We start with two results (Lemmas 4 and 5 below) on properties of the metric space $(\mathcal{X}, \rho)$ which affect the behavior of a distance-based regressor such as $f_{n,\epsilon,\rho}$. All omitted proofs are given in the appendix.

The first Lemma 4 concerns the size of minimal covers (at different scales) of the metric $(\mathcal{X}, \rho)$. Such cover sizes influence the variance of a distance-based regressor operating on $(\mathcal{X}, \rho)$. If $(\mathcal{X}, \rho)$ has small cover-sizes, it can typically be covered by large balls, each ball likely to contain enough data for small regression variance. Lemma 4 roughly states that, while a minimal ϵ-cover of the Euclidean space $\mathcal{X} \subset \mathbb{R}^d$ has size $O\left(\epsilon^{-d}\right)$, an $\epsilon\rho(\mathcal{X})$-cover of $(\mathcal{X}, \rho)$ has smaller size $C\epsilon^{-r}$ where $|R| \leq r \xrightarrow{\epsilon \to 0} d$. Both C and the function $r(\epsilon)$ depend on the relative distribution of weights $\mathbf{W}_i$ as captured by the quantities $|R|$, $\epsilon_{R\!\!R}$ and κ_R.

Lemma 4 (Covering numbers) *Consider $R \subset [d]$ such that $\max_{i \notin R} \mathbf{W}_i < \min_{i \in R} \mathbf{W}_i$. There exist $C \leq C'(4\kappa_R)^{|R|}$ such that, for any $\epsilon > 0$, the smallest $\epsilon\rho(\mathcal{X})$-cover of $(\mathcal{X}, \rho)$ has size at most $C\epsilon^{-r(\epsilon)}$, where $r(\epsilon)$ is a nondecreasing function of ϵ satisfying*

$$r(\epsilon) \leq \begin{cases} |R| & \text{if } \epsilon \geq \epsilon_{R\!\!R}/\rho(\mathcal{X}) \\ d - (d - |R|) \cdot \frac{\log(\rho(\mathcal{X})/\epsilon_{R\!\!R})}{\log(1/\epsilon)} & \text{if } \epsilon < \epsilon_{R\!\!R}/\rho(\mathcal{X}) \end{cases}$$

The function $r(\epsilon)$ captures the *dimension* of $(\mathcal{X}, \rho)$[2]. We thus want r to be small so that the transformation ρ acts like a low-dimensional projection and hence helps reduce variance. The function r is smallest when most weights are concentrated in a small subset R, i.e. we want small $|R|$ and small $\epsilon_{R\!\!R}/\rho(\mathcal{X})$ (this term captures the difference in magnitude between weights not in R and weights in R). It might therefore seem preferable to choose ρ in this way, but we have to be careful: not all dimension reduction is good since such a transformation ρ might introduce additional regression bias. We therefore need to understand how regression bias is affected by the distribution of weights $\mathbf{W}_i$ in the transformation ρ.

Lemma 5 below captures the smoothness properties of the target function f in the transformed metric $(\mathcal{X}, \rho)$. These smoothness properties affect the bias of distance-based regressors on $(\mathcal{X}, \rho)$.

2. The logarithm of covering numbers is a common measure of metric dimension, see e.g. Clarkson (2005) for an overview of the subject.

Lemma 5 (Change in Lipschitz smoothness for f) *Suppose each derivative f_i' is bounded on $\mathcal{X}$ by $|f_i'|_{sup}$. Assume $\mathbf{W}_i > 0$ whenever $|f_i'|_{sup} > 0$. Denote by R the largest subset of $[d]$ such that $|f_i'|_{sup} > 0$ for $i \in R$. We have for all $x, x' \in X$,*

$$\left|f(x) - f(x')\right| \leq \left(\sum_{i \in R} \frac{|f_i'|_{sup}}{\sqrt{\mathbf{W}_i}}\right) \rho(x, x').$$

We want f to be as smooth as possible, in other words we want the Lipschitz parameter $\left(\sum_{i \in R} \frac{|f_i'|_{\sup}}{\sqrt{\mathbf{W}_i}}\right)$ as small as possible. Suppose $\mathbf{W}_i$ is uncorrelated with the variation of f along i, e.g. $\mathbf{W}_i$ is small for those coordinates where $|f_i'|_{\sup}$ is large, then the function f might end up lacking smoothness in the modified space $(\mathcal{X}, \rho)$. While it is hard to estimate $|f_i'|_{\sup}$, we can expect it to be correlated with $\|f_i'\|_{1,\mu}$ which is easier to estimate (Section 3). Thus by keeping the weights $\mathbf{W}_i$ correlated with the gradient norms $\|f_i'\|_{1,\mu}$, we expect the function f to remain relatively smooth in the space $(\mathcal{X}, \rho)$ and hence we expect to maintain control on regression bias. Since it is unlikely in practice that f varies equally in all coordinates (Figure 3), in light of Lemma 20, we will expect better regression performance in the space $(\mathcal{X}, \rho)$ as variance should decrease while bias remains controlled.

Remark 2.2 *As previously mentioned, there are many ways to incorporate the coordinate-wise variability of f into the weights ρ, and GW (or Relief heuristics discussed in Section 6.2) is just one of this. In light of the Lipschitz parameter $\left(\sum_{i \in R} \frac{|f_i'|_{sup}}{\sqrt{\mathbf{W}_i}}\right)$, we could reasonably set $\mathbf{W}_i$ to approximate $\|f_i'\|_{1,\mu}^q$ for some $q > 0$ ($q = 1, 2$ in this work), or to $\|f_i'\|_{1,\mu}^{q_i}$ for some power q_i depending on i. These are interesting questions deserving further investigation.*

We now go further in formalizing the intuition discussed so far by considering the case of kernel regression in $(\mathcal{X}, \rho)$. We will derive exact conditions on the distribution of weights $\mathbf{W}_i$ that allow improvements over the minimax rate of $O\left(n^{-2/(2+d)}\right)$ in the non-asymptotic regime.

The box-kernel regression estimate is defined as follows.

Definition 6 *Given $\epsilon > 0$ and $x \in \mathcal{X}$, the box-kernel estimate at x is defined as follows. Recall that $\rho(\mathcal{X}) \triangleq \sup_{x,x' \in \mathcal{X}} \rho(x, x')$ denotes the ρ-diameter of $\mathcal{X}$:*

$$f_{n,\epsilon,\rho}(x) \triangleq \text{average } Y_i \text{ of points } X_i \in B(x, \epsilon\rho(\mathcal{X})), \text{ or } 0 \text{ if } B(x, \epsilon\rho(\mathcal{X})) \text{ is empty.}$$

The next lemma establishes the convergence rate for a box-kernel regressor using any given bandwidth $\epsilon\rho(\mathcal{X})$. The lemma is a simple application of known results on the bias and variance of a kernel regressor combined with the previous two lemmas on the dimension of $(\mathcal{X}, \rho)$ and the smoothnness of f on $(\mathcal{X}, \rho)$.

Lemma 7 (Rate for $f_{n,\epsilon,\rho}$, arbitrary ϵ) *Consider any $R \subset [d]$ such that $\max_{i \notin R} \mathbf{W}_i < \min_{i \in R} \mathbf{W}_i$. There exist $1 \leq C_{\kappa_R} \leq C'(4\kappa_R)^{|R|}$, a universal constant C, and $\lambda_\rho \geq \sup_i |f_i'|_{sup} / \sqrt{\mathbf{W}_i}$ such that*

$$\mathop{\mathbb{E}}_{\mathbf{X}^n, \mathbf{Y}^n} |f_{n,\epsilon,\rho} - f|^2 \leq C_{\kappa_R} \frac{\epsilon^{-r(\epsilon)}}{n} + C^2 d^2 \lambda_\rho^2 \epsilon^2 \rho(\mathcal{X})^2,$$

where $r(\epsilon)$ is defined as in Lemma 4.

Proof By Lemma 5, f is $(d\lambda_\rho)$-Lipschitz on $(\mathcal{X}, \rho)$. We can then apply Theorem 5.2 of Gyorfi et al. (2002)[3] to bound the L_2 error as

$$\mathop{\mathbb{E}}_{\mathbf{X}^n, \mathbf{Y}^n} \mathop{\mathbb{E}}_{X} |f_{n,\epsilon,\rho}(X) - f(X)|^2 \leq C_1^2 \frac{N_\epsilon}{n} + C^2 d^2 \lambda_\rho^2 \epsilon^2 \rho(\mathcal{X})^2,$$

for some universal constants C_1, C, where N_ϵ denotes the size of a minimal $\epsilon\rho(\mathcal{X})$-cover of $(\mathcal{X}, \rho)$. Apply Lemma 4 to conclude. ■

We can now derive conditions on the distribution of weights $(\mathcal{X}, \rho)$ that permit good performance relative to the minimax rate of $O\left(n^{-2/(2+d)}\right)$. These conditions are given in equation (2). The main message of Corollary 8 below is that improvement in rate is possible in the non-asymptotic regime under rather mild conditions on the distribution of weights $\mathbf{W}_i$, even though improvement might not be possible in the asymptotic regime. In light of (2) sparseness (as described in Section 2.1) is not required, we simply need the function f to vary more along a small subset of coordinates ($R \subset [d]$) than along other coordinates, provided the weights $\mathbf{W}_i$ are properly correlated with the variation in f along coordinates. The correlation between $\mathbf{W}_i$ and gradients of f is implicit in the ratio $\lambda_\rho \rho(\mathcal{X})/\lambda$ of (2). The quantity λ captures the smoothness of f before the data transformation ρ, while λ_ρ captures the smoothness of f after the transformation ρ. The ratio $\lambda_\rho \rho(\mathcal{X})/\lambda$ thus captures the loss in smoothness (taking into account the change in diameter from 1 to $\rho(\mathcal{X})$) due to the transformation ρ, and this loss is controlled if $\mathbf{W}_i$ is correlated with the magnitude of the coordinate-wise derivatives of f.

Corollary 8 (Rate for $f_{n,\epsilon,\rho}$, optimal ϵ) *Let $\lambda \triangleq \sup_{i \in [d]} |f_i'|_{sup}$ and $\lambda_\rho \triangleq \sup_{i \in [d]} |f_i'|_{sup} / \sqrt{\mathbf{W}_i}$. Note that by definition $f \in \mathcal{F}_\lambda$. Let C_{κ_R} and C be defined as in Lemma 7, and $\tilde{c}$ as in Theorem 2. Suppose the following holds for some $R \subset [d]$:*

$$(d - |R|) \log\left(\frac{\rho(\mathcal{X})}{\epsilon_R}\right) \geq d \log\left(C \frac{\lambda_\rho \rho(\mathcal{X})}{\lambda}\right) + \log\left(\frac{C_{\kappa_R}}{\tilde{c}}\right). \tag{2}$$

Then there exists n_0 for which the following holds. For all $n \geq n_0$, there exist a bandwidth ϵ_n, and $r = r(\epsilon_n)$, where $|R| \leq r < d$, such that,

$$\mathbb{E} \|f_{n,\epsilon_n,\rho} - f\|^2 \leq 2C_{\kappa_R}^{2/2+r} (Cd\lambda_\rho \rho(\mathcal{X}))^{2r/(2+r)} n^{-2/2+r} < \inf_{f_n} \sup_{\mathcal{F}_\lambda} \mathbb{E} \|f_n - f\|^2.$$

Proof For $\epsilon > 0$, and $n \in \mathbb{N}$. Let $r(\epsilon)$ as in Lemma 4. Define the functions $\psi_{n,\rho}(\epsilon) = C_{\kappa_R} \epsilon^{-r(\epsilon)}/n$, and $\psi_{n,\not\rho}(\epsilon) = C_1' \epsilon^{-d}/n$, where $C_1' = \tilde{c}\left(\lambda / C\lambda_\rho \rho(\mathcal{X})\right)^d$. We also define $\phi(\epsilon) = C^2 d^2 \lambda_\rho^2 \rho(\mathcal{X})^2 \cdot \epsilon^2$.

Now recall (Theorem 2) that the minimax rate can be bounded below by

$$2\tilde{c}^{2/(2+d)} (d\lambda)^{2d/(2+d)} n^{-2/2+d}.$$

For any fixed n, let $\epsilon_{n,\not\rho}$ be a solution to $\psi_{n,\not\rho}(\epsilon) = \phi(\epsilon)$. Solving for $\epsilon_{n,\not\rho}$, we see that the minimax rate is bounded below by

$$2\phi\left(\epsilon_{n,\not\rho}\right) = 2\tilde{c}^{2/(2+d)} (d\lambda)^{2d/(2+d)} n^{-2/2+d}.$$

3. The theorem is stated for a Euclidean metric, but extends directly to any metric.

For any $n \in \mathbb{N}$, there exists a solution $\epsilon_{n,\rho}$ to the equation $\psi_{n,\rho}(\epsilon) = \phi(\epsilon)$ since $r(\epsilon)$ is nondecreasing. Therefore, by Lemma 7, we have

$$\mathop{\mathbb{E}}_{\mathbf{X}^n,\mathbf{Y}^n} \|f_{n,\epsilon,\rho} - f\|^2 \leq 2\phi\left(\epsilon_{n,\rho}\right).$$

We therefore want to show for a certain range of $n \in \mathbb{N}$ that $\phi\left(\epsilon_{n,\rho}\right) < \phi\left(\epsilon_{n,\not\rho}\right)$, equivalently that $\epsilon_{n,\rho} < \epsilon_{n,\not\rho}$. First notice that, since ϕ is independent of n, and both $\psi_{n,\rho}$ and $\psi_{n,\not\rho}$ are strictly decreasing functions of n, we have that $\epsilon_{n,\rho}$ and $\epsilon_{n,\not\rho}$ both tend to 0 as $n \to \infty$. Therefore we can define n_0 such that, for all $n \geq n_0$, both $\epsilon_{n,\rho}$ and $\epsilon_{n,\not\rho}$ are less than $\epsilon_{\not R}/\rho(\mathcal{X})$.

Thus, $\forall n \geq n_0$, we have $\epsilon_{n,\rho} < \epsilon_{n,\not\rho}$ if, for all $0 < \epsilon < \epsilon_{\not R}/\rho(\mathcal{X})$, $\psi_{n,\rho}(\epsilon) < \psi_{n,\not\rho}(\epsilon)$. This is insured by the conditions of equation (2), which are derived by recalling the bound of Lemma 4 on $r(\epsilon)$ for the range $0 < \epsilon < \epsilon_{\not R}/\rho(\mathcal{X})$. ■

2.3 The Case of Classification

We continue the intuition developed in the last section about the GW method with the case of classification, more precisely *plug-in* classification, defined as follows. Let $Y \in \{0,1\}$, and let η_n denote an estimate of the error function $\eta(x) \triangleq \mathbb{E}[Y|x] = \mathbb{P}(Y = 1|x)$. Then $\mathbf{1}\{\eta_n(x) > 1/2\}$ is a plug-in classification rule, emulating the Bayes optimal-classification rule $\mathbf{1}\{\eta(x) > 1/2\}$.

Two common examples of plug-in classification rules are the k-NN classifier and the ϵ-NN classifier which estimate Y at x as the majority label amongst, respectively, the k nearest neighbors of x, and the neighbors within distance ϵ of x. For both methods, the implicit estimate η_n of η is the average Y value of the neighbors of x.

The GW method for classification naturally corresponds to estimating the gradient norms $\|\eta_i'\|_{1,\mu}$ of the directional derivatives η_i'.

Since η_n is actually a regression estimate of the function $\eta(x)$, the 0-1 classification error of plug-in methods is related to that of regression as shown in the following well-known result.

Lemma 9 (Devroye et al. (1996)) *Let $\eta_n(x)$ be an estimator of $\eta(x)$, and let err(η), err(η_n), denote respectively the classification error rates of the Bayes classifier and that of the plug-in classification rule $\mathbf{1}\{\eta_n(x) > 1/2\}$. We have*

$$err(\eta_n) - err(\eta) \leq 2 \mathop{\mathbb{E}}_{X} |\eta_n(X) - \eta(X)|.$$

A bound on the classification error of ϵ-NN (operating in $(\mathcal{X},\rho)$) easily follows from Lemma 9 above and the analysis of the previous section on the properties of the space $(\mathcal{X},\rho)$.

Lemma 10 *Define $\eta_{n,\epsilon,\rho}(x)$ as the average Y value of the points in $\mathbf{X}^n \cap B_\rho(x, \epsilon\rho(\mathcal{X}))$ for some $\epsilon > 0$. Let $r(\epsilon)$ be defined as in Corollary 4. There exist a constant $1 \leq C_{\kappa_R} \leq C'(4\kappa_R)^{|R|/2}$, a universal constant C, and a constant $\lambda_\rho \geq \sup_i |\eta_i'|_{sup}/\sqrt{\mathbf{W}_i}$ such that*

$$\mathop{\mathbb{E}}_{\mathbf{X}^n,\mathbf{Y}^n} |err(\eta_{n,\epsilon,\rho}) - err(\eta)| \leq C_{\kappa_R}\sqrt{\frac{\epsilon^{-r(\epsilon)}}{n}} + Cd\lambda_\rho\epsilon\rho(\mathcal{X}).$$

Proof Using Lemma 9 and applying Jensen's inequality twice, we have

$$\mathop{\mathbb{E}}_{\mathbf{X}^n,\mathbf{Y}^n} |\text{err}(\eta_{n,\epsilon,\rho}) - \text{err}(\eta)| \leq \sqrt{\mathop{\mathbb{E}}_{\mathbf{X}^n,\mathbf{Y}^n} \mathop{\mathbb{E}}_{X} |\eta_{n,\epsilon,\rho}(X) - \eta(X)|^2}.$$

Thus, we just need to bound the L_2 error of $\eta_{n,\epsilon,\rho}$, which is a kernel regressor with a box kernel of bandwidth $\epsilon\rho(\mathcal{X})$. Apply Lemma 7 and conclude. ■

It follows similarly as in the case of regression that it is possible to achieve faster rates than the minimax rates even when the regression function η is not sparse, provided η does not vary equally in all coordinates. The exact conditions are exactly those of equation (2) with the constants C_{κ_R} and C of Lemma 10 above (this is easily derived from the above lemma as it was done for regression).

3. Estimating the GW $\mathbf{W}_i$

In all that follows we are given n i.i.d samples $(\mathbf{X}^n, \mathbf{Y}^n) = \{(X_i, Y_i)\}_{i=1}^n$ from some unknown distribution with marginal μ. The marginal μ has support $\mathcal{X} \subset \mathbb{R}^d$ while the output $Y \in \mathbb{R}$.

The kernel estimate at x is defined using any kernel $K(u)$, positive on $[0, 1/2]$, and 0 for $u > 1$. If $B(x,h) \cap \mathbf{X}^n = \emptyset$, $f_{n,h}(x) = \mathbb{E}_n Y$, otherwise

$$f_{n,\bar\rho,h}(x) = \sum_{i=1}^n \frac{K(\bar\rho(x,X_i)/h)}{\sum_{j=1}^n K(\bar\rho(x,X_j)/h)} \cdot Y_i = \sum_{i=1}^n w_i(x) Y_i, \tag{3}$$

for some metric $\bar\rho$ and a bandwidth parameter h.

For the kernel regressor $f_{n,h}$ used to learn the metric ρ below, $\bar\rho$ is the Euclidean metric. In the analysis we assume the bandwidth for $f_{n,h}$ is set as $h \geq \left(\log^2(n/\delta)/n\right)^{1/d}$, given a confidence parameter $0 < \delta < 1$. In practice we would learn h by cross-validation, but for the analysis we only need to know the existence of a good setting of h.

We estimate the norm $\|f_i'\|_{1,\mu}$ as follows:

$$\nabla_{n,i} \triangleq \mathbb{E}_n \frac{|f_{n,h}(X + te_i) - f_{n,h}(X - te_i)|}{2t} \cdot \mathbf{1}\{A_{n,i}(X)\} = \mathbb{E}_n\left[\Delta_{t,i} f_{n,h}(X) \cdot \mathbf{1}\{A_{n,i}(X)\}\right], \tag{4}$$

where $A_{n,i}(X)$ is the event that *enough* samples contribute to the estimate $\Delta_{t,i} f_{n,h}(X)$. For the consistency result, we assume the following setting:

$$A_{n,i}(X) \equiv \min_{s\in\{-t,t\}} \mu_n(B(X + se_i, h/2)) \geq \alpha_n \text{ where } \alpha_n \triangleq \frac{2d\ln 2n + \ln(4/\delta)}{n}.$$

The metric ρ is then obtained by setting the weights $\mathbf{W}_i$ to either $\nabla_{n,i}$ or the squared estimate $\nabla_{n,i}^2$ in all our experiments.

4. Consistency of the estimator $\mathbf{W}_i$ of $\|f_i'\|_{1,\mu}$

4.1 Theoretical setup

4.1.1 MARGINAL μ

Without loss of generality we assume $\mathcal{X}$ has bounded diameter 1. The marginal is assumed to have a continuous density on $\mathcal{X}$ and has mass everywhere on $\mathcal{X}$: $\forall x \in \mathcal{X}, \forall h > 0, \mu(B(x,h)) \geq C_\mu h^d$.

This is for instance the case if μ has a lower-bounded density on $\mathcal{X}$. Under this assumption, for samples X in dense regions, $X \pm te_i$ is also likely to be in a dense region.

4.1.2 REGRESSION FUNCTION AND NOISE

The output $Y \in \mathbb{R}$ is given as $Y = f(X) + \eta(X)$, where $\mathbb{E}\eta(X) = 0$. We assume the following general noise model: $\forall \delta > 0$ there exists $c > 0$ such that $\sup_{x \in \mathcal{X}} \mathbb{P}_{Y|X=x}(|\eta(x)| > c) \leq \delta$.

We denote by $C_Y(\delta)$ the infimum over all such c. For instance, suppose $\eta(X)$ has exponentially decreasing tail, then $\forall \delta > 0$, $C_Y(\delta) \leq O(\ln 1/\delta)$. A last assumption on the noise is that the variance of $(Y|X = x)$ is upper-bounded by a constant σ_Y^2 uniformly over all $x \in \mathcal{X}$.

Define the *τ-envelope* of $\mathcal{X}$ as $\mathcal{X} + B(0,\tau) \triangleq \{z \in B(x,\tau), x \in \mathcal{X}\}$. We assume there exists τ such that f is continuously differentiable on the τ-envelope $\mathcal{X} + B(0,\tau)$. Furthermore, each derivative $f_i'(x) = e_i^\top \nabla f(x)$ is upper bounded on $\mathcal{X} + B(0,\tau)$ by $|f_i'|_{\sup}$ and is uniformly continuous on $\mathcal{X} + B(0,\tau)$ (this is automatically the case if the support $\mathcal{X}$ is compact).

4.1.3 DISTRIBUTIONAL PARAMETERS

Our consistency results are expressed in terms of the following distributional quantities. For $i \in [d]$, define the *(t,i)-boundary* of $\mathcal{X}$ as $\partial_{t,i}(\mathcal{X}) \triangleq \{x : \{x + te_i, x - te_i\} \not\subset \mathcal{X}\}$. The smaller the mass $\mu(\partial_{t,i}(\mathcal{X}))$ at the boundary, the better we approximate $\|f_i'\|_{1,\mu}$.

The second type of quantity is $\epsilon_{t,i} \triangleq \sup_{x \in \mathcal{X}, s \in [-t,t]} |f_i'(x) - f_i'(x + se_i)|$.

Since μ has continuous density on $\mathcal{X}$ and ∇f is uniformly continuous on $\mathcal{X} + B(0,\tau)$, we automatically have $\mu(\partial_{t,i}(\mathcal{X})) \xrightarrow{t \to 0} 0$ and $\epsilon_{t,i} \xrightarrow{t \to 0} 0$.

4.2 Main theorem

Our main theorem bounds the error in estimating each norm $\|f_i'\|_{1,\mu}$ with $\nabla_{n,i}$. The main technical hurdles are in handling the various sample inter-dependencies introduced by both the estimates $f_{n,h}(X)$ and the events $A_{n,i}(X)$, and in analyzing the estimates at the boundary of $\mathcal{X}$.

Theorem 11 *Let $t + h \leq \tau$, and let $0 < \delta < 1$. There exist $C = C(\mu, K(\cdot))$ and $N = N(\mu)$ such that the following holds with probability at least $1 - 2\delta$. Define $A(n) \triangleq Cd \cdot \log(n/\delta) \cdot C_Y^2(\delta/2n) \cdot \sigma_Y^2 / \log^2(n/\delta)$. Let $n \geq N$, we have for all $i \in [d]$:*

$$\left| \nabla_{n,i} - \left\| f_i' \right\|_{1,\mu} \right| \leq \frac{1}{t} \left(\sqrt{\frac{A(n)}{nh^d}} + h \cdot \sum_{i \in [d]} \left| f_i' \right|_{sup} \right) + 2 \left| f_i' \right|_{sup} \left(\sqrt{\frac{\ln 2d/\delta}{n}} + \mu\left(\partial_{t,i}(\mathcal{X})\right) \right) + \epsilon_{t,i}.$$

The bound suggests to set t in the order of h or larger. We need t to be small in order for $\mu(\partial_{t,i}(\mathcal{X}))$ and $\epsilon_{t,i}$ to be small, but t needs to be sufficiently large (relative to h) for the estimates $f_{n,h}(X + te_i)$ and $f_{n,h}(X - te_i)$ to differ sufficiently so as to capture the variation in f along e_i.

The theorem immediately implies consistency for $t \xrightarrow{n \to \infty} 0$, $h \xrightarrow{n \to \infty} 0$, $h/t \xrightarrow{n \to \infty} 0$, and $(n/\log n) h^d t^2 \xrightarrow{n \to \infty} \infty$. This is satisfied for many settings, for example $t \propto \sqrt{h}$ and $h \propto 1/\log n$.

4.3 Proof of Theorem 11

The main difficulty in bounding $\left| \nabla_{n,i} - \|f_i'\|_{1,\mu} \right|$ results from certain dependencies between random quantities: both quantities $f_{n,h}(X)$ and $A_{n,i}(X)$ depend not just on $X \in \mathbf{X}^n$, but on other samples

in $\mathbf{X}^n$, and thus introduce inter-dependencies between the estimates $\Delta_{t,i} f_{n,h}(X)$ for different points X in the sample $\mathbf{X}^n$.

To handle these dependencies, we carefully decompose $\left| \nabla_{n,i} - \|f_i'\|_{1,\mu} \right|$, $i \in [d]$, starting with:

$$\left| \nabla_{n,i} - \left\| f_i' \right\|_{1,\mu} \right| \leq \left| \nabla_{n,i} - \mathbb{E}_n \left| f_i'(X) \right| \right| + \left| \mathbb{E}_n \left| f_i'(X) \right| - \left\| f_i' \right\|_{1,\mu} \right|. \tag{5}$$

The following simple lemma bounds the second term of (5).

Lemma 12 *With probability at least $1 - \delta$, we have for all $i \in [d]$,*

$$\left| \mathbb{E}_n \left| f_i'(X) \right| - \left\| f_i' \right\|_{1,\mu} \right| \leq \left| f_i' \right|_{sup} \cdot \sqrt{\frac{\ln 2d/\delta}{n}}.$$

Proof Apply a Chernoff bound, and a union bound on $i \in [d]$. ■

Now the first term of equation (5) can be further bounded as

$$\begin{aligned} \left| \nabla_{n,i} - \mathbb{E}_n \left| f_i'(X) \right| \right| &\leq \left| \nabla_{n,i} - \mathbb{E}_n \left| f_i'(X) \right| \cdot \mathbf{1}\{A_{n,i}(X)\} \right| + \mathbb{E}_n \left| f_i'(X) \right| \cdot \mathbf{1}\left\{ \bar{A}_{n,i}(X) \right\} \\ &\leq \left| \nabla_{n,i} - \mathbb{E}_n \left| f_i'(X) \right| \cdot \mathbf{1}\{A_{n,i}(X)\} \right| + \left| f_i' \right|_{\sup} \cdot \mathbb{E}_n \mathbf{1}\left\{ \bar{A}_{n,i}(X) \right\}. \end{aligned} \tag{6}$$

We will bound each term of (6) separately.

The next lemma bounds the second term of (6). It is proved in the appendix. The main technicality in this lemma is that, for any X in the sample $\mathbf{X}^n$, the event $\bar{A}_{n,i}(X)$ depends on other samples in $\mathbf{X}^n$.

Lemma 13 *Let $\partial_{t,i}(\mathcal{X})$ be defined as in Section (4.1.3). For $n \geq n(\mu)$, with probability at least $1 - 2\delta$, we have for all $i \in [d]$,*

$$\mathbb{E}_n \mathbf{1}\left\{ \bar{A}_{n,i}(X) \right\} \leq \sqrt{\frac{\ln 2d/\delta}{n}} + \mu\left(\partial_{t,i}(\mathcal{X})\right).$$

It remains to bound $|\nabla_{n,i} - \mathbb{E}_n |f_i'(X)| \cdot \mathbf{1}\{A_{n,i}(X)\}|$. To this end we need to bring in f through the following quantities:

$$\widetilde{\nabla}_{n,i} \triangleq \mathbb{E}_n \left[\frac{|f(X + te_i) - f(X - te_i)|}{2t} \cdot \mathbf{1}\{A_{n,i}(X)\} \right] = \mathbb{E}_n \left[\Delta_{t,i} f(X) \cdot \mathbf{1}\{A_{n,i}(X)\} \right]$$

and for any $x \in \mathcal{X}$, define $\tilde{f}_{n,h}(x) \triangleq \mathbb{E}_{\mathbf{Y}^n | \mathbf{X}^n} f_{n,h}(x) = \sum_i w_i(x) f(x_i)$.

The quantity $\widetilde{\nabla}_{n,i}$ is easily related to $\mathbb{E}_n |f_i'(X)| \cdot \mathbf{1}\{A_{n,i}(X)\}$. This is done in Lemma 14 below. The quantity $\tilde{f}_{n,h}(x)$ is needed when relating $\nabla_{n,i}$ to $\widetilde{\nabla}_{n,i}$.

Lemma 14 *Define $\epsilon_{t,i}$ as in Section (4.1.3). With probability at least $1 - \delta$, we have for all $i \in [d]$,*

$$\left| \widetilde{\nabla}_{n,i} - \mathbb{E}_n \left| f_i'(X) \right| \cdot \mathbf{1}\{A_{n,i}(X)\} \right| \leq \epsilon_{t,i}.$$

Proof We have $f(x+te_i) - f(x-te_i) = \int_{-t}^{t} f_i'(x+se_i)\,ds$ and therefore

$$2t\left(f_i'(x) - \epsilon_{t,i}\right) \leq f(x+te_i) - f(x-te_i) \leq 2t\left(f_i'(x) + \epsilon_{t,i}\right).$$

It follows that $\left|\frac{1}{2t}\left|f(x+te_i) - f(x-te_i)\right| - \left|f_i'(x)\right|\right| \leq \epsilon_{t,i}$, therefore

$$\left|\widetilde{\nabla}_{n,i} - \mathbb{E}_n\left|f_i'(X)\right| \cdot \mathbf{1}\{A_{n,i}(X)\}\right| \leq \mathbb{E}_n\left|\frac{1}{2t}\left|f(x+te_i) - f(x-te_i)\right| - \left|f_i'(x)\right|\right| \leq \epsilon_{t,i}.$$

■

It remains to relate $\mathbf{W}_i$ to $\widetilde{\nabla}_{n,i}$. We have

$$\begin{aligned}
2t\left|\nabla_{n,i} - \widetilde{\nabla}_{n,i}\right| =& 2t\left|\mathbb{E}_n(\Delta_{t,i}f_{n,h}(X) - \Delta_{t,i}f(X)) \cdot \mathbf{1}\{A_{n,i}(X)\}\right| \\
\leq& 2\max_{s\in\{-t,t\}} \mathbb{E}_n\left|f_{n,h}(X+se_i) - f(X+se_i)\right| \cdot \mathbf{1}\{A_{n,i}(X)\} \\
\leq& 2\max_{s\in\{-t,t\}} \mathbb{E}_n\left|f_{n,h}(X+se_i) - \tilde{f}_{n,h}(X+se_i)\right| \cdot \mathbf{1}\{A_{n,i}(X)\} \qquad (7) \\
&+ 2\max_{s\in\{-t,t\}} \mathbb{E}_n\left|\tilde{f}_{n,h}(X+se_i) - f(X+se_i)\right| \cdot \mathbf{1}\{A_{n,i}(X)\}. \qquad (8)
\end{aligned}$$

We first handle the bias term (8) in the next lemma which is given in the appendix.

Lemma 15 (Bias) *Let $t+h \leq \tau$. We have for all $i \in [d]$, and all $s \in \{t,-t\}$:*

$$\mathbb{E}_n\left|\tilde{f}_{n,h}(X+se_i) - f(X+se_i)\right| \cdot \mathbf{1}\{A_{n,i}(X)\} \leq h \cdot \sum_{i\in[d]} \left|f_i'\right|_{sup}.$$

The variance term in (7) is handled in the lemma below. The proof is given in the appendix.

Lemma 16 (Variance terms) *There exist $C = C(\mu, K(\cdot))$ such that, with probability at least $1-2\delta$, we have for all $i \in [d]$, and all $s \in \{-t,t\}$:*

$$\mathbb{E}_n\left|f_{n,h}(X+se_i) - \tilde{f}_{n,h}(X+se_i)\right| \cdot \mathbf{1}\{A_{n,i}(X)\} \leq \sqrt{\frac{Cd\cdot\log(n/\delta)C_Y^2(\delta/2n)\cdot\sigma_Y^2}{n(h/2)^d}}.$$

The next lemma summarizes the above results:

Lemma 17 *Let $t+h \leq \tau$ and let $0<\delta<1$. There exist $C = C(\mu, K(\cdot))$ such that the following holds with probability at least $1-2\delta$. Define $A(n) \triangleq Cd\cdot\log(n/\delta)\cdot C_Y^2(\delta/2n)\cdot\sigma_Y^2/\log^2(n/\delta)$. We have*

$$\left|\nabla_{n,i} - \mathbb{E}_n\left|f_i'(X)\right| \cdot \mathbf{1}\{A_{n,i}(X)\}\right| \leq \frac{1}{t}\left(\sqrt{\frac{A(n)}{nh^d}} + h\cdot\sum_{i\in[d]}\left|f_i'\right|_{sup}\right) + \epsilon_{t,i}.$$

Proof Apply lemmas 14, 15 and 16, in combination with equations 7 and 8. ■

To complete the proof of Theorem 11, apply lemmas 17 and 12 in combination with equations 5 and 6.

5. Experimental Evaluation of the GW Approach

We have so far derived GW based on the theoretical principles of Section 2, namely that performance improvements are possible if data coordinates are weighted according to the coordinate-wise variation of the unknown f, and if f varies unevenly across coordinates. In this section, we verify these theoretical principles empirically on various real-world datasets. The code and all the data sets used in these experiments are publicly available at `http://goo.gl/bCfS78`

We consider kernel, k-NN and SVM (support vector) approaches on a variety of controlled (artificial) and real-world datasets. We emphasize that our goal is to demonstrate the benefits of GW in improving the performance of these successful and popular procedures on a wide range of datasets. We do not aim to beat results that may have been obtained on these data using procedures other than kernel, k-NN and SVM approaches, since this is not required for a practical validation of our theoretical results. We also note that, throughout the experiments, we only retain the numerical attributes in each data set, and discard all the categorical attributes. Therefore, our reported prediction errors on some datasets might differ from others reported in the literature at large.

Parameter settings and general comments: Recall that, for the GW approach, we might set the components $\mathbf{W}_i$ of the metric ρ to $\nabla_{n,i}^q$. The exponent q (cf. Remark 2.2) is a parameter left open by our theoretical analysis. In our experiments, we explore the choices $q=1$, as in Kpotufe and Boularias (2012), and $q=2$ which serves to further emphasize the difference in importance between coordinates.

The resulting performance of the GW approach depends on the parameters used to learn $\nabla_{n,i} \triangleq \mathbb{E}_n\left[\Delta_{t,i}f_{n,h}(X)\cdot\mathbf{1}\{A_{n,i}(X)\}\right]$. These are the bandwidth h used in the estimate $f_{n,h}(X)$ and the parameter t in $\Delta_{t,i}f_{n,h}(X) \triangleq \left|f_{n,h}(X+te_i) - f_{n,h}(X-te_i)\right|/2t$. In the majority of experiments (reported in the main body of the paper) we tune h, but we don't tune t and simply set $t = h/2$ as a rule of thumb. This results in faster training time, and although not optimal, still results in significant performance gains for the various regression and classification procedures where GW is used to preprocess the data. If in addition we properly tune t, the observed performance gains are even more significant as reported in Tables 4 and 5 of the Appendix.

We emphasize that the GW approach is computationally cheap: it only adds to training time since it only involves pre-processing the data. No significant difference is observed in estimation time, i.e. in computing regression or classification estimates using the preprocessed data vs using the original data. In fact estimation time can even be smaller after preprocessing since GW can act as an approximate dimension-reduction given the sparsity in the data. The average prediction times are reported in Table 6 of the appendix.

Our experiments are divided as follows. First we show the attainable performance gains by using GW for regression, then we show that GW works well also for classification. At the end of the section we explore the tradeoffs between feature selection and feature weigthing.

5.1 Regression experiments

In this section, we present experiments on several real-world regression data sets. We compare the performances of both kernel regression and k-NN regression in the Euclidean metric space and in the learned gradient weights metric space.

5.1.1 DATA DESCRIPTION

The first two data sets describe the dynamics of 7 degrees of freedom of robotic arms, Barrett WAM and SARCOS (Nguyen-Tuong et al., 2009; Nguyen-Tuong and Peters, 2011). The input points are 21-dimensional and correspond to samples of the positions, velocities, and accelerations of the 7 joints. The output points correspond to the torque of each joint. The far joints (1, 5, 7) correspond to different regression problems and are the only results reported. As expected, results for other joints were found to be similarly good.

Another data set describes the probabilities of achieving successful grasping actions performed by a robot on different piles of objects (Boularias et al., 2014a,b). Each data point describes one grasping action performed at a particular location on the surface of a pile of objects. The objects are mostly rocks and rubble with unknown and irregular shapes. An input point is a 150-dimensional vector and corresponds to a patch of a depth image obtained by projecting the robotic hand on the scene. The output is a value between 0 and 1.

The other data sets are taken from the UCI repository (Frank and Asuncion, 2012) and from (Torgo, 2012). The concrete strength data set (Concrete Strength) contains 8-dimensional input points, describing age and ingredients of concrete, the output points are the compressive strength. The wine quality data set (Wine Quality) contains 11-dimensional input points corresponding to the physicochemistry of wine samples, the output points are the wine quality. The ailerons data set (Ailerons) is taken from the problem of flying a F16 aircraft. The 5-dimensional input points describe the status of the aeroplane, while the goal is to predict the control action on the ailerons of the aircraft. The housing data set (Housing) concerns the task of predicting housing values in areas of Boston, the input points are 13-dimensional. The Parkinson's Telemonitoring data set (Parkison's) is used to predict the clinician's Parkinson's disease symptom score using biomedical voice measurements represented by 21-dimensional input points. We also consider a telecommunication problem (Telecom), wherein the 47-dimensional input points and the output points describe the bandwidth usage in a network.

5.1.2 EXPERIMENTAL SETUP

For all data sets, we normalize each coordinate with its standard deviation from the training data. To learn the metric, we set h by cross-validation on half the training points, and we set $t = h/2$ for all data sets. Note that in practice we might want to also tune t in the range of h for even better performance than reported here. The event $A_{n,i}(X)$ is set to reject the gradient estimate $\Delta_{n,i} f_{n,h}(X)$ at X if no sample contributed to one of the estimates $f_{n,h}(X \pm te_i)$.

In each experiment, we compare kernel regression in the Euclidean metric space (KR) and in the learned metric space with gradient weights (KR-ρ) and with squared gradient weights (KR-ρ^2), where we use a box kernel for the three methods. Similar comparisons are made using k-NN, k-NN-ρ and k-NN-ρ^2. All methods are implemented using a fast neighborhood search procedure, namely the cover-tree of (Beygelzimer et al., 2006), and we also report in the supplementary material the average prediction times so as to confirm that, on average, time-performance is not affected by using the metric.

The parameter k in k-NN, k-NN-ρ, k-NN-ρ^2, and the bandwidth in KR, KR-ρ, KR-ρ^2 are learned by cross-validation on half of the training points. We try the same range of k (from 1 to $5 \log n$) for the three k-NN methods (k-NN, k-NN-ρ). We try the same range of bandwidth/space-diameter h (a grid of size 0.02 from 1 to 0.02) for the three KR methods (KR, KR-ρ, KR-ρ^2): this

is done efficiently by starting with a log search to quickly reduce the search space, followed by a grid search on the resulting smaller range.

Table 1 shows the normalized Mean Square Errors (nMSE) where the MSE on the test set is normalized by variance of the test output. We use 1000 training points in the robotic, Telecom, Parkinson's, and Ailerons data sets, and 2000 training points in Wine Quality, 730 in Concrete Strength, and 300 in Housing. We used 2000 test points in all of the problems, except for Concrete, 300 points, Housing, 200 points, and Robot Grasping, 10000 points. Averages over 10 random experiments are reported. For the larger data sets (SARCOS, Ailerons, Telecom, Grasping) we also report the behavior of the algorithms, with and without metric, as the training size n increases (Figure 4).

	Barrett 1	Barrett 5	SARCOS 1	SARCOS 5	Housing

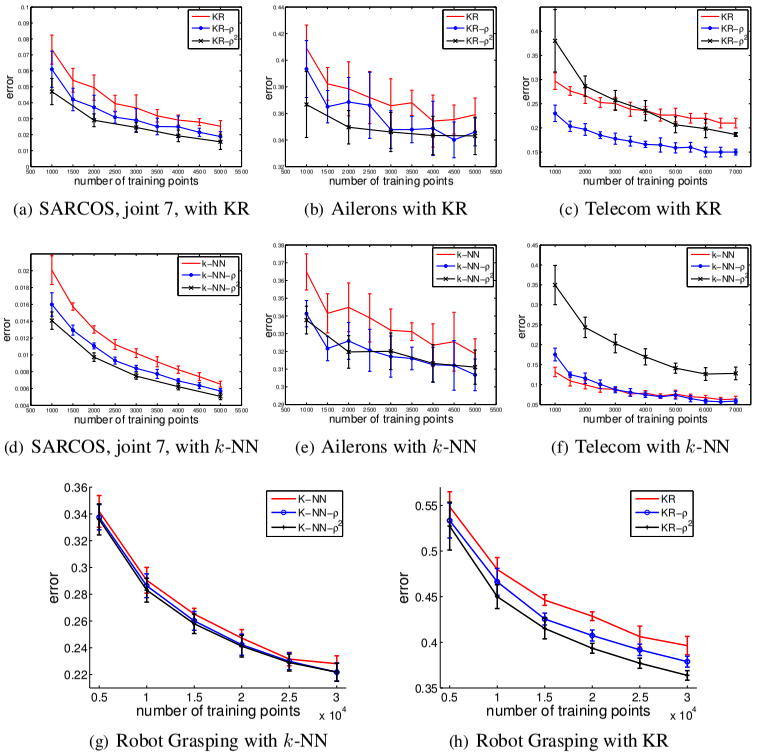
Table 1: Normalized mean square prediction errors show that, in almost all cases, gradient weights improve accuracy in practice. The top three tables are for KR vs KR-ρ and KR-ρ^2, the bottom three for k-NN vs k-NN-ρ and k-NN-ρ^2. k-NN-unnormalized and KR-unnormalized refer to k-NN and KR used on unnormalized data. For all the other methods, data vectors are normalized by dividing each data vector by the standard deviation of the training data in each dimension.

5.1.3 DISCUSSION OF RESULTS

From the results in Table 1 we see that virtually on all data sets the metric helps improve the performance of the distance based-regressor even though we did not tune t to the particular problem (remember $t = h/2$ for all experiments). The only exception is for Telecom with k-NN. We noticed



(a) SARCOS, joint 7, with KR (b) Ailerons with KR (c) Telecom with KR

(d) SARCOS, joint 7, with k-NN (e) Ailerons with k-NN (f) Telecom with k-NN

(g) Robot Grasping with k-NN (h) Robot Grasping with KR

Figure 4: Plotting regression error as a function of the number of training points shows that gradient weights lead to a clear improvement even for small sample sizes, indicating that our estimator of $\|f_i'\|_{1,\mu}$ produces useful results even from relatively few samples.

that the Telecom data set has a lot of outliers and this probably explains the discrepancy, besides the fact that we did not attempt to tune t (see Trivedi et al. (2014) for experiments where t is additionally tuned, and where GW clearly outperforms the baselines for the Telecom dataset).

For the baseline methods (kernel and k-NN), we report both the errors when the data is unnormalized, and when the features are normalized by their standard deviation. For all other methods, the data is normalized. This is to show that, while variance normalization is a first step in reducing the error of the baseline, such errors are further reduced, significantly, through our approach of weighing by estimated derivatives.

Also notice that the error of k-NN is already low for small sample sizes, making it harder to outperform. However, as shown in Figure 4, for larger training sizes k-NN-ρ gains on k-NN. We also note that methods using squared gradient weights (k-NN-ρ^2 and KR-ρ^2) achieved a better performance compared to other methods. The only exception here is also Telecom, where the non-squared gradient weights yield a lower prediction error. The rest of the results in Figure 4 where we vary n are self-descriptive: gradient weighting clearly improves the performance of the distance-based regressors.

Finally, we note that the average prediction times (reported in the supplementary material) is nearly the same for all the methods. Last, remember that the metric can be learned online at the cost of only $2d$ times the average kernel estimation time reported.

5.2 Classification experiments

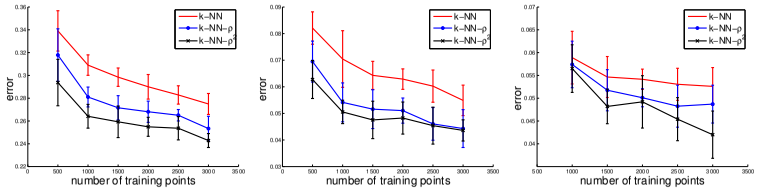
5.2.1 DATA DESCRIPTION

We tested the gradient weights method on six different data sets taken from the UCI repository (Frank and Asuncion, 2012) and from the LIBSVM website (Fan, 2012). The covertype data set contains predictions of binary forest cover types from cartographic features given by 10 real variables among 54 other variables. This data set originally consists of seven different cover types, but only the two largest categories are selected for binary classification. The MAGIC gamma data set consists of 10 features and predicts the registration of high energy gamma particles in a ground-based atmospheric Cherenkov gamma telescope. The IJCNN data set contains predictions of one binary output from four different time series, described by 10 categorical variables and 12 real variables. The shuttle data set contains 9 numerical attributes. The original data set has seven different categories, but for binary classification we merged all the classes into one class, except the first class which corresponds to approximately 80% of all the data. The page blocks data set predicts whether a block in a given document is a text block using 10 real-valued features. We also consider the thyroid data set where the problem is to determine whether a given patient is hypothyroid. There are three different output classes in this data set, the condition of a patient is described by 6 real variables and 15 categorical variables.

5.2.2 EXPERIMENTAL SETUP

The setup for the classification experiments is similar to the one used in the regression experiments. For all data sets, we normalize each coordinate with its standard deviation from the training data. We use the training data to compute the gradient weights. Parameter t is set proportionally to the difference between the minimum and the maximum values of each feature to account for the differences between features scales that remain after normalization. One can also consider using the learned gradient weights to set t and to re-estimate the gradient weights again, in a repeated iterative process. The probability $P(C_i|\mathbf{x})$ of each class C_i, used for calculating the feature weights, is estimated by weighted k-NN with Gaussian kernel.

In each experiment, we compare a k nearest neighbor classifier in the Euclidean metric space (k-NN), the learned metric space with gradient weights (k-NN-ρ), and a metric space in which gradient weights have been squared (k-NN-ρ^2). Analogous results have been obtained using an ϵ-NN classifier (ϵ-NN, ϵ-NN-ρ, ϵ-NN-ρ^2) which uses all training samples within an ϵ-ball around the test point, rather than the k nearest neighbors. Parameters k and ϵ have been set by cross-validation with half the training points. As in the regression experiments, k and ϵ are found by using a log search,



(a) Covertype with k-NN (b) IJCNN with k-NN (c) Thyroid with k-NN

Figure 5: As in the regression case, classification benefits from gradient weights even if they were estimated from relatively few samples.

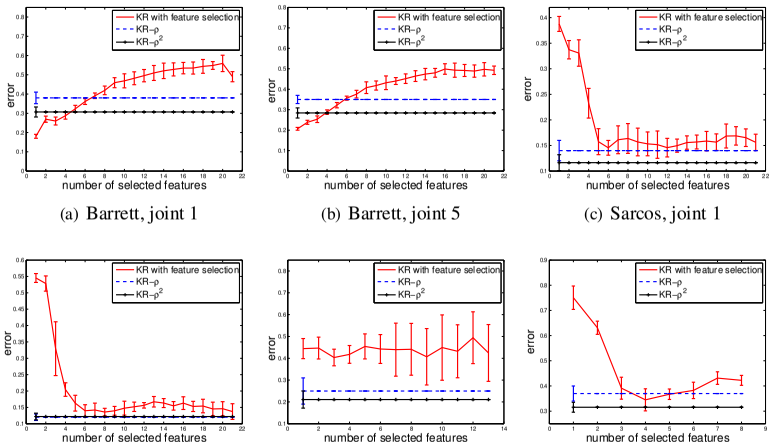
Table 2: Error rates with and without gradient weights show that they improve classification accuracy, especially when they are used in their squared form. This is true for two different distance-based classifiers, k-NN (top), and ϵ-NN (bottom).

followed by a linear search in a smaller interval. All classification experiments are performed using 2000 points for testing and up to 3000 points for learning. Averages over 10 random experiments are reported. The purpose of varying the size of training data is to report the performance as a function of the number of training points (Figure 5). Table 2 shows the classification error rates of the different methods.

5.2.3 DISCUSSION OF RESULTS

From the results in Table 2, we see that the gradient weights metric improves the performance of the two different distance-based classifiers, k-NN and ϵ-NN. We also notice that the squared gradient weights perform better than the non-squared weights in almost all cases. The only exception is the MAGIC Gamma data set where the performance of the different classifiers seems unaffected by the choice of the metric. This is due to the fact that the gradient weights in this particular problem are nearly the same for every feature, as shown in the appendix.

Figure 5 shows improvements for GW over the baseline even with relatively small sample sizes. The improvement of GW over the baseline decreases with larger training sizes except in the Thyroid data set where the advantage of GW is more pronounced with a larger training size. Recall that, from the theoretical insights developed in Section 2, we only expect large improvements in a sample size



(a) Barrett, joint 1 (b) Barrett, joint 5 (c) Sarcos, joint 1

(d) Sarcos, joint 5 (e) Housing (f) Concrete Strength

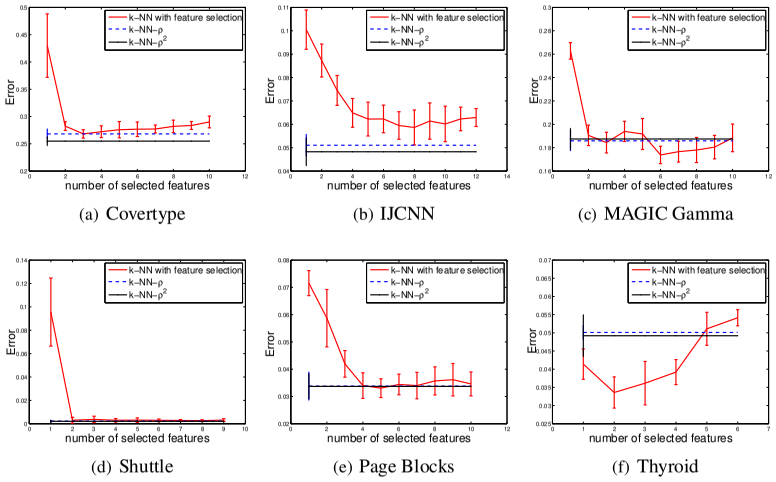
Figure 6: Kernel regression with feature selection, versus GW. On these datasets, feature weighting tends to outperform feature selection, especially when all features happen to be relevant.

regime depending on the problem, so the same behavior (as for the other data sets) is likely for the Thyroid case if we had larger samples to work with.

5.3 Feature selection vs feature weighting

How does feature weighting compare with feature selection? Feature weighting, as done with GW, has the obvious advantage of avoiding the combinatorial problem of having to select a subset of features, and gets rid of the ill-defined problem of selecting a good *importance threshold* for feature selection. Another less obvious advantage of feature weighting is that we do not lose much in performance if it so happens that all features are relevant, since weighting uses all features. However, feature selection reduces dimension and therefore variance, and would be expected to be the better option if some features are much more important than all others (i.e. f is nearly sparse); how much do we lose by feature weighting in this sort of situation, i.e. does the computational advantage of weighting justify its use? This of course depends on problem-specific costs, but we will attempt here to better understand the differences between the two approaches.

We compare our proposed GW method with feature selection, where features are added in order of importance, i.e. we first add the features most correlated with the output Y. The same training sets are used to compute the gradient weigths and feature correlations with Y, under similar time complexity. Keep in mind that feature selection here requires the additional complexity of comparing the performance gain from various combinations of features; here for simplicity we would just compare n ordered subsets, although more subsets might be compared in practice. An alternative to



(a) Covertype (b) IJCNN (c) MAGIC Gamma

(d) Shuttle (e) Page Blocks (f) Thyroid

Figure 7: Experiments on k-NN classification with feature selection versus GW. Again, GW generally performs better, while little is lost when feature selection is preferable.

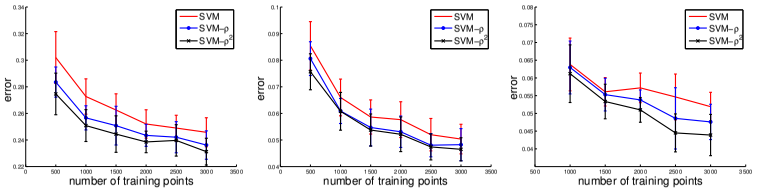
comparing combinations of features is to use some kind of thresholding, but as mentioned earlier, it is often unclear how to properly threshold feature importance.

Figure 6 shows that overall GW with kernel regression is competitive with the more expensive feature selection, and even often achieves better performance in those situations where all features happen to be relevant (Sarcos, Housing, Concrete). Similar results are achieved for k-NN regression, and are reported in the supplementary material.

Notice that, in those cases where feature selection performs best (Barret datasets), its gain over GW is smallest when we used the squared version $\nabla^2_{n,i}$ of GW (denoted KR-ρ^2 in the figure). This is because squaring emphasizes the differences in variability of f between features and is thus closer to feature selection.

Figure 7 repeats the same experiments in the case of classification with k-NN. Here the performance of feature selection depends more crucially on the number of selected features, and can be bad in most cases if too few features are selected. GW outperforms feature selection in most cases but the Thyroid dataset. However, even in the Thyroid case, the advantage is small, less than 2%.

While a more elaborate feature selection procedure might produce a bigger advantage over feature weighting, the computational cost might be even higher. Feature weighting with GW offers a cheap alternative which moreover often outperforms natural feature selection routines such as the one just discussed. However, we do not claim that our method can replace sophisticated feature selection schemes that are specialized for high-dimensional applications in *parametric* settings (e.g., (Zhou et al., 2014)); we emphasize however that there are few alternatives to the present approach for nonparametric settings; one popular such alternative, Relieff, is discussed below.



(a) Covertype with SVM (b) IJCNN with SVM (c) Thyroid with SVM

Figure 8: Classification error rates of a support vector machine suggest that pre-multiplying features by their gradient weight also improves performance of that classifier.

6. Discussion

In this section we further discuss the ideas presented so far by addressing some interesting questions that arise naturally. In particular we will consider the applicability of the GW approach outside the context of distance-based learning methods in the next section. In the following section we take a look at existing heuristics for feature weighting and show how, although not by design, their success might be explained by the theoretical intuition developed in the present work. We finish the section and the paper with open questions and a discussion of future directions.

6.1 Feature Weighting for Support Vector Machines

Even though the intuition for our method has been developed for distance-based regressors and classifiers, we have found empirically that pre-processing features by multiplying them with their corresponding gradient weight also improves the performance of other popular classifiers, such as support vector machines (SVMs). This is demonstrated in Figure 8, which reports results on the same classification tasks as in Figure 5, but uses an SVM instead of a k-NN classifier. We have used a Gaussian kernel, and we have cross-validated its kernel bandwidth h separately for the Euclidean and the learned metric space on half the training points. As before, h is found by a log search, followed by a linear search.

6.2 Relation to the Relief family of Heuristics

Early approaches for feature selection have exhaustively enumerated all possible subsets of features, or have employed heuristics to reduce the search space. In this section we relate our GW approach to the Relief approach, which from its introduction in Kira and Rendell (1992), has gained much popularity and evolved into a larger family of related heuristics (Kononenko, 1994; Robnik-Šikonja and Kononenko, 2003).

The success of Relief is due to its ease of implementation, computational efficiency in avoiding the combinatorial problems of earlier approaches, and more importantly its good performance on real-world problems. While Relief has mostly been used for binary feature selection, some variants were also used for feature weighting (Wettschereck et al., 1997; Sun, 2007), similar to our proposed GW approach.

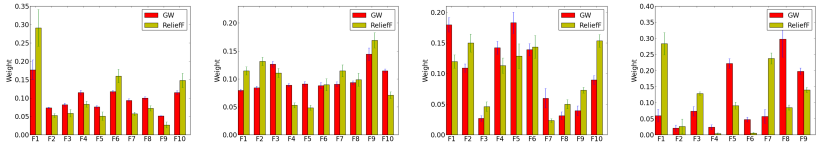
Table 3: Comparing the improvement in classification error over the k-NN baseline when using squared gradient weights or ReliefF shows that none of the two methods dominates the other one. Negative numbers indicate cases where ReliefF led to increased errors.

While Relief and our GW approach have similar practical benefits, GW is grounded in the theoretical insights developed earlier in this work. Corollary 8 allows us to theoretically understand the conditions under which GW improves regression rates in a minimax sense, opening up potential directions for further development of feature weighting methods. To the best of our knowledge, no such theoretical results are available for Relief although various works have provided theoretical interpretation (e.g. (Sun, 2007)) without actually analyzing the direct effect of Relief weights on regression or classification convergence rates. We will argue here that the theoretical intuition developed in this work helps explain some of the success of Relief: the weights computed by Relief, similar to those of GW, are generally correlated with the coordinate-wise variation of the unknown regression function f.



(a) Covertype (b) MAGIC Gamma (c) Page Blocks (d) Shuttle

Figure 9: Comparing GW feature weights (i.e. $\nabla_{n,i}$) and those of ReliefF, averaged over 10 random repeats of the experiment. There is a clear correlation in most cases but the right-most.

First, upon computing weights for several real-world data sets, we can observe empirically that the weights assigned by ReliefF (Kononenko, 1994) are often correlated with those computed by GW which are by design correlated with the coordinate-wise variation of f (Figure 9).

Both methods, when used for feature-weighting, yield similar improvement in classification error rates, as shown in Table 3. For GW we use $\mathbf{W}_i = \nabla^2_{n,i}$, i.e. coordinates are weighted by $\nabla_{n,i}$; correspondingly, we pre-multiply features by their ReliefF weights as done in Wettschereck et al. (1997). For a fair comparison, the number k of neighbors used in ReliefF was found by cross-validation on the training data, just as in our method. None of the two methods dominates the other on all examples. However, unlike the weights found by ReliefF, gradient weights never led to an average increase in error.

We can gain additional insight on the relationship to the Relief family by considering RReliefF, an extension to regression problems (Robnik-Šikonja and Kononenko, 2003). In RReliefF, the

weight $\hat{\mathbf{W}}_\mathbf{i}$ of a feature i is estimated as

$$\hat{\mathbf{W}}_i = \frac{\sum_x \sum_{x' \in N(x)} |f_n(x) - f_n(x')||x_i - x'_i| \text{dis}(x,x')}{\sum_x \sum_{x' \in N(x)} |f_n(x) - f_n(x')| \text{dis}(x,x')} - \frac{\sum_x \sum_{x' \in N(x)} \Big(|x_i - x'_i| \text{dis}(x,x') - |f_n(x) - f_n(x')||x_i - x'_i| \text{dis}(x,x') \Big)}{n - \sum_x \sum_{x' \in N(x)} |f_n(x) - f_n(x')| \text{dis}(x,x')},$$

where x is a training input point, x_i is the ith attribute of x, n is the number of training points, f_n is a k-NN estimate of f, $N(x)$ is the set of k nearest neighbors of x with respect to the Euclidean metric, and dis is a dissimilarity function, defined as $\text{dis}(x,x') = \exp\Big(-\frac{1}{h}\big(\text{rank}(x,x')\big)^2\Big)$ where $\text{rank}(x,x')$ is obtained by ranking the neighbors of x according to their increasing distance from x, and h is some bandwidth. By rearranging the terms of the equation above, we have

$$\begin{aligned}\hat{\mathbf{W}}_i = & \left(\frac{1}{A(f_n)} + \frac{1}{B(f_n)}\right) \sum_x \sum_{x' \in N(x)} |f_n(x) - f_n(x')||x_i - x'_i| \text{dis}(x,x') \\ & - \frac{1}{B(f_n)} \sum_x \sum_{x' \in N(x)} |x_i - x'_i| \text{dis}(x,x') \\ = & \left(\frac{1}{A(f_n)} + \frac{1}{B(f_n)}\right) \hat{\mathbf{W}}_{i,I} + \frac{1}{B(f_n)} \hat{\mathbf{W}}_{i,II},\end{aligned}$$

where

$$\begin{aligned}A(f_n) = & \sum_x \sum_{x' \in N(x)} |f_n(x) - f_n(x')| \text{dis}(x,x'), \\ B(f_n) = & \; n - \sum_x \sum_{x' \in N(x)} |f_n(x) - f_n(x')| \text{dis}(x,x').\end{aligned}$$

Notice that $A(f_n)$ and $B(f_n)$ are global parameters that do not depend on the feature i for which the weight $\hat{\mathbf{W}}_i$ is calculated.

The term $\frac{1}{B(f_n)} \hat{\mathbf{W}}_{i,II}$ can be interpreted as a measure of the spread of the input points around axis i, and has little dependence on the output Y. Moreover this term would generally be negligible: suppose w.l.o.g. that $|Y|$ is normalized to be at most 1, then $B(f_n) = \Omega(n)$ so the term goes to 0.

The other term $\left(\frac{1}{A(f_n)} + \frac{1}{B(f_n)}\right) \hat{\mathbf{W}}_{i,I}$ is most important and is correlated with the variation of f_n (hence of f) in direction i. In particular, $\hat{\mathbf{W}}_{i,I}$ has the essential ingredients of an estimator of $\|f'_i\|_{1,\mu}$: it is a weighted average of differences in f_n, where the weights $(|x_i - x'_i| \text{dis}(x,x'))$ are (1) larger for pairs of points aligned along coordinate i (via $|x_i - x'_i|$), and (2) larger for the closest pairs of points (via the dissimilarity $\text{dis}(x,x')$).

In fact the differences between $\hat{\mathbf{W}}_{i,I}$ and our estimator $\nabla_{n,i}$ are simply in the way we accomplish (1) and (2) above: we directly look at pairs of points $(x \pm te_i)$, t-close and aligned with the coordinate i. This is similar to setting the neighborhood $N(x)$ in Relieff to $x \pm te_i$ and using a dissimilarity of the form $\text{dis}(x,x') = \big(2nt^2\big)^{-1}$.

The success of GW is best understood in terms of how they reduce the variance of distance-based regressors while controlling bias, as elucidated in Section 2.2. Even though no such analysis is available for Relief, our results extend the same theoretical intuition to the RReliefF heuristic which also estimates a quantity that is correlated with the coordinate-wise variation of f.

6.3 Final Remarks and Future Directions

We have shown both theoretically and empirically that it is possible to gain significantly in regression and classification performance by weighting features according to the way the unknown regression function f varies along coordinates, provided f does not vary equally across coordinates, which is often the case. We derived a simple procedure to estimate the variation in f and showed its consistency. The present brings up many new questions which we hope would be the subject of future investigation. We list some of these questions below.

The approach results in a two-phase prediction procedure, which however might be iterated into a multiple phase procedure for a potentially better estimation of f. A natural question is how to detect convergence of a multiple phase approach. This is unclear for now, but is worth pursuing since even the simple two-phase approach discussed here works well.

The approach presented in this paper weights coordinates with some power of the estimate $\nabla_{n,i}$ of the gradient norm $\|f_i'\|_{1,\mu}$. Should all coordinates be weighted with the same power of $\nabla_{n,i}$, or is there a better way to weights coordinates according to the way f varies? This question requires refined theoretical understanding of how coordinate-weighting affects particular regression and classification procedures.

The current approach does not take into account the fact that the input X might not be full-dimensional. It is often the case that data lies near lower-dimensional subspaces of $\mathbb{R}^d$. How does one capture the directional variation of f in these cases?

Given the simplicity and success of the approach presented here, we believe even better feature-weigthing approaches are lurking close, and some of the above questions are potential directions for further improvement.

Acknowledgments

A significant part of this work was conducted when the authors were at the Max Planck Institute for Intelligent Systems, Tuebingen, Germany.

Appendix A. Consistency lemmas

We need the following VC result.

Lemma 18 (Relative VC bounds (Vapnik and Chervonenkis, 1971)) *Let $0 < \delta < 1$ and define $\alpha_n = (2d \ln 2n + \ln(4/\delta))/n$.*

Then with probability at least $1-\delta$ over the choice of $\mathbf{X}^n$, all balls $B \in \mathbb{R}^d$ satisfy

$$\mu(B) \leq \mu_n(B) + \sqrt{\mu_n(B)\alpha_n} + \alpha_n.$$

Proof [Lemma 13] Let $\bar{A}_i(X)$ denote the event that $\min_{s\in\{-t,t\}} \mu(B(X+se_i, h/2)) < 3\alpha_n$. By Lemma 18, with probability at least $1-\delta$, $\forall i \in [d]$, $\bar{A}_{n,i}(X) \implies \bar{A}_i(X)$ so that $\mathbb{E}_n \mathbf{1}\{\bar{A}_{n,i}(X)\} \leq \mathbb{E}_n \mathbf{1}\{\bar{A}_i(X)\}$.

Using a Chernoff bound, followed by a union bound on $[d]$, we also have with probability at least $1-\delta$ that $\mathbb{E}_n \mathbf{1}\{\bar{A}_i(X)\} \leq \mathbb{E}\mathbf{1}\{\bar{A}_i(X)\} + \sqrt{\ln(2d/\delta)/n}$.

Finally, $\mathbb{E}\mathbf{1}\{\bar{A}_i(X)\} \leq \mathbb{E}\left[\mathbf{1}\{\bar{A}_i(X)\}|X \in \mathcal{X} \setminus \partial_{t,i}(\mathcal{X})\right] + \mu\left(\partial_{t,i}(\mathcal{X})\right)$. The first term is 0 for large n. This is true since, for $x \in \mathcal{X} \setminus \partial_{t,i}(\mathcal{X})$, for all $i \in [d]$ and $s \in \{-t, t\}$, $x + se_i \in \mathcal{X}$, and

therefore $\mu(B(x+se_i, h/2)) \geq C_\mu (h/2)^d \geq 3\alpha_n$ for our setting of h (see Section 3). ■

Proof [Lemma 15] Let $x = X + se_i$. For any $X_i \in \mathbf{X}^n$, let v_i denote the unit vector in direction $(X_i - x)$. We have

$$\begin{aligned}\left|\tilde{f}_{n,h}(x) - f(x)\right| &\leq \sum_i w_i(x) \left|f(X_i) - f(x)\right| = \sum_i w_i(x) \left|\int_0^{\|X_i - x\|} v_i^\top \nabla f(x + sv_i)\, ds\right| \\ &\leq \sum_i w_i(x) \left\|X_i - x\right\| \cdot \max_{x' \in \mathcal{X} + B(0,\tau)} \left\|v_i^\top \nabla f(x')\right\| \leq h \cdot \sum_{i\in[d]} \left|f_i'\right|_{\text{sup}}.\end{aligned}$$

Multiply the l.h.s. by $\mathbf{1}\{A_{n,i}(X)\}$, take the empirical expectation and conclude. ■

The variance (Lemma 16) is handled in a way similar to an analysis of (Kpotufe, 2011) on k-NN regression. The additional technicality in the present result is due to the fact that, unlike in the case of k-NN, the number of points contributing to the estimate (and hence the variance) is not a constant.

Proof [Lemma 16] Assume that $A_{n,i}(X)$ is true, and fix $x = X + se_i$. The following variance bound is quickly obtained:

$$\mathbb{E}_{\mathbf{Y}^n|\mathbf{X}^n} \left|f_{n,h}(x) - \tilde{f}_{n,h}(x)\right|^2 \leq \sigma_Y^2 \cdot \sum_{i\in[n]} w_i(x) \leq \sigma_Y^2 \cdot \max_{i\in[n]} w_i(x).$$

Let $\mathbf{Y}^n{}_x$ denote the Y values of samples $X_i \in B(x,h)$, and write $\psi(\mathbf{Y}^n{}_x) \triangleq \left|f_{n,h}(x) - \tilde{f}_{n,h}(x)\right|$. We next relate $\psi(\mathbf{Y}^n{}_x)$ to the above variance.

Let $\mathcal{Y}_\delta$ denote the event that for all $Y_i \in \mathbf{Y}^n$, $|Y_i - f(X_i)| \leq C_Y(\delta/2n) \cdot \sigma_Y$. By definition of $C_Y(\delta/2n)$, the event $\mathcal{Y}_\delta$ happens with probability at least $1 - \delta/2 \geq 1/2$. We therefore have that

$$\begin{aligned}\mathbb{P}_{\mathbf{Y}^n|\mathbf{X}^n}\left(\psi(\mathbf{Y}^n{}_x) > 2\mathbb{E}_{\mathbf{Y}^n|\mathbf{X}^n}\psi(\mathbf{Y}^n{}_x) + \epsilon\right) &\leq \mathbb{P}_{\mathbf{Y}^n|\mathbf{X}^n}\left(\psi(\mathbf{Y}^n{}_x) > \mathbb{E}_{\mathbf{Y}^n|\mathbf{X}^n,\mathcal{Y}_\delta}\psi(\mathbf{Y}^n{}_x) + \epsilon\right) \\ &\leq \mathbb{P}_{\mathbf{Y}^n|\mathbf{X}^n,\mathcal{Y}_\delta}\left(\psi(\mathbf{Y}^n{}_x) > \mathbb{E}_{\mathbf{Y}^n|\mathbf{X}^n,\mathcal{Y}_\delta}\psi(\mathbf{Y}^n{}_x) + \epsilon\right) + \delta/2.\end{aligned}$$

Now, it can be verified that, by McDiarmid's inequality, we have

$$\mathbb{P}_{\mathbf{Y}^n|\mathbf{X}^n,\mathcal{Y}_\delta}\left(\psi(\mathbf{Y}^n{}_x) > \mathbb{E}_{\mathbf{Y}^n|\mathbf{X}^n,\mathcal{Y}_\delta}\psi(\mathbf{Y}^n{}_x) + \epsilon\right) \leq \exp\left\{-2\epsilon^2 / C_Y^2(\delta/2n) \cdot \sigma_Y^2 \sum_{i\in[n]} w_i^2(x)\right\}.$$

Notice that the number of possible sets $\mathbf{Y}^n{}_x$ (over $x \in \mathcal{X}$) is at most the n-shattering number of balls in $\mathbb{R}^d$. By Sauer's lemma we know this number is bounded by $(2n)^{d+2}$. We therefore have by a union bound that, with probability at least $1-\delta$, for all $x \in \mathcal{X}$ satisfying $B(x, h/2) \cap \mathbf{X}^n \neq \emptyset$,

$$\begin{aligned}\psi(\mathbf{Y}^n{}_x) &\leq 2\mathbb{E}_{\mathbf{Y}^n|\mathbf{X}^n}\psi(\mathbf{Y}^n{}_x) + \sqrt{(d+2)\cdot\log(n/\delta) C_Y^2(\delta/2n)\cdot\sigma_Y^2 \sum_{i\in[n]} w_i^2(x)} \\ &\leq 2\left(\mathbb{E}_{\mathbf{Y}^n|\mathbf{X}^n}\psi^2(\mathbf{Y}^n{}_x)\right)^{1/2} + \sqrt{(d+2)\cdot\log(n/\delta) C_Y^2(\delta/2n)\cdot\sigma_Y^2 \cdot \max_i w_i(x)} \\ &\leq \sqrt{Cd\cdot\log(n/\delta) C_Y^2(\delta/2n)\cdot\sigma_Y^2/n\mu_n((B(x,h/2))},\end{aligned}$$

where the second inequality is obtained by applying Jensen's, and the last inequality is due to the fact that the kernel weights are upper and lower-bounded on $B(x, h/2)$.

Now by Lemma 18, with probability at least $1-\delta$, for all X such that $A_{n,i}(X)$ is true, we have for all $s \in \{-t, t\}$, $3\mu_n((B(x, h/2)) \geq \mu((B(x, h/2)) \geq C_\mu(h/2)^d$. Integrate this into the above inequality, take the empirical expectation and conclude. ■

Appendix B. Properties of the metric space $(\mathcal{X}, \rho)$

B.1 Covering numbers

We assume throughout this section that $\Delta_\mathcal{X} \triangleq \sup_{x,x' \in \mathcal{X}} \|x - x'\| = 1$. Recall Definition 3 of Section 2.2.

We start with the following easily obtained lemma.

Lemma 19 *Consider $R \subset [d]$ such that $\max_{i \notin R} < \min_{i \in R} \mathbf{W}_i$. Define $\rho_R(x, x') \triangleq \sqrt{\min_{i \in R} \mathbf{W}_i} \cdot \sum_{i \in R} \left(x^i - x'^i\right)^2$. For any $x, x' \in \mathcal{X}$,*

$$\rho_R(x, x') \leq \rho(x, x') \leq \kappa_R \rho_R(x, x') + \epsilon_{\not R}/2.$$

Proof We have

$$\begin{aligned}
\rho^2(x, x') &= \sum_{i \in R} \mathbf{W}_i (x^i - x'^i)^2 + \sum_{i \notin R} \mathbf{W}_i (x^i - x'^i)^2 \\
&\leq \kappa_R^2 \cdot \min_{i \in R} \mathbf{W}_i \cdot \left\|x - x'\right\|_R^2 + \max_{i \notin R} \mathbf{W}_i \cdot \|\mathcal{X}\| \\
&\leq \left(\kappa_R \rho_R(x, x') + \epsilon_{\not R}/2\right)^2.
\end{aligned}$$

■

The next lemma bounds ϵ-covering numbers for large ϵ (relative to $\epsilon_{\not R}$).

Lemma 20 (Covering numbers at large scale) *Consider any $R \subsetneq [d]$ such that $\max_{i \notin R} \mathbf{W}_i < \min_{i \in R} \mathbf{W}_i$. Let $\rho(\mathcal{X})$ denote the ρ-diameter of $\mathcal{X}$. For any $\epsilon\rho(\mathcal{X}) \geq \epsilon_{\not R}$, $(\mathcal{X}, \rho)$ can be covered by $C_R \epsilon^{-|R|}$ ρ-balls of radius $\epsilon\rho(\mathcal{X})$, where $C_R \leq C(4\kappa_R)^{|R|}$.*

Proof Let $x, x' \in \mathcal{X}$ and define $\|x - x'\|_R \triangleq \sqrt{\sum_{i \in R} (x^i - x'^i)^2}$. Notice that in the pseudo-metric space $(\mathcal{X}, \|x - x'\|_R)$, every ball B of radius r can be covered by at most $C\epsilon^{-|R|}$ balls of radius ϵr for any $\epsilon > 0$. This is also true for any scaling of $\|x - x'\|_R$, in particular for ρ_R. We next relate the covering numbers of $(\mathcal{X}, \rho)$ to those of $(\mathcal{X}, \rho_R)$.

Let $\mathbf{Z}$ denote an $\epsilon\rho(\mathcal{X})$-packing of $(\mathcal{X}, \rho)$, i.e. $\rho(z, z') > \epsilon\rho(\mathcal{X})$ for all $z, z' \in \mathbf{Z}$. The size of $\mathbf{Z}$ is an upper-bound on the mininum $\epsilon\rho(\mathcal{X})$-cover size of $(\mathcal{X}, \rho)$. We have by Lemma 19, $\rho_R(z, z') > (\epsilon\rho(\mathcal{X}) - \epsilon_{\not R}/2)/\kappa_R \geq (\epsilon\rho(\mathcal{X})/2\kappa_R)$. Thus, the size of $\mathbf{Z}$ is at most that of a $(\epsilon\rho(\mathcal{X})/4\kappa_R)$-cover of $(\mathcal{X}, \rho_R)$. Since the ρ_R-diameter of $\mathcal{X}$ is at most $\rho(R)$, we have $|\mathbf{Z}| \leq C(4\kappa_R)^{|R|}\epsilon^{-|R|}$. ■

Using the above lemma, we can now prove Lemma 4 which bounds covering numbers of the space $(\mathcal{X}, \rho)$ at all scales.

Proof [Lemma 4] The first part of Lemma 4 was obtained in Lemma 20 above. The second part is obtained as follows.

We only consider dyadic values $\epsilon = 2^{-m} < \epsilon_{\not R}/\rho(\mathcal{X})$, since, for nondyadic values of ϵ, the bound on the smallest cover can only be within a constant factor depending on d.

To construct a small $\epsilon\rho(\mathcal{X})$-cover, start with an $\epsilon_{\not R}$-cover Z of $\mathcal{X}$. This has size at most $C_R(\epsilon_{\not R}/\rho(\mathcal{X}))^{-|R|}$ by Lemma 20. Consider any $z \in Z$. The ball $B(z, \epsilon_{\not R})$ has an $\epsilon\rho(\mathcal{X})$-cover of size at most $C'(\epsilon_{\not R}/\epsilon\rho(\mathcal{X}))^d$ by the doubling property of bounded subsets of $\mathbb{R}^d$. The union over $z \in Z$ of the covers of the balls $B(z, \epsilon_{\not R})$ is an $\epsilon\rho(\mathcal{X})$-cover of $\mathcal{X}$, and has size at most $C_R \cdot C'\epsilon^{-r(\epsilon)} \leq C_R(\epsilon_{\not R}/\rho(\mathcal{X}))^{-|R|} \cdot C'(\epsilon_{\not R}/\epsilon\rho(\mathcal{X}))^d$, for some $r(\epsilon)$ defined as in the lemma statement. ■

B.2 Change in Lipschitz constant

Next, Lemma 5 which bounds the change in Lipschitz constant is obtained as follows.

Proof [Lemma 5] Let $x \neq x'$ and $v = (x - x')/\|x - x'\|$. Clearly $v^i \leq \rho(x, x')/(\|x - x'\| \cdot \sqrt{\mathbf{W}_i})$. We have

$$\begin{aligned}
\left|f(x) - f(x')\right| &\leq \int_0^{\|x-x'\|} \left|v^\top \nabla f(x + sv)\right| \, ds \leq \int_0^{\|x-x'\|} \sum_{i \in R} \left|v^i \cdot f_i'(x + sv)\right| \, ds \\
&\leq \sum_{i \in R} \int_0^{\|x-x'\|} \left|v^i\right| \cdot \left|f_i'\right|_{\text{sup}} \leq \sum_{i \in R} \frac{\rho(x, x')}{\sqrt{\mathbf{W}_i}} \left|f_i'\right|_{\text{sup}}.
\end{aligned}$$

■

Appendix C. Asymptotic rate for norm-induced metrics

A norm-induced metric ρ on a space $\mathcal{X} \subset \mathbb{R}^d$ is one where there exists a norm $\bar{\rho} : \mathcal{X} \to \mathbb{R}$ such that for every $x, x' \in \mathcal{X}$, $\rho(x, x') = \bar{\rho}(x - x')$. We show in this section that, for such metrics, a regressor operating on the space $(\mathcal{X}, \rho)$ has worst-case rate of $\Omega\left(n^{-2/(2+d)}\right)$ for large n.

Without loss of generality, let $(\mathcal{X}, \rho)$ have diameter 1. We assume further, throughout the section, that the space $\mathcal{X}$ is compact under ρ.

The main argument consists of showing that ϵ-cover sizes for $(\mathcal{X}, \rho)$ are of the form ϵ^{-d} for sufficiently small ϵ. This is then enough to call on the regression lower-bound result of Kpotufe (2011) to conclude the argument.

Abstract

For the prediction with expert advice setting, we consider methods to construct algorithms that have low adaptive regret. The adaptive regret of an algorithm on a time interval $[t_1, t_2]$ is the loss of the algorithm minus the loss of the best expert over that interval. Adaptive regret measures how well the algorithm approximates the best expert locally, and so is different from, although closely related to, both the classical regret, measured over an initial time interval $[1, t]$, and the tracking regret, where the algorithm is compared to a good sequence of experts over $[1, t]$.

We investigate two existing intuitive methods for deriving algorithms with low adaptive regret, one based on specialist experts and the other based on restarts. Quite surprisingly, we show that both methods lead to the same algorithm, namely Fixed Share, which is known for its tracking regret. We provide a thorough analysis of the adaptive regret of Fixed Share. We obtain the exact worst-case adaptive regret for Fixed Share, from which the classical tracking bounds follow. We prove that Fixed Share is optimal for adaptive regret: the worst-case adaptive regret of any algorithm is at least that of an instance of Fixed Share.

Keywords: online learning, adaptive regret, Fixed Share, specialist experts

1. Introduction

This paper deals with the prediction with expert advice setting. Nature generates outcomes step by step. At every step Learner tries to predict the outcome. Then the actual outcome is revealed and the quality of Learner's prediction is measured by a loss function.

No assumptions are made about the nature of the data. Instead, at every step Learner is presented with the predictions of a pool of experts and he may base his predictions on these. The goal of Learner in the classical setting is to guarantee small regret, that is, to suffer cumulative loss that is not much larger than that of the best (in hindsight) expert from the pool. Several classical algorithms exist for this task, including the Aggregating Algorithm (Vovk, 1990) and the Exponentially Weighted Forecaster (Cesa-Bianchi and Lugosi, 2006). In the standard logarithmic loss game the regret incurred by those algorithms when competing with N experts is at most $\ln N$, independent of the number of steps.

A common extension of the framework takes into account the fact that the best expert could change with time. In this case we may be interested in competing with the best *sequence* of experts from the pool. Known algorithms for this task include Fixed Share (Herbster and Warmuth, 1998) and Mixing Past Posteriors (Bousquet and Warmuth, 2002).

In this paper we focus on the related task of obtaining small *adaptive* regret, a notion first considered by Littlestone and Warmuth (1994) and later studied by Hazan and Seshadhri (2009). The adaptive regret of an algorithm on a time interval $[t_1, t_2]$ is the loss that the algorithm accumulates there, minus the loss of the best expert for that interval:

$$R_{[t_1,t_2]} \coloneqq L_{[t_1,t_2]} - \min_n L^n_{[t_1,t_2]} \,. \tag{1}$$

The goal is now to ensure small adaptive regret on all intervals simultaneously. Note that adaptive regret was defined by Hazan and Seshadhri (2009) with a maximum over intervals, but we need the fine-grained dependence on the endpoint times to be able to prove matching upper and lower bounds.

Our results. The contribution of our paper is threefold.

1. We study two constructions to get adaptive regret algorithms from existing classical regret algorithms. The first one is a simple construction proposed by Freund et al. (1997) and slightly generalised by Chernov and Vovk (2009) that involves so called specialists (sleeping experts), and the second one uses restarts, as proposed by Hazan and Seshadhri (2009). Although conceptually dissimilar, we show that both constructions yield the Fixed Share algorithm with a time-varying switching rate.

2. We compute the exact worst-case adaptive regret of Fixed Share. We re-derive the tracking regret bounds from these adaptive regret bounds, showing that the latter are in fact more fundamental.

3. We show that Fixed Share is the optimal algorithm for adaptive regret, in the sense that the worst-case adaptive regret of any candidate algorithm is at least that of an instance of Fixed Share.

Here is a sneak preview of the adaptive bounds we obtain, presented in a slightly relaxed form for simplicity. The refined statement can be found in Theorem 4 below. In the logarithmic loss game for each of the following adaptive regret bounds there is an algorithm satisfying it, simultaneously for all intervals $[t_1, t_2]$:

$$\ln N + \ln t_2 \,, \tag{2a}$$
$$\ln N + \ln t_1 + \ln\ln t_2 + 2 \,, \tag{2b}$$
$$\ln N + 2\ln t_1 + 1 \,, \tag{2c}$$

where $\ln\ln 1$ is interpreted as 0.

Protocol 1 Mix-loss prediction

for $t = 1, 2, \ldots$ **do**
  Learner announces probability vector $\boldsymbol{u}_t \in \triangle_N$
  Reality announces vector $\boldsymbol{\ell}_t \in (-\infty, \infty]^N$ of expert losses
  Learner suffers loss $\ell_t := -\ln \sum_n u_t^n e^{-\ell_t^n}$
end for

Outline. The structure of the paper is as follows. In Section 2 we give the description of the protocol and review standard algorithms. In Section 3 we study two intuitive ways of obtaining adaptive regret algorithms from classical algorithms. We show that curiously both resulting algorithms turn out to be Fixed Share. In Section 4 we study in detail the adaptive regret of Fixed Share and establish its optimality.

2. Setup

We phrase our results in the setting defined in Protocol 1, which, for lack of a standard name, we call *mix loss*. We choose this fundamental setting because it is universal, in the sense that many other common settings reduce to it. For example probability forecasting, sequential investment and data compression are straightforward instances (Cesa-Bianchi and Lugosi, 2006).[1] In addition, mix loss is the baseline for the wider class of *mixable loss functions*, which includes e.g. square loss (Vovk, 2001). Classical (entire $[1, t]$ interval) regret upper bounds transfer from mix loss to mixable losses almost by definition, and the same reasoning extends to adaptive regret bounds (see Appendix A). In addition, mix-loss methods and upper bounds carry over in a modular way (via the individual-sequence versions of Hoeffding-type bounds, e.g. by Cesa-Bianchi et al. 2012) to non-mixable games, which include the Hedge setting (Freund and Schapire, 1997) and Online Convex Optimisation (Zinkevich, 2003). The number N of experts is fixed throughout the paper.

Let us review the specialisation for our setup of two standard algorithms.[2] The *Aggregating Algorithm*, or AA, by Vovk (1998) predicts[3] in trial t with

$$u_t^n := \frac{e^{-\sum_{s<t} \ell_s^n}}{\sum_j e^{-\sum_{s<t} \ell_s^j}}, \tag{3a}$$

which we may also maintain incrementally using the update rule

$$u_{t+1}^n = \frac{u_t^n e^{-\ell_t^n}}{\sum_j u_t^j e^{-\ell_t^j}}. \tag{3b}$$

1. Namely, if ℓ_t^n contains the negative log returns of stock n over trading round t, the mix loss is the negative log return of the portfolio $\boldsymbol{u}_t$. Similarly, if ℓ_t^n contains the negative log likelihoods that probability model n assign to the t-th outcome, then the mix loss is the negative log likelihood of the model average $\boldsymbol{u}_t$.
2. The algorithms we review maintain weights on experts, and originally come with a strategy for subsequently issuing predictions by aggregating the experts' predictions. For mix loss the predictions are abstracted away and an algorithm is evaluated just by its weights.
3. The AA can be parametrised by a prior distribution. As we only need the uniform prior in this section we specialised to that case immediately. The same holds for Fixed Share below.

For this algorithm the classical regret bound states that for each expert n

$$\sum_{t=1}^T \ell_t - \sum_{t=1}^T \ell_t^n \leq \ln N \tag{4}$$

(here and below $\infty - \infty$ is interpreted as 0; i.e., Learner never feels regret w.r.t. an expert who suffers infinite loss). Note that the AA is minimax for classical mix-loss regret since regret $\geq \ln N$ can be inflicted on any algorithm already in the first round.

