance, if the solution is sparse, say with s non-zero entries and the least-squares program involves an ℓ_1-constraint, then we have $\mathcal{W}^2(\mathcal{K}^{\text{LS}}) \precsim s\log d$. Using a standard interior point method to solve the sketched problem, the total complexity for obtaining an ε-accurate solution is upper bounded by $\mathcal{O}((nd\log(s) + s^2 d\log^2(d))\log(1/\varepsilon))$. Although the sparsity s is not known a priori, there are bounds on it that can be computed in $\mathcal{O}(nd)$ time (for instance, see Ghaoui et al. (2011)).

3. Consequences for concrete models

In this section, we derive some consequences of Corollary 1 for particular classes of least-squares problems. Our goal is to provide empirical confirmation of the sharpness of our theoretical predictions, namely the minimal sketch dimension required in order to match the accuracy of the original least-squares solution.

3.1 Unconstrained least squares

We begin with the simplest case, namely the unconstrained least-squares problem ($\mathcal{C} = \mathbb{R}^d$). For a given pair (n,d) with $n > d$, we generated a random ensemble of least-square problems according to the following procedure:

- first, generate a random data matrix $A \in \mathbb{R}^{n\times d}$ with i.i.d. $N(0,1)$ entries
- second, choose a regression vector x^* uniformly at random from the sphere $\mathcal{S}^{d-1}$
- third, form the response vector $y = Ax^* + w$, where $w \sim N(0, \sigma^2 I_n)$ is observation noise with $\sigma = 1$.

As discussed following Lemma 1, for this class of problems, taking a sketch dimension $m \gtrsim \frac{d}{\rho^2}$ guarantees ρ-contractivity of the IHS iterates with high probability. Consequently, we can

obtain a ε-accurate approximation to the original least-squares solution by running roughly $\log(1/\varepsilon)/\log(1/\rho)$ iterations.

Now how should the tolerance ε be chosen? Recall that the underlying reason for solving the least-squares problem is to approximate x^*. Given this goal, it is natural to measure the approximation quality in terms of $\|x^t - x^*\|_A$. Panel (b) of Figure 2 shows the convergence of the iterates to x^*. As would be expected, this measure of error levels off at the ordinary least-squares error

$$\|x^{\mathrm{LS}} - x^*\|_A^2 \asymp \frac{\sigma^2 d}{n} \approx 0.10.$$

Consequently, it is reasonable to set the tolerance parameter proportional to $\sigma^2 \frac{d}{n}$, and then perform roughly $1 + \frac{\log(1/\varepsilon)}{\log(1/\rho)}$ steps. The following corollary summarizes the properties of the resulting procedure:

Corollary 2 *For some given $\rho \in (0, 1/2)$, suppose that we run the IHS algorithm for*

$$N = 1 + \lceil \frac{\log \sqrt{n}\, \frac{\|x^{LS}\|_A}{\sigma}}{\log(1/\rho)} \rceil$$

iterations using $m = \frac{c_0}{\rho^2} d$ projections per round. Then the output $\widehat{x}$ satisfies the bounds

$$\|\widehat{x} - x^{LS}\|_A \leq \sqrt{\frac{\sigma^2 d}{n}}, \qquad \text{and} \qquad \|x^N - x^*\|_A \leq \sqrt{\frac{\sigma^2 d}{n}} + \|x^{LS} - x^*\|_A \tag{30}$$

with probability greater than $1 - c_1 N e^{-c_2 \frac{m\rho^2}{\log^4(d)}}$.

In order to confirm the predicted bound (30) on the error $\|\widehat{x} - x^{\mathrm{LS}}\|_A$, we performed a second experiment. Fixing $n = 100d$, we generated $T = 20$ random least squares problems from the ensemble described above with dimension d ranging over $\{32, 64, 128, 256, 512\}$. By our previous choices, the least-squares estimate should have error $\|x^{\mathrm{LS}} - x^*\|_2 \approx \sqrt{\frac{\sigma^2 d}{n}} = 0.1$ with high probability, independently of the dimension d. This predicted behavior is confirmed by the blue bars in Figure 3; the bar height corresponds to the average over $T = 20$ trials, with the standard errors also marked. On these same problem instances, we also ran the IHS algorithm using $m = 6d$ samples per iteration, and for a total of

$$N = 1 + \lceil \frac{\log\left(\sqrt{\frac{n}{d}}\right)}{\log 2} \rceil \; = 4 \qquad \text{iterations.}$$

Since $\|x^{\mathrm{LS}} - x^*\|_A \asymp \sqrt{\frac{\sigma^2 d}{n}} \approx 0.10$, Corollary 2 implies that with high probability, the sketched solution $\widehat{x} = x^N$ satisfies the error bound

$$\|\widehat{x} - x^*\|_2 \leq c_0' \sqrt{\frac{\sigma^2 d}{n}}$$

for some constant $c_0' > 0$. This prediction is confirmed by the green bars in Figure 3, showing that $\|\widehat{x} - x^*\|_A \approx 0.11$ across all dimensions. Finally, the red bars show the results of running the classical sketch with a sketch dimension of $(6 \times 4)d = 24d$ sketches, corresponding to the total number of sketches used by the IHS algorithm. Note that the error is roughly twice as large.

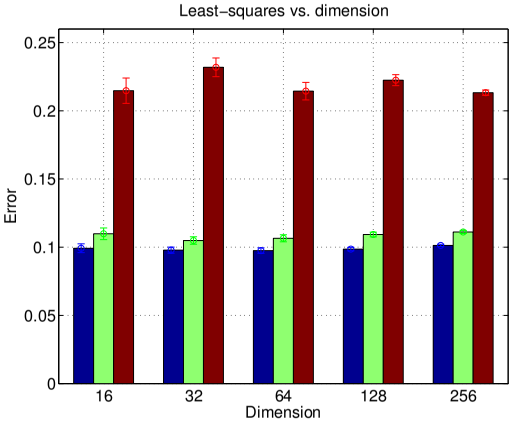


Figure 3. Simulations of the IHS algorithm for unconstrained least-squares. In these experiments, we generated random least-squares problem of dimensions $d \in \{16, 32, 64, 128, 256\}$, on all occasions with a fixed sample size $n = 100d$. The initial least-squares solution has error $\|x^{\mathrm{LS}} - x^*\|_A \approx 0.10$, as shown by the blue bars. We then ran the IHS algorithm for $N = 4$ iterations with a sketch size $m = 6d$. As shown by the green bars, these sketched solutions show an error $\|\widehat{x} - x^*\|_A \approx 0.11$ independently of dimension, consistent with the predictions of Corollary 2. Finally, the red bars show the error in the classical sketch, based on a sketch size $M = Nm = 24d$, corresponding to the total number of projections used in the iterative algorithm. This error is roughly twice as large.

3.2 Sparse least-squares

We now turn to a study of an ℓ_1-constrained form of least-squares, referred to as the Lasso or relaxed basis pursuit program (Chen et al., 1998; Tibshirani, 1996). In particular, consider the convex program

$$x^{\mathrm{LS}} = \arg \min_{\|x\|_1 \leq R} \{\frac{1}{2}\|y - Ax\|_2^2\}, \tag{31}$$

where $R > 0$ is a user-defined radius. This estimator is well-suited to the problem of sparse linear regression, based on the observation model $y = Ax^* + w$, where x^* has at most s non-zero entries, and $A \in \mathbb{R}^{n \times d}$ has i.i.d. $N(0, 1)$ entries. For the purposes of this illustration, we assume[3] that the radius is chosen such that $R = \|x^*\|_1$.

Under these conditions, the proof of Corollary 3 shows that a sketch size $m \geq \gamma\, s \log\left(\frac{ed}{s}\right)$ suffices to guarantee geometric convergence of the IHS updates. Panel (a) of Figure 4 illustrates the accuracy of this prediction, showing the resulting convergence rate of the the IHS

3. In practice, this unrealistic assumption of exactly knowing $\|x^*\|_1$ is avoided by instead considering the ℓ_1-penalized form of least-squares, but we focus on the constrained case to keep this illustration as simple as possible.

algorithm, measured in terms of the error $\|x^t - x^{\mathrm{LS}}\|_A$, for different values $\gamma \in \{2, 5, 25\}$. As predicted by Theorem 2, the convergence rate is geometric (linear on the log scale shown), with the rate increasing as the parameter γ is increased.

As long as $n \gtrsim s \log\left(\frac{ed}{s}\right)$, it also follows as a corollary of Proposition 2 that

$$\|x^{\mathrm{LS}} - x^*\|_A^2 \precsim \frac{\sigma^2 s \log\left(\frac{ed}{s}\right)}{n}. \tag{32}$$

with high probability. This bound suggests an appropriate choice for the tolerance parameter ε in Theorem 2, and leads us to the following guarantee.

Corollary 3 *For the stated random ensemble of sparse linear regression problems, suppose that we run the IHS algorithm for* $N = 1 + \lceil \frac{\log \sqrt{n}}{\log(1/\rho)} \frac{\|x^{LS}\|_A}{\sigma} \rceil$ *iterations using* $m = \frac{c_0}{\rho^2} s \log\left(\frac{ed}{s}\right)$ *projections per round. Then with probability greater than* $1 - c_1 N e^{-c_2 \frac{m\rho^2}{\log^4(d)}}$, *the output* $\widehat{x}$ *satisfies the bounds*

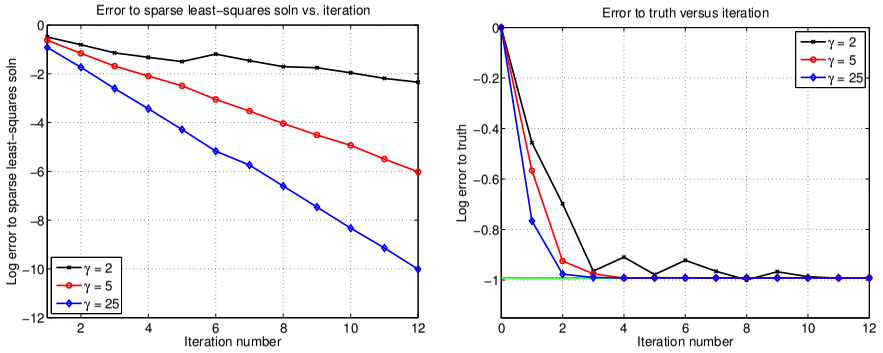
$$\|\widehat{x} - x^{LS}\|_A \leq \sqrt{\frac{\sigma^2 s \log\left(\frac{ed}{s}\right)}{n}} \qquad \text{and} \qquad \|x^N - x^*\|_A \leq \sqrt{\frac{\sigma^2 s \log\left(\frac{ed}{s}\right)}{n}} + \|x^{LS} - x^*\|_A. \tag{33}$$

In order to verify the predicted bound (33) on the error $\|\widehat{x} - x^{\mathrm{LS}}\|_A$, we performed a second experiment. Fixing $n = 100 s \log\left(\frac{ed}{s}\right)$. we generated $T = 20$ random least squares problems (as described above) with the regression dimension ranging as $d \in \{32, 64, 128, 256\}$, and sparsity $s = \lceil 2\sqrt{d} \rceil$. Based on these choices, the least-squares estimate should have error $\|x^{\mathrm{LS}} - x^*\|_A \approx \sqrt{\frac{\sigma^2 s \log\left(\frac{ed}{s}\right)}{n}} = 0.1$ with high probability, independently of the pair (s, d). This predicted behavior is confirmed by the blue bars in Figure 5; the bar height corresponds to the average over $T = 20$ trials, with the standard errors also marked.

On these same problem instances, we also ran the IHS algorithm using $N = 4$ iterations with a sketch size $m = 4 s \log\left(\frac{ed}{s}\right)$. Together with our earlier calculation of $\|x^{\mathrm{LS}} - x^*\|_A$, Corollary 2 implies that with high probability, the sketched solution $\widehat{x} = x^N$ satisfies the error bound

$$\|\widehat{x} - x^*\|_A \leq c_0 \sqrt{\frac{\sigma^2 s \log\left(\frac{ed}{s}\right)}{n}} \tag{34}$$

for some constant $c_0 \in (1, 2]$. This prediction is confirmed by the green bars in Figure 5, showing that $\|\widehat{x} - x^*\|_A \gtrsim 0.11$ across all dimensions. Finally, the green bars in Figure 5 show the error based on using the naive sketch estimate with a total of $M = Nm$ random projections in total; as with the case of ordinary least-squares, the resulting error is roughly twice as large. We also note that a similar bound also applies to problems where a parameter constrained to unit simplex is estimated, such as in portfolio analysis and density estimation (Markowitz, 1959; Pilanci et al., 2012).



(a) (b)

Figure 4. Simulations of the IHS algorithm for a sparse least-squares problem with noise variance $\sigma^2 = 1$, and of dimensions $(d, n, s) = (256, 8872, 32)$. Simulations based on sketch sizes $m = \gamma s \log d$, for a parameter $\gamma > 0$ to be set. (a) Plots of the log error $\|x^t - x^{\mathrm{LS}}\|_2$ versus the iteration number t. Three different curves for $\gamma \in \{2, 5, 25\}$. Consistent with the theory, the convergence is geometric, with the rate increasing as the sampling factor γ is increased. (b) Plots of the log error $\|x^t - x^*\|_2$ versus the iteration number t. Three different curves for $\gamma \in \{2, 5, 25\}$. As expected, all three curves flatten out at the level of the least-squares error $\|x^{\mathrm{LS}} - x^*\|_2 = 0.10 \approx \sqrt{\frac{s \log(ed/s)}{n}}$.

3.3 Some larger-scale experiments

In order to further explore the computational gains guaranteed by IHS, we performed some larger scale experiments on sparse regression problems, with the sample size n ranging over the set $\{2^{12}, 2^{13}, ..., 2^{19}\}$ with a fixed input dimension $d = 500$. As before, we generate observations from the linear model $y = Ax^* + w$, where x^* has at most s non-zero entries, and each row of the data matrix $A \in \mathbb{R}^{n \times d}$ is distributed i.i.d. according to a $N(1_d, \Sigma)$ distribution. Here the d-dimensional covariance matrix Σ has entries $\Sigma_{jk} = 2 \times 0.9^{|j-k|}$, so that the columns of the matrix A will be correlated. Setting a sparsity $s = \lceil 3 \log(d) \rceil$, we chose the unknown regression vector x^* with its support uniformly random with entries $\pm \frac{1}{\sqrt{s}}$ with equal probability.

Baseline: In order to provide a baseline for comparison, we used the homotopy algorithm—that is, the Lasso modification of the LARS updates (Osborne et al., 2000; Efron et al., 2004)—to solve the original ℓ_1 constrained problem with ℓ_1-ball radius $R = \sqrt{s}$. The homotopy algorithm is especially efficient when the Lasso solution x^{LS} is sparse. Since the columns of A are correlated in our ensemble, standard first-order algorithms—among them iterative soft-thresholding, FISTA, spectral projected gradient methods, as well as (block) coordinate descent methods, see, e.g., Beck and Teboulle (2009); Wu and Lange (2008)—performed poorly

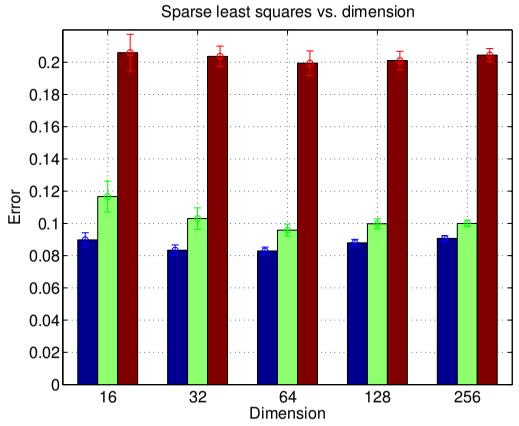


Figure 5. Simulations of the IHS algorithm for ℓ_1-constrained least-squares. In these experiments, we generated random sparse least-squares problem of dimensions $d \in \{16, 32, 64, 128, 256\}$ and sparsity $s = \lceil 2\sqrt{d} \rceil$, on all occasions with a fixed sample size $n = 100 s \log\left(\frac{ed}{s}\right)$. The initial Lasso solution has error $\|x^{\mathrm{LS}} - x^*\|_2 \approx 0.10$, as shown by the blue bars. We then ran the IHS algorithm for $N = 4$ iterations with a sketch size $m = 4s \log\left(\frac{ed}{s}\right)$. These sketched solutions show an error $\|\widehat{x} - x^*\|_A \approx 0.11$ independently of dimension, consistent with the predictions of Corollary 3. Red bars show the error in the naive sketch estimate, using a sketch of size $M = Nm = 16 s \log\left(\frac{ed}{s}\right)$, equal to the total number of random projections used by the IHS algorithm. The resulting error is roughly twice as large.

relative to the homotopy algorithm in terms of computation time; see Bach et al. (2011) for observations of this phenomenon in past work.

IHS implementation: For comparison, we implemented the IHS algorithm with a projection dimension $m = \lfloor 4s \log(d) \rfloor$. After projecting the data, we then used the homotopy method to solve the projected sub-problem at each step. In each trial, we ran the IHS algorithm for $N = \lceil \log n \rceil$ iterations.

Table 1 provides a summary comparison of the running times for the baseline method (homotopy method on the original problem), versus the IHS method (running time for computing the iterates using the homotopy method), and IHS method plus sketching time. Note that with the exception of the smallest problem size ($n = 4096$), the IHS method including sketching time is the fastest, and it is more than two times faster for large problems. The gains are somewhat more significant if we remove the sketching time from the comparison.

One way in which to measure the quality of the least-squares solution x^{LS} as an estimate of x^* is via its mean-squared (in-sample) prediction error $\|x^{\mathrm{LS}} - x^*\|_A^2 = \frac{\|A(x^{\mathrm{LS}} - x^*)\|_2^2}{n}$. For the random ensemble of problems that we have generated, the bound (34) guarantees that the squared error should decay at the rate $1/n$ as the sample size n is increased with the

Samples n	4096	8192	16384	32768	65536	131072	262144	524288
Baseline	0.0840	0.1701	0.3387	0.6779	1.4083	2.9052	6.0163	12.0969
IHS	0.0783	0.0993	0.1468	0.2174	0.3601	0.6846	1.4748	3.1593
IHS+Sketch	0.0877	0.1184	0.1887	0.3222	0.5814	1.1685	2.5967	5.5792

Table 1. Running time comparison in seconds of the Baseline (homotopy method applied to original problem), IHS (homotopy method applied to sketched subproblems), and IHS plus sketching time. Each running time estimate corresponds to an average over 300 independent trials of the random sparse regression model described in the main text.

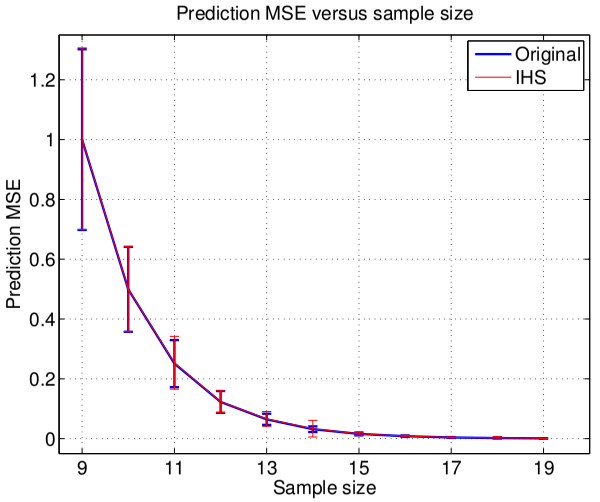

Figure 6. Plots of the mean-squared prediction errors $\frac{\|A(\widetilde{x} - x^*)\|_2^2}{n}$ versus the sample size $n \in 2^{\{9,10,\ldots,19\}}$ for the original least-squares solution ($\widetilde{x} = x^{\mathrm{LS}}$ in blue) versus the sketched solution ($\widehat{x} = x^{\mathrm{LS}}$ in red). Each point on each curve corresponds to the average over 300 independent trials of the same type used to generate the data in Table 1; the error bars correspond to one standard errors. In generating the plots, all errors have been renormalized so that the error for sample size $n = 2^9$ is equal to one. As can be seen, the sketched method generates solutions with prediction MSE that are essentially indistinguishable from the original solution.

dimension d and sparsity s fixed. Figure 6 compares the prediction MSE of x^{LS} versus the analogous quantity $\|\widehat{x} - x^*\|_A^2$ for the sketched solution. Note that the two curves are essentially indistinguishable, showing that the sketched solution provides an estimate of x^* that is as good as the original least-squares estimate.

3.4 Matrix estimation with nuclear norm constraints

We now turn to the study of nuclear-norm constrained form of least-squares matrix regression. This class of problems has proven useful in many different application areas, among them matrix completion, collaborative filtering, multi-task learning and control theory (e.g., (Fazel, 2002; Yuan et al., 2007; Bach, 2008; Recht et al., 2010; Negahban and Wainwright, 2012)). In particular, let us consider the convex program

$$X^{\mathrm{LS}} = \arg \min_{X \in \mathbb{R}^{d_1 \times d_2}} \left\{ \frac{1}{2} \|Y - AX\|_{\mathrm{fro}}^2 \right\} \qquad \text{such that } \|X\|_{\mathrm{nuc}} \leq R, \tag{35}$$

where $R > 0$ is a user-defined radius as a regularization parameter.

3.4.1 Simulated data

Recall the linear observation model previously introduced in Example 3: we observe the pair (Y, A) linked according to the linear $Y = AX^* + W$, where the unknown matrix $X^* \in \mathbb{R}^{d_1 \times d_2}$ is an unknown matrix of rank r. The matrix W is observation noise, formed with i.i.d. $N(0, \sigma^2)$ entries. This model is a special case of the more general class of matrix regression problems (Negahban and Wainwright, 2012). As shown in Appendix D.2, if we solve the nuclear-norm constrained problem with $R = \|X^*\|_{\mathrm{nuc}}$, then it produces a solution such that $\mathbb{E}\big[\|X^{\mathrm{LS}} - X^*\|_{\mathrm{fro}}^2\big] \precsim \sigma^2 \frac{r\,(d_1+d_2)}{n}$. The following corollary characterizes the sketch dimension and iteration number required for the IHS algorithm to match this scaling up to a constant factor.

Corollary 4 (IHS for nuclear-norm constrained least squares) *Suppose that we run the IHS algorithm for* $N = 1 + \lceil \frac{\log \sqrt{n}}{\log(1/\rho)} \frac{\|X^{LS}\|_A}{\sigma} \rceil$ *iterations using* $m = c_0 \rho^2 r\big(d_1 + d_2\big)$ *projections per round. Then with probability greater than* $1 - c_1\, N\, e^{-c_2 \frac{m\rho^2}{\log^4(d_1 d_2)}}$, *the output* X^N *satisfies the bound*

$$\|X^N - X^*\|_A \leq \sqrt{\frac{\sigma^2 r\big(d_1 + d_2\big)}{n}} + \|X^{LS} - X^*\|_A. \tag{36}$$

We have also performed simulations for low-rank matrix estimation, and observed that the IHS algorithm exhibits convergence behavior qualitatively similar to that shown in Figures 3 and 5. Similarly, panel (a) of Figure 8 compares the performance of the IHS and classical methods for sketching the optimal solution over a range of row sizes n. As with the unconstrained least-squares results from Figure 1, the classical sketch is very poor compared to the original solution whereas the IHS algorithm exhibits near optimal performance.

3.4.2 Application to multi-task learning

To conclude, let us illustrate the use of the IHS algorithm in speeding up the training of a classifier for facial expressions. In particular, suppose that our goal is to separate a collection of facial images into different groups, corresponding either to distinct individuals or to different facial expressions. One approach would be to learn a different linear classifier $(a \mapsto \langle a, x \rangle)$

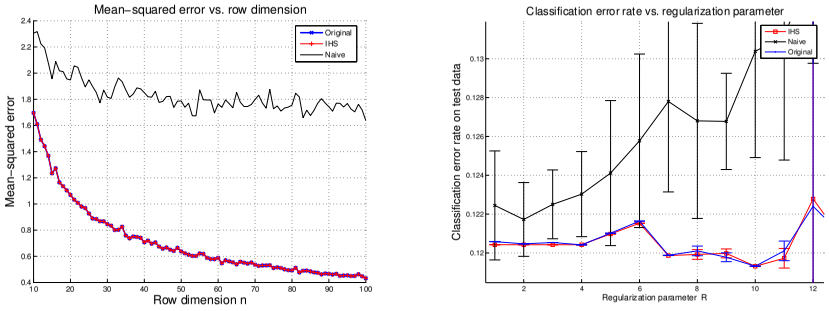
for each separate task, but since the classification problems are so closely related, the optimal classifiers are likely to share structure. One way of capturing this shared structure is by concatenating all the different linear classifiers into a matrix, and then estimating this matrix in conjunction with a nuclear norm penalty (Amit et al., 2007; Argyriou et al., 2008).

Figure 7. Japanese Female Facial Expression (JAFFE) Database: The JAFFE database consists of 213 images of 7 different emotional facial expressions (6 basic facial expressions + 1 neutral) posed by 10 Japanese female models.

In more detail, we performed a simulation study using the The Japanese Female Facial Expression (JAFFE) database (Lyons et al., 1998). It consists of $N = 213$ images of 7 facial expressions (6 basic facial expressions + 1 neutral) posed by 10 different Japanese female models; see Figure 7 for a few example images. We performed an approximately $80:20$ split of the data set into $n_{\mathrm{train}} = 170$ training and $n_{\mathrm{test}} = 43$ test images respectively. Then we consider classifying each facial expression and each female model as a separate task which gives a total of $d_{\mathrm{task}} = 17$ tasks. For each task $j = 1, \ldots, d_{\mathrm{task}}$, we construct a linear classifier of the form $a \mapsto \mathrm{sign}(\langle a, x_j \rangle)$, where $a \in \mathbb{R}^d$ denotes the vectorized image features given by Local Phase Quantization (Ojansivu and Heikkil, 2008). In our implementation, we fixed the number of features $d = 32$. Given this set-up, we train the classifiers in a joint manner, by optimizing simultaneously over the matrix $X \in \mathbb{R}^{d \times d_{\mathrm{task}}}$ with the classifier vector $x_j \in \mathbb{R}^d$ as its j^{th} column. The image data is loaded into the matrix $A \in \mathbb{R}^{n_{\mathrm{train}} \times d}$, with image feature vector $a_i \in \mathbb{R}^d$ in column i for $i = 1, \ldots, n_{\mathrm{train}}$. Finally, the matrix $Y \in \{-1, +1\}^{n_{\mathrm{train}} \times d_{\mathrm{task}}}$ encodes class labels for the different classification problems. These instantiations of the pair (Y, X) give us an optimization problem of the form (35), and we solve it over a range of regularization radii R.

More specifically, in order to verify the classification accuracy of the classifier obtained by IHT algorithm, we solved the original convex program, the classical sketch based on ROS sketches of dimension $m = 100$, and also the corresponding IHS algorithm using ROS sketches of size 20 in each of 5 iterations. In this way, both the classical and IHS procedures use the same total number of sketches, making for a fair comparison. We repeated each of these three procedures for all choices of the radius $R \in \{1, 2, 3, \ldots, 12\}$, and then applied the resulting classifiers to classify images in the test dataset. For each of the three procedures, we calculated the classification error rate, defined as the total number of mis-classified images divided by $n_{\mathrm{test}} \times d_{\mathrm{task}}$. Panel (b) of Figure 8 plots the resulting classification errors versus the regularization parameter. The error bars correspond to one standard deviation calculated

over the randomness in generating sketching matrices. The plots show that the IHS algorithm yields classifiers with performance close to that given by the original solution over a range of regularizer parameters, and is superior to the classification sketch. The error bars also show that the IHS algorithm has less variability in its outputs than the classical sketch.



(a) (b)

Figure 8. Simulations of the IHS algorithm for nuclear-norm constrained problems. The blue curves correspond to the solution of the original (unsketched problem), whereas red curves correspond to the IHS method applied for $N = 1 + \lceil \log(n) \rceil$ rounds using a sketch size of m. Black curves correspond to the naive sketch applied using $M = Nm$ projections in total, corresponding to the same number used in all iterations of the IHS algorithm. (a) Mean-squared error versus the row dimension $n \in [10, 100]$ for recovering a 20×20 matrix of rank $r2$, using a sketch dimension $m = 60$. Note how the accuracy of the IHS algorithm tracks the error of the unsketched solution over a wide range of n, whereas the classical sketch has essentially constant error. (b) Classification error rate versus regularization parameter $R \in \{1, \ldots, 12\}$, with error bars corresponding to one standard deviation over the test set. Sketching algorithms were applied to the JAFFE face expression using a sketch dimension of $M = 100$ for the classical sketch, and $N = 5$ iterations with $m = 20$ sketches per iteration for the IHS algorithm.

4. Discussion

In this paper, we focused on the problem of solution approximation (as opposed to cost approximation) for a broad class of constrained least-squares problem. We began by showing that the classical sketching methods are sub-optimal, from an information-theoretic point of view, for the purposes of solution approximation. We then proposed a novel iterative scheme, known as the iterative Hessian sketch, for deriving ε-accurate solution approximations. We proved a general theorem on the properties of this algorithm, showing that the sketch dimension per iteration need grow only proportionally to the statistical dimension of the optimal solution, as measured by the Gaussian width of the tangent cone at the optimum. By taking $\log(1/\varepsilon)$ iterations, the IHS algorithm is guaranteed to return an ε-accurate solution approximation with exponentially high probability.

In addition to these theoretical results, we also provided empirical evaluations that reveal the sub-optimality of the classical sketch, and show that the IHS algorithm produces near-optimal estimators. Finally, we applied our methods to a problem of facial expression using a multi-task learning model applied to the JAFFE face database. We showed that IHS algorithm applied to a nuclear-norm constrained program produces classifiers with considerably better classification accuracy compared to the naive sketch.

There are many directions for further research, but we only list here some of them. The idea behind iterative sketching can also be applied to problems beyond minimizing a least-squares objective function subject to convex constraints. Examples include penalized forms of regression, e.g., see the recent work (Yang et al., 2015), and various other cost functions. An important class of such problems are ℓ_p-norm forms of regression, based on the convex program

$$\min_{x \in \mathbb{R}^d} \|Ax - y\|_p^p \qquad \text{for some } p \in [1, \infty].$$

The case of ℓ_1-regression ($p = 1$) is an important special case, known as robust regression; it is especially effective for data sets containing outliers (Huber, 2001). Recent work (Clarkson et al., 2013) has proposed to find faster solutions of the ℓ_1-regression problem using the classical sketch (i.e., based on (SA, Sy)) but with sketching matrices based on Cauchy random vectors. Based on the results of the current paper, our iterative technique might be useful in obtaining sharper bounds for solution approximation in this setting as well. Finally, we refer the reader to the more recent work (Pilanci and Wainwright, 2015b) on sketching for general convex objective functions.

Appendix A. Proof of lower bounds

This appendix is devoted to the verification of condition (9) for different model classes, followed by the proof of Theorem 1.

A.1 Verification of condition (9)

We verify the condition for three different types of sketches.

A.1.1 Gaussian sketches:

First, let $S \in \mathbb{R}^{m \times n}$ be a random matrix with i.i.d. Gaussian entries. We use the singular value decomposition to write $S = U \Lambda V^T$ where both U and V are orthonormal matrices of left and right singular vectors. By rotation invariance, the columns $\{v_i\}_{i=1}^m$ are uniformly

distributed over the sphere $\mathcal{S}^{n-1}$. Consequently, we have

$$\mathbb{E}_S\big[S^T\big(SS^T\big)^{-1}S\big] = \mathbb{E}\sum_{i=1}^m v_i v_i^T = \frac{m}{n} I_n, \tag{37}$$

showing that condition (9) holds with $\eta = 1$.

A.1.2 ROS sketches (sampled without replacement):

In this case, we have $S = \sqrt{n}PHD$, where $P \in \mathbb{R}^{m\times n}$ is a random picking matrix with each row being a standard basis vector sampled without replacement. We then have $SS^T = nI_m$ and also $\mathbb{E}_P[P^TP] = \frac{m}{n}I_n$, so that

$$\mathbb{E}_S[S^T(SS^T)^{-1}S] = \mathbb{E}_{D,P}[DH^TP^TPHD] = \mathbb{E}_D[DH^T(\frac{m}{n}I_n)HD] = \frac{m}{n}I_n,$$

showing that the condition holds with $\eta = 1$.

A.1.3 Weighted row sampling:

Finally, suppose that we sample m rows independently using a distribution $\{p_j\}_{j=1}^n$ on the rows of the data matrix that is α-balanced (7). Letting $\mathcal{R} \subseteq \{1, 2, \ldots, n\}$ be the subset of rows that are sampled, and let N_j be the number of times each row is sampled. We then have

$$\mathbb{E}\Big[S^T\big(SS^T\big)^{-1}S\Big] = \sum_{j\in\mathcal{R}} \mathbb{E}[e_j e_j^T] \;=\; D,$$

where $D \in \mathbb{R}^{n\times n}$ is a diagonal matrix with entries $D_{jj} = \mathbb{P}[j \in \mathcal{R}]$. Since the trials are independent, the j^{th} row is sampled at least once in m trials with probability $q_j = 1-(1-p_j)^m$, and hence

$$\mathbb{E}_S\big[S^T\big(SS^T\big)^{-1}S\big] = \operatorname{diag}\big(\{1-(1-p_i)^m\}_{i=1}^m\big) \;\preceq\; \big(1-(1-p_\infty)^m\big)I_n \;\preceq mp_\infty,$$

where $p_\infty = \max_{j\in[n]} p_j$. Consequently, as long as the row weights are α-balanced (7) so that $p_\infty \le \frac{\alpha}{n}$, we have

$$\big\|\mathbb{E}_S\big[S^T\big(SS^T\big)^{-1}S\big]\big\|_{\text{op}} \le \alpha\frac{m}{n}$$

showing that condition (9) holds with $\eta = \alpha$, as claimed.

A.2 Proof of Theorem 1

Let $\{z^j\}_{j=1}^M$ be a 1/2-packing of $\mathcal{C}_0 \cap \mathbb{B}_A(1)$ in the semi-norm $\|\cdot\|_A$, and for a fixed $\delta \in (0, 1/4)$, define $x^j = 4\delta z^j$. Sine $4\delta \in (0,1)$, the star-shaped assumption guarantees that each x^j belongs to $\mathcal{C}_0$. We thus obtain a collection of M vectors in $\mathcal{C}_0$ such that

$$2\delta \le \underbrace{\frac{1}{\sqrt{n}}\|A(x^j - x^k)\|_2}_{\|x^j-x^k\|_A} \le 8\delta \qquad \text{for all } j \neq k.$$

Letting J be a random index uniformly distributed over $\{1, \ldots, M\}$, suppose that conditionally on $J = j$, we observe the sketched observation vector $Sy = SAx^j + Sw$, as well as the sketched matrix SA. Conditioned on $J = j$, the random vector Sy follows a $\mathcal{N}(SAx^j, \sigma^2 SS^T)$ distribution, denoted by $\mathbb{P}_{x^j}$. We let $\overline{Y}$ denote the resulting mixture variable, with distribution $\frac{1}{M}\sum_{j=1}^M \mathbb{P}_{x^j}$.

Consider the multiway testing problem of determining the index J based on observing $\overline{Y}$. With this set-up, a standard reduction in statistical minimax (e.g., (Birgé, 1987; Yu, 1997)) implies that, for any estimator $x^\dagger$, the worst-case mean-squared error is lower bounded as

$$\sup_{x^*\in\mathcal{C}} \mathbb{E}_{S,w}\|x^\dagger - x^*\|_A^2 \ge \delta^2 \inf_\psi \mathbb{P}[\psi(\overline{Y}) \neq J], \tag{38}$$

where the infimum ranges over all testing functions ψ. Consequently, it suffices to show that the testing error is lower bounded by 1/2.

In order to do so, we first apply Fano's inequality (Cover and Thomas, 1991) conditionally on the sketching matrix S to see that

$$\mathbb{P}[\psi(\overline{Y}) \neq J] \;=\; \mathbb{E}_S\Big\{\mathbb{P}[\psi(\overline{Y}) \neq J \mid S]\Big\} \ge 1 - \frac{\mathbb{E}_S\big[I_S(\overline{Y}; J)\big] + \log 2}{\log M}, \tag{39}$$

where $I_S(\overline{Y}; J)$ denotes the mutual information between $\overline{Y}$ and J with S fixed. Our next step is to upper bound the expectation $\mathbb{E}_S[I(\overline{Y}; J)]$.

Letting $D(\mathbb{P}_{x^j} \,\|\, \mathbb{P}_{x^k})$ denote the Kullback-Leibler divergence between the distributions $\mathbb{P}_{x^j}$ and $\mathbb{P}_{x^k}$, the convexity of Kullback-Leibler divergence implies that

$$I_S(\overline{Y}; J) = \frac{1}{M}\sum_{j=1}^M D(\mathbb{P}_{x^j} \,\|\, \frac{1}{M}\sum_{k=1}^M \mathbb{P}_{x^k}) \;\le\; \frac{1}{M^2}\sum_{j,k=1}^M D(\mathbb{P}_{x^j} \,\|\, \mathbb{P}_{x^k}).$$

Computing the KL divergence for Gaussian vectors yields

$$I_S(\overline{Y}; J) \le \frac{1}{M^2}\sum_{j,k=1}^M \frac{1}{2\sigma^2}(x^j - x^k)^T A^T\Big[S^T(SS^T)^{-1}S\Big]A(x^j - x^k).$$

Thus, using condition (9), we have

$$\mathbb{E}_S[I(\overline{Y}; J)] \le \frac{1}{M^2}\sum_{j,k=1}^M \frac{m\,\eta}{2\,n\sigma^2}\|A(x^j - x^k)\|_2^2 \;\le \frac{32\,m\,\eta}{\sigma^2}\,\delta^2,$$

where the final inequality uses the fact that $\|x^j - x^k\|_A \le 8\delta$ for all pairs.

Combined with our previous bounds (38) and (39), we find that

$$\sup_{x^*\in\mathcal{C}} \mathbb{E}\|\widehat{x} - x^*\|_2^2 \ge \delta^2\Big\{1 - \frac{32\frac{m\,\eta\,\delta^2}{\sigma^2} + \log 2}{\log M}\Big\}.$$

Setting $\delta = \frac{\sigma^2\log(M/2)}{64\,\eta\,m}$ yields the lower bound (10).

Appendix B. Proof of Proposition 1

Since $\widehat{x}$ and x^{LS} are optimal and feasible, respectively, for the Hessian sketch program (16), we have

$$\langle A^T S^T \big(SA\widehat{x} - y\big),\, x^{\mathrm{LS}} - \widehat{x}\rangle \geq 0 \tag{40a}$$

Similarly, since x^{LS} and $\widehat{x}$ are optimal and feasible, respectively, for the original least squares program

$$\langle A^T(Ax^{\mathrm{LS}} - y),\, \widehat{x} - x^{\mathrm{LS}}\rangle \geq 0. \tag{40b}$$

Adding these two inequalities and performing some algebra yields the basic inequality

$$\frac{1}{m}\|SA\Delta\|_2^2 \leq \Big|(Ax^{\mathrm{LS}})^T\big(I_n - \frac{S^TS}{m}\big)A\Delta\Big|. \tag{41}$$

Since Ax^{LS} is independent of the sketching matrix and $A\Delta \in \mathcal{K}^{\mathrm{LS}}$, we have

$$\frac{1}{m}\|SA\Delta\|_2^2 \geq Z_1\,\|A\Delta\|_2^2, \qquad \text{and} \quad \Big|(Ax^{\mathrm{LS}})^T\big(I_n - S^TS\big)A\Delta\Big| \leq Z_2\|Ax^{\mathrm{LS}}\|_2\,\|A\Delta\|_2,$$

using the definitions (18a) and (18b) of the random variables Z_1 and Z_2 respectively. Combining the pieces yields the claim.

Appendix C. Proof of Theorem 2

It suffices to show that, for each iteration $t = 0, 1, 2, \ldots$, we have

$$\|x^{t+1} - x^{\mathrm{LS}}\|_A \leq \frac{Z_2(S^{t+1})}{Z_1(S^{t+1})}\|x^t - x^{\mathrm{LS}}\|_A. \tag{42}$$

The claimed bounds (27a) and (27b) then follow by applying the bound (42) successively to iterates 1 through N.

For simplicity in notation, we abbreviate S^{t+1} to S and x^{t+1} to $\widehat{x}$. Define the error vector $\Delta = \widehat{x} - x^{\mathrm{LS}}$. With some simple algebra, the optimization problem (25) that underlies the update $t+1$ can be re-written as

$$\widehat{x} = \arg\min_{x\in\mathcal{C}}\Big\{\frac{1}{2m}\|SAx\|_2^2 - \langle A^T\widetilde{y},\, x\rangle\Big\},$$

where $\widetilde{y} := y - \Big[I - \frac{S^TS}{m}\Big]Ax^t$. Since $\widehat{x}$ and x^{LS} are optimal and feasible respectively, the usual first-order optimality conditions imply that

$$\langle A^T\frac{S^TS}{m}Ax - A^T\widetilde{y},\, x^{\mathrm{LS}} - \widehat{x}\rangle \geq 0.$$

As before, since x^{LS} is optimal for the original program, we have

$$\langle A^T(Ax^{\mathrm{LS}} - \widetilde{y} + \Big[I - \frac{S^TS}{m}\Big]Ax^t),\, \widehat{x} - x^{\mathrm{LS}}\rangle \geq 0.$$

Adding together these two inequalities and introducing the shorthand $\Delta = \widehat{x} - x^{\mathrm{LS}}$ yields

$$\frac{1}{m}\|SA\Delta\|_2^2 \leq \Big|(A(x^{\mathrm{LS}} - x^t)^T\big[I - \frac{S^TS}{m}\big]A\Delta\Big| \tag{43}$$

Note that the vector $A(x^{\mathrm{LS}} - x^t)$ is independent of the randomness in the sketch matrix S^{t+1}. Moreover, the vector $A\Delta$ belongs to the cone $\mathcal{K}$, so that by the definition of $Z_2(S^{t+1})$, we have

$$\Big|(A(x^{\mathrm{LS}} - x^t)^T\Big[I - \frac{S^TS}{m}\Big]A\Delta\Big| \leq \|A(x^{\mathrm{LS}} - x^t)\|_2\,\|A\Delta\|_2\,Z_2(S^{t+1}). \tag{44a}$$

Similarly, note the lower bound

$$\frac{1}{m}\|SA\Delta\|_2^2 \geq \|A\Delta\|_2^2\,Z_1(S^{t+1}). \tag{44b}$$

Combining the two bounds (44a) and (44b) with the earlier bound (43) yields the claim (42).

Appendix D. Maximum likelihood estimator and examples

In this section, we a general upper bound on the error of the constrained least-squares estimate. We then use it (and other results) to work through the calculations underlying Examples 1 through 3 from Section 2.2.

D.1 Upper bound on MLE

The accuracy of x^{LS} as an estimate of x^* depends on the "size" of the star-shaped set

$$\mathcal{K}(x^*) = \big\{v \in \mathbb{R}^d \mid v = \frac{t}{\sqrt{n}}A(x - x^*) \quad \text{for some } t \in [0,1] \text{ and } x \in \mathcal{C}\big\}. \tag{45}$$

When the vector x^* is clear from context, we use the shorthand notation $\mathcal{K}^*$ for this set. By taking a union over all possible $x^* \in \mathcal{C}_0$, we obtain the set $\overline{\mathcal{K}} := \bigcup_{x^*\in\mathcal{C}_0}\mathcal{K}(x^*)$, which plays an important role in our bounds. The complexity of these sets can be measured of their *localized Gaussian widths*. For any radius $\varepsilon > 0$ and set $\Theta \subseteq \mathbb{R}^n$, the Gaussian width of the set $\Theta \cap \mathbb{B}_2(\varepsilon)$ is given by

$$\mathcal{W}_\varepsilon(\Theta) := \mathbb{E}_g\Big[\sup_{\substack{\theta\in\Theta\\ \|\theta\|_2\leq\varepsilon}}|\langle w,\, \theta\rangle|\Big], \tag{46a}$$

where $g \sim N(0, I_{n\times n})$ is a standard Gaussian vector. Whenever the set Θ is star-shaped, then it can be shown that, for any $\sigma > 0$ and positive integer ℓ, the inequality

$$\frac{\mathcal{W}_\varepsilon(\Theta)}{\varepsilon\sqrt{\ell}} \leq \frac{\varepsilon}{\sigma} \tag{46b}$$

has a smallest positive solution, which we denote by $\varepsilon_\ell(\Theta;\sigma)$. We refer the reader to Bartlett et al. (2005) for further discussion of such localized complexity measures and their properties. The following result bounds the mean-squared error associated with the constrained least-squares estimate:

Proposition 2 *For any set $\mathcal{C}$ containing x^*, the constrained least-squares estimate* (1) *has mean-squared error upper bounded as*

$$\mathbb{E}_w\big[\|x^{LS} - x^*\|_A^2\big] \leq c_1\big\{\varepsilon_n^2(\mathcal{K}^*) + \frac{\sigma^2}{n}\big\} \;\leq\; c_1\big\{\varepsilon_n^2(\overline{\mathcal{K}}) + \frac{\sigma^2}{n}\big\}. \tag{47}$$

We provide the proof of this claim in Section D.3.

D.2 Detailed calculations for illustrative examples

In this appendix, we collect together the details of calculations used in our illustrative examples from Section 2.2. In all cases, we make use tof the convenient shorthand $\widetilde{A} = A/\sqrt{n}$.

D.2.1 Unconstrained least squares: Example 1

By definition of the Gaussian width, we have

$$\mathcal{W}_\delta(\mathcal{K}^*) = \mathbb{E}_g\big[\sup_{\|\widetilde{A}(x-x^*)\|_2 \leq \delta} |\langle g,\, \widetilde{A}(x - x^*)\rangle|\big] \;\leq\; \delta\sqrt{d}$$

since the vector $\widetilde{A}(x - x^*)$ belongs to a subspace of dimension $\operatorname{rank}(A) = d$. The claimed upper bound (11a) thus follows as a consequence of Proposition 2.

D.2.2 Sparse vectors: Example 2

The RIP property of order $8s$ implies that

$$\frac{\|\Delta\|_2^2}{2} \overset{(i)}{\leq} \|\widetilde{A}\Delta\|_2^2 \overset{(ii)}{\leq} 2\|\Delta\|_2^2 \qquad \text{for all vectors with } \|\Delta\|_0 \leq 8s,$$

a fact which we use throughout the proof. By definition of the Gaussian width, we have

$$\mathcal{W}_\delta(\mathcal{K}^*) = \mathbb{E}_g\big[\sup_{\substack{\|x\|_1 \leq \|x^*\|_1 \\ \|\widetilde{A}(x-x^*)\|_2 \leq \delta}} |\langle g,\, \widetilde{A}(x - x^*)\rangle|\big].$$

Since $x^* \in \mathbb{B}_0(s)$, it can be shown (e.g., see the proof of Corollary 3 in Pilanci and Wainwright (2015a)) that for any vector $\|x\|_1 \leq \|x^*\|_1$, we have $\|x - x^*\|_1 \leq 2\sqrt{s}\|x - x^*\|_2$. Thus, it suffices to bound the quantity

$$F(\delta; s) := \mathbb{E}_g\big[\sup_{\substack{\|\Delta\|_1 \leq 2\sqrt{s}\|\Delta\|_2 \\ \|\widetilde{A}\Delta\|_2 \leq \delta}} |\langle g,\, \widetilde{A}\Delta\rangle|\big].$$

By Lemma 11 in Loh and Wainwright (2012), we have

$$\mathbb{B}_1(\sqrt{s}) \cap \mathbb{B}_2(1) \subseteq 3\,\mathrm{clconv}\Big\{\mathbb{B}_0(s) \cap \mathbb{B}_2(1)\Big\},$$

where clconv denotes the closed convex hull. Applying this lemma with $s = 4s$, we have

$$F(\delta; s) \leq 3\big[\sup_{\substack{\|\Delta\|_0 \leq 4s \\ \|\widetilde{A}\Delta\|_2 \leq \delta}} |\langle g,\, \widetilde{A}\Delta\rangle|\big] \;\leq\; 3\mathbb{E}\big[\sup_{\substack{\|\Delta\|_0 \leq 4s \\ \|\Delta\|_2 \leq 2\delta}} |\langle g,\, \widetilde{A}\Delta\rangle|\big],$$

using the lower RIP property (i). By the upper RIP property, for any pair of vectors Δ, Δ' with ℓ_0-norms at most $4s$, we have

$$\operatorname{var}\big(\langle g,\, \widetilde{A}\Delta\rangle - \langle g,\, \widetilde{A}\Delta'\rangle\big) \leq 2\|\Delta - \Delta'\|_2^2 \;=\; 2\operatorname{var}\big(\langle g,\, \Delta - \Delta'\rangle\big)$$

Consequently, by the Sudakov-Fernique comparison (Ledoux and Talagrand, 1991), we have

$$\mathbb{E}\big[\sup_{\substack{\|\Delta\|_0 \leq 4s \\ \|\Delta\|_2 \leq 2\delta}} |\langle g,\, \widetilde{A}\Delta\rangle|\big] \leq 2\mathbb{E}\big[\sup_{\substack{\|\Delta\|_0 \leq 4s \\ \|\Delta\|_2 \leq 2\delta}} |\langle g,\, \Delta\rangle|\big] \;\leq c\,\delta\sqrt{s\log\big(\frac{ed}{s}\big)},$$

where the final inequality standard results on Gaussian widths (Gordon et al., 2007). All together, we conclude that

$$\varepsilon_n^2(\mathcal{K}^*; \sigma) \leq c_1\sigma^2\frac{s\log\big(\frac{ed}{s}\big)}{n}.$$

Combined with Proposition 2, the claimed upper bound (12a) follows.

In the other direction, a straightforward argument (e.g., Raskutti et al. (2011)) shows that there is a universal constant $c > 0$ such that $\log M_{1/2} \geq c\,s\log\big(\frac{ed}{s}\big)$, so that the stated lower bound follows from Theorem 1.

D.2.3 Low rank matrices: Example 3:

By definition of the Gaussian width, we have width, we have

$$\mathcal{W}_\delta(\mathcal{K}^*) = \mathbb{E}_g\left[\sup_{\substack{\|\widetilde{A}(X-X^*)\|_{\mathrm{fro}} \leq \delta \\ \|X\|_{\mathrm{nuc}} \leq \|X^*\|_{\mathrm{nuc}}}} |\langle\!\langle \widetilde{A}^T G,\; (X - X^*)\rangle\!\rangle|\right],$$

where $G \in \mathbb{R}^{n\times d_2}$ is a Gaussian random matrix, and $\langle\!\langle C,\; D\rangle\!\rangle$ denotes the trace inner product between matrices C and D. Since X^* has rank at most r, it can be shown that $\|X - X^*\|_{\mathrm{nuc}} \leq 2\sqrt{r}\|X - X^*\|_{\mathrm{fro}}$; for instance, see Lemma 1 in Negahban and Wainwright (2011). Recalling that $\gamma_{\min}(\widetilde{A})$ denotes the minimum singular value, we have

$$\|X - X^*\|_{\mathrm{fro}} \leq \frac{1}{\gamma_{\min}(\widetilde{A})}\|\widetilde{A}(X - X^*)\|_{\mathrm{fro}} \leq \frac{\delta}{\gamma_{\min}(\widetilde{A})}.$$

Thus, by duality between the nuclear and operator norms, we have

$$\mathbb{E}_g\left[\sup_{\substack{\|\widetilde{A}(X-X^*)\|_{\mathrm{fro}} \leq \delta \\ \|X\|_{\mathrm{nuc}} \leq \|X^*\|_{\mathrm{nuc}}}} |\langle\!\langle G,\; \widetilde{A}(X - X^*)\rangle\!\rangle|\right] \leq \frac{2\sqrt{r}\,\delta}{\gamma_{\min}(A)}\,\mathbb{E}\big[\|\widetilde{A}^T G\|_{\mathrm{op}}\big].$$

Now consider the matrix $A^T G \in \mathbb{R}^{d_1\times d_2}$. For any fixed pair of vectors $(u, v) \in \mathcal{S}^{d_1-1} \times \mathcal{S}^{d_2-1}$, the random variable $Z = u^T\widetilde{A}^T G v$ is zero-mean Gaussian with variance at most $\gamma_{\max}^2(\widetilde{A})$. Consequently, by a standard covering argument in random matrix theory Vershynin (2012), we have $\mathbb{E}\big[\|\widetilde{A}^T G\|_{\mathrm{op}}\big] \precsim \gamma_{\max}(\widetilde{A})\big(\sqrt{d_1 + d_2}\big)$. Putting together the pieces, we conclude that

$$\varepsilon_n^2 \preceq \sigma^2\,\frac{\gamma_{\max}^2(A)}{\gamma_{\min}^2(A)}\,r\,(d_1 + d_2),$$

so that the upper bound (15a) follows from Proposition 2.

D.3 Proof of Proposition 2

Throughout this proof, we adopt the shorthand $\varepsilon_n = \varepsilon_n(\mathcal{K}^*)$. Our strategy is to prove the following more general claim: for any $t \geq \varepsilon_n$, we have

$$\mathbb{P}_{S,w}\big[\|x^{\mathrm{LS}} - x^*\|_A^2 \geq 16 t\varepsilon_n\big] \leq c_1 e^{-c_2 \frac{nt\varepsilon_n}{\sigma^2}}. \tag{48}$$

A simple integration argument applied to this tail bound implies the claimed bound (47) on the expected mean-squared error.

Since x^* and x^{LS} are feasible and optimal, respectively, for the optimization problem (1), we have the basic inequality

$$\frac{1}{2n}\|y - Ax^{\mathrm{LS}}\|_2^2 \leq \frac{1}{2n}\|y - Ax^*\|_2 \;=\; \frac{1}{2n}\|w\|_2^2.$$

Introducing the shorthand $\Delta = x^{\mathrm{LS}} - x^*$ and re-arranging terms yields

$$\frac{1}{2}\|\Delta\|_A^2 \;=\; \frac{1}{2n}\|A\Delta\|_2^2 \leq \frac{\sigma}{n}\big|\sum_{i=1}^n \langle g,\, A\Delta\rangle\big|, \tag{49}$$

where $g \sim N(0, I_n)$ is a standard normal vector.

For a given $u \geq \varepsilon_n$, define the "bad" event

$$\mathcal{B}(u) := \big\{\exists \quad z \in \mathcal{C} - x^* \quad \text{with } \|z\|_A \geq u, \text{ and } |\tfrac{\sigma}{n}\textstyle\sum_{i=1}^n g_i (Az)_i| \geq 2u\,\|z\|_A\big\}$$

The following lemma controls the probability of this event:

Lemma 2 *For all $u \geq \varepsilon_n$, we have $\mathbb{P}[\mathcal{B}(u)] \leq e^{-\frac{nu^2}{2\sigma^2}}$.*

Returning to prove this lemma momentarily, let us prove the bound (48). For any $t \geq \varepsilon_n$, we can apply Lemma 2 with $u = \sqrt{t\varepsilon_n}$ to find that

$$\mathbb{P}[\mathcal{B}^c(\sqrt{t\varepsilon_n})] \geq 1 - e^{-\frac{nt\varepsilon_n}{2\sigma^2}}.$$

If $\|\Delta\|_A < \sqrt{t\,\varepsilon_n}$, then the claim is immediate. Otherwise, we have $\|\Delta\|_A \geq \sqrt{t\,\varepsilon_n}$. Since $\Delta \in \mathcal{C} - x^*$, we may condition on $\mathcal{B}^c(\sqrt{t\varepsilon_n})$ so as to obtain the bound

$$\big|\frac{\sigma}{n}\sum_{i=1}^n g_i(A\Delta)_i\big| \leq 2\,\|\Delta\|_A\,\sqrt{t\varepsilon_n}.$$

Combined with the basic inequality (49), we see that

$$\frac{1}{2}\|\Delta\|_A^2 \leq 2\,\|\Delta\|_A\,\sqrt{t\varepsilon_n}, \qquad \text{or equivalently } \|\Delta\|_A^2 \leq 16 t\varepsilon_n,$$

a bound that holds with probability greater than $1 - e^{-\frac{nt\varepsilon_n}{2\sigma^2}}$ as claimed.

It remains to prove Lemma 2. Our proof involves the auxiliary random variable

$$V_n(u) \;:= \sup_{\substack{z \in \mathrm{star}(\mathcal{C}-x^*) \\ \|z\|_A \leq u}} |\frac{\sigma}{n}\sum_{i=1}^n g_i\,(Az)_i|,$$

Inclusion of events: We first claim that $\mathcal{B}(u) \subseteq \{V_n(u) \geq 2u^2\}$. Indeed, if $\mathcal{B}(u)$ occurs, then there exists some $z \in \mathcal{C} - x^*$ with $\|z\|_A \geq u$ and

$$|\frac{\sigma}{n}\sum_{i=1}^n g_i\,(Az)_i| \geq 2u\,\|z\|_A. \tag{50}$$

Define the rescaled vector $\widetilde{z} = \frac{u}{\|z\|_A} z$. Since $z \in \mathcal{C} - x^*$ and $\frac{u}{\|z\|_A} \leq 1$, the vector $\widetilde{z} \in \mathrm{star}(\mathcal{C} - x^*)$. Moreover, by construction, we have $\|\widetilde{z}\|_A = u$. When the inequality (50) holds, the vector $\widetilde{z}$ thus satisfies $|\frac{\sigma}{n}\sum_{i=1}^n g_i\,(A\widetilde{z})_i| \geq 2u^2$, which certifies that $V_n(u) \geq 2u^2$, as claimed.

Controlling the tail probability: The final step is to control the probability of the event $\{V_n(u) \geq 2u^2\}$. Viewed as a function of the standard Gaussian vector $(g_1, \ldots, g_n)$, it is easy to see that $V_n(u)$ is Lipschitz with constant $L = \frac{\sigma u}{\sqrt{n}}$. Consequently, by concentration of measure for Lipschitz Gaussian functions, we have

$$\mathbb{P}\big[V_n(u) \geq \mathbb{E}[V_n(u)] + u^2\big] \leq e^{-\frac{nu^2}{2\sigma^2}}. \tag{51}$$

In order to complete the proof, it suffices to show that $\mathbb{E}[V_n(u)] \leq u^2$. By definition, we have $\mathbb{E}[V_n(u)] = \frac{\sigma}{\sqrt{n}}\mathcal{W}_u(\mathcal{K}^*)$. Since $\mathcal{K}^*$ is a star-shaped set, the function $v \mapsto \mathcal{W}_v(\mathcal{K}^*)/v$ is non-increasing (Bartlett et al., 2005). Since $u \geq \varepsilon_n$, we have

$$\sigma\frac{\mathcal{W}_u(\mathcal{K}^*)}{u} \leq \sigma\frac{\mathcal{W}_{\varepsilon_n}(\mathcal{K}^*)}{\varepsilon_n} \;\leq\; \varepsilon_n.$$

where the final step follows from the definition of ε_n. Putting together the pieces, we conclude that $\mathbb{E}[V_n(u)] \leq \varepsilon_n u \leq u^2$ as claimed.

Abstract

This paper considers inference of causal structure in a class of graphical models called conditional DAGs. These are directed acyclic graph (DAG) models with two kinds of variables, primary and secondary. The secondary variables are used to aid in the estimation of the structure of causal relationships between the primary variables. We prove that, under certain assumptions, such causal structure is identifiable from the joint observational distribution of the primary and secondary variables. We give causal semantics for the model class, put forward a score-based approach for estimation and establish consistency results. Empirical results demonstrate gains compared with formulations that treat all variables on an equal footing, or that ignore secondary variables. The methodology is motivated by applications in biology that involve multiple data types and is illustrated here using simulated data and in an analysis of molecular data from the Cancer Genome Atlas.

Keywords: Graphical Models, Causal Inference, Directed Acyclic Graphs, Instrumental Variables, Data Integration

1. Introduction

This paper considers learning causal structure among a set of *primary variables* $(Y_i)_{i\in V}$, using additional *secondary variables* $(X_i)_{i\in W}$ to aid in estimation. The primary variables are those of direct scientific interest while the secondary variables are variables that are known to influence the primary variables, but whose mutual relationships are not of immediate interest and perhaps not amenable to estimation using the available data. As we discuss further below, the primary/secondary distinction is common in biostatistical applications and is often dealt with in an *ad hoc* manner, for example by leaving some relationships or edges implicit in causal diagrams. Our aim is to define a class of graphical models for this setting and to clarify the conditions under which secondary variables can aid in causal estimation. We focus on causal estimation in the sense of estimation of the presence or absence of edges in the causal graph rather than estimation of quantitative causal effects.

The fact that primary variables of direct interest are often part of a wider context, including additional secondary variables, presents challenges for graphical modelling and causal inference, since in general the secondary variables will not be independent and simply marginalising may introduce spurious dependencies (Evans and Richardson, 2014). Motivated by this observation, we define conditional DAG (CDAG) models and discuss their semantics. Nodes in a CDAG are of two kinds, corresponding to primary and secondary variables, and as detailed below the semantics of CDAGs allow causal inferences to be made about the primary variables $(Y_i)_{i\in V}$ whilst accounting for the secondary variables $(X_i)_{i\in W}$. To limit scope, we focus on the setting where each primary variable has a known cause among the secondary variables. Specifically we suppose there is a bijection $\phi : V \to W$, between the primary and secondary index sets V and W, such that for each $i \in V$ a direct[1] causal dependency $X_{\phi(i)} \to Y_i$ exists. Under explicit assumptions we show that such secondary variables can aid in causal inference for the primary variables, because known relationships between secondary and primary variables render "primary-to-primary" causal links of the form $Y_i \to Y_j$ identifiable from joint data on primary and secondary variables. We put forward score-based estimators of CDAG structure that we show are asymptotically consistent under certain conditions; importantly, independence assumptions on the secondary variables are not needed.

This work is motivated by current efforts in biology aimed at exploiting high-throughput data to better understand causal molecular mechanisms, such as those involved in gene regulation or protein signaling. A notable feature of molecular biology is the fact that some causal links are relatively clearly defined by known sequence specificity. For example, the DNA sequence has a causal influence on the level of corresponding mRNA; mRNAs have a causal influence on corresponding total protein levels; and total protein levels have a causal influence on levels of post-translationally modified protein. This means that in a study involving a certain molecular variable (a protein, say), a subset of the causal influences upon it may be clear at the outset (e.g. the corresponding mRNA) and typically it is the unknown influences that are the subject of the study. Then, it is natural to ask whether accounting for the known influences can aid in identification of the unknown influences. For example, if interest focuses on causal relationships between proteins, known mRNA-protein links could be exploited to aid in causal identification at the protein-protein level. We show below an example using protein data.

Our development of the CDAG can be considered dual to the acyclic directed mixed graphs (ADMGs) developed by Evans and Richardson (2014), in the sense that we investigate conditioning as an alternative to marginalisation. In this respect our work mirrors recently developed undirected graphical models called conditional graphical models (CGMs; Li *et al*, 2012; Cai *et al.*, 2013) In CGMs, Gaussian random variables $(Y_k)_{k\in V}$ satisfy

$$Y_i \perp\!\!\!\perp Y_j | (Y_k)_{k\in V\setminus\{i,j\}}, (X_k)_{k\in W} \text{ if and only if } (i,j) \notin G \tag{1}$$

where G is an undirected acyclic graph and $(X_k)_{k\in W}$ are auxiliary random variables that are conditioned upon. CGMs have recently been applied to gene expression data $(Y_i)_{i\in V}$. In that setting Zhang and Kim (2014) used single nucleotide polymorphisms (SNPs) as the

1. Throughout, we use the term "direct" in the sense of Pearl (2009) and note that the causal influence need not be *physically* direct.

$(X_i)_{i\in W}$, while Logsdon and Mezey (2010); Yin and Li (2011); Cai *et al.* (2013) used expression qualitative trait loci (e-QTL) as the $(X_i)_{i\in W}$. The latter work was recently extended to jointly estimate several such graphical models in Chun *et al.* (2013). Also in the context of undirected graphs, van Wieringen and van de Wiel (2014) recently considered encoding a bijection between DNA copy number and mRNA expression levels into inference. Our work complements these efforts by using directed models that are arguably more appropriate for causal inference (Pearl, 2009). Evans (2015) uses a similar directed graphical characterisation and nomenclature. However, secondary variables in Evans (2015) are unobserved and can have multiple children in the set of primary variables, while ours are observed and have exactly one child among the primary variables. CDAGs are also related to instrumental variables and Mendelian randomisation approaches (Didelez and Sheehan, 2007) that we discuss below (Section 2.2).

CDAGs share some similarity with the influence diagrams (IDs) introduced by Dawid (2002) as an extension of DAGs that distinguish between variable nodes and decision nodes. This generalised the augmented DAGs of Spirtes *et al.* (2000); Lauritzen (2000); Pearl (2009) in which each variable node is associated with a decision node that represents an intervention on the corresponding variable. However, the semantics of IDs are not well suited to the scientific contexts that we consider, where secondary nodes represent variables to be observed, not the outcomes of decisions. The notion of a non-atomic intervention (Pearl, 2003), where many variables are intervened upon simultaneously, shares similarity with CDAGs in the sense that the secondary variables are in general non-independent. However again the semantics differ, since our secondary nodes represent random variables rather than interventions. In a different direction, Neto *et al.* (2010) recently observed that the use of e-QTL data $(X_i)_{i\in W}$ can help to identify causal relationships among gene expression levels $(Y_i)_{i\in V}$. However, Neto *et al.* (2010) require independence of the $(X_i)_{i\in W}$; this is too restrictive for general settings, including in molecular biology, since the secondary variables will typically themselves be subject to regulation and far from independent. An important and novel aspect of our approach is that no independence or conditional independence assumptions need to be placed on the secondary variables in order to draw causal conclusions about the primary variables.

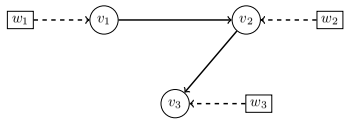
This paper begins in Sec. 2 by defining CDAGs and discussing identifiability of their structure from observational data on primary and secondary variables. Sufficient conditions are then given for consistent estimation of CDAG structure along with an algorithm based on integer linear programming. The methodology is illustrated in Section 3 on simulated data, including data sets that violate CDAG assumptions, and on protein data from cancer samples, the latter from the Cancer Genome Atlas (TCGA).

2. Methodology

Below we define CDAGS, study their theoretical properties and propose consistent estimators for CDAG structure.

2.1 A Statistical Framework for Conditional DAG Models

Consider index sets V, W and a bijection $\phi : V \to W$ between them. We will distinguish between the nodes in graphs and the random variables (RVs) that they represent. Specif-



(a)

type	index	node	variable
primary	$i \in V$	$v_i \in N(V)$	Y_i
secondary	$i \in W$	$w_i \in N(W)$	X_i

(b)

Figure 1: A conditional DAG model with primary nodes $N(V) = \{v_1, v_2, v_3\}$ and secondary nodes $N(W) = \{w_1, w_2, w_3\}$. Here primary nodes represent primary random variables $(Y_i)_{i\in V}$ and solid arrows correspond to a DAG G on these vertices. Square nodes are secondary variables $(X_i)_{i\in W}$ that, in the causal interpretation of CDAGs, represent known direct causes of the corresponding $(Y_i)_{i\in V}$ (dashed arrows represent known relationships; the random variables $(X_i)_{i\in W}$ need not be independent). The name conditional DAG refers to the fact that conditional upon $(X_i)_{i\in W}$, the solid arrows encode conditional independence relationships among the $(Y_i)_{i\in V}$.

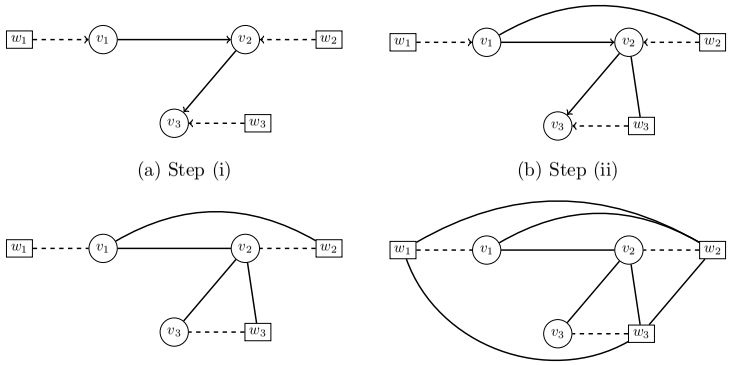
ically, indices correspond to nodes in graphical models; this is signified by the notation $N(V) = \{v_1, \ldots, v_p\}$ and $N(W) = \{w_1, \ldots, w_p\}$. Each node $v_i \in N(V)$ corresponds to a primary RV Y_i and similarly each node $w_i \in N(W)$ corresponds to a secondary RV X_i.

Definition 1 (CDAG) *A* conditional DAG *(CDAG)* $\overline{G}$*, with primary and secondary index sets* V*,* W *respectively and a bijection* ϕ *between them, is a DAG on the primary node set* $N(V)$ *with additional directed edges from each secondary node* $w_{\phi(i)} \in N(W)$ *to its corresponding primary node* $v_i \in N(V)$*.*

In other words, a CDAG $\overline{G}$ has node set $N(V) \cup N(W)$ and an edge set that can be generated by starting with a DAG on the primary nodes $N(V)$ and adding a directed edge from each secondary node in $N(W)$ to its corresponding primary node in $N(V)$, with the correspondence specified by the bijection ϕ. An example of a CDAG is shown in Fig. 1a. To further distinguish V and W in the graphical representation we employ circular and square vertices respectively. In addition we use dashed lines to represent edges that are required by definition and must therefore be present in any CDAG $\overline{G}$.

Since the DAG on the primary nodes $N(V)$ is of particular interest, throughout we use G to denote a DAG on $N(V)$. We use $\mathcal{G}$ to denote the set of all possible DAGs with $|V|$ vertices. For notational clarity, and without loss of generality, below we take the bijection to simply be the identity map $\phi(i) = i$. The parents of node v_i in a DAG G are indexed by $\mathrm{pa}_G(i) \subseteq V \setminus \{i\}$. Write $\mathrm{an}_{\overline{G}}(S)$ for the ancestors of nodes $S \subseteq N(V) \cup N(W)$ in the CDAG $\overline{G}$ (which by definition includes the nodes in S). For disjoint sets of nodes A, B, C in an undirected graph, we say that C *separates* A and B if every path between a node in A and a node in B in the graph contains a node in C.

Definition 2 (c-separation) *Consider disjoint* $A, B, C \subseteq N(V) \cup N(W)$ *and a CDAG* $\overline{G}$*. We say that* A *and* B *are* c-separated *by* C *in* $\overline{G}$*, written* $A \perp\!\!\!\perp B | C\ [\overline{G}]$*, when* C *separates*



(a) Step (i) (b) Step (ii)

(c) Step (iii) (d) Step (iv)

Figure 2: Illustrating c-separation. Here we ask whether v_3 and v_1 are c-separated by $\{v_2\}$ in $\overline{G}$, the CDAG shown in Fig. 1a. [Step (i): Take the subgraph induced by $\mathrm{an}_{\overline{G}}(\{v_1, v_2, v_3\})$. Step (ii): Moralise this subgraph (i.e. join with an undirected edge any parents of a common child that are not already connected by a directed edge). Step (iii): Take the skeleton of the moralised subgraph (i.e. remove the arrowheads). Step (iv): Add an undirected edge between every pair (w_i, w_j). In the final panel (d) we ask whether there exists a path from v_3 to v_1 that does not pass through v_2; the answer is positive (e.g. $v_3 - w_3 - w_1 - v_1$) and hence we conclude that $v_3 \not\perp\!\!\!\perp v_1 | v_2 [\overline{G}]$, i.e. v_3 and v_1 are not c-separated by $\{v_2\}$ in $\overline{G}$.]