The second algorithm, *Fixed Share* by Herbster and Warmuth (1998), requires a sequence of switching rates $\alpha_2, \alpha_3, \ldots$. Intuitively, α_t is the probability of a switch to a different expert in the sequence of "best-at-the-step" experts between trials $t-1$ and t. Like the AA, FS starts with uniform weights $u_1^n = 1/N$. The weights are now updated as

$$u_{t+1}^n := \frac{\alpha_{t+1}}{N-1} + \left(1 - \frac{N}{N-1}\alpha_{t+1}\right) \frac{u_t^n e^{-\ell_t^n}}{\sum_j u_t^j e^{-\ell_t^j}}. \tag{5}$$

The intuition behind this expression is that if an expert's normalized weight is w and each expert redistributes a fraction α of his weight uniformly to the other experts, his resulting weight will become $\frac{\alpha}{N-1}(1-w) + (1-\alpha)w = \frac{\alpha}{N-1} + (1 - \frac{N}{N-1}\alpha)w$. We see that the AA is the special case when all α_t are 0 (on the other hand, Fixed Share is a special case of the AA for a certain infinite set of experts as mentioned by Vovk 1999). The tracking regret bound by Herbster and Warmuth (1998) for Fixed Share with constant $\alpha_t = \alpha$ switching rate states that for any reference sequence $n_1, \ldots, n_T$ of experts with m blocks (and hence $m-1$ switches)

$$\sum_{t=1}^T \ell_t - \sum_{t=1}^T \ell_t^{n_t} \leq \ln N + (m-1)\ln(N-1) - (m-1)\ln\alpha - (T-m)\ln(1-\alpha). \tag{6}$$

We will see later (Lemma 11 below) that the interesting values of α_t are in the range $[0, \frac{N-1}{N}]$. Intuitively, a value $\alpha_t > \frac{N-1}{N}$ corresponds to assigning larger weights to poor experts, and this always hurts the worst-case adaptive regret (in the borderline case $\alpha = \frac{N-1}{N}$, (5) becomes $u_{t+1}^n := \frac{1}{N}$). We will also set

$$\alpha_1 := \frac{N-1}{N}; \tag{7}$$

since the algorithm only involves $\alpha_2, \alpha_3, \ldots$ this causes no harm (but simplifies some formulas). Having introduced the standard classical and tracking regret algorithms, we now turn to adaptive regret.

3. Intuitive Algorithms with Low Adaptive Regret

Two methods have been proposed in the literature that can be used to obtain adaptive regret bounds: specialists (sleeping experts) (Freund et al., 1997) and restarts (Hazan and Seshadhri, 2009). We discuss both and show that each of them yields Fixed Share with a particular choice of time-dependent switching rate α_t.

3.1 Specialist Experts

To discuss the first method we need a simple extension of the mix-loss prediction protocol to the case of *specialist experts*, who are absent at some steps ("are asleep"). At the beginning of each round t the subset $A_t \subseteq \{1,\dots,N\}$ of experts who are awake is revealed, and the other experts are said to be asleep. The algorithm is required to assign probabilities only to the experts who are awake, and its loss is now defined by the formula $\ell_t := -\ln \sum_{n\in A_t} u_t^n e^{-\ell_t^n}$. The *specialist AA* is the extension of the AA to specialists. Like the AA it maintains weights on all experts, starting from some prior $\boldsymbol{u}_1$. Each round, it predicts by conditioning the current weights $\boldsymbol{u}_t$ on the set A_t of experts who are awake, thus assigning to such an expert n weight $u_t^n / \sum_{j\in A_t} u_t^j$. After observing the losses the weight of each expert who is awake, $n \in A_t$, is updated multiplicatively as $u_{t+1}^n := u_t^n e^{\ell_t - \ell_t^n}$ and the weight of each sleeping expert $n \notin A_t$ stays put at $u_{t+1}^n := u_t^n$.

The AA and specialist AA are related in a useful manner: Chernov and Vovk (2009) obtain the specialist AA from the AA by imagining that all sleeping experts suffer the same loss as the algorithm. This observation immediately leads to a relativised analogue of regret bound (4). The specialist AA guarantees, for each specialist n,

$$\sum_{t\le T: n\in A_t} \ell_t - \sum_{t\le T: n\in A_t} \ell_t^j \;\le\; \ln N. \tag{8}$$

The loss of expert n is defined only during the rounds when he is awake. This bound tells us that the cumulative loss of the specialist AA incurred during those rounds does not exceed the cumulative loss of expert n by much.

We now turn to obtaining adaptive regret bounds for the vanilla expert setting by running the specialist AA on imaginary (virtual) sleeping experts of our own design.

3.1.1 Specialist Experts

One way of getting an adaptive algorithm is the following. We create a pool of virtual experts. For each real expert n and time t, we include a virtual expert that sleeps during the first $t-1$ trials, and subsequently predicts as expert n from trial t onward. The specialist regret (in the sense of 8) w.r.t. this virtual expert on $[1,T]$ is the same as the adaptive regret w.r.t. the real expert n on $[t,T]$. The natural idea is to feed all those virtual experts into the existing algorithm capable of obtaining good classical regret, the specialist AA. For fixed t_2, the uniform prior on wake-up time $t_1 \le t_2$ and expert n this would lead to adaptive regret $\ln(Nt_2)$. It turns out that the same holds even without knowledge of t_2.

At first glance, it is very inefficient, even in the case of a finite horizon T, to maintain weights of TN specialists. However, we do not need to, since we may merge the weights of all specialists who are awake and associated to the same real expert, resulting in Algorithm 1. To verify that this algorithm is correct, denote this merged (unnormalised) weight in trial t by v_t^n for each real expert n. The merged (unnormalised) weight v_{t+1}^n of this real expert n in the next trial $t+1$ consists of the prior weight, denoted $p(t+1)$, of the newly awaken virtual specialist plus v_t^n, the sum of the weights of the previously awaken specialists, each multiplied by the same factor $e^{\ell_t - \ell_t^n}$ (as they were all awake). Thus we can update the sum directly, and this is reflected by our update rule.

Algorithm 1 Adaptive Aggregating Algorithm

Input: Prior nonnegative weights $p(t)$, $t = 1,2,\dots$, with $p(1) > 0$
$v_1^n := p(1)$, $n = 1,\dots,N$
for $t = 1,2,\dots$ **do**
  Play weights $u_t^n := \frac{v_t^n}{\sum_{j=1}^N v_t^j}$
  Read the experts losses ℓ_t^n, $n = 1,\dots,N$
  Set $v_{t+1}^n := p(t+1) + v_t^n \frac{e^{-\ell_t^n}}{\sum_{j=1}^N u_t^j e^{-\ell_t^j}}$, $n = 1,\dots,N$
end for

Note that for simplicity, we have taken the (unnormalised) priors on experts and wake-up times independent, i.e.

$$p^{(n,t)} \;=\; p(t)\,.$$

(There is no need for the prior weights $p^{(n,t)}$ to normalise, as the predictions are normalised explicitly.)

Now we will see that Algorithm 1 turns out to be Fixed Share with variable switching rate. In the rest of this section we derive this. Let $P(t) = \sum_{s=1}^t p(s)$.

Fact 1 *The update step of Algorithm 1 preserves the following: for all $t \ge 1$*

$$\sum_n v_t^n = \sum_n \sum_{s\le t} p(s) = NP(t)\,.$$

Proof This follows immediately from expanding the one-step update rule:

$$\begin{aligned}
\sum_n v_{t+1}^n &= \sum_n p(t+1) + \sum_n v_t^n \frac{e^{-\ell_t^n}}{\sum_k u_t^k e^{-\ell_t^k}} \\
&= \sum_n p(t+1) + \sum_n v_t^n \frac{e^{-\ell_t^n}}{\sum_k \frac{v_t^k}{\sum_n v_t^n} e^{-\ell_t^k}} \\
&= Np(t+1) + \sum_n v_t^n \overset{\text{Induction}}{=} NP(t+1)\,. \qquad \blacksquare
\end{aligned}$$

We now show that Algorithm 1 can be seen as Fixed Share (and vice versa).

Lemma 2 *Suppose the probabilities $\alpha_t \in [0, \frac{N-1}{N}]$ of a Fixed Share switch before trial t and the prior weights $p(t)$ of a specialist waking up in trial t in Algorithm 1 satisfy*

$$p(t) \;=\; \frac{\frac{N}{N-1}\alpha_t}{\prod_{s=2}^t (1 - \frac{N}{N-1}\alpha_s)}$$

(where we use the convention 7) or, equivalently,

$$\alpha_t \;=\; \frac{N-1}{N} \frac{p(t)}{\sum_{s=1}^t p(s)}\,.$$

Then the two algorithms output identical predictions.

Proof Let us rewrite the update step of Algorithm 1 for the normalised weights.

$$\begin{aligned} u_{t+1}^n &= \frac{v_{t+1}^n}{\sum_j v_{t+1}^j} = \frac{p(t+1)}{NP(t+1)} + \frac{1}{NP(t+1)} v_t^n \frac{e^{-\ell_t^n}}{\sum_j u_t^j e^{-\ell_t^j}} \\ &= \frac{p(t+1)}{NP(t+1)} + \frac{1}{NP(t+1)} NP(t) u_t^n \frac{e^{-\ell_t^n}}{\sum_j u_t^j e^{-\ell_t^j}} \\ &= \frac{\alpha_{t+1}}{N-1} + \frac{P(t+1) - p(t+1)}{P(t+1)} u_t^n \frac{e^{-\ell_t^n}}{\sum_j u_t^j e^{-\ell_t^j}} \\ &= \frac{\alpha_{t+1}}{N-1} + \left(1 - \frac{N}{N-1}\alpha_{t+1}\right) u_t^n \frac{e^{-\ell_t^n}}{\sum_j u_t^j e^{-\ell_t^j}}. \end{aligned}$$

We see that the weight update is the update of the Fixed Share algorithm with variable switching rate α_t. ■

The idea to use specialist experts for obtaining adaptive bounds was introduced by Freund et al. (1997). There a virtual specialist is created for every interval $[t_1, t_2]$ which leads to redundancy and suboptimal bounds. Their adaptive regret bounds include a term which exceeds $2 \ln t_2$ whereas our bounds (2) have at most a single $\ln t_2$.

3.2 Restarts

A second intuitive method to obtain adaptive regret bounds, called Follow the Leading History (FLH), was introduced by Hazan and Seshadhri (2007, 2009).[4] One starts with a base algorithm that ensures low classical regret. FLH then obtains low adaptive regret by restarting a copy of this base algorithm at each trial, and aggregating the predictions of these copies. To get low adaptive regret w.r.t. N experts[5], it is natural to take the AA as the base algorithm. We now show that FLH with this choice equals Fixed Share with switching rate $\alpha_t = \frac{N-1}{Nt}$.

For each n, s and $t \geq s$, let $p_t^{n|s}$ denote the weight allocated to expert n by the copy of the AA started at time s. By definition $p_s^{n|s} = 1/N$, and these weights evolve according to (3b). We denote by p_t^s the weight allocated by FLH in trial $t \geq s$ to the copy of the AA started at time s. Hazan and Seshadhri (2009) define these weights as follows. Initially $p_1^1 = 1$ and subsequently

$$p_{t+1}^{t+1} = \frac{1}{t+1} \quad \text{and} \quad p_{t+1}^s = \left(1 - p_{t+1}^{t+1}\right) \frac{p_t^s e^{-\left(-\ln \sum_n p_t^{n|s} e^{-\ell_t^n}\right)}}{\sum_{r=1}^t p_t^r e^{-\left(-\ln \sum_n p_t^{n|r} e^{-\ell_t^n}\right)}} \quad \text{for all } 1 \leq s \leq t.$$

4. Here we present the version of Follow the Leading History with the best performancee guarantee. This version is called FLH1 by Hazan and Seshadhri (2007). It can be recovered from FLH by Hazan and Seshadhri (2009) by omitting the pruning step, which considerably improves computational efficiency at the cost of predictive performance. Alghough such tradeoffs are not the focus of our paper, they are of great practical significance. We refer to György et al. (2012) for an in-depth analysis.
5. More broadly, for any exp-concave loss function FLH can upgrade classic regret bounds for any baseline algorithm to their adaptive analogues, resulting in efficient adaptive regret algorithms for continuous online optimisation.

We now show that this construction is a reparametrisation of Fixed Share. In fact, this is true for any choice of the restart probabilities p_t^t.

Lemma 3 *For mix loss, FLH with the AA as the base algorithm issues the same predictions as Fixed Share with learning rate* $\alpha_t = \frac{N-1}{N} p_t^t$.

Proof We prove by induction on t that the FS and FLH weights coincide:

$$u_t^n = \sum_{s=1}^t p_t^{n|s} p_t^s.$$

The base case $t = 1$ is obvious. For the induction step we expand

$$\begin{aligned} \sum_{s=1}^{t+1} p_{t+1}^{n|s} p_{t+1}^s &= \sum_{s=1}^t p_{t+1}^{n|s} p_{t+1}^s + p_{t+1}^{t+1}/N \\ &= \left(1 - p_{t+1}^{t+1}\right) \sum_{s=1}^t \left(\frac{p_t^{n|s} e^{-\ell_t^n}}{\sum_n p_t^{n|s} e^{-\ell_t^n}} \frac{p_t^s \left(\sum_n p_t^{n|s} e^{-\ell_t^n}\right)}{\sum_{r=1}^t p_t^r \left(\sum_n p_t^{n|r} e^{-\ell_t^n}\right)} \right) + \frac{1}{N} p_{t+1}^{t+1} \\ &= \left(1 - p_{t+1}^{t+1}\right) \frac{\sum_{s=1}^t p_t^s p_t^{n|s} e^{-\ell_t^n}}{\sum_{r=1}^t \sum_n p_t^r p_t^{n|r} e^{-\ell_t^n}} + \frac{1}{N} p_{t+1}^{t+1} \\ &\overset{\text{Induction}}{=} \left(1 - p_{t+1}^{t+1}\right) \frac{u_t^n e^{-\ell_t^n}}{\sum_n u_t^n e^{-\ell_t^n}} + \frac{1}{N} p_{t+1}^{t+1} = u_{t+1}^n, \end{aligned}$$

and find the Fixed Share update equation (5) for switching rate $\alpha_t = \frac{N-1}{N} p_t^t$. ■

Discussion. This unification points out that the Fixed Share algorithm can be viewed/implemented in three different ways. Depending on the situation, one of these may be more attractive. For example, Hazan and Seshadhri (2009) show that the FLH viewpoint scales up naturally to continuous optimization, and Luo and Schapire (2015) use our specialists viewpoint to design parameterless adaptive regret algorithms for the Hedge setting.

4. The Adaptive Regret of Fixed Share

We have seen in the previous section that both intuitive approaches to obtain algorithms with low adaptive regret result in Fixed Share. We take this convergence to mean that Fixed Share is the most fundamental adaptive algorithm. The tracking regret for Fixed Share is already well-studied. In Section 4.1 we thoroughly analyse the adaptive regret of Fixed Share. We obtain the worst-case adaptive regret for mix loss. This result implies the known tracking regret bounds. Then in Section 4.2 we characterise the achievable (by means of any algorithm) bounds on worst-case adaptive regret. We prove an information-theoretic lower bound for mix loss that must hold for any algorithm, and which is tight for Fixed Share. We show that the Pareto optimal bounds are exactly the Fixed Share bounds. This establishes Fixed Share as *the* answer for adaptive regret. Finally, in Section 4.3, we investigate the possibility of improving the adaptive regret for all "late" intervals by completely forgoing the regret guarantees on "early" intervals. We conclude that this is basically impossible.

4.1 The Exact Worst-case Mix-loss Adaptive Regret for Fixed Share

Define the *worst-case adaptive regret* on $[t_1, t_2]$ to be the supremum of (1) over all data sequences (cf. Definition 7 below). In this section we first compute the exact worst-case adaptive regret of Fixed Share with arbitrary switching rate $\alpha_t \in [0, \frac{N-1}{N}]$. Then we obtain certain regret bounds of interest, including the tracking regret bound, for particular choices of α_t.

Theorem 4 *The worst-case adaptive regret of Fixed Share with $\alpha_t \in [0, \frac{N-1}{N}]$ and with N experts on interval $[t_1, t_2]$ equals*

$$-\ln\left(\frac{\alpha_{t_1}}{N-1}\prod_{t=t_1+1}^{t_2}(1-\alpha_t)\right) \tag{9}$$

with the convention (7).

Proof The proof consists of two parts. First we claim that the worst-case data for the interval $[t_1, t_2]$ in the setting of Protocol 1 is rather simple: on the interval there is one *good* expert (all others get infinite losses) and on the single trial before the interval (if $t_1 > 1$) this expert suffers infinite loss while others do not. The proof of this fact can be found in Appendix B.

Now we will compute the regret on this data. The regret of Fixed Share on the interval $[t_1, t_2]$ is $-\ln$ of the product of the weights put on the good expert (say, n) on this interval:

$$R^{\mathrm{FS}}_{[t_1,t_2]} = -\ln \prod_{t_1 \le t \le t_2} u^n_t \,.$$

It is straightforward to derive u^n_t from (5):

$$u^n_{t_1} \;=\; \frac{\alpha_{t_1}}{N-1} \qquad \text{and} \qquad u^n_t \;=\; 1-\alpha_t \qquad \text{for } t \in [t_1+1, t_2]$$

(this is also true when $t_1 = 1$); this implies the statement. ■

Next we discuss the bounds resulting from three settings of the switching rate α_t.

4.1.1 Example 1: Constant Switching Rate

This is the original Fixed Share by Herbster and Warmuth (1998).

Corollary 5 *Fixed Share with constant switching rate $\alpha_t = \alpha$ for $t > 1$ (recall that $\alpha_1 = \frac{N-1}{N}$) has worst-case adaptive regret equal to*

$$\begin{aligned} &\ln(N-1) - \ln\alpha - (t_2 - t_1)\ln\bigl(1-\alpha\bigr) && \text{for } t_1 > 1, \text{ and} \\ &\ln N - (t_2 - 1)\ln\bigl(1-\alpha\bigr) && \text{for } t_1 = 1. \end{aligned}$$

A slightly weaker upper bound was obtained by Cesa-Bianchi et al. (2012). The clear advantage of our analysis with equality is that we can obtain the standard Fixed Share

tracking regret bound by summing the above adaptive regret bounds on individual intervals. Comparing Fixed Share with the best sequence S of experts on the interval $[1, T]$ with m blocks, we obtain the bound

$$L^{\mathrm{FS}}_{[1,T]} - L^S_{[1,T]} \;\le\; \ln N + (m-1)\ln(N-1) - (m-1)\ln\alpha - (T-m)\ln(1-\alpha)\,,$$

which is exactly the standard Fixed Share tracking bound (6). So we see that the reason why Fixed Share can effectively compete with switching sequences is that it can, in fact, effectively compete with any expert on any interval, that is, has small adaptive regret.

4.1.2 Example 2: Slowly Decreasing Switching Rate

The idea of slowly decreasing the switching rate was considered by Shamir and Merhav (1999) in the context of source coding, and later analysed for expert switching by Koolen and De Rooij (2008); we saw in Section 3.2 that it also underlies Follow the Leading History of Hazan and Seshadhri (2009). It results in tracking regret bounds that are almost as good as the bounds for constant α *with optimally tuned* α. These tracking bounds are again implied by the following corresponding adaptive regret bound.

Corollary 6 *Fixed Share with switching rate $\alpha_t = 1/t$ (except for $\alpha_1 = \frac{N-1}{N}$) has worst-case adaptive regret*

$$-\ln\left(\frac{1}{(N-1)t_1}\prod_{t=t_1+1}^{t_2}\frac{t-1}{t}\right) \;=\; \ln(N-1) + \ln t_2 \qquad \text{for } t_1 > 1, \text{ and} \tag{10a}$$

$$-\ln\left(\frac{1}{N}\prod_{t=2}^{t_2}\frac{t-1}{t}\right) \;=\; \ln N + \ln t_2 \qquad \text{for } t_1 = 1. \tag{10b}$$

Comparing Fixed Share with the best sequence S of experts on $[1, T]$ with m blocks we obtain, by summing the bound in Corollary 6 over all blocks,

$$L^{\mathrm{FS}}_{[1,T]} - L^S_{[1,T]} \;\le\; \ln N + (m-1)\ln(N-1) + m\ln T. \tag{11}$$

For comparison, the bound for Fixed Share aggregated over the αs with a suitable prior is

$$L^{\mathrm{AFS}}_{[1,T]} - L^S_{[1,T]} \;\le\; \ln N + (m-1)\ln(N-1) + m\ln T - \ln\bigl((m-1)!\bigr) \tag{12}$$

(see Vovk (1999), Theorem 2, setting $\eta := 1$, $k := m-1$, and $\epsilon := 1$). Our bound (11) is not as good as (12) in that the latter has the nonpositive (negative for $m > 2$) addend $-\ln\bigl((m-1)!\bigr) \sim -m\ln m$. However, the difference does not appear great unless the number m of blocks is very large.[6] And whereas Fixed Share can be implemented in time $O(N)$ per trial, this aggregate seems to require work per-trial scaling with $\sqrt{t}$ (Monteleoni and Jaakkola, 2003; De Rooij and Van Erven, 2009).

6. If $m \le T^c$ for some $c \in (0,1)$, then $(1-c)m\ln T \;\le\; m\ln\frac{T}{m} \;\le\; m\ln T$, so the block timing overheads of (11) and (12) differ by at most a constant factor.

4.1.3 Example 3: Quickly Decreasing Switching Rate

The bounds we have obtained so far depend on t_2 either linearly or logarithmically. To get bounds that depend on t_2 sub-logarithmically, or even not at all, one may instead decrease the switching rate faster than $1/t$, as analysed by Shamir and Merhav (1999) and Koolen and De Rooij (2013). To obtain a controlled trade-off, we consider setting the switching rate to $\alpha_t = \frac{1}{t \ln t}$, except for $\alpha_1 = \frac{N-1}{N}$ and, in the case $N \in \{2,3\}$, $\alpha_2 = \frac{N-1}{N}$ (this is needed since $\frac{1}{2\ln 2} \approx 0.72 > \frac{N-1}{N}$). This leads to adaptive regret at most

$$\ln(N-1) + \ln t_1 + \ln\ln t_1 - \sum_{t=t_1+1}^{t_2} \ln\left(1 - \frac{1}{t \ln t}\right) \;\leq\; \ln(N-1) + \ln t_1 + \ln\ln t_2 \quad (13a)$$

when $t_1 > 2$ or both $t_1 = 2$ and $N > 3$, at most

$$\ln N - \sum_{t=3}^{t_2} \ln\left(1 - \frac{1}{t \ln t}\right) \;\leq\; \ln N + \ln\ln t_2 + 0.37 \quad (13b)$$

when $t_1 = 2$ and $N \in \{2,3\}$, and at most

$$\ln N - \sum_{t=2}^{t_2} \ln\left(1 - \frac{1}{t \ln t}\right) \;\leq\; \ln N + \ln\ln t_2 + 1.65 \quad (13c)$$

when $t_1 = 1$ and $N > 3$ (remember that $\ln\ln 1$ is understood to be 0). In the case where $t_1 = 1$ and $N \in \{2,3\}$, the term $\frac{1}{2\ln 2}$ in (13c) (when it is present, i.e., when $t_2 > 1$) should be replaced by the smaller term $\frac{N-1}{N}$; this does not affect the validity of the bound. In all the cases, the bounds, (13a)–(13c), are stronger than (2b).

The dependence on t_2 in (13) is extremely mild. We can suppress it completely by increasing the dependence on t_1 just ever so slightly. If we set $\alpha_t = t^{-1-\epsilon}$, where $\epsilon > 0$, then the sum of the series $\sum_t \alpha_t$ is finite and the bound becomes

$$\ln(N-1) + (1+\epsilon)\ln t_1 + c_\epsilon \qquad \text{for } t_1 > 1, \text{ and} \quad (14a)$$

$$\ln N + c_\epsilon \qquad \text{for } t_1 = 1, \quad (14b)$$

where $c_\epsilon = -\sum_{t=2}^{\infty} \ln(1 - t^{-1-\epsilon})$. It is clear that the bound (14a) is far from optimal when t_1 is large: c_ϵ can be replaced by a quantity that tends to 0 as $O(t_1^{-\epsilon})$ as $t_1 \to \infty$. In particular, for $\epsilon = 1$ we have the bound

$$\ln N + 2\ln t_1 + \ln 2.$$

An interesting feature of this switching rate is that for the full interval $[t_1, t_2] = [1, T]$ the bound differs from the standard AA bound only by an additive term less than 1. In words, the overhead for small adaptive regret is negligible.

4.2 Fixed Share is Pareto Optimal for Adaptive Regret

We started by considering several intuitive constructions for adaptive algorithms, and saw that they all result in Fixed Share. We then obtained the worst-case adaptive regret of

Fixed Share. Intuitive as it may be, we have not answered the question whether Fixed Share is a good algorithm in the sense that its worst-case adaptive regret bounds are small. It is conceivable that there are smarter algorithms with better adaptive regret guarantees. See for example the palette of tracking algorithms proposed by Koolen and De Rooij (2013). And even if no better algorithms exist, there may still be algorithms that exhibit different trade-offs, in the sense that their worst-case adaptive regret is incomparable to that of Fixed Share.

So in this section we start from the other end and derive lower bounds that hold for any algorithm. As expected, we conclude that the bounds of Fixed Share (with any switching rate sequence $\alpha_t \leq \frac{N-1}{N}$) are Pareto optimal. But it came to us as a surprise that actually *all other bounds are strictly dominated*. No matter how smart the algorithm, its worst-case adaptive regret will be dominated by that of an instance of Fixed Share.

We call a mapping ϕ of intervals to regrets a *candidate guarantee*. Such a candidate guarantee is *realisable* if there is an algorithm for mix-loss prediction (Protocol 1) with adaptive regret at most ϕ. That is, we demand

$$R_{[t_1,t_2]} \;\leq\; \phi(t_1, t_2)$$

for all sequences of expert losses $\boldsymbol{\ell}_1, \boldsymbol{\ell}_2, \ldots$ in $(-\infty, \infty]^N$ and all choices of the interval $1 \leq t_1 \leq t_2$. We say that a realizable guarantee ϕ *dominates* a realizable guarantee ψ if $\phi(t_1, t_2) \leq \psi(t_1, t_2)$ for all intervals $[t_1, t_2]$; and we say that ϕ *strictly dominates* ψ if, furthermore, $\phi(t_1, t_2) < \psi(t_1, t_2)$ for some interval $[t_1, t_2]$. A realisable guarantee ϕ is *Pareto optimal* if it is not strictly dominated by any realizable guarantee.

We are interested in Pareto-optimal guarantees. Every such guarantee is, by definition, the worst-case regret of an algorithm. Let us make that precise:

Definition 7 *We say that ϕ is the* worst-case adaptive regret *of a given algorithm if*

$$\phi(t_1, t_2) \;=\; \sup_{\boldsymbol{\ell}_1, \boldsymbol{\ell}_2, \ldots} R_{[t_1,t_2]} \qquad \text{for all } 1 \leq t_1 \leq t_2.$$

The main step in characterising the Pareto optimal guarantees is showing that worst-case adaptive regrets cannot be too small.

Theorem 8 *Let ϕ be the worst-case adaptive regret of some algorithm. Then*

$$\phi(t, t) \;\geq\; \ln N \qquad \text{for all } 1 \leq t \text{ and} \quad (15a)$$

$$\phi(t_1, t_2) \;\geq\; \phi(t_1, t_1) + \sum_{t=t_1+1}^{t_2} -\ln\left(1 - (N-1)e^{-\phi(t,t)}\right) \qquad \text{for all } 1 \leq t_1 < t_2. \quad (15b)$$

Proof We first show (15a). Since at any time t the N weights played must sum to one, the smallest weight must be $\leq 1/N$. By hitting all others with infinite loss we force regret at least $\ln N$ over the interval $[t, t]$. Now suppose (15a) holds throughout, and consider any interval $[t_1, t_2]$. Fix $\epsilon > 0$. Let $\boldsymbol{\ell}_1, \ldots, \boldsymbol{\ell}_{t_1}$ be data on which the regret over $[t_1, t_1]$ exceeds $\phi(t_1, t_1) - \epsilon$. Let n^* be the (any) best expert in trial t_1. Now for all $t \in (t_1, t_2]$ choose $\ell_t^{n^*} = 0$ and $\ell_t^n = \infty$ for all $n \neq n^*$. In any trial t, the algorithm must allocate at least

weight $e^{-\phi(t,t)}$ to each expert to guarantee ϕ on the singleton interval $\{t\}$. Since the weights sum to one, the weight allocated to expert n^* during each trial $t \in (t_1, t_2]$ can be at most $1-(N-1)e^{-\phi(t,t)}$. Hence the loss of the algorithm must be at least $-\ln\bigl(1-(N-1)e^{-\phi(t,t)}\bigr)$. Since the loss of the best expert n^* on $(t_1, t_2]$ is zero, the regret is at least the right-hand side of (15b) minus ϵ. The worst-case regret $\phi(t_1, t_2)$ must be at least as large. Since this holds for all ϵ, we have proved (15b). ■

A realisable guarantee is witnessed by some algorithm, and is therefore dominated by the worst-case adaptive regret of that algorithm. We proved that this worst-case adaptive regret must satisfy (15). We now show that any guarantee satisfying (15) is realised by an instance of Fixed Share.

Theorem 9 *Let ϕ satisfy* (15). *Then Fixed Share with switching rate sequence $\alpha_2, \alpha_3, \ldots$ where $\alpha_t = (N-1)e^{-\phi(t,t)}$ guarantees ϕ.*

Proof From (15a) we know that $\alpha_t \le (N-1)/N$, so the worst case regret of Fixed Share is given by Theorem 4. In particular (9) with our choice of α_t equals the right-hand side of (15b), and so FS guarantees ϕ. Note that the fact that α_1 is always set to the specific value $(N-1)/N$ only works in our favour here. ■

By combining the preceding two theorems, in the following two corollaries we characterize realizable guarantees and obtain canonical representatives of the Pareto guarantees for adaptive regret.

Corollary 10 *Let ϕ be a candidate guarantee. The following are equivalent:*

- *ϕ is realisable*
- *there exists $\psi \le \phi$ such that ψ satisfies* (15)
- *ϕ is dominated by the worst-case adaptive regret of a Fixed Share.*

Before stating the second corollary we need to tackle the problem of big α_ts.

Lemma 11 *Fixed Share with $\alpha_t \in [0, \frac{N-1}{N}]$ is Pareto optimal. If $\sup_t \alpha_t > \frac{N-1}{N}$, Fixed Share with such parameters α_t is strictly dominated by Fixed Share with parameters $\alpha_t \wedge \frac{N-1}{N}$.*

Proof Suppose Fixed Share with parameters $\alpha_t \in [0, \frac{N-1}{N}]$ dominates Fixed Share with parameters $\beta_t \in [0, \frac{N-1}{N}]$. Equation (9) with $t_1 = t_2$ then implies $\alpha_t \ge \beta_t$ for all t. Combining this with (9) with $t_1 = 1$ now implies $\alpha_t = \beta_t$ for all t. In combination with the last statement of Corollary 10 this proves the first statement of the lemma.

For the second statement of the lemma, we should prove that in the case $\sup_t \alpha_t > \frac{N-1}{N}$ the worst-case regret of Fixed Share with parameters α_t for a fixed interval $[t_1, t_2]$ containing t with $\alpha_t > \frac{N-1}{N}$ will be greater than the worst-case regret of Fixed Share with parameters $\alpha_t \wedge \frac{N-1}{N}$) (given by (9) with α_t replaced by $\alpha_t \wedge \frac{N-1}{N}$). To see this, modify the "worst-case data" described in the proof of Theorem 4 (which are no longer worst-case for α_t) as follows: if $\alpha_{t_1} > \frac{N-1}{N}$ (and so $t_1 > 1$), make the loss of the good expert at step $t_1 - 1$ finite and

make the losses of all other experts at step $t_1 - 1$ infinite; if $\alpha_t > \frac{N-1}{N}$ for $t \in (t_1, t_2]$, make the loss of the good expert at step $t-1$ infinite and make the loss of another expert at step $t-1$ finite. ■

We conclude that Fixed Share is *the* answer for worst-case adaptive regret bounds.

Corollary 12 *Let ϕ be a candidate guarantee. The following are equivalent:*

- *ϕ is Pareto optimal*
- *ϕ satisfies* (15a) *with equality for $t = 1$ and satisfies* (15b) *with equality throughout*
- *ϕ is the worst-case adaptive regret of a Fixed Share with parameters $\alpha_t \in [0, \frac{N-1}{N}]$.*

Proof First, let ϕ be Pareto optimal. Since it is then the worst-case adaptive regret of some algorithm, it satisfies (15). By Theorem 9 ϕ is guaranteed by a Fixed Share with $\alpha_t \in [0, \frac{N-1}{N}]$, and so ϕ is the worst-case adaptive regret of such a Fixed Share. And, as noted in the proof of Theorem 9, the worst case adaptive regret of such a Fixed Share satisfies (15a) with equality for $t = 1$ and (15b) with equality throughout. Second, let ϕ satisfy (15a) with equality for $t = 1$ and (15b) with equality throughout. By Theorem 9 ϕ is guaranteed by Fixed Share with $\alpha_t = (N-1)e^{\phi(t,t)} \in [0, \frac{N-1}{N}]$. Now Theorem 4 implies that ϕ is the worst-case adaptive regret of this Fixed Share. Third, let ϕ be the worst-case adaptive regret of a Fixed Share with parameters $\alpha_t \in [0, \frac{N-1}{N}]$. Then ϕ is Pareto optimal by Lemma 11. ■

4.3 Sacrifice Early to Benefit Later? Impossible

We have seen that the Pareto optimal guarantees are those witnessed by Fixed Share. We saw several bounds (2), worked out in detail in Section 4.1, with different dependencies on the interval endpoints t_1 and t_2. In this section we investigate the possibility of forgoing completely the guarantees on early intervals to substantially improve the guarantees on all late intervals. We conclude that this is essentially impossible.

The main tool in this section is a slight relaxation of Theorem 8 that holds for all guarantees, not only for worst-case regrets.

Corollary 13 *If $\phi(t_1, t_2)$ is realisable, then*

$$\phi(t_1, t_2) \;\ge\; \ln N + \sum_{t=t_1+1}^{t_2} -\ln\Bigl(1-(N-1)e^{-\phi(t,t)}\Bigr) \qquad \text{for all } 1 \le t_1 \le t_2. \tag{16}$$

Proof Plug (15a) into (15b) and notice that increasing ϕ increases the left-hand side and decreases the right-hand side of (16). ■

The following corollary shows that the stronger form (10) of (2a) is essentially tight: for large t_1 and t_2 we cannot even improve the right-hand side of (10a) by a positive constant (it is not sufficient to ignore all intervals with $t_1 < T_0$ for an arbitrarily large T_0).

Corollary 14 *Fix a constant $C < \ln(N-1)$ and an arbitrarily large positive integer constant T_0. The following guarantee is not realisable:*

$$\phi(t_1,t_2) \;=\; \begin{cases} C+\ln t_2 & \text{if } t_1 \ge T_0 \\ \infty & \text{otherwise.} \end{cases} \tag{17}$$

Proof For $t_1 \ge T_0 - 1$, the right hand side of (16) is at least (using $-\ln(1-x) \ge x$ and Euler's summation formula)

$$\ln N - \sum_{t=t_1+1}^{t_2} \ln\left(1 - \frac{N-1}{e^C t}\right) \;\ge\; \ln N + \frac{N-1}{e^C} \sum_{t=t_1+1}^{t_2} \frac{1}{t} \;\ge\; \ln N + \frac{N-1}{e^C}\left(\ln t_2 - \ln t_1 - D\right),$$

for some constant D. (The inequality $-\ln(1-x) \ge x$ assumes only $x < 1$ and so is applicable if T_0 is sufficiently large.) For a fixed t_1 (say, $t_1 = T_0$), this will exceed $C + \ln t_2$ (the guarantee 17) when t_2 is sufficiently large. Contradiction. ■

Our next corollary is about the tightness of (2b) and its elaboration (13) (especially 13a).

Corollary 15 *Fix a constant $C < \ln(N-1)$ and positive integer T_0. The following candidate guarantee is not realisable:*

$$\phi(t_1,t_2) \;=\; \begin{cases} C+\ln t_1 + \ln\ln t_2 & \text{if } t_1 \ge T_0 \\ \infty & \text{otherwise.} \end{cases}$$

Proof As in the previous proof, we can see that for $t_1 \ge T_0 - 1$ the right hand side of (16) is at least

$$\ln N - \sum_{t=t_1+1}^{t_2} \ln\left(1 - \frac{N-1}{e^C t \ln t}\right) \;\ge\; \ln N + \sum_{t=t_1+1}^{t_2} \frac{N-1}{e^C t \ln t} \;\ge\; \ln N + \frac{N-1}{e^C}\left(\ln\ln t_2 - \ln\ln t_1 - D\right).$$

For a fixed t_1 and a large enough t_2 this will exceed $C + \ln t_1 + \ln\ln t_2$. Contradiction. ■

Finally, we explore the tightness of (2c) and its elaboration given later in the paper: see (14) and the discussion afterwards. Let us say that a sequence $a(1), a(2), \ldots$ is $O(1)$-*realisable* if there is a C such that the candidate guarantee $\phi(t_1,t_2) = a(t_1) + C$ is realisable. Let us say that a sequence $a(1), a(2), \ldots$ is $O(1)$-*realisable in the long run* if there are C and T_0 such that the candidate guarantee

$$\phi(t_1,t_2) \;=\; \begin{cases} a(t_1) + C & \text{if } t_1 \ge T_0 \\ \infty & \text{otherwise} \end{cases} \tag{18}$$

is realisable.

Corollary 16 *A sequence $a(t)$ is $O(1)$-realisable*

- *if and only if it is $O(1)$-realisable in the long run, and*

- *if and only if $\sum_t e^{-a(t)} < \infty$.*

Proof Suppose $\sum_t e^{-a(t)} < \infty$. Then $a(t)$ is $O(1)$-realisable by Theorem 4 (set $\alpha_t = e^{-a(t)}$ from some t on). To prove that the series converges when $a(t)$ is $O(1)$-realisable in the long run, suppose $\sum_t e^{-a(t)} = \infty$. If (18) is realisable, we can again see that for $t_1 \ge T_0 - 1$ the right hand side of (16) is at least

$$\ln N + \sum_{t=t_1+1}^{t_2} -\ln\left(1 - (N-1)e^{-C}e^{-a(t)}\right) \;\ge\; \ln N + \sum_{t=t_1+1}^{t_2} (N-1)e^{-C}e^{-a(t)}.$$

For a fixed t_1 and a large enough t_2 this will exceed $a(t_1) + C$. Contradiction. ■

The first statement of Corollary 16 can be interpreted as a weak statement of impossibility to sacrifice early in order to benefit later: we can gain at most a constant when we sacrifice early. (And we saw below (14) that we can indeed gain a constant.) This statement, however, is very general, as the following simple argument shows.

Let us say that a candidate guarantee $\phi(t_1,t_2)$ is $O(1)$-*realisable* if there is a C such that the candidate guarantee $\psi(t_1,t_2) = \phi(t_1,t_2) + C$ is realisable. Let us say that the candidate guarantee $\phi(t_1,t_2)$ is $O(1)$-*realisable in the long run* if there are C and T_0 such that the candidate guarantee

$$\psi(t_1,t_2) \;=\; \begin{cases} \phi(t_1,t_2) + C & \text{if } t_1 \ge T_0 \\ \infty & \text{otherwise} \end{cases} \tag{19}$$

is realisable.

Lemma 17 *A candidate guarantee ϕ is $O(1)$-realisable if and only if it is $O(1)$-realisable in the long run.*

Proof Suppose ϕ is $O(1)$-realisable in the long run and let C and T_0 be such that (19) is realisable. Aggregate using the AA the following prediction strategies: a prediction algorithm that realises ϕ; a prediction algorithm suffering a bounded regret over all $[1,t]$; a prediction algorithm suffering a bounded regret over all $[2,t]$;...; a prediction algorithm suffering a bounded regret over all $[T_0 - 1, t]$. ■

5. Conclusion

We examined the problem of guaranteeing small adaptive regret for the setting of prediction with expert advice. In the first part we considered two techniques to obtain adaptive algorithms: using virtual specialist experts and restarting classical algorithms. We showed that both result in Fixed Share with a variable switching rate. In the second part we computed the exact worst-case adaptive regret for Fixed Share, thus tightening the existing upper bounds. So much, in fact, that by summing these worst-case regrets over a partition of the interval $[1,T]$ we recover the standard Fixed Share tracking bound. In other words, the tracking performance of Fixed Share is a consequence of its adaptivity.

Protocol 2 Prediction with Expert Advice

for $t = 1, 2, \ldots$ **do**
  Expert n announces prediction $\gamma_t^n \in \Gamma$ for each $n = 1, \ldots, N$
  Learner announces prediction $\gamma_t \in \Gamma$
  Reality announces outcome $\omega_t \in \Omega$
  Learner suffers loss $\lambda(\gamma_t, \omega_t)$
end for

We then give an information-theoretic characterisation of the achievable worst-case adaptive regrets, and conclude that the Pareto optimal regrets are exactly the Fixed Share regrets. Fixed Share simply is the optimal adaptive algorithm.

Open problem. Whereas upper bounds readily transfer to mixable losses, obtaining adaptive regret lower bounds for mixable losses is much more tricky. It is fair to call the lower bound argument by Vovk (1998) for classical regret complicated, and this would be a special case for adaptive regret lower bounds.

Appendix A. Adaptive Regret for Mix Loss Transfers to Mixable Losses

The protocol of prediction with expert advice is given as Protocol 2. Predictions are made sequentially, their quality is measured by the loss function λ and Learner has access to a (finite) pool of N experts. An important class of loss functions that allow for effective algorithms are mixable losses.

Definition 18 *A loss function λ is called* η-mixable*, where $\eta > 0$, if for every N, every sequence of predictions $\gamma^1, \ldots, \gamma^N$ and every sequence of normalised nonnegative weights $u^1, \ldots, u^N$ there exists a prediction $\gamma \in \Gamma$ such that for every outcome $\omega \in \Omega$*

$$\lambda(\gamma, \omega) \;\le\; -\frac{1}{\eta} \ln \left(\sum_{n=1}^{N} u^n e^{-\eta \lambda(\gamma^n, \omega)} \right). \tag{20}$$

A function Σ that maps every sequence of predictions $\gamma^1, \ldots, \gamma^N$ and every sequence of normalised nonnegative weights $u^1, \ldots, u^N$ of the same length to $\gamma \in \Gamma$ satisfying (20) is called an η-perfect substitution function.

To establish mixability it is sufficient to verify (20) for $N = 2$. Examples of mixable games are discussed by Vovk (2001). Note that $1/\eta$-scaled mix loss is the baseline used in

the definition of mixability: see (20). In this sense the mix loss is the hardest mixable loss. It is hence no surprise that adaptive regret bounds for mix loss immediately transfer to any mixable loss:

Fact 19 *Let X be a mix-loss algorithm with worst-case adaptive regret $\phi(t_1, t_2)$. If λ is η-mixable then there is an algorithm Y with adaptive regret at most $\phi(t_1, t_2)/\eta$.*

Proof Let Σ be an η-perfect substitution function for λ. We choose Y to be the algorithm that operates as follows. At each trial $t = 1, 2, \ldots$ it obtains prediction $\boldsymbol{u}_t$ from X, predicts with $\gamma_t = \Sigma(\boldsymbol{u}_t, \boldsymbol{\gamma}_t)$, and feeds into X losses $\ell_t^n = \eta\lambda(\gamma_t^n, \omega_t)$ (from the point of view of Y these are scaled losses rather than losses). Then for each interval $[t_1, t_2]$ and reference expert n we have

$$\begin{aligned} L^Y_{[t_1,t_2]} - L^n_{[t_1,t_2]} \;&=\; \sum_{t=t_1}^{t_2} \lambda(\gamma_t, \omega_t) - \sum_{t=t_1}^{t_2} \lambda(\gamma_t^n, \omega_t) \\ &\le\; -\frac{1}{\eta} \sum_{t=t_1}^{t_2} \ln \sum_j u_t^j e^{-\eta\lambda(\gamma_t^j, \omega_t)} - \sum_{t=t_1}^{t_2} \lambda(\gamma_t^n, \omega_t) \\ &=\; -\frac{1}{\eta} \sum_{t=t_1}^{t_2} \ln \sum_j u_t^j e^{-\ell_t^j} - \frac{1}{\eta} \sum_{t=t_1}^{t_2} \ell_t^n \;=\; \frac{1}{\eta} \left(L^X_{[t_1,t_2]} - L^n_{[t_1,t_2]} \right) \;\le\; \frac{1}{\eta}\phi(t_1, t_2), \end{aligned}$$

where the first inequality follows from the definition of an η-perfect substitution function and the last one from our assumption about X. ■

Fact 19 shows that all our performance guarantees for the mix-loss protocol carry over to the protocol of prediction with expert advice with a mixable loss function.

Appendix B. Worst-case Adaptive Regret Data for Fixed Share

In this subsection we prove that the worst-case data for Fixed Share has the following form. On the interval $[t_1, t_2]$ we are interested in all but one expert suffer infinite loss and on the step preceding t_1 (if $t_1 \neq 1$) this one expert suffers infinite loss himself. The construction is iterative and we start constructing the data from the end of the interval.

Lemma 20 *For any history prior to the step t_2 the adaptive regret $R^n_{[t_1,t_2]}$ w.r.t. expert n on the interval $[t_1, t_2]$ is maximised with $\ell^k_{t_2} = \infty$ for $k \neq n$.*

Proof Let us differentiate the adaptive regret w.r.t. $\ell^k_{t_2}$:

$$\frac{\partial R^n_{[t_1,t_2]}}{\partial \ell^k_{t_2}} \;=\; \frac{\partial(\ell_{t_2} - \ell^n_{t_2})}{\partial \ell^k_{t_2}} \;=\; -\frac{\partial}{\partial \ell^k_{t_2}} \ln \sum_j u^j_{t_2} e^{-\ell^j_{t_2}} - \mathbf{1}_{\{n=k\}} \;=\; \frac{u^k_{t_2} e^{-\ell^k_{t_2}}}{\sum_j u^j_{t_2} e^{-\ell^j_{t_2}}} - \mathbf{1}_{\{n=k\}}.$$

This is positive for all $k \neq n$ and becomes zero for $k = n$ when we plug in $\ell^k_{t_2} = \infty$ for those. ■

Lemma 21 *Consider switching rates $\alpha_t \in [0, \frac{N-1}{N}]$. Fix a comparator expert n. Let $t \in [t_1, t_2]$. Suppose that the losses for steps $s = t+1, \ldots, t_2$ satisfy $\ell_s^k = \infty$ for $k \neq n$. Then for the adaptive regret $R^n_{[t_1,t_2]}$ is maximised with $\ell_t^k = \infty$ for $k \neq n$.*

Proof Let us start with showing that on the steps $t+1$ and $t+2$ the data is organised as we want to, that is, the n-th expert is good and all others suffer infinite loss, then Learner's loss on step $t+2$ is not dependent on what happens at time t and before. This follows immediately from (5), as

$$\ell_{t+2} \;=\; -\ln\left(1-\alpha_{t+2}\right)\,.$$

Now let us differentiate the adaptive regret $R^n_{[t_1,t_2]}$ w.r.t. ℓ_t^k assuming that the future losses are set up as we want. Let us show that the derivatives w.r.t. ℓ_t^k where $k \neq n$ are all positive. For those,

$$\frac{\partial R^n_{[t_1,t_2]}}{\partial \ell_t^k} \;=\; \frac{\partial \ell_t}{\partial \ell_t^k} + \frac{\partial \ell_{t+1}}{\partial \ell_t^k}\,.$$

Expanding the second one gives (as before, $k \neq n$):

$$\begin{aligned}\frac{\partial \ell_{t+1}}{\partial \ell_t^k} \;&=\; \frac{\partial}{\partial \ell_t^k} - \ln\left(\frac{\alpha_{t+1}}{N-1} + (1 - \frac{N}{N-1}\alpha_{t+1})u_t^n e^{\ell_t - \ell_t^n}\right)\\ &=\; -\frac{(1-\frac{N}{N-1}\alpha_{t+1})u_t^n e^{\ell_t-\ell_t^n}\frac{\partial}{\partial \ell_t^k}\ell_t}{\frac{\alpha_{t+1}}{N-1} + (1-\frac{N}{N-1}\alpha_{t+1})u_t^n e^{\ell_t-\ell_t^n}}\,.\end{aligned}$$

So we see that

$$\begin{aligned}\frac{\partial R^n_{[t_1,t_2]}}{\partial \ell_t^k} \;&=\; \frac{\partial \ell_t}{\partial \ell_t^k}\left(1 - \frac{(1-\frac{N}{N-1}\alpha_{t+1})u_t^n e^{\ell_t-\ell_t^n}}{\frac{\alpha_{t+1}}{N-1} + (1-\frac{N}{N-1}\alpha_{t+1})u_t^n e^{\ell_t-\ell_t^n}}\right)\\ &=\; \frac{\partial \ell_t}{\partial \ell_t^k}\left(\frac{\frac{\alpha_{t+1}}{N-1}}{\frac{\alpha_{t+1}}{N-1} + (1-\frac{N}{N-1}\alpha_{t+1})u_t^n e^{\ell_t-\ell_t^n}}\right) \;>\; 0\,.\end{aligned}$$

So our worst-case pattern of losses extends one trial backwards. ■

Finally, we need to state the almost obvious fact that in order to maximise the adaptive regret we need to insert an infinite loss for the comparator expert right before the start of the interval, thus killing all the previous weight on him.

Lemma 22 *Consider switching rates $\alpha_t \in [0, \frac{N-1}{N}]$. Fix a comparator expert n. Suppose that the losses for steps $s = t_1, \ldots, t_2$ satisfy $\ell_s^k = \infty$ for $k \neq n$. Then the adaptive regret $R^n_{[t_1,t_2]}$ is maximised with $\ell^n_{t-1} = \infty$.*

Proof As before, the adaptive regret on steps starting from t_1+1 does not depend on $\ell^k_{t_1-1}$. So let us show that $\frac{\partial R^n_{[t_1,t_2]}}{\partial \ell^n_{t_1-1}} > 0$. We can reuse the proofs of previous lemmas for that:

$$\frac{\partial R^n_{[t_1,t_2]}}{\partial \ell^n_{t_1-1}} \;=\; \frac{\partial \ell_{t_1}}{\partial \ell^n_{t_1-1}} \;=\; -\frac{(1-\frac{N}{N-1}\alpha_{t_1})u^n_{t_1-1}e^{\ell_{t_1-1}-\ell^n_{t_1-1}}}{\frac{\alpha_{t_1}}{N-1} + (1-\frac{N}{N-1}\alpha_{t_1})u^n_{t_1-1}e^{\ell_{t_1-1}-\ell^n_{t_1-1}}}\frac{\partial\left(\ell_{t_1-1}-\ell^n_{t_1-1}\right)}{\partial \ell^n_{t_1-1}} \;>\; 0\,,$$

since $\frac{\partial\left(\ell_{t_1-1}-\ell^n_{t_1-1}\right)}{\partial \ell^n_{t_1-1}}$ is negative as follows from the proof of Lemma 20. ■

Abstract

Traditionally the machine-learning community has viewed the No Free Lunch (NFL) theorems for search and optimization as a limitation. We review, analyze, and unify the NFL theorem with the perspectives of "blind" search and meta-learning to arrive at necessary conditions for improving black-box optimization. We survey meta-learning literature to determine when and how meta-learning can benefit machine learning. Then, we generalize meta-learning in the context of the NFL theorems, to arrive at a novel technique called *anti-training with sacrificial data* (ATSD). Our technique applies at the meta level to arrive at domain specific algorithms. We also show how to generate sacrificial data. An extensive case study is presented along with simulated annealing results to demonstrate the efficacy of the ATSD method.

Keywords: Machine Learning, Optimization, Meta Optimization, No Free Lunch, Anti-Training, Sacrificial Data

1. Introduction

Most types of machine learning involve fitting a model to data. These models may be artificial neural networks, Bayesian networks, cluster centers, decision trees, etc. The fitting process uses objective/fitness functions to determine how well the learned model represents the training data. While many models (*e.g.,* artificial neural networks) have training algorithms (*e.g.,* backpropagation), it is not always clear which algorithm is best to use for a particular data set. This is the issue John Rice describes as the algorithm selection problem (Rice, 1976).

Knowledge about a problem must be used to solve it efficiently (Wolpert and Macready, 1997). It is a poor choice to use an algorithm that ignores derivatives or convex properties when the optimization problem exhibits these features. Similarly, it is a poor choice to use such features when they are absent. It may even be that the features change as the problem's parameters change. For instance, the number of local minima for a single neuron grows exponentially in the dimensionality of the input (Auer et al., 1995). The standard learning algorithm may not remain the most efficient as the dimensionality grows. Worse yet, some learning depends upon black-box optimizers such as simulated annealing (Goodsell and Olson, 1990), genetic algorithms (Wang et al., 2001), particle swarm (Zhang et al., 2004), and random search (Bergstra and Bengio, 2012).

The same virtue that makes black-box optimizers so widely used is also their inherent weakness—black-box optimizers use only a history of inputs into, and outputs from an objective function. This allows black-box optimizers to function on symbolic representations, experimental data, or results from simulations. The black-box optimizer does not use any knowledge about the symbolic function, data, or simulation. The No Free Lunch (NFL) theorems for search and optimization state that any such black-box optimization is expected to perform on average as well as a random guesser (Wolpert and Macready, 1997). If the objective function comes from a slow simulation or a physical experiment, then every function evaluation is precious. Thus, an algorithm tailored toward a particular problem distribution can make better use of the function evaluations.

In this work, we introduce a completely novel concept: *anti-training with sacrificial data*, for tailoring learning and optimization algorithms to problem distributions. At its base, anti-training is a generalization of a type of meta-learning. We take advantage of the fact that all optimization algorithms perform the same on average (according to the NFL theorems). Essentially, anti-training worsens the performance over problems suspected to be impossible or exceedingly unlikely to occur. Since the average performance remains constant, the performance elsewhere must increase. Consider the following water balloon analogy: the NFL theorems function as the conservation of volume. Squeezing the water (performance) out of one area of the balloon will transfer it to other areas.

Unlike many forms of meta-learning, anti-training inherently adheres to the NFL theorems since it is derived through the manipulation of the NFL theorems. Anti-training is expected to benefit learning performance whenever the objective functions are compressible. Moreover, because the sacrificial data used by anti-training is inexpensive to generate, it is possible to use anti-training where meta-learning cannot be applied. It can also be applied in conjunction with meta-learning and can prevent overtraining.

Following preliminaries and nomenclature in Section 2, we rewrite an NFL theorem to derive our technique and proceed to analyze it in Section 3. Section 4 discusses how to generate the sacrificial data required for anti-training. We extensively discuss several experiments in Section 5 and the results in Section 6. We then conclude with a discussion and future work in Section 7.

2. Preliminaries and Background

The original NFL theorems apply to arbitrarily large finite domains (*e.g.,* combinatorial optimization problems). Wolpert and Macready (1997) argue that this makes sense since computers only have a finite number of bits; the search space $\mathcal{X}$ and output space $\mathcal{Y}$ are typically bit sequences. Continuing with their notation, let f be a function representing an optimization problem (*e.g.,* error function, distance, etc.) and $\mathcal{F}$ be the set of all functions having an input $x \in \mathcal{X}$ and an output $y \in \mathcal{Y}$. If $|\mathcal{X}|$ is the size of the search space and $|\mathcal{Y}|$ is the size of the output space, then the size of the function space is $|\mathcal{F}| = |\mathcal{Y}|^{|\mathcal{X}|}$ (Wolpert and Macready, 1997). (Just to realize the order of magnitude of $|\mathcal{F}|$, consider a function with a 16-bit input and an 8-bit output; then $|\mathcal{F}| = 2^{2^{19}} \approx 2.6 \cdot 10^{157826}$. This is a large number of possible functions, but it is still finite.)

Moreover, let

- $f \in \mathcal{F}$ be a function to be optimized,

- $P(f)$ be a probability mass function, describing the probability of f occurring,
- $\hat{P}(f)$ be an estimate of $P(f)$,
- a be a black-box algorithm that samples f and uses the input-output data to generate the next input into f,
- $m \in \{1, \ldots, |\mathcal{X}|\}$ be the number of unique inputs,
- d_m^x be a set of the first m unique inputs,[1]
- d_m^y be a set of the corresponding outputs,
- d_m be shorthand for d_m^y and d_m^x combined,
- $P\left(d_m^y | f, m, a\right)$ be the conditional probability of finding d_m^y given an algorithm a iterated m times on a fitness function f, and
- $\Phi\left(d_m^y\right)$ be a function that converts the output to some performance metric.

For brevity, we provide the following terms:

- *anti-training with sacrificial data* is shortened to *ATSD*,
- *anti-training with sacrificial data combined with meta-learning* is abbreviated as *ATSD+ML*,
- *meta-learning* is abbreviated as *ML*, and
- *No Free Lunch* to be abbreviated as *NFL*.

2.1 NFL

Briefly, the NFL theorems state that for both static and time-varying optimization problems, all algorithms perform the same when averaged across all problems (Wolpert and Macready, 1997). We will focus on static problems. The NFL theorems are cast in a probabilistic framework:

Theorem 1

$$\sum_{f \in \mathcal{F}} P\left(d_m^y | f, m, a_1\right) = \sum_{f \in \mathcal{F}} P\left(d_m^y | f, m, a_2\right). \tag{1}$$

In the words of the authors: "this means in particular that if some algorithm's performance is superior to that of another algorithm over some set of optimization problems, then the reverse must be true over the set of all other optimization problems." The above equation is true regardless of the problem distribution, $P(f)$. This is different from saying all algorithms are equal. For all algorithms to be equal we require:

1. Algorithms are considered to never reevaluate a previously investigated input (allow previous function evaluations to be recalled without incrementing m).

Theorem 2

$$\sum_{f \in \mathcal{F}} P\left(f\right) P\left(d_m^y | f, m, a_1\right) = \sum_{f \in \mathcal{F}} P\left(f\right) P\left(d_m^y | f, m, a_2\right). \tag{2}$$

This explicitly depends on $P(f)$. Following the proof provided in Wolpert and Macready (1997), (2) requires

$$\sum_{f \in \mathcal{F}} P\left(f\right) P\left(d_1^y | f, m = 1, a\right) = \sum_{f \in \mathcal{F}} P\left(f\right) \delta\left(d_1^y, f\left(d_1^x\right)\right) \tag{3}$$

to be independent of d_1^x and hence a. This sum is used in the base case for the inductive proof in Wolpert and Macready (1997), where for information theoretic reasons, they assume a $P(f)$ to be uniform. $P(f)$ could also be any distribution following $\prod_{x \in \mathcal{X}} P(y = f(x))$, or certain distributions with specific correlations between costs and inputs (Wolpert and Macready, 1997).

The NFL theorems have been extended to include additional priors and results. Schumacher et al. (2001) extend this to include sets of functions closed under permutations of the input-space. Thus, all algorithms sum to the same performance and generate the same collection of d_m when all functions are considered (Schumacher et al., 2001). Other analyses and extensions can be found in Culberson (1998); Droste et al. (2002); Corne and Knowles (2003a,b); Igel and Toussaint (2003, 2004); Giraud-Carrier and Provost (2005); Whitley and Watson (2005); Wolpert and Macready (2005); Auger and Teytaud (2007, 2010)). The results of these studies show that the No Free Lunch theorems are valid, but their relevance varies depending on the situation. Yet, despite all the extensions and debate, "there are no specific methods or algorithms that directly follow from NFL" (Whitley and Watson, 2005). In the paper, we provide a method that stems from the NFL theorems.

The NFL theorems treat the definition of "algorithms" differently than the typical definition of algorithm implies. In the NFL theorems, the "algorithms" are more about exploring the search space (points) in some order than about the actual instructions carried out by the computer. Two "algorithms" are considered identical if they always visit points in the same order, even if the underlying programming code is different. Likewise, the NFL theorems call two "algorithms" different even if they share the same code, but run with different hyper-parameters (*e.g.,* step-size, branching preference, etc.) so long as points are visited in a different order.

In the following subsections, we briefly summarize information theory and meta-learning prerequisites needed to establish the foundations for ATSD.

2.2 Information Theory

Information theory is a useful tool for studying learning (Bialek et al., 2001; Rissanen, 1984, 1986, 1987, 1989) and analyzing the NFL theory (Schumacher et al., 2001). In information theory, there are two common measures of complexity: "entropy" and "Kolmogorov complexity." Entropy is typically defined as:

$$H(X) = \sum_{x \in \mathcal{X}} -P(x) \log P(x),$$

where X is a discrete random variable and $\mathcal{X}$ is the support of X. Entropy is sometimes interpreted as random variable's uncertainty. Kolmogorov complexity, sometimes called algorithmic entropy or complexity under analysis, cannot be specified so concisely. Essentially Kolmogorov complexity describes the size of the smallest program needed to reproduce a specified sequence (*e.g.,* bits, characters, numbers, etc.). Since there are multiple languages and machine architectures, Kolmogorov complexity is an incomputable function (Cover and Thomas, 2006; Li and Vitányi, 2008). In this paper, when we say something is compressible or incompressible, we mean this in the sense of Kolmogorov complexity. Information theory shows most functions are incompressible (a proof can be found in the work of Cover and Thomas (2006)). One should be careful to distinguish the ideas of a function being compressible versus being represented in polynomial space. If the number of bits needed to represent a sequence can be halved, there are still an exponential number of such bit sequences.

Culberson (1998) indirectly uses entropy when discussing the NFL theorems from different degrees of "blindness." The degrees of "blindness" range from complete information (the objective function is known) to no information. When these degrees of "blindness" are recast in a probabilistic framework, one can see that the random variable describing the objective function has zero entropy in the case of complete information and maximal entropy when nothing is known. Thus a main point of Culberson (1998) is that optimization performance degrades as the problem distribution becomes more complex.

2.3 Meta-learning

Before we begin our formulation of ATSD, due to the strong ties between ML and ATSD, it is important to address questions pertaining to the NFL theorems and ML. The first and probably most important question is: "can ML successfully improve performance in light of the NFL theorems?" If so, when does ML help? How can one judge the quality of an algorithm's learning biases?

ML is generally concerned with learning to learn better. Nevertheless, it can be applied to learning to optimize better. One perspective of ML is the algorithm selection problem (Rice, 1976). That is, given a specific instance of a problem, which algorithm solves the problem best? Giraud-Carrier and Provost (2005) address whether ML can escape the limitations imposed by the NFL theorems. Their ultimate conclusion is that only techniques that learn about the problem distribution $P(f)$ can overcome the NFL theorems. Hence, ML can be useful in light of the NFL theorems.

Vilalta and Drissi (2002) introduce two important ML concepts. One is that of structured versus random problems. Structured problems have lower Kolmogorov complexity than random problems. This structure can be exploited by algorithms to solve these problems more efficiently. By this definition, random problems have no such structure that ML can exploit. Consequently, ML is limited (with respect to its effectiveness) to structured problems. In terms of entropy, structured problems may still require exponential space to represent. To see this let there be $|\mathcal{F}|$ functions represented by 2^n bits, then there are about $2^{\alpha\, n}$ compressible functions with a Kolmogorov complexity of $2^{\alpha\, n}$, for $\alpha < 1$. The more structured the problem domain, the more quickly the percentage of structured problems approaches zero. Therefore, the percentage of structured problems decays geometrically

with the size of $|\mathcal{F}|$. In other words, ML applies as long as most problems are considered irrelevant.

One may like to know how to measure one's success in selecting an algorithm. To do so, we first need a definition of success. Vilalta and Drissi (2002) introduce the concept of algorithm biases expressed as restrictions and rankings of potential hypotheses (the true f). In our formal notation, this means each algorithm assumes some $P(f)$. Then successfully selecting an algorithm means that the selected algorithm's assumed problem distribution matches the actual problem distribution. Both a theoretical and realistic measure exist to judge how well these match. Wolpert and Macready (1997) propose using the inner product between $P(f)$ and $P(d_m^y|f,m,a)$ over $f \in \mathcal{F}$ for a desired d_m^y. However, this method is only theoretical as computing the inner product is difficult due to the size of $\mathcal{F}$. A much more realistic measure is the off-training-set error (Wolpert, 2001).

We can use the answers to these three questions to lead us down a path of investigation. When ML samples from the problem distribution, the distributions are compressible (most problems are irrelevant), and the current method is suboptimal, then ML may operate within the NFL framework. Therefore, we will investigate how ML may manifest itself in the NFL framework. Second, due to the similarities between ML and ATSD, we will derive ATSD by applying an opposite goal to the opposite data. This in effect forms a "dual problem," which leads to our formulation of ATSD.

3. Anti-training

Section 2.3 gives us a research direction: derive ML from the NFL theorems, and subsequently, ATSD from that. To ensure our technique follows from (1), we begin by rewriting one side. First, we split $\mathcal{F}$ into three partitions (non-overlapping sets that cover the whole set):

$$\sum_{f\in\mathcal{F}} P\left(d_m^y|f,m,a\right) = \sum_{f\in\mathcal{F}_+} P\left(d_m^y|f,m,a\right) + \sum_{f\in\mathcal{F}_0} P\left(d_m^y|f,m,a\right) + \sum_{f\in\mathcal{F}_-} P\left(d_m^y|f,m,a\right). \quad (4)$$

Here $\mathcal{F}_+$, is the partition of problems already encountered, considered likely, or relevant; $\mathcal{F}_-$ represents the partition of problems that cannot occur (in the given context) or are considered unlikely to occur; and $\mathcal{F}_0$ consists of problems that are borderline likely or undefined. Equation 4 explicitly shows that we can trade-off performance between problem sets. Performance gained over $f \in \mathcal{F}_+$ must be lost over $f \in \mathcal{F}_0 \cup \mathcal{F}_-$.

The inquisitive reader may wonder why we use three partitions and particularly why we include the $\mathcal{F}_0$ partition. We include $\mathcal{F}_0$ for three reasons: first, an objective function does not always cleanly lie in either $\mathcal{F}_+$ or $\mathcal{F}_-$. This is because we avoid strict mathematical definitions of $\mathcal{F}_+$, $\mathcal{F}_0$, and $\mathcal{F}_-$. One may choose, for example, $\mathcal{F}_+ = \{f|P(f) > {}^{100}/_{|\mathcal{F}|}\}$ and $\mathcal{F}_- = \{f|P(f) < {}^{0.01}/_{|\mathcal{F}|}\}$. This flexibility necessitates $\mathcal{F}_0$. Second, $\mathcal{F}_0$ is useful for describing an important difference between ML and ATSD: the difference between the forthcoming (6) and (7). Third, when approximating $\mathcal{F}_+$ and $\mathcal{F}_-$, $\mathcal{F}_0$ is a catch-all for the remaining cases. Thus, three partitions are the minimum number needed to capture these degrees of freedom.

Equation 1 implies (4) is independent of a. However, each sum over a partition of $\mathcal{F}$ is generally allowed to change provided one important condition: $\mathcal{F}_+$, $\mathcal{F}_0$, and $\mathcal{F}_-$ are

sets of functions not closed under permutation.[2] Schumacher et al. (2001) show in their Lemmas 1 and 2 that the NFL theorems apply if and only if the set of functions is closed under permutation. Since the fraction of sets closed under permutation is exceedingly rare (Igel and Toussaint, 2003), the NFL theorems fail to apply, with high probability, to each partitioning of $\mathcal{F}$. In turn, this means that each sum is generally allowed to change, implying that it is possible to improve the performance over $\mathcal{F}_+$.

Let us extend (4) in two ways. First, multiply by $\Phi\left(d_m^y\right)$ (a performance metric such as final error) and bring it inside the sum. Second, sum several $\sum_{f\in\mathcal{F}} \Phi\left(d_m^y\right) P\left(d_m^y|f,m,a\right)$ together for different values of d_m^y. Then we have

$$\sum_{d_m^y}\sum_{f\in\mathcal{F}} u = \sum_{d_m^y}\left(\sum_{f\in\mathcal{F}_+} u + \sum_{f\in\mathcal{F}_0} u + \sum_{f\in\mathcal{F}_-} u\right), \tag{5}$$

where

$$u = \Phi\left(d_m^y\right) P\left(d_m^y|f,m,a\right).$$

3.1 Anti-training as Meta-learning

Recall that a type of ML taking into account the NFL theorems is the one that attempts to learn $P(f)$ directly (Giraud-Carrier and Provost, 2005). However, this is often infeasible due to the cardinality of $\mathcal{F}$. A simple alternative to approximate this method is to learn an optimizer that performs well on the empirically common functions. This is a meta-optimization problem to improve the performance over $\mathcal{F}_+$. More accurately, the meta-optimization will improve the conditional expected value of $\Phi\left(d_m^y\right)$. Without loss of generality, hence forth assume Φ is a performance metric to be minimized (*e.g.,* an error function). Then, improving (minimizing) the conditional expected value means:

$$a^\star = \arg\min_a \sum_{d_m^y}\sum_{f\in\mathcal{F}_+} \Phi\left(d_m^y\right)\hat{P}_+(f)P\left(d_m^y|f,m,a\right).$$

However, the above equation is neither governed by nor does it follow from the NFL theorems! The introduction of a function dependent on f, in this case the approximation $\hat{P}_+(f)$, generally voids the NFL requirement that (3) is independent of a. Nevertheless, if we consider the typical approximation of $\hat{P}_+(f)$ used in practice, we realize that rarely does an identical objective function occur twice. See Appendix A for further justification of this assertion. This means $\hat{P}_+(f)$ is practically going to be a two-valued function: 0 and $\left|\hat{P}_+(f)\right|^{-1}$. Thus, in practice we drop the term $\hat{P}_+(f)$. This recovers the first term on the right-hand-side of (5), which follows from the NFL theorems:

$$a^\star = \arg\min_a \sum_{d_m^y}\sum_{f\in\mathcal{F}_+} \Phi\left(d_m^y\right) P\left(d_m^y|f,m,a\right). \tag{6}$$

2. A set of functions being closed under permutation means no new functions may be generated when the input space is bijectively remapped into itself (*i.e.,* a random permutation of the input space).

We make several more notes about the above equation. First, when using a deterministic a (or a random algorithm with a fixed random seed) $P\left(d_m^y|f,m,a\right)$ will be either 0 or 1; only a single d_m^y will be produced. This makes it easier to optimize in practice. Second, $\Phi\left(d_m^y\right)$ determines the behavior of $a^\star$; $a^\star$ could produce a low final error, low cumulative error, etc. While it is also possible to modify (6) to optimize over the cross-validation error, care must be taken as cross-validation alone is subject to the NFL theorem (Wolpert, 2001). Typically $\mathcal{F}_+$ will be approximated using samples from a problem distribution $P(f)$ arising from a limited domain. Additionally, (6) says nothing about the search for $a^\star$. Unless a is being modified intelligently, the meta-optimization problem will be subject to the NFL theorems itself. This means that finding better algorithms will be possible, but costly.

The NFL theorems say that any performance gained over a set of functions must be lost over the set's complement. Equation 4 must remain constant. Thus, ML improves the performance over $\mathcal{F}_+$ at the cost of performance over $\mathcal{F}_0 \cup \mathcal{F}_-$. This is potentially detrimental for prediction, generalization, and avoiding overfitting. To help mitigate this issue we now introduce *anti-training with sacrificial data* (ATSD). This means ATSD is about the optimization of one of the terms from (5):

$$a^\star = \arg\max_a \sum_{d_m^y}\sum_{f\in\mathcal{F}_-} \Phi\left(d_m^y\right) P\left(d_m^y|f,m,a\right). \tag{7}$$

This translates into

$$a^\star = \arg\min_a \sum_{d_m^y}\sum_{f\in\mathcal{F}_0\cup\mathcal{F}_+} \Phi\left(d_m^y\right) P\left(d_m^y|f,m,a\right).$$

Again, without loss of generality, we treat Φ as an error function to be minimized. As one can see, ATSD is an approximate dual of ML. ATSD achieves an improvement in the *sum* of performance over $\mathcal{F}_+ \cup \mathcal{F}_0$ by directly worsening the performance over $\mathcal{F}_-$. If the performance over $\mathcal{F}_-$ decreases, then by (4), the sum over $\mathcal{F}_0 \cup \mathcal{F}_+$ must improve. Despite ATSD being less efficient than ML, it has other benefits. For a more complete discussion, please see Sections 3.2 and 3.3.

It is critical to note that the performance improvement is over $\mathcal{F}_0 \cup \mathcal{F}_+$. Without additional care, ATSD could drop the performance over $\mathcal{F}_+$, but improve the performance over $\mathcal{F}_0$. To help avoid this, ATSD should be combined with ML (ATSD+ML). Combining (6) and (7), we have

$$a^\star = \arg\min_a \sum_{d_m^y}\left(\sum_{f\in\mathcal{F}_+} \Phi\left(d_m^y\right) P\left(d_m^y|f,m,a\right) - \beta \sum_{f\in\mathcal{F}_-} \Phi\left(d_m^y\right) P\left(d_m^y|f,m,a\right)\right) \tag{8}$$

where $\beta \geq 0$ determines the relative strength of anti-training. The above optimization technique is just one straightforward approach to combining ML and ATSD. ATSD+ML can be achieved by using a meta-optimization technique similar to the aforementioned process for ML. According to Bergstra and Bengio (2012), a random search for $a^\star$ is in some sense optimal. Although, preliminary tests suggest that local searches find locally optimal continuous hyper-parameters on continuous domains.

We feel it is important to note that ATSD+ML is not strictly limited to operating over $\sum_{f\in\mathcal{F}_+}$ and $\sum_{f\in\mathcal{F}_-}$. Other statistics can be used, too. For instance, the mean reduces

to simply using (8) with an adjusted β. The median is another statistic that could be used. Meta-optimizing using the medians would be the same as dynamically selecting one or two f to improve or worsen their performance. For the same reason, percentiles are valid statistics to improve or degrade. Since percentiles could be used, one may wonder if the interquartile-range (IQR) is a valid statistic for ATSD+ML. ATSD+ML should avoid using the IQR statistic over $\mathcal{F}_-$, as this amounts to improving the performance over some $f \in \mathcal{F}_-$.

Algorithm 1 demonstrates the basic approach. The parameter *metaSearch* is a search algorithm for finding black-box search/optimization/learning algorithms; *metaMetric* is

Algorithm 1 Anti-Training Combined with Meta-Learning

Procedure Anti-Meta-Search(
metaSearch, *metaMetric*, *pMetric*, $\hat{\mathcal{F}}_+$, $\hat{\mathcal{F}}_-$, m)
$metaOut \leftarrow empty$
repeat
  $searchAlg \leftarrow metaSearch(metaOut)$
  $listPosPerfs \leftarrow empty$
  for all $objFunc \in \hat{\mathcal{F}}_+$ **do**
    $optResults \leftarrow$ Optimize($searchAlg$, $pMetric$, $objFunc$, m)
    Append $optResults \rightarrow listPosPerfs$ {Accumulate results from $\hat{\mathcal{F}}_+$}
  end for
  $listNegPerfs \leftarrow empty$
  for all $objFunc \in \hat{\mathcal{F}}_-$ **do**
    $optResults \leftarrow$ Optimize($searchAlg$, $pMetric$, $objFunc$, m)
    Append $optResults \rightarrow listNegPerfs$ {Accumulate results from $\hat{\mathcal{F}}_-$}
  end for
  $algPerformance \leftarrow$ metaMetric ($listPosPerfs, listNegPerfs$) {e.g., (8)}
  Append $(searchAlg, algPerformance) \rightarrow metaOut$
until $algPerformance$ is good enough
Return Argmin($metaOut$)

Procedure Optimize($searchAlg$, $performanceMetric$, $objFunc$, m)
$d_m \leftarrow empty$
for $itr = 1$ to $itr = m$ **do**
  $x \leftarrow searchAlg(d_m)$
  Append $(x) \rightarrow d_m^x$
  $y \leftarrow objFunc(d_m^x)$
  Append $(y) \rightarrow d_m^y$
  Append $(d_m^x, d_m^y) \rightarrow d_m$
  $performance \leftarrow performanceMetric(d_m)$
end for{Alternatively end when performance is good enough}
return $performance$ {If ending when performance is good enough return number of iterations}

the metric for preferring one black-box algorithm over another, such as (8); and *pMetric* is $\Phi\left(d_m^y\right)$, which rates the quality of outputs. The subroutine Optimize is a black-box search/optimization algorithm that runs the *searchAlg* to generate the input d_m^x into the black-box objective function *objFunc*.

Algorithm 1 starts by selecting, generating, or modifying a search/optimization/learning algorithm. For simplicity, let us assume the goal is optimization. The optimization subroutine generates the next input x from the history of inputs and outputs. The objective function (from $\hat{\mathcal{F}}_-$ or $\hat{\mathcal{F}}_+$) is evaluated at x. This process is repeated, building up the d_m vector. After enough iterations, the subroutine returns the performance metric, $\Phi\left(d_m^y\right)$. The performance over each $f \in \hat{\mathcal{F}}_+ \cup \hat{\mathcal{F}}_-$ is computed and stored using this subroutine. The meta-fitness function evaluates the optimization algorithm using ATSD+ML. This whole process is repeated for enough iterations or until the algorithm's performance is good enough.

3.2 Analysis

We now present how effective the ATSD is from a theoretical perspective. An extensive, empirical study follows in Section 5. It is difficult to analyze ATSD without making strong assumptions. Thus, we make the following assumptions as general as possible and defend them using logic similar to that used in the original NFL theorems (Wolpert and Macready, 1997).

Allow an algorithm to be represented by its learning biases as discussed by Vilalta and Drissi (2002). We choose to interpret these biases as an *a priori* rank ordering of functions. To help illustrate this point, imagine an algorithm represented by a deck of cards, where each card represents an objective function f to be optimized. Denote $R_a(f) \in \left\{1, 2, \ldots, |\mathcal{F}|\right\}$ as algorithm a's ranking (i.e., position in the deck) of f. A lower ranking means the algorithm is more biased toward finding the optimal solution in fewer iterations. The function with rank one will have its optimum input guessed first. Then all $f \in \mathcal{F}$ in violation of the first input-output pair, d_1, are removed from the deck of hypotheses and the process is repeated.

Allow $\hat{\mathcal{F}}_+$ and $\hat{\mathcal{F}}_-$ to be samples from $\mathcal{F}_+$ and $\mathcal{F}_-$ respectively. Furthermore, since we are working with domain specific optimizers, we may assume the majority of problems are not highly relevant:

$$\left|\mathcal{F}_+\right| \ll |\mathcal{F}_0|$$
$$\left|\mathcal{F}_+\right| \ll \left|\mathcal{F}_-\right|.$$

Rather than debate the percent $f \in \mathcal{F}_-$, allow

$$|\mathcal{F}| = c\left|\mathcal{F}_-\right|,$$

for a constant c. For example, if $\left|\mathcal{F}_-\right| \approx |\mathcal{F}_0|$ then $c \approx 2.0$. Nevertheless, we will continue to use c symbolically to remain more flexible and general, allowing the reader to impose their own assumptions.

We will assume that the learning tasks are compressible, as this is necessary for meta-learning to work (Vilalta and Drissi, 2002). We will interpret compressibility as implying a correlation between rankings of functions. Particularly, if through meta-optimization some

$f \in \hat{\mathcal{F}}_+$ lowers in rank, then on average allow all $g \in \mathcal{F}_+$ to lower proportionally by a factor of ρ_+.[3] This will provide the average behavior for describing why ML works. To capture the corresponding effects of ATSD, when some $f' \in \hat{\mathcal{F}}_-$ rises in rank due to meta-optimization, allow all $g' \in \mathcal{F}_-$ to rise proportionally by a factor of ρ_-. We use the symbols g and g' to denote objective functions that are "dragged" along due to correlations in rankings. The two factors, ρ_+ and ρ_-, are functions of the compressibility of $\hat{\mathcal{F}}_+$ and $\hat{\mathcal{F}}_-$ respectively.

Assume that the meta-optimization task improves/degrades the rankings by p_c (percent change). That is, for $f \in \hat{\mathcal{F}}_+$ and $f \in \hat{\mathcal{F}}_-$ the ranking changes from $R_a(f)$ to

$$R_a\left(f\right)\left(1-p_c\right)+p_c, \text{ and}$$
$$\left|\mathcal{F}\right| p_c + R_a\left(f\right)\left(1-p_c\right)$$

respectively. Thus the differences in rank after ML and subsequently ATSD are approximately

$$\left(R_a\left(f\right)-1\right) p_c, \text{ and}$$
$$\left(\left|\mathcal{F}\right| - R_a\left(f\right)\right) p_c.$$

If we assume the starting algorithm is chosen at random, then we can assume the rankings are uniformly distributed: $P(R_a(f)) \sim U\left(1, \left|\mathcal{F}\right|\right)$. This follows from the same reasoning Wolpert and Macready (1997) use to argue that $P(f)$ ought to assume a uniform distribution when lacking further information. Then

$$E\left[R_a\left(f\right)\right] = \frac{\left|\mathcal{F}\right|+1}{2}$$

Now, we will proceed to show that the expected rank improvements from ML and ATSD are comparable. After accounting for rank correlations, improving a single $f \in \hat{\mathcal{F}}_+$ produces on average

$$\mu_+\left(f\right) = p_c\left(R_a\left(f\right) - 1 - \left(R_a(f)-1\right)\rho_+ \sum_{g\in\mathcal{F}_+}\left(R_a(g)-1\right)\rho_+\right)$$

rank improvements. The term $\left(R_a(f)-1\right)\rho_+$ is subtracted to avoid double counting f as $f \in \mathcal{F}_+$, and the term $R_a(g)|g \in \mathcal{F}_+$ is any function that may have its rank improved due to correlations between problems. Substituting in the expected values of $R_a(f)$ and $R_a(g)$ produces

$$\begin{aligned} E\left[\mu_+\left(f\right)\right] &= p_c\left(\frac{\left|\mathcal{F}\right|-1}{2}\left(1-\rho_+\right) + \frac{\left|\mathcal{F}\right|-1}{2}\left|\mathcal{F}_+\right|\rho_+\right) \\ &= p_c\left(\frac{\left|\mathcal{F}\right|-1}{2}\right)\left(1+\left(\left|\mathcal{F}_+\right|-1\right)\rho_+\right). \end{aligned} \tag{9}$$

3. Since the effects of correlation are modeled in a deterministic fashion, this model can only be used to assess the expected values and not higher moments, such as variance.

Next we will compute the number of ranks degraded during ATSD. After accounting for correlations, but being careful to avoid double counting f', the number of ranks degraded on average for anti-training a single $f' \in \hat{\mathcal{F}}_-$ is

$$\mu_-\left(f'\right) = p_c\left(\left(\left|\mathcal{F}\right| - R_a\left(f'\right)\right)\left(1-\rho_-\right) + \sum_{g'\in\mathcal{F}_-}\left(\left|\mathcal{F}\right| - R_a\left(g'\right)\right)\rho_-\right).$$

Substituting in the expected values of $R_a(f')$ and $R_a(g')$ produces

$$E\left[\mu_-\left(f'\right)\right] = p_c\left(\frac{\left|\mathcal{F}\right|-1}{2}\right)\left(1+\left(\left|\mathcal{F}_-\right|-1\right)\rho_-\right). \tag{10}$$

We cannot directly compare (9) and (10) yet. Equation 10 is in terms of ranks degraded for $f' \in \mathcal{F}_-$, not ranks improved for $f \in \mathcal{F}_+$. We can calculate the expected number of $f \in \mathcal{F}_+$ promotions as a result of anti-training demotions by multiplying (10) by the ratio $\left|\mathcal{F}_+\right| / \left|\mathcal{F}\right|$. Recalling $\left|\mathcal{F}\right| = c\left|\mathcal{F}_-\right|$, we have

$$E\left[\mu'_-(f)\right] = p_c\left(\frac{\left|\mathcal{F}\right|-1}{2}\right)\left(\zeta + \left(\frac{\left|\mathcal{F}_+\right|}{c} - \zeta\right)\rho_-\right)$$

where $\zeta = \frac{\left|\mathcal{F}_+\right|}{c\left|\mathcal{F}_-\right|}$. Thus the relative power of ATSD versus ML is given by

$$\frac{E\left[\mu'_-(f)\right]}{E\left[\mu_+(f)\right]} = \frac{\left(\zeta + \left(\frac{\left|\mathcal{F}_+\right|}{c} - \zeta\right)\rho_-\right)}{\left(1+\left(\left|\mathcal{F}_+\right|-1\right)\rho_+\right)}. \tag{11}$$

Note $\zeta = \frac{\left|\mathcal{F}_+\right|}{\left|\mathcal{F}\right|} \approx 0$ by assumption. Provided a sufficiently large $\left|\mathcal{F}_+\right|$, we are justified in dropping additive terms on the order of 1 or less. Then (11) becomes

$$\frac{E\left[\mu'_-\right]}{E\left[\mu_+\right]} \approx \frac{\rho_-}{c\,\rho_+}. \tag{12}$$

If we allow ρ_- and ρ_+ to be on the same order of magnitude and let $c \approx 2.0$, then ATSD will be roughly half as powerful per training sample as ML.

3.3 Other Considerations

Here, we consider several questions about ATSD+ML. Can performance over some elements in $\mathcal{F}_-$ decrease, only to increase performance on other elements in $\mathcal{F}_-$? What happens if $\mathcal{F}_-$ is specified incorrectly? What benefits does ATSD+ML have over traditional ML?

Even though performance over the sacrificial data $\mathcal{F}_-$ is minimized, there is no reason to believe that all $f \in \mathcal{F}_-$ always perform worse after optimization. Yes, performance on

some elements in $\mathcal{F}_-$ may increase. However, ATSD+ML only requires the *net* performance over $f \in \mathcal{F}_-$ to decrease. There are two things that can make the net performance over $\mathcal{F}_-$ improve during the meta-optimization procedure (8). First, $\mathcal{F}_-$ may be too "similar" to $\mathcal{F}_+$, meaning the algorithms being investigated treat both sets of problems similarly. This can occur when the search for $a^\star$ is incomplete, such as when searching only for an optimizer's hyper-parameters instead of program code. The fixed program code may be biased toward treating both sets similarly. Alternatively, the β value in (8) needs to be greater.

ATSD's behavior is similar to ML's behavior when the data sets are specified incorrectly. To the contrary, ATSD+ML is more robust than ML when $\hat{\mathcal{F}}_-$ is specified correctly. Consider the case when $\hat{\mathcal{F}}_+$ poorly approximates $\mathcal{F}_+$. If the approximation is sufficiently poor, performance over $\mathcal{F}_+$ will decrease and performance over $\mathcal{F}_-$ will change randomly. ATSD+ML helps ensure a drop in performance over $\mathcal{F}_-$, regardless. This is assuming $\hat{\mathcal{F}}_-$ is specified correctly, which is generally easy. Section 4 addresses this issue. Alternatively, consider the scenario where $\hat{\mathcal{F}}_+ = \hat{\mathcal{F}}_-$. One of three things may happen according to (8). If $\beta < 1$, then the behavior defaults back to traditional ML. If $\beta = 1$, all algorithms appear equal and nothing happens. If $\beta > 1$, then the performance $\hat{\mathcal{F}}_+$ worsens. In general, even when $\hat{\mathcal{F}}_+ \neq \hat{\mathcal{F}}_-$, a safe value for β is $\beta < \left|\hat{\mathcal{F}}_+\right| / \left|\hat{\mathcal{F}}_-\right|$, as this ensures the traditional ML term dominates the meta-optimization procedure. However, to strictly follow the NFL derivation one should set $\beta = \left|\hat{\mathcal{F}}_+\right| / \left|\hat{\mathcal{F}}_-\right|$ so that each objective function is weighted equally.

ATSD's use of $\mathcal{F}_-$ helps define where the learning algorithm will fail. Specifying some of the failure cases removes some unknown failure cases. This follows from the fact, as shown by Schumacher et al. (2001), that all algorithms produce the same collection of d_m^y when all functions are considered. Also, in theory when $\mathcal{F}_-$ includes a model of noise, then the algorithm learns to fail at fitting the noise. This is entirely different from using a less powerful model that cannot represent the noise. The algorithm could still represent the noise, but ATSD would make it more difficult for the algorithm to find models that do so.

ATSD also helps when data is hard to come by. When real problems or data are scarce or expensive, ML is limited. Just like normal data fitting, if few data points are provided then overfitting is problematic. However, $\mathcal{F}_-$ can be easy and cheap to generate (for more on this see Section 4). As long as there is a balance between preserving/maximizing performance over a small $\mathcal{F}_+$ and minimizing the performance over a large $\mathcal{F}_-$, then this should help avoid overfitting $\mathcal{F}_+$.

4. Generation of Sacrificial Data

In this section, we present five methods for generating sacrificial data (*i.e.,* $f \in \mathcal{F}_-$). We classify these methods into three categories: randomized, empirical, and theoretical. First, we discuss the possibility and consequences of generating the sacrificial data purely randomly. Yet randomly generated sacrificial data may still lie in $\mathcal{F}_+$, so next we discuss rejecting randomly generated sacrificial data that is too similar to $\hat{\mathcal{F}}_+$ (using confidence intervals or other measures of similarity). A similar approach starts with functions in $\mathcal{F}_+$ and "destroys" patterns that are initially present. A different approach is to use empirical "pure" noise. Last, we analyze the efficacy of using a model similar to the source for $f \in \mathcal{F}_+$, but changing the model to violate logical/physical laws, use unlikely distributions,

etc. Since $\mathcal{F}_-$ will usually be large, $\hat{\mathcal{F}}_-$ may be generated with any combination of these techniques.

One technique is to randomly generate functions. Surprisingly, this method works with a high probability of success given a sufficiently large $|\mathcal{F}|$. Vilalta and Drissi (2002) conjecture that failing to learn unstructured tasks (*i.e.,* tasks with a large relative Kolmogorov complexity) carries no negative consequences. As discussed in Section 2.3, the percentage of structured problems decays geometrically with the size of $|\mathcal{F}|$. Thus, for a sufficiently large problem space, randomly generated objective functions will be, with high probability, unstructured.[4] Therefore, we can exploit structure present in learning tasks with high probability, even without knowing the structure. Ergo, sacrificial data can be randomly generated for problems with sufficiently large input and output spaces. While randomly generated functions may work with high probability, they may be a poor choice for the sacrificial data. Consider the result given by (12). Due to the nature of randomly generated functions, they will probably have larger Kolmogorov complexity and hence a smaller ρ_- than other methods.

If randomly generated sacrificial data is too similar to a problem in $\hat{\mathcal{F}}_+$, it may be rejected. This can be accomplished with confidence intervals or other measures of similarity. Suppose the objective function's output is suspected to follow an unknown ergodic process. Since ergodic processes have estimable statistical properties (by definition), confidence intervals can be constructed on these statistics. New random functions can be generated to have their output lie outside these confidence intervals. One could analyze other metrics besides the functions' outputs, such as correlations, covariance, and mutual information between the input and output. By appropriately selecting the confidence intervals, the randomly generated functions can be in $\mathcal{F}_-$ with arbitrary confidence. However, randomly generating functions will (probabilistically) have a small ρ_-.

To improve ρ_-, one approach would be to take problems from $\hat{\mathcal{F}}_+$ and modify the functions with a few simple steps. This will barely alter the Kolmogorov complexity, by its very definition (*i.e.,* minimally sized program to generate the data). Yet, this approach may be ineffective unless these modifications are "natural." Since the Kolmogorov complexity is dependent on the description language (Li and Vitányi, 2008) and the description language is dependent on the optimizer, the types of modifications should somehow match the possible optimizers. This is what we mean when we say "natural." For instance, consider an attempt to determine an optimal step-size for a local search over a set of smooth objective functions. Generating $\hat{\mathcal{F}}_-$ using simple pseudo-randoms would be "unnatural," and possibly result in a minuscule ρ_- in (12). Whereas, scaling the smooth functions may be more useful for generating $\hat{\mathcal{F}}_-$. Again, to ensure the modified functions belong to $\mathcal{F}_-$, the modifications should destroy any patterns originally present, modify correlations, and alter other metrics.

For objective functions that are data-based, another technique is to generate objective functions $f \in \mathcal{F}_-$ from signal-less empirical noise. Most would agree that a learner failing to see patterns in empirical noise is a positive quality. If it is expensive to collect large quantities of empirical noise, then pseudo-random noise could be generated from a random process modeling the empirical noise. If the empirical noise cannot be measured

4. Hardware random generators make it easier to generate functions with high Kolmogorov complexity.

Table 1: Experiment summary

Name	Objective type	Meta-iterations	Trials × subtrials	Tests	Hypothesis
Satellite Trajectory	Continuous optimization	≈ 900	4 × 4	100	ATSD works
High-dimensional TSP	Discrete optimization	10,000	5 × 4	10,000	ATSD fails
Low-dimensional TSP	Discrete optimization	2,000	4 × 200	400	ATSD works
$50k Classification	Learning with a SVM	3,500	10 × 1	1	ATSD works

directly, time-series analysis offers standard procedures for isolating noise from data carrying trends (Gershenfeld, 1999; Brockwell and Davis, 2002; Shumway and Stoffer, 2011).

The last procedure for generating $\hat{\mathcal{F}}_-$ makes use of models, simulations, or subject matter experts (SMEs). The models or simulations can be altered to contradict logical or physical laws. Replacing typical distributions with unlikely or impossible distributions can likewise lead to $f \in \hat{\mathcal{F}}_-$. Those $f \in \mathcal{F}_-$ that come from models and simulations will tend to have lower Kolmogorov complexity than randomly generated functions. We conjecture that this translates into a larger ρ_-. Even without a simulation, SMEs can help provide high quality $\mathcal{F}_-$ due to their knowledge of what is likely, unlikely, and impossible. Furthermore, models, simulations, and SMEs provide an implicit distribution of $P(f)$. Yet, the downside to this approach is that it takes a significant amount of knowledge about the domain from which the problems come, so it might be impractical. This approach is most useful when much is known about the problems, but little is known about which optimizer or learner to use.

5. Experiments

To help verify the theory and investigate the possible interactions between traditional ML and ATSD, we conducted four, very extensive experiments mimicking how meta-optimization procedures are used in practice. The first experiment focuses on finding an efficient algorithm for optimizing a satellite's trajectory to monitor space debris. The second experiment involves the search for an algorithm that performs well on highly random traveling salesperson problems (TSP). The third experiment is also a TSP, but this time the cities occur on a ring and their distances are calculated from that. The last experiment tries to maximize the predictive accuracy on a classification problem. We summarize these experiments, their objectives, size, and purpose in Table 1.

In Table 1 "objective type" shows what the meta-optimization process was optimizing. The column titled "meta-iterations" describes how many unique algorithms were tried in the search for the best algorithm for the task. "Trials × subtrials" describes how many ML and ATSD trials were conducted. Specifically, a trial refers to a specific configuration with a fixed $\hat{\mathcal{F}}_+$ and $\hat{\mathcal{F}}_-$. Subtrials were conducted to capture the variability of the meta-

optimized algorithms found after the specified number of meta-iterations. Each resulting algorithm produced by the meta-optimization process was then tested across the number of tests listed in the "tests" column. Lastly, the column titled "hypothesis," describes our hypothesized outcomes according to theory.

Throughout the course of conducting the experiments, we discovered multiple possible ways the meta-optimization process may fail, for both ML and ATSD. When the search for optimizer algorithms or supervised learning algorithms is constrained (*e.g.,* only adjusting hyper-parameters), the algorithms may fail to exploit structure, which is embedded in the problem. This was demonstrated with the high-dimensional TSP; it has structure that the investigated optimizers have no capabilities to exploit. Another way for the process to fail is when the number of unique function evaluations is not fixed. Unless the number of unique function evaluations is fixed, some algorithms will use fewer unique function evaluations on problems from $\mathcal{F}_-$. The next problem is two fold: (1) the meta-optimization may fail to return a near optimal algorithm for the approximate problem distribution ($\hat{\mathcal{F}}_+$ and $\hat{\mathcal{F}}_-$), and (2) this approximation of the problem distribution may be poor. Thus, the accuracy of the approximation and the quality of the meta-optimization solution must be balanced;[5] the optimal algorithm for a poor approximation is undesirable. These problems affect both ML and ATSD alike.

Below we describe each experiment in more detail, including the domain where the objective functions come from, the meta-optimization procedure, which common ML practices we follow, individual tests within the experiment, and the computer setup. Results for each experiment are presented in Section 6. Just a quick note before delving into the first experiment. Whenever we say something is "low-level," we are referring to the base optimization or learning problem. Similarly, if we mention something is "meta-level" we are referring to the meta-optimization required for ML and ATSD that optimizes the "low-level" algorithm.

5.1 Satellite Trajectory Problem

For the first experiment we use a physics based domain where the pilot problems involve monitoring space debris around a small artificial planet. Monitoring space debris presents a trade-off between the quality of observations and the time until revisiting the same debris. If the satellite were to have nearly the same orbit as a single piece of debris, then the satellite would pass by the debris slower and closer, resulting in higher quality observations. Similarly, a different orbit that is closer to or further from the planet would result in seeing the debris more frequently, but from further away. The low-level optimization objective is to find an orbit for a satellite that visits all debris within a specified distance and with minimal mean-time between visits.

We simplify the domain for the experiment in the following ways. Gravity of the planet is assumed to be uniform. Space debris are treated as points, meaning they have no physical size. Collisions are ignored. We use only 10 pieces of space debris to minimize simulation time. All orbits are in a two-dimensional space. Thus, an orbit's degrees of freedom are its: eccentricity (shape), orientation (angle of the ellipse), semi-major axis (size), and true

5. One may liken this scenario to the processing inequality in information theory.

Table 2: Comparison of Pilot Problem Distributions

Data Set	$\mathcal{F}_+$	$\mathcal{F}_-$
Semi-Major Axis	$\sim N(400km, 30km)$	half from $\sim N(520km, 30km)$ half from $\sim N(280km, 30km)$
Eccentricity	$\sim N(0.1, 0.1)$	$\sim Exp(1/3)$, but ≤ 1.0
True Anomaly	$\sim U(0, 2\pi)$	$\sim U(\pi/4, 7\,\pi/4)$
Orientation	$\sim U(0, 2\pi)$	$\sim U(\pi/2, 2\,\pi)$

anomaly (phase of the orbit). In spite of these simplifications and the fact all the variables are continuous, the multiple pieces of space debris introduce many local extrema.

Recall that our methods discussed in Section 3.1 require multiple objective functions. We create multiple instantiations of problems from this domain. Each problem has space debris in a different configuration, but drawn from one of two distributions. These distributions correspond to $\mathcal{F}_+$ and $\mathcal{F}_-$. More details can be found in Table 2. To ensure there were no large gaps, we used Latin hypercube sampling (McKay et al., 1979).

5.1.1 Meta-Optimization Procedure

The meta-level problem that we investigate is the meta-optimization of an optimizer. We chose to use Matlab's simulated annealing (SA) procedure as our low-level optimizer. SA was chosen for this experiment due to its large number of hyper-parameters and behavior dependent upon these hyper-parameters (Ingber, 1993, 1996). The hyper-parameters we investigate are:

- step length function (two choices),
- initial temperatures (four real numbers),
- cooling function (three choices),
- reannealing time (one integer),
- upper bounds (four real numbers), and
- lower bounds (four real numbers).

The meta-optimization procedure is designed to find an optimizer that quickly minimizes the mean-time between the satellite visiting debris and the satellite's closest approach to each piece of debris. It does this by searching for good values for the above hyper-parameters. We searched for hyper-parameters that produce a low cumulative objective value, meaning finding a lower objective value sooner was preferred (*i.e.,* $\Phi\left(d_m^y\right) = \sum_{i=1}^{m} \min\{d_i^y\}$).

The meta-optimization consisted of three phases: differentiation, SA optimization, and a local search. The starting hyper-parameters were differentiated using SA for 35 iterations. While we recorded only the best solution during these 35 iterations, all remaining optimization iterations were recorded. Then, SA was used to further investigate the hyper-parameters, due to its global search properties.[6] Last, a gradient descent method (Matlab's

6. We acknowledge the NFL-theorems apply to meta-search.

Table 3: Four Types of Trials

Methods	ATSD+ML3	ML9	ML3	Control
$\hat{\mathcal{F}}_+$	3	9	3	1
$\hat{\mathcal{F}}_-$	9	0	0	0
Subtrials	4	4	1	1
Control?	No	No	Yes	Yes

`fmincon`) was used to finish the search process. We discovered that gradient descent worked well to search for real-valued hyper-parameters on this particular problem. The meta-optimization problem was setup to minimize the median of $\hat{\mathcal{F}}_+$ and maximize the median of $\hat{\mathcal{F}}_-$. We used $\beta = 1/3$, because our ATSD+ML test uses three times as many sacrificial functions as probable functions.

5.1.2 Practices Followed

One common practice involves searching for hyper-parameters (e.g., model selection) to minimize the bootstrap- or cross-validation error (Kohavi, 1995; Arlot and Celisse, 2010). Following these practices, we tested ATSD+ML according to (8), to search for good hyper-parameters for an optimization procedure on a collection of pilot problems. However, our experiment differs in three key aspects from common practice. First, we only test (i.e., judge the final performance) against data the optimizer has never seen, as stipulated by Wolpert (2001); Giraud-Carrier and Provost (2005). Second, the meta-optimization occurs across multiple objective functions from a limited domain, as advised by Giraud-Carrier and Provost (2005). Another common practice we purposefully chose to ignore is the partitioning of the data into training, probe/validation, and test partitions. We only use training and test partitions. The reason for this is the need to test if ATSD+ML limits the effects of overtraining. We test the algorithms from only the final iteration for the same reason.

5.1.3 Trials

We conduct four types of trials, summarized in Table 3: ATSD+ML3, ML with three samples (ML3), ML with nine samples (ML9), and a control where no ML nor ATSD are applied. ML9's $\hat{\mathcal{F}}_+$ consisted of nine sample problems. ML3 and ATSD+ML3 share a subset of ML9's $\hat{\mathcal{F}}_+$. The control uses one problem from the set ATSD+ML3 and ML3 share. We chose these trials to demonstrate how performance can be improved. The ML3 performance could be improved by either increasing the number of samples from $\mathcal{F}_+$ (ML9) or by introducing ATSD (ATSD+ML3). Both these alternatives are tested four times. Each algorithm generated from the table is then tested against 100 samples of never seen before data from the $\mathcal{F}_+$ distribution. We leave the analysis over $\mathcal{F}_0$ for another experiment.

5.1.4 Experiment Computer Setup

We ran the experiments using a cluster of three standard-grade (as of the year 2008) computers. One computer is a Gateway E6610Q model, using the Intel QX6700 quad-core processor. Two other computers are custom built, one using the Intel Q6600 quad-core

processor and the third using the Intel i7-3770K quad-core processor. All computers have 4GB of RAM (DDR2 800, DDR3 1033, DDR3 1600). All file I/O is carried out using a virtual drive hosted over the Internet. Both results and computations that could be reused are saved to the virtual drive. Two of the three computers run Matlab on Windows 7. The third computer runs Matlab in Ubuntu.

We acknowledge that this hardware is now dated and that there are better suited environments that should, and will, be used in the future. However, due to the lengthy process to gain access to high performance computing clusters, we only use a small cluster here. Anyone wishing to reproduce the results or to extend them will easily be able to use the coarse-grain parallelism that we built into our code to exploit larger clusters.

The meta-optimization code is written to exploit coarse-grain parallelism, to take advantage of each core available, while avoiding the need to use Matlab's parallel computing toolbox. Each computer performs meta-optimization for one of the ATSD+ML3, ML9, and ML3 trials. To keep one computer responsive for daily tasks, only one trial was performed on ML3. The control case did not use any meta-optimization.

The meta-optimization process takes about 1.5 months to finish for the ML3 experiment, about 4.5 months to finish the ML9 experiment, and approximately 6.0 months to complete the ATSD+ML3 experiment. After six months, we collect about 1.7 GB of data.[7] After the meta-optimization, we run the algorithms over 100 different problems from the $\mathcal{F}_+$ to collect statistical performance data. Each algorithm takes about 10 hours to run over this set of 100 problems. Due to how relatively quick it is to test an algorithm over 100 problems, we did not need to partition the trials over the cluster. This generates another 1.4 GB of data over the course of a week. All 3.1 GB of the data is available, but we also offer just the Matlab scripts (only 100KB) that can generate statistically similar data.

Because the meta-optimization run times were deemed too slow to reproduce statistically similar results, we found ways to improve the execution speed. Since the core kernel of the simulation is already optimized and Matlab's ODE45 was still the bottleneck (taking over 98% of the time), we copied the ODE45 code and removed all the code for options. Further improvements were made by turning off Matlab's ODE45's interpolation, as we were already interpolating ODE45 results at specific points.

These changes give us approximately a 2x speedup in total. Trimming the ODE45 code improves the speed by about 50%. We are surprised how much this helps; we attribute it to avoiding the majority of the ODE45's if-branches, removing its switch statement, and reduction in code size. Turning off Matlab's ODE45's interpolation provides another 30% speed up. With modern hardware and these revisions, it should take only approximately two months to produce statistically similar results.

5.2 High Dimensional Traveling Salesperson Problems

In this experiment we try to demonstrate that theory correctly predicts when ATSD should fail. Theory predicts that if ML fails, then so should ATSD. We believe this is an important experiment as it tries to disprove the theory from the opposite direction; we would be

7. Most of the data was saved computation to avoid resimulating space debris trajectories and check-pointing to prevent loss of data in advent of system crashes. Unfortunately some of the earlier data was lost, as the check-pointing system was implemented after the first system crash.

Table 4: Correlation Matrix by Problem Distribution

	$\mathcal{F}_+$	$\mathcal{F}_0$	$\mathcal{F}_-$
$\Sigma_{i,j} =$	$\frac{2.82}{(1+\lvert i-j\rvert)^2}$	$\frac{0.5}{\lvert i-j\rvert^2}$	$\delta(i,j)$

surprised to find that ATSD works where ML fails. ML and ATSD require structure in the input-output pairs. Structure, only in the problem itself but not the input-output pairs, is of little use for an optimizer or learner unless one is attempting to discover the underlying problem (*e.g.,* the TSP cost matrix) and then solve it with a non-black-box solver. This is actually one method discussed in (Culberson, 1998).

For all TSP problems in this experiment, we limit the input to only valid sequences of cities. Thus, the entire input space is valid. Only total distance traveled is analyzed. No information from partial solutions is used. The problem distributions are generated with the following technique:

- For each row of the cost matrix, sample a 20 dimensional multivariate normal distribution.
- Compose a cost matrix from 20 such samples.
- Make the cost matrix symmetric by adding it to its own transpose.
- The minimum value is set to zero.

The covariance matrix is defined in Table 4. $\mathcal{F}_+$ has a nearly singular covariance matrix, producing 20 random numbers, which approximately follow a random walk.[8] Before making the cost matrix symmetric, each row is an independent sample. This structure is not readily exploitable by the low-level optimizer. The low-level optimizer avoids analyzing trends in these random walks. $\mathcal{F}_-$ produces a random cost matrix where each element is independently normally distributed. We will assume this is sufficient to make the probability of particular outputs independent of the inputs, implying $P(f) = \prod_x P(y = f(x))$.

5.2.1 Meta-Optimization Procedure

The meta-optimization problem is to find the hyper-parameters for a custom genetic algorithm. The hyper parameters include five initial paths, a mutation rate, a max swap-size schedule, and a swap-size parameter. The initial paths and mutation rate should be self-explanatory. The swap-size parameter defines a random variable distributed according to the exponential distribution, but this value is clamped to never exceed the max swap-size. The max swap-size schedule provides 10 maximum values, each one valid for 10% of the low-level optimization procedure. The clamped exponentially distributed swap-size determines how many cities are swapped at once.

The custom genetic algorithm primarily differs from a traditional genetic algorithm in that it only generates valid inputs for the TSP problems. Random mutations are implemented as random swaps. The crossover operation uses the differences in the paths

8. It is not technically a random walk, but when plotted the values resemble a random walk.

Table 5: Five Types of Trials

Methods	ML5	ML10	ML15	ATSD250+ML5	ATSD250+ML5 Weak
$\left\|\hat{\mathcal{F}}_+\right\|$	5	10	15	5	5
$\left\|\hat{\mathcal{F}}_-\right\|$	0	0	0	250	250
Subtrials	4	4	4	4	4
β	0	0	0	1	0.2

of the two top performing individuals to guide which cities to swap. We use a population size of five. At the time the experiment was run, the implementation permitted duplicate individuals. This means it is probable that the number of unique function evaluations differ for all trials; this is significant since any subtrial may be put at a disadvantage by exploring fewer possible solutions. However, considering the cost to rerun the experiment, we still present the results. A future experiment should retest this experiment with the number of unique function evaluations fixed. The number of unique function evaluations is made more consistent for the ring-based TSP experiment.

We chose to use Matlab's SA algorithm to perform the meta-optimization, primarily due to its global search property. Any global search meta-optimization routine could be used instead. Instead of using (8) verbatim, we replace the sums with averages. This allows us to vary $\left|\hat{\mathcal{F}}_+\right|$ and $\left|\hat{\mathcal{F}}_-\right|$ while continuing to give the same relative importance β.

5.2.2 Practices Followed

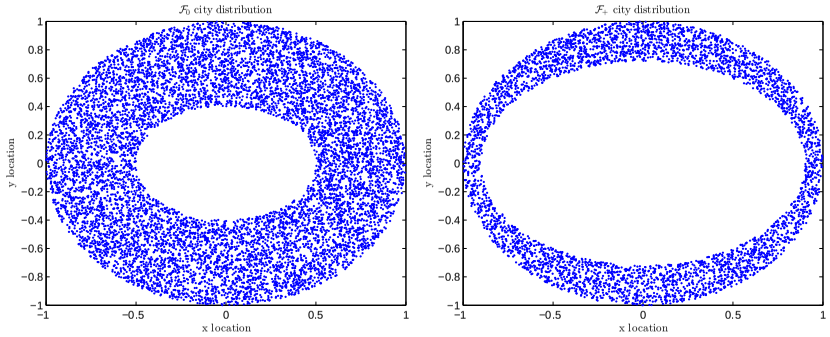
We followed the same practices as discussed in Section 5.1.2.

5.2.3 Trials

We conduct five types of trials, outlined in Table 5: ML5, ML10, ML15, ATSD250+ML5, and ATSD250+ML5 Weak. ML5 can be viewed as the control. We chose the trials ML5, ML10, and ML15 to demonstrate the effects of increasing $\left|\hat{\mathcal{F}}_+\right|$ on a domain where little to no patterns should be exploitable. The ATSD+ML trials, ATSD250+ML5 and ATSD250+ML5 Weak, demonstrate the effects of using random TSP problems for sacrificial data at differing weights of ML compared to ATSD.

Four subtrials are conducted per trial, all using the same $\hat{\mathcal{F}}_+$, $\hat{\mathcal{F}}_-$, or both. The subtrials only differ in the random seed used in the meta-optimization process (*i.e.,* the simulated annealing random seed). This is designed to roughly estimate the variability of the quality of the algorithms returned from the meta-optimization process. Since we hypothesize ATSD and ML should fail, we want to give every chance for ML and ATSD to work. So we use 10,000 simulated annealing iterations to have a greater chance to exploit structure that only works on $\hat{\mathcal{F}}_+$.

We test each resulting algorithm (a total of 20 algorithms) against 10,000 samples of never seen before data from the $\mathcal{F}_+$, $\mathcal{F}_0$, and $\mathcal{F}_-$ distributions.



(a) The $\mathcal{F}_0$ city distribution (b) The $\mathcal{F}_+$ city distribution

Figure 1: City distributions by problem distribution

5.2.4 Computer setup

The computer setup is very similar to that described in Section 5.1.4. We only use the first two computers as this experiment ran faster, taking only about three days to complete. We use the same Internet based virtual drive for all I/O. The meta-optimization process generates about 963 MB of data including checkpointing every 50 iterations. The code is written to exploit coarse-grain parallelism, scaling up to about 20 instances of Matlab (avoids using the Matlab parallel computing toolbox).

5.3 Traveling Salesperson on a Ring

In this experiment, we investigate ATSD and ML over a discrete optimization problem where multiple properties from the domain should be exploitable. This experiment is in contrast to the high dimensional TSP. As in the previous experiment, we limit the input to only valid sequences of cities. Thus, all input is valid. Only the total distance traveled is analyzed. No information from partial solutions is used. However, rather than generate a correlated cost matrix from random values directly, the cities are randomly placed on a ring and their cost values are computed as the Euclidean distance between cities (*cf.* Figure 1). As the ring's inner and outer diameter become the same, the optimal path converges to traveling in a circular loop. Furthermore, cities are labeled in a clockwise fashion.

The problem distribution comes from the following. $\mathcal{F}_+$ comes from a narrow ring (*cf.* Figure 1b). $\mathcal{F}_0$ comes from a wide ring (*cf.* Figure 1a). $\mathcal{F}_-$ are TSP problems with randomly generated cost matrices, similar to the $\mathcal{F}_-$ in the previous experiment (the high dimensional TSP experiment).

5.3.1 Meta-Optimization Procedure

The meta-optimization steps are similar to the high dimensional TSP's meta-optimization case. We investigate the same hyper-parameters as before: initial paths, mutation rate, max

Table 6: Four Types of Trials

Methods	ML5	ML10	ATSD15+ML5	ATSD50+ML5
$\left\|\hat{\mathcal{F}}_+\right\|$	5	10	5	5
$\left\|\hat{\mathcal{F}}_-\right\|$	0	0	15	50
Subtrials	200	200	200	200
β	0	0	0.2	0.2

swap-size schedule, and swap-size parameter. We use the same custom genetic algorithm as before, with two exceptions. First, we modify the low-level algorithm to force all individuals in the population to represent unique paths. Duplicate paths are replaced with random paths. Because this slows down the low-level algorithm to about half its original speed, we further optimize the low-level algorithm to nearly restore its original performance. We still use Matlab's SA algorithm to find the hyper-parameters. The sums are still replaced with the averages in (8).

5.3.2 Practices Followed

We follow the same practices as discussed in Section 5.1.2.

5.3.3 Trials

We conduct four types of trials, summarized in Table 6: ML5, ML10, ATSD15+ML5, and ATSD50+ML5. ML5 can be viewed as the control. We chose the trials ML5 and ML10 to demonstrate the effects of increasing $\left|\hat{\mathcal{F}}_+\right|$. The ATSD+ML trials, ATSD15+ML5 and ATSD50+ML5, demonstrate the effects of increasing the number of random TSP problems.

200 subtrials are conducted per trial, all using the same $\hat{\mathcal{F}}_+$, $\hat{\mathcal{F}}_-$, or both. The subtrials only differ in the random seed used in the meta-optimization process (*i.e.,* the simulated annealing random seed). This is designed to accurately estimate the variability of the quality of the algorithms returned from the meta-optimization process. Because we are using a total of 800 subtrials, we limit the meta-optimization search to 2,000 simulated annealing iterations for time considerations.

We test each resulting algorithm (a total of 800 algorithms) against 400 samples of never seen before data from the $\mathcal{F}_+$, $\mathcal{F}_0$, and $\mathcal{F}_-$ distributions.

5.3.4 Computer setup

The computer setup is very similar to that described in Section 5.1.4. We only use the first two computers as this experiment took only about one week to complete. We use the same Internet based virtual drive for all I/O. The meta-optimization process generates about 1020 MB of data including checkpointing every 100 iterations. The code is written to exploit coarse-grain parallelism, scaling up to about 800 instances of Matlab. Our parallelism techniques avoid the need for Matlab's parallel computing toolbox.

5.4 Classification Problem

This experiment tests ATSD+ML against a supervised machine learning problem. Specifically, the task is to learn to classify whether an individual makes more than $50K per year based on 14 attributes such as the sector in which the person works (private, local government, state government, etc.), job type, level of education, sex, age, hours per week, native-country, etc. This data, referred to as the "adult" data, is made publicly available and can be found in the UCI Machine Learning Repository (Bache and Lichman, 2013).

This experiment's goal is to demonstrate how ATSD can be used to boost machine learning performance, not to beat previous classification performance. We compare the classification accuracy of support vector machines (SVMs). The kernel and its parameters are meta-optimized using differing numbers of cross-validation samples and sacrificial problems. Cross-validations are used for $\hat{\mathcal{F}}_+$, which is arguably insufficient (Wolpert, 2001). This is not so much a drawback for the experiment as it demonstrates how quality $\hat{\mathcal{F}}_+$ may be difficult to obtain, further motivating the use of ATSD.

We use three types of sacrificial data. One third of $\hat{\mathcal{F}}_-$ uses real tuples of the attributes, but with random classification results. Another third of $\hat{\mathcal{F}}_-$ uses both random tuples of attributes and classification results. The last third of $\hat{\mathcal{F}}_-$ uses real tuples of attributes, but with a very simple classification problem where the result is wholly determined by a logical conjunction based on the sex, age, and number of years of education. This third set of sacrificial data exhibits several properties absent in the actual data: it is noise free, it depends only on three parameters (ignoring important information such as the job type) and has very low Kolmogorov complexity.

5.4.1 Meta-Optimization Procedure

The meta-optimization objective is to find a good set of SVM hyper-parameters. Specifically, the SVM's kernel, box constraint (training error versus complexity), and kernel parameters (*e.g.* Gaussian kernel width). We investigate seven SVM kernels including:

- Linear: $u^\intercal v$
- Gaussian: $\exp(-\left|u-v\right|^2/(2\sigma^2))$
- Laplace: $\exp(-\left|u-v\right|/\sigma)$
- Cauchy: $(1+\left|u-v\right|^2/\sigma^2)^{-1}$
- Tanh (Multilayer Perception): $\tanh(\alpha u^\intercal v + c)$
- Inhomogeneous polynomial: $(\alpha u^\intercal v + c)^p$
- Logarithmic kernel: $-\log(c+\left|x-y\right|^p)$.[9]

σ, α, c, and p in this context are kernel parameters. u and v are data. Note that some of these kernels are only conditionally positive definite. Meaning, if used, the SVM may fail to converge to globally optimal results.

9. Less common kernels were adopted from Cesar Souza's blog: `http://crsouza.blogspot.com/2010/03/kernel-functions-for-machine-learning.html`

The meta-optimization procedure is conducted differently in this experiment than in the other experiments. Unlike the other experiments' meta-optimization procedure, we first sample the algorithm space blindly, then optimize after sampling. This ensures each trial gets the same quality search since they all evaluate the same hyper-parameters. For each kernel, we sample 500 hyper-parameter configurations using low discrepancy Halton sequences (Kuipers and Niederreiter, 1974; Kalos and Whitlock, 2008). This samples the hyper parameters in a roughly uniform manner. All $\hat{\mathcal{F}}_+$ and $\hat{\mathcal{F}}_-$ are evaluated and their results are stored. To evaluate each ML or ATSD trial, we calculate the meta-objective function from the stored results. The hyper-parameters that optimize the meta-objective function for each trial are selected for testing. This makes the search for the optimal algorithm less dependent on a random search (the other experiments used SA). All trials get the same quality search. This also removes the need to test hundreds of different seeds in the meta-optimization process.

When meta-optimizing to select the kernel and kernel parameters that work best for a particular trial, we use a slightly modified (8). Instead of using (8) verbatim, we replace the sums with averages. This allows us to vary $\left|\hat{\mathcal{F}}_+\right|$ and $\left|\hat{\mathcal{F}}_-\right|$ while continuing to give the same relative importance β.

5.4.2 Practices Followed

We mostly follow the same practices as discussed in Section 5.1.2, with one exception. Because we are working with real data in this experiment, we only have a single $f \in \mathcal{F}_+$. So in order to make $\left|\hat{\mathcal{F}}_+\right|$ larger than one, we partition the data into training, validation, and test partitions. We partitioned the data as follows. For the test partition, we used the official test data, `adult_test.csv`, from the UCI Machine Learning Repository (Bache and Lichman, 2013). After removing incomplete data and NaNs, the `adult_test.csv` contains 30162 records. We partition the `adult_data.csv` data into 1/4 for training and 3/4 for validation for each $f \in \mathcal{F}_+$. By making the training data smaller than the validation data, we decreas the time the meta-optimization process uses.

We take the following additional steps to decrease SVM training time. We allow the SVM decision boundary to violate up to 15% of the Karush-Kuhn-Tucker (KKT) conditions (Bazaraa et al., 2006). This means that the result of training the SVM may not be a globally optimal solution, but should in no way invalidate the effects of ATSD. Moreover, we increase the KKT tolerance from 0.001 to 0.05. This means that the KKT conditions close to being satisfied will count as satisfied. This should not invalidate the effects of ATSD, either.

It is trivial to show that relaxing the KKT constraints translates to testing different learning algorithms, other than SVMs. In the NFL framework for supervised learning, each learner is trying to guess the function generating the data (Wolpert, 2001). SVMs trained with relaxed constraints may produce different predictions (*i.e.,* guesses at the function generating the data). This translates as using different learning algorithms than the canonical SVM algorithm. Using a different learning algorithm other than SVMs would have the same consequence. Hence, relaxing the constraints does not invalidate the experiment.

5.4.3 Trials

Because we are meta-optimizing differently, reusing the same function evaluations for each trial, we can test more trials quickly. We vary $\left|\hat{\mathcal{F}}_+\right|$ and $\left|\hat{\mathcal{F}}_-\right|$ with $\beta = 0.1774$ to get 20 trials. We also vary β over zero and 13 logarithmically spaced levels with $\left|\hat{\mathcal{F}}_+\right| = 2$ and $\left|\hat{\mathcal{F}}_-\right| = 4$. Similarly, we vary β over zero and 13 logarithmically spaced levels with $\left|\hat{\mathcal{F}}_+\right| = 4$ and $\left|\hat{\mathcal{F}}_-\right| = 4$. Thus, in total there are 46 unique trials, each denoted using the notation ATSD+X-Y@B. Here $X = \left|\hat{\mathcal{F}}_+\right|$, $Y = \left|\hat{\mathcal{F}}_-\right|$, and $B = \beta$. Trial ATSD+2-12@0.1774 corresponds to the trial with two cross-validations, 12 sacrificial problems, and using $\beta = 0.1774$. When $\beta = 0$, the sacrificial data is given no weight and ATSD+ML degenerates to ML.

5.4.4 Computer setup

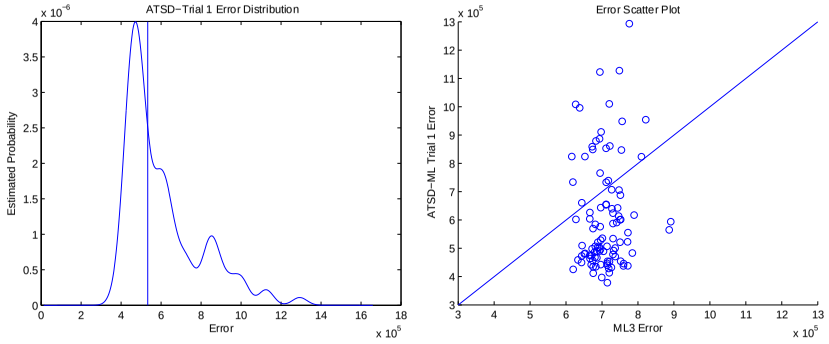
The computer setup is very similar to that described in Section 5.1.4. We only use the first two computers as this experiment takes only about two weeks to complete. We use the same Internet based virtual drive for all I/O. The meta-optimization process generates about 11.9 GB of data, saving all function evaluations (required for optimization after sampling). The code is written to exploit coarse-grain parallelism, scaling up to about 3500 instances of Matlab. Our parallelism techniques avoid the need for Matlab's parallel computing toolbox.

6. Results

We present the results of the four experiments here. In summary: the satellite trajectory experiment showed ATSD helped, but to lesser extent than ML, as predicted in (12). ATSD also had two of four subtrials drop degrees of freedom in their search. The high dimensional traveling salesperson experiment showed that neither ATSD nor ML have any benefit when no problem knowledge is exploitable. The traveling salesperson on a ring experiment is inconclusive due to an NFL artifact. While the classification problem lacks statistical backing—due to there being a single test problem—some general trends suggest, but are inconclusive, that in the case of a limited search for a better learner, it may be best to limit the sum $\left|\hat{\mathcal{F}}_+\right| + \left|\hat{\mathcal{F}}_-\right|$. Increasing either $\left|\hat{\mathcal{F}}_+\right|$ or $\left|\hat{\mathcal{F}}_-\right|$ after a certain degree produced worse results. A single cross-validation combined with nine sacrificial problems ($\left|\hat{\mathcal{F}}_+\right| = 1, \left|\hat{\mathcal{F}}_-\right| = 9$) outperformed any ML alone.

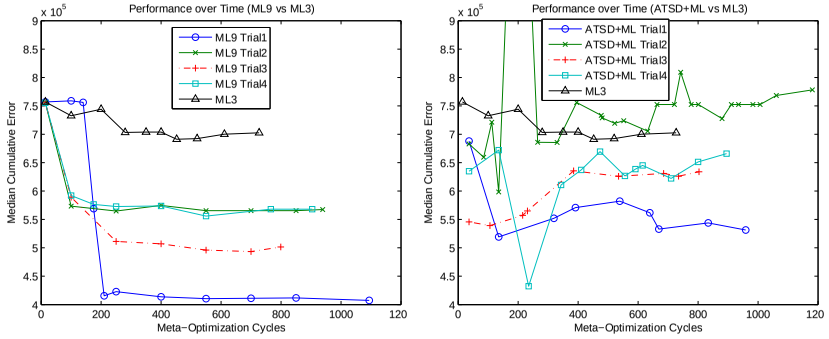
6.1 Satellite Trajectory Results

We analyze the median performance of our algorithms for two primary reasons. First, we optimized over the median performance. Second, after we collected the data from our experiments, it became evident that the performance distributions of the algorithms are highly skewed (see Figure 2a). Thereupon, we follow the advice of Luke (2013) and Wineberg (2004) and analyze our results using the median rather than the mean.



(a) The estimated error distribution (b) Error from ML3 and ATSD+ML3

Figure 2: Depictions of the cumulative error distribution



(a) ML9 and ML3 performance over time (b) ATSD+ML3 and ML3 performance over time

Figure 3: Depictions of the cumulative error over time

While we do not analyze the performance over time, we still present the data in Figure 3a and Figure 3b. Notice that while all the trials in Figure 3a start at the same value, the same cannot be said about the trials in Figure 3b (this is due to an unexpected system crash). Thus, the optimization number of function evaluations are incorrect on the ATSD+ML3 trials. This did not influence the final analysis, just the temporal performance seen in Figure 3b. Meta-optimization stopped when Matlab determined insufficient progress was being made.

Table 7 summarizes the median cumulative error of each technique, meaning lower is better. Since there were four trials for each ATSD+ML3 and ML9, to make their analysis easier, we introduced the terms "ATSD+ML3-1," "ATSD+ML3-2," etc. to indicate

Table 7: Summary of Median Performance between Methods

	Median Cumulative Error
Initial	$7.461 \cdot 10^5$
ML3	$7.026 \cdot 10^5$
ATSD+ML3	$6.637 \cdot 10^5$
ML9	$5.249 \cdot 10^5$

particular trials. "ATSD+ML3" and "ML9" are 100 median samples, where the median was taken over the corresponding four trials. Thus, the table reflects the median of medians for ATSD+ML3 and ML9. This table shows that the control performed worst, ML3 was third, ATSD+ML3 was second, and ML9 performed best. We discuss these results after making sure they are statistically significant.

We must analyze the data further to determine if the differences in medians are statistically significant. Due to the great asymmetry, possible dependencies in the data, and multimodal nature of the ATSD+ML3 performance distributions, we avoid using the standard T-tests to compare performance between algorithms. While the Wilcoxon signed rank test is more robust, it is usually employed in the context of symmetric distributions, especially for paired (one-sample) tests (Lehmann, 2004). For this reason, we use the paired sign-test. It usually lacks the power of the other tests but makes fewer assumptions about the data (Lehmann, 2004). Due to the lack of power of the paired sign test, we may permit a lower significance (Lehmann and Romano, 2008).

Table 8 shows the results of the paired sign-tests comparing ATSD+ML3 with ML9. We present the results from the algorithms at the final iteration to reflect the possible effects of overtraining. This table confirms that ML9 outperforms ATSD+ML3: this is to be expected according to theory derived in Section 3.2. According to (12), even with equal compressibility of the meta data and sacrificial data ($\rho_- = \rho_+$), the samples for $\hat{\mathcal{F}}_-$ are expected to be half as efficient.[10] Since ATSD+ML3 uses three samples for $\hat{\mathcal{F}}_+$ and nine samples for $\hat{\mathcal{F}}_-$, according to theory this should perform on par with ML using 7.5 ($3 + 9/2$) samples for $\hat{\mathcal{F}}_+$.

Table 9 shows the results of the paired sign-tests comparing ATSD+ML3 with ML3. This shows that ATSD appears to improve performance, at least on the median. The paired-sign test shows $p = 4.431 \cdot 10^{-2}$, indicating that the null hypothesis (ATSD+ML3 = ML3) is unlikely. Again, the paired-sign test lacks statistical power in general, so $p = 4.431 \cdot 10^{-2}$ is statistically significant.

We also calculated a Bayes factor to directly compare the two hypotheses: median(ML3 − ATSD+ML3) > 0 and median(ML3 − ATSD+ML3) < 0. The difference between ML3 and ATSD+ML3 is distributed approximately as an extreme-value distribution (*cf.* Figure 4).[11] Matlab's extreme-value distribution has its median at $\mu + \sigma \log(\log(2))$. Thus, for our first hypothesis, we integrated over the range of parameters where $\mu > -\log(\log(2))\sigma$ and for the second hypothesis we used $\mu < -\log(\log(2))\sigma$. Since Bayes factors use a prior

10. Our $\hat{\mathcal{F}}_-$ comes from a more complicated distribution, so we expect a lower ρ_- than ρ_+. This is supported by the fact that ATSD+ML3 performs more similarly to ML3 than ML9.
11. We have no reason to believe the data should be distributed as such, but extreme-value distributions provided the best fit.

Table 8: Sign Test (H_a: ATSD+ML3 > ML9)

	ML9-1	ML9-2	ML9-3	ML9-4	ML9
ATSD+ML3-1	$1.30 \cdot 10^{-12}$	0.972	$6.02 \cdot 10^{-3}$	0.903	0.382
ATSD+ML3-2	$7.97 \cdot 10^{-29}$	$6.55 \cdot 10^{-12}$	$1.60 \cdot 10^{-19}$	$1.35 \cdot 10^{-10}$	$1.53 \cdot 10^{-17}$
ATSD+ML3-3	$1.32 \cdot 10^{-25}$	$9.05 \cdot 10^{-8}$	$6.26 \cdot 10^{-23}$	$9.05 \cdot 10^{-8}$	$1.00 \cdot 10^{-21}$
ATSD+ML3-4	$1.27 \cdot 10^{-16}$	$2.04 \cdot 10^{-4}$	$5.58 \cdot 10^{-10}$	$2.04 \cdot 10^{-4}$	$2.76 \cdot 10^{-8}$
ATSD+ML3	$1.32 \cdot 10^{-25}$	$1.35 \cdot 10^{-10}$	$1.32 \cdot 10^{-25}$	$2.41 \cdot 10^{-13}$	$6.26 \cdot 10^{-23}$

Table 9: Sign Test (H_a: ATSD+ML3 < ML3)

	ML3
ATSD+ML3-1	$9.050 \cdot 10^{-8}$
ATSD+ML3-2	0.9334
ATSD+ML3-3	$1.759 \cdot 10^{-3}$
ATSD+ML3-4	0.2421
ATSD+ML3	$4.431 \cdot 10^{-2}$

distribution, we chose μ to be distributed normally about σ with a standard deviation corresponding to the range of Matlab's `evfit`'s 95% confidence interval. σ is distributed half-normal with a standard deviation corresponding to the range of its 95% confidence interval. The resulting Bayes factor, $k = 5.571$, means that it is more than five times as likely that ATSD+ML3 has a lower (better) median than ML3. According to Robert et al. (2009), this is *substantial* evidence.

There were two surprising, unanticipated results that only occurred for the experiments using anti-training with sacrificial data combined with meta-learning (ATSD+ML3). Two out of the four ATSD+ML3 meta-optimization runs (trials 2 and 3) halted early with the message "distance between lower and upper bounds, in dimension 4 is too small to compute finite-difference approximation of derivative." This corresponds to the two runs limiting their search by dropping a degree of freedom corresponding to the elliptical orientation of the satellite's orbit.[12] This is plausible: the debris in $\mathcal{F}_+$ have no large angular gaps, but the debris in $\mathcal{F}_-$ did have angular gaps. Thus, on average no orientation is to be preferred on $\mathcal{F}_+$, but some orientations are significantly worse for $\mathcal{F}_-$. Recall that in general ATSD+ML maximizes the performance difference between $\mathcal{F}_+$ and $\mathcal{F}_-$. As such, we suspect that ATSD+ML3 extracted this information from this difference. It seems unlikely that this result occurred due to random chance as two trials from ATSD+ML3 dropped this degree of freedom, but none of the five ML did so.

Another surprise is that the second ATSD+ML3 subtrial also dropped a second degree of freedom from its search: the initial true anomaly. Dropping this variable appears to be a valid choice for speeding the search for good solutions, albeit less obvious. Provided that the ratio of orbital periods are irrational (or requiring very large rational numbers) and ignoring highly eccentric orbits, the equidistribution theorem can be applied to show that

12. Meta-optimization was allowed to continue with the variable replaced by the average of the lower and upper bounds.

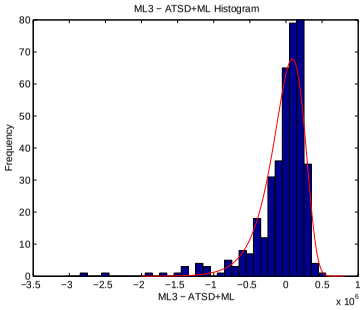


Figure 4: ML3 − ATSD+ML3 and its best fit distribution

the difference in orbital-phases will be uniform (or nearly uniform). Thus, provided enough time, the initial true anomaly may also be ignored. How can we reconcile this with the fact that the second ATSD+ML3 trial performed the worst out of all the ATSD+ML trials? We do not know the answer, but speculate it is because we only tested the performance over $\hat{\mathcal{F}}_+$. It is possible that this reduced degree of freedom would be beneficial in the more general $\mathcal{F}_+ \cup \mathcal{F}_0$. Further testing is required.

6.2 Random TSP Results

As expected, neither ML nor ATSD produce optimization algorithms that reduce error when no problem structure may be exploited. Table 10 shows the mean and standard deviation (taken across the four subtrials) of the mean cumulative error across 10000 tests. Notice that the cumulative error for ML15 over $\mathcal{F}_+$ is worse than ML10's error, although by a statistically insignificant amount. ML10's improvement over ML5's error is also statistically insignificant ($p = 0.4315$). The evidence suggests that increasing the number of meta-learning samples has an insignificant effect on algorithm performance. Similarly, the two ATSD tests (ATSD250+ML5 and ATSD250+ML5 Weak) show no improvement over ML5 alone. They actually show higher mean error over $\mathcal{F}_+$. This could be due to random chance or by the fact that this version of the GA optimizer permits duplicate function evaluations, putting those trials at a disadvantage.[13]

Another issue of concern is whether the meta-optimization procedure succeeded in optimizing (8). Note that we replaced the sums with averages, so β reflects the relative weight of ATSD compared to ML. This is used in Table 11 for the meta-fitness column. It shows how well the discovered algorithms perform according to their meta-optimization criteria. The ATSD250+ML5 trial has the most negative meta-fitness when $\beta = 1.0$, meaning it provides the better solution to (8) than any other algorithms investigated. However, ATSD250+ML5 Weak which was optimized with respect to $\beta = 0.2$, fails to have the lowest meta-fitness for that column. This means that the algorithms discovered

13. The following experiment, the TSP problem on a ring, forces the GA optimizer to use unique function evaluations within each iteration.

Table 10: Mean and Standard Deviation of Means

Trial	$\mathcal{F}_-$		$\mathcal{F}_0$		$\mathcal{F}_+$	
	μ	σ	μ	σ	μ	σ
ML5	47.20	0.4175	47.37	0.3774	47.12	0.3710
ML10	47.12	0.3888	47.28	0.3629	47.07	0.3642
ML15	47.13	0.5617	47.31	0.5370	47.07	0.5196
ATSD250+ML5	49.83	1.981	49.90	1.870	49.56	1.811
ATSD250+ML5 Weak	48.35	1.043	48.47	0.9683	48.18	0.9645

Table 11: Meta Objective Function Values

Trial	mean meta-fitness ($\beta = 1.0$)	mean meta-fitness ($\beta = 0.2$)
ML5	$-7.972 \cdot 10^{-2}$	37.68
ML10	$-4.700 \cdot 10^{-2}$	37.65
ML15	$-5.931 \cdot 10^{-2}$	37.65
ATSD250+ML5	-0.2708	39.59
ATSD250+ML5 Weak	-0.1695	38.51

in ATSD250+ML5 Weak are, even according to theory, inferior to the algorithms from the ML15 trials. This is a side-effect of the NFL theorems: it may be better to search for something else rather than the desired objective function.

6.3 TSP Ring Results

Because this experiment uses a large number of subtrials, we can illustrate the differential error distributions. Figure 5 shows how the ATSD15+ML5 and ATSD50+ML5 trials compare to the ML5 and ML10 trials. Since these distributions are symmetric with few outliers, it makes sense to use the standard T-test to compare means. Furthermore, since the individual test problems are the same for each algorithm, we are permitted to use the paired T-test. Negative values favor ATSD and positive values favor ML.

Contrary to what we anticipated, all the distributions in Figure 5 have a positive average, meaning the algorithms found from the ML trials are to be preferred. The mean error and its standard deviation for each trial over each problem distribution $\mathcal{F}_-, \mathcal{F}_0, \mathcal{F}_+$ are shown in Table 12. Table 13 shows the results of the T-tests, where the alternative hypotheses are that ATSD15+ML5 and ATSD50+ML5 have greater means than ML5 and ML10.[14] Since all the p values are sufficiently small, the null hypotheses should be rejected in favor of the alternatives. The algorithms found in the ATSD15+ML5 and ATSD50+ML5 trials perform worse than the algorithms found in the ML5 and ML10 trials.

Even though the algorithms found in the ATSD trials perform statistically significantly worse than the algorithms found in the ML trials, these results do not contradict our theory. To see why these results do not contradict our theory, we need to investigate the meta-objective function values. These values are shown in Table 14. The meta-optimization

14. The significances in Table 13 were so small, arbitrary precision arithmetic was required to compute them.

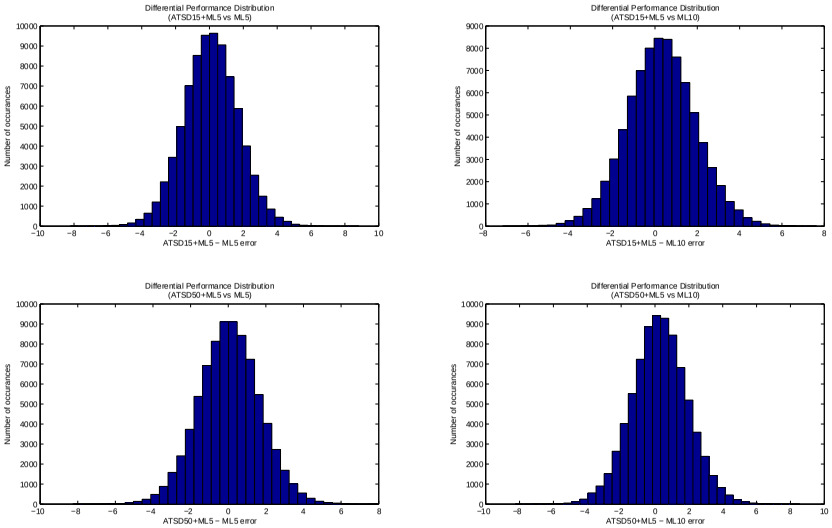

Figure 5: Error differences as a distribution

Table 12: Mean and Standard Deviation of Means

Trial	$\mathcal{F}_-$		$\mathcal{F}_0$		$\mathcal{F}_+$	
	μ	σ	μ	σ	μ	σ
ML5	17.29	1.210	15.57	1.309	16.96	1.438
ML10	17.19	1.216	15.39	1.309	16.74	1.448
ATSD15+ML5	17.37	1.212	15.65	1.304	17.05	1.427
ATSD50+ML5	17.35	1.221	15.62	1.323	17.02	1.453

Table 13: Significance of Differential Performance

Distribution	Significance
ATSD15+ML5 - ML5	$3.783 \cdot 10^{-63}$
ATSD15+ML5 - ML10	$1.150 \cdot 10^{-642}$
ATSD50+ML5 - ML5	$9.566 \cdot 10^{-30}$
ATSD50+ML5 - ML10	$7.845 \cdot 10^{-508}$

Table 14: Meta Objective Function Values when $\beta = 0.2$

Trial	mean meta-fitness
ML5	13.50
ML10	13.30
ATSD15+ML5	13.58
ATSD50+ML5	13.55

for ML5 and ML10 found better solutions for the ATSD+ML meta-objective function than the ATSD15+ML5 and ATSD50+ML5 trials! This is a side-effect of the NFL theorems. Without knowing anything about the search for optimization algorithms, we naïvely used a SA search. Using SA to reduce the meta-objective function with $\beta = 0.2$ actually performed worse at reducing it than when trying to reduce meta-objective function with $\beta = 0.0$ (ML alone). To better understand what happened consider the following analogy. When a dog (an algorithm) was told to find (optimize) the yellow ball (the ATSD objective function), it found nothing. However, when told to find the violet ball (the ML objective function), it found both the yellow and violet balls (good solutions to both meta-optimization functions).

So while this experiment does not confirm our theory, neither does the experiment deny it. Instead, it provided meaningful feedback. Matlab's SA algorithm performs better on ML than ATSD+ML for the small set of problems investigated in this experiment. We can prevent this problem from occurring by ensuring all trials evaluate an identical set of algorithms. This effectively amounts to sampling algorithms first, recording their performance, then optimizing after all algorithms have been tested on all problems. Thus, it is impossible for ML to find an algorithm that outperforms ATSD+ML on ATSD+ML's own objective function. If ML were to find such an algorithm, because ATSD+ML would test it too, ATSD+ML must at least match it (assuming the function values are deterministic). The following experiment uses this adjustment.

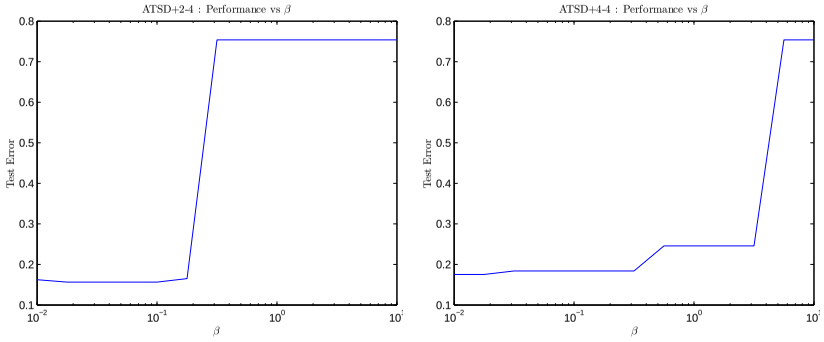
6.4 Classification Results

The results from this experiment lack statistical backing since we use only a single test problem. We considered using bootstrapping to estimate the variance of the error rates presented in this experiment but ultimately avoided it due to time considerations—the experiment already took two weeks to complete. A ten-fold cross-validation would take much longer than an additional two weeks.[15] Future work will include bootstrapping to estimate the variance in this experiment.

Despite this, some general trends are still evident. We modified (8) by replacing the sums with averages so β reflects the relative weight of ATSD. Figures 6a and 6b show that large values of β cause more harm than good. Figure 6a shows $2 \cdot 10^{-2} < \beta < 10^{-1}$ as being ideal, whereas Figure 6b shows that ATSD should be avoided. Since this difference in behavior could be noise, we further investigated the error rate's behavior.

Table 15 shows several patterns. First, in terms of error, ATSD+1-9@0.1778 and ATSD+1-12@0.1778 perform best. These two trials even outperform the best performing ML (ATSD+3-0@0). Another point is that the best performing trials have a negatively

15. Although, it should take less than twenty weeks to complete a ten-fold cross validation study.



(a) Error rate when $\left|\hat{\mathcal{F}}_+\right| = 2$ and $\left|\hat{\mathcal{F}}_-\right| = 12$ (b) Error rate when $\left|\hat{\mathcal{F}}_+\right| = 4$ and $\left|\hat{\mathcal{F}}_-\right| = 12$

Figure 6: Error rate versus β

Table 15: Error versus $\left|\hat{\mathcal{F}}_+\right|$ and $\left|\hat{\mathcal{F}}_-\right|$ with β=0.1778

	$\left\|\hat{\mathcal{F}}_-\right\|$=0	$\left\|\hat{\mathcal{F}}_-\right\| = 3$	$\left\|\hat{\mathcal{F}}_-\right\| = 6$	$\left\|\hat{\mathcal{F}}_-\right\| = 9$	$\left\|\hat{\mathcal{F}}_-\right\| = 12$
$\left\|\hat{\mathcal{F}}_+\right\|$=1	0.1624	0.1624	0.1624	**0.1558**	**0.1558**
$\left\|\hat{\mathcal{F}}_+\right\|$=2	0.1624	0.1629	0.1624	**0.1564**	0.1652
$\left\|\hat{\mathcal{F}}_+\right\|$=3	**0.1564**	0.1579	0.1579	**0.1564**	0.1839
$\left\|\hat{\mathcal{F}}_+\right\|$=4	**0.1752**	**0.1752**	0.1839	0.1839	0.1839

correlated $\left|\hat{\mathcal{F}}_-\right|$ and $\left|\hat{\mathcal{F}}_+\right|$. The bold diagonal highlights this. This pattern lacks statistical significance, thus one should not read into it too much. Figure 7 also visualizes these results.

While we are not trying to beat historical classification performance on this data set, it is worthwhile to note preexisting performance on this data set. Kohavi (1996) used naïve Bayes classification trees to produce predictions with errors ranging from about 15.7% to 16.7%, and the C4.5 algorithm produced predictions with errors ranging from about 13.7% to 14.8%.

7. Discussion and Conclusion

We used the statistical entropy of the objective function distributions to address when meta-learning (ML) is possible. For ML to benefit learning, the typical problems should have low Kolmogorov complexity. This implies that it is necessary for the problem distribution to be at least compressible, but not necessarily fit in polynomial space.

We introduced a novel theoretical approach, anti-training with sacrificial data, to improve machine-learning performance. ATSD directly follows from and relies on the No Free Lunch (NFL) theorems. It can be seen as an approximate dual of ML. As

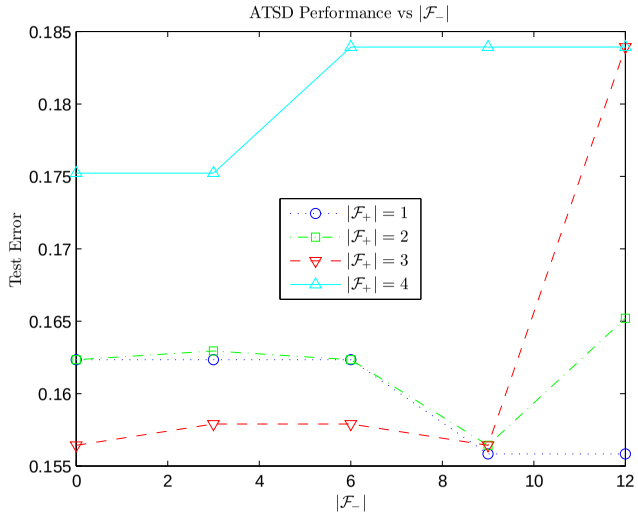


Figure 7: Error rate versus $\left|\hat{\mathcal{F}}_-\right|$

such, the theory dictates that ATSD works where ML works, namely when the probable problems are compressible. While ML directly improves performance over a set of common problems, ATSD worsens performance over sacrificial (impossible and unlikely) problems. Due to the NFL theorems, performance must increase over the remaining sum of all other problem, although it is possible for performance to transfer from the typical problems to any unspecified problems. To help counter-balance this possibility, ATSD ought to be combined with ML (ATSD+ML).

We examined the theoretical efficiency of ATSD using a deck of cards analogy. We arrived at a function relating the percent of implausible functions, the compressibility of typical functions, and the compressibility of implausible functions with the efficiency of ATSD. Assuming that about half of all functions are exceedingly unlikely and the ML objective functions are as compressible as the sacrificial objective functions, then the relative efficiency of ATSD is half as efficient as ML. Moreover, we addressed how to generate sacrificial data and qualitatively assess their compressibility.

ATSD+ML has other helpful properties. Since sacrificial data is easy to generate, it can be applied even when real data is scarce. The theory suggests this is when ATSD+ML is expected to be most effective. The fourth experiment provides supportive, but inconclusive evidence of this. According to the theory, it also helps prevent overtraining. By providing an empirical definition of noise, theoretically the learning algorithm can fail to learn noise. Also when combined with ML, ATSD+ML makes it less likely to overfit the original ML objective function. ATSD+ML also allows for the specification of failure cases, reducing the number of unexpected failures.

ATSD+ML is a technique still in its infancy. Much work remains to be done on accurately estimating how much and what kind of sacrificial data ATSD+ML needs. We only touched on the proper balance between ATSD and ML. In general, a safe value for β in (8) is $0 \leq \beta < \left|\hat{\mathcal{F}}_+\right| / \left|\hat{\mathcal{F}}_-\right|$, or when the sums are replaced with averages $0 \leq \beta < 1$. Another future research direction includes studying the implications of the NFL theorems approximately holding, when the equality in (1) is replaced with upper and lower bounds. We conjecture that the benefits from anti-training would diminish as the equality becomes less strict. However, this would need to be investigated more thoroughly. ATSD+ML could be viewed as a form of regularization and studied as such. It might also be able to be applied to model selection rather than algorithm selection. A probabilistic model would be useful in answering these questions.

The basic concept of ATSD—improving performance by training to perform worse on irrelevant data—may have benefits for selecting solutions (not algorithms) to improve predictive accuracy. This baseline ATSD does not follow from the NFL theorems in the same manner. It may still follow from the NFL theorems, but for a different reason. However, baseline ATSD may be justifiable in terms of regularization. If a solution fits random noise in addition to the actual data, then the solution may be unnecessarily complex.

We conducted four experiments showing how ATSD may function in practice. The first experiment produced results showing ATSD improves performance for optimizers. The second experiment confirmed that ATSD should fail when ML fails. The third experiment was inconclusive as the algorithms discovered from ML outperformed the ATSD candidates even at their own meta-objective function; a side effect of the NFL algorithms. The fourth experiment provides supportive, but inconclusive evidence that ATSD benefits classification algorithms. More experiments are left for future work. Such experiments include repeating similar experiments that take significantly less time to complete, using 10-fold cross-validation for machine learning experiments, and comparing direct meta-optimization (as in the first three experiments) to sampling based approached (as in the fourth experiment).

Convex optimization is a desirable property needed for more sophisticated machine learning procedures. This is the issue when extending ATSD to work with support-vector machines, support-vector regression, or any other optimization that depends on convex optimization problems. The results from the third experiment motivate a convex meta-optimization framework to ensure algorithms actually optimize their meta-objective function. The issue is that it is possible for the global minimum to occur whenever the sacrificial performance approaches positive infinity; this drives the objective function to negative infinity. This in turn causes the traditional objective function to be largely ignored. The most natural approach would be to apply some convex non-decreasing saturating function (*e.g.,* $exp(-x)$) to the sacrificial term. The effects of this saturating ATSD on convex optimization techniques should be studied, as well as other techniques to extend ATSD to a convex optimization framework.

Appendix A. Proof of the two-valued nature of $\hat{P}_+(f)$ in practice

The estimate of $P_+(f)$ is denoted $\hat{P}_+(f)$. We argue that $\hat{P}_+(f)$ is practically going to be a two-valued function: 0 and $1/\left|\hat{\mathcal{F}}_+(f)\right|$. This is demonstrated by showing that when independently sampling from $\mathcal{F}_+$, the probability that any two functions are identical is exceedingly small in practice. If one stops to ponder for a moment about similar problems, one realizes this problem reduces to the well known birthday problem in probability theory.

The birthday problem asks "what is the probability that out of n people (samples), some pair of them will have the same birthday (function)." The answer is 100% if the number of people exceed the number of days in a year, but otherwise it is:

$$1 - \frac{n!\binom{365}{n}}{365^n}.$$

When replacing days with functions and people with samples this becomes

$$1 - \frac{n!\binom{|\mathcal{F}_+|}{n}}{\left|\mathcal{F}_+\right|^n}. \tag{13}$$

While (13) is exact, it must be used iteratively to figure out how much larger $\left|\mathcal{F}_+\right|$ must be than n to ensure a small probability of failure (that two functions will be identical). We provide an approximate n which limits the probability of failure to ϵ. Consider the probability of two samples having different functions,

$$\left(1 - \frac{1}{\left|\mathcal{F}_+\right|}\right).$$

If there are n samples, then there exist $n(n-1)/2$ pairs of samples. Assuming each comparison is independent (this is approximately true if $n \ll \left|\mathcal{F}_+\right|$), then the probability that all samples are unique is

$$\left(1 - \frac{1}{\left|\mathcal{F}_+\right|}\right)^{n(n-1)/2}$$

Using the binomial theorem, this expands to

$$1 - \binom{\frac{n^2-n}{2}}{1}\frac{1}{\left|\mathcal{F}_+\right|} + \binom{\frac{n^2-n}{2}}{2}\frac{1}{\left|\mathcal{F}_+\right|^2} - \binom{\frac{n^2-n}{2}}{3}\frac{1}{\left|\mathcal{F}_+\right|^3} + \binom{\frac{n^2-n}{2}}{4}\frac{1}{\left|\mathcal{F}_+\right|^4} - \ldots. \tag{14}$$

We will bound the lth term of (14) using the well known inequality $\binom{n}{l} \leq \frac{n^l}{l!}$ to get

$$\begin{aligned}
\binom{\frac{n^2-n}{2}}{l}\frac{1}{\left|\mathcal{F}_+\right|^l} &\leq \frac{\left(\frac{n^2-n}{2}\right)^l}{l!}\frac{1}{\left|\mathcal{F}_+\right|^l} \\
&\leq \left(\frac{n^2-n}{2}\right)^l \frac{1}{\left|\mathcal{F}_+\right|^l} \\
&= \left(\frac{n^2-n}{2\left|\mathcal{F}_+\right|}\right)^l.
\end{aligned}$$

Thus, all higher order terms are negligible so long as

$$\frac{n^2-n}{2\left|\mathcal{F}_+\right|} \ll 1$$

The first two terms are kept and set equal to the desired level of probability

$$\begin{aligned}
1 - \binom{\frac{n^2-n}{2}}{1}\frac{1}{\left|\mathcal{F}_+\right|} &\geq 1 - \epsilon \\
\binom{\frac{n^2-n}{2}}{1}\frac{1}{\left|\mathcal{F}_+\right|} &\leq \epsilon \\
\frac{n^2-n}{2\left|\mathcal{F}_+\right|} &\leq \epsilon \\
n^2 - n &\leq 2\left|\mathcal{F}_+\right|\epsilon \\
n &\leq \frac{\sqrt{8\left|\mathcal{F}_+\right|\epsilon + 1} + 1}{2}
\end{aligned} \tag{15}$$

where ϵ is the probability that two functions will be the same. When $\left|\mathcal{F}_+\right| \cdot \epsilon$ is much larger than one, then this is well approximated by:

$$n \leq \sqrt{2\left|\mathcal{F}_+\right|\epsilon}. \tag{16}$$

For example, problems as small as those with a 16-bit input and an 8-bit output have $|\mathcal{F}| \approx 2.6 \cdot 10^{157826}$. Assuming $n = 10^{12}$ and $\left|\mathcal{F}_+\right| = 10^{100}$ (hundreds of thousands of orders of magnitude smaller), (13) states the probability that any two samples will have the same function is approximately $5.0 \cdot 10^{-77}$. Thus, in sampling the problem domain to build $\hat{P}_+(f)$, it is extremely likely that a particular function will be sampled once or not at all. This leads to the two-valued nature of $\hat{P}_+(f)$ in practice. Equation (16) shows how many samples are permitted while maintaining the two-valued nature with approximately $1 - \epsilon$ confidence. Continuing the above example, when setting the probability of failure $\epsilon \approx e^{-100}$, we see n may be as large as $2.7 \cdot 10^{28}$.

Abstract

This paper presents a general vector-valued reproducing kernel Hilbert spaces (RKHS) framework for the problem of learning an unknown functional dependency between a structured input space and a structured output space. Our formulation encompasses both Vector-valued Manifold Regularization and Co-regularized Multi-view Learning, providing in particular a unifying framework linking these two important learning approaches. In the case of the least square loss function, we provide a closed form solution, which is obtained by solving a system of linear equations. In the case of Support Vector Machine (SVM) classification, our formulation generalizes in particular both the binary Laplacian SVM to the multi-class, multi-view settings and the multi-class Simplex Cone SVM to the semi-supervised, multi-view settings. The solution is obtained by solving a single quadratic optimization problem, as in standard SVM, via the Sequential Minimal Optimization (SMO) approach. Empirical results obtained on the task of object recognition, using several challenging data sets, demonstrate the competitiveness of our algorithms compared with other state-of-the-art methods.

Keywords: kernel methods, vector-valued RKHS, multi-view learning, multi-modality learning, multi-kernel learning, manifold regularization, multi-class classification

1. Introduction

Reproducing kernel Hilbert spaces (RKHS) and kernel methods have been by now established as among the most powerful paradigms in modern machine learning and statistics (Schölkopf and Smola, 2002; Shawe-Taylor and Cristianini, 2004). While most of the literature on kernel methods has so far focused on scalar-valued functions, RKHS of vector-valued functions have received increasing research attention in machine learning recently, from both theoretical and practical perspectives (Micchelli and Pontil, 2005; Carmeli et al., 2006; Reisert and Burkhardt, 2007; Caponnetto et al., 2008; Brouard et al., 2011; Dinuzzo et al., 2011; Kadri et al., 2011; Minh and Sindhwani, 2011; Zhang et al., 2012; Sindhwani et al., 2013). In this paper, we present a general learning framework in the setting of vector-valued RKHS that encompasses learning across three different paradigms, namely vector-valued, multi-view, and semi-supervised learning, simultaneously.

The direction of Multi-view Learning we consider in this work is Co-Regularization, see e.g. (Brefeld et al., 2006; Sindhwani and Rosenberg, 2008; Rosenberg et al., 2009; Sun, 2011). In this approach, different hypothesis spaces are used to construct target functions based on different views of the input data, such as different features or modalities, and a data-dependent regularization term is used to enforce consistency of output values from different views of the same input example. The resulting target functions, each corresponding to one view, are then naturally combined together in a principled way to give the final solution.

The direction of Semi-supervised Learning we follow here is Manifold Regularization (Belkin et al., 2006; Brouard et al., 2011; Minh and Sindhwani, 2011), which attempts to learn the geometry of the input space by exploiting the given unlabeled data. The latter two papers are recent generalizations of the original scalar version of manifold regularization of (Belkin et al., 2006) to the vector-valued setting. In (Brouard et al., 2011), a vector-valued version of the graph Laplacian L is used, and in (Minh and Sindhwani, 2011), L is a general symmetric, positive operator, including the graph Laplacian. The vector-valued setting allows one to capture possible dependencies between output variables by the use of, for example, an output graph Laplacian.

The formulation we present in this paper gives a unified learning framework for the case the hypothesis spaces are vector-valued RKHS. Our formulation is general, encompassing many common algorithms as special cases, including both Vector-valued Manifold Regularization and Co-regularized Multi-view Learning. The current work is a significant extension of our conference paper (Minh et al., 2013). In the conference version, we stated the general learning framework and presented the solution for multi-view least square regression and classification. In the present paper, we also provide the solution for multi-view multi-class Support Vector Machine (SVM), which includes multi-view binary SVM as a special case. Furthermore, we present a principled optimization framework for computing the optimal weight vector for combining the different views, which correspond to different kernels defined on the different features in the input data. An important and novel feature of our formulation compared to traditional multiple kernel learning methods is that it does *not* constrain the combining weights to be non-negative, leading a considerably simpler optimization problem, with an almost closed form solution in the least square case.

Our numerical experiments were performed using a special case of our framework, namely Vector-valued Multi-view Learning. For the case of least square loss function, we give a closed form solution which can be implemented efficiently. For the multi-class SVM case, we implemented our formulation, under the simplex coding scheme, using a Sequential Minimal Optimization (SMO) algorithm, which we obtained by generalizing the SMO technique of (Platt, 1999) to our setting.

We tested our algorithms on the problem of multi-class image classification, using three challenging, publicly available data sets, namely Caltech-101 (Fei-Fei et al., 2006), Caltech-UCSD-Birds-200-2011 (Wah et al., 2011), and Oxford Flower 17 (Nilsback and Zisserman,

2006). The results obtained are promising and demonstrate the competitiveness of our learning framework compared with other state-of-the-art methods.

1.1 Related Work

Recent papers in the literature that are closely related to our work include (Rosenberg et al., 2009; Sun, 2011; Luo et al., 2013a,b; Kadri et al., 2013). We analyze and compare each of these methods to our proposed framework in the following.

In the scalar setting, two papers that seek to generalize the manifold regularization framework of (Belkin et al., 2006) to the multi-view setting are (Rosenberg et al., 2009; Sun, 2011). In (Sun, 2011), the author proposed a version of the Multi-view Laplacian SVM, which, however, only deals with *two views* and is not generalizable to any number of views. In (Rosenberg et al., 2009), the authors formulated a version of the semi-supervised Multi-view learning problem for any number of views, but instead of solving it directly like we do, they proposed to compute the Multi-view kernel and reduce the problem to the supervised case. One problem with this approach is that the Multi-view kernel is complicated analytically, which makes it difficult to implement efficiently in practice. It is also unclear how this approach can be generalized to the multi-class setting.

In the vector-valued setting, papers dealing with multi-view learning include (Luo et al., 2013a,b), where each view is used to define a kernel and a graph Laplacian, and the resulting kernels and graph Laplacians are respectively linearly combined to give the final kernel and final graph Laplacian. Thus this approach does not take into account between-view consistency as in our approach. In (Luo et al., 2013a), which generalizes the vector-valued regularization formulation of (Minh and Sindhwani, 2011), the loss function is the least square loss. In (Luo et al., 2013b), the authors employed a multi-class SVM loss function, which is the average of the binary SVM hinge loss across all components of the output vector. To the best of our knowledge, we are not aware of any theoretical result on the statistical consistency of this loss function.

In the direction of multi-class learning, many versions of multi-class SVM have appeared in the literature, e.g. (Lee et al., 2004; Weston and Watkins, 1999; Crammer and Singer, 2001; Mroueh et al., 2012). In this paper, we employ a generalization of the multi-class Simplex Cone SVM (SC-SVM) loss function proposed in (Mroueh et al., 2012), where it was proved to be theoretically consistent.

Another work dealing with multi-view learning in the vector-valued approach is (Kadri et al., 2013), which considers multi-view learning from the multi-task learning perspective, see e.g. (Evgeniou et al., 2005), where different views of the same input example correspond to different tasks which share the same output label. Their formulation does not have an explicit view combination mechanism and is restricted to scalar-valued tasks and the supervised setting. The resulting optimization problem is vector-valued regularized least square regression in (Micchelli and Pontil, 2005), which is a special case of our general learning framework.

Our multi-view learning approach can also be viewed as a form of multiple kernel learning, but it is different from typical multiple kernel learning approaches, see e.g. (Bach et al., 2004; Bucak et al., 2014) in several aspects. First, it is formulated in both supervised and semi-supervised settings. Second, it incorporates between-view interactions. Third,

it makes no mathematical constraints, such as non-negativity, on the combining weights. This last aspect of our framework contrasts sharply with typical multiple kernel learning methods, which need to constrain the combining weights to be non-negative in order to guarantee the positive definiteness of the combined kernel. As a consequence, our optimization procedure for the combining weights is considerably simpler and has an almost closed form solution in the least square case. We give a brief technical description on the connections between our framework and multiple kernel and multi-task learning in the final part of the paper. Empirically, experimental results reported in the current paper show that our framework performs very favorably compared with state of the art multiple kernel learning methods.

We compared the proposed framework from a methodological point of view with approaches that focus on combining different features in the input data. Our work is complementary to other approaches such as (Zeiler and Fergus, 2014; Razavian et al., 2014; He et al., 2015), which are focused on engineering or learning the best features for the task at hand. In fact, an interesting research direction would be the application of our framework on top of those methods, which will be explored in a future work.

1.2 Our Contributions

Our learning framework provides a unified formulation for Manifold Regularization and Co-regularized Multi-view Learning in the vector-valued setting. In particular, it generalizes the Vector-valued Manifold Regularization framework of (Minh and Sindhwani, 2011), which was formulated in the single-view setting, with the least square loss, to the multi-view setting, with both least square and multi-class SVM loss functions. Consequently, it generalizes the Vector-valued Regularized Least Square formulation of (Micchelli and Pontil, 2005), which was formulated in the supervised, single-view settings, with the least square loss, to the semi-supervised, multi-view settings, with both the least square and multi-class SVM loss functions.

For the case of SVM classification, our framework is a generalization of the multi-class SC-SVM of (Mroueh et al., 2012), which is supervised and single-view, to the semi-supervised and multi-view learning settings. The loss function that we employ here is also a generalization of the SC-SVM loss functions proposed in (Mroueh et al., 2012). We also show that our formulation is a generalization of the semi-supervised Laplacian SVM of (Belkin et al., 2006), which is binary and single-view, to the multi-class and multi-view learning settings.

The generality and advantage of our vector-valued RKHS approach is illustrated by the fact that it can simultaneously (i) deal with any number of classes in multi-class classification, (ii) combine any number of views, (iii) combine the views using an arbitrary weight vector, and (iv) compute all the different output functions associated with the individual views, all by solving a single system linear of equations (in the case of least square loss) or a single quadratic optimization problem (in the case of SVM loss). To the best of our knowledge, this work is the first attempt to present a unified general learning framework whose components have been only individually and partially covered in the literature.

Our optimization framework for computing the optimal weight vector for combining the different views is also novel compared to typical multiple kernel learning methods in that

it does *not* constrain the combining weights to be non-negative, leading to a considerably simpler optimization problem, with an almost closed form solution in the least square case.

1.3 Organization

We start by giving a review of vector-valued RKHS in Section 2. In Section 3, we state the general optimization problem for our learning formulation, together with the Representer Theorem, the explicit solution for the vector-valued least square case, and the quadratic optimization problem for the vector-valued SVM case. We describe Vector-valued Multi-view Learning in Section 4 and its implementations in Section 5, both for the least square and SVM loss functions. Section 6 provides the optimization of the operator that combines the different views for the least square case. Empirical experiments are described in detail in Section 7. Connections between our framework and multi-kernel learning and multi-task learning are briefly described in Section 8. **Proofs for all mathematical results in the paper are given in Appendix A.**

2. Vector-Valued RKHS

In this section, we give a brief review of RKHS of vector-valued functions[1], for more detail see e.g. (Carmeli et al., 2006; Micchelli and Pontil, 2005; Caponnetto et al., 2008; Minh and Sindhwani, 2011). In the following, denote by $\mathcal{X}$ a nonempty set, $\mathcal{W}$ a real, separable Hilbert space with inner product $\langle \cdot, \cdot \rangle_{\mathcal{W}}$, $\mathcal{L}(\mathcal{W})$ the Banach space of bounded linear operators on $\mathcal{W}$. Let $\mathcal{W}^{\mathcal{X}}$ denote the vector space of all functions $f : \mathcal{X} \to \mathcal{W}$. A function $K : \mathcal{X} \times \mathcal{X} \to \mathcal{L}(\mathcal{W})$ is said to be an **operator-valued positive definite kernel** if for each pair $(x, z) \in \mathcal{X} \times \mathcal{X}$, $K(x, z)^* = K(z, x)$, and

$$\sum_{i,j=1}^{N} \langle y_i, K(x_i, x_j) y_j \rangle_{\mathcal{W}} \geq 0 \tag{1}$$

for every finite set of points $\{x_i\}_{i=1}^N$ in $\mathcal{X}$ and $\{y_i\}_{i=1}^N$ in $\mathcal{W}$. Given such a K, there exists a unique $\mathcal{W}$-valued RKHS $\mathcal{H}_K$ with reproducing kernel K, which is constructed as follows. For each $x \in \mathcal{X}$ and $y \in \mathcal{W}$, form a function $K_x y = K(., x)y \in \mathcal{W}^{\mathcal{X}}$ defined by

$$(K_x y)(z) = K(z, x)y \quad \text{for all} \quad z \in \mathcal{X}.$$

Consider the set $\mathcal{H}_0 = \text{span}\{K_x y \mid x \in \mathcal{X},\ y \in \mathcal{W}\} \subset \mathcal{W}^{\mathcal{X}}$. For $f = \sum_{i=1}^N K_{x_i} w_i$, $g = \sum_{i=1}^N K_{z_i} y_i \in \mathcal{H}_0$, we define the inner product

$$\langle\ f, g\ \rangle_{\mathcal{H}_K} = \sum_{i,j=1}^{N} \langle w_i, K(x_i, z_j) y_j \rangle_{\mathcal{W}},$$

which makes $\mathcal{H}_0$ a pre-Hilbert space. Completing $\mathcal{H}_0$ by adding the limits of all Cauchy sequences gives the Hilbert space $\mathcal{H}_K$. The **reproducing property** is

$$\langle f(x), y \rangle_{\mathcal{W}} = \langle f, K_x y \rangle_{\mathcal{H}_K} \quad \text{for all} \quad f \in \mathcal{H}_K. \tag{2}$$

1. Some authors, e.g. (Kadri et al., 2011) employ the terminology *function-valued*, which is equivalent to *vector-valued*: a function is a vector in a vector space of functions (e.g. a Hilbert space of functions), and an n-dimensional vector is a discrete function defined on n points.

Sampling Operators. For each $x \in \mathcal{X}$, let $K_x : \mathcal{W} \to \mathcal{H}_K$ be the operator with $K_x y$ defined as above, then

$$||K_x y||^2_{\mathcal{H}_K} = \langle K(x, x)y, y \rangle_{\mathcal{W}} \leq ||K(x, x)||\ ||y||^2_{\mathcal{W}},$$

which implies that

$$||K_x : \mathcal{W} \to \mathcal{H}_K|| \leq \sqrt{||K(x, x)||},$$

so that K_x is a bounded operator. Let $K_x^* : \mathcal{H}_K \to \mathcal{W}$ be the adjoint operator of K_x, then from (2), we have

$$f(x) = K_x^* f \qquad \text{for all} \quad x \in \mathcal{X}, f \in \mathcal{H}_K. \tag{3}$$

From this we deduce that for all $x \in \mathcal{X}$ and all $f \in \mathcal{H}_K$,

$$||f(x)||_{\mathcal{W}} \leq ||K_x^*||\ ||f||_{\mathcal{H}_K} \leq \sqrt{||K(x, x)||}\ ||f||_{\mathcal{H}_K},$$

that is the *sampling operator* $S_x : \mathcal{H}_K \to \mathcal{W}$ defined by

$$S_x f = K_x^* f = f(x)$$

is bounded. Let $\mathbf{x} = (x_i)_{i=1}^l \in \mathcal{X}^l$, $l \in \mathbb{N}$. For the sampling operator $S_{\mathbf{x}} : \mathcal{H}_K \to \mathcal{W}^l$ defined by $S_{\mathbf{x}}(f) = (f(x_i))_{i=1}^l$, for any $\mathbf{y} = (y_i)_{i=1}^l \in \mathcal{W}^l$,

$$\begin{aligned} \langle S_{\mathbf{x}} f, \mathbf{y} \rangle_{\mathcal{W}^l} &= \sum_{i=1}^{l} \langle f(x_i), y_i \rangle_{\mathcal{W}} = \sum_{i=1}^{l} \langle K_{x_i}^* f, y_i \rangle_{\mathcal{H}_K} \\ &= \sum_{i=1}^{l} \langle f, K_{x_i} y_i \rangle_{\mathcal{H}_K} = \langle f, \sum_{i=1}^{l} K_{x_i} y_i \rangle_{\mathcal{H}_K}. \end{aligned}$$

Thus the adjoint operator $S_{\mathbf{x}}^* : \mathcal{W}^l \to \mathcal{H}_K$ is given by

$$S_{\mathbf{x}}^* \mathbf{y} = S_{\mathbf{x}}^*(y_1, \ldots, y_l) = \sum_{i=1}^{l} K_{x_i} y_i, \quad \mathbf{y} \in \mathcal{W}^l, \tag{4}$$

and the operator $S_{\mathbf{x}}^* S_{\mathbf{x}} : \mathcal{H}_K \to \mathcal{H}_K$ is given by

$$S_{\mathbf{x}}^* S_{\mathbf{x}} f = \sum_{i=1}^{l} K_{x_i} f(x_i) = \sum_{i=1}^{l} K_{x_i} K_{x_i}^* f. \tag{5}$$

Data-dependent Semi-norms. Let $(x_1, \ldots, x_{u+l}) \subset \mathcal{X}$, $u, l \in \mathbb{N}$. Let $M : \mathcal{W}^{u+l} \to \mathcal{W}^{u+l} \in \mathcal{L}(\mathcal{W}^{u+l})$ be a symmetric, positive operator, that is $\langle y, My \rangle_{\mathcal{W}^{u+l}} \geq 0$ for all $y \in \mathcal{W}^{u+l}$. For $f \in \mathcal{H}_K$, let $\mathbf{f} = (f(x_1), \ldots, f(x_{u+l})) \in \mathcal{W}^{u+l}$. The operator $M : \mathcal{W}^{u+l} \to \mathcal{W}^{u+l}$ can be expressed as an operator-valued matrix $M = (M_{ij})_{i,j=1}^{u+l}$ of size $(u+l) \times (u+l)$, with each $M_{ij} : \mathcal{W} \to \mathcal{W}$ being a linear operator, so that

$$(M\mathbf{f})_i = \sum_{j=1}^{u+l} M_{ij} \mathbf{f}_j = \sum_{j=1}^{u+l} M_{ij} f(x_j). \tag{6}$$

We can then define the following semi-norm for f, which depends on the x_i's:

$$\langle \mathbf{f}, M\mathbf{f} \rangle_{\mathcal{W}^{u+l}} = \sum_{i,j=1}^{u+l} \langle f(x_i), M_{ij} f(x_j) \rangle_{\mathcal{W}}. \tag{7}$$

This form of semi-norm was utilized in vector-valued manifold regularization (Minh and Sindhwani, 2011).

3. General Learning Framework

In this section, we state the general minimization problem that we wish to solve, which includes Vector-valued Manifold Regularization and Multi-view Learning as special cases.

Let the input space be $\mathcal{X}$, an arbitrary non-empty set. Let $\mathcal{Y}$ be a separable Hilbert space, denoting the output space. Assume that there is an unknown probability measure ρ on $\mathcal{X} \times \mathcal{Y}$, and that we have access to a random training sample $\mathbf{z} = \{(x_i, y_i)\}_{i=1}^{l} \cup \{x_i\}_{i=l+1}^{u+l}$ of l labeled and u unlabeled examples.

Let $\mathcal{W}$ be a separable Hilbert space. Let $K : \mathcal{X} \times \mathcal{X} \to \mathcal{L}(\mathcal{W})$ be an operator-valued positive definite kernel and $\mathcal{H}_K$ its induced Reproducing Kernel Hilbert Space of $\mathcal{W}$-valued functions.

Let $M : \mathcal{W}^{u+l} \to \mathcal{W}^{u+l}$ be a symmetric, positive operator. For each $f \in \mathcal{H}_K$, let

$$\mathbf{f} = (f(x_1), \ldots, f(x_{u+l})) \in \mathcal{W}^{u+l}. \tag{8}$$

Let $V : \mathcal{Y} \times \mathcal{Y} \to \mathbb{R}$ be a convex loss function. Let $C : \mathcal{W} \to \mathcal{Y}$ be a bounded linear operator, with $C^* : \mathcal{Y} \to \mathcal{W}$ its adjoint operator.

The following is the general minimization problem that we wish to solve:

$$f_{\mathbf{z},\gamma} = \text{argmin}_{f \in \mathcal{H}_K} \frac{1}{l} \sum_{i=1}^{l} V(y_i, Cf(x_i)) + \gamma_A ||f||^2_{\mathcal{H}_K} + \gamma_I \langle \mathbf{f}, M\mathbf{f} \rangle_{\mathcal{W}^{u+l}}, \tag{9}$$

with regularization parameters $\gamma_A > 0$, $\gamma_I \geq 0$.