A and B in the undirected graph U_4 that is formed as follows: (i) Take the subgraph U_1 induced by $\mathrm{an}_{\overline{G}}(A \cup B \cup C)$. (ii) Moralise U_1 to obtain U_2 (i.e. join with an undirected edge any parents of a common child that are not already connected by a directed edge). (iii) Take the skeleton of the moralised subgraph U_2 to obtain U_3 (i.e. remove the arrowheads). (iv) Add an undirected edge between every pair of nodes in $N(W)$ to obtain U_4.

The c-separation procedure is illustrated in Fig. 2, where we show that v_3 is not c-separated from v_1 by the set $\{v_2\}$ in the CDAG from Fig. 1a.

Remark 3 *The classical notion of d-separation for DAGs is equivalent to omitting step (iv) in c-separation. Notice that v_3* is *d-separated from v_1 by the set $\{v_2\}$ in the DAG G, underlining the need for a custom notion of separation for CDAGs.*

The topology (i.e. the set of edges) of a CDAG carries formal (potentially causal) semantics on the primary RVs, conditional on the secondary RVs, as specified below. Write $T(S)$ for the collection of triples $\langle A, B | C \rangle$ where A, B, C are disjoint subsets of S.

Definition 4 (Independence model) *The CDAG $\overline{G}$, together with c-separation, implies a formal* independence model *(p.12 of Studený, 2005)*

$$\mathcal{M}_G = \{\langle A, B | C \rangle \in T(N(V) \cup N(W)) : A \perp\!\!\!\perp B | C \, [\overline{G}]\} \tag{2}$$

where $\langle A, B | C \rangle \in \mathcal{M}_G$ carries the interpretation that the RVs corresponding to A are conditionally independent of the RVs corresponding to B when given the RVs corresponding to C. We will write $A \perp\!\!\!\perp B | C \, [\mathcal{M}_G]$ as a shorthand for $\langle A, B | C \rangle \in \mathcal{M}_G$.

Remark 5 *An independence model $\mathcal{M}_G$ does not contain any information on the structure of the marginal distribution $\mathbb{P}^{(X_i)}$ of the secondary variables, due to the additional step (iv) in c-separation.*

Lemma 6 (Equivalence classes) *The map $G \mapsto \mathcal{M}_G$ is an injection.*

Proof Consider two distinct DAGs $G, H \in \mathcal{G}$ and suppose that, without loss of generality, the edge $v_i \to v_j$ belongs to G and not to H. It suffices to show that $\mathcal{M}_G \neq \mathcal{M}_H$. First notice that G represents the relations (i) $w_i \not\perp\!\!\!\perp v_j | w_j \, [\overline{G}]$, (ii) $w_i \not\perp\!\!\!\perp v_j | w_j, (v_k)_{k \in V \setminus \{i,j\}} \, [\overline{G}]$, and (iii) $w_j \perp\!\!\!\perp v_i | w_i \, [\overline{G}]$. (These can each be directly verified by c-separation.) We show below that H cannot also represent (i-iii) and hence, from Def. 4, it follows that $\mathcal{M}_G \neq \mathcal{M}_H$. We distinguish between two cases for H, namely (a) $v_i \leftarrow v_j \notin H$, and (b) $v_i \leftarrow v_j \in H$.

Case (a): Suppose (i) also holds for H; that is, $w_i \not\perp\!\!\!\perp v_j | w_j \, [\overline{H}]$. Then since $v_i \to v_j \notin H$, it follows from c-separation that the variable v_i must be connected to v_j by directed path(s) whose interior vertices must only belong to $N(V) \setminus \{v_i, v_j\}$. Thus H implies the relation $w_i \perp\!\!\!\perp v_j | w_j, (v_k)_{k \in V \setminus \{i,j\}} \, [\overline{H}]$, so that (ii) cannot also hold.

Case (b): Since $v_i \leftarrow v_j \in H$ it follows from c-separation that $w_j \not\perp\!\!\!\perp v_i | w_i \, [\overline{H}]$, so that (iii) does not hold for H. ■

Remark 7 *More generally the same argument shows that a DAG $G \in \mathcal{G}$ satisfies $v_i \to v_j \notin G$ if and only if $\exists S \subseteq pa_G(j) \setminus \{i\}$ such that $w_i \perp\!\!\!\perp v_j | w_j, (v_k)_{k \in S} \, [\overline{G}]$. As a consequence, we have the interpretation that conditional upon the (secondary variables) $(X_i)_{i \in W}$, the solid arrows in Fig. 1a encode conditional independence relationships among the (primary variables) $(Y_i)_{i \in V}$, motivating the CDAG nomenclature.*

It is well known that conditional independence (and causal) relationships can usefully be described through a qualitative, graphical representation. However to be able to use a graph for *reasoning* it is necessary for that graph to embody certain assertions that themselves obey a logical calculus. Pearl and Verma (1987) proposed such a set of rules (the semi-graphoid axioms) that any reasonable set of assertions about how one set of variables might be irrelevant to the prediction of a second, given the values of a third, might hold (see also Dawid, 2001; Studený, 2005). This can then be extended to causal assertions (Pearl, 2009), thereby permitting study of causal hypotheses and their consequences without the need to first construct elaborate probability spaces and their extensions under control. Below we establish that the independence models $\mathcal{M}_G$ induced by c-separation on CDAGs are semi-graphoids and thus enable reasoning in the present setting with two kinds of variables:

Lemma 8 (Semi-graphoid) *For any DAG $G \in \mathcal{G}$, the set $\mathcal{M}_G$ is semi-graphoid (Pearl and Paz, 1985). That is to say, for all disjoint $A, B, C, D \subseteq N(V) \cup N(W)$ we have*

(i) (triviality) $A \perp\!\!\!\perp \emptyset | C$ $[\mathcal{M}_G]$

(ii) (symmetry) $A \perp\!\!\!\perp B | C$ $[\mathcal{M}_G]$ implies $B \perp\!\!\!\perp A | C$ $[\mathcal{M}_G]$

(iii) (decomposition) $A \perp\!\!\!\perp B, D | C$ $[\mathcal{M}_G]$ implies $A \perp\!\!\!\perp D | C$ $[\mathcal{M}_G]$

(iv) (weak union) $A \perp\!\!\!\perp B, D | C$ $[\mathcal{M}_G]$ implies $A \perp\!\!\!\perp B | C, D$ $[\mathcal{M}_G]$

(v) (contraction) $A \perp\!\!\!\perp B | C, D$ $[\mathcal{M}_G]$ and $A \perp\!\!\!\perp D | C$ $[\mathcal{M}_G]$ implies $A \perp\!\!\!\perp B, D | C$ $[\mathcal{M}_G]$

Proof The simplest proof is to note that our notion of c-separation is equivalent to classical d-separation applied to an extension $\underline{G}$ of the CDAG $\overline{G}$. The semi-graphoid properties then follow immediately by the facts that (i) d-separation satisfies the semi-graphoid properties (p.48 of Studený, 2005), and (ii) the restriction of a semi-graphoid to a subset of vertices is itself a semi-graphoid (p.14 of Studený, 2005).

Construct an extended graph $\underline{G}$ from the CDAG $\overline{G}$ by the addition of a node z and directed edges from z to each of the secondary vertices $N(W)$. Then for disjoint $A, B, C \subseteq N(V) \cup N(W)$ we have that A and B are c-separated by C in $\overline{G}$ if and only if A and B are d-separated by C in $\underline{G}$. This is because every path in the undirected graph $U_4(\overline{G})$ (recall the definition of c-separation) that contains an edge $w_i \to w_j$ corresponds uniquely to a path in $U_3(\underline{G})$ that contains the sub-path $w_i \to z \to w_j$. ■

2.2 Causal CDAG Models

The previous section defined CDAG models using the framework of formal independence models. However, CDAGs can also be embellished with a causal interpretation, that we make explicit below. In this paper we make a causal sufficiency assumption that the $(X_i)_{i \in W}$ are the only source of confounding for the $(Y_i)_{i \in V}$ and below we talk about direct causes at the level of $(X_i)_{i \in W} \cup (Y_i)_{i \in V}$.

Definition 9 (Causal CDAG) *A CDAG is* causal *when an edge $v_i \to v_j$ exists if and only if Y_i is a direct cause of Y_j. It is further assumed that X_i is a direct cause of Y_i and not a direct cause of Y_j for $j \neq i$. Finally it is assumed that no Y_i is a direct cause of any X_j.*

Remark 10 *Here* direct cause *is understood to mean that the parent variable has a "controlled direct effect" on the child variable in the framework of Pearl (e.g. Def. 4.5.1 of Pearl, 2009) (it is not necessary that the effect is physically direct). No causal assumptions are placed on interaction between the secondary variables $(X_i)_{i \in W}$.*

Remark 11 *In a causal CDAG the secondary variables $(X_i)_{i \in W}$ share some of the properties of instrumental variables (Didelez and Sheehan, 2007). Consider estimating the average causal effect of Y_i on Y_j. Then, conditioning on X_j in the following, X_i can be used as a natural experiment (Greenland, 2000) to determine the size and sign of this causal effect.*

When we are interested in the controlled direct effect, we can repeat this argument with additional conditioning on the $(Y_k)_{k \in V \setminus \{i,j\}}$ (or a smaller subset of conditioning variables if the structure of G is known).

2.3 Identifiability of CDAGs

There exist well-known identifiability results for independence models $\mathcal{M}$ that are induced by Bayesian networks; see for example Spirtes *et al.* (2000); Pearl (2009). These relate the observational distribution $\mathbb{P}^{(Y_i)}$ of the random variables $(Y_i)_{i \in V}$ to an appropriate DAG representation by means of d-separation, Markov and faithfulness assumptions (discussed below). The problem of identification for CDAGs is complicated by the fact that (i) the primary variables $(Y_i)_{i \in V}$ are insufficient for identification, (ii) the joint distribution $\mathbb{P}^{(X_i) \cup (Y_i)}$ of the primary variables $(Y_i)_{i \in V}$ and the secondary variables $(X_i)_{i \in W}$ need not be Markov with respect to the CDAG $\overline{G}$, and (iii) we must work with the alternative notion of c-separation. Below we propose novel "partial" Markov and faithfulness conditions that will permit, in the next section, an identifiability theorem for CDAGs. We make the standard assumption that there is no selection bias (for example by conditioning on common effects). We also assume throughout that there exists a true CDAG $\overline{G}$. In other words, the observational distribution $\mathbb{P}^{(X_i) \cup (Y_i)}$ induces an independence model that can be expressed as $\mathcal{M}_G$ for some DAG $G \in \mathcal{G}$.

Definition 12 (Partial Markov) *Let G denote the true DAG. We say that the observational distribution $\mathbb{P}^{(X_i) \cup (Y_i)}$ is* partially Markov *with respect to G when the following holds: For all disjoint subsets $\{i\}, \{j\}, C \subseteq \{1, \ldots, p\}$ we have $w_i \perp\!\!\!\perp v_j | w_j, (v_k)_{k \in C}$ $[\mathcal{M}_G]$ $\Rightarrow$ $X_i \perp\!\!\!\perp Y_j | X_j, (Y_k)_{k \in C}$.*

Definition 13 (Partial faithfulness) *Let G denote the true DAG. We say that the observational distribution $\mathbb{P}^{(X_i) \cup (Y_i)}$ is* partially faithful *with respect to G when the following holds: For all disjoint subsets $\{i\}, \{j\}, C \subseteq \{1, \ldots, p\}$ we have $w_i \perp\!\!\!\perp v_j | w_j, (v_k)_{k \in C}$ $[\mathcal{M}_G] \Leftarrow$ $X_i \perp\!\!\!\perp Y_j | X_j, (Y_k)_{k \in C}$*

Remark 14 *The partial Markov property implies that $\mathbb{P}^{(X_i) \cup (Y_i)}$ admits the factorisation*

$$p((x_i)_{i=1,\ldots,p}, (y_i)_{i=1,\ldots,p}) = p((x_i)_{i=1,\ldots,p}) \prod_{i=1}^{p} p(y_i | (y_k)_{k \in pa_G(i)}, x_i), \tag{3}$$

while partial faithfulness ensures that none of the terms inside the product in Eqn. 3 can be further decomposed. In this work we will prove only estimation consistency; for more refined convergence analysis the partial faithfulness property must be strengthened. See e.g. Uhler et al. (2013) for a recent discussion of faithfulness in the DAG setting.

Remark 15 *The partial Markov and partial faithfulness properties do not place any constraint on the marginal distribution $\mathbb{P}^{(X_i)}$ of the secondary variables.*

The following is an immediate corollary of Lem. 6:

Theorem 16 (Identifiability) *Suppose that the observational distribution $\mathbb{P}^{(X_i) \cup (Y_i)}$ is partially Markov and partially faithful with respect to the true DAG G. Then*

(i) It is not possible to identify the true DAG G based on the observational distribution $\mathbb{P}^{(Y_i)}$ of the primary variables alone.

(ii) It is possible to identify the true DAG G based on the observational distribution $\mathbb{P}^{(X_i)\cup(Y_i)}$.

Proof (i) We have already seen that $\mathbb{P}^{(Y_i)}$ is not Markov with respect to the DAG G: Indeed a statistical association $Y_i \not\perp\!\!\!\perp Y_j|(Y_k)_{k\in V\setminus\{i,j\}}$ observed in the distribution $\mathbb{P}^{(Y_i)}$ could either be due to a direct interaction $Y_i \to Y_j$ (or $Y_j \to Y_i$), or could be mediated entirely through variation in the secondary variables $(X_k)_{k\in W}$. (ii) It follows immediately from Lemma 6 that observation of both the primary and secondary variables $(Y_i)_{i\in V} \cup (X_i)_{i\in W}$ is sufficient for identification of G. ■

2.4 Estimating CDAGs From Data

In this section we assume that the partial Markov and partial faithfulness properties hold, so that the true DAG G is identifiable from the joint observational distribution of the primary and secondary variables. Below we consider score-based estimation for CDAGs and prove consistency of certain score-based CDAG estimators.

Definition 17 (Score function; Chickering (2003)) *A* score function *is a map $S : \mathcal{G} \to [0,\infty)$ with the interpretation that if two DAGs $G, H \in \mathcal{G}$ satisfy $S(G) < S(H)$ then H is preferred to G.*

We will study the asymptotic behaviour of $\hat{G}_S$, the estimate of graph structure obtained by maximising $S(G)$ over all $G \in \mathcal{G}$ based on observations $(X_i^j, Y_i^j)_{i=1,\dots,p}^{j=1,\dots,n}$. Let $\mathbb{P}_n = \mathbb{P}^{(X_i^j, Y_i^j)}$ denote the finite-dimensional distribution of the n observations.

Definition 18 (Partial local consistency) *We say the score function S is* partially locally consistent *if, whenever H is constructed from G by the addition of one edge $Y_i \to Y_j$, we have*

1. $X_i \not\perp\!\!\!\perp Y_j|X_j, (Y_k)_{k\in pa_G(j)} \Rightarrow \lim_{n\to\infty} \mathbb{P}_n[S(H) > S(G)] = 1$
2. $X_i \perp\!\!\!\perp Y_j|X_j, (Y_k)_{k\in pa_G(j)} \Rightarrow \lim_{n\to\infty} \mathbb{P}_n[S(H) < S(G)] = 1.$

Theorem 19 (Consistency) *If S is partially locally consistent then $\lim_{n\to\infty} \mathbb{P}_n[\hat{G}_S = G] = 1$, so that $\hat{G}_S$ is a consistent estimator of the true DAG G.*

Proof It suffices to show that $\lim_{n\to\infty} \mathbb{P}_n[\hat{G}_S = H] = 0$ whenever $H \neq G$. There are two cases to consider:

Case (a): Suppose $v_i \to v_j \in H$ but $v_i \to v_j \notin G$. Let H' be obtained from H by the removal of $v_i \to v_j$. From c-separation we have $w_i \perp\!\!\!\perp v_j|w_j, (v_k)_{k\in \mathrm{pa}_G(j)}$ $[\overline{G}]$ and hence from the partial Markov property we have $X_i \perp\!\!\!\perp Y_j|X_j, (Y_k)_{k\in \mathrm{pa}_G(j)}$. Therefore if S is partially locally consistent then $\lim_{n\to\infty} \mathbb{P}_n[S(H) < S(H')] = 1$, so that $\lim_{n\to\infty} \mathbb{P}_n[\hat{G}_S = H] = 0$.

Case (b): Suppose $v_i \to v_j \notin H$ but $v_i \to v_j \in G$. Let H' be obtained from H by the addition of $v_i \to v_j$. From c-separation we have $w_i \not\perp\!\!\!\perp v_j|w_j, (v_k)_{k\in \mathrm{pa}_G(j)}$ $[\overline{G}]$ and hence from the partial faithfulness property we have $X_i \not\perp\!\!\!\perp Y_j|X_j, (Y_k)_{k\in \mathrm{pa}_G(j)}$. Therefore if S is partially locally consistent then $\lim_{n\to\infty} \mathbb{P}_n[S(H) < S(H')] = 1$, so that $\lim_{n\to\infty} \mathbb{P}_n[\hat{G}_S = H] = 0$. ■

Remark 20 *In this paper we adopt a maximum a posteriori (MAP) -Bayesian approach and consider score functions given by a posterior probability $p(G|(x_i^l, y_i^l)_{i=1,\dots,p}^{l=1,\dots,n})$ of the DAG G given the data $(x_i^l, y_i^l)_{i=1,\dots,p}^{l=1,\dots,n}$. This requires that a prior $p(G)$ is specified over the space $\mathcal{G}$ of DAGs. From the partial Markov property we have that, for n independent observations, such score functions factorise as*

$$S(G) = p(G) \prod_{l=1}^{n} p((x_i^l)_{i=1,\dots,p}) \prod_{i=1}^{p} p(y_i^l|(y_k^l)_{k\in pa_G(i)}, x_i^l). \tag{4}$$

We further assume that the DAG prior $p(G)$ factorises over parent sets $pa_G(i) \subseteq V \setminus \{i\}$ as

$$p(G) = \prod_{i=1}^{p} p(pa_G(i)). \tag{5}$$

This implies that the score function in Eqn. 4 is decomposable *and the maximiser $\hat{G}_S$, i.e. the MAP estimate, can be obtained via integer linear programming (ILP). In Sec. 2.6 we derive an ILP that targets the CDAG $\hat{G}_S$ and thereby allows exact (i.e. deterministic) estimation in this class of models.*

Lemma 21 *A score function of the form Eqn. 4 is partially locally consistent if and only if, whenever H is constructed from G by the addition of one edge $v_i \to v_j$, we have*

1. $X_i \not\perp\!\!\!\perp Y_j|X_j, (Y_k)_{k\in pa_G(j)} \Rightarrow \lim_{n\to\infty} \mathbb{P}_n[B_{H,G} > 1] = 1$
2. $X_i \perp\!\!\!\perp Y_j|X_j, (Y_k)_{k\in pa_G(j)} \Rightarrow \lim_{n\to\infty} \mathbb{P}_n[B_{H,G} < 1] = 1$

where

$$B_{H,G} = \frac{p((Y_j^l)^{l=1,\dots,n}|(Y_k^l)_{k\in pa_H(j)}^{l=1,\dots,n}, (X_j^l)^{l=1,\dots,n})}{p((Y_j^l)^{l=1,\dots,n}|(Y_k^l)_{k\in pa_G(j)}^{l=1,\dots,n}, (X_j^l)^{l=1,\dots,n})} \tag{6}$$

is the Bayes factor between two competing local models $pa_G(j)$ and $pa_H(j)$.

2.5 Bayes Factors and Common Variables

The characterisation in Lemma 21 justifies the use of any consistent Bayesian variable selection procedure to obtain a score function. To be clear, although our local scores derive from the variable selection literature, we do *not* perform node-wise variable selection, which would not produce a DAG in general. Instead, the local scores form the basis for a global search over DAGs via ILPs; see Sec. 2.6.

The secondary variables $(X_i^l)^{l=1,\ldots,n}$ are included in all models, and parameters relating to these variables should therefore share a common prior. Below we discuss a formulation of the Bayesian linear model that is suitable for CDAGs. Consider variable selection for node j and candidate parent (index) set $\mathrm{pa}_G(j) = \pi \subseteq V \setminus \{j\}$. We construct a linear model for the observations

$$Y_j^l = [1\ X_j^l]\boldsymbol{\beta}_0 + \boldsymbol{Y}_\pi^l \boldsymbol{\beta}_\pi + \epsilon_j^l, \quad \epsilon_j^l \sim N(0, \sigma^2) \tag{7}$$

where $\boldsymbol{Y}_\pi^l = (Y_k^l)_{k\in\pi}$ is used to denote a row vector and the noise ϵ_j^l is assumed independent for $j = 1, \ldots, p$ and $l = 1, \ldots, n$. Although suppressed in the notation, the parameters $\boldsymbol{\beta}_0$, $\boldsymbol{\beta}_\pi$ and σ are specific to node j. This regression model can be written in vectorised form as

$$\boldsymbol{Y}_j = \boldsymbol{M}_0\boldsymbol{\beta}_0 + \boldsymbol{Y}_\pi\boldsymbol{\beta}_\pi + \boldsymbol{\epsilon} \tag{8}$$

where $\boldsymbol{M}_0$ is the $n \times 2$ matrix whose rows are the $[1\ X_j^l]$ for $l = 1, \ldots, n$ and $\boldsymbol{Y}_\pi$ is the matrix whose rows are $\boldsymbol{Y}_\pi^l$ for $l = 1, \ldots, n$.

We orthogonalize the regression problem by defining $\boldsymbol{M}_\pi = (\boldsymbol{I} - \boldsymbol{M}_0(\boldsymbol{M}_0^T\boldsymbol{M}_0)^{-1}\boldsymbol{M}_0^T)\boldsymbol{Y}_\pi$ so that the model can be written as

$$\boldsymbol{Y}_j = \boldsymbol{M}_0\tilde{\boldsymbol{\beta}}_0 + \boldsymbol{M}_\pi\tilde{\boldsymbol{\beta}}_\pi + \boldsymbol{\epsilon} \tag{9}$$

where $\tilde{\boldsymbol{\beta}}_0$ and $\tilde{\boldsymbol{\beta}}_\pi$ are Fisher orthogonal parameters (see Deltell, 2011, for details).

In the conventional approach of Jeffreys (1961), the prior distribution is taken as

$$p_{j,\pi}(\tilde{\boldsymbol{\beta}}_\pi, \tilde{\boldsymbol{\beta}}_0, \sigma) = p_{j,\pi}(\tilde{\boldsymbol{\beta}}_\pi|\tilde{\boldsymbol{\beta}}_0, \sigma)p_j(\tilde{\boldsymbol{\beta}}_0, \sigma) \tag{10}$$

$$p_j(\tilde{\boldsymbol{\beta}}_0, \sigma) \propto \sigma^{-1} \tag{11}$$

where Eqn. 11 is the reference or independent Jeffreys prior. (For simplicity of exposition we leave conditioning upon $\boldsymbol{M}_0$, and $\boldsymbol{M}_\pi$ implicit.) The use of the reference prior here is motivated by the observation that the common parameters $\boldsymbol{\beta}_0, \sigma$ have the same meaning in each model π for variable Y_j and should therefore share a common prior distribution (Jeffreys, 1961). Alternatively, the prior can be motivated by invariance arguments that derive $p(\boldsymbol{\beta}_0, \sigma)$ as a right Haar measure (Bayarri *et al.*, 2012). Note however that σ does not carry the same meaning across $j \in V$ in the application that we consider below, so that the prior is specific to fixed j. For the parameter prior $p_{j,\pi}(\tilde{\boldsymbol{\beta}}_\pi|\tilde{\boldsymbol{\beta}}_0, \sigma)$ we use the g-prior (Zellner, 1986)

$$\tilde{\boldsymbol{\beta}}_\pi|\tilde{\boldsymbol{\beta}}_0, j, \pi \sim N(\boldsymbol{0}, g\sigma^2(\boldsymbol{M}_\pi^T\boldsymbol{M}_\pi)^{-1}) \tag{12}$$

where g is a positive constant to be specified. Due to orthogonalisation, $\mathrm{cov}(\hat{\boldsymbol{\beta}}_\pi) = \sigma^2(\boldsymbol{M}_\pi^T\boldsymbol{M}_\pi)^{-1}$ where $\hat{\boldsymbol{\beta}}_\pi$ is the maximum likelihood estimator for $\tilde{\boldsymbol{\beta}}_\pi$, so that the prior is specified on the correct length scale (Deltell, 2011). We note that many alternatives to Eqn. 12 are available in the literature (including Johnson and Rossell, 2010; Bayarri *et al.*, 2012). For discrete data we mention recent work by Massam and Wesołowski (2014).

Under the prior specification above, the marginal likelihood for a candidate model π has the following closed-form expression:

$$p_j(\boldsymbol{y}_j|\pi) = \frac{1}{2}\Gamma\left(\frac{n-2}{2}\right)\frac{1}{\pi^{(n-2)/2}}\frac{1}{|\boldsymbol{M}_0^T\boldsymbol{M}_0|^{1/2}}\left(\frac{1}{g+1}\right)^{|\pi|/2} b^{-(n-2)/2} \tag{13}$$

$$b = \boldsymbol{y}_j^T\left(\boldsymbol{I} - \boldsymbol{M}_0(\boldsymbol{M}_0^T\boldsymbol{M}_0)^{-1}\boldsymbol{M}_0^T - \frac{g}{g+1}\boldsymbol{M}_\pi(\boldsymbol{M}_\pi^T\boldsymbol{M}_\pi)^{-1}\boldsymbol{M}_\pi^T\right)\boldsymbol{y}_j \tag{14}$$

Following Scott and Berger (2010), we control multiplicity via the prior

$$p(\pi) \propto \binom{p}{|\pi|}^{-1}. \tag{15}$$

Proposition 22 (Consistency) *Let $g = n$. Then the Bayesian score function $S(G)$ defined above is partially locally consistent, and hence the corresponding estimator $\hat{G}_S$ is consistent.*

Proof This result is an immediate consequence of Lemma 21 and the well-known variable selection consistency property for the unit-information g-prior (see e.g. Fernández *et al.*, 2001). ■

2.6 Computation via Integer Linear Programming

Structure learning for DAGs is a well-studied problem, with contributions including Friedman and Koller (2003); Silander and Myllymäkki (2006); Tsamardinos *et al.* (2006); Cowell (2009); Cussens (2011); Yuan and Malone (2013). Discrete optimisation via ILP can be used to allow efficient estimation for graphical models, exploiting the availability of powerful (and exact) ILP solvers (Nemhauser and Wolsey, 1988; Wolsey, 1998; Achterberg, 2009), as discussed in Bartlett and Cussens (2013). Below we extend the ILP approach to CDAG models.

We begin by computing and caching the quantities

$$p((y_i^l)^{l=1,\ldots,n}|(y_k^l)_{k\in\pi}^{l=1,\ldots,n}, (x_i^l)^{l=1,\ldots,n}) \tag{16}$$

that summarise evidence in the data for the local model $\mathrm{pa}_G(i) = \pi \subseteq V \setminus \{i\}$ for variable i. These cached quantities are transformed to obtain "local scores"

$$s(i, \pi) := \log(p((y_i^l)^{l=1,\ldots,n}|(y_k^l)_{k\in\pi}^{l=1,\ldots,n}, (x_i^l)^{l=1,\ldots,n})) + \log(p(\pi)). \tag{17}$$

These are the (log-) evidence from Eqn. 16 with an additional penalty term that provides multiplicity correction over varying $\pi \subseteq V \setminus \{i\}$, arising from Eqn. 5. Then we define binary indicator variables that form the basis of our ILP as follows:

$$\Pi(i, \pi) := [\mathrm{pa}_G(i) = \pi] \quad \forall i = 1, \ldots, p,\ \pi \subseteq V \setminus \{i\}. \tag{18}$$

The information in the variables Π contains all information on the DAG G. However it will be necessary to impose constraints that ensure the Π correspond to a well-defined DAG:

$$\sum_{\pi\subseteq V\setminus\{i\}} \Pi(i, \pi) = 1 \quad \forall i = 1, \ldots, p \qquad \text{(C1; convexity)}$$

Constraint (C1) requires that every node i has exactly one parent set (i.e. there is a well-defined graph G). To ensure G is acyclic we require further constraints:

$$\sum_{i\in C}\sum_{\substack{\pi\subseteq V\setminus\{i\}\\ \pi\cap C=\emptyset}} \Pi(i, \pi) \geq 1 \quad \forall\, C \subseteq V, C \neq \emptyset. \qquad \text{(C2; acyclicity)}$$

(C2) states that for every non-empty set C there must be at least one node in C that does not have a parent in C.

Proposition 23 *The MAP estimate $\hat{G}_S$ is characterised as the solution of the ILP*

$$\hat{G}_S = \arg\max_{G\in\mathcal{G}} \sum_{i=1}^{p} \sum_{\pi\subseteq V\setminus\{i\}} s(i,\pi)\Pi(i,\pi) \tag{19}$$

subject to constraints (C1) and (C2).

Proof It was proven in Jaakola *et al.* (2010) that (C1) and (C2) together exactly characterise the space $\mathcal{G}$ of DAGs. ■

For the applications in this paper, all ILP instances were solved using the GOBNILP software that is freely available to download from `http://www.cs.york.ac.uk/aig/sw/gobnilp/`.

3. Results

Below we present results based on simulated data and data from molecular biology.

3.1 Simulated Data

We simulated data from linear-Gaussian structural equation models (SEMs). Here we summarise the simulation procedure, with full details provided in the supplement. We first sampled a DAG G for the primary variables and a second DAG G' for the secondary variables (independently of G), following a sampling procedure described in the supplement. That is, G is the causal structure of interest, while G' governs dependence between the secondary variables. Data for the secondary variables $(X_i)_{i\in W}$ were generated from an SEM with structure G'. The strength of dependence between secondary variables was controlled by a parameter $\theta \in [0,1]$. Here $\theta = 0$ renders the secondary variables independent and $\theta = 1$ corresponds to a deterministic relationship between secondary variables, with intermediate values of θ giving different degrees of covariation among the secondary variables. Finally, conditional on the $(X_i)_{i\in W}$, we simulated data for the primary variables $(Y_i)_{i\in V}$ from an SEM with structure G. To manage computational burden, for all estimators we considered only models of size $|\pi| \leq 5$. Performance was quantified by the structural Hamming distance (SHD) between the estimated DAG $\hat{G}_S$ and true, data-generating DAG G, taking into account directionality; we report the mean SHD as computed over 10 independent realisations of the data. We emphasise that the secondary variables need not be generated from a DAG model, however this is a convenient and familiar approach. We note that in the biological application below a DAG for the secondary variables might not be appropriate.

In Table 1 we compare the proposed score-based CDAG estimator with the corresponding score-based DAG estimator that uses only the primary variable data $(Y_i^l)_{i=1,\ldots,p}^{l=1,\ldots,n}$. We also considered an alternative (DAG2) where a standard DAG estimator is applied to *all* of the variables $(X_i)_{i\in W}$, $(Y_i)_{i\in V}$, with the subgraph induced on the primary variables giving the estimate for G. We considered values $\theta = 0,\ 0.5,\ 0.99$ corresponding to zero, mild

Table 1: Simulated data results. Here we display the mean structural Hamming distance from the estimated to the true graph structure, computed over 10 independent realisations, along with corresponding standard errors. [Data were generated using linear-Gaussian structural equations. $\theta \in [0,1]$ quantifies dependence between the secondary variables $(X_i)_{i\in W}$, n is the number of data points and p is the number of primary variables $(Y_i)_{i\in V}$. "DAG" = estimation based only on primary variables $(Y_i)_{i\in V}$, "DAG2" = estimation based on the full data $(X_i)_{i\in W}\cup(Y_i)_{i\in V}$, "CDAG" = estimation based on the full data and enforcing CDAG structure.]

and strong covariation among the secondary variables. In each data-generating regime we found that CDAGs were either competitive with, or (typically) more effective than, the DAG and DAG2 estimators. In the $p = 15$, $n = 1000$ regime (that is closest to the biological application that we present below) the CDAG estimator dramatically outperforms these two alternatives. Inference using DAG2 and CDAG (that both use primary as well as secondary variables) is robust to large values of θ, whereas in the $p = 15$, $n = 1000$ regime, the performance of the DAG estimator based on only the primary variables deteriorates for large θ. This agrees with intuition since association between the secondary X_i's may induce correlations between the primary Y_i's. CDAGs outperformed DAG2 at large n (see also Table 1).

To better understand the limitations of CDAGs we considered three data-generating regimes that violate the CDAG assumptions. Firstly we focused on the $\theta = 0$, $p = 15$, $n = 1000$ regime where the CDAG estimator performs well when data are generated "from the model". We then introduced a number E of edges of the form $X_i \to Y_j$ where $Y_i \to Y_j \in G$. These edges (strongly) violate the structural assumptions implied by the CDAG model because their presence means that X_i is no longer a suitable instrument for $Y_i \to Y_j$ as it is no longer conditionally independent of the variable Y_j given Y_i. We assessed performance of the CDAG, DAG and DAG2 estimators as the number E of such misspecified edges is increased (Fig. 3). We find that whilst CDAG continues to perform well up to a moderate fraction of misspecified edges, for larger fractions performance degrades and eventually coincides with DAG and DAG2. Secondly, we fixed $\theta = 0$, $p = 15$, $n = 1000$ and reduced the dependence of the Y_i on the X_i from 100% (relative to values used in the above simulations)

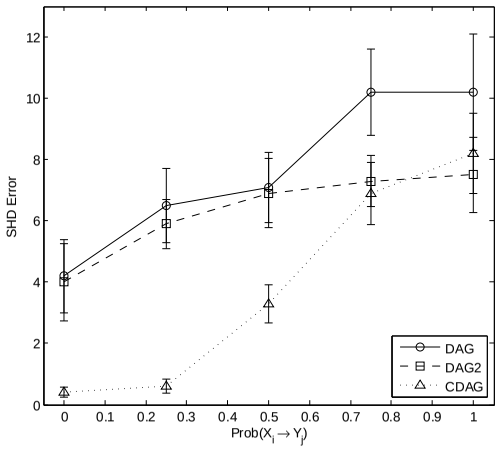

Figure 3: Simulated data results; model misspecification. [Data were generated using linear-Gaussian structural equations. Here we fixed $\theta = 0$, $p = 15$, $n = 1000$ and considered varying the number E of misspecified edges as described in the main text. On the x-axis we display the marginal probability that any given edge $Y_i \to Y_j$ has an associated misspecified edge $X_i \to Y_j$, so that when $\text{Prob}(X_i \to Y_j) = 1$ the number E of misspecified edges is equal to the number of edges in G. "DAG" = estimation based only on primary variables $(Y_i)_{i \in V}$, "DAG2" = estimation based on the full data $(X_i)_{i \in W} \cup (Y_i)_{i \in V}$, "CDAG" = CDAG estimation based on the full data $(X_i)_{i \in W} \cup (Y_i)_{i \in V}$.]

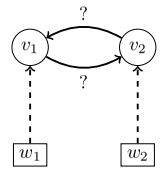
down to 0%. At 0% the partial faithfulness assumption is violated and estimators are no longer consistent. Results (SFig. 1) show that CDAG remains effective over a wide range of data-generating regimes, but eventually degrades when faithfulness is strictly violated. Thirdly, we considered removing the $X_i \to Y_i$ dependence from a random subset of the indices $i \in \{1, \ldots, p\}$, so that faithfulness is violated in a more heterogeneous way across the CDAG, similar to the situation considered by Neto *et al.* (2010). Results (SFig. 2) showed CDAG remained effective when only a handful of deletions occur, but eventually degraded as all the dependencies on secondary variables were removed.

3.2 Molecular Biological Data

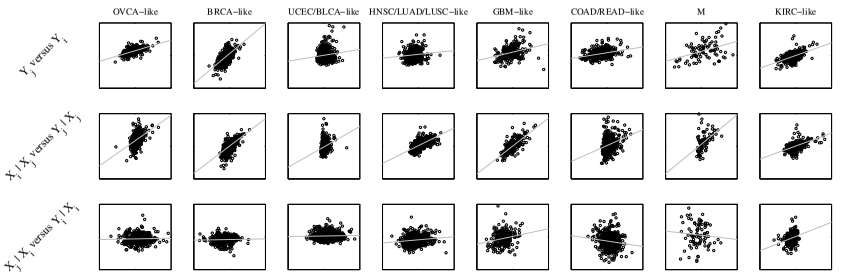
In this section we illustrate the use of CDAGs in an analysis of molecular data from cancer samples. We focus on causal links between post-translationally modified proteins involved in a process called cell signalling. The estimation of signalling networks has been a prominent topic in computational biology for some years (see, among others, Sachs *et al.*, 2005;

protein	node	variable
CHK1	w_i	X_i
p-CHK1	v_i	Y_i
CHK2	w_j	X_j
p-CHK2	v_j	Y_j

(a)



(b)



(c)

Figure 4: CHK1 total protein (t-CHK1) as a natural experiment for phosphorylation of CHK2 (p-CHK2). (a) Description of the variables. (b) A portion of the CDAG relating to these variables. It is desired to estimate whether there is a causal relationship $Y_i \to Y_j$ (possibly mediated by other protein species) or *vice versa*. (c) Top row: Plotting phosphorylated CHK1 (p-CHK1; Y_i) against p-CHK2 (Y_j) we observe weak correlation in some of the cancer subtypes. Middle row: We plot the residuals when t-CHK1 is regressed on total CHK2 (t-CHK2; x-axis) against the residuals when p-CHK2 is regressed on t-CHK2 (y-axis). The plots show a strong (partial) correlation in each subtype that suggests a causal effect in the direction p-CHK1 $\to$ p-CHK2. Bottom row: Reproducing the above but with the roles of CHK1 and CHK2 reversed, we see much reduced and in many cases negligible partial correlation, suggesting lack of a causal effect in the reverse direction, i.e. p-CHK1 $\not\leftarrow$ p-CHK2. [The grey line in each panel is a least-squares linear regression.]

Nelander *et al.*, 2008; Hill *et al.*, 2012; Oates and Mukherjee, 2012). Aberrations to causal signalling networks are central to cancer biology (Weinberg, 2013).

In this application, the primary variables $(Y_i)_{i \in V}$ represent abundance of phosphorylated protein (p-protein) while the secondary variables $(X_i)_{i \in W}$ represent abundance of corresponding total proteins (t-protein). A t-protein can be modified by a process called phosphorylation to form the corresponding p-protein and the p-proteins play a key role in signalling. An edge $v_i \to v_j$ has the biochemical interpretation that the phosphorylated form of protein i acts as a causal influence on phosphorylation of protein j. The DAG2

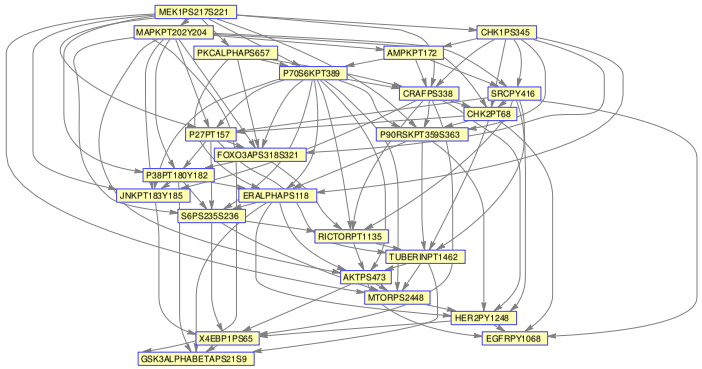


Figure 5: *Maximum a posteriori* conditional DAG, estimated from protein data from cancer samples (from the Cancer Genome Atlas, samples belonging to the BRCA-like group, see text). Here vertices represent phosphorylated proteins (primary variables) and edges have the biochemical interpretation that the parent protein plays a causal role in phosphorylation of the child protein.

method described in Sec. 3.1 may not be suitable for use here since the t-proteins are likely confounded by unobserved variables.

The data we analyse are from the TCGA "pan-cancer" project (Akbani *et al.*, 2014) and comprise measurements of protein levels (including both t- and p-proteins) using a technology called reverse phase protein arrays (RPPAs). We focus on $p = 24$ proteins for which (total, phosphorylated) pairs are available; the data span eight different cancer types (as defined by a clustering analysis due to Städler *et al.*, 2015) with a total sample size of $n = 3,467$ patients. We first illustrate the key idea of using secondary variables to inform causal inference regarding primary variables with an example from these data:

Example 1 (CHK1 t-protein as a natural experiment for CHK2 phosphorylation) *Consider RVs (Y_i, Y_j) corresponding respectively to p-CHK1 and p-CHK2, the phosphorylated forms of CHK1 and CHK2 proteins. Fig. 4c (top row) shows that these variables are weakly correlated in most of the 8 cancer subtypes. There is a strong partial correlation between t-CHK1 (X_i) and p-CHK2 (Y_j) in each of the subtypes when conditioning on t-CHK2 (X_j) (middle row), but there is essentially no partial correlation between t-CHK2 (X_j) and p-CHK1 (Y_i) in the same subtypes when conditioning on t-CHK1 (bottom row). Thus, under the CDAG assumptions, this suggests that there exists a directed causal path from p-CHK1 to p-CHK2, but not vice versa.*

Example 1 provides an example from the TCGA data where controlling for a secondary variable (here, t-protein abundance) may be important for causal inference concerning primary variables (p-protein abundance).

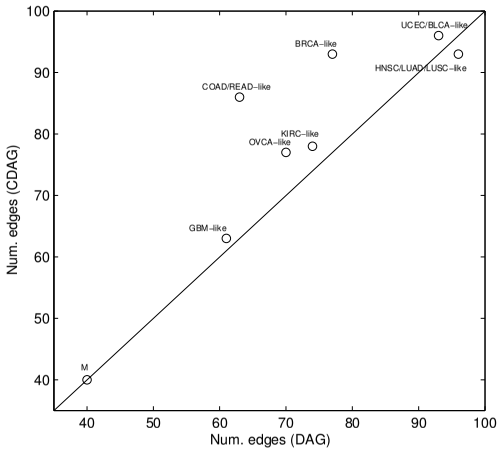

Figure 6: Cancer patient data; relative density of estimated protein networks. Here we plot the number of edges in the networks inferred by estimators based on DAGs (x-axis) and based on CDAGs (y-axis). [Each point corresponds to a cancer subtype (see text). "DAG" = estimation based only on primary variables $(Y_i)_{i \in V}$, "CDAG" = estimation based on the full data and enforcing CDAG structure.]

We now apply the CDAG methodology to all $p = 24$ primary variables that we consider, using data from the largest subtype in the study (namely BRCA-like). The estimated graph is shown in Fig. 5. We note that assessment of the biological validity of this causal graph is a nontrivial matter, and outside the scope of the present paper. However, we observe that several well known edges, such as from p-MEK to p-MAPK, appear in the estimated graph and are oriented in the expected direction. Interestingly, in several of these cases, the edge orientation is different when a standard DAG estimator is applied to the same data, showing that the CDAG formulation can reverse edge orientation with respect to a classical DAG (see supplement). We note also that the CDAG is denser, with more edges, than the DAG (Fig. 6), demonstrating that in many cases, accounting for secondary variables can render candidate edges more salient. These differences support our theoretical results insofar as they demonstrate that in practice CDAG estimation can give quite different results from a DAG analysis of the same primary variables but we note that proper assessment of estimated causal structure in this setting is beyond the scope of this paper.

4. Conclusions

Practitioners of causal inference understand that it is important to distinguish between variables of direct interest and others that can play a supporting role in analysis. In this

work we put forward CDAGs as a simple class of graphical models that make this distinction explicit. Motivated by molecular biological applications, we developed CDAGs that use bijections between primary and secondary index sets. The general approach presented here could be extended to other multivariate settings where variables are in some sense non-exchangeable. Naturally many of the philosophical considerations and practical limitations and caveats of classical DAGs remain relevant for CDAGs and we refer the reader to Dawid (2010) for an illuminating discussion of these issues.

The application to biological data presented above represents a principled approach to integrate different molecular data types (here, total and phosphorylated protein, but the ideas are general) for causal inference. Our results suggest that integration in a causal framework may be useful in some settings. Theoretical and empirical results showed that CDAGs can improve estimation of causal structure relative to classical DAGs when the CDAG assumptions are even approximately satisfied.

We briefly mention three natural extensions of the present work: (i) The CDAGs put forward here allow exactly one secondary variable X_i for each primary variable Y_i. In many settings this may be overly restrictive. In biology there are many examples of known causal relationships that are one-to-many or many-to-one. It would be natural to extend CDAGs in this direction. Examples of a more general formulation along these lines were recently discussed by Neto *et al.* (2010) in the context of eQTL data. Conversely we could extend the recent ideas of Kang *et al.* (2014) by allowing for multiple secondary variables for each primary variable, not all of which may be valid as instruments. (ii) In many applications data may be available from multiple related but causally non-identical groups, for example disease types. It could then be useful to consider *joint* estimation of multiple CDAGs, following recent work on estimation for multiple DAGs (Oates *et al.*, 2015, 2014). (iii) Biotechnological advances now mean that the number p of variables is frequently very large. Estimation for high-dimensional CDAGs may be possible using recent results for high-dimensional DAGs (e.g. Kalisch and Bühlmann, 2007; Loh and Bühlmann, 2014, and others).

Abstract

High dimensional Poisson regression has become a standard framework for the analysis of massive counts datasets. In this work we estimate the intensity function of the Poisson regression model by using a dictionary approach, which generalizes the classical basis approach, combined with a Lasso or a group-Lasso procedure. Selection depends on penalty weights that need to be calibrated. Standard methodologies developed in the Gaussian framework can not be directly applied to Poisson models due to heteroscedasticity. Here we provide data-driven weights for the Lasso and the group-Lasso derived from concentration inequalities adapted to the Poisson case. We show that the associated Lasso and group-Lasso procedures satisfy fast and slow oracle inequalities. Simulations are used to assess the empirical performance of our procedure, and an original application to the analysis of Next Generation Sequencing data is provided.

Keywords: Functional Poisson regression, adaptive lasso, adaptive group-lasso, calibration, concentration

Introduction

Poisson functional regression has become a standard framework for image or spectra analysis, in which case observations are made of n independent couples $(Y_i, X_i)_{i=1,\dots,n}$, and can be modeled as

$$Y_i|X_i \sim \mathcal{P}oisson(f_0(X_i)).$$

The X_i's (random or fixed) are supposed to lie in a known compact support of $\mathbb{R}^d$ ($d \geq 1$), say $[0,1]^d$, and the purpose is to estimate the unknown intensity function f_0 assumed to be positive. Wavelets have been used extensively for intensity estimation, and the statistical challenge has been to propose thresholding procedures in the spirit of Donoho and Johnstone (1994), that were adapted to the variance's spatial variability associated with the Poisson framework. An early method to deal with high dimensional count data has been to apply a variance stabilizing-transform (see Anscombe (1948)) and to treat the transformed data as if they were Gaussian. More recently, the same idea has been applied to the data's decomposition in the Haar-wavelet basis, see Fryzlewicz and Nason (2004) and Fryzlewicz (2008), but these methods rely on asymptotic approximations and tend to show lower performance when the level of counts is low (see Besbeas et al. (2004)). Dedicated wavelet thresholding methods were developed in the Poisson setting by Kolaczyk (1999) and Sardy et al. (2004), and a recurrent challenge has been to define an appropriate threshold like the universal threshold for shrinkage and selection, as the heteroscedasticity of the model calls for component-wise thresholding.

In this work we first propose to enrich the standard wavelet approach by considering the so-called dictionary strategy. We assume that $\log f_0$ can be well approximated by a linear combination of p known functions, and we reduce the estimation of f_0 to the estimation of p coefficients. Dictionaries can be built from classical orthonormal systems such as wavelets, histograms or the Fourier basis, which results in a framework that encompasses wavelet methods. Considering overcomplete (*ie* redundant) dictionaries is efficient to capture different features in the signal, by using sparse representations (see Chen et al. (2001) or Tropp (2004)). For example, if $\log f_0$ shows piece-wise constant trends along with some periodicity, combining both Haar and Fourier bases will be more powerful than separate strategies, and the model will be sparse in the coefficients domain. To ensure sparse estimations, we consider the Lasso and the group-Lasso procedures. Group estimators are particularly well adapted to the dictionary framework, especially if we consider dictionaries based on a wavelet system, for which it is well known that coefficients can be grouped scale-wise for instance (see Chicken and Cai (2005)). Finally, even if we do not make any assumption on p itself, it may be larger than n and methodologies based on ℓ_1-penalties, such as the Lasso and the group-Lasso appear appropriate.

The statistical properties of the Lasso are particularly well understood in the context of regression with *i.i.d.* errors, or for density estimation for which a range of oracle inequalities have been established. These inequalities, now widespread in the literature, provide theoretical error bounds that hold on events with a controllable (large) probability. See for instance Bertin et al. (2011), Bickel et al. (2009), Bunea et al. (2007a,b) and the references therein. For generalized linear models, Park and Hastie (2007) studied ℓ_1-regularization path algorithms and van de Geer (2008) established non-asymptotic oracle inequalities. The sign consistency of the Lasso has been studied by Jia et al. (2013) for a very specific Poisson model. Finally, we also mention than the Lasso has also been extensively consid-

ered in survival analysis. See for instance Gaïffas and Guilloux (2012), Zou (2008), Kong and Nan (2014), Bradic et al. (2011), Lemler (2013) and Hansen et al. (2014).

Here we consider not only the Lasso estimator but also its extension, the group-Lasso proposed by Yuan and Lin (2006), which is relevant when the set of parameters can be partitioned into groups. The analysis of the group-Lasso has been led in different contexts. For instance, consistency has been studied by Bach (2008), Obozinski et al. (2011) and Wei and Huang (2010). In the linear model, Nardi and Rinaldo (2008) derived conditions ensuring various asymptotic properties such as consistency, oracle properties or persistence. Still for the linear model, Lounici et al. (2011) established oracle inequalities and, in the Gaussian setting, pointed out advantages of the group-Lasso with respect to the Lasso, generalizing the results of Chesneau and Hebiri (2008) and Huang and Zhang (2010). We also mention Meier et al. (2008) who studied the group-Lasso for logistic regression, Blazere et al. (2014) for generalized linear model with Poisson regression as a special case and Dalalyan et al. (2013) for other linear heteroscedastic models.

As pointed out by empirical comparative studies (see Besbeas et al. (2004)), the calibration of any thresholding rule is of central importance. Here we consider Lasso and group-Lasso penalties of the form

$$\mathrm{pen}(\boldsymbol{\beta}) = \sum_{j=1}^{p} \lambda_j |\beta_j|$$

and

$$\mathrm{pen}^g(\boldsymbol{\beta}) = \sum_{k=1}^{K} \lambda_k^g \|\boldsymbol{\beta}_{G_k}\|_2,$$

where $G_1 \cup \cdots \cup G_K$ is a partition of $\{1, \ldots, p\}$ into non-overlapping groups (see Section 1 for more details). By calibration we refer to the definition and to the suitable choice of the weights λ_j and λ_k^g, which is intricate in heteroscedastic models, especially for the group-Lasso. For functional Poissonian regression, the ideal shape of these weights is unknown, even if for the group-Lasso, the λ_k^g's should of course depend on the groups size. As for the Lasso, most proposed weights in the literature are non-random and constant such that the penalty is proportional to $\|\boldsymbol{\beta}\|_1$, but when facing variable selection and consistency simultaneously, Zou (2006) showed the interest in considering non-constant data-driven ℓ_1-weights even in the simple case where the noise is Gaussian with constant variance. This issue becomes even more critical in Poisson functional regression in which variance shows spatial heterogeneity. As Zou (2006), our first contribution is to propose here adaptive procedures with weights depending on the data. Weights λ_j for the Lasso are derived by using sharp concentration inequalities, in the same spirit as Bertin et al. (2011), Gaïffas and Guilloux (2012), Lemler (2013) and Hansen et al. (2014), but adapted to the Poissonian setting. To account for heteroscedasticity, weights λ_j are component-specific and depend

on the data (see Theorem 1). We propose a similar procedure for the calibration of the group-Lasso. In most proposed procedures, the analogs of the λ_k^g's are proportional to the $\sqrt{|G_k|}$'s (see Nardi and Rinaldo (2008), Bühlmann and van de Geer (2011) or Blazere et al. (2014)). But to the best of our knowledge, adaptive group-Lasso procedures (with weights depending on the data) have not been proposed yet. This is the purpose of Theorem 2, which is the main result of this work, generalizing Theorem 1 by using sharp concentration inequalities for infinitely divisible vectors. We show the shape relevance of the data-driven weights λ_k^g by comparing them to the weights proposed by Lounici et al. (2011) in the Gaussian framework. In Theorem 2, we do not impose any condition on the groups size. However, whether $|G_k|$ is smaller than $\log p$ or not highly influences the order of magnitude of λ_k^g.

Our second contribution consists in providing the theoretical validity of our approach by establishing slow and fast oracle inequalities under RE-type conditions in the same spirit as Bickel et al. (2009). Closeness between our estimates and f_0 is measured by using the empirical Kullback-Leibler divergence. We show that classical oracle bounds are achieved. We also show the relevance of considering the group-Lasso instead of the Lasso in some situations. Our results, that are non-asymptotic, are valid under very general conditions on the design $(X_i)_{i=1,\ldots,n}$ and on the dictionary. However, to shed some light on our results, we illustrate some of them in the asymptotic setting with classical dictionaries like wavelets, histograms or Fourier bases. Our approach generalizes the classical basis approach and in particular block wavelet thresholding which is equivalent to group-Lasso in that case (see Yuan and Lin (2006)). We refer the reader to Chicken and Cai (2005) for a deep study of block wavelet thresholding in the context of density estimation whose framework shows some similarities with ours in terms of heteroscedasticity. Note that sharp estimation of variance terms proposed in this work can be viewed as an extension of coarse bounds provided by Chicken and Cai (2005). Finally, we emphasize that our procedure differs from Blazere et al. (2014)'s one in several aspects: First, in their Poisson regression setting, they do not consider a dictionary approach. Furthermore, their weights are constant and not data-driven, so are strongly different from ours. Finally, rates of Blazere et al. (2014) are established under much stronger assumptions than ours (see Section 3.1 for more details).

Finally, we explore the empirical properties of our calibration procedures by using simulations. We show that our procedures are very easy to implement, and we compare their performance with variance-stabilizing transforms and cross-validation. The calibrated Lasso and group-Lasso are associated with excellent reconstruction properties, even in the case of low counts. We also propose an original application of functional Poisson regression to the analysis of Next Generation Sequencing data, with the denoising of a Poisson intensity applied to the detection of replication origins in the human genome (see Picard et al. (2014)).

This article is organized as follows. In Section 1, we introduce the Lasso and group-Lasso procedures we propose in the dictionary approach setting. In Section 2, we derive

data-driven weights of our procedures that are extensively commented. Theoretical performance of our estimates are studied in Section 3 in the oracle approach. In Section 4, we investigate the empirical performance of the proposed estimators using simulated data, and an application is provided on next generation sequencing data in Section 5.

1. Penalized log-likelihood estimates for Poisson regression and dictionary approach

We consider the functional Poisson regression model, with n observed counts $Y_i \in \mathbb{N}$ modeled such that:

$$Y_i|X_i \sim \mathcal{P}oisson(f_0(X_i)), \tag{1.1}$$

with the X_i's (random or fixed) supposed to lie in a known compact support, say $[0,1]^d$. Since the goal here is to estimate the function f_0 assumed to be positive on $[0,1]^d$, a natural candidate is a function f of the form $f = \exp(g)$. Then, we consider the so-called dictionary approach which consists in decomposing g as a linear combination of the elements of a given finite dictionary of functions denoted by $\Upsilon = \{\varphi_j\}_{j\in\mathcal{J}}$, with $\|\varphi_j\|_2 = 1$ for all j. Consequently, we choose g of the form:

$$g = \sum_{j\in\mathcal{J}} \beta_j \varphi_j,$$

with $p = \text{card}(\mathcal{J})$ that may depend on n (as well as the elements of Υ). Without loss of generality we will assume in the following that $\mathcal{J} = \{1,\dots,p\}$. In this framework, estimating f_0 is equivalent to estimating the vector of regression coefficients $\boldsymbol{\beta} = (\beta_j)_{j\in\mathcal{J}} \in \mathbb{R}^p$. In the sequel, we write $g_{\boldsymbol{\beta}} = \sum_{j\in\mathcal{J}} \beta_j\varphi_j$, $f_{\boldsymbol{\beta}} = \exp(g_{\boldsymbol{\beta}})$, for all $\boldsymbol{\beta} \in \mathbb{R}^p$. Note that we do not require the model to be true, that is we do not suppose the existence of $\boldsymbol{\beta}_0$ such that $f_0 = f_{\boldsymbol{\beta}_0}$.

The strength of the dictionary approach lies in its ability to capture different features of the function to estimate (smoothness, sparsity, periodicity,...) by sparse combinations of elements of the dictionary so that only few coefficients need to be selected, which limits its estimation errors. Obviously, the dictionary approach encompasses the classical basis approach consisting in decomposing g on an orthonormal system. The richer the dictionary, the sparser the decomposition, so p can be larger than n and the model becomes high-dimensional.

We consider a likelihood-based penalized criterion to select $\boldsymbol{\beta}$, the coefficients of the dictionary decomposition. We denote by $\mathbf{A}$ the $n \times p$-design matrix with $A_{ij} = \varphi_j(X_i)$, $\mathbf{Y} = (Y_1,\dots,Y_n)^T$ and the log-likelihood associated with this model is

$$l(\boldsymbol{\beta}) = \sum_{j\in\mathcal{J}} \beta_j (\mathbf{A}^T\mathbf{Y})_j - \sum_{i=1}^n \exp\Big(\sum_{j\in\mathcal{J}} \beta_j A_{ij}\Big) - \sum_{i=1}^n \log(Y_i!),$$

which is a concave function of $\boldsymbol{\beta}$. Next sections propose two different ways to penalize $-l(\boldsymbol{\beta})$.

1.1 The Lasso estimate

The first penalty we propose is based on the (weighted) ℓ_1-norm and we obtain a Lasso-type estimate by considering

$$\widehat{\boldsymbol{\beta}}^L \in \underset{\boldsymbol{\beta}\in\mathbb{R}^p}{\text{argmin}} \left\{ -l(\boldsymbol{\beta}) + \sum_{j=1}^p \lambda_j|\beta_j| \right\}. \tag{1.2}$$

The penalty term $\sum_{j=1}^p \lambda_j|\beta_j|$ depends on positive weights $(\lambda_j)_{j\in\mathcal{J}}$ that vary according to the elements of the dictionary and are chosen in Section 2.1. This choice of varying weights instead of a unique λ stems from heteroscedasticity due to the Poisson regression, and a first part of our work consists in providing theoretical data-driven values for these weights, in the same spirit as Bertin et al. (2011) or Hansen et al. (2014) for instance. From the first order optimality conditions (see Bühlmann and van de Geer (2011)), $\widehat{\boldsymbol{\beta}}^L$ satisfies

$$\begin{cases} \mathbf{A}_j^T(\mathbf{Y} - \exp(\mathbf{A}\widehat{\boldsymbol{\beta}}^L)) = \lambda_j \dfrac{\widehat{\beta}_j^L}{|\widehat{\beta}_j^L|} & \text{if } \widehat{\beta}_j^L \neq 0, \\ |\mathbf{A}_j^T(\mathbf{Y} - \exp(\mathbf{A}\widehat{\boldsymbol{\beta}}^L))| \leq \lambda_j & \text{if } \widehat{\beta}_j^L = 0, \end{cases}$$

where $\exp(\mathbf{A}\boldsymbol{\beta}) = (\exp((\mathbf{A}\boldsymbol{\beta})_1),\dots,\exp((\mathbf{A}\boldsymbol{\beta})_n))^T$ and $\mathbf{A}_j$ is the j-th column of the matrix $\mathbf{A}$. Note that the larger the λ_j's, the sparser the estimates. In particular $\widehat{\boldsymbol{\beta}}^L$ belongs to the set of the vectors $\boldsymbol{\beta} \in \mathbb{R}^p$ that satisfies for any $j \in \mathcal{J}$,

$$|\mathbf{A}_j^T(\mathbf{Y} - \exp(\mathbf{A}\boldsymbol{\beta}))| \leq \lambda_j. \tag{1.3}$$

The Lasso estimator of f_0 is now easily derived.

Definition 1 *The Lasso estimator of f_0 is defined as*

$$\widehat{f}^L(x) := \exp(\widehat{g}^L(x)) := \exp\left(\sum_{j=1}^p \widehat{\beta}_j^L \varphi_j(x)\right).$$

We also propose an alternative to $\widehat{f}^L$ by considering the group-Lasso.

1.2 The group-Lasso estimate

We also consider the grouping of coefficients into non-overlapping blocks. Indeed, group estimates may be better adapted than their single counterparts when there is a natural group structure. The procedure keeps or discards all the coefficients within a block and can increase estimation accuracy by using information about coefficients of the same block. In our setting, we partition the set of indices $\mathcal{J} = \{1,\dots,p\}$ into K non-empty groups:

$$\{1,\dots,p\} = G_1 \cup G_2 \cup \dots \cup G_K.$$

For any $\boldsymbol{\beta} \in \mathbb{R}^p$, $\boldsymbol{\beta}_{G_k}$ stands for the sub-vector of $\boldsymbol{\beta}$ with elements indexed by the elements of G_k, and we define the block ℓ_1-norm on $\mathbb{R}^p$ by

$$\|\boldsymbol{\beta}\|_{1,2} = \sum_{k=1}^{K} \|\boldsymbol{\beta}_{G_k}\|_2.$$

Similarly, $\mathbf{A}_{G_k}$ is the $n \times |G_k|$ submatrix of $\mathbf{A}$ whose columns are indexed by the elements of G_k. Then the group-Lasso $\widehat{\boldsymbol{\beta}}^{gL}$ is a solution to the following convex optimization problem:

$$\widehat{\boldsymbol{\beta}}^{gL} \in \underset{\boldsymbol{\beta}\in\mathbb{R}^p}{\operatorname{argmin}} \Big\{ -l(\boldsymbol{\beta}) + \sum_{k=1}^{K} \lambda_k^g \|\boldsymbol{\beta}_{G_k}\|_2 \Big\},$$

where the λ_k^g's are positive weights for which we also provide a theoretical data-driven expression in Section 2.2. This group-estimator is constructed similarly to the Lasso, with the block ℓ_1-norm being used instead of the ℓ_1-norm. In particular, note that if all groups are of size one then we recover the Lasso estimator. Convex analysis states that $\widehat{\boldsymbol{\beta}}^{gL}$ is a solution of the above optimization problem if the p-dimensional vector $\mathbf{0}$ is in the subdifferential of the objective function. Therefore, $\widehat{\boldsymbol{\beta}}^{gL}$ satisfies:

$$\begin{cases} \mathbf{A}_{G_k}^T(\mathbf{Y} - \exp(\mathbf{A}\widehat{\boldsymbol{\beta}}^{gL})) = \lambda_k^g \dfrac{\widehat{\boldsymbol{\beta}}_{G_k}^{gL}}{\|\widehat{\boldsymbol{\beta}}_{G_k}^{gL}\|_2} & \text{if } \widehat{\boldsymbol{\beta}}_{G_k}^{gL} \neq \mathbf{0}, \\ \|\mathbf{A}_{G_k}^T(\mathbf{Y} - \exp(\mathbf{A}\widehat{\boldsymbol{\beta}}^{gL}))\|_2 \leq \lambda_k^g & \text{if } \widehat{\boldsymbol{\beta}}_{G_k}^{gL} = \mathbf{0}. \end{cases}$$

This procedure naturally enhances group-sparsity as analyzed by Yuan and Lin (2006), Lounici et al. (2011) and references therein.

Obviously, $\widehat{\boldsymbol{\beta}}^{gL}$ belongs to the set of the vectors $\boldsymbol{\beta} \in \mathbb{R}^p$ that satisfy for any $k \in \{1, \ldots, K\}$,

$$\|\mathbf{A}_{G_k}^T(\mathbf{Y} - \exp(\mathbf{A}\boldsymbol{\beta}))\|_2 \leq \lambda_k^g. \tag{1.4}$$

Now, we set

Definition 2 *The group Lasso estimator of f_0 is defined as*

$$\widehat{f}^{gL}(x) := \exp(\widehat{g}^{gL}(x)) := \exp\left(\sum_{j=1}^{p} \widehat{\beta}_j^{gL} \varphi_j(x)\right).$$

In the following our results are given conditionally on the X_i's, and $\mathbb{E}$ (resp. $\mathbb{P}$) stands for the expectation (resp. the probability measure) conditionally on $X_1, \ldots, X_n$. In some situations, to give orders of magnitudes of some expressions, we will use the following definition:

Definition 3 *We say that the design $(X_i)_{i=1,\ldots,n}$ is regular if either the design is deterministic and the X_i's are equispaced in $[0,1]$ or the design is random and the X_i's are i.i.d. with density h, with*

$$0 < \inf_{x\in[0,1]^d} h(x) \leq \sup_{x\in[0,1]^d} h(x) < \infty.$$

2. Weights calibration using concentration inequalities

Our first contribution is to derive theoretical data-driven values of the weights λ_j's and λ_k^g's, specially adapted to the Poisson model. In the classical Gaussian framework with noise variance σ^2, weights for the Lasso are chosen to be proportional to $\sigma\sqrt{\log p}$ (see Bickel et al. (2009) for instance). The Poisson setting is more involved due to heteroscedasticity and such simple tuning procedures cannot be generalized easily. Sections 2.1 and 2.2 give closed forms of parameters λ_j and λ_k^g. They are based on concentration inequalities specific to the Poisson model. In particular, λ_j is used to control the fluctuations of $\mathbf{A}_j^T\mathbf{Y}$ around its mean, which enhances the key role of V_j, a variance term (the analog of σ^2) defined by

$$V_j = \mathrm{Var}(\mathbf{A}_j^T\mathbf{Y}) = \sum_{i=1}^{n} f_0(X_i)\varphi_j^2(X_i). \tag{2.1}$$

2.1 Data-driven weights for the Lasso procedure

For any j, we choose a data-driven value for λ_j as small as possible so that with high probability, for any $j \in \mathcal{J}$,

$$|\mathbf{A}_j^T(\mathbf{Y} - \mathbb{E}[\mathbf{Y}])| \leq \lambda_j. \tag{2.2}$$

Such a control is classical for Lasso estimates (see the references above) and is also a key point of the technical arguments of the proofs. Requiring that the weights are as small as possible is justified, from the theoretical point of view, by oracle bounds depending on the λ_j's (see Corollaries 1 and 2). Furthermore, as discussed in Bertin et al. (2011), choosing theoretical Lasso weights as small as possible is also a suitable guideline for practical purposes. Finally, note that if the model were true, *i.e.* if there existed a true sparse vector $\boldsymbol{\beta}_0$ such that $f_0 = f_{\boldsymbol{\beta}_0}$, then $\mathbb{E}[\mathbf{Y}] = \exp(\mathbf{A}\boldsymbol{\beta}_0)$ and $\boldsymbol{\beta}_0$ would belong to the set defined by (1.3) with large probability. The smaller the λ_j's, the smaller the set within selection of $\widehat{\boldsymbol{\beta}}^L$ is performed. So, with a sharp control in (2.2), we increase the probability to select $\boldsymbol{\beta}_0$. The following theorem provides the data-driven weights λ_j's. The main theoretical ingredient we use to choose the weights λ_j's is a concentration inequality for Poisson processes and to proceed, we link the quantity $\mathbf{A}_j^T\mathbf{Y}$ to a specific Poisson process, as detailed in the proofs Section 7.1.

Theorem 1 *Let j be fixed and $\gamma > 0$ be a constant. Define $\widehat{V}_j = \sum_{i=1}^n \varphi_j^2(X_i)Y_i$ the natural unbiased estimator of V_j and*

$$\widetilde{V}_j = \widehat{V}_j + \sqrt{2\gamma \log p \widehat{V}_j \max_i \varphi_j^2(X_i)} + 3\gamma \log p \max_i \varphi_j^2(X_i).$$

Set

$$\lambda_j = \sqrt{2\gamma \log p \widetilde{V}_j} + \frac{\gamma \log p}{3} \max_i |\varphi_j(X_i)|, \tag{2.3}$$

then

$$\mathbb{P}\Big(|\mathbf{A}_j^T(\mathbf{Y} - \mathbb{E}[\mathbf{Y}])| \geq \lambda_j\Big) \leq \frac{3}{p^\gamma}. \tag{2.4}$$

The first term $\sqrt{2\gamma \log p \widetilde{V}_j}$ in λ_j is the main one, and constitutes a variance term depending on $\widetilde{V}_j$ that slightly overestimates V_j (see Section 7.1 for more details about the derivation of $\widetilde{V}_j$). Its dependence on an estimate of V_j was expected since we aim at controlling fluctuations of $\mathbf{A}_j^T\mathbf{Y}$ around its mean. The second term comes from the heavy tail of the Poisson distribution, and is the price to pay, in the non-asymptotic setting, for the added complexity of the Poisson framework compared to the Gaussian framework.

To shed more lights on the form of the proposed weights from the asymptotic point of view, assume that the design is regular (see Definition 3). In this case, it is easy to see that under mild assumptions on f_0, V_j is asymptotically of order n. If we further assume that

$$\max_i |\varphi_j(X_i)| = o(\sqrt{n/\log p}), \tag{2.5}$$

then, when p is large, with high probability, $\widehat{V}_j$ (and then $\widetilde{V}_j$) is also of order n (using Remark 2 in the proofs Section 7.1), and the second term in λ_j is negligible with respect to the first one. In this case, λ_j is of order $\sqrt{n \log p}$. Note that Assumption (2.5) is quite classical in heteroscedastic settings (see Bertin et al. (2011)). By taking the hyperparameter γ larger than 1, then for large values of p, (2.2) is true for any $j \in \mathcal{J}$, with large probability.

2.2 Data-driven weights for the group Lasso procedure

Current group-Lasso procedures are tuned by choosing the analog of λ_k^g proportional to $\sqrt{|G_k|}$ (see Nardi and Rinaldo (2008), Chapter 4 of Bühlmann and van de Geer (2011) or Blazere et al. (2014)). A more refined version of tuning group-Lasso is provided by Lounici et al. (2011) in the Gaussian setting (see below for a detailed discussion). To the best of our knowledge, data-driven weights (with theoretical validation) for the group-Lasso have not been proposed yet. It is the purpose of Theorem 2. Similarly to the previous section, we propose data-driven theoretical derivations for the weights λ_k^g's that are chosen as small as possible, but satisfying for any $k \in \{1, \dots, K\}$,

$$\|\mathbf{A}_{G_k}^T(\mathbf{Y} - \mathbb{E}[\mathbf{Y}])\|_2 \leq \lambda_k^g \tag{2.6}$$

with high probability (see (1.4)). Choosing the smallest possible weights is also recommended by Lounici et al. (2011) in the Gaussian setting (see in their Section 3 the discussion about weights and comparisons with coarser weights of Nardi and Rinaldo (2008)). Obviously, λ_k^g should depend on sharp estimates of the variance parameters $(V_j)_{j \in G_k}$. The following theorem is the equivalent of Theorem 1 for the group-Lasso. Relying on specific concentration inequalities established for infinitely divisible vectors by Houdré et al. (2008), it requires a known upper bound for f_0, which can be chosen as $\max_i Y_i$ in practice.