Let us give a general multi-view learning interpretation of the different terms in our framework. If each input instance x has many views, then $f(x) \in \mathcal{W}$ represents the output values from all the views, constructed by their corresponding hypothesis spaces. These values are combined by the operator C to give the final output value in $\mathcal{Y}$, which is not necessarily the same as $\mathcal{W}$. In (9), the first term measures the error between the final output $Cf(x_i)$ for x_i with the given output y_i, $1 \leq i \leq l$.

The second summand is the standard RKHS regularization term.

The third summand, Multi-view Manifold Regularization, is a generalization of vector-valued Manifold Regularization in (Minh and Sindhwani, 2011) and Multi-view Point Cloud regularization in (Rosenberg et al., 2009): if there is only one view, then it is simply manifold regularization; if there are many views, then it consists of manifold regularization along each view, as well as consistency regularization across different views. We describe one concrete realization of this term in Section 4.2.

Remark 1 *The framework is readily generalizable to the case the point evaluation functional $f(x)$ is replaced by a general bounded linear operator. We describe this in Appendix B.*

3.1 Representer Theorem

The minimization problem (9) is guaranteed to always have a unique global solution, whose form is given by the following Representer Theorem.

Theorem 2 *The minimization problem (9) has a unique solution, given by $f_{\mathbf{z},\gamma} = \sum_{i=1}^{u+l} K_{x_i} a_i$ for some vectors $a_i \in \mathcal{W}$, $1 \leq i \leq u+l$.*

In the next two sections, we derive the forms of the solution $f_{\mathbf{z},\gamma}$ for the cases where V is the least square loss and the SVM loss, both in the binary and multi-class settings.

3.2 Least Square Case

For the case V is the least square loss function, we solve the following problem:

$$f_{\mathbf{z},\gamma} = \text{argmin}_{f \in \mathcal{H}_K} \frac{1}{l} \sum_{i=1}^{l} ||y_i - Cf(x_i)||^2_{\mathcal{Y}} + \gamma_A ||f||^2_{\mathcal{H}_K} + \gamma_I \langle \mathbf{f}, M\mathbf{f} \rangle_{\mathcal{W}^{u+l}}, \tag{10}$$

which has an explicit solution, given by the following.

Theorem 3 *The minimization problem (10) has a unique solution $f_{\mathbf{z},\gamma} = \sum_{i=1}^{u+l} K_{x_i} a_i$, where the vectors $a_i \in \mathcal{W}$ are given by*

$$l\gamma_I \sum_{j,k=1}^{u+l} M_{ik} K(x_k, x_j) a_j + C^* C (\sum_{j=1}^{u+l} K(x_i, x_j) a_j) + l\gamma_A a_i = C^* y_i, \tag{11}$$

for $1 \leq i \leq l$, and

$$\gamma_I \sum_{j,k=1}^{u+l} M_{ik} K(x_k, x_j) a_j + \gamma_A a_i = 0, \tag{12}$$

for $l+1 \leq i \leq u+l$.

3.2.1 Operator-valued Matrix Formulation

The system of equations (11) and (12) can be reformulated in matrix form, which is more readable and more convenient to implement efficiently. Let $K[\mathbf{x}]$ denote the $(u+l) \times (u+l)$ operator-valued matrix whose (i,j) entry is $K(x_i, x_j)$. Let $J_l^{\mathcal{W},u+l} : \mathcal{W}^{u+l} \to \mathcal{W}^{u+l}$ denote the diagonal matrix whose first l entries on the main diagonal are the identity operator $I : \mathcal{W} \to \mathcal{W}$, with the rest being 0. Let $\mathbf{C}^*\mathbf{C} : \mathcal{W}^{u+l} \to \mathcal{W}^{u+l}$ be the $(u+l) \times (u+l)$ diagonal matrix, with each diagonal entry being $C^*C : \mathcal{W} \to \mathcal{W}$. Let $\mathbf{C}^* : \mathcal{Y}^l \to \mathcal{W}^{u+l}$ be the $(u+l) \times l$ block matrix defined by $\mathbf{C}^* = I_{(u+l)\times l} \otimes C^*$, where $I_{(u+l)\times l} = [I_l, 0_{l \times u}]^T$ and $C^* : \mathcal{Y} \to \mathcal{W}$.

Theorem 4 *The system of equations (11) and (12) in Theorem 3 is equivalent to*

$$(\mathbf{C}^*\mathbf{C} J_l^{\mathcal{W},u+l} K[\mathbf{x}] + l\gamma_I M K[\mathbf{x}] + l\gamma_A I)\mathbf{a} = \mathbf{C}^*\mathbf{y}, \tag{13}$$

which has a unique solution $\mathbf{a}$, where $\mathbf{a} = (a_1, \ldots, a_{u+l})$, $\mathbf{y} = (y_1, \ldots, y_l)$ are considered as column vectors in $\mathcal{W}^{u+l}$ and $\mathcal{Y}^l$, respectively.

3.3 Vector-valued Multi-view SVM

In this section, we give the solution of the optimization problem (9) when V is a generalization of the binary SVM hinge loss function to the multi-class setting. We first point out one main difference between the least square and SVM cases. In the least square case, there is a natural generalization from the scalar setting to the vector-valued setting, which we treated in the previous section. In contrast, in the SVM case, many different versions of the multi-class SVM loss function have been proposed. In the following, we consider a generalization of the Simplex Cone SVM (SC-SVM) loss function proposed by (Mroueh et al., 2012), where it was shown to be theoretically consistent.

Let the input space $\mathcal{X}$ be an arbitrary non-empty set and the output label space be the discrete set $\text{cl}(\mathcal{Y}) = \{1, \ldots, P\}$, with $P \in \mathbb{N}$, $P \geq 2$, representing the number of classes. In this setting, the random sample $\mathbf{z} = \{(x_i, y_i)\}_{i=1}^{l} \cup \{x_i\}_{i=l+1}^{u+l}$ is drawn from $\mathcal{X} \times \text{cl}(\mathcal{Y})$.

Let $\mathcal{W}$ be a separable Hilbert space, $K : \mathcal{X} \times \mathcal{X} \to \mathcal{L}(\mathcal{W})$ be a positive definite kernel with value in the Banach space of bounded linear operators $\mathcal{L}(\mathcal{W})$ on $\mathcal{W}$, and $\mathcal{H}_K$ be the RKHS of $\mathcal{W}$-valued functions induced by K. Let $\mathcal{Y}$ be a separable Hilbert space. Let $S = [s_1, \ldots, s_P]$ as a matrix, which is potentially infinite, with the ith column being $s_i \in \mathcal{Y}$, then S can be considered as a linear operator $S : \mathbb{R}^P \to \mathcal{Y}$, so that for $\mathbf{b} = (b_i)_{i=1}^P$, $S\mathbf{b} = \sum_{i=1}^P b_i s_i$.

Let $C : \mathcal{W} \to \mathcal{Y}$ be a bounded linear operator. Consider the following minimization problem

$$f_{\mathbf{z},\gamma} = \text{argmin}_{f \in \mathcal{H}_K} \frac{1}{l} \sum_{i=1}^{l} \sum_{k=1, k \neq y_i}^{P} \max\left(0, -\langle s_k, s_{y_i} \rangle_{\mathcal{Y}} + \langle s_k, Cf(x_i) \rangle_{\mathcal{Y}}\right) + \gamma_A ||f||_{\mathcal{H}_K}^2 + \gamma_I \langle \mathbf{f}, M\mathbf{f} \rangle_{\mathcal{W}^{u+l}}, \tag{14}$$

with regularization parameters $\gamma_A > 0$ and $\gamma_I \geq 0$.

The components of (14) and their multi-class and multi-view learning interpretations are as follows.

The vectors s_k's in S represent the P different classes. One particular case for S, which we employ in our numerical experiments, is the *simplex coding* for multi-class encoding, see e.g. (Hill and Doucet, 2007; Wu and Lange, 2010; Saberian and Vasconcelos, 2011; Mroueh et al., 2012). Recall that a simplex coding is a map $s : \{1, \ldots, P\} \to \mathbb{R}^{P-1}$, such that: (i) $||s_k||^2 = 1$; (ii) $\langle s_j, s_k \rangle = -\frac{1}{P-1}$, $j \neq k$; and (iii) $\sum_{k=1}^P s_k = 0$. The simplex codes s_k's form P maximally and equally separated vectors on the sphere $\mathbb{S}^{P-2}$ in $\mathbb{R}^{P-1}$, each representing one category. For example, for $P = 3$, one set of three $\mathbb{R}^2$-valued code vectors is: $s_1 = (1, 0)$, $s_2 = (-1/2, \sqrt{3}/2)$, $s_3 = (-1/2, -\sqrt{3}/2)$. In general, the simplex codes can be computed by a recursive algorithm, see e.g. (Mroueh et al., 2012). The decoding process is straightforward: given a vector $\mathbf{b} \in \mathbb{R}^{P-1}$, the category we assign to $\mathbf{b}$ is

$$\text{argmax}_{1 \leq k \leq P} \langle \mathbf{b}, s_k \rangle. \tag{15}$$

In the following, we assume that the map s is fixed for each P and also refer to the matrix $S = [s_1, \ldots, s_P]$, with the ith column being s_i, as the simplex coding, whenever this coding scheme is being used.

If the number of classes is P and S is the simplex coding, then $\mathcal{Y} = \mathbb{R}^{P-1}$ and S is a $(P-1) \times P$ matrix. Let the number of views be $m \in \mathbb{N}$. Let $\mathcal{W} = \mathcal{Y}^m = \mathbb{R}^{(P-1)m}$. Then K is a matrix-valued kernel: for each pair $(x, t) \in \mathcal{X} \times \mathcal{X}$, $K(x, t)$ is a $(P-1)m \times (P-1)m$ matrix. The Hilbert space $\mathcal{H}_K$ induced by K consists of functions $f : \mathcal{X} \to \mathcal{W} = \mathbb{R}^{(P-1)m}$, that is for each $x \in \mathcal{X}$, $f(x) = (f^1(x), \ldots, f^m(x)) \in \mathbb{R}^{(P-1)m}$.

In the first component of (14), the loss function

$$\sum_{k=1, k \neq y_i}^{P} \max\left(0, -\langle s_k, s_{y_i} \rangle_{\mathcal{Y}} + \langle s_k, Cf(x_i) \rangle_{\mathcal{Y}}\right)$$

measures the error between the combined outputs from all the views for x_i with every code vector s_k such that $k \neq y_i$. It is a generalization of the SC-SVM loss function proposed in (Mroueh et al., 2012).

For any $x \in \mathcal{X}$,

$$f_{\mathbf{z},\gamma}(x) \in \mathcal{W}, \quad Cf_{\mathbf{z},\gamma}(x) \in \mathcal{Y}, \tag{16}$$

and the category assigned to x is

$$\text{argmax}_{1 \leq k \leq P} \langle s_k, Cf_{\mathbf{z},\gamma}(x) \rangle_{\mathcal{Y}}. \tag{17}$$

Remark 5 *We give the multi-class and multi-view learning interpretations and provide numerical experiments for $\mathcal{Y} = \mathbb{R}^{P-1}$, $\mathcal{W} = \mathcal{Y}^m = \mathbb{R}^{(P-1)m}$, with S being the simplex coding. However, we wish to emphasize that optimization problems (14) and (18) and Theorems 6 and 7 are formulated for $\mathcal{W}$ and $\mathcal{Y}$ being arbitrary separable Hilbert spaces.*

3.3.1 Solution of the Soft-Margin Multi-view SVM

Introducing slack variables ξ_{ki}'s into the optimization problem (14), we obtain the minimization problem

$$f_{\mathbf{z},\gamma} = \text{argmin}_{f \in \mathcal{H}_K, \xi_{ki} \in \mathbb{R}} \frac{1}{l} \sum_{i=1}^{l} \sum_{k=1, k \neq y_i}^{P} \xi_{ki} + \gamma_A ||f||_{\mathcal{H}_K}^2 + \gamma_I \langle \mathbf{f}, M\mathbf{f} \rangle_{\mathcal{W}^{u+l}}, \tag{18}$$

subject to the constraints

$$\xi_{ki} \geq -\langle s_k, s_{y_i} \rangle_{\mathcal{Y}} + \langle s_k, Cf(x_i) \rangle_{\mathcal{Y}}, \quad 1 \leq i \leq l, k \neq y_i, \tag{19}$$

$$\xi_{ki} \geq 0, \quad 1 \leq i \leq l, k \neq y_i. \tag{20}$$

Let $\alpha_i = (\alpha_{1i}, \ldots, \alpha_{Pi})^T \in \mathbb{R}^P$ as a column vector, with $\alpha_{y_i,i} = 0$. Let $\alpha = (\alpha_1, \ldots, \alpha_l) \in \mathbb{R}^{P \times l}$ as a matrix of size $P \times l$.

Theorem 6 *The minimization problem (18) has a unique solution given by*

$$f_{\mathbf{z},\gamma}(x) = \sum_{i=1}^{u+l} K(x, x_i) a_i, \quad a_i \in \mathcal{W}, 1 \leq i \leq u+l, \tag{21}$$

with $\mathbf{a} = (a_1, \ldots, a_{u+l}) \in \mathcal{W}^{u+l}$ given by

$$\mathbf{a} = -\frac{1}{2}(\gamma_I MK[\mathbf{x}] + \gamma_A I)^{-1} (I_{(u+l) \times l} \otimes C^* S) \text{vec}(\alpha^{\text{opt}}), \tag{22}$$

where $\otimes$ denotes the Kronecker tensor product, $K[\mathbf{x}]$ is the $(u+l)\times(u+l)$ operator-valued matrix, with entry $K[\mathbf{x}]_{ij}$ being the operator $K(x_i,x_j):\mathcal{W}\to\mathcal{W}$, $I_{(u+l)\times l}$ is the $(u+l)\times l$ matrix of the form $I_{(u+l)\times l}=[I_l\ \ 0_{l\times u}]^T$, and $\alpha^{\text{opt}}=(\alpha_1^{\text{opt}},\ldots,\alpha_l^{\text{opt}})\in\mathbb{R}^{P\times l}$ is a solution of the quadratic minimization problem

$$\alpha^{\text{opt}}=\text{argmin}_{\alpha\in\mathbb{R}^{P\times l}}\frac{1}{4}\text{vec}(\alpha)^TQ[\mathbf{x},C]\text{vec}(\alpha)+\sum_{i=1}^{l}\sum_{k=1}^{P}\langle s_k,s_{y_i}\rangle_{\mathcal{Y}}\alpha_{ki}, \tag{23}$$

subject to the constraints

$$0\le\alpha_{ki}\le\frac{1}{l}(1-\delta_{k,y_i}),\quad 1\le i\le l, 1\le k\le P. \tag{24}$$

The symmetric, positive semidefinite, $Pl\times Pl$ matrix $Q[\mathbf{x},C]$ is given by

$$Q[\mathbf{x},C]=(I_{(u+l)\times l}^T\otimes S^*C)K[\mathbf{x}](\gamma_IMK[\mathbf{x}]+\gamma_AI)^{-1}(I_{(u+l)\times l}\otimes C^*S). \tag{25}$$

If S is the simplex coding, then

$$\alpha^{\text{opt}}=\text{argmin}_{\alpha\in\mathbb{R}^{P\times l}}\frac{1}{4}\text{vec}(\alpha)^TQ[\mathbf{x},C]\text{vec}(\alpha)-\frac{1}{P-1}\mathbf{1}_{Pl}^T\text{vec}(\alpha), \tag{26}$$

with $\mathbf{1}_{Pl}=(1,\ldots,1)^T\in\mathbb{R}^{Pl}$, under the same constraints.

Special case: Simplex Cone Support Vector Machine (Mroueh et al., 2012). For $u=0$, $\gamma_I=0$, $\mathcal{W}=\mathcal{Y}=\mathbb{R}^{P-1}$, $C=I_{P-1}$ (single-view), we obtain

$$\mathbf{a}=-\frac{1}{2\gamma_A}(I_l\otimes S)\text{vec}(\alpha^{\text{opt}}), \tag{27}$$

$$Q[\mathbf{x},C]=\frac{1}{\gamma_A}(I_l\otimes S^*)K[\mathbf{x}](I_l\otimes S), \tag{28}$$

If S is the simplex coding, these together give us the quadratic optimization problem for the Simplex Cone Support Vector Machine (SC-SVM) of (Mroueh et al., 2012).

3.3.2 An Equivalent Formulation

For $P=2$, the simplex coding is $S=[1,-1]$. With this choice of S and $\mathcal{W}=\mathcal{Y}=\mathbb{R}$, $C=1$, our formulation reduces to single-view binary SVM with manifold regularization, which is precisely the Laplacian SVM of (Belkin et al., 2006). In this section, we give an equivalent result to Theorem 6, namely Theorem 7 below, which includes the formulation of the Laplacian SVM as a special case.

Let $S_{\hat{y}_i}$ be the matrix obtained from S by removing the y_ith column and $\beta_i\in\mathbb{R}^{P-1}$ be the vector obtained from α_i by deleting the y_ith entry, which is equal to zero by assumption. As a linear operator, $S_{\hat{y}_i}:\mathbb{R}^{P-1}\to\mathcal{Y}$ and

$$S\alpha_i=\sum_{k=1,k\ne y_i}^{P}\alpha_{ki}s_k=S_{\hat{y}_i}\beta_i. \tag{29}$$

Let $\text{diag}(S_{\hat{\mathbf{y}}})$ be the $l\times l$ block diagonal matrix, with block (i,i) being $S_{\hat{y}_i}$ and $\beta=(\beta_1,\ldots,\beta_l)$ be the $(P-1)\times l$ matrix with column i being β_i. As a linear operator, $\text{diag}(S_{\hat{\mathbf{y}}}):\mathbb{R}^{(P-1)l}\to\mathcal{Y}^l$.

Theorem 7 *The minimization problem (18) has a unique solution given by $f_{\mathbf{z},\gamma}(x)=\sum_{i=1}^{u+l}K(x,x_i)a_i$, with $\mathbf{a}=(a_1,\ldots,a_{u+l})\in\mathcal{W}^{u+l}$ given by*

$$\mathbf{a}=-\frac{1}{2}(\gamma_IMK[\mathbf{x}]+\gamma_AI)^{-1}(I_{(u+l)\times l}\otimes C^*)\text{diag}(S_{\hat{\mathbf{y}}})\text{vec}(\beta^{\text{opt}}), \tag{30}$$

where $\beta^{\text{opt}}=(\beta_1^{\text{opt}},\ldots,\beta_l^{\text{opt}})\in\mathbb{R}^{(P-1)\times l}$ is a solution of the quadratic minimization problem

$$\beta^{\text{opt}}=\text{argmin}_{\beta\in\mathbb{R}^{(P-1)\times l}}\frac{1}{4}\text{vec}(\beta)^TQ[\mathbf{x},\mathbf{y},C]\text{vec}(\beta)+\sum_{i=1}^{l}\langle s_{y_i},S_{\hat{y}_i}\beta_i\rangle_{\mathcal{Y}}, \tag{31}$$

subject to the constraints

$$0\le\beta_{ki}\le\frac{1}{l},\quad 1\le i\le l, 1\le k\le P-1. \tag{32}$$

The symmetric, positive semidefinite, $(P-1)l\times(P-1)l$ matrix $Q[\mathbf{x},\mathbf{y},C]$ is given by

$$Q[\mathbf{x},\mathbf{y},C]=\text{diag}(S_{\hat{\mathbf{y}}}^*)(I_{(u+l)\times l}^T\otimes C)K[\mathbf{x}](\gamma_IMK[\mathbf{x}]+\gamma_AI)^{-1}(I_{(u+l)\times l}\otimes C^*)\text{diag}(S_{\hat{\mathbf{y}}}). \tag{33}$$

If S is the simplex coding, then, under the same constraints,

$$\beta^{\text{opt}}=\text{argmin}_{\beta\in\mathbb{R}^{(P-1)\times l}}\frac{1}{4}\text{vec}(\beta)^TQ[\mathbf{x},\mathbf{y},C]\text{vec}(\beta)-\frac{1}{P-1}\mathbf{1}_{(P-1)l}^T\text{vec}(\beta). \tag{34}$$

It is straightforward to switch between α and β. Let $I_{P,\hat{y}_i}$ be the $P\times(P-1)$ matrix obtained by removing the y_i column from the $P\times P$ identity matrix, then

$$\alpha_i=I_{P,\hat{y}_i}\beta_i\quad\text{and}\quad\beta_i=I_{P,\hat{y}_i}^T\alpha_i. \tag{35}$$

Binary case with simplex coding. For $P=2$, we represent the discrete output label set $\text{cl}(\mathcal{Y})$ as $\text{cl}(\mathcal{Y})=\{\pm1\}$. In this case, β is simply a vector in $\mathbb{R}^l$, and we solve the optimization problem

$$\beta^{\text{opt}}=\text{argmin}_{\beta\in\mathbb{R}^l}\frac{1}{4}\beta^TQ[\mathbf{x},\mathbf{y},C]\beta-\mathbf{1}_l^T\beta, \tag{36}$$

subject to the constraints $0\le\beta_i\le\frac{1}{l}$, $1\le i\le l$. The binary simplex code is $S=[1,-1]$, with $S_{\hat{1}}=-1$ and $S_{\hat{-1}}=1$. Thus $S_{\hat{y}_i}=-y_i$. Furthermore, because $\mathcal{Y}=\mathbb{R}$, by the Riesz representation theorem, the bounded linear operator $C:\mathcal{W}\to\mathbb{R}$ and its adjoint $C^*:\mathbb{R}\to\mathcal{W}$ necessarily have the form

$$Cf(x)=\langle\mathbf{c},f(x)\rangle_{\mathcal{W}}\quad\text{and}\quad C^*y=y\mathbf{c}, \tag{37}$$

respectively, for a unique vector $\mathbf{c}\in\mathcal{W}$. It follows immediately that

Corollary 8 (Binary case) *Let S be the simplex coding and $P=2$. Then in Theorem 7,*

$$\mathbf{a}=\frac{1}{2}(\gamma_IMK[\mathbf{x}]+\gamma_AI)^{-1}(I_{(u+l)\times l}\otimes\mathbf{c})\text{diag}(\mathbf{y})(\beta^{\text{opt}}), \tag{38}$$

$$Q[\mathbf{x},\mathbf{y},C]=\text{diag}(\mathbf{y})(I_{(u+l)\times l}^T\otimes\mathbf{c}^T)K[\mathbf{x}](\gamma_IMK[\mathbf{x}]+\gamma_AI)^{-1}(I_{(u+l)\times l}\otimes\mathbf{c})\text{diag}(\mathbf{y}). \tag{39}$$

Special case: Laplacian SVM (Belkin et al., 2006). In (38) and (39), by setting $\mathbf{c}=1$ ($\mathcal{W}=\mathcal{Y}=\mathbb{R}$) (single-view) and M to be the graph Laplacian on the training data $\{x_i\}_{i=1}^{u+l}$, we obtain the Laplacian SVM of (Belkin et al., 2006).

3.4 Previous Work as Special Cases of the Current Framework

We have shown above that in the SVM case, our framework includes the multi-class, supervised Simplex Cone SVM of (Mroueh et al., 2012) and the binary, semi-supervised Laplacian SVM of (Belkin et al., 2006) as special cases. Before delving into concrete implementations, in this section we give a list of other common kernel-based learning algorithms which are special cases of our learning framework.

Vector-valued Regularized Least Squares. If $\mathbf{C}^*\mathbf{C} = I : \mathcal{W}^{u+l} \to \mathcal{W}^{u+l}$, then (13) reduces to

$$(J_l^{\mathcal{W},u+l} K[\mathbf{x}] + l\gamma_I M K[\mathbf{x}] + l\gamma_A I)\mathbf{a} = \mathbf{C}^*\mathbf{y}. \tag{40}$$

If $u = 0$, $\gamma_I = 0$, and $\gamma_A = \gamma$, then we have

$$(K[\mathbf{x}] + l\gamma I)\mathbf{a} = \mathbf{C}^*\mathbf{y}. \tag{41}$$

One particular case for this scenario is when $\mathcal{W} = \mathcal{Y}$ and $C : \mathcal{Y} \to \mathcal{Y}$ is a unitary operator, that is $C^*C = CC^* = I$. If $\mathcal{Y} = \mathbb{R}^n$ and $C : \mathbb{R}^n \to \mathbb{R}^n$ is real, then C is an orthogonal matrix. If $C = I$, then we recover the vector-valued Regularized Least Squares algorithm (Micchelli and Pontil, 2005).

Vector-valued Manifold Regularization. Let $\mathcal{W} = \mathcal{Y}$ and $C = I$. Then we obtain the minimization problem for vector-valued Manifold Regularization (Minh and Sindhwani, 2011):

$$f_{\mathbf{z},\gamma} = \text{argmin}_{f \in \mathcal{H}_K} \frac{1}{l}\sum_{i=1}^{l} V(y_i, f(x_i)) + \gamma_A ||f||^2_{\mathcal{H}_K} + \gamma_I \langle \mathbf{f}, M\mathbf{f}\rangle_{\mathcal{W}^{u+l}}. \tag{42}$$

Scalar Multi-view Learning. Let us show that the scalar multi-view learning formulation of (Sindhwani and Rosenberg, 2008; Rosenberg et al., 2009) can be cast as a special case of our framework. Let $\mathcal{Y} = \mathbb{R}$ and $k^1, \ldots, k^m$ be real-valued positive definite kernels on $\mathcal{X} \times \mathcal{X}$, with corresponding RKHS $\mathcal{H}_{k^i}$ of functions $f^i : \mathcal{X} \to \mathbb{R}$, with each $\mathcal{H}_{k^i}$ representing one view. Let $f = (f^1, \ldots, f^m)$, with $f^i \in \mathcal{H}_{k^i}$. Let $\mathbf{c} = (c_1, \ldots, c_m) \in \mathbb{R}^m$ be a fixed weight vector. In the notation of (Rosenberg et al., 2009), let

$$\mathbf{f} = (f^1(x_1), \ldots, f^1(x_{u+l}), \ldots, f^m(x_1), \ldots, f^m(x_{u+l}))$$

and $M \in \mathbb{R}^{m(u+l)\times m(u+l)}$ be positive semidefinite. The objective of Multi-view Point Cloud Regularization (formula (4) in (Rosenberg et al., 2009)) is

$$\text{argmin}_{\varphi:\varphi(x)=\langle \mathbf{c}, f(x)\rangle} \frac{1}{l}\sum_{i=1}^{l} V(y_i, \varphi(x_i)) + \sum_{i=1}^{m} \gamma_i ||f^i||^2_{k^i} + \gamma \langle \mathbf{f}, M\mathbf{f}\rangle_{\mathbb{R}^{m(u+l)}}, \tag{43}$$

for some convex loss function V, with $\gamma_i > 0$, $i = 1, \ldots, m$, and $\gamma \geq 0$. Problem (43) admits a natural formulation in vector-valued RKHS. Let

$$K = \text{diag}(\frac{1}{\gamma_1}, \ldots, \frac{1}{\gamma_m}) * \text{diag}(k^1, \ldots, k^m) : \mathcal{X} \times \mathcal{X} \to \mathbb{R}^{m\times m}, \tag{44}$$

then $f = (f^1, \ldots, f^m) \in \mathcal{H}_K : \mathcal{X} \to \mathbb{R}^m$, with

$$||f||^2_{\mathcal{H}_K} = \sum_{i=1}^{m} \gamma_i ||f^i||^2_{k^i}. \tag{45}$$

By the reproducing property, we have

$$\langle \mathbf{c}, f(x)\rangle_{\mathbb{R}^m} = \langle f, K_x\mathbf{c}\rangle_{\mathcal{H}_K}. \tag{46}$$

We can now recast (43) into

$$f_{\mathbf{z},\gamma} = \text{argmin}_{f\in\mathcal{H}_K} \frac{1}{l}\sum_{i=1}^{l} V(y_i, \langle \mathbf{c}, f(x_i)\rangle_{\mathbb{R}^m}) + ||f||^2_{\mathcal{H}_K} + \gamma\langle \mathbf{f}, M\mathbf{f}\rangle_{\mathbb{R}^{m(u+l)}}. \tag{47}$$

This is a special case of (9), with $\mathcal{W} = \mathbb{R}^m$, $\mathcal{Y} = \mathbb{R}$, and $C : \mathbb{R}^m \to \mathbb{R}$ given by

$$Cf(x) = \langle \mathbf{c}, f(x)\rangle_{\mathbb{R}^m} = c_1 f^1(x) + \cdots + c_m f^m(x). \tag{48}$$

The vector-valued formulation of scalar multi-view learning has the following advantages:

(i) The kernel K is diagonal matrix-valued and is obviously positive definite. In contrast, it is nontrivial to prove that the multi-view kernel of (Rosenberg et al., 2009) is positive definite.

(ii) The kernel K is independent of the c_i's, unlike the multi-view kernel of (Rosenberg et al., 2009), which needs to be recomputed for each different set c_i's.

(iii) One can recover all the component functions f^i's using K. In contrast, in (Sindhwani and Rosenberg, 2008), it is shown how one can recover the f^i's only when $m = 2$, but not in the general case.

4. Vector-valued Multi-view Learning

In this and subsequent sections, we focus on a special case of our formulation, namely vector-valued multi-view learning. For a general separable Hilbert space $\mathcal{Y}$, let $\mathcal{W} = \mathcal{Y}^m$ and $C_1, \ldots, C_m : \mathcal{Y} \to \mathcal{Y}$ be bounded linear operators. For $f(x) = (f^1(x), \ldots, f^m(x))$, with each $f^i(x) \in \mathcal{Y}$, we define the combination operator $C = [C_1, \ldots, C_m] : \mathcal{Y}^m \to \mathcal{Y}$ by

$$Cf(x) = C_1 f^1(x) + \cdots + C_m f^m(x) \in \mathcal{Y}. \tag{49}$$

This gives rise to a vector-valued version of multi-view learning, where outputs from m views, each one being a vector in the Hilbert space $\mathcal{Y}$, are linearly combined. In the following, we give concrete definitions of both the combination operator C and the multi-view manifold regularization term M for our multi-view learning model.

4.1 The Combination Operator

In the present context, the bounded linear operator $C : \mathcal{W} \to \mathcal{Y}$ is a (potentially infinite) matrix of size $\dim(\mathcal{Y}) \times m\dim(\mathcal{Y})$. This operator transforms the output vectors obtained from the m views f^i's in $\mathcal{Y}^m$ into an output vector in $\mathcal{Y}$. The simplest form of C is the average operator:

$$Cf(x) = \frac{1}{m}(f^1(x) + \cdots + f^m(x)) \in \mathcal{Y}. \tag{50}$$

Let $\otimes$ denote the Kronecker tensor product. For $m \in \mathbb{N}$, let $\mathbf{1}_m = (1, \ldots, 1)^T \in \mathbb{R}^m$. The matrix C is then

$$C = \frac{1}{m}\mathbf{1}_m^T \otimes I_{\mathcal{Y}} = \frac{1}{m}[I_{\mathcal{Y}}, \ldots, I_{\mathcal{Y}}]. \tag{51}$$

More generally, we consider a weight vector $\mathbf{c} = (c_1, \ldots, c_m)^T \in \mathbb{R}^m$ and define C as

$$C = \mathbf{c}^T \otimes I_{\mathcal{Y}}, \text{ with } Cf(x) = \sum_{i=1}^{m} c_i f^i(x) \in \mathcal{Y}. \tag{52}$$

4.2 Multi-view Manifold Regularization

Generalizing the formulation in (Minh et al., 2013), we decompose the multi-view manifold regularization term $\gamma_I \langle \mathbf{f}, M\mathbf{f} \rangle_{\mathcal{W}^{u+l}}$ in (9) into two components

$$\gamma_I \langle \mathbf{f}, M\mathbf{f} \rangle_{\mathcal{W}^{u+l}} = \gamma_B \langle \mathbf{f}, M_B \mathbf{f} \rangle_{\mathcal{W}^{u+l}} + \gamma_W \langle \mathbf{f}, M_W \mathbf{f} \rangle_{\mathcal{W}^{u+l}}, \tag{53}$$

where $M_B, M_W : \mathcal{W}^{u+l} \to \mathcal{W}^{u+l}$ are symmetric, positive operators, and $\gamma_B, \gamma_W \geq 0$. We call the first term *between-view regularization*, which measures the consistency of the component functions across different views, and the second term *within-view regularization*, which measures the smoothness of the component functions in their corresponding views. We describe next two concrete choices for M_B and M_W.

Between-view Regularization. Let

$$M_m = mI_m - \mathbf{1}_m \mathbf{1}_m^T. \tag{54}$$

This is the $m \times m$ matrix with $(m-1)$ on the diagonal and -1 elsewhere. Then for $\mathbf{a} = (a_1, \ldots, a_m) \in \mathbb{R}^m$,

$$\mathbf{a}^T M_m \mathbf{a} = \sum_{j,k=1, j<k}^{m} (a_j - a_k)^2. \tag{55}$$

If each $a_i \in \mathcal{Y}$, then we have $\mathbf{a} \in \mathcal{Y}^m$ and

$$\mathbf{a}^T (M_m \otimes I_{\mathcal{Y}}) \mathbf{a} = \sum_{j,k=1, j<k}^{m} ||a_j - a_k||_{\mathcal{Y}}^2. \tag{56}$$

We define M_B by

$$M_B = I_{u+l} \otimes (M_m \otimes I_{\mathcal{Y}}). \tag{57}$$

Then M_B is a diagonal block matrix of size $m(u+l)\dim(\mathcal{Y}) \times m(u+l)\dim(\mathcal{Y})$, with each block (i,i) being $M_m \otimes I_{\mathcal{Y}}$. For $\mathbf{f} = (f(x_1), \ldots, f(x_{u+l})) \in \mathcal{Y}^{m(u+l)}$, with $f(x_i) \in \mathcal{Y}^m$,

$$\langle \mathbf{f}, M_B \mathbf{f} \rangle_{\mathcal{Y}^{m(u+l)}} = \sum_{i=1}^{u+l} \langle f(x_i), (M_m \otimes I_{\mathcal{Y}}) f(x_i) \rangle_{\mathcal{Y}^m} = \sum_{i=1}^{u+l} \sum_{j,k=1, j<k}^{m} ||f^j(x_i) - f^k(x_i)||_{\mathcal{Y}}^2. \tag{58}$$

This term thus enforces the consistency between the different components f^i's which represent the outputs on the different views. For $\mathcal{Y} = \mathbb{R}$, this is precisely the Point Cloud regularization term for scalar multi-view learning (Rosenberg et al., 2009; Brefeld et al., 2006). In particular, for $m = 2$, we have $M_2 = \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix}$, and

$$\langle \mathbf{f}, M_B \mathbf{f} \rangle_{\mathbb{R}^{2(u+l)}} = \sum_{i=1}^{u+l} (f^1(x_i) - f^2(x_i))^2, \tag{59}$$

which is the Point Cloud regularization term for co-regularization (Sindhwani and Rosenberg, 2008).

Within-view Regularization. One way to define M_W is via the graph Laplacian. For view i, $1 \leq i \leq m$, let G^i be a corresponding undirected graph, with symmetric, nonnegative weight matrix W^i, which induces the scalar graph Laplacian L^i, a matrix of size $(u+l) \times (u+l)$. For a vector $\mathbf{a} \in \mathbb{R}^{u+l}$, we have

$$\mathbf{a}^T L^i \mathbf{a} = \sum_{j,k=1, j<k}^{u+l} W_{jk}^i (a_j - a_k)^2.$$

Let L be the block matrix of size $(u+l) \times (u+l)$, with block (i,j) being the $m \times m$ diagonal matrix given by

$$L_{i,j} = \text{diag}(L_{ij}^1, \ldots L_{ij}^m). \tag{60}$$

Then for $\mathbf{a} = (a_1, \ldots, a_{u+l})$, with $a_j \in \mathbb{R}^m$, we have

$$\mathbf{a}^T L \mathbf{a} = \sum_{i=1}^{m} \sum_{j,k=1, j<k}^{u+l} W_{jk}^i (a_j^i - a_k^i)^2. \tag{61}$$

If $a_j \in \mathcal{Y}^m$, with $a_j^i \in \mathcal{Y}$, then

$$\mathbf{a}^T (L \otimes I_{\mathcal{Y}}) \mathbf{a} = \sum_{i=1}^{m} \sum_{j,k=1, j<k}^{u+l} W_{jk}^i ||a_j^i - a_k^i||_{\mathcal{Y}}^2. \tag{62}$$

Define

$$M_W = L \otimes I_{\mathcal{Y}}, \quad \text{then} \tag{63}$$

$$\langle \mathbf{f}, M_W \mathbf{f} \rangle_{\mathcal{Y}^{m(u+l)}} = \sum_{i=1}^{m} \sum_{j,k=1, j<k}^{u+l} W_{jk}^i ||f^i(x_j) - f^i(x_k)||_{\mathcal{Y}}^2. \tag{64}$$

The ith summand in the sum $\sum_{i=1}^m$ is precisely a manifold regularization term within view i. This term thus enforces the consistency of the output along each view i, $1 \leq i \leq m$.

Single View Case. When $m = 1$, we have $M_m = 0$ and therefore $M_B = 0$. In this case, we simply carry out manifold regularization within the given single view, using M_W.

5. Numerical Implementation

In this section, we give concrete forms of Theorems 4, for vector-valued multi-view least squares regression, and Theorem 6, for vector-valued multi-view SVM, that can be efficiently implemented. For our present purposes, let $m \in \mathbb{N}$ be the number of views and $\mathcal{W} = \mathcal{Y}^m$. Consider the case $\dim(\mathcal{Y}) < \infty$. Without loss of generality, we set $\mathcal{Y} = \mathbb{R}^{\dim(\mathcal{Y})}$.

The Kernel. For the current implementations, we define the kernel $K(x,t)$ by

$$K(x,t) = G(x,t) \otimes R, \tag{65}$$

where $G : \mathcal{X} \times \mathcal{X} \to \mathbb{R}^{m \times m}$ is a matrix-valued positive definite kernel, with $G(x,t)$ being an $m \times m$ matrix for each pair $(x,t) \in \mathcal{X} \times \mathcal{X}$. A concrete example of G, which we use in our experiments, is given in Section 7. The bounded linear operator $R : \mathcal{Y} \to \mathcal{Y}$ is symmetric and positive, and when $\dim(\mathcal{Y}) < \infty$, R is a symmetric, positive semi-definite matrix of size $\dim(\mathcal{Y}) \times \dim(\mathcal{Y})$. The Gram matrices of K and G are block matrices $K[\mathbf{x}]$ and $G[\mathbf{x}]$, respectively, of size $(u+l) \times (u+l)$, with blocks (i,j) given by $(K[\mathbf{x}])_{ij} = K(x_i, x_j)$ and $(G[\mathbf{x}])_{ij} = G(x_i, x_j)$. They are related by

$$K[\mathbf{x}] = G[\mathbf{x}] \otimes R. \tag{66}$$

Lemma 9 *The matrix-valued kernel K is positive definite.*

5.1 Numerical Implementation for Vector-valued Multi-view Least Squares

With the kernel K as defined in (65) and C and M as defined in Section 4, the system of linear equations (13) in Theorem 4 becomes a Sylvester equation, which can be solved efficiently, as follows.

Theorem 10 *For $C = \mathbf{c}^T \otimes I_{\mathcal{Y}}$, $\mathbf{c} \in \mathbb{R}^m$, $M_W = L \otimes I_{\mathcal{Y}}$, $M_B = I_{u+l} \otimes (M_m \otimes I_{\mathcal{Y}})$, and the kernel K as defined in (65), the system of linear equations (13) in Theorem 4 is equivalent to the Sylvester equation*

$$BAR + l\gamma_A A = Y_C, \tag{67}$$

where

$$B = \left((J_l^{u+l} \otimes \mathbf{c}\mathbf{c}^T) + l\gamma_B (I_{u+l} \otimes M_m) + l\gamma_W L \right) G[\mathbf{x}], \tag{68}$$

which is of size $(u+l)m \times (u+l)m$, A is the matrix of size $(u+l)m \times \dim(\mathcal{Y})$ such that $\mathbf{a} = \mathrm{vec}(A^T)$, and Y_C is the matrix of size $(u+l)m \times \dim(\mathcal{Y})$ such that $\mathbf{C}^*\mathbf{y} = \mathrm{vec}(Y_C^T)$. $J_l^{u+l} : \mathbb{R}^{u+l} \to \mathbb{R}^{u+l}$ is a diagonal matrix of size $(u+l) \times (u+l)$, with the first l entries on the main diagonal being 1 and the rest being 0.

Special cases. For $m = 1$, $\mathbf{c} = 1$, equation (67) reduces to Equation 17 in (Minh and Sindhwani, 2011). For $R = I_{\mathcal{Y}}$, with $\mathcal{Y} = \mathbb{R}^P$, equation (67) reduces to Equation 43 in (Minh et al., 2013).

Evaluation on a testing sample. Having solved for the matrix A, and hence the vector $\mathbf{a}$ in Theorem 10, we next show how the resulting functions can be efficiently evaluated on a testing set. Let $\mathbf{v} = \{v_1, \ldots, v_t\} \in \mathcal{X}$ be an arbitrary set of testing input examples, with $t \in \mathbb{N}$. Let $\mathbf{f}_{\mathbf{z},\gamma}(\mathbf{v}) = (\{f_{\mathbf{z},\gamma}(v_1), \ldots, f_{\mathbf{z},\gamma}(v_t)\})^T \in \mathcal{Y}^{mt}$, with

$$f_{\mathbf{z},\gamma}(v_i) = \sum_{j=1}^{u+l} K(v_i, x_j) a_j.$$

Let $K[\mathbf{v}, \mathbf{x}]$ denote the $t \times (u+l)$ block matrix, where block (i,j) is $K(v_i, x_j)$ and similarly, let $G[\mathbf{v}, \mathbf{x}]$ denote the $t \times (u+l)$ block matrix, where block (i,j) is the $m \times m$ matrix $G(v_i, x_j)$. Then

$$\mathbf{f}_{\mathbf{z},\gamma}(\mathbf{v}) = K[\mathbf{v}, \mathbf{x}]\mathbf{a} = (G[\mathbf{v}, \mathbf{x}] \otimes R)\mathbf{a} = \mathrm{vec}(RA^T G[\mathbf{v}, \mathbf{x}]^T),$$

Algorithm 1 $\mathcal{Y}$-valued, m-view, semi-supervised least square regression and classification

This algorithm implements and evaluates the solution of Theorem 10.

Input:
- Training data $\mathbf{z} = \{(x_i, y_i)\}_{i=1}^l \cup \{x_i\}_{i=l+1}^{u+l}$, with l labeled and u unlabeled examples.
- Number of views: m.
- Output values: vectors in $\mathcal{Y}$.
- Testing example: v.

Parameters:
- The regularization parameters $\gamma_A, \gamma_B, \gamma_W$.
- The weight vector $\mathbf{c}$.
- A matrix-valued kernel G, with $G(x,t)$ being an $m \times m$ matrix for each pair (x,t).

Procedure:
- Compute kernel matrix $G[\mathbf{x}]$ on input set $\mathbf{x} = (x_i)_{i=1}^{u+l}$.
- Compute matrix C according to (52).
- Compute graph Laplacian L according to (60).
- Compute matrices B, Y_C according to Theorem 10.
- Solve matrix equation $BAR + l\gamma_A A = Y_C$ for A.
- Compute kernel matrix $G[v, \mathbf{x}]$ between v and $\mathbf{x}$.

Output: $f_{\mathbf{z},\gamma}(v) = \mathrm{vec}(RA^T G[v, \mathbf{x}]^T) \in \mathcal{Y}^m$.
$\mathcal{Y}$-valued regression: return $Cf_{\mathbf{z},\gamma}(v) \in \mathcal{Y}$.
Multi-class classification: return index of $\max(Cf_{\mathbf{z},\gamma}(v))$.

In particular, for $\mathbf{v} = \mathbf{x} = (x_i)_{i=1}^{u+l}$, the original training sample, we have $G[\mathbf{v}, \mathbf{x}] = G[\mathbf{x}]$.

Algorithm. All the necessary steps for implementing Theorem 10 and evaluating its solution are summarized in Algorithm 1. For P-class classification, $\mathcal{Y} = \mathbb{R}^P$, and $y_i = (-1, \ldots, 1, \ldots, -1)$, $1 \le i \le l$, with 1 at the kth location if x_i is in the kth class.

5.2 Numerical Implementation for Vector-valued Multi-view SVM

This section gives a concrete form of Theorem 6 for vector-valued multi-view SVM which can be efficiently implemented. Let $\{\lambda_{i,R}\}_{i=1}^{\dim(\mathcal{Y})}$ be the eigenvalues of R, which are all nonnegative, with corresponding orthonormal eigenvectors $\{\mathbf{r}_i\}_{i=1}^{\dim(\mathcal{Y})}$. Then R admits the orthogonal spectral decomposition

$$R = \sum_{i=1}^{\dim(\mathcal{Y})} \lambda_{i,R} \mathbf{r}_i \mathbf{r}_i^T. \tag{69}$$

Under this representation of R and with the kernel K as defined in (65), Theorem 6 takes the following concrete form.

Theorem 11 *Let $\gamma_I M = \gamma_B M_B + \gamma_W M_W$, $C = \mathbf{c}^T \otimes I_{\mathcal{Y}}$, and $K(x,t)$ be defined as in (65). Then in Theorem 6,*

$$\mathbf{a} = -\frac{1}{2}[\sum_{i=1}^{\dim(\mathcal{Y})} M_{\mathrm{reg}}^i (I_{(u+l)\times l} \otimes \mathbf{c}) \otimes \mathbf{r}_i \mathbf{r}_i^T S] \mathrm{vec}(\alpha^{\mathrm{opt}}), \tag{70}$$

$$Q[\mathbf{x}, C] = \sum_{i=1}^{\dim(\mathcal{Y})} (I^T_{(u+l)\times l} \otimes \mathbf{c}^T) G[\mathbf{x}] M^i_{\text{reg}} (I_{(u+l)\times l} \otimes \mathbf{c}) \otimes \lambda_{i,R} S^* \mathbf{r}_i \mathbf{r}_i^T S, \tag{71}$$

where

$$M^i_{\text{reg}} = [\lambda_{i,R}(\gamma_B I_{u+l} \otimes M_m + \gamma_W L) G[\mathbf{x}] + \gamma_A I_{m(u+l)}]^{-1}. \tag{72}$$

Evaluation phase. Having solved for α^{opt} and hence $\mathbf{a}$ in Theorem 11, we next show how the resulting functions can be efficiently evaluated on a testing set $\mathbf{v} = \{v_i\}_{i=1}^t \subset \mathcal{X}$.

Proposition 12 *Let $f_{\mathbf{z},\gamma}$ be the solution obtained in Theorem 11. For any example $v \in \mathcal{X}$,*

$$f_{\mathbf{z},\gamma}(v) = -\frac{1}{2}\text{vec}[\sum_{i=1}^{\dim(\mathcal{Y})} \lambda_{i,R} \mathbf{r}_i \mathbf{r}_i^T S \alpha^{\text{opt}} (I^T_{(u+l)\times l} \otimes \mathbf{c}^T)(M^i_{\text{reg}})^T G[v, \mathbf{x}]^T]. \tag{73}$$

The combined function, using the combination operator C, is $g_{\mathbf{z},\gamma}(v) = C f_{\mathbf{z},\gamma}(v)$ and is given by

$$g_{\mathbf{z},\gamma}(v) = -\frac{1}{2} \sum_{i=1}^{\dim(\mathcal{Y})} \lambda_{i,R} \mathbf{r}_i \mathbf{r}_i^T S \alpha^{\text{opt}} (I^T_{(u+l)\times l} \otimes \mathbf{c}^T)(M^i_{\text{reg}})^T G[v, \mathbf{x}]^T \mathbf{c}. \tag{74}$$

The final SVM decision function is $h_{\mathbf{z},\gamma}(v) = S^T g_{\mathbf{z},\gamma}(v) \in \mathbb{R}^P$ and is given by

$$h_{\mathbf{z},\gamma}(v) = -\frac{1}{2} \sum_{i=1}^{\dim(\mathcal{Y})} \lambda_{i,R} S^T \mathbf{r}_i \mathbf{r}_i^T S \alpha^{\text{opt}} (I^T_{(u+l)\times l} \otimes \mathbf{c}^T)(M^i_{\text{reg}})^T G[v, \mathbf{x}]^T \mathbf{c}. \tag{75}$$

On a testing set $\mathbf{v} = \{v_i\}_{i=1}^t \subset \mathcal{X}$,

$$h_{\mathbf{z},\gamma}(\mathbf{v}) = -\frac{1}{2} \sum_{i=1}^{\dim(\mathcal{Y})} \lambda_{i,R} S^T \mathbf{r}_i \mathbf{r}_i^T S \alpha^{\text{opt}} (I^T_{(u+l)\times l} \otimes \mathbf{c}^T)(M^i_{\text{reg}})^T G[\mathbf{v}, \mathbf{x}]^T (I_t \otimes \mathbf{c}), \tag{76}$$

as a matrix of size $P \times t$, with the ith column being $h_{\mathbf{z},\gamma}(v_i)$.

Algorithm. All the necessary steps for implementing Theorem 11 and Proposition 12 are summarized in Algorithm 2.

5.2.1 Special case

Consider the case $R = I_{\mathcal{Y}}$. Then Theorem 11 and Proposition 12 simplify to the following.

Theorem 13 *Let $\gamma_I M = \gamma_B M_B + \gamma_W M_W$, $C = \mathbf{c}^T \otimes I_{\mathcal{Y}}$, and $K(x,t)$ be defined as in (65) with $R = I_{\mathcal{Y}}$. Then in Theorem 6,*

$$\mathbf{a} = -\frac{1}{2}[M_{\text{reg}}(I_{(u+l)\times l} \otimes \mathbf{c}) \otimes S]\text{vec}(\alpha^{\text{opt}}), \tag{77}$$

and

$$Q[\mathbf{x}, C] = (I^T_{(u+l)\times l} \otimes \mathbf{c}^T) G[\mathbf{x}] M_{\text{reg}} (I_{(u+l)\times l} \otimes \mathbf{c}) \otimes S^* S, \tag{78}$$

where

$$M_{\text{reg}} = [(\gamma_B I_{u+l} \otimes M_m + \gamma_W L) G[\mathbf{x}] + \gamma_A I_{m(u+l)}]^{-1}. \tag{79}$$

Algorithm 2 Multi-class Multi-view SVM

This algorithm implements Theorem 11 and Proposition 12. In the case $R = I_{\mathcal{Y}}$, it implements Theorem 13 and Proposition 14, with $M^i_{\text{reg}} = M_{\text{reg}}$ in (79), and equations (71), (73), and (75) are replaced by (78), (80), and (82), respectively.

Input:
- Training data $\mathbf{z} = \{(x_i, y_i)\}_{i=1}^l \cup \{x_i\}_{i=l+1}^{u+l}$, with l labeled and u unlabeled examples.
- Number of classes: P. Number of views: m.
- Testing example: v.

Parameters:
- The regularization parameters $\gamma_A, \gamma_B, \gamma_W$.
- The weight vector $\mathbf{c}$.
-A matrix-valued kernel G, with $G(x,t)$ being an $m \times m$ matrix for each pair (x,t).

Procedure:
- Compute kernel matrices $G[\mathbf{x}]$ on $\mathbf{x} = (x_i)_{i=1}^{u+l}$ and $G[v, \mathbf{x}]$ between v and $\mathbf{x}$.
- Compute graph Laplacian L according to (60).
- Compute matrices M^i_{reg} according to (72).
- Compute matrix $Q[\mathbf{x}, C]$ according to (71)
- Solve quadratic optimization problem (23) for α^{opt}.

Output: $f_{\mathbf{z},\gamma}(v)$, computed according to (73).
Classification: return $\text{argmax}(h_{\mathbf{z},\gamma}(v))$, with $h_{\mathbf{z},\gamma}(v) \in \mathbb{R}^P$ computed according to (75).

Proposition 14 *Let $f_{\mathbf{z},\gamma}$ be the solution obtained in Theorem 13. For any example $v \in \mathcal{X}$,*

$$f_{\mathbf{z},\gamma}(v) = -\frac{1}{2}\text{vec}(S \alpha^{\text{opt}} (I^T_{(u+l)\times l} \otimes \mathbf{c}^T) M^T_{\text{reg}} G[v, \mathbf{x}]^T). \tag{80}$$

The combined function, using the combination operator C, is $g_{\mathbf{z},\gamma}(v) = C f_{\mathbf{z},\gamma}(v) \in \mathbb{R}^{P-1}$ and is given by

$$g_{\mathbf{z},\gamma}(v) = -\frac{1}{2} S \alpha^{\text{opt}} (I^T_{(u+l)\times l} \otimes \mathbf{c}^T) M^T_{\text{reg}} G[v, \mathbf{x}]^T \mathbf{c}. \tag{81}$$

The final SVM decision function is $h_{\mathbf{z},\gamma}(v) = S^T g_{\mathbf{z},\gamma}(v) \in \mathbb{R}^P$ and is given by

$$h_{\mathbf{z},\gamma}(v) = -\frac{1}{2} S^T S \alpha^{\text{opt}} (I^T_{(u+l)\times l} \otimes \mathbf{c}^T) M^T_{\text{reg}} G[v, \mathbf{x}]^T \mathbf{c}. \tag{82}$$

On a testing set $\mathbf{v} = \{v_i\}_{i=1}^t$, let $h_{\mathbf{z},\gamma}(\mathbf{v}) \in \mathbb{R}^{P \times t}$ be the matrix with the ith column being $h_{\mathbf{z},\gamma}(v_i)$, then

$$h_{\mathbf{z},\gamma}(\mathbf{v}) = -\frac{1}{2} S^T S \alpha^{\text{opt}} (I^T_{(u+l)\times l} \otimes \mathbf{c}^T) M^T_{\text{reg}} G[\mathbf{v}, \mathbf{x}]^T (I_t \otimes \mathbf{c}). \tag{83}$$

5.2.2 Sequential Minimal Optimization (SMO)

We provide an SMO algorithm, which is described in detail in Appendix A.4, to solve the quadratic optimization problem (23) in Theorem 6, as part of Algorithm 2.

6. Optimizing the Combination Operator

In the learning formulation thus far, we have assumed that the combination operator C is given and fixed. Our task then is to find the optimal function $f_{\mathbf{z},\gamma} \in \mathcal{H}_K$ that minimizes the general learning objective (9) in Section 3, given the training data $\mathbf{z}$ and C. In this section, we go one step further and show that both $f_{\mathbf{z},\gamma}$ and C can be simultaneously optimized given the training data $\mathbf{z}$ alone.

For the time being, we consider the m-view least square learning setting, where C is represented by a vector $\mathbf{c} \in \mathbb{R}^m$. Let $\mathcal{S}_\alpha^{m-1}$ denote the sphere centered at the origin in $\mathbb{R}^m$ with radius $\alpha > 0$, that is $\mathcal{S}_\alpha^{m-1} = \{x \in \mathbb{R}^m : \|x\| = \alpha\}$. Consider the problem of optimizing over both $f \in \mathcal{H}_K$ and $\mathbf{c} \in \mathcal{S}_\alpha^{m-1}$,

$$f_{\mathbf{z},\gamma} = \text{argmin}_{f \in \mathcal{H}_K, \mathbf{c} \in \mathcal{S}_\alpha^{m-1}} \frac{1}{l} \sum_{i=1}^{l} ||y_i - Cf(x_i)||_{\mathcal{Y}}^2 + \gamma_A \|f\|_{\mathcal{H}_K}^2 + \gamma_I \langle \mathbf{f}, M\mathbf{f} \rangle_{\mathcal{W}u+l}. \quad (84)$$

We first point out a *crucial difference* between our framework and a typical multi-kernel learning approach. Since our formulation does not place any constraint on $\mathbf{c}$, we do not require that $c_i \geq 0$, $i = 1, \ldots, m$. Thus $\mathbf{c}$ is allowed to range over the whole sphere S_α^{m-1}, which considerably simplifies the optimization procedure.

The optimization problem (84) is not convex and one common approach to tackle it is via Alternating Minimization. First we fix $\mathbf{c} \in S_\alpha^{m-1}$ and solve for the optimal $f_{\mathbf{z},\gamma} \in \mathcal{H}_K$, which is what we have done so far. Then we fix f and solve for $\mathbf{c}$. Consider f of the form

$$f = \sum_{j=1}^{u+l} K_{x_j} a_j.$$

Then

$$f(x_i) = \sum_{j=1}^{u+l} K(x_i, x_j) a_j = K[x_i]\mathbf{a},$$

where $K[x_i] = (K(x_i, x_1), \ldots, K(x_i, x_{u+l}))$. Since $K[x_i] = G[x_i] \otimes R$, we have

$$f(x_i) = (G[x_i] \otimes R)\mathbf{a}, \quad G[x_i] \in \mathbb{R}^{m \times m(u+l)}.$$

Since A is a matrix of size $m(u+l) \times \dim(\mathcal{Y})$, with $\mathbf{a} = \text{vec}(A^T)$, we have

$$Cf(x_i) = (\mathbf{c}^T \otimes I_{\mathcal{Y}})(G[x_i] \otimes R)\mathbf{a} = (\mathbf{c}^T G[x_i] \otimes R)\mathbf{a} = \text{vec}(RA^T G[x_i]^T \mathbf{c}) = RA^T G[x_i]^T \mathbf{c} \in \mathcal{Y}.$$

Let $F[\mathbf{x}]$ be an $l \times 1$ block matrix, with block $F[\mathbf{x}]_i = RA^T G[x_i]^T$, which is of size $\dim(\mathcal{Y}) \times m$, so that $F[\mathbf{x}]$ is of size $\dim(\mathcal{Y})l \times m$ and $F[\mathbf{x}]\mathbf{c} \in \mathcal{Y}^l$. Then

$$\frac{1}{l} \sum_{i=1}^{l} ||y_i - Cf(x_i)||_{\mathcal{Y}}^2 = \frac{1}{l} ||\mathbf{y} - F[\mathbf{x}]\mathbf{c}||_{\mathcal{Y}^l}^2.$$

Thus for f fixed, so that $F[\mathbf{x}]$ is fixed, the minimization problem (84) over $\mathbf{c}$ is equivalent to the following optimization problem

$$\min_{\mathbf{c} \in \mathcal{S}_\alpha^{m-1}} \frac{1}{l} ||\mathbf{y} - F[\mathbf{x}]\mathbf{c}||_{\mathcal{Y}^l}^2. \quad (85)$$

While the sphere S_α^{m-1} is not convex, it is a compact set and consequently, any continuous function on S_α^{m-1} attains a global minimum and a global maximum. We show in the next section how to obtain an almost closed form solution for the global minimum of (85) in the case $\dim(\mathcal{Y}) < \infty$.

6.1 Quadratic Optimization on the Sphere

Let A be an $n \times m$ matrix, $\mathbf{b}$ be an $n \times 1$ vector, and $\alpha > 0$. Consider the optimization problem

$$\min_{\mathbf{x} \in \mathbb{R}^m} ||A\mathbf{x} - \mathbf{b}||_{\mathbb{R}^n} \text{ subject to } ||\mathbf{x}||_{\mathbb{R}^m} = \alpha. \quad (86)$$

The function $\psi(\mathbf{x}) = ||A\mathbf{x} - \mathbf{b}||_{\mathbb{R}^n} : \mathbb{R}^m \to \mathbb{R}$ is continuous. Thus over the sphere $\|\mathbf{x}\|_{\mathbb{R}^m} = \alpha$, which is a compact subset of $\mathbb{R}^m$, $\psi(\mathbf{x})$ has a global minimum and a global maximum.

The optimization problem (86) has been analyzed before in the literature under various assumptions, see e.g. (Forsythe and Golub, 1965; Gander, 1981; Golub and von Matt, 1991). In this work, we employ the singular value decomposition approach described in (Gander, 1981), but we *do not impose any constraint* on the matrix A (in (Gander, 1981), it is assumed that $\text{rank}\begin{pmatrix} A \\ I \end{pmatrix} = m$ and $n \geq m$). We next describe the form of the global minimum of $\psi(\mathbf{x})$.

Consider the singular value decomposition for A,

$$A = U\Sigma V^T, \quad (87)$$

where $U \in \mathbb{R}^{n \times n}$, $\Sigma \in \mathbb{R}^{n \times m}$, $V \in \mathbb{R}^{m \times m}$, with $UU^T = U^T U = I_n$, $VV^T = V^T V = I_m$. Let $r = \text{rank}(A)$, $1 \leq r \leq \min\{m, n\}$, then the main diagonal of Σ has the form $(\sigma_1, \ldots, \sigma_r, 0, \ldots, 0)$, with $\sigma_1 \geq \cdots \sigma_r > 0$. Then

$$A^T A = V\Sigma^T \Sigma V^T = VDV^T, \quad (88)$$

where $D = \Sigma^T \Sigma = \text{diag}(\sigma_1^2, \ldots, \sigma_r^2, 0, \ldots, 0) = \text{diag}(\mu_1, \ldots, \mu_m) \in \mathbb{R}^{m \times m}$, with μ_i, $1 \leq i \leq m$, being the eigenvalues of $A^T A \in \mathbb{R}^{m \times m}$.

Theorem 15 *Assume that $A^T\mathbf{b} = 0$. A global solution of the minimization problem (86) is an eigenvector $\mathbf{x}^*$ of $A^T A$ corresponding to the smallest eigenvalue μ_m, appropriately normalized so that $||\mathbf{x}^*||_{\mathbb{R}^m} = \alpha$. This solution is unique if and only if μ_m is single. Otherwise, there are infinitely many solutions, each one being a normalized eigenvector in the eigenspace of μ_m.*

Theorem 16 *Assume that $A^T\mathbf{b} \neq 0$. Let $\mathbf{c} = U^T\mathbf{b}$. Let γ^* be the unique real number in the interval $(-\sigma_r^2, \infty)$ such that*

$$s(\gamma^*) = \sum_{i=1}^{r} \frac{\sigma_i^2 c_i^2}{(\sigma_i^2 + \gamma^*)^2} = \alpha^2. \quad (89)$$

(I) The vector

$$\mathbf{x}(\gamma^*) = (A^T A + \gamma^* I_m)^{-1} A^T \mathbf{b}, \quad (90)$$

is the unique global solution of the minimization problem (86) in one of the following cases:

1. $\text{rank}(A) = m$.
2. $\text{rank}(A) = r < m$ *and* $\gamma^* > 0$.
3. $\text{rank}(A) = r < m$, $\gamma^* < 0$, *and* $\sum_{i=1}^{r} \frac{c_i^2}{\sigma_i^2} > \alpha^2$.

(II) In the remaining case, namely $\text{rank}(A) = r < m$, $\gamma^* \leq 0$, *and* $\sum_{i=1}^{r} \frac{c_i^2}{\sigma_i^2} \leq \alpha^2$, *then the global solution of the minimization problem (86) is given by*

$$\mathbf{x}(0) = V\mathbf{y}, \tag{91}$$

where $y_i = \frac{c_i}{\sigma_i}$, $1 \leq i \leq r$, *with* y_i, $r+1 \leq i \leq m$, *taking arbitrary values such that*

$$\sum_{i=r+1}^{m} y_i^2 = \alpha^2 - \sum_{i=1}^{r} \frac{c_i^2}{\sigma_i^2}. \tag{92}$$

This solution is unique if and only if $\sum_{i=1}^{r} \frac{c_i^2}{\sigma_i^2} = \alpha^2$. *If* $\sum_{i=1}^{r} \frac{c_i^2}{\sigma_i^2} < \alpha^2$, *then there are infinitely many solutions.*

Remark 17 *To solve equation (89), the so-called secular equation, we note that the function* $s(\gamma) = \sum_{i=1}^{r} \frac{\sigma_i^2 c_i^2}{(\sigma_i^2+\gamma)^2}$ *is monotonically decreasing on* $(-\sigma_r^2, \infty)$ *and thus (89) can be solved via a bisection procedure.*

Remark 18 *We have presented here the solution to the problem of optimizing* C *in the least square case. The optimization of* C *in the SVM case is substantially different and will be treated in a future work.*

7. Experiments

In this section, we present an extensive empirical analysis of the proposed methods on the challenging tasks of multiclass image classification and species recognition with attributes. We show that the proposed framework[2] is able to combine different types of views and modalities and that it is competitive with other state-of-the-art approaches that have been developed in the literature to solve these problems.

The following methods, which are instances of the presented theoretical framework, were implemented and tested: multi-view learning with least square loss function (MVL-LS), MVL-LS with the optimization of the combination operator (MVL-LS-optC), multi-view learning with binary SVM loss function in the one-vs-all setup (MVL-binSVM), and multi-view learning with multi-class SVM loss function (MVL-SVM).

Our experiments demonstrate that: 1) multi-view learning achieves significantly better performance compared to single-view learning (Section 7.4); 2) unlabeled data can be particularly helpful in improving performance when the number of labeled data is small

2. The code for our multi-view learning methods is available at `https://github.com/lorisbaz/Multiview-learning`.

(Section 7.4 and Section 7.5); 3) the choice and therefore the optimization of the combination operator C is important (Section 7.6); and 4) the proposed framework outperforms other state-of-the-art approaches even in the case when we use fewer views (Section 7.7).

In the following sections, we first describe the designs for the experiments: the construction of the kernels is described in Section 7.1, the used data sets and evaluation protocols in Section 7.2 and the selection/validation of the regularization parameters in Section 7.3. Afterward, Sections 7.4, 7.5, 7.6, and 7.7 report the analysis of the obtained results with comparisons to the literature.

7.1 Kernels

Assume that each input x has the form $x = (x^1, \ldots, x^m)$, where x^i represents the ith view. We set $G(x,t)$ to be the diagonal matrix of size $m \times m$, with

$$(G(x,t))_{i,i} = k^i(x^i, t^i), \quad \text{that is} \quad G(x,t) = \sum_{i=1}^{m} k^i(x^i, t^i)\mathbf{e}_i\mathbf{e}_i^T, \tag{93}$$

where k^i is a scalar-valued kernel defined on view i and $\mathbf{e}_i = (0, \ldots, 1, \ldots, 0) \in \mathbb{R}^m$ is the ith coordinate vector. The corresponding Gram matrices are related by

$$G[\mathbf{x}] = \sum_{i=1}^{m} k^i[\mathbf{x}] \otimes \mathbf{e}_i\mathbf{e}_i^T. \tag{94}$$

Note that for each pair (x,t), $G(x,t)$ is a diagonal matrix, but it is *not* separable, that is it cannot be expressed in the form $k(x,t)D$ for a scalar kernel k and a positive semi-definite matrix D, because the kernels k^i's are in general different.

To carry out multi-class classification with P classes, $P \geq 2$, using vector-valued least squares regression (Algorithm 1), we set $\mathcal{Y} = \mathbb{R}^P$, and $K(x,t) = G(x,t) \otimes R$, with $R = I_P$. For each y_i, $1 \leq i \leq l$, in the labeled training sample, we set $y_i = (-1, \ldots, 1, \ldots, -1)$, with 1 at the kth location if x_i is in the kth class. When using vector-valued multi-view SVM (Algorithm 2), we set S to be the simplex coding, $\mathcal{Y} = \mathbb{R}^{P-1}$, and $K(x,t) = G(x,t) \otimes R$, with $R = I_{P-1}$.

We remark that since the views are coupled by both the loss functions and the multi-view manifold regularization term M, even in the simplest scenario, that is fully supervised multi-view binary classification, Algorithm 1 with a diagonal $G(x,t)$ is not equivalent to solving m independent scalar-valued least square regression problems, and Algorithm 2 is not equivalent to solving m independent binary SVMs.

We used $R = I_{\mathcal{Y}}$ for the current experiments. For multi-label learning applications, one can set R to be the output graph Laplacian as done in (Minh and Sindhwani, 2011).

We empirically analyzed the optimization framework of the combination operator $\mathbf{c}$ in the least square setting, as theoretically presented in Section 6. For the experiments with the SVM loss, we set the weight vector $\mathbf{c}$ to be the uniform combination $\mathbf{c} = \frac{1}{m}(1, \ldots, 1)^T \in \mathbb{R}^m$, leaving its optimization, which is substantially different from the least square case, to future work.

In all experiments, the kernel matrices are used as the weight matrices for the graph Laplacians, unless stated otherwise. This is not necessarily the best choice in practice but

we did not use additional information to compute more informative Laplacians at this stage to have a fair comparison with other state of the art techniques.

7.2 Data sets and Evaluation Protocols

Three data sets were used in our experiments to test the proposed methods, namely, the Oxford flower species (Nilsback and Zisserman, 2006), Caltech-101 (Fei-Fei et al., 2006), and Caltech-UCSD Birds-200-2011 (Wah et al., 2011). For these data sets, the views are the different features extracted from the input examples as detailed below.

The Flower species data set (Nilsback and Zisserman, 2006) consists of 1360 images of 17 flower species segmented out from the background. We used the following 7 extracted features in order to fairly compare with (Gehler and Nowozin, 2009): HOG, HSV histogram, boundary SIFT, foreground SIFT, and three features derived from color, shape and texture vocabularies. The features, the respective χ^2 kernel matrices and the training/testing splits[3] are taken from (Nilsback and Zisserman, 2006) and (Nilsback and Zisserman, 2008). The total training set provided by (Nilsback and Zisserman, 2006) consists of 680 labeled images (40 images per class). In our experiments, we varied the number of labeled data $l_c = \{1, 5, 10, 20, 40\}$ images per category and used 85 unlabeled images ($u_c = 5$ per class) taken from the validation set in (Nilsback and Zisserman, 2006) when explicitly stated. The testing set consists of 20 images per class as in (Nilsback and Zisserman, 2006).

The Caltech-101 data set (Fei-Fei et al., 2006) is a well-known data set for object recognition that contains 102 classes of objects and about 40 to 800 images per category. We used the features and χ^2 kernel matrices[4] provided in (Vedaldi et al., 2009), consisting of 4 descriptors extracted using a spatial pyramid of three levels, namely PHOW gray and color, geometric blur, and self-similarity. In our experiments, we selected only the lower level of the pyramid, resulting in 4 kernel matrices as in (Minh et al., 2013). We report results using all 102 classes (background class included) averaged over three splits as provided in (Vedaldi et al., 2009). In our tests, we varied the number of labeled data ($l_c = \{5, 10, 15\}$ images per category) in the supervised setup. The test set contained 15 images per class for all of the experiments.

The Caltech-UCSD Birds-200-2011 data set (Wah et al., 2011) is used for bird categorization and contains both images and manually-annotated attributes (two modalities)[5]. This data set is particularly challenging because it contains 200 very similar bird species (classes) for a total of 11,788 annotated images split between training and test sets. We used the same evaluation protocol and kernel matrices of (Minh et al., 2013). Different training sets were created by randomly selecting 5 times a set of $l_c = \{1, 5, 10, 15\}$ images for each class. All testing samples were used to evaluate the method. We used 5 unlabeled images per class in the semi-supervised setup. The descriptors consist of two views: PHOW gray (Vedaldi et al., 2009) from images and the 312-dimensional binary vector representing attributes provided in (Wah et al., 2011). The χ^2 and Gaussian kernels were used for the appearance and attribute features, respectively.

3. The complete data is available at `http://www.robots.ox.ac.uk/~vgg/data/flowers/17/index.html`.
4. The complete data is available at `http://www.robots.ox.ac.uk/~vgg/software/MKL/`.
5. The data set is available at `http://www.vision.caltech.edu/visipedia/CUB-200-2011.html`.

7.3 Regularization Parameters

Let us specify the parameters we used in the experiments. Each method has three regularization parameters, namely, γ_A for the standard RKHS regularization, and γ_B and γ_W for the multi-view manifold regularization. The only data set for which it was possible to perform independent cross-validation is the Flower species data set which has a separate validation set from the training set. For the other data sets, cross-validation was omitted in order to have the same number of training examples and therefore to have a fair comparison with the other state-of-the-art methods.

Cross-validation on the flower species data set was performed using the following set of parameters: $\gamma_A = \{10^{-5}, 10^{-6}, 10^{-7}\}$, $\gamma_B = \{10^{-6}, 10^{-8}, 10^{-9}\}$ and $\gamma_W = \{10^{-6}, 10^{-8}, 10^{-9}\}$. Cross-validation was run on the experiment with $l_c = 10$ labeled data per category. The parameters found during validation were left the same for all the other experiments $l_c = \{1, 5, 20, 40\}$ to have a fair comparison.

The parameters that performed the best on the validation set for the Flower species data set are reported in Table 1, column a. We also report the parameters chosen for Caltech-101 and the Caltech-UCSD Birds-200-2011 data set in Table 1 columns b and c, respectively. Notice that the parameters vary across the different implementations of the proposed framework and especially across the different data sets, as might be expected.

	(a) Flower species			(b) Caltech-101			(c) Caltech Birds		
Method	γ_A	γ_B	γ_W	γ_A	γ_B	γ_W	γ_A	γ_B	γ_W
MVL-LS	10^{-7}	10^{-9}	10^{-8}	10^{-5}	10^{-6}	10^{-6}	10^{-5}	10^{-6}	10^{-6}

7.4 Single-view Vs. Multi-view

The purpose of the experimental analysis in this section is to demonstrate that multi-view learning significantly outperforms single-view learning.

First, we analyzed the contributions of each of the between-view and within-view regularization terms, given by (58) and (64), respectively, in the optimization problem (9). To this end, we tested multi-view learning with the least squares loss function on Caltech-101. A subset of 10 images for each class were randomly selected, with half used as labeled data $l_c = 5$ and the other half as unlabeled data $u_c = 5$ (see Table 2, last column). We also tested the proposed method in the one-shot learning setup, where the number of labeled images is one per class $l_c = 1$ (see Table 2, third column). The testing set consisted of 15 images per category. For this test, we selected the features at the bottom of each pyramid, because they give the best performance in practice. We can see from Table 2 that both the between-view and within-view regularization terms contribute to increase the recognition rate, *e.g.* with $l_c = 1$ the improvement is 2.35%. As one would expect, the improvement

resulting from the use of unlabeled data is bigger when there are more unlabeled data than labeled data, which can be seen by comparing the third and forth columns.

γ_B	γ_W	Accuracy $l_c = 1, u_c = 5$	Accuracy $l_c = u_c = 5$
0	0	30.59%	63.68%
0	10^{-6}	31.81%	63.97%
10^{-6}	0	32.44%	64.18%
10^{-6}	10^{-6}	**32.94**%	**64.2**%

Table 2: Results of MVL-LS on Caltech-101 using PHOW color and gray L2, SSIM L2 and GB. The training set consists of 1 or 5 labeled data l_c and 5 unlabeled data per class u_c, and 15 images per class are left for testing.

To demonstrate that multi-view learning is able to combine features properly, we report in Table 3 the performance in terms of average accuracy of each feature independently and of the proposed methods with all 10 views combined (last three rows). The improvement with respect to the view that gives the best results (PHOW gray L2) is 4.77% for the case with $l_c = 1$ (second column) and 5.62% for the case with $l_c = 5$ (last column). It is also worth noticing that all the proposed methods outperform the best single view (PHOW gray L2). Moreover, it is important to point out that the best views for each feature correspond to the L2 level. We show in Section 7.6 that the optimization of the combination operator leads to very similar findings.

Feature	Accuracy $l_c = 1, u_c = 5$	Accuracy $l_c = u_c = 5$
PHOW color L0	13.66%	33.14%
PHOW color L1	17.1%	42.03%
PHOW color L2	18.71%	45.86%
PHOW gray L0	20.31%	45.38%
PHOW gray L1	24.53%	54.86%
PHOW gray L2	25.64%	56.75%

MVL-binSVM (semi-sup. $u_c = 5$)	**32.4**% (1.2%)	**64.4**% (0.4%)	*71.4*% (0.2%)	N/A

Table 5: Results on Caltech-101 when increasing the number of labeled data and comparisons with other state of the art methods reported by (Gehler and Nowozin, 2009). Best score in bold, second best score in italic.

multi-view learning methods (last three rows) when increasing the number of labeled data per class $l_c = \{1, 5, 10, 15\}$. In all the cases shown in the table, we obtain better results using the proposed multi-view learning framework compared with single-view learning.

7.5 Increasing the Label Set Size

In this section, we analyze the behavior of the proposed methods when increasing the size of the set of labeled data, in both supervised and semi-supervised settings.

In Table 5, we reported the results in terms of accuracy and its standard deviation (between brackets) on the Caltech-101 data set comparing with other state of the art methods. The first three rows report the results of the methods tested by (Gehler and Nowozin, 2009). The forth, fifth and sixth rows show the statistics of the proposed methods in the supervised setup. We also reported the results of the best methods among the proposed ones in the semi-supervised setup (with 5 unlabeled data for each class).

First, the results demonstrate that the proposed methods improve significantly when increasing the size of the labeled set. This fact can be observed also for the Caltech-UCSD Birds-200-2011 experiment in Table 4. More interestingly, when the number of labeled data

	$l_c = 1$	$l_c = 5$	$l_c = 10$	$l_c = 20$	$l_c = 40$
MVL-LS	39.41% (1.06%)	*65.78%* (3.68%)	74.41% (1.28%)	81.76% (3.28%)	**86.37%** (1.80%)
MVL-binSVM	39.71% (1.06%)	64.80% (4.42%)	*74.41%* (0.29%)	81.08% (3.09%)	86.08% (2.21%)
MVL-SVM	39.31% (1.62%)	65.29% (4.04%)	74.41% (1.28%)	81.67% (2.78%)	86.08% (1.80%)
MVL-LS (semi-sup.)	**41.86%** (2.50%)	**66.08%** (3.45%)	**75.00%** (1.06%)	**82.35%** (2.70%)	85.78% (2.78%)
MVL-binSVM (semi-sup.)	*40.59%* (2.35%)	65.49% (4.58%)	74.22% (0.68%)	81.57% (2.67%)	85.49% (0.74%)
MVL-SVM (semi-sup.)	34.80% (1.11%)	65.49% (4.17%)	74.41% (0.49%)	*81.78%* (2.61%)	*86.08%* (1.51%)

Table 6: Results on the Flower data set (17 classes) when increasing the number of training images per class. Best score in bold, second best score in italic.

is 5 per class (third column), our methods strongly improve the best result of (Gehler and Nowozin, 2009) by at least 9.4 percentage points. Similar observations can be made by examining the results obtained by Bucak et al. (2014) for $l_c = 10$ (Table 4 in their paper): our best result in Table 5 (71.4%) outperforms their best result (60.3%) by 11.1 percentage points. Moreover, one can see that the improvement when using unlabeled data (last row) is bigger when there are many more of them compared with labeled data, as expected (see the columns with 1 and 5 labeled images per class). When the number of labeled data increases, the proposed methods in the supervised setup can give comparable or better results (see the column with 10 labeled images per class). A similar behavior is shown in Table 6, when dealing the problem of species recognition with the Flower data set. The best improvement we obtained in the semi-supervised setup is with 1 labeled data per category. This finding suggests that the unlabeled data provide additional information about the distribution in the input space when there are few labeled examples. On the other hand, when there are sufficient labeled data to represent well the distribution in the input space, the unlabeled data will not provide an improvement of the results.

7.6 Optimizing the Combination Operator

In the previous experiments, the combination weight vector $\mathbf{c}$ was uniform, meaning that each view (*i.e.* kernel) has the same importance during classification. However, in practice it often happens that some views are more useful and informative than others. We observed this in our experiments, where different choices of the weights $\mathbf{c}$ gave rise to different classification accuracies. In particular, we empirically found for the Flower data set using MVL-LS that $\mathbf{c} = (0.1431, 0.1078, 0.1452, 0.1976, 0.0991, 0.1816, 0.1255)^T$ yields an accuracy of 87.75%, the state-of-the-art result for that data set. This suggests that there exists at least one better choice for $\mathbf{c}$.

In this section, we carry out an empirical analysis of the strategy presented in Section 6 which performs optimization to obtain the optimal weight vector $\mathbf{c}$. We call this method MVL-LS-optC. The analysis was performed on the Caltech-101 data set and the Flower data set. For the experiment using the Caltech-101 data set, we created a validation set by selecting 5 examples for each class from the training set. For the experiment using the Flower data set, the validation set was already provided (see Section 7.2 for detail). The

validation set is used to determine the best value of $\mathbf{c}$ found over all the iterations using different initializations. We carried out the iterative optimization procedure 20 times, each time with a different random unit vector as the initialization vector for $\mathbf{c}$, and reported the run with the best performance over the validation set.

The results of MVL-LS-optC for the Caltech-101 data set and the Flower data set are reported in Tables 7, 8 and 9. We empirically set $\alpha = 2$ and $\alpha = 1$ in the optimization problem (86) for the Caltech-101 data set and the Flower data set, respectively. MVL-LS-optC is compared with MVL-LS which uses uniform weights. We analyze in the next section how MVL-LS-optC compares with MVL-binSVM, MVL-SVM, and the state of the art.

We first discuss the results on the Caltech-101 data set using all 10 kernels. Table 7 shows that there is a significant improvement from 0.4% to 2.5% with respect to the results with uniform weights for the Caltech-101 data set. The best $\mathbf{c}$ found during training in the case of $l_c = 10$ was $\mathbf{c}^* = (0.1898, 0.6475, -0.7975, 0.3044, 0.1125, -0.4617, -0.1531, 0.1210, 1.2634, 0.9778)^T$. Note that the c_i's can assume negative values (as is the case here) and as we show in Section 8.1, the contribution of the ith view is determined by the square weight c_i^2. This experiment confirms our findings in Section 7.4: the best 4 views are PHOW color L2, PHOW gray L2, SSIM L2 and GB, which are the c_3, c_6, c_9 and c_{10} components of $\mathbf{c}$, respectively.

We now focus on the top 4 views and apply again the optimization method to see if there is still a margin of improvement. We expect to obtain better results with respect to 10 views because the 4-dimensional optimization should in practice be easier than the 10-dimensional one, given that the size of the search space is smaller. Table 8 shows the results with the top 4 kernels. We observe that there is an improvement with respect to MVL-LS that varies from 0.3% to 1.1%. We can also notice that there is not a significant improvement of the results when using more iteration (25 vs. 50 iterations). We again inspected the learned combination weights and discovered that in average they are very close to the uniform distribution, *i.e.* $\mathbf{c}^* = (-0.4965, -0.5019, -0.4935, -0.5073)^T$. This is mainly because we pre-selected the best set of 4 kernels accordingly to the previous 10-kernel experiment.

We finally used the best $\mathbf{c}$ learned in the case of $l_c = 10$ to do an experiment[6] with $l_c = 15$ on the Caltech-101. MVL-LS-optC obtains an accuracy of 73.85%, outperforming MVL-LS (uniform), which has an accuracy of 73.33% (see Table 10).

For the Flower data set, Table 9 shows consistent results with the previous experiment. MVL-LS-optC outperforms MVL-LS (uniform weights) in terms of accuracy with an improvement ranging from 0.98% to 4.22%. To have a deeper understanding about which views are more important, we analyzed the combination weights of the best result in Table 9 (last row, last column). The result of the optimization procedure is $\mathbf{c}^* = (-0.3648, -0.2366, 0.3721, 0.5486, -0.4108, 0.3468, 0.2627)^T$ which suggests that the best accuracy is obtained by exploiting the complementarity between shape-based features (c_3 and c_4) and color-based features (c_5) relevant for flower recognition[7].

6. We did not run the optimization of $\mathbf{c}$ for $l_c = 15$ because there is no validation set available for this case.
7. In our experiments, we used the following order: c_1 = HOG, c_2 = HSV, c_3 = boundary SIFT, c_4 = foreground SIFT, c_5 = color bag-of-features, c_6 = texture bag-of-features, c_7 = shape bag-of-features.

	$l_c = 1$	$l_c = 5$	$l_c = 10$
MVL-LS (uniform)	28.4% (1.8%)	61.4% (1.1%)	68.1% (0.3%)
MVL-LS-optC (25 it.)	**28.8**% (1.7%)	**63.1**% (0.1%)	**70.6**% (0.5%)

Table 7: Results using the procedure to optimize the combination operator on Caltech-101 considering all 10 kernels. Best score in bold.

	$l_c = 1$	$l_c = 5$	$l_c = 10$
MVL-LS (uniform)	31.2% (1.1%)	64.0% (1.0%)	71.0% (0.3%)
MVL-LS-optC (25 it.)	**32.1**% (1.5%)	*64.5*% (0.9%)	**71.3**% (0.4%)
MVL-LS-optC (50 it.)	*32.1*% (2.3%)	**64.7**% (1.1%)	*71.3*% (0.5%)

Table 8: Results using the procedure to optimize the combination operator on Caltech-101 using the top 4 kernels. Best score in bold, second best score in italic.

The proposed optimization procedure is powerful, with clear improvements in classification accuracies over the uniform weight approach. However, it comes with a price during the training phase. Firstly, it is an iterative procedure, and therefore it is more computationally expensive with respect to the original MVL-LS formulation. In particular, it is N_C times more expensive than MVL-LS, where N_C is the number of iterations. Secondly, since the joint optimization of $(\mathbf{c}, f_{\mathbf{z},\gamma})$ is non-convex, even though we are guaranteed to obtain the global minimum for $\mathbf{c}$ *during each single iteration*, the final $\mathbf{c}$ is *not* guaranteed to be the global minimum of the joint optimization problem itself.

7.7 Comparing with the State of the Art

In this section, we show how the proposed methods compare with other state-of-the-art approaches for each recognition problem.

In Table 10, we reported the best results we obtained for the task of object recognition using Caltech-101 in the supervised setup. Observe that all the proposed methods outperform the other techniques, even though they use much less information: 4 kernels versus e.g. 39 kernels in (Gehler and Nowozin, 2009).

In particular, we obtained the best result with the binary version of MVL in the one-vs-all setup. This is not surprising since the one-vs-all approach has often been shown to be very competitive in many computer vision tasks compared to proper multi-class formulations. The second best result is obtained by MVL-LS-optC since it uses an additional optimization step (of $\mathbf{c}$) with respect to the other methods. The optimization of $\mathbf{c}$ for MVL-binSVM and MVL-SVM is substantially different from the least square case and will be treated in a future work.

In Table 11, we reported the best results obtained for the task of species recognition using the Flower data set in the supervised setup. The proposed methods are compared

	$l_c = 1$	$l_c = 5$	$l_c = 10$	$l_c = 20$	$l_c = 40$
MVL-LS (uniform)	39.41% (1.06%)	65.78% (3.68%)	74.41% (1.28%)	*81.76*% (3.28%)	86.37% (1.80%)
MVL-LS-optC (25 it.)	*43.14*% (3.38%)	*68.53*% (2.90%)	*75.00*% (0.29%)	81.47% (2.06%)	*87.25*% (1.51%)
MVL-LS-optC (50 it.)	**43.63**% (3.25%)	**68.63**% (2.86%)	**75.39**% (0.90%)	**82.45**% (3.51%)	**87.35**% (1.35%)

Table 9: Results using the procedure to optimize the combination operator on the Flower data set. Best score in bold, second best score in italic.

Method	# of Kernels	Accuracy
(Yang et al., 2009)	≥ 10	73.2%
(Christoudias et al., 2009)	4	73.00%

MKL (Vedaldi et al., 2009)	10	71.10%
MVL-LS	4	73.33%
MVL-LS-optC	4	*73.85*%
MVL-binSVM	4	**74.05**%
MVL-SVM	4	73.55%

Table 10: Comparison with state-of-the-art methods on the Caltech-101 data set using PHOW color and gray L2, SSIM L2 and GB in the supervised setup (15 labeled images per class). Best score in bold, second best score in italic.

with MKL, LP-B and LP-β by (Gehler and Nowozin, 2009) as well as the more recent results of MK-SVM Shogun, MK-SVM OBSCURE and MK-FDA from (Yan et al., 2012). For this data set, our best result is obtained by the MVL-LS-optC method outperforming also the recent method MK-FDA from (Yan et al., 2012). We note also, that even with the uniform weight vector (MVL-LS), our methods outperform MK-FDA on Caltech-101, which uses 10 kernels, see Figures 6 and 9 in (Yan et al., 2012).

Method	Accuracy
MKL (SILP)	85.2% (1.5%)
MKL (Simple)	85.2% (1.5%)
LP-B	85.4% (2.4%)
LP-β	85.5% (3.0%)
MK-SVM Shogun	86.0% (2.4%)
MK-SVM OBSCURE	85.6% (0.0%)
MK-FDA	*87.2*% (1.6%)
MVL-LS	86.4% (1.8%)
MVL-LS-optC	**87.35**% (1.3%)
MVL-binSVM	86.1% (2.2%)
MVL-SVM	86.1% (1.8%)

Table 11: Results on the Flower data set comparing the proposed method with other state-of-the-art techniques in the supervised setup. The first four rows are from (Gehler and Nowozin, 2009) while rows 5-7 are methods presented by (Yan et al., 2012).

8. Further Theoretical Analysis

There are two purposes in this brief section, which shows the close connection between our framework and standard approaches in multi-kernel learning and multi-task learning. Firstly, we show that in the supervised setting, our framework is a form of multi-kernel learning, but with a crucial difference compared to typical multi-kernel learning methods, namely the combination weight vector is *not constrained* to be non-negative. Secondly, we also point out explicitly that several common scenarios in multi-task learning are special cases of our general formulation.

8.1 Connection with Multiple Kernel Learning

In this section, we briefly explore the connection between our multi-view learning framework and multiple kernel learning, see e.g. (Bach et al., 2004). We show that in the purely supervised setting, when $\gamma_I = 0$, $u = 0$, that is without unlabeled data and without between-view regularization, for $C = \mathbf{c}^T \otimes I_{\mathcal{Y}}$, $K(x,t) = G(x,t) \otimes I_{\mathcal{Y}}$, $G(x,t) = \sum_{i=1}^m k^i(x,t)\mathbf{e}_i\mathbf{e}_i^T$, we obtain supervised learning (vector-valued least square regression and SVM) with the combined kernel $\sum_{i=1}^m c_i^2 k^i(x,t) I_{\mathcal{Y}}$, where k^i is a scalar-valued kernel corresponding to view i. In particular, for $\mathcal{Y} = \mathbb{R}$, we obtain scalar-values least square regression and binary SVM with the combined kernel $\sum_{i=1}^m c_i^2 k^i(x,t)$. Specifically, we have the following results.

Corollary 19 *Consider the special case $\gamma_I = 0$, $u = 0$. The system of linear equations (13) in Theorem 4 has solution*

$$\mathbf{a} = (I_l \otimes C^*)\left[(I_l \otimes C)K[\mathbf{x}](I_l \otimes C^*) + l\gamma_A I_{\mathcal{Y}^l}\right]^{-1}\mathbf{y}. \tag{95}$$

For $C = \mathbf{c}^T \otimes I_{\mathcal{Y}}$, $K(x,t) = G(x,t) \otimes I_{\mathcal{Y}}$, and $G(x,t) = \sum_{i=1}^m k^i(x,t)\mathbf{e}_i\mathbf{e}_i^T$, for any $v \in \mathcal{X}$,

$$Cf_{\mathbf{z},\gamma}(v) = \left\{\sum_{i=1}^m c_i^2 k^i[v,\mathbf{x}]\left(\sum_{i=1}^m c_i^2 k^i[\mathbf{x}] + l\gamma_A I_l\right)^{-1} \otimes I_{\mathcal{Y}}\right\}\mathbf{y}. \tag{96}$$

In particular, if $\mathcal{Y} = \mathbb{R}$, then

$$Cf_{\mathbf{z},\gamma}(v) = \left\{\sum_{i=1}^m c_i^2 k^i[v,\mathbf{x}]\left(\sum_{i=1}^m c_i^2 k^i[\mathbf{x}] + l\gamma_A I_l\right)^{-1}\right\}\mathbf{y}. \tag{97}$$

This is precisely the solution of scalar-valued regularized least square regression with the combined kernel $\sum_{i=1}^m c_i^2 k^i(x,t)$.

Corollary 20 *Consider the special case $\gamma_I = 0$, $u = 0$. Then in Theorem 7,*

$$Q[\mathbf{x},\mathbf{y},C] = \frac{1}{\gamma_A}\mathrm{diag}(S^*_{\hat{\mathbf{y}}})(I_l \otimes C)K[\mathbf{x}](I_l \otimes C^*)\mathrm{diag}(S_{\hat{\mathbf{y}}}).$$

For $C = \mathbf{c}^T \otimes I_{\mathcal{Y}}$, $K(x,t) = G(x,t) \otimes I_{\mathcal{Y}}$, $G(x,t) = \sum_{i=1}^m k^i(x,t)\mathbf{e}_i\mathbf{e}_i^T$,

$$Q[\mathbf{x},\mathbf{y},C] = \frac{1}{\gamma_A}\mathrm{diag}(S^*_{\hat{\mathbf{y}}})\left(\sum_{i=1}^m c_i^2 k^i[\mathbf{x}] \otimes I_{\mathcal{Y}}\right)\mathrm{diag}(S_{\hat{\mathbf{y}}}),$$

and for any $v \in \mathcal{X}$,

$$Cf_{\mathbf{z},\gamma}(v) = -\frac{1}{2\gamma_A}\left(\sum_{i=1}^m c_i^2 k^i[v,\mathbf{x}] \otimes I_{\mathcal{Y}}\right)\mathrm{diag}(S_{\hat{\mathbf{y}}})\mathrm{vec}(\beta^{\mathrm{opt}}).$$

In the binary case, $\mathcal{Y} = \mathbb{R}$, so that

$$Q[\mathbf{x},\mathbf{y},C] = \frac{1}{\gamma_A}\mathrm{diag}(\mathbf{y})\left(\sum_{i=1}^m c_i^2 k^i[\mathbf{x}]\right)\mathrm{diag}(\mathbf{y}),$$

$$Cf_{\mathbf{z},\gamma}(v) = -\frac{1}{2\gamma_A}\left(\sum_{i=1}^m c_i^2 k^i[v,\mathbf{x}]\right)\mathrm{diag}(\mathbf{y})\beta^{\mathrm{opt}}.$$

This is precisely the solution of binary SVM with the combined kernel $\sum_{i=1}^m c_i^2 k^i(x,t)$.

Remark 21 *In the sum $\sum_{i=1}^m c_i^2 k^i(x,t)$, the coefficients c_i's are automatically non-negative. This is in accordance with the fact that our formulation makes no mathematical constraint on the coefficients c_i's in the sum $\sum_{i=1}^m c_i f^i(x)$. This is one difference between our approach and the typical multiple kernel learning setting (Bach et al., 2004), where one considers a sum of the form $\sum_{i=1}^m d_i k^i(x,t)$, where the d_i's must be non-negative to guarantee the positive definiteness of the combined kernel.*

8.2 Connection with Multi-task Learning

In this section, we briefly explore the connection between our learning formulation and multi-task learning, see e.g. (Evgeniou et al., 2005) . Let n be the number of tasks, $n \in \mathbb{N}$.

Consider the case where the tasks have the same input space. Let $\mathcal{T}$ be a separable Hilbert space. Let $G : \mathcal{X} \times \mathcal{X} \to \mathcal{L}(\mathcal{T})$ be an operator-valued positive definite kernel, which induces an RKHS of functions with values in the Hilbert space $\mathcal{T}$. Consider the kernel $K(x,t)$ of the form

$$K(x,t) = R \otimes G(x,t), \tag{98}$$

where R is a symmetric, positive semidefinite matrix of size $n \times n$. The kernel $K(x,t)$ induces an RKHS of functions with values in the Hilbert space $\mathcal{T}^n$. Each function $f \in \mathcal{H}_K$ has the form $f(x) = (f^1(x), \ldots, f^n(x))$, with $f^k \in \mathcal{H}_G$, where $f^k(x)$ represents the output corresponding to the kth task.

In the simplest scenario, $\mathcal{W} = \mathcal{Y} = \mathcal{T}^n$, $C = I$, and the minimization problem (9) thus gives us a vector-valued semi-supervised multi-task learning formulation.

The tasks f^k's are related by the following, which is a generalization of (Evgeniou et al., 2005) (see their formulas (19), (20), (23)) to the nonlinear setting.

Lemma 22 *Let K be defined by (98), where R is strictly positive definite. For $f = (f^1, \ldots, f^n) \in \mathcal{H}_K$, with $f^k \in \mathcal{H}_G$, we have*

$$||f||^2_{\mathcal{H}_K} = \sum_{k,l=1}^n R^{-1}_{kl}\langle f^k, f^l\rangle_{\mathcal{H}_G}. \tag{99}$$

In particular, for

$$R = I_n + \frac{1-\lambda}{n\lambda}\mathbf{1}_n\mathbf{1}_n^T, \quad 0 < \lambda \leq 1, \tag{100}$$

we have

$$||f||^2_{\mathcal{H}_K} = \lambda \sum_{k=1}^{n} ||f^k||^2_{\mathcal{H}_G} + (1-\lambda)\sum_{k=1}^{n} ||f^k - \frac{1}{n}\sum_{l=1}^{n} f^l||^2_{\mathcal{H}_G}. \tag{101}$$

Consider the case when the tasks have different input spaces, such as in the approach to multi-view learning (Kadri et al., 2013), in which each view corresponds to one task and the tasks all share the same output label. Then we have m tasks for m views and we define

$$K(x,t) = G(x,t) \otimes R,$$

as in Section 5, where $G : \mathcal{X} \times \mathcal{X} \to \mathbb{R}^{m\times m}$ is a matrix-valued positive definite kernel, $R \in \mathcal{L}(\mathcal{T})$ is a symmetric, positive operator, so that each task has output in the Hilbert space $\mathcal{T}$. We obtain the formulation of (Kadri et al., 2013) if we set $\mathcal{T} = \mathbb{R}$, so that $R = 1$, duplicate each label $y_i \in \mathbb{R}$ into a vector $(y_i, \ldots, y_i) \in \mathbb{R}^m$, and set $G(x,t)$ to be their covariance-based kernel, with $\gamma_I = 0$, $u = 0$.

We have thus shown how two different scenarios in multi-task learning fall within the scope of our learning formulation. A more in-depth study of our framework in connection with multi-task learning is left to future work.

9. Discussion, Conclusion, and Future Work

We have presented a general learning framework in vector-valued RKHS which encompasses and generalizes many kernel-based learning algorithms in the literature. In particular, we generalize

- the Vector-valued Manifold Regularization framework of (Minh and Sindhwani, 2011), and thus also the vector-valued Regularized Least Square regression formulation of (Micchelli and Pontil, 2005), which are single-view and formulated with the least square loss, to the multi-view setting, formulated with both the least square and multi-class SVM loss functions;
- the Simplex Cone SVM of (Mroueh et al., 2012) , which is supervised, to the multi-view and semi-supervised settings, together with a more general loss function;
- the Laplacian SVM of (Belkin et al., 2006), which is binary and single-view, to the multi-class and multi-view settings.

The generality of the framework and the competitive numerical results we have obtained so far demonstrate that this is a promising venue for further research exploration. Some potential directions for our future work include

- a principled optimization framework for the weight vector $\mathbf{c}$ in the SVM setting, as well as the study of more general forms of the combination operator C;
- numerical experiments with different forms of the matrix-valued kernel K;

- theoretical and empirical analysis for the SVM under different coding schemes other than the simplex coding;
- theoretical analysis of our formulation, in particular when the numbers of labeled and unlabeled data points go to infinity;
- further connections between our framework and Multi-task learning;
- exploration of our framework in combination with feature learning methods, particularly those coming from deep learning;
- further analysis to optimize the framework for large-scale classification problems.

Apart from the numerical experiments on object recognition reported in this paper, practical applications for our learning framework so far include person re-identification in computer vision (Figueira et al., 2013) and user recognition and verification in Skype chats (Roffo et al., 2013). As we further develop and refine the current formulation, we expect to apply it to other applications in computer vision, image processing, and bioinformatics.

Appendices.

The Appendices contain three sections. First, in Appendix A, we give the proofs for all the main mathematical results in the paper. Second, in Appendix B, we provide a natural generalization of our framework to the case the point evaluation operator $f(x)$ is replaced by a general bounded linear operator. Last, in Appendix C, we provide an exact description of Algorithm 1 with the Gaussian or similar kernels in the degenerate case, when the kernel width $\sigma \to \infty$.

Appendix A. Proofs of Main Results

Notation: The definition of $\mathbf{f}$ as given by

$$\mathbf{f} = (f(x_1), \ldots, f(x_{u+l})) \in \mathcal{W}^{u+l}, \tag{102}$$

is adopted because it is also applicable when $\mathcal{W}$ is an infinite-dimensional Hilbert space. For $\mathcal{W} = \mathbb{R}^m$,

$$\mathbf{f} = (f^1(x_1), \ldots, f^m(x_1), \ldots, f^1(x_{u+l}), \ldots, f^m(x_{u+l})).$$

This is different from (Rosenberg et al., 2009), where

$$\mathbf{f} = (f^1(x_1), \ldots, f^1(x_{u+l}), \ldots, f^m(x_1), \ldots, f^m(x_{u+l})).$$

This means that our matrix M is necessarily a permutation of the matrix M in (Rosenberg et al., 2009) when they give rise to the same semi-norm.

A.1 Proof of the Representer Theorem

Since $f(x) = K_x^* f$, the minimization problem (9) is

$$f_{\mathbf{z},\gamma} = \text{argmin}_{f\in\mathcal{H}_K} \frac{1}{l}\sum_{i=1}^{l} V(y_i, CK_{x_i}^* f) + \gamma_A ||f||_{\mathcal{H}_K}^2 + \gamma_I \langle \mathbf{f}, M\mathbf{f}\rangle_{\mathcal{W}^{u+l}}. \tag{103}$$

Consider the operator $E_{C,\mathbf{x}} : \mathcal{H}_K \to \mathcal{Y}^l$, defined by

$$E_{C,\mathbf{x}} f = (CK_{x_1}^* f, \ldots, CK_{x_l}^* f), \tag{104}$$

with $CK_{x_i}^* : \mathcal{H}_K \to \mathcal{Y}$ and $K_{x_i} C^* : \mathcal{Y} \to \mathcal{H}_K$. For $\mathbf{b} = (b_1, \ldots, b_l) \in \mathcal{Y}^l$, we have

$$\langle \mathbf{b}, E_{C,\mathbf{x}} f\rangle_{\mathcal{Y}^l} = \sum_{i=1}^{l} \langle b_i, CK_{x_i}^* f\rangle_{\mathcal{Y}} = \sum_{i=1}^{l} \langle K_{x_i} C^* b_i, f\rangle_{\mathcal{H}_K}. \tag{105}$$

The adjoint operator $E_{C,\mathbf{x}}^* : \mathcal{Y}^l \to \mathcal{H}_K$ is thus

$$E_{C,\mathbf{x}}^* : (b_1, \ldots, b_l) \to \sum_{i=1}^{l} K_{x_i} C^* b_i. \tag{106}$$

The operator $E_{C,\mathbf{x}}^* E_{C,\mathbf{x}} : \mathcal{H}_K \to \mathcal{H}_K$ is then

$$E_{C,\mathbf{x}}^* E_{C,\mathbf{x}} f \to \sum_{i=1}^{l} K_{x_i} C^* C K_{x_i}^* f, \tag{107}$$

with $C^*C : \mathcal{W} \to \mathcal{W}$.

Proof of Theorem 2. Denote the right handside of (9) by $I_l(f)$. Then $I_l(f)$ is coercive and strictly convex in f, and thus has a unique minimizer. Let $\mathcal{H}_{K,\mathbf{x}} = \{\sum_{i=1}^{u+l} K_{x_i} w_i : \mathbf{w} \in \mathcal{W}^{u+l}\}$. For $f \in \mathcal{H}_{K,\mathbf{x}}^{\perp}$, the operator $E_{C,\mathbf{x}}$ satisfies

$$\langle \mathbf{b}, E_{C,\mathbf{x}} f\rangle_{\mathcal{Y}^l} = \langle f, \sum_{i=1}^{l} K_{x_i} C^* b_i\rangle_{\mathcal{H}_K} = 0,$$

for all $\mathbf{b} \in \mathcal{Y}^l$, since $C^* b_i \in \mathcal{W}$. Thus

$$E_{C,\mathbf{x}} f = (CK_{x_1}^* f, \ldots, CK_{x_l}^* f) = 0.$$

Similarly, by the reproducing property, the sampling operator $S_{\mathbf{x}}$ satisfies

$$\langle S_{\mathbf{x}} f, \mathbf{w}\rangle_{\mathcal{W}^{u+l}} \quad = \quad \langle f, \sum_{i=1}^{u+l} K_{x_i} w_i\rangle_{\mathcal{H}_K} = 0,$$

for all $\mathbf{w} \in \mathcal{W}^{u+l}$. Thus

$$\mathbf{f} = S_{\mathbf{x}} f = (f(x_1), \ldots, f(x_{u+l})) = 0.$$

For an arbitrary $f \in \mathcal{H}_K$, consider the orthogonal decomposition $f = f_0 + f_1$, with $f_0 \in \mathcal{H}_{K,\mathbf{x}}$, $f_1 \in \mathcal{H}_{K,\mathbf{x}}^{\perp}$. Then, because $||f_0 + f_1||_{\mathcal{H}_K}^2 = ||f_0||_{\mathcal{H}_K}^2 + ||f_1||_{\mathcal{H}_K}^2$, the result just obtained shows that

$$I_l(f) = I_l(f_0 + f_1) \geq I_l(f_0)$$

with equality if and only if $||f_1||_{\mathcal{H}_K} = 0$, that is $f_1 = 0$. Thus the minimizer of (9) must lie in $\mathcal{H}_{K,\mathbf{x}}$. ■

A.2 Proofs for the Least Square Case

We have for the least square case:

$$f_{\mathbf{z},\gamma} = \text{argmin}_{f\in\mathcal{H}_K} \frac{1}{l}\sum_{i=1}^{l} ||y_i - CK_{x_i}^* f||_{\mathcal{Y}}^2 + \gamma_A ||f||_{\mathcal{H}_K}^2 + \gamma_I \langle \mathbf{f}, M\mathbf{f}\rangle_{\mathcal{W}^{u+l}}. \tag{108}$$

With the operator $E_{C,\mathbf{x}}$, (108) is transformed into the minimization problem

$$f_{\mathbf{z},\gamma} = \text{argmin}_{f\in\mathcal{H}_K} \frac{1}{l}||E_{C,\mathbf{x}} f - \mathbf{y}||_{\mathcal{Y}^l}^2 + \gamma_A ||f||_{\mathcal{H}_K}^2 + \gamma_I \langle \mathbf{f}, M\mathbf{f}\rangle_{\mathcal{W}^{u+l}}. \tag{109}$$

Proof of Theorem 3. By the Representer Theorem, (10) has a unique solution. Differentiating (109) and setting the derivative to zero gives

$$(E_{C,\mathbf{x}}^* E_{C,\mathbf{x}} + l\gamma_A I + l\gamma_I S_{\mathbf{x},u+l}^* M S_{\mathbf{x},u+l}) f_{\mathbf{z},\gamma} = E_{C,\mathbf{x}}^* \mathbf{y}.$$

By definition of the operators $E_{C,\mathbf{x}}$ and $S_{\mathbf{x}}$, this is

$$\sum_{i=1}^{l} K_{x_i} C^* C K_{x_i}^* f_{\mathbf{z},\gamma} + l\gamma_A f_{\mathbf{z},\gamma} + l\gamma_I \sum_{i=1}^{u+l} K_{x_i} (M\mathbf{f}_{\mathbf{z},\gamma})_i = \sum_{i=1}^{l} K_{x_i} C^* y_i,$$

which we rewrite as

$$f_{\mathbf{z},\gamma} = -\frac{\gamma_I}{\gamma_A}\sum_{i=1}^{u+l} K_{x_i} (M\mathbf{f}_{\mathbf{z},\gamma})_i + \sum_{i=1}^{l} K_{x_i} \frac{C^* y_i - C^* C K_{x_i}^* f_{\mathbf{z},\gamma}}{l\gamma_A}.$$

This shows that there are vectors a_i's in $\mathcal{W}$ such that

$$f_{\mathbf{z},\gamma} = \sum_{i=1}^{u+l} K_{x_i} a_i.$$

We have $f_{\mathbf{z},\gamma}(x_i) = \sum_{j=1}^{u+l} K(x_i, x_j) a_j$, and

$$(M\mathbf{f}_{\mathbf{z},\gamma})_i = \sum_{k=1}^{u+l} M_{ik} \sum_{j=1}^{u+l} K(x_k, x_j) a_j = \sum_{j,k=1}^{u+l} M_{ik} K(x_k, x_j) a_j.$$

Also $K^*_{x_i} f_{\mathbf{z},\gamma} = f_{\mathbf{z},\gamma}(x_i) = \sum_{j=1}^{u+l} K(x_i, x_j) a_j$. Thus for $1 \leq i \leq l$:

$$a_i = -\frac{\gamma_I}{\gamma_A} \sum_{j,k=1}^{u+l} M_{ik} K(x_k, x_j) a_j + \frac{C^* y_i - C^* C(\sum_{j=1}^{u+l} K(x_i, x_j) a_j)}{l \gamma_A},$$

which gives the formula

$$l\gamma_I \sum_{j,k=1}^{u+l} M_{ik} K(x_k, x_j) a_j + C^* C(\sum_{j=1}^{u+l} K(x_i, x_j) a_j) + l\gamma_A a_i = C^* y_i.$$

Similarly, for $l+1 \leq i \leq u+l$,

$$a_i = -\frac{\gamma_I}{\gamma_A} \sum_{j,k=1}^{u+l} M_{ik} K(x_k, x_j) a_j,$$

which is equivalent to

$$\gamma_I \sum_{j,k=1}^{u+l} M_{ik} K(x_k, x_j) a_j + \gamma_A a_i = 0.$$

This completes the proof. ■

Proof (first proof) of Theorem 4. This is straightforward to obtain from Theorem 3 using the operator-valued matrix formulation described in the main paper. ■

In the following, we give a second proof of Theorem 4, which is based entirely on operator-theoretic notations. The proof technique should be of interest in its own right.

Proof (second proof) of Theorem 4. By the Representer Theorem, (10) has a unique solution. Differentiating (109) and setting the derivative to zero gives

$$(E^*_{C,\mathbf{x}} E_{C,\mathbf{x}} + l\gamma_A I + l\gamma_I S^*_{\mathbf{x},u+l} M S_{\mathbf{x},u+l}) f_{\mathbf{z},\gamma} = E^*_{C,\mathbf{x}} \mathbf{y}. \tag{110}$$

For $\gamma_A > 0, \gamma_I \geq 0$, the operator

$$E^*_{C,\mathbf{x}} E_{C,\mathbf{x}} + l\gamma_A I + l\gamma_I S^*_{\mathbf{x},u+l} M S_{\mathbf{x},u+l} \tag{111}$$

is clearly symmetric and strictly positive, so that the unique solution $f_{\mathbf{z},\gamma}$ is given by

$$f_{\mathbf{z},\gamma} = (E^*_{C,\mathbf{x}} E_{C,\mathbf{x}} + l\gamma_A I + l\gamma_I S^*_{\mathbf{x},u+l} M S_{\mathbf{x},u+l})^{-1} E^*_{C,\mathbf{x}} \mathbf{y}.$$

Recall the definitions of the operators $S_{\mathbf{x},u+l} : \mathcal{H}_K \to \mathcal{W}^{u+l}$ and $S^*_{\mathbf{x},u+l} : \mathcal{W}^{u+l} \to \mathcal{H}_K$:

$$S_{\mathbf{x},u+l} f = (K^*_{x_i} f)_{i=1}^{u+l}, \quad S^*_{\mathbf{x},u+l} \mathbf{b} = \sum_{i=1}^{u+l} K_{x_i} b_i$$

with the operator $S_{\mathbf{x},u+l} S^*_{\mathbf{x},u+l} : \mathcal{W}^{u+l} \to \mathcal{W}^{u+l}$ given by

$$S_{\mathbf{x},u+l} S^*_{\mathbf{x},u+l} \mathbf{b} = \left(K^*_{x_i} \left(\sum_{j=1}^{u+l} K_{x_j} b_j \right) \right)_{i=1}^{u+l} = \left(\sum_{j=1}^{u+l} K(x_i, x_j) b_j \right)_{i=1}^{u+l} = K[\mathbf{x}]\mathbf{b},$$

so that

$$S_{\mathbf{x},u+l} S^*_{\mathbf{x},u+l} = K[\mathbf{x}].$$

The operator $E_{C,\mathbf{x}} : \mathcal{H}_K \to \mathcal{Y}^l$ is

$$E_{C,\mathbf{x}} f = (C K^*_{x_i} f)_{i=1}^l = (I^T_{(u+l)\times l} \otimes C) S_{\mathbf{x},u+l} f,$$

so that

$$E_{C,\mathbf{x}} = (I^T_{(u+l)\times l} \otimes C) S_{\mathbf{x},u+l}, \tag{112}$$

and the operator $E^*_{C,\mathbf{x}} : \mathcal{Y}^l \to \mathcal{H}_K$ is

$$E^*_{C,\mathbf{x}} = S^*_{\mathbf{x},u+l} (I_{(u+l)\times l} \otimes C^*). \tag{113}$$

As operators, $I_{(u+l)\times l} \otimes C^* : \mathcal{Y}^l \to \mathcal{W}^{u+l}$ and $I^T_{(u+l)\times l} \otimes C : \mathcal{W}^{u+l} \to \mathcal{Y}^l$. The operator $E^*_{C,\mathbf{x}} E_{C,\mathbf{x}} : \mathcal{H}_K \to \mathcal{H}_K$ is then given by

$$E^*_{C,\mathbf{x}} E_{C,\mathbf{x}} = S^*_{\mathbf{x},u+l} (J^{u+l}_l \otimes C^* C) S_{\mathbf{x},u+l} : \mathcal{H}_K \to \mathcal{H}_K, \tag{114}$$

where $J^{u+l}_l = I_{(u+l)\times l} I^T_{(u+l)\times l}$ is the $(u+l) \times (u+l)$ diagonal matrix, with the first l entries on the main diagonal being 1, and the rest 0. As an operator, $J^{u+l}_l \otimes C^* C : \mathcal{W}^{u+l} \to \mathcal{W}^{u+l}$. The operator $E_{C,\mathbf{x}} E^*_{C,\mathbf{x}} : \mathcal{W}^{u+l} \to \mathcal{W}^{u+l}$ is given by

$$E_{C,\mathbf{x}} E^*_{C,\mathbf{x}} = (I^T_{(u+l)\times l} \otimes C) S_{\mathbf{x},u+l} S^*_{\mathbf{x},u+l} (I_{(u+l)\times l} \otimes C^*) = (I^T_{(u+l)\times l} \otimes C) K[\mathbf{x}] (I_{(u+l)\times l} \otimes C^*). \tag{115}$$

Equation (110) becomes

$$\left[S^*_{\mathbf{x},u+l} (J^{u+l}_l \otimes C^* C + l\gamma_I M) S_{\mathbf{x},u+l} + l\gamma_A I \right] f_{\mathbf{z},\gamma} = S^*_{\mathbf{x},u+l} (I_{(u+l)\times l} \otimes C^*) \mathbf{y}, \tag{116}$$

which gives

$$f_{\mathbf{z},\gamma} = S^*_{\mathbf{x},u+l} \left[\frac{-(J^{u+l}_l \otimes C^* C + l\gamma_I M) S_{\mathbf{x},u+l} f_{\mathbf{z},\gamma} + (I_{(u+l)\times l} \otimes C^*) \mathbf{y}}{l\gamma_A} \right] \tag{117}$$

$$= S^*_{\mathbf{x},u+l} \mathbf{a}, \tag{118}$$

where $\mathbf{a} = (a_i)_{i=1}^{u+l} \in \mathcal{W}^{u+l}$ is

$$\mathbf{a} = \frac{-(J^{u+l}_l \otimes C^* C + l\gamma_I M) S_{\mathbf{x},u+l} f_{\mathbf{z},\gamma} + (I_{(u+l)\times l} \otimes C^*) \mathbf{y}}{l\gamma_A}. \tag{119}$$

By definition of $S_{\mathbf{x},u+l}$ and $S^*_{\mathbf{x},u+l}$,

$$S_{\mathbf{x},u+l} f_{\mathbf{z},\gamma} = S_{\mathbf{x},u+l} S^*_{\mathbf{x},u+l} \mathbf{a} = K[\mathbf{x}]\mathbf{a}.$$

Substituting this into equation (119), we obtain

$$\mathbf{a} = \frac{-(J_l^{u+l} \otimes C^*C + l\gamma_I M)K[\mathbf{x}]\mathbf{a} + (I_{(u+l)\times l} \otimes C^*)\mathbf{y}}{l\gamma_A},$$

or equivalently

$$[(J_l^{u+l} \otimes C^*C + l\gamma_I M)K[\mathbf{x}] + l\gamma_A I_{\mathcal{W}^{u+l}}]\mathbf{a} = (I_{(u+l)\times l} \otimes C^*)\mathbf{y}. \tag{120}$$

The operator-valued matrix on the left hand side,

$$(J_l^{u+l} \otimes C^*C + l\gamma_I M)K[\mathbf{x}] + l\gamma_A I_{\mathcal{W}^{u+l}} : \mathcal{W}^{u+l} \to \mathcal{W}^{u+l},$$

is invertible by Lemma 25, with a bounded inverse. Thus the above system of linear equations always has a unique solution

$$\mathbf{a} = [(J_l^{u+l} \otimes C^*C + l\gamma_I M)K[\mathbf{x}] + l\gamma_A I_{\mathcal{W}^{u+l}}]^{-1}(I_{(u+l)\times l} \otimes C^*)\mathbf{y}.$$

This completes the proof of the theorem. ■

Remark 23 (Uniqueness of a) . *While the solution $\mathbf{f}_{\mathbf{z},\gamma} = \sum_{i=1}^{u+l} K_{x_i} a_i$ in Theorem 2 is always unique, the expansion coefficient vectors a_i's for $f_{\mathbf{z},\gamma}$ need not be unique. In fact, we have*

$$||f_{\mathbf{z},\gamma}||^2_{\mathcal{H}_K} = \langle S^*_{\mathbf{x},u+l}\mathbf{a}, S^*_{\mathbf{x},u+l}\mathbf{a}\rangle_{\mathcal{H}_K} = \langle \mathbf{a}, S_{\mathbf{x},u+l}S^*_{\mathbf{x},u+l}\mathbf{a}\rangle_{\mathcal{W}^{u+l}} = \langle \mathbf{a}, K[\mathbf{x}]\mathbf{a}\rangle_{\mathcal{W}^{u+l}}.$$

By the reproducing property,

$$f_{\mathbf{z},\gamma} = 0 \Longleftrightarrow ||f_{\mathbf{z},\gamma}||_{\mathcal{H}_K} = 0 \Longleftrightarrow \mathbf{a} = 0 \text{ or } \mathbf{a} \in \text{null}(K[\mathbf{x}]).$$

Thus $\mathbf{a}$ is unique if and only if $K[\mathbf{x}]$ is invertible, or equivalently, $K[\mathbf{x}]$ is of full rank. For us, our choice for $\mathbf{a}$ is always the unique solution of the system of linear equations (13) in Theorem 4 (see also Remark 24 below).

Remark 24 *The coefficient matrix of the system of linear equations (13) in Theorem 4 has the form $(\gamma I + AB)$, where A, B are two symmetric, positive operators on a Hilbert space $\mathcal{H}$. We show in Lemma 25 that the operator $(\gamma I + AB)$ is always invertible for $\gamma > 0$ and that the inverse operator $(\gamma I + AB)^{-1}$ is bounded, so that the system (13) is always guaranteed a unique solution, as we claim in Theorem 4. Furthermore, the eigenvalues of AB, when they exist, are always non-negative, as we show in Lemma 26. This gives another proof of the invertibility of $(\gamma I + AB)$ when $\mathcal{H}$ is finite-dimensional, in Corollary 27. This invertibility is also necessary for the proofs of Theorems 6 and 7 in the SVM case.*

Lemma 25 *Let $\mathcal{H}$ be a Hilbert space and $A, B : \mathcal{H} \to \mathcal{H}$ be two bounded, symmetric, positive operators. Then the operator $(\gamma I + AB)$ is invertible for any $\gamma > 0$ and the inverse $(\gamma I + AB)^{-1}$ is bounded.*

Proof Let $T = \gamma I + AB$. We need to show that T is 1-to-1 and onto. First, to show that T is 1-to-1, suppose that

$$Tx = \gamma x + ABx = 0.$$

This implies that

$$BTx = \gamma Bx + BABx = 0 \Longrightarrow \langle x, BTx\rangle = \gamma\langle x, Bx\rangle + \langle x, BABx\rangle = 0.$$

By the symmetry and positivity of A and B, this is equivalent to

$$\gamma||B^{1/2}x||^2 + ||A^{1/2}Bx||^2 = 0.$$

This is possible if and only if $x = 0$ or $B^{1/2}x = 0$. If $B^{1/2}x = 0$, $x \neq 0$, then $Tx = \gamma x \neq 0$. Thus

$$Tx = 0 \Longleftrightarrow x = 0.$$

This shows that T is 1-to-1. Similar arguments show that its adjoint $T^* = \gamma I + BA$ is 1-to-1, so that

$$\overline{\text{range}(T)} = (\ker(T^*))^\perp = \{0\}^\perp = \mathcal{H}.$$

It thus remains for us to show that range(T) is closed. Let $\{y_n\}_{n\in\mathbb{N}}$ be a Cauchy sequence in range(T), with $y_n = Tx_n$ for $x_n \in \mathcal{H}$. Then we have

$$By_n = \gamma Bx_n + BABx_n \Longrightarrow \langle x_n, By_n\rangle = \gamma\langle x_n, Bx_n\rangle + \langle x_n, BABx_n\rangle.$$

By the symmetry and positivity of A and B, this is

$$\langle x_n, By_n\rangle = \gamma||B^{1/2}x_n||^2 + ||A^{1/2}Bx_n||^2.$$

It follows that

$$\gamma||B^{1/2}x_n||^2 \leq \langle x_n, By_n\rangle \leq ||B^{1/2}x_n||\ ||B^{1/2}y_n||,$$

so that

$$\gamma||B^{1/2}x_n|| \leq ||B^{1/2}y_n|| \leq ||B^{1/2}||\ ||y_n||.$$

From the assumption $y_n = Tx_n = \gamma x_n + ABx_n$, we have

$$\gamma x_n = y_n - ABx_n.$$

This implies that

$$\gamma||x_n|| \leq ||y_n|| + ||AB^{1/2}||\ ||B^{1/2}x_n|| \leq ||y_n|| + \frac{||AB^{1/2}||\ ||B^{1/2}||}{\gamma}\ ||y_n||,$$

which simplifies to

$$||x_n|| \leq \frac{1}{\gamma}\left(1 + \frac{||AB^{1/2}||\ ||B^{1/2}||}{\gamma}\right)||y_n||.$$

Since T is linear, $y_{n+1} - y_n = T(x_{n+1} - x_n)$ and thus

$$||x_{n+1} - x_n|| \leq \frac{1}{\gamma}\left(1 + \frac{||AB^{1/2}||\,||B^{1/2}||}{\gamma}\right)||y_{n+1} - y_n||.$$

Thus if $\{y_n\}_{n\in\mathbb{N}}$ is a Cauchy sequence in $\mathcal{H}$, then $\{x_n\}_{n\in\mathbb{N}}$ is also a Cauchy sequence in $\mathcal{H}$. Let $x_0 = \lim_{n\to\infty} x_n$ and $y_0 = Tx_0$, then clearly $\lim_{n\to\infty} y_n = y_0$. This shows that range$(T)$ is closed, as we claimed, so that range(T) = range(T) $= \mathcal{H}$, showing that T is onto. This completes the proof. ■

Lemma 26 *Let $\mathcal{H}$ be a Hilbert space. Let A and B be two symmetric, positive, bounded operators in $\mathcal{L}(\mathcal{H})$. Then all eigenvalues of the product operator AB, if they exist, are real and non-negative.*

Proof Let λ be an eigenvalue of AB, corresponding to eigenvector x. Then

$$ABx = \lambda x \Longrightarrow BABx = \lambda Bx \Longrightarrow \langle x, BABx\rangle = \lambda\langle x, Bx\rangle.$$

Since both A and B are symmetric, positive, the operator BAB is symmetric, positive, and therefore $\langle x, BABx\rangle \geq 0$. Since B is symmetric, positive, we have $\langle x, Bx\rangle \geq 0$, with $\langle x, Bx\rangle = ||B^{1/2}x||^2 = 0$ if and only if $x \in$ null$(B^{1/2})$.

If $x \in$ null$(B^{1/2})$, then $ABx = 0$, so that $\lambda = 0$.

If $x \notin$ null$(B^{1/2})$, then $\langle x, Bx\rangle > 0$, and

$$\lambda = \frac{\langle x, BABx\rangle}{\langle x, Bx\rangle} \geq 0.$$

Consequently, we always have $\lambda \geq 0$. ■

Corollary 27 *Let A and B be two symmetric positive semi-definite matrices. Then the matrix $(\gamma I + AB)$ is invertible for any $\gamma > 0$.*

Proof The eigenvalues of $(\gamma I + AB)$ have the form $\gamma + \lambda$, where λ is an eigenvalue of AB and satisfies $\lambda \geq 0$ by Lemma 26. Thus all eigenvalues of $(\gamma I + AB)$ are strictly positive, with magnitude at least γ. It follows that $\det(\gamma I + AB) > 0$ and therefore $(\gamma I + AB)$ is invertible. ■

Proof of Theorem 10. Recall some properties of the Kronecker tensor product:

$$(A \otimes B)(C \otimes D) = AC \otimes BD, \tag{121}$$

$$(A \otimes B)^T = A^T \otimes B^T, \tag{122}$$

and

$$\text{vec}(ABC) = (C^T \otimes A)\text{vec}(B). \tag{123}$$

Thus the equation

$$AXB = C \tag{124}$$

is equivalent to

$$(B^T \otimes A)\text{vec}(X) = \text{vec}(C). \tag{125}$$

In our context,$\gamma_I M = \gamma_B M_B + \gamma_W M_W$, which is

$$\gamma_I M = \gamma_B I_{u+l} \otimes M_m \otimes I_{\mathcal{Y}} + \gamma_W L \otimes I_{\mathcal{Y}}.$$

Using the properties stated in 121 and 122, we have for $C = \mathbf{c}^T \otimes I_{\mathcal{Y}}$,

$$C^*C = (\mathbf{c} \otimes I_{\mathcal{Y}})(\mathbf{c}^T \otimes I_{\mathcal{Y}}) = (\mathbf{c}\mathbf{c}^T \otimes I_{\mathcal{Y}}). \tag{126}$$

So then

$$\mathbf{C}^*\mathbf{C} = (I_{u+l} \otimes \mathbf{c}\mathbf{c}^T \otimes I_{\mathcal{Y}}). \tag{127}$$

$$J_l^{\mathcal{W},u+l} = J_l^{u+l} \otimes I_m \otimes I_{\mathcal{Y}}. \tag{128}$$

It follows that

$$\mathbf{C}^*\mathbf{C}J_l^{\mathcal{W},u+l} = (J_l^{u+l} \otimes \mathbf{c}\mathbf{c}^T \otimes I_{\mathcal{Y}}). \tag{129}$$

Then with

$$K[\mathbf{x}] = G[\mathbf{x}] \otimes R,$$

we have

$$\mathbf{C}^*\mathbf{C}J_l^{\mathcal{W},u+l}K[\mathbf{x}] = (J_l^{u+l} \otimes \mathbf{c}\mathbf{c}^T)G[\mathbf{x}] \otimes R.$$
$$\gamma_I MK[\mathbf{x}] = (\gamma_B I_{u+l} \otimes M_m + \gamma_W L)G[\mathbf{x}] \otimes R.$$

Consider again now the system

$$(\mathbf{C}^*\mathbf{C}J_l^{\mathcal{W},u+l}K[\mathbf{x}] + l\gamma_I MK[\mathbf{x}] + l\gamma_A I)\mathbf{a} = \mathbf{C}^*\mathbf{y}.$$

The left hand side is

$$(B \otimes R + l\gamma_A I_{(u+l)m} \otimes I_{\mathcal{Y}})\text{vec}(A^T),$$

where $\mathbf{a} = \text{vec}(A^T)$, A is of size $(u+l)m \times \dim(\mathcal{Y})$, and

$$B = \left((J_l^{u+l} \otimes \mathbf{c}\mathbf{c}^T) + l\gamma_B(I_{u+l} \otimes M_m) + l\gamma_W L\right)G[\mathbf{x}].$$

Then we have the linear system

$$(B \otimes R + l\gamma_A I_{(u+l)m} \otimes I_{\mathcal{Y}})\text{vec}(A^T) = \text{vec}(Y_C^T),$$

which, by properties (124) and (125), is equivalent to

$$RA^TB^T + l\gamma_A A^T = Y_C^T \Longleftrightarrow BAR + l\gamma_A A = Y_C.$$

This completes the proof. ■

Remark 28 *The* vec *operator is implemented by the flattening operation* (:) *in MATLAB. To compute the matrix* Y_C^T*, note that by definition*

$$\text{vec}(Y_C^T) = \mathbf{C}^*\mathbf{y} = (I_{(u+l)\times l} \otimes C^*)\mathbf{y} = \text{vec}(C^* Y_l I_{(u+l)\times l}^T) = \text{vec}(C^* Y_{u+l}),$$

where Y_l *is the* $\dim(\mathcal{Y}) \times l$ *matrix, whose* i*th column is* y_i*,* $1 \leq i \leq l$*, that is*

$$Y_l = [y_1, \ldots, y_l], \quad \textit{with} \quad \mathbf{y} = \text{vec}(Y_l),$$

and Y_{u+l} *is the* $\dim(\mathcal{Y}) \times (u+l)$ *matrix with the* i*th column being* y_i*,* $1 \leq i \leq l$*, with the remaining* u *columns being zero, that is*

$$Y_{u+l} = [y_1, \ldots, y_l, 0, \ldots, 0] = [Y_l, 0, \ldots, 0] = Y_l I_{(u+l)\times l}^T.$$

Note that Y_C^T *and* $C^* Y_{u+l}$ *in general are not the same:* Y_C^T *is of size* $\dim(\mathcal{Y}) \times (u+l)m$*, whereas* $C^* Y_{u+l}$ *is of size* $\dim(\mathcal{Y})m \times (u+l)$*.*

Proof of Corollary 19 For $\gamma_I = 0$, $u = 0$, equation (110) becomes

$$(E_{C,\mathbf{x}}^* E_{C,\mathbf{x}} + l\gamma_A I) f_{\mathbf{z},\gamma} = E_{C,\mathbf{x}}^* \mathbf{y},$$

which is equivalent to

$$f_{\mathbf{z},\gamma} = (E_{C,\mathbf{x}}^* E_{C,\mathbf{x}} + l\gamma_A I_{\mathcal{H}_K})^{-1} E_{C,\mathbf{x}}^* \mathbf{y} = E_{C,\mathbf{x}}^* (E_{C,\mathbf{x}} E_{C,\mathbf{x}}^* + l\gamma_A I_{\mathcal{Y}^l})^{-1} \mathbf{y},$$

that is

$$f_{\mathbf{z},\gamma} = S_{\mathbf{x},l}^* (I_l \otimes C^*) \left[(I_l \otimes C) K[\mathbf{x}] (I_l \otimes C^*) + l\gamma_A I_{\mathcal{Y}^l} \right]^{-1} \mathbf{y}.$$

Thus in this case $f_{\mathbf{z},\gamma} = S_{\mathbf{x},l}^* \mathbf{a}$, where $\mathbf{a} = (a_i)_{i=1}^l$ is given by

$$\mathbf{a} = (I_l \otimes C^*) \left[(I_l \otimes C) K[\mathbf{x}] (I_l \otimes C^*) + l\gamma_A I_{\mathcal{Y}^l} \right]^{-1} \mathbf{y}.$$

In this expression, the operator $[(I_l \otimes C) K[\mathbf{x}] (I_l \otimes C^*) + l\gamma_A] : \mathcal{Y}^l \to \mathcal{Y}^l$ is clearly symmetric and strictly positive, hence is invertible. For $C = \mathbf{c}^T \otimes I_{\mathcal{Y}}$ and $K[\mathbf{x}] = G[\mathbf{x}] \otimes R$, we have

$$\mathbf{a} = (I_l \otimes \mathbf{c} \otimes I_{\mathcal{Y}}) \left[(I_l \otimes \mathbf{c}^T) G[\mathbf{x}] (I_l \otimes \mathbf{c}) \otimes R + l\gamma_A I_{\mathcal{Y}^l} \right]^{-1} \mathbf{y}.$$

With $R = I_{\mathcal{Y}}$, this becomes

$$\mathbf{a} = \{ (I_l \otimes \mathbf{c}) \left[(I_l \otimes \mathbf{c}^T) G[\mathbf{x}] (I_l \otimes \mathbf{c}) + l\gamma_A I_l \right]^{-1} \otimes I_{\mathcal{Y}} \} \mathbf{y}.$$

For any $v \in \mathcal{X}$,

$$f_{\mathbf{z},\gamma}(v) = K[v, \mathbf{x}]\mathbf{a} = \{ G[v, \mathbf{x}] (I_l \otimes \mathbf{c}) \left[(I_l \otimes \mathbf{c}^T) G[\mathbf{x}] (I_l \otimes \mathbf{c}) + l\gamma_A I_l \right]^{-1} \otimes I_{\mathcal{Y}} \} \mathbf{y}.$$

$$C f_{\mathbf{z},\gamma}(v) = \{ \mathbf{c}^T G[v, \mathbf{x}] (I_l \otimes \mathbf{c}) \left[(I_l \otimes \mathbf{c}^T) G[\mathbf{x}] (I_l \otimes \mathbf{c}) + l\gamma_A I_l \right]^{-1} \otimes I_{\mathcal{Y}} \} \mathbf{y}.$$

With $G[\mathbf{x}] = \sum_{i=1}^m k^i[\mathbf{x}] \otimes \mathbf{e}_i \mathbf{e}_i^T$, we have

$$(I_l \otimes \mathbf{c}^T) G[\mathbf{x}] (I_l \otimes \mathbf{c}) = (I_l \otimes \mathbf{c}^T) (\sum_{i=1}^m k^i[\mathbf{x}] \otimes \mathbf{e}_i \mathbf{e}_i^T) (I_l \otimes \mathbf{c}) = \sum_{i=1}^m c_i^2 k^i[\mathbf{x}],$$

$$\mathbf{c}^T G[v, \mathbf{x}] (I_l \otimes \mathbf{c}) = \mathbf{c}^T (\sum_{i=1}^m k^i[v, \mathbf{x}] \otimes \mathbf{e}_i \mathbf{e}_i^T) (I_l \otimes \mathbf{c}) = \sum_{i=1}^m c_i^2 k^i[v, \mathbf{x}].$$

With these, we obtain

$$C f_{\mathbf{z},\gamma}(v) = \left\{ \sum_{i=1}^m c_i^2 k^i[v, \mathbf{x}] \left(\sum_{i=1}^m c_i^2 k^i[\mathbf{x}] + l\gamma_A I_l \right)^{-1} \otimes I_{\mathcal{Y}} \right\} \mathbf{y}.$$

In particular, for $\mathcal{Y} = \mathbb{R}$, we obtain

$$C f_{\mathbf{z},\gamma}(v) = \left\{ \sum_{i=1}^m c_i^2 k^i[v, \mathbf{x}] \left(\sum_{i=1}^m c_i^2 k^i[\mathbf{x}] + l\gamma_A I_l \right)^{-1} \right\} \mathbf{y}.$$

This completes the proof. ■

Proof of Lemma 22 Consider the function $f \in \mathcal{H}_K$ of the form

$$f(x) = \sum_{i=1}^m K(x, x_i) a_i = \sum_{i=1}^m [R \otimes G(x, x_i)] a_i \in \mathcal{T}^n,$$

where $a_i \in \mathcal{T}^n$. Let A_i be the (potentially infinite) matrix of size $\dim(\mathcal{T}) \times n$ such that $a_i = \text{vec}(A_i)$. Then

$$f(x) = \sum_{i=1}^m [R \otimes G(x, x_i)] \text{vec}(A_i) = \sum_{i=1}^m \text{vec}(G(x, x_i) A_i R),$$

with norm

$$\begin{aligned} ||f||_{\mathcal{H}_K}^2 &= \sum_{i,j=1}^m \langle a_i, K(x_i, x_j) a_j \rangle_{\mathcal{T}^n} = \sum_{i,j=1}^m \langle a_i, (R \otimes G(x_i, x_j)) a_j \rangle_{\mathcal{T}^n} \\ &= \sum_{i,j=1}^m \langle \text{vec}(A_i), \text{vec}(G(x_i, x_j) A_j R) \rangle_{\mathcal{T}^n} = \sum_{i,j=1}^m \text{tr}(A_i^T G(x_i, x_j) A_j R). \end{aligned}$$

Each component f^k, $1 \leq k \leq n$, has the form

$$f^k(x) = \sum_{i=1}^m G(x, x_i) A_i R_{:,k} \in \mathcal{H}_G,$$

where $R_{:,k}$ is the kth column of R, with norm

$$||f^k||_{\mathcal{H}_G}^2 = \sum_{i,j=1}^m \langle A_i R_{:,k}, G(x_i, x_j) A_j R_{:,k} \rangle_{\mathcal{T}} = \sum_{i,j=1}^m R_{:,k}^T A_i^T G(x_i, x_j) A_j R_{:,k}.$$

For

$$f^l(x) = \sum_{i=1}^m G(x, x_i) A_i R_{:,l},$$

we have

$$\langle f^k, f^l\rangle_{\mathcal{H}_G} = \sum_{i,j=1}^{m} R^T_{:,k} A_i^T G(x_i, x_j) A_j R_{:,l}.$$

Let B be a symmetric, positive definite matrix of size $n \times n$. Consider the form

$$\begin{aligned}\sum_{k,l=1}^{n} B_{kl}\langle f^k, f^l\rangle_{\mathcal{H}_G} &= \sum_{k,l=1}^{n}\sum_{i,j=1}^{m} B_{kl} R^T_{:,k} A_i^T G(x_i, x_j) A_j R_{:,l} \\ &= \sum_{i,j=1}^{m}\sum_{k,l=1}^{n} B_{kl} R^T_{:,k} A_i^T G(x_i, x_j) A_j R_{:,l} = \sum_{i,j=1}^{m} \mathrm{tr}(BR^T A_i^T G(x_i, x_j) A_j R) \\ &= \sum_{i,j=1}^{m} \mathrm{tr}(BRA_i^T G(x_i, x_j) A_j R), \quad \text{since } R \text{ is symmetric.}\end{aligned}$$

It follows that for R strictly positive definite and $B = R^{-1}$, we have

$$||f||^2_{\mathcal{H}_K} = \sum_{k,l=1}^{n} B_{kl}\langle f^k, f^l\rangle_{\mathcal{H}_G}.$$

In particular, for $0 < \lambda \leq 1$ and

$$R = I_n + \frac{1-\lambda}{n\lambda}\mathbf{1}_n\mathbf{1}_n^T,$$

we have

$$B = R^{-1} = I_n - \frac{1-\lambda}{n}\mathbf{1}_n\mathbf{1}_n^T.$$

Then

$$\begin{aligned}||f||^2_{\mathcal{H}_K} &= \sum_{k,l=1}^{n} B_{kl}\langle f^k, f^l\rangle_{\mathcal{H}_G} = \sum_{k=1}^{n} ||f^k||^2_{\mathcal{H}_G} - \frac{1-\lambda}{n}\sum_{k,l=1}^{n}\langle f^k, f^l\rangle_{\mathcal{H}_G} \\ &= \lambda\sum_{k=1}^{n} ||f^k||^2_{\mathcal{H}_G} + (1-\lambda)\sum_{k=1}^{n}||f^k - \frac{1}{n}\sum_{l=1}^{n} f^l||^2_{\mathcal{H}_G}.\end{aligned}$$

This result then extends to all $f \in \mathcal{H}_K$ by a limiting argument. This completes the proof. ■

A.3 Proofs for the SVM case

Recall the optimization problem that we aim to solve

$$f_{\mathbf{z},\gamma} = \mathrm{argmin}_{f\in\mathcal{H}_K, \xi_{ki}\in\mathbb{R}} \frac{1}{l}\sum_{i=1}^{l}\sum_{k=1,k\neq y_i}^{P} \xi_{ki} + \gamma_A||f||^2_{\mathcal{H}_K} + \gamma_I\langle \mathbf{f}, M\mathbf{f}\rangle_{\mathcal{W}^{u+l}},$$

subject to the constraints

$$\begin{aligned}&\xi_{ki} \geq -\langle s_k, s_{y_i}\rangle_{\mathcal{Y}} + \langle s_k, Cf(x_i)\rangle_{\mathcal{Y}}, \quad 1 \leq i \leq l, k \neq y_i, \\ &\xi_{ki} \geq 0, \quad 1 \leq i \leq l, k \neq y_i.\end{aligned}$$

Proof of Theorem 6 The Lagrangian is

$$\begin{aligned}L(f, \xi, \alpha, \beta) = &\frac{1}{l}\sum_{i=1}^{l}\sum_{k\neq y_i}\xi_{ki} + \gamma_A||f||^2_{\mathcal{H}_K} + \gamma_I\langle \mathbf{f}, M\mathbf{f}\rangle_{\mathcal{W}^{u+l}} \\ &- \sum_{i=1}^{l}\sum_{k\neq y_i}\alpha_{ki}\left(\xi_{ki} - [-\langle s_k, s_{y_i}\rangle_{\mathcal{Y}} + \langle s_k, Cf(x_i)\rangle_{\mathcal{Y}}]\right) - \sum_{i=1}^{l}\sum_{k\neq y_i}\beta_{ki}\xi_{ki}, \quad (130)\end{aligned}$$

where

$$\alpha_{ki} \geq 0, \beta_{ki} \geq 0, \quad 1 \leq i \leq l, k \neq y_i. \quad (131)$$

By the reproducing property

$$\langle s_k, Cf(x_i)\rangle_{\mathcal{Y}} = \langle C^* s_k, f(x_i)\rangle_{\mathcal{W}} = \langle f, K_{x_i}(C^* s_k)\rangle_{\mathcal{H}_K}. \quad (132)$$

Thus the Lagrangian is

$$\begin{aligned}L(f, \xi, \alpha, \beta) = &\frac{1}{l}\sum_{i=1}^{l}\sum_{k\neq y_i}\xi_{ki} + \gamma_A||f||^2_{\mathcal{H}_K} + \gamma_I\langle \mathbf{f}, M\mathbf{f}\rangle_{\mathcal{W}^{u+l}} \\ &- \sum_{i=1}^{l}\sum_{k\neq y_i}\alpha_{ki}\left(\xi_{ki} - [-\langle s_k, s_{y_i}\rangle_{\mathcal{Y}} + \langle f, K_{x_i}(C^* s_k)\rangle_{\mathcal{H}_K}]\right) - \sum_{i=1}^{l}\sum_{k\neq y_i}\beta_{ki}\xi_{ki}. \quad (133)\end{aligned}$$

Since

$$\langle \mathbf{f}, M\mathbf{f}\rangle_{\mathcal{W}^{u+l}} = \langle S_{\mathbf{x},u+l} f, MS_{\mathbf{x},u+l} f\rangle_{\mathcal{W}^{u+l}} = \langle f, S^*_{\mathbf{x},u+l} MS_{\mathbf{x},u+l} f\rangle_{\mathcal{H}_K}, \quad (134)$$

we have

$$\frac{\langle \mathbf{f}, M\mathbf{f}\rangle_{\mathcal{W}^{u+l}}}{\partial f} = 2S^*_{\mathbf{x},u+l} MS_{\mathbf{x},u+l} f = 2\sum_{i=1}^{u+l} K_{x_i}(M\mathbf{f})_i. \quad (135)$$

Differentiating the Lagrangian with respect to ξ_{ki} and setting to zero, we obtain

$$\frac{\partial L}{\partial \xi_{ki}} = \frac{1}{l} - \alpha_{ki} - \beta_{ki} = 0 \Longleftrightarrow \alpha_{ki} + \beta_{ki} = \frac{1}{l}. \quad (136)$$

Differentiating the Lagrangian with respect to f, we obtain

$$\frac{\partial L}{\partial f} = 2\gamma_A f + 2\gamma_I S^*_{\mathbf{x},u+l} MS_{\mathbf{x},u+l} f + \sum_{i=1}^{l}\sum_{k\neq y_i}\alpha_{ki} K_{x_i}(C^* s_k). \quad (137)$$

Setting this derivative to zero, we obtain

$$f = -\frac{\gamma_I}{\gamma_A}\sum_{i=1}^{u+l} K_{x_i}(M\mathbf{f})_i - \frac{1}{2\gamma_A}\sum_{i=1}^{l}\sum_{k\neq y_i}\alpha_{ki} K_{x_i}(C^* s_k). \quad (138)$$

This means there are vectors $a_i \in \mathcal{W}$, $1 \leq i \leq u+l$, such that

$$f = \sum_{i=1}^{u+l} K_{x_i} a_i.$$

This gives

$$\mathbf{f}_k = f(x_k) = \sum_{j=1}^{u+l} K(x_k, x_j) a_j,$$

so that

$$(M\mathbf{f})_i = \sum_{k=1}^{u+l} M_{ik}\mathbf{f}_k = \sum_{k=1}^{u+l} M_{ik} \sum_{j=1}^{u+l} K(x_k, x_j) a_j = \sum_{j,k=1}^{u+l} M_{ik} K(x_k, x_j) a_j. \tag{139}$$

For $1 \leq i \leq l$,

$$a_i = -\frac{\gamma_I}{\gamma_A} \sum_{j,k=1}^{u+l} M_{ik} K(x_k, x_j) a_j - \frac{1}{2\gamma_A} \sum_{k \neq y_i} \alpha_{ki} (C^* s_k), \tag{140}$$

or equivalently,

$$\gamma_I \sum_{j,k=1}^{u+l} M_{ik} K(x_k, x_j) a_j + \gamma_A a_i = -\frac{1}{2} \sum_{k \neq y_i} \alpha_{ki} (C^* s_k) = -\frac{1}{2} C^* S \alpha_i, \tag{141}$$

since $\alpha_{y_i, i} = 0$. For $l+1 \leq i \leq u+l$,

$$a_i = -\frac{\gamma_I}{\gamma_A} \sum_{j,k=1}^{u+l} M_{ik} K(x_k, x_j) a_j, \tag{142}$$

or equivalently,

$$\gamma_I \sum_{j,k=1}^{u+l} M_{ik} K(x_k, x_j) a_j + \gamma_A a_i = 0. \tag{143}$$

In operator-valued matrix notation, (141) and (143) together can be expressed as

$$(\gamma_I M K[\mathbf{x}] + \gamma_A I)\mathbf{a} = -\frac{1}{2}(I_{(u+l)\times l} \otimes C^* S)\mathrm{vec}(\alpha). \tag{144}$$

By Lemma 25, the operator $(\gamma_I M K[\mathbf{x}] + \gamma_A I) : \mathcal{W}^{u+l} \to \mathcal{W}^{u+l}$ is invertible, with a bounded inverse, so that

$$\mathbf{a} = -\frac{1}{2}(\gamma_I M K[\mathbf{x}] + \gamma_A I)^{-1}(I_{(u+l)\times l} \otimes C^* S)\mathrm{vec}(\alpha). \tag{145}$$

With condition (136), the Lagrangian (133) simplifies to

$$\begin{aligned} L(f, \xi, \alpha, \beta) = {} & \gamma_A ||f||_K^2 + \gamma_I \langle \mathbf{f}, M\mathbf{f} \rangle_{\mathcal{W}^{u+l}} \\ & + \sum_{i=1}^{l} \sum_{k \neq y_i} \alpha_{ki} \left([-\langle s_k, s_{y_i} \rangle_{\mathcal{Y}} + \langle s_k, C f(x_i) \rangle_{\mathcal{Y}}] \right). \end{aligned} \tag{146}$$

From expression (137), we have

$$\frac{\partial L}{\partial f} = 0 \Longleftrightarrow \gamma_A f + \gamma_I S^*_{\mathbf{x}, u+l} M S_{\mathbf{x}, u+l} f = -\frac{1}{2} \sum_{i=1}^{l} \sum_{k \neq y_i} \alpha_{ki} K_{x_i}(C^* s_k). \tag{147}$$

Taking inner product with f on both sides, we get

$$\gamma_A ||f||^2_{\mathcal{H}_K} + \gamma_I \langle \mathbf{f}, M\mathbf{f} \rangle_{\mathcal{W}^{u+l}} = -\frac{1}{2} \sum_{i=1}^{l} \sum_{k \neq y_i} \alpha_{ki} \langle f, K_{x_i}(C^* s_k) \rangle_{\mathcal{H}_K}. \tag{148}$$

With $f = \sum_{j=1}^{u+l} K_{x_j} a_j$, we have

$$\langle f, K_{x_i}(C^* s_k) \rangle_{\mathcal{H}_K} = \sum_{j=1}^{u+l} \langle K(x_i, x_j) a_j, C^* s_k \rangle_{\mathcal{W}}, \tag{149}$$

so that

$$\begin{aligned} \sum_{k \neq y_i} \alpha_{ki} \langle f, K_{x_i}(C^* s_k) \rangle_{\mathcal{H}_K} &= \sum_{j=1}^{u+l} \langle K(x_i, x_j) a_j, \sum_{k \neq y_i} \alpha_{ki} C^* s_k \rangle_{\mathcal{W}} \\ &= \sum_{j=1}^{u+l} \langle K(x_i, x_j) a_j, C^* S \alpha_i \rangle_{\mathcal{W}}. \end{aligned} \tag{150}$$

Combining this with (148), we obtain

$$\begin{aligned} \gamma_A ||f||^2_{\mathcal{H}_K} + \gamma_I \langle \mathbf{f}, M\mathbf{f} \rangle_{\mathcal{W}^{u+l}} &= -\frac{1}{2} \sum_{i=1}^{l} \langle \sum_{j=1}^{u+l} K(x_i, x_j) a_j, C^* S \alpha_i \rangle_{\mathcal{W}} \\ &= -\frac{1}{2} \sum_{i=1}^{l} \langle S^* C \sum_{j=1}^{u+l} K(x_i, x_j) a_j, \alpha_i \rangle_{\mathbb{R}^P}. \end{aligned} \tag{151}$$

In operator-valued matrix notation, this is

$$\gamma_A ||f||^2_{\mathcal{H}_K} + \gamma_I \langle \mathbf{f}, M\mathbf{f} \rangle_{\mathcal{W}^{u+l}} = -\frac{1}{2} \mathrm{vec}(\alpha)^T (I^T_{(u+l)\times l} \otimes S^* C) K[\mathbf{x}]\mathbf{a}. \tag{152}$$

Substituting the expression for $\mathbf{a}$ in (145) into (152), we obtain

$$\begin{aligned} \gamma_A ||f||^2_{\mathcal{H}_K} + \gamma_I \langle \mathbf{f}, M\mathbf{f} \rangle_{\mathcal{W}^{u+l}} = {} & \frac{1}{4} \mathrm{vec}(\alpha)^T (I^T_{(u+l)\times l} \otimes S^* C) K[\mathbf{x}] \\ & \times (\gamma_I M K[\mathbf{x}] + \gamma_A I)^{-1} (I_{(u+l)\times l} \otimes C^* S) \mathrm{vec}(\alpha). \end{aligned} \tag{153}$$

Combining (146), (148), and (153), we obtain the final form of the Lagrangian

$$L(\alpha) = -\sum_{i=1}^{l} \sum_{k \neq y_i} \langle s_k, s_{y_i} \rangle_{\mathcal{Y}} \alpha_{ki} - \frac{1}{4} \mathrm{vec}(\alpha)^T Q[\mathbf{x}, C] \mathrm{vec}(\alpha), \tag{154}$$

where the matrix $Q[\mathbf{x}, C]$ is given by

$$Q[\mathbf{x}, C] = (I^T_{(u+l)\times l} \otimes S^* C) K[\mathbf{x}] (\gamma_I M K[\mathbf{x}] + \gamma_A I)^{-1} (I_{(u+l)\times l} \otimes C^* S). \tag{155}$$

We need to maximize the Lagrangian subject to the constraints

$$0 \leq \alpha_{ki} \leq \frac{1}{l}, \quad 1 \leq i \leq l, k \neq y_i. \tag{156}$$

Since $\alpha_{y_i,i} = 0$, these constraints can be written as

$$0 \leq \alpha_{ki} \leq \frac{1}{l}(1 - \delta_{k,y_i}), \quad 1 \leq i \leq l, 1 \leq k \leq P. \tag{157}$$

Equivalently, under the same constraints, we minimize

$$D(\alpha) = \frac{1}{4}\text{vec}(\alpha)^T Q[\mathbf{x}, C]\text{vec}(\alpha) + \sum_{i=1}^{l}\sum_{k=1}^{P}\langle s_k, s_{y_i}\rangle_{\mathcal{Y}}\alpha_{ki}. \tag{158}$$

When S is the simplex coding, we have $\langle s_k, s_{y_i}\rangle_{\mathcal{Y}} = -\frac{1}{P-1}$ for $k \neq y_i$, and $\alpha_{y_i,i} = 0$, so that

$$\sum_{i=1}^{l}\sum_{k=1}^{P}\langle s_k, s_{y_i}\rangle_{\mathcal{Y}}\alpha_{ki} = -\frac{1}{P-1}\sum_{i=1}^{l}\sum_{k=1}^{P}\alpha_{ki} = -\frac{1}{P-1}\mathbf{1}_{Pl}^T\text{vec}(\alpha).$$

This gives the last expression of the theorem.

Let us show that $Q[\mathbf{x}, C]$ is symmetric and positive semidefinite. To show that $Q[\mathbf{x}, C]$ is symmetric, it suffices to show that $K[\mathbf{x}](\gamma_I MK[\mathbf{x}] + \gamma_A I)^{-1}$ is symmetric. We have

$$(\gamma_I K[\mathbf{x}]M + \gamma_A I)K[\mathbf{x}] = K[\mathbf{x}](\gamma_I MK[\mathbf{x}] + \gamma_A I),$$

which is equivalent to

$$K[\mathbf{x}](\gamma_I MK[\mathbf{x}] + \gamma_A I)^{-1} = (\gamma_I K[\mathbf{x}]M + \gamma_A I)^{-1}K[\mathbf{x}] = (K[\mathbf{x}](\gamma_I MK[\mathbf{x}] + \gamma_A I)^{-1})^T$$

by the symmetry of $K[\mathbf{x}]$ and M, showing that $K[\mathbf{x}](\gamma_I MK[\mathbf{x}] + \gamma_A I)^{-1}$ is symmetric. The positive semidefiniteness of $Q[\mathbf{x}, C]$ simply follows from (153). This completes the proof of the theorem. ■

Proof of Theorem 7 Let $S_{\hat{y}_i}$ be the matrix obtained from S by removing the y_ith column and $\beta_i \in \mathbb{R}^{P-1}$ be the vector obtained from α_i by deleting the y_ith entry, which is equal to zero by assumption. As in the proof of Theorem 6, for $1 \leq i \leq l$,

$$\gamma_I \sum_{j,k=1}^{u+l} M_{ik}K(x_k, x_j)a_j + \gamma_A a_i = -\frac{1}{2}C^* S\alpha_i = -\frac{1}{2}C^* S_{\hat{y}_i}\beta_i. \tag{159}$$

For $l + 1 \leq i \leq u + l$,

$$\gamma_I \sum_{j,k=1}^{u+l} M_{ik}K(x_k, x_j)a_j + \gamma_A a_i = 0. \tag{160}$$

Let $\text{diag}(S_{\hat{\mathbf{y}}})$ be the $l \times l$ block diagonal matrix, with block (i, i) being $S_{\hat{y}_i}$. Let $\beta = (\beta_1, \ldots, \beta_l)$ be the $(P-1) \times l$ matrix with column i being β_i. In operator-valued matrix notation, (159) and (160) together can be expressed as

$$(\gamma_I MK[\mathbf{x}] + \gamma_A I)\mathbf{a} = -\frac{1}{2}(I_{(u+l)\times l} \otimes C^*)\text{diag}(S_{\hat{\mathbf{y}}})\text{vec}(\beta). \tag{161}$$

By Lemma 25, the operator $(\gamma_I MK[\mathbf{x}] + \gamma_A I) : \mathcal{W}^{u+l} \to \mathcal{W}^{u+l}$ is invertible, with a bounded inverse, so that

$$\mathbf{a} = -\frac{1}{2}(\gamma_I MK[\mathbf{x}] + \gamma_A I)^{-1}(I_{(u+l)\times l} \otimes C^*)\text{diag}(S_{\hat{\mathbf{y}}})\text{vec}(\beta). \tag{162}$$

As in the proof of Theorem 6,

$$\begin{aligned}\gamma_A\|f\|_{\mathcal{H}_K}^2 + \gamma_I\langle\mathbf{f}, M\mathbf{f}\rangle_{\mathcal{W}^{u+l}} &= -\frac{1}{2}\sum_{i=1}^{l}\langle\sum_{j=1}^{u+l}K(x_i, x_j)a_j, C^*S\alpha_i\rangle_{\mathcal{W}} \\ &= -\frac{1}{2}\sum_{i=1}^{l}\langle\sum_{j=1}^{u+l}K(x_i, x_j)a_j, C^*S_{\hat{y}_i}\beta_i\rangle_{\mathcal{W}} \\ &= -\frac{1}{2}\sum_{i=1}^{l}\langle S_{\hat{y}_i}^* C\sum_{j=1}^{u+l}K(x_i, x_j)a_j, \beta_i\rangle_{\mathbb{R}^{P-1}}.\end{aligned} \tag{163}$$

In operator-valued matrix notation, this is

$$\gamma_A\|f\|_{\mathcal{H}_K}^2 + \gamma_I\langle\mathbf{f}, M\mathbf{f}\rangle_{\mathcal{W}^{u+l}} = -\frac{1}{2}\text{vec}(\beta)^T\text{diag}(S_{\hat{\mathbf{y}}}^*)(I_{(u+l)\times l}^T \otimes C)K[\mathbf{x}]\mathbf{a}. \tag{164}$$

Substituting the expression for $\mathbf{a}$ in (162) into (164), we obtain

$$\begin{aligned}\gamma_A\|f\|_{\mathcal{H}_K}^2 + \gamma_I\langle\mathbf{f}, M\mathbf{f}\rangle_{\mathcal{W}^{u+l}} = &\frac{1}{4}\text{vec}(\beta)^T\text{diag}(S_{\hat{\mathbf{y}}}^*)(I_{(u+l)\times l}^T \otimes C)K[\mathbf{x}] \\ &\times (\gamma_I MK[\mathbf{x}] + \gamma_A I)^{-1}(I_{(u+l)\times l} \otimes C^*)\text{diag}(S_{\hat{\mathbf{y}}})\text{vec}(\beta).\end{aligned} \tag{165}$$

We now note that

$$\sum_{i=1}^{l}\sum_{k\neq y_i}\alpha_{ki}\langle s_k, s_{y_i}\rangle_{\mathcal{Y}} = \sum_{i=1}^{l}\langle s_{y_i}, S_{\hat{y}_i}\beta_i\rangle_{\mathcal{Y}}. \tag{166}$$

Combining (146), (166), (148), and (165), we obtain the final form of the Lagrangian

$$L(\beta) = -\sum_{i=1}^{l}\langle s_{y_i}, S_{\hat{y}_i}\beta_i\rangle_{\mathcal{Y}} - \frac{1}{4}\text{vec}(\beta)^T Q[\mathbf{x}, \mathbf{y}, C]\text{vec}(\beta), \tag{167}$$

where the matrix $Q[\mathbf{x}, \mathbf{y}, C]$ is given by

$$Q[\mathbf{x}, \mathbf{y}, C] = \text{diag}(S_{\hat{\mathbf{y}}}^*)(I_{(u+l)\times l}^T \otimes C)K[\mathbf{x}](\gamma_I MK[\mathbf{x}] + \gamma_A I)^{-1}(I_{(u+l)\times l} \otimes C^*)\text{diag}(S_{\hat{\mathbf{y}}}). \tag{168}$$

We need to maximize the Lagrangian subject to the constraints

$$0 \leq \beta_{ki} \leq \frac{1}{l}, \quad 1 \leq i \leq l, 1 \leq k \leq P - 1. \tag{169}$$

Equivalently, under the same constraints, we minimize

$$D(\beta) = \frac{1}{4}\text{vec}(\beta)^T Q[\mathbf{x}, \mathbf{y}, C]\text{vec}(\beta) + \sum_{i=1}^{l}\langle s_{y_i}, S_{\hat{y}_i}\beta_i\rangle_{\mathcal{Y}}. \tag{170}$$

If S is the simplex coding, then

$$\langle s_{y_i}, S_{\hat{y}_i}\beta_i\rangle_{\mathcal{Y}} = \langle S_{\hat{y}_i}^T s_{y_i}, \beta_i\rangle_{\mathcal{Y}} = -\frac{1}{P-1}\mathbf{1}_{P-1}^T\beta_i.$$

It follows then that

$$\sum_{i=1}^{l}\langle s_{y_i}, S_{\hat{y}_i}\beta_i\rangle_{\mathcal{Y}} = -\frac{1}{P-1}\mathbf{1}_{(P-1)l}^T \mathrm{vec}(\beta),$$

giving the last expression of the theorem. This completes the proof. ■

Lemma 29 *The matrix-valued kernel K is positive definite.*

Proof Let $d = \dim(\mathcal{Y})$. Consider an arbitrary set of points $\mathbf{x} = \{x_i\}_{i=1}^N$ in $\mathcal{X}$ and an arbitrary set of vectors $\{y_i\}_{i=1}^N$ in $\mathbb{R}^{md}$. We need to show that

$$\sum_{i,j=1}^{N}\langle y_i, K(x_i, x_j)y_j\rangle_{\mathbb{R}^{md}} = \mathbf{y}^T K[\mathbf{x}]\mathbf{y} \geq 0,$$

where $\mathbf{y} = (y_1, \ldots, y_N) \in \mathbb{R}^{mdN}$ as a column vector. This is equivalent to showing that the Gram matrix $K[\mathbf{x}]$ of size $mdN \times mdN$ is positive semi-definite for any set $\mathbf{x}$.

By assumption, G is positive definite, so that the Gram matrix $G[\mathbf{x}]$ of size $mN \times mN$ is positive semi-definite for any set $\mathbf{x}$. Since the Kronecker tensor product of two positive semi-definite matrices is positive semi-definite, the matrix

$$K[\mathbf{x}] = G[\mathbf{x}] \otimes R$$

is positive semi-definite for any set $\mathbf{x}$. This completes the proof. ■

To prove Theorem 11, we need the following result.

Lemma 30 *Let $N, n \in \mathbb{N}$ and $\gamma > 0$. Let U be an orthogonal matrix of size $n \times n$, with columns $\mathbf{u}_1, \ldots, \mathbf{u}_n$. Let A_i be $N \times N$ matrices such that $(A_i + \gamma I_N)$ is invertible for all i, $1 \leq i \leq n$. Then*

$$\left(\sum_{i=1}^{n} A_i \otimes \mathbf{u}_i\mathbf{u}_i^T + \gamma I_{Nn}\right)^{-1} = \sum_{i=1}^{n}(A_i + \gamma I_N)^{-1} \otimes \mathbf{u}_i\mathbf{u}_i^T. \tag{171}$$

Proof By definition of orthogonal matrices, we have $UU^T = I_n$, which is equivalent to $\sum_{i=1}^n \mathbf{u}_i\mathbf{u}_i^T = I_n$, so that

$$\sum_{i=1}^{n} A_i \otimes \mathbf{u}_i\mathbf{u}_i^T + \gamma I_{Nn} = \sum_{i=1}^{n} A_i \otimes \mathbf{u}_i\mathbf{u}_i^T + \gamma I_N \otimes \sum_{i=1}^{n}\mathbf{u}_i\mathbf{u}_i^T = \sum_{i=1}^{n}(A_i + \gamma I_N) \otimes \mathbf{u}_i\mathbf{u}_i^T.$$

Noting that $\langle \mathbf{u}_i, \mathbf{u}_j\rangle = \delta_{ij}$, the expression for the inverse matrix then follows immediately by direct verification. ■

Proof of Theorem 11 From the property $K[\mathbf{x}] = G[\mathbf{x}] \otimes R$ and the definitions $M_B = I_{u+l} \otimes M_m \otimes I_{\mathcal{Y}}$, $M_W = L \otimes I_{\mathcal{Y}}$, we have

$$\begin{aligned}
&\gamma_I MK[\mathbf{x}] + \gamma_A I_{\mathcal{W}^{u+l}} = (\gamma_B M_B + \gamma_W M_W)K[\mathbf{x}] + \gamma_A I_{u+l} \otimes I_{\mathcal{W}} \\
&= (\gamma_B I_{u+l} \otimes M_m \otimes I_{\mathcal{Y}} + \gamma_W L \otimes I_{\mathcal{Y}})(G[\mathbf{x}] \otimes R) + \gamma_A I_{u+l} \otimes I_m \otimes I_{\mathcal{Y}} \\
&= (\gamma_B I_{u+l} \otimes M_m + \gamma_W L)G[\mathbf{x}] \otimes R + \gamma_A I_{m(u+l)} \otimes I_{\mathcal{Y}}.
\end{aligned}$$

With the spectral decomposition of R,

$$R = \sum_{i=1}^{\dim(\mathcal{Y})} \lambda_{i,R}\mathbf{r}_i\mathbf{r}_i^T,$$

we have

$$(\gamma_B I_{u+l} \otimes M_m + \gamma_W L)G[\mathbf{x}] \otimes R = \sum_{i=1}^{\dim(\mathcal{Y})} \lambda_{i,R}(\gamma_B I_{u+l} \otimes M_m + \gamma_W L)G[\mathbf{x}] \otimes \mathbf{r}_i\mathbf{r}_i^T.$$

It follows from Lemma 30 that

$$(\gamma_I MK[\mathbf{x}] + \gamma_A I_{\mathcal{W}^{u+l}})^{-1} = \sum_{i=1}^{\dim(\mathcal{Y})} [\lambda_{i,R}(\gamma_B I_{u+l} \otimes M_m + \gamma_W L)G[\mathbf{x}] + \gamma_A I_{m(u+l)}]^{-1} \otimes \mathbf{r}_i\mathbf{r}_i^T$$

$$= \sum_{i=1}^{\dim(\mathcal{Y})} M_{\mathrm{reg}}^i \otimes \mathbf{r}_i\mathbf{r}_i^T, \quad \text{where} \quad M_{\mathrm{reg}}^i = [\lambda_{i,R}(\gamma_B I_{u+l} \otimes M_m + \gamma_W L)G[\mathbf{x}] + \gamma_A I_{m(u+l)}]^{-1}.$$

For $C = \mathbf{c}^T \otimes I_{\mathcal{Y}} \in \mathbb{R}^{\dim(\mathcal{Y}) \times m\dim(\mathcal{Y})}$, we have

$$\begin{aligned}
C^*S &= (\mathbf{c} \otimes I_{\mathcal{Y}})S = \mathbf{c} \otimes S, \\
S^*C &= S^*(\mathbf{c}^T \otimes I_{\mathcal{Y}}) = \mathbf{c}^T \otimes S^*, \\
I_{(u+l)\times l}^T \otimes S^*C &= I_{(u+l)\times l}^T \otimes \mathbf{c}^T \otimes S^*, \\
I_{(u+l)\times l} \otimes C^*S &= I_{(u+l)\times l} \otimes \mathbf{c} \otimes S.
\end{aligned}$$

It follows that

$$\begin{aligned}
(\gamma_I MK[\mathbf{x}] + \gamma_A I_{\mathcal{W}^{u+l}})^{-1}(I_{(u+l)\times l} \otimes C^*S) &= (\sum_{i=1}^{\dim(\mathcal{Y})} M_{\mathrm{reg}}^i \otimes \mathbf{r}_i\mathbf{r}_i^T)(I_{(u+l)\times l} \otimes \mathbf{c} \otimes S) \\
&= \sum_{i=1}^{\dim(\mathcal{Y})} M_{\mathrm{reg}}^i(I_{(u+l)\times l} \otimes \mathbf{c}) \otimes \mathbf{r}_i\mathbf{r}_i^T S,
\end{aligned}$$

from which we obtain the expression for $\mathbf{a}$. Next,

$$\begin{aligned}
K[\mathbf{x}](\gamma_I MK[\mathbf{x}] + \gamma_A I)^{-1} &= (G[\mathbf{x}] \otimes R)(\sum_{i=1}^{\dim(\mathcal{Y})} M_{\mathrm{reg}}^i \otimes \mathbf{r}_i\mathbf{r}_i^T) \\
= (\sum_{i=1}^{\dim(\mathcal{Y})} G[\mathbf{x}] \otimes \lambda_{i,R}\mathbf{r}_i\mathbf{r}_i^T)(\sum_{i=1}^{\dim(\mathcal{Y})} M_{\mathrm{reg}}^i \otimes \mathbf{r}_i\mathbf{r}_i^T) &= \sum_{i=1}^{\dim(\mathcal{Y})} G[\mathbf{x}]M_{\mathrm{reg}}^i \otimes \lambda_{i,R}\mathbf{r}_i\mathbf{r}_i^T.
\end{aligned}$$

Thus for $Q[\mathbf{x}, C]$, we have

$$\begin{aligned}
Q[\mathbf{x}, C] &= (I^T_{(u+l)\times l} \otimes S^* C) K[\mathbf{x}](\gamma_I M K[\mathbf{x}] + \gamma_A I)^{-1}(I_{(u+l)\times l} \otimes C^* S) \\
&= (I^T_{(u+l)\times l} \otimes \mathbf{c}^T \otimes S^*)(\sum_{i=1}^{\dim(\mathcal{Y})} G[\mathbf{x}] M^i_{\text{reg}} \otimes \lambda_{i,R} \mathbf{r}_i \mathbf{r}_i^T)(I_{(u+l)\times l} \otimes \mathbf{c} \otimes S) \\
&= (\sum_{i=1}^{\dim(\mathcal{Y})} (I^T_{(u+l)\times l} \otimes \mathbf{c}^T) G[\mathbf{x}] M^i_{\text{reg}} \otimes \lambda_{i,R} S^* \mathbf{r}_i \mathbf{r}_i^T)(I_{(u+l)\times l} \otimes \mathbf{c} \otimes S) \\
&= \sum_{i=1}^{\dim(\mathcal{Y})} (I^T_{(u+l)\times l} \otimes \mathbf{c}^T) G[\mathbf{x}] M^i_{\text{reg}} (I_{(u+l)\times l} \otimes \mathbf{c}) \otimes \lambda_{i,R} S^* \mathbf{r}_i \mathbf{r}_i^T S.
\end{aligned}$$

This completes the proof of the theorem. ■

Proof of Theorem 13 For $R = I_{\mathcal{Y}}$ we have $\lambda_{i,R} = 1$, $1 \le i \le \dim(\mathcal{Y})$, so that in Theorem 11

$$M^i_{\text{reg}} = M_{\text{reg}} = [(\gamma_B I_{u+l} \otimes M_m + \gamma_W L) G[\mathbf{x}] + \gamma_A I_{m(u+l)}]^{-1}.$$

Since $\sum_{i=1}^{\dim(\mathcal{Y})} \mathbf{r}_i \mathbf{r}_i^T = I_{\mathcal{Y}}$, by substituting $M^i_{\text{reg}} = M_{\text{reg}}$ into the formulas for $\mathbf{a}$ and $Q[\mathbf{x}, C]$ in Theorem 11, we obtain the corresponding expressions (77) and (78). ■

Proof of Propositions 12 and 14 By Theorems 6 and 11, we have

$$\begin{aligned}
f_{\mathbf{z},\gamma}(v) &= \sum_{j=1}^{u+l} K(v, x_j) a_j = K[v, \mathbf{x}]\mathbf{a} = (G[v, \mathbf{x}] \otimes R)\mathbf{a} \\
&= -\frac{1}{2}(G[v, \mathbf{x}] \otimes \sum_{i=1}^{\dim(\mathcal{Y})} \lambda_{i,R} \mathbf{r}_i \mathbf{r}_i^T)[\sum_{i=1}^{\dim(\mathcal{Y})} M^i_{\text{reg}} (I_{(u+l)\times l} \otimes \mathbf{c}) \otimes \mathbf{r}_i \mathbf{r}_i^T S]\text{vec}(\alpha^{\text{opt}}) \\
&= -\frac{1}{2}[\sum_{i=1}^{\dim(\mathcal{Y})} G[v, \mathbf{x}] M^i_{\text{reg}} (I_{(u+l)\times l} \otimes \mathbf{c}) \otimes \lambda_{i,R} \mathbf{r}_i \mathbf{r}_i^T S]\text{vec}(\alpha^{\text{opt}}) \\
&= -\frac{1}{2}\text{vec}(\sum_{i=1}^{\dim(\mathcal{Y})} \lambda_{i,R} \mathbf{r}_i \mathbf{r}_i^T S \alpha^{\text{opt}} (I^T_{(u+l)\times l} \otimes \mathbf{c}^T)(M^i_{\text{reg}})^T G[v, \mathbf{x}]^T).
\end{aligned}$$

The combined function, using the combination operator C, is

$$\begin{aligned}
g_{\mathbf{z},\gamma}(v) &= C f_{\mathbf{z},\gamma}(v) = (\mathbf{c}^T \otimes I_{\mathcal{Y}})(G[v, \mathbf{x}] \otimes R)\mathbf{a} = (\mathbf{c}^T G[v, \mathbf{x}] \otimes R)\mathbf{a} \\
&= -\frac{1}{2}[\sum_{i=1}^{\dim(\mathcal{Y})} \mathbf{c}^T G[v, \mathbf{x}] M^i_{\text{reg}} (I_{(u+l)\times l} \otimes \mathbf{c}) \otimes \lambda_{i,R} \mathbf{r}_i \mathbf{r}_i^T S]\text{vec}(\alpha^{\text{opt}}) \\
&= -\frac{1}{2}\text{vec}(\sum_{i=1}^{\dim(\mathcal{Y})} \lambda_{i,R} \mathbf{r}_i \mathbf{r}_i^T S \alpha^{\text{opt}} (I^T_{(u+l)\times l} \otimes \mathbf{c}^T)(M^i_{\text{reg}})^T G[v, \mathbf{x}]^T \mathbf{c}) \\
&= -\frac{1}{2}\sum_{i=1}^{\dim(\mathcal{Y})} \lambda_{i,R} \mathbf{r}_i \mathbf{r}_i^T S \alpha^{\text{opt}} (I^T_{(u+l)\times l} \otimes \mathbf{c}^T)(M^i_{\text{reg}})^T G[v, \mathbf{x}]^T \mathbf{c} \in \mathbb{R}^{\dim(\mathcal{Y})}.
\end{aligned}$$

It follows that on a set $\mathbf{v} = \{v_i\}_{i=1}^t \subset \mathcal{X}$,

$$g_{\mathbf{z},\gamma}(\mathbf{v}) = -\frac{1}{2}\sum_{i=1}^{\dim(\mathcal{Y})} \lambda_{i,R} \mathbf{r}_i \mathbf{r}_i^T S \alpha^{\text{opt}} (I^T_{(u+l)\times l} \otimes \mathbf{c}^T)(M^i_{\text{reg}})^T G[\mathbf{v}, \mathbf{x}]^T (I_t \otimes \mathbf{c}) \in \mathbb{R}^{\dim(\mathcal{Y})\times t}.$$

The final SVM decision function is then given by

$$\begin{aligned}
h_{\mathbf{z},\gamma}(\mathbf{v}) &= S^T g_{\mathbf{z},\gamma}(\mathbf{v}) \\
&= -\frac{1}{2}\sum_{i=1}^{\dim(\mathcal{Y})} \lambda_{i,R} S^T \mathbf{r}_i \mathbf{r}_i^T S \alpha^{\text{opt}} (I^T_{(u+l)\times l} \otimes \mathbf{c}^T)(M^i_{\text{reg}})^T G[\mathbf{v}, \mathbf{x}]^T (I_t \otimes \mathbf{c}) \in \mathbb{R}^{P\times t}.
\end{aligned}$$

This completes the proof for Proposition 12. Proposition 14 then follows by noting that in Theorem 13, with $R = I_{\mathcal{Y}}$, we have $M^i_{\text{reg}} = M_{\text{reg}}$, $\lambda_{i,R} = 1$, $1 \le i \le \dim(\mathcal{Y})$, and $\sum_{i=1}^{\dim(\mathcal{Y})} \mathbf{r}_i \mathbf{r}_i^T = I_{\mathcal{Y}}$. ■

Proof of Corollary 20 Clearly, for $\gamma_I = 0$ and $u = 0$, we have

$$Q[\mathbf{x}, \mathbf{y}, C] = \frac{1}{\gamma_A}\text{diag}(S^*_{\hat{\mathbf{y}}})(I_l \otimes C) K[\mathbf{x}](I_l \otimes C^*)\text{diag}(S_{\hat{\mathbf{y}}}).$$

For $C = \mathbf{c}^T \otimes I_{\mathcal{Y}}$ and $K[\mathbf{x}] = G[\mathbf{x}] \otimes R$, this is

$$Q[\mathbf{x}, \mathbf{y}, C] = \frac{1}{\gamma_A}\text{diag}(S^*_{\hat{\mathbf{y}}})[(I_l \otimes \mathbf{c}^T) G[\mathbf{x}](I_l \otimes \mathbf{c}) \otimes R]\text{diag}(S_{\hat{\mathbf{y}}}).$$

For $R = I_{\mathcal{Y}}$, we have

$$Q[\mathbf{x}, \mathbf{y}, C] = \frac{1}{\gamma_A}\text{diag}(S^*_{\hat{\mathbf{y}}})[(I_l \otimes \mathbf{c}^T) G[\mathbf{x}](I_l \otimes \mathbf{c}) \otimes I_{\mathcal{Y}}]\text{diag}(S_{\hat{\mathbf{y}}}).$$

With $G[\mathbf{x}] = \sum_{i=1}^m k^i[\mathbf{x}] \otimes \mathbf{e}_i \mathbf{e}_i^T$,

$$(I_l \otimes \mathbf{c}^T) G[\mathbf{x}](I_l \otimes \mathbf{c}) = \sum_{i=1}^m c_i^2 k^i[\mathbf{x}],$$

so that

$$Q[\mathbf{x},\mathbf{y},C] = \frac{1}{\gamma_A}\text{diag}(S^*_{\hat{\mathbf{y}}})\left(\sum_{i=1}^m c_i^2 k^i[\mathbf{x}]\otimes I_{\mathcal{Y}}\right)\text{diag}(S_{\hat{\mathbf{y}}}),$$

which, when $\mathcal{Y}=\mathbb{R}$, reduces to

$$Q[\mathbf{x},\mathbf{y},C] = \frac{1}{\gamma_A}\text{diag}(\mathbf{y})\left(\sum_{i=1}^m c_i^2 k^i[\mathbf{x}]\right)\text{diag}(\mathbf{y}).$$

Similarly, when $\gamma_I = 0$, $u = 0$, we have

$$\mathbf{a} = -\frac{1}{2\gamma_A}(I_l\otimes C^*)\text{diag}(S_{\hat{\mathbf{y}}})\text{vec}(\beta^{\text{opt}}).$$

For $C = \mathbf{c}\otimes I_{\mathcal{Y}}$, $K(x,t) = G(x,t)\otimes R$, we have for any $v\in\mathcal{X}$,

$$\begin{aligned} Cf_{\mathbf{z},\gamma}(v) = CK[v,\mathbf{x}]\mathbf{a} &= -\frac{1}{2\gamma_A}(\mathbf{c}^T\otimes I_{\mathcal{Y}})(G[v,\mathbf{x}]\otimes R)(I_l\otimes\mathbf{c}\otimes I_{\mathcal{Y}})\text{diag}(S_{\hat{\mathbf{y}}})\text{vec}(\beta^{\text{opt}}) \\ &= -\frac{1}{2\gamma_A}[\mathbf{c}^T G[v,\mathbf{x}](I_l\otimes\mathbf{c})\otimes R]\text{diag}(S_{\hat{\mathbf{y}}})\text{vec}(\beta^{\text{opt}}), \end{aligned}$$

which for $R = I_{\mathcal{Y}}$, simplifies to

$$Cf_{\mathbf{z},\gamma}(v) = -\frac{1}{2\gamma_A}[\mathbf{c}^T G[v,\mathbf{x}](I_l\otimes\mathbf{c})\otimes I_{\mathcal{Y}}]\text{diag}(S_{\hat{\mathbf{y}}})\text{vec}(\beta^{\text{opt}}),$$

With $G(x,t) = \sum_{i=1}^m k^i(x,t)\otimes\mathbf{e}_i\mathbf{e}_i^T$,

$$\mathbf{c}^T G[v,\mathbf{x}](I_l\otimes\mathbf{c}) = \sum_{i=1}^m c_i^2 k^i[v,\mathbf{x}],$$

so that

$$Cf_{\mathbf{z},\gamma}(v) = -\frac{1}{2\gamma_A}\left(\sum_{i=1}^m c_i^2 k^i[v,\mathbf{x}]\otimes I_{\mathcal{Y}}\right)\text{diag}(S_{\hat{\mathbf{y}}})\text{vec}(\beta^{\text{opt}}).$$

For $\mathcal{Y}=\mathbb{R}$, this simplifies to

$$Cf_{\mathbf{z},\gamma}(v) = -\frac{1}{2\gamma_A}\left(\sum_{i=1}^m c_i^2 k^i[v,\mathbf{x}]\right)\text{diag}(\mathbf{y})\beta^{\text{opt}}.$$

This completes the proof. ■

A.4 Sequential Minimal Optimization

This section describes the Sequential Minimal Optimization (SMO) algorithm we use to solve the quadratic optimization problem for MV-SVM in Theorem 6. It is a generalization of the one-step SMO technique described in (Platt, 1999). For simplicity and clarity, we

consider the case of the simplex coding, that is the quadratic optimization problem (26). The ideas presented here are readily extendible to the general setting.