Theorem 2 *Let $k \in \{1, \dots, K\}$ be fixed and $\gamma > 0$ be a constant. Assume that there exists $M > 0$ such that for any x, $|f_0(x)| \leq M$. Let*

$$c_k = \sup_{\mathbf{x} \in \mathbb{R}^n} \frac{\|\mathbf{A}_{G_k}\mathbf{A}_{G_k}^T\mathbf{x}\|_2}{\|\mathbf{A}_{G_k}^T\mathbf{x}\|_2}. \tag{2.7}$$

For all $j \in G_k$, still with $\widehat{V}_j = \sum_{i=1}^n \varphi_j^2(X_i)Y_i$, define

$$\widetilde{V}_j^g = \widehat{V}_j + \sqrt{2(\gamma \log p + \log|G_k|)\widehat{V}_j \max_i \varphi_j^2(X_i)} + 3(\gamma \log p + \log|G_k|) \max_i \varphi_j^2(X_i). \tag{2.8}$$

Let $\gamma > 0$ be fixed. Define $b_k^i = \sqrt{\sum_{j \in G_k} \varphi_j^2(X_i)}$ and $b_k = \max_i b_k^i$. Finally, we set

$$\lambda_k^g = \left(1 + \frac{1}{2\sqrt{2\gamma \log p}}\right) \sqrt{\sum_{j \in G_k} \widetilde{V}_j^g} + 2\sqrt{\gamma \log p \, D_k}, \tag{2.9}$$

where $D_k = 8Mc_k^2 + 16b_k^2\gamma \log p$. Then,

$$\mathbb{P}\left(\|\mathbf{A}_{G_k}^T(\mathbf{Y} - \mathbb{E}[\mathbf{Y}])\|_2 \geq \lambda_k^g\right) \leq \frac{2}{p^\gamma}. \tag{2.10}$$

Similarly to the weights λ_j's of the Lasso, each weight λ_k^g is the sum of two terms. The term $\widetilde{V}_j^g$ is an estimate of V_j so it plays the same role as $\widetilde{V}_j$. In particular, $\widetilde{V}_j^g$ and $\widetilde{V}_j$ are of the same order since $\log|G_k|$ is not larger than $\log p$. The first term in λ_k^g is a variance term, and the leading constant $1 + 1/(2\sqrt{2\gamma \log p})$ is close to 1 when p is large. So, the first term is close to the square root of the sum of sharp estimates of the $(V_j)_{j \in G_k}$, as expected for a grouping strategy (see Chicken and Cai (2005)).

The second term, namely $2\sqrt{\gamma \log p \, D_k}$, is more involved. To shed light on it, since b_k and c_k play a key role, we first state the following proposition controlling values of these terms.

Proposition 1 *Let k be fixed. We have*

$$b_k \leq c_k \leq \sqrt{n} b_k. \tag{2.11}$$

Furthermore,

$$c_k^2 \leq \max_{j\in G_k} \sum_{j'\in G_k} \Big|\sum_{l=1}^n \varphi_j(X_l)\varphi_{j'}(X_l)\Big|. \tag{2.12}$$

The first inequality of Proposition 1 shows that $2\sqrt{\gamma \log p\, D_k}$ is smaller than $c_k\sqrt{\log p}+b_k \log p \leq 2c_k \log p$ up to a constant depending on γ and M. At first glance, the second inequality of Proposition 1 shows that c_k is controlled by the coherence of the dictionary (see Tropp (2004)) and b_k depends on $(\max_i |\varphi_j(X_i)|)_{j\in G_k}$. In particular, if for a given block G_k, the functions $(\varphi_j)_{j\in G_k}$ are orthonormal, then for fixed $j \neq j'$, if the X_i's are deterministic and equispaced on $[0,1]$ or if the X_i's are i.i.d. with a uniform density on $[0,1]^d$, then, when n is large

$$\frac{1}{n}\sum_{l=1}^n \varphi_j(X_l)\varphi_{j'}(X_l) \approx \int \varphi_j(x)\varphi_{j'}(x)dx = 0$$

and we expect

$$c_k^2 \lesssim \max_{j\in G_k} \sum_{l=1}^n \varphi_j^2(X_l).$$

In any case, by using the Cauchy-Schwarz Inequality, Condition (2.12) gives

$$c_k^2 \leq \max_{j\in G_k} \sum_{j'\in G_k} \left(\sum_{l=1}^n \varphi_j^2(X_l)\right)^{1/2} \left(\sum_{l=1}^n \varphi_{j'}^2(X_l)\right)^{1/2}. \tag{2.13}$$

To further discuss orders of magnitude for the c_k's, we consider the following condition

$$\max_{j\in G_k} \sum_{l=1}^n \varphi_j^2(X_l) = O(n), \tag{2.14}$$

which is satisfied for instance for fixed k if the design is regular, since $\|\varphi_j\|_2 = 1$. Under Assumption (2.14), Inequality (2.13) gives

$$c_k^2 = O(|G_k|n).$$

We can say more on b_k and c_k (and then on the order of magnitude of λ_k^g) by considering classical dictionaries of the literature to build the blocks G_k, which is of course realized in practice. In the subsequent discussions, the balance between $|G_k|$ and $\log p$ plays a key role. Note also that $\log p$ is the group size often recommended in the classical setting ($p = n$) for block thresholding (see Theorem 1 of Chicken and Cai (2005)).

2.2.1 Order of magnitude of λ_k^g by considering classical dictionaries.

Let G_k be a given block and assume that it is built by using only one of the subsequent systems. For each example, we discuss the order of magnitude of the term $D_k = 8Mc_k^2 + 16b_k^2\gamma \log p$. For ease of exposition, we assume that f_0 is supported by $[0,1]$ but we could easily generalize the following discussion to the multidimensional setting.

Bounded dictionary. Similarly to Blazere et al. (2014), we assume that there exists a constant L not depending on n and p such that for any $j \in G_k$, $\|\varphi_j\|_\infty \leq L$. For instance, atoms of the Fourier basis satisfy this property. We then have

$$b_k^2 \leq L^2|G_k|.$$

Finally, under Assumption (2.14),

$$D_k = O(|G_k|n + |G_k|\log p). \tag{2.15}$$

Compactly supported wavelets. Consider the one-dimensional Haar dictionary: For $j = (j_1, k_1) \in \mathbb{Z}^2$ we set $\varphi_j(x) = 2^{j_1/2}\psi(2^{j_1}x - k_1)$, $\psi(x) = 1_{[0,0.5]}(x) - 1_{]0.5,1]}(x)$. Assume that the block G_k depends on only one resolution level j_1: $G_k = \{j = (j_1, k_1) : \quad k_1 \in B_{j_1}\}$, where B_{j_1} is a subset of $\{0, 1, \ldots, 2^{j_1} - 1\}$. In this case, since for $j, j' \in G_k$ with $j \neq j'$, for any x, $\varphi_j(x)\varphi_{j'}(x) = 0$,

$$b_k^2 = \max_i \sum_{j\in G_k} \varphi_j^2(X_i) = \max_{i,j\in G_k} \varphi_j^2(X_i) = 2^{j_1}$$

and Inequality (2.12) gives

$$c_k^2 \leq \max_{j\in G_k} \sum_{l=1}^n \varphi_j^2(X_l).$$

If, similarly to Condition (2.5), we assume that $\max_{i,j\in G_k} |\varphi_j(X_i)| = o(\sqrt{n/\log p})$, then

$$b_k^2 = o(n/\log p),$$

and under Assumption (2.14),

$$D_k = O(n),$$

which improves (2.15). This property can be easily extended to general compactly supported wavelets ψ, since, in this case, for any $j = (j_1, k_1)$

$$S_j = \left\{j' = (j_1, k_1') : \quad k_1' \in \mathbb{Z},\ \varphi_j \times \varphi_{j'} \not\equiv 0\right\}$$

is finite with cardinal only depending on the support of ψ.

Regular histograms. Consider a regular grid of the interval $[0,1]$, $\{0,\delta,2\delta,\ldots\}$ with $\delta>0$. Consider then $(\varphi_j)_{j\in G_k}$ such that for any $j\in G_k$, there exists ℓ such that $\varphi_j=\delta^{-1/2}1_{(\delta(\ell-1),\delta\ell]}$. We have $\|\varphi_j\|_2=1$ and $\|\varphi_j\|_\infty=\delta^{-1/2}$. As for the wavelet case, for $j,j'\in G_k$ with $j\neq j'$, for any x, $\varphi_j(x)\varphi_{j'}(x)=0$, then

$$b_k^2=\max_i\sum_{j\in G_k}\varphi_j^2(X_i)=\max_{i,j\in G_k}\varphi_j^2(X_i)=\delta^{-1}.$$

If, similarly to Condition (2.5), we assume that $\max_{i,j\in G_k}|\varphi_j(X_i)|=o(\sqrt{n/\log p})$, then

$$b_k^2=o(n/\log p),$$

and under Assumption (2.14),

$$D_k=O(n).$$

The previous discussion shows that we can exhibit dictionaries such that c_k^2 and D_k are of order n and the term $b_k^2\log p$ is negligible with respect to c_k^2. Then, if similarly to Section 2.1, the terms $(\widetilde{V}_j^g)_{j\in G_k}$ are all of order n, λ_k^g is of order $\sqrt{n\times\max(\log p;|G_k|)}$ and the main term in λ_k^g is the first one as soon as $|G_k|\geq\log p$. In this case, λ_k^g is of order $\sqrt{|G_k|n}$.

2.2.2 Comparison with the Gaussian framework.

Now, let us compare the λ_k^g's to the weights proposed by Lounici et al. (2011) in the Gaussian framework. Adapting their notations to ours, Lounici et al. (2011) estimate the vector $\boldsymbol{\beta}_0$ in the model $\mathbf{Y}\sim\mathcal{N}(\mathbf{A}\boldsymbol{\beta}_0,\sigma^2\mathbf{I}_n)$ by using the group-Lasso estimate with weights equal to

$$\widetilde{\lambda}_k^g=2\sqrt{\sigma^2\Big(Tr(\mathbf{A}_{G_k}^T\mathbf{A}_{G_k})+2|||\mathbf{A}_{G_k}^T\mathbf{A}_{G_k}|||(2\gamma\log p+\sqrt{|G_k|\gamma\log p})\Big)},$$

where $|||\mathbf{A}_{G_k}^T\mathbf{A}_{G_k}|||$ denotes the maximal eigenvalue of $\mathbf{A}_{G_k}^T\mathbf{A}_{G_k}$ (see (3.1) in Lounici et al. (2011)). So, if $|G_k|\leq\log p$, the above expression is of the same order as

$$\sqrt{\sigma^2Tr(\mathbf{A}_{G_k}^T\mathbf{A}_{G_k})}+\sqrt{\sigma^2|||\mathbf{A}_{G_k}^T\mathbf{A}_{G_k}|||\gamma\log p}. \tag{2.16}$$

Neglecting the term $16b_k^2\gamma\log p$ in the definition of D_k (see the discussion in Section 2.2.1), we observe that λ_k^g is of the same order as

$$\sqrt{\sum_{j\in G_k}\widetilde{V}_j^g}+\sqrt{Mc_k^2\gamma\log p}. \tag{2.17}$$

Since M is an upper bound of $\mathrm{Var}(Y_i)=f_0(X_i)$ for any i, strong similarities can be highlighted between the forms of the weights in the Poisson and Gaussian settings:

- For the first terms, $\widetilde{V}_j^g$ is an estimate of V_j and

$$\sum_{j\in G_k}V_j\leq M\sum_{j\in G_k}\sum_{i=1}^n\varphi_j^2(X_i)=M\times Tr(\mathbf{A}_{G_k}^T\mathbf{A}_{G_k}).$$

- For the second terms, in view of (2.7), c_k^2 is related to $|||\mathbf{A}_{G_k}^T\mathbf{A}_{G_k}|||$ since we have

$$c_k^2=\sup_{\mathbf{x}\in\mathbb{R}^n}\frac{\|\mathbf{A}_{G_k}\mathbf{A}_{G_k}^T\mathbf{x}\|_2^2}{\|\mathbf{A}_{G_k}^T\mathbf{x}\|_2^2}\leq\sup_{\mathbf{y}\in\mathbb{R}^{|G_k|}}\frac{\|\mathbf{A}_{G_k}\mathbf{y}\|_2^2}{\|\mathbf{y}\|_2^2}=|||\mathbf{A}_{G_k}^T\mathbf{A}_{G_k}|||.$$

These strong similarities between the Gaussian and the Poissonian settings strongly support the shape relevance of the weights we propose.

2.2.3 Suboptimality of the naive procedure

Finally, we show that the naive procedure that considers $\sqrt{\sum_{j\in G_k}\lambda_j^2}$ instead of λ_k^g is suboptimal even if, obviously due to Theorem 1, with high probability,

$$\|\mathbf{A}_{G_k}^T(\mathbf{Y}-\mathbb{E}[\mathbf{Y}])\|_2\leq\sqrt{\sum_{j\in G_k}\lambda_j^2}.$$

Suboptimality is justified by following heuristic arguments. Assume that for all j and k, the first terms in (2.3) and (2.9) are the main ones and $\widetilde{V}_j\approx\widetilde{V}_j^g\approx V_j$. Then by considering λ_k^g instead of $\sqrt{\sum_{j\in G_k}\lambda_j^2}$, we improve our weights by the factor $\sqrt{\log p}$, since in this situation,

$$\lambda_k^g\approx\sqrt{\sum_{j\in G_k}V_j}$$

and

$$\sqrt{\sum_{j\in G_k}\lambda_j^2}\approx\sqrt{\log p\sum_{j\in G_k}V_j}\approx\sqrt{\log p}\,\lambda_k^g.$$

Remember that our previous discussion shows the importance to consider weights as small as possible as soon as (2.6) is satisfied with high probability. The next section will confirm this point.

3. Oracle inequalities

In this section, we establish oracle inequalities to study theoretical properties of our estimation procedures. The X_i's are still assumption-free, and the performance of our procedures will be only evaluated at the X_i's. To measure the closeness between f_0 and an estimate,

we use the empirical Kullback-Leibler divergence associated with our model, denoted by $K(\cdot,\cdot)$. Straightforward computations (see for instance Leblanc and Letué (2006)) show that for any positive function f,

$$\begin{aligned} K(f_0,f) &= \mathbb{E}\left[\log\left(\frac{\mathcal{L}(f_0)}{\mathcal{L}(f)}\right)\right] \\ &= \sum_{i=1}^{n}\left[(f_0(X_i)\log f_0(X_i) - f_0(X_i))\right] - \left[(f_0(X_i)\log f(X_i) - f(X_i))\right], \end{aligned}$$

where $\mathcal{L}(f)$ is the likelihood associated with f. We speak about *empirical divergence* to emphasize its dependence on the X_i's. Note that we can write

$$K(f_0,f) = \sum_{i=1}^{n} f_0(X_i)(e^{u_i} - u_i - 1), \tag{3.1}$$

where $u_i = \log\frac{f(X_i)}{f_0(X_i)}$. This expression clearly shows that $K(f_0,f)$ is non-negative and $K(f_0,f) = 0$ if and only if for all $i \in \{1,\dots,n\}$, we have $u_i = 0$, that is $f(X_i) = f_0(X_i)$ for all $i \in \{1,\dots,n\}$.

Remark 1 *To weaken the dependence on n in the asymptotic setting, an alternative, not considered here, would consist in considering $n^{-1}K(\cdot,\cdot)$ instead of $K(\cdot,\cdot)$.*

If the classical $\mathbb{L}_2$-norm is the natural loss-function for penalized least squares criteria, the empirical Kullback-Leibler divergence is a natural alternative for penalized likelihood criteria. In next sections, oracle inequalities will be expressed by using $K(\cdot,\cdot)$.

3.1 Oracle inequalities for the group-Lasso estimate

In this section, we state oracle inequalities for the group-Lasso. These results can be viewed as generalizations of results by Lounici et al. (2011) to the case of the Poisson regression model. They will be established on the set Ω_g where

$$\Omega_g = \left\{\|\mathbf{A}_{G_k}^T(\mathbf{Y} - \mathbb{E}[\mathbf{Y}])\|_2 \le \lambda_k^g \quad \forall\, k \in \{1,\dots,K\}\right\}. \tag{3.2}$$

Under assumptions of Theorem 2, we have $\mathbb{P}(\Omega_g) \ge 1 - \frac{2K}{p^\gamma} \ge 1 - 2p^{1-\gamma}$. By considering $\gamma > 1$, we have that $\mathbb{P}(\Omega_g)$ goes to 1 at a polynomial rate of convergence when p goes to $+\infty$. Even if our procedure is applied with weights defined in Section 2.2, note that subsequent oracle inequalities would hold for any weights $(\lambda_k^g)_{k=1,\dots,K}$ such that the associated set Ω_g has high probability. For any $\boldsymbol{\beta} \in \mathbb{R}^p$, we denote by

$$f_{\boldsymbol{\beta}}(x) = \exp\left(\sum_{j=1}^{p}\beta_j\varphi_j(x)\right),$$

the candidate associated with $\boldsymbol{\beta}$ to estimate f_0. We first give a *slow oracle inequality* (see for instance Bunea et al. (2007a), Gaïffas and Guilloux (2012) or Lounici et al. (2011)) that does not require any assumption.

Theorem 3 *On Ω_g,*

$$K(f_0,\widehat{f}^{gL}) \le \inf_{\boldsymbol{\beta}\in\mathbb{R}^p}\left\{K(f_0,f_\beta) + 2\sum_{k=1}^{K}\lambda_k^g\|\boldsymbol{\beta}_{G_k}\|_2\right\}. \tag{3.3}$$

Note that

$$\sum_{k=1}^{K}\lambda_k^g\|\boldsymbol{\beta}_{G_k}\|_2 \le \max_{k\in\{1,\dots,K\}}\lambda_k^g \times \|\boldsymbol{\beta}\|_{1,2}$$

and (3.3) is then similar to Inequality (3.9) of Lounici et al. (2011). We can improve the rate of (3.3) at the price of stronger assumptions on the matrix $\mathbf{A}$. We consider the following assumptions:

Assumption 1. We assume that

$$m := \max_{i\in\{1,\dots,n\}}|\log f_0(X_i)| < \infty.$$

This assumption is equivalent to assuming that f_0 is bounded from below and from above by positive constants. We do not assume that m is known in the sequel.

Assumption 2. For some integer $s \in \{1,\dots,K\}$ and some constant r, the following condition holds:

$$0 < \kappa_n(s,r) := \min\left\{\frac{(\boldsymbol{\beta}^T\mathbf{G}\boldsymbol{\beta})^{1/2}}{\|\boldsymbol{\beta}_J\|_2} :\ |J| \le s,\ \boldsymbol{\beta}\in\mathbb{R}^p\setminus\{0\},\ \sum_{k\in J^c}\lambda_k^g\|\boldsymbol{\beta}_{G_k}\|_2 \le r\sum_{k\in J}\lambda_k^g\|\boldsymbol{\beta}_{G_k}\|_2\right\},$$

where $\mathbf{G}$ is the Gram matrix defined by $\mathbf{G} = \mathbf{A}^T\mathbf{C}\mathbf{A}$, where $\mathbf{C}$ is the diagonal matrix with $C_{i,i} = f_0(X_i)$. With a slight abuse, $\boldsymbol{\beta}_J$ stands for the sub-vector of $\boldsymbol{\beta}$ with elements indexed by the indices of the groups $(G_k)_{k\in J}$.

This assumption is the natural extension of the classical *Restricted Eigenvalue condition* introduced by Bickel et al. (2009) to study the Lasso estimate where the ℓ_1-norm is replaced with the weighted $\|\cdot\|_{1,2}$-norm. In the Gaussian setting, Lounici et al. (2011) considered similar conditions to establish oracle inequalities for their group-Lasso procedure (see their Assumption (3.1)). RE-type assumptions are among the mildest ones to establish oracle inequalities (see van de Geer and Bühlmann (2009)). In particular, if the Gram matrix G has a positive minimal eigenvalue, say $d_{G,min}$, then Assumption 2 is satisfied with $\kappa_n^2(s,r) \ge d_{G,min}$. Assumption 2 can be connected to stronger coherence type conditions involving

the ratio $\frac{\max_k \lambda_k^g}{\min_k \lambda_k^g}$ (see Appendix B.3. of Lounici et al. (2011)). Furthermore, if c_0 is a positive lower bound for f_0, then for all $\boldsymbol{\beta} \in \mathbb{R}^p$,

$$\boldsymbol{\beta}^T \mathbf{G} \boldsymbol{\beta} = (\mathbf{A}\boldsymbol{\beta})^T \mathbf{C} (\mathbf{A}\boldsymbol{\beta}) \geq c_0 \|\mathbf{A}\boldsymbol{\beta}\|_2^2 = c_0 \sum_{i=1}^n \Big(\sum_{j=1}^p \beta_j \varphi_j(X_i) \Big)^2 = c_0 \sum_{i=1}^n g_{\boldsymbol{\beta}}^2(X_i),$$

with $g_{\boldsymbol{\beta}} = \sum_{j=1}^p \beta_j \varphi_j$. If $(\varphi_j)_{j \in \mathcal{J}}$ is orthonormal on $[0,1]^d$ and if the design is regular, then the last term is the same order as

$$n \int g_{\boldsymbol{\beta}}^2(x) dx = n \|\boldsymbol{\beta}\|_2^2 \geq n \|\boldsymbol{\beta}_J\|_2^2$$

for any subset $J \subset \{1, \ldots, K\}$. Under these assumptions, $\kappa_n^{-2}(s,r) = O(n^{-1})$.

We now introduce for any $\mu > 0$

$$\Gamma(\mu) = \left\{ \boldsymbol{\beta} \in \mathbb{R}^p : \quad \max_{i \in \{1,\ldots,n\}} \left| \sum_{j=1}^p \beta_j \varphi_j(X_i) \right| \leq \mu \right\}.$$

In the sequel, we restrict our attention to estimates belonging to the convex set $\Gamma(\mu)$. Of course, if m were known we would take $\mu = m$ (or μ a bit larger than m). Note that we do not impose any upper bound on μ so this condition is quite mild. The role of $\Gamma(\mu)$ consists in connecting $K(.,.)$ to some empirical quadratic loss functions (see the proof of Theorem 4). Alternative stronger assumptions have been considered by Lemler (2013) relying on van de Geer (2008) and Kong and Nan (2014). The value of μ only influences constants in subsequent oracle inequalities.

We consider the slightly modified group-Lasso estimate. Let $\alpha > 1$ and let us set

$$\widehat{\boldsymbol{\beta}}_{\mu,\alpha}^{gL} \in \operatorname*{argmin}_{\boldsymbol{\beta} \in \Gamma(\mu)} \Big\{ -l(\boldsymbol{\beta}) + \alpha \sum_{k=1}^K \lambda_k^g \|\boldsymbol{\beta}_{G_k}\|_2 \Big\}, \quad \widehat{f}_{\mu,\alpha}^{gL}(x) = \exp\left(\sum_{j=1}^p (\widehat{\boldsymbol{\beta}}_{\mu,\alpha}^{gL})_j \varphi_j(x) \right)$$

for which we obtain the following fast oracle inequality.

Theorem 4 *Let $\varepsilon > 0$ and s a positive integer. Let Assumption 2 be satisfied with s and*

$$r = \frac{\alpha + 1 + 2\alpha/\varepsilon}{\alpha - 1}.$$

Then, under Assumption 1, there exists a constant $B(\varepsilon, m, \mu)$ depending on ε, m and μ such that, on Ω_g,

$$K(f_0, \widehat{f}_{\mu,\alpha}^{gL}) \leq (1+\varepsilon) \inf_{\substack{\boldsymbol{\beta} \in \Gamma(\mu) \\ |J(\boldsymbol{\beta})| \leq s}} \left\{ K(f_0, f_{\boldsymbol{\beta}}) + B(\varepsilon, m, \mu) \frac{\alpha^2 |J(\boldsymbol{\beta})|}{\kappa_n^2} \times \left(\max_{k \in \{1,\ldots,K\}} \lambda_k^g \right)^2 \right\}, \quad (3.4)$$

where κ_n stands for $\kappa_n(s,r)$, and $J(\boldsymbol{\beta})$ is the subset of $\{1, \ldots, K\}$ such that $\boldsymbol{\beta}_{G_k} = \mathbf{0}$ if and only if $k \notin J(\boldsymbol{\beta})$.

The estimate $\widehat{\boldsymbol{\beta}}_{\mu,\alpha}^{gL}$ studied in Theorem 4 slightly differs from the estimate $\widehat{\boldsymbol{\beta}}^{gL}$ introduced in Section 1.2 since it depends on α and minimization is only performed on $\Gamma(\mu)$. Both estimates coincide when $\mu = +\infty$ and when $\alpha = 1$. An examination of the proof of Theorem 4 shows that $\lim_{\mu \to +\infty} B(\varepsilon, m, \mu) = +\infty$. In practice, we observe that most of the time, with $\alpha = 1$ and μ large enough, $\widehat{\boldsymbol{\beta}}_{\mu,\alpha}^{gL}$ and $\widehat{\boldsymbol{\beta}}^{gL}$ coincide. So, when α is close to 1 and μ is large, Theorem 4 gives a good flavor of theoretical performances satisfied by our group-Lasso procedure.

Let us comment each term of the right-hand side of (3.4). The first term is an approximation term, which can vanish if f_0 can be decomposed on the dictionary. The second term is a variance term, according to the usual terminology, which is proportional to the size of $J(\boldsymbol{\beta})$. Its shape is classical in the high dimensional setting. See for instance Theorem 3.2 of Lounici et al. (2011) for the group-Lasso in linear models, or Theorem 6.1 of Bickel et al. (2009) and Theorem 3 of Bertin et al. (2011) for the Lasso. If the order of magnitude of λ_k^g is $\sqrt{n \times \max(\log p; |G_k|)}$ (see Section 2.2.1) and if $\kappa_n^{-2} = O(n^{-1})$, the order of magnitude of this variance term is not larger than $|J(\boldsymbol{\beta})| \times \max(\log p; |G_k|)$. Finally, if f_0 can be well approximated (for the empirical Kullback-Leibler divergence) by a group-sparse combination of the functions of the dictionary, then the right hand side of (3.4) will take small values. So, the previous result justifies our group-Lasso procedure from the theoretical point of view. Note that (3.3) and (3.4) also show the interest of considering weights as small as possible.

Blazere et al. (2014) established rates of convergence under stronger assumptions, namely all coordinates of the analog of $\mathbf{A}$ are bounded by a quantity L, where L is viewed as a constant. Rates depend on L in an exponential manner and would highly deteriorate if L depended on n and p. So, this assumption is not reasonable if we consider dictionaries such as wavelets or histograms (see Section 2.2.1).

3.2 Oracle inequalities for the Lasso estimate

For the sake of completeness, we provide oracle inequalities for the Lasso. Theorems 3 and 4 that deal with the group-Lasso estimate can be adapted to the non-grouping strategy when we take groups of size 1. Subsequent results are similar to those established by Lemler (2013) who studied the Lasso estimate for the high-dimensional Aalen multiplicative intensity model. The block ℓ_1-norm $\|\cdot\|_{1,2}$ becomes the usual ℓ_1-norm and the group support $J(\boldsymbol{\beta})$ is simply the support of $\boldsymbol{\beta}$. As previously, we only work on the probability set Ω defined by

$$\Omega = \Big\{ |\mathbf{A}_j^T (\mathbf{Y} - \mathbb{E}[\mathbf{Y}])| \leq \lambda_j \quad \forall j \in \{1, \ldots, p\} \Big\}. \quad (3.5)$$

Theorem 1 asserts that $\mathbb{P}(\Omega) \geq 1 - \frac{3}{p^{\gamma - 1}}$ that goes to 1 as soon as $\gamma > 1$. As previously, subsequent oracle inequalities would hold for any weights $(\lambda_j)_{j=1,\ldots,p}$ such that the asso-

ciated probability set Ω has high probability. We obtain a slow oracle inequality for $\widehat{f}^L$:

Corollary 1 *On Ω,*

$$K(f_0, \widehat{f}^L) \leq \inf_{\boldsymbol{\beta}\in\mathbb{R}^p} \Big\{ K(f_0, f_{\boldsymbol{\beta}}) + 2\sum_{j=1}^{p} \lambda_j |\beta_j| \Big\}.$$

Now, let us consider fast oracle inequalities. In this framework, Assumption 2 is replaced with the following:

Assumption 3. For some integer $s \in \{1, \dots, p\}$ and some constant r, the following condition holds:

$$0 < \kappa_n(s, r) := \min \left\{ \frac{(\boldsymbol{\beta}^T \mathbf{G} \boldsymbol{\beta})^{1/2}}{\|\boldsymbol{\beta}_J\|_2} : \ |J| \leq s, \ \boldsymbol{\beta} \in \mathbb{R}^p \setminus \{0\}, \ \sum_{j\in J^c} \lambda_j |\boldsymbol{\beta}_j| \leq r \sum_{j\in J} \lambda_j |\boldsymbol{\beta}_j| \right\},$$

where $\mathbf{G}$ is the Gram matrix defined by $\mathbf{G} = \mathbf{A}^T \mathbf{C} \mathbf{A}$, where $\mathbf{C}$ is the diagonal matrix with $C_{i,i} = f_0(X_i)$.

As previously, we consider the slightly modified Lasso estimate. Let $\alpha > 1$ and let us set

$$\widehat{\boldsymbol{\beta}}^L_{\mu,\alpha} \in \operatorname*{argmin}_{\boldsymbol{\beta}\in\Gamma(\mu)} \Big\{ -l(\boldsymbol{\beta}) + \alpha \sum_{j=1}^{p} \lambda_j |\boldsymbol{\beta}_j| \Big\}, \quad \widehat{f}^L_{\mu,\alpha}(x) = \exp\left(\sum_{j=1}^{p} (\widehat{\boldsymbol{\beta}}^L_{\mu,\alpha})_j \varphi_j(x) \right)$$

for which we obtain the following fast oracle inequality.

Corollary 2 *Let $\varepsilon > 0$ and s a positive integer. Let Assumption 3 be satisfied with s and*

$$r = \frac{\alpha + 1 + 2\alpha/\varepsilon}{\alpha - 1}.$$

Then, under Assumption 1, there exists a constant $B(\varepsilon, m, \mu)$ depending on ε, m and μ such that, on Ω,

$$K(f_0, \widehat{f}^L_{\mu,\alpha}) \leq (1+\varepsilon) \inf_{\substack{\boldsymbol{\beta}\in\Gamma(\mu) \\ |J(\boldsymbol{\beta})|\leq s}} \left\{ K(f_0, f_{\boldsymbol{\beta}}) + B(\varepsilon, m, \mu) \frac{\alpha^2 |J(\boldsymbol{\beta})|}{\kappa_n^2} (\max_{j\in\{1,\dots,p\}} \lambda_j{}^2) \right\},$$

where κ_n stands for $\kappa_n(s, r)$, and $J(\boldsymbol{\beta})$ is the support of β.

This corollary is derived easily from Theorem 4 by considering all groups of size 1. Comparing Corollary 2 and Theorem 4, we observe that the group-Lasso can improve the Lasso estimate when the function f_0 can be well approximated by a function $f_{\boldsymbol{\beta}}$ so that the number of non-zero groups of $\boldsymbol{\beta}$ is much smaller than the total number of non-zero coefficients. The simulation study of the next section illustrates this comparison from the numerical point of view.

4. Simulation study

Simulation settings. Even if our theoretical results do not concern model selection properties, we propose to start the simulation study by considering a simple toy example such that $\log(f_0) = \mathbf{A}\boldsymbol{\beta}_0$ is generated from a true sparse vector of coefficients of size $p = 2^J$ in the Haar basis, such that $J = 10$ and scales $j = 1, 3, 4$ have all non-null coefficients. More details on this function can be found in our code that is freely available [1]. In this setting, $\log(f_0)$ can be decomposed on the dictionary and we can assess the accuracy of selection of different methods.

We then explore the empirical performance of the Lasso and the group Lasso strategies using simulations. By performance we mean the quality of reconstruction of simulated signals as our theoretical results concern reconstruction properties. We considered different forms for intensity functions by taking the standard functions of Donoho and Johnstone (1994): blocks, bumps, doppler, heavisine, to set g_0. These functions do not have an exact decomposition on any dictionary considered below. The signal to noise ratio was increased by multiplying the intensity functions by a factor α taking values in $\{1, \dots, 7\}$, $\alpha = 7$ corresponding to the most favorable configuration. Observations Y_i were generated such that $Y_i | X_i \sim \mathcal{P}oisson(f_0(X_i))$, with $f_0 = \alpha \exp(g_0)$, and $(X_1, \dots, X_n)$ was set as the regular grid of length $n = 2^{10}$. Each configuration was repeated 20 times. Our method was implemented using the `grpLasso` `R` package of Meier et al. (2008) to which we provide our concentration-based weights (the code is fully available [1]).

The basis and the dictionary frameworks. The dictionary we consider is built on the Haar basis, on the Daubechies basis with 6 vanishing moments, and on the Fourier basis, in order to catch piece-wise constant trends, localized peaks and periodicities. Each orthonormal system has n elements, which makes $p = n$ when systems are considered separately, and $p = 2n$ or $3n$ depending on the considered dictionary. For wavelets, the dyadic structure of the decomposition allows us to group the coefficients scale-wise by forming groups of coefficients of size 2^q. As for the Fourier basis, groups (also of size 2^q) are formed by considering successive coefficients (while keeping their natural ordering). When grouping strategies are considered, we set all groups at the same size.

Weights calibration in practice. First for both the Lasso and the group Lasso introduced in Section 1, following the arguments at the end of Section 2.1 that provide some theoretical guarantees, we take γ larger than 1. More precisely, we take $\gamma = 1.01$. Our theoretical results do not provide any information about values smaller than 1, so we conduct an empirical study on a very simple case, namely we estimate f_0 such that $\log(f_0) = 1_{[0,1]}$ on the Haar basis, so that only one parameter should be selected. Fig. 1 shows that when γ is too small, the risk of the selected models explodes (left panel), because too many coefficients are selected (right panel). Taking $\gamma = 1.01$ actually corresponds to a conservative choice avoiding the explosion of the MSE and of the number of selected

1. `http://pbil.univ-lyon1.fr/members/fpicard/software.html`

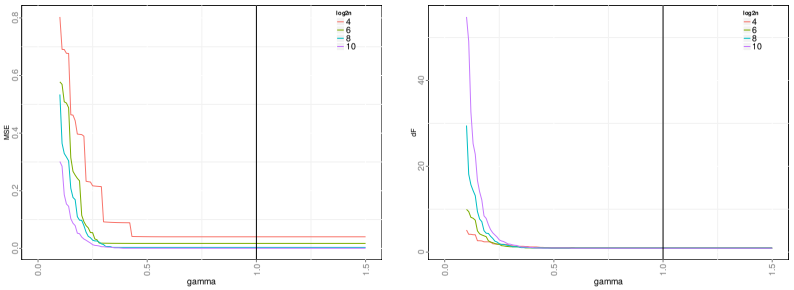

Figure 1: Tuning of the hyperparameter γ for the Lasso penalty. The simulated function is $\log(f_0) = 1_{[0,1]}$, so that only one parameter should be selected on the Haar basis. For different values of n, the left/right panels represent the mean square error / the number of estimated parameters with respect to γ (averaged over 20 simulations). The vertical line corresponds to $\gamma = 1$.

parameters. Furthermore this automatic choice provides good results in practice, as shown by our simulation study that considers many shapes of intensity functions (see below).

Then we estimate V_j (resp V_j^g) by $\widetilde{V}_j$ (resp $\widetilde{V}_j^g$). Note that $\widehat{V}_j$ (resp $\widehat{V}_j^g$) can also be used: these variances are easier to compute in practice, and this slight modification does not significantly change the performance of the procedures (not shown). The parameter γ being fixed, we use the expression (2.3) for Lasso weights. As for the group Lasso weights (Theorem 2), the first term is replaced by $\sqrt{\sum_{j\in G_k} \widetilde{V}_j}$, as it is governed by a quantity that tends to one when p is large. We conducted a preliminary numerical study (not shown) to calibrate the second term, that depends on quantities M, c_k and b_k defined in Theorem 2. The best empirical performance were achieved so that the left- and right-hand terms of (2.9) were approximatively equal. This resumes to group-Lasso weights of the form $2\sqrt{\sum_{j\in G_k} \widetilde{V}_j}$.

Competitors. We compete our Lasso procedure (`Lasso.exact` in the sequel), with the Haar-Fisz transform (using the `haarfisz` package), applied to the same data followed by soft-thresholding. Here we mention that we did not perform cycle-spinning (that is often included in denoising procedures) in order to focus on the effects of thresholding only. We also implemented the half-fold cross-validation proposed by Nason (1996) in the Poisson case to set the weights in the penalty, with the proper scaling ($2^{s/2}\lambda$, with s the scale of the wavelet coefficients) as proposed by Sardy et al. (2004). Briefly, this cross-validation procedure is used to calibrate λ by estimating f_0 on a training set made of even positions (for different values of λ), and by measuring the reconstruction error on the test set made

by odd positions (see Nason (1996)). This procedure is referred to cross-validation in the sequel. Then we compare the performance of the group-Lasso with varying group sizes (2,4,8) to the Lasso, to assess the benefits or grouping wavelet coefficients.

Performance measurement. For any estimate $\hat{f}$, reconstruction performance were measured using the (normalized) mean-squared error $MSE = \|\widehat{f} - f_0\|_2^2/\|f_0\|_2^2$. When there is a true sparse $\boldsymbol{\beta}_0$, model selection performance were measured by the standard indicators: accuracy on support recovery, sensitivity (proportion of true non-null coefficients among selected coefficients) and specificity of detection (proportion of true null coefficients among non-selected coefficients), based on the support of $\boldsymbol{\beta}_0$ and on the support of its estimate.

Model selection performance with a true sparse $\boldsymbol{\beta}_0$. The simple toy example described above for model selection perfectly shows the performance of our Lasso procedure (Figure 2). Even if our theoretical results do not concern support recovery, our theoretically calibrated weights provide the best accuracy in support selection, along with the best sensitivity, specificity and reconstruction errors. This example also shows the interest of the theoretical weights calibration compared with the cross-validation procedure that shows bad performance, and also compared with the Haar-Fisz transform. Also, this toy example illustrates the need of scaling for the cross-validated vanilla Lasso: if the procedure proposed by Sardy et al. (2004) is not used, the cross-validated vanilla Lasso lacks of adaptation to heteroscedasticity, which leads to poor results on selection (lack of accuracy and specificity, or too many selected coefficients), and thus to overfitted reconstruction (Fig. 3). Thus, in further simulations we only considered the scaled version of the cross-validated Lasso, in order to compare methods that account for heteroscedasticity.

Performance in the basis setting. Here we focus on wavelet basis (Haar for blocks and Daubechies for bumps, doppler and heavisine) and not on a dictionary approach (considered in a second step) in order to compare our calibrated weights with other methods that rely on penalized strategy. It appears that, except for the `bumps` function, the Lasso with exact weights shows the lowest reconstruction error whatever the shape of the intensity function (Figure 4). Moreover, better performance of the Lasso with exact weights in cases of low intensity emphasize the interest of theoretically calibrated procedures rather than asymptotic approximations (like the Haar-Fisz transform). In the case of `bumps`, cross-validation seems to perform better than the Lasso, but when looking at reconstructed average function (Figure 5a) this lower reconstruction error of cross-validation is associated with higher local variations around the peaks. Compared with Haar-Fisz, the gain of using exact weights is substantial even when the signal to noise ratio is high, which indicates that even in the validity domain of the Haar-Fisz transform (large intensities), the Lasso combined with exact thresholds is more suitable (Figure 5a). As for the group Lasso, its performance highly depend on the group size: while groups of size 2 show similar performance as the Lasso, groups of size 4 and 8 increase the reconstruction error (Figure

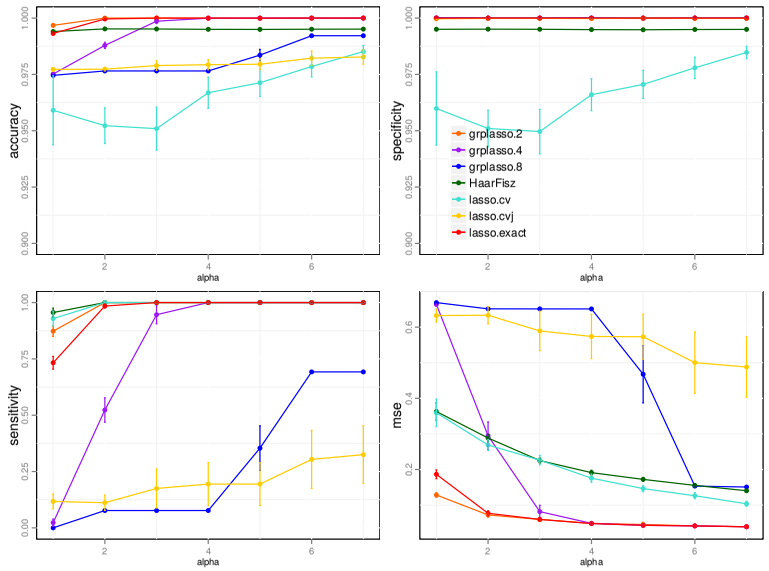

Figure 2: Average (over 20 repetitions) accurracy in support recovery for the toy function f_0 with a true sparse $\boldsymbol{\beta}_0$ and the Haar basis, specificity and sensitivity of selection, and Mean Square Error of reconstruction. `Lasso.exact`: Lasso penalty with our data-driven theoretical weights, `Lasso.cv`: Lasso penalty with weights calibrated by cross validation without scaling, `Lasso.cvj`: Lasso penalty with weights calibrated by cross validation with scaling $2^{s/2}\lambda$, `group.Lasso.2/4/8`: group Lasso penalty with our data-driven theoretical weights with group sizes 2/4/8, `HaarFisz`: Haar-Fisz tranform followed by soft-thresholding. Alpha (α) stands for the signal strength.

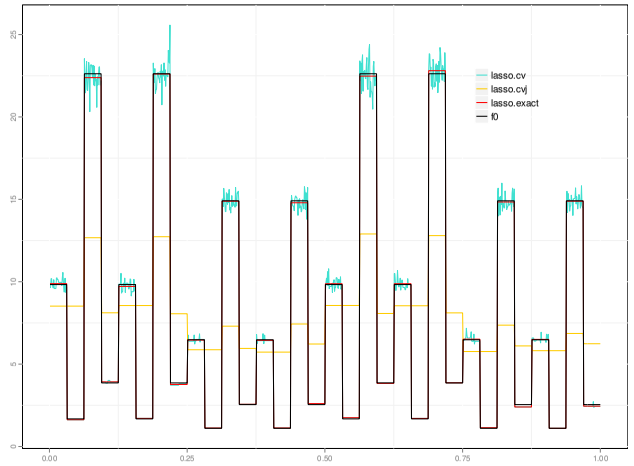

Figure 3: Example of reconstruction for the toy function f_0 with a true sparse $\boldsymbol{\beta}_0$ and the Haar basis. The reconstruction with the vanilla-lasso is based on too many coefficients which leads to over-fitting. `Lasso.exact`: Lasso penalty with our data-driven theoretical weights, `Lasso.cv`: Lasso penalty with weights calibrated by cross validation without scaling, `Lasso.cvj`: Lasso penalty with weights calibrated by cross validation with scaling $2^{s/2}\lambda$

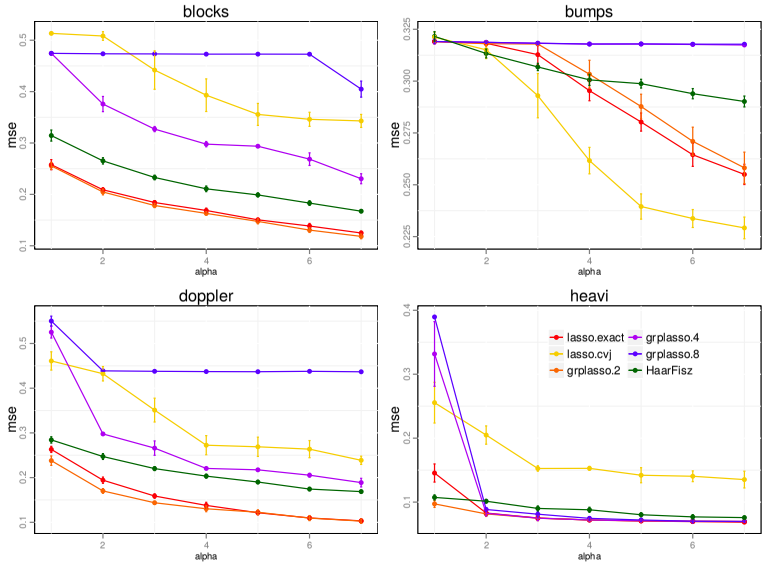

Figure 4: Average (over 20 repetitions) Mean Square Error of reconstruction of different methods for the estimation of simulated intensity functions according to function shapes (blocks, bumps, doppler, heavisine) and signal strength (α). `Lasso.exact`: Lasso penalty with our data-driven theoretical weights, `Lasso.cvj`: Lasso penalty with weights calibrated by cross validation with scaling $2^{s/2}\lambda$, `group.Lasso.2/4/8`: group Lasso penalty with our data-driven theoretical weights with group sizes 2/4/8, `HaarFisz`: Haar-Fisz tranform followed by soft-thresholding.

4 and 5b), since they are not scaled to the size of the irregularities in the signal. This trend is not systematic as the group Lasso appears to be adapted to functions that are more regular (Heavisine), and seems to avoid edge effects in some situations.

Performance in the dictionary framework. Lastly, we explored the performance of the dictionary approach, by considering different dictionaries to estimate each function: Daubechies (D), Fourier (F), Haar (H), or their combinations (Figure 6). Rich dictionaries can be very powerful to catch complex shapes in the true intensity function (like the notch in the heavisine case Figure 6b), and the richest dictionary (DFH) often leads to the lowest reconstruction error (MSE) on average. However the richest dictionary (DFH) is not always

the best choice in terms of reconstruction error, which is stricking in the case of the `blocks` function. In this case the Haar system only would be preferable for the Lasso (Figure 6a). For the group-Lasso and the `blocks` intensity function, the combination of the Daubechies and the Haar systems provides the best MSE, but when looking at the reconstructed intensity (Figure 6b-blocks), the Daubechies system introduces wiggles that are not relevant for `blocks`. Also, richer dictionaries do not necessarily lead to more selected parameters (Figure 6a), which illustrates that selection depends on the redundancies between the systems elements of the dictionary. In practice we often do not have any *prior* knowledge concerning the elements that shape the signal, and these simulations suggest that the blind use of the richest dictionary may not be the best strategy in terms of reconstructed functions. Consequently, in the following application, we propose to adapt the half-fold cross validation of Nason (1996) to choose the best combinations of systems.

5. Applications

The analysis of biological data has faced a new challenge with the extensive use of next generation sequencing (NGS) technologies. NGS experiments are based on the massive parallel sequencing of short sequences (reads). The mapping of these reads onto a reference genome (when available) generates counts data (Y_t) spatially organized (in 1D) along the genome (at position X_t). These technologies have revolutionized the perspectives of many fields in molecular biology, and among many applications, one is to get a local quantification of DNA or of a given DNA-related molecule (like transcription factors for instance with chIP-Seq experiments, Furey (2012)). This technology has recently been applied to the identification of replication origins along the human genome. Replication is the process by which a genome is duplicated into two copies. This process is tightly regulated in time and space so that the duplication process takes place in the highly regulated cell cycle. The human genome is replicated at many different starting points called origins of replication, that are loci along the genome at which the replication starts. Until very recently, the number of such origins remained controversial, and thanks to the application of NGS technologies, first estimates of this number could be obtained. The signal is made of counts along the human genome such that reads accumulations indicate an origin activity (see Picard et al. (2014)). Scan statistics were first applied to these data, to detect significant local enrichments reads accumulation, but there is currently no consensus on the best method to analyze such data. Here we propose to use the Poisson functional regression to estimate the intensity function of the data on a portion of the human chromosomes X and 20. Half-fold cross-validation was used to select the appropriate dictionary between Daubechies, Fourier, Haar (and their combinations), and our theoretical weights were used to calibrate the Lasso (Figure 7). Our results are very promising as the sparse dictionary approach is very efficient for denoising (Chromosome X, Figure 7b) and produces null intensities when the signal is low (higher specificity). Another aspect of our method is that it seems to be more powerful in the identification of peaks that are more precise (Chromosome 20,

(b) Reconstructed functions for the dictionaries with the smallest MSE.

Figure 6: Average (over 20 repetitions) Mean Square Errors and number of selected coefficients (df) (6a), and reconstructed functions (6b) for different dictionaries: Daubechies (D), Fourier (F), Haar (H) and their combinations. `Lasso.exact`: Lasso penalty with our data-driven theoretical weights, `group.Lasso.2`: group Lasso penalty with our data-driven theoretical weights with group sizes 2, `HaarFisz`: Haar-Fisz tranform followed by soft-thresholding.

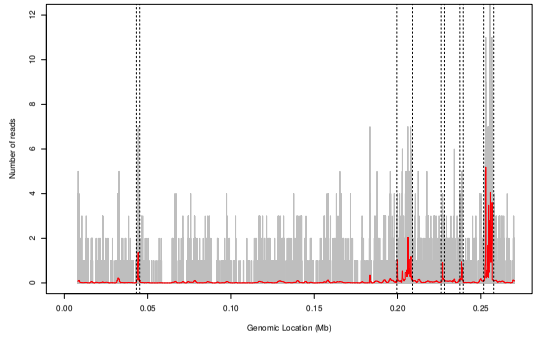
positions 0.20 and 0.25Mb, Figure 7a), which indicates that the dictionary approach may be more sensitive to detect peaks. Given the spread of NGS data and the importance of peak detection in the analysis process, for chIP-Seq Furey (2012), FAIRE-Seq Thurman et al. (2012), OriSeq Picard et al. (2014), our preliminary results suggest that the sparse dictionary approach will be a very promising framework for the analysis of such data.

6. Conclusion

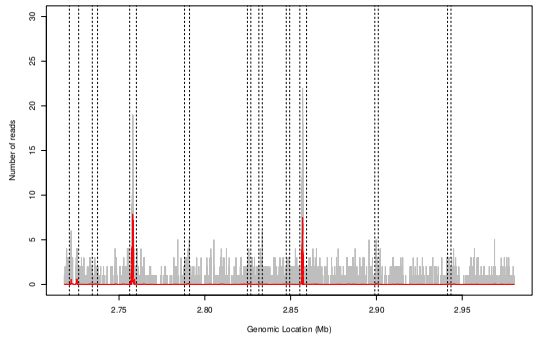
We proposed new adaptive Lasso and group-Lasso procedures to estimate the regression function in high dimensional Poisson regression, with a special focus on the calibration of weights involved in the penalties. Inspired from the adaptive Lasso procedure proposed by Zou (2006) in the context of model selection, we derived data-driven component-specific weights, whose shape appears to be relevant from both theoretical and practical points of view. In the dictionary approach, which extends the classical basis approach, we obtain slow and fast oracle inequalities under RE-type conditions. These theoretical results are enhanced by a numerical study that illustrates the good performance of our procedure on simulated and experimental data. Moreover, even if our main objective is functional reconstruction (that is different from model selection), a numerical toy example shows very promising results of our Lasso and group-Lasso procedures for model selection. The theoretical study of this problem is an exciting challenge we wish to investigate in further works.

The purpose of our data-driven weights is to control the random fluctuations of the normalized observations, namely $(\mathbf{A}_j^T\mathbf{Y})_j$ and $(\mathbf{A}_{G_k}^T\mathbf{Y})_k$, around their expectation. To obtain controls as sharp as possible, we use concentration inequalities for infinitely divisible vectors, which allows us to account for the heteroscedasticity that characterizes the Poisson setting. So, our approach is very different from Zou (2006) who considered weights proportional to the inverse of preliminary estimates (ordinary least squares estimates or maximum likelihood estimates). But both approaches confirm that random weighting schemes can provide suitable procedures for inference in regression models.

Finally, we mention that the constants of our procedure were tuned by using theoretical arguments, and our numerical studies show that they are suitable. Other values for these constants would probably be appropriate for some signals. Even if our empirical results show that the performance with $\gamma = 1.01$ are excellent, whatever the form of f_0 we considered, our procedure could be enriched by an additional calibration step for γ, with associated extra computational time.



(a) Chromosome 20



(b) Chromosome X

Figure 7: Estimation of the intensity function of Ori-Seq data (chromosomes 20 7a and X 7b). Grey bars indicate the number of reads that match genomic positions (x-axis, in MegaBases). The red line corresponds to the estimated intensity function, and vertical dotted lines stand for the detected origins by scanning statistics.

7. Proofs

7.1 Proof of Theorem 1

We denote by μ the Lebesgue measure on $\mathbb{R}^d$ and we introduce a partition of the set $[0,1]^d$ denoted $\cup_{i=1}^n S_i$ so that for any $i=1,\dots,n$, $X_i \in S_i$ and $\mu(S_i)>0$. Let h the function defined for any $t\in[0,1]^d$ by

$$h(t)=\sum_{i=1}^n \frac{f_0(X_i)}{\mu(S_i)} 1_{S_i}(t).$$

Finally, we introduce N the Poisson process on $[0,1]^d$ with intensity h (see Kingman (1993)). Therefore, for any $i=1,\dots,n$, $N(S_i)$ is a Poisson variable with parameter $\int_{S_i} h(t)dt = f_0(X_i)$ and since $\cup_{i=1}^n S_i$ is a partition of $[0,1]^d$, $(N(S_1),\dots,N(S_n))$ has the same distribution as $(Y_1,\dots,Y_n)$. We observe that if for any $j=1,\dots,p$,

$$\widetilde{\varphi}_j(t)=\sum_{i=1}^n \varphi_j(X_i)1_{S_i}(t),$$

then

$$\int \widetilde{\varphi}_j(t)dN(t) \sim \sum_{i=1}^n \varphi_j(X_i)Y_i = \mathbf{A}_j^T\mathbf{Y}.$$

We use the following exponential inequality (see Inequality (5.2) of Reynaud-Bouret (2003)). If g is bounded, for any $u>0$,

$$\mathbb{P}\left(\int g(x)(dN(x)-h(x)dx) \geq \sqrt{2u\int g^2(x)h(x)dx} + \frac{u}{3}\|g\|_\infty\right) \leq \exp(-u). \tag{7.1}$$

By taking successively $g=\widetilde{\varphi}_j$ and $g=-\widetilde{\varphi}_j$, we obtain

$$\mathbb{P}\left(|\mathbf{A}_j^T(\mathbf{Y}-\mathbb{E}[\mathbf{Y}])| \geq \sqrt{2u\int \widetilde{\varphi}_j^2(x)h(x)dx} + \frac{u}{3}\|\widetilde{\varphi}_j\|_\infty\right) \leq 2e^{-u}.$$

Since

$$\int \widetilde{\varphi}_j^2(x)h(x)dx = \sum_{i=1}^n \varphi_j^2(X_i)f_0(X_i) = V_j,$$

we obtain

$$\mathbb{P}\left(|\mathbf{A}_j^T(\mathbf{Y}-\mathbb{E}[\mathbf{Y}])| \geq \sqrt{2uV_j} + \frac{u}{3}\|\widetilde{\varphi}_j\|_\infty\right) \leq 2e^{-u}. \tag{7.2}$$

To control V_j, we use (7.1) with $g=-\widetilde{\varphi}_j^2$ and we have:

$$\mathbb{P}\left(V_j - \widehat{V}_j \geq \sqrt{2u\int \widetilde{\varphi}_j^4(t)h(t)dt} + \frac{u}{3}\|\widetilde{\varphi}_j\|_\infty^2\right) \leq e^{-u}.$$

We observe that

$$\int \widetilde{\varphi}_j^4(t)h(t)dt \leq \|\widetilde{\varphi}_j\|_\infty^2 \int \widetilde{\varphi}_j^2(t)h(t)dt = \|\widetilde{\varphi}_j\|_\infty^2 V_j.$$

Setting $v_j = u\|\widetilde{\varphi}_j\|_\infty^2$, we have:

$$\mathbb{P}\left(V_j - \sqrt{2v_jV_j} - \frac{v_j}{3} - \widehat{V}_j \geq 0\right) \leq e^{-u}.$$

Let $\alpha_j = \sqrt{\widehat{V}_j + \frac{5}{6}v_j} + \sqrt{\frac{v_j}{2}}$, such that α_j is the positive solution to $\alpha_j^2 - \sqrt{2v_j}\alpha_j - (\widehat{V}_j + \frac{v_j}{3}) = 0$. Then

$$\mathbb{P}\Big(V_j \geq \alpha_j^2\Big) = \mathbb{P}\Big(\sqrt{V_j} \geq \alpha_j\Big) \leq e^{-u}. \tag{7.3}$$

We choose $u=\gamma\log p$ and observe that $\alpha_j^2 \leq \widetilde{V}_j$. Then, by combining (7.2) and (7.3), we have

$$\mathbb{P}\left(|\mathbf{A}_j^T(\mathbf{Y}-\mathbb{E}[\mathbf{Y}])| \geq \sqrt{2\gamma\log p\widetilde{V}_j} + \frac{\gamma\log p}{3}\|\widetilde{\varphi}_j\|_\infty\right) \leq \frac{3}{p^\gamma}.$$

As $\|\widetilde{\varphi}_j\|_\infty = \max_i|\varphi_j(X_i)|$, the theorem follows. □

Remark 2 *By slightly extending previous computations, we easily show that for $u>0$,*

$$\mathbb{P}\left(|V_j - \widehat{V}_j| \geq \sqrt{2uV_j\|\widetilde{\varphi}_j\|_\infty^2} + \frac{u}{3}\|\widetilde{\varphi}_j\|_\infty^2\right) \leq 2e^{-u},$$

which leads to

$$\mathbb{P}\left(|V_j - \widehat{V}_j| \geq \frac{V_j}{2} + \frac{4\gamma\log p}{3}\|\widetilde{\varphi}_j\|_\infty^2\right) \leq \frac{2}{p^\gamma}.$$

7.2 Proof of Theorem 2

For each $k\in\{1,\dots,K\}$, we recall that $b_k^i = \sqrt{\sum_{j\in G_k}\varphi_j^2(X_i)}$, so $b_k^i = \|\mathbf{A}_{G_k}^T\mathbf{e}_i\|_2$, where $\mathbf{e}_i$ is the vector whose i-th coordinate is equal to 1 and all others to 0. We first state the following lemma:

Lemma 1 *Let k be fixed. Assume that there exists some $M>0$ such that $\forall\, x, |f_0(x)|\leq M$. Assume further that there exists some $c_k\geq 0$ such that $\forall\,\mathbf{y}\in\mathbb{R}^n, \|\mathbf{A}_{G_k}\mathbf{A}_{G_k}^T\mathbf{y}\|_2 \leq c_k\|\mathbf{A}_{G_k}^T\mathbf{y}\|_2$. Then, $\forall\, x>0, \forall\,\varepsilon>0$,*

$$\mathbb{P}\left(\|\mathbf{A}_{G_k}^T(\mathbf{Y}-\mathbb{E}[\mathbf{Y}])\|_2 \geq (1+\varepsilon)\sqrt{\sum_{j\in G_k} V_j} + x\right) \leq \exp\left(\frac{x}{b_k} - \Big(\frac{x}{b_k} + \frac{D_k^\varepsilon}{b_k^2}\Big)\log\Big(1+\frac{b_k x}{D_k^\varepsilon}\Big)\right),$$

where $D_k^\varepsilon = 8Mc_k^2 + \frac{2}{\varepsilon^2}b_k^2$.

Proof With $k \in \{1,\dots,K\}$ being fixed, we define $f:\mathbb{R}^n \to \mathbb{R}$ by $f(\mathbf{y}) = \Big(\|\mathbf{A}_{G_k}^T\mathbf{y}\|_2 - E\Big)_+$, where $E>0$ is a constant chosen later. We use Corollary 1 from Houdré et al. (2008), applied to the infinitely divisible vector $\mathbf{Y}-\mathbb{E}[\mathbf{Y}] \in \mathbb{R}^n$, whose components are independent, and to f. First note that for any $t>0$,

$$\begin{aligned}\mathbb{E}e^{tb_k^i|Y_i-\mathbb{E}Y_i|} &\leq \mathbb{E}e^{tb_k^i(Y_i+f_0(X_i))}\\ &= \exp\Big(f_0(X_i)(e^{tb_k^i}+tb_k^i-1)\Big) < \infty.\end{aligned}$$

Furthermore, for any $i\in\{1,...,n\}$, any $\mathbf{y}\in\mathbb{R}^n$ and any $u\in\mathbb{R}$,

$$\begin{aligned}|f(\mathbf{y}+u\mathbf{e}_i)-f(\mathbf{y})| &\leq \Big|\|\mathbf{A}_{G_k}^T(\mathbf{y}+u\mathbf{e}_i)\|_2 - \|\mathbf{A}_{G_k}^T\mathbf{y}\|_2\Big|\\ &\leq \|\mathbf{A}_{G_k}^T(u\mathbf{e}_i)\|_2\\ &= |u|b_k^i.\end{aligned}$$

Therefore, for all $x>0$,

$$\mathbb{P}\Big(f(\mathbf{Y}-\mathbb{E}[\mathbf{Y}]) - \mathbb{E}[f(\mathbf{Y}-\mathbb{E}[\mathbf{Y}])] \geq x\Big) \leq \exp\Big(-\int_0^x h_f^{-1}(s)ds\Big),$$

where h_f is defined for all $t>0$ by

$$h_f(t) = \sup_{\mathbf{y}\in\mathbb{R}^n}\sum_{i=1}^n\int_{\mathbb{R}}|f(\mathbf{y}+u\mathbf{e}_i)-f(\mathbf{y})|^2\frac{e^{tb_k^i|u|}-1}{b_k^i|u|}\widetilde{\nu}_i(du)$$

and $\widetilde{\nu}_i$ is the Lévy measure associated with $Y_i-\mathbb{E}[Y_i]$. It is easy to show that $\widetilde{\nu}_i = f_0(X_i)\delta_1$, and so

$$h_f(t) = \sup_{\mathbf{y}\in\mathbb{R}^n}\sum_{i=1}^n f_0(X_i)\Big(f(\mathbf{y}+\mathbf{e}_i)-f(\mathbf{y})\Big)^2\frac{e^{tb_k^i}-1}{b_k^i}.$$

Furthermore, writing $A_i = \Big\{\|\mathbf{A}_{G_k}^T(\mathbf{y}+\mathbf{e}_i)\|_2 \geq E \text{ or } \|\mathbf{A}_{G_k}^T\mathbf{y}\|_2 \geq E\Big\}$, we have

$$\begin{aligned}|f(\mathbf{y}+\mathbf{e}_i)-f(\mathbf{y})| &\leq \Big|\|\mathbf{A}_{G_k}^T(\mathbf{y}+\mathbf{e}_i)\|_2 - \|\mathbf{A}_{G_k}^T\mathbf{y}\|_2\Big|1_{A_i}\\ &= \frac{1_{A_i}\Big|\|\mathbf{A}_{G_k}^T(\mathbf{y}+\mathbf{e}_i)\|_2^2 - \|\mathbf{A}_{G_k}^T\mathbf{y}\|_2^2\Big|}{\|\mathbf{A}_{G_k}^T(\mathbf{y}+\mathbf{e}_i)\|_2 + \|\mathbf{A}_{G_k}^T\mathbf{y}\|_2}\\ &= \frac{1_{A_i}\Big|2<\mathbf{A}_{G_k}^T\mathbf{e}_i,\mathbf{A}_{G_k}^T\mathbf{y}> + \|\mathbf{A}_{G_k}^T\mathbf{e}_i\|_2^2\Big|}{\|\mathbf{A}_{G_k}^T(\mathbf{y}+\mathbf{e}_i)\|_2 + \|\mathbf{A}_{G_k}^T\mathbf{y}\|_2}\\ &\leq 2\frac{\Big|<\mathbf{A}_{G_k}^T\mathbf{e}_i,\mathbf{A}_{G_k}^T\mathbf{y}>\Big|}{\|\mathbf{A}_{G_k}^T\mathbf{y}\|_2} + \frac{\|\mathbf{A}_{G_k}^T\mathbf{e}_i\|_2^2}{E},\end{aligned}$$

with $<\cdot,\cdot>$ the usual scalar product. We now have

$$\Big(f(\mathbf{y}+\mathbf{e}_i)-f(\mathbf{y})\Big)^2 \leq 8\frac{<\mathbf{A}_{G_k}^T\mathbf{e}_i,\mathbf{A}_{G_k}^T\mathbf{y}>^2}{\|\mathbf{A}_{G_k}^T\mathbf{y}\|_2^2} + 2\frac{\|\mathbf{A}_{G_k}^T\mathbf{e}_i\|_2^4}{E^2}.$$

The first term can be rewritten as $8\frac{<\mathbf{e}_i,\mathbf{A}_{G_k}\mathbf{A}_{G_k}^T\mathbf{y}>^2}{\|\mathbf{A}_{G_k}^T\mathbf{y}\|_2^2}$ and the second one is equal to $2\frac{{b_k^i}^4}{E^2}$, so we can now bound $h_f(t)$ as follows.

$$\begin{aligned}h_f(t) &\leq \sup_{\mathbf{y}}\sum_i f_0(X_i)\frac{e^{tb_k^i}-1}{b_k^i}\left(8\frac{<\mathbf{e}_i,\mathbf{A}_{G_k}\mathbf{A}_{G_k}^T\mathbf{y}>^2}{\|\mathbf{A}_{G_k}^T\mathbf{y}\|_2^2} + 2\frac{{b_k^i}^4}{E^2}\right)\\ &\leq \frac{e^{tb_k}-1}{b_k}\sup_{\mathbf{y}}\left(8M\frac{\|\mathbf{A}_{G_k}\mathbf{A}_{G_k}^T\mathbf{y}\|_2^2}{\|\mathbf{A}_{G_k}^T\mathbf{y}\|_2^2} + \frac{2}{E^2}\sum_i f_0(X_i){b_k^i}^4\right)\\ &\leq \frac{e^{tb_k}-1}{b_k}\left(8Mc_k^2 + \frac{2}{E^2}\sum_i f_0(X_i){b_k^i}^4\right).\end{aligned}$$

Now, we set

$$E = \varepsilon\sqrt{\sum_{j\in G_k}V_j}.$$

So we have:

$$\begin{aligned}E^2 &= \varepsilon^2\sum_{j\in G_k}\sum_{i=1}^n f_0(X_i)\varphi_j^2(X_i)\\ &= \varepsilon^2\sum_{i=1}^n f_0(X_i)\sum_{j\in G_k}\varphi_j^2(X_i)\\ &= \varepsilon^2\sum_{i=1}^n f_0(X_i){b_k^i}^2.\end{aligned}$$

Thus, we can finally bound the function h_f by the increasing function h defined by

$$h(t) = D_k^\varepsilon\frac{e^{tb_k}-1}{b_k},$$

with $D_k^\varepsilon = 8Mc_k^2 + \frac{2b_k^2}{\varepsilon^2}$. Therefore,

$$\begin{aligned}\exp\Big(-\int_0^x h_f^{-1}(s)ds\Big) &\leq \exp\Big(-\int_0^x h^{-1}(s)ds\Big)\\ &= \exp\left(\frac{x}{b_k} - \Big(\frac{x}{b_k}+\frac{D_k^\varepsilon}{b_k^2}\Big)\log\Big(1+\frac{b_k x}{D_k^\varepsilon}\Big)\right).\end{aligned}$$

Now,

$$\begin{aligned} f(\mathbf{Y}-\mathbb{E}[\mathbf{Y}]) - \mathbb{E}[f(\mathbf{Y}-\mathbb{E}[\mathbf{Y}])] &= \Big(\|\mathbf{A}_{G_k}^T(\mathbf{Y}-\mathbb{E}[\mathbf{Y}])\|_2 - E\Big)_+ - \mathbb{E}\Big(\|\mathbf{A}_{G_k}^T(\mathbf{Y}-\mathbb{E}[\mathbf{Y}])\|_2 - E\Big)_+ \\ &\geq \|\mathbf{A}_{G_k}^T(\mathbf{Y}-\mathbb{E}[\mathbf{Y}])\|_2 - E - \mathbb{E}\|\mathbf{A}_{G_k}^T(\mathbf{Y}-\mathbb{E}[\mathbf{Y}])\|_2. \end{aligned}$$

Furthermore, by Jensen's inequality, we have

$$\begin{aligned} \mathbb{E}\|\mathbf{A}_{G_k}^T(\mathbf{Y}-\mathbb{E}[\mathbf{Y}])\|_2 &\leq \sqrt{\mathbb{E}\|\mathbf{A}_{G_k}^T(\mathbf{Y}-\mathbb{E}[\mathbf{Y}])\|_2^2} \\ &= \sqrt{\sum_{j\in G_k}\mathbb{E}[(\mathbf{A}_j^T(\mathbf{Y}-\mathbb{E}\mathbf{Y}))^2]} \\ &= \sqrt{\sum_{j\in G_k}\mathrm{Var}(\mathbf{A}_j^T\mathbf{Y})} \\ &= \sqrt{\sum_{j\in G_k} V_j}. \end{aligned}$$

Recalling that $E = \varepsilon\sqrt{\sum_{j\in G_k} V_j}$, we thus have

$$\mathbb{P}\Big(f(\mathbf{Y}-\mathbb{E}[\mathbf{Y}]) - \mathbb{E}f(\mathbf{Y}-\mathbb{E}[\mathbf{Y}]) \geq x\Big) \geq \mathbb{P}\Big(\|\mathbf{A}_{G_k}^T(\mathbf{Y}-\mathbb{E}[\mathbf{Y}])\|_2 - (1+\varepsilon)\sqrt{\sum_{j\in G_k} V_j} \geq x\Big),$$

which concludes the proof. ■

We apply Lemma 1 with

$$\varepsilon = \frac{1}{2\sqrt{2\gamma\log p}} \quad \text{and} \quad x = 2\sqrt{\gamma\log p D_k^\varepsilon}.$$

Then,

$$\begin{aligned} \frac{b_k x}{D_k^\varepsilon} &= \frac{2b_k\sqrt{\gamma\log p}}{\sqrt{D_k^\varepsilon}} \\ &= \frac{2b_k\sqrt{\gamma\log p}}{\sqrt{8Mc_k^2 + \frac{2b_k^2}{\varepsilon^2}}} \\ &\leq \varepsilon\sqrt{2\gamma\log p} = \frac{1}{2}. \end{aligned}$$

Finally, using the fact that $\log(1+u) \geq u - \frac{u^2}{2}$, we have:

$$\begin{aligned} \exp\left(\frac{x}{b_k} - \Big(\frac{x}{b_k} + \frac{D_k^\varepsilon}{b_k^2}\Big)\log\Big(1+\frac{b_k x}{D_k^\varepsilon}\Big)\right) &\leq \exp\left(\frac{x}{b_k} - \Big(\frac{x}{b_k} + \frac{D_k^\varepsilon}{b_k^2}\Big)\Big(\frac{b_k x}{D_k^\varepsilon} - \frac{b_k^2 x^2}{2D_k^{\varepsilon 2}}\Big)\right) \\ &= \exp\left(\frac{-x^2}{2D_k^\varepsilon} + \frac{b_k x^3}{2D_k^{\varepsilon 2}}\right) \\ &= \exp\left(\frac{-x^2}{2D_k^\varepsilon}\Big(1 - \frac{b_k x}{D_k^\varepsilon}\Big)\right) \\ &\leq \exp\Big(\frac{-x^2}{4D_k^\varepsilon}\Big) = \frac{1}{p^\gamma}. \end{aligned}$$