Let us first consider the SMO technique for the quadratic optimization problem

$$\text{argmin}_{\alpha\in\mathbb{R}^{Pl}} D(\alpha) = \frac{1}{4}\alpha^T Q\alpha - \frac{1}{P-1}\mathbf{1}_{Pl}^T\alpha, \tag{172}$$

where Q is a symmetric, positive semidefinite matrix of size $Pl\times Pl$, such that $Q_{ii} > 0$, $1\le i\le Pl$, under the constraints

$$0\le\alpha_i\le\frac{1}{l},\quad 1\le i\le Pl. \tag{173}$$

For i fixed, $1\le i\le Pl$, as a function of α_i,

$$D(\alpha) = \frac{1}{4}Q_{ii}\alpha_i^2 + \frac{1}{2}\sum_{j=1,j\neq i}^{Pl} Q_{ij}\alpha_i\alpha_j - \frac{1}{P-1}\alpha_i + Q_{\text{const}}, \tag{174}$$

where Q_{const} is a quantity constant in α_i. Differentiating with respect to α_i gives

$$\frac{\partial D}{\partial\alpha_i} = \frac{1}{2}Q_{ii}\alpha_i + \frac{1}{2}\sum_{j=1,j\neq i}^{Pl} Q_{ij}\alpha_j - \frac{1}{P-1}. \tag{175}$$

Under the condition that $Q_{ii} > 0$, setting this partial derivative to zero gives

$$\alpha_i^* = \frac{1}{Q_{ii}}\left(\frac{2}{P-1} - \sum_{j=1,j\neq i}^{Pl} Q_{ij}\alpha_j\right) = \alpha_i + \frac{1}{Q_{ii}}\left(\frac{2}{P-1} - \sum_{j=1}^{Pl} Q_{ij}\alpha_j\right). \tag{176}$$

Thus the iterative sequence for α_i at step t is

$$\alpha_i^{t+1} = \alpha_i^t + \frac{1}{Q_{ii}}\left(\frac{2}{P-1} - \sum_{j=1}^{Pl} Q_{ij}\alpha_j^t\right), \tag{177}$$

after which we perform a clipping operation, defined by

$$\text{clip}(\alpha_i) = \begin{cases} 0 & \text{if } \alpha_i < 0, \\ \alpha_i & \text{if } 0\le\alpha_i\le\frac{1}{l}, \\ \frac{1}{l} & \text{if } \alpha_i > \frac{1}{l}. \end{cases} \tag{178}$$

Let us now apply this SMO technique for the quadratic optimization (26) in Theorem 6. Recall that this problem is

$$\alpha^{\text{opt}} = \text{argmin}_{\alpha\in\mathbb{R}^{P\times l}}\left\{D(\alpha) = \frac{1}{4}\text{vec}(\alpha)^T Q[\mathbf{x},C]\text{vec}(\alpha) - \frac{1}{P-1}\mathbf{1}_{Pl}^T\text{vec}(\alpha)\right\},$$

with $\mathbf{1}_{Pl} = (1,\ldots,1)^T\in\mathbb{R}^{Pl}$, subject to the constraints

$$0\le\alpha_{ki}\le\frac{1}{l}(1-\delta_{k,y_i}),\quad 1\le i\le l, 1\le k\le P.$$

The choice of which α_{ki} to update at each step is made via the Karush-Kuhn-Tucker (KKT) conditions. In the present context, the KKT conditions are:

$$\alpha_{ki}\left(\xi_{ki} - \left[\frac{1}{P-1} + \langle s_k, Cf(x_i)\rangle_{\mathcal{Y}}\right]\right) = 0, \quad 1 \leq i \leq l, k \neq y_i, \tag{179}$$

$$\left(\frac{1}{l} - \alpha_{ki}\right)\xi_{ki} = 0, \quad 1 \leq i \leq l, k \neq y_i. \tag{180}$$

At an optimal point α^{opt},

$$\xi_{ki}^{\text{opt}} = \max\left(0, \frac{1}{P-1} + \langle s_k, Cf(x_i)\rangle_{\mathcal{Y}}\right), \quad 1 \leq i \leq l, k \neq y_i. \tag{181}$$

We have the following result.

Lemma 31 *For $1 \leq i \leq l$, $k \neq y_i$,*

$$\alpha_{ki}^{\text{opt}} = 0 \Longrightarrow \langle s_k, Cf_{\mathbf{z},\gamma}(x_i)\rangle_{\mathcal{Y}} \leq -\frac{1}{P-1}, \tag{182}$$

$$0 < \alpha_{ki}^{\text{opt}} < \frac{1}{l} \Longrightarrow \langle s_k, Cf_{\mathbf{z},\gamma}(x_i)\rangle_{\mathcal{Y}} = -\frac{1}{P-1}, \tag{183}$$

$$\alpha_{ki}^{\text{opt}} = \frac{1}{l} \Longrightarrow \langle s_k, Cf_{\mathbf{z},\gamma}(x_i)\rangle_{\mathcal{Y}} \geq -\frac{1}{P-1}. \tag{184}$$

Conversely,

$$\langle s_k, Cf_{\mathbf{z},\gamma}(x_i)\rangle_{\mathcal{Y}} < -\frac{1}{P-1} \Longrightarrow \alpha_{ki}^{\text{opt}} = 0, \tag{185}$$

$$\langle s_k, Cf_{\mathbf{z},\gamma}(x_i)\rangle_{\mathcal{Y}} > -\frac{1}{P-1} \Longrightarrow \alpha_{ki}^{\text{opt}} = \frac{1}{l}. \tag{186}$$

Remark 32 *Note that the inequalities in (182) and (184) are not strict. Thus from $\langle s_k, Cf_{\mathbf{z},\gamma}(x_i)\rangle_{\mathcal{Y}} = -\frac{1}{P-1}$ we cannot draw any conclusion about α_{ki}^{opt}.*

Proof To prove (182), note that if $\alpha_{ki}^{\text{opt}} = 0$, then from (180), we have $\xi_{ki}^{\text{opt}} = 0$. From (181), we have

$$\frac{1}{P-1} + \langle s_k, Cf(x_i)\rangle_{\mathcal{Y}} \leq 0 \Longrightarrow \langle s_k, Cf(x_i)\rangle_{\mathcal{Y}} \leq -\frac{1}{P-1}.$$

To prove (183), note that if $0 < \alpha_{ki}^{\text{opt}} < \frac{1}{l}$, then from (180), we have $\xi_{ki}^{\text{opt}} = 0$. On the other hand, from (179), we have

$$\xi_{ki}^{\text{opt}} = \frac{1}{P-1} + \langle s_k, Cf(x_i)\rangle_{\mathcal{Y}}.$$

It follows that

$$\frac{1}{P-1} + \langle s_k, Cf(x_i)\rangle_{\mathcal{Y}} = 0 \Longleftrightarrow \langle s_k, Cf(x_i)\rangle_{\mathcal{Y}} = -\frac{1}{P-1}.$$

For (184), note that if $\alpha_{ki}^{\text{opt}} = \frac{1}{l}$, then from (179), we have

$$\xi_{ki}^{\text{opt}} = \frac{1}{P-1} + \langle s_k, Cf(x_i)\rangle_{\mathcal{Y}} \geq 0 \Longrightarrow \langle s_k, Cf(x_i)\rangle_{\mathcal{Y}} \geq -\frac{1}{P-1}.$$

Conversely, if $\langle s_k, Cf(x_i)\rangle_{\mathcal{Y}} < -\frac{1}{P-1}$, then from (181), we have $\xi_{ki}^{\text{opt}} = 0$. It then follows from (179) that $\alpha_{ki}^{\text{opt}} = 0$. If $\langle s_k, Cf(x_i)\rangle_{\mathcal{Y}} > -\frac{1}{P-1}$, then from (181) we have $\xi_{ki}^{\text{opt}} = \frac{1}{P-1} + \langle s_k, Cf(x_i)\rangle_{\mathcal{Y}}$. Then from (180) it follows that $\alpha_{ki}^{\text{opt}} = \frac{1}{l}$. ■

Binary case ($P = 2$). The binary simplex code is $S = [-1, 1]$. Thus $k \neq y_i$ means that $s_k = -y_i$. Therefore for $1 \leq i \leq l$, $k \neq y_i$, the KKT conditions are:

$$\alpha_{ki}^{\text{opt}} = 0 \Longrightarrow y_i\langle \mathbf{c}, f_{\mathbf{z},\gamma}(x_i)\rangle_{\mathcal{W}} \geq 1, \tag{187}$$

$$0 < \alpha_{ki}^{\text{opt}} < \frac{1}{l} \Longrightarrow y_i\langle \mathbf{c}, f_{\mathbf{z},\gamma}(x_i)\rangle_{\mathcal{W}} = 1, \tag{188}$$

$$\alpha_{ki}^{\text{opt}} = \frac{1}{l} \Longrightarrow y_i\langle \mathbf{c}, f_{\mathbf{z},\gamma}(x_i)\rangle_{\mathcal{W}} \leq 1. \tag{189}$$

Conversely,

$$y_i\langle \mathbf{c}, f_{\mathbf{z},\gamma}(x_i)\rangle_{\mathcal{W}} > 1 \Longrightarrow \alpha_{ki}^{\text{opt}} = 0, \tag{190}$$

$$y_i\langle \mathbf{c}, f_{\mathbf{z},\gamma}(x_i)\rangle_{\mathcal{W}} < 1 \Longrightarrow \alpha_{ki}^{\text{opt}} = \frac{1}{l}. \tag{191}$$

Algorithm 3 summarizes the SMO procedure described in this section.

A.4.1 Numerical implementation of SMO

Let us elaborate on the steps of Algorithm 3 under the hypotheses of Theorem 13, that is the simplex coding with $K[\mathbf{x}] = G[\mathbf{x}] \otimes R$ for $R = I_{P-1}$, which we implement numerically.

Verifying the Karush-Kuhn-Tucker conditions on the labeled training data. To verify Lemma 31 on the set of labeled training data $\mathbf{x}_{1:l} = \{x_i\}_{i=1}^l \subset \mathbf{x}$, according to Proposition 14, we compute

$$h_{\mathbf{z},\gamma}(\mathbf{x}_{1:l}) = -\frac{1}{2}S^T S\alpha^{\text{opt}}(I_{(u+l)\times l}^T \otimes \mathbf{c}^T)M_{\text{reg}}^T G[\mathbf{x}_{1:l}, \mathbf{x}]^T(I_l \otimes \mathbf{c}) \in \mathbb{R}^{P\times l}, \tag{192}$$

as a matrix of size $P \times l$, with the ith column being $h_{\mathbf{z},\gamma}(x_i) = (\langle s_k, Cf_{\mathbf{z},\gamma}(x_i)\rangle_{\mathcal{Y}})_{k=1}^P$, which is then compared with the margin value $-\frac{1}{P-1}$.

Efficient evaluation of the update step (193). The most important factor underlying the efficiency of Algorithm 3 is that we never compute the whole matrix Q of size $Pl \times Pl$, which can be prohibitively large. At each update step, i.e. (193), we only use the ith row of Q, which we denote $Q(i, :)$, which need not be computed explicitly. Recall that we have

$$Q = Q[\mathbf{x}, C] = (I_{(u+l)\times l}^T \otimes \mathbf{c}^T)G[\mathbf{x}]M_{\text{reg}}(I_{(u+l)\times l} \otimes \mathbf{c}) \otimes S^*S = Q_G \otimes Q_S,$$

where

$$Q_G = (I_{(u+l)\times l}^T \otimes \mathbf{c}^T)G[\mathbf{x}]M_{\text{reg}}(I_{(u+l)\times l} \otimes \mathbf{c}), \tag{194}$$

Algorithm 3 Sequential Minimal Optimization for Multi-class Multi-view SVM

Note: We use $\alpha \in \mathbb{R}^{P\times l}$ as a matrix and $\alpha_{\text{vec}} = \text{vec}(\alpha) \in \mathbb{R}^{Pl}$ as a column vector interchangeably.
Initialization: Set $\alpha^0 = 0$.
Stopping criterion: $\frac{|D(\alpha^{t+1}) - D(\alpha^t)|}{|D(\alpha^{t+1})|} < \epsilon$, for some $\epsilon > 0$.
Repeat: - Verify KKT conditions according to Lemma 31.
- Randomly pick an $i \in \mathbb{N}$ such that $\alpha^t_{\text{vec},i}$ is a KKT violator.
- Perform update:

$$\alpha^{t+1}_{\text{vec},i} = \text{clip}\left(\alpha^t_{\text{vec},i} + \frac{1}{Q_{ii}}\left(\frac{2}{P-1} - \sum_{j=1}^{Pl} Q_{ij}\alpha^t_{\text{vec},j}\right)\right), \tag{193}$$

where $Q = Q[\mathbf{x}, C]$.
Until: There are no KKT violators or the stopping criterion is met.

and

$$Q_S = S^*S. \tag{195}$$

Thus for each i, the ith row of Q is

$$Q(i,:) = Q_G(i_G,:) \otimes Q_S(i_S,:), \tag{196}$$

for a unique pair of indices i_G and i_S. It then follows that

$$\begin{aligned} Q(i,:)\text{vec}(\alpha) &= (Q_G(i_G,:) \otimes Q_S(i_S,:))\text{vec}(\alpha) = \text{vec}(Q_S(i_S,:)\alpha Q_G(i_G,:)^T) \\ &= Q_S(i_S,:)\alpha Q_G(i_G,:)^T = Q_S(i_S,:)\alpha Q_G(:,i_G) \end{aligned} \tag{197}$$

since Q_G is symmetric. Also

$$Q_{ii} = Q_G(i_G, i_G)Q_S(i_S, i_S). \tag{198}$$

When proceeding in this way, each update step (193) only uses *one* row from the $l \times l$ matrix Q_G and *one* row from the $P \times P$ matrix Q_S. This is the key to the computational efficiency of Algorithm 3.

Remark 33 *In the more general setting of Theorem 11, with $K[\mathbf{x}] = G[\mathbf{x}] \otimes R$, where R is a positive semi-definite matrix, the evaluation of the matrix $Q = Q[\mathbf{x}, C]$ is done in the same way, except that we need to sum over all non-zero eigenvalues of R, as in (71).*

A.5 Proofs for the Optimization of the Combination Operator

In this section, we prove Theorems 15 and 16 stated in Section 6.1. Consider the optimization problem (86), namely

$$\min_{\mathbf{x}\in\mathbb{R}^m} ||A\mathbf{x} - \mathbf{b}||_{\mathbb{R}^n} \text{ subject to } ||\mathbf{x}||_{\mathbb{R}^m} = \alpha.$$

The Lagrangian, with Lagrange multiplier γ, is given by

$$L(\mathbf{x}, \gamma) = ||A\mathbf{x} - \mathbf{b}||^2 + \gamma(||\mathbf{x}||^2 - \alpha^2).$$

Setting $\frac{\partial L}{\partial \mathbf{x}} = 0$ and $\frac{\partial L}{\partial \gamma} = 0$, we obtain the normal equations

$$(A^TA + \gamma I_m)\mathbf{x} = A^T\mathbf{b}, \tag{199}$$

$$||\mathbf{x}||^2 = \alpha^2. \tag{200}$$

The solutions of the normal equations (199) and (200), if they exist, satisfy the following properties (Gander, 1981).

Lemma 34 *If $(\mathbf{x}_1, \gamma_1)$ and $(\mathbf{x}_2, \gamma_2)$ are solutions of the normal equations (199) and (200), then*

$$||A\mathbf{x}_2 - \mathbf{b}||^2 - ||A\mathbf{x}_1 - \mathbf{b}||^2 = \frac{\gamma_1 - \gamma_2}{2}||\mathbf{x}_1 - \mathbf{x}_2||^2. \tag{201}$$

Lemma 35 *The right hand side of equation (201) is equal to zero only if $\gamma_1 = \gamma_2 = -\mu$, where $\mu \geq 0$ is an eigenvalue of A^TA and*

$$\mathbf{x}_1 = \mathbf{x}_2 + \mathbf{v}(\mu), \tag{202}$$

where $\mathbf{v}(\mu)$ is an eigenvector corresponding to μ.

According to Lemmas 34 and 35, if $(\mathbf{x}_1, \gamma_1)$ and $(\mathbf{x}_2, \gamma_2)$ are solutions of the normal equations (199) and (200), then

$$\gamma_1 > \gamma_2 \Longrightarrow ||A\mathbf{x}_2 - \mathbf{b}|| > ||A\mathbf{x}_1 - \mathbf{b}||. \tag{203}$$

Consequently, among all possible solutions of the normal equations (199) and (200), we choose the solution $(\mathbf{x}, \gamma)$ with the largest γ.
Proof of Theorem 15 Using the assumption $A^T\mathbf{b} = 0$, the first normal equation (199) implies that

$$A^TA\mathbf{x} = -\gamma\mathbf{x}, \tag{204}$$

so that $-\gamma$ is an eigenvalue of A^TA and $\mathbf{x}$ is its corresponding eigenvector, which can be appropriately normalized such that $||\mathbf{x}||_{\mathbb{R}^m} = \alpha$. Since we need the largest value for γ, we have $\gamma^* = -\mu_m$. The minimum value is then

$$\begin{aligned} ||A\mathbf{x}^* - \mathbf{b}||^2_{\mathbb{R}^n} &= \langle A\mathbf{x}^*, A\mathbf{x}^*\rangle_{\mathbb{R}^n} - 2\langle A\mathbf{x}^*, \mathbf{b}\rangle_{\mathbb{R}^n} + ||\mathbf{b}||^2_{\mathbb{R}^n} \\ &= \langle \mathbf{x}^*, A^TA\mathbf{x}^*\rangle_{\mathbb{R}^m} - 2\langle \mathbf{x}^*, A^T\mathbf{b}\rangle_{\mathbb{R}^m} + ||\mathbf{b}||^2_{\mathbb{R}^n} = -\gamma^*||\mathbf{x}^*||^2_{\mathbb{R}^m} + ||\mathbf{b}||^2_{\mathbb{R}^n} \\ &= \mu_m\alpha^2 + ||\mathbf{b}||^2_{\mathbb{R}^n}. \end{aligned}$$

This solution is clearly unique if and only if μ_m is a single eigenvalue. Otherwise, there are infinitely many solutions, each being a vector of length α in the eigenspace of μ_m. This completes the proof of the theorem. ■

Proof of Theorem 16 We first show that under the assumption $A^T\mathbf{b} \neq 0$ and $\mathbf{c} = U^T\mathbf{b}$, we have $||\mathbf{c}_{1:r}||_{\mathbb{R}^r} \neq 0$, that is $c_i \neq 0$ for at least one index i, $1 \leq i \leq r$. To see this, assume that $c_i = 0$ for all i, $1 \leq i \leq r$. Then

$$A^T\mathbf{b} = V\Sigma^T U^T\mathbf{b} = V\Sigma^T\mathbf{c} = 0,$$

which is a contradiction. Thus $||\mathbf{c}_{1:r}||_{\mathbb{R}^r} \neq 0$.

There are two cases in this scenario.

(I) If $\gamma \neq -\mu_i$, $1 \leq i \leq m$, then the matrix $(A^TA + \gamma I_m)$ is nonsingular, thus

$$\begin{aligned}\mathbf{x}(\gamma) &= (A^TA + \gamma I_m)^{-1}A^T\mathbf{b} = (VDV^T + \gamma I_m)^{-1}V\Sigma^T U^T\mathbf{b} \\ &= V(DV^TV + \gamma I_m)^{-1}\Sigma^T U^T\mathbf{b} = V(D + \gamma I_m)^{-1}\Sigma^T U^T\mathbf{b}.\end{aligned}$$

Since the matrix V is orthogonal, we have

$$||\mathbf{x}(\gamma)||^2_{\mathbb{R}^m} = ||(D + \gamma I_m)^{-1}\Sigma^T U^T\mathbf{b}||^2_{\mathbb{R}^m} = \sum_{i=1}^{r} \frac{\sigma_i^2 c_i^2}{(\sigma_i^2 + \gamma)^2},$$

where $\mathbf{c} = U^T\mathbf{b}$. We now need to find γ such that $||\mathbf{x}(\gamma)||_{\mathbb{R}^m} = \alpha$. Consider the function

$$s(\gamma) = \sum_{i=1}^{r} \frac{\sigma_i^2 c_i^2}{(\sigma_i^2 + \gamma)^2} \tag{205}$$

on the interval $(-\sigma_r^2, \infty)$. Under the condition that at least one of the c_i's, $1 \leq i \leq r$, is nonzero, the function s is strictly positive and monotonically decreasing on $(-\sigma_r^2, \infty)$, with

$$\lim_{\gamma\to\infty} s(\gamma) = 0, \quad \lim_{\gamma\to-\sigma_r^2} s(\gamma) = \infty. \tag{206}$$

Thus there must exist a unique $\gamma^* \in (-\sigma_r^2, \infty)$ such that

$$s(\gamma^*) = \sum_{i=1}^{r} \frac{\sigma_i^2 c_i^2}{(\sigma_i^2 + \gamma^*)^2} = \alpha^2. \tag{207}$$

1) If $\text{rank}(A) = m$, then $r = m$ and $\gamma^* > -\sigma_m^2 = -\mu_m \geq -\mu_i$ for all $1 \leq i \leq m$. Thus $\mathbf{x}(\gamma^*)$ is the unique global solution.

2) If $\text{rank}(A) < m$ but $\gamma^* > 0$, then we still have $\gamma^* > -\mu_i$ for all i, $1 \leq i \leq m$, and thus $\mathbf{x}(\gamma^*)$ is the unique global solution.

(II) Consider now the case $\text{rank}(A) < m$ and $\gamma^* \leq 0$.

Since $\mu_m = \ldots = \mu_{r+1} = 0$ and $-\mu_r = -\sigma_r^2 < \gamma^* \leq 0$, we need to consider the possible solution of the normal equations with $\gamma = 0$. For $\gamma = 0$, we have

$$A^TA\mathbf{x} = A^T\mathbf{b} \Longleftrightarrow VDV^T\mathbf{x} = V\Sigma^T U^T\mathbf{b} \Longleftrightarrow DV^T\mathbf{x} = \Sigma^T U^T\mathbf{b}. \tag{208}$$

Let $\mathbf{y} = V^T\mathbf{x} \in \mathbb{R}^m$. By assumption, the vector $D\mathbf{y} \in \mathbb{R}^m$ satisfies $(D\mathbf{y})_i = 0$, $r+1 \leq i \leq m$. The vector $\mathbf{z} = \Sigma^T U^T\mathbf{b} \in \mathbb{R}^m$ also satisfies $z_i = 0$, $r + 1 \leq i \leq m$. Thus the equation

$$D\mathbf{y} = \mathbf{z} \tag{209}$$

has infinitely many solutions, with y_i, $r + 1 \leq i \leq m$, taking arbitrary values. Let $\mathbf{y}_{1:r} = (y_i)_{i=1}^r$, $\mathbf{z}_{1:r} = (z_i)_{i=1}^r$, $D_r = \text{diag}(\mu_1, \ldots, \mu_r)$, $\Sigma_r = \Sigma(:, 1:r)$ consisting of the first r columns of Σ. Then

$$\mathbf{y}_{1:r} = D_r^{-1}\mathbf{z}_{1:r}, \tag{210}$$

or equivalently,

$$y_i = \frac{c_i}{\sigma_i}, \quad 1 \leq i \leq r.$$

Since V is orthogonal, we have

$$\mathbf{x} = (V^T)^{-1}\mathbf{y} = V\mathbf{y},$$

with

$$||\mathbf{x}||_{\mathbb{R}^m} = ||V\mathbf{y}||_{\mathbb{R}^m} = ||\mathbf{y}||_{\mathbb{R}^m}.$$

The second normal equation, namely

$$||\mathbf{x}||_{\mathbb{R}^m} = \alpha,$$

then is satisfied if and only if

$$||\mathbf{y}_{1:r}||_{\mathbb{R}^r} \leq ||\mathbf{y}||_{\mathbb{R}^m} = ||\mathbf{x}||_{\mathbb{R}^m} = \alpha. \tag{211}$$

This condition is equivalent to

$$\sum_{i=1}^{r} \frac{c_i^2}{\sigma_i^2} \leq \alpha^2. \tag{212}$$

Assuming that this is satisfied, then

$$\begin{aligned}A\mathbf{x}(0) &= U\Sigma V^T\mathbf{x} = U\Sigma V^TV\mathbf{y} = U\Sigma\mathbf{y} = U\Sigma_r\mathbf{y}_{1:r} = U\Sigma_r D_r^{-1}\mathbf{z}_{1:r} \\ &= U\Sigma_r D_r^{-1}\Sigma_r^T(U^T\mathbf{b}) = UJ_r^nU^T\mathbf{b}.\end{aligned}$$

The minimum value is thus

$$\begin{aligned}||A\mathbf{x}(0) - \mathbf{b}||_{\mathbb{R}^n} &= ||(UJ_r^nU^T - I_n)\mathbf{b}||_{\mathbb{R}^n} = ||(UJ_r^nU^T - UU^T)\mathbf{b}||_{\mathbb{R}^n} \\ &= ||U(J_r^n - I_n)U^T\mathbf{b}||_{\mathbb{R}^n} = ||(J_r^n - I_n)U^T\mathbf{b}||_{\mathbb{R}^n}.\end{aligned}$$

If $r = n$, then $J_r^n = I_n$, and

$$||A\mathbf{x}(0) - \mathbf{b}||_{\mathbb{R}^m} = 0.$$

Since $s(0) = \sum_{i=1}^r \frac{c_i^2}{\sigma_i^2}$ and s is monotonically decreasing on $(-\sigma_r^2, \infty)$, we have

$$\sum_{i=1}^{r} \frac{c_i^2}{\sigma_i^2} = \alpha^2 \Longleftrightarrow \gamma^* = 0. \tag{213}$$

In this case, because $\sum_{i=1}^r y_i^2 = \alpha^2$, we must have $y_{r+1} = \cdots = y_m = 0$ and consequently $\mathbf{x}(0)$ is the unique global minimum. If

$$\sum_{i=1}^{r} \frac{c_i^2}{\sigma_i^2} < \alpha^2, \tag{214}$$

then $\gamma^* \neq 0$. In this case, we can choose arbitrary values $y_{r+1}, \ldots, y_m$ such that $y_{r+1}^2 + \cdots + y_m^2 = \alpha^2 - \sum_{i=1}^r \frac{c_i^2}{\sigma_i^2}$. Consequently, there are infinitely many solutions $\mathbf{x} = V\mathbf{y}$ which achieve the global minimum.

If condition (212) is not met, that is $\sum_{i=1}^r \frac{c_i^2}{\sigma_i^2} > \alpha^2$, then the second normal equation $||\mathbf{x}||_{\mathbb{R}^m} = \alpha$ cannot be satisfied and thus there is no solution for the case $\gamma = 0$. Thus the global solution is still $\mathbf{x}(\gamma^*)$. This completes the proof of the theorem. ■

For completeness, we provide the proofs of Lemmas 34 and 35 here. Lemma 34 is a special case of Theorem 1 in (Gander, 1981) and thus the proof given here is considerably simpler. Our proof for Lemma 35 is different from that given in (Gander, 1981), since we do *not* make the assumption that rank $\begin{pmatrix} A \\ I \end{pmatrix} = m$.

Proof of Lemma 34 By equation (200), we have

$$\frac{\gamma_1 - \gamma_2}{2}||\mathbf{x}_1 - \mathbf{x}_2||^2 = \frac{\gamma_1 - \gamma_2}{2}(||\mathbf{x}_1||^2 + ||\mathbf{x}_2||^2 - 2\langle \mathbf{x}_1, \mathbf{x}_2\rangle) = (\gamma_1 - \gamma_2)\alpha^2 + (\gamma_2 - \gamma_1)\langle \mathbf{x}_1, \mathbf{x}_2\rangle$$

From equation (199),

$$\begin{aligned}
&||A\mathbf{x}_2 - \mathbf{b}||^2 - ||A\mathbf{x}_1 - \mathbf{b}||^2 = (\langle \mathbf{x}_2, A^TA\mathbf{x}_2\rangle - 2\langle \mathbf{x}_2, A^T\mathbf{b}\rangle) - (\langle \mathbf{x}_1, A^TA\mathbf{x}_1\rangle - 2\langle \mathbf{x}_1, A^T\mathbf{b}\rangle) \\
&= (\langle \mathbf{x}_2, A^T\mathbf{b} - \gamma_2\mathbf{x}_2\rangle - 2\langle \mathbf{x}_2, A^T\mathbf{b}\rangle) - (\langle \mathbf{x}_1, A^T\mathbf{b} - \gamma_1\mathbf{x}_1\rangle - 2\langle \mathbf{x}_1, A^T\mathbf{b}\rangle) \\
&= \gamma_1||\mathbf{x}_1||^2 + \langle \mathbf{x}_1, A^T\mathbf{b}\rangle - \gamma_2||\mathbf{x}_2||^2 - \langle \mathbf{x}_2, A^T\mathbf{b}\rangle = (\gamma_1 - \gamma_2)\alpha^2 + \langle \mathbf{x}_1, A^T\mathbf{b}\rangle - \langle \mathbf{x}_2, A^T\mathbf{b}\rangle.
\end{aligned}$$

Also from equation (199), we have

$$\langle \mathbf{x}_1, (A^TA + \gamma_2 I_m)\mathbf{x}_2\rangle = \langle \mathbf{x}_1, A^T\mathbf{b}\rangle,$$

$$\langle \mathbf{x}_2, (A^TA + \gamma_1 I_m)\mathbf{x}_1\rangle = \langle \mathbf{x}_2, A^T\mathbf{b}\rangle,$$

Subtracting the second expression from the first, we obtain

$$\langle \mathbf{x}_1, A^T\mathbf{b}\rangle - \langle \mathbf{x}_2, A^T\mathbf{b}\rangle = (\gamma_2 - \gamma_1)\langle \mathbf{x}_1, \mathbf{x}_2\rangle.$$

Thus

$$||A\mathbf{x}_2 - \mathbf{b}||^2 - ||A\mathbf{x}_1 - \mathbf{b}||^2 = (\gamma_1 - \gamma_2)\alpha^2 + (\gamma_2 - \gamma_1)\langle \mathbf{x}_1, \mathbf{x}_2\rangle = \frac{\gamma_1 - \gamma_2}{2}||\mathbf{x}_1 - \mathbf{x}_2||^2.$$

This completes the proof. ■

Proof of Lemma 35 There are two possible cases under which the right hand side of (201) is equal to zero.

(I) $\gamma_1 = \gamma_2 = \gamma$ and $\mathbf{x}_1 \neq \mathbf{x}_2$. By equation (199),

$$(A^TA + \gamma I_m)(\mathbf{x}_1 - \mathbf{x}_2) = 0 \Longleftrightarrow A^TA(\mathbf{x}_1 - \mathbf{x}_2) = -\gamma(\mathbf{x}_1 - \mathbf{x}_2).$$

This means that $\gamma = -\mu$, where $\mu \geq 0$ is an eigenvalue of A^TA and

$$\mathbf{x}_1 = \mathbf{x}_2 + \mathbf{v}(\mu),$$

where $\mathbf{v}(\mu)$ is an eigenvector corresponding to μ.

(II) $\gamma_1 \neq \gamma_2$ and $\mathbf{x}_1 = \mathbf{x}_2 = \mathbf{x}$. This case is not possible, since by equation (199), we have

$$(A^TA + \gamma_1 I_m)\mathbf{x} = A^T\mathbf{b} = (A^TA + \gamma_2 I_m)\mathbf{x} \Longrightarrow (\gamma_1 - \gamma_2)\mathbf{x} = 0 \Longrightarrow \mathbf{x} = 0,$$

contradicting the assumption $\alpha > 0$. ■

Appendix B. Learning with General Bounded Linear Operators

The present framework generalizes naturally beyond the point evaluation operator

$$f(x) = K_x^* f.$$

Let $\mathcal{H}$ be a separable Hilbert space of functions on $\mathcal{X}$. We are *not* assuming that the functions in $\mathcal{H}$ are defined pointwise or with values in $\mathcal{W}$, rather we assume that $\forall x \in \mathcal{X}$, there is a bounded linear operator

$$E_x : \mathcal{H} \to \mathcal{W}, \quad ||E_x|| < \infty, \tag{215}$$

with adjoint $E_x^* : \mathcal{W} \to \mathcal{H}$. Consider the minimization

$$\begin{aligned}
f_{\mathbf{z},\gamma} = \text{argmin}_{\mathcal{H}_K} \frac{1}{l}\sum_{i=1}^l V(y_i, CE_{x_i}f) + \gamma_A||f||_{\mathcal{H}}^2 \\
+\gamma_I\langle \mathbf{f}, M\mathbf{f}\rangle_{\mathcal{W}^{u+l}}, \quad \text{where} \quad \mathbf{f} = (E_{x_i}f)_{i=1}^{u+l},
\end{aligned} \tag{216}$$

and its least square version

$$f_{\mathbf{z},\gamma} = \text{argmin}_{\mathcal{H}_K} \frac{1}{l}\sum_{i=1}^l ||y_i - CE_{x_i}f||_{\mathcal{Y}}^2 + \gamma_A||f||_{\mathcal{H}}^2 + \gamma_I\langle \mathbf{f}, M\mathbf{f}\rangle_{\mathcal{W}^{u+l}}. \tag{217}$$

Following are the corresponding Representer Theorem and Proposition stating the explicit solution for the least square case. When $\mathcal{H} = \mathcal{H}_K$, $E_x = K_x^*$, we recover Theorem 2 and Theorem 3, respectively.

Theorem 36 *The minimization problem (216) has a unique solution, given by* $f_{\mathbf{z},\gamma} = \sum_{i=1}^{u+l} E_{x_i}^* a_i$ *for some vectors* $a_i \in \mathcal{W}$, $1 \leq i \leq u + l$.

Proposition 37 *The minimization problem (217) has a unique solution* $f_{\mathbf{z},\gamma} = \sum_{i=1}^{u+l} E_{x_i}^* a_i$, *where the vectors* $a_i \in \mathcal{W}$ *are given by*

$$l\gamma_I \sum_{j,k=1}^{u+l} M_{ik}E_{x_k}E_{x_j}^* a_j + C^*C(\sum_{j=1}^{u+l} E_{x_i}E_{x_j}^* a_j) + l\gamma_A a_i = C^* y_i, \tag{218}$$

for $1 \leq i \leq l$, *and*

$$\gamma_I \sum_{j,k=1}^{u+l} M_{ik}E_{x_k}E_{x_j}^* a_j + \gamma_A a_i = 0, \tag{219}$$

for $l + 1 \leq i \leq u + l$.

The reproducing kernel structures come into play through the following.

Lemma 38 *Let $E : \mathcal{X} \times \mathcal{X} \to \mathcal{L}(\mathcal{W})$ be defined by*

$$E(x,t) = E_x E_t^*. \tag{220}$$

Then E is a positive definite operator-valued kernel.

Proof of Lemma 38. For each pair $(x,t) \in \mathcal{X} \times \mathcal{X}$, the operator $E(x,t)$ satisfies

$$E(t,x)^* = (E_t E_x^*)^* = E_x E_t^* = E(x,t).$$

For every set $\{x_i\}_{i=1}^N$ in $\mathcal{X}$ and $\{w_i\}_{i=1}^N$ in $\mathcal{W}$,

$$\sum_{i,j=1}^N \langle w_i, E(x_i,x_j)w_j\rangle_{\mathcal{W}} = \sum_{i,j=1}^N \langle w_i, E_{x_i}E_{x_j}^* w_j\rangle_{\mathcal{W}}$$

$$= \sum_{i,j=1}^N \langle E_{x_i}^* w_i, E_{x_j}^* w_j\rangle_{\mathcal{H}} = ||\sum_{i=1}^N E_{x_i}^* w_i||_{\mathcal{H}}^2 \geq 0.$$

Thus E is an $\mathcal{L}(\mathcal{W})$-valued positive definite kernel. ■

Proof of Theorem 36 and Proposition 37. These are entirely analogous to those of Theorem 2 and Theorem 3, respectively. Instead of the sampling operator $S_{\mathbf{x}}$, we consider the operator $E_{\mathbf{x}} : \mathcal{H} \to \mathcal{W}^l$, with

$$E_{\mathbf{x}} f = (E_{x_i} f)_{i=1}^l, \tag{221}$$

with the adjoint $E_{\mathbf{x}}^* : \mathcal{W}^l \to \mathcal{H}$ given by

$$E_{\mathbf{x}}^* \mathbf{b} = \sum_{i=1}^l E_{x_i}^* b_i. \tag{222}$$

for all $\mathbf{b} = (b_i)_{i=1}^l \in \mathcal{W}^l$. The operator $E_{C,\mathbf{x}} : \mathcal{H} \to \mathcal{Y}^l$ is now defined by

$$E_{C,\mathbf{x}} f = (CE_{x_1} f, \ldots, CE_{x_l} f). \tag{223}$$

The adjoint $E_{C,\mathbf{x}}^* : \mathcal{Y}^l \to \mathcal{H}$ is

$$E_{C,\mathbf{x}}^* \mathbf{b} = \sum_{i=1}^l E_{x_i}^* C^* b_i, \tag{224}$$

for all $\mathbf{b} \in \mathcal{Y}^l$, and $E_{C,\mathbf{x}}^* E_{C,\mathbf{x}} : \mathcal{H} \to \mathcal{H}$ is

$$E_{C,\mathbf{x}}^* E_{C,\mathbf{x}} f = \sum_{i=1}^l E_{x_i}^* C^* C E_{x_i} f. \tag{225}$$

We then apply all the steps in the proofs of Theorem 2 and Theorem 3 to get the desired results. ■

Remark 39 *We stress that in general, the function $f_{\mathbf{z},\gamma}$ is not defined pointwise, which is the case in the following example. Thus one cannot make a statement about $f_{\mathbf{z},\gamma}(x)$ for all $x \in \mathcal{X}$ without additional assumptions.*

Example 1 *Wahba (1977) $\mathcal{X} = [0,1]$, $\mathcal{H} = L^2(\mathcal{X})$, $\mathcal{W} = \mathbb{R}$. Let $G : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ be continuous and*

$$E_x f = \int_0^1 G(x,t) f(t) dt. \tag{226}$$

for $f \in \mathcal{H}$. One has the reproducing kernel

$$E_x E_t^* = E(x,t) = \int_0^1 G(x,u)G(t,u)du. \tag{227}$$

Appendix C. The Degenerate Case

This section considers the Gaussian kernel $k(x,t) = \exp\left(-\frac{||x-t||^2}{\sigma^2}\right)$ when $\sigma \to \infty$ and other kernels with similar behavior. We show that for $G(x,t) = \sum_{i=1}^m k^i(x,t)\mathbf{e}_i\mathbf{e}_i^T$, $R = I_{\mathcal{Y}}$, the matrix A in Theorem 10 has an analytic expression. This can be used to verify the correctness of an implementation of Algorithm 1.

At $\sigma = \infty$, for $R = I_{\mathcal{Y}}$, for each pair (x,t), we have

$$K(x,t) = I_{\mathcal{Y}^m},$$

and

$$f_{\mathbf{z},\gamma}(x) = \sum_{i=1}^{u+l} K(x_i,x)a_i = \sum_{i=1}^{u+l} a_i.$$

Thus $f_{\mathbf{z},\gamma}$ is a constant function. Let us examine the form of the coefficients a_i's for the case

$$C = \frac{1}{m}\mathbf{1}_m^T \otimes I_{\mathcal{Y}}.$$

We have

$$G[\mathbf{x}] = \mathbf{1}_{u+l}\mathbf{1}_{u+l}^T \otimes I_m.$$

For $\gamma_I = 0$, we have

$$B = \frac{1}{m^2}(J_l^{u+l} \otimes \mathbf{1}_m\mathbf{1}_m^T)(\mathbf{1}_{u+l}\mathbf{1}_{u+l}^T \otimes I_m),$$

which is

$$B = \frac{1}{m^2}(J_l^{u+l}\mathbf{1}_{u+l}\mathbf{1}_{u+l}^T \otimes \mathbf{1}_m\mathbf{1}_m^T).$$

Equivalently,

$$B = \frac{1}{m^2}(J_{ml}^{(u+l)m}\mathbf{1}_{(u+l)m}\mathbf{1}_{(u+l)m}^T).$$

The inverse of $B + l\gamma_A I_{(u+l)m}$ in this case has a closed form

$$(B + l\gamma_A I_{(u+l)m})^{-1} = \frac{I_{(u+l)m}}{l\gamma_A} - \frac{J_{ml}^{(u+l)m}\mathbf{1}_{(u+l)m}\mathbf{1}_{(u+l)m}^T}{l^2 m\gamma_A(m\gamma_A + 1)}, \tag{228}$$

where we have used the identity

$$\mathbf{1}_{(u+l)m}\mathbf{1}_{(u+l)m}^T J_{ml}^{(u+l)m}\mathbf{1}_{(u+l)m}\mathbf{1}_{(u+l)m}^T = ml\mathbf{1}_{(u+l)m}\mathbf{1}_{(u+l)m}^T. \tag{229}$$

We have thus

$$A = (B + l\gamma_A I_{(u+l)m})^{-1}Y_C = \left(\frac{I_{(u+l)m}}{l\gamma_A} - \frac{J_{ml}^{(u+l)m}\mathbf{1}_{(u+l)m}\mathbf{1}_{(u+l)m}^T}{l^2 m\gamma_A(m\gamma_A+1)}\right)Y_C. \tag{230}$$

Thus in this case we have an analytic expression for the coefficient matrix A, as we claimed.

Abstract

This work develops formal statistical inference procedures for predictions generated by supervised learning ensembles. Ensemble methods based on bootstrapping, such as bagging and random forests, have improved the predictive accuracy of individual trees, but fail to provide a framework in which distributional results can be easily determined. Instead of aggregating full bootstrap samples, we consider predicting by averaging over trees built on subsamples of the training set and demonstrate that the resulting estimator takes the form of a U-statistic. As such, predictions for individual feature vectors are asymptotically normal, allowing for confidence intervals to accompany predictions. In practice, a subset of subsamples is used for computational speed; here our estimators take the form of incomplete U-statistics and equivalent results are derived. We further demonstrate that this setup provides a framework for testing the significance of features. Moreover, the internal estimation method we develop allows us to estimate the variance parameters and perform these inference procedures at no additional computational cost. Simulations and illustrations on a real data set are provided.

Keywords: trees, u-statistics, bagging, subbagging, random forests

1. Introduction

This paper develops tools for performing formal statistical inference for predictions generated by a broad class of methods developed under the algorithmic framework of data analysis. In particular, we focus on ensemble methods—combinations of many individual, frequently tree-based, prediction functions—which have played an important role. We present a variant of bagging and random forests, both initially introduced by Breiman (1996, 2001b), in which base learners are built on randomly chosen subsamples of the training data and the final prediction is taken as the average over the individual outputs. We demonstrate that this fits into the statistical framework of U-statistics, which were shown to have minimum variance by Halmos (1946) and later demonstrated to be asymptotically normal by Hoeffding (1948). This allows us to demonstrate that under weak regularity conditions, predictions generated by these subsample ensemble methods are asymptotically normal. We also provide a method to consistently estimate the variance in the limiting distribution without increasing the computational cost so that we may produce confidence intervals and formally test feature significance in practice. Though not the focus of this paper, it is worth noting that this subbagging procedure—suggested by Andonova et al. (2002) for use in model selection—was shown by Zaman and Hirose (2009) to outperform traditional bagging in many situations.

We consider a general supervised learning framework in which an outcome $Y \in \mathbb{R}$ is predicted as a function of d features $\boldsymbol{X} = (X_1, ..., X_d)$ by the function $\mathbb{E}[Y|\boldsymbol{X}] = F(\boldsymbol{X})$. We also allow binary classification so long as the model predicts the probability of success, as opposed to a majority vote, so that the prediction remains real valued. Additionally, we assume a training set $\{(\boldsymbol{X}_1, Y_1), ..., (\boldsymbol{X}_n, Y_n)\}$ consisting of n independent examples from the process that is used to produce the prediction function $\hat{F}$. Throughout the remainder of this paper, we implicitly assume that the dimension of the feature space d remains fixed, though nothing in the theory provided prohibits a growing number of features so long as our other explicit conditions on the statistical behavior of trees are met.

Statistical inference proceeds by asking the counterfactual question, "What would our results look like if we regenerated these data." That is, if a new training set was generated and we reproduced $\hat{F}$, how different might we expect the predictions to be? To illustrate, consider the hypothesis that the feature X_1 does not contribute to the outcome at any point in the feature space:

$$H_0 : \exists\, F_1 \;\; s.t. \;\; F(x_1, ..., x_d) = F_1(x_2, ..., x_d) \quad \forall\, (x_1, ..., x_d) \in \mathcal{X}$$

A formal statistical test begins by calculating a test statistic $t_0 = t((\boldsymbol{X}_1, Y_1), \ldots, (\boldsymbol{X}_n, Y_n))$ and asks, "If our data was generated according to H_0 and we generated a new training set and recalculated t, what is the probability that this new statistic would be larger than t_0?" That is, we are interested in estimating $P(t > t_0|H_0)$. In most fields, a probability of less than 0.05 is considered sufficient evidence to reject the assumption that the data was generated according to H_0. Of course, a 0.05 chance can be obtained by many methods (tossing a biassed coin, for example) so we also seek a statistic t such that when H_0 is false, we are likely to reject. This probability of correctly rejecting H_0 is known as the power of the test, with more powerful tests clearly being more useful.

Here we propose to conduct the above test by comparing predictions generated by $\hat{F}$ and $\hat{F}_1$. Before doing so however, we consider the simpler hypothesis involving the value of a prediction:

$$H_0' : F(x_1, \ldots, x_p) = f_0.$$

Though often of less scientific importance, hypotheses of this form allow us to generate confidence intervals for predictions. These intervals are defined to be those values of f_0 for which we do not have enough evidence to reject H_0'. In practice, we choose f_0 to be the prediction $\hat{F}(x_1, ..., x_p)$ generated by the ensemble method in order to provide a formalized notion of plausible values of the prediction, which is, of course, of genuine interest. Our results begin here because the statistical machinery we develop will provide a distribution for the values of the prediction. This allows us to address H_0', after which we can combine these tests to address hypotheses like H_0.

Although this form of statistical analysis is ubiquitous in scientific literature, it is worthwhile contrasting this form of analysis with an alternative based on probably approximately correct (PAC) theory, as developed by Vapnik and Chervonenkis (1971) and Valiant (1984).

PAC theory provides a uniform bound on the difference between the true error and observed training error of a particular estimator, also referred to as a hypothesis. In this framework, $err(F)$ is some error of the function F which is estimated by $\widehat{err}(F)$ based on the data. A bound is then found for $P(\sup_{F\in\mathcal{F}}|\widehat{err}(F)-err(F)|>\epsilon)$ where $\mathcal{F}$ is some class of functions that includes $\hat{F}$. Since this bound is uniform over $\mathcal{F}$, it applies to $\hat{F}$ and we might think of comparing $\widehat{err}(\hat{F})$ with $\widehat{err}(\hat{F}_1)$ using such bounds. While appealing, these bounds provide the accuracy of our estimate of $err(\hat{F})$ but do not account for how the true $err(\hat{F})$ might change when $\hat{F}$ is reproduced with new training data. The uniformity of these bounds could be used to account for the uncertainty in $\hat{F}$ if it is chosen to minimize $\widehat{err}(F)$ over $\mathcal{F}$, but this is not always the case, for example, when using tree-based methods. We also expect the same uniformity to make PAC bounds conservative, thereby resulting in tests with lower power than those we develop.

Our analysis relies on the structure of subsample-based ensemble methods, specifically making use of classic U-statistic theory. These estimators have a long history (see, for example, original work by Kendall (1938) or Wilcoxon (1945), or Lee (1990) which has a modern overview), frequently focussed on rank-based non-parametric tests, and have been shown to have an asymptotically normal sampling distribution by Hoeffding (1948). Our application to subsample ensembles requires the extension of these results to some new cases as well as methods to estimate the asymptotic variance, both of which we provide.

U-statistics have traditionally been employed in the context of statistical parameter estimation. From this classical statistical perspective, we treat ensemble-tree methods like bagging and random forests as estimators and thus the limiting distributions and inference procedures we develop are with respect to the expected prediction generated by the ensemble. That is, given a particular prediction point $\boldsymbol{x}^*$, our limiting normal distributions are centered at the expected ensemble-based prediction at $\boldsymbol{x}^*$ and not necessarily $F(\boldsymbol{x}^*)$. Such forms of distributional analysis are common in other nonparametric regression settings—see Eubank (1999) Section 4.8, for example. More details on appropriate interpretations of the results are provided throughout the paper, in particular in Section 4.1.

In order to claim that the inference procedures proposed here are asymptotically valid for $F(\boldsymbol{x}^*)$, the ensemble must consistently predict $F(\boldsymbol{x}^*)$ at a rate of $\sqrt{n}$ or faster. Though this is the case for many classical estimators, establishing fast uniform rates of convergence for tree-based ensembles has proven extremely difficult. Breiman et al. (1984) discuss consistency of general partition-type models in the final chapter of their seminal book in the context of both classification and regression. Biau et al. (2008) restrict their attention to classification, but prove consistency of certain idealized bagging and random forest estimators, provided the individual trees are consistent. This paper also discusses a more general version of bagging, where the samples used to construct individual base learners may be proper subsamples of the training set taken with replacement as opposed to full bootstrap samples, so as to include the subbagging approach. Biau (2012) further examines the consistency of random forests and investigates their behavior in the presence of a sparse feature space. Recently, Denil et al. (2013) proved consistency for a mathematically tractable variant of random forests and in some cases, achieved empirical performance on par with the original random forest procedure suggested by Breiman. Zhu et al. (2015) prove consistency for their Reinforcement Learning Trees, where embedded random forests are used to decide splitting variables, and achieve significant improvements in empirical MSE for some data

sets. However, no rates of convergence have been developed that could be applied to analyze the ensemble methods we consider here.

Beyond these consistency efforts, mathematical analyses of ensemble learners has been somewhat limited. Sexton and Laake (2009) propose estimating the standard error of bagged trees and random forests using jackknife and bootstrap estimators. Recently, Wager et al. (2014) proposed applying the jackknife and infinitesimal jackknife procedures introduced by Efron (2014) for estimating standard errors in random forest predictions. Chipman et al. (2010) have received significant attention for developing *BART*, a Bayesian "sum-of-trees" statistical model for the underlying regression function that allows for pointwise posterior inference throughout the feature space as well as estimates for individual feature effects. Recently, Bleich et al. (2014) extended the BART approach by suggesting a permutation-based approach for determining feature relevance and by introducing a procedure to allow variable importance information to be reflected in the prior.

The layout of this paper is as follows: we demonstrate in Section 2 that ensemble methods based on subsampling can be viewed as U-statistics. In Section 3 we provide consistent estimators of the limiting variance parameters so that inference may be carried out in practice. Inference procedures, including a test of significance for features, are discussed in Section 4. Simulations illustrating the limiting distributions and inference procedures are provided in Section 5 and the inference procedures are applied to a real data set provided by Cornell University's Lab of Ornithology in Section 6.

2. Ensemble Methods as U-statistics

We begin by introducing the subbagging and subsampled random forest procedures that result in estimators in the form of U-statistics. In both cases, we provide an algorithm to make the procedure explicit.

2.1 Subbagging

We begin with a brief introduction to U-statistics; see Lee (1990) for a more thorough treatment. Let $Z_1,...,Z_n \overset{iid}{\sim} F_{Z,\theta}$ where θ is the parameter of interest and suppose that there exists an unbiased estimator h of θ that is a function of $k\leq n$ arguments. Then we can write

$$\theta = \mathbb{E}h(Z_1,...,Z_k)$$

and without loss of generality, we may further assume that h is permutation symmetric in its arguments since any given h may be replaced by an equivalent permutation symmetric version. The minimum variance unbiased estimator for θ is given by

$$U_n = \frac{1}{\binom{n}{k}}\sum_{(i)} h(Z_{i_1},...,Z_{i_k}) \tag{1}$$

where the sum is taken over all $\binom{n}{k}$ subsamples of size k and is referred to as a U-statistic with kernel h of rank k. When both the kernel and rank remain fixed, Hoeffding (1948) showed that these statistics are asymptotically normal with limiting variance $\frac{k^2}{n}\zeta_{1,k}$ where

$$\zeta_{1,k} = cov(h(Z_1, ..., Z_k), h(Z_1, Z_2^{'}, ..., Z_k^{'})) \tag{2}$$

and $Z_2^{'}, ..., Z_k^{'} \overset{iid}{\sim} F_{Z,\theta}$. The 1 in the subscript comes from the fact that there is 1 example in common between the two subsamples. In general, $\zeta_{c,k}$ denotes a covariance in the form of (2) with c examples in common.

Given infinite computing power and a consistent estimate of $\zeta_{1,k}$, Hoeffding's original result is enough to produce a subbagging procedure with asymptotically normal predictions. Suppose that as our training set, we observe $Z_1 = (\boldsymbol{X}_1, Y_1), ..., Z_n = (\boldsymbol{X}_n, Y_n) \overset{iid}{\sim} F_{\boldsymbol{X},Y}$ where $\boldsymbol{X} = (X_1, ..., X_d)$ is a vector of features and $Y \in \mathbb{R}$ is the response. Fix $k \leq n$ and let $(\boldsymbol{X}_{i_1}, Y_{i_1}), ..., (\boldsymbol{X}_{i_k}, Y_{i_k})$ be a subsample of the training set. Given a feature vector $\boldsymbol{x}^* \in \mathcal{X}$ where we are interested in making a prediction, we can write the prediction at $\boldsymbol{x}^*$ generated by a tree that was built using the subsample $(\boldsymbol{X}_{i_1}, Y_{i_1}), ..., (\boldsymbol{X}_{i_k}, Y_{i_k})$ as a function $T_{\boldsymbol{x}^*}$ from $(\mathcal{X} \times \mathbb{R}) \times \cdots \times (\mathcal{X} \times \mathbb{R})$ to $\mathbb{R}$. Taking all $\binom{n}{k}$ subsamples, building a tree and predicting at $\boldsymbol{x}^*$ with each, we can write our final subbagged prediction at $\boldsymbol{x}^*$ as

$$b_n(\boldsymbol{x}^*) = \frac{1}{\binom{n}{k}} \sum_{(i)} T_{\boldsymbol{x}^*}((\boldsymbol{X}_{i_1}, Y_{i_1}), ..., (\boldsymbol{X}_{i_k}, Y_{i_k})). \tag{3}$$

by averaging the $\binom{n}{k}$ tree-based predictions. Treating each ordered pair as one of k inputs into the function $T_{\boldsymbol{x}^*}$, the estimator in (3) is in the form of a U-statistic since tree-based estimators produce the same predictions independent of the order of the training data. Thus, provided the distribution of predictions at $\boldsymbol{x}^*$ has a finite second moment and $\zeta_{1,k} > 0$, the distribution of subbagged predictions at $\boldsymbol{x}^*$ is asymptotically normal. Note that in this context, $\zeta_{1,k}$ is the covariance between predictions at $\boldsymbol{x}^*$ generated by trees trained on data sets with 1 sample in common.

Of course, building $\binom{n}{k}$ trees is compuationally infeasible for even moderately sized training sets and an obvious substantial improvement in computationally efficiency can be achieved by building and averaging over only $m_n < \binom{n}{k}$ trees. In this case, the estimator in (3), appropriately scaled, is called an *incomplete* U-statistic. When the m_n subsamples are selected uniformly at random with replacement from the $\binom{n}{k}$ possibilities, the resulting incomplete U-statistic remains asymptotically normal; see Janson (1984) or Lee (1990) page 200 for details.

Though more computationally efficient, there remains a major shortcomming with this approach: the number of samples used to build each tree, k, remains fixed as $n \to \infty$. We would instead like k to grow with n so that trees can be grown to a greater depth, thereby presumably producing more accurate predictions. Incorporating this, our estimator becomes

$$b_{n,k_n,m_n}(\boldsymbol{x}^*) = \frac{1}{m_n} \sum_{(i)} T_{\boldsymbol{x}^*,k_n}((\boldsymbol{X}_{i_1}, Y_{i_1}), ..., (\boldsymbol{X}_{i_{k_n}}, Y_{i_{k_n}})). \tag{4}$$

Statistics of this form were discussed by Frees (1989) and called *Infinite Order* U-statistics (IOUS) in the complete case, when $m_n = \binom{n}{k_n}$, and *resampled* statistics in the incomplete case. Specifically, Frees considers the situation where, given an *i.i.d* sample $Z_1, Z_2, ...$ and kernel h_{k_n}, $\lim_{n\to\infty} h_{k_n}(Z_{i_1}, ..., Z_{i_{k_n}}) = h(Z_1, Z_2, ...)$ and $\theta = \mathbb{E}h(Z_1, Z_2, ...)$

and goes on to develop sufficient conditions for consistency and asymptotic normality whenever m_n grows faster than n. In contrast, the theorem below introduces a central limit theorem for estimators of the same form as in (4) but with respect to their individual means $\mathbb{E}b_{n,k_n,m_n}(\boldsymbol{x}^*)$ and covers all possible growth rates of m_n with respect to n. In this context, only minimal regularity conditions are required for asymptotic normality. We begin with an assumption on the distribution of estimates for the general U-statistic case.

Condition 1: *Let $Z_1, Z_2, ... \overset{iid}{\sim} F_Z$ with $\theta_{k_n} = \mathbb{E}h_{k_n}(Z_1, ..., Z_{k_n})$ and define $h_{1,k_n}(z) = \mathbb{E}h_{k_n}(z, Z_2, ..., Z_{k_n}) - \theta_{k_n}$. Then for all $\delta > 0$,*

$$\lim_{n\to\infty} \frac{1}{\zeta_{1,k_n}} \int_{|h_{1,k_n}(Z_1)| \geq \delta\sqrt{n\zeta_{1,k_n}}} h_{1,k_n}^2(Z_1) dP = 0.$$

This condition serves to control the tail behavior of the predictions and allows us to satisfy the Lindeberg condition needed to obtain part *(i)* of Theorem 1 below.

Theorem 1 *Let $Z_1, Z_2, ... \overset{iid}{\sim} F_Z$ and let U_{n,k_n,m_n} be an incomplete, infinite order U-statistic with kernel h_{k_n} that satisfies Condition 1. Let $\theta_{k_n} = \mathbb{E}h_{k_n}(Z_1, ..., Z_{k_n})$ such that $\mathbb{E}h_{k_n}^2(Z_1, ..., Z_{k_n}) \leq C < \infty$ for all n and some constant C, and let $\lim \frac{n}{m_n} = \alpha$. Then as long as $\lim \frac{k_n}{\sqrt{n}} = 0$ and $\lim \zeta_{1,k_n} \neq 0$,*

(i) if $\alpha = 0$, then $\frac{\sqrt{n}(U_{n,k_n,m_n} - \theta_{k_n})}{\sqrt{k_n^2 \zeta_{1,k_n}}} \xrightarrow{d} \mathcal{N}(0,1)$.

(ii) if $0 < \alpha < \infty$, then $\frac{\sqrt{m_n}(U_{n,k_n,m_n} - \theta_{k_n})}{\sqrt{\frac{k_n^2}{\alpha}\zeta_{1,k_n} + \zeta_{k_n,k_n}}} \xrightarrow{d} \mathcal{N}(0,1)$.

(iii) if $\alpha = \infty$, then $\frac{\sqrt{m_n}(U_{n,k_n,m_n} - \theta_{k_n})}{\sqrt{\zeta_{k_n,k_n}}} \xrightarrow{d} \mathcal{N}(0,1)$.

Condition 1, though necessary for the general U-statistic setting, is a bit obscure. However, in our regression context, when the regression function is bounded and the errors have exponential tails, a more intuitive Lipschitz-type condition given in Proposition 1 is sufficient. Though stronger than necessary, this alternative condition allows us to satisfy the Lindeberg condition and is reasonable to expect of any supervised learning method.

Proposition 1: *For a bounded regression function F, if there exists a constant c such that for all $k_n \geq 1$,*

$$\begin{aligned}\Big|h((\boldsymbol{X}_1, Y_1), ..., (\boldsymbol{X}_{k_n}, Y_{k_n}), (\boldsymbol{X}_{k_n+1}, Y_{k_n+1})) - h((\boldsymbol{X}_1, Y_1), ..., (\boldsymbol{X}_{k_n}, Y_{k_n}), (\boldsymbol{X}_{k_n+1}, Y_{k_n+1}^*))\Big| \\ \leq c\Big|Y_{k_n+1} - Y_{k_n+1}^*\Big|\end{aligned}$$

where $Y_{k_n+1} = F(\boldsymbol{X}_{k_n+1}) + \epsilon_{k_n+1}$, $Y_{k_n+1}^* = F(\boldsymbol{X}_{k_n+1}) + \epsilon_{k_n+1}^*$, and where ϵ_{k_n+1} and $\epsilon_{k_n+1}^*$ are i.i.d. with exponential tails, then Condition 1 is satisfied.

A number of important aspects of these results are worth pointing out. First, note from Theorem 1 that the trees are built with subsamples that are approximately square root of the size of the full training set. This condition is not necessary for the proof, but ensures that the variance of the U-statistic in part (i) converges to 0 as is typically the case in central limit theorems. By maintaining this relatively small subsample size, we can build many more trees and maintain a procedure that is computationally equivalent to traditional bagging based on full bootstrap samples. Also note that no particular assumptions are placed on the dimension d of the feature space; the number of features may grow with n so long as the stated conditions remain satisfied.

The final condition of Theorem 1, that $\lim \zeta_{1,k_n} \neq 0$, though not explicitly controllable, should be easily satisfied in many cases. As an example, suppose that the terminal node size is bounded by $\mathcal{T}$ so that trees built with larger training sets are grown to greater depths. Then if the form of the response is $Y = F(\boldsymbol{X}) + \epsilon$ where ϵ has variance σ^2, ζ_{1,k_n} will be bounded below by $\sigma^2/\mathcal{T}$. Finally, note that the assumption of exponential tails on the distribution of regression errors in Proposition 1 is stronger than necessary. Indeed, so long as $k_n = o(\sqrt{n})$, we need only insist that $nP\left(\left|\epsilon\right| > \sqrt{n}\right) \to 0$.

The proofs of Theorem and Proposition 1 are provided in Appendix A. The subbagging algorithm that produces asymptotically normal predictions at each point in the feature space is provided in Algorithm 1.

Algorithm 1 Subbagging

Load training set
Select size of subsamples k_n and number of subsamples m_n
for i in 1 to m_n **do**
  Take subsample of size k_n from training set
  Build tree using subsample
  Use tree to predict at $\boldsymbol{x}^*$
end for
Average the m_n predictions to get final estimate $b_{n,k_n,m_n}(\boldsymbol{x}^*)$

Note that this procedure is precisely the original bagging algorithm suggested by Breiman, but with proper subsamples used to build trees instead of full bootstrap samples. In Section 3, we provide consistent estimators for the limiting variance parameters in Theorem 1 so that we may carry out inference in practice.

We would also like to acknowledge similar work currently in progress by Wager (2014). Wager builds upon the potential nearest neighbor framework introduced by Lin and Jeon (2006) and seeks to provide a limiting distribution for the case where many trees are used in the ensemble, roughly corresponding to our result (i) in Theorems 1 and 2. The author considers only an idealized class of trees based on the assumptions in Meinshausen (2006) as well as additional *honesty* and *regularity* conditions that allow k_n to grow at a faster rate, and demonstrates that when many Monte Carlo samples are employed, the infinitesimal jackknife estimator of variance is consistent and predictions are asymptotically normal. This estimator has roughly the same computational complexity as those we propose in Section 3 and should scale well subject to some additional bookkeeping. In contrast, the theory we provide here takes into account all possible rates of Monte Carlo sampling via the

three cases discussed in Theorems 1 and 2 and we provide a consistent means for estimating each corresponding variance.

2.2 Random Forests

The distributional results described above for subbagging do not insist on a particular tree building method. So long as the trees generate predictions that satisfy minimal regularity conditions, the experimenter is free to use whichever building method is preferred. The subbagging procedure does, however, require that each tree in the ensemble is built according to the same method.

This insistence on a uniform, non-randomized building method is in contrast with random forests. The original random forests procedure suggested by Breiman (2001b) dictates that at each node in each tree, the split may occur on only a randomly selected subset of features. Thus, we may think of each tree in a random forest as having an additional randomization parameter ω that determines the eligible features that may potentially be split at each node. In a general U-statistic context, we can write this *random kernel* U-statistic as

$$U_{\omega;n,k_n,m_n} = \frac{1}{m_n}\sum_{(i)} h_{k_n}^{(\omega_i)}(Z_{i_1},...,Z_{i_{k_n}}) \tag{5}$$

so that we can write a random forest estimator as

$$r_{n,k_n,m_n}(\boldsymbol{x}^*) = \frac{1}{m_n}\sum_{(i)} T_{\boldsymbol{x}^*,k_n}^{(\omega_i)}((\boldsymbol{X}_{i_1},Y_{i_1}),...,(\boldsymbol{X}_{i_{k_n}},Y_{i_{k_n}})).$$

Due to this additional randomness, random forests and random kernel U-statistics in general do not fit within the framework developed in the previous section so we develop new theory for this expanded class. Suppose $\omega_1,...,\omega_{m_n} \overset{iid}{\sim} F_\omega$ and that these randomization parameters are selected independently of the original sample $Z_1,...,Z_n$. Consider the statistic

$$U^*_{\omega;n,k_n,m_n} = \mathbb{E}_\omega\left(\frac{1}{m_n}\sum_{(i)} h_{k_n}^{(\omega_i)}(Z_{i_1},...,Z_{i_{k_n}})\right)$$

so that $U^*_{\omega;n,k_n,m_n} = \mathbb{E}_\omega U_{\omega;n,k_n,m_n}$. Taking the expectation with respect to ω, the kernel becomes fixed and hence $U^*_{\omega;n,k_n,m_n}$ conforms to the non-random kernel U-statistic theory. Thus, $U^*_{\omega;n,k_n,m_n}$ is asymptotically normal in both the complete and incomplete cases, as well as in the complete and incomplete infinite order cases, by Theorem 1. Given this asymptotic normality of $U^*_{\omega;n,k_n,m_n}$, in order to retain asymptotic normality of the corresponding random kernel version, we need only show that

$$\sqrt{n}(U^*_{\omega;n,k_n,m_n} - U_{\omega;n,k_n,m_n}) \xrightarrow{P} 0.$$

We make use of this idea in the proof of the following theorem, which is provided in Appendix A.

Theorem 2 *Let $U_{\omega;n,k_n,m_n}$ be a random kernel U-statistic of the form defined in equation (5) such that $U^*_{\omega;n,k_n,m_n}$ satisfies Condition 1 and suppose that $\mathbb{E}h^2_{k_n}(Z_1,...,Z_{k_n}) < \infty$ for all n, $\lim \frac{k_n}{\sqrt{n}} = 0$, and $\lim \frac{n}{m_n} = \alpha$. Then, letting β index the subsamples, so long as $\lim \zeta_{1,k_n} \neq 0$ and*

$$\lim_{n\to\infty} \mathbb{E}\left(h^{(\omega)}_{k_n}(Z_{\beta_1},...,Z_{\beta_{k_n}}) - \mathbb{E}_\omega h^{(\omega)}_{k_n}(Z_{\beta_1},...,Z_{\beta_{k_n}})\right)^2 \neq \infty,$$

$U_{\omega;n,k_n,m_n}$ is asymptotically normal and the limiting distributions are the same as those provided in Theorem 1.

Note that the variance parameters ζ_{1,k_n} and ζ_{k_n,k_n} in the context of random kernel U-statistics are still defined as the covariance between estimates generated by the (now random) kernels. Thus, in the specific context of random forests, these variance parameters correspond to the covariance between predictions generated by trees, but each tree is built according to its own randomization parameter ω and this covariance is taken over ω as well. The final condition of Theorem 2 that

$$\lim_{n\to\infty} \mathbb{E}\left(h^{(\omega)}_{k_n}(Z_{\beta_1},...,Z_{\beta_{k_n}}) - \mathbb{E}_\omega h^{(\omega)}_{k_n}(Z_{\beta_1},...,Z_{\beta_{k_n}})\right)^2 \neq \infty,$$

simply ensures that the randomization parameter ω does not continually pull predictions from the same subsample further apart as $n \to \infty$. This condition is satisfied, for example, if the response Y is bounded and should also be easily satisfied for any reasonable implementation of random forests.

The subsampled random forest algorithm that produces asymptotically normal predictions is provided in Algorithm 2. As with subbagging, this subsampled random forest algorithm is exactly a random forest with subsamples used to build trees instead of full bootstrap samples.

Algorithm 2 Subsampled Random Forest

Load training set
Select size of subsamples k_n and number of subsamples m_n
for i in 1 to m_n **do**
  Select subsample of size k_n from training set
  Build tree based on randomization parameter ω_i
  Use this tree to predict at $\boldsymbol{x}^*$
end for
Average the m_n predictions to obtain final estimate $r_{n,k_n,m_n}(\boldsymbol{x}^*)$

Another random-forest-type estimator based on a crossed design that results in an infinite order *generalized* U-statistic is provided in Appendix B. However, the above formulation most resembles Breiman's original procedure and is more computationally feasible than the method mentioned in Appendix B, so we consider only this random kernel version of random forests in the simulations and other work that follows.

3. Estimating the Variance

The limiting distributions provided in Theorem 1 depend on the unknown mean parameter $\theta_{k_n} = \mathbb{E}U_{n,k_n,m_n}$ as well as the unknown variance parameters ζ_{1,k_n} and ζ_{k_n,k_n}. In order for us to be able to use these distributions for statistical inference in practice, we must establish consistent estimators of these parameters. It is obvious that we can use the sample mean—i.e. the prediction from our ensemble—as a consistent estimate of θ_{k_n}, but determining an appropriate variance estimate is less straightforward.

In equation (2) of the previous section, we defined ζ_{c,k_n} as the covariance between two instances of the kernel with c shared arguments, so the sample covariance between predictions may serve as a consistent estimator for both ζ_{1,k_n} and ζ_{k_n,k_n}. However, in practice we find that this often results in estimates close to 0, which may then lead to an overall negative variance estimate.

It is not difficult to show - see Lee (1990) page 11 for details - that an equivalent expression for ζ_{c,k_n} is given by

$$\zeta_{c,k_n} = var\Big(\mathbb{E}\big(h_{k_n}(Z_1,...,Z_{k_n}) \mid Z_1 = z_1,...,Z_c = z_c\big)\Big).$$

To estimate ζ_{c,k_n} for our tree-based ensembles, we begin by selecting c observations $\tilde{\boldsymbol{z}}_1,...,\tilde{\boldsymbol{z}}_c$, which we refer to as initial fixed points, from the training set. We then select several subsamples of size k_n from the training set, each of which must include $\tilde{\boldsymbol{z}}_1,...,\tilde{\boldsymbol{z}}_c$, build a tree with each subsample, and record the mean of the predictions at $\boldsymbol{x}^*$. Let n_{MC} (MC for "Monte Carlo") denote the number of subsamples drawn so that this average is taken over n_{MC} predictions. We then repeat the process for $n_{\tilde{\boldsymbol{z}}}$ initial sets of fixed points and take our final estimate of ζ_{c,k_n} as the variance over the $n_{\tilde{\boldsymbol{z}}}$ final averages, yielding the estimator

$$\hat{\zeta}_{c,k_n} = var\left(\frac{1}{n_{MC}}\sum_{i=1}^{n_{MC}} T_{\boldsymbol{x}^*,k_n}(\mathcal{S}_{\tilde{\boldsymbol{z}}^{(1)},i})\ ,...,\ \frac{1}{n_{MC}}\sum_{i=1}^{n_{MC}} T_{\boldsymbol{x}^*,k_n}(\mathcal{S}_{\tilde{\boldsymbol{z}}^{(n_{\tilde{\boldsymbol{z}}})},i})\right)$$

where $\tilde{\boldsymbol{z}}^{(j)}$ denotes the j^{th} set of initial fixed points and $\mathcal{S}_{\tilde{\boldsymbol{z}}^{(j)},i}$ denotes the i^{th} subsample that includes $\tilde{\boldsymbol{z}}^{(j)}$ (which is used here as shorthand for the argument to the tree function $T_{\boldsymbol{x}^*,k_n}$). Now, since we assume that the orginal data in the training set is i.i.d., the random variables $\frac{1}{n_{MC}}\sum_{i=1}^{n_{MC}} T_{\boldsymbol{x}^*,k_n}(\mathcal{S}_{\tilde{\boldsymbol{z}}^{(1)},i})$ are also i.i.d. and since the sample variance is a U-statistic, $\hat{\zeta}_{c,k_n}$ is a consistent estimator. The algorithm for calculating $\hat{\zeta}_{1,k_n}$ is provided in Algorithm 3. Note that when $c = k_n$, each of the subsamples is identical so we need only use $n_{MC} = 1$ which simplifies the estimation procedure for ζ_{k_n,k_n}. The procedure for calculating $\hat{\zeta}_{k_n,k_n}$ is provided in Algorithm 4.

Choosing the values of $n_{\tilde{\boldsymbol{z}}}$ and n_{MC} will depend on the situation. The number of iterations required to accurately estimate the variance depends on a number of factors, including the tree building method and true underlying regression function. Of course, ideally these estimation parameters should be chosen as large as is computationally feasible. In our simulations, we find that in most cases, only a relatively small number of initial fixed point sets are needed, but many more Monte Carlo samples are often necessary for accurate estimation. In most cases, we used an n_{MC} of at least 500. Recall that because our trees are built with small subsamples, we can build correspondingly more trees at the same computational cost.

Algorithm 3 ζ_{1,k_n} Estimation Procedure

for i in 1 to $n_{\tilde{\boldsymbol{z}}}$ **do**
  Select initial fixed point $\tilde{\boldsymbol{z}}^{(i)}$
  for j in 1 to n_{MC} **do**
    Select subsample $\mathcal{S}_{\tilde{\boldsymbol{z}}^{(i)},j}$ of size k_n from training set that includes $\tilde{\boldsymbol{z}}^{(i)}$
    Build tree using subsample $\mathcal{S}_{\tilde{\boldsymbol{z}}^{(i)},j}$
    Use tree to predict at $\boldsymbol{x}^*$
  end for
  Record average of the n_{MC} predictions
end for
Compute the variance of the $n_{\tilde{\boldsymbol{z}}}$ averages

Algorithm 4 ζ_{k_n,k_n} Estimation Procedure

for i in 1 to $n_{\tilde{\boldsymbol{z}}}$ **do**
  Select subsample of size k_n from training set
  Build tree using subsample this subsample
  Use tree to predict at $\boldsymbol{x}^*$
end for
Compute the variance of the $n_{\tilde{\boldsymbol{z}}}$ predictions

3.1 Internal vs. External Estimation

The algorithms for producing the subbagged or subsampled random forest predictions as well as the above algorithms for estimating the variance parameters are all that is needed to perform statistical inference. We can begin with Algorithm 1 or 2 to generate the predictions, followed by Algorithms 3 and 4 to estimate the variance parameters ζ_{1,k_n} and ζ_{k_n,k_n}. This procedure of running these 3 algorithms seperately is what we will refer to as the *external* variance estimation method, since the the variance parameters are estimated outside of the orginal ensemble. By contrast, we could instead generate the predictions and estimate the variance parameters in one procedure by taking the mean and variance of the predictions generated by the trees used to estimate ζ_{1,k_n}. Algorithm 5 outlines the steps in this *internal* variance estimation method.

This internal variance estimation method is more computationally efficient and has the added benefit of producing variance estimates by simply changing the way in which the subsamples are selected. This means that we are able to obtain all parameter estimates we need to conduct inference at no greater computational cost than building the original ensemble. Although Theorems 1 and 2 dictate that the subsamples used in the ensemble be selected uniformly at random, we find that the additional correlation introduced by selecting the subsamples in this way and using the same subsamples to estimate all parameters does not affect the limiting distribution.

Algorithm 5 Internal Variance Estimation Method

for i in 1 to $n_{\tilde{\boldsymbol{z}}}$ **do**
  Select initial fixed point $\tilde{\boldsymbol{z}}^{(i)}$
  for j in 1 to n_{MC} **do**
    Select subsample $\mathcal{S}_{\tilde{\boldsymbol{z}}^{(i)},j}$ of size k_n from training set that includes $\tilde{\boldsymbol{z}}^{(i)}$
    Build tree using subsample $\mathcal{S}_{\tilde{\boldsymbol{z}}^{(i)},j}$

Compute the variance of the $n_{\tilde{\boldsymbol{z}}}$ averages to estimate ζ_{1,k_n}
Compute the variance of all predictions to estimate ζ_{k_n,k_n}
Compute the mean of all predictions to estimate θ_{k_n}

4. Inference Procedures

In this section, we describe the inference procedures that may be carried out after performing the estimation procedures.

4.1 Confidence Intervals

In Section 2, we showed that predictions from subbagging and subsampled random forests are asymptotically normal and in Section 3 we provided consistent estimators for the parameters in the limiting normal distributions. Thus, given a training set, we can estimate the approximate distribution of predictions at any given feature vector of interest $\boldsymbol{x}^*$. To produce a confidence interval for predictions at $\boldsymbol{x}^*$, we need only estimate the variance parameters and take quantiles from the appropriate limiting distribution. Formally, our confidence interval is $[LB, UB]$ where the lower and upper bounds, LB and UB, are the $\alpha/2$ and $1-\alpha/2$ quantiles respectively of the normal distribution with mean $\hat{\theta}_{k_n}$ and variance $\frac{k_n^2}{\hat{\alpha}}\hat{\zeta}_{1,k_n} + \hat{\zeta}_{k_n,k_n}$ where $\hat{\zeta}_{1,k_n}$ and $\hat{\zeta}_{k_n,k_n}$ are the variance estimates and $\hat{\alpha} = n/m_n$. This limiting distribution is that given in result (ii) of Theorem 1 which is the distribution we recommend using in practice.

As mentioned in the introduction, these confidence intervals can also be used to address hypotheses of the form

$$H_0 : \theta_{k_n} = c$$
$$H_1 : \theta_{k_n} \neq c.$$

Formally, we can define the test statistic

$$t = \frac{\hat{\theta}_{k_n} - c}{sd(\hat{\theta}_{k_n})}$$

and reject H_0 if $|t|$ is greater than the the $1 - \frac{\alpha}{2}$ quantile of the standard normal. This corresponds to a test with type 1 error rate α so that $P[\text{reject } H_0 \mid H_0 \text{ true}] = P[\ |t| >$

$1 - \frac{\alpha}{2} \mid \theta_{k_n} = c] = \alpha$. However, this testing procedure is equivalent to simply checking whether c is within the calculated confidence interval: if c is in the confidence interval, then we fail to reject this hypothesis that the true mean prediction is equal to c, otherwise we reject.

Finally, recall that these confidence intervals are for the expected prediction θ_{k_n} and not necessarily for the true value of the underlying regression function $\theta = F(\boldsymbol{x}^*)$. If the tree building method employed is consistent so that $\theta_{k_n} \xrightarrow{P} \theta$, then as the sample size increases, the tree should be (on average) producing more accurate predictions, but in order to claim that our confidence intervals are asymptotically valid for θ, we need for this convergence to occur at rate of $\sqrt{n}$ or faster. However, in general, the rate of convergence will depend on not only the tree-building method and true underlying regression function, but also on the location of the prediction point within the feature space.

Note that Theorems 1 and 2 apply not only to tree-based ensembles, but to any estimator that can be written in the form of an infinite order U-statistic, as in equation (4). Some of these ensembles may be straightforward to analyze, but for others, such as random forest predictions near the edge of the feature space, it may be difficult to establish a universal rate of consistency. However, even when $\sqrt{n}$-consistency cannot be guaranteed, these intervals still provide valuable information not currently available with existing tools. In these cases, the confidence interval provides a reasonable range of values for where the prediction might fall if the ensemble was recomputed using a new training set; areas of the feature space where confidence intervals are relatively large indicate regions where the ensemble is particularly unstable.

Compare this, for example, to the standard approach of withholding some (usually small) portion of the training set and comparing predictions made at these hold-out points to the corresponding known responses. Such an approach provides some information as to the *accuracy* of the learner at specific locations throughout the feature space, but says nothing about the *stability* of these predictions. Thus, instead of relying only on measures of overall goodness-of-fit such as MSE or SSE, these intervals allow users to investigate prediction variability at particular points or regions and in this sense, can be seen as a measure of how much the accuracy of predictions at that point is due to chance.

4.2 Tests of Significance

The limiting distributions developed in Theorems 1 and 2 also allow us a way to test the significance of features. In many situations, data are recorded for a large number of features but a sparse true regression structure is suspected. Suppose that the training set consists of d features, $X_1, ..., X_d$ and consider a reduced set $\boldsymbol{X}^{(R)} \subset \{X_1, ..., X_d\}$. Let $\boldsymbol{x}_{\text{TEST}} = \{\boldsymbol{x}_1, ..., \boldsymbol{x}_N\}$ be a set of feature vectors where we are interested in making predictions. Also, let g denote the function that maps feature vectors to their corresponding true mean prediction and let $g^{(R)}$ denote the same type of function that maps from the reduced feature space. That is, for a particular prediction point of interest $\boldsymbol{x}^*$, $g(\boldsymbol{x}^*)$ is the true mean prediction θ_{k_n} generated by trees built using the full feature space, and $g^{(R)}(\boldsymbol{x}^*)$ is the true mean prediction $\theta^{(R)}_{k_n}$ generated by trees that are only permitted to utilize features in the reduced set. Then, for each test point $\boldsymbol{x}_i \in \boldsymbol{x}_{\text{TEST}}$, we would like to know whether

$g(\boldsymbol{x}_i) = g^{(R)}(\boldsymbol{x}_i)$ so that we can determine the predictive influence of features not in $\boldsymbol{X}^{(R)}$. More formally, we would like to test the hypothesis

$$\begin{aligned} H_0 &: g(\boldsymbol{x}_i) = g^{(R)}(\boldsymbol{x}_i) \;\; \forall\, \boldsymbol{x}_i \in \boldsymbol{x}_{\text{TEST}} \\ H_1 &: g(\boldsymbol{x}_i) \neq g^{(R)}(\boldsymbol{x}_i) \;\; \text{for some } \boldsymbol{x}_i \in \boldsymbol{x}_{\text{TEST}}. \end{aligned} \tag{6}$$

Rejecting this null hypothesis means that a feature not in the reduced feature space $\boldsymbol{X}^{(R)}$ makes a significant contribution to the prediction at at least one of the test points.

To perform this test with a training set of size n, we take m_n subsamples, each of size k_n, and build a tree with each subsample. Denote these subsamples $S_1, ..., S_{m_n}$ and for a given feature vector $\boldsymbol{x}_i$, let $\hat{g}(\boldsymbol{x}_i)$ denote the average over the predictions at $\boldsymbol{x}_i$ generated from the m_n trees. Then, using the same subsamples $S_1, ..., S_{m_n}$, again build a tree with each, but using only those features in $\boldsymbol{X}^{(R)}$, and let $\hat{g}^{(R)}(\boldsymbol{x}_i)$ be the average prediction at $\boldsymbol{x}_i$ generated by these trees. Finally, define the difference function

$$\hat{D}(\boldsymbol{x}_i) = \hat{g}(\boldsymbol{x}_i) - \hat{g}^{(R)}(\boldsymbol{x}_i)$$

as the difference between the two ensemble predictions. Note that we can write

$$\begin{aligned} \hat{D}(\boldsymbol{x}_i) &= \hat{g}(\boldsymbol{x}_i) - \hat{g}^{(R)}(\boldsymbol{x}_i) \\ &= \frac{1}{m_n} \sum_{(j)} T_{\boldsymbol{x}_i, k_n}(S_j) - \frac{1}{m_n} \sum_{(j)} T^{(R)}_{\boldsymbol{x}_i, k_n}(S_j) \\ &= \frac{1}{m_n} \sum_{(j)} \left(T_{\boldsymbol{x}_i, k_n}(S_j) - T^{(R)}_{\boldsymbol{x}_i, k_n}(S_j) \right) \end{aligned}$$

so that this difference function is a U-statistic. Thus, if we have only a single test point of interest, $\hat{D}$ is asymptotically normal, so $\hat{D}^2$ is asymptotically χ^2_1 and we can use $\hat{D}^2$ as a test statistic.

However, it is more often the case that we have several test points of interest. In this case, define $\hat{\mathbb{D}}$ to be the vector of observed differences in the predictions

$$\hat{\mathbb{D}} = \left(\hat{D}(\boldsymbol{x}_1), ..., \hat{D}(\boldsymbol{x}_N) \right)$$

so that, provided a joint distribution exists with respect to Lebesgue measure, $\hat{\mathbb{D}}$ has a multivariate normal distribution with mean vector

$$\boldsymbol{\mu} = \left(g(\boldsymbol{x}_1) - g^{(R)}(\boldsymbol{x}_1), ..., g(\boldsymbol{x}_N) - g^{(R)}(\boldsymbol{x}_N) \right)^T$$

which we estimate with

$$\hat{\boldsymbol{\mu}} = \hat{\mathbb{D}}^T$$

as well as a covariance matrix Σ. This covariance matrix has parameters Σ_{1,k_n} and Σ_{k_n,k_n}, the multivariate analogues of ζ_{1,k_n} and ζ_{k_n,k_n}. Consistent estimators for these multivariate

parameters can be obtained by simply replacing the variance calculation in Algorithms 3 and 4 with a covariance. For clarity, the procedure for obtaining $\hat{\Sigma}_{1,k_n}$ is provided in Algorithm 6 in Appendix C.

Finally, combining these predictions to form a consistent estimator $\hat{\Sigma}$ we have that

$$\hat{\boldsymbol{\mu}}^T \hat{\Sigma}^{-1} \hat{\boldsymbol{\mu}} \sim \chi^2_N$$

under H_0. Thus, in order to test the hypothesis in (6), we compare the test statistic $\hat{\boldsymbol{\mu}}^T \hat{\Sigma}^{-1} \hat{\boldsymbol{\mu}}$ to the $1-\alpha$ quantile of the χ^2_N distribution to produce a test with type 1 error rate α. If our test statistic is larger than this critical value, we reject the null hypothesis.

4.3 Further Testing Procedures

This setup, though straightforward, may not always definitively decide the significance of features. In some cases, even randomly generated features that are unrelated to the response can be reported significant. Depending on the building method, tree-based algorithms may take advantage of additional randomness in features even when the particular values of those features do not directly contribute to the response. For this reason, we also recommend repeating the testing procedure by comparing predictions generated using the full data set to predictions generated by a data set with randomly generated values—commonly obtained by permuting the values in the training set—for the features not in the reduced feature set to test hypostheses of the form

$$H_0 : g(\boldsymbol{x}_i) = g^{(RAND)}(\boldsymbol{x}_i) \;\; \forall \; \boldsymbol{x}_i \in \boldsymbol{x}_{\text{TEST}}$$
$$H_1 : g(\boldsymbol{x}_i) \neq g^{(RAND)}(\boldsymbol{x}_i) \;\; \text{for some } \boldsymbol{x}_i \in \boldsymbol{x}_{\text{TEST}}.$$

The testing procedure remains exactly the same except that to calculate the second set of trees, we simply substitute the reduced training set for a training set with the same number of features, but with randomized values taking the place of the original values for the additional features. Rejecting this null hypothesis allows us to conclude that not only do the additional features not in the reduced training set make a significant contribution to the predictions, but that the contribution is significantly more than could be obtained simply by adding additional randomness.

There are also two additional tests that may be performed. First, we can test whether predictions generated by a training set with randomized values for the additional features are significantly different from predictions generated by the reduced feature set. If a significant difference is found, then the trees in the ensemble are making use of the additional randomness or possibly an accidental structure in the randomized features. As a final check, we can compare predictions generated by two training sets, each with randomized values for the features not in the reduced set. In the unlikely event that a significant difference is found between these predictions, it is again likely due to an accidental structure in the randomized values. Both of these tests can be performed in exactly the same fashion by substituting the appropriate training sets.

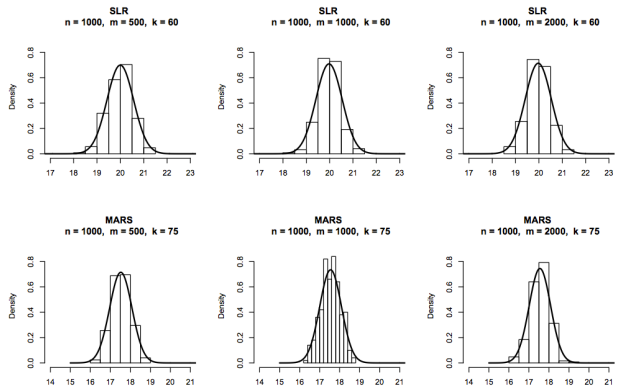

Figure 1: Histograms of subbagged predictions at $x_1 = 10$ in the SLR case (top row) and at $x_1 = \cdots = x_5 = 0.5$ in the MARS case (bottom row). The total sample size, number of subsamples, and size of each subsample are denoted by n,m, and k, respectively in the plot titles.

5. Simulations

We present here a small simulation study in order to illustrate the limiting distributions derived in Section 2 and also to demonstrate the inference procedures proposed in the previous section. We consider two different underlying regression functions:

1. $g(x_1) = 2x_1; \quad \mathcal{X} = [0, 20]$
2. $g(\boldsymbol{x}) = 10\sin(\pi x_1 x_2) + 20(x_3 - 0.05)^2 + 10x_4 + 5x_5; \quad \mathcal{X} = [0, 1]^5$

The first function corresponds to simple linear regression (SLR) and was chosen for simplicity and ease of visualization. The second was initially considered by Friedman (1991) in development of the Multivariate Adaptive Regression Spline (MARS) procedure and was recently investigated by Biau (2012). In each case, features were selected uniformly at random from the feature spaces and responses were sampled from $g(\boldsymbol{x})+\epsilon$, where $\epsilon \overset{iid}{\sim} \mathcal{N}(0, 10)$, to form the training sets.

5.1 Limiting Distributions

We begin by illustrating the distributions of subbagged predictions. In the SLR case, predictions were made at $x_1 = 10$ and in the MARS case, predictions were made at $x_1 = \cdots = x_5 = 0.5$. The histograms of subbagged predictions are shown in Figure 1. Each histogram is comprised of 250 simulations.

For each histogram, the size of the training set n, number of subsamples m, and size of each subsample k, is provided in the title. Each tree in the ensembles was built using the

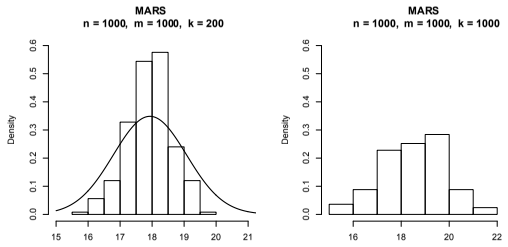

Figure 2: Histograms of subbagged predictions with larger subsample size k and full bootstrap samples. Predictions are made at $x_1 = \cdots = x_5 = 0.5$.

`rpart` function in `R`, with the additional restriction that at least 3 observations per node were needed in order for the algorithm to consider splitting on that node. Overlaying each histogram is the density obtained by estimating the parameters in the limiting distribution. In each case, we take the limiting distribution to be that given in result *(ii)* of Theorem 1; namely that the predictions are normally distributed with mean $\mathbb{E}b_{n,k,m}(\boldsymbol{x}^*)$ and variance $\frac{1}{\alpha}\frac{k^2}{m}\zeta_{1,k} + \frac{1}{m}\zeta_{k,k}$.

The mean $\mathbb{E}b_{n,k,m}(\boldsymbol{x}^*) = \theta_k$ was estimated as the empirical mean across the 250 subbagged predictions. To estimate $\zeta_{k,k}$, 5000 new subsamples of size k were selected and with each subsample, a tree was built and used to predict at $x_1 = 10$ and $\hat{\zeta}_{k,k}$ was taken as the empirical variance between these predictions. To estimate $\zeta_{1,k}$, we follow the procedure in Algorithm 3 with $n_{\tilde{\boldsymbol{z}}} = 50$ and $n_{MC} = 1000$ in the SLR cases and with $n_{\tilde{\boldsymbol{z}}} = 250$ and $n_{MC} = 1000$ in the MARS cases. Note that since we are only interested in verifying the distributions of predictions, the variance parameters are estimated only once for each case and not for each ensemble.

It is worth noting that the same variance estimation procedure with $n_{\tilde{\boldsymbol{z}}} = 250$ and $n_{MC} = 250$ lead to an overestimate of the variance, so we reiterate that using a large n_{MC} seems to provide better results, even when $n_{\tilde{\boldsymbol{z}}}$ is relatively small. In each case, we use $\frac{n}{m}$ as a plug-in estimate for $\alpha = \lim \frac{n}{m}$. We also repeated this procedure and generated the distribution of predictions according to the internal variance estimation method described in Algorithm 5. Details and histograms are provided in Appendix D. These distributions appear to be the same as when the subsamples are selected uniformly at random, as in the external variance estimation method.

Note that the distributional results in Theorem 1 require $\lim \frac{k}{\sqrt{n}} = 0$, so in practice, the subsample size k should be small relative to n. In the above simulations, we choose k slightly larger than $\sqrt{n}$ and the distributions appear normally distributed with the correct limiting distribution. However, though this restriction on the growth rate of the subsample size is sufficient for asymptotic normality, it is perhaps not necessary. In our simulations, we found that ensembles built with larger k are still approximately normal, but begin to

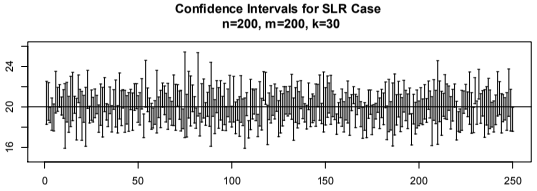

Figure 3: Confidence Intervals for subbagged predictions.

look increasingly further from normal as k increases. The histograms in Figure 2 show the distribution of subbagged predictions in the MARS case with $n = m = 1000$ and $k = 200$ and also with $n = m = k = 1000$ so that we are using full bootstrap samples to build the ensembles in the latter case. The parameters in the limiting distribution are estimated in exactly the same manner as with the smaller k for the case where $k = 200$. In the bootstrap case, we cannot follow our subbagging procedure exactly since the bootstrap samples used to build each tree in the ensemble must be taken with replacement, so we do not attempt to estimate the variance. These distributions look less normal and we begin to overestimate the variance in the case where $k = 200$.

5.2 Confidence Intervals

We move now to building confidence intervals for predictions and examine their coverage probabilities. We begin with the SLR case, with $n = 200$, $m = 200$, and $k = 30$ and as above, predict at $x_1 = 10$. To build the confidence intervals, we generate 250 data sets and with each data set, we produce a subbagged ensemble, estimate the parameters in the limiting distribution, and take the 0.025 and 0.975 quantiles from the estimated limiting normal distribution to form an approximate 95% confidence interval. The mean of this limiting normal θ_k was estimated as the mean of the predictions generated by the ensemble. The variance parameter $\zeta_{k,k}$ was estimated by drawing 500 new subsamples, not necessarily used in the ensemble, and calculating the variance between predictions generated by the resulting 500 trees and $\zeta_{1,k}$ was estimated externally using $n_{\tilde{\boldsymbol{z}}} = 50$ and $n_{MC} = 250$.

In order to assess the coverage probability of our confidence intervals, we first need to estimate the true mean prediction θ_k at $x_1 = 10$ that would be generated by this subbagging ensemble. To estimate this true mean, we built 1000 subbagged ensembles and took the mean prediction generated by these ensembles, which we found to be 20.02 - very close to the true underlying value of 20. In this case, we found a coverage probability of 0.912, which means that 228 of our 250 confidence intervals contained our estimate of the true mean prediction. These confidence intervals are shown in Figure 3. The horizontal line in the plot is at 20.02 and represents our estimate of the true expected prediction.

This same procedure was repeated for the SLR case with $n = m = 1000$ and $k = 60$, the MARS case with $n = m = 500$ and $k = 50$, and the MARS case with $n = m = 1000$ and $k = 75$. In each case, we produced 250 confidence intervals and the coverage probabilities

are shown in Table 1. The parameters in the limiting distributions were estimated externally in exactly the same fashion, using $n_{\tilde{\boldsymbol{z}}} = 50$ and $n_{MC} = 250$ to estimate $\zeta_{1,k}$. These slightly higher coverage probabilities mean that we are overestimating the variance, which is likely due to smaller values of the estimation parameters $n_{\tilde{\boldsymbol{z}}}$ and n_{MC} being used to estimate $\zeta_{1,k}$.

Underlying Function	n	k	θ_k	**Coverage Probability**	
				External Variance Est.	Internal Variance Est.
SLR	200	30	19.94	0.912	0.912
SLR	1000	60	19.99	0.956	0.936
MARS	500	50	17.43	0.980	0.984
MARS	1000	75	17.56	0.996	0.996

Table 1: Coverage probabilities

We also repeated this procedure for generating confidence intervals using the internal variance estimation method. The resulting coverage probabilities are remarkably similar to the external variance estimation method and are shown in Table 1. These ensembles were built using $n_{\tilde{\boldsymbol{z}}} = 50$ and $n_{MC} = 250$.

5.3 Hypothesis Testing

We now explore the hypothesis testing procedure for assessing feature significance. We focus on the MARS case, where our training set now consists of 6 features $X_1, ..., X_6$, but the response Y depends only on the first 5. The values of the additional feature X_6 are sampled uniformly at random from the interval $[0, 1]$ and independently of the first 5 features.

We begin by looking at the distribution of test statistics when the test set consists 41 equally spaced points between 0 and 1. That is, the first test point is $x_1 = \cdots = x_6 = 0$, the second is $x_1 = \cdots = x_6 = 0.025$, and so on so that the last test point is $x_1 = \cdots = x_6 = 1$. For this test, we are interested in looking at the difference between trees built using all features and those built using only the first 5 so that in the notation in Section 4.2, $\boldsymbol{X}^{(R)} = \{X_1, ..., X_5\}$. We ran 250 simulations with $n = 1000$, $m = 1000$, and $k = 75$ using a test set consisting of all 41 test points, the 20 central-most points, and the 5 central-most points. The parameter $\Sigma_{1,k}$ was estimated externally using $n_{\tilde{\boldsymbol{z}}} = 100$ and $n_{MC} = 5000$ and $\Sigma_{k,k}$ was estimated by taking the covariance of the difference in predictions generated by 5000 trees. These covariance parameters are estimated only once instead of within each ensemble since we are only interested in the distribution of test statistics. Histograms of the resulting test statistics along with an overlay of the estimated χ^2 densities are shown in the top row of Figure 4.

We repeated this procedure, this time with a test set consisting of points in the center of the hypercube so we are not predicting close to any edge of the feature space. The value of each feature in the test set was selected uniformly at random from $[0.25, 0.75]$. A total of 41 such test points were generated, and histograms of the 250 resulting test statistics were produced in the cases where we use 5 of these test points, 20 test points, and all 41 test points. These histograms and estimated χ^2 densities are shown in the bottom row of

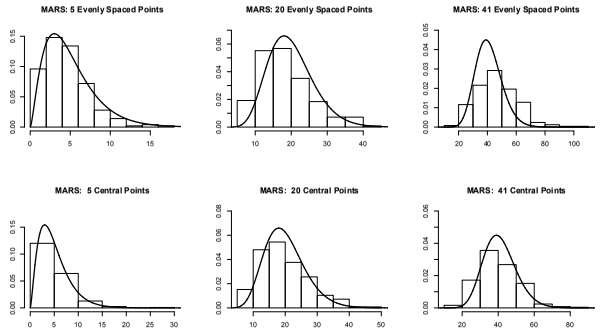

Figure 4: Histograms of simulated test statistics with estimated χ^2 overlay. The top row of histograms involve test points equally spaced between 0 and 1 and the bottom row corresponds to points randomly selected from the interior of the feature space.

Figure 4. Note that the bottom row appears to be a better fit and thus there appears to be some bias occuring when test points are selected near the edges of the feature space.

To check the alpha level of the test—the probability of incorrectly rejecting the null hypothesis—we simulated 250 new training sets and used the test set consisting of 41 randomly selected central points. For each training set, we built full and reduced subbagged estimates, allowed and not allowed to utilize X_6 respectively, estimated the parameters, and performed the hypothesis test. For each ensemble, the variance parameter $\Sigma_{1,k}$ was estimated externally using $n_{\tilde{\boldsymbol{z}}} = 50$ and $n_{MC} = 1000$ and $\Sigma_{k,k}$ was estimated externally on an independently generated set of trees.

In this setup, none of the 250 simulations resulted in rejecting the null hypothesis, so our empirical alpha level was 0. A histogram of the resulting test statistics is shown on the left of Figure 5; the critical value, the 0.95 quantile of the χ^2_{41}, is 56.942. Thus, as with the confidence intervals, we are being conservative. Recall that our confidence interval simulations with $n = 1000$, $m = 1000$, and $k = 75$ predicting at $\boldsymbol{x} = (0.5, ..., 0.5)$ captured our true value 99.6% of the time, so this estimate of 0, though conservative, is not necessarily unexpected. We also repeated this procedure using an internal variance estimate with $n_{\tilde{\boldsymbol{z}}} = 50$ and $n_{MC} = 1000$ and found an alpha level of 0.14. The histogram of test statistics resulting from the internal variance estimation method is shown on the right in Figure 5. Here we see that the correlation introduced by not taking an i.i.d. selection of subsamples to build the ensemble may be slightly inflating the test statistics.

5.4 Random Forests

Thus far, our simulations have dealt only with subbagged ensembles, but recall that Theorem 2 established the asymptotic normality for predictions generated by random forests as

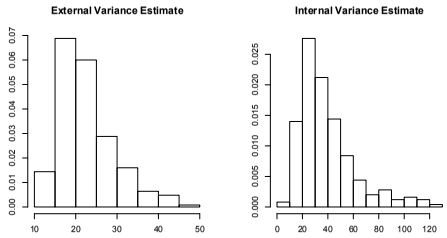

Figure 5: Histograms of simulated test statistics

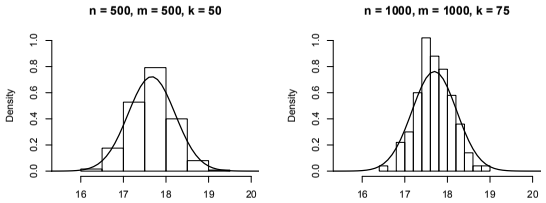

Figure 6: Histograms of random forest predictions at $x_1 = \cdots = x_5 = 0.5$ with estimated normal density overlaid.

well. The histograms in Figure 6 show the distribution of predictions generated by subsampled random forests at $x_1 = \cdots = x_5 = 0.5$ when the true underlying function is the MARS function. These trees were grown using the `randomForest` function in `R` with the `ntree` argument set to 1. At each node in each tree, 3 of the 5 features $X_1, ..., X_5$ were selected at random as candidates for splits and we insisted on at least 2 observations in each terminal node. The histograms show the empirical distribution of 250 subsampled random forest predictions and the overlaid density is the limiting normal $\mathcal{N}(\mathbb{E}r_{n,k,m}(\boldsymbol{x}^*), \frac{1}{\alpha}\frac{k^2}{m}\zeta_{1,k} + \frac{1}{m}\zeta_{k,k})$ with the variance parameters estimated externally. Our estimate of the mean of this distribution was taken as the empirical mean of the 250 predictions. Our estimate of $\zeta_{k,k}$ was taken as the empirical variance of predictions across 5000 new trees and the estimate for $\zeta_{1,k}$ was calculated with $n_{\tilde{\boldsymbol{z}}} = 250$ and $n_{MC} = 2000$.

6. Real Data

We now apply our inference methods to a real data set provided by the Lab of Ornithology at Cornell University. The data is part of the ongoing *eBird* citizen science project described in Sullivan et al. (2009). This project is hosted by Cornell's Lab of Ornithology and relies

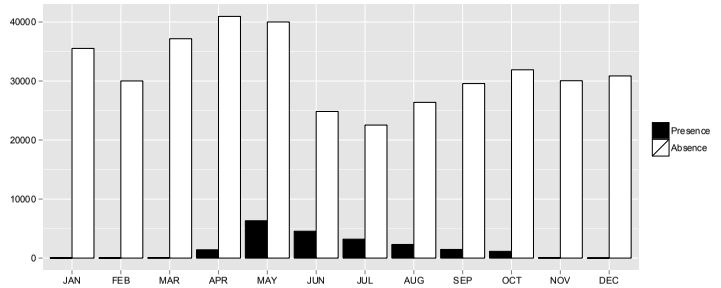

Figure 7: Monthly counts of Indigo Bunting observations.

on citizens, referred to as *birders*, to submit reports of bird observations. Location, bird species observed and not observed, effort level, and number of birds of each species observed are just a few of the variables participants are asked to provide. In addition to the data contained in these reports, landcover characteristics as reported in the 2006 United States National Land Cover Database are also available so that information about the local terrain may be used to help predict species abundance.

For our analysis, we restrict our attention to observations (and non-observations) of the Indigo Bunting species. For the first part of our analysis, we further restrict our attention to observations made during the year 2010. A little more than 400,000 reports of either presence or absence of Indigo Buntings were recorded during 2010 and the data set consists of 23 features. Like many species, the abundance of Indigo Buntings is known to fluctuate throughout the year, so we have two primary goals: (1) to produce confidence intervals for monthly abundance and (2) to show that the feature 'month' is significant for predicting abundance.

A presence/absence plot of Indigo Buntings by month is shown in Figure 7. A few features of this plot are worth pointing out. Most obviously, there are many more absence observations each month than presence observations. This makes sense because each time a birder submits a report, they note when Indigo Buntings are not present. Next, we see that this species is only observed during the warmer months, so month seems highly significant for predicting abundance. Finally, we see that all months have a large number of reports, so we need not worry about underreporting issues throughout the year.

First we produce the confidence intervals. The goal is to get an idea of the monthly abundance, which we can think of as 'probability of observation', so our test points will be 12 vectors, one for each month. For the values of the other features, we will use the average of the values recorded for that feature, or, in the case of categorical features, use the most popular category. Some features, such as elevation, have missing values which are not included in calculating the averages. We also removed the *day* feature from the training set, since day of the year is able to capture any effect of month. Since the training set consists of approximately 400,000 observations, we use a subsample size $k = 650$, slightly more than

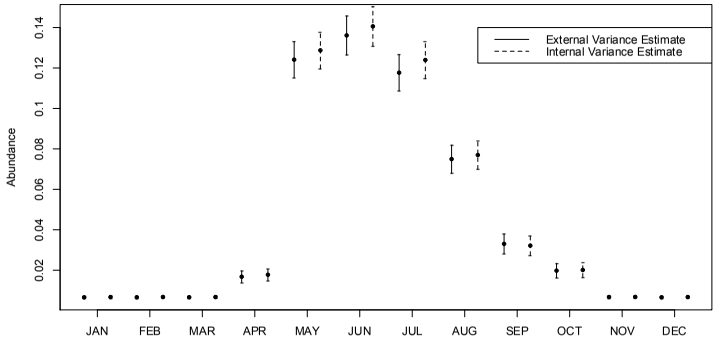

Figure 8: Monthly confidence intervals for Indigo Bunting abundance.

the square root of the training set size. We build a total of $m = 5000$ trees and take the variance of these predictions at each point to be our estimates of $\zeta_{k,k}$. We use an external estimate with $n_{\tilde{\boldsymbol{z}}} = 250$ and $n_{MC} = 5000$ to estimate $\zeta_{1,k}$. For each tree built, we require a minimum of 20 observations to consider splitting an internal node. We also repeat this procedure using an internal estimate of variance with $n_{\tilde{\boldsymbol{z}}} = 250$ and $n_{MC} = 5000$.

The confidence intervals are shown in Figure 8. Note that the pattern seen in Figure 7 is mirrored in the confidence interval plot: the confidence intervals are higher during months where more positive observations are recorded. It is also interesting to note that the width of the confidence intervals is larger during months of higher abundance. Observe in Figure 7 that even for months with many positive observations reported, many more negative observations are also reported. Thus, for these months there are likely a number of trees in the ensemble with nearly all positive or negative observations so we expect a higher variance in predictions. For months when very few positive observations are made, nearly all observations in the terminal node will be abscence observations, thus resulting in a very small variance and much narrower confidence intervals. Based on a visual inspection of the confidence intervals, there appears to be a clear significant difference in abundance between certain months, but we need to account for correlations in our predictions so we also conduct hypothesis tests.

We conduct these formal tests for the significance of month, following the procedure in Section 4.2. To perform this test, we randomly selected 20 points from the training set as the test set and calculated the test statistic based on an internal variance estimate with $n_{\tilde{\boldsymbol{z}}} = 250$ and $n_{MC} = 5000$. We calculated a test statistic of 4233.10 and a critical value, the 0.95 quantile of the χ^2_{20}, of only 31.41 which yields a p-value of approximately 0, so it seems that month is highly significant for predicting abundance. However, when we generated random values for month and repeated the testing procedure, we calculated a

test statistic of 58.02 which, though significantly smaller than the test statistic calculated on the original training set, is still significant. To ensure that the randomized months we selected did not add any accidental structure, we compared predictions generated using this training set to those generated by another training set, also with randomized months. Here we find a test statistic of only 2.36 and thus there is no significant difference between these predictions, so the trees are simply taking advantage of additional randomness. Finally, we test for a difference in predictions generated by the original training set and those generated by the training set with random values of month. In this case, we calculated a test statistic of 2336.14 which is highly significant so we can conclude that month is significant for predicting abundance and the contribution to the prediction is significantly more than would be expected by simply adding a random feature to the model.

This significant effect of month comes as no surprise as Indigo Buntings are known to be a migratory species. However, many scientists also believe that migrations may change from year to year and thus year may also be significant for predicting abundance. For this test, we used the full training data set consisting of approximately 1 million observations from 2004 to 2010 and as a test set, randomly selected 20 observations from the training set. Given this larger training set, we increased our subsample size to $k = 1000$ and our Monte Carlo sample size to $n_{MC} = 8000$ and again performed the tests using the internel variance estimation method. In the first setup where we test predictions from the full training set against predictions generated from the training set without year, we find a test statistic of 94.43 which means that year is significant for making predictions as it is larger than the critical value of 31.41. However, as was the case in testing the significance of month, we find that a randomly generated year feature is also significant with a test statistic of 52.51. Following in the same manner as above, we compare predictions from two training sets, each with a randomized year feature, and we find no significant difference in these predictions with a test statistic of only 4.70. Finally, we test for a difference in predictions between the full training set and a data set with random year and find that there is a significant difference in these predictions with a test statistic of 109.72. Thus, as was the case with month, we can conclude that year is significant for predicting abundance and the contribution to the prediction is significantly more than would be expected by simply adding a random feature to the model.

7. Discussion

This work demonstrates that formal statistical inference procedures are possible within the context of supervised ensemble learning, even when individual base learners are difficult to analyze mathematically. Demonstrating that ensembles built with subsamples can be viewed as U-statistics allows us to calculate limiting distributions for predictions and consistent estimation procedures for the parameters allow us to compute confidence intervals for predictions and formally test the significance of features. Moreover, using the internal variance estimation procedure, we are able to do so at no additional computational cost. In his controversial paper, Breiman (2001a) contrasted traditional statistical data analysis models that emphasize interpretation with the modern algorithmic approach of machine learning where the primary goal is prediction and among the differences invoked was the statisti-

cian's concern for formalized inference. Our hope is that this work be seen as something of a bridge between Breiman's two cultures.

The distributions and procedures we discuss apply to a very general class of supervised learning algorithms. We focus on bagging and random forests with tree-based base learners due to their popularity, but any supervised ensemble method that satisfies the conditions in Theorems 1 and 2 will generate predictions that have these limiting distributions and the inference procedures can be carried out in the same way. By the same reasoning, our procedures also make no restrictions on the tree-building method.

There are also some small modifications that can be made to our procedure which would still allow for an asymptotically normal limiting distribution. First, we assumed that our subsamples were selected with replacement so that in theory, the same subsample could be selected multiple times. This choice was based primarily on the fact that ensuring the exact subsample was not taken twice would typically require extra computational work. However, even for relatively small data sets, the probability of selecting the same subsample more than once is very small, and not surprisingly, the limiting distributions remain identical when the subsamples are taken without replacement. Furthermore, we also did not allow repeat observations within subsamples, which made the resulting estimator a U-statistic. Had we selected the subsamples themselves with replacement, our estimator would be a V-statistic—a closely related class of estimators introduced by von Mises (1947)—and similar theory could be developed. It is also worth pointing out that in practice, we always selected the same number of subsamples m_n and subsample size k_n for each prediction point $\boldsymbol{x}^*$ but in theory, these could be chosen differently for each point of interest and the same can be said of the estimation parameters $n_{\tilde{\boldsymbol{z}}}$ and n_{MC}. However, choosing different values of these parameters for different prediction points involves significantly more bookkeeping and we advise against it in practice.

Our approach also raises some issues. Perhaps most obviously, the parameter in our inference procedures is the expected prediction generated by trees built in the prescribed fashion, as opposed to the true value of the underlying regression function, $F(\boldsymbol{x}^*)$. Though some tree-building methods have been shown to be consistent, the bias introduced may not be negligible so we have to be careful about interpreting our results. It may be possible to employ a residual bootstrap to try and correct for bias and we plan to explore this in future work. Another open question that we hope to address in future work is how to select the test points when testing feature significance. In the eBird application, we randomly selected points from the training set, but it would be beneficial to investigate optimal strategies for selecting both the number and location of test points. Finally, the distributional results we provide could potentially allow us to test more complex hypotheses about the structure of the underlying regression function, for example, the interaction between covariates.

Acknowledgments

We would like to thank the action editor and reviewers for their careful and thoughtful remarks. We would also like to thank the Lab of Ornithology at Cornell University for providing interesting data. Appendix A.

We present here the proofs of the theorems provided in Section 2. We begin with a lemma from Lee (1990).

Lemma 3 *(Lee 1990, Lemma A, page 201) Let $a_1, a_2, ...$ be a sequence of constants such that $\lim_{n\to\infty} \frac{1}{n}\sum_{i=1}^n a_i = 0$ and $\lim_{n\to\infty} \frac{1}{n}\sum_{i=1}^n a_i^2 = \sigma^2$ and let the random variables $M_1, ..., M_n$ have a multinomial distribution, multinomial$(m_n; \frac{1}{m_n}, ..., \frac{1}{m_n})$. Then as $m_n, n \to \infty$, the limiting distribution of*

$$m_n^{-1/2}\sum_{i=1}^n a_i(M_i - m_n/n)$$

is $\mathcal{N}(0, \sigma^2)$.

Additionally, it will be useful to have the limiting distribution of complete infinite order U-statistics, which we provide in the lemma below.

Lemma 4 *Let $Z_1, Z_2, ... \overset{iid}{\sim} F_Z$ and let U_{n,k_n} be a complete, infinite order U-statistic with kernel h_{k_n} satisfying Condition 1 and $\theta_{k_n} = \mathbb{E}h_{k_n}(Z_1, ..., Z_{k_n})$ such that $\mathbb{E}h_{k_n}^2(Z_1, ..., Z_{k_n}) \leq C < \infty$ for all n and some constant C and $\lim \frac{k_n}{\sqrt{n}} = 0$. Then*

$$\frac{\sqrt{n}(U_{n,k_n} - \theta_{k_n})}{\sqrt{k_n^2\zeta_{1,k_n}}} \xrightarrow{d} \mathcal{N}(0,1).$$

The proof of Lemma 3 is provided in Lee (1990) page 201. The proof of Lemma 4 follows in exactly the same fashion as the proof of result *(i)* in Theorem 1 below. We take advantage of these lemmas in the following proofs.

Theorem 1 *Let $Z_1, Z_2, ... \overset{iid}{\sim} F_Z$ and let U_{n,k_n,m_n} be an incomplete, infinite order U-statistic with kernel h_{k_n} that satisfies Condition 1. Let $\theta_{k_n} = \mathbb{E}h_{k_n}(Z_1, ..., Z_{k_n})$ such that $\mathbb{E}h_{k_n}^2(Z_1, ..., Z_{k_n}) \leq C < \infty$ for all n and some constant C, and let $\lim \frac{n}{m_n} = \alpha$. Then as long as $\lim \frac{k_n}{\sqrt{n}} = 0$ and $\lim \zeta_{1,k_n} \neq 0$,*

(i) if $\alpha = 0$, then $\frac{\sqrt{n}(U_{n,k_n,m_n} - \theta_{k_n})}{\sqrt{k_n^2\zeta_{1,k_n}}} \xrightarrow{d} \mathcal{N}(0,1)$.

(ii) if $0 < \alpha < \infty$, then $\frac{\sqrt{m_n}(U_{n,k_n,m_n} - \theta_{k_n})}{\sqrt{\frac{k_n^2}{\alpha}\zeta_{1,k_n} + \zeta_{k_n,k_n}}} \xrightarrow{d} \mathcal{N}(0,1)$.

(iii) if $\alpha = \infty$, then $\frac{\sqrt{m_n}(U_{n,k_n,m_n} - \theta_{k_n})}{\sqrt{\zeta_{k_n,k_n}}} \xrightarrow{d} \mathcal{N}(0,1)$.

Proof:

(i) Suppose first that $\alpha = 0$. In the interest of clarity, we follow the Hájek projection method discussed in Van der Vaart (2000) chapters 11 and 12. Define the Hájek projection of $U_{n,k_n,m_n} - \theta_{k_n}$ as

$$\begin{aligned}\hat{U}_{n,k_n,m_n} &= \sum_{i=1}^{n} \mathbb{E}(U_{n,k_n,m_n} - \theta_{k_n} \mid Z_i) - (n-1)\mathbb{E}(U_{n,k_n,m_n} - \theta_{k_n})\\ &= \sum_{i=1}^{n} \mathbb{E}(U_{n,k_n,m_n} - \theta_{k_n} \mid Z_i)\end{aligned}$$

so that for each term in the sum, we have

$$\begin{aligned}\mathbb{E}(U_{n,k_n,m_n} - \theta_{k_n} \mid Z_i) &= \mathbb{E}\left(\frac{1}{m_n}\sum_{\beta} h_{k_n}(Z_{\beta_1},...,Z_{\beta_{k_n}}) - \theta_{k_n} \;\middle|\; Z_i\right)\\ &= \frac{1}{m_n}\sum_{\beta} \mathbb{E}\big(h_{k_n}(Z_{\beta_1},...,Z_{\beta_{k_n}}) - \theta_{k_n} \mid Z_i\big) \qquad (7)\end{aligned}$$

where, in keeping with the notation in Van der Vaart (2000), we let β index the subsamples. Define $h_{1,k_n}(x) = \mathbb{E}h_{k_n}(x, Z_2, ..., Z_{k_n}) - \theta_{k_n}$ and let W be the number of subsamples that contain i. Since we assume that the subsamples are selected uniformly at random with replacement,

$$W \sim Binom\left(m_n, \frac{\binom{n-1}{k_n-1}}{\binom{n}{k}}\right)$$

so we can rewrite (7) as

$$\begin{aligned}&\frac{1}{m_n}\sum_{\beta}\mathbb{E}\Big(\mathbb{E}(h_{k_n}(Z_{\beta_1},...,Z_{\beta_{k_n}}) - \theta_{k_n}|Z_i) \mid W\Big)\\ &= \frac{1}{m_n}\mathbb{E}(W h_{1,k_n}(Z_i))\\ &= \frac{1}{m_n}\left(m_n\left(\frac{\binom{n-1}{k_n-1}}{\binom{n}{k}}\right)h_{1,k_n}(Z_i)\right)\\ &= \frac{k_n}{n}h_{1,k_n}(Z_i)\end{aligned}$$

so that taking the sum yields

$$\hat{U}_{n,k_n,m_n} = \frac{k_n}{n}\sum_{i=1}^{n} h_{1,k_n}(Z_i).$$

Now we establish the asymptotic normality of $\hat{U}_{n,k_n,m_n}$. Define the triangular array

$$\begin{array}{l}k_{n_1}h_{1,k_{n_1}}(Z_1), \;\dots\;, k_{n_1}h_{1,k_{n_1}}(Z_{n_1})\\ k_{n_1+1}h_{1,k_{n_1+1}}(Z_1), \;\dots\;\dots\;, k_{n_1+1}h_{1,k_{n_1+1}}(Z_{n_1+1})\\ \quad\vdots\\ k_{n_1+j}h_{1,k_{n_1+j}}(Z_1), \;\dots\;\dots\;\dots\;\dots\;\dots\;\dots\;, k_{n_1+j}h_{1,k_{n_1+j}}(Z_{n_1+j})\end{array}$$

so that for each variable in the array, we have

$$\mathbb{E}(k_n h_{1,k_n}(Z_i)) = k_n(\theta_{k_n} - \theta_{k_n}) = 0$$

and

$$var(k_n h_{1,k_n}(Z_i)) = k_n^2 var(h_{1,k_n}(Z_i)) = k_n^2\zeta_{1,k_n}$$

and thus the row-wise sum of the variances is

$$s_n^2 = \sum_{i=1}^{n} var(k_n h_{1,k_n}(Z_i)) = nk_n^2\zeta_{1,k_n}.$$

For $\delta > 0$, the Lindeberg condition is given by

$$\begin{aligned}&\lim_{n\to\infty}\sum_{i=1}^{n}\frac{1}{nk_n^2\zeta_{1,k_n}}\int_{|k_n h_{1,k_n}(Z_i)|\geq\delta k_n\sqrt{n\zeta_{1,k_n}}} k_n^2 h_{1,k_n}^2(Z_i)dP\\ &= \lim_{n\to\infty}\sum_{i=1}^{n}\frac{1}{n\zeta_{1,k_n}}\int_{|h_{1,k_n}(Z_i)|\geq\delta\sqrt{n\zeta_{1,k_n}}} h_{1,k_n}^2(Z_i)dP\\ &\leq \lim_{n\to\infty}\max_{1\leq i\leq n}\frac{1}{\zeta_{1,k_n}}\int_{|h_{1,k_n}(Z_i)|\geq\delta\sqrt{n\zeta_{1,k_n}}} h_{1,k_n}^2(Z_i)dP\\ &= \lim_{n\to\infty}\frac{1}{\zeta_{1,k_n}}\int_{|h_{1,k_n}(Z_1)|\geq\delta\sqrt{n\zeta_{1,k_n}}} h_{1,k_n}^2(Z_1)dP \qquad (8)\\ &= 0\end{aligned}$$

by Condition 1, and thus the Lindeberg condition is satisfied. Thus, by the Lindeberg-Feller central limit theorem,

$$\frac{\sum_j k_n h_{1,k_n}(Z_j)}{s_n} \xrightarrow{d} \mathcal{N}(0,1)$$

or, rewriting,

$$\frac{\sqrt{n}\hat{U}_{n,k_n,m_n}}{\sqrt{k_n^2\zeta_{1,k_n}}} \xrightarrow{d} \mathcal{N}(0,1).$$

Now, we need to compare the limiting variance ratio of U_{n,k_n,m_n} and its Hájek projection $\hat{U}_{n,k_n,m_n}$. For incomplete U-statistics of fixed rank, Blom (1976) showed that the variance of the incomplete U-statistic U_m consisting of m subsamples selected uniformly at random with replacement is given by

$$\frac{\zeta_k}{m_n} + \left(1 - \frac{1}{m_n}\right) var(U)$$

where U is the complete U-statistic analogue. Extending this result to our situation where k and m may both depend on n, we have

$$var(U_{n,k_n,m_n}) = \frac{\zeta_{k_n,k_n}}{m_n} + \left(1 - \frac{1}{m_n}\right) var(U_{n,k_n})$$

where the variance of the complete U-statistic U_{n,k_n} is given by

$$\sum_{c=1}^{k_n} \frac{k_n!^2}{c!(k_n-c)!^2} \frac{(n-k_n)(n-k_n-1)\cdots(n-2k_n+c+1)}{n(n-1)\cdots(n-k_n+1)} \zeta_{c,k_n}.$$

The details of this calculation are described in Van der Vaart (2000) page 163. Thus, looking at the limit of the variance ratio, we have

$$\begin{aligned}
\lim_{n\to\infty}\left(\frac{var(U_{n,k_n,m_n})}{var(\hat{U}_{n,k_n,m_n})}\right) &= \lim_{n\to\infty}\left(\frac{\frac{\zeta_{k_n,k_n}}{m_n} + \left(1-\frac{1}{m_n}\right) var(U_{n,k_n})}{\frac{k_n^2}{n}\zeta_{1,k_n}}\right) \\
&= \lim_{n\to\infty}\left(\frac{n\ \zeta_{k_n,k_n}}{m_n\ k_n^2\ \zeta_{1,k_n}}\right) + \lim_{n\to\infty}\left(1-\frac{1}{m_n}\right)\lim_{n\to\infty}\left(\frac{n\ var(U_{n,k_n})}{k_n^2\ \zeta_{1,k_n}}\right) \\
&= 0 + \lim_{n\to\infty}\left(\frac{n\ var(U_{n,k_n})}{k_n^2\ \zeta_{1,k_n}}\right) \\
&= \lim_{n\to\infty}\left(\frac{\sum_{c=1}^{k_n} \frac{k_n!^2}{c!(k_n-c)!^2} \frac{(n-k_n)(n-k_n-1)\cdots(n-2k_n+c+1)}{(n-1)\cdots(n-k_n+1)} \zeta_{c,k_n}}{k_n^2\zeta_{1,k_n}}\right) \\
&= \lim_{n\to\infty}\left(\frac{\frac{k_n!^2}{(k_n-1)!^2} \frac{(n-k_n)(n-k_n-1)\cdots(n-2k_n+2)}{(n-1)\cdots(n-k_n+1)} \zeta_{1,k_n}}{k_n^2\zeta_{1,k_n}}\right) \\
&= \lim_{n\to\infty}\left(\frac{(n-k_n)(n-k_n-1)\cdots(n-2k_n+2)}{(n-1)\cdots(n-k_n+1)}\right) \\
&= 1.
\end{aligned}$$

Note that in the second line, $\lim\left(\frac{n\ \zeta_{k_n,k_n}}{m_n\ k_n^2\ \zeta_{1,k_n}}\right) = 0$ since $\frac{n}{m_n} \to 0$, $\zeta_{1,k_n} \nrightarrow 0$ by assumption, and $\zeta_{k_n,k_n} \nrightarrow \infty$ since $\mathbb{E}h_{k_n}^2(Z_1,...,Z_{k_n})$ is bounded. Finally, by Slutsky's Theorem and Theorem 11.2 in Van der Vaart (2000), we have

$$\frac{\sqrt{n}(U_{n,k_n,m_n} - \theta_{k_n})}{\sqrt{k_n^2\zeta_{1,k_n}}} = \frac{\sqrt{n}(U_{n,k_n,m_n} - \theta_{k_n} - \hat{U}_{n,k_n,m_n} + \hat{U}_{n,k_n,m_n})}{\sqrt{k_n^2\zeta_{1,k_n}}}$$

$$= \frac{\sqrt{n}(U_{n,k_n,m_n} - \theta_{k_n} - \hat{U}_{n,k_n,m_n})}{\sqrt{k_n^2\zeta_{1,k_n}}} + \frac{\sqrt{n}\hat{U}_{n,k_n,m_n}}{\sqrt{k_n^2\zeta_{1,k_n}}}$$

where $\sqrt{n}(U_{n,k_n,m_n} - \theta_{k_n} - \hat{U}_{n,k_n,m_n})/\sqrt{k_n^2\zeta_{1,k_n}} \xrightarrow{P} 0$ and

$$\frac{\sqrt{n}\hat{U}_{n,k_n,m_n}}{\sqrt{k_n^2\zeta_{1,k_n}}} \xrightarrow{d} \mathcal{N}(0,1)$$

so that

$$\frac{\sqrt{n}(U_{n,k_n,m_n} - \theta_{k_n})}{\sqrt{k_n^2\zeta_{1,k_n}}} \xrightarrow{d} \mathcal{N}(0,1)$$

as desired. □

(ii) & (iii) Now suppose $\alpha > 0$. We follow the proof technique in Lee (1990) page 200 which is based on the work of Janson (1984). Let $\mathcal{S}_{(n,k_n)} = \{S_i : i = 1,...,\binom{n}{k_n}\}$ denote the set of all possible subsamples of size k_n. In the following work, we use the notation (n,k_n) in place of $\binom{n}{k_n}$ in subscripts and summation notation. Consider the random vector $M_{n,k_n} = (M_{S_1},...,M_{S_{(n,k_n)}})$, where the i^{th} element denotes the number of times the i^{th} subsample appears in U_{n,k_n,m_n}. Since the subsamples are selected uniformly at random with replacement, $M_{n,k_n} \sim multinomial(m_n; \frac{1}{\binom{n}{k_n}},...,\frac{1}{\binom{n}{k_n}})$. Let ϕ_{n,k_n,m_n} be the characteristic function of $\sqrt{m_n}(U_{n,k_n,m_n} - \theta_{k_n})$ and let ϕ denote the limiting characteristic function of $\sqrt{n}(U_{n,k_n} - \theta_{k_n})$ where U_{n,k_n} is the corresponding complete U-statistic. Additionally, let $\phi^{(M)}_{n,k_n,m_n}$ be the characteristic function of the random variable

$$m_n^{-1/2} \sum_{i=1}^{(n,k)} \left(M_{S_i} - \frac{m_n}{\binom{n}{k_n}}\right)\Big(h_{k_n}(S_i) - \theta_{k_n}\Big)\Big| Z_1,...,Z_n.$$

Then we have

$$\begin{aligned}
\phi_{n,k_n,m_n}(t) &= \mathbb{E}\left(exp\left[it\sqrt{m_n}(U_{n,k_n,m_n} - \theta_{k_n})\right]\right) \\
&= \mathbb{E}\left(exp\left[itm_n^{-1/2}\left(\sum_{i=1}^{(n,k_n)} M_{S_i}(h_{k_n}(S_i) - \theta_{k_n})\right)\right]\right) \\
&= \mathbb{E}\left(\mathbb{E}\left(exp\left[itm_n^{-1/2}\left(\sum_{i=1}^{(n,k_n)} M_{S_i}(h_{k_n}(S_i) - \theta_{k_n})\right)\right]\Bigg| Z_1,...,Z_n\right)\right) \\
&= \mathbb{E}\Bigg(\mathbb{E}\Bigg(exp\Bigg[itm_n^{-1/2}\Bigg(\sum_{i=1}^{(n,k_n)}\left(M_{S_i} + \frac{m_n}{\binom{n}{k_n}} - \frac{m_n}{\binom{n}{k_n}}\right) \\
&\qquad\qquad \times \left(h_{k_n}(S_i) - \theta_{k_n}\right)\Bigg)\Bigg]\Bigg| Z_1,...,Z_n\Bigg)\Bigg)
\end{aligned}$$

$$
\begin{aligned}
&= \mathbb{E}\left(\mathbb{E}\left(exp\left[itm_n^{-1/2}\left(\sum_{i=1}^{(n,k_n)}\frac{m_n}{\binom{n}{k_n}}(h_{k_n}(S_i)-\theta_{k_n})\right)\right]\right.\right.\\
&\quad\left.\left.\times exp\left[itm_n^{-1/2}\left(\sum_{i=1}^{(n,k)}\left(M_{S_i}-\frac{m_n}{\binom{n}{k_n}}\right)(h_{k_n}(S_i)-\theta_{k_n})\right)\right]\Big|Z_1,...,Z_n\right)\right)\\
&= \mathbb{E}\left(exp\left[itm_n^{-1/2}\left(\sum_{i=1}^{(n,k_n)}\frac{m_n}{\binom{n}{k_n}}(h_{k_n}(S_i)-\theta_{k_n})\right)\right]\right.\\
&\quad\left.\times\,\mathbb{E}\left(exp\left[itm_n^{-1/2}\left(\sum_{i=1}^{(n,k_n)}\left(M_{S_i}-\frac{m_n}{\binom{n}{k_n}}\right)(h_{k_n}(S_i)-\theta_{k_n})\right)\right]\Big|Z_1,...,Z_n\right)\right)\\
&= \mathbb{E}\left(exp\left[it\sqrt{m_n}U_{n,k_n}\right]\;\phi^{(M)}_{n,k_n,m_n}(t)\right)
\end{aligned}
$$

and now, taking limits, we have

$$
\begin{aligned}
\lim_{n\to\infty}\phi_{n,k_n,m_n}(t) &= \lim_{n\to\infty}\mathbb{E}\left(exp\left[it\sqrt{m_n}U_{n,k_n}\right]\;\phi^{(M)}_{n,k_n,m_n}(t)\right)\\
&= \mathbb{E}\left(\lim_{n\to\infty}exp\left[it\sqrt{m_n}U_{n,k_n}\right]\;\lim_{n\to\infty}\phi^{(M)}_{n,k_n,m_n}(t)\right)
\end{aligned}
$$

so that by the preceeding lemmas,

$$
\begin{aligned}
\lim_{n\to\infty}\phi_{n,k_n,m_n}(t) &= \lim_{n\to\infty}\mathbb{E}\left(exp\left[it\sqrt{m_n}U_{n,k_n}\right]\right)exp\left[-t^2\zeta_{k_n,k_n}/2\right]\\
&= \lim_{n\to\infty}\mathbb{E}\left(exp\left[it\Big(\frac{\sqrt{m_n}}{\sqrt{n}}\Big)\sqrt{n}U_{n,k_n}\right]\right)exp\left[-t^2\zeta_{k_n,k_n}/2\right]\\
&= \phi(\alpha^{-1/2}t)exp\left[-t^2\zeta_{k_n,k_n}/2\right]\\
&= exp\left[-(t\alpha^{-1/2})^2k_n^2\zeta_{1,k_n}/2\right]exp\left[-t^2\zeta_{k_n,k_n}/2\right]\\
&= exp\left[-t^2\Big(\frac{k_n^2}{\alpha}\zeta_{1,k_n}+\zeta_{k_n,k_n}\Big)/2\right]
\end{aligned}
$$

which is the characteristic function of a Normal distribution with mean 0 and variance $\frac{k_n^2}{\alpha}\zeta_{1,k_n}+\zeta_{k_n,k_n}$. Note that when $\alpha=\infty$, the first term in the variance is 0, so the limiting variance reduces to ζ_{k_n,k_n}, as desired. ■

Proposition 1: *For a bounded regression function F, if there exists a constant c such that for all $k_n \geq 1$,*

$$
\begin{aligned}
\big|h((\boldsymbol{X}_1,Y_1),...,(\boldsymbol{X}_{k_n},Y_{k_n}),(\boldsymbol{X}_{k_n+1},Y_{k_n+1})) - h((\boldsymbol{X}_1,Y_1),...,(\boldsymbol{X}_{k_n},Y_{k_n}),(\boldsymbol{X}_{k_n+1},Y^*_{k_n+1}))\big|\\
\leq c\big|Y_{k_n+1}-Y^*_{k_n+1}\big|
\end{aligned}
$$

where $Y_{k_n+1}=F(\boldsymbol{X}_{k_n+1})+\epsilon_{k_n+1}$, $Y^*_{k_n+1}=F(\boldsymbol{X}_{k_n+1})+\epsilon^*_{k_n+1}$, and where ϵ_{k_n+1} and $\epsilon^*_{k_n+1}$ are i.i.d. with exponential tails, then Condition 1 is satisfied.

Proof. First consider the particular $Y^*_j=F(\boldsymbol{X}_j)$. Since F is bounded, we can define

$$\sup_{\boldsymbol{X}_j\in\mathcal{X}}\big|F(\boldsymbol{X}_j)\big|\leq M<\infty$$

and since tree-based predictions cannot fall outside the range of responses in the training set, $\big|h\big((\boldsymbol{X}_1,Y^*_1),...,(\boldsymbol{X}_{k_n},Y^*_{k_n})\big)\big|\leq M$ for all possible $\boldsymbol{X}_1,...,\boldsymbol{X}_{k_n}$. Furthermore, by the Lipschitz condition,

$$\big|h\big((\boldsymbol{X}_1,Y^*_1),...,(\boldsymbol{X}_{k_n},Y^*_{k_n})\big)-h\big((\boldsymbol{X}_1,Y^*_1),(\boldsymbol{X}_2,Y_2),...,(\boldsymbol{X}_{k_n},Y_{k_n})\big)\big|\leq c\sum_{j=2}^{k_n}\big|\epsilon_j\big|$$

and thus, applying Jensen's Inequality, we have

$$
\begin{aligned}
&\sup_{\boldsymbol{X}_1\in\mathcal{X}}\big|h_{1,k_n}\big((\boldsymbol{X}_1,Y^*_1)\big)\big|\\
&=\sup_{\boldsymbol{X}_1\in\mathcal{X}}\left|\int h\big((\boldsymbol{X}_1,Y^*_1),(\boldsymbol{X}_2,Y_2),...,(\boldsymbol{X}_{k_n},Y_{k_n})\big)-h\big((\boldsymbol{X}_1,Y^*_1),...,(\boldsymbol{X}_{k_n},Y^*_{k_n})\big)\right.\\
&\qquad\left.+\,h\big((\boldsymbol{X}_1,Y^*_1),...,(\boldsymbol{X}_{k_n},Y^*_{k_n})\big)dP-\theta_{k_n}\right|\\
&\leq\sup_{\boldsymbol{X}_1\in\mathcal{X},...,\boldsymbol{X}_{k_n}\in\mathcal{X}}\int\Big|h\big((\boldsymbol{X}_1,Y^*_1),(\boldsymbol{X}_2,Y_2),...,(\boldsymbol{X}_{k_n},Y_{k_n})\big)-h\big((\boldsymbol{X}_1,Y^*_1),...,(\boldsymbol{X}_{k_n},Y^*_{k_n})\big)\Big|dP\\
&\qquad+\sup_{\boldsymbol{X}_1\in\mathcal{X}}h\big((\boldsymbol{X}_1,Y^*_1),...,(\boldsymbol{X}_{k_n},Y^*_{k_n})\big)-\theta_{k_n}\\
&\leq ck_n\mathbb{E}\big|\epsilon_1\big|+M-\theta_{k_n}.
\end{aligned}
$$

Now, define the set of interest in the Lindeberg condition as A_n so that we may write

$$
\begin{aligned}
A_n &= \left\{ \left| h_{1,k_n}\big((\boldsymbol{X}_1, Y_1)\big) \right| \geq \delta \sqrt{n\zeta_{1,k_n}} \right\} \\
&= \left\{ \left| h_{1,k_n}\big((\boldsymbol{X}_1, Y_1)\big) - h_{1,k_n}\big((\boldsymbol{X}_1, Y_1^*)\big) + h_{1,k_n}\big((\boldsymbol{X}_1, Y_1^*)\big) \right| \geq \delta \sqrt{n\zeta_{1,k_n}} \right\} \\
&\subseteq \left\{ \left| h_{1,k_n}\big((\boldsymbol{X}_1, Y_1)\big) - h_{1,k_n}\big((\boldsymbol{X}_1, Y_1^*)\big) \right| \geq \delta \sqrt{n\zeta_{1,k_n}} + \left| h_{1,k_n}\big((\boldsymbol{X}_1, Y_1^*)\big) \right| \right\} \\
&\subseteq \left\{ \left|\epsilon_1\right| \geq \frac{1}{c} \left(\delta \sqrt{n\zeta_{1,k_n}} + M - \theta_{k_n} \right) + k_n \mathbb{E}\left|\epsilon_1\right| \right\} \\
&=: A_n^*
\end{aligned}
$$

Finally, continuing from equation (8) of Theorem 1,

$$
\begin{aligned}
&\lim_{n\to\infty} \frac{1}{\zeta_{1,k_n}} \int_{A_n} h_{1,k_n}^2\big((\boldsymbol{X}_1, Y_1)\big) dP \\
&= \lim_{n\to\infty} \frac{1}{\zeta_{1,k_n}} \int_{A_n} \left(h_{1,k_n}\big((\boldsymbol{X}_1, Y_1)\big) - h_{1,k_n}\big((\boldsymbol{X}_1, Y_1^*) + h_{1,k_n}\big((\boldsymbol{X}_1, Y_1^*)\big) \right)^2 dP \\
&\leq \lim_{n\to\infty} \frac{2}{\zeta_{1,k_n}} \int_{A_n} \left(h_{1,k_n}\big((\boldsymbol{X}_1, Y_1)\big) - h_{1,k_n}\big((\boldsymbol{X}_1, Y_1^*)\big) \right)^2 dP \\
&\qquad\qquad + \lim_{n\to\infty} \frac{2}{\zeta_{1,k_n}} \int_{A_n} h_{1,k_n}^2\big((\boldsymbol{X}_1, Y_1^*) dP \\
&\leq \lim_{n\to\infty} \frac{2}{\zeta_{1,k_n}} \int_{A_n^*} c^2 \epsilon_1^2 dP + \lim_{n\to\infty} \frac{2}{\zeta_{1,k_n}} P(A_n^*) \left(c k_n \mathbb{E}\left|\epsilon_1\right| + M - \theta_{k_n} \right)^2 \\
&= \lim_{n\to\infty} \frac{2}{\zeta_{1,k_n}} P\left[\left|\epsilon_1\right| \geq \frac{1}{c} \left(\sqrt{n\zeta_{1,k_n}} + M - \theta_{k_n} \right) + k \mathbb{E}\left|\epsilon_1\right| \right] \\
&\qquad\qquad \times \left(c k_n \mathbb{E}\left|\epsilon_1\right| + M - \theta_{k_n} \right)^2 \\
&= 0
\end{aligned}
$$

as desired, so long as $nP\left(\left|\epsilon_1\right| > \sqrt{n}\right) \to 0$, which is the case with exponential tails, and $k_n = o(\sqrt{n})$. ■

Theorem 2 *Let $U_{\omega;n,k_n,m_n}$ be a random kernel U-statistic of the form defined in equation (5) such that $U^*_{\omega;n,k_n,m_n}$ satisfies Condition 1 and suppose that $\mathbb{E}h^2_{k_n}(Z_1, ..., Z_{k_n}) < \infty$ for all n, $\lim \frac{k_n}{\sqrt{n}} = 0$, and $\lim \frac{n}{m_n} = \alpha$. Then, letting β index the subsamples, so long as $\lim \zeta_{1,k_n} \neq 0$ and*

$$
\lim_{n\to\infty} \mathbb{E}\left(h_{k_n}^{(\omega)}(Z_{\beta_1}, ..., Z_{\beta_{k_n}}) - \mathbb{E}_\omega h_{k_n}^{(\omega)}(Z_{\beta_1}, ..., Z_{\beta_{k_n}}) \right)^2 \neq \infty,
$$

$U_{\omega;n,k_n,m_n}$ is asymptotically normal and the limiting distributions are the same as those provided in Theorem 1.

Proof. We begin with the case where $\alpha = 0$ and we make use of this result in the proof of the case where $\alpha > 0$. As in Section 2.2, define $U^*_{\omega;n,k_n,m_n} = \mathbb{E}_\omega U_{\omega;n,k_n,m_n}$. We have

$$
\begin{aligned}
&\mathbb{E}(U_{\omega;n,k_n,m_n} - U^*_{\omega;n,k_n,m_n})^2 \\
&= \mathbb{E}\left[\left(\frac{1}{m_n} \sum_\beta h_{k_n}^{(\omega)}(Z_{\beta_1}, ..., Z_{\beta_{k_n}}) - \mathbb{E}_\omega \left(\frac{1}{m_n} \sum_\beta h_{k_n}^{(\omega)}(Z_{\beta_1}, ..., Z_{\beta_{k_n}}) \right) \right)^2 \right] \\
&= \mathbb{E}\left[\frac{1}{m_n^2} \left(\sum_\beta h_{k_n}^{(\omega)}(Z_{\beta_1}, ..., Z_{\beta_{k_n}}) - \mathbb{E}_\omega \left(\sum_\beta h_{k_n}^{(\omega)}(Z_{\beta_1}, ..., Z_{\beta_{k_n}}) \right) \right)^2 \right] \\
&= \mathbb{E}\frac{1}{m_n^2} \left(\sum_\beta h_{k_n}^{(\omega)}(Z_{\beta_1}, ..., Z_{\beta_{k_n}}) - \left(\sum_\beta \mathbb{E}_\omega h_{k_n}^{(\omega)}(Z_{\beta_1}, ..., Z_{\beta_{k_n}}) \right) \right)^2 \\
&= \mathbb{E}\left[\frac{1}{m_n^2} \sum_\beta \left(h_{k_n}^{(\omega)}(Z_{\beta_1}, ..., Z_{\beta_{k_n}}) - \mathbb{E}_\omega h_{k_n}^{(\omega)}(Z_{\beta_1}, ..., Z_{\beta_{k_n}}) \right)^2 \right] \\
&\quad + \mathbb{E}\left[\frac{1}{m_n^2} \sum_{\beta_i \neq \beta_j} \left(h_{k_n}^{(\omega)}(Z_{\beta_{i_1}}, ..., Z_{\beta_{i_{k_n}}}) - \mathbb{E}_\omega h_{k_n}^{(\omega)}(Z_{\beta_{i_1}}, ..., Z_{\beta_{i_{k_n}}}) \right) \right. \\
&\qquad\qquad \left. \times \left(h_{k_n}^{(\omega)}(Z_{\beta_{j_1}}, ..., Z_{\beta_{j_{k_n}}}) - \mathbb{E}_\omega h_{k_n}^{(\omega)}(Z_{\beta_{j_1}}, ..., Z_{\beta_{j_{k_n}}}) \right) \right]
\end{aligned}
$$

We focus now on the second term, involving the cross terms with different subsamples and randomization parameters. Splitting apart the expectation and moving the expectation with respect to ω inside, we can write the second term as

$$
\begin{aligned}
&\mathbb{E}\left[\frac{1}{m_n^2} \sum_{\beta_i \neq \beta_j} \left(h_{k_n}^{(\omega)}(Z_{\beta_{i_1}}, ..., Z_{\beta_{i_{k_n}}}) - \mathbb{E}_\omega h_{k_n}^{(\omega)}(Z_{\beta_{i_1}}, ..., Z_{\beta_{i_{k_n}}}) \right) \right. \\
&\qquad\qquad \left. \times \left(h_{k_n}^{(\omega)}(Z_{\beta_{j_1}}, ..., Z_{\beta_{j_{k_n}}}) - \mathbb{E}_\omega h_{k_n}^{(\omega)}(Z_{\beta_{j_1}}, ..., Z_{\beta_{j_{k_n}}}) \right) \right] \\
&= \mathbb{E}_{\boldsymbol{X}}\left[\frac{1}{m_n^2} \sum_{\beta_i \neq \beta_j} \mathbb{E}_\omega \left(h_{k_n}^{(\omega)}(Z_{\beta_{i_1}}, ..., Z_{\beta_{i_{k_n}}}) - \mathbb{E}_\omega h_{k_n}^{(\omega)}(Z_{\beta_{i_1}}, ..., Z_{\beta_{i_{k_n}}}) \right) \right. \\
&\qquad \left. \times \mathbb{E}_\omega \left(h_{k_n}^{(\omega)}(Z_{\beta_{j_1}}, ..., Z_{\beta_{j_{k_n}}}) - \mathbb{E}_\omega h_{k_n}^{(\omega)}(Z_{\beta_{j_1}}, ..., Z_{\beta_{j_{k_n}}}) \right) \right] \\
&= \mathbb{E}_{\boldsymbol{X}}\left[\frac{1}{m_n^2} \sum_{\beta_i \neq \beta_j} \left(\mathbb{E}_\omega h_{k_n}^{(\omega)}(Z_{\beta_{i_1}}, ..., Z_{\beta_{i_{k_n}}}) - \mathbb{E}_\omega h_{k_n}^{(\omega)}(Z_{\beta_{i_1}}, ..., Z_{\beta_{i_{k_n}}}) \right) \right.
\end{aligned}
$$

$$\times \left(\mathbb{E}_\omega h_{k_n}^{(\omega)}(Z_{\beta_{j_1}}, ..., Z_{\beta_{j_{k_n}}}) - \mathbb{E}_\omega h_{k_n}^{(\omega)}(Z_{\beta_{j_1}}, ..., Z_{\beta_{j_{k_n}}}) \right) \Bigg]$$
$$= \mathbb{E}_{\boldsymbol{X}} \left[\frac{1}{m_n^2} \sum_{\beta_i \neq \beta_j} 0 \times 0 \right]$$
$$= 0$$

and thus we need only investigate the first term. We have

$$\begin{aligned}
&\mathbb{E}\left[\frac{1}{m_n^2} \sum_{\beta} \left(h_{k_n}^{(\omega)}(Z_{\beta_1}, ..., Z_{\beta_{k_n}}) - \mathbb{E}_\omega h_{k_n}^{(\omega)}(Z_{\beta_1}, ..., Z_{\beta_{k_n}}) \right)^2 \right] \\
&= \frac{1}{m_n^2} \sum_{\beta} \mathbb{E}\left(h_{k_n}^{(\omega)}(Z_{\beta_1}, ..., Z_{\beta_{k_n}}) - \mathbb{E}_\omega h_{k_n}^{(\omega)}(Z_{\beta_1}, ..., Z_{\beta_{k_n}}) \right)^2 \\
&= \frac{1}{m_n^2} m_n \mathbb{E}\left(h_{k_n}^{(\omega)}(Z_{\beta_1}, ..., Z_{\beta_{k_n}}) - \mathbb{E}_\omega h_{k_n}^{(\omega)}(Z_{\beta_1}, ..., Z_{\beta_{k_n}}) \right)^2 \\
&= \frac{1}{m_n} \mathbb{E}\left(h_{k_n}^{(\omega)}(Z_{\beta_1}, ..., Z_{\beta_{k_n}}) - \mathbb{E}_\omega h_{k_n}^{(\omega)}(Z_{\beta_1}, ..., Z_{\beta_{k_n}}) \right)^2.
\end{aligned}$$

Putting all of this together, we have

$$\begin{aligned}
&\lim_{n\to\infty} \mathbb{E}\left(\frac{\sqrt{n}\left(U_{\omega;n,k_n,m_n} - U^*_{\omega;n,k_n,m_n} \right)}{\sqrt{k_n^2 \zeta_{1,k_n}}} \right)^2 \\
&= \lim_{n\to\infty} \frac{n}{m_n} \frac{1}{k_n^2 \zeta_{1,k_n}} \mathbb{E}\left(h_{k_n}^{(\omega)}(Z_{\beta_1}, ..., Z_{\beta_{k_n}}) - \mathbb{E}_\omega h_{k_n}^{(\omega)}(Z_{\beta_1}, ..., Z_{\beta_{k_n}}) \right)^2 \\
&= 0
\end{aligned}$$

so long as $k_n^2 \zeta_{1,k_n} \nrightarrow 0$ and $\lim_{n\to\infty} \mathbb{E}\left(h_{k_n}^{(\omega)}(Z_{\beta_1}, ..., Z_{\beta_{k_n}}) - \mathbb{E}_\omega h_{k_n}^{(\omega)}(Z_{\beta_1}, ..., Z_{\beta_{k_n}}) \right)^2 \neq \infty$, as desired. □

Now we handle the case where $\alpha > 0$. First note that when $k_n = 1$ for all n, this reduces to simply averaging over an *i.i.d.* sample and thus asymptotic normality can be obtained via the classic central limit theorem so assume that eventually $k_n > 1$. The remaining steps in this proof are nearly identical to the proof of results *(ii)* and *(iii)* of Theorem 1. Again, let $\mathcal{S}_{(n,k_n)} = \{S_i : i = 1, ..., \binom{n}{k_n}\}$ denote the set of all possible subsamples of size k_n and let $M_{n,k_n} = (M_{S_1}, ..., M_{S_{(n,k_n)}})$ denote the random vector that counts the number of times each subsample appears so that $M_{n,k_n} \sim multinomial(m_n; \frac{1}{\binom{n}{k_n}}, ..., \frac{1}{\binom{n}{k_n}})$ since we assume the subsamples are selected uniformly at random with replacement. Define

$\theta^*_{k_n} = \mathbb{E}U^*_{\omega;n,k_n,m_n}$, let ϕ_{n,k_n,m_n} be the characteristic function of $\sqrt{m_n}(U_{\omega;n,k_n,m_n} - \theta^*_{k_n})$, and let ϕ denote the limiting characteristic function of $\sqrt{n}(U^*_{\omega;n,k_n,m_n} - \theta^*_{k_n})$. Finally, let $\phi^{(M)}_{n,k_n,m_n}$ be the characteristic function of the random variable

$$m_n^{-1/2} \sum_{i=1}^{(n,k)} \left(M_{S_i} - \frac{m_n}{\binom{n}{k_n}} \right) \left(h_{k_n}^{(\omega_i)}(S_i) - \theta^*_{k_n} \right) \Big| Z_1, ..., Z_n, \omega.$$

Then we have

$$\begin{aligned}
\phi_{n,k_n,m_n}(t) &= \mathbb{E}\left(exp\left[it\sqrt{m_n}(U_{\omega;n,k_n,m_n} - \theta^*_{k_n}) \right] \right) \\
&= \mathbb{E}\left(exp\left[itm_n^{-1/2} \left(\sum_{i=1}^{(n,k_n)} M_{S_i}(h_{k_n}^{(\omega_i)}(S_i) - \theta^*_{k_n}) \right) \right] \right) \\
&= \mathbb{E}\left(\mathbb{E}\left(exp\left[itm_n^{-1/2} \left(\sum_{i=1}^{(n,k_n)} M_{S_i}(h_{k_n}^{(\omega_i)}(S_i) - \theta^*_{k_n}) \right) \right] \Big| Z_1, ..., Z_n, \omega \right) \right) \\
&= \mathbb{E}\Bigg(\mathbb{E}\Bigg(exp\Bigg[itm_n^{-1/2} \Bigg(\sum_{i=1}^{(n,k_n)} \left(M_{S_i} + \frac{m_n}{\binom{n}{k_n}} - \frac{m_n}{\binom{n}{k_n}} \right) \\
&\qquad \times \left(h_{k_n}^{(\omega_i)}(S_i) - \theta^*_{k_n} \right) \Bigg) \Bigg] \Bigg| Z_1, ..., Z_n, \omega \Bigg) \Bigg) \\
&= \mathbb{E}\Bigg(\mathbb{E}\Bigg(exp\Bigg[itm_n^{-1/2} \left(\sum_{i=1}^{(n,k_n)} \frac{m_n}{\binom{n}{k_n}} (h_{k_n}^{(\omega_i)}(S_i) - \theta^*_{k_n}) \right) \Bigg] \\
&\qquad \times exp\left[itm_n^{-1/2} \left(\sum_{i=1}^{(n,k)} \left(M_{S_i} - \frac{m_n}{\binom{n}{k_n}} \right) (h_{k_n}^{(\omega_i)}(S_i) - \theta^*_{k_n}) \right) \right] \Big| Z_1, ..., Z_n, \omega \Bigg) \Bigg) \\
&= \mathbb{E}\Bigg(exp\Bigg[itm_n^{-1/2} \left(\sum_{i=1}^{(n,k_n)} \frac{m_n}{\binom{n}{k_n}} (h_{k_n}^{(\omega_i)}(S_i) - \theta^*_{k_n}) \right) \Bigg] \\
&\quad \times \mathbb{E}\Bigg(exp\left[itm_n^{-1/2} \left(\sum_{i=1}^{(n,k_n)} \left(M_{S_i} - \frac{m_n}{\binom{n}{k_n}} \right) (h_{k_n}^{(\omega_i)}(S_i) - \theta^*_{k_n}) \right) \right] \Big| Z_1, ..., Z_n, \omega \Bigg) \Bigg) \\
&= \mathbb{E}\Bigg(exp\Bigg[itm_n^{-1/2} \Bigg(\sum_{i=1}^{(n,k_n)} \frac{m_n}{\binom{n}{k_n}} \Big(h_{k_n}^{(\omega_i)}(S_i) - \mathbb{E}_\omega h_{k_n}^{(\omega_i)}(S_i) \\
&\qquad + \mathbb{E}_\omega h_{k_n}^{(\omega_i)}(S_i) - \theta^*_{k_n} \Big) \Bigg) \Bigg] \ \phi^{(M)}_{n,k_n,m_n}(t) \Bigg) \\
&= \mathbb{E}\Bigg(exp\Bigg[it\sqrt{m_n} \Bigg(\frac{1}{\binom{n}{k_n}} \sum_{i=1}^{(n,k_n)} \left(h_{k_n}^{(\omega_i)}(S_i) - \mathbb{E}_\omega h_{k_n}^{(\omega_i)}(S_i) \right)
\end{aligned}$$

$$+ \frac{1}{\binom{n}{k_n}} \sum_{i=1}^{(n,k_n)} \left(\mathbb{E}_\omega h_{k_n}^{(\omega_i)}(S_i) - \theta_{k_n}^* \right) \Bigg) \Bigg] \phi_{n,k_n,m_n}^{(M)}(t) \Bigg).$$

Now, note that since we are in the case where $\alpha > 0$, $m_n = O(n) \ll (n, k_n)$ and thus, by the previous result in the case where $\alpha = 0$, the first term converges to 0 and we have

$$\begin{aligned} \lim_{n\to\infty} \phi_{n,k_n,m_n}(t) &= \mathbb{E}\left(\lim_{n\to\infty} exp\left[it\sqrt{m_n}\, \frac{1}{\binom{n}{k_n}} \sum_{i=1}^{(n,k_n)} \left(\mathbb{E}_\omega h_{k_n}^{(\omega_i)}(S_i) - \theta_{k_n}^* \right) \right] \lim_{n\to\infty} \phi_{n,k_n,m_n}^{(M)}(t) \right) \\ &= \mathbb{E}\left(\lim_{n\to\infty} exp\left[it\sqrt{m_n}\, U_{\omega;n,k_n,m_n}^* \right] \lim_{n\to\infty} \phi_{n,k_n,m_n}^{(M)}(t) \right) \end{aligned}$$

so that by exactly the same arguments as in the proof of Theorem 1

$$\lim_{n\to\infty} \phi_{n,k_n,m_n}(t) = exp\left[-t^2 \Big(\frac{k_n^2}{\alpha} \zeta_{1,k_n}^* + \zeta_{k_n,k_n}^* \Big) / 2 \right]$$

which is the characteristic function of a Normal distribution with mean 0 and variance $\frac{k_n^2}{\alpha}\zeta_{1,k_n}^* + \zeta_{k_n,k_n}^*$. Further, when $\alpha = \infty$, the variance reduces to ζ_{k_n,k_n}^*, as desired. ■

Appendix B.

Crossed Design Random Forests

Typically, each tree in a random forest is built according to an independently selected randomization parameter ω. Alternatively, for each ω, we could choose to build an entire set of trees, one for each of the m_n subsamples, so that if Ω_n randomization parameters are used, a total of $\Omega_n \times m_n$ trees are built. We could then write the prediction at $\boldsymbol{x}^*$ generated by this alternative random forest estimator as

$$\frac{1}{\Omega_n} \frac{1}{m_n} \sum_{(i)} \sum_{(j)} T_{\boldsymbol{x}^*,k_n}((\boldsymbol{X}_{i_1}, Y_{i_1}), ..., (\boldsymbol{X}_{i_{k_n}}, Y_{i_{k_n}});\ \omega_j) \tag{9}$$

where here, we explicitly treat ω as an input to the function. Statistics of the form in (9) are referred to as *two-sample* or *generalized* U-statistics and similar results regarding asymptotic normality have been established for fixed-rank kernels; see Lee (1990) or Van der Vaart (2000) for details.

We mention this as a possible alternative only because the resulting estimator takes the well established form of a generalized U-statistic. Readers familiar with U-statistics may be more comfortable with this approach than with the random kernel approach that more closely resembles the type of random forests used in practice. However, since this formulation strays from Breiman's original procedure and is far more computationally intensive, we consider only the random kernel version described in Section 2.2.

Appendix C.

The algorithm for estimating Σ_{1,k_n} as needed for the hypothesis testing procedure is given below.

Algorithm 6 Σ_{1,k_n} Estimation Procedure

```
for i in 1 to n_z̃ do
    Select initial fixed point z̃^(i)
    for j in 1 to n_MC do
        Select subsample S_z̃^(i),j of size k_n from training set that includes z̃^(i)
        Build full tree using subsample S_z̃^(i),j
        Build reduced tree using subsample S_z̃^(i),j utilizing only reduced feature space
        Use both full tree and reduced tree to predict at each test point
        Record difference in predictions
    end for
    Record average of the n_MC differences in predictions
end for
Compute the covariance of the n_z̃ averages
```

Appendix D.

Distribution of Subbagged Predictions using an Internal Variance Estimate

Here we examine the distribution of predictions when the ensemble is built according to the internal variance estimation method described in Algorithm 5. Since we are only interested in the distribution of predictions, we omit the steps in Algorithm 5 for estimating the variance parameters and use the same estimates as in the external case above. For both the SLR case with $n = 1000, k = 60$ and the MARS case with $n = 1000, k = 75$, we use $n_{\tilde{\boldsymbol{z}}} = 50$ and $n_{MC} = 250$ to produce a total of $m = 12500$ predictions in each ensemble. A total of 250 ensembles were built and the resulting histograms with estimated normal densities overlaid are shown in Figure 9 below. We see that these distributions appear to be the same as when the subsamples are selected uniformly at random, as in the external variance estimation method.

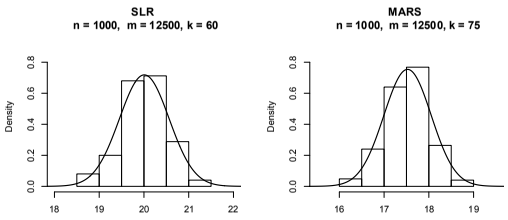

Figure 9: Histograms of subbagged predictions with using an internal estimate of variance. Predictions are made at $x_1 = 10$ in the SLR case and at $x_1 = \cdots = x_5 = 0.5$ in the MARS case.

Abstract

We consider two closely related problems: planted clustering and submatrix localization. In the planted clustering problem, a random graph is generated based on an underlying cluster structure of the nodes; the task is to recover these clusters given the graph. The submatrix localization problem concerns locating hidden submatrices with elevated means inside a large real-valued random matrix. Of particular interest is the setting where the number of clusters/submatrices is allowed to grow unbounded with the problem size. These formulations cover several classical models such as planted clique, planted densest subgraph, planted partition, planted coloring, and the stochastic block model, which are widely used for studying community detection, graph clustering and bi-clustering.

For both problems, we show that the space of the model parameters (cluster/submatrix size, edge probabilities and the mean of the submatrices) can be partitioned into four disjoint regions corresponding to decreasing statistical and computational complexities: (1) the *impossible* regime, where all algorithms fail; (2) the *hard* regime, where the computationally expensive Maximum Likelihood Estimator (MLE) succeeds; (3) the *easy* regime, where the polynomial-time convexified MLE succeeds; (4) the *simple* regime, where a local counting/thresholding procedure succeeds. Moreover, we show that each of these algorithms provably fails in the harder regimes.

Our results establish the minimax recovery limits, which are tight up to universal constants and hold even with a growing number of clusters/submatrices, and provide order-wise stronger performance guarantees for polynomial-time algorithms than previously known. Our study demonstrates the tradeoffs between statistical and computational considerations, and suggests that the minimax limits may not be achievable by polynomial-time algorithms.

Keywords: planted partition, planted clique, planted coloring, submatrix localization, graph clustering, bi-clustering, minimax recovery, computational hardness, convex relaxation

*. Partial preliminary results are presented in the conference paper Chen and Xu (2014).

1. Introduction

In this paper we consider two closely related problems: planted clustering and submatrix localization, both concerning the recovery of hidden structures from a noisy random graph or matrix.

- *Planted Clustering:* Suppose that out of a total of n nodes, rK of them are partitioned into r clusters of size K, and the remaining $n - rK$ nodes do not belong to any clusters; each pair of nodes is connected by an edge with probability p if they are in the same cluster, and with probability q otherwise. Given the adjacency matrix A of the graph, the goal is to recover the underlying clusters (up to a permutation of cluster indices). By varying the values of the model parameters, this formulation covers several classical models including planted clique, planted coloring, planted densest subgraph, planted partition, and stochastic block model (cf. Definition 1 and discussion thereafter).

- *Submatrix Localization:* Suppose $A \in \mathbb{R}^{n_L \times n_R}$ is a random matrix with independent Gaussian entries with unit variance, where there are r submatrices of size $K_L \times K_R$ with disjoint row and column supports, such that the entries inside these submatrices have mean $\mu > 0$, and the entries outside have mean zero. The goal is to identify the locations of these hidden submatrices given A. This formulation generalizes the submatrix detection and bi-clustering models with a single bi-submatrix/cluster that are studied in previous work (cf. Definition 14 and discussion thereafter).

We are particularly interested in the setting where the number r of clusters or submatrices may grow unbounded with the problem dimensions n, n_L, and n_R at an arbitrary rate. We call this the *high-rank* setting because r equals the rank of a matrix representation of the clusters and submatrices (cf. Definitions 1 and 14). The other parameters K, p, q, and μ are also allowed to scale with n or (n_L, n_R).

These two problems have been studied extensively, under various names such as *community detection*, *graph clustering/bi-clustering*, and *reconstruction in stochastic block models*, and have a broad range of applications. They are used as generative models for approximating real-world networks and data arrays with natural cluster/community structures, such as social networks (Fortunato, 2010), gene expressions (Shabalin et al., 2009), and online ratings (Xu et al., 2014). They serve as benchmarks in the evaluation of algorithms for clustering (Mathieu and Schudy, 2010), bi-clustering (Balakrishnan et al., 2011a), community detection (Newman and Girvan, 2004), and other network inference problems. They also provide a venue for studying the average-case behaviors of many graph theoretic problems including max-clique, max-cut, graph partitioning, and coloring (Bollobás and Scott, 2004; Condon and Karp, 2001). The importance of these two problems are well-recognized in areas across computer science, statistics, and physics (Rohe et al., 2011; Arias-Castro and Verzelen, 2014; Nadakuditi and Newman, 2012; Decelle et al., 2011; Mossel et al., 2013; Lelarge et al., 2013; Anandkumar et al., 2014; Bickel and Chen, 2009; Amini et al., 2013).

The planted clustering and submatrix localization problems exhibit an interplay between *statistical* and *computational* considerations. From a statistical point of view, we are interested in identifying the range of the model parameters for which the hidden structures—in this case the clusters and submatrices—can be recovered from the noisy data A. The values of the parameters n, r, K, p, q, μ govern the statistical hardness of the problems: the problems become more difficult with smaller values of $p - q$, μ, K, and larger r, because the observations are noisier and the sought-

after structures are more complicated. A statistically powerful algorithm is one that can recover the hidden structures for a large region of the model parameter space.

From a computational point of view, we are concerned with the running time of different recovery algorithms. An exhaustive search over the solution space (i.e., all possible clusterings or submatrix locations) may make for a statistically powerful algorithm, but is computationally intractable. A simpler algorithm with lower running time is computationally more desirable, but may succeed only in a smaller region of the model parameter space and thus has weaker statistical power.

Therefore, it is important to take a joint statistical-computational view to the planted clustering and submatrix localization problems, and to understand the *tradeoffs* between these two considerations. How do algorithms with different computational complexity achieve different statistical performance? For these two problems, what are the *information limit* (under what conditions on the model parameters does recovery become infeasible for any algorithm) and the *computational limit* (when does it become infeasible for computationally tractable algorithms)?

We take a step in answering questions in this paper. For both problems, our results demonstrate, in a precise quantitative way, the following phenomenon: the parameter space can be partitioned into four disjoint regions, such that each region corresponds to statistically easier instances of the problem than the previous one, and recovery can be achieved by simpler algorithms with lower running time. Significantly, there might exist a large gap between the statistical performance of computationally intractable algorithms and that of computationally efficient algorithms. We elaborate in the next two subsections.

1.1 Planted Clustering: The Four Regimes

For concreteness, we first consider the planted clustering problem in the setting $r \geq 2$, $p > q$ and $p/q = \Theta(1)$. This covers the standard planted bisection/partition/r-disjoint-clique models.

The statistical hardness of cluster recovery is captured by the quantity $\frac{(p-q)^2}{q(1-q)}$, which is essentially a measure of the Signal-to-Noise Ratio (SNR). Our main theorems identify the following four regimes of the problem defined by the value of this quantity. (Here for simplicity, we use the notation $\dot{\gtrsim}$ and $\dot{\lesssim}$, which ignore constant and $\log n$ factors; note that our main theorems do sharply characterize the $\log n$ factors.)

- *The Impossible Regime:* $\frac{(p-q)^2}{q(1-q)} \dot{\lesssim} \frac{1}{K}$. In this regime, there is no algorithm, regardless of its computational complexity, that can recover the clusters with a vanishing probability of error.
- *The Hard Regime:* $\frac{1}{K} \dot{\lesssim} \frac{(p-q)^2}{q(1-q)} \dot{\lesssim} \frac{n}{K^2}$. There exists a computationally expensive algorithm—specifically the Maximum Likelihood Estimator (MLE)—that recovers the clusters with high probability in this regime (as well as in the next two easier regimes; we omit such implications in the sequel). There is no known polynomial-time algorithm that succeeds in this regime.
- *The Easy Regime:* $\frac{n}{K^2} \dot{\lesssim} \frac{(p-q)^2}{q(1-q)} \dot{\lesssim} \frac{\sqrt{n}}{K}$. There exists a polynomial-time algorithm—specifically a convex relaxation of the MLE—that recovers the clusters with high probability in this regime. Moreover, this algorithm provably fails in the hard regime above.
- *The Simple Regime:* $\frac{(p-q)^2}{q(1-q)} \dot{\gtrsim} \frac{\sqrt{n}}{K}$. A simple algorithm based on counting node degrees and common neighbors recovers the clusters with high probability in this regime, and provably fails outside this regime (i.e., in the hard and easy regimes).

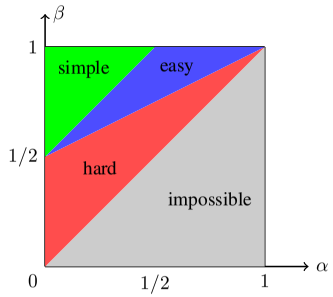

Figure 1: Illustration of the four regimes. The figure applies to the planted clustering problem with $p = 2q = \Theta(n^{-\alpha})$ and $K = \Theta(n^{\beta})$, as well as to the submatrix localization problem with $n_L = n_R = n$, $\mu^2 = \Theta(n^{-\alpha})$ and $K_L = K_R = \Theta(n^{\beta})$.

We illustrate these four regimes in Figure 1 assuming the scaling $p = 2q = \Theta(n^{-\alpha})$ and $K = \Theta(n^{\beta})$ for two constants $\alpha, \beta \in (0, 1)$. Here cluster recovery becomes harder with larger α and smaller β. In this setting, the four regimes correspond to four disjoint and non-empty regions of the parameter space. Therefore, a computationally more expensive algorithm leads to a *significant* (polynomial in n) enhancement in the statistical power. For example, when $\alpha = 1/4$, the simple, polynomial-time, and computationally intractable algorithms succeeds for β larger than 0.75, 0.625, and 0.25, respectively. There is a similar hierarchy for the allowable sparsity of the graph, given by $\alpha < 0.25$, $\alpha < 0.5$, and $\alpha < 0.75$ assuming $\beta = 0.75$.

The results in the impossible and hard regimes together establish the *minimax recovery boundary* of the planted clustering problem, and show that the MLE is statistically order-wise optimal. These two regimes are separated by an "information barrier": in the impossible regime the graph does not carry enough information to distinguish different cluster structures, so recovery is statistically impossible.