We obtain

$$\mathbb{P}\left(\|\mathbf{A}_{G_k}^T(\mathbf{Y}-\mathbb{E}[\mathbf{Y}])\|_2 \geq (1+\varepsilon)\sqrt{\sum_{j\in G_k} V_j} + 2\sqrt{\gamma\log p D_k^\varepsilon}\right) \leq \frac{1}{p^\gamma}.$$

We control V_j as in the proof of Theorem 1, but we take $u = \gamma\log p + \log|G_k|$. The analog of (7.3) is

$$\mathbb{P}\Big(V_j > \widetilde{V}_j^g\Big) \leq e^{-u} = \frac{1}{|G_k|p^\gamma}$$

and thus

$$\mathbb{P}\Big(\exists\, j\in G_k,\, V_j > \widetilde{V}_j^g\Big) \leq \frac{1}{p^\gamma}.$$

This concludes the proof of Theorem 2. □

7.3 Proof of Proposition 1

For the first point, we write:

$$\|\mathbf{A}_{G_k}\mathbf{A}_{G_k}^T\mathbf{x}\|_2^2 = \sum_{l=1}^n\left(\sum_{j\in G_k}\varphi_j(X_l)\sum_{i=1}^n\varphi_j(X_i)x_i\right)^2.$$

Then, we apply the Cauchy-Schwarz inequality:

$$\begin{aligned}
\|\mathbf{A}_{G_k}\mathbf{A}_{G_k}^T\mathbf{x}\|_2^2 &\leq \sum_{l=1}^{n}\left(\sum_{j\in G_k}\varphi_j^2(X_l)\right)\left(\sum_{j\in G_k}\Big(\sum_{i=1}^{n}\varphi_j(X_i)x_i\Big)^2\right)\\
&= \|\mathbf{A}_{G_k}^T\mathbf{x}\|_2^2\sum_{l=1}^{n}\left(\sum_{j\in G_k}\varphi_j^2(X_l)\right)\\
&= \|\mathbf{A}_{G_k}^T\mathbf{x}\|_2^2\sum_{l=1}^{n}(b_k^l)^2\\
&\leq nb_k^2\|\mathbf{A}_{G_k}^T\mathbf{x}\|_2^2,
\end{aligned}$$

which proves the upper bound of (2.11). For the lower bound, we just observe that for any $i = 1, \ldots, n$, with $\mathbf{e}_i$ the vector whose i-th coordinate is equal to 1 and all others to 0,

$$\begin{aligned}
{b_k^i}^2 &= \|\mathbf{A}_{G_k}^T\mathbf{e}_i\|_2^2\\
&= <\mathbf{A}_{G_k}^T\mathbf{e}_i, \mathbf{A}_{G_k}^T\mathbf{e}_i>\\
&= <\mathbf{e}_i, \mathbf{A}_{G_k}\mathbf{A}_{G_k}^T\mathbf{e}_i>\\
&\leq \|\mathbf{e}_i\|_2\|\mathbf{A}_{G_k}\mathbf{A}_{G_k}^T\mathbf{e}_i\|_2\\
&\leq c_k\|\mathbf{A}_{G_k}^T\mathbf{e}_i\|_2\\
&= c_k b_k^i,
\end{aligned}$$

which obviously entails $b_k \leq c_k$. For the last point, we observe that

$$\|\mathbf{A}_{G_k}^T\mathbf{x}\|_2^2 = \sum_{j\in G_k}K_j^2,$$

where $K_j = \sum_{i=1}^n \varphi_j(X_i)x_i$. By expressing $\|\mathbf{A}_{G_k}\mathbf{A}_{G_k}^T\mathbf{x}\|_2^2$ with respect to the K_j's, we obtain:

$$\begin{aligned}
\|\mathbf{A}_{G_k}\mathbf{A}_{G_k}^T\mathbf{x}\|_2^2 &= \sum_{l=1}^{n}\left(\sum_{j\in G_k}\varphi_j(X_l)\sum_{i=1}^{n}\varphi_j(X_i)x_i\right)^2\\
&= \sum_{l=1}^{n}\sum_{j\in G_k}\varphi_j(X_l)\sum_{i=1}^{n}\varphi_j(X_i)x_i\sum_{j'\in G_k}\varphi_{j'}(X_l)\sum_{i'=1}^{n}\varphi_{j'}(X_{i'})x_{i'}\\
&= \sum_{j\in G_k}\sum_{j'\in G_k}\sum_{l=1}^{n}\varphi_j(X_l)\varphi_{j'}(X_l)\sum_{i=1}^{n}\varphi_j(X_i)x_i\sum_{i'=1}^{n}\varphi_{j'}(X_{i'})x_{i'}\\
&= \sum_{j\in G_k}\sum_{j'\in G_k}\sum_{l=1}^{n}\varphi_j(X_l)\varphi_{j'}(X_l)K_jK_{j'}\\
&\leq \frac{1}{2}\sum_{j\in G_k}\sum_{j'\in G_k}\Big|\sum_{l=1}^{n}\varphi_j(X_l)\varphi_{j'}(X_l)\Big|(K_j^2+K_{j'}^2)\\
&= \sum_{j\in G_k}\sum_{j'\in G_k}\Big|\sum_{l=1}^{n}\varphi_j(X_l)\varphi_{j'}(X_l)\Big|K_j^2,
\end{aligned}$$

from which we deduce (2.12). □

7.4 Proof of Theorem 3

For any $\boldsymbol{\beta} \in \mathbb{R}^p$, we have

$$\begin{aligned}
K(f_0, f_{\boldsymbol{\beta}}) &= \sum_{i=1}^{n} f_0(X_i)\big(\log f_0(X_i) - \log f_{\boldsymbol{\beta}}(X_i)\big) + f_{\boldsymbol{\beta}}(X_i) - f_0(X_i)\\
&= \sum_{i=1}^{n} Y_i\big(\log f_0(X_i) - \log f_{\boldsymbol{\beta}}(X_i)\big) + f_{\boldsymbol{\beta}}(X_i) - f_0(X_i)\\
&\qquad + \sum_{i=1}^{n}(f_0(X_i) - Y_i)\big(\log f_0(X_i) - \log f_{\boldsymbol{\beta}}(X_i)\big)\\
&= \log\mathcal{L}(f_0) - \log\mathcal{L}(f_{\boldsymbol{\beta}}) + \sum_{i=1}^{n}(f_0(X_i) - Y_i)\big(\log f_0(X_i) - \log f_{\boldsymbol{\beta}}(X_i)\big).
\end{aligned}$$

Therefore, for all $\boldsymbol{\beta} \in \mathbb{R}^p$,

$$\begin{aligned} K(f_0, \widehat{f}^{gL}) - K(f_0, f_{\boldsymbol{\beta}}) &= l(\boldsymbol{\beta}) - l(\widehat{\boldsymbol{\beta}}^{gL}) + \sum_{i=1}^{n} \big(f_0(X_i) - Y_i\big)\big(\log f_{\boldsymbol{\beta}}(X_i) - \log \widehat{f}^{gL}(X_i)\big) \\ &= l(\boldsymbol{\beta}) - l(\widehat{\boldsymbol{\beta}}^{gL}) + \sum_{i=1}^{n} \big(f_0(X_i) - Y_i\big) \sum_{j=1}^{p} (\beta_j - \widehat{\beta}_j^{gL})\varphi_j(X_i) \\ &= l(\boldsymbol{\beta}) - l(\widehat{\boldsymbol{\beta}}^{gL}) + \sum_{j=1}^{p} (\widehat{\beta}_j^{gL} - \beta_j) \sum_{i=1}^{n} \varphi_j(X_i)(Y_i - f_0(X_i)). \end{aligned}$$

Let us write $\eta_j = \sum_{i=1}^n \varphi_j(X_i)(Y_i - f_0(X_i)) = \mathbf{A}_j^T(\mathbf{Y} - \mathbb{E}[\mathbf{Y}])$. We have

$$K(f_0, \widehat{f}^{gL}) = K(f_0, f_{\boldsymbol{\beta}}) + l(\boldsymbol{\beta}) - l(\widehat{\boldsymbol{\beta}}^{gL}) + (\widehat{\boldsymbol{\beta}}^{gL} - \boldsymbol{\beta})^T \boldsymbol{\eta}. \tag{7.4}$$

By definition of $\widehat{\boldsymbol{\beta}}^{gL}$,

$$-l(\widehat{\boldsymbol{\beta}}^{gL}) + \sum_{k=1}^{K} \lambda_k^g \|\widehat{\boldsymbol{\beta}}_{G_k}^{gL}\|_2 \leq -l(\boldsymbol{\beta}) + \sum_{k=1}^{K} \lambda_k^g \|\boldsymbol{\beta}_{G_k}\|_2.$$

Furthermore, on Ω_g,

$$\begin{aligned} |(\widehat{\boldsymbol{\beta}}^{gL} - \boldsymbol{\beta})^T \boldsymbol{\eta}| &= \Big| \sum_{j=1}^{p} (\widehat{\beta}_j^{gL} - \beta_j)(\mathbf{A}_j^T(\mathbf{Y} - \mathbb{E}\mathbf{Y})) \Big| \\ &\leq \sum_{k=1}^{K} \sum_{j \in G_k} |\widehat{\beta}_j^{gL} - \beta_j| |\mathbf{A}_j^T(\mathbf{Y} - \mathbb{E}\mathbf{Y})| \\ &\leq \sum_{k=1}^{K} \Big(\sum_{j \in G_k} (\widehat{\beta}_j^{gL} - \beta_j)^2 \Big)^{1/2} \Big(\sum_{j \in G_k} (\mathbf{A}_j^T(\mathbf{Y} - \mathbb{E}\mathbf{Y}))^2 \Big)^{1/2} \\ &= \sum_{k=1}^{K} \|\widehat{\boldsymbol{\beta}}_{G_k}^{gL} - \boldsymbol{\beta}_{G_k}\|_2 \|\mathbf{A}_{G_k}^T(\mathbf{Y} - \mathbb{E}\mathbf{Y})\|_2 \\ &\leq \sum_{k=1}^{K} \lambda_k^g \|\widehat{\boldsymbol{\beta}}_{G_k}^{gL} - \boldsymbol{\beta}_{G_k}\|_2. \end{aligned} \tag{7.5}$$

Therefore, for all $\boldsymbol{\beta} \in \mathbb{R}^p$,

$$K(f_0, \widehat{f}^{gL}) \leq K(f_0, f_{\boldsymbol{\beta}}) + \sum_{k=1}^{K} \lambda_k^g \Big(\|\widehat{\boldsymbol{\beta}}_{G_k}^{gL} - \boldsymbol{\beta}_{G_k}\|_2 - \|\widehat{\boldsymbol{\beta}}_{G_k}^{gL}\|_2 + \|\boldsymbol{\beta}_{G_k}\|_2 \Big),$$

from which we deduce (3.3). □

7.5 Proof of Theorem 4

To avoid too tedious notations, we denote $\widehat{f}^{gL}$ instead of $\widehat{f}_{\mu,\alpha}^{gL}$ and $\widehat{\boldsymbol{\beta}}^{gL}$ instead of $\widehat{\boldsymbol{\beta}}_{\mu,\alpha}^{gL}$. We start from Equality (7.4) combined with Inequality (7.5). Then, we have that on Ω_g, for any $\boldsymbol{\beta} \in \Gamma(\mu)$,

$$K(f_0, \widehat{f}^{gL}) + (\alpha - 1) \sum_{k=1}^{K} \lambda_k^g \|\widehat{\boldsymbol{\beta}}_{G_k}^{gL} - \boldsymbol{\beta}_{G_k}\|_2 \leq K(f_0, f_{\boldsymbol{\beta}}) + \sum_{k=1}^{K} \alpha \lambda_k^g \Big(\|\widehat{\boldsymbol{\beta}}_{G_k}^{gL} - \boldsymbol{\beta}_{G_k}\|_2 - \|\widehat{\boldsymbol{\beta}}_{G_k}^{gL}\|_2 + \|\boldsymbol{\beta}_{G_k}\|_2 \Big).$$

On $J(\boldsymbol{\beta})^c$, $\|\widehat{\boldsymbol{\beta}}_{G_k}^{gL} - \boldsymbol{\beta}_{G_k}\|_2 - \|\widehat{\boldsymbol{\beta}}_{G_k}^{gL}\|_2 + \|\boldsymbol{\beta}_{G_k}\|_2 = 0$ and

$$K(f_0, \widehat{f}^{gL}) + (\alpha - 1) \sum_{k=1}^{K} \lambda_k^g \|\widehat{\boldsymbol{\beta}}_{G_k}^{gL} - \boldsymbol{\beta}_{G_k}\|_2 \leq K(f_0, f_{\boldsymbol{\beta}}) + 2\alpha \sum_{k \in J(\boldsymbol{\beta})} \lambda_k^g \|\widehat{\boldsymbol{\beta}}_{G_k}^{gL} - \boldsymbol{\beta}_{G_k}\|_2. \tag{7.6}$$

By applying the Cauchy-Schwarz inequality we also have

$$K(f_0, \widehat{f}^{gL}) + (\alpha - 1) \sum_{k=1}^{K} \lambda_k^g \|\widehat{\boldsymbol{\beta}}_{G_k}^{gL} - \boldsymbol{\beta}_{G_k}\|_2 \leq K(f_0, f_{\boldsymbol{\beta}}) + 2\alpha |J(\boldsymbol{\beta})|^{1/2} \Big(\sum_{k \in J(\boldsymbol{\beta})} (\lambda_k^g)^2 \|\widehat{\boldsymbol{\beta}}_{G_k}^{gL} - \boldsymbol{\beta}_{G_k}\|_2^2 \Big)^{1/2}. \tag{7.7}$$

If we write $\boldsymbol{\Delta} = \mathbf{D}(\widehat{\boldsymbol{\beta}}^{gL} - \boldsymbol{\beta})$, where $\mathbf{D}$ is a diagonal matrix with $D_{j,j} = \lambda_k^g$ if $j \in G_k$, then we can rewrite (7.6) as

$$K(f_0, \widehat{f}^{gL}) + (\alpha - 1)\|\boldsymbol{\Delta}\|_{1,2} \leq K(f_0, f_{\boldsymbol{\beta}}) + 2\alpha \|\boldsymbol{\Delta}_{J(\boldsymbol{\beta})}\|_{1,2} \tag{7.8}$$

and we deduce from (7.7)

$$K(f_0, \widehat{f}^{gL}) \leq K(f_0, f_{\boldsymbol{\beta}}) + 2\alpha (|J(\boldsymbol{\beta})|)^{1/2} \|\boldsymbol{\Delta}_{J(\boldsymbol{\beta})}\|_2. \tag{7.9}$$

Now, on the event $\big\{2\alpha \|\boldsymbol{\Delta}_{J(\boldsymbol{\beta})}\|_{1,2} \leq \varepsilon K(f_0, f_{\boldsymbol{\beta}})\big\}$, the theorem follows immediately from (7.8). We now assume that $\varepsilon K(f_0, f_{\boldsymbol{\beta}}) \leq 2\alpha \|\boldsymbol{\Delta}_{J(\boldsymbol{\beta})}\|_{1,2}$. Since K is non-negative, we deduce from (7.8) that

$$(\alpha - 1)\|\boldsymbol{\Delta}\|_{1,2} \leq 2\alpha \Big(1 + \frac{1}{\varepsilon}\Big) \|\boldsymbol{\Delta}_{J(\boldsymbol{\beta})}\|_{1,2},$$

$$(\alpha - 1)\|\boldsymbol{\Delta}_{J(\boldsymbol{\beta})^c}\|_{1,2} \leq \left(2\alpha \Big(1 + \frac{1}{\varepsilon}\Big) - (\alpha - 1) \right) \|\boldsymbol{\Delta}_{J(\boldsymbol{\beta})}\|_{1,2}$$

and

$$\|\boldsymbol{\Delta}_{J(\boldsymbol{\beta})^c}\|_{1,2} \leq \left(\frac{\alpha + 1 + 2\alpha/\varepsilon}{\alpha - 1} \right) \|\boldsymbol{\Delta}_{J(\boldsymbol{\beta})}\|_{1,2}.$$

This is equivalent to

$$\sum_{k\in J(\beta)^c}\lambda_k^g\|(\widehat{\boldsymbol{\beta}}^{gL}-\boldsymbol{\beta})_{G_k}\|_2\leq\left(\frac{\alpha+1+2\alpha/\varepsilon}{\alpha-1}\right)\sum_{k\in J(\beta)}\lambda_k^g\|(\widehat{\boldsymbol{\beta}}^{gL}-\boldsymbol{\beta})_{G_k}\|_2.$$

From Assumption 2 we have that, if $\boldsymbol{\beta}$ is such that $|J(\boldsymbol{\beta})|\leq s$, then

$$\|(\widehat{\boldsymbol{\beta}}^{gL}-\boldsymbol{\beta})_{J(\boldsymbol{\beta})}\|_2\leq\frac{1}{\kappa_n}\big((\widehat{\boldsymbol{\beta}}^{gL}-\boldsymbol{\beta})^T\mathbf{G}(\widehat{\boldsymbol{\beta}}^{gL}-\boldsymbol{\beta})\big)^{1/2}.$$

Since

$$\mathbf{G}_{j,j'}=\sum_{i=1}^n\varphi_j(X_i)\varphi_{j'}(X_i)f_0(X_i),$$

by setting

$$u_i=\log f_{\boldsymbol{\beta}}(X_i)-\log f_0(X_i)\quad\text{and}\quad\widehat{u}_i^{gL}=\log f_{\widehat{\boldsymbol{\beta}}^{gL}}(X_i)-\log f_0(X_i),$$

we have

$$\begin{aligned}(\widehat{\boldsymbol{\beta}}^{gL}-\boldsymbol{\beta})^T\mathbf{G}(\widehat{\boldsymbol{\beta}}^{gL}-\boldsymbol{\beta}) &= \sum_{j=1}^p\sum_{j'=1}^p(\widehat{\beta}_j^{gL}-\beta_j)(\widehat{\beta}_{j'}^{gL}-\beta_{j'})\mathbf{G}_{j,j'}\\ &= \sum_{i=1}^n f_0(X_i)\Big(\sum_{j=1}^p(\widehat{\beta}_j^{gL}-\beta_j)\varphi_j(X_i)\Big)^2\\ &= \sum_{i=1}^n f_0(X_i)(\widehat{u}_i^{gL}-u_i)^2.\end{aligned}$$

We set $h(f_0,f_{\boldsymbol{\beta}})=\sum_{i=1}^n f_0(X_i)u_i^2$ and $h(f_0,\widehat{f}^{gL})=\sum_{i=1}^n f_0(X_i)(\widehat{u}_i^{gL})^2$. From (7.9) and since

$$\begin{aligned}\|\boldsymbol{\Delta}_{J(\boldsymbol{\beta})}\|_2 &\leq (\max_k\lambda_k^g)\|(\widehat{\boldsymbol{\beta}}^{gL}-\boldsymbol{\beta})_{J(\boldsymbol{\beta})}\|_2\\ &\leq \frac{\max_k\lambda_k^g}{\kappa_n}\big((\widehat{\boldsymbol{\beta}}^{gL}-\boldsymbol{\beta})^T\mathbf{G}(\widehat{\boldsymbol{\beta}}^{gL}-\boldsymbol{\beta})\big)^{1/2},\end{aligned}$$

we have

$$K(f_0,\widehat{f}^{gL})\leq K(f_0,f_{\boldsymbol{\beta}})+\frac{2\alpha}{\kappa_n}|J(\boldsymbol{\beta})|^{1/2}(\max_k\lambda_k^g)\Big(\sqrt{h(f_0,\widehat{f}^{gL})}+\sqrt{h(f_0,f_{\boldsymbol{\beta}})}\Big).$$

To conclude, we use arguments similar to Lemler (2013). We recall them for the safe of completeness. To connect $h(f_0,f_{\boldsymbol{\beta}})$ to $K(f_0,f_{\boldsymbol{\beta}})$, we use Lemma 1 of Bach (2010) that is recalled now.

Lemma 2 *Let g be a convex three times differentiable function $g:\mathbb{R}\to\mathbb{R}$ such that for all $t\in\mathbb{R}$, $|g'''(t)|\leq Sg''(t)$ for some $S\geq 0$. Then, for all $t\geq 0$,*

$$\frac{g''(0)}{S^2}\phi(-St)\leq g(t)-g(0)-g'(0)t\leq\frac{g''(0)}{S^2}\phi(St),$$

where $\phi(x)=e^x-x-1$.

Let h be a real function. We set

$$G(h)=\sum_{i=1}^n\big(e^{h(X_i)}-f_0(X_i)h(X_i)\big)$$

and

$$g(t)=G(h+tk),$$

where h and k are functions and $t\in\mathbb{R}$. We have :

$$g'(t)=\sum_{i=1}^n\big(k(X_i)e^{h(X_i)+tk(X_i)}-f_0(X_i)k(X_i)\big),$$

$$g''(t)=\sum_{i=1}^n\big(k^2(X_i)e^{h(X_i)+tk(X_i)}\big)$$

and

$$g'''(t)=\sum_{i=1}^n\big(k^3(X_i)e^{h(X_i)+tk(X_i)}\big).$$

Therefore $|g'''(t)|\leq Sg''(t)$ with $S=\max_i|k(X_i)|$. We choose $h(X_i)=\log f_0(X_i)$ and $k(X_i)=u_i=\log f_{\boldsymbol{\beta}}(X_i)-\log f_0(X_i)$ and we apply Lemma 2 to g with $t=1$. Computations yield that $g(1)-g(0)=K(f_0,f_{\boldsymbol{\beta}})$, $g'(0)=0$ and $g''(0)=\sum_{i=1}^n f_0(X_i)u_i^2=h(f_0,f_{\boldsymbol{\beta}})$. Therefore

$$\frac{\phi(-S)}{S^2}h(f_0,f_{\boldsymbol{\beta}})\leq K(f_0,f_{\boldsymbol{\beta}})\leq\frac{\phi(S)}{S^2}h(f_0,f_{\boldsymbol{\beta}}).$$

Finally, for $\boldsymbol{\beta}\in\Gamma(\mu)$, $S=\max_i|u_i|\leq\mu+m$. Furthermore, $x\longrightarrow\frac{\phi(x)}{x^2}$ is a nonnegative increasing function and therefore we have

$$\mu' h(f_0,f_{\boldsymbol{\beta}})\leq K(f_0,f_{\boldsymbol{\beta}})\leq\mu'' h(f_0,f_{\boldsymbol{\beta}}),$$

where $\mu'=\frac{\phi(-\mu-m)}{(\mu+m)^2}$ and $\mu''=\frac{\phi(\mu+m)}{(\mu+m)^2}$. It follows that, for $\boldsymbol{\beta}\in\Gamma(\mu)$ such that $|J(\boldsymbol{\beta})|\leq s$,

$$K(f_0,\widehat{f}^{gL})\leq K(f_0,f_{\boldsymbol{\beta}})+\frac{2\alpha}{\kappa_n\sqrt{\mu'}}|J(\boldsymbol{\beta})|^{1/2}(\max_k\lambda_k^g)\Big(\sqrt{K(f_0,\widehat{f}^{gL})}+\sqrt{K(f_0,f_{\boldsymbol{\beta}})}\Big).$$

We use twice the inequality $2uv \leq bu^2 + \frac{v^2}{b}$ for any $b > 0$, applied to $u = \frac{\alpha}{\kappa_n}\sqrt{|J(\boldsymbol{\beta})|}(\max_k \lambda_k^g)$ and v being either $\sqrt{\frac{1}{\mu'}K(f_0, \widehat{f}^{gL})}$ or $\sqrt{\frac{1}{\mu'}K(f_0, f_{\boldsymbol{\beta}})}$. We have

$$\Big(1 - \frac{1}{\mu' b}\Big)K(f_0, \widehat{f}^{gL}) \leq \Big(1 + \frac{1}{\mu' b}\Big)K(f_0, f_{\boldsymbol{\beta}}) + 2b\frac{\alpha^2|J(\boldsymbol{\beta})|}{\kappa_n^2}(\max_k \lambda_k^g)^2.$$

Finally,

$$K(f_0, \widehat{f}^{gL}) \leq \Big(\frac{\mu' b + 1}{\mu' b - 1}\Big)K(f_0, f_{\boldsymbol{\beta}}) + 2\frac{\mu' b^2}{\mu' b - 1}\frac{\alpha^2|J(\boldsymbol{\beta})|}{\kappa_n^2}(\max_k \lambda_k^g)^2.$$

We choose $b > 1/\mu'$ such that $\frac{\mu' b+1}{\mu' b-1} = 1 + \varepsilon$ and we set $B(\varepsilon, m, \mu) = 2(1+\varepsilon)^{-1}\frac{\mu' b^2}{\mu' b - 1}$. Finally, we have, for any $\boldsymbol{\beta} \in \Gamma(\mu)$ such that $|J(\boldsymbol{\beta})| \leq s$,

$$K(f_0, \widehat{f}^{gL}) \leq (1+\varepsilon)\left(K(f_0, f_{\boldsymbol{\beta}}) + B(\varepsilon, m, \mu)\frac{\alpha^2|J(\boldsymbol{\beta})|}{\kappa_n^2}(\max_k \lambda_k^g)^2\right).$$

This completes the proof of Theorem 4. □

Abstract

One of the most fundamental problems in causal inference is the estimation of a causal effect when treatment and outcome are confounded. This is difficult in an observational study, because one has no direct evidence that all confounders have been adjusted for. We introduce a novel approach for estimating causal effects that exploits observational conditional independencies to suggest "weak" paths in an unknown causal graph. The widely used faithfulness condition of Spirtes et al. is relaxed to allow for varying degrees of "path cancellations" that imply conditional independencies but do not rule out the existence of confounding causal paths. The output is a posterior distribution over bounds on the average causal effect via a linear programming approach and Bayesian inference. We claim this approach should be used in regular practice as a complement to other tools in observational studies.

Keywords: Causal inference, instrumental variables, Bayesian inference, linear programming

1. Contribution

We provide a new methodology for obtaining bounds on the average causal effect (ACE) of a treatment variable X on an outcome variable Y. We introduce methods for binary models and for linear continuous models. For binary variables, the ACE is defined as

$$E[Y \mid do(X = 1)] - E[Y \mid do(X = 0)] = P(Y = 1 \mid do(X = 1)) - P(Y = 1 \mid do(X = 0)), \quad (1)$$

where $do(\cdot)$ is the operator of Pearl (2000), denoting distributions where a set of variables has been intervened on by an external agent.

In this paper, we assume the reader is familiar with the concept of causal graphs, the basics of the *do* operator, and the basics of causal discovery algorithms such as the PC algorithm of Spirtes et al. (2000). We provide a short summary for context in Section 2.

The ACE is in general not identifiable from observational data. We obtain upper and lower bounds on the ACE by exploiting a set of covariates, which we assume are not affected by X or Y as justified by temporal ordering or other background assumptions. Such covariate sets are often found in real-world problems, and form the basis of many of the

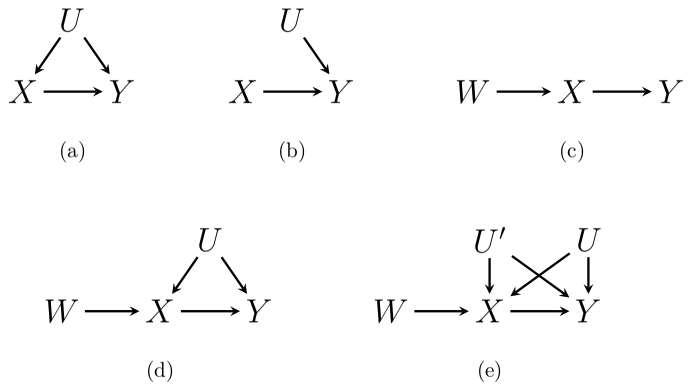

Figure 1: (a) A generic causal graph where X and Y are confounded by some U. (b) The same system in (a) where X is intervened upon by an external agent. (c) A system where W and Y are independent given X. (d) A system where it is possible to use faithfulness to discover that U is sufficient to block all back-door paths between X and Y. (e) Here, U itself is not sufficient.

observational studies done in practice (Rosenbaum, 2002a). However, it is not obvious how to obtain the ACE as a function of the covariates. Our contribution modifies the results of Entner et al. (2013), who exploit conditional independence constraints to obtain point estimates of the ACE but rely on assumptions that might be unstable with finite sample sizes. Our modification provides a different interpretation of their search procedure, which we use to generate candidate *instrumental variables* (Manski, 2007). The linear programming approach of Dawid (2003), inspired by Balke and Pearl (1997) and further refined by Ramsahai (2012), is then modified to generate bounds on the ACE by introducing constraints on some causal paths, motivated as relaxations of Entner et al. (2013). The new setup can be computationally expensive, so we introduce further relaxations to the linear program to generate novel symbolic bounds, and a fast algorithm that sidesteps the full linear programming optimization.

In Section 2, we discuss the background of the problem. In Section 3 we provide an overview of the methodology, which is divided into several subcomponents and described through Sections 4–8. Section 9 contains experiments with synthetic and real data.

2. Background: Instrumental Variables, Witnesses and Admissible Sets

Assuming X is a potential cause of Y, but not the opposite, a cartoon of the possibly complex real-world causal system containing X and Y is shown in Figure 1(a). U represents the universe of common causes of X and Y. In control and policy-making problems, we

would like to know what will happen to the system when the distribution of X is overridden by some external agent (e.g., a doctor, a robot or an economist). The resulting modified system is depicted in Figure 1(b), and represents the family of distributions indexed by $do(X = x)$: the graph in (a) has undergone a "surgery" that removes incoming edges to X. Spirtes et al. (2000) provide an account of the first graphical methods exploiting this idea, which are related to the overriding of structural equations proposed by Haavelmo (1943). Notice that if U is observed in the data set, then we can obtain the distribution $P(Y = y \,|\, do(X = x))$ by simply calculating $\sum_u P(Y = y \,|\, X = x, U = u)P(U = u)$ (Spirtes et al., 2000). This was popularized by Pearl (2000) as the *back-door adjustment*. In general $P(Y = y \,|\, do(X = x))$ can be substantially different from $P(Y = y \,|\, X = x)$.

The ACE can usually be estimated via a trial in which X is randomized: this is equivalent to estimating the conditional distribution of Y given X under data generated as in Figure 1(b). In contrast, in an *observational study* (Rosenbaum, 2002a) we obtain data generated by the system in Figure 1(a). If one believes all relevant confounders U have been recorded in the data then the back-door adjustment can be used, though such completeness is uncommon. By postulating knowledge of the causal graph relating components of U, one can infer whether a measured subset of the causes of X and Y is enough (Pearl, 2000; VanderWeele and Shpitser, 2011; Pearl, 2009). Without knowledge of the causal graph, assumptions such as *faithfulness* (Spirtes et al., 2000) are used to infer it.

The faithfulness assumption states that a conditional independence constraint in the observed distribution exists if and only if a corresponding structural independence exists in the underlying causal graph. For instance, observing the independence $W \perp\!\!\!\perp Y \,|\, X$, and assuming faithfulness and the causal order, we can infer the causal graph Figure 1(c); in all the other graphs this conditional independence in not implied. We deduce that no unmeasured confounders between X and Y exist. This simple procedure for identifying chains $W \to X \to Y$ is useful in exploratory data analysis (Chen et al., 2007; Cooper, 1997), where a large number of possible causal relations $X \to Y$ are unquantified but can be screened off using observational data before experiments are performed. The purpose of using faithfulness is to be able to sometimes identify such quantities.

Entner et al. (2013) generalize the discovery of chain models to situations where a non-empty set of covariates is necessary to block all back-doors. Suppose $\mathbf{W}$ is a set of covariates which are known not to be effects of either X or Y, and we want to find an *admissible set* contained in $\mathbf{W}$: a set of observed variables which we can use for back-door adjustment to obtain $P(Y = y \,|\, do(X = x))$. Entner et al.'s "Rule 1" states the following:

Rule 1: *If there exists a variable $W \in \mathbf{W}$ and a set $\mathbf{Z} \subseteq \mathbf{W} \backslash \{W\}$ such that*

$$(i) \quad W \not\perp\!\!\!\perp Y \,|\, \mathbf{Z} \qquad\qquad (ii) \quad W \perp\!\!\!\perp Y \,|\, \mathbf{Z} \cup \{X\},$$

then infer that $\mathbf{Z}$ is an admissible set.

Entner et al. (2013) also provide ways of identifying zero effects with a "Rule 2." For simplicity of presentation, for now we assume that the effect of interest was already identified as non-zero. Section 7 discusses the case of zero effects.

A point estimate of the ACE can then be found using $\mathbf{Z}$. Given that $(W, \mathbf{Z})$ satisfies Rule 1, we call W a *witness* for the admissible set $\mathbf{Z}$. The model in Figure 1(c) can be

identified with Rule 1, where W is the witness and $\mathbf{Z} = \emptyset$. In this case, for binary models a so-called "naïve" functional $P(Y = 1 \,|\, X = 1) - P(Y = 1 \,|\, X = 0)$ will provide the correct ACE. If U is observable in Figure 1(d), then it can be identified as an admissible set for witness W. Notice that in Figure 1(a), taking U as a scalar, it is not possible to find a witness since there are no remaining variables. Also, if in Figure 1(e) our covariate set $\mathbf{W}$ is $\{W, U\}$, then no witness can be found since U' cannot be blocked. Hence, it is possible for a procedure based on Rule 1 to answer "I don't know," even when a back-door adjustment would be possible *if* one knew the causal graph. However, using the faithfulness assumption alone one cannot do better: Rule 1 is complete for non-zero effects if no further information is available (Entner et al., 2013).

Despite its appeal, the faithfulness assumption is not without difficulties. Even if unfaithful distributions can be ruled out as pathological under seemingly reasonable conditions (Meek, 1995), distributions which lie close to (but not on) an unfaithful model may in practice be indistinguishable from distributions within that unfaithful model at finite sample sizes.

To appreciate these complications, consider the structure in Figure 1(d) with U unobservable and the remaining (observable) variables binary. Here W is randomized but X is not, and we would like to know the ACE of X on Y[1]. W is sometimes known as an *instrumental variable* (IV), and we call Figure 1(d) the *standard IV structure* (SIV); the distinctive features here being the constraints $W \perp\!\!\!\perp U$ and $W \perp\!\!\!\perp Y \mid \{X, U\}$, statements which include latent variables. If this structure is known, optimal bounds

$$\mathcal{L}_{SIV} \leq E[Y \mid do(X = 1)] - E[Y \mid do(X = 0)] \leq \mathcal{U}_{SIV}$$

can be obtained without further assumptions, and estimated using only observational data over the binary variables W, X and Y (Balke and Pearl, 1997). This structure cannot be found using faithfulness, as the only independence constraints involve a latent variable. However, there exist distributions faithful to the IV structure but which at finite sample sizes may appear to satisfy the Markov property for the structure $W \to X \to Y$; in practice this can occur at any finite sample size (Robins et al., 2003). The true average causal effect may lie anywhere in the interval $[\mathcal{L}_{SIV}, \mathcal{U}_{SIV}]$, which can be rather wide even when $W \perp\!\!\!\perp Y \,|\, X$, as shown by the following result:

Proposition 1 *If $W \perp\!\!\!\perp Y \,|\, X$ and the model follows the causal structure of the standard IV graph, then $\mathcal{U}_{SIV} - \mathcal{L}_{SIV} = 1 - |P(X = 1 \,|W = 1) - P(X = 1 \,|\, W = 0)|$.*

All proofs in this manuscript are given in Appendix A. For a fixed joint distribution $P(W, X, Y)$, the length of such an interval cannot be further minimized (Balke and Pearl, 1997). Notice that the length of the interval will depend on how strongly associated W and X are: $W = X$ implies $\mathcal{U}_{IV} - \mathcal{L}_{IV} = 0$ as expected, since this is the scenario of a perfect intervention. The scenario where $W \perp\!\!\!\perp X$ is analogous to not having any instrumental variable, and the length of the corresponding interval is 1.

1. A classical example is in non-compliance: suppose W is the assignment of a patient to either drug or placebo, X is whether the patient actually took the medicine or not, and Y is a measure of health status. The doctor controls W but not X. This problem is discussed by Pearl (2000) and Dawid (2003).

Thus, the true ACE may differ considerably from the "naïve" functional supported by Enter et al.'s Rule 1, appropriate for the simpler structure $W \to X \to Y$ but not for the standard IV structure. While we emphasize that this is a worst-case scenario analysis and by itself should not rule out faithfulness as a useful assumption, it is desirable to provide a method that gives greater control over violations of faithfulness.

3. Outline

In **Section 4**, we introduce the main algorithm, the *Witness Protection Program*. The core idea is (i) to *invert the usage of Entner et al.'s Rule 1*, so that pairs $(W, \mathbf{Z})$ should provide an instrumental variable bounding method instead of a back-door adjustment; (ii) express violations of faithfulness as *bounded violations of local independence*; (iii) find bounds on the ACE using *a linear programming formulation*. Unless stated otherwise, it is assumed that all observed variables are binary.

A simplified version of the algorithm is shown in Algorithm 1. This version assumes we know the distribution of the observed variables, $P(\mathbf{W}, X, Y)$, which simplifies the exposition of the method. The loops in Steps 2 and 3 are a search for pairs $(W, \mathbf{Z})$ of witness-admissible sets that satisfy Enter et al.'s Rule 1, done by verifying independence constraints in the given joint distribution. If we assumed faithfulness, the job would be complete: we either obtain an empty set or the true ACE. This is essentially the contribution of Entner et al. (2013).

However, we assume that faithfulness need not hold, and that all variables can be connected to each other in the causal graph, including a set U of hidden common causes of X and Y. At the same time, we cannot allow for arbitrary violations of faithfulness, as the presence of hidden common causes leads to only very weak constraints on the ACE. Instead, we allow for the expression of a subset of possible violations, expressed as "weak edges" on the fully connected causal graph of $W, \mathbf{Z}, X, Y$ and U. The meaning of a "weak edge" is given in detail in Section 4, and it is fully defined by a set of hyperparameters $\aleph$ that needs to be provided to the algorithm, also explained in Section 4. Given $\aleph$, a generalization of the linear programming problem for instrumental variables described by Ramsahai (2012) can be used to find tight lower and upper bounds on the ACE. As the approach provides each witness a degree of protection against faithfulness violations, using a linear program, we call this framework the *Witness Protection Program* (WPP).

Thus, *this procedure unifies back-door adjustments and (a generalization of) instrumental variable approaches in a single framework, while not requiring knowing the true causal graph and relying on assumptions weaker than faithfulness.* This is the main message of the paper.

The output of the algorithm provides a set of lower/upper bounds on the ACE. If one could assume that $\aleph$ is conservative (that is, the actual edges are "weaker" than the ones implied by the set of causal models $(W, X, Y, \mathbf{Z}, U)$ compatible with $\aleph$), then a tight interval containing the ACE will be given by the largest lower bound and the smallest upper bound. However, there are several practical issues that need to be solved, the main ones being: (i) we do not know $P(\mathbf{W}, X, Y)$ and hence it needs to estimated from data; (ii) once statistical errors are introduced, it is not clear how to combine the different constraints implied by the algorithm; (iii) the computational cost of the procedure can be high, particularly if

input : A distribution $P(\mathbf{W}, X, Y)$;
A set of relaxation parameters $\aleph$;
Covariate index set $\mathbf{W}$ and cause-effect indices X and Y;
output: A set of quadruplets $(W, \mathbf{Z}, \mathcal{L}_{W\mathbf{Z}}, \mathcal{U}_{W\mathbf{Z}})$, where $(W, \mathbf{Z})$ is a witness-admissible set pair and $(\mathcal{L}_{W\mathbf{Z}}, \mathcal{U}_{W\mathbf{Z}})$ are a lower and upper bound on the ACE, respectively;

1 $\mathcal{R} \leftarrow \emptyset$;
2 **for** *each* $W \in \mathbf{W}$ **do**
3 **for** *every admissible set* $\mathbf{Z} \subseteq \mathbf{W} \backslash \{W\}$ *identified by* W **do**
4 $(\mathcal{L}_{W\mathbf{Z}}, \mathcal{U}_{W\mathbf{Z}}) \leftarrow$ bounds on the ACE as given by $P(W, X, Y, \mathbf{Z})$ and $\aleph$;
5 $\mathcal{R} \leftarrow \mathcal{R} \cup \{(W, \mathbf{Z}, \mathcal{L}_{W\mathbf{Z}}, \mathcal{U}_{W\mathbf{Z}})\}$;
6 **end**
7 **end**
8 **return** $\mathcal{R}$

Algorithm 1: A simplified Witness Protection Program algorithm, assuming the observable distribution $P(\mathbf{W}, X, Y)$ is known.

uncertainty estimates are required; (iv) we would like to have some results for continuous data; (v) the set of hyperparameters $\aleph$ needs to be chosen somehow, and some objective criterion to choose them is important in practice.

Section 4.2 addresses points (i) and (ii) using a Bayesian approach. This requires a likelihood function. Since the latent variable model that includes U is not identifiable, we work directly on the marginal observable distribution under the constraints implied by the linear program. Independence constraints can be tested using Bayesian model selection, but optionally can be ignored in the linear programming step to provide a more stringent test of feasibility of $\aleph$, as the feasible region for the ACE might be empty if the tested independence does not fit the data well enough even if it passes the test. An interpretation of this usage of independence tests is given in **Section 4.3**. We criticize naïve uses of Bayesian inference for latent variable models in **Section 4.4**.

A convenient implication of using Bayesian inference is that credible intervals for the ACE bounds can be computed in a conceptually simple way, using Monte Carlo methods. However, numerically running a linear program for each sample is expensive. A fully analytical solution to the linear program is not known, but a solution to a relaxed version of it can be found in a much cheaper and more numerically stable iterative algorithm (compared to a black-box solver) given in **Section 5**. This addresses point (iii), but bounds are looser than those obtained with a numerical solver as a consequence.

Point (iv) is partially addressed by **Section 6**, where we derive bounding methods for linear models. This complements Entner et al. (2012), which relies on non-Gaussianity and faithfulness using conditions weaker than Rule 1. Conceptually the method can be adapted to discrete non-binary data without major modifications, although presentation gets considerably more complicated. Treating continuous $\mathbf{W}$ is not a theoretical problem (at least by discretizing each W on demand while keeping $\mathbf{Z}$ continuous), although different estimation techniques and parametric assumptions would be required. Likewise, it is theoretically

possible to get bounds on the cumulative distribution function of Y by dichotomizing it at different levels $Y \leq y$, but we will not further discuss these generalizations in this paper.

Section 7 is a final note concerning the main procedure, where we discuss the possibility of exploiting Enter et al.'s Rule 2 for detecting zero effects. Although we do not further analyze this modification in our experiments, this section provides further insights on how WPP is related to sensitivity analysis methods for observational studies previously found in the literature.

Finally, **Section 8** is an extensive discussion on point (v), the choice of $\aleph$ and the need to deal with possibly incoherent bounds, which also relates back to point (ii). While this discussion is orthogonal to the main algorithm, which takes $\aleph$ as a given and it is guaranteed to be at least as conservative as Entner et al. (2013), it is a important practical issue. This section also complements the discussion started in **Section 7** on the relation between WPP and sensitivity analysis methods.

4. The Witness Protection Program

Let $(W, \mathbf{Z})$ be any pair found by a search procedure that decides when Rule 1 holds. W will play the role of an instrumental variable, instead of being discarded. Conditional on $\mathbf{Z}$, the lack of an edge $W \to Y$ can be justified by faithfulness (as $W \perp\!\!\!\perp Y \,|\, \{X, \mathbf{Z}\}$). For the same reason, there should not be any (conditional) dependence between W and a possible unmeasured common parent[2] U of X and Y. Hence, $W \perp\!\!\!\perp U$ and $W \perp\!\!\!\perp Y \mid \{U, X\}$ hold given $\mathbf{Z}$. A standard IV bounding procedure such as (Balke and Pearl, 1997) can then be used conditional on each individual value $\mathbf{z}$ of $\mathbf{Z}$, then averaged over $P(\mathbf{Z})$. That is, we can independently obtain lower and upper bounds $\{\mathcal{L}(\mathbf{z}), \mathcal{U}(\mathbf{z})\}$ for each value $\mathbf{z}$, and bound the ACE by

$$\sum_{\mathbf{z}} \mathcal{L}(\mathbf{z}) P(\mathbf{Z} = \mathbf{z}) \leq E[Y \mid do(X = 1)] - E[Y \mid do(X = 0)] \leq \sum_{\mathbf{z}} \mathcal{U}(\mathbf{z}) P(\mathbf{Z} = \mathbf{z}), \qquad (2)$$

since $E[Y \mid do(X = 1)] - E[Y \mid do(X = 0)] = \sum_{\mathbf{z}} (E[Y \mid do(X = 1), \mathbf{Z} = \mathbf{z}] - E[Y \mid do(X = 0), \mathbf{Z} = \mathbf{z}]) P(\mathbf{Z} = \mathbf{z})$.

Under the assumption of faithfulness and the satisfiability of Rule 1, the calculation of the above interval is redundant, as Rule 1 allows the direct use of the back-door adjustment using $\mathbf{Z}$. Our goal is to not enforce faithfulness, but use Rule 1 as a motivation to allow for a subset of violations of faithfulness, but not arbitrary violations.

In what follows, assume $\mathbf{Z}$ is set to a particular value $\mathbf{z}$ and all references to distributions are implicitly assumed to be defined conditioned on the event $\mathbf{Z} = \mathbf{z}$. That is, for simplicity of notation, we will neither represent nor condition on $\mathbf{Z}$ explicitly. The causal ordering where X and Y cannot precede any other variable is also assumed, as well as the causal ordering between X and Y.

Consider a standard parameterization of a directed acyclic graph (DAG) model, not necessarily causal, in terms of conditional probability tables (CPTs): let $\theta^V_{v,\mathbf{p}}$ represent $P(V = v \mid Par(V) = \mathbf{p})$ where $V \in \{W, X, Y, U\}$ denotes both a random variable and a vertex in the corresponding DAG; $Par(V)$ is the corresponding set of parents of V.

2. In this manuscript, we will sometimes refer to U as a *set* of common parents, although we do not change our notation to bold face to reflect that.

Faithfulness violations occur when independence constraints among observables are not *structural*, but due to "path cancellations." This means that parameter values are arranged so that $W \perp\!\!\!\perp Y \mid X$ holds, but paths connecting W and U, or W and Y, may exist so that either $W \not\perp\!\!\!\perp U$ or $W \not\perp\!\!\!\perp Y \mid \{U, X\}$. In this situation, some combination of the following should hold true:

$$\begin{aligned} P(Y = y \mid X = x, W = w, U = u) &\neq P(Y = y \mid X = x, U = u) \\ P(Y = y \mid X = x, W = w, U = u) &\neq P(Y = y \mid X = x, W = w) \\ P(X = x \mid W = w, U = u) &\neq P(X = x \mid W = w) \\ P(U = u \mid W = w) &\neq P(U = u), \end{aligned} \qquad (3)$$

for some $\{w, x, y, u\}$ in the sample space of $P(W, X, Y, U)$.

For instance, if the second and third statements above are true, this implies the existence of an active path into X and Y via U, conditional on W[3], such as $X \leftarrow U \to Y$. If the first statement is true, this corresponds to an active path between W and Y that is not blocked by $\{X, U\}$. If the fourth statement is true, U and W are marginally dependent, with a corresponding active path. Notice that some combinations are still compatible with a model where $W \perp\!\!\!\perp U$ and $W \perp\!\!\!\perp Y \mid \{U, X\}$ hold: if the second statement in (3) is false, this does not mean that U is necessarily a common parent of X and Y. Such a family of models is observationally equivalent[4] to one where U is independent of all variables.

When translating the conditions (3) into parameters $\{\theta^V_{v,\mathbf{p}}\}$, we need to define parent sets for each vertex, which only need to respect the partial causal ordering being assumed; similarly to the Prediction Algorithm of Spirtes et al. (2000), we do not need to fully specify a causal model in order to identify some of its interventional distributions. In our conditional probability table (CPT) factorization, we define $Par(X) = \{W, U\}$ and $Par(Y) = \{W, X, U\}$. The joint distribution of $\{W, U\}$ can be factorized arbitrarily: the causal directionality among W, U (and $\mathbf{Z}$) is not relevant to the only interventional distribution of interest, $do(X)$. In the next subsection, we refine the parameterization of our model by introducing *redundancies*: we provide a parameterization for the latent variable model $P(W, X, Y, U)$, the interventional distribution $P(W, Y, U \mid do(X))$ and the corresponding (latent-free) marginals $P(W, X, Y)$, $P(W, Y \mid do(X))$. These parameters cannot vary fully independently of each other. It is this fact that will allow us to bound the ACE using only $P(W, X, Y)$.

4.1 Encoding Faithfulness Relaxations with Linear Constraints

We define a *relaxation of faithfulness* as any set of assumptions that allows the relations in (3) to be true, but not necessarily in an *arbitrary* way: this means that while the left-hand and right-hand sides of each entry of (3) are indeed different, their difference is bounded by either the absolute difference or by ratios. Without such restrictions, (3) will only imply uninteresting bounds, as discussed in our presentation of Proposition 1.

Consider the following parameterization of the distribution of $\{W, X, Y, U\}$ under the observational and interventional regimes, and their respective marginals obtained by in-

3. That is, a path that d-connects X and Y and includes U, conditional on W; it is "into" X (and Y) because the edge linking X to the path points to X. See Spirtes et al. (2000) and Pearl (2000) for formal definitions and more examples.
4. Meaning a family of models where $P(W, X, Y)$ satisfies the same constraints.

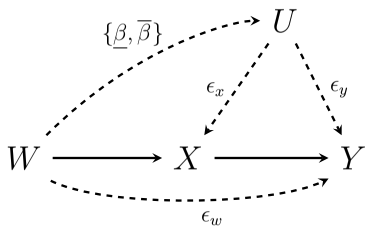

Figure 2: A visual depiction of the family of assumptions introduced in our framework. Dashed edges correspond to conditional dependencies that are constrained according to free parameters, displayed along each corresponding edge. This is motivated by observing $W \perp\!\!\!\perp Y \mid X$.

tegrating U away[5]. Again we condition everywhere on a particular value $\mathbf{z}$ of $\mathbf{Z}$ but, for simplicity of presentation, we suppress this from our notation, since it is not crucial to the developments in this section:

$$\begin{aligned}
\zeta^\star_{yx.w} &\equiv P(Y=y, X=x \,|\, W=w, U) \\
\zeta_{yx.w} &\equiv \textstyle\sum_U P(Y=y, X=x \,|\, W=w, U) P(U \,|\, W=w) \\
&= P(Y=y, X=x \,|\, W=w) \\
\\
\eta^\star_{xw} &\equiv P(Y=1 \,|\, X=x, W=w, U) \\
\eta_{xw} &\equiv \textstyle\sum_U P(Y=1 \,|\, X=x, W=w, U) P(U \,|\, W=w) \\
&= P(Y=1 \,|\, do(X=x), W=w) \\
\\
\delta^\star_w &\equiv P(X=1 \,|\, W=w, U) \\
\delta_w &\equiv \textstyle\sum_U P(X=x \,|\, W=w, U) P(U \,|\, W=w) \\
&= P(X=1 \,|\, W=w).
\end{aligned}$$

Under this encoding, the ACE is given by

$$\eta_{11} P(W=1) + \eta_{10} P(W=0) - \eta_{01} P(W=1) - \eta_{00} P(W=0). \tag{4}$$

Notice that we do not explicitly parameterize the marginal of U, for reasons that will become clear later.

We introduce the following assumptions, as illustrated by Figure 2:

$$|\eta^\star_{x1} - \eta^\star_{x0}| \leq \epsilon_w \tag{5}$$
$$|\eta^\star_{xw} - P(Y=1 \,|\, X=x, W=w)| \leq \epsilon_y \tag{6}$$
$$|\delta^\star_w - P(X=1 \,|\, W=w)| \leq \epsilon_x \tag{7}$$
$$\underline{\beta} P(U) \leq P(U \,|\, W=w) \leq \overline{\beta} P(U). \tag{8}$$

5. Notice from the development in this section that U is not necessarily a scalar, nor discrete.

Setting $\epsilon_w = 0$, $\underline{\beta} = \overline{\beta} = 1$ recovers the standard IV structure. Further assuming $\epsilon_y = \epsilon_x = 0$ recovers the chain structure $W \to X \to Y$. Under this parameterization in the case $\epsilon_y = \epsilon_x = 1$, $\underline{\beta} = \overline{\beta} = 1$, Ramsahai (2012), extending Dawid (2003), used linear programming to obtain bounds on the ACE. We will briefly describe the four main steps of the framework of Dawid (2003), and refer to the cited papers for more details of their implementation.

For now, assume that $\zeta_{yx.w}$ and $P(W=w)$ are known constants—that is, treat $P(W, X, Y)$ as known. This assumption will be dropped later. Dawid's formulation of a bounding procedure for the ACE is as follows.

Step 1 *Notice that parameters $\{\eta^\star_{xw}\}$ take values in a 4-dimensional polytope. Find the extreme points of this polytope. Do the same for $\{\delta^\star_w\}$.*

In particular, for $\epsilon_w = \epsilon_y = 1$, the polytope of feasible values for the four dimensional vector $(\eta^\star_{00}, \eta^\star_{01}, \eta^\star_{10}, \eta^\star_{11})$ is the unit hypercube $[0,1]^4$, a polytope with a total of 16 vertices $(0,0,0,0), (0,0,0,1), \ldots (1,1,1,1)$. Dawid (2003) covered the case $\epsilon_w = 0$, where a two-dimensional vector $\{\eta^\star_x\}$ replaces $\{\eta^\star_{xw}\}$. In Ramsahai (2012), the case $0 \leq \epsilon_w < 1$ is also covered: some of the corners in $[0,1]^4$ disappear and are replaced by others. The case where $\epsilon_w = \epsilon_x = \epsilon_y = 1$ is vacuous, in the sense that the consecutive steps cannot infer non-trivial constraints on the ACE.

Step 2 *Find the extreme points of the joint space $\{\zeta^\star_{yx.w}\} \times \{\eta^\star_{xw}\}$ by mapping them from the extreme points of $\{\delta^\star_w\} \times \{\eta^\star_{xw}\}$, since $\zeta^\star_{yx.w} = (\delta^\star_w)^x (1-\delta^\star_w)^{(1-x)} \eta^\star_{xw}$.*

The extreme points of the joint space $\{\delta^\star_w\} \times \{\eta^\star_{xw}\}$ are just the combination of the extreme points of each space. Some combinations $\delta^\star_w \times \eta^\star_{xw}$ map to the same $\zeta^\star_{yx.w}$, while the mapping from a given $\delta^\star_w \times \eta^\star_{xw}$ to $\eta^\star_{xw}$ is just the trivial projection. At this stage, we obtain all the extreme points of the polytope $\{\zeta^\star_{yx.w}\} \times \{\eta^\star_{xw}\}$ that are entailed by the factorization of $P(W, X, Y, U)$ and our constraints.

Step 3 *Using the extreme points of the joint space $\{\zeta^\star_{yx.w}\} \times \{\eta^\star_{xw}\}$, find the dual polytope of this space in terms of linear inequalities. Points in this polytope are convex combinations of $\{\zeta^\star_{yx.w}\} \times \{\eta^\star_{xw}\}$, shown by Dawid (2003) to correspond to the marginalizations over some $P(U)$, and each $P(U)$ corresponds to some point in the polytope. This results in constraints over $\{\zeta_{yx.w}\} \times \{\eta_{xw}\}$.*

This is the core step in Dawid (2003): points in the polytope $\{\zeta_{yx.w}\} \times \{\eta_{xw}\}$ correspond to different marginalizations of U according to different $P(U)$. Describing the polytope in terms of inequalities provides all feasible distributions that result from marginalizing U according to some $P(U)$. Because we included both $\zeta^\star_{yx.w}$ and $\eta^\star_{xw}$ in the same space, this will tie together $P(Y, X \mid W)$ and $P(Y \mid do(X), W)$.

Step 4 *Finally, maximize/minimize (4) with respect to $\{\eta_{xw}\}$ subject to the constraints found in Step 3 to obtain upper/lower bounds on the ACE.*

Allowing for the case where $\epsilon_x < 1$ or $\epsilon_y < 1$ is just a matter of changing the first step, where box constraints are set on each individual parameter as a function of the known $P(Y = y, X = x \,|\, W = w)$, prior to the mapping in Step 2. The resulting constraints are now implicitly non-linear in $P(Y = y, X = x \,|\, W = w)$, but at this stage this does not matter as the distribution of the observables is treated as a constant. That is, each resulting constraint in Step 3 is a linear function of $\{\eta_{xw}\}$ and a multilinear function on $\{\{\zeta_{yx.w}\}, \epsilon_x, \epsilon_y, \epsilon_w, \overline{\beta}, \underline{\beta}, P(W)\}$, as discussed in Section 5. Within the objective function (4), the only decision variables are $\{\eta_{xw}\}$, and hence Step 4 still sets up a linear programming problem even if there are multiplicative interactions between $\{\zeta_{yx.w}\}$ and other parameters.

To allow for the case $\underline{\beta} < 1 < \overline{\beta}$, we substitute every occurrence of $\zeta_{yx.w}$ due to the dualization in Step 3 above[6] by $\kappa_{yx.w} \equiv \sum_U \zeta^\star_{yx.w} P(U)$; notice the difference between $\kappa_{yx.w}$ and $\zeta_{yx.w}$. Likewise, we substitute every occurrence of η_{xw} in the constraints by $\omega_{xw} \equiv \sum_U \eta^\star_{xw} P(U)$. Instead of plugging in constants for the values of $\kappa_{yx.w}$ and turning the crank of a linear programming solver, we treat $\{\kappa_{yx.w}\}$ (and $\{\omega_{xw}\}$) as unknowns, linking them to observables and η_{xw} by the constraints

$$\begin{array}{rcl} \eta_{xw}/\overline{\beta} \leq & \omega_{xw} & \leq \min(1, \eta_{xw}/\underline{\beta}), \\ \zeta_{yx.w}/\overline{\beta} \leq & \kappa_{yx.w} & \leq \zeta_{yx.w}/\underline{\beta}, \end{array} \tag{9}$$

$$\sum_{yx} \kappa_{yx.w} = 1. \tag{10}$$

Finally, the steps requiring finding extreme points and converting between representations of a polytope can be easily implemented using a package such as Polymake[7] or the SCDD package[8] for R. Once bounds are obtained for each particular value of $\mathbf{Z}$, Equation (2) is used to obtain the unconditional bounds assuming $P(\mathbf{Z})$ is known.

In Section 8, we provide some guidance on how to choose the free parameters of the relaxation. However, it is relevant to point out that any choice of $\epsilon_w \geq 0, \epsilon_y \geq 0, \epsilon_x \geq 0, 0 \leq \underline{\beta} \leq 1 \leq \overline{\beta}$ is *guaranteed to provide bounds that are at least as conservative* as the back-door adjusted point estimator of Entner et al. (2013), which is always covered by the bounds. Background knowledge, after a user is suggested a witness and admissible set, can also be used to set relaxation parameters.

So far, the linear programming formulated through Steps 1–4 assumes one has already identified an appropriate witness W and admissible set $\mathbf{Z}$, and that the joint distribution $P(W, X, Y, \mathbf{Z})$ is known. In the next section, we discuss how this procedure is integrated with statistical inference for $P(W, X, Y, \mathbf{Z})$ and the search procedure of Entner et al. (2013).

6. Notice the subtlety: the values of $P(y, x \mid w)$ appear within the extreme points of $\{\zeta^\star_{yx.w}\} \times \{\eta^\star_{xw}\}$, but here we are only concerned about the symbols $\zeta_{yx.w}$ emerging from convex combinations of $\zeta^\star_{yx.w}$. In the original formulation of Dawid (2003), $\kappa_{yx.w} = P(y, x \mid w)$ is satisfied, because $P(U) = P(U \mid W)$ is assumed, but in our case in general this will not be true. Hence, the need for a different symbol. Ramsahai (2012) deals with the $P(U) \neq P(U \mid W)$ relaxation in a different way by conditioning on each value of W, but his ACE intervals always include zero.

4.2 Bayesian Learning and Result Summarization

In the previous section, we treated (the conditional) $\zeta_{yx.w}$ and $P(W = w)$ as known. A common practice is to replace them by plug-in estimators (and in the case of a non-empty admissible set $\mathbf{Z}$, an estimate of $P(\mathbf{Z})$ is also necessary). Such models can also be falsified, as the constraints generated are typically only supported by a strict subset of the probability simplex. In principle, one could fit parameters without constraints, and test the model by a direct check of satisfiability of the inequalities using the plug-in values. However, this does not take into account the uncertainty in the estimation. For the standard IV model, Ramsahai and Lauritzen (2011) discuss a proper way of testing such models in a frequentist sense.

Our models can be considerably more complicated. Recall that constraints will depend on the extreme points of the $\{\zeta^\star_{yx.w}\}$ parameters. As implied by (6) and (7), extreme points will be functions of $\zeta_{yx.w}$. Writing the constraints fully in terms of the observed distribution will reveal non-linear relationships. We approach the problem in a Bayesian way. We will assume first the dimensionality of $\mathbf{Z}$ is modest (say, 10 or less), as this is the case in most applications of faithfulness to causal discovery. We parameterize $\zeta^{\mathbf{z}}_{yxw} \equiv P(Y = y, X = x, W = w \mid \mathbf{Z} = \mathbf{z})$ as a full $2 \times 2 \times 2$ contingency table[9]. In the context of the linear programming problem of the previous section, for a given $\mathbf{z}$, we have $\zeta_{yx.w} = \zeta_{yxw}/P(W = w)$, $P(W = w) = \sum_{yx} \zeta_{yxw}$.

Given that the dimensionality of the problem is modest, we assign to each three-variate distribution $P(Y, X, W \,|\, \mathbf{Z} = \mathbf{z})$ an independent Dirichlet prior for every possible assignment of $\mathbf{Z}$, constrained by the inequalities implied by the model (and renormalized accordingly).

9. That is, we allow for dependence between W and Y given $\{X, \mathbf{Z}\}$, interpreting the decision of independence used in Rule 1 as being only an indicator of approximate independence.

The posterior is also a 8-dimensional constrained Dirichlet distribution, where we use rejection sampling to obtain a posterior sample by proposing from the unconstrained Dirichlet. A Dirichlet prior is assigned to $P(\mathbf{Z})$. Using a sample from the posterior of $P(\mathbf{Z})$ and a sample (for each possible value $\mathbf{z}$) from the posterior of $P(Y, X, W \mid \mathbf{Z} = \mathbf{z})$, we obtain a sample upper and lower bound for the ACE by just running the linear program for each sample of $\{\eta^{\mathbf{z}}_{yxw}\}$ and $\{P(\mathbf{Z} = \mathbf{z})\}$.

The full algorithm is shown in Algorithm 2, where $\aleph \equiv \{\epsilon_w, \epsilon_x, \epsilon_y, \underline{\beta}, \overline{\beta}\}$. The search procedure is left unspecified, as different existing approaches can be plugged into this step. See Entner et al. (2013) for a discussion. In Section 9 we deal with small dimensional problems only, using the brute-force approach of performing an exhaustive search for $\mathbf{Z}$. In practice, brute-force can be still valuable by using a method such as discrete PCA (Buntine and Jakulin, 2004) to reduce $\mathbf{W}\backslash\{W\}$ to a small set of binary variables. To decide whether the premises in Rule 1 hold, we merely perform Bayesian model selection with the BDeu score (Buntine, 1991) between the full graph $\{W \to X, W \to Y, X \to Y\}$ (conditional on $\mathbf{Z}$) and the graph with the edge $W \to Y$ removed.

Step 5 in Algorithm 2 is a "falsification test." Since the data might provide a bad fit to the constraints entailed by the model[10], we opt not to accept every pair $(W, \mathbf{Z})$ that passes Rule 1. One possibility is to calculate the posterior distribution of the model where constraints are enforced, and compare it against the posteriors of the saturated model given by the unconstrained contingency table. This requires another prior over the constraint hypothesis and the calculation of the corresponding marginal likelihoods. As an alternative approach, we adopt the pragmatic rule of thumb suggested by Richardson et al. (2011): sample M samples from the $\{\zeta^{\mathbf{z}}_{yxw}\}$ posterior given the *unconstrained* model, and check the proportion of values that are rejected. If more than 95% of them are rejected, we take this as an indication that the proposed model provides a bad fit and reject the given choice of $(W, \mathbf{Z})$.

The final result provides a set of posterior distributions over bounds, possibly contradictory, which should be summarized as appropriate. One possibility is to check for the union of all intervals or, as a simpler alternative, report the lowest of the lower bound estimates and the highest of the upper bound estimates using a point estimate for each bound:

1. for each $(W, \mathbf{Z})$ in $\mathcal{R}$, calculate the posterior expected value of the lower and upper bounds[11];
2. report the interval $\mathcal{L} \leq ACE \leq \mathcal{U}$ where $\mathcal{L}$ is the minimum of the lower bounds and $\mathcal{U}$ the maximum of the upper bounds.

In our experiments, we use a different summary. As we calculate the log-marginal posterior M_1, M_2, M_3, M_4 for the hypotheses $W \not\perp\!\!\!\perp Y \mid \mathbf{Z}$, $W \perp\!\!\!\perp Y \mid \mathbf{Z}$, $W \perp\!\!\!\perp Y \mid \mathbf{Z} \cup \{X\}$, $W \not\perp\!\!\!\perp Y \mid \mathbf{Z} \cup \{X\}$, respectively, we use the score

$$(M_1 - M_2) + (M_3 - M_4) \tag{11}$$

10. This is a result of not enforcing $W \perp\!\!\!\perp Y \mid \mathbf{Z} \cup \{X\}$ in $\eta^{\mathbf{z}}_{yxw}$.
11. Alternatively to using the expected posterior estimator for the lower/upper bounds, one can, for instance, report the 0.025 quantile of the marginal lower bound distribution and the 0.975 quantile of the marginal upper bound distribution. Notice, however, this does not give a 0.95 credible interval over ACE intervals as the lower bound and the upper bound are dependent in the posterior.

to assess the quality of the bounds obtained with the corresponding witness-admissible set pair. $M_1 - M_2$ and $M_3 - M_4$ are the log-posterior odds for the models required by the premises of Rule 1 against the respective alternatives. Just reporting the posterior of each $(W, \mathbf{Z})$ model to rank witness-admissible set pairs would not be entirely appropriate, as we are comparing models for different random variables. Adding the log-posteriors instead of a different combination is done for the sake of simplicity, contrasted to the idea of comparing the posterior of $W \to X \to Y$ against the other seven combinations of edges involving $\{W, X, Y\}$.

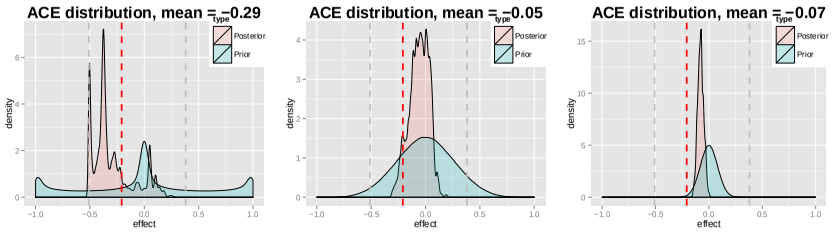
Given the score, we then report the corresponding top-scoring interval and evaluation metric based on this criterion. The reason for reporting a single representative interval is our belief that it is more productive to accommodate most of the (possibly large) discrepancies among estimated ACE intervals in the selection of $\aleph$, as done in Section 8. By selecting a single baseline with a unique lower/upper bound pair, it is simpler to communicate uncertainty, as we can then provide credible intervals or full distributions for the selected lower/upper bounds[12].

4.3 A Note on Weak Dependencies

As we briefly mentioned in the previous section, our parameterization $\{\zeta^{\mathbf{z}}_{yxw}\}$ does not enforce the independence condition $W \perp\!\!\!\perp Y \mid \mathbf{Z} \cup \{X\}$ required by Rule 1. Our general goal is to let WPP accept "near independencies," in which the meaning of the symbol $\perp\!\!\!\perp$ in practice means weak dependence[13]. We do not define what a weak dependence should mean, except for the general guideline that some agreed measure of conditional association should be "small." Our pragmatic view on WPP is that Rule 1, when supported by weak dependencies, should be used as a motivation for the constraints in Section 4.1. That is, one makes the assumption that "weak dependencies are not generated by arbitrary near-path cancellations," reflecting the belief that very weak associations should correspond to weak direct causal effects (and, where this is unacceptable, WPP should either be adapted to exclude relevant cases, or not be used). At the same time, users of WPP do not need to accept this view, as the method does not change under the usual interpretation of $\perp\!\!\!\perp$.

However, it is worthwhile to point out that computational gains can be obtained by using a parameterization that encodes the independence: that is, if we change our parameterization to enforce the independence constraint $W \perp\!\!\!\perp Y \mid \mathbf{Z} \cup \{X\}$, then there is no need to perform the check in line 5 of Algorithm 2, as the model is compatible with the (conditional on $\mathbf{Z}$) chain $W \to X \to Y$ regardless of $\aleph$. One can then generate full posterior distribution bounds only for those witness-admissible sets for which uncertainty estimates are required. The validity of point estimates of a bound is guaranteed by running a single linear programming on a point estimate of the distribution implied by the Bayesian net-

12. One should not confuse credible intervals with ACE intervals, as these are two separate concepts: each lower or upper bound is a function of the unknown $P(W, X, Y, \mathbf{Z})$ and needs to be estimated. There is posterior uncertainty over each lower/upper bound as in any problem where a functional of a distribution needs to be estimated. So the posterior distribution and the corresponding *credible intervals* over the *ACE intervals* are perfectly well-defined as in any standard Bayesian inference problem.
13. The procedure that decides conditional independencies in Section 4.2 is a method for testing exact independencies, although the prior on the independence assumption regulates how strong the evidence in the data should be for independence to be accepted.



(a) (b) (c)

Figure 3: Posterior over the ACE obtained by three different priors conditioned on a synthetic data set of size 1,000,000. Posterior computed by running 1,000,000 iterations of Gibbs sampling. The (independent) priors for $\theta^{Y}_{1.xu}$ and $\theta^{X}_{x.wu}$ are Beta (α, α), while θ^{U}_{u} is given a Dirichlet $(\alpha, \alpha, \alpha, \alpha)$. We set $\alpha = 0.1, 1, 10$ for the cases shown in (a), (b) and (c), respectively. Vertical red line shows the true ACE, while the population IV bounds are shown with gray lines. As the prior gets less informative (moving from (c) to (a)), the erratic shape of the posterior distribution also shows the effect of bad Gibbs sampling mixing. Even with a very large data set, the concentration of the posterior is highly dependent on the concentration of the prior.

work $W \to X \to Y$ (for every instance of $\mathbf{Z}$), as no further constraints in the observable distribution will exist. That is, if one wants to enforce the independence constraints, Line 4 of Algorithm 2 can be modified to directly generate just point estimates of the bounds for any witness-admissible set pair where a full posterior distribution is not required, and the falsification test in Step 5 (with the costly polytope construction) can also be skipped.

4.4 A Note on Unidentifiability

An alternative to bounding the ACE or using back-door adjustments is to put priors directly on the latent variable model for $\{W, X, Y, U\}$. Using the standard IV model as an example, we can define parameters $\theta^{Y}_{y.xu} \equiv P(Y = y \mid X = x, U = u)$, $\theta^{X}_{x.wu} \equiv P(X = x \mid W = w, U = u)$ and $\theta^{U}_{u} \equiv P(U = u)$, on which priors are imposed[14]. No complicated procedure for generating constraints in the observable marginal is necessary, and the approach provides point estimates of the ACE instead of bounds.

This sounds too good to be true, and indeed it is: results strongly depend on the prior, regardless of sample size. To illustrate this, consider a simulation from a standard IV model (Figure 1(c)), with $\mathbf{Z} = \emptyset$ and U an unobservable discrete variable of 4 levels. We generated a model by setting $P(W = w) = 0.5$ and sampling parameters $\theta^{Y}_{1.xu}$ and $\theta^{X}_{1.wu}$ from the uniform $[0, 1]$ distribution, while the 4-dimensional vector θ^{U}_{u} comes from a

14. $P(W = w)$ is not necessary, as the standard IV bounds (Balke and Pearl, 1997) do not depend on it.

Dirichlet $(1, 1, 1, 1)$. The resulting model had an ACE of -0.20, with a wide IV interval $[-0.50, 0.38]$ as given by the method of Balke and Pearl (1997). Narrower intervals can only be obtained by making more assumptions: there is no free lunch. However, as in this case where WPP cannot identify any witness, one might put priors on the latent variable model to get a point estimate, such as the posterior expected value of the ACE.

To illustrate the pitfalls of this approach, we perform Bayesian inference by putting priors directly on the CPT parameters of the latent variable model, assuming we know the correct number of levels for U. Figure 3 shows some results with a few different choices of priors. The sample size is large enough so that the posterior is essentially entirely within the population bounds and the estimation of $P(W, X, Y, Z)$ is itself nearly exact. The posterior over the ACE covers a much narrower area than the IV interval, and its behavior is erratic.

This is not to say that informative priors on a latent variable model cannot produce important results. For instance, Steenland and Greenland (2004) discuss how empirical priors on smoking habits among blue-collar workers were used in their epidemiological question: the causal effect of the occupational hazard of silica exposure on lung cancer incidence among industrial sand workers. Smoking is a confounding factor given the evidence that smoking and occupation are associated. The issue was that smoking was unrecorded among the workers, and so priors on the latent variable relationship to the observables were necessary. Notice, however, that this informative prior is essentially a way of performing a back-door adjustment when the adjustment set $\mathbf{Z}$ and treatment-outcome pair $\{X, Y\}$ are not simultaneously measured within the same subjects. When latent variables are "unknown unknowns," a prior on $P(Y \mid X, U)$ may be hard to justify. Richardson et al. (2011) discuss more issues on priors over latent variable models as a way of obtaining ACE point estimates, one alternative being the separation of identifiable and unidentifiable parameters to make transparent the effect of prior (mis)specification.

5. Algebraic Bounds and the Back-substitution Algorithm

Posterior sampling is expensive within the context of Bayesian WPP: constructing the dual polytope for possibly millions of instantiations of the problem is time consuming, even if each problem is small. Moreover, the numerical procedure described in Section 4 does not provide any insight on how the different free parameters $\{\epsilon_w, \epsilon_x, \epsilon_y, \underline{\beta}, \overline{\beta}\}$ interact to produce bounds, unlike the analytical bounds available in the standard IV case. Ramsahai (2012) derives analytical bounds under (5) given a *fixed*, *numerical* value of ϵ_w. We know of no previous analytical bounds as an algebraic function of ϵ_w.

5.1 Algebraic Bounds

We derive a set of bounds, whose validity are proved by three theorems. The first theorem derives separate upper and lower bounds on ω_{xw} using all the assumptions except Equation (5); this means constraints which do not link distributions under different values of $W = w$. The second theorem derives linear constraints on $\{\omega_{xw}\}$ using (5) and more elementary constraints. Our final result will construct less straightforward bounds, again using Equation (5) as the main assumption. As before, assume we are implicitly conditioning on some $\mathbf{Z} = \mathbf{z}$ everywhere.

We introduce the notation

$$\begin{array}{rcl} L^{YU}_{xw} & \equiv & \max(P(Y=1|X=x,W=w)-\epsilon_y,0) \\ U^{YU}_{xw} & \equiv & \min(P(Y=1|X=x,W=w)+\epsilon_y,1) \\ L^{XU}_{w} & \equiv & \max(P(X=1|W=w)-\epsilon_x,0) \\ U^{XU}_{w} & \equiv & \min(P(X=1|W=w)+\epsilon_x,1) \end{array}$$

and define $\underline{L} \equiv \min\{L^{YU}_{xw}\}, \overline{U} \equiv \max\{U^{YU}_{xw}\}$. Moreover, some further redundant notation is used to simplify the description of the constraints:

$$\begin{array}{rcl} \delta^{\star}_{1.w} & \equiv & \delta^{\star}_{w} \\ \delta^{\star}_{0.w} & \equiv & 1-\delta^{\star}_{w} \\ L^{XU}_{11} & \equiv & L^{XU}_{1} \\ L^{XU}_{01} & \equiv & 1-U^{XU}_{1} \\ U^{XU}_{11} & \equiv & U^{XU}_{1} \\ U^{XU}_{01} & \equiv & 1-L^{XU}_{1} \end{array}$$

and, following Ramsahai (2012), for any $x \in \{0,1\}$, we define x' as the complementary binary value (i.e. $x' = 1-x$). The same convention applies to pairs $\{w, w'\}$. Finally, define $\chi_{x.w} \equiv \sum_U P(X=x \mid W=w,U)P(U) = \kappa_{1x.w} + \kappa_{0x.w}$.

Theorem 2 *The following constraints are entailed by the assumptions expressed in Equations (6), (7) and (8):*

$$\omega_{xw} \leq \min \begin{cases} \kappa_{1x.w} + U^{YU}_{xw}(\kappa_{0x'.w} + \kappa_{1x'.w}) \\ \kappa_{1x.w}/L^{XU}_{xw} \\ 1 - \kappa_{0x.w}/U^{XU}_{xw} \end{cases} \tag{12}$$

$$\omega_{xw} \geq \max \begin{cases} \kappa_{1x.w} + L^{YU}_{xw}(\kappa_{0x'.w} + \kappa_{1x'.w}) \\ \kappa_{1x.w}/U^{XU}_{xw} \\ 1 - \kappa_{0x.w}/L^{XU}_{xw} \end{cases} \tag{13}$$

Theorem 3 *The following constraints are entailed by the assumptions expressed in Equations (5), (6), (7) and (8):*

$$\omega_{xw} \leq \min \begin{cases} (\kappa_{1x.w'} + \epsilon_w(\kappa_{0x.w'} + \kappa_{1x.w'}))/L^{XU}_{xw'} \\ 1 - (\kappa_{0x.w'} - \epsilon_w(\kappa_{0x.w'} + \kappa_{1x.w'}))/U^{XU}_{xw'} \end{cases} \tag{14}$$

$$\omega_{xw} \geq \max \begin{cases} (\kappa_{1x.w'} - \epsilon_w(\kappa_{0x.w'} + \kappa_{1x.w'}))/U^{XU}_{xw'} \\ 1 - (\kappa_{0x.w'} + \epsilon_w(\kappa_{0x.w'} + \kappa_{1x.w'}))/L^{XU}_{xw'} \end{cases} \tag{15}$$

$$\begin{array}{rcl} \omega_{xw} - \omega_{xw'}U^{XU}_{x'w} & \leq & \kappa_{1x.w} + \epsilon_w(\kappa_{0x'.w} + \kappa_{1x'.w}) \\ \omega_{xw} - \omega_{xw'}L^{XU}_{x'w} & \geq & \kappa_{1x.w} - \epsilon_w(\kappa_{0x'.w} + \kappa_{1x'.w}) \\ \omega_{xw} - \omega_{xw'}U^{XU}_{x'w} & \geq & 1 - \kappa_{0x.w} - U^{XU}_{x'w} - \epsilon_w(\kappa_{0x'.w} + \kappa_{1x'.w}) \\ \omega_{xw} - \omega_{xw'}L^{XU}_{x'w} & \leq & 1 - \kappa_{0x.w} - L^{XU}_{x'w} + \epsilon_w(\kappa_{0x'.w} + \kappa_{1x'.w}) \\ \omega_{xw} - \omega_{xw'} & \leq & \epsilon_w \\ \omega_{xw} - \omega_{xw'} & \geq & -\epsilon_w \end{array} \tag{16}$$

Theorem 4 *The following constraints are entailed by the assumptions expressed in Equations (5), (6), (7) and (8):*

$$\omega_{xw} \leq \min \begin{cases} \kappa_{1x'.w'} + \kappa_{1x.w'} + \kappa_{1x.w} - \kappa_{1x'.w} + \chi_{x'w}(\overline{U} + \underline{L} + 2\epsilon_w) - \underline{L} \\ \kappa_{1x'.w} + \kappa_{1x.w} + \kappa_{1x.w'} - \kappa_{1x'.w'} + 2\chi_{x'w}\epsilon_w + \chi_{x'w'}(\overline{U} + \underline{L}) - \underline{L} \end{cases} \tag{17}$$

$$\omega_{xw} \geq \max \begin{cases} -\kappa_{1x'.w'} + \kappa_{1x.w'} + \kappa_{1x'.w} + \kappa_{1x.w} + \chi_{x'w'}(\overline{U} + \underline{L}) - 2\epsilon_w\chi_{x'w} - \overline{U} \\ -\kappa_{1x'.w} + \kappa_{1x.w} + \kappa_{1x'.w'} + \kappa_{1x.w'} - \chi_{x'w}(2\epsilon_w - \overline{U} - \underline{L}) - \overline{U} \end{cases} \tag{18}$$

$$\begin{array}{rcl} \omega_{xw} + \omega_{x'w} - \omega_{x'w'} & \geq & \kappa_{1x'.w} + \kappa_{1x.w} - \kappa_{1x'.w'} + \kappa_{1x.w'} - \chi_{xw'}(\overline{U} + \underline{L} + 2\epsilon_w) + \underline{L} \\ \omega_{xw} + \omega_{x'w'} - \omega_{x'w} & \geq & \kappa_{1x'.w'} + \kappa_{1x.w'} - \kappa_{1x'.w} + \kappa_{1x.w} - 2\chi_{xw'}\epsilon_w - \chi_{xw}(\overline{U} + \underline{L}) + \underline{L} \\ \omega_{xw} + \omega_{x'w'} - \omega_{x'w} & \leq & -\kappa_{1x'.w} + \kappa_{1x.w} + \kappa_{1x'.w'} + \kappa_{1x.w'} - \chi_{xw}(\overline{U} + \underline{L}) + 2\epsilon_w\chi_{xw'} + \overline{U} \\ \omega_{xw} + \omega_{x'w} - \omega_{x'w'} & \leq & -\kappa_{1x'.w'} + \kappa_{1x.w'} + \kappa_{1x'.w} + \kappa_{1x.w} + \chi_{xw'}(2\epsilon_w - \overline{U} - \underline{L}) + \overline{U} \end{array} \tag{19}$$

Although at first such relations seem considerably more complex than those given by Ramsahai (2012), on closer inspection they illustrate qualitative aspects of our free parameters. For instance, consider

$$\omega_{xw} \geq \kappa_{1x.w} + L^{YU}_{xw}(\kappa_{0x'.w} + \kappa_{1x'.w}),$$

one of the instances of (13). If $\epsilon_y = 1$ and $\underline{\beta} = \overline{\beta} = 1$, then $L^{YU}_{xw} = 0$ and this relation collapses to $\eta_{xw} \geq \zeta_{1x.w}$, one of the original relations found by Balke and Pearl (1997) for the standard IV model. Decreasing ϵ_y will linearly increase L^{YU}_{xw} only after $\epsilon_y \leq P(Y = 1 \mid X = x, W = w)$, tightening the corresponding lower bound given by this equation.

Consider now

$$\omega_{xw} \leq 1 - (\kappa_{0x.w'} - \epsilon_w(\kappa_{0x.w'} + \kappa_{1x.w'}))/U^{XU}_{xw'}.$$

If also $\epsilon_w = 0$ and $\epsilon_x = 1$, from this inequality it follows that $\eta_{xw} \leq 1 - \zeta_{0x.w'}$. This is another of the standard IV inequalities (Balke and Pearl, 1997).

Equation (5) implies $|\omega_{x'w} - \omega_{x'w'}| \leq \epsilon_w$, and as such by setting $\epsilon_w = 0$ we have that

$$\omega_{xw} + \omega_{x'w} - \omega_{x'w'} \geq \kappa_{1x'.w} + \kappa_{1x.w} - \kappa_{1x'.w'} + \kappa_{1x.w'} - \chi_{xw'}(\overline{U} + \underline{L} + 2\epsilon_w) + \underline{L} \tag{20}$$

implies $\eta_{xw} \geq \eta_{1x.w} + \eta_{1x.w'} - \eta_{1x'.w'} - \eta_{0x.w'}$, one of the most complex relationships in (Balke and Pearl, 1997). Further geometric intuition about the structure of the binary standard IV model is given by Richardson and Robins (2010).

These bounds are not tight, in the sense that we opt not to fully exploit all possible algebraic combinations for some results, such as (20): there we use $\underline{L} \leq \eta^{\star}_{xw} \leq \overline{U}$ and $0 \leq \delta^{\star}_{w} \leq 1$ instead of all possible combinations resulting from (6) and (7). The proof idea in Appendix A can be further refined, at the expense of clarity. Because our derivation is a further relaxation, our final bounds are more conservative (that is, looser).

5.2 Efficient Optimization and Falsification Tests

Besides providing insight into the structure of the problem, the algebraic bounds give an efficient way of checking whether a proposed parameter vector $\{\zeta_{yxw}\}$ is valid in Step 5 of Algorithm 2, as well as finding the ACE bounds: we can now use back-substitution on the symbolic set of constraints to find box constraints $\mathcal{L}_{xw} \leq \omega_{xw} \leq \mathcal{U}_{xw}$. The proposed parameter will be rejected whenever an upper bound is smaller than a lower bound, and (4) can be trivially optimized conditioning only on the box constraints—this is yet another relaxation, added on top of the ones used to generate the algebraic inequalities. We initialize by intersecting all algebraic box constraints (of which (12) and (14) are examples); next we refine these by scanning relations $\pm\omega_{xw} - a\omega_{xw'} \leq c$ (the family given by (16)) in lexicographical order, and tightening the bounds of ω_{xw} using the current upper and lower bounds on $\omega_{xw'}$ where possible. We then identify constraints $\mathcal{L}_{xww'} \leq \omega_{xw} - \omega_{xw'} \leq \mathcal{U}_{xww'}$ starting from $-\epsilon_w \leq \omega_{xw} - \omega_{xw'} \leq \epsilon_w$ and the existing bounds, and plug them into relations $\pm\omega_{xw} + \omega_{x'w} - \omega_{x'w'} \leq c$ (as exemplified by (20)) to get refined bounds on ω_{xw} as functions of $(\mathcal{L}_{x'ww'}, \mathcal{U}_{x'ww'})$. We iterate this until convergence, which is guaranteed since lower/upper bounds never decrease/increase at any iteration. This back-substitution of inequalities follows the spirit of message-passing, in the sense that we iteratively update quantities of interest (intervals bounding the decision variables of the linear program) based on a small subset of other quantities, and it can be orders of magnitude more efficient than the fully numerical solution, while not increasing the width of the intervals by too much. In Section 9, we provide evidence for this claim. The back-substitution method is used in our experiments, combined with the fully numerical linear programming approach as explained in Section 9. The full method is given in Algorithm 3.

6. Linear Models

Entner et al. (2012) present a variant of their methodology for linear non-Gaussian models. The main difference is that in this case no witness variable W is necessary: it is possible to validate $\mathbf{Z}$ as an admissible set from a regression of X on $\mathbf{Z}$ and Y on $\{X, \mathbf{Z}\}$. Faithfulness is not necessary under some non-Gaussianity assumptions, although not all of these assumptions are testable without faithfulness and assumptions of parameter stability are still necessary for constraints other than independence constraints.

In this section, we adapt WPP to linear models. Vanishing partial correlations are used in the premise of Rule 1 instead of independence constraints, even if variables are non-Gaussian. The computation of the ACE bounds is vastly simplified. It complements Entner et al. (2012) in the sense that, although the method does not provide point estimates of the ACE and it might fail to identify some admissible sets, it does not require either faithfulness or non-Gaussianity[15]. Only second-order moments are necessary in the construction of the bound, although nonparametric linear models for testing partial correlations or sampling from the posterior distribution of covariance matrices might be necessary.

15. Even if variables are clearly non-Gaussian, the residuals of their regression on the admissible set might be close to Gaussian—this is after all the motivation for Gaussian likelihoods in most regression models, parametric or not.

input : Distributions $\{\zeta_{yx.w}\}$ and $\{P(W = w)\}$;
output: Lower and upper bounds $(\mathcal{L}_{xw}, \mathcal{U}_{xw})$ for every ω_{xw}

Find tightest lower and upper bounds $(\mathcal{L}_{xw}, \mathcal{U}_{xw})$ for each ω_{xw} using inequalities (12), (13) (14), (15), (17) and (18);
Let $\mathcal{L}^{\epsilon_w}_{xw}$ and $\mathcal{U}^{\epsilon_w}_{xw}$ be lower/upper bounds of $\omega_{xw} - \omega_{xw'}$;
for *each pair* $(x, w) \in \{0, 1\}^2$ **do**
  $\mathcal{L}^{\epsilon_w}_{xw} \leftarrow -\epsilon_w$;
  $\mathcal{U}^{\epsilon_w}_{xw} \leftarrow \epsilon_w$;
end
while *TRUE* **do**
  for *each relation* $\omega_{xw} - b \times \omega_{xw'} \leq c$ *in (16)* **do**
    $\mathcal{U}^{\epsilon_w}_{xw} \leftarrow \min\{\mathcal{U}^{\epsilon_w}_{xw}, (b-1)\mathcal{L}_{xw} + c\}$
  end
  for *each relation* $\omega_{xw} - b \times \omega_{xw'} \geq c$ *in (16)* **do**
    $\mathcal{L}^{\epsilon_w}_{xw} \leftarrow \max\{\mathcal{L}^{\epsilon_w}_{xw}, (b-1)\mathcal{U}_{xw} + c\}$
  end
  for *each relation* $\omega_{xw} + \omega_{x'w} - \omega_{x'w'} \leq c$ *in (19)* **do**
    $\mathcal{U}_{xw} \leftarrow \min\{\mathcal{U}_{xw}, c - \mathcal{L}^{\epsilon_w}_{xw'}\}$
  end
  for *each relation* $\omega_{xw} - (\omega_{x'w} - \omega_{x'w'}) \leq c$ *in (19)* **do**
    $\mathcal{U}_{xw} \leftarrow \min\{\mathcal{U}_{xw}, c + \mathcal{U}^{\epsilon_w}_{xw'}\}$
  end
  for *each relation* $\omega_{xw} + \omega_{x'w} - \omega_{x'w'} \geq c$ *in (19)* **do**
    $\mathcal{U}_{xw} \leftarrow \max\{\mathcal{U}_{xw}, c - \mathcal{U}^{\epsilon_w}_{xw'}\}$

  if *no changes in* $\{(\mathcal{L}_{xw}, \mathcal{U}_{xw})\}$ **then**
    break
  end
end
return $(\mathcal{L}_{xw}, \mathcal{U}_{xw})$ *for each* $(x, w) \in \{0, 1\}^2$

Algorithm 3: The iterative back-substitution procedure for bounding $\mathcal{L}_{xw} \leq \omega_{xw} \leq \mathcal{U}_{xw}$ for all combinations of x and w in $\{0, 1\}^2$.

6.1 A Bounding Procedure for Linear Models

Consider for now the linear model case with an empty admissible set $\mathbf{Z}$:

$$\begin{aligned} X &= aW + U_x \\ Y &= bX + cW + U_y, \end{aligned} \tag{21}$$

where $\{W, U_x, U_y\}$ are assumed to be zero mean variables, and $\{U_x, U_y\}$ are unobservable. The case with non-empty $\mathbf{Z}$ is analogous and discussed in the next section. The ACE is

given by b. We denote as s_{ww}, s_{wx}, s_{wy}, ... the corresponding variances/covariances of $\{W, U_x, U_y\}$. Moreover, let the variances of $\{W, U_x, U_y\}$ be set such that each element of $\{W, X, Y\}$ has unit variance, and denote as $\rho_{wx}, \rho_{wy}, \rho_{xy}$ the corresponding correlations of $\{W, X, Y\}$. Notice that $s_{ww} = 1$, and no assumptions about Gaussianity are being made. As before, we assume for now that $\rho_{wx}, \rho_{wy}, \rho_{xy}$ are known constants, and we would like to bound b as a function of this observable correlation matrix. The *implied* correlation matrix of model (21) needs to match the observable correlation matrix:

$$\rho_{wx} = a + s_{wx} \tag{22}$$
$$\rho_{wy} = b\rho_{wx} + c + s_{wy} \tag{23}$$
$$\rho_{xx} = 1 = a^2 + 2as_{wx} + s_{xx} \tag{24}$$
$$\rho_{xy} = b + c\rho_{wx} + as_{wy} + s_{xy} \tag{25}$$
$$\rho_{yy} = 1 = b^2 + 2bc\rho_{wx} + c^2 + s_{yy} + 2[b(as_{wy} + s_{xy}) + cs_{wy}], \tag{26}$$

where the above identities follow directly from (21). The feasible values of the parameters are given by the intersection of the above and

$$-\epsilon_c \leq c \leq \epsilon_c \tag{27}$$

$$-\epsilon_{wx} \leq s_{wx} \leq \epsilon_{wx}, \quad -\epsilon_{wy} \leq s_{wy} \leq \epsilon_{wy}, \quad -\epsilon_{xy} \leq s_{xy} \leq \epsilon_{xy} \tag{28}$$

$$0 \leq s_{xx} \leq 1, \quad 0 \leq s_{yy} \leq 1. \tag{29}$$

We ignore the positive semidefiniteness requirement of the covariance matrix of $\{W, U_X, U_Y\}$ for simplicity.

The set of constraints can be simplified as follows:

Theorem 5 *Assume*[16] $\rho_{wy} = \rho_{wx}\rho_{xy}$. *If an assignment of values to* $\{a, b, c, s_{wx}, s_{xx}, s_{xy}, s_{xx}\}$ *satisfies (27)-(29), then it satisfies (22)-(26) if and only it satisfies the following:*

$$\rho_{wy} = b\rho_{wx} + c + s_{wy} \tag{30}$$

$$\begin{cases} \rho_{xy} - \epsilon_{xy} - \mathcal{U}_a s_{wy} \leq b + c\rho_{wx} \leq \rho_{xy} + \epsilon_{xy} - \mathcal{L}_a s_{wy}, & \text{if } s_{wy} \geq 0 \\ \rho_{xy} - \epsilon_{xy} - \mathcal{L}_a s_{wy} \leq b + c\rho_{wx} \leq \rho_{xy} + \epsilon_{xy} - \mathcal{U}_a s_{wy}, & \text{if } s_{wy} < 0 \end{cases} \tag{31}$$

$$b^2 + 2bc\rho_{wx} + c^2 - 2(b\rho_{xy} + c\rho_{wy}) \leq 0 \tag{32}$$

where $\mathcal{L}_a \equiv \max(\min(0, 2\rho_{wx}), \rho_{wx} - \epsilon_{wx})$ *and* $\mathcal{U}_a \equiv \min(\max(0, 2\rho_{wx}), \rho_{wx} + \epsilon_{wx})$.

This means that optimizing b subject to constraints (27)−(32) is a convex program on $\{b, c, s_{wy}\}$ (conditioned on the sign of s_{wy}). Notice that, because of the assumption $\rho_{wy} = \rho_{wx}\rho_{xy}$, the system is always satisfiable. It can nevertheless rule out some the possible values of b (e.g. $b = \rho_{xy} = \rho_{wy}/\rho_{wx}$ if $\epsilon_{xy} = \epsilon_{wy}$ or $\epsilon_c = \epsilon_{wy} = 0$). Given $\{\rho_{wx}, \rho_{xy}\}$ (and setting $\rho_{wy} = \rho_{wx}\rho_{xy}$), we can find an upper bound for the ACE by maximizing b under the constraints (27)−(32) and $0 \leq s_{wy} \leq \epsilon_{wy}$, followed by maximization under the condition $-\epsilon_{wy} \leq s_{wy} \leq 0$. The upper bound is the maximum of the two conditional maxima. The lower bound is derived in an analogous way.

16. This assumption can be dropped, but the proof of Theorem 5 gets more complicated.

6.2 Algorithm for Gaussian Copula Models

One general model family in which vanishing partial correlations are closely connected to independence is the Gaussian copula (Elidan, 2013; Nelsen, 2007). Consider the following generative model:

$$\begin{aligned} \mathbf{V}^\star &\sim \mathcal{N}(0, R) \\ V_i &= F_i^{-1}(\phi(V_i^\star)), i = 1, 2, \ldots, p, \end{aligned} \tag{33}$$

where $\mathbf{V}^\star$ is a p-dimensional random vector generated according to the Gaussian with $p \times p$ correlation matrix R, $F_i(\cdot)$ is some arbitrary cumulative distribution function (CDF), and $\phi(\cdot)$ is standard Gaussian CDF. In continuous distributions, $F_i(\cdot)$ is invertible, and Markov properties of $\mathbf{V}^\star$ are preserved in the distribution of $\mathbf{V}$. See Harris and Drton (2013) for a discussion of Gaussian copula models in the context of causal inference, in particular for structure learning using the PC algorithm (Spirtes et al., 2000). Causal structure and effects are defined for $\mathbf{V}^*$ as in a typical linear causal system. Conditional independencies can be tested by copula-based measures, such as Spearman's rank correlation, by testing for the corresponding vanishing partial correlations. Given a target treatment $X \in \mathbf{V}$ and outcome $Y \in \mathbf{V}$, we are interested in bounding the ACE of $X^\star$ in $Y^\star$, the Gaussian variables underlying the possibly non-Gaussian X and Y.

For simplicity, we search for admissible sets $\mathbf{Z}$ with corresponding witness W using a Gaussian copula correlation matrix estimate $\hat{R}$. The unobserved data for $\mathbf{V}^\star$ is then for simplicity assumed to have zero empirical mean and empirical covariance matrix $\hat{R}$. We score models entailing independence of some V_i and V_j given $\mathbf{V}_Z$ by scoring two Gaussian networks, $G_1 \equiv \{\mathbf{V}_Z^\star \to V_i^\star, \mathbf{V}_Z^\star \to V_j^\star\}$ against $G_2 \equiv \{\mathbf{V}_Z^\star \to V_i^\star, \mathbf{V}_Z^\star \to V_j^\star, V_i^\star \to V_j^\star\}$. This is analogous to the binary case, where here we use the corrected BGe score (Kuipers et al., 2014). Notice this test is approximate, as $\hat{R}$ is used as a surrogate for the empirical covariance matrix of the unobserved data $\mathbf{V}^\star$, which is required by BGe[17].

For a given $(W, \mathbf{Z})$ accepted by Rule 1, we calculate the empirical residual (rank) correlation matrix obtained by regressing $W^\star$ on $\mathbf{Z}^\star$, $X^\star$ on $W^\star$ and $\mathbf{Z}^\star$, and $Y^\star$ on $X^\star$ and $\mathbf{Z}^\star$, so that the partial (residual) correlation of W and Y given X and $\mathbf{Z}$ is zero. Regression of subsets of $\mathbf{V}^\star$ on other subsets is done by standard regression using $\hat{R}$: let $\{\hat{\sigma}_{ww.\mathbf{z}}, \hat{\sigma}_{xx.\mathbf{z}}, \hat{\sigma}_{yy.\mathbf{z}}\}$ be the residual variances of the regression of $\{W^\star, X^\star, Y^\star\}$ on $\mathbf{Z}^\star$ as defined by $\hat{R}$. The resulting residual covariance matrix is scaled to unit variance, and the method in Section 6.1 is used to generate scaled bounds $\mathcal{L}_{b_s} \leq b_{standardized} \leq \mathcal{U}_{b_s}$, which are converted in bounds on the ACE in the original scale as $[\sqrt{\hat{\sigma}_{xx}\hat{\sigma}_{yy}}\mathcal{L}_{b_s}, \sqrt{\hat{\sigma}_{xx}\hat{\sigma}_{yy}}\mathcal{U}_{b_s}]$.

The algorithm is basically the same as Algorithm 2, except we report only point estimates for the bounds instead of posteriors, and no falsification step is necessary (Step 5 of Algorithm 2) as the model cannot be falsified given the accepted conditional independence.

17. Alternatively, one could test for the corresponding vanishing partial correlations in the empirical Spearman rank correlation matrix, as suggested by Harris and Drton (2013), at a particular significance level α. However, this only provides p-values, which are not ideal to sort witness/admissible sets by a score, as p-values measure only the surprise of seeing the observed data under a constraint. This does not measure strength of dependence nor a posterior over models. A fully Bayesian version of this approach is conceptually simple, although nonparametric modeling of $\{F_i(\cdot)\}$ (the so-called nonparanormal model) might require Markov chain Monte Carlo methods and computing marginal likelihoods is computationally very intensive.

7. Zero Effects

Under faithfulness, the premise of Rule 1 will not be true in a system where X is not a cause of Y. The result is that no conclusion about the ACE can be made, but identifiability can still be achieved by other means. Rule 2 (Entner et al., 2013) covers all identifiable cases where X is not a cause of Y:

Rule 2a: *If there exists a set* $\mathbf{Z} \subseteq \mathbf{W}$ *such that* $X \perp\!\!\!\perp Y \,|\, \mathbf{Z}$, *then infer an ACE of zero.*

Rule 2b: *If there exists a variable* $W \in \mathbf{W}$ *and a set* $\mathbf{Z} \subseteq \mathbf{W} \backslash \{W\}$ *such that:*

$$\textit{(i)} \quad W \not\perp\!\!\!\perp X \,|\, \mathbf{Z} \qquad\qquad \textit{(ii)} \quad W \perp\!\!\!\perp Y \,|\, \mathbf{Z},$$

then infer an ACE of zero.

Rule 2a is a direct application of faithfulness, while Rule 2b essentially corresponds to the "unshielded collider" check in the FCI algorithm of Spirtes et al. (2000). Figure 4 illustrates the paths that can be weakened under Rules 2a and 2b, excluding any a priori restrictions on $X \to Y$, since this is the relation that we want to bound given conditions on other paths. It is clear that for 2a not much of interest can be said beyond this: any association that cancels the causal effect of X and Y should be due to a corresponding association generated by unmeasured confounders. If such a strong contribution due to confounders does not exist, then we should not expect the ACE to be strong[18].

Rule 2b seems more interesting. However, as suggested by Figure 4(b), we are forcing *fewer* structural constraints in the linear program compared to Rule 1, as there is nothing from Rule 2b that motivates weak confounding effects. The reason for that is that Rule 2b concerns the removal of $X \to Y$, which corresponds to the effect we want to bound as a consequence of assumptions elsewhere (instead of assuming a priori, say, $|ACE| \leq \epsilon_\emptyset$ for some new hyperparameter $\epsilon_\emptyset$). One possibility is that for a pair $(W, \mathbf{Z})$ that satisfies Rule 2b, we perform the standard WPP bounding with $\epsilon_x = \epsilon_y = 1$ and, if desired, the added constraint $|ACE| \leq \epsilon_\emptyset$ to be assumed given the firing of Rule 2b.

Another possibility is to exploit Rule 2 to learn something about the possible effects of W on Y: in this case, we condition on constraints $|\eta^\star_{0w} - \eta^\star_{1w}| \leq \epsilon_\emptyset$ to derive bounds on the direct effect of W on Y (Cai et al., 2008). In the context of our ACE problem, it might suggest information about ϵ_w that can be reused in another suggested pair $(W, \mathbf{Z}')$, but this will require further assumptions or tests, as the differences between $\mathbf{Z}$ and $\mathbf{Z}'$ will make this transfer of information not trivial. For the rest of the paper, we will ignore the use of Rule 2 for simplicity. In the next section, however, we will consider the implications of having different pairs of witness/admissible set as a way of learning information about our hyperparameters.

18. This is *not* to say that such an observation has little scientific value. A similar statement is that a strong association between X and Y should be indicative of some causal effect, in the absence of a set of confounders that could fully explain this association. Simple as this is, this type of reasoning has long been explored in observational studies (Cornfield et al., 1959), and it is essentially what is behind Rosenbaum's sensitivity analysis methods (Rosenbaum, 2002a). Our point is that the linear programming approach for this setup is trivial.

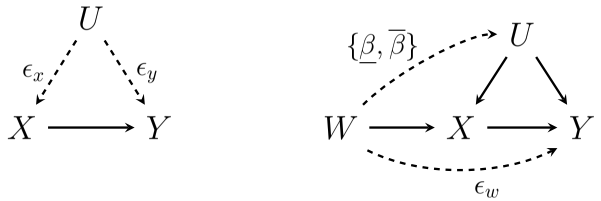

Figure 4: An illustration of conditional dependencies to be weakened under the acceptance of Rule 2. (a) Unmeasured confounding between X and Y is considered when these two variables are (conditionally) independent (given a possibly non-empty set $\mathbf{Z}$). (b) (Conditional) observable independence of W and Y is used to suggest that W and Y have bounded dependence conditioned on U, as well as weak dependence between W and U. Notice no weakening of effects $\{U \to X, U \to Y\}$.

8. Choosing Relaxation Parameters

The free parameters $\aleph \equiv \{\epsilon_w, \epsilon_x, \epsilon_y, \underline{\beta}, \overline{\beta}\}$ do not have a unique, clear-cut, domain-free procedure by which they can be calibrated. However, as we briefly discussed in Section 4, it is useful to state explicitly the following simple guarantee of WPP:

Corollary 6 *Given* $W \not\perp\!\!\!\perp Y \mid \mathbf{Z}$ *and* $W \perp\!\!\!\perp Y \mid \{X, \mathbf{Z}\}$, *the* WPP *population bounds on the ACE will always include the back-door adjusted population ACE based on* $\mathbf{Z}$.

Proof The proof follows directly by plugging in the quantities $\epsilon_w = \epsilon_y = \epsilon_x = 0$, $\underline{\beta} = \overline{\beta} = 1$, into the analytical bounds of Section 5.1, which will give the tightest bounds on the ACE (generalized to accommodate a background set $\mathbf{Z}$): a single point, which is also the functional obtained by the back-door adjustment. ■

The implication is that, regardless of the choice of free parameters, the result is guaranteed to be more conservative than the one obtained using the faithfulness assumption. This does not mean that a judicious choice of relaxation parameters is of secondary importance. Ideally, domain knowledge should be used: given a witness and admissible set, an expert decides which relaxations are reasonable. This is domain dependent, and might not be easier than choosing an admissible set from background knowledge. As an alternative, this section covers more generic methods for choosing relaxation parameters. Two main approaches are discussed:

- $\aleph$ is deduced by the outcome of a sensitivity analysis procedure; given a particular interval length L, we derive a quantification of faithfulness violations (represented by $\aleph$) required to generate causal models compatible with the observational data and an interval of length L containing the ACE. This is covered in Section 8.1;

- exploit the multiplicity of solutions (pairs of candidate witness/admissible sets) usually provided by Rule 1 to learn about the extent of possible faithfulness violations. Combine the multiple solutions with constraints or prior distributions for $\aleph$ to obtain estimates of the relaxation parameters. This is covered in Section 8.2.

8.1 Choice by Grid Search Conditioned on Acceptable Information Loss

One pragmatic default method is to first ask how wide an ACE interval can be so that the result is still useful for the goals of the analysis (e.g., sorting possible control variables X as candidates for a lab experiment based on lower bounds on the ACE). Let L be the interval width the analyst is willing to accept. Set $\epsilon_w = \epsilon_x = \epsilon_y = k_\epsilon$ and $\underline{\beta} = c$, $\overline{\beta} = 1/c$, for some pair (k_ϵ, c) such that $0 \leq k_\epsilon < 1$, $0 < c \leq 1$, and let (k_ϵ, c) vary over a grid of values. For each witness/admissible set candidate pair, pick the (k_ϵ, c) choice(s) entailing interval(s) of length closest to L. In case of more than one solution, summarize them by a criterion such the union of the intervals.

This methodology provides an explicit trade-off between length of the interval and tightness of assumptions. Notice that, starting from the back-door adjusted point estimator of Entner et al. (2013), it is not obvious how the trade-off could be obtained: that is, how to build an interval around the back-door point estimate that can be interpreted as bounds under an acceptable amount of information loss. WPP provides a principled way of building such an interval, with the resulting assumptions on $\aleph$ being explicitly revealed as a by-product. If the analyst believes that the resulting values of $\aleph$ are not strict enough, and no substantive knowledge exists that allows particular parameters to be tightened up, then one either has to concede that wider intervals are necessary or to find other means of identifying the ACE without the faithfulness assumption[19].

In the experiments in Section 9.2, we define a parameter space of $k_\epsilon \in \{0.05, 0.10, \ldots, 0.30\}$ and $c \in \{0.9, 1\}$. More than one interval of approximately the same width is identified. For instance, the configurations $(k_\epsilon = 0.25, c = 1)$ and $(k_\epsilon = 0.05, c = 0.9)$ both produced intervals of approximately length 0.30.

8.2 Linking Selection on the Observables to Selection on the Unobservables

Observational studies cannot be carried out without making assumptions that are untestable given the data at hand. There will always be degrees of freedom that must be chosen, even if such choices are open to criticism. The game is to provide a language to express assumptions in as transparent a manner as possible. Our view on priors for the latent variable model (Section 4.4) is that such prior knowledge is far too difficult to justify when the interpretation of U is unclear. Moreover, putting a prior on a parameter such as $P(Y = 1 \,|X = x, W = w, U = u)$ so that this prior is bounded by the constraint $|P(Y = 1 \,|X = x, W = w, U = u) - P(Y = 1 \mid X = w, W = w)| \leq \epsilon_w$ has no clear advantage over WPP: a specification of the shape of this prior is still necessary and may have undesirable side effects; it has no computational advantages, as constraints will have to be dealt with now within a Markov chain Monte Carlo procedure; it provides no insight on how constraints are related to one another (Section 5); it still suggests a point estimate that should not be trusted lightly, and posterior bounds which cannot be interpreted as data-driven bounds; and it still requires a choice of ϵ_w.

That is not to say that subjective priors on the relationship between U and the observables cannot be exploited, but the level of abstraction at which they need to be specified should have advantages when compared to the latent variable model approach. For instance, Altonji et al. (2005) introduced a framework to deal with violations of the IV assumptions (in the context of linear models). Their main idea is to linearly decompose the (observational) dependence of W and $\mathbf{Z}$, and the (causal) dependence of Y and $\mathbf{Z}$, as two signal-plus-noise decompositions, and assume that dependence among the signals allows one to infer the dependence among the noise terms. In this linear case, the dependence among noise terms gives the association between W and Y through unmeasured confounders. The constraint given by the assumption can then be used to infer bounds on the (differential) ACE. The details are not straightforward, but the justification for the assumption is indirectly derived by assuming $\mathbf{Z}$ is chosen by a sampling mechanism that picks covariates from the space of confounders U, so that $|\mathbf{Z}|$ and $|U|$ are large. The core idea is that the dependence between the covariates which are observed (i.e. $\mathbf{Z}$) and the other variables (W, X, Y) should tell us something about the impact of the unmeasured confounders. Their method is presented for linear models only, and the justification requires a very large $|\mathbf{Z}|$.

We introduce a very different method inspired by the same general principle, but exploiting the special structure of our procedure. Instead of relying on linearity and a fixed set of covariates, consider the following postulate: the variability of back-door adjusted ACE estimators based on different admissible sets, as implied by Rule 1, should provide some information about the extent of faithfulness violations in the given domain. In what follows, let $\aleph$ be simplified so that $\aleph \equiv \{\epsilon_w, \epsilon_{xy}, \beta\}$, where $\epsilon_{xy} \equiv \epsilon_x = \epsilon_y$ and $\beta \equiv \overline{\beta} = 1/\underline{\beta}$. The task then is to choose the three parameters in this set.

8.2.1 Method 1: Tightest ACE Coverage

Let $\{(W_1, \mathbf{Z}_1), \ldots, (W_k, \mathbf{Z}_k)\}$ be the set of all pairs found by WPP. Let A_i be the ACE calculated by the back-door adjustment on $\mathbf{Z}_i$, which will be the true ACE if faithfulness holds (we assume for now the joint distribution of the observables is known, so no statistical uncertainty plays a role yet). Let $(\mathcal{L}_i(\aleph), \mathcal{U}_i(\aleph))$ be the corresponding lower bound and upper bound implied by $(W_i, \mathbf{Z}_i)$ and $\aleph$. Finally, let $i^\star \in \{1, 2, \ldots, k\}$ be the index of a witness/admissible set that will be our reference pair[20] to output the final bounds on the ACE, once we choose $\aleph$.

The idea is simple: minimize $(\epsilon_w, \epsilon_{xy}, \beta)$ subject to $A_j \in [\mathcal{L}_{i^\star}(\aleph), \mathcal{U}_{i^\star}(\aleph)]$ for $1 \leq j \leq k$. This is a multi-objective minimization problem, of which we can return the Pareto frontier. Because this is a small dimensional problem in which high precision is not needed, a simple grid search will suffice, as performed in Section 9. Given that the Pareto frontier is likely to contain multiple points, we can report all intervals implied by each possible choice of $\aleph$.

19. That is, expert knowledge should of course still be invoked to decide whether the resulting relaxation is plausible or not (and hence, whether the resulting interval is believable), although communication by sensitivity analysis might facilitate discussion and criticism of the study. In his rejoinder to the discussion of (Rosenbaum, 2002b), Rosenbaum points out that the sensitivity analysis procedure just states the logical outcome of the structural assumptions: the deviation of (say) $P(Y = 1 \mid X = x, W = w)$ from $P(Y = 1 \mid X = x, W = w, U = u)$, required to explain the given magnitude of variation of plausible ACEs, is not imposed a priori by expert knowledge, but deduced.

20. The score in Equation (11) is used to pick $i^\star$.

Alternatively, we can provide a summary of the resulting bounds, such as the union of the intervals.

The rationale for this is as follows: if faithfulness is true, then all A_i will collapse to the same value, which implies that all bounds will collapse to a single point. Differences among A_i are the result of faithfulness violations, and we explain the contradictions via our $\aleph$ parameters. Contradictions in constraints entailed by faithfulness have been exploited before to achieve robust causal inference, as in the Conservative PC algorithm of Ramsey et al. (2006). To the best of our knowledge, we provide here the first algorithm for accommodating faithfulness contradictions in a space of constraints other than conditional independence constraints among observables.

For the real case where the observable joint distribution needs to be estimated from data, one simple alternative is just to use empirical estimates of the unconstrained joint. In one sense, this provides a conservative choice of $\aleph$, as one could modify the constraints in the minimization of $(\epsilon_w, \epsilon_{xy}, \beta)$ to require instead a less stringent criterion: that (say) the 95% credible interval for each A_j overlaps with credible intervals for $[\mathcal{L}_{i^*}(\aleph), \mathcal{U}_{i^*}(\aleph)]$. Credible intervals can be obtained as a function of the posterior distribution of the parameters of the joint of $\{X, Y, W_1, \ldots, W_k\} \cup \bigcup_{i=1}^{k} \mathbf{Z}_i$, where a prior over the multivariate binary distributions is subject to the WPP constraints for $(W_i, \mathbf{Z}_i)$ and the independence constraints for all other pairs, at each candidate value of $\aleph$. This is very costly, and better sampling procedures than the off-the-shelf rejection sampler will be necessary. We adopt the simple conservative approach with plug-in estimators instead.

8.2.2 Method 2: Bayesian Learning of Relaxation Parameters

A criticism of the tightest ACE coverage method is that it does not take into account the size of k: for $k = 1$, it will return $\epsilon_w = \epsilon_{xy} = 0$, for instance. Judgment is necessary on whether k is large enough in order to trust the results of this analysis. Alternatively, one may cast the problem of learning $\aleph$ as yet another Bayesian learning problem, with $\{(W_1, \mathbf{Z}_1), \ldots, (W_k, \mathbf{Z}_k)\}$ providing evidence for $\aleph$ according to some reasonable definition of "likelihood function." In what follows, again we assume the joint distribution of the observables is given, so that the back-door ACE functionals $A_1, A_2, \ldots, A_k$ given by Rule 1 are observable. As in the previous section, in our implementation we just plug-in the empirical distribution of the observables, but more sophisticated approaches accounting for the uncertainty in this estimate can in principle be constructed.

The principle is: if we allow for many ways in which faithfulness violations might be detected by contradictory results, but contradictions are not found, then this should be evidence that faithfulness violations do not exist. If contradictions are "small" (i.e., ACEs implied by different back-door adjustments are close), faithfulness violations should be small. Our uncertainty should decrease as more opportunities for contradictions are allowed. In particular, we want the posterior to converge to the single values $\epsilon_w = 0, \epsilon_{xy} = 0$ and $\beta = 1$ as the number of witness/admissible set pairs increase and they agree on the same value.

We start by defining

$$d_w \equiv \max_{i,x,\mathbf{z}} |P(Y = 1 \mid X = x, W_i = 1, \mathbf{Z}_i = \mathbf{z}, U) - P(Y = 1 \mid X = x, W_i = 0, \mathbf{Z}_i = \mathbf{z}, U)|,$$

for $i = 1, 2, \ldots, k$. An analogous definition is given for d_{xy} and d_β. Next, we define the "likelihood" function for d_w under "data set" $\{A_1, A_2, \ldots A_k\}$ as follows;

$$P(A_1, A_2, \ldots, A_k \mid d_w, d_{xy}, d_\beta) = \prod_{i=1}^{k} p_{U[\mathcal{L}(d_w, d_{xy}, d_\beta), \mathcal{U}(d_w, d_{xy}, d_\beta)]}(A_i), \tag{34}$$

where $p_{U[a,b]}(\cdot)$ is the uniform distribution in $[a, b]$. Functions $\mathcal{L}(d_w, d_{xy}, d_\beta), \mathcal{U}(d_w, d_{xy}, d_\beta)$ are the respective lower bound and upper bound implied by the WPP constraints parameterized by $\{d_w, d_{xy}, d_\beta\}$, and the (given) joint distribution of the observables. A uniform (discrete) prior for $\{d_w, d_{xy}, d_\beta\}$ is given over a pre-defined grid of values for these parameters[21]. We then choose a set of $\{\epsilon_w, \epsilon_{xy}, \beta\}$ as the high posterior density region defined by sorting all $\{d_w, d_{xy}, d_\beta\}$ in decreasing value of posterior mass, picking the minimum set that adds up to at least 95% of posterior mass. We summarize the implied set of bounds as necessary, see Section 9.

There is no reason why a uniform prior and the uniform likelihood (34) should be the only choices. Our motivation is that the chosen likelihood function penalizes parameters that imply wide intervals, while remaining agnostic about the position of each ACE within bounds. More importantly, the penalization increases as k increases, making the posterior more peaked. It however forces all intervals of equal length to be distinguished based on the prior only. Priors matter in applied work, but in our experiments we choose the uniform prior for its simplicity. We leave the discussion of other choices of likelihood and priors for future work.

A criticism of Equation (34) is that the pairs in set $\{(W_1, \mathbf{Z}_1), \ldots, (W_k, \mathbf{Z}_k)\}$ might have much overlap (in the sense that a same witness may appear in many pairs, and the intersection among $\{\mathbf{Z}_i\}$ may be large). As such, the multiplication in Equation (34) provides overconfident posteriors, as pairs are considered to be independent pieces of information for the relaxation parameters. More free parameters accounting for the dependence of $\{A_i\}$ given $\{d_w, d_{xy}, d_\beta\}$ should be added. However, while we remove a class of irrelevant pairs (any $(W_j, \mathbf{Z}_j)$ such that there is some $i \neq j$ where $\mathbf{Z}_i \subset \mathbf{Z}_j$ and $W_i = W_j$), in this work we ignore more complex adjustments for simplicity.

9. Experiments

In this section, we start with a comparison of the back-substitution algorithm of Section 5.2 against the fully numerical procedure, which generates constraints using standard algorithms for changing between polytope representations. We then perform studies with synthetic data, comparing different back-door estimation algorithms against WPP. Finally, we perform studies with real data sets.

21. See Section 9. Using a pre-defined discretization simplifies computation, as no MCMC is required and we do not need high precision in estimating relaxation parameters. A continuous space would also imply challenges to the MCMC approach, as the posterior can be flat in some regions where different parameter settings imply intervals of same length $\mathcal{U}(d_w, d_{xy}, d_\beta) - \mathcal{L}(d_w, d_{xy}, d_\beta)$.

9.1 Empirical Investigation of the Back-substitution Algorithm

We compare the back-substitution algorithm introduced in Section 5.2 with the fully numerical algorithm. Comparison is done in two ways: (i) computational cost, as measured by the wallclock time taken to generate 100 samples by rejection sampling; (ii) width of the generated intervals. As discussed in Section 5.2, bounds obtained by the back-substitution algorithm are at least as wide as in the numerical algorithm, barring rounding problems[22].

We ran two batches of 1000 trials each, varying the level of the relaxation parameters. In the first batch, we set $\epsilon_x = \epsilon_y = \epsilon_w = 0.2$, and $\underline{\beta} = 0.9$, $\overline{\beta} = 1.1$. In the second batch, we change parameters so that $\underline{\beta} = \overline{\beta} = 1$. Experiments were run on a Intel Xeon E5-1650 at 3.20Ghz. Models were simulated according the the structure $W \to X \to Y$, sampling each conditional distribution of a vertex being equal to 1 given its parent from the uniform $(0, 1)$ distribution. The numerical procedure of converting extreme points to linear inequalities was done using the package RCDD, a R wrapper for the *cddlib* by Komei Fukuda. Inference is done by rejection sampling, requiring 100 samples per trial. We fix the number of iterations of the back-substitution method to 4, which is more than enough to achieve convergence. All code was written in R.

For the first batch, the average time difference between the fully numerical method and the back-substitution algorithm was 1 second, standard deviation (s.d.) 0.34. The ratio between times had a mean of 203 (s.d. 82). Even with a more specialized implementation of the polytope dualization step[23], two orders of magnitude of difference seem hard to remove by better coding. Concerning interval widths, the mean difference was 0.15 (s.d. 0.06), meaning that the back-substitution on average has intervals where the upper bound minus the lower bound difference is 0.15 units more than the numerical method, under this choice of relaxation parameters and averaged over problems generated according to our simulation scheme. There is a correlation between the width difference and the interval width given by the numerical method the gap, implying that differences tend to be larger when bounds are looser: the gap between methods was as small as 0.04 for a fully numerical interval of width 0.19, and as large as 0.23 for a fully numerical interval of width 0.49. For the case where $\overline{\beta} = \underline{\beta} = 1$, the average time difference was 0.92 (s.d. of 0.24), ratio of 152 (s.d. 54.3), interval width difference of 0.09 (s.d. 0.03); The gap was as small as 0.005 for a fully numerical interval of width 0.09, and as large as 0.17 for a fully numerical interval of with 0.23.

9.2 Synthetic Studies

We describe a set of synthetic studies for binary data where, for procedures that estimate ACE intervals, we assess the trade-off between its correctness (that is, how far from the true ACEs the intervals are, for a suitable definition of distance) and its informativeness (how wide the intervals are).

22. We did not use rational arithmetic in the polytope generator in order to speed it up; consequently, about 1% of the time we observed numerical problems. Those were excluded from the statistics reported in this section.
23. One advantage of the analytical bounds, as used by the back substitution method, is that it is easy to express them as matrix operations over all Monte Carlo samples, while the polytope construction requires iterations over the samples.

In the synthetic study setup, we compare our method against NE1 and NE2, two naïve point estimators defined by back-door adjustment on the whole of set of available covariates $\mathbf{W}$ and on the empty set, respectively. The former is widely used in practice, even when there is no causal basis for doing so (Pearl, 2009). The point estimator of Entner et al. (2013), based solely on the faithfulness assumption, is also assessed.

We generate problems where conditioning on the whole set $\mathbf{W}$ is guaranteed to give incorrect estimates. In detail: we generate graphs where $\mathbf{W} \equiv \{Z_1, Z_2, \ldots, Z_8\}$. Four independent latent variables $L_1, \ldots, L_4$ are added as parents of each $\{Z_5, \ldots, Z_8\}$; L_1 is also a parent of X, and L_2 a parent of Y. L_3 and L_4 are each randomly assigned to be a parent of either X or Y, but not both. $\{Z_5, \ldots, Z_8\}$ have no other parents. The graph over $Z_1, \ldots, Z_4$ is chosen by adding edges uniformly at random according to a fixed topological order. As a consequence, using the full set $\mathbf{W}$ for back-door adjustment is always incorrect, as at least four paths $X \leftarrow L_1 \to Z_i \leftarrow L_2 \to Y$ are active for $i = 5, 6, 7, 8$. The conditional probabilities of a vertex given its parents are generated by a logistic regression model with pairwise interactions, where parameters are sampled according to a zero mean Gaussian with standard deviation 20 / number of parents. Parameter values are also further bounded, so that if the generated value if greater than 0.975 or less than 0.025, it is resampled uniformly in $[0.950, 0.975]$ or $[0.025, 0.050]$, respectively.

We analyze two variations: in the first, it is guaranteed that at least one valid pair witness-admissible set exists; in the second, all latent variables in the graph are set also as common parents also of X and Y, so no valid witness exists. We divide each variation into two subcases: in the first, "hard" subcase, parameters are chosen (by rejection sampling, proposing from the model described in the previous paragraph) so that NE1 has a bias of at least 0.1 in the population; in the second, no such a selection is enforced, and as such our exchangeable parameter sampling scheme makes the problem relatively easy. We summarize each WPP interval by the posterior expected value of the lower and upper bounds. In general WPP returns more than one bound: we select the upper/lower bound corresponding to the $(W, \mathbf{Z})$ pair which maximizes the score described at the end of Section 4.2. A BDeu prior with an equivalent sample size of 10 was used.

Our main evaluation metric for an estimate is the Euclidean distance (henceforth, "error") between the true ACE and the closed point in the given estimate, whether the estimate is a point or an interval. For methods that provide point estimates (NE1, NE2, and faithfulness), this means just the absolute value of the difference between the true ACE and the estimated ACE. For WPP, the error of the interval $[\mathcal{L}, \mathcal{U}]$ is zero if the true ACE lies in this interval. We report *error average* and *error tail mass at 0.1*, the latter meaning the proportion of cases where the error exceeds 0.1. Moreover, the faithfulness estimator is defined by averaging over all estimated ACEs as given by the accepted admissible sets in each problem.

As discussed in Section 8.1, WPP can be understood as providing a trade-off between information loss and accuracy. For instance, while the trivial interval $[-1, 1]$ will always have zero error, it is not an interesting solution. We assess the trade-off by running simulations at different levels of k_ϵ, where $\epsilon_w = \epsilon_y = \epsilon_x = k_\epsilon$. We also have two configurations for $\{\underline{\beta}, \overline{\beta}\}$: we set them at either $\underline{\beta} = \overline{\beta} = 1$ or $\underline{\beta} = 0.9, \overline{\beta} = 1.1$.

For the cases where no witness exists, Entner's Rule 1 should theoretically report no solution. Entner et al. (2013) used stringent thresholds for deciding when the two conditions

of Rule 1 held, we refer to that paper for an evaluation on how well Rule 1 can be correctly activated under the more conservative setup. Instead we take a more relaxed approach, using a uniform prior on the hypothesis of independence. As such, due to the nature of our parameter randomization, more often than not it will propose at least one witness. That is, for the problems where no exact solution exists, we assess how sensitive the methods are given conclusions taken from "approximate independencies" instead of exact ones.

The analytical bounds are combined with the numerical procedure as follows. We use the analytical bounds to test each proposed model using the rejection sampling criterion. Under this scheme, we calculate the posterior expected value of the contingency table and, using this single point, calculate the bounds using the fully numerical method. This is not guaranteed to work: the point estimator using the analytical bounds might lie outside the polytope given by the full set of constraints. If this situation is detected, we revert to calculating the bounds using the analytical method. The gains in interval length reduction using the full numerical method are relatively modest (e.g., at $k_\epsilon = 0.20$, the average interval width reduced from 0.30 to 0.24) but depending on the application they might make a sizeable difference.

We simulate 100 data sets for each one of the four cases (hard case/easy case, with theoretical solution/without theoretical solution), 5000 points per data set, 1000 Monte Carlo samples per decision. Results for the point estimators (NE1, NE2, faithfulness) are obtained using the population contingency tables. Results are summarized in Table 1. The first observation is that at very low levels of k_ϵ we increase the ability to reject all witness candidates: this is due mostly not because Rule 1 never fires, but because the falsification rule of WPP (which does not enforce independence constraints) rejects the proposed witnesses found by Rule 1. The trade-off set by WPP is quite stable, where larger intervals are indeed associated with smaller error. The point estimates vary in quality, being particularly bad in the situation where no witness should theoretically exist. The set-up where $\underline{\beta} = 0.9, \overline{\beta} = 1.1$ is especially uninformative compared to $\underline{\beta} = \overline{\beta} = 1$. At $k_\epsilon = 0.2$, we obtain interval widths around 0.50. As Manski (2007) emphasizes, this is the price for making fewer assumptions. Even there, they typically cover only about 25% of the interval $[-1, 1]$ of *a priori* possibilities for the ACE.

9.2.1 Selection of Relaxation Parameters

We performed an automated choice of relaxation parameters applying the methods in Section 8.2 to the same synthetic data sets. For each data set and each parameter choice method, we obtain a set B of intervals defined by a lower/upper bound. We summarize B in two ways: the *tightest* bound, meaning we choose the narrowest interval in B; the *loosest* bound, defined as the interval where the lower (upper) bound is the smallest lower (largest upper) bound in B. We then report results for each of the four synthetic case scenarios and each of the two methods: the Tightest ACE Coverage (TAC) method from Section 8.2.1 and the high posterior density (HPD) method of Section 8.2.2. Each parameter ϵ_w and $\epsilon_{xy} = \epsilon_x = \epsilon_y$ was allowed to assume values in the discretized grid $\{0.01, 0.05, 0.10, \ldots, 0.50\}$. Parameter $\beta = \overline{\beta} = 1/\underline{\beta}$ was allowed to take values in $\{1, 1.05, \ldots, 1.20\}$. Results are summarized in Table 2.

Hard, Solvable: NE1 = $(0.12, 1.00)$, NE2 = $(0.02, 0.03)$

Table 1: Summary of the outcome of the synthetic studies. Columns labeled WPP1 refer to results obtained for $\underline{\beta} = \overline{\beta} = 1$, while WPP2 refers to the case $\underline{\beta} = 0.9, \overline{\beta} = 1.1$. The first column is the level in which we set the remaining parameters, $\epsilon_x = \epsilon_y = \epsilon_w = k_\epsilon$. The second column is the frequency by which a WPP solution has been found among 100 runs. For each particular method (NE1, NE2, Faithfulness and WPP) we report the pair (error average, error tail mass at 0.1), as explained in the main text. The Faithfulness estimator is the back-door adjustment obtained by using as the admissible set the same set found by WPP1. Averages are taken only over the cases where a witness-admissible set pair has been found. The columns following each WPP results are the median width of the respective WPP interval across the 100 runs.

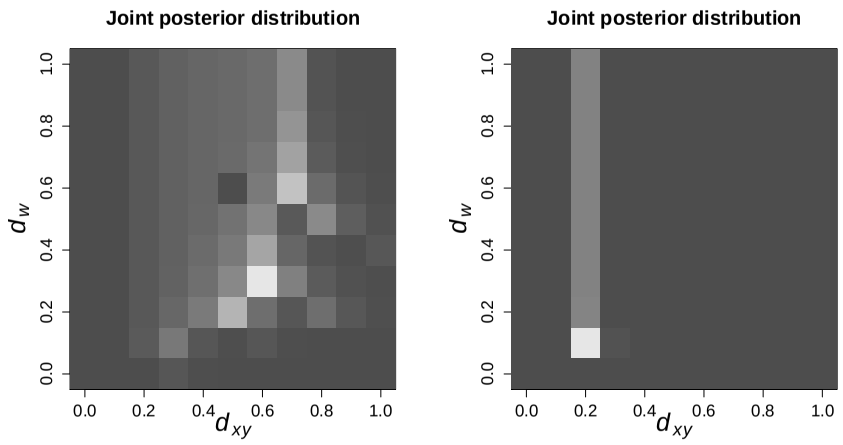
Case	Tightest				Loosest			
	TAC		HPD		TAC		HPD	
	error	width	error	width	error	width	error	width
Hard, Solvable	0.004	0.18	0.004	0.18	0.002	0.24	0.00009	0.40
Easy, Solvable	0.002	0.13	0.002	0.13	0.001	0.20	0.002	0.26
Hard, Not Solvable	0.12	0.14	0.12	0.14	0.10	0.20	0.07	0.33
Easy, Not Solvable	0.07	0.14	0.07	0.14	0.05	0.20	0.04	0.35

Table 2: Applying the criteria for choosing relaxation parameters from Section 8.2 to the four synthetic case scenarios. "Error" is the average error, as formalized for Table 1. "Width" is the average width over all 100 subcases of the respective study. "Tightest" and "Loosest" are the two criteria for summarizing a set of intervals, as explained in the main text.

Comparing it against Table 1, results seem to be slightly worse than WPP1 at the same interval width, but without making prior assumptions on β. Compared to WPP2, overall widths are much smaller. The HPD method agrees with TAC on the tightest interval, as our choice of prior will always imply a posterior mode on the TAC solution. The loosest interval for HPD will always be larger or equal to the loosest in TAC, as the 95% posterior mass that generates intervals will include the Pareto frontier and possibly many other candidates. In our simulations, the reduction in error for HPD with the loosest bound came with a non-trivial increase on the length of the corresponding intervals. While we do not explicitly advocate one method over another, the HPD method can be used to classify problems as harder than others by assessing how much of the posterior mass of hyperparameters is not on the Pareto frontier. In Figure 5, we visualize the marginal posterior distribution of $\{d_{xy}, d_w\}$ for two synthetic problems in the easy/solvable case, where in one problem the tightest interval failed to cover the true ACE, while in the other the ACE was correctly accounted for.

9.3 Influenza Study

Our empirical study concerns the effect of influenza vaccination on a patient being later on hospitalized with chest problems. $X = 1$ means the patient got a flu shot, $Y = 1$ indicates the patient was hospitalized. A negative ACE therefore suggests a desirable vaccine. The study was originally discussed by McDonald et al. (1992). Shots were not randomized, but doctors were randomly assigned to receive a reminder letter to encourage their patients to be inoculated, an event recorded as binary variable *GRP*. This suggests the standard IV model in Figure 1(d), with $W = GRP$ and U unobservable. That is, W and U are independent because W is randomized, and there are reasonable justifications to believe the lack of a direct effect of letter randomization on patient hospitalization. Richardson et al. (2011) and Hirano et al. (2000) provide further discussion.



(a) (b)

Figure 5: Marginal posterior distribution for $\{d_{xy}, d_w\}$ in two problems instances. Darker values represent smaller probabilities. In instance (a), the length of the tightest interval was 0.32 and did not contain the true ACE (but the error was still < 0.01). In instance (b), the length of the tightest interval was 0.11 and did contain the true ACE. Parameter d_w does not seem to be as influential conditional on d_{xy}, and the uniform prior allows for little variability in the d_w posterior away from the mode.

From this randomization, it is possible to directly estimate the ACE[24] of W on Y: -0.01. This is called *intention-to-treat* (ITT) analysis (Rothman et al., 2008), as it is based on the treatment assigned by randomization and not on the variable of interest (X), which is not randomized. While the ITT can be used for policy making, the ACE of X on Y would be a more relevant result, as it reveals features of the vaccine that are not dependent on the encouragement design. X and Y can be confounded, as X is not controlled. For instance, the patient choice of going to be vaccinated might be caused by her general health status, which will be a factor for hospitalization in the future.

The data contains records of 2,681 patients, with some demographic indicators (age, sex and race) and some historical medical data (for instance, whether the patient is diabetic). A total of 9 covariates is available. Using the bounds of Balke and Pearl (1997) and observed

24. Notice that while the ACE might be small, this does not mean that in another scale, such as odd-ratios, the results do not reveal an important effect. This depends on the domain.

frequencies produces an interval of $[-0.23, 0.64]$ for the ACE. WPP could *not* validate *GRP* as a witness for any admissible set.

Instead, when forbidding *GRP* to be included in an admissible set (since the theory says *GRP* cannot be a common direct cause of vaccination and hospitalization), WPP selected as the highest-scoring pair the witness *DM* (patient had history of diabetes prior to vaccination) with admissible set composed of *AGE* (dichotomized as "60 or less years old," and "above 60") and *SEX*. Choosing, as an illustration, $\epsilon_w = \epsilon_y = \epsilon_x = 0.2$ and $\underline{\beta} = 0.9$, $\overline{\beta} = 1.1$, we obtain the posterior expected interval $[-0.10, 0.17]$. This does *not* mean the vaccine is more likely to be bad (positive ACE) than good: the posterior distribution is over bounds, not over points, being completely agnostic about the distribution within the bounds. Notice that even though we allow for full dependence between all of our variables, the bounds are stricter than in the standard IV model due to the weakening of hidden confounder effects postulated by observing conditional independencies. It is also interesting that two demographic variables ended up being chosen by Rule 1, instead of other indicators of past diseases.

When allowing *GRP* to be included in an admissible set, the pair (*DM*, {*AGE*, *SEX*}) is now ranked second among all pairs that satisfy Rule 1, with the first place being given by *RENAL* as the witness (history of renal complications), with the admissible set being *GRP, COPD* (history of pulmonary disease), and *SEX*. In this case, the expected posterior interval was approximately the same, $[-0.08, 0.16]$. It is worthwhile to mention that, even though this pair scored highest by our criterion that measures the posterior probability distribution of each premise of Rule 1, it is clear that the fit of this model is not as good as the one with *DM* as the witness, as measured by the much larger proportion of rejected samples when generating the posterior distribution. This suggests future work on how to rank such models.

In Figure 6 we show a scatter plot of the posterior distribution over lower and upper bounds on the influenza vaccination, where *DM* is the witness. In Figure 7(a) and (b) we show kernel density estimators based on the Monte Carlo samples for the cases where *DM* and *RENAL* are the witnesses, respectively. While the witnesses were tested using the analytical bounds, the final set of samples shown here were generated with the fully numerical optimization procedure, which is quite expensive.

We also analyze how to select $\aleph = \{\epsilon_w, \epsilon_{xy} = \epsilon_x = \epsilon_y, \beta = \overline{\beta} = 1/\underline{\beta}\}$ using the Tightest ACE Coverage (TAC) method of Section 8.2.1. The motivation is that this is a domain with overall weak dependencies among variables. From one point of view, this is bad as instruments will be weak and generate wide intervals (as suggested by Proposition 1). From another perspective, this suggests that the effect of hidden confounders may also be weak.

A total of 48 witness/admissible sets were proposed by WPP via Rule 1. The TAC Pareto frontier, using the same parameter space as in Section 9.2.1, included only two possibilities, $\epsilon_{xy} = 0.05, \epsilon_w = 0.01, \beta = 1$ and $\epsilon_{xy} = 0.01, \epsilon_w = 0.01, \beta = 1.05$. Using the empirical distribution as an estimator of the joint of the observables, the respective ACE intervals were $[-0.01, 0.01]$ and $[-0.02, 0.02]$. Although the sign of the ACE is not determined from the data, the WPP procedure suggests that the magnitude of the ACE is no greater than 0.02, which by itself is of interest.

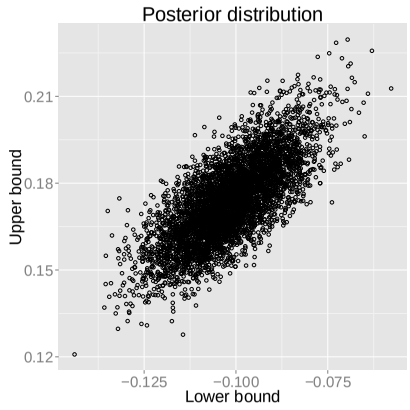


Figure 6: Scatterplot of the joint posterior distribution of lower bounds and upper bounds, Pearson correlation coefficient of 0.71.

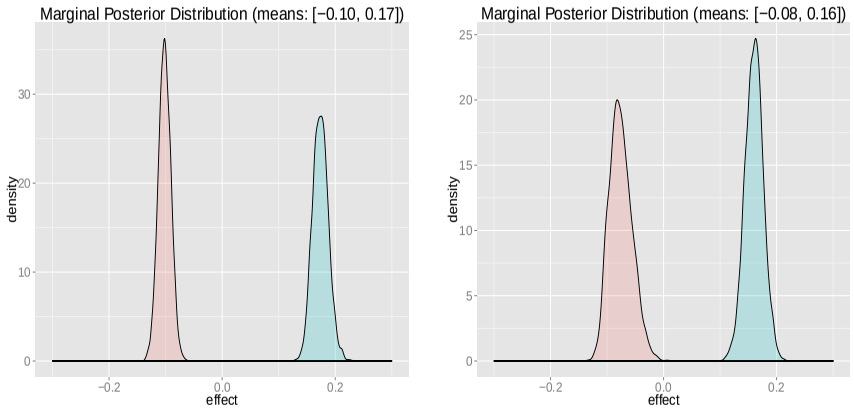
9.4 Linear Models

In this section, we assess the usage of the method in the linear case. Independently, we also introduce a complementary way of summarizing the outcome of a WPP analysis.

We first check the performance of the method with a small synthetic study. We generate models following the same pattern of the "hard/solvable" case of Section 9.2, the ACE being the coefficient of $X^\star$ in the equation for $Y^\star$. Each conditional model for a variable $V_i^\star$ given its parents is generated by sampling its coefficients from independent standard Gaussians, sampling the variance of the error term from a uniform $[0, 0.5]$, then rescaling the coefficients such that the marginal variance of $V_i^\star$ is 1. Observable data is then generated by transforming each $V_i^\star$ to follow a gamma distribution with mean and variance equal to 2. We generated 100 data sets with a sample size of 1000 each. We perform experiments[25] setting all hyperparameters $\epsilon_c = \epsilon_{wx} = \epsilon_{wy} = \epsilon_{xy} = 0.2$ and $\epsilon_c = \epsilon_{wx} = \epsilon_{wy} = \epsilon_{xy} = 0.1$. Estimates of the Gaussian copula correlation matrices are obtained using function HUGE.NPN from the R package HUGE to transform the data, of which we compute the empirical correlation matrix. We obtained average errors of 0.04 for the method with parameters set at 0.2, and 0.07 for parameters set at 0.1. The average length of the proposed intervals were 0.5 and 0.26, respectively. For comparison, the population error for the two naïve estimators was 0.23 and 0.18.

25. The test for conditional independencies is done with the corrected BGe score (Kuipers et al., 2014) as discussed in Section 6.2. The hyperparameters are a prior of 0.5 for the independence constraint hypothesis, and a inverse Wishart prior with $\upsilon \equiv p + 2$ degrees of freedom and a scale matrix given by the $p \times p$ identity matrix multiplied by υ, where p is the number of variables in the test.



(a) (b)

Figure 7: In (a), the marginal densities for the lower bound (red) and upper bound (blue) on the ACE, smoothed kernel density estimates based on 5000 Monte Carlo samples. Bounds were derived using DM as the witness. In (b), a similar plot using $RENAL$ as the witness.

We performed an empirical study with the 1976 Panel Study of Income Dynamics. The study uses data from 1975, assessing incoming of couples in 1976. Our outcome variable Y is the wife's reported wage at the time of the 1976 interview, and the treatment X is the number of years of the wife's previous labor market experience. The data was discussed by Mroz (1987) and can be obtained from the R package AER (Kleiber and Zeileis, 2008). Covariate set $\mathbf{W}$ includes a combination of discrete and continuous variables, such as husband's wages, number of children, and whether the wife went to college. We infer a Gaussian copula correlation matrix using the extended rank likelihood method of Hoff (2007) with the R package sbgcop, which can deal with discrete and continuous variables but requires expensive MCMC sampling. Notice that conditional independencies among the discrete observable elements of $\mathbf{V} \equiv \{X, Y\} \cup \mathbf{W}$ do not follow from conditional independencies among the unobservable Gaussian variables $\mathbf{V}^\star$. We nevertheless test Rule 1 among $\mathbf{V}^\star$ using the estimated copula correlation matrix and the relatively high prior of 0.5 for the hypothesis of independence, for any given independence assessment. Sample size is 753, with 17 covariates[26]. We then make the (strong) assumption that work experience in 1975 is not a cause of any other variable in the covariate set.

26. We removed two covariates from the original data set: the indicator of economical participation, which is a deterministic function of other covariates; and the estimated wage of the wife in 1975, which for that year was not available directly via self-report. In order to speed up the search algorithm, for each witness candidate W, the space of variables to test for an admissible set is composed of the 10 covariates mostly

Setting all relaxation parameters $\epsilon_c = \epsilon_{wx} = \epsilon_{wy} = \epsilon_{xy}$ to 0.1, we obtain in Figure 8(a) all corresponding intervals, with black dots representing the corresponding estimated ACE for the chosen admissible set. An explanation of all variables can be found in the documentation of package AER (Kleiber and Zeileis, 2008). Recall that the units here are given in the latent Gaussian space, where each $V_i^\star$ is a non-linear transformation of the corresponding V_i, as explained in Section 6.2. This analysis reveals two clear clusters of behavior, which internally show little variability but are very different from one another, even accounting for a violation of 0.1. This illustrates possible ways of communicating the output of a WPP analysis so that issues with assumptions and data can be raised.

In this case, the two clusters of intervals differ in one variable in the admissible set: variable *HOURS* is present in cases where the intervals are closer to zero. This variable measures the number of work hours of the wife in 1975, and is partially embedded in the definition of the experience level measured at 1975. By removing all admissible sets that include the *HOURS* variable, we obtain the summary given as Figure 8(b). This type of visualization step can be used to flag major contradictions that cannot be easily explained by allowing mild violations of faithfulness, but which might suggest problematic measurements to be reconsidered in the analysis.

10. Conclusion

Our model provides a novel compromise between point estimators given by the faithfulness assumption and bounds based on instrumental variables. We believe such an approach should become a standard item in the toolbox of methodologies for observational studies, as it provides means to draw conclusions from a complementary set of assumptions. Ongoing updates of software for WPP is provided as part of the R package CausalFX, available at the Comprehensive R Network[27] and GitHub[28]. A snapshot of the code used in this paper is available at `http://www.homepages.ucl.ac.uk/~ucgtrbd/wpp`.

In particular, unlike Bayesian approaches that put priors directly on the parameters of the unidentifiable latent variable model $P(Y, X, W, U \mid \mathbf{Z})$, the constrained Dirichlet prior on the observed distribution does not suffer from massive sensitivity to the choice of hyperparameters. When a strongly informative prior is lacking, WPP keeps inference more honest by focusing on bounds. While it is tempting to look for an alternative that will provide a point estimate of the ACE, it is also important to have a method that trades-off information for fewer assumptions. WPP provides a framework to express such assumptions.

The brute-force search used in the implementation of Rule 1 can be substituted by other combinatorial search procedures and dimensionality reduction methods. Entner et al. (2013) provide alternatives by borrowing ideas from the PC algorithm, for instance. Package CausalFX implements the idea discussed briefly in Section 9.4, where for each witness candidate W we pre-select a small set of candidates from $\mathbf{W}\backslash\{W\}$ and perform a brute-force search for admissible sets within this candidate set only. Pre-selection in CausalFX 1.0 is done by first sorting all $Z \in \mathbf{W}\backslash\{W\}$ according to the empirical mutual information

strongly associated with W, measured by the absolute value of the corresponding copula correlation matrix entry.

(a) (b)

Figure 8: The diagrams depict some ACE intervals obtained for the linear model of the impact of work experience up to 1975 of a married woman into her salary in 1976. On the y-axis, we show the witness in brackets, followed by all variables in the admissible set; the x-axis shows the point estimates of the interval for the ACE using $\epsilon_c = \epsilon_{wx} = \epsilon_{wy} = \epsilon_{xy} = 0.1$. Black dots are the corresponding point estimates of the ACE using the back-door method. All variable names are explained in the documentation of package AER (Kleiber and Zeileis, 2008). In (a), we allow all other recorded variables into the covariate set $\mathbf{W}$ from which witnesses and admissible sets are generated. In (b), we remove *HOURS* from the pool of possible covariates.

of Z and W given X and then picking the top K candidates, in descending value of mutual information (the heuristic being that we should look first at paths $W \to X \leftarrow Z$ that are "strong"). K is chosen such that enumerating 2^K candidate admissible sets is possible within the available computer resources. Although this restricted search procedure might miss some admissible sets, it has the advantage of avoiding sensitivity to propagation of statistical mistakes that creates difficulties for the PC algorithm and similar methods.

We emphasize that the credible intervals obtained by the procedure are conditioned on the search results, discarding uncertainty coming from the choices of witnesses, admissible sets and relaxation parameters. Ideally, uncertainty concerning the outcome of the Rule 1 search should also be taken into account. An approach analogous to (Friedman and Koller, 2003) is necessary, which we leave as future work.

As further future work, we will look at a generalization of the procedure beyond relaxations of chain structures $W \to X \to Y$. Much of the machinery here developed, including Entner et al.'s Rules, can be adapted to the case where causal ordering is unknown: starting from the algorithm of Mani et al. (2006) to search for "Y-structures," it is possible to generalize Rule 1 to setups where we have an outcome variable Y that needs to be controlled, but where there is no covariate X known not to be a cause of other covariates. Mooij and Cremers (2015) investigate the robustness of the faithfulness condition in this setup. Finally, the techniques used to derive the symbolic bounds in Section 5 may prove useful in a more general context, and complement other methods to find subsets of useful constraints such as the graphical approach of Evans (2012).

Acknowledgments

We thank McDonald, Hiu and Tierney for their flu vaccine data and the anonymous reviewers for their many suggestions to improve our paper. Much of this work was done while RS was hosted by the Department of Statistics at the University of Oxford. Parts of this work were previously published in the 2014 Neural Information Processing Systems Conference (Silva and Evans, 2014). Section 6, 7 and 8 are completely new, and all remaining sections have new material added, including the appendix.

Appendix A. Proofs

In this Appendix, we prove the results mentioned in the main text.

A.1 Basic Results

We divide the proofs in four main sections. The first section provides the basic methods, including how classical results in instrumental variable bounding can be rederived. The second and third sections are proofs for the most complex types of bounds. Finally, the fourth section covers the linear continuous case.

Proof of Proposition 1 In the standard IV case, simple analytical bounds are known for $P(Y = y \mid do(X = x))$ (Balke and Pearl, 1997; Dawid, 2003):

$$\eta_0 \leq \min \begin{cases} 1 - \zeta_{00.0} \\ 1 - \zeta_{00.1} \\ \zeta_{01.0} + \zeta_{10.0} + \zeta_{10.1} + \zeta_{11.1} \\ \zeta_{10.0} + \zeta_{11.0} + \zeta_{01.1} + \zeta_{10.1} \end{cases} \qquad \eta_0 \geq \max \begin{cases} \zeta_{10.1} \\ \zeta_{10.0} \\ \zeta_{10.0} + \zeta_{11.0} - \zeta_{00.1} - \zeta_{11.1} \\ -\zeta_{00.0} - \zeta_{11.0} + \zeta_{10.1} + \zeta_{11.1} \end{cases}$$

$$\eta_1 \leq \min \begin{cases} 1 - \zeta_{01.1} \\ 1 - \zeta_{01.0} \\ \zeta_{10.0} + \zeta_{11.0} + \zeta_{00.1} + \zeta_{11.1} \\ \zeta_{00.0} + \zeta_{11.0} + \zeta_{10.1} + \zeta_{11.1} \end{cases} \qquad \eta_1 \geq \max \begin{cases} \zeta_{11.1} \\ \zeta_{11.0} \\ -\zeta_{01.0} - \zeta_{10.0} + \zeta_{10.1} + \zeta_{11.1} \\ \zeta_{10.0} + \zeta_{11.0} - \zeta_{01.1} - \zeta_{10.1} \end{cases}$$

where $\eta_x \equiv P(Y=1 \mid do(X=x))$ and $\zeta_{yx.w} \equiv P(Y=y, X=x \mid W=w)$. Define also $\alpha_x \equiv P(Y=1 \mid X=x)$ and $\beta_w \equiv P(X=1 \mid W=w)$ so that

$$\zeta_{yx.w} = \alpha_x^{I(y=1)}(1-\alpha_x)^{I(y=0)}\beta_w^{I(x=1)}(1-\beta_w)^{I(x=0)}, \tag{35}$$

where $I(\cdot)$ is the indicator function returning 1 or 0 depending on whether its argument is true or false, respectively.

Assume for now that $\beta_1 \geq \beta_0$, that is, $P(X=1 \mid W=1) \geq P(X=1 \mid W=0)$. We will first show that $1-\zeta_{00.0} \leq \min\{1-\zeta_{00.1}, \zeta_{01.0}+\zeta_{10.0}+\zeta_{10.1}+\zeta_{11.1}, \zeta_{10.0}+\zeta_{11.0}+\zeta_{01.1}+\zeta_{10.1}\}$.

That $1-\zeta_{00.0} \leq 1-\zeta_{00.1}$ follows directly from the relationship (35) and the assumptions $W \perp\!\!\!\perp Y \mid X$ and $\beta_1 \geq \beta_0$: $(1-\zeta_{00.0})-(1-\zeta_{00.1}) = -(1-\alpha_0)(1-\beta_0)+(1-\alpha_0)(1-\beta_1) = (1-\alpha_0)(\beta_0-\beta_1) \leq 0$.

Now consider $(1-\zeta_{00.0})-(\zeta_{01.0}+\zeta_{10.0}+\zeta_{10.1}+\zeta_{11.1})$. This is equal to

$$\begin{aligned}
&= (1-(1-\alpha_0)(1-\beta_0)) - ((1-\alpha_1)\beta_0 + \alpha_0(1-\beta_0) + \alpha_0(1-\beta_1) + \alpha_1\beta_1) \\
&= (\beta_0 + \alpha_0(1-\beta_0)) - (\beta_0 - \alpha_1\beta_0 + \alpha_0(1-\beta_0) + \alpha_0 - \alpha_0\beta_1 + \alpha_1\beta_1) \\
&= \alpha_1(\beta_0-\beta_1) - \alpha_0(1-\beta_1) \leq 0
\end{aligned}$$

Analogously, we can show that $1-\zeta_{00.0} \leq \zeta_{10.0}+\zeta_{11.0}-\zeta_{01.1}-\zeta_{10.1}$. Tedious but analogous manipulations lead to the overall conclusion

$$1-\zeta_{00.0} = \min\begin{cases} 1-\zeta_{00.0} \\ 1-\zeta_{00.1} \\ \zeta_{01.0}+\zeta_{10.0}+\zeta_{10.1}+\zeta_{11.1} \\ \zeta_{10.0}+\zeta_{11.0}+\zeta_{01.1}+\zeta_{10.1} \end{cases} \qquad \zeta_{10.0} = \max\begin{cases} \zeta_{10.1} \\ \zeta_{10.0} \\ \zeta_{10.0}+\zeta_{11.0}-\zeta_{00.1}-\zeta_{11.1} \\ -\zeta_{00.0}-\zeta_{11.0}+\zeta_{10.1}+\zeta_{11.1} \end{cases}$$

$$1-\zeta_{01.1} = \min\begin{cases} 1-\zeta_{01.1} \\ 1-\zeta_{01.0} \\ \zeta_{10.0}+\zeta_{11.0}+\zeta_{00.1}+\zeta_{11.1} \\ \zeta_{00.0}+\zeta_{11.0}+\zeta_{10.1}+\zeta_{11.1} \end{cases} \qquad \zeta_{11.1} = \max\begin{cases} \zeta_{11.1} \\ \zeta_{11.0} \\ -\zeta_{01.0}-\zeta_{10.0}+\zeta_{10.1}+\zeta_{11.1} \\ \zeta_{10.0}+\zeta_{11.0}-\zeta_{01.1}-\zeta_{10.1} \end{cases}$$

The upper bound on the ACE $\eta_1-\eta_0$ is obtained by subtracting the lower bound on η_0 from the upper bound on η_1. That is, $\eta_1-\eta_0 \leq (1-\zeta_{01.1})-\zeta_{10.0} = \mathcal{U}_{SIV}$. Similarly, $\eta_1-\eta_0 \geq \zeta_{11.1}-(1-\zeta_{00.0}) = \mathcal{L}_{SIV}$. It follows that $\mathcal{U}_{SIV}-\mathcal{L}_{SIV} = 1-(P(X=1 \mid W=1)-P(X=1 \mid W=0))$.

Finally, assuming $\beta_1 \leq \beta_0$ gives by symmetry the interval width $1-(P(X=1 \mid W=0)-P(X=1 \mid W=1))$, implying the width in the general case is given by $1-|P(X=1 \mid W=1)-P(X=1 \mid W=0)|$. ■

Now we will prove the main theorems stated in Section 5. To facilitate reading, we repeat here the notation used in the description of the constraints with a few additions, as well as the identities mapping different parameter spaces and the corresponding assumptions exploited in the derivation.

We start with the basic notation,

$$\begin{aligned}
\zeta^\star_{yx.w} &\equiv P(Y=y, X=x \mid W=w, U) \\
\zeta_{yx.w} &\equiv \textstyle\sum_U P(Y=y, X=x \mid W=w, U)P(U \mid W=w) \\
&= P(Y=y, X=x \mid W=w) \\
\kappa_{yx.w} &\equiv \textstyle\sum_U P(Y=y, X=x \mid W=w, U)P(U)
\end{aligned}$$

$$\begin{aligned}
\eta^\star_{xw} &\equiv P(Y=1 \mid X=x, W=w, U) \\
\eta_{xw} &\equiv \textstyle\sum_U P(Y=1 \mid X=x, W=w, U)P(U \mid W=w) \\
&= P(Y=1 \mid do(X=x), W=w) \\
\omega_{xw} &\equiv \textstyle\sum_U P(Y=1 \mid X=x, W=w, U)P(U)
\end{aligned}$$

$$\begin{aligned}
\delta^\star_w &\equiv P(X=1 \mid W=w, U) \\
\delta_w &\equiv \textstyle\sum_U P(X=1 \mid W=w, U)P(U \mid W) = P(X=1 \mid W=w) \\
&= \zeta_{11.w} + \zeta_{01.w} \\
\chi_{x.w} &\equiv \textstyle\sum_U P(X=x \mid W=w, U)P(U) \\
&= \kappa_{1x.w} + \kappa_{0x.w}
\end{aligned}$$

The explicit relationship between parameters describing the latent variable model is:

$$\begin{aligned}
\zeta^\star_{00.0} &= (1-\eta^\star_{00})(1-\delta^\star_0) \\
\zeta^\star_{01.0} &= (1-\eta^\star_{10})\delta^\star_0 \\
\zeta^\star_{10.0} &= \eta^\star_{00}(1-\delta^\star_0) \\
\zeta^\star_{11.0} &= \eta^\star_{10}\delta^\star_0 \\
\zeta^\star_{00.1} &= (1-\eta^\star_{01})(1-\delta^\star_1) \\
\zeta^\star_{01.1} &= (1-\eta^\star_{11})\delta^\star_1 \\
\zeta^\star_{10.1} &= \eta^\star_{01}(1-\delta^\star_1) \\
\zeta^\star_{11.1} &= \eta^\star_{11}\delta^\star_1
\end{aligned}$$

All upper bound constants $U^{YU}_{\cdot\cdot}$ are assumed to be positive. For $L^{YU}_{\cdot\cdot}=0$, $c \geq 0$, all ratios $c/L^{YU}_{\cdot\cdot}$ are defined to be positive infinite.

In what follows, we define "the standard IV model" as the one which obeys exogeneity of W and exclusion restriction—that is, the model following the directed acyclic graph $\{W \to X \to Y, X \leftarrow U \to Y\}$. All variables are binary, and the goal is to bound the average causal effect (ACE) of X on Y given a non-descendant W and a possible (set of) confounder(s) U of X and Y.

Proof of Theorem 2 Start with the relationship between η_{xw} and its upper bound:

$$\begin{aligned}
\eta^\star_{xw} &\leq U^{YU}_{xw} && \text{(Multiply both sides by } \delta^\star_{x'.w}\text{)} \\
\eta^\star_{xw}(1-(1-\delta^\star_{x'.w})) &\leq U^{YU}_{xw}\delta^\star_{x'.w} && \text{(Marginalize over } P(U)\text{)} \\
\omega_{xw} - \kappa_{1x.w} &\leq U^{YU}_{xw}\chi_{x'.w} \\
\omega_{xw} &\leq \kappa_{1x.w} + U^{YU}_{xw}(\kappa_{0x'.w}+\kappa_{1x'.w})
\end{aligned}$$

and an analogous series of steps gives $\omega_{xw} \geq \kappa_{1x.w} + L^{YU}_{xw}(\kappa_{0x'.w}+\kappa_{1x'.w})$. Notice such bounds above will depend on how tight ϵ_y is. As an illustration of its implications, consider

the derived identity $\zeta^\star_{0x.w} = (1-\eta^\star_{xw})\delta^\star_{x.w} \Rightarrow 1-\eta^\star_{xw} = \zeta^\star_{0x.w}/\delta^\star_{x.w} \Rightarrow 1-\eta^\star_{xw} \geq \zeta^\star_{0x.w} \Rightarrow \eta^\star_{xw} \leq 1-\zeta^\star_{0x.w} = \zeta^\star_{0x.w} + \zeta^\star_{0x'.w} + \zeta^\star_{1x'.w} \Rightarrow \omega_{xw} \leq \kappa_{0x.w} + \kappa_{0x'.w} + \kappa_{1x'.w}$.

It follows from $U^{YU}_{xw} \leq 1$ that that the derived bound $\omega_{xw} \leq \kappa_{1x.w} + U^{YU}_{xw}(\kappa_{0x'.w} + \kappa_{1x'.w})$ is at least as tight as the one obtained via $\eta^\star_{xw} \leq 1-\zeta^\star_{0x.w}$. Notice also that the standard IV bound $\eta_{xw} \leq 1-\zeta_{0x.w}$ (Balke and Pearl, 1997; Dawid, 2003) is a special case for $\epsilon_y = 0$, $\underline{\beta} = \overline{\beta} = 1$.

For the next bounds, consider

$$\begin{array}{rcll} \delta^\star_{x.w} & \leq & U^{XU}_{xw} & \\ \eta^\star_{xw}\delta^\star_{x.w} & \leq & U^{XU}_{xw}\eta^\star_{xw} & \text{(Marginalize over } P(U)) \\ \kappa_{1x.w} & \leq & U^{XU}_{xw}\omega_{xw} & \\ \omega_{xw} & \geq & \kappa_{1x.w}/U^{XU}_{xw} & \end{array}$$

where the bound $\omega_{xw} \leq \kappa_{1x.w}/L^{XU}_{xw}$ can be obtained analogously. The corresponding bound for the standard IV model (with possible direct effect $W \to Y$) is $\eta_{xw} \geq \zeta_{1x.w}$, obtained again by choosing $\epsilon_x = 1$, $\underline{\beta} = \overline{\beta} = 1$. The corresponding bound $\omega_{xw} \geq \kappa_{1x.w}$ is a looser bound for $U^{XU}_{xw} < 1$. Notice that if $L^{XU}_{xw} = 0$, the upper bound is defined as infinite.

Finally, the last bounds are similar to the initial ones, but as a function of ϵ_x instead of ϵ_y:

$$\begin{array}{rcll} \delta^\star_{x.w} & \leq & U^{XU}_{xw} & \\ (1-\eta^\star_{xw})\delta^\star_{x.w} & \leq & U^{XU}_{xw}(1-\eta^\star_{xw}) & \text{(Marginalize over } P(U)) \\ \kappa_{0x.w} & \leq & U^{XU}_{xw}(1-\omega_{xw}) & \\ \omega_{xw} & \leq & 1-\kappa_{0x.w}/U^{XU}_{xw} & \end{array}$$

The lower bound $\omega_{xw} \geq 1-\kappa_{0x.w}/L^{XU}_{xw}$ is obtained analogously, and implied to be minus infinite if $L^{XU}_{xw} = 0$. ■

Proof of Theorem 3 We start with the following derivation,

$$\begin{array}{rcll} \eta^\star_{xw'} - \eta^\star_{xw} & \leq & \epsilon_w & \\ \eta^\star_{xw'}\delta^\star_{x.w'} - \eta^\star_{xw}\delta^\star_{x.w'} & \leq & \epsilon_w\delta^\star_{x.w'} & \text{(Use } -U^{XU}_{xw'} \leq -\delta^\star_{x.w'}) \\ \eta^\star_{xw'}\delta^\star_{x.w'} - \eta^\star_{xw}U^{XU}_{xw'} & \leq & \epsilon_w\delta^\star_{x.w'} & \text{(Marginalize over } P(U)) \\ \kappa_{1x.w'} - \omega_{xw}U^{XI}_{xw} & \leq & \epsilon_w\chi_{x.w'} & \\ \omega_{xw} & \geq & (\kappa_{1x.w'} - \epsilon_w\chi_{x.w'})/U^{XU}_{xw'} & \\ \omega_{xw} & \geq & (\kappa_{1x.w'} - \epsilon_w(\kappa_{0x.w'} + \kappa_{1x.w'}))/U^{XU}_{xw'} & \end{array}$$

Analogously, starting from $\eta^\star_{xw'} - \eta^\star_{xw} \geq \epsilon_w$, we obtain $\omega_{xw} \leq (\kappa_{1x.w'} + \epsilon_w(\kappa_{0x.w'} + \kappa_{1x.w'}))/L^{XU}_{xw'}$. Notice that for the special case ϵ_w and $U^{XU}_{xw'} = 1$, we obtain the corresponding lower bound $\omega_{xw} \geq \kappa_{1x.w'}$ that relates ω and κ across different values of W.

The result corresponding to the upper bound $\eta_{xw} \leq 1-\zeta_{0x.w'}$ can be obtained as follows:

$$\begin{array}{rcll} \eta^\star_{xw'} - \eta^\star_{xw} & \geq & -\epsilon_w & \\ 1+\eta^\star_{xw'} - 1 - \eta^\star_{xw} & \geq & -\epsilon_w & \\ (1-\eta^\star_{xw}) - (1-\eta^\star_{xw'}) & \geq & -\epsilon_w & \\ (1-\eta^\star_{xw})\delta^\star_{x.w'} - (1-\eta^\star_{xw'})\delta^\star_{x.w'} & \geq & -\epsilon_w\delta^\star_{x.w'} & \\ (1-\eta^\star_{xw})U^{XU}_{xw'} - (1-\eta^\star_{xw'})\delta^\star_{x.w'} & \geq & -\epsilon_w\delta^\star_{x.w'} & \text{(Marginalize over } P(U)) \\ (1-\omega_{xw})U^{XU}_{xw'} - \kappa_{0x.w'} & \geq & -\epsilon_w\chi_{x.w'} & \\ \omega_{xw} & \leq & 1-(\kappa_{0x.w'} - \epsilon_w(\kappa_{0x.w'} + \kappa_{1x.w'}))/U^{XU}_{xw'} & \end{array}$$

with the corresponding lower bound (non-trivial for $L^{XU}_{xw'} > 0$) given by $\omega^\star_{xw} \geq 1-(\kappa_{0x.w'} + \epsilon_w(\kappa_{0x.w'} + \kappa_{1x.w'}))/L^{XU}_{xw'}$.

The final block of relationships can be derived as follows:

$$\begin{array}{rcll} \eta^\star_{xw} - \eta^\star_{xw'} & \leq & \epsilon_w & \\ \eta^\star_{xw}\delta^\star_{x'.w} - \eta^\star_{xw'}\delta^\star_{x'.w} & \leq & \epsilon_w\delta^\star_{x'.w} & \\ \eta^\star_{xw}(1-(1-\delta^\star_{x'.w})) - \eta^\star_{xw'}\delta^\star_{x'.w} & \leq & \epsilon_w\delta^\star_{x'.w} & \text{(Use } -U^{XU}_{x'w} \leq -\delta^\star_{x'.w}) \\ \eta^\star_{xw} - \eta^\star_{xw}(1-\delta^\star_{x'.w}) - \eta^\star_{xw'}U^{XU}_{x'w} & \leq & \epsilon_w\delta^\star_{x'.w} & \text{(Marginalize over } P(U)) \\ \omega_{xw} - \kappa_{1x.w} - \omega_{xw'}U^{XU}_{x'w} & \leq & \epsilon_w\chi_{x'.w} & \\ \omega_{xw} - \omega_{xw'}U^{XU}_{x'w} & \leq & \kappa_{1x.w} + \epsilon_w(\kappa_{0x'.w} + \kappa_{1x'.w}) & \end{array}$$

with the lower bound $\omega_{xw} - \omega_{xw'}L^{XU}_{x'w} \geq \kappa_{1x.w} - \epsilon_w(\kappa_{0x'.w} + \kappa_{1x'.w})$ derived analogously. Moreover,

$$\begin{array}{rcl} \eta^\star_{xw'} - \eta^\star_{xw} & \leq & \epsilon_w \\ (1-\eta^\star_{xw})\delta^\star_{x'.w} - (1-\eta^\star_{xw'})\delta^\star_{x'.w} & \leq & \epsilon_w\delta^\star_{x'.w} \\ (1-\eta^\star_{xw})(1-(1-\delta^\star_{x'.w})) - (1-\eta^\star_{xw'})U^{XU}_{x'w} & \leq & \epsilon_w\delta^\star_{x'.w} \\ 1-\omega_{xw} - \kappa_{0x.w} - (1-\omega_{xw'})U^{XU}_{x'w} & \leq & \epsilon_w\chi_{x'.w} \\ \omega_{xw} - \omega_{xw'}U^{XU}_{x'w} & \geq & 1-\kappa_{0x.w} - U^{XU}_{x'w} - \epsilon_w(\kappa_{0x'.w} + \kappa_{1x'.w}) \end{array}$$

and the corresponding $\omega_{xw} - \omega_{xw'}L^{XU}_{x'w} \leq 1-\kappa_{0x.w} - L^{XU}_{x'w} + \epsilon_w(\kappa_{0x'.w} + \kappa_{1x'.w})$. The last two relationships follow immediately from the definition of ϵ_w. ■

Our constraints found so far collapse to some of the constraints found in the standard IV models (Balke and Pearl, 1997; Dawid, 2003) given $\epsilon_w = 0$, $\underline{\beta} = \overline{\beta} = 1$. Namely,

$$\begin{array}{rcl} \eta_{xw} & \leq & 1-\zeta_{0x.w} \\ \eta_{xw} & \leq & 1-\zeta_{0x.w'} \\ \eta_{xw} & \geq & \zeta_{1x.w} \\ \eta_{xw} & \geq & \zeta_{1x.w'} \end{array}$$

However, none of the constraints so far found counterparts in the following:

$$\begin{array}{rcl} \eta_{xw} & \leq & \zeta_{0x.w} + \zeta_{1x.w} + \zeta_{1x.w'} + \zeta_{1x'.w'} \\ \eta_{xw} & \leq & \zeta_{0x.w'} + \zeta_{1x.w'} + \zeta_{1x.w} + \zeta_{1x'.w} \\ \eta_{xw} & \geq & \zeta_{1x.w} + \zeta_{1x'.w} - \zeta_{0x.w'} - \zeta_{1x'.w'} \\ \eta_{xw} & \geq & \zeta_{1x.w'} + \zeta_{1x'.w'} - \zeta_{0x.w} - \zeta_{1x'.w} \end{array}$$

These constraints have the distinctive property of being functions of both $P(Y=x, X=x \mid W=w)$ and $P(Y=x, X=x \mid W=w')$, simultaneously. So far, we have only used the basic identities and constraints, without attempting at deriving constraints that are not a direct application of such identities. In the framework of (Dawid, 2003; Ramsahai, 2012), it is clear that general linear combinations of functions of $\{\delta^\star_{x.w}\eta^\star_{1x.w}, \delta^\star_{x.w}, \eta^\star_{1x.w}\}$ can generate constraints on observable quantities $\zeta_{yx.w}$ and causal quantities of interest, η_{xw}. We need to encompass these possibilities in such a way that we get a framework for generating symbolic constraints as a function of $\{\epsilon_w, \epsilon_y, \epsilon_x, \underline{\beta}, \overline{\beta}\}$.

One of the difficulties on exploiting a black-box polytope package for that is due to the structure of the process, which exploits the constraints in Section 4 by first finding the extreme points of the feasible region of $\{\delta^\star_w\}$, $\{\eta^\star_{xw}\}$. If we use the constraints

$$|\eta^\star_{x1} - \eta^\star_{x0'}| \leq \epsilon_w$$
$$0 \leq \eta^\star_{xw} \leq 1$$

then assuming $0 < \epsilon_w < 1$, we always obtain the following six extreme points,

$$(0,0)$$
$$(0,\epsilon_w)$$
$$(\epsilon_w,0)$$
$$(1-\epsilon_w,1)$$
$$(1,1-\epsilon_w)$$
$$(1,1)$$

In general, however, once we introduce constraints $L^{YU}_{xw} \leq \eta^\star_{xw} \leq U^{XU}_{xw}$, the number of extreme points will vary. Moreover, when multiplied with the extreme points of the space $\delta^\star_1 \times \delta^\star_0$, the resulting extreme points of $\zeta^\star_{yx.w}$ might be included or excluded of the polytope depending on the relationship among $\{\epsilon_w, \epsilon_x, \epsilon_y\}$ and the observable $P(Y, X \mid W)$. Numerically, this is not a problem (barring numerical instabilities, which do occur with a nontrivial frequency). Algebraically, this makes the problem considerably complicated[29]. Instead, in what follows we will define a simpler framework that will not give tight constraints, but will shed light on the relationship between constraints, observable probabilities and the ϵ parameters. This will also be useful to scale up the full Witness Protection Program, as discussed in the main paper.

A.2 Methodology for Cross-W Constraints

Consider the standard IV model again, i.e., where W is exogenous with no direct effect on Y. So far, we have not replicated anything such as e.g. $\eta_1 \leq \zeta_{00.0} + \zeta_{11.0} + \zeta_{10.1} + \zeta_{11.1}$. We call this a "cross-W" constraint, as it relates observables under different values of $W \in \{0,1\}$. These are important when considering weakening the effect $W \to Y$. The recipe for deriving them will be as follows. Consider the template

$$\delta^\star_0 f_1(\eta^\star_0, \eta^\star_1) + \delta^\star_1 f_2(\eta^\star_0, \eta^\star_1) + f_3(\eta^\star_0, \eta^\star_1) \geq 0 \tag{36}$$

such that $f_i(\cdot,\cdot)$ are linear. Linearity is imposed so that this function will correspond to a linear function of $\{\zeta^\star, \eta^\star, \delta^\star\}$, of which expectations will give observed probabilities or interventional probabilities.

We will require that evaluating this expression at each of the four extreme points of the joint space $(\delta^\star_0, \delta^\star_1) \in \{0,1\}^2$ will translate into one of the basic constraints $1 - \eta^\star_i \geq 0$ or $\eta^\star_i \geq 0$, $i \in \{0,1\}$. This implies any combination of $\{\delta^\star_0, \delta^\star_1, \eta^\star_0, \eta^\star_1\}$ will satisfy (36) (more on that later).

29. As a counterpart, imagine we defined a polytope through the matrix inequality $A\mathbf{x} \leq \mathbf{b}$. If we want to obtain its extreme point representation as an algebraic function of the entries of matrix A and vector $\mathbf{b}$, this will be a complicated problem since we cannot assume we know the magnitudes and signs of the entries.

Given a choice of basic constraint (say, $\eta^\star_1 \geq 0$), and setting $\delta^\star_0 = \delta^\star_1 = 0$, this immediately identifies $f_3(\cdot,\cdot)$. We assign the constraint corresponding to $\delta^\star_0 = \delta^\star_1 = 1$ with the "complementary constraint" for η_1 (in this case, $\eta^\star_1 \leq 1$). This leaves two choices for assigning the remaining constraints.

Why do we associate the $\delta^\star_0 = \delta^\star_1 = 1$ case with the complementary constraint? Let us parameterize each function as $f_i(\eta^\star_0, \eta^\star_1) \equiv a_i\eta^\star_0 + b_i\eta^\star_1 + c_i$. Let $a_3 = q$, where either $q = 1$ (case $\eta^\star_0 \geq 0$) or $q = -1$ (case $1 - \eta^\star_0 \geq 0$). Without loss of generality, assume case $(\delta^\star_0 = 1, \delta^\star_1 = 0)$ is associated with the complementary constraint where the coefficient of $\eta^\star_0$ should be $-q$. For the other two cases, the coefficient of $\eta^\star_0$ should be 0 by construction. We get the system

$$\begin{aligned} a_3 &= q \\ a_1 + a_3 &= -q \\ a_2 + a_3 &= 0 \\ a_1 + a_2 + a_3 &= 0 \end{aligned}$$

This system has no solution. Assume instead $\delta^\star_0 = \delta^\star_1 = 1$ is associated with the complementary constraint where the coefficient of $\eta^\star_0$ should be $-q$. The system now is:

$$\begin{aligned} a_3 &= q \\ a_1 + a_3 &= 0 \\ a_2 + a_3 &= 0 \\ a_1 + a_2 + a_3 &= -q \end{aligned}$$

This system always have the solution $a_1 = a_2 = -q$. We do have freedom with b_1, b_2, b_3, which means we can choose to allocate the remaining two cases in two different ways.

Lemma 7 *Consider the constraints derived by the above procedure. Then any choice of* $(\delta^\star_0, \delta^\star_1, \eta^\star_0, \eta^\star_1) \in [0,1]^4$ *will satisfy these constraints.*

Proof Without loss of generality, let $f_3(\eta^\star_0, \eta^\star_1) = q\eta^\star_0 + (1-q)/2$, $q \in \{-1, 1\}$. That is, $a_3 = q, b_3 = 0, c_3 = (1-q)/2$. This implies $a_1 = a_2 = -q$ (as above). Associating $(\delta^\star_0 = 1, \delta^\star_1 = 0)$ with $\eta^\star_1 \geq 0$ gives $\{b_1 = 1, c_1 = (q-1)/2\}$ and consequently associating $(\delta^\star_0 = 0, \delta^\star_0 = 1)$ with $1 - \eta^\star_1 \geq 0$ implies $\{b_2 = -1, c_2 = (1+q)/2\}$. Plugging this into the expression $\delta^\star_0 f_1(\eta^\star_0, \eta^\star_1) + \delta^\star_1 f_2(\eta^\star_0, \eta^\star_1) + f_3(\eta^\star_0, \eta^\star_1)$ we get

$$\begin{aligned} &= \delta^\star_0(-q\eta^\star_0 + \eta^\star_1 + (q-1)/2) + \delta^\star_1(-q\eta^\star_0 - \eta^\star_1 + (1+q)/2) + q\eta^\star_0 + (1-q)/2 \\ &= \eta^\star_0(q - (\delta^\star_0 + \delta^\star_1)q) + \eta^\star_1(\delta^\star_0 - \delta^\star_1) + \delta^\star_0(q-1)/2 + \delta^\star_1(1+q)/2 + (1-q)/2 \\ &= \eta^\star_0(q - (\delta^\star_0 + \delta^\star_1)q) + \eta^\star_1(\delta^\star_0 - \delta^\star_1) + (-q + (\delta^\star_0 + \delta^\star_1)q)/2 + (\delta^\star_1 - \delta^\star_0 + 1)/2 \\ \\ &= q((\delta^\star_1 + \delta^\star_0) - 1)(1 - 2\eta^\star_0)/2 + ((\delta^\star_1 - \delta^\star_0)(1 - 2\eta^\star_1) + 1)/2 \\ &= (\delta^\star_1 + \delta^\star_0 - 1)s/2 + (\delta^\star_1 - \delta^\star_0)t/2 + 1/2 \end{aligned}$$

where $s = q(1 - 2\eta^\star_0) \in [-1, 1]$ and $t = (1 - 2\eta^\star_1) \in [-1, 1]$. Then evaluating at the four extreme points $s, t \in \{-1, +1\}$ we get $\delta_0, \delta_1, 1-\delta_0, 1-\delta_1$, all of which are non-negative. ■

The procedure derives 8 bounds (4 cases that we get by associating f_3 with either $\eta_x \geq 0$ or $1 - \eta_x \geq 0$. For each of these cases, 2 subcases what we get by assigning $(\delta^\star_0 = 1, \delta^\star_1 = 0)$

with either $\eta_{x'} \geq 0$ or $1 - \eta_{x'} \geq 0$). Now, for an illustration of one case:

Deriving a constraint for the standard IV model, example: $f_3(\eta_0^\star, \eta_1^\star) \equiv \eta_0^\star \geq 0$

Associate $\eta_1^\star \geq 0$ with assignment $(\delta_0^\star = 1, \delta_1^\star = 0)$ (implying we associate $\eta_1^\star \leq 1$ with assignment $(\delta_0^\star = 0, \delta_1^\star = 1)$ and $\eta_0^\star \leq 1$ with $(\delta_0^\star = 1, \delta_1^\star = 1)$). This uniquely gives $f_1(\eta_0^\star, \eta_1^\star) = \eta_1^\star - \eta_0^\star$, $f_2(\eta_0^\star, \eta_1^\star) = -\eta_1^\star - \eta_0^\star + 1$. The resulting expression is

$$\delta_0^\star(\eta_1^\star - \eta_0^\star) + \delta_1^\star(-\eta_1^\star - \eta_0^\star + 1) + \eta_0^\star \geq 0$$

from which we can verify that the assignment $(\delta_0^\star = 1, \delta_1^\star = 1)$ gives $\eta_0^\star \leq 1$. Now, we need to take the expectation of the above with respect to U to obtain observables ζ and causal distributions η. However, first we need some rearrangement so that we match $\eta_0^\star$ with corresponding $(1 - \delta_w^\star)$ and so on.

$$\begin{array}{rcl} \eta_1^\star(\delta_0^\star - \delta_1^\star) + \eta_0^\star(1 - \delta_0^\star - \delta_1^\star) + \delta_1^\star & \geq & 0 \\ \eta_1^\star(\delta_0^\star - \delta_1^\star) + \eta_0^\star((1 - \delta_0^\star) + (1 - \delta_1^\star) - 1) + \delta_1^\star & \geq & 0 \\ \zeta_{11.0}^\star - \zeta_{11.1}^\star + \zeta_{10.0}^\star + \zeta_{10.1}^\star - \eta_0^\star + \zeta_{01.1}^\star + \zeta_{11.1}^\star & \geq & 0 \end{array}$$

Taking expectations and rearranging it, we have

$$\eta_0 \leq \zeta_{11.0} + \zeta_{10.0} + \zeta_{10.1} + \zeta_{01.1}$$

rediscovering one of the IV bounds for η_0. Choosing to associate $\eta_1^\star \geq 0$ with assignment $(\delta_0^\star = 0, \delta_1^\star = 1)$ will give instead

$$\eta_0 \leq \zeta_{11.1} + \zeta_{10.1} + \zeta_{10.0} + \zeta_{01.0}$$

Basically the effect of one of the two choices within any case is to switch $\zeta_{yx.w}$ with $\zeta_{yx.w'}$. ■

A.3 Deriving Cross-W Constraints

What is left is a generalization of that under the condition $|\eta_{xw} - \eta_{xw'}| \leq \epsilon_w$, $w \neq w'$, instead of $\eta_{xw} = \eta_{xw'}$. In this situation, we exploit the constraint $\underline{L} \leq \eta_{xw}^\star \leq \overline{U}$ instead of $0 \leq \eta_{xw}^\star \leq 1$ or $L_{xw}^{YU} \leq \eta_{xw}^\star \leq U_{xw}^{YU}$, where $\underline{L} \equiv \min\{L_{xw}^{YU}\}, \overline{U} \equiv \max\{U_{xw}^{YU}\}$. Using $L_{xw}^{YU} \leq \eta_{xw}^\star \leq U_{xw}^{YU}$ complicates things considerably. Also, we will not derive here the analogue proof of Lemma 1 for the case where $(\eta_0^\star, \eta_1^\star) \in [\underline{L}, \overline{U}]^2$, as it is analogous but with a more complicated notation.

Proof of Theorem 4 We demonstrate this through two special cases.
General Model, Special Case 1: $f_3(\eta_{0w}^\star, \eta_{1w}^\star) \equiv \eta_{xw}^\star - \underline{L} \geq 0$

There are two modifications. First, we perform the same associations as before, but with respect to $\underline{L} \leq \eta_{xw}^\star \leq \overline{U}$ instead of $0 \leq \eta_x^\star \leq 1$. Second, before we take expectations, we swap some of the $\eta_{xw}^\star$ with $\eta_{xw'}^\star$ up to some error ϵ_w.

Following the same sequence as in the example for the IV model, we get the resulting expression (where $x' \equiv \{0,1\} \backslash x$):

$$\delta_w^\star(\eta_{x'w}^\star - \eta_{xw}^\star) + \delta_{w'}^\star(-\eta_{x'w}^\star - \eta_{xw}^\star + \overline{U} + \underline{L}) + \eta_{xw}^\star - \underline{L} \geq 0$$

from which we can verify that the assignment $(\delta_w^\star = 1, \delta_{w'}^\star = 1)$ gives $\overline{U} - \eta_{xw}^\star \geq 0$. Now, we need to take the expectation of the above with respect to U to obtain "observables" κ and causal effects ω. However, the difficulty now is that terms $\eta_{xw}^\star \delta_{w'}^\star$ and $\eta_{xw'}^\star \delta_w^\star$ have no observable counterpart under expectation. We get around this transforming $\eta_{xw'}^\star \delta_w^\star$ into $\eta_{xw}^\star \delta_w^\star$ (and $\eta_{xw}^\star \delta_{w'}^\star$ into $\eta_{xw'}^\star \delta_{w'}^\star$) by adding the corresponding correction $-\eta_{xw}^\star \leq -\eta_{xw'}^\star + \epsilon_w$:

$$\begin{array}{rcl} \delta_w^\star(\eta_{x'w}^\star - \eta_{xw}^\star) + \delta_{w'}^\star(-\eta_{x'w}^\star - \eta_{xw}^\star + \overline{U} + \underline{L}) + \eta_{xw}^\star - \underline{L} & \geq & 0 \\ \delta_w^\star(\eta_{x'w}^\star - \eta_{xw}^\star) + \delta_{w'}^\star(-\eta_{x'w'}^\star + \epsilon_w - \eta_{xw'}^\star + \epsilon_w + \overline{U} + \underline{L}) + \eta_{xw}^\star - \underline{L} & \geq & 0 \\ \eta_{x'w}^\star \delta_w^\star + \eta_{xw}^\star(1 - \delta_w^\star) - \eta_{x'w'} \delta_{w'}^\star - \eta_{xw'} \delta_{w'}^\star + \delta_{w'}^\star(\overline{U} + \underline{L} + 2\epsilon_w) - \underline{L} & \geq & 0 \end{array}$$

Now, the case for $x = 1$ gives

$$\begin{array}{rcl} \eta_{0w}^\star \delta_w^\star + \eta_{1w}^\star(1 - \delta_w^\star) - \eta_{0w'} \delta_{w'}^\star - \eta_{1w'} \delta_{w'}^\star + \ldots & \geq & 0 \\ \eta_{0w}^\star(1 - (1 - \delta_w^\star)) + \eta_{1w}^\star(1 - \delta_w^\star) - \eta_{0w'}^\star(1 - (1 - \delta_{w'}^\star)) - \eta_{1w'}^\star \delta_{w'}^\star + \ldots & \geq & 0 \end{array}$$

Taking the expectations:

$$\omega_{0w} - \kappa_{10.w} + \omega_{1w} - \kappa_{11.w} - \omega_{0w'} + \kappa_{10.w'} - \kappa_{11.w'} + \chi_{w'}(\overline{U} + \underline{L} + 2\epsilon_w) - \underline{L} \geq 0 \quad (37)$$

Notice that for $\underline{\beta} = \overline{\beta} = 1$, $\underline{L} = 0$, $\overline{U} = 1$, $\epsilon_w = 0$, this implies $\eta_{xw} = \eta_{xw'}$ and this collapses to

$$\eta_{0w} - \zeta_{10.w} + \eta_{1w} - \zeta_{11.w} - \eta_{0w'} + \zeta_{10.w'} - \zeta_{11.w'} + \delta_{w'} \geq 0$$

$$\eta_{1w} \geq \zeta_{10.w} + \zeta_{11.w} - \zeta_{10.w'} - \zeta_{01.w'}$$

which is one of the lower bounds one obtains under the standard IV model.

The case for $x = 0$ is analogous and gives

$$\omega_{0w'} \leq \kappa_{11.w} + \kappa_{10.w} + \kappa_{10.w'} - \kappa_{11.w'} + \chi_{w'}(\overline{U} + \underline{L} + 2\epsilon_w) - \underline{L} \quad (38)$$

The next subcase is when we exchange the assignment of $(\delta_w^\star, \delta_{w'}^\star)$ to other constraints. We obtain the following inequality:

$$\delta_{w'}^\star(\eta_{x'w}^\star - \eta_{xw}^\star) + \delta_w^\star(-\eta_{x'w}^\star - \eta_{xw}^\star + \overline{U} + \underline{L}) + \eta_{xw}^\star - \underline{L} \geq 0$$

which from an analogous sequence of steps leads to

$$\begin{array}{rcl} \delta_{w'}^\star(\eta_{x'w}^\star - \eta_{xw}^\star) + \delta_w^\star(-\eta_{x'w}^\star - \eta_{xw}^\star + \overline{U} + \underline{L}) + \eta_{xw}^\star - \underline{L} & \geq & 0 \\ \delta_{w'}^\star(\eta_{x'w'}^\star + \epsilon_w - \eta_{xw'}^\star + \epsilon_w) + \delta_w^\star(-\eta_{x'w}^\star - \eta_{xw}^\star + \overline{U} + \underline{L}) + \eta_{xw}^\star - \underline{L} & \geq & 0 \\ \eta_{x'w'}^\star \delta_{w'}^\star - \eta_{xw'}^\star \delta_{w'}^\star + 2\delta_{w'}^\star \epsilon_w - \eta_{x'w}^\star \delta_w^\star + \eta_{xw}^\star(1 - \delta_w^\star) + \delta_w^\star(\overline{U} + \underline{L}) - \underline{L} & \geq & 0 \end{array}$$

For $x = 1$,

$$\begin{array}{rcl} \eta_{0w'}^\star \delta_{w'}^\star - \eta_{1w'}^\star \delta_{w'}^\star + \eta_{0w}^\star \delta_w^\star + \eta_{1w}^\star(1 - \delta_w^\star) + \ldots & \geq & 0 \\ \eta_{0w'}^\star(1 - (1 - \delta_{w'}^\star)) - \eta_{1w'}^\star \delta_{w'}^\star - \eta_{0w}^\star(1 - (1 - \delta_w^\star)) + \eta_{1w}^\star(1 - \delta_w^\star) + \ldots & \geq & 0 \end{array}$$

Taking expectations,

$$\omega_{0w'} - \kappa_{10.w'} - \kappa_{11.w'} - \omega_{0w} + \kappa_{10.w} + \omega_{1w} - \kappa_{11.w} + 2\chi_{w'}\epsilon_w + \chi_w(\overline{U} + \underline{L}) - \underline{L} \geq 0 \quad (39)$$

For $x = 0$,

$$\begin{aligned}
\eta^\star_{1w'}\delta^\star_{w'} - \eta^\star_{0w'}\delta^\star_{w'} + \eta^\star_{1w}\delta^\star_w + \eta^\star_{0w}(1-\delta^\star_w) + \ldots &\geq 0\\
\eta^\star_{1w'}\delta^\star_{w'} - \eta^\star_{0w'}(1-(1-\delta^\star_{w'})) - \eta^\star_{1w}\delta^\star_w + \eta^\star_{0w}(1-\delta^\star_w) + \ldots &\geq 0\\
\kappa_{11.w'} - \omega_{0w'} + \kappa_{10.w'} - \kappa_{11.w} + \kappa_{10.w} + 2\chi_{w'}\epsilon_w + \chi_w(\overline{U}+\underline{L}) - \underline{L} &\geq 0\\
\omega_{0w'} \leq \kappa_{11.w'} + \kappa_{10.w'} - \kappa_{11.w} + \kappa_{10.w} + 2\chi_{w'}\epsilon_w + \chi_w(\overline{U}+\underline{L}) - \underline{L} &\quad (40)
\end{aligned}$$

General Model, Special Case 2: $f_3(\eta^\star_{0w}, \eta^\star_{1w}) \equiv \overline{U} - \eta^\star_{xw} \geq 0$

Associate $\eta^\star_{x'w} \geq \underline{L}$ with assignment $(\delta^\star_w = 1, \delta^\star_{w'} = 0)$ (implying we associate $\eta^\star_{x'w} \leq \overline{U}$ with assignment $(\delta^\star_w = 0, \delta^\star_{w'} = 1)$ and $\eta^\star_{xw} \geq \underline{L}$ with $(\delta^\star_w = 1, \delta^\star_{w'} = 1)$). The resulting expression is

$$\delta^\star_w(\eta^\star_{x'w} + \eta^\star_{xw} - \overline{U} - \underline{L}) + \delta^\star_{w'}(-\eta^\star_{x'w} + \eta^\star_{xw}) + \overline{U} - \eta^\star_{xw} \geq 0$$

Following the same line of reasoning as before, we get this for $x = 1$:

$$\omega_{0w} - \omega_{0w'} - \omega_{1w} - \kappa_{10.w} + \kappa_{11.w} + \kappa_{10.w'} + \kappa_{11.w'} - \chi_w(\overline{U}+\underline{L}) + 2\epsilon_w\chi_{w'} + \overline{U} \geq 0 \quad (41)$$

We get this for $x = 0$:

$$\omega_{0w'} \geq -\kappa_{11.w} + \kappa_{10.w} + \kappa_{11.w'} + \kappa_{10.w'} + \chi_w(\overline{U}+\underline{L}) - 2\epsilon_w\chi_{w'} - \overline{U} \quad (42)$$

With the complementary assignment, we start with the relationship

$$\delta^\star_{w'}(\eta^\star_{x'w} + \eta^\star_{xw} - \overline{U} - \underline{L}) + \delta^\star_w(-\eta^\star_{x'w} + \eta^\star_{xw}) + \overline{U} - \eta^\star_{xw} \geq 0$$

For $x = 1$,

$$\omega_{0w'} - \omega_{0w} - \omega_{1w} - \kappa_{10.w'} + \kappa_{11.w'} + \kappa_{10.w} + \kappa_{11.w} + \chi_{w'}(2\epsilon_w - \overline{U} - \underline{L}) + \overline{U} \geq 0 \quad (43)$$

For $x = 0$,

$$\omega_{0w'} \geq -\kappa_{11.w'} + \kappa_{10.w'} + \kappa_{11.w} + \kappa_{10.w} - \chi_{w'}(2\epsilon_w - \overline{U} - \underline{L}) - \overline{U} \quad (44)$$

Notice that the bounds obtained are asymmetric in x, i.e., we derive different bounds for ω_{0w} and ω_{1w}. Symmetry is readily obtained by the same derivation where $\delta^\star_w$ is interpreted as $P(X = 0 \mid W = w, U)$ and x is swapped with x'. ■

A.4 Linear Case

Our final proof refers to results introduced in Section 6.

Proof of Theorem 5 Variable s_{xx} appears only in Equation (24) and the inequalities $0 \leq s_{xx} \leq 1$. The intersection of these relationships is satisfiable if and only if $0 \leq a^2 + 2as_{wx} \leq 1$ is satisfiable. Moreover, s_{wx} appears only in Equation (22). Solving this equation for s_{wx} and plugging it in $0 \leq a^2 + 2as_{wx} \leq 1$, we obtain $0 \leq -a^2 + 2a\rho_{wx} \leq 1$. The quadratic

expression for a achieves a unique maximum at $a^\star = \rho_{wx}$, implying $-a^{\star 2} + 2a^\star\rho_{wx} = \rho^2_{wx} \leq 1$. We can then drop the inequality $-a^2 + 2a\rho_{wx} \leq 1$ as this is always satisfied. The resulting interval is $a^2 - 2a\rho_{wx} \leq 0$, and the set of values of a satisfying it is either the interval $[2\rho_{wx}, 0]$ or $[0, 2\rho_{wx}]$ depending on the sign of ρ_{wx}. This can be written as

$$\min(0, 2\rho_{wx}) \leq a \leq \max(0, 2\rho_{wx}) \quad (45)$$

The intersection of Equation (22) and $-\epsilon_{wx} \leq s_{wx} \leq \epsilon_{wx}$ is satisfiable only if $\rho_{wx} - \epsilon_{wx} \leq a \leq \rho_{wx} + \epsilon_{wx}$. Combining this interval with (45), we obtain the inequality

$$\max(\min(0, 2\rho_{wx}), \rho_{wx} - \epsilon_{wx}) \leq a \leq \min(\max(0, 2\rho_{wx}), \rho_{wx} + \epsilon_{wx}) \quad (46)$$

which $\mathcal{L}_a$ and $\mathcal{U}_a$ being defined as the lower and upper bounds, respectively, in the interval above.

Since a now only appears in (46) and Equation (25), and assuming $s_{wy} \geq 0$, the intersection of the two equations is satisfiable if and only if

$$\rho_{xy} - \mathcal{U}_a s_{wy} \leq b + c\rho_{wx} + s_{xy} \leq \rho_{xy} - \mathcal{L}_a s_{wy} \quad (47)$$

Equation (31) follows from s_{xy} not appearing anywhere else but in the relationship $-\epsilon_{xy} \leq s_{xy} \leq \epsilon_{xy}$, and also considering the case $s_{wy} < 0$.

Equation (26) and the relationship $0 \leq s_{yy} \leq 1$ is satisfiable if and only if

$$0 \leq b^2 + 2bc\rho_{wx} + c^2 + 2[b(as_{wy} + s_{xy}) + cs_{wy}] \leq 1 \quad (48)$$

is satisfiable. From Equation (25) we have $as_{wy} + s_{xy} = \rho_{xy} - b - c\rho_{wx}$ and from Equation (23) we have $s_{wy} = \rho_{wy} - b\rho_{wx} - c$. Making these substitutions into (48), we get

$$0 \leq -b^2 - 2bc\rho_{wx} - c^2 + 2(b\rho_{xy} + c\rho_{wy}) \leq 1.$$

The quadratic function in (b, c) has a unique maximum. Assuming for now c is unconstrained, taking the derivatives of $-b^2 - 2bc\rho_{wx} - c^2 + 2(b\rho_{xy} + c\rho_{wy})$ with respect to b and c, and setting them to zero, we obtain the stationary point

$$b^\star = \frac{\rho_{xy} - \rho_{wx}\rho_{wy}}{1 - \rho^2_{wx}}, \quad c^\star = \frac{\rho_{wy} - \rho_{wx}\rho_{xy}}{1 - \rho^2_{wx}}, \quad (49)$$

and by assumption it follows that $c^\star = 0$. Plugging $c^\star$ in $-b^2 - 2bc\rho_{wx} - c^2 + 2(b\rho_{xy} + c\rho_{wy})$, we get $b(2\rho_{xy} - b) \leq \rho^2_{xy} \leq 1$. So, it is sufficient to satisfy

$$b^2 + 2bc\rho_{wx} + c^2 - 2(b\rho_{xy} + c\rho_{wy}) \leq 0. \quad (50)$$

Editor: Edo Airoldi

Abstract

We present methods based on Metropolis-coupled Markov chain Monte Carlo (MC^3) and annealed importance sampling (AIS) for estimating the posterior distribution of Bayesian networks. The methods draw samples from an appropriate distribution of partial orders on the nodes, continued by sampling directed acyclic graphs (DAGs) conditionally on the sampled partial orders. We show that the computations needed for the sampling algorithms are feasible as long as the encountered partial orders have relatively few down-sets. While the algorithms assume suitable modularity properties of the priors, arbitrary priors can be handled by dividing the importance weight of each sampled DAG by the number of topological sorts it has—we give a practical dynamic programming algorithm to compute these numbers. Our empirical results demonstrate that the presented partial-order-based samplers are superior to previous Markov chain Monte Carlo methods, which sample DAGs either directly or via linear orders on the nodes. The results also suggest that the convergence rate of the estimators based on AIS are competitive to those of MC^3. Thus AIS is the preferred method, as it enables easier large-scale parallelization and, in addition, supplies good probabilistic lower bound guarantees for the marginal likelihood of the model.

Keywords: annealed importance sampling, directed acyclic graph, fast zeta transform, linear extension, Markov chain Monte Carlo

∗. Preliminary versions of this work have appeared in the proceedings of AISTATS 2010, UAI 2011, and IJCAI 2013 (Parviainen and Koivisto, 2010; Niinimäki et al., 2011; Niinimäki and Koivisto, 2013b). All correspondence should be addressed to the first author.

1. Introduction

The Bayesian paradigm to structure learning in Bayesian networks is concerned with the posterior distribution of the underlying directed acyclic graph (DAG) given data on the variables associated with the nodes of the graph (Buntine, 1991; Cooper and Herskovits, 1992; Madigan and York, 1995). The paradigm is appealing as it offers an explicit way to incorporate prior knowledge as well as full characterization of posterior uncertainty about the quantities of interest, including proper treatment of any non-identifiability issues. However, a major drawback of the Bayesian paradigm is its large computational requirements. Indeed, because the number of DAGs grows very rapidly with the number of nodes, exact computation of the posterior distribution becomes impractical already when there are more than about a dozen of nodes.

There are two major approaches to handle the posterior distribution of DAGs without explicitly computing and representing the entire distribution. One is to summarize the posterior distribution by a relatively small number of summary statistics, of which perhaps the most extensively used is a *mode* of the distribution, that is, a maximum a posteriori DAG (Cooper and Herskovits, 1992). Other useful statistics are the marginal posterior probabilities of so-called *structural features*, such as individual arcs or larger subgraphs (Buntine, 1991; Cooper and Herskovits, 1992; Friedman and Koller, 2003). When the interest is in how well the chosen Bayesian model fits the data, say in comparison to some alternative model, then the key quantity is the *marginal likelihood* of the model—also known as the *integrated likelihood*, *evidence*, or the *normalizing constant*—which is simply the marginal probability (density) of the observed data. Provided that the model satisfies certain modularity conditions, all these statistics can be computed in a dynamic programming fashion, and thereby avoiding exhaustive traversing through individual DAGs. Specifically, assuming a very basic form of modularity one can find a mode over n-node DAGs in $O(2^n n^2)$ time (Koivisto and Sood, 2004; Ott et al., 2004; Singh and Moore, 2005; Silander and Myllymäki, 2006) and the arc posterior probabilities and the marginal likelihood in $O(3^n n)$ time (Tian and He, 2009). Assuming a more convoluted form of modularity, also the latter quantities can be computed in $O(2^n n^2)$ time (Koivisto and Sood, 2004; Koivisto, 2006). In practice, these algorithms scale up to about 25 nodes. For mode finding, there are also algorithms based on the A* search heuristic (Yuan and Malone, 2013) and integer linear programming (Bartlett and Cussens, 2013), which often can solve even larger problem instances.

The other approach is to approximate the posterior distribution by collecting a sample of DAGs, each of which assigned a weight reflecting how representative the DAG is of the posterior distribution. Having such a collection at hand, various quantities, including the aforementioned statistics, can be estimated by appropriate weighted averages. Principled implementations of the approach have used the Markov chain Monte Carlo (MCMC) methodology in various forms: Madigan and York (1995) simulated a Markov chain that moves in the space of DAGs by simple arc changes such that the chain's stationary distribution is the posterior distribution. Friedman and Koller (2003) obtained a significantly faster mixing chain by operating, not directly on DAGs, but in the much smaller and smoother space of node orderings, or *linear orders* on the nodes more formally. The sampler, called *order-MCMC* in the sequel, requires the prior to be of a particular form that favors DAGs that are compatible with many node orderings, thus introducing a "bias." Ellis and Wong

(2008) enhanced order-MCMC by presenting a sophisticated sampler based on tempering techniques, and a heuristic for removing the bias. Also other refinements to Madigan and York's sampler have been presented (Eaton and Murphy, 2007; Grzegorczyk and Husmeier, 2008; Corander et al., 2008), however with somewhat more limited advantages over order-MCMC. More recently, Battle et al. (2010) extended Madigan and York's sampler in yet another direction by applying annealed importance sampling (AIS) (Neal, 2001) to sample fully specified Bayesian networks (i.e., DAGs equipped with the associated conditional distributions).

While the current MCMC methods for structure learning seem to work well in many cases, they also leave the following central questions open:

1. *Smoother sampling spaces.* Can we take the idea of Friedman and Koller (2003) further: are there sampling spaces that yield still a better tradeoff between computation time and accuracy?

2. *Arbitrary structure priors.* Can we efficiently remove the bias due to sampling node orderings? Specifically, is it computationally feasible to estimate posterior expectations under an arbitrary structure prior, yet exploiting the smoother sampling space of node orderings? (The method of Ellis and Wong (2008) relies on heuristic arguments and becomes computationally infeasible when the data set is small.)

3. *Efficient parallel computation.* Can we efficiently and easily exploit parallel computation, that is, to run the algorithm in parallel on thousands of processors, preferably without frequent synchronization or communication between the parallel processes. (Existing MCMC methods are designed rather for a small number of very long runs, and thus do not enable large-scale parallelization.)

4. *Quality guarantees.* Can we measure how accurate the algorithm's output is? For instance, is it a lower bound, an upper bound, or an approximation to within some multiplicative or additive term? (Existing MCMC methods offer such guarantees only in the limit of running the algorithm infinitely many steps.)

In this article, we make a step toward answering these questions in the affirmative. Specifically, we advance the state of the art by presenting three new ideas, published in a preliminary form in three conference proceedings (Parviainen and Koivisto, 2010; Niinimäki et al., 2011; Niinimäki and Koivisto, 2013b), and their combination that has not been investigated prior to the present work. The next paragraphs give an overview of our contributions.

We address the first question by introducing a sampling space, in which each state is a partial order on the nodes. Compared to the space of node orderings (i.e., linear orders on the nodes), the resulting sampling space is smaller and the induced sampling distribution is smoother. We will also show that going from linear orders to partial orders does not increase the computational cost per sampled order, as long as the partial orders are sufficiently thin, that is, they have relatively few so-called downsets. These algorithmic results build on and extend our earlier work on finding an *optimal* DAG subject to a given partial order constraint (Parviainen and Koivisto, 2013).

To address the second question, we take a somewhat straightforward approach: per sampled partial order, we draw one or several DAGs independently from the corresponding conditional distribution, and assign each DAG a weight that compensates the difference of the structure prior of interest and the "proxy prior" we employ to make order-based sampling efficient. Specifically, we show that the number of linear extensions (or, topological sorts) of a given DAG—that we need for the weight—can be computed sufficiently fast in practice for moderate-size DAGs, even though the problem is #P-hard in general (Brightwell and Winkler, 1991).

Our third contribution applies both to the third and the fourth question. Motivated by the desire for accuracy guarantees, we seek a sampler such that we know exactly from which distribution the samples are drawn. Here, the annealed importance sampling (AIS) method of Neal (2001) provides an appealing solution. It enables drawing independent and identically distributed samples and computing the associated importance weights, so that the expected value of each weighted sample matches the quantity of interest. Due to the independence of the samples, already a small number of samples may suffice, not only for producing an accurate estimate, but also for finding a relatively tight, high-confidence lower bound on the true value (Gomes et al., 2007; Gogate et al., 2007; Gogate and Dechter, 2011). Furthermore, the independence of the samples renders the approach embarrassingly parallel, requiring interaction of the parallel computations only at the very end when the independent samples are collected in a Monte Carlo estimator. We note that Battle et al. (2010) adopted AIS for quite different reasons. Namely, due to the structure of their model, they had to sample fully specified Bayesian networks whose posterior distribution is expected to be severely multimodal, in which case AIS is a good alternative to the usual MCMC methods.

Finally, we evaluate the significance of the aforementioned advances empirically. As a benchmark we use Friedman and Koller's (2003) simple Markov chain on the space of node orderings, however, equipped with the Metropolis-coupling technique (Geyer, 1991) to enhance the chain's mixing properties. Our implementation of the *Metropolis-coupled MCMC* (MC^3) method for the space of node orderings also serves as a proxy of a related implementation[1] of Ellis and Wong (2008). Our experimental study aims to answer two main questions: First, does the squeezing of the space of linear orders into a space of partial orders yield a significantly faster mixing Markov chain when we already use the Metropolis coupling technique to help mixing? This question was left unanswered in our preliminary work (Niinimäki et al., 2011) that only considered a single simple Markov chain similar to that of Friedman and Koller (2003). Second, are the Monte Carlo estimators based on AIS competitive to the MC^3-based estimators when we sample partial orders instead of linear orders? This question was left unanswered in our preliminary work (Niinimäki and Koivisto, 2013b) that only considered sampling linear orders.

The remainder of this article is organized as follows. We begin in Section 2 with an introduction to some basic properties of graphs and partial orders. The section also contains some more advanced algorithmic results, which will serve as building blocks of our method for learning Bayesian networks. In Section 3, we review the Bayesian formulation of the structure learning problem in Bayesian networks, and also outline the approach of Friedman and Koller (2003) based on sampling node orderings. In Section 4, we extend the idea of

1. The software used in the work of Ellis and Wong (2008) is not publicly available (W. H. Wong, personal communication, January 29, 2013).

sampling node orderings to partial orders and formulate the two sampling methods, MC^3 and AIS, in that context. We dedicate Section 5 to the description of fast algorithms for computing several quantities needed by the samplers. Experimental results are reported in Section 6. We conclude and discuss directions for future research in Section 7.

2. Partial Orders and DAGs

This section introduces concepts, notation, and algorithms associated with graphs and partial orders. In later sections, we will apply them as building blocks in the context of structure learning in Bayesian networks. The content of the first subsection will be needed already in Section 3. The content of the latter subsections will be needed only in Section 5, and the reader may wish to skip them on the first read.

2.1 Antisymmetric Binary Relations

We use the standard concepts of graphs and partial orders. Our notation is however somewhat nonstandard, which warrants a special attention. Let N be a finite set, and let $R \subseteq N \times N$ be a binary relation on N. We shall denote an element (u, v) of R by uv for short. We say that R is

$$\begin{aligned} \textit{reflexive} &\quad \text{if } u \in N \text{ implies } uu \in R\,; \\ \textit{antisymmetric} &\quad \text{if } uv, vu \in R \text{ implies } u = v\,; \\ \textit{transitive} &\quad \text{if } uv, vw \in R \text{ implies } uw \in R\,; \\ \textit{total} &\quad \text{if } u, v \in N \text{ implies } uv \in R \text{ or } vu \in R\,. \end{aligned}$$

If R has the first three properties, it is called a *partial order*. If it has all the four properties, it is called a *total* or *linear order*. The set N is the *ground set* of the order and the pair (N, R) is called a linearly or partially ordered set.

We will also consider relations that are antisymmetric but that need not have any other of the above the properties. We say that R is

$$\begin{aligned} \textit{acyclic} &\quad \text{if there are no elements } u_1, \ldots, u_l \text{ such that} \\ &\quad u_1 = u_l \text{ and } u_{i-1}u_i \in R \text{ for each } i = 2, \ldots, l\,. \end{aligned}$$

Note that acyclicity implies irreflexivity, that is, that $uu \notin R$ for all $u \in N$. If R is acyclic, we call the pair (N, R) a *directed acyclic graph* (DAG), N its *node set*, and R its *arc set*.

When the set N is clear from the context—as it will often be in our applications—we identify the structure (N, R) with the relation R. We will typically use the letters P, L, and A for a partial order, linear order, and a DAG, respectively.

The following relationships among the three objects are central in later sections of this article. Let R and Q be relations on N. We say that Q is an *extension* of R if simply $R \subseteq Q$. If Q is a linear order, then we may also call it a *linear extension* of R. Note that in the literature, a linear extension of a DAG is sometimes called a topological sort of the DAG. Sometimes we will be interested in the *number of linear extensions* of R, which we denote by $\ell(R)$. Furthermore, we say that R and Q are *compatible* with each other if they have a common linear extension $L \supseteq R, Q$. While this relationship is symmetric, in our applications one of the R, Q will be a partial order and the other one a DAG. Also,

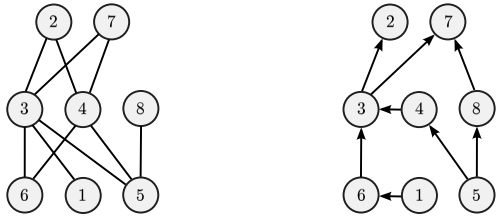

Figure 1: The Hasse diagram of a partial order on eight nodes (left) and a DAG compatible with the partial order (right).

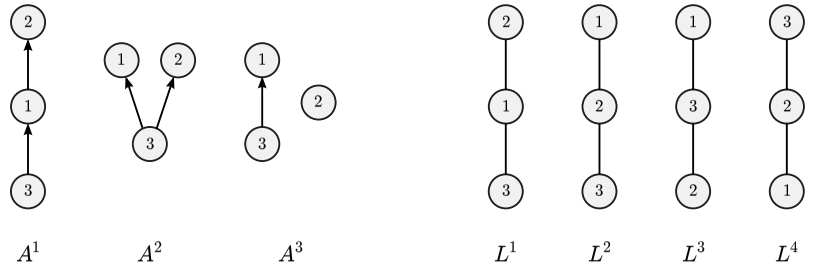

Figure 2: Three DAGs (left) and the Hasse diagrams of four linear orders (right), some of which are compatible with some of the DAGs. DAG A^1 has only one linear extension: L^1. DAG A^2 has two linear extensions: L^1 and L^2. DAG A^3 has three linear extensions: L^1, L^2 and L^3. None of the DAGs is compatible with L^4.

we say that Q is the *transitive closure* of R if Q is the minimal transitive relation that contains R. Finally, we say that R is the *transitive reduction* of Q if R is the minimal relation with the same transitive closure as Q. The transitive reduction of a partial order Q is sometimes called the *covering relation* and visualized graphically by means of the Hasse diagram. Figures 1 and 2 illustrate some of these concepts.

Some of the above described relationships can be characterized locally, in terms of the in-neighbors of each element of N. To this end we let R_v denote the set of elements that precede v in R, formally

$$R_v = \{u : uv \in R, u \neq v\}\,.$$

We will call the elements of R_v the *parents* of v and the set R_v the *parent set* of v. If R is a partial order we may call the parents also the *predecessors* of v. We observe that if Q is reflexive, then Q is an extension of R if and only if $R_v \subseteq Q_v$ for all $v \in N$.

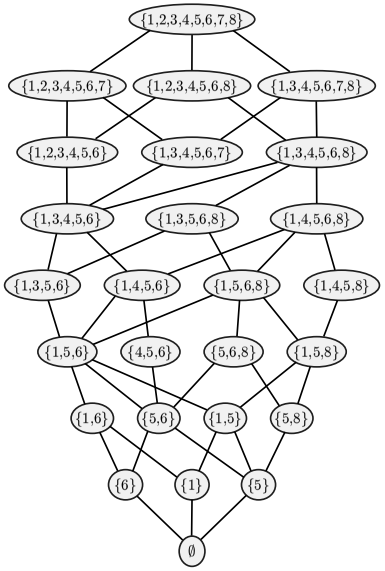

Figure 3: The covering graph of the downset lattice of the partial order shown in Figure 1.

2.2 Downsets and Counting Linear Extensions

Let P be a partial order on a set N. A subset $Y \subseteq N$ is a *downset* of P if $v \in Y$ and $uv \in P$ imply that $u \in Y$. In the literature downsets are sometimes called also *order ideals* or just *ideals*. We denote the set of downsets by $\mathcal{D}(P)$, or shorter $\mathcal{D}$ when there is no ambiguity about the partial order. The *downset lattice* of P is the set of downsets ordered by inclusion, $(\mathcal{D}, \subseteq)$. While we do not define the notion of lattice here, we note that every lattice is a partially ordered set and thus can be represented by its *covering graph*, that is, $\mathcal{D}$ equipped with the covering relation. An example of a covering graph is shown in Figure 3. Observe that in the covering graph a node X is a parent of another node Y if and only if X is obtained from Y by removing some maximal element of Y, that is, an element of

$$\max Y = \big\{u \in Y : uv \notin P \text{ for all } v \in Y \setminus \{u\}\big\}\,.$$

(Later we may use the notation $\max Y$ also for a set Y that is not a downset.)

The following result of Habib et al. (2001) guarantees us an efficient access to the downset lattice of a given partial order:

Theorem 1 *Given a partial order P on an n-element set, the covering graph of the downset lattice of P can be constructed in $O(n|\mathcal{D}|)$ time and space.*

Remark 2 Actually Habib et al. (2001) show a stronger result, namely that the factor n in the time and space complexity can be reduced to the width of the partial order.

As a first use of these concepts we consider the problem of counting the linear extensions of a given partial order P on N. Recall that we denote this count by $\ell(P)$. It is immediate that $\ell(P)$ equals the number of paths from the empty set $\emptyset$ to the ground set N in the covering graph of the downset lattice of P. Thus, letting $F(\emptyset) = 1$ and, recursively for nonempty $Y \in \mathcal{D}$,

$$F(Y) = \sum_{\substack{v \in Y \\ Y \setminus \{v\} \in \mathcal{D}}} F\big(Y \setminus \{v\}\big)\,,$$

we have that $F(N) = \ell(P)$. This result is a special case of Lemma 18 that will be given in Section 5.2. Because the covering graph provides us with an efficient access to the downsets and their parents in the covering graph, we have the following result:

Theorem 3 *Given a partial order P on an n-element set, the number of linear extensions of P can be computed in $O(n|\mathcal{D}|)$ time and space.*

This result extends to counting the linear extensions of a given DAG A. Namely, we observe that $\ell(A)$ equals the number of linear extensions of the partial order $P(A)$ that is obtained by taking the transitive closure of A and adding the self-loop vv for each node $v \in N$. The transitive closure can be computed relatively fast, in $O(n^3)$ time, using the Floyd–Warshall algorithm.

Corollary 4 *Given a DAG A on an n-element set, the number of linear extensions of A can be computed in $O\big(n^3 + n|\mathcal{D}(P(A))|\big)$ time and $O\big(n|\mathcal{D}(P(A))|\big)$ space.*

Remark 5 In the worst case the number of downsets is 2^n. We are not aware of any algorithm that would compute the exact number of linear extensions faster than in $O(n2^n)$ time in the worst case. As the problem is #P-complete (Brightwell and Winkler, 1991), there presumably is no polynomial time exact algorithm for the problem. It is possible to *approximate* the count to within any relative error $\varepsilon > 0$, roughly, in $O(\varepsilon^{-2} n^5 \log^3 n)$ time (see Sect. 4 of Bubley and Dyer, 1999). Unfortunately, the large hidden constants and the large degree of the polynomial render the approximation algorithms impractical even for moderate values of ε. It is also known that the linear extensions of P can be enumerated in constant amortized time, which enables counting in $O(n^2 + \ell(P))$ time (Pruesse and Ruskey, 1994; Ono and Nakano, 2005). However, the enumeration approach to counting is not feasible when $\ell(P)$ is large.

2.3 Fast Zeta Transforms

Denote by 2^N the power set of N and by $\mathbb{R}$ the set of real numbers. For a function $\varphi : 2^N \to \mathbb{R}$ the *zeta transform* of φ over the subset lattice $(2^N, \subseteq)$ is the function $\widehat{\varphi} : 2^N \to \mathbb{R}$ defined by

$$\widehat{\varphi}(Y) = \sum_{X \subseteq Y} \varphi(X)\,, \quad \text{for } Y \subseteq N\,. \tag{1}$$

We shall introduce two computational problems that concern the evaluation of the zeta transform in restricted settings where the input function is sparse (has a small support) and also the output function is evaluated only at some subsets. In the *inflating zeta transform* problem we are given a partial order P on N, a function $\varphi : \mathcal{D} \to \mathbb{R}$ from the downsets of P to real numbers, and an arbitrary collection $\mathcal{C}$ of subsets of N. The task is to compute the zeta transform $\widehat{\varphi}$ restricted to $\mathcal{C}$, that is, to compute $\widehat{\varphi}(Y)$ for every $Y \in \mathcal{C}$. To make the formula (1) applicable, we understand that $\varphi(X) = 0$ for $X \in 2^N \setminus \mathcal{D}$. In the *deflating zeta transform* problem we are given a partial order P on N, a collection $\mathcal{C}$ of subsets of N, and a function $\varphi : \mathcal{C} \to \mathbb{R}$. The task is to compute the zeta transform $\widehat{\varphi}$ restricted to $\mathcal{D}$. Again, we understand that $\varphi(X) = 0$ for $X \in 2^N \setminus \mathcal{C}$. Clearly, the problems coincide if we take $\mathcal{C} = \mathcal{D}$, and the resulting transform is known as the *zeta transform over the downset lattice*. In these problems we assume that the input function is given as a list of argument–value pairs $(X, \varphi(X))$, where X ranges over the domain of the function (i.e., $\mathcal{C}$ or $\mathcal{D}$).

We begin with the problem of computing a zeta transform over the downset lattice:

Theorem 6 *Given a partial order P on an n-element set and a function $\varphi : \mathcal{D} \to \mathbb{R}$, the zeta transform of φ over the downset lattice $(\mathcal{D}, \subseteq)$ can be computed in $O(n|\mathcal{D}|)$ time and space.*

To prove this result we consider the following algorithm. First construct the covering graph of the downset lattice and associate each downset Y with the value $\varphi_0(Y) = \varphi(Y)$. Then find an ordering $v_1, \ldots, v_n$ of the elements of N such that $v_i v_j \in P$ implies $i \leq j$. Next, for each downset Y and for each $i = 1, \ldots, n$, let

$$\varphi_i(Y) = \varphi_{i-1}(Y) + \begin{cases} \varphi_{i-1}(Y \setminus \{v_i\}) & \text{if } v_i \in Y \text{ and } Y \setminus \{v_i\} \in \mathcal{D}\,, \\ 0 & \text{otherwise}\,. \end{cases}$$

Finally return the values $\varphi_n(Y)$ for $Y \in \mathcal{D}$. We can show that the algorithm is correct:

Lemma 7 *It holds that $\varphi_n(Y) = \widehat{\varphi}(Y)$ for all $Y \in \mathcal{D}$.*

The proof of this lemma and Lemmas 9–11 below are given in the appendix.

To complete the proof of Theorem 6, it remains to analyze the time and space requirements of the algorithm. The time and space requirement of constructing the covering graph are within the budget by Theorem 1. Finding a valid ordering takes $O(n^2)$ time and space using standard algorithms for topological sorting. Finally, for each $Y \in \mathcal{D}$, running the n steps and storing the values $\varphi_i(Y)$ takes $O(n)$ time and space, thus $O(n|\mathcal{D}|)$ in total. Note that the covering graph representation enables constant-time accessing of the downsets $Y \setminus \{v_i\}$ for a given downset Y.

Let us then turn to the two more general problems.

Theorem 8 *The deflating zeta transform problem and the inflating zeta transform problem can be solved in $O(n^2|\mathcal{C}| + n|\mathcal{D}|)$ time and $O(n|\mathcal{C}| + n|\mathcal{D}|)$ space.*

We prove first the claim for the deflating zeta transform problem. We develop our algorithm in two stages so as to split the sum in the zeta transform into two nested sums: the outer sum will be only over the downsets X of P, while the inner sum will gather the needed terms for each X.

The key concept is the *tail* of a downset Y, which we define as the set interval

$$\mathcal{T}_Y = \{X : \max Y \subseteq X \subseteq Y\}\,.$$

The following lemma shows that the tails are pairwise disjoint.

Lemma 9 *Let Y and Y' be distinct downsets. Then the tails $\mathcal{T}_Y$ and $\mathcal{T}_{Y'}$ are disjoint.*

We also have that each subset of the ground set belongs to some tail:

Lemma 10 *Let $X \subseteq N$. Let $Y = \{u : uv \in P, v \in X\}$, that is, the downward-closure of X. Then $Y \in \mathcal{D}$ and $X \in \mathcal{T}_Y$.*

Lemmas 9 and 10 imply that for any downset $S \in \mathcal{D}$ the tails $\{\mathcal{T}_Y : Y \in \mathcal{D} \cap 2^S\}$ partition the power set 2^S. This allows us to split the zeta transform into two nested summations. Let

$$\beta(Y) = \sum_{X \in \mathcal{T}_Y} \varphi(X)\,, \quad \text{for } Y \in \mathcal{D}\,.$$

Now

$$\widehat{\varphi}(Y) = \widehat{\beta}(Y) = \sum_{\substack{X \subseteq Y \\ X \in \mathcal{D}}} \beta(X)\,, \quad \text{for } Y \in \mathcal{D}\,.$$

Our algorithm computes $\widehat{\varphi}$ in two stages: first, given φ, it evaluates β at all downsets of P; second, given β, it evaluates $\widehat{\varphi}$ at all downsets of P. We have already seen how the second stage can be computed within the claimed time and space budget (Theorem 6).

The first stage is computationally relatively straightforward, since each $X \in \mathcal{C}$ contributes to exactly one term $\beta(Y)$. Specifically, we can compute the function β by initializing the values $\beta(Y)$ to zero, then considering each $X \in \mathcal{C}$ in turn and incrementing the value $\beta(Y)$ by $\varphi(X)$ for the unique downset Y satisfying $X \in \mathcal{T}_Y$. Using the observation that Y is the downward-closure of X, as given by Lemma 10, the set Y can be found in $O(n^2)$ time. This completes the proof of the first claim of Theorem 8.

Consider then the inflating zeta transform problem. We use the same idea as above, however, reversing the order of the two stages. Specifically, the algorithm first computes the zeta transform over the downset lattice $\mathcal{D}$, resulting in the values $\widehat{\varphi}(Y)$ for all $Y \in \mathcal{D}$. Then, the algorithm extends the output function to the domain $\mathcal{C}$ using the observation that the zeta transform is piecewise constant, that is, for any $Z \subseteq N$ we have $\widehat{\varphi}(Z) = \widehat{\varphi}(Y)$ for a unique downset Y:

Lemma 11 *Let $Z \subseteq N$. Then $\mathcal{D} \cap 2^Z = \mathcal{D} \cap 2^Y$, where the set $Y \in \mathcal{D}$ is given by*

$$Y = \{v \in Z : \text{if } uv \in P, \text{ then } u \in Z\}\,;$$

in words, Y consists of all elements of Z whose predecessors also are in Z.

Clearly the set Y can be constructed in $O(n^2)$ time for a given set Z. This completes the proof of Theorem 8.

Remark 12 The zeta transforms studied in this subsection have natural "upward-variants" where the condition $X \subseteq Y$ is replaced by the condition $X \supseteq Y$. The presented results readily apply to these variants, by complementation. Indeed, letting P be a partial order on N and denoting by $\bar{Y}$ the complement $N \setminus Y$ and by $\bar{P}$ the reversed partial order $\{vu : uv \in P\}$, we have the equivalences

$$X \supseteq Y \iff \bar{X} \subseteq \bar{Y} \quad \text{and} \quad Y \in \mathcal{D}(P) \iff \bar{Y} \in \mathcal{D}(\bar{P})\,.$$

Thus an upward-variant can be solved by first complementing the arguments of the input function, then solving the "downward-variants", and finally complementing back the arguments of the output function.

2.4 Random Sampling Variants

The above described zeta transform algorithms compute recursively large sums of nonnegative weights $\varphi(Z)$ each corresponding to a subset $Z \subseteq N$. Later we will also need a way to draw independent samples of the subsets $Z \subseteq Y$, proportionally to the weights. Coincidentally, the introduced summation algorithms readily provide us an efficient way to do this: for each sample we only need to stochastically backtrack the recursive steps.

We illustrate this generic approach to extend a summation algorithm into a sampling algorithm by considering the deflating zeta transform problem. Suppose we are given a partial order P on N, a collection of $\mathcal{C}$ of subsets of N, and a function $\varphi : \mathcal{C} \mapsto \mathbb{R}$. As an additional input we now also assume a downset $Y \in \mathcal{D}$. We consider the problem of generating a random subset $Z \in \mathcal{C} \cap 2^Y$ proportionally to $\varphi(Z)$. We show next that this problem can be solved in $O(n)$ time, provided that the deflating zeta transform has been precomputed and the intermediate results are stored in memory.

In the first stage the algorithm backtracks the zeta transform over the downset lattice, as follows. Let $Y_n = Y$. For $i = n, n-1, \ldots, 1$,

> if $Y_i \setminus \{v_i\} \in \mathcal{D}$, then with probability $\beta_{i-1}(Y_i \setminus \{v_i\})/\beta_i(Y_i)$ let $Y_{i-1} = Y_i \setminus \{v_i\}$;
> otherwise let $Y_{i-1} = Y_i$.

By the proof of Theorem 6, the resulting set Y_1 is a random draw from the subsets in $\mathcal{D} \cap 2^Y$ proportionally to $\beta(Y_1)$. This first stage takes clearly $O(n)$ time.

In the second stage the algorithm generates a random set $X \in \mathcal{T}_{Y_1}$ proportionally to $\varphi(X)$. In this case, the number of alternative options is not constant, and we need an efficient way to sample from the respective discrete probability distribution. A particularly efficient solution to this subproblem is known as the *Alias method* (Walker, 1977; Vose, 1991):

Theorem 13 (Alias method) *Given positive numbers $q_1, q_2, \ldots, q_r$, one can in $O(r)$ time construct a data structure, which enables drawing a random $i \in \{1, \ldots, r\}$ proportionally to q_i in constant time.*

We can view the list of the terms $\varphi(X)$, for $X \in \mathcal{T}_{Y_1}$, as an intermediate result, which has been precomputed and stored in memory using the Alias method. Thus the second stage takes only $O(1)$ time.

3. Bayesian Learning of Bayesian Networks

In this section we review the Bayesian approach to structure learning in Bayesian networks. Our emphasis will be on the notion of modularity of the various components of the Bayesian model. From the works of Friedman and Koller (2003) and Koivisto and Sood (2004) we also adopt the notion of order-modularity that is central in the partial-order-MCMC method, which we introduce in the next section.

3.1 The Bayesian Approach to Structure Learning

We shall consider probabilistic models for n *attributes*, the vth attribute taking values in a set $\mathcal{X}_v$. We will also assume the availability of a *data set* D consisting of m records over the attributes. We denote by D_v^j the datum for the vth attribute in the jth record. We will denote by N the index set $\{1, \ldots, n\}$, and often apply indexing by subsets. For example, if $S \subseteq N$, we write D_S^j for $\{D_v^j : v \in S\}$ and simply D^j for D_N^j.

We build a Bayesian network model for the data *a priori*, before seeing the actual data. To this end, we treat each datum D_v^j as a random variable with the state space $\mathcal{X}_v$. We model the random vectors $D^j = (D_1^j, \ldots, D_n^j)$ as independent draws from an n-variate distribution θ which is Markov with respect to some directed acyclic graph $G = (N, A)$, that is,

$$\theta(D^j) = \prod_{v \in N} \theta(D_v^j \,|\, D_{A_v}^j)\,. \tag{2}$$

Recall that $A_v = \{u : uv \in A\}$ denotes the set of parents of node v in G. We call the pair (G, θ) a *Bayesian network*, G its *structure*, and θ its *parameter*. As our interest will be in settings where the node set N is considered fixed, whereas the arc set A varies, we will identify the structure with the arc set A and drop G from the notation.

Because our interest is in learning the structure from the data, we include the Bayesian network in the model as a random variable. Thus we compose a joint distribution $p(A, \theta, D)$ as the product of a *structure prior* $p(A)$, a *parameter prior* $p(\theta \mid A)$, and the *likelihood* $p(D \,|\, A, \theta) = \prod_j \theta(D^j)$. Once the data D have been observed, our interest is in the *structure posterior* $p(A \mid D)$, which, using Bayes's rule, is obtained as the ratio $p(A)p(D \mid A)/p(D)$, where $p(D \,|\, A)$ is the *structure likelihood* and $p(D)$ the *marginal likelihood*. Note that as the parameter θ is not of direct interest, it is marginalized out. With suitable choices of the parameter prior, the marginalization can be carried out analytically; we will illustrate this below in Example 1.

Various quantities that are central in structure discovery, as well as in prediction of yet unobserved data, can be cast as the posterior expectation

$$\mathbb{E}(f \,|\, D) = \sum_A f(A) p(A \,|\, D) \tag{3}$$

of some function f that associates each structure A with a real number, or more generally, an element of a vector space. For example, if we let f be the indicator function of the structures where s is a parent of t, then $\mathbb{E}(f \mid D)$ equals the posterior probability that $st \in A$. For another example, define f in relation to the observed data D and to unobserved data D' as the conditional distribution $p(D' \mid D, A)$. Then $\mathbb{E}(f \mid D)$ equals the *posterior predictive*

distribution $p(D' \,|\, D)$. Note that in this instantiation we allowed the function f depend on the observed data D, which is only implicitly enabled in the expression (3). The marginal likelihood $p(D)$ is yet another variant of (3), obtained as the *prior expectation* $\mathbb{E}(f)$ of the function $f(A) = p(D \,|\, A)$. We will generally refer to the function f of interest as the *feature*.

3.2 Modularity and Node Orderings

From a computational point of view, the main challenge is to carry out the summation over all possible structures A, either exactly or approximately. As the number of possible structures grows very rapidly in the number of nodes, the hope is in exploiting the properties of both the posterior distribution and the feature. Here, a central role is played by functions that are modular in the sense that they factorize into a product of "local" factors, one term per pair (v, A_v), in concordance with the factorization (2).

We define the notion of modularity so that it applies equally to features, structure prior, and structure likelihood. Let φ be a mapping that associates each binary relation R on N with a real number. We say that φ is *modular* if for each node v there exists a mapping φ_v from the subsets of $N \setminus \{v\}$ to real numbers such that $\varphi(R) = \prod_{v \in N} \varphi_v(R_v)$. We call the functions φ_v the *factors* of φ.

In what follows, the relation R will typically be the arc set of a DAG. For example, the indicator function for a fixed arc st mentioned above is modular, with the factors f_v satisfying $f_v(A_v) = 0$ if $v = t$ and $s \notin A_t$ and $f_v(A_v) = 1$ otherwise.

Modular structure priors can take various specific forms. For example, a simple prior is obtained by assigning each node pair uv a real number $\kappa_{uv} > 0$ and letting the prior $p(A)$ be proportional to $\kappa(A) = \prod_{uv \in A} \kappa_{uv}$. Such prior allows giving separate weight for each arc according to its prior plausibility. The *uniform prior* is a special case where $\kappa_{uv} = 1$ for all node pairs uv. Note that proportionality guarantees modularity, since the n factors of the prior can absorb the normalizing constant $c = \sum_A \kappa(A)$, for example, by setting the vth factor to $\kappa_v(A_v)c^{-1/n}$. Another example is the prior proposed by Heckerman et al. (1995), that penalizes the distance between A and a user-defined prior DAG A^0. This can be obtained by letting $p(A)$ be proportional to $\prod_{v \in N} \kappa_v(A_v)$ where $\kappa_v(A_v) = \delta^{|(A_v \cup A_v^0) \setminus (A_v \cap A_v^0)|}$ and $0 < \delta \leq 1$ is a user-defined constant that determines the penalization strength. Modular structure priors also enable a straightforward way to bound the indegrees of the nodes. Indeed, we often consider the case where $p(A)$ vanishes if there exists a node v for which $|A_v|$ exceeds some fixed *maximum indegree*, denoted by k. Note, however, that modular structure priors do not allow similar controlling of the outdegrees of the nodes. For a node v we will call a set S a *potential parent set* if the prior does not vanish when S is the parent set of v, that is, $p(A) > 0$ for some structure A with $A_v = S$. Specifically, if p is modular, then S is a potential parent set of v if and only if $p_v(S) > 0$.

The following example describes a frequently used modular structure likelihood (Buntine, 1991; Heckerman et al., 1995):

Example 1 (Dirichlet–multinomial likelihood) Suppose that each set $\mathcal{X}_v$ is finite. Consider a fixed structure $A \subseteq N \times N$. For each node v and its parent set A_v, let the conditional distribution of D_v^j given $D_{A_v}^j = y$ be categorical with parameters $\theta_{v \cdot y} = \{\theta_{vxy} : x \in \mathcal{X}_v\}$. Define a distribution θ of D^j as the product of the conditional distributions and observe that (A, θ) is a Bayesian network. Assign each set of parameters $\theta_{v \cdot y}$ a Dirichlet prior with

parameters $r_{vxy} > 0$, for $x \in \mathcal{X}_v$, and compose the prior $p(\theta \,|\, A)$ by assuming independence of the components. Let m_{vxy} denote the number of data records j where $D_v^j = x$ and $D_{A_v}^j = y$. Then

$$\begin{aligned} p(D \,|\, A) &= \int p(\theta \,|\, A) p(D \,|\, A, \theta) \mathrm{d}\theta \\ &= \prod_{v \in N} \prod_{y \in \mathcal{X}_{A_v}} \frac{\Gamma(r_{v \cdot y})}{\Gamma(r_{v \cdot y} + m_{v \cdot y})} \prod_{x \in \mathcal{X}_v} \frac{\Gamma(r_{vxy} + m_{vxy})}{\Gamma(r_{vxy})}, \end{aligned}$$

where $r_{v \cdot y}$ and $m_{v \cdot y}$ are the sums of the numbers r_{vxy} and m_{vxy}, respectively, and Γ is the gamma function. In an important special case, each parameter r_{vxy} is set to a so-called *equivalent sample size* $\alpha \geq 0$ divided by the number of joint configurations of x and y (i.e., by $|X_v|$ if A_v is empty and by $|\mathcal{X}_v||\mathcal{X}_{A_v}|$ otherwise).

By a *modular model* we will refer to a Bayesian model, where both the structure likelihood and the structure prior are modular. We will assume that such a model is represented in terms of the factors λ_v and κ_v of a likelihood λ and an unnormalized prior κ, respectively. In our empirical study we have used the following simple model:

Example 2 (uniform Dirichlet–multinomial model, UDM) In this modular model, the structure prior is specified by letting $\kappa_v(A_v) = 1$ if $|A_v| \leq k$, and $\kappa_v(A_v) = 0$ otherwise. The likelihood is the Dirichlet–multinomial likelihood with the equivalent sample size parameter set to 1 (see Example 1). The maximum indegree k is a parameter of the model.

For a demonstration of the computational benefit of modularity, let us consider the probability (density) of the data D conditioning on the constraint that the unknown DAG A is compatible with a given linear order L on the nodes. We may express this compatibility constraint by writing simply L, and hence the quantity of interest by $p(D \,|\, L)$. Write first

$$p(D \,|\, L) = \sum_A p(A, D \,|\, L) = \frac{\sum_{A \subseteq L} p(A) p(D \,|\, A)}{\sum_{A \subseteq L} p(A)} = \frac{\sum_{A \subseteq L} \kappa(A) \lambda(A)}{\sum_{A \subseteq L} \kappa(A)}.$$

Here the last equality holds because the normalizing constants of the prior cancel out. Then we use the key implication of the constraint $A \subseteq L$, namely, that the set of possible structures A decomposes into a Cartesian product of the sets of potential parent sets A_v for each node v (Buntine, 1991; Cooper and Herskovits, 1992):

$$p(D \,|\, L) = \prod_{v \in N} \sum_{A_v \subseteq L_v} \kappa_v(A_v) \lambda_v(A_v) \Bigg/ \prod_{v \in N} \sum_{A_v \subseteq L_v} \kappa_v(A_v). \tag{4}$$

This factorization enables independent processing of the parent sets for each node, which amounts to significant computational savings compared to exhaustive enumeration of all possible structures. A similar factorization can be derived for the conditional posterior expectation $\mathbb{E}(f \,|\, D, L)$ of a modular feature f.

Motivated by the savings, Friedman and Koller (2003) addressed the unconstrained setting where no node ordering is given. They proposed averaging $\mathbb{E}(f \,|\, D, L)$ over a sample

of linear orders drawn from a distribution that is proportional to the marginal likelihood $p(D \mid L)$, as we will describe in the next subsection. For *exact* averaging over all linear orders, Koivisto and Sood (2004) gave exponential-time dynamic programming algorithm. We will obtain that algorithm as a special case of the algorithm we give in Section 5.

When the modularity is exploited as described above, the actual joint model of the data and structures does not remain modular. This is essentially because some DAGs are consistent with fewer linear orders than other DAGs. We will discuss this issue further at the end of the next subsection. To characterize the model, for which the node-ordering based methods work correctly, we follow Koivisto and Sood (2004) and call a model *order-modular* if the likelihood function is modular and the structure prior $p(A)$ is proportional to $\kappa(A) \sum_{L \supseteq A} \mu(L)$, for some modular functions κ and μ. Thus an order-modular model can be interpreted as a "modular" joint model for the structure A and the linear order L. Note, that if $\mu(L) > 0$ for all linear orders L, then the support of such a prior contains the same DAGs as the support of the corresponding modular prior determined by κ. We will also use the terms *order-modular prior* and *order-modular posterior* in an obvious manner.

Example 3 (order-modular UDM) In this model, the structure likelihood and the factors κ_v are as in a modular UDM (see Example 2), and the maximum indegree k is a parameter of the model. The difference to the modular UDM is that we specify instead an order-modular prior by letting $\mu(L) = 1$ for all linear orders L on N. Thus the prior $p(A)$ is proportional to $\kappa(A)\ell(A)$.

3.3 Sampling-based Approximations

We next review the basic sampling-based approaches for structure learning in Bayesian networks. For a broader introduction to the subject in the machine learning context, we refer to the survey by Andrieu et al. (2003).

Importance sampling methods provide us with a generic approach to approximate the expectation $\mathbb{E}(f \,|\, D)$ by a sample average

$$\frac{1}{T} \sum_{t=1}^{T} \frac{f(A^t) p(A^t \,|\, D)}{q(A^t)}\,, \qquad A^1, A^2, \ldots, A^T \sim q(A)\,, \tag{5}$$

where $q(A)$ is some appropriate *sampling distribution*. It would be desirable that (i) $q(A)$ is as close to the function $|f(A^t)p(A^t \,|\, D)|$ as possible, up to a multiplicative constant, and (ii) that the samples A^t are independent. In order to compute the average we also need, for any given sample A^t, (iii) an access to the value $q(A^t)$ either exactly or up to a small error. If the function q can be evaluated only up to a constant factor, then one typically uses the *self-normalized importance sampling estimate*, which is obtained by dividing the sample average (5) by the sample average of $1/q(A^t)$. In practice, it is possible to simultaneously satisfy only some of the desiderata (i–iii).

The *structure-MCMC* method of Madigan and York (1995), in particular, draws the samples by simulating a Markov chain whose stationary distribution is $p(A \,|\, D)$. Thus, while the sampling distribution tends to $p(A \,|\, D)$ in the limit, after a finitely many simulation steps there is no guarantee about the quality of the sampling distribution. Furthermore, since the samples are dependent, their number has to be relatively large to obtain the efficiency that

could be obtained with a smaller number of independent samples. Finally, the computation of $q(A^t)$ is avoided by assuming it to be a good approximation to $p(A^t \,|\, D)$ and thus canceling in the estimator. The performance of structure-MCMC depends crucially on the mixing rate of the Markov chain, that is, how fast the chain "forgets" its initial state so that the draws will be (approximately) from $p(A \,|\, D)$. The main shortcoming of structure-MCMC is that the chain may get easily trapped at small regions near local maxima of the posterior.

The *order-MCMC* method of Friedman and Koller (2003), which we already mentioned in the previous subsection, aims at better performance by sampling node orderings from a distribution that is proportional to $p(D \mid L)$. Compared to the space of DAGs, the space of node orderings is not only significantly smaller but it also smoothens the sampling distribution, because for any L the marginal likelihood $p(D \,|\, L)$ is a sum over exponentially many DAGs. The resulting estimator becomes

$$\frac{1}{T} \sum_{t=1}^{T} \mathbb{E}(f \,|\, D, L^t)\,, \qquad L^1, L^2, \ldots, L^T \sim p'(L \,|\, D)\,,$$

where $p'(L \,|\, D) \propto p(D \,|\, L) p'(L)$ is obtained via $p(D \,|\, L)$ by re-modelling the $n!$ possible node ordering constraints L as mutually exclusive events, assigned with a uniform prior, $p'(L)$. In cases where exact computation of the expectation $\mathbb{E}(f \,|\, D, L^t)$ is not feasible, it can, in turn, be approximated by a single evaluation at a sampled DAG,

$$f(A^t)\,, \qquad A^t \sim p(A \,|\, D, L^t)\,,$$

or, more accurately, by an average over several independent samples from $p(A \mid D, L^t)$. Importantly, the latter sampling step, if needed, is again computationally easy thanks to the fixed node ordering. Thus the difficulty of sampling only concerns the sampling of node orderings. Friedman and Koller (2003) showed that simple local changes, namely swaps of two nodes, yield a Markov chain that mixes relatively fast in their sets of experiments. We omit a more detailed description of the order-MCMC method here, as the method is obtained as a special instantiation of the method we will introduce in Section 4.

The innocent-looking treatment of node ordering constraints as mutually exclusive events, however, introduces a "bias" to the estimator. Indeed, it is easy to see that the samples A^t will be generated from the distribution

$$\sum_{L \supseteq A} p'(L \,|\, D) p(A \,|\, D, L) \propto p(A \,|\, D) \ell(A)\,.$$

In other words, compared to sampling from the true posterior $p(A \,|\, D)$, sampling via node orderings favors DAGs that are compatible with larger numbers of linear orders. But also a different interpretation is valid: the DAGs are sampled from the correct posterior under a modified (order-modular) model where the original, modular structure prior $p(A)$ is replaced by the order-modular prior that is proportional to $p(A)\ell(A)$ (as in Example 3). Oftentimes, the modularity of the structure prior is preferred, as it can express priors that are uniform over all DAGs (subject to a maximum indegree constraint). That being said, Friedman and Koller (2003) give supportive arguments also for the other viewpoint.

4. Sampling Partial Orders

Our key idea is to extend the order-MCMC of Friedman and Koller (2003) by replacing the state space of node orderings by an appropriately defined space of partial orders on the nodes. Throughout this section we will denote (perhaps counter to the reader's anticipation) by π' the modular posterior distribution and by π its "biased" order-modular counterpart that arises due to treating node orderings as mutually exclusive events. Our goal is to perform Bayesian inference under the modular posterior π'. Because our approach is to sample from the order-modular posterior π, we obtain, as a by-product, also an inference method for order-modular models. When needed, we will refer to the underlying modular model by p' and to the induced order-modular model by p.

4.1 Sampling Spaces of Partial Orders

We will consider sampling from a state space that consists of partial orders on the node set N. We will denote the state space by $\mathcal{P}$. The idea is that the states in $\mathcal{P}$ partition the set of all linear orders on N. To this end, we require $\mathcal{P}$ to be an *exact cover* on N, that is, every linear order on N must be an extension of exactly one partial order P in $\mathcal{P}$. Examples 4 and 5 below illustrate the concept and also introduce the notion of a bucket order, which is central in our implementation of the proposed methods.

Example 4 (bucket orders) A partial order B is a *bucket order* if the ground set admits a partition into pairwise disjoint sets, $B_1, B_2, \ldots, B_h$, called the *buckets*, such that $uv \in B$ if and only if $u = v$ or $u \in B_i$ and $v \in B_j$ for some $i < j$. Intuitively, the order of elements in different buckets is determined by the buckets' order, while within each bucket the elements are incomparable. We say that the bucket order is of *type* $(b_1, b_2, \ldots, b_h)$, when b_i is the size of B_i. We call the bucket order a *balanced bucket order* with a *maximum bucket size* b if $b = b_1 = b_2 = \cdots = b_{h-1} \geq b_h$. Furthermore, we call two bucket orders *reorderings* of each other if they have the same ground set and they are of the same type. It is immediate that the set (equivalence class) of reorderings of a bucket order P constitute an exact cover on their common ground set (Koivisto and Parviainen, 2010). For a later reference, we also note that the number of downsets of the bucket order is $1 + \sum_i (2^{b_i} - 1)$.

The next example gives a straightforward extension of bucket orders.

Example 5 (parallel bucket orders) A partial order P is a parallel composition of bucket orders, or *parallel bucket order* for short, if P can be partitioned into r bucket orders $B^1, B^2, \ldots, B^r$ on disjoint ground sets. We call two parallel bucket orders P and Q *reorderings* of each other if their bucket orders can be labelled as $P^1, P^2, \ldots, P^r$ and $Q^1, Q^2, \ldots, Q^r$ such that each P^j is a reordering of Q^j. It is known that the set (equivalence class) of reorderings of a parallel bucket order P is an exact cover on their common ground set (Koivisto and Parviainen, 2010). Compared to bucket orders, parallel bucket orders make it possible to obtain better time–space tradeoffs in the context of exact structure discovery. However, our preliminary calculations (Niinimäki et al., 2011) show that parallel bucket orders are unlikely to yield substantive advantages in the sampling context.

Because the methods we shall consider are based on local moves in the sampling space, we equip the sampling space with a neighborhood structure. Formally, a neighborhood

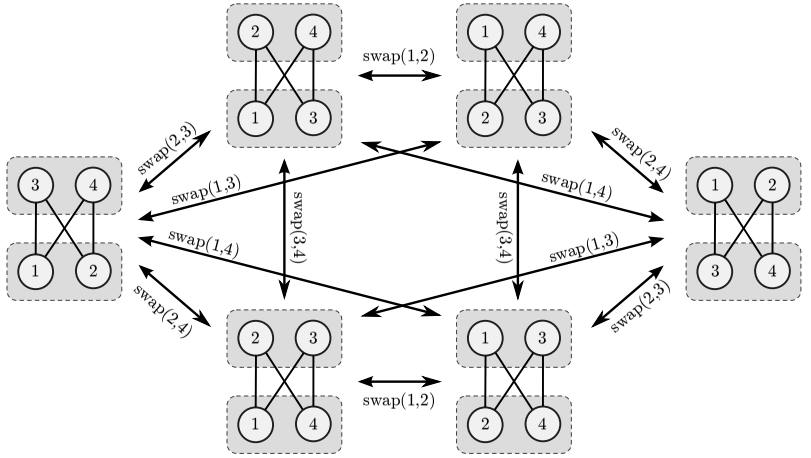

Figure 4: All reorderings of a bucket order of type $(2, 2)$ on the node set $\{1, 2, 3, 4\}$. Adjacency in the swap neighborhood is indicated by arrows labeled by the corresponding swap operation. Each bucket order is visualized using a Hasse diagram, with rectangles indicating individual buckets.

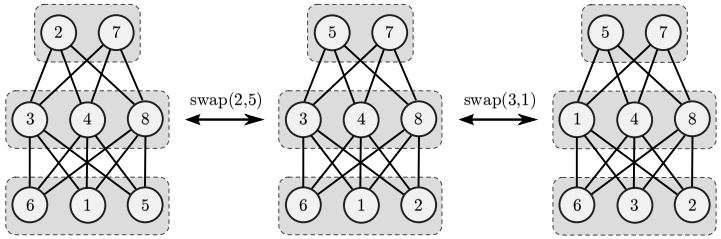

Figure 5: Three adjacent states in the space of reorderings of a bucket order of type $(3, 3, 2)$.

structure on $\mathcal{P}$ is just a graph on $\mathcal{P}$, the adjacency relation specifying the neighborhood relation. Here, we do not make an attempt to give any specific neighborhood structure that would be appropriate for an arbitrary exact cover $\mathcal{P}$. Instead, we continue with an example:

Example 6 (swap neighborhood) Let P be a (parallel) bucket order on N, and let $\mathcal{P}$ the set of reorderings of P. The *swap neighborhood* on $\mathcal{P}$ is a graph in which the vertex set consists of the reorderings $\mathcal{P}$ and two members $Q, R \in \mathcal{P}$ are adjacent if Q is obtained from

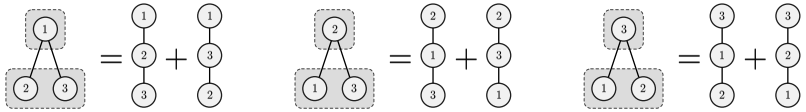

Figure 6: There are in total six linear orders on the node set $\{1, 2, 3\}$ and three reorderings of a bucket order of type (2,1). As shown in the figure, the probability of each bucket order is the sums of the probabilities of its linear extensions. Observe, how the bucket orders form an exact cover and hence partition the set of linear orders into three disjoint subsets.

R by *swapping* two nodes $s, t \in N$, more formally:

$$uv \in R \iff \sigma(u)\sigma(v) \in Q\,,$$

where σ is the transposition $N \to N$ that swaps s and t. Clearly, the swap neighborhood is connected. See Figures 4 and 5 for an illustration of bucket orders and swap neighborhoods.

For each partial order P in an exact cover $\mathcal{P}$, the posterior probability $\pi(P)$ is obtained simply as the sum of the posterior probabilities $\pi(L)$ of all linear extensions L of P. This is illustrated in Figure 6. Note that the choice of the state space $\mathcal{P}$ does not affect the posterior π and consequently leaves the bias untouched. The correction of the bias will be taken care of separately, as shown in the next subsection.

4.2 Partial-Order-MCMC and Bias Correction

The basic *partial-order-MCMC* method has three steps. It first samples states from $\mathcal{P}$ along a Markov chain whose stationary distribution is π. Then it draws a DAG from each sampled partial order. Finally, it estimates the posterior expectation of the feature in interest by taking a weighted average of the samples. In more detail, these steps are as follows:

1. *Sample partial orders along a Markov chain using the Metropolis–Hastings algorithm.* Start from a random partial order $P^1 \in \mathcal{P}$. To move from state P^t to the next state, first draw a candidate state $P^\star$ from a proposal distribution $q(P^\star \,|\, P^t)$. Then accept the candidate with probability

$$\min\left\{1, \frac{\pi(P^\star)q(P^t \,|\, P^\star)}{\pi(P^t)q(P^\star \,|\, P^t)}\right\},$$

   and let $P^{t+1} = P^\star$; otherwise let $P^{t+1} = P^t$. This produces a sample of partial orders $P^1, P^2, \ldots, P^T$. Each move constitutes one *iteration* of the algorithm.

2. *Sample DAGs from the sampled partial orders.* For each sampled partial order P^t, draw a DAG A^t compatible with P^t from the conditional posterior distribution $\pi(A^t \,|\, P^t)$. This produces a sample of DAGs $A^1, A^2, \ldots, A^T$.

3. *Estimate the expected value of the feature by a weighted sample average.* Return

$$f_{\text{MCMC}} = \sum_t \frac{f(A^t)}{\ell(A^t)} \Bigg/ \sum_t \frac{1}{\ell(A^t)}$$

   as an estimate of $\mathbb{E}_{\pi'}(f)$. Recall that $\ell(A^t)$ is the number of linear extensions of A^t.

Several standard MCMC techniques can be applied to enhance the method in practice. Specifically, it is computationally advantageous to thin the set of samples P^t by keeping only, say, every 100th sample. Also, it is often a good idea to start collecting the samples only after a burn-in period that may cover, say, as much as 50% of the total allocated running time. On the other hand, we can compensate these savings in step 2 of the method by drawing *multiple*, independent DAGs per sampled partial order P^t, which can improve considerably the estimate obtained in step 3. We will consider these techniques in more detail in the context of our empirical study in Section 6.

It is worth noting that access to the exact posterior probabilities $\pi(P^t)$ are not needed in step 1. It suffices that we can evaluate a function g that is proportional to π. An appropriate function is given by

$$g(P^t) = \sum_{L \supseteq P^t} \sum_{A \subseteq L} p'(A, D)\,. \tag{6}$$

We will see later that the modularity of the model p' enables fast computation of $g(P^t)$.

We can show that under mild conditions on the proposal distribution q, the Markov chain constructed in step 1 converges to the target distribution $\pi(P)$, and consequently, the estimate f_{MCMC} tends to $\mathbb{E}_{\pi'}(f)$ as the number of samples T grows. In the next paragraphs we justify these two claims.

For the first claim it suffices to show that the chain is irreducible, that is, from any state P the chain can reach any other state $P^\star$ with some number of moves (with a positive probability). In principle, this condition would be easily satisfied by a proposal distribution $q(P^\star \mid P)$ whose support is the entire $\mathcal{P}$ for every P. From a practical point of view, however, it is essential for good mixing of the chain to have a proposal distribution that concentrates the proposes locally to a few *neighbors* of the current state P. In that case it is crucial to show that the induced neighborhood graph on $\mathcal{P}$ is strongly connected, thus implying irreducibility of the chain. In the order-MCMC method, connectedness was obtained because any two node orderings can be reached from each other by some number of swaps of two nodes. It is easy to see that this proposal distribution applies to partial orders as well, only noting that some swaps of nodes may result in partial orders that are outside the fixed state space $\mathcal{P}$ and must thus be rejected (or avoid proposing). Rather than pursuing the issue in full generality, we extend the swap proposal for the sampling space of parallel bucket orders:

Example 7 (swap proposal for parallel bucket orders) Consider the set of reorderings $\mathcal{P}$ and the swap-neighborhood described in Example 6. For any $P \in \mathcal{P}$, let the conditional proposal distribution $q(P^\star \,|\, P)$ be uniform over the neighbors $P^\star$ of P (and vanish otherwise). Note that it is possible to sample directly from this conditional distribution by drawing two nodes s, t that belong to the same part but different buckets in the partition of N, uniformly at random, and proposing the swap of s and t.

We then turn to the second claim that the estimate tends to the posterior expectation of the feature. We investigate the behavior of the estimate f_{MCMC}. By the properties of the Markov chain we may assume that the $P^1, P^2, \ldots, P^T$ are an ergodic sample from $\pi(P)$, that is, any sample average tends to the corresponding expected value as T grows. Consequently, the $A^1, A^2, \ldots, A^T$ are an ergodic sample from the biased posterior

$$\pi(A) = \sum_{P \in \mathcal{P}} \pi(P)\, \pi(A \,|\, P) = \sum_{P \in \mathcal{P}} \sum_{L \supseteq P} \pi(P, L, A) = \sum_{L} \pi(L, A) \propto \pi'(A)\ell(A)\,.$$

Here the last equation holds because $\mathcal{P}$ is an exact cover on N; and the last proportionality holds because $\pi(L, A)$ vanishes if L is not an extension of A, and is otherwise proportional to $\pi'(A)$. The ergodicity now guarantees that the average of the $1/\ell(A^t)$ tends to the expectation $\mathbb{E}_\pi(1/\ell(A^t)) = 1/c$, where

$$c = \sum_{A} \pi'(A)\ell(A)\,, \tag{7}$$

and that the average of the $f(A^t)/\ell(A^t)$ tends to the ratio $\mathbb{E}_{\pi'}(f)/c$. This implies that f_{MCMC} approaches $\mathbb{E}_{\pi'}(f)$ as the number of samples T grows.

The computational complexity of partial-order-MCMC is determined, in addition to the number of samples T, by the complexity of the problems solved for each sampled partial order P^t and DAG A^t. These problems—of which analysis we postpone to Section 5—are:

(a) *Unnormalized posterior:* Compute $g(P^t)$ for a given P^t.

(b) *Sample DAGs:* Draw a DAG A^t from $\pi(A^t \,|\, P^t)$ for a given partial order P^t .

(c) *Number of linear extensions:* Compute $\ell(A^t)$ for a given DAG A^t.

We will see that problems (a) and (b) can be solved in time that scales, roughly, as $C + |\mathcal{D}|$, where C is the total number of potential parent sets and $|\mathcal{D}|$ is the number of downsets of the partial order P^t.

The problem (c) of counting the linear extensions was already discussed in Section 2, Corollary 4. We note that if the target model is order-modular, then there is no need to compute the terms $\ell(A^t)$, as no bias correction is needed. Moreover, for an order-modular model also the DAG sampling step can be avoided if the interest is in a modular feature f. Namely, then the estimate is obtained simply as an average of the conditional expectations $\mathbb{E}_\pi(f \,|\, P^t)$, which gives us one more problem to solve:

(a') *Expectation of a modular feature:* Compute $\mathbb{E}_\pi(f \,|\, P^t)$ for a given partial order P^t.

We will see in Section 5 that this problem can be computed in almost the same way as the unnormalized posterior probability of P^t, which justifies the label (a').

4.3 Metropolis-coupled Markov Chain Monte Carlo (MC^3)

Tempering techniques can enhance mixing of the chain and, as a byproduct, they also offer a good estimator for the marginal likelihood $p(D)$. Here we consider one such technique, *Metropolis-coupled MCMC* (MC^3) (Geyer, 1991). In MC^3, several Markov chains, indexed

by $0, 1, \ldots, K$, are simulated in parallel, each chain i having its own stationary distribution π_i. The idea is to take π_0 as a "hot" distribution, for example, the uniform distribution, and then let the π_i be increasingly "cooler" and closer approximations of the posterior π, putting finally $\pi_K = \pi$. Usually, powering schemes of the form

$$\pi_i \propto \pi^{\beta_i}\,, \quad 0 \leq \beta_0 < \beta_1 < \cdots < \beta_K = 1$$

are used. For instance, Geyer and Thompson (1995) suggest harmonic stepping, $\beta_i = 1/(K + 1 - i)$; in our experiments we have used linear stepping, $\beta_i = i/K$.

In addition to running the chains in parallel, every now and then we propose a swap of the states P_i and P_j of two randomly chosen chains i and $j = i + 1$. The proposal is accepted with probability

$$\min\left\{1, \frac{\pi_i(P_j)\pi_j(P_i)}{\pi_i(P_i)\pi_j(P_j)}\right\}.$$

We note that each π_i needs to be known only up to some constant factor, that is, it suffices that we can efficiently evaluate a function g_i that is proportional to π_i. By using samples from the coolest chain only, an estimate of the expectation $\mathbb{E}_{\pi'}(f)$, which we denote by f_{MC3}, is obtained by following steps 2 and 3 of the partial-order-MCMC method. In Section 4.5 we will show that, by using samples from all chains, we can also get good estimates of the marginal likelihood $p'(D)$. This technique is a straightforward extension of the technique for estimating $p(D)$.

4.4 Annealed Importance Sampling (AIS)

AIS produces independent samples of partial orders $P^1, P^2, \ldots, P^T$ and associated importance weights $w^1, w^2, \ldots, w^T$. Like in MC^3, a sequence of distributions $\pi_0, \pi_1, \ldots, \pi_K$ is introduced, such that sampling from π_0 is easy, and as i increases, the distributions π_i provide gradually improving approximations to the posterior distribution π, until finally π_K equals π. In our experiments we have used the same scheme as for MC^3, however, with a much larger value of K. For each π_i we assume the availability of a corresponding function g_i that is proportional to π_i and that can be evaluated fast at any given point.

To sample P^t, we first sample a sequence of partial orders $P_0, P_1, \ldots, P_{K-1}$ along a Markov chain, starting from π_0 and moving according to suitably defined transition kernels τ_i, as follows:

Generate P_0 from π_0.
Generate P_1 from P_0 using τ_1.
$\vdots$
Generate P_{K-1} from P_{K-2} using τ_{K-1}.

The transition kernels τ_i are constructed by a simple Metropolis–Hastings move: At state P_{i-1} a candidate state $P_\star$ is drawn from a proposal distribution $q(P_\star \,|\, P_{i-1})$; the candidate is accepted as the state P_i with probability

$$\min\left\{1, \frac{g_i(P_\star)q(P_{i-1} \,|\, P_\star)}{g_i(P_{i-1})q(P_\star \,|\, P_{i-1})}\right\},$$

and otherwise P_i is set to P_{i-1}. It follows that the transition kernel τ_i leaves π_i invariant. Finally, we set $P^t = P_{K-1}$ and assign the importance weight as

$$w^t = \frac{g_1(P_0)}{g_0(P_0)} \frac{g_2(P_1)}{g_1(P_1)} \cdots \frac{g_K(P_{K-1})}{g_{K-1}(P_{K-1})} .$$

We then generate a DAG A^t from each P^t as in step 2 of the partial-order-MCMC method. An estimate of $\mathbb{E}_{\pi'}(f)$ is given by

$$f_{\text{AIS}} = \sum_t \frac{w^t f(A^t)}{\ell(A^t)} \Bigg/ \sum_t \frac{w^t}{\ell(A^t)} . \tag{8}$$

To see that this self-normalized importance sampling estimate is consistent, we examine separately the expected values of the numerator and the denominator, and show that their ratio equals $\mathbb{E}_{\pi'}(f)$. To this end, consider a fixed t and any function h of partial orders. Denote by q the joint sampling distribution of the partial orders $P_0^t, P_1^t, \ldots, P_K^t$ and the DAG A^t. The general result of Neal (2001) implies the following: Let ρ denote the ratio of the normalizing constants of g_K and g_0. Then

$$\mathbb{E}_q\big(w^t h(P_K^t)\big) = \rho \cdot \mathbb{E}_\pi\big(h(P_K^t)\big) \quad \text{and} \quad \mathbb{E}_q\big(w^t\big) = \rho .$$

Using the fact that $\mathbb{E}_q\big(w^t\, h'(A^t)\big) = \mathbb{E}_q\big(w^t\, \mathbb{E}_q(h'(A^t) \,|\, P_0^t, \ldots, P_K^t)\big) = \mathbb{E}_q\big(w^t\, \mathbb{E}_\pi(h'(A^t) \,|\, P_K^t)\big)$ and applying the above result with a particular choice of the functions h and h' yields

$$\mathbb{E}_q\left(w^t \cdot \frac{f(A^t)}{\ell(A^t)}\right) = \mathbb{E}_q\left(w^t \cdot \mathbb{E}_\pi\left(\frac{f(A^t)}{\ell(A^t)} \,\middle|\, P_K^t\right)\right) = \rho \cdot \mathbb{E}_\pi\left(\frac{f(A^t)}{\ell(A^t)}\right) = \frac{\rho}{c} \cdot \mathbb{E}_{\pi'}\big(f(A^t)\big) ,$$

where c is, as given before in (7), the normalizing constant of $\pi'(A)\ell(A)$. From this we also see that the expected value of each term in the denominator in (8) equals ρ/c. Thus the ratio of the expectations is $\mathbb{E}_{\pi'}(f)$ as desired.

4.5 Estimating the Marginal Likelihood

We now turn to the estimation of the marginal likelihood $p'(D)$ using samples produced by either MC^3 or AIS. We will view $p'(D)$ as the normalizing constant of the function $g'(A) = p'(A, D)$, and denote the constant by c' for short. We will estimate c' indirectly, by estimating a ratio $\rho' = c'/c_0$, where c_0 is another normalizing constant that we can compute exactly. In fact, c_0 will be the normalizing constant g_0/π_0, and in general, we will denote by c_i the normalizing constant g_i/π_i.

With a sample generated by MC^3, our estimate for the marginal likelihood is obtained, in essence, as a product of estimates of the ratios c_{i+1}/c_i, as given by

$$\rho'_{\text{MC3}} = \prod_{i=0}^{K-1} \left(\frac{1}{T} \sum_t \frac{g_{i+1}(P_i^t)}{g_i(P_i^t)}\right) \left(\frac{1}{T} \sum_t \frac{1}{\ell(A^t)}\right) .$$

To see that the estimate is asymptotically unbiased, observe first that

$$\mathbb{E}_{\pi_i}\left(\frac{g_{i+1}(P_i^t)}{g_i(P_i^t)}\right) = \frac{c_{i+1}}{c_i} \quad \text{and} \quad \mathbb{E}_\pi\left(\frac{1}{\ell(A^t)}\right) = \frac{c'}{c_K} .$$

Here the former equation is easy to verify. For the latter we recall that $\mathbb{E}_\pi\big(1/\ell(A^t)\big) = 1/c$ and write the normalizing constant of $g_K = g$ using (6) as

$$c_K = \sum_P g(P) = \sum_L \sum_{A \subseteq L} p'(A, D) = p'(D) \sum_A \pi'(A)\ell(A) = c'c .$$

Now, if the estimates were independent and, moreover, the samples P_i^t were exactly from π_i, then ρ'_{MC3} would be an unbiased estimate of the marginal likelihood. While neither condition is satisfied in our case, the ergodicity of the chains guarantees that each estimate, and thereby their product, is asymptotically unbiased.

With a sample generated by AIS, our estimate for the marginal likelihood is

$$\rho'_{\text{AIS}} = \frac{1}{T} \sum_t \frac{w^t}{\ell(A^t)} .$$

It is not difficult to see that this estimate is unbiased. Namely, we have already seen that the expected value of this estimate is ρ/c, where $\rho = c_K/c_0$. Because we just showed that $1/c = c'/c_K$, we obtain $\rho/c = c'/c_0 = \rho'$, as desired.

The AIS-based estimate has two main advantages over the MC^3-based estimate. One is that we can use a fairly large number of steps K in AIS, which renders the estimate more accurate. In MC^3 we have to use a much smaller K to reserve time for simulating each chain a large number of steps. A smaller K is expected to yield less accurate estimates. The other advantage of the AIS-based estimate stems from the unbiasedness and independence of the samples. Indeed, these two properties allow us to compute high-confidence *lower bounds* for the marginal likelihood. We will make use the following elementary theorem; for variations and earlier uses in other contexts, we refer to the works of Gomes et al. (2007) and Gogate and Dechter (2011).

Theorem 14 (lower bound) *Let $Z_1, Z_2, \ldots, Z_s$ be independent nonnegative random variables with mean μ. Let $0 < \delta < 1$. Then, with probability at least $1 - \delta$, we have*

$$\delta^{1/s} \min\{Z_1, Z_2, \ldots, Z_s\} \leq \mu .$$

Proof By Markov's inequality, $Z_i > \delta^{-1/s}\mu$ with probability at most $\delta^{1/s}$, for each i. Taking the product gives that $\min\{Z_1, Z_2, \ldots, Z_s\} > \delta^{-1/s}\mu$ with probability at most δ. To complete the proof, multiply both sides by $\delta^{1/s}$ and consider the complement event. ■

We apply this result by dividing our T samples into s bins of equal size and letting Z_i be the estimate of the marginal likelihood based on the samples in the ith bin. There is a tradeoff in choosing a good value of s. Namely, to obtain good individual estimates Z_i, we would like to set s as small as possible. On the other hand, we would like to use a large s in order to have a *slack* factor $\delta^{1/s}$ as close to 1 as possible. The following examples show two different ways to address this tradeoff.

Example 8 (slack-2 lower bound) Put $\delta = 2^{-5} = 0.03125$ and $s = 5$. Then $\delta^{1/s} = 1/2$.

Example 9 (square-root lower-bounding scheme) Put $\delta = 2^{-5}$ and $s = \lfloor \sqrt{T} \rfloor$ for T samples. Then $\delta^{1/s}$ grows with T, being 2^{-1}, $2^{-1/2}$, $2^{-1/4}$ at $T = 25, 100, 400$, respectively.

5. Per-Sample Computations

In the previous section we encountered a number of computational problems associated with each sampled partial order and DAG (see the end of Section 4.2). In this section we give algorithms to solve those problems. We begin by formulating the computational problems and stating the main results in Section 5.1. The proofs are given in Sections 5.2–5.4. Finally, in Section 5.5 we discuss the possibility to reduce the time and space requirements in certain special cases that are relevant for the present applications.

5.1 Problems and Results

We shall derive solutions to the computational problems (a), (b), and (a') of Section 4.2 as specific instantiations of slightly more abstract problems concerning modular functions. Recall that the problem (c) was already discussed in Section 2.

We abstract the core algorithmic problem underlying problems (a) and (a') as what we call the *DAG-extensions* (DAGE) problem, defined as follows. As input we are given a modular function φ that associates each DAG on N with a real number. We assume that each factor φ_v, for $v \in N$, is given explicitly as a list of argument–value pairs $(X, \varphi_v(X))$ where X runs through some collection $\mathcal{C}_v$ of subsets of $N \setminus \{v\}$. We further assume that the factor vanishes outside this collection. As input we are also given a partial order P on N. Our task is to compute the value $\varphi(P)$ defined by

$$\varphi(P) = \sum_{L \supseteq P} \sum_{A \subseteq L} \varphi(A)\,.$$

We denote by C the sum of the sizes $|\mathcal{C}_v|$, and by $\mathcal{D}$ the set of downsets of P.

Problems (a) and (a') reduce to the DAGE problem: We obtain the unnormalized posterior probability $g(P)$ as $\varphi(P)$ by letting $\varphi(A) = \kappa(A)\lambda(A)$. The collections $\mathcal{C}_v$ consists of the potential parent sets of node v. Similarly, we obtain the expectation $\mathbb{E}_\pi(f \mid P)$ of a modular feature f as a ratio $\varphi^f(P)/g(P)$ by letting $\varphi^f(A) = f(A)\kappa(A)\lambda(A)$.

In the next subsection we prove:

Theorem 15 (DAG-extensions) *Given a partial order P on N and a modular function φ over N, we can compute $\varphi(P)$ in $O\big(n^2(C + |\mathcal{D}|)\big)$ time and $O\big(n(C + |\mathcal{D}|)\big)$ space.*

To address problem (b), we define the *DAG sampling* problem as follows. Our input is as in the DAGE problem, except that we are also given a number T. Our task is to sample T independent DAGs from a distribution that is proportional to $\varphi(A)\ell(A \cup P)$. Observe that $\varphi(P)$ can be written as a sum of $\varphi(A)\ell(A \cup P)$ over all DAGs A on N. Problem (b) reduces to the DAG sampling problem in an obvious manner.

In Section 5.3 we prove:

Theorem 16 (DAG sampling) *Given a partial order P on N, a modular nonnegative function φ over N, and a number $T > 0$, we can draw T independent DAGs A on N proportionally to $\varphi(A)\ell(A \cup P)$ in $O\big(n^2(C + |\mathcal{D}| + T)\big)$ time and $O\big(nC + n^2|\mathcal{D}|\big)$ space.*

We also consider the following variant of the DAGE problem, which we call the *arc probabilities* problem. Our input is as in the DAGE problem. For a pair of nodes $s, t \in N$,

define φ^{st} as the modular function obtained from φ by setting each factor as

$$\varphi_v^{st}(A_v) \equiv \begin{cases} 0 & \text{if } t = v \text{ and } s \notin A_v\,, \\ \varphi_v(A_v) & \text{otherwise}\,. \end{cases}$$

Our task is to compute the values $\varphi^{st}(P)$ for all node pairs st. This problem models the task of computing the posterior probabilities of all arcs: we see that $\varphi^{st}(P)/g(P)$ equals $\mathbb{E}_\pi(f)$ when we set $\varphi(A) = \kappa(A)\lambda(A)$, and $f(A) = 1$ if $st \in A$ and $f(A) = 0$ otherwise.

In Section 5.4 we prove:

Theorem 17 (arc probabilities) *Given a partial order P on N and a modular function φ over N, we can compute the values $\varphi^{st}(P)$ for every pair of two nodes $s, t \in N$ simultaneously in $O\big(n^2(C + |\mathcal{D}|)\big)$ time and $O\big(n(C + |\mathcal{D}|)\big)$ space.*

5.2 Proof of Theorem 15

We prove Theorem 15 by giving an algorithm that evaluates $\varphi(P)$ in the claimed time and space. The algorithm consists of two phases, which stem from the sum–product expression

$$\varphi(P) = \sum_{L \supseteq P} \prod_v \alpha_v(L_v)\,, \quad \text{where} \quad \alpha_v(L_v) = \sum_{A_v \subseteq L_v} \varphi_v(A_v)\,. \tag{9}$$

This expression is obtained by applying the same decomposition that was used to obtain factorization (4). In the first phase of the algorithm, we compute the values $\alpha_v(L_v)$ for each $v \in N$ and every relevant subset $L_v \subseteq N \setminus \{v\}$—we will see that only the downsets of P can be relevant. In the second phase, we compute the sum over all linear extensions of P by dynamic programming across the downsets of P, now assuming efficient access to each (precomputed) value $\alpha_v(L_v)$.

Let us first consider the first phase for a fixed node v. We observe that the problem of computing the values $\alpha_v(Y)$ for all downsets $v \notin Y \in \mathcal{D}$ reduces trivially to the deflating zeta transform problem, and can thus, by Theorem 8, be solved in $O(n^2|\mathcal{C}_v| + n|\mathcal{D}|)$ time and $O(n(|\mathcal{C}_v| + |\mathcal{D}|))$ space. Summing the time bounds over the n nodes yields a time bound of $O(n^2(C + |\mathcal{D}|)$ in total. Because the working space can be reused for different nodes v, the space requirement is dominated by the input and the output size, which is $O(n(C + |\mathcal{D}|)$ in total.

Consider then the second phase. Define the function F from $\mathcal{D}$ to real numbers by letting $F(\emptyset) = 1$ and for nonempty $Y \in \mathcal{D}$ recursively:

$$F(Y) = \sum_{\substack{v \in Y \\ Y \setminus \{v\} \in \mathcal{D}}} \alpha_v\big(Y \setminus \{v\}\big)\, F\big(Y \setminus \{v\}\big)\,. \tag{10}$$

Lemma 18 below shows that $F(N) = \varphi(P)$. Thus $\varphi(P)$ can be evaluated in $O(n|\mathcal{D}|)$ time and space using the covering graph of the downset lattice (Theorem 1).

Lemma 18 *We have $F(N) = \varphi(P)$.*

Proof For any subset $Y \subseteq N$ denote by $P[Y]$ the induced partial order $\{xy \in P : x, y \in Y\}$. We show by induction on the size of Y that

$$F(Y) = \sum_{L \supseteq P[Y]} \prod_{v \in Y} \alpha_v(L_v)\,,$$

where the sum is over all linear extensions of $P[Y]$.

For the base case, consider an arbitrary singleton $Y = \{v\} \in \mathcal{D}$. From the definition we get that $F(Y) = \alpha_v(\emptyset)F(\emptyset) = \alpha_v(\emptyset)$. Likewise, the induction claim evaluates to $F(Y) = \alpha_v(\emptyset)$, as $P[Y] = \{vv\}$.

For the induction step, let $\emptyset \neq Y \in \mathcal{D}$. We write the induction claim as

$$\begin{aligned}\sum_{L \supseteq P[Y]} \prod_{v \in Y} \alpha_v(L_v) &= \sum_{u \in \max Y} \alpha_u\big(Y \setminus \{u\}\big) \sum_{L' \supseteq P[Y \setminus \{u\}]} \prod_{v \in Y \setminus \{u\}} \alpha_v(L'_v) \\ &= \sum_{\substack{u \in Y \\ Y \setminus \{u\} \in \mathcal{D}}} \alpha_u\big(Y \setminus \{u\}\big)\, F\big(Y \setminus \{u\}\big)\,,\end{aligned}$$

which equals $F(Y)$ by the recursive definition (10). ■

5.3 Proof of Theorem 16

Consider the following algorithm. First solve the corresponding instance of the DAGE problem as described in the proof of Theorem 15. Store the intermediate results in the way described in Section 2.4. This takes $O\big(n^2(C + |\mathcal{D}|)\big)$ time and $O\big(nC + n^2|\mathcal{D}|\big)$ space. (Now we do not reuse the space.)

Then, to generate one of the T independent samples, do the following:

1. Generate a random linear extension $L \supseteq P$ proportionally to $\prod_v \alpha_v(L_v)$ by stochastically backtracking the recurrence (10). Using the Alias method (Theorem 13) this takes only $O(n)$ time and space, since there are n recursive steps.

2. For each node $v \in N$, generate a random parent set $A_v \in \mathcal{C}_v \cap 2^{L_v}$ by stochastically backtracking the deflating zeta transform as described in Section 2.4. This takes $O(n^2)$ time and space by the arguments given in Section 2.4.

3. Output the obtained DAG A.

Thus the algorithm has the claimed complexity in total.

5.4 Proof of Theorem 17

We will derive an algorithm that solves the problem in the claimed time and space. The algorithm extends the forward–backward algorithm of Koivisto (2006) to accommodate the partial order constraint.

Let the functions α_v, for each node $v \in N$, be as defined in the proof of Theorem 15. Define the "forward" function $F : \mathcal{D} \to \mathbb{R}$ as in definition (10), that is, by letting $F(\emptyset) = 1$

and, recursively,

$$F(Y) = \sum_{\substack{v \in Y \\ Y \setminus \{v\} \in \mathcal{D}}} F\big(Y \setminus \{v\}\big)\, \alpha_v\big(Y \setminus \{v\}\big)\,, \quad \text{for } \emptyset \subset Y \in \mathcal{D}\,.$$

Likewise, define the "backward" function $B : \mathcal{D} \to \mathbb{R}$ by letting $B(N) = 1$ and, recursively,

$$B(Y) = \sum_{\substack{v \in N \setminus Y \\ Y \cup \{v\} \in \mathcal{D}}} \alpha_v\big(Y\big)\, B\big(Y \cup \{v\}\big)\,, \quad \text{for } N \supset Y \in \mathcal{D}\,.$$

Furthermore, for each node $t \in N$, let

$$\gamma_t(A_t) = \sum_{\substack{Y \in \mathcal{D} \\ Y \supseteq A_t}} F\big(Y\big)\, B\big(Y \cup \{t\}\big)\,, \quad \text{for } A_t \in \mathcal{C}_t\,.$$

Lemma 19 *It holds that*

$$\varphi^{st}(P) = \sum_{s \in A_t \in \mathcal{C}_t} \varphi_t(A_t)\, \gamma_t(A_t)\,. \tag{11}$$

Proof Consider a fixed pair of nodes $s, t \in N$. Starting from (9), write

$$\varphi^{st}(P) = \sum_{L \supseteq P} \left(\sum_{A_t \subseteq L_t} \varphi_t^{st}(A_t) \right) \prod_{v \neq t} \alpha_v(L_v) = \sum_{A_t \subseteq N \setminus \{t\}} \varphi_t^{st}(A_t) \overbrace{\sum_{\substack{L \supseteq P \\ L_t \supseteq A_t}} \prod_{v \neq t} \alpha_v(L_v)}^{\text{Denote by } \gamma'_t(A_t).}\,.$$

Note, that $\varphi_t^{st}(A_t)$ vanishes unless $s \in A_t$ and otherwise equals $\varphi_t(A_t)$, which in turn vanishes unless $A_t \in \mathcal{C}_t$. Thus, it remains to show that the just-introduced function γ'_t equals γ_t. To see this, we split the sum over $L \supseteq P$ and $L_t \supseteq A_t$ into two nested sums that first iterate over $L_t \supseteq A_t$ such that $L_t \in \mathcal{D}$ and then over L_v for $v \neq t$. Furthermore, once L_t is fixed in the outer sum, then the inner sum must have $L_v \subset L_t$ for $v \in L_t$ and $L_v \supseteq L_t \cup \{t\}$ for $v \in N \setminus (L_t \cup \{t\})$. The inner sum can thus be split into two independent sums, as follows:

$$\gamma'_t(A_t) = \sum_{\substack{L_t \supseteq A_t \\ L_t \in \mathcal{D}}} \left(\sum_{L' \supseteq P[L_t]} \prod_{v \in L_t} \alpha_v(L'_v) \right) \left(\sum_{L' \supseteq P[N \setminus L_{t+}]} \prod_{v \in N \setminus L_{t+}} \alpha_v(L'_v \cup L_{t+}) \right),$$

where L_{t+} is a shorthand for $L_t \cup \{t\}$. To complete the proof, we have to show that

$$F(L_t) = \sum_{L' \supseteq P[L_t]} \prod_{v \in L_t} \alpha_v(L'_v)$$

and

$$B(L_{t+}) = \sum_{L' \supseteq P[N \setminus L_{t+}]} \prod_{v \in N \setminus L_{t+}} \alpha_v(L'_v \cup L_{t+})\,.$$

The first equation follows directly from the proof of Lemma 18. The proof for the second equation is analogous, and is thus not repeated here. ■

We arrive at the following algorithm:

Algorithm AllArcs
Input: partial order P on N and $\varphi_v(A_v)$ for $(v, A_v) \in N \times \mathcal{C}_v$.
Output: $\varphi^{st}(P)$ for all pairs $s, t \in N$.

1. Compute $\alpha_v(Y)$ for all $(v, Y) \in N \times \mathcal{D}$.
2. Compute $F(Y)$ and $B(Y)$ for all $Y \in \mathcal{D}$.
3. For each $t \in N$:
   (a) Compute $\gamma_t(A_t)$ for all $A_t \in \mathcal{C}_t$.
   (b) For each $s \in N \setminus \{t\}$:
   Compute $\varphi^{st}(P)$ using (11).

The complexity of the first two steps is clearly within the claimed budget—these steps are essentially the same as in our algorithm for the DAGE problem.

Step 3a is the upward-variant of the inflating zeta transform problem and can thus, by Theorem 8 and Remark 12, be solved in $O(n^2|\mathcal{C}_t| + n|\mathcal{D}|)$ time, for each t. This gives $O(n^2(C + |\mathcal{D}|))$ time in total. The space requirement is, again, clearly within the claimed budget, since the same space can be reused for different nodes t.

Step 3b takes only $O(n|\mathcal{C}_t|)$ time for each t, thus $O(nC)$ in total. The additional space requirement is negligible.

5.5 Special Cases: Regular Parent Set Collections and Bucket Orders

We have formulated our results in a very general setting where (i) the collections $\mathcal{C}_v$ of potential parent sets can be arbitrary for each node v, and (ii) the partial order P can be arbitrary. In our bounds for the time and space requirements we have paid a relatively high cost for this generality: in many cases we obtained a running time bound of $O(n^2(C+|\mathcal{D}|))$.

It appears that these bounds can be reduced significantly if we restrict (i') the parent set collections to all sets of size at most some maximum indegree k, and (ii') the partial orders to bucket orders. This restricted setting was, in fact, considered already by Koivisto and Sood (2004, Theorem 12), who showed that (using our terminology) the DAGE problem can be solved in $O(C + n2^b)$ time, when the maximum bucket size is b. We note that this bound hides a factor that is linear in k. For the term that depends on the number of downsets, the improvement is thus from about $n^2(n/b)2^b$ to $n2^b$, assuming a balanced bucket order (see Example 4). We have observed that in this restricted setting similar improved bounds can be obtained also for the DAG sampling problem and for the arc probabilities problem (we omit details).

6. Experimental Results

We have implemented the proposed partial-order-MCMC method, including the extensions based on MC^3 and AIS, for the special case of bucket orders (see Examples 4–7).[2] We will refer to these three variants of the methods simply as MCMC, MC^3, and AIS. This section reports experimental results on a selection of data sets of different characteristics. Details of the data sets and the employed Bayesian models are given in Section 6.1. Implementation details of the computational methods are given in Section 6.2.

We aim to answer four main questions: Does sampling partial orders provide us with a significant advantage over sampling linear orders? How accurate is AIS as compared to MC^3? Does the bias correction approach (i.e., scaling by the number of linear extensions) work in practice? How well can we estimate and lower bound the marginal likelihood of the model? We address these questions in Sections 6.3–6.6, respectively.

6.1 Data Sets, Model Parameters, and Features of Interest

Table 1 lists the data sets used in our experiments. The *Flare*, *German*, *Mushroom*, and *Spambase* data sets are obtained from the UCI Machine Learning Repository (Lichman, 2013). The *Alarm* data set was generated from the Alarm network (Beinlich et al., 1989). Of the *Mushroom* data set we used both the whole data set and a subsample consisting of 1000 randomly selected records of the data set. We will refer to these two versions as *Mushroom-8124* and *Mushroom-1000*. The data set with the fewest attributes, *Flare*, was used only for examining the performance of the bias correction method of Ellis and Wong (2008).

For each data set we employed the modular and the order-modular uniform Dirichlet–multinomial model described in Examples 2 and 3. In these models we set the maximum indegree parameter k to 4 for all data sets, except for *Spambase*, for which we set the value to 3 in order to keep the per-sample computations feasible.

We focus on the estimation of the arc posterior probabilities and the marginal likelihood of the model. For comparison purposes, we also computed exact values of these quantities on the *Flare*, *German*, and *Mushroom* data sets using the algorithms of Koivisto and Sood (2004; 2006) and Tian and He (2009).

6.2 Implementation Details

We made the following implementation choices in the MCMC method:

Sampling space. The sampling space was set to the balanced bucket orders of maximum bucket size b (see Example 4). Separately for each data, we set the parameter b to a value as large as possible, subject to the condition that its impact to the running time is no more than about 2 times the impact of the terms that do not depend on b. Table 1 shows the obtained values. Note that linear orders correspond to the special case of $b = 1$.

Proposal distribution. We employed swap proposals, as described in Example 7.

2. The program BEANDisco, written in C++, is publicly available at `www.cs.helsinki.fi/u/tzniinim/BEANDisco/`.

Name	n	m	k	b	CPU time	Number of iterations: Linear orders	Number of iterations: Bucket orders
Flare	13	1066	4	–	1 d	6.1×10^8	–
German	20	1000	4	7	4 d	2.4×10^8	1.0×10^8
Mushroom	22	8124	4	7	4 d	1.9×10^8	9.6×10^7
Spambase	58	4601	3	9	4 d	1.5×10^7	9.6×10^6
Alarm	37	1000	4	10	4 d	1.0×10^7	6.3×10^6

Table 1: Data sets and basic parameters used in the experiments. Abbreviations: number of attributes n, number of data records m, maximum indegree k, maximum bucket size b.

Burn-in iterations. Always 50% of the samples were treated as burn-in samples that were not included in the estimates of the quantities of interest.

Thinning. We included only every 1024th of the visited states in the final sample.

Number of DAG samples. Per sampled partial order (after thinning), we draw as many independent DAGs as was possible within 25% of the time needed for sampling the partial order (i.e., 1024 partial orders due to thinning). In order to ensure that the varying per-DAG processing time does not cause any bias, the DAGs were drawn in two phases: First, 10% of the time budget is used to get an estimate T' for the number of DAGs that can be drawn within the remaining time budget. Then, exactly T' DAGs are drawn for the use of the algorithm.

Running time. Per configuration we allowed a total running time of 4 days (excluding the additional time used to sample the DAGs), except for the *Flare* data set, for which we only ran some of configurations and at the maximum of 1 day. Table 1 shows the approximate total number of iterations made, both for linear orders and bucket orders.

Independent runs. We ran each configuration 7 times, starting from states drawn independently and uniformly at random.

In addition to the above choices, we made the following additional choices in the MC^3 and AIS methods:

Tempering scheme. We used the linear stepping scheme. For MC^3 we varied the number of temperature levels K in $\{3, 15, 63\}$, and the thinning factor was reduced to $1024/(K+1)$ correspondingly. For AIS we set the number of levels proportionally to the data size, $K = K'mn$ where the factor K' varied in $\{1/4, 1, 4\}$. These values were found by preliminary experiments (results not shown).

Number of chain swap proposals. For MC^3 swaps of adjacent chains were proposed $1000 \times K$ times every time before moving all the chains one step. Here the rationale is that chain

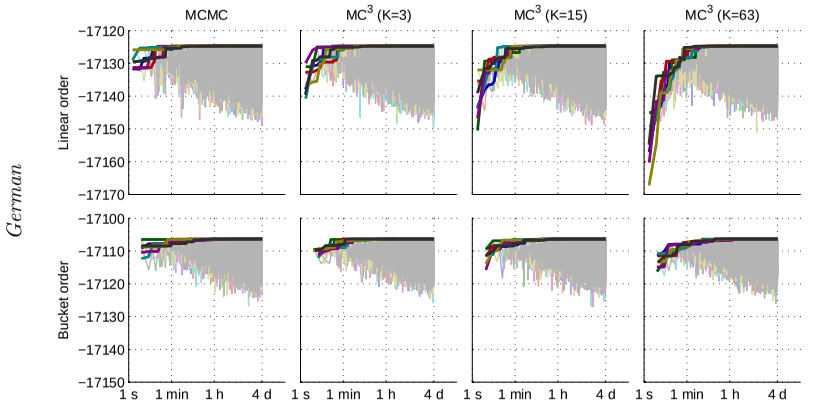

Figure 7: Mixing and convergence of MCMC and MC^3 on the *German* data set, for linear orders (top) and bucket orders (bottom). Each panel shows the traces of 7 independent runs (thin pale lines), that is, the natural logarithm of the unnormalized posterior probability of the visited state (y-axis) as a function of the time elapsed (x-axis). The cumulative maximum of these values are also shown for all the 7 runs (thick dark lines). If mixing is good, then all 7 runs should quickly converge to approximately same posterior probability levels. This seems to be the case in all eight panels. Note that posterior probabilities of linear orders and bucket orders are not directly comparable.

swaps are computationally cheap and improve mixing considerably especially when K is large.

Number of iterations along the coolest chain. For AIS we ran $K/4$ iterations along the coolest chain. Here the rationale is that collecting a large number of samples from the coolest chain is relatively cheap in comparison to the long annealing schedule. Note that thinning concerns only these $K/4$ iterations.

We will mainly examine the methods' performance as functions of running time. For visualization purposes we did a second round of thinning by an additional factor of 10. Note however that this additional thinning does not affect the estimates, which are based on the full set of samples obtained after the first round of thinning.

6.3 Advantage of Partial Orders

We first compared the effect of the sampling space—whether linear orders or bucket orders—to the mixing rate and convergence speed of the Markov chains. We did this for the basic MCMC as well as for MC^3 with varying number of temperature levels K (Figures 7–9). We found that on the *German* and *Alarm* data sets the two sampling spaces perform about

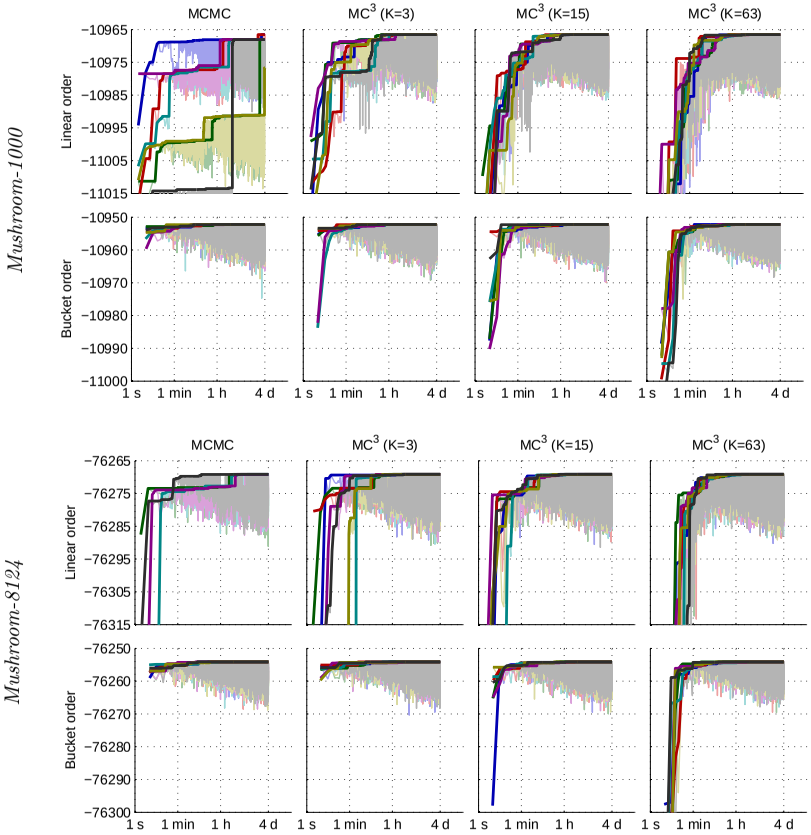

Figure 8: Mixing and convergence of MCMC and MC^3 on the *Mushroom* data sets. See the caption of Figure 7 for further descriptions. The top left panels of both data sets are examples of bad mixing. Note that MCMC with linear orders fails completely on the *Mushroom-8124* data set for 3 out of the 7 runs, and consequently the traces do not achieve the visible range of the y-axis.

equally well. On both these data sets, the chains seem to converge within a couple of minutes. We also observe that that tempering is not particularly beneficial. The results confirm that linear orders can perform very well on some data sets. The harder data sets, *Mushroom* and *Spambase*, on the other hand, separate the two sampling spaces: the performance of bucket orders is superior to linear orders. While the difference is particularly

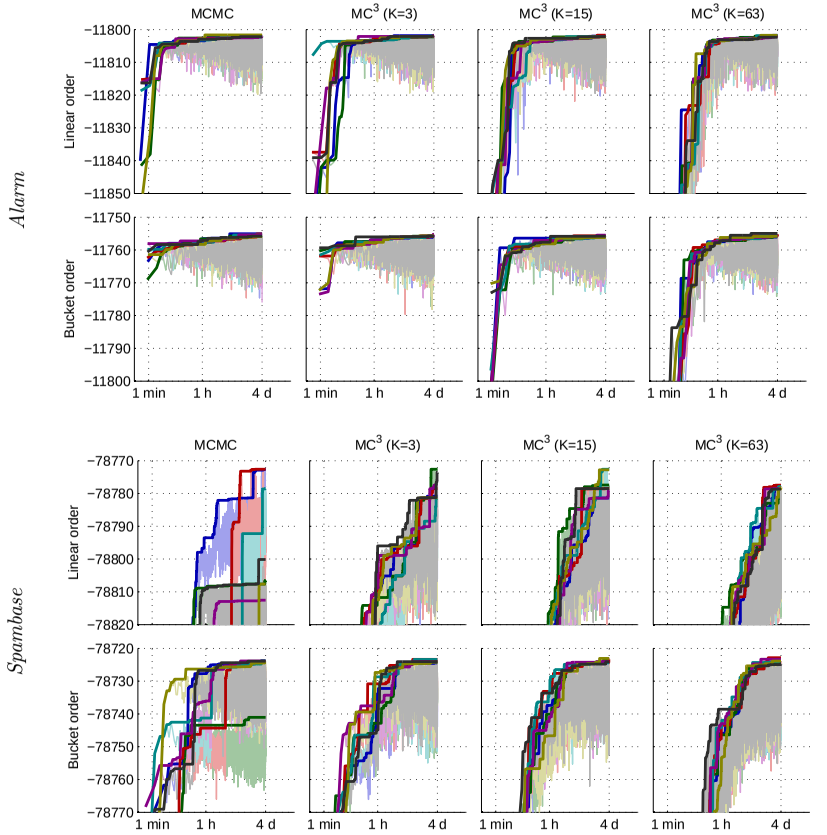

Figure 9: Mixing and convergence of MCMC and MC^3 on the *Alarm* and *Spambase* data sets. See the caption of Figure 7 for further descriptions.

large for the basic MCMC method, the difference remains significant for the MC^3 variants: On *Mushroom*, all MC^3 runs seem to converge, but the convergence is quicker when using bucket orders. On *Spambase*, it is not clear if any of the linear-order-based runs managed to converge within the given time budged, while all the bucket-order-based MC^3 runs appear to converge.

Next we investigated how the differences in mixing and convergence rates translate to differences in the accuracy of the arc posterior probability estimates under the order-modular model (i.e., without bias correction). For each pair of nodes, we measure the

accuracy by the standard deviation of the estimates in the 7 independent runs. When the exact values were available we also gauged the accuracy by the median of the 7 absolute errors. In a worst-case spirit, we report the respective the *largest standard deviation* and the *largest median error*, which we obtain by taking the maximum over the node pairs. We found that, qualitatively, the results follow closely the mixing and convergence behavior of the methods (Figure 10). Specifically, on the *German* and *Alarm* data sets all the methods perform about equally well, whereas on the *Mushroom* data sets the estimates we obtain with bucket orders are significantly more accurate than the estimates we obtain with linear orders, the difference being about one order of magnitude. On the *Spambase* data set none of the methods performs particularly well, which can be probably explained by the insufficiency of the allocated running time for achieving proper convergence. As the exact values are not available for *Spambase*, the small empirical standard deviations might be just due to similar yet insufficient convergence of the 7 runs. On the other hand, we also observe that, in general, the largest standard deviation reflects very well the largest median error.

Based on these results with different number of temperature levels K for MC^3, we fixed $K = 15$ for presenting the remaining results in the next subsections. This value of K appears to make a good compromise between a large number of iterations and fast mixing.

6.4 Accuracy of AIS

To study to performance of AIS, we compared the obtained arc posterior probability estimates to those obtained with MC^3, now with $K = 15$ only (Figure 11, left; Figure 12, left). We found that on the easiest data set, *German*, the methods perform almost identically, regardless of the value of the K' parameter. This holds also on the *Mushroom* data sets, provided that K' is large enough (1 or 4). Furthermore, we observe that bucket orders are superior to linear orders also in the case of AIS. On the *Alarm* data set AIS is slightly behind MC^3 even when sampling bucket orders, and on the *Spambase* data set the difference of the methods is larger.

Based on these results with different values of K', we fixed $K' = 1$ for presenting the remaining results in the next subsections. This value of K' appears to make a good compromise between a long annealing schedule and a relatively large number of independent samples.

6.5 Efficiency of Bias Correction

So far we have only discussed the results obtained under the order-modular model. We next turn to the results under the modular model, which we obtain by applying the bias-corrected estimators. The results are presented graphically in Figures 11–13.

First we studied the subproblem of counting the linear extensions of a given DAG. We generated random DAGs for a varying number of nodes n, setting the maximum indegree to either 3 or 6, and then ran the exact dynamic programming algorithm (from Section 2.2). We found that while both the time and the space complexity of the algorithm grow exponentially in n, the computations are feasible as long as n is at most about 40 for sparse DAGs, or at most about 60 for dense DAGs (Figure 13a). For example, the linear extensions of a 49-node DAG of maximum indegree 6 can typically be counted within a couple of seconds.

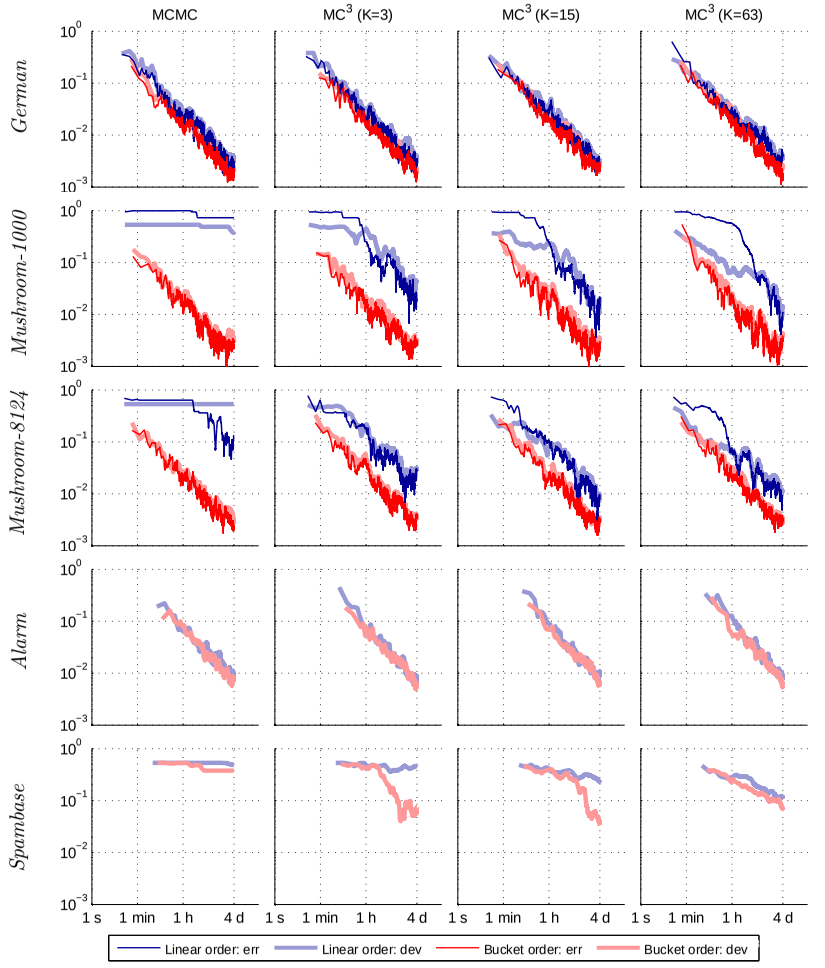

Figure 10: The accuracy of the arc posterior probability estimates under an order-modular model, for MCMC and MC^3. For each method the largest median error (err) and the largest standard deviation (dev) are shown as a function of the time elapsed.

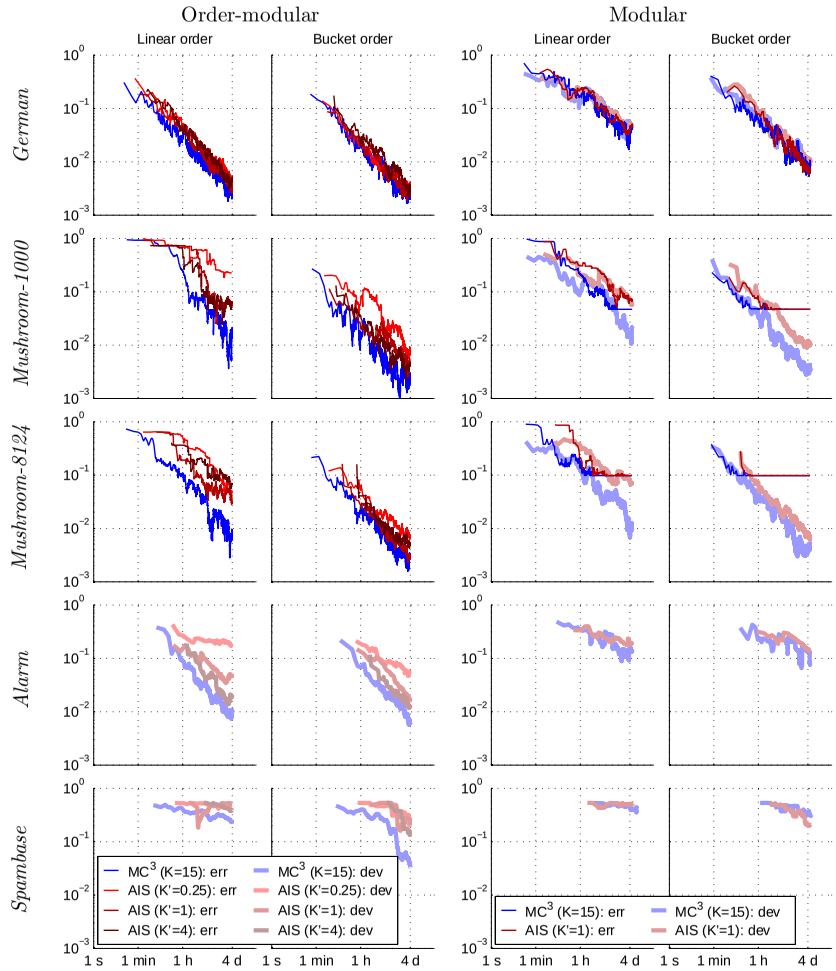

Figure 11: The accuracy of the arc posterior probability estimates under an order-modular model (left) and a modular model (right), for AIS and MC^3. For clarity, only the largest median errors are shown for the *German* and *Mushroom* data sets.

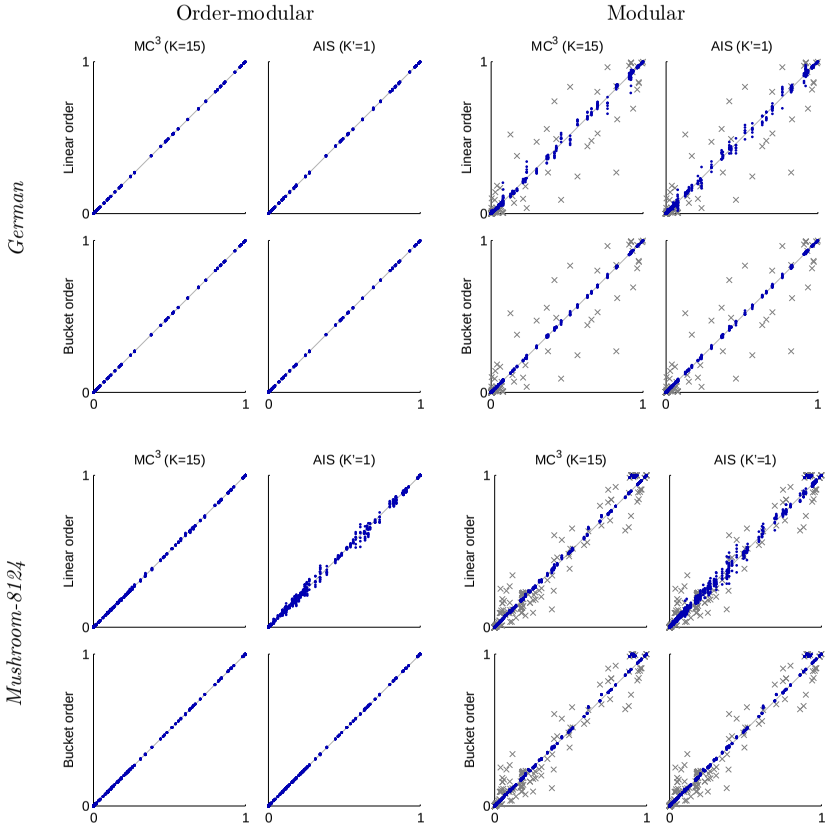

Figure 12: The arc posterior probability estimates for 7 independent runs (y-axis) plotted against the exact values (x-axis), under an order-modular and modular model. For the modular model also the biased values (exact under the order-modular model) are plotted against the unbiased exact values (gray $\times$).

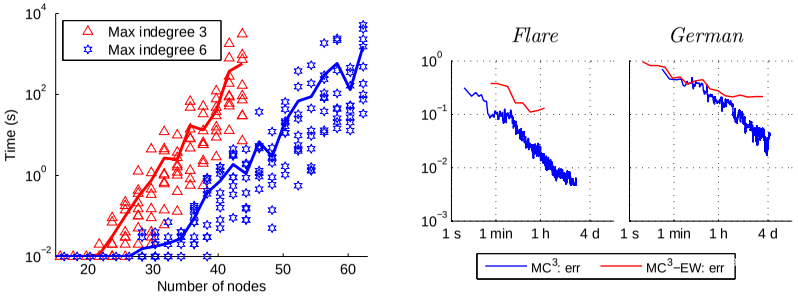
However, the simple dynamic programming algorithm does not exploit sparsity well and so the performance degrades for maximum indegree 3.

Then we compared our bias correction method to that of Ellis and Wong (2008), which we refer to as the *EW method* in the sequel. The EW method works as follows. First it draws a sample of node orderings from an approximate posterior distribution, like the order-MCMC method of Friedman and Koller (2003). Then, from each sampled node ordering, it



(a) The speed of counting linear extensions.

(b) The accuracy of bias correction methods.

Figure 13: (a) The runtime required to count the linear extensions of 9 random DAGs with a varying number of nodes and a varying maximum indegree. Runtimes less than 0.01 seconds are rounded up to 0.01. The mean of the runtimes is shown by a solid line. The available memory was limited to 16 GB. No runtime estimates are shown when the memory requirement exceeded the limit for at least one of the 9 DAGs. (b) The accuracy of the proposed bias correction method (MC^3) compared to the EW method with $\epsilon = 0.05$ (MC^3-EW). Both methods are based on sampling linear orders by MC^3 under an order-modular model. The largest median error of the arc posterior probability estimates over 7 independent runs is shown as a function of the time elapsed. The runs of the EW method terminated as soon as one of the 7 runs ran out the 20 GB of memory allocated for storing the DAGs. For the EW method the estimates were computed at doubling sample sizes $2, 4, 8, \ldots$, to make sliding burn-in periods computationally feasible.

generates a number of independent DAGs from the conditional posterior distribution until the total posterior mass of the unique DAGs obtained is at least $1 - \epsilon$, where $\epsilon > 0$ is a parameter of the method. Finally, the DAGs so obtained for each node ordering are merged into a single set, duplicates are removed, and each DAG is assigned an importance weight proportional to the posterior probability of the DAG.

The results of the comparison on the *Flare* and *German* data sets are shown in Figure 13b. On these data sets the EW method turned out to be inferior to the proposed method. On the other data sets (*Mushroom-1000*, *Mushroom-8124*, *Alarm*, *Spambase*), the EW method either ran out of memory immediately or was able to process only a couple of node ordering samples, yielding poor estimates (the largest media error close to 1; results not shown).

Finally we compared the arc posterior probability estimates under the two models, order-modular and modular (Figure 11, right). The results confirm the expectation that the estimates are less accurate under the modular model. The weaker performance is due to the additional importance sampling step needed for bias correction, which reduces the effective sample size. Otherwise, the earlier conclusions hold also under the modular model:

bucket orders outperform linear orders and MC^3 is slightly superior to AIS. However, the bias correction method also brings a new feature: on the *Mushroom* data sets the largest median error stops decreasing at some point, stagnating at an error of about 0.10 (while the largest standard deviation continues decreasing). This phenomenon is due to a few node pairs for which the arc posterior probability is very close to 1 under the order-modular model, but around 0.90 under the modular model. The culprits can be located in Figure 12 (right) as a cluster of points in the upper-right corner of the panels. Note that for the other node pairs the arc posterior probability estimates are very accurate.

6.6 Estimating the Marginal Likelihood

For estimating the marginal likelihood AIS clearly outperforms MC^3, as expected (Figure 14). The relatively small number of chains (i.e., temperature levels) in MC^3 leads to a large fluctuation in the estimates within a single run and between independent runs. AIS, on the other hand, benefits from the long annealing scheme and produces very accurate estimates on the *German* and *Mushroom* data sets. On the *Alarm* data set the variance of the estimates is larger for both methods. Yet the estimates of AIS seem to converge well. The *Spambase* data set is, again, the hardest instance for both method, the results suggesting insufficient convergence of the samplers.

We also observed that when the estimates of AIS are close to the exact value, then also the high-confidence lower bounds are very good. Indeed, on the *German* and *Mushroom* data sets the lower bounds obtained with the square-root lower-bounding scheme are within an absolute error of about 0.4 or less in the logarithmic scale, hence within a relative error of about $e^{0.4} - 1 \approx 0.4$ or less. Whether the model is order-modular or modular affects the accuracy of the marginal likelihood estimates considerably on the *German* data set but very little on the *Mushroom* data sets.

7. Conclusions and Future Work

We have investigated a sampling-based approach to Bayesian structure learning in Bayesian networks. Our work has been inspired to a large extent by the order-MCMC method of Friedman and Koller (2003), in which the sampling space consists of all possible linear orders of the nodes. Our partial-order-MCMC methods advance the methodology in four dimensions:

1. *Smoother sampling space.* The space of partial orders is smaller still than the space of linear orders. Also, the posterior distribution tends to be smoother, because the posterior probability of each partial order is obtained by summing the posterior probabilities of its linear extensions. Our empirical results agree with these expectations, and show instances where partial-order-MCMC performs significantly better than order-MCMC.

2. *Arbitrary structure priors.* We proposed a method to correct the bias that arises because the samples are drawn (approximately) from an order-modular rather than a modular posterior distribution. The correction amounts to a simple scaling term per sampled DAG. The term only depends on the number of linear extensions of the DAG, and as we showed, it can be computed sufficiently fast when the number of

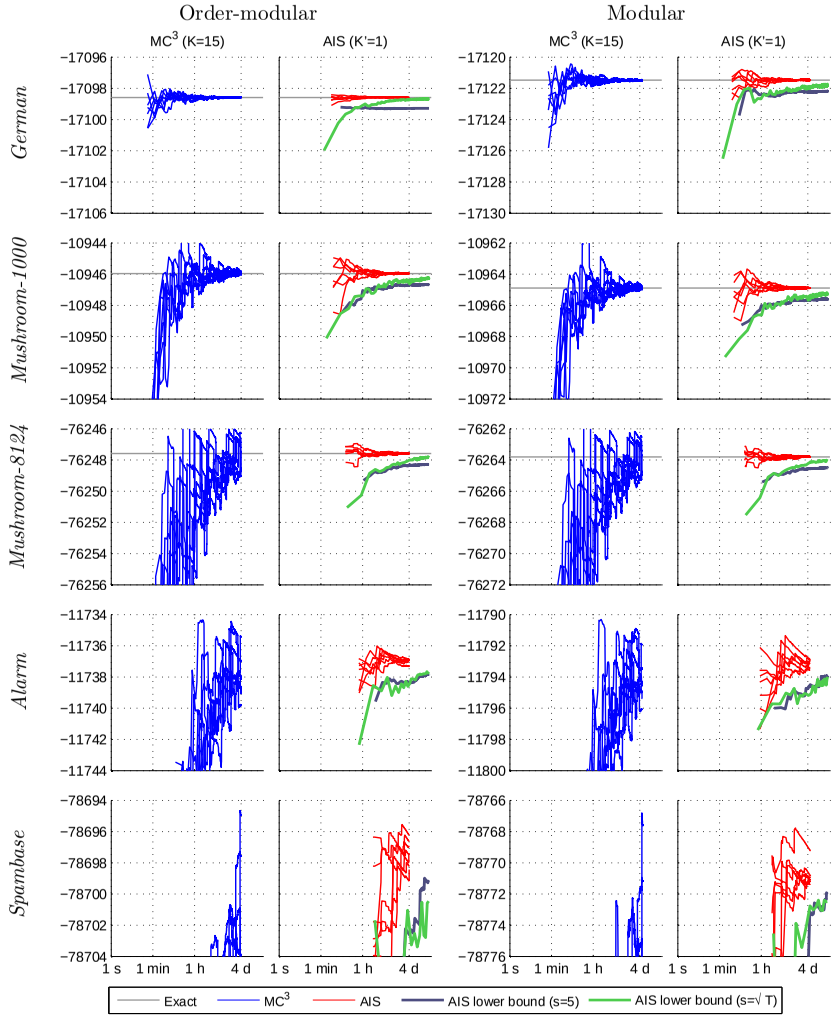


Figure 14: The marginal likelihood of the model estimated by 7 independent runs of AIS and MC^3. For AIS, shown are also lower bound estimates obtained with all the samples pooled together (thus extending the total running). The lower bound schemes are as described in Example 8 and 9. On the y-axis is the natural logarithm of the estimate or exact value.

nodes is moderate, say, at most 40. Our empirical results confirmed that, in general, the correction works well also in practice—some rare cases where the correction fails are discussed below.

For convenience, we focused on the special case where the correct model is the modular counterpart of an order-modular model. In principle, it is straightforward to extend the estimators to accommodate an arbitrary model, as long as the corresponding posterior probability function (a) can be efficiently evaluated for any given DAG (up to a normalizing constant) and (b) has a support that is contained in the support of the order-modular sampling distribution. The statistical efficiency of the estimator may, however, deteriorate if the true distribution is far from the sampling distribution.

3. *Efficient parallel computation.* We observed that the annealed importance sampling method (AIS) is easy to run in parallel, since the method is designed to produce independent samples. We compared AIS empirically to another tempering method, Metropolis-coupled MCMC (MC^3), and found that AIS-based estimates are slightly less accurate for arc posterior probabilities but significantly more accurate for the marginal likelihood of the model.

4. *Quality guarantees.* We also observed that AIS allows us to compute high-confidence lower bounds for the marginal likelihood. We showed that the lower bounds are very good, within a factor of about 1.2 on the data sets for which exact values were available. Admitted, lower bounds on the marginal likelihood is just a small step toward accuracy guarantees more generally.

These advancements (1–4) upon the order-MCMC method come essentially "for free" concerning both computational and statistical efficiency. Indeed, sampling partial orders is not more expensive than sampling linear orders, provided that the partial orders are sufficiently thin (i.e., the number of downsets is small). Namely, the bottleneck in both methods is the need to visit a large number of potential parent sets of the nodes. Likewise, while counting the linear extensions of a sampled DAG can be computationally demanding, the computational cost is compensated by the relatively small number of sampled DAGs (after thinning) as compared to the total number of partial order samples (before thinning).

The proposed methods also have shortcomings that call for further investigations. First, the complexity of the per-sample computations grows rapidly with the number of nodes n. In particular, the complexity of computing the unnormalized posterior probability of a partial order does not scale well with the indegree k, and the computations become impractical when, say, $n \geq 60$ and $k \geq 4$. For example, on the *Spambase* data set ($n = 58$, $k = 3$) we observed that the large number of potential parent sets rendered the allocated running time of 4 days insufficient for proper convergence of the sampling methods. To significantly expedite these computations, a plausible idea is to resort to approximations instead of exact computation. In the sampling space of *linear* node orders, the approach has proved successful, provided that the number of data records is large (Friedman and Koller, 2003; Niinimäki and Koivisto, 2013a). In contrast, the problem of counting the linear extensions of a sampled DAG seems to get harder for sparser DAGs. However, we believe this is rather a feature of our simple algorithm—our preliminary results with a more sophisticated algorithm suggest that sparsity can actually be turned into a computational advantage.

Second, the theoretical accuracy guarantees of the proposed methods are quite modest. For example, currently the methods do not produce good lower or upper bounds for the arc posterior probabilities. Thus the user has to resort to monitoring empirical variance and related statistics that do not always generalize well beyond the obtained sample. We saw a warning example of that on the *Mushroom* data set, where the bias-corrected estimates had small variance over 7 independent runs, but where the estimates were biased and the bias did not decrease as the number of samples grew. While this failure concerned only a few node pairs (the estimates being very accurate for the rest), it shows that sometimes the proposed bias correction method is not efficient. It may happen that all the sampled DAGs contain the arc of interest, because the biased, order-modular posterior probability of the arc is close to 1, and yet the unbiased, modular posterior probability of the arc can be much below 1, say, 0.90. In such cases the present bias correction approach may fail. It is an intriguing open question how situations of this kind can be treated or circumvented.

Acknowledgments

The authors would like to thank Kustaa Kangas for valuable discussions about the problem of counting linear extensions, and Tianqi Li for her contributions to preliminary experiments on the bias correction heuristic of Ellis and Wong (2008). Appendix A. Proofs

Lemma 7 *It holds that $\varphi_n(Y) = \widehat{\varphi}(Y)$ for all $Y \in \mathcal{D}$.*

Proof For a set X write X_i for $X \cap \{v_i\}$, and for sets X, Y write $X \subseteq_i Y$ as a shorthand for $X \subseteq Y$ and $X_j = Y_j$ for $j > i$. Let $Y \in \mathcal{D}$. We prove by induction on i that

$$\varphi_i(Y) = \sum_{\substack{X \in \mathcal{D} \\ X \subseteq_i Y}} \varphi(X)\,.$$

The claim then follows, for the condition $X \subseteq_n Y$ is equivalent to $X \subseteq Y$. Note also that the base case of $i = 0$ clearly holds, since $X \subseteq_0 Y$ is equivalent to $X = Y$.

Let then $i > 0$. Suppose first that $v_i \notin Y$ or $Y \setminus \{v_i\} \notin \mathcal{D}$. Then $\varphi_i(Y) = \varphi_{i-1}(Y)$. If $v_i \notin Y$, then the conditions $X \subseteq_i Y$ and $X \subseteq_{i-1} Y$ are equivalent, and by the induction hypothesis the claim follows. Assume then that $v_i \in Y$ and $Y \setminus \{v_i\} \notin \mathcal{D}$. By the induction hypothesis it suffices to show that, if $X \in \mathcal{D}$, then the conditions $X \subseteq_i Y$ and $X \subseteq_{i-1} Y$ are equivalent. Because the latter condition implies the former, it remains to consider the other direction. To this end, suppose the contrary, $X \subseteq_i Y$ but $X_i \neq Y_i$. Thus we must have $v_i \notin X$. However, the assumption $Y \setminus \{v_i\} \notin \mathcal{D}$ and the fact that $Y \in \mathcal{D}$ imply that there is an element $v_j \in Y \setminus \{v_i\}$ such that $v_i v_j \in P$, which, together with the ordering of the elements imply that $i < j$. Therefore, as $X \subseteq_i Y$, we have $v_j \in X$, which contradicts our assumption that $X \in \mathcal{D}$.

Suppose then that $v_i \in Y$ and $Y \setminus \{v_i\} \in \mathcal{D}$. Then $\varphi_i(Y) = \varphi_{i-1}(Y) + \varphi_{i-1}(Y \setminus \{v_i\})$. Let $X \in \mathcal{D}$. Denote the conditions of interest by

$$\begin{aligned} E &= X \subseteq_i Y\,, \\ E_1 &= X \subseteq_{i-1} Y\,, \\ E_2 &= X \subseteq_{i-1} Y \setminus \{v_i\}\,. \end{aligned}$$

By the recurrence and the induction hypothesis, it suffices to show that E holds if and only if exactly one the conditions E_1 and E_2 holds. Clearly, if either E_1 or E_2 holds, so does E. Suppose therefore that E holds. Now, either $X_i = \{v_i\} = Y_i$, in which case E_1 holds (but E_2 does not); or $X_i = \emptyset$, in which case E_2 holds (but E_1 does not). ■

Lemma 9 *Let Y and Y' be distinct downsets. Then the tails $\mathcal{T}_Y$ and $\mathcal{T}_{Y'}$ are disjoint.*

Proof Suppose the contrary that there exists a $X \in \mathcal{T}_Y \cap \mathcal{T}_{Y'}$. Since Y and Y' are distinct, by symmetry we may assume $Y \setminus Y'$ contains an element w. Thus $w \notin X$, because $X \subseteq Y'$. Since $\max Y \subseteq X$, we have $w \notin \max Y$. On the other hand, from the definition of $\max Y$ together with transitivity and acyclicity of P it follows that, for every $u \in Y \setminus \max Y$ there exists a $v \in \max Y$ such that $uv \in P$. In particular, there exists a $v \in \max Y$ such that $wv \in P$. Since $w \notin Y'$ and Y' is in $\mathcal{D}$, it follows from the definition of a downset that $v \notin Y'$. But this is a contradiction, because we had $v \in \max Y$ and $\max Y \subseteq X \subseteq Y'$, which imply $v \in Y'$. ■

Lemma 10 *Let $X \subseteq N$. Let $Y = \{u : uv \in P, v \in X\}$, that is, the downward-closure of X. Then $Y \in \mathcal{D}$ and $X \in \mathcal{T}_Y$.*

Proof To see that Y is a downset, suppose the contrary that there exist $v \in Y$ and $uv \in P$ such that $u \notin Y$. By the definition of Y, there must be $vw \in P$ such that $w \in X$. But since P is transitive, $uw \in P$ and thus $u \in Y$ which is a contradiction.

Consider then the second claim, that $\max Y \subseteq X \subseteq Y$. The second inclusion follows from the reflexivity of P. For the first inclusion, note that that $\max Y = \max X$, since Y only contains elements u such that $uv \in P$ for some $v \in X$.

■

Lemma 11 *Let $Z \subseteq N$. Then $\mathcal{D} \cap 2^Z = \mathcal{D} \cap 2^Y$, where the set $Y \in \mathcal{D}$ is given by*

$$Y = \{v \in Z : \textit{if } uv \in P, \textit{ then } u \in Z\}\,;$$

in words, Y consists of all elements of Z whose predecessors also are in Z.

Proof We show first that $Y \in \mathcal{D}$. Suppose the contrary that $v \in Y$ and $uv \in P$ but $u \notin Y$. By the definition of Y we have $u \in Z$. Since $u \notin Y$, there is a $wu \in P$ such that $w \notin Z$. However, as P is transitive, we have $wv \in P$ and thus $w \in Z$ which is a contradiction.

To complete the proof, we show that $\mathcal{D} \cap 2^Z = \mathcal{D} \cap 2^Y$. Clearly $\mathcal{D} \cap 2^Z \supseteq \mathcal{D} \cap 2^Y$. For the other direction, we consider an arbitrary $X \in \mathcal{D} \cap 2^Z$ and show that $X \subseteq Y$. To this end, consider any $v \in X$. Now, if $uv \in P$, then $u \in X$ (because X is a downset)

and consequently $u \in Z$ (because $X \subseteq Z$). Thus, by the definition of Y we get that $v \in Y$. ■

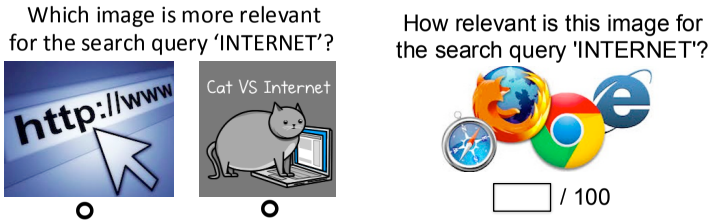
Abstract

Data in the form of pairwise comparisons arises in many domains, including preference elicitation, sporting competitions, and peer grading among others. We consider parametric ordinal models for such pairwise comparison data involving a latent vector $w^* \in \mathbb{R}^d$ that represents the "qualities" of the d items being compared; this class of models includes the two most widely used parametric models—the Bradley-Terry-Luce (BTL) and the Thurstone models. Working within a standard minimax framework, we provide tight upper and lower bounds on the optimal error in estimating the quality score vector w^* under this class of models. The bounds depend on the topology of the comparison graph induced by the subset of pairs being compared, via the spectrum of the Laplacian of the comparison graph. Thus, in settings where the subset of pairs may be chosen, our results provide principled guidelines for making this choice. Finally, we compare these error rates to those under cardinal measurement models and show that the error rates in the ordinal and cardinal settings have identical scalings apart from constant pre-factors.

1. Introduction

In an increasing range of applications, it is of interest to elicit judgments from non-expert humans. For instance, in marketing, elicitation of preferences of consumers about products, either directly or indirectly, is a common practice (Green et al., 1981). The gathering of this and related data types has been greatly facilitated by the emergence of "crowdsourcing"



(a) Asking for a pairwise comparison. (b) Asking for a numeric score.

Figure 1: An example of eliciting judgments from people: rating the relevance of the result of a search query.

platforms such as Amazon Mechanical Turk: they have become powerful, low-cost tools for collecting human judgments (Khatib et al., 2011; Lang and Rio-Ross, 2011; von Ahn et al., 2008). Crowdsourcing is employed not only for collection of consumer preferences, but also for other types of data, including counting the number of malaria parasites in an image of a blood smear (Luengo-Oroz et al., 2012); rating responses of an online search engine to search queries (Kazai, 2011); or for labeling data for training machine learning algorithms (Hinton et al., 2012; Raykar et al., 2010; Deng et al., 2009). In a different domain, competitive sports can be understood as a mechanism for sequentially performing comparisons between individuals or teams (Ross, 2007; Herbrich et al., 2007). Finally, peer-grading in massive open online courses (MOOCs) (Piech et al., 2013) can be viewed as another form of elicitation.

A common method of elicitation is through pairwise comparisons. For instance, the decision of a consumer to choose one product over another constitutes a pairwise comparison between the two products. Workers in a crowdsourcing setup are often asked to compare pairs of items: for instance, they might be asked to identify the better of two possible results of a search engine, as shown in Figure 1a. Competitive sports such as chess or basketball also involve sequences of pairwise comparisons. From a modeling point of view, we can think of pairwise comparisons as a means of estimating the underlying "qualities" or "weights" of the items being compared (e.g., skill levels of chess players, relevance of search engine results, etc.). Each pairwise comparison can be viewed as a noisy sample of some function of the underlying pair of (real-valued) weights. Noise can arise from a variety of sources. When objective questions are posed to human subjects, noise can arise from their differing levels of expertise. In a sports competition, many sources of randomness can influence the outcome of any particular match between a pair of competitors. Thus, one important goal is to estimate the latent qualities based on noisy data in the form of pairwise comparisons. A related problem is that of experimental design: assuming that we can choose the subset of pairs to be compared (e.g., in designing a chess tournament), what choice leads to the most accurate estimation? Characterizing the fundamental difficulty of estimating the weights allow us to make this choice judiciously. These tasks are the primary focus of this paper.

In more detail, the focus of this paper is the aggregation from pairwise comparisons in a fairly broad class of parametric models. This class includes as special cases the two most

popular models for pairwise comparisons—namely, the Thurstone (Case V) (Thurstone, 1927) and the Bradley-Terry-Luce (BTL) (Bradley and Terry, 1952; Luce, 1959) models. The Thurstone (Case V) model has been used in a variety of both applied (Swets, 1973; Ross, 2007; Herbrich et al., 2007) and theoretical papers (Bramley, 2005; Krabbe, 2008; Nosofsky, 1985). Similarly, the BTL model has been popular in both theory and practice (Nosofsky, 1985; Atkinson et al., 1998; Koehler and Ridpath, 1982; Heldsinger and Humphry, 2010; Loewen et al., 2012; Green et al., 1981; Khairullah and Zionts, 1987).

1.1 Related work

There is a vast literature on the Thurstone and BTL models, and we focus on those most closely related to our own work. Negahban et al. (2012) provide minimax bounds for the BTL model in the special case where the comparisons are evenly distributed. They focus on this case in order to complement their analysis of an algorithm based on a random walk. In their analysis, there is a gap between the achievable rate of the MLE and the lower bound. In contrast, our analysis eliminates this discrepancy and shows that MLE is an optimal estimator (up to constant factors) and achieves the minimax rate. In a work concurrent with our initial submission to arXiv (Shah et al., 2014), Hajek et al. (2014) consider the problem of estimation in the Plackett-Luce model, which extends the BTL model to comparisons of two or more items. They derive bounds on the minimax error rates under this model which, under certain conditions on the comparison graphs, are tight up to logarithmic factors. In general, their topology-dependent bounds rely on the degrees of the vertices in the comparison graph which makes the bounds quite loose. In contrast, our results are tight up to constants and, as we detail in the following sections, provide deeper insights into the role of the topology of the comparison graph. We elaborate on these differences in the appropriate sections in the sequel. We also note that the models studied in the present paper as well as in the aforementioned works fall under the broader paradigm of random utility models (Thurstone, 1927; Train, 2009; Azari Soufiani et al., 2013).

In other related works, Jagabathula and Shah (2008) design an algorithm for aggregating ordinal data when the underlying distribution over the permutations is assumed to be sparse. Ammar and Shah (2011) employ a different, maximum entropy approach towards parameterization and inference from partially ranked data. Rajkumar and Agarwal (2014) study the statistical convergence properties of several rank aggregation algorithms.

Our work assumes a fixed design setup. In this setup, the choice of which pairs to compare and the number of times to compare them is chosen ahead of time in a non-adaptive fashion. There is a parallel line of literature on "sorting" or "active ranking" from pairwise comparisons. For instance, Braverman and Mossel (2008) assume a noise model where the outcome of a pairwise comparison depends only on the relative ranks of the items being compared, and not on their actual ranks or values. On the other hand, Jamieson and Nowak (2011) consider the problem of ranking a set of items assuming that items can be embedded into a smaller-dimensional Euclidean space, and that the outcomes of the pairwise comparisons are based on the relative distances of these items from a fixed reference point in the Euclidean space.

A recent line of work considers a variant of the BTL and the Thurstone models where the comparisons may depend on some auxiliary unknown variable in addition to the items being compared; for instance, the accuracy of the individual making the comparison in an objective task. Chen et al. (2013) consider a crowdsourcing setup where the outcome depends on the worker's expertise. They present algorithms for inference under such a model and present empirical evaluations. Yi et al. (2013) consider a problem in the spirit of collaborative filtering where certain unknown preferences of a certain user must be predicted based on the preferences of other users as well as of that user over other items. Lee et al. (2011) consider the inverse problem of measuring the expertise of individuals based on the rankings submitted by them, and the proposed algorithms assume an underlying Thurstone model. Shah et al. (2013) make a case for ordinal evaluations in certain types of MOOC homeworks/exams and study a variant of the BTL model.

1.2 Our contributions

Both the Thurstone (Case V) and BTL models involve an unknown vector $w^* \in \mathbb{R}^d$ corresponding to the underlying qualities of d items, and in a pairwise comparison between items j and k, the probability of j being ranked above k is some function F of the difference $w^*_j - w^*_k$. The Thurstone (Case V) and BTL are based on different choices of F, and both belong to the broader class of models analyzed in this paper, in which F is required only to be strongly log-concave.

With this context, the main contributions of this paper are to provide some answers to the following questions:

- How does the minimax error for estimating the weight vector w^* in various norms scale with the problem dimension (the number of items) and the number of observations?
  - We derive upper and lower bounds on the minimax estimation rates under the model described above. Our upper/lower bounds on the estimation error agree up to constant factors: to the best of our knowledge, despite the voluminous literature on these two models, this provides the first sharp characterization of the associated minimax rates. Moreover, our error guarantees provide guidance to the practitioner in assessing the number of pairwise comparisons to be made in order to guarantee a pre-specified accuracy.
- Given a budget of n comparisons, which pairs of items should be compared?
  - The bounds that we derive depend on the comparison graph induced by the subset of pairs that are compared. Our theoretical analysis reveals that the spectral gap of a certain scaled version of the graph Laplacian plays a fundamental role, and provides guidelines for the practitioner on how to choose the subset of comparisons to be made.
- When is it better to elicit pairwise comparisons versus numeric scores?
  - When eliciting data, one often has the liberty to ask for either cardinal values (Figure 1b) or for pairwise comparisons (Figure 1a) from the human subjects. One would like to adopt the approach that would lead to a better estimate. One may be tempted to think that cardinal elicitation methods are superior, since each cardinal measurement

gives a real-valued number whereas an ordinal measurement provides at most one bit of information. Our bounds show, however, that the scaling of the error in the cardinal and ordinal settings is identical up to constant pre-factors. As we demonstrate, this result allows for a comparison of cardinal and ordinal data elicitation methods in terms of the per-measurement noise alone, *independent* of the number of measurements and the number of items. A priori, there is no obvious reason for the relative performance to be independent of the number of measurements and items.

Notation: For any symmetric matrix M of size $(m \times m)$, we let $\lambda_1(M) \leq \lambda_2(M) \leq \cdots \leq \lambda_m(M)$ denote its ordered eigenvalues. We use the notation $D_{\mathrm{KL}}(\mathbb{P}_1 \| \mathbb{P}_2)$ to denote the Kullback-Leibler divergence between the two distributions $\mathbb{P}_1$ and $\mathbb{P}_2$. For any integer m, we let $[m]$ denote the set $\{1, \ldots, m\}$. For any pair of vectors u and v of the same length, we let $\langle u, v \rangle$ denote their inner product.

2. Problem formulation

We begin with some background followed by a precise formulation of the problem.

2.1 Generative models for ranking

Given a collection of d items to be evaluated, we suppose that each item has a certain numeric *quality score*, and a comparison of any pair of items is generated via a comparison of the two quality scores in the presence of noise. We represent the quality scores as a vector $w^* \in \mathbb{R}^d$, so item $j \in [d]$ has quality score w_j^*. Now suppose that we make n pairwise comparisons: if comparison $i \in [n]$ pertains to comparing item a_i with item b_i, then it can be described by a differencing vector $x_i \in \mathbb{R}^d$, with entry a_i equal to one, entry b_i equal to -1, and the remaining entries set to 0.

With this notation, we study the problem of estimating the weight vector w^* based on observing a collection of n independent samples $y_i \in \{-1, 1\}$ drawn from the distribution

$$\mathbb{P}\big[y_i = 1 | x_i, w^*\big] = F\Big(\frac{\langle x_i,\, w^* \rangle}{\sigma}\Big) \quad \text{for } i \in [n], \tag{Ordinal}$$

where F is a known function taking values in $[0, 1]$. Since the probability of item a_i dominating b_i should be independent of the order of the two items being compared, we require throughout that $F(x) = 1 - F(-x)$.

In any model of the general form (Ordinal), the parameter $\sigma > 0$, assumed to be known, plays the role of a noise parameter, with a higher value of σ leading to more uncertainty in the comparisons. Moreover, we assume that F is *strongly log-concave* in a neighborhood of the origin, meaning that there is some curvature parameter $\gamma > 0$ such that

$$\frac{d^2}{dt^2}(-\log F(t)) \geq \gamma \quad \text{for all } t \in [-2B/\sigma, 2B/\sigma]. \tag{1}$$

Here the known parameter B denotes a bound on the ℓ_∞-norm of the weight vector, namely

$$\|w^*\|_\infty \leq B.$$

As our analysis shows, a bound of this form is fundamental: the minimax error for estimating w^* diverges to infinity if we are allowed to consider models in which B is arbitrarily large (see Proposition 17 in Appendix G). Informally, this behavior is related to the difficulty of estimating very small (or very large) probabilities that can arise in the two models for large $\|w^*\|_\infty$. Note that any model of the form (Ordinal) is invariant to shifts in w^*, that is, it does not differentiate between the vector w^* and the shifted vector $w^* + 1$, where 1 denotes the vector of all ones. Therefore, in order to ensure identifiability of w^*, we assume throughout that $\langle 1,\, w^* \rangle = 0$. We use the notation $\mathcal{W}_B$ to denote the set of permissible quality score vectors

$$\mathcal{W}_B := \big\{ w \in \mathbb{R}^d \mid \|w\|_\infty \leq B, \quad \text{and} \quad \langle 1,\, w \rangle = 0 \big\}. \tag{2}$$

Both the Thurstone (Case V) model with Gaussian noise (Thurstone, 1927) and Bradley-Terry-Luce (BTL) models (Bradley and Terry, 1952; Luce, 1959) are special cases of this general set-up, as we now describe.

Thurstone (Case V): This model is is a special case of the family (Ordinal), obtained by setting

$$F(t) = \int_{-\infty}^{t} \frac{1}{\sqrt{2\pi}} e^{-u^2/2} du, \tag{3}$$

corresponding to the CDF of the standard normal distribution. Consequently, the Thurstone model can alternatively be written as making n i.i.d. observations of the form

$$y_i = \operatorname{sign}\Big\{ \langle x_i,\, w^* \rangle + \epsilon_i \Big\}, \quad \text{for } i \in [n], \tag{Thurstone}$$

where $\epsilon_i \sim N(0, \sigma^2)$ is observation noise. It can be verified that the Thurstone model is strongly log-concave over the set $\mathcal{W}_B$ (e.g., see Tsukida and Gupta (2011)).

Bradley-Terry-Luce: The Bradley-Terry-Luce (BTL) model (Bradley and Terry, 1952; Luce, 1959) is another special case in which

$$F(t) = \frac{1}{1 + e^{-t}},$$

and hence

$$\mathbb{P}\big[y_i = 1 | x_i, w^*\big] = \frac{1}{1 + \exp\big(-\frac{\langle x_i, w^* \rangle}{\sigma}\big)} \quad \text{for } i \in [n]. \tag{BTL}$$

It can also be verified that the BTL model is strongly log-concave over the set $\mathcal{W}_B$.

Cardinal observation models: While our primary focus is on the pairwise-comparison setting, for comparison purposes we also analyze analogous cardinal settings where each observation is real valued. In particular, we consider the following two cardinal analogues of the Thurstone model. In the Cardinal model we consider, each observation $i \in [n]$ consists of a numeric evaluation $y_i \in \mathbb{R}$ of a single item,

$$y_i = \langle u_i,\, w^* \rangle + \epsilon_i \qquad \text{for } i \in [n], \tag{Cardinal}$$

where u_i in this case is a coordinate vector with one of its entries equal to 1 and remaining entries equal to 0, and ϵ_i is independent Gaussian noise $N(0, \sigma^2)$. One may alternatively elicit cardinal values of the differences between pairs of items

$$y_i = \langle x_i, w^* \rangle + \epsilon_i \qquad \text{for } i \in [n], \tag{Paired Cardinal}$$

where ϵ_i are i.i.d. $N(0, \sigma^2)$. We term this model the Paired Cardinal model.

2.2 Fixed design and the graph Laplacian

We analyze the estimation error when a fixed subset of pairs is chosen for comparison. Of interest to us is the *comparison graph* defined by these chosen pairs, with each pair inducing an edge in the graph. Edge weights are determined by the fraction of times a given pair is compared. The analysis in the sequel reveals the central role played by the Laplacian of this weighted graph. Note that we are operating in a fixed-design setup where the graph is constructed offline and does not depend on the observations.

In the ordinal models, the i^{th} measurement is related to the difference between the two items being compared, as defined by the measurement vector $x_i \in \mathbb{R}^d$. We let $X \in \mathbb{R}^{n \times d}$ denote the measurement matrix with the vector x_i^T as its i^{th} row. The Laplacian matrix L associated with this differencing matrix is given by

$$L := \frac{1}{n} X^T X \;=\; \frac{1}{n} \sum_{i=1}^{n} x_i x_i^T. \tag{4}$$

By construction, for any vector $v \in \mathbb{R}^d$, we have $v^T L v = \sum_{j \neq k} L_{jk} (v_j - v_k)^2$, where L_{jk} is the fraction of the measurement vectors $\{x_i\}_{i=1}^n$ in which items (j, k) are compared.

The Laplacian matrix is positive semidefinite, and has at least one zero-eigenvalue, corresponding to the all-ones eigenvector. The Laplacian matrix induces a graph on the vertex set $\{1, \ldots, d\}$, in which a given pair (j, k) is included as an edge if and only if $L_{jk} \neq 0$, and the weight on an edge (j, k) equals L_{jk}. We emphasize that throughout our analysis, we assume that the comparison graph is *connected*, since otherwise, the quality score vector w^* is not identifiable. Note that the Laplacian matrix L induces a semi-norm[1] on $\mathbb{R}^d$, given by

$$\|u - v\|_L := \sqrt{(u - v)^T L (u - v)}. \tag{5}$$

We study optimal rates of estimation in this semi-norm, as well as the usual ℓ_2-norm. As will be clearer in the sequel the L semi-norm is a natural metric in our setup, and estimation in this induced metric can be done at a topology independent rate. The estimation error in the L semi-norm is closely related to the prediction risk in generalized linear models. In particular, for an estimate $\widehat{w}$ of w^* from n_{ij} comparisons between each pair of items (i, j), we have $\|\widehat{w} - w^*\|_L^2 = \sum_{i<j} n_{ij} \big((\widehat{w}_i - \widehat{w}_j) - (w_i^* - w_j^*)\big)^2$. It arises naturally when one is interested in predicting the probability of a certain outcome for a new comparison.

1. A semi-norm differs from a norm in that the semi-norm of a non-zero element is allowed to be zero.

3. Bounds on the minimax risk

In this section, we state the main results of the paper, and discuss some of their consequences.

3.1 Minimax rates in the squared L semi-norm

Our first main result provides bounds on the minimax risk under the squared L semi-norm (5) in the pairwise comparison models introduced earlier. In all of the statements, we use c_1, c_2, etc. to denote positive numerical constants, independent of the sample size n, number of items d and other problem-dependent parameters.

Apart from the curvature parameter γ defined earlier in (1), the bounds presented subsequently depend on F through a second parameter ζ, defined as

$$\zeta := \frac{\max\limits_{x \in [0, 2B/\sigma]} F'(x)}{F(2B/\sigma)(1 - F(2B/\sigma))}. \tag{6}$$

In the BTL and the Thurstone models, we have $\zeta := \frac{F'(0)}{F(2B/\sigma)(1-F(2B/\sigma))}$. For instance, when $B = \sigma = 1$, then under the BTL model we have $\gamma = 0.25$ and $\zeta = 1.43$. As observed in Negahban et al. (2015), the reader may consider the parameters B, σ, γ and ζ as having $\mathcal{O}(1)$ values: a fixed value of B is the hardest regime, and furthermore, in situations of practical interest, the problem dependent parameters σ, γ and ζ, are typically independent of d and n. Consequently, in the sequel, we treat these parameters as fixed.

Theorem 1 (Bounds on minimax rates in L semi-norm)

(a) For a sample size $n \geq \frac{c_1 \sigma^2 \operatorname{tr}(L^\dagger)}{\zeta B^2}$, any estimator $\widetilde{w}$ based on n samples from the Ordinal *model has Laplacian squared error lower bounded as*

$$\sup_{w^* \in \mathcal{W}_B} \mathbb{E}\Big[\|\widetilde{w} - w^*\|_L^2\Big] \geq \frac{c_{1\ell}}{\zeta}\, \sigma^2 \frac{d}{n}. \tag{7a}$$

(b) For any instance of the Ordinal *model with γ-strong log-concavity and any $w^* \in \mathcal{W}_B$, the maximum likelihood estimator satisfies the bound*

$$\mathbb{P}\Big[\|\widehat{w}_{ML} - w^*\|_L^2 > t \frac{c \zeta^2 \sigma^2}{\gamma^2} \frac{d}{n}\Big] \leq e^{-t} \quad \text{for all } t \geq 1,$$

and consequently

$$\sup_{w^* \in \mathcal{W}_B} \mathbb{E}\Big[\|\widehat{w}_{ML} - w^*\|_L^2\Big] \leq \frac{c_{1u} \zeta^2}{\gamma^2} \sigma^2 \frac{d}{n}. \tag{7b}$$

The results of Theorem 1 characterize the minimax risk in the squared L semi-norm up to constant factors. The upper bounds follow from an analysis of the maximum likelihood estimator, which turns out to be a convex optimization problem. On the other hand, the lower bounds are based on a combination of information-theoretic techniques and carefully constructed packings of the parameter set $\mathcal{W}_B$. The main technical difficulty is in constructing a packing in the semi-norm induced by the Laplacian L. See Appendix A for the full proof.

3.2 Minimax rates in the squared ℓ_2-norm

Let us now turn to optimizing the minimax risk under the squared Euclidean norm. Theorem 2 below presents upper and lower bounds on this quantity.

Theorem 2 (Bounds on minimax rates in ℓ_2-norm)

(a) For a sample size $n \geq \frac{c_2 \sigma^2 \mathrm{tr}(L^\dagger)}{\zeta B^2}$, any estimator $\widetilde{w}$ based on n samples from the Ordinal *model has squared Euclidean error lower bounded as*

$$\sup_{w^* \in \mathcal{W}_B} \mathbb{E}\Big[\|\widetilde{w} - w^*\|_2^2\Big] \geq c_{2\ell} \frac{\sigma^2}{n} \max\Big\{d^2, \max_{d' \in \{2,\ldots,d\}} \sum_{i=\lceil 0.99 d' \rceil}^{d'} \frac{1}{\lambda_i(L)}\Big\}. \tag{8a}$$

(b) For any instance of the Ordinal *model with γ-strong log-concavity and any $w^* \in \mathcal{W}_B$, the maximum likelihood estimator satisfies the bound*

$$\mathbb{P}\Big[\|\widehat{w}_{ML} - w^*\|_2^2 > t \frac{c\zeta^2\sigma^2}{\gamma^2} \frac{d}{\lambda_2(L)n}\Big] \leq e^{-t} \quad \textit{for all } t \geq 1, \tag{8b}$$

and consequently

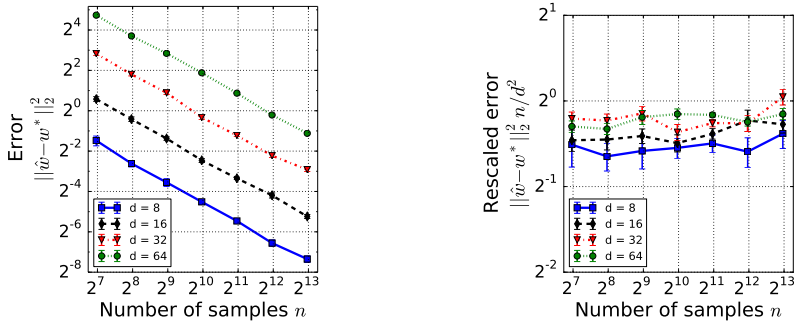
$$\sup_{w^* \in \mathcal{W}_B} \mathbb{E}\Big[\|\widehat{w}_{ML} - w^*\|_2^2\Big] \leq \frac{c_{2u}\zeta^2}{\gamma^2} \sigma^2 \frac{d}{\lambda_2(L)n}. \tag{8c}$$

See Appendix B for the proof of this theorem. As we describe in the next section, the upper and lower bounds on minimax risk from Theorem 2 to identify the comparison graph(s) that lead to the best possible minimax risk over all possible graph topologies.

Figure 2 depicts results from simulations under the Thurstone model, depicting the squared ℓ_2 error for the maximum likelihood estimator for various values of n and d. In the simulations, the true vector w^* is generated by first drawing a d-length vector uniformly at random from $[-1, 1]^d$, followed by a scale and shift to ensure $w^* \in \mathcal{W}_B$. The n pairs are chosen uniformly (with replacement) at random from the set of $\binom{d}{2}$ possible pairs of items. The value of σ and B are both fixed to be 1. Given the n samples, inference is performed via the maximum likelihood estimator for the Thurstone model. Each point in the plots is an average of 20 such trials.

The error in Figure 2 reduces linearly with n, exactly as predicted by our Theorem 2. For the complete graph, $\frac{1}{\lambda_2(L)} = \frac{d-1}{2}$. Theorem 2 thus predicts a quadratic increase in the error with d. As predicted, the error when normalized by $\frac{1}{d^2}$ in Figure 2 converges to the same curve for all values of d.

Detailed comparison with other work: Having stated our main theoretical results we are now in a position to revisit the results of the earlier works of Negahban et al. (2012, 2015); Hajek et al. (2014). The papers by Negahban et al. (2012, 2015) consider the BTL model under a restricted sampling setting in which every pair considered is compared the same number of times. For the problem of recovering the vector w^* (as considered in the present paper), they derive upper bounds when the pairs considered for comparisons arise



(a) Error (b) Rescaled error

Figure 2: Simulation results under the Thurstone model. The comparison topology chosen here is the complete graph.

from an Erdős-Rényi comparison graph; setting $t = \log d$ in equation (8b) in Theorem 2 above recovers their results. The two papers also provide results pertaining to inference of a set of parameters that are an exponentiated form of w^*. Their upper bounds for these parameters are derived in terms of the random-walk normalized Laplacian matrix of the comparison graph, while our bounds for w^* are derived in terms of the (combinatorial) Laplacian matrix. Their associated information-theoretic lower bounds also assume an Erdős-Rényi comparison graph whereas our lower bounds apply to general comparison graphs.

A concurrent paper by Hajek et al. (2014) also considers the specific BTL model, but a general comparison topology. Their high-probability upper bounds can be recovered by setting $t = \log d$ in equation (8b) of Theorem 2, while their upper bounds on the expected error are loose by a logarithmic factor. On the other hand, the lower bounds of Hajek et al. (2014), although dependent on topology, are quite loose due to their reliance on the degrees of the vertices in the comparison graph. On the other hand, our results are derived in terms of the graph Laplacian which better captures the critical aspects of the problem. For instance, considering a disconnected graph where every node has at least one neighbor as a sanity check, the degree-based lower bounds of Hajek et al. (2014) do not reflect the non-identifiability of w^* due to their reliance on only the degrees of the vertices, whereas the presence of the spectral gap in our bound (8a) indicates non-identifiability. As another example, the bounds of Hajek et al. (2014) cannot distinguish between a star graph and a path graph, whereas our results establish the star graph as an optimal comparison graph and the path graph as strictly suboptimal. In Section 4 below, we further describe deeper insights on the graph topology derived from our analytical results.

The Paired Cardinal *model:* Before concluding this section, we also look at the Paired Cardinal model (Section 2.1), the cardinal analogue of the Thurstone model.

Theorem 3 (Bounds on minimax rates in ℓ_2-norm) *For the* Paired Cardinal *model, the minimax risk is sandwiched as*

$$c_{3\ell}\,\sigma^2\frac{\mathrm{tr}(L^\dagger)}{n} \le \inf_{\widehat{w}}\sup_{w^*\in\mathcal{W}_\infty}\mathbb{E}\Big[\|\widehat{w}-w^*\|_2^2\Big] \le c_{3u}\,\sigma^2\frac{\mathrm{tr}(L^\dagger)}{n}. \tag{9}$$

The proof of Theorem 3 is available in Appendix C.

We conjecture that the dependence of the squared ℓ_2 minimax risk under the Ordinal models on the problem parameters n, d and the graph topology is identical to that derived in Theorem 3 for the Paired Cardinal model, i.e., is proportional to $\frac{\mathrm{tr}(L^\dagger)}{n}$. Note that the condition $\mathrm{tr}(L)=2$ implies that $\frac{d^2}{9} \le \mathrm{tr}(L^\dagger) \le \frac{d}{\lambda_2(L)}$.

3.3 Extension to m-ary comparisons

Suppose instead of eliciting pairwise comparisons, one can instead ask the workers to make comparisons between more than two options. In particular, we assume that each sample is a selection of the item with the largest perceived quality among some m presented items. The setting of pairwise comparisons is a special case with $m=2$. Recall from Theorem 2 that the minimum squared ℓ_2 minimax risk in the pairwise comparison setting is of the order $\frac{d^2}{n}$. Our goal in this section is to bring the concept of multiple-item comparison under the same framework as the pairwise case, and via a generalization of our earlier theoretical analysis, understand how the error exponent depends on m.

Consider d items, where every item $j\in[d]$ has a certain underlying quality score $w_j^*\in[-B,B]$. Suppose you have access to n samples, with each sample being a selection of the item with the largest perceived value among some m presented items.

Consider $(d\times m)$ matrices $E_1,\ldots,E_n$ such that for each $i\in[n]$, the m columns of E_i are distinct unit vectors. The positions of the non-zero elements in the m columns of E_i represent the identities of the m items compared in the i^{th} sample. One can visualize the choices of the items compared as a hyper-graph, with d vertices representing the d items and hyper-edge $i\in[n]$ containing the m items compared in observation i.

Let $R_1,\ldots,R_m$ be $(m\times m)$ permutation matrices representing m cyclic shifts in an arbitrary (but fixed) direction. Consider the observation model

$$\mathbb{P}(y_i=j|w^*,E_i) = F((w^*)^TE_iR_j)$$

for all $j\in[m]$, where $F:[-B,B]^m\to[0,1]$ represents the probability of choosing the *first* among the m items presented. We also assume that F does not depend on the *order* of the last $(m-1)$ coordinates in its input, meaning that the likelihood of choosing an item is independent of the ordering of the m items in the argument to F. For every $x\in[-B,B]^m$, $F(x)$ is assumed to satisfy:

- Shift-invariance: the probabilities depend only on the *differences* in the weights of the items presented, i.e, $F(x)$ depends only on $\{x_i-x_j\}_{i,j\in[m]}$.
- Strong log-concavity: $\nabla^2(-\log F(x)) \succeq H$ for some $(m\times m)$ symmetric matrix H with $\lambda_2(H)>0$.

Note that the shift-invariance assumption implies $1\in\mathrm{nullspace}(\nabla^2(-\log F(x)))$, thereby necessitating $\mathrm{nullspace}(H)=\mathrm{span}(1)$ and $\lambda_1(H)=0$. One can also verify that the model proposed here reduces to the Ordinal model of Section 2.1 when $m=2$.