Our performance guarantees for the convexified MLE improve upon existing results for polynomial time algorithms in terms of scaling with n, particularly in the setting when the number of clusters are allowed to grow with n.

We *conjecture* that no polynomial-time algorithm can perform significantly better and succeed in the hard regime, i.e., the convexified MLE achieves the *computational limit* order-wise. While we do not prove the conjecture, there are many supporting evidences; cf. Section 2.3. For instance, there is a "spectral barrier", determined by the spectrum of an appropriately defined noise matrix, that prevents the convexified MLE and spectral clustering algorithms from succeeding in the hard regime. In the special setting with a single cluster, the work by Ma and Wu (2015); Hajek et al. (June, 2014) proves that no polynomial-time algorithm can reliably recover the cluster if $\beta < \alpha/4 + 1/2$ conditioned on the planted clique hardness hypothesis.

The simple counting algorithm is an example of an algorithm that uses only "local information": the cluster relation between a pair of nodes is inferred from only their two-hop connection. In

contrast, the convexified MLE crucially uses the global information in the graph spectrum. The counting algorithm fails outside the simple regime due to a "variance barrier" associated with the fluctuations in the node degrees and the numbers of common neighbors, and is statistically order-wise weaker than the global approach of the convexified MLE.

Our main theorems apply beyond the above specific setting and allow for general scalings of p, q, K, and r. The four regimes and the statistical-computational tradeoffs are observed for a broad spectrum of planted problems, including planed partition, planted coloring, planted r-disjoint-clique, and planted densest-subgraph models. Table 1 summarizes the implications of our results for some of these models. More precise and general results are given in Section 2.

1.2 Submatrix Localization: The Four Regimes

Similar results hold for the submatrix localization problem. Consider the setting with $n_L = n_R = n$ and $K_L = K_R = K$. The statistical hardness of submatrix localization is captured by the quantity μ^2, which is again a measure of the SNR. In the high SNR setting with $\mu^2 = \Omega(\log n)$, the submatrices can be trivially identified by element-wise thresholding. In the more interesting low SNR setting with $\mu^2 = O(\log n)$, our main theorems identify the following four regimes, which have the same meanings as before:

- *The Impossible Regime:* $\mu^2 \dot{\lesssim} \frac{1}{K}$. All algorithms fail in this regime.
- *The Hard Regime:* $\frac{1}{K} \dot{\lesssim} \mu^2 \dot{\lesssim} \frac{n}{K^2}$. The computationally expensive MLE succeeds, and it is conjectured that no polynomial-time algorithm succeeds here.
- *The Easy Regime:* $\frac{n}{K^2} \dot{\lesssim} \mu^2 \dot{\lesssim} \frac{\sqrt{n}}{K}$. The polynomial-time convexified MLE succeeds, and provably fails in the hard regime.
- *The Simple Regime:* $\frac{\sqrt{n}}{K} \dot{\lesssim} \mu^2 \dot{\lesssim} 1$. A simple thresholding algorithm succeeds, and provably fails outside this regime.

We illustrate these four regimes in Figure 1 assuming $\mu^2 = \Theta(n^{-\alpha})$ and $K = \Theta(n^{\beta})$. In fact, the results above hold in the more general setting where the entries of A are *sub-Gaussian*.

1.3 Discussions

This paper presents a systematic study of planted clustering and submatrix localization with a growing number of clusters/submatrices. We provide sharp characterizations of the minimax recovery boundary with the lower and upper bounds matching up to constants. We also give improved performance guarantees for convex optimization approaches and the simple counting/thresholding algorithms. In addition, complementary results are given for the *failure conditions* for these algorithms, hence characterizing their performance limits. Our analysis addresses several technical challenges that arise in the high-rank setting. The results in this paper highlight the similarity between planted clustering and submatrix localization, and place several classical problems under a unified framework including planted clique, planted partition, planted coloring, and planted densest subgraph.

The central theme of our investigation is the interaction between the statistical and the computational aspects in the problems, i.e., how to handle more noise and more complicated structures using more computation. Our study parallels a recent line of work that takes a joint statistical and

	Planted r-Disjoint-Clique $1 = p > q \geq 0, r \geq 1$	**Planted Partition/ Stochastic Blockmodel** $1 \geq p > q \geq 0, rK = n$	**Planted Coloring** $0 = p < q \leq 1, rK = n$

Table 1: Our results specialized to different planted models. Here the notations $\gtrsim$ and $\lesssim$ ignore constant factors. This table shows the *necessary conditions* for any algorithm to succeed under a mild assumption $K \gtrsim \log(rK)$, as well as the *sufficient* conditions under which the algorithms in this paper succeed, thus corresponding to the four regimes described in Section 1.1. The relevant theorems/corollaries are also listed. The conditions for convexified MLE and simple counting can further be shown to be also *necessary* in a broad range of settings; cf. Theorems 8 and 12. The results in this table are not the strongest possible; see the referenced theorems for more precise statements.

computational view on inference problems (Balakrishnan et al., 2011a; Oymak et al., 2015; Berthet and Rigollet, 2013; Chandrasekaran and Jordan, 2013; Ma and Wu, 2015); several of these works are closely related to special cases of the planted clustering and bi-clustering models. In this sense, we investigate an emblematic and fundamental problem, and therefore expect that the phenomena and principles described in this paper are relevant more generally. Below we provide additional discussion, and comment on connections with the existing work.

1.3.1 HIGH RANK VERSUS RANK ONE

Several recent works investigate the problems of single-submatrix detection/localization (Kolar et al., 2011; Arias-Castro et al., 2011), planted densest subgraph detection (Arias-Castro and Verzelen, 2014), and sparse principal component analysis (PCA) (Amini and Wainwright, 2009) (cf. Section 1.4 for a literature review). Even earlier is the extensive study of the statistical/computational hardness of Planted Clique. The majority of these results focus on the *rank-one* setting with a single clique, cluster, submatrix or principal component. This paper considers the more general *high-rank* setting, where the number r of clusters/submatrices may grow rapidly with the problem size. This setting is important in many real-world networks (see e.g., Leskovec et al., 2008; Rohe et al., 2011), and poses significant challenges to the analysis. Moreover, there are qualitative differences between these two settings. We discuss one such difference in the next paragraph.

1.3.2 THE POWER OF CONVEX RELAXATION

In previous work on the rank-one case of submatrix detection/localization (Ma and Wu, 2015; Balakrishnan et al., 2011a) and sparse PCA (Krauthgamer et al., 2015), it is shown that simple algorithms based on averaging/thresholding have order-wise similar statistical performance as more sophisticated convex relaxation approaches. In contrast, for the problems of finding multiple clusters/submatrices, we show that convex relaxation of MLE is statistically much more powerful than the simple counting/thresholding algorithm. Our analysis reveals that the power of convex relaxation lies in *separating different clusters/submatrices*, but not in identifying a single cluster/submatrix. Our results thus provide one explanation for the (somewhat curious) observation in previous work regarding the lack of benefit of using sophisticated methods, and demonstrate a finer spectrum of computational-statistical tradeoffs.

1.3.3 DETECTION VERSUS ESTIMATION

Several recent works on planted densest subgraph and submatrix detection have focused on the *detection* or *hypothesis testing* version of the problems, i.e., detecting the existence of a dense cluster or an elevated submatrix (cf. Section 1.4 for literature review). In this paper, we study the (support) *estimation* version of the problems, where the goal is to find the precise locations of the clusters/submatrices. In general estimation appears to be harder than detection. For example, if we consider the scalings of μ and K in Figure 1 of this paper, and compare with Figure 1 in Ma and Wu (2015) which studies submatrix detection, we see that the minimax localization boundary is $\beta = \alpha$, whereas the minimax detection boundary is at a lower value $\beta = \min\{\alpha, \alpha/4 + 1/2\}$. For the planted densest subgraph problem, we see a similar gap between the minimax detection and estimation boundaries if we compare our results with results in Arias-Castro and Verzelen (2014); Hajek et al. (June, 2014). In addition, it is shown in (Ma and Wu, 2015; Hajek et al., June, 2014) that if $\beta > \alpha/4 + 1/2$, the planted submatrix or densest subgraph can be detected in linear time; if

$\beta < \alpha/4+1/2$, no polynomial-time test exists assuming the hardness of the planted clique detection problem. For estimation, we prove the sufficient condition $\beta > \alpha/2+1/2$, which is the best known performance guarantee for polynomial-time algorithms—again we see a gap between detection and estimation. For detecting a sparse principal component, see the seminar work Berthet and Rigollet (2013) for proving computational lower bounds conditioned on the hardness of Planted Clique.

1.3.4 EXTENSIONS

It is a simple exercise to extend our results to a variant of the planted clustering model where the graph adjacency matrix has sub-Gaussian entries instead of Bernoulli, corresponding to a weighted graph clustering problem. Similarly, we can also extend the submatrix location problem to the setting with Bernoulli entries, which is the bi-clustering problem on an unweighted graph and covers the *planted bi-clique* problem (Feldman et al., 2013; Ames and Vavasis, 2011) as a special case.

1.4 Related Work

There is a large body of literature, from the physics, computer science and statistics communities, on models and algorithms for graph clustering and bi-clustering, as well as on their various extensions and applications. A complete survey is beyond the scope of this paper. Here we focus on theoretical work on planted clustering/submatrix localization concerning *exact recovery* of the clusters/submatrices. Detailed comparisons of existing results with ours are provided after we present each of our theorems in Sections 2 and 3. We emphasize that our results are *non-asymptotic* for finite values of n, n_L and n_R, whereas some of the results below require $n \to \infty$.

1.4.1 PLANTED CLIQUE, PLANTED DENSEST SUBGRAPH

The planted clique model ($r = 1$, $p = 1$, $q = 1/2$) is the most widely studied planted model. If the clique has size $K = o(\log n)$, recovery is impossible as the random graph $\mathcal{G}(n, 1/2)$ will have a clique with at least the same size; if $K = \Omega(\log n)$, an exhaustive search succeeds (Alon et al., 1998); if $K = \Omega(\sqrt{n})$, various polynomial-time algorithms work (Alon et al., 1998; Dekel et al., 2014; Deshpande and Montanari, 2013); if $K = \Omega(\sqrt{n \log n})$, the nodes in the clique can be easily identified by counting degrees (Kučera, 1995). It is an open problem to find polynomial-time algorithms which succeed in the regime with $K = o(\sqrt{n})$, and it is believed that this cannot be done (Hazan and Krauthgamer, 2011; Juels and Peinado, 2000; Alon et al., 2007; Feldman et al., 2013). The four regimes above can be considered as a special case of our results for the general planted clustering model. The planted densest subgraph model generalizes the planted clique model by allowing general values of p and q. The detection version of this problem is studied in Arias-Castro and Verzelen (2014); Verzelen and Arias-Castro (2013), and conditional computational hardness results are obtained in Hajek et al. (June, 2014).

1.4.2 PLANTED r-DISJOINT-CLIQUES, PARTITION, AND COLORING

Subsequent work considers the setting with $r \geq 1$ planted cliques (McSherry, 2001), as well as the planted partition model (a.k.a. stochastic block model) with general values of $p > q$ (Condon and Karp, 2001; Holland et al., 1983). A subset of these results allow for a growing number r of clusters (e.g., Rohe et al., 2011). Most existing work focuses on the recovery performance of polynomial-time algorithms. The state-of-the-art for planted r-disjoint-clique are given in McSherry

(2001); Chen et al. (2012); Ames and Vavasis (2014), and for planted partition in Chen et al. (2012); Anandkumar et al. (2014); Cai and Li (2015); see Chen et al. (2014b) for a survey. The setting with $p < q$ is sometimes called the *heterophily* case, with the planted coloring model ($p = 0$) as an important special case (Alon and Kahale, 1997; Coja-Oghlan, 2004). Our results on the convexified MLE (cf. Table 1) improve upon the previously known statistical performance of polynomial-time algorithms in the general r setting. The information-theoretic limits (both lower and upper bounds) of cluster recovery were largely unknown when r is growing. Here we identify these limits up to constant factors for general values of p, q, K and r. In particular, our results show that the information limit is achievable by MLE order-wise, while there is a significant gap between the information limit and the performance guarantee of the convexified MLE.

1.4.3 CONVERSE RESULTS FOR PLANTED PROBLEMS

Complementary to the *achievability* results, another line of work focuses on *converse* results, i.e., identifying necessary conditions for recovery, either for any algorithm, or for any algorithm in a specific class. For the planted partition model with $K = \Theta(n)$, necessary conditions for any algorithm to succeed are obtained by information-theoretic arguments in Chaudhuri et al. (2012); Chen et al. (2012); Balakrishnan et al. (2011b); Abbe et al. (2014). For spectral clustering algorithms and convex optimization approaches, more stringent conditions are shown to be needed (Nadakuditi and Newman, 2012; Vinayak et al., 2014). We generalize and improve upon these existing results in the setting with general r and K.

1.4.4 SHARP THRESHOLDS WITH A BOUNDED NUMBER OF CLUSTERS

Since the conference version of this paper was published (Chen and Xu, 2014), several papers have appeared on the asymptotic information-theoretic limits for exact recovery of planted partition. In the restricted setting with $r = 2$ and $K = n/2$, the recovery thresholds *with sharp constants* are identified and shown to be achievable in polynomial-time in Abbe et al. (2014) for $p, q = O(\log n/n)$, and in Mossel et al. (2015b) for more general scalings of (p, q). Very recently, Abbe and Sandon (2015) established the sharp recovery threshold for the case where $r = O(1)$, $K = \Theta(n)$, and the in-cluster and cross-cluster edge probabilities are heterogeneous and scale as $\log n/n$; the recovery threshold is further shown to be achievable in $o(n^{1+\epsilon})$ time for any $\epsilon > 0$. In this bounded r setting, it is further shown in Hajek et al. (2014); Bandeira (2015); Hajek et al. (2015) that the sharp recovery thresholds are achieved by the semidefinite programming relaxation of the MLE. In comparison, the results in this paper are non-asymptotic and optimal up to universal constant factors, and apply to the general setting with a growing number of clusters/submatrices of size sublinear in n.

1.4.5 APPROXIMATE RECOVERY

While not the focus of this paper, approximate cluster recovery (under various criteria) has also been studied, e.g., for planted partition with $r = O(1)$ clusters in Mossel et al. (2015a, 2013); Massoulié (2014); Yun and Proutiere (2014); Decelle et al. (2011). These results are not directly comparable to ours, but often the approximate recovery conditions differ from the ones for exact recovery by a $\log n$ factor. When constant factors are concerned, the existence of a hard regime was conjectured in Decelle et al. (2011); Mossel et al. (2015a).

1.4.6 SUBMATRIX LOCALIZATION

The statistical-computational tradeoffs in locating a single submatrix (i.e., $r = 1$) are discussed in Balakrishnan et al. (2011a); Kolar et al. (2011); the information limit is shown to be achieved (order-wise) by a computationally intractable algorithm, and the success and failure conditions for various polynomial-time procedures are also derived. The work in Ames (2013) focuses on success conditions for a convex relaxation approach; we improve on their results particularly in the high-rank setting. The single-submatrix *detection* problem is studied in Butucea and Ingster (2013); Shabalin et al. (2009); Sun and Nobel (2013); Arias-Castro et al. (2011); Bhamidi et al. (2012), and conditional hardness results are established in the recent work in Ma and Wu (2015).

1.5 Paper Organization and Notation

The remainder of this paper is organized as follows. In Section 2 we set up the planted clustering model and present our main theorems for the impossible, hard, easy, and simple regimes. In Section 3 we turn to the submatrix localization problem and provide the corresponding theorems for the four regimes. Section 4 provides a brief summary with a discussion of future directions. We prove the main theorems for planted clustering and submatrix localization in Sections 5 and 6, respectively.

The following notation is used in the paper. Let $a \vee b = \max\{a, b\}$ and $a \wedge b = \min\{a, b\}$, and $[m] = \{1, 2, \ldots, m\}$ for any positive integer m. We use c_1, c_2 etc. to denote absolute numerical constants whose values can be made explicit and are independent of the model parameters. We use the standard big-O notations: for two sequences $\{a_n\}, \{b_n\}$, we write $a_n \lesssim b_n$ or $a_n = O(b_n)$ to mean $a_n \le c_1 b_n$ for an absolute constant c_1 and all n; similarly, $a_n \gtrsim b_n$ and $a_n = \Omega(b_n)$ mean $a_n \ge c_2 b_n$. Moreover, $a_n \asymp b_n$ and $a_n = \Theta(b_n)$ mean both $a_n \lesssim b_n$ and $a_n \gtrsim b_n$ hold.

2. Main Results for Planted Clustering

The planted clustering problem is defined by five parameters $n, r, K \in \mathbb{N}$ and $p, q \in [0, 1]$ with $n \ge rK$.

Definition 1 (Planted Clustering) *Suppose n nodes (which are identified with $[n]$) are divided into two subsets V_1 and V_2 with $|V_1| = rK$ and $|V_2| = n - rK$. The nodes in V_1 are partitioned into r disjoint clusters $C_1^*, \ldots, C_r^*$ (called* true clusters*), where $|C_m^*| = K$ for each $m \in [r]$ and $\bigcup_{m=1}^r C_m^* = V_1$. Nodes in V_2 do not belong to any of the clusters and are called* isolated nodes*. A random graph is generated based on the cluster structure: for each pair of nodes and independently of all others, we connect them by an edge with probability p (called* in-cluster edge density*) if they are in the same cluster, and otherwise with probability q (called* cross-cluster edge density*).*

We emphasize again that the values of p, q, r, and K are allowed to be functions of n. The goal is to exactly recover the true clusters $\{C_m^*\}_{m=1}^r$ up to a permutation of cluster indices given the random graph.

The model parameters (p, q, r, K) are assumed to be known to the algorithms. This assumption is often not necessary and can be relaxed (Chen et al., 2012; Arias-Castro and Verzelen, 2014). It is also possible to allow for non-uniform cluster sizes (Ailon et al., 2013) as well as heterogeneous edge probabilities and node degrees (Chaudhuri et al., 2012; Chen et al., 2014b; Cai and Li, 2015). These extensions are certainly important in practical applications; we do not delve into them, and point to the referenced papers above and the references therein for work in this direction.

To facilitate subsequent discussion, we introduce a matrix representation of the planted clustering problem. We represent the true clusters $\{C_m^*\}_{m=1}^r$ by a *cluster matrix* $Y^* \in \{0,1\}^{n\times n}$, where $Y_{ii}^* = 1$ for $i \in V_1$, $Y_{ii}^* = 0$ for $i \in V_2$, and $Y_{ij}^* = 1$ if and only if nodes i and j are in the same true cluster. Note that the rank of Y^* equals r, hence the name of the high-rank setting. The adjacency matrix of the graph is denoted as A, with the convention $A_{ii} = 0, \forall i \in [n]$. Under the planted clustering model, we have $\mathbb{P}(A_{ij} = 1) = p$ if $Y_{ij}^* = 1$ and $\mathbb{P}(A_{ij} = 1) = q$ if $Y_{ij}^* = 0$ for all $i \neq j$. The problem reduces to recovering Y^* given A.

The planted clustering model generalizes several classical planted models.

- *Planted r-Disjoint-Clique* (McSherry, 2001). Here $p = 1$ and $0 < q < 1$, so r cliques of size K are planted into an Erdős-Rényi random graph $G(n, q)$. The special case with $r = 1$ is known as the *planted clique* problem (Alon et al., 1998).

- *Planted Densest Subgraph* (Arias-Castro and Verzelen, 2014). Here $0 < q < p < 1$ and $r = 1$, so there is a subgraph of size K and density p planted into a $G(n, q)$ graph.

- *Planted Partition* (Condon and Karp, 2001). Also known as the *stochastic blockmodel* (Holland et al., 1983). Here $n = rK$ and $p, q \in (0, 1)$. The special case with $r = 2$ can be called *planted bisection* (Condon and Karp, 2001). The case with $p < q$ is sometimes called *planted noisy coloring* or *planted r-cut* (Decelle et al., 2011; Bollobás and Scott, 2004).

- *Planted r-Coloring* (Alon and Kahale, 1997). Here $n = rK$ and $0 = p < q < 1$, so each cluster corresponds to a group of disconnected nodes that are assigned with the same color.

For clarity we shall focus on the homophily setting with $p > q$; results for the $p < q$ case are similar. In fact, any achievability or converse result for the $p > q$ case immediately implies a corresponding result for $p < q$. To see this, observe that if the graph A is generated from the planted clustering model with $p < q$, then the flipped graph $A' := J - A - I$ (J is the all-one matrix and I is the identity matrix) can be considered as generated with in/cross-cluster edge densities $p' = 1-p$ and $q' = 1-q$, where $p' > q'$. Therefore, a problem with $p < q$ can be reduced to one with $p' > q'$. Clearly the reduction can also be done in the other direction.

2.1 The Impossible Regime: Minimax Lower Bounds

In this section, we characterize the necessary conditions for cluster recovery. Let $\mathcal{Y}$ be the set of cluster matrices corresponding to r clusters of size K; i.e.,

$$\mathcal{Y} = \big\{ Y \in \{0,1\}^{n\times n} \,\big|\, \text{there exist disjoint clusters } \{C_m\}_{m=1}^r \text{ such that } |C_m| = K, \forall m \in [r], \\ \text{and } Y \text{ is the corresponding cluster matrix} \big\}.$$

We use $\widehat{Y} \equiv \widehat{Y}(A)$ to denote an estimator which takes as input the graph A and outputs an element of $\mathcal{Y}$ as an estimate of the true Y^*. Our results are stated in terms of the Kullback-Leibler (KL) divergence between two Bernoulli distributions with means u and v, denoted by $D(u\|v) := u \log \frac{u}{v} + (1-u) \log \frac{1-u}{1-v}$. The following theorem gives a lower bound on the minimax error probability of recovering Y^*.

Theorem 2 (Impossible) *Suppose $128 \le K \le n/2$. Under the planted clustering model with $p > q$, if one of the following two conditions holds:*

$$K \cdot D(q\|p) \le \frac{1}{192} \left[\log(rK) \wedge K\right], \tag{1}$$

$$K \cdot D(p\|q) \le \frac{1}{192} \log n, \tag{2}$$

then

$$\inf_{\widehat{Y}} \sup_{Y^* \in \mathcal{Y}} \mathbb{P}\left[\widehat{Y} \neq Y^*\right] \ge \frac{1}{4},$$

where the infimum ranges over all measurable function of the graph.

The theorem shows it is fundamentally impossible to recover the clusters with success probability close to 1 in the regime where (1) or (2) holds, which is thus called the *impossible regime*. This regime arises from an *information/statistical barrier*: The KL divergence on the LHSs of (1) and (2) determines how much information of Y^* is contained in the data A. If the in-cluster and cross-cluster edge distributions are close (measured by the KL divergence) or the cluster size is small, then A does not carry enough information to distinguish different cluster matrices.

It is sometimes more convenient to use the following corollary, derived by upper-bounding the KL divergence in (1) and (2) using its Taylor expansion. This corollary was used when we overviewed our results in Section 1.1. See table 1 for its implications for specific planted models.

Corollary 3 *Suppose $128 \le K \le n/2$. Under the planted clustering model with $p > q$, if any one of the following three conditions holds:*

$$K(p-q)^2 \le \frac{1}{192} q(1-q) \log n, \tag{3}$$

$$Kp \le \frac{1}{193} \left[\log(rK) \wedge K\right], \tag{4}$$

$$Kp \log \frac{p}{q} \le \frac{1}{192} \log n, \tag{5}$$

then $\inf_{\widehat{Y}} \sup_{Y^* \in \mathcal{Y}} \mathbb{P}[\widehat{Y} \neq Y^*] \ge \frac{1}{4}$.

Note the asymmetry between the roles of p and q in the conditions (1) and (2); this is made apparent in Corollary 3. To see why the asymmetry is natural, recall that by a classical result of Grimmett and McDiarmid (1975), the largest clique in a random graph $G(n, q)$ has size $k_q = \Theta(\log n / \log(1/q))$ almost surely. Such a clique cannot be distinguished from a true cluster if $K \lesssim k_q$, even when $p = 1$. This is predicted by the condition (5). When $q = 0$, cluster recovery requires $p \gtrsim \frac{\log(rK)}{K}$ to ensure all true clusters are connected within themselves, matching the condition (4). The term K on the RHS of (1) and (4) is relevant only when $K \le \log(rK)$. Potential improvement on this term is left to future work.

Comparison with previous work: When $r = 1$ and $q = 1/2$, our results recover the $K = \Theta(\log n)$ threshold for the classical planted clique problem. For planted partition with $r = O(1)$ clusters of size $K = \Theta(n)$ and $p/q = \Theta(1)$, the work in Chaudhuri et al. (2012); Chen et al. (2014a) establishes the necessary condition $p - q \lesssim \sqrt{p/n}$; our result is stronger by a logarithmic factor.

The work in Abbe et al. (2014) also considers planted partition with $r = 2$ and focus on the special case with the scaling $p, q = \Theta(\log(n)/n)$; they establish the condition $p+q-2\sqrt{pq} < 2\log(n)/n$, which is consistent with our results up to constants in this regime. Compared to previous work, we handle the more general setting where p, q and r may scale arbitrarily with n.

2.2 The Hard Regime: An Optimal Algorithm

In this subsection, we characterize the sufficient conditions for cluster recovery which match the necessary conditions given in Theorem 2 up to constant factors. We consider the Maximum Likelihood Estimator of Y^* under the planted clustering model, which we now derive. The log-likelihood of observing the graph A given a cluster matrix $Y \in \mathcal{Y}$ is

$$\begin{aligned}\log \mathbb{P}_Y(A) &= \log \prod_{i<j} p^{A_{ij}Y_{ij}} q^{A_{ij}(1-Y_{ij})}(1-p)^{(1-A_{ij})Y_{ij}}(1-q)^{(1-A_{ij})(1-Y_{ij})} \\ &= \log \frac{p(1-q)}{q(1-p)} \sum_{i<j} A_{ij}Y_{ij} + \log \frac{1-p}{1-q} \sum_{i<j} Y_{ij} + \log \frac{q}{1-q} \sum_{i<j} A_{ij} + \sum_{i<j} \log(1-q). \quad (6)\end{aligned}$$

Given A, the MLE maximizes the the log-likelihood over the set $\mathcal{Y}$ of all possible cluster matrices. Note that $\sum_{i<j} Y_{ij} = r\binom{K}{2}$ for all $Y \in \mathcal{Y}$, so the last three terms in (6) are independent of Y. Therefore, the MLE for the $p > q$ case is given as in Algorithm 1.

Algorithm 1 Maximum Likelihood Estimator ($p > q$)

$$\widehat{Y} = \arg\max_{Y} \sum_{i,j} A_{ij}Y_{ij} \quad (7)$$

$$\text{s.t. } Y \in \mathcal{Y}. \quad (8)$$

Algorithm 1 is equivalent to finding r disjoint clusters of size$K$ that maximize the number of edges inside the clusters (similar to Densest K-Subgraph), or minimize the number of edges outside the clusters (similar to Balanced Cut) or the disagreements between A and Y (similar to Correlation Clustering in Bansal et al. 2004). Therefore, while Algorithm 1 is derived from the planted clustering model, it is in fact quite general and not tied to the modeling assumptions. Enumerating over the set $\mathcal{Y}$ is computationally intractable in general since $|\mathcal{Y}| = \Omega(e^{rK})$.

The following theorem provides a success condition for the MLE.

Theorem 4 (Hard) . *Under the planted clustering model with $p > q$, there exists a universal constant c_1 such that for any $\gamma \geq 1$, the optimal solution $\widehat{Y}$ to the problem (7)–(8) is unique and equal to Y^* with probability at least $1 - 16(\gamma rK)^{-1} - 256n^{-1}$ if both of the following hold:*

$$\begin{aligned} K \cdot D(q\|p) &\geq c_1 \log(\gamma rK), \\ K \cdot D(p\|q) &\geq c_1 \log n. \end{aligned} \quad (9)$$

We refer to the regime in which the condition (9) holds but (14) below fails as the *hard regime*, as clustering is statistically possible but conjectured to be computationally hard (cf. Conjecture 9). The conditions (9) above and (1)–(2) in Theorem 2 match up to a constant factor under the mild assumption $K \geq \log(rK)$. This establishes the minimax recovery boundary for planted clustering and the minimax optimality of the MLE up to constant factors.

By lower bounding the KL divergence, we obtain the following corollary, which is sometimes more convenient to use. See Table 1 for its implications for specific planted models.

Corollary 5 *For planted clustering with $p > q$, there exists a universal constant c_2 such that for any $\gamma \geq 1$, the optimal solution $\widehat{Y}$ to the problem (7)–(8) is unique and equal to Y^* with probability at least $1 - 16(\gamma rK)^{-1} - 256n^{-1}$ provided*

$$K(p-q)^2 \geq c_2 q(1-q)\log n, \quad Kp \geq c_2 \log(\gamma rK) \quad \textit{and} \quad Kp \log \frac{p}{q} \geq c_2 \log n. \quad (10)$$

The condition (10) can be simplified to $K(p-q)^2 \gtrsim q(1-q)\log n$ if $q = \Theta(p)$, and to $Kp\log\frac{p}{q} \gtrsim \log n, Kp \gtrsim \log(rK)$ if $q = o(p)$. These match the converse conditions in Corollary 3 up to constants.

Comparison with previous work: Theorem 4 provides the first minimax results (tight up to constant factors) when the number of clusters is allowed to grow, potentially at a *nearly-linear* rate $r = O(n/\log n)$. Interestingly, for a fixed cluster size, the recovery boundary (9) depends very weakly on the number of clusters r though the logarithmic term. For $r = 1$ and $p = 2q = 1$, we recover the recovery boundary for planted clique $K \asymp \log n$. For the planted densest subgraph model where $p/q = \Theta(1)$, p bounded away from 1 and $Kq \gg 1$, the minimax *detection* boundary is shown in Arias-Castro and Verzelen (2014) to be $\frac{(p-q)^2}{q} \asymp \min\{\frac{1}{K}\log\frac{n}{K}, \frac{n^2}{K^4}\}$; our results show that the minimax *recovery* boundary is $\frac{(p-q)^2}{q} \asymp \frac{\log n}{K}$, which is strictly above the detection boundary because $\frac{n^2}{K^4}$ can be much smaller than $\frac{\log n}{K}$. For the planted bisection model with two equal-sized clusters: if $p, q = \Theta(\log(n)/n)$, the sharp recovery boundary is found in Abbe et al. (2014) and Mossel et al. (2015b) to be $K(\sqrt{p}-\sqrt{q})^2 > \log n$, which is consistent with our results up to constants; if $p, q = O(1/n)$, the correlated recovery limit is shown in Mossel et al. (2015a); Massoulié (2014); Mossel et al. (2013) to be $K(p-q)^2 > p+q$, which is consistent with our results up to a logarithmic factor.

2.3 The Easy Regime: Polynomial-Time Algorithms

In this subsection, we present a polynomial-time algorithm for the planted clustering problem and show that it succeeds in the easy regime described in the introduction.

Our algorithm is based on taking a convex relaxation of the MLE in Algorithm 1. Note that the objective function (7) in the MLE is linear, but the constraint $Y \in \mathcal{Y}$ involves a set $\mathcal{Y}$ that is discrete, non-convex and exponentially large. We replace this non-convex constraint with a trace norm (a.k.a. nuclear norm) constraint and a set of linear constraints. This leads to the convexified MLE given in Algorithm 2. Here the trace norm $\|Y\|_*$ is defined as the sum of the singular values of Y. Note that the true Y^* is feasible to the optimization problem (11)–(13) since $\|Y^*\|_* = \text{trace}(Y^*) = rK$.

Algorithm 2 Convexified Maximum Likelihood Estimator ($p > q$)

$$\widehat{Y} = \arg\max_{Y \in \mathbb{R}^{n\times n}} \sum_{i,j} A_{ij} Y_{ij} \tag{11}$$

$$\text{s.t. } \|Y\|_* \le rK, \tag{12}$$

$$\sum_{i,j} Y_{ij} = rK^2, \quad 0 \le Y_{ij} \le 1, \forall i,j. \tag{13}$$

The optimization problem in Algorithm 2 is a semidefinite program (SDP) and can be solved in polynomial time by standard interior point methods or various fast specialized algorithms such as ADMM; e.g., see Jalali and Srebro (2012); Ames (2013). Similarly to Algorithm 1, this algorithm is not strictly tied to the planted clustering model as it can also be considered as a relaxation of Correlation Clustering or Balanced Cut. In the case where the values of r and K are unknown, one may replace the hard constraints (12) and (13) with an appropriately weighted objective function; cf. Chen et al. (2014b).

The following theorem provides a sufficient condition for the success of the convexified MLE. See Table 1 for its implications for specific planted models.

Theorem 6 (Easy) *Under the planted clustering model with $p > q$, there exists a universal constant c_1 such that with probability at least $1 - n^{-10}$, the optimal solution to the problem (11)–(13) is unique and equal to Y^* provided*

$$K^2(p-q)^2 \ge c_1 \left[p(1-q)K \log n + q(1-q)n\right]. \tag{14}$$

When $r = 1$, we refer to the regime where the condition (14) holds and (17) below fails as the *easy regime*. When $r > 1$, the easy regime is where (14) holds and (17) or (18) below fails.

If $p/q = \Theta(1)$, it is easy to see that the smallest possible cluster size allowed by (14) is $K = \Theta(\sqrt{n})$ and the largest number of clusters is $r = \Theta(\sqrt{n})$, both of which are achieved when $p, q, |p-q| = \Theta(1)$. This generalizes the tractability threshold $K = \Omega(\sqrt{n})$ of the classic planted clique problem. If $q = o(p)$ (we call it the high SNR setting), the condition (14) becomes to $Kp \gtrsim \max\{\log n, \sqrt{qn}\}$. In this case, it is possible to go beyond the $\sqrt{n}$ limit on the cluster size. In particular, when $p = \Theta(1)$, the smallest possible cluster size is $K = \Theta(\log n \vee \sqrt{qn})$, which can be much smaller than $\sqrt{n}$.

Remark 7 *Theorem 6 immediately implies guarantees for other tighter convex relaxations. Define the sets $\mathcal{B} := \{Y \mid Eq.(13)\ holds\}$ and*

$$\mathcal{S}_1 := \{Y \mid \|Y\|_* \le rK\},$$
$$\mathcal{S}_2 := \{Y \mid Y \succeq 0; trace(Y) = rK\}.$$

The constraint in Algorithm 2 corresponds to $Y \in \mathcal{S}_1 \cap \mathcal{B}$, while $Y \in \mathcal{S}_2 \cap \mathcal{B}$ is the constraint in a so-called standard SDP relaxation. Clearly $(\mathcal{S}_1 \cap \mathcal{B}) \supseteq (\mathcal{S}_2 \cap \mathcal{B}) \supseteq \mathcal{Y}$. Therefore, if we replace the constraint (12) with $Y \in \mathcal{S}_2$, we obtain a tighter *relaxation of the MLE, and Theorem 6 guarantees that it also succeeds to recover Y^* under the condition (14). The same is true if we consider other tighter relaxations, such as those involving the triangle inequalities (Mathieu and Schudy, 2010),*

the row-wise constraints $\sum_j Y_{ij} \le K, \forall i$ (Ames, 2013), the max norm (Jalali and Srebro, 2012) or the Fantope constraint (Vu et al., 2013). For the purpose of this work, these variants of the convex formulation make no significant difference, and we choose to focus on (11)–(13) for generality.

Comparison with previous work: We refer to Chen et al. (2014b) for a survey of the performance of state-of-the-art polynomial-time algorithms under various planted models. Theorem 6 matches and in many cases improves upon existing results in terms of the scaling. For example, for planted partition with general r, the previous best results are $(p-q)^2 \gtrsim p(K\log^4 n + n)/K^2$ in Chen et al. (2012) and $(p-q)^2 \gtrsim pn\,\mathrm{polylog}\, n/K^2$ in Anandkumar et al. (2014). Theorem 6 removes some extra $\log n$ factors, and is also order-wise better when $q = o(p)$ (the high SNR case) or $1-q = o(1)$. For planted r-disjoint-clique, existing results require $1-q$ to be $\Omega((rn + rK\log n)/K^2)$ (McSherry, 2001), $\Omega(\sqrt{n}/K)$ (Ames and Vavasis, 2014) or $\Omega((n + K\log^4 n)/K^2)$ (Chen et al., 2012). We improve them to $\Omega((n + K\log n)/K^2)$.

2.3.1 CONVERSE FOR THE TRACE NORM RELAXATION APPROACH

We have a partial converse to the achievability result in Theorem 6. The following theorem characterizes the conditions under which the trace norm relaxation (11)–(13) provably fails with high probability; we suspect the standard SDP relaxation with the constraint $Y \in \mathcal{S}_2 \cap \mathcal{B}$ also fails with high probability under the same conditions, but we do not have a proof.

Theorem 8 (Easy, Converse) *Under the planted clustering model with $p > q$, for any constant $1 > \epsilon_0 > 0$, there exist positive universal constants c_1, c_2 for which the following holds. Suppose $c_1 \log n \le K \le \frac{n}{2}$, $q \ge c_1 \frac{\log n}{n}$ and $p \le 1 - \epsilon_0$. If*

$$K^2(p-q)^2 \le c_2(Kp + qn),$$

then with probability at least $1 - n^{-10}$, Y^* is not an optimal solution of the program (11)–(13).

Theorem 8 proves the failure of our trace norm relaxation that has access to the *exact* number and sizes of the clusters. Consequently, replacing the constraints (12) and (13) with a Lagrangian penalty term in the objective would not help for *any* value of the Lagrangian multipliers. Under the assumptions of Theorems 6 and 8, by ignoring log factors, the *sufficient and necessary* condition for the success of our convexified MLE is

$$\frac{p}{K(p-q)^2} + \frac{qn}{K^2(p-q)^2} \dot{\lesssim} 1. \tag{15}$$

We can compare (15) with the success condition (10) for the MLE, which simplifies to

$$\frac{p}{K(p-q)^2} \dot{\lesssim} 1.$$

We see that the convexified MLE is statistically sub-optimal due to the extra second term in (15). This term is responsible for the $K = \Omega(\sqrt{n})$ threshold on the cluster size for the tractability of planted clique. The term has an interesting interpretation. Let $\widetilde{A} := A - q\mathbf{1}\mathbf{1}^\top + qI$ be the centered adjacency matrix. The matrix $E := (Y - \mathbf{1}\mathbf{1}^\top) \circ (\widetilde{A} - \mathbb{E}\widetilde{A})$, [1] i.e., the deviation $\widetilde{A} - \mathbb{E}\widetilde{A}$ restricted to

1. Here $\circ$ denotes the element-wise product.

the inter-cluster node pairs, can be viewed as the "cross-cluster noise matrix". Note that the squared largest singular value of the matrix $\mathbb{E}\widetilde{A} = (p-q)Y^*$ is $K^2(p-q)^2$, whereas the squared largest singular value of E concentrates around $\Theta(qn)$ (see e.g., Chatterjee 2014). Therefore, the second term $\frac{qn}{K^2(p-q)^2}$ in (15) is the "spectral noise-to-signal ratio" that determines the performance of the convexified MLE. In fact, our proofs for Theorems 6 and 8 build on this intuition.

Comparison with previous work: Our converse result in Theorem 8 is inspired by, and improves upon, the recent work in Vinayak et al. (2014), which focuses on the special case $p > 1/2 > q$ and considers a convex relaxation approach that is equivalent to our relaxation (11)–(13) but without the additional equality constraint in (13). The approach is shown to fail when $K^2(p-\frac{1}{2})^2 \lesssim qn$. Our result is stronger in the sense that it applies to a tighter relaxation and a larger region of the parameter space.

2.3.2 LIMITS OF POLYNOMIAL-TIME ALGORITHMS

We compare the minimax recovery threshold in Theorems 2 and 4 with the performance boundary of the polynomial-time convexified MLE in Theorem 6. In general, there exists a substantial gap between these two boundaries (cf. Figure 1). We conjecture that no polynomial-time algorithm has order-wise better statistical performance than the convexified MLE and succeeds significantly beyond the condition (14) in Theorem 6.

Conjecture 9 *For any constant $\epsilon > 0$, there is no algorithm with running time polynomial in n that, for all n and with probability at least $1/2$, outputs the true Y^* of the planted clustering problem with $p > q$ and*

$$(p-q)^2K^2 \le n^{-\epsilon}\left(Kp(1-p) + q(1-q)n\right). \tag{16}$$

If the conjecture is true, then in the asymptotic setting $p = 2q = n^{-\alpha}$ and $K = n^{\beta}$, the *computational limit* for the cluster recovery is given by $\beta = \frac{\alpha}{2} + \frac{1}{2}$, i.e., the boundary between the green and red regimes in Figure 1.

A rigorous proof of Conjecture 9 seems difficult with current techniques. There are other possible convex formulations for planted clustering. The space of possible polynomial-time algorithms is even larger. It is impossible for us to study each of them separately and obtain a converse result as in Theorem 8. There are however several evidences that support the conjecture:

- The special case with $p = 2q = 1$ corresponds to the $K = o(\sqrt{n})$ regime for the classical Planted Clique problem, which is conjectured to be computationally hard (Alon et al., 2007; Rossman, 2010; Feldman et al., 2013), and has been used as an assumption for proving other hardness results (Hazan and Krauthgamer, 2011; Juels and Peinado, 2000; Koiran and Zouzias, 2014). Graphically, the Planted Clique hardness corresponds to the division of the $\alpha = 0$ line of the parameter space shown in Figure 1 (with $r = 1$). Conjecture 9 can be considered as *a generalization of the Planted Clique conjecture* to the whole parameter space, that is, to the setting with multiple clusters and general values of p and q. This generalized conjecture may be used to study the hardness of other problems (Chen, 2015).

- A weaker version of such generalization is proved in Hajek et al. (June, 2014): they show that in the setting with a single cluster, no polynomial-time algorithm can reliably recover the planted clusters if $\beta < \alpha/4 + 1/2$ conditioned on the planted clique hardness hypothesis.

- As discussed earlier, if (16) holds, then the graph spectrum is dominated by noise and fails to reveal the underlying cluster structure. The condition (16) therefore represents a "spectral barrier" for clustering. The work in Nadakuditi and Newman (2012) uses this spectral barrier argument to prove the failure of a large class of algorithms that rely on the graph spectrum. The proof of our Theorem 8 reveals that the convexified MLE fails for a similar reason.

- In the sparse graph case with $p, q = O(1/n)$, it is argued in Decelle et al. (2011), using non-rigorous but deep arguments from statistical physics, that it is intractable to achieve the correlated recovery under Condition (16).

We note that in the "high SNR" case with $\frac{p}{q} \gtrsim \frac{n}{K\log n}$ and $\log K \gtrsim \log n$, the minimax limit and performance boundary of the convexified MLE coincide up to constant factors at $K(p-q)^2 \asymp p(1-q)\log n$. This means, up to constants, the convex relaxation is tight and hence a computationally efficient and statistically order-optimal estimator, so the hard regime disappears. [2] Similar phenomenon can be observed in the setting with linear size clusters $K \asymp n$ (which implies $r \lesssim 1$) and $p \asymp q$, as is illustrated by the $\beta = 1$ line in Figure 1.

2.4 The Simple Regime: A Counting Algorithm

In this subsection, we consider a simple recovery procedure in Algorithm 3, which is based on counting node degrees and common neighbors.

Algorithm 3 A Simple Counting Algorithm

1. (Identify isolated nodes) For each node i, compute its degree d_i. Declare i as isolated if $d_i < \frac{(p-q)K}{2} + qn$.
2. (Identify clusters when $r > 1$) For every pair of non-isolated nodes i, j, compute the number of common neighbors $S_{ij} := \sum_{k:k\neq i,k\neq j} A_{ik}A_{jk}$, and assign them into the same cluster if $S_{ij} > \frac{(p-q)^2K}{3} + 2Kpq + q^2(n-2K)$. Declare error if inconsistency found.

We note that steps 1 and 2 of Algorithm 3 are considered in Kučera (1995) and Dyer and Frieze (1989) respectively for the special cases of recovering a single planted clique or two planted clusters. Let E be the set of edges. It is not hard to see that step 1 runs in time $O(|E|)$ and step 2 runs in time $O(n|E|)$, since each node only needs to look up its local neighborhood up to distance two. It is possible to achieve even smaller expected running time using clever data structures.

The following theorem provides sufficient conditions for the simple counting algorithm to succeed. Compared to the previous work in Kučera (1995); Dyer and Frieze (1989), our results apply to general values of p, q, r, and K. See Table 1 for its implications for specific planted models.

Theorem 10 (Simple) *For planted clustering with $p > q$, there exist universal constants c_1, c_2 such that Algorithm 3 correctly finds the isolated nodes with probability at least $1 - 2n^{-1}$ if*

$$K^2(p-q)^2 \ge c_1[Kp(1-q) + nq(1-q)]\log n, \tag{17}$$

and finds the clusters with probability at least $1 - 4n^{-1}$ if further

$$K^2(p-q)^4 \ge c_2[Kp^2(1-q^2) + nq^2(1-q^2)]\log n. \tag{18}$$

2. The hard regime may still exist if constant factors are concerned; cf. Mossel et al. 2015a; Decelle et al. 2011.

Remark 11 *If $p, q \to 1$ as $n \to \infty$, we can obtain slightly better performance by counting the common* non-*neighbors in Step 2, which succeeds under condition (18) with p and q replaced by $1-p$ and $1-q$, respectively, i.e., the RHS of (18) simplifies to $c_2 n(1-q)^2 \log n$.*

In the case with a single clusters $r = 1$, we refer to the regime where the condition (17) holds as the *simple regime*; in the case with $r > 1$, the simple regime is where both conditions (17) and (18) hold. It is instructive to compare these conditions with the success condition (14) for the convexified MLE. The condition (17) has an additional $\log n$ factor on the RHS. This means when $r = 1$ and the only task is to find the isolated nodes, the counting algorithm performs nearly as well as the sophisticated convexified MLE. On the other hand, when $r > 1$ and one needs to distinguish between different clusters, the convexified MLE order-wise outperforms the counting algorithm whenever $p/q = \Theta(1)$, as the condition (18) is order-wise more restrictive than (14). Nevertheless, when $p, q, p-q = \Theta(1)$, both algorithms can recover $\widetilde{O}(\sqrt{n})$ clusters of size $\widetilde{\Omega}(\sqrt{n})$, making the simple counting algorithm a legitimate candidate in such a setting and a benchmark to which other algorithms can be compared with.

In the high SNR case with $q = o(p)$, the counting algorithm can recover clusters with size much smaller than $\sqrt{n}$; e.g., if $p = \Theta(1)$ and $q = o(1)$, it only requires $K \gtrsim \max\{\log n, \sqrt{qn \log n}\}$.

2.4.1 CONVERSE FOR THE COUNTING ALGORITHM

We have a (nearly-)matching converse to Theorem 10. The following theorem characterizes when the counting algorithm provably fails.

Theorem 12 (Simple, Converse) *Under the planted clustering model with $p > q$, for any constant $0 < \epsilon_0 < 1$, there exist universal constants $c_1, c_2 > 0$ for which the following holds. Suppose $K \le \frac{n}{2}$, $p \le 1 - \epsilon_0$, $q \ge c_1 \log n/n$ and $Kp^2 + nq^2 \ge c_1 \log n$. Algorithm 3 fails to correctly identify all the isolated nodes with probability at least $1/4$ if*

$$K^2(p-q)^2 < c_2 \left[(Kp+nq)\log(rK) + nq\log(n-rK)\right], \tag{19}$$

and fails to correctly recover all the clusters with probability at least $1/4$ if

$$K^2(p-q)^4 < c_2(Kp^2+nq^2)\log(rK). \tag{20}$$

Remark 13 *Theorem 12 requires a technical condition $Kp^2+nq^2 \ge c_1 \log n$, which is actually not too restrictive. If $Kp^2+nq^2 = o(\log n)$, then two nodes from the same cluster will have no common neighbor with probability $(1-p^2)^K(1-q^2)^{n-K} \ge \exp[-\Theta(p^2K+q^2(n-K))] = \exp[-o(\log n)]$, so Algorithm 3 cannot succeed with the probability specified in Theorem 10.*

Apart from some technical conditions, Theorems 10 and 12 show that the conditions (17) and (18) are both sufficient and necessary. In particular, the counting algorithm cannot succeed outside the simple regime, and is indeed strictly weaker in separating different clusters as compared to the convexified MLE. Our proof reveals that the performance of the counting algorithm is limited by a *variance barrier*: The RHS of (17) and (18) are associated with the variance of the node degrees and common neighbors (i.e., d_i and S_{ij} in Algorithm 3), respectively. There exist nodes whose degrees deviate from their expected value on the order of the standard deviation, and if the condition (17) does not hold, then the deviation will outweigh the difference between the expected degrees of the isolated nodes and those of the non-isolated nodes. A similar argument applies to the number of common neighbors.

3. Main Results for Submatrix Localization

In this section, we turn to the submatrix localization problem, sometimes known as bi-clustering (Balakrishnan et al., 2011a). We consider the following specific setting, which is defined by six parameters $n_L, n_R, K_L, K_R, r \in \mathbb{N}$, and $\mu \in \mathbb{R}_+$ such that $n_L \ge rK_L$ and $n_R \ge rK_R$. We use the shorthand notation $n := n_L \vee n_R$.

Definition 14 (Submatrix Localization) *A random matrix $A \in \mathbb{R}^{n_L \times n_R}$ is generated as follows. Suppose that rK_L rows of A are partitioned into r disjoint subsets $\{C_1^*, \dots, C_r^*\}$ of equal size K_L, and rK_R columns of A are partitioned into r disjoint subsets $\{D_1^*, \dots, D_r^*\}$ of equal size K_R. For each (i,j), we have $A_{ij} = \mu + \Delta_{ij}$ if $(i,j) \in C_m^* \times D_m^*$ for some $m \in [r]$ and $A_{ij} = \Delta_{ij}$ otherwise, where $\mu > 0$ is a fixed number and (Δ_{ij}) are i.i.d. zero-mean sub-Gaussian random variables with parameter* 1. [3] *The goal is to recover the locations of the hidden submatrices $\{(C_m^*, D_m^*), m \in [r]\}$ given the matrix A.*

In the language of bi-clustering, the sets $\{C_1^*, \dots, C_r^*\}$ are called *left clusters* and $\{D_1^*, \dots, D_r^*\}$ are called *right clusters*. Row (column, resp.) indices which do not belong to any cluster are called *isolated* left (right, resp.) nodes. One can think of A as the bipartite affinity matrix between the n_L left nodes and n_R right nodes, and the goal is to recover the left and right clusters. Similarly as before, we define the *bi-clustering matrix* $Y^* \in \{0,1\}^{n_L \times n_R}$, where $Y_{ij}^* = 1$ if and only if $(i,j) \in C_m^* \times D_m^*$ for some $m \in [r]$. The problem reduces to recovering Y^* given A.

As before, all the parameters μ, K_L, K_R, r are allowed to scale with n_L and n_R, and we assume that their values are known. Note that it is without loss of generality to assume the mean of A_{ij} is zero outside the submatrices and the variance of A_{ij} is one, because otherwise we can shift and rescale A. The above model generalizes the previous submatrix localization/detection models (Ma and Wu, 2015; Butucea and Ingster, 2013; Arias-Castro et al., 2011) and bi-clustering models (Kolar et al., 2011; Balakrishnan et al., 2011a) which consider the special case with a *single* submatrix (i.e., $r = 1$).

In the next four subsections, we shall focus on the low-SNR setting $\mu^2 = O(\log n)$ and present theorems establishing the four regimes. These results parallel those for the planted clustering. In the high SNR setting $\mu^2 = \Omega(\log n)$, the submatrices can be easily identified by naive element-wise thresholding, so we deal with this case separately in the last subsection.

3.1 The Impossible Regime: Minimax Lower Bounds

The following theorem gives conditions on $(n_L, n_R, K_L, K_R, \mu)$ under which the minimax error probability is large and thus it is statistically impossible to reliably locate the submatrices. With slight abuse of notation, we use $\mathcal{Y} \subset \{0,1\}^{n_L \times n_R}$ to denote the set of all possible bi-clustering matrices corresponding to r left (right, resp.) clusters of equal size K_L (K_R, resp.).

Theorem 15 (Impossible) *Under the submatrix localization model, suppose $\{A_{ij}\}$ are Gaussian random variables, $K_L \le n_L/2$, $K_R \le n_R/2$, and $n_L, n_R \ge 128$. If*

$$\mu^2 \le \frac{1}{12} \max\left\{ \frac{\log(n_R - K_R)}{K_L}, \frac{\log(n_L - K_L)}{K_R} \right\}, \tag{21}$$

then $\inf_{\widehat{Y}} \sup_{Y^* \in \mathcal{Y}} \mathbb{P}\left[\widehat{Y} \ne Y^*\right] \ge \frac{1}{2}$, where the infimum ranges over all measurable functions of A.

3. A random variable X is said to be sub-Gaussian with parameter 1 if $\mathbb{E}[e^{tX}] \le e^{t^2/2}$ for all $t \in \mathbb{R}$.

The regime where (21) holds is called the *impossible* regime, corresponding to an information barrier that no algorithm can break. We note the similarity between the impossible regimes for submatrix localization and planted clustering. In particular, if we assume the in/cross-cluster edges in planted clustering have comparable variance, i.e., $\frac{p(1-p)}{q(1-q)} = \Theta(1)$, then the conditions (21) and (3) coincide up to constant factors by setting $n_L = n_R = n, K_L = K_R = K$, and $\mu = \frac{p-q}{\sqrt{q(1-q)}}$. Such correspondence also exists in the next three regimes.

Comparison with previous work: Theorem 15 holds in the general high rank setting with arbitrary $r \geq 1$. In $r = 1$ case, our result recovers the minimax lower bound in Kolar et al. (2011).

3.2 The Hard Regime: Optimal Algorithm

Recall that $\mathcal{Y}$ is the set of all valid bi-clustering matrices. We consider the combinatorial optimization problem given in Algorithm 4. In the setting where $\{\Delta_{ij}\}$ are Gaussian random variables, this can be shown to be the MLE of Y^*.

Algorithm 4 Maximum Likelihood Estimator

$$\widehat{Y} = \arg\max_{Y \in \mathcal{Y}} \sum_{i,j} A_{ij} Y_{ij}. \tag{22}$$

Theorem 16 below provides a success condition for Algorithm 4.

Theorem 16 (Hard) *Suppose $K_L, K_R \geq 8$. There exists a constant c_1 such that with probability at least $1 - 512en^{-1}$, the optimal solution to the problem (22) is unique and equals Y^* if*

$$\mu^2 \geq c_1 \frac{\log n}{K_L \wedge K_R}. \tag{23}$$

We refer to the regime where the condition (23) holds and (27) fails as the *hard* regime. Note that the bound (23) matches (21) up to a constant factor, so Algorithm 4 is minimax optimal up to a constant factor. Theorems 15 and 16 together establish the minimax recovery boundary for submatrix localization at $\mu^2 \asymp \frac{\log n}{K_L \wedge K_R}$.

Comparison with previous work: Theorem 16 provides the first minimax-optimal achievability result when the number r of submatrices may grow with n_L and n_R. In particular, r is allowed to grow at a nearly linear rate $r = O(n/\log n)$ assuming $n_L = n_R = n$. In the special case with a single planted submatrix ($r = 1$), Theorem 16 recovers the achievability result in Kolar et al. (2011).

3.3 The Easy Regime: Polynomial-Time Algorithms

As previous, we obtain a convex relaxation of the combinatorial MLE formulation (22) by replacing the constraint $Y \in \mathcal{Y}$ with the trace norm and linear constraints, for which we use the fact that the true Y^* satisfies $\|Y^*\|_* = r\sqrt{K_L K_R}$. This is given as Algorithm 5, which is a semidefinite program (SDP) and can be solved in polynomial time.

Algorithm 5 Convexified Maximum Likelihood Estimator

$$\widehat{Y} = \arg\max_{Y \in \mathbb{R}^{n \times n}} \sum_{i,j} A_{ij} Y_{ij} \tag{24}$$

$$\|Y\|_* \leq r\sqrt{K_L K_R}, \tag{25}$$

$$\sum_{i,j} Y_{ij} = rK_L K_R, \quad 0 \leq Y_{ij} \leq 1, \forall i, j. \tag{26}$$

The following theorem provides a sufficient condition for the success of Algorithm 5.

Theorem 17 (Easy) *There exists a universal constant c_1 such that with probability at least $1 - n^{-10}$, the optimal solution to the program (24)–(26) in Algorithm 5 is unique and equals Y^* if*

$$\mu^2 \geq c_1 \left(\frac{\log n}{K_L \wedge K_R} + \frac{n}{K_L K_R} \right). \tag{27}$$

When $r = 1$, the *easy regime* refers to where the condition (27) holds but (29) fails. When $r > 1$, the easy regime is where the condition (27) holds but (30) fails. Suppose $n_L = n_R = n$ and $K_L = K_R = K$; the convexified MLE is guaranteed to succeed when $\mu^2 \gtrsim \frac{K \log n + n}{K^2}$.

The following theorem provides a nearly matching converse to Theorem 17.

Theorem 18 (Easy, Converse) *There exist positive universal constants c_1, c_2 such that the following holds. Under the submatrix localization model, suppose $\mu \leq 1/100$, $n_L = n_R = n$, $K_L = K_R = K$, $c_1 \log n \leq K \leq \frac{n}{2}$, and (Δ_{ij}) are Gaussian random variables. If*

$$\mu^2 \leq c_2 \frac{n}{K^2}, \tag{28}$$

then with probability at least $1 - n^{-10}$, Y^* is not an optimal solution of the program (24)–(26).

Theorems 17 and 18 together establish that the recovery boundary for the convexified MLE in Algorithm 5 is $\mu^2 \asymp \frac{n}{K^2}$ ignoring logarithmic factors. There is a substantial gap from the minimax boundary $\mu^2 \asymp \frac{1}{K}$ established in the last two subsections (again ignoring logarithmic factors). Our analysis reveals that the performance of the convexified MLE is determined by a spectral barrier similar to that in planted clustering. In particular, the squared largest singular values of the *signal matrix* Y^* and the *noise matrix* $A - \mathbb{E}A$ are $\Theta(\mu^2 K^2)$ and $\Theta(n)$, respectively, so the condition $\mu^2 \gtrsim \frac{n}{K^2}$ for the convexified MLE can be seen as an spectral SNR condition.

As in the planted clustering model, we conjecture that no polynomial-time algorithm can achieve better statistical performance than the convexified MLE.

Conjecture 19 *For any constant $\epsilon > 0$, there is no algorithm with running time polynomial in n that, for all n and with probability at least $1/2$, outputs the true Y^* for the submatrix localization problem with $\mu \leq 1$, $n_L = n_R = n$, $K_L = K_R = K \geq c_1 \log n$ and*

$$\mu^2 \leq \frac{n^{1-\epsilon}}{K^2}.$$

Comparison with previous work: The achievability and converse results in Theorems 17 and 18 hold even when r grows with n. In the special case with $r = 1$, the work in Kolar et al. (2011) considers a convex relaxation of sparse singular value decomposition; they focus on the high SNR regime with $\mu^2 \gtrsim \log n$, and show that the performance of their convex relaxation is no better than a simple element-wise thresholding approach (cf. Section 3.5). Our convex program is different from theirs, and succeeds in the low SNR regime provided $\mu^2 \gtrsim \frac{K \log n + n}{K^2}$. The work in Ames (2013) studies the success conditions of a convex formulation similar to Kolar et al. (2011); with the additional assumption of bounded support of the distribution of A_{ij}, they show that their approach succeeds under an order-wise more restricted condition $\mu^2 \gtrsim \frac{n \cdot r}{K^2}$.

3.4 The Simple Regime: A Thresholding Algorithm

We consider a simple thresholding algorithm as given in Algorithm 6. The algorithm computes the column and row sums of A as well as the correlation between the columns and rows. It is similar in spirit to the simple counting Algorithm 3 for the planted clustering problem.

Algorithm 6 A Simple Thresholding Algorithm

1. (Identify isolated nodes) For each left node $i \in [n_L]$, declare it as isolated if the row sum $d_i := \sum_{j=1}^{n_R} A_{ij} \leq \frac{\mu K_R}{2}$. For each right node $j \in [n_R]$, declare it as isolated if the column sum $d'_j := \sum_{i=1}^{n_L} A_{ij} \leq \frac{\mu K_L}{2}$.
2. (Identify clusters when $r > 1$) For each pair of non-isolated left nodes $i, i' \in [n_L]$, assign them to the same cluster if $S_{ii'} := \sum_{j=1}^{n_R} A_{ij} A_{i'j} \geq \frac{\mu^2 K_R}{2}$. Declare error if inconsistency is found. Assign the non-isolated right nodes into clusters in a similar manner. Let $\{C_k\}$ and $\{D_k\}$ be the resulting left and right clusters.
3. (Associate left and right clusters) For each $k \in [r]$ and $l \in [r]$, associate the left cluster C_k with the right cluster D_l if the block sum $B_{kl} := \sum_{i \in C_k, j \in D_l} A_{ij} \geq \mu K_L K_R / 2$.

Steps 1, 2 and 3 of the algorithm run in time $O(n_L n_R)$, $O(n_L^2 n_R + n_R^2 n_L)$ and $O(n_L n_R)$, respectively. We note that Step 1 is previously considered in Kolar et al. (2011) for locating a single submatrix. The following theorem provides success conditions for this simple algorithm.

Theorem 20 (Simple) *There exist universal constants c_1, c_2 such that Algorithm 6 identifies the isolated nodes with probability at least $1 - en_L^{-1} - en_R^{-1}$ if*

$$\mu^2 \geq c_1 \max\left\{ \frac{n_L \log n_R}{K_L^2}, \frac{n_R \log n_L}{K_R^2} \right\}, \tag{29}$$

and exactly recovers Y^* with probability at least $1 - e(rK_L)^{-1} - e(rK_R)^{-1} - en^{-1}$ if further

$$\mu^4 \geq c_2 \max\left\{ \frac{n_L \log(rK_R)}{K_L^2}, \frac{n_R \log(rK_L)}{K_R^2} \right\}. \tag{30}$$

When $r = 1$, we refer to the regime for which the condition (29) holds as the *simple* regime. When $r > 1$, the simple regime is where both conditions (29) and (30) hold.

We provide a converse to Theorem 20. The following theorem shows that the conditions (29) and (30) are also (nearly) necessary for the simple thresholding algorithm to succeed.

Theorem 21 (Simple, Converse) *Under the submatrix localization model where the distributions of $\{A_{ij}\}$ are Gaussian, there exist universal constants c_1, c_2 such that with probability at least $1 - e^{-(rK_L)^{\Omega(1)}} - e^{-(rK_R)^{\Omega(1)}}$, Algorithm 6 fails to correctly identify all the isolated nodes if*

$$\mu^2 \leq c_1 \max\left\{ \frac{n_L \log n_R}{K_L^2}, \frac{n_R \log n_L}{K_R^2} \right\}, \tag{31}$$

and fails to correctly recover all the clusters if $n_L = \Omega(rK_R)$, $n_R = \Omega(rK_L)$ and

$$\mu^4 \leq c_2 \max\left\{ \frac{n_L \log(rK_R)}{K_L^2}, \frac{n_R \log(rK_L)}{K_R^2} \right\}. \tag{32}$$

When $n_L = n_R = n$, $K_L = K_R = K$, Theorems 20 and Theorem 21 establish that the recovery boundary for the simple thresholding algorithm is $\mu^2 \asymp \frac{n \log n}{K^2}$ if $r = 1$, and $\mu^2 \asymp \frac{\sqrt{n \log n}}{K}$ if $r > 1$ and $rK = \Theta(n)$. Comparing with the success condition (27) for the convex optimization approach, we see that the simple thresholding algorithm is order-wise less powerful in separating different submatrices. Similar to planted clustering, the performance is determined by the variance barrier associated with the variance of the quantities d_i and $S_{ii'}$ computed in Algorithm 6.

3.5 The High SNR Setting

As mentioned before, the high SNR setting with $\mu^2 = \Omega(\log n)$ can be handled by a simple element-wise thresholding algorithm, which is given in Algorithm 7.

Algorithm 7 Element-wise Thresholding for Submatrix Localization

For each $(i, j) \in [n_L] \times [n_R]$, set $\widehat{Y}_{ij} = 1$ if $A_{ij} \geq \frac{1}{2}\mu$, and $\widehat{Y}_{ij} = 0$ otherwise. Output $\widehat{Y}$.

For the special case with one submatrix ($r = 1$), the success of element-wise thresholding in the high SNR setting is proved in Kolar et al. (2011). Their result can be easily extended to the general case with $r \geq 1$. We record this extension in Theorem 22 below. The theorem also shows that element-wise thresholding fails if $\mu^2 = o(\log n)$, so it is not very useful in the low SNR setting.

Theorem 22 (Element-wise Thresholding) *There exists a universal constant $c_1 > 4$ such that the following holds. Algorithm 7 outputs $\widehat{Y} = Y^*$ with probability at least $1 - n^{-3}$ provided*

$$\mu^2 > c_1 \log n. \tag{33}$$

If the distributions of the A_{ij}'s are Gaussian, then with probability at least $1 - n^{-3}$, the output of Algorithm 7 satisfies $\widehat{Y} \neq Y^*$ provided

$$\mu^2 \leq 4 \log n. \tag{34}$$

4. Discussion and Future Work

In this paper, we show that the planted clustering problem and the submatrix localization problem admit successively faster algorithms with weaker statistical performance. We provide sufficient and

necessary conditions for the success of the intractable MLE, the convexified MLE and the simple counting/thresholding algorithm, showing that they work in progressively smaller regions of the parameter space. This thus represents a series of tradeoffs between the statistical and computational performance. Our results hold in the high-rank setting with a growing number of clusters or submatrices. Our results indicate that there may exist a large gap between the information limit and the computational limit, i.e., the information limit might not be achievable via polynomial-time algorithms.

Several future directions are of interest. Immediate goals include removing some of the technical assumptions in our theorems. It is useful in practice to identify a finer spectrum, ideally close to a continuum, of computational-statistical tradeoffs. It is also interesting to extend to the settings with overlapping clusters and submatrices, and to the those where the values of the model parameters are unknown. Proving our conjectures on the computational hardness in the hard regime is also interesting, and this direction is pursued in Ma and Wu (2015); Hajek et al. (June, 2014).

5. Proofs for Planted Clustering

Throughout this section, we consider the planted clustering model with $p > q$. Let $n_1 := rK = |V_1|$ and $n_2 := n - rK = |V_2|$ be the numbers of non-isolated and isolated nodes, respectively.

5.1 Proof of Theorem 2 and Corollary 3

In the sequel we will make use of the following upper and lower bounds on the KL divergence $D(u\|v)$ between two Bernoulli distributions with parameter $u \in [0,1]$ and $v \in [0,1]$. We have

$$D(u\|v) := u\log\frac{u}{v} + (1-u)\log\frac{1-u}{1-v} \overset{(a)}{\le} u\frac{u-v}{v} + (1-u)\frac{v-u}{1-v} = \frac{(u-v)^2}{v(1-v)}, \tag{35}$$

where (a) follows from the inequality $\log x \le x-1, \forall x \ge 0$. Moreover, viewing $D(x\|v)$ as a function of x and using the Taylor's expansion, we can find some $\xi \in [u\wedge v, u\vee v]$ such that

$$D(u\|v) = D(v\|v) + (u-v)D'(v\|v) + \frac{(u-v)^2}{2}D''(\xi\|v) \overset{(b)}{\ge} \frac{(u-v)^2}{2(u\vee v)[1-(u\wedge v)]}, \tag{36}$$

where (b) follows from $D'(v\|v) = 0$ and $D''(\xi\|v) = 1/[\xi(1-\xi)]$.

Theorem 2 is established through the following three lemmas, each of which provides a sufficient condition for having a non-vanishing error probability.

Lemma 23 *Suppose that* $128 \le K \le n/2$. *Let* $\delta := \frac{n_1(K-1)}{n(n-1)}$ *and* $\bar{p} := \delta p + (1-\delta)q$. *We have* $\inf_{\widehat{Y}}\sup_{Y^*\in\mathcal{Y}}\mathbb{P}\left[\widehat{Y} \ne Y^*\right] \ge \frac{1}{2}$ *if*

$$K\cdot D(p\|\bar{p}) + \frac{n^2}{n_1}(1-\delta)\frac{(q-\bar{p})^2}{\bar{p}(1-\bar{p})} \le \frac{1}{4}\log\frac{n}{K}. \tag{37}$$

Moreover, the condition (37) *is implied by*

$$K(p-q)^2 \le \frac{1}{4}q(1-q)\log\frac{n}{K}. \tag{38}$$

Proof We use an information theoretical argument via Fano's inequality. Recall that $\mathcal{Y}$ is the set of all cluster matrices corresponding to r clusters of size K. Let $\mathbb{P}_{(Y^*,A)}$ be the joint distribution of (Y^*, A) when Y^* is sampled from $\mathcal{Y}$ uniformly at random and then A is generated according to the planted clustering model with Y^* being the true cluster matrix. Lower-bounding the supremum by the average, we have

$$\inf_{\widehat{Y}}\sup_{Y^*\in\mathcal{Y}}\mathbb{P}\left[\widehat{Y} \ne Y^*\right] \ge \inf_{\widehat{Y}}\mathbb{P}_{(Y^*,A)}\left[\widehat{Y} \ne Y^*\right].$$

Therefore it suffices to bound $\mathbb{P}_{(Y^*,A)}\left[\widehat{Y} \ne Y^*\right]$ from below. Let $H(X)$ denote the entropy of a random variable X and $I(X;Z)$ the mutual information between X and Z. By Fano's inequality, we have for any $\widehat{Y}$,

$$\mathbb{P}_{(Y^*,A)}\left[\widehat{Y} \ne Y^*\right] \ge 1 - \frac{I(Y^*;A)+1}{\log|\mathcal{Y}|}. \tag{39}$$

We first bound $\log|\mathcal{Y}|$. Simple counting gives that $|\mathcal{Y}| = \binom{n}{n_1}\frac{n_1!}{r!(K!)^r}$. Note that $\binom{n}{n_1} \ge (\frac{n}{n_1})^{n_1}$ and $\sqrt{n}(\frac{n}{e})^n \le n! \le e\sqrt{n}(\frac{n}{e})^n$. It follows that

$$|\mathcal{Y}| \ge (n/n_1)^{n_1}\frac{\sqrt{n_1}(n_1/e)^{n_1}}{e\sqrt{r}(r/e)^r e^r K^{r/2}(K/e)^{n_1}} \ge \left(\frac{n}{K}\right)^{n_1}\frac{1}{e(r\sqrt{K})^r}.$$

This implies $\log|\mathcal{Y}| \ge \frac{1}{2}n_1\log\frac{n}{K}$ under the assumption that $8 \le K \le n/2$ and $n \ge 32$.

We next upper bound $I(Y^*;A)$. Note that $H(A) \le \binom{n}{2}H(A_{12})$ because the A_{ij}'s are identically distributed by symmetry. Furthermore, the A_{ij}'s are mutually independent conditioned on Y^*, so $H(A|Y^*) = \binom{n}{2}H(A_{12}|Y^*_{12})$. It follows that $I(Y^*;A) = H(A) - H(A|Y^*) \le \binom{n}{2}I(Y^*_{12};A_{12})$. We can bound $I(Y^*_{12};A_{12})$ below. Direct counting gives

$$\mathbb{P}(Y^*_{12}=1) = \frac{\binom{n-2}{K-2}\binom{n-K}{K}\cdots\binom{n-rK+K}{K}\frac{1}{(r-1)!}}{|\mathcal{Y}|} = \frac{n_1(K-1)}{n(n-1)} = \delta,$$

and thus $\mathbb{P}(A_{12}=1) = \bar{p} := \delta p + (1-\delta)q$. Therefore, $I(Y^*_{12};A_{12}) = \delta D(p\|\bar{p}) + (1-\delta)D(q\|\bar{p})$. Using the upper bound (35) on the KL divergence and the condition (37), we obtain

$$I(Y^*_{12};A_{12}) = \delta D(p\|\bar{p}) + (1-\delta)D(q\|\bar{p}) \le \delta D(p\|\bar{p}) + (1-\delta)\frac{(q-\bar{p})^2}{\bar{p}(1-\bar{p})} \le \frac{n_1}{4n^2}\log\frac{n}{K}.$$

It follows that $I(Y^*;A) \le \binom{n}{2}I(Y^*_{12}\|A_{12}) \le \frac{n_1}{8}\log\frac{n}{K}$. Substituting into (39) gives

$$\mathbb{P}_{(Y^*,A)}[Y \ne Y^*] \ge 1 - \frac{\frac{n_1}{4}\log\frac{n}{K}+2}{n_1\log\frac{n}{K}} = \frac{3}{4} - \frac{2}{n_1\log\frac{n}{K}} \ge \frac{1}{2},$$

where the last inequality holds because $K \le n/2$ and $n_1 \ge 32$. This proves the sufficiency of (37).

We turn to the second part of the lemma. Observe that

$$\begin{aligned} K\cdot D(p\|\bar{p}) + \frac{n^2}{n_1}(1-\delta)\frac{(q-\bar{p})^2}{\bar{p}(1-\bar{p})} &\overset{(a)}{\le} K\frac{(p-\bar{p})^2}{\bar{p}(1-\bar{p})} + \frac{K}{\delta}(1-\delta)\frac{(q-\bar{p})^2}{\bar{p}(1-\bar{p})} \\ &= K\frac{\delta(1-\delta)(p-q)^2}{\bar{p}(1-\bar{p})} \overset{(b)}{\le} \frac{K(p-q)^2}{q(1-q)}, \end{aligned}$$

where (a) holds due to $\delta \le \frac{n_1 K}{n^2}$ and (35), and (b) holds because $\bar{p}(1-\bar{p}) \ge \delta p(1-p) + (1-\delta)q(1-q) \ge (1-\delta)q(1-q)$ thanks to the concavity of $x(1-x)$. Combining the last display equation with (38) gives (37). ■

Lemma 24 *Suppose* $128 \le K \le n/2$. *We have* $\inf_{\widehat{Y}} \sup_{Y^* \in \mathcal{Y}} \mathbb{P}\left[\widehat{Y} \neq Y^*\right] \ge \frac{1}{2}$ *if*

$$K \max\{D(p\|q), D(q\|p)\} \le \frac{1}{24}\log(n-K). \tag{40}$$

Proof Let $\bar{M} := n - K$, and $\bar{\mathcal{Y}} := \{Y_0, Y_1, \ldots, Y_{\bar{M}}\}$ be a subset of $\mathcal{Y}$ with cardinality $\bar{M}+1$ to be specified later. Let $\bar{\mathbb{P}}_{(Y^*,A)}$ denote the joint distribution of (Y^*, A) when we first sample Y^* from $\bar{\mathcal{Y}}$ uniformly at random, and then sample A according to the planted clustering model with Y^* being the true cluster matrix. By Fano's inequality, we have

$$\inf_{\widehat{Y}} \sup_{Y^* \in \mathcal{Y}} \mathbb{P}\left[\widehat{Y} \neq Y^*\right] \ge \inf_{\widehat{Y}} \bar{\mathbb{P}}_{(Y^*,A)}\left[\widehat{Y} \neq Y^*\right] \ge 1 - \frac{I(Y^*; A) + 1}{\log|\bar{\mathcal{Y}}|}. \tag{41}$$

We construct $\bar{\mathcal{Y}}$ as follows. Let Y_0 be the cluster matrix such that the clusters $\{C_l\}_{l=1}^r$ are given by $C_l = \{(l-1)K+1, \ldots, lK\}$. Informally, each Y_i with $i \ge 1$ is obtained from Y_0 by swapping the cluster memberships of the nodes K and $K+i$. Formally, for each $i \in [\bar{M}]$: (1) if the node $(K+i)$ belongs to cluster C_l for some l, then Y_i is the cluster matrix for which the first cluster consists of the nodes $\{1, 2, \ldots, K-1, K+i\}$, the l-th cluster is given by $C_l \setminus \{K+i\} \cup \{K\}$, and all the other clusters are identical to those given by Y_0; (2) if the node $(K+i)$ is an isolated node in Y_0 (i.e., it does not belong to any cluster), then Y_i is the cluster matrix for which the first cluster consists of the nodes $\{1, 2, \ldots, K-1, K+i\}$, the node K is an isolated node, and all the other clusters identical to those given by Y_0.

Let $\mathbb{P}_i$ be the distribution of the graph A conditioned on $Y^* = Y_i$. Note that each $\mathbb{P}_i$ is the product of $\frac{1}{2}n(n-1)$ Bernoulli distributions. We have the following chain of inequalities:

$$I(Y^*; A) \overset{(a)}{\le} \frac{1}{(\bar{M}+1)^2}\sum_{i,i'=0}^{\bar{M}} D\left(\mathbb{P}_i \| \mathbb{P}_{i'}\right) \overset{(b)}{\le} 3K \cdot D\left(p\|q\right) + 3K \cdot D\left(q\|p\right),$$

where (a) follows from the convexity of KL divergence, and (b) follows by our construction of $\{Y_i\}$. If the condition (40) in the lemma holds, then $I(Y^*; A) \le \frac{1}{4}\log(n-K) = \frac{1}{4}\log|\bar{\mathcal{Y}}|$. Since $\log(n-K) \ge \log(n/2) \ge 4$ when $n \ge 128$, it follows from (41) that the minimax error probability is at least $1/2$. ■

Lemma 25 *Suppose* $128 \le K \le n/2$. *We have* $\inf_{\widehat{Y}} \sup_{Y^* \in \mathcal{Y}} \mathbb{P}\left[\widehat{Y} \neq Y^*\right] \ge \frac{1}{4}$ *if*

$$Kp \le \frac{1}{8}\min\{\log(rK/2), K\}, \tag{42}$$

$$\textbf{\textit{or}} \quad K(1-q) \le \frac{1}{4}\log K. \tag{43}$$

Proof We first prove the sufficiency of the condition (42). We call a node a *disconnected node* if it is not connected to any other node in its own cluster. Let E be the event that there exist two disconnected nodes from two different clusters, and set $\rho := \mathbb{P}[E|Y^*]$, which is in fact independent of what value Y^* takes in $\mathcal{Y}$. Suppose Y^* is uniformly distributed over $\mathcal{Y}$; we claim that $\mathbb{P}\left[\widehat{Y} \neq Y^*\right] \ge \rho/2$ for all $\widehat{Y}$. To see this, consider the maximum likelihood estimator (MLE) of Y^*, which is given by $\widehat{Y}_{\mathrm{ML}}(a) := \arg\max_y \mathbb{P}[A = a | Y^* = y]$ with tie broken uniformly at random. It is a standard fact that the MLE minimizes the error probability under the uniform prior, so for all $\widehat{Y}$ we have

$$\mathbb{P}\left[\widehat{Y} \neq Y^*\right] \ge \frac{1}{|\mathcal{Y}|}\sum_{y \in \mathcal{Y}}\sum_{a \in \{0,1\}^{n\times n}} \mathbb{P}\left[\widehat{Y}_{\mathrm{ML}}(a) \neq y\right]\mathbb{P}\left[A = a | Y^* = y\right]. \tag{44}$$

Let $\mathcal{A}_y \subseteq \{0,1\}^{n\times n}$ denote the set of adjacency matrices with at least two disconnected nodes in two different clusters with respect to the clusters defined by $y \in \mathcal{Y}$. For each $a \in \mathcal{A}_y$, let $y'(a)$ denote the cluster matrix obtained by swapping the two rows and columns of y corresponding to the first two disconnected nodes in a. It is easy to check that for each $a \in \mathcal{A}_y$, the likelihood satisfies $\mathbb{P}[A = a|Y^* = y] \le \mathbb{P}[A = a|Y^* = y'(a)]$ and therefore $\mathbb{P}[\widehat{Y}_{\mathrm{ML}}(a) \neq y] \ge 1/2$. It follows from (44) that

$$\mathbb{P}\left[\widehat{Y} \neq Y^*\right] \ge \frac{1}{|\mathcal{Y}|}\sum_{y}\sum_{a \in \mathcal{A}_y}\frac{1}{2}\cdot\mathbb{P}[A = a|Y^* = y] = \frac{1}{2}\rho,$$

where the last equality holds because $\mathbb{P}[\mathcal{A}_y|Y^* = y] \equiv \rho$ independently of y. This proves our claim.

Since the maximum error probability is lower bounded by the average error probability, to establish the lemma it suffices to show $\rho \ge 1/2$. Without loss of generality, suppose r is even and we fix the clusters Y^* to be such that the first $rK/2$ nodes $\{1, \ldots, rK/2\}$ form $r/2$ clusters, and the next $rk/2$ nodes $\{rK/2+1, \ldots, rK\}$ form another $r/2$ clusters. For each $i \in [rK/2]$, let ξ_i be the indicator random variable for node i being a disconnected node. Then $\rho_1 := \mathbb{P}\left[\sum_{i=1}^{rK/2}\xi_i \ge 1\right]$ is the probability that there exits at least one disconnected node among the first $rK/2$ nodes. We use a second moment argument (Durrett, 2007) to lower-bound ρ_1. Observe that $\xi_1, \ldots, \xi_{rK/2}$ are (dependent) Bernoulli variables with mean $\mu := (1-p)^{K-1}$. For $i \neq j$, we have

$$\mathbb{E}\left[\xi_i\xi_j\right] = \mathbb{P}\left[\xi_i = 1, \xi_j = 1\right] \le (1-p)^{2K-3} = \frac{1}{1-p}\mu^2.$$

Therefore, we obtain

$$\begin{aligned}\mathrm{Var}\left[\sum_{i=1}^{rK/2}\xi_i\right] &\le \frac{1}{2}rK\mu(1-\mu) + \frac{1}{2}rK(rK/2-1)\left(\frac{1}{1-p}-1\right)\mu^2 \\ &\le \frac{1}{2}rK\mu + \frac{1}{4}r^2K^2\mu^2\frac{p}{1-p}.\end{aligned}$$

Under the condition (42) we have $p \le 1/8$ and

$$\mu = (1-p)^{K-1} \overset{(a)}{\ge} e^{-2(K-1)p} \ge (rK/2)^{-1/4}, \tag{45}$$

where (a) uses the inequality $1-x \geq e^{-2x}, \forall x \in [0, \frac{1}{2}]$. Applying the Chebyshev's inequality, we get

$$\mathbb{P}\left[\left|\sum_{i=1}^{rK/2} \xi_i - rK\mu/2\right| \geq rK\mu/2\right] \leq \frac{\frac{1}{2}rK\mu + \frac{1}{4}(rK\mu)^2 \frac{p}{1-p}}{r^2K^2\mu^2/4} \leq \frac{2}{rK\mu} + \frac{p}{1-p} \leq \frac{1}{4},$$

where the last inequality holds due to (45) and $p \leq 1/8$. It follows that $\rho_1 \geq \frac{3}{4}$. If we let ρ_2 denote the probability that there exits a disconnected node among the next $rK/2$ nodes $\{rK/2+1, \ldots, rK\}$, then by symmetry $\rho_2 \geq \frac{3}{4}$. Therefore $\rho \geq \rho_1\rho_2 \geq 1/2$, proving the sufficiency of (42).

We next prove the sufficiency of the condition (43) by bounding the error probability using a similar strategy. For $k = 1, 2$, we call a node in cluster k a *betrayed node* if it is connected to all nodes in cluster $3-k$. Let E' be the event of having a betrayed node in each of the clusters 1 and 2, and let $\rho' := \mathbb{P}[E']$. Suppose Y^* is uniformly distributed over $\mathcal{Y}$; we can use a similar argument as above to show that $\mathbb{P}[\widehat{Y} \neq Y^*] \geq \rho'/2$ for any $\widehat{Y}$. Fix Y^* to be such that the clusters 1 and 2 are given by the nodes $[K]$ and $\{K+1, \ldots, 2K\}$, respectively. For each $i \in [K]$, let ξ_i' be the indicator for node i being is a betrayed node. Then $\rho_1' := \mathbb{P}\left[\sum_{i=1}^K \xi_i' > 0\right]$ is the probability of having a betrayed node in cluster 1. Note that the condition (43) implies $1-q \leq 1/2$. We have

$$\mathbb{P}\left[\sum_{i=1}^K \xi_i' = 0\right] = \left(1-q^K\right)^K \leq \exp\left(-Kq^K\right) \overset{(b)}{\leq} \exp\left[-K\exp\left(-2(1-q)K\right)\right] \overset{(c)}{\leq} \exp(-K^{1/2}) \leq 1/4,$$

where (b) follows from the inequality $q^K = (1-(1-q))^K \geq \exp(-2(1-q)K)$ for $1-q \leq 1/2$, and (c) holds under the condition (43). We therefore obtain $\rho_1' \geq \frac{3}{4}$. Let ρ_2' be the probability of having a betrayed node in cluster 2; by symmetry $\rho_2' \geq 3/4$. By the union bound we get $\rho' \geq 1-(1-\rho_1')-(1-\rho_2') \geq 1/2$, proving the sufficiency of (43). ■

We can now prove Theorem 2 by combining the above three lemmas.

Proof [of Theorem 2] Since $256 \leq 2K \leq n$, we have the following relations for the logarithmic terms:

$$\log(n-K) \geq \log(n/2) \geq \frac{1}{2}\log n, \quad \text{and} \quad \log(rK/2) \geq \frac{1}{2}\log(rK). \tag{46}$$

Our goal is to show that if the condition (1) or (2) holds, then we can draw the conclusion that the minimax error probability is large.

First assume (1) holds. By (36), we know the condition (1) implies

$$K(p-q)^2 \leq \frac{1}{96}p(1-q)\left(\log(rK) \wedge K\right). \tag{47}$$

We distinguish between two cases. (i) If $p \leq 2q$, then (47) implies $K(p-q)^2 \leq \frac{1}{48}q(1-q)\log(rK)$; it follows from (35) and (46) that $KD(p\|q) \leq \frac{1}{48}\log(rK) \leq \frac{1}{24}\log(n-K)$, and thus Lemma 24 proves the conclusion. (ii) If $p > 2q$, then (47) implies $Kp \leq \frac{1}{24}\log(rK) \wedge K \leq \min\{\frac{1}{24}K, \frac{1}{12}\log(\frac{rK}{2})\}$, and Lemma 25 proves the conclusion.

Next assume the condition (2) holds. Using the lower-bound (36) on the KL divergence, we know that (2) implies

$$K(p-q)^2 \leq \frac{1}{96}p(1-q)\log n. \tag{48}$$

We distinguish between two cases. (i) If $1-q \leq 2(1-p)$, then (48) implies $K(p-q)^2 \leq \frac{1}{48}p(1-p)\log n$; it follows from (35) and (46) that $KD(q\|p) \leq \frac{1}{48}\log n \leq \frac{1}{24}\log(n-K)$, and thus Lemma 24 implies the conclusion. (ii) If $1-q > 2(1-p)$ and $K \geq \log n$, then (48) implies

$$K(1-q) \leq \frac{1}{24}\log n \leq \frac{1}{12}\max\left\{\log\frac{n}{K}, \log K\right\}. \tag{49}$$

We further divide the analysis into two sub-cases.

Case $(ii.1)$: $K \geq \log n$. It follows from (49) that $1-q \leq \frac{1}{24}$, i.e., $q \geq \frac{23}{24}$, and thus $(p-q)^2 \leq 2q(1-q)^2$. Therefore, the inequality (49) implies either the condition (38) in Lemma 23 or the condition (43) in Lemma 25, which proves the conclusion.

Case $(ii.2)$: $K < \log n$. It follows that $\delta := \frac{n_1(K-1)}{n(n-1)} \leq \frac{1}{10}$ and $\log\frac{n}{K} \geq \frac{1}{2}\log n$. Note that $\bar{p} := \delta p + (1-\delta)q \geq \max\{\delta p, q\}$ and $1-\bar{p} \geq \frac{9}{10}(1-q)$. Therefore, we have

$$\frac{n^2(q-\bar{p})^2}{n_1\bar{p}(1-\bar{p})} = \frac{n^2\delta^2(p-q)^2}{n_1\bar{p}(1-\bar{p})} \leq \frac{2n^2\delta(p-q)^2}{n_1p(1-q)} \overset{(a)}{\leq} 4KD(p\|q) \overset{(b)}{\leq} \frac{1}{24}\log\frac{n}{K}, \tag{50}$$

where we use (36) in (a) and (2) in (b). On the other hand, we have

$$\begin{aligned} D(p\|\bar{p}) &= p\log\frac{p}{\bar{p}} + (1-p)\log\frac{1-p}{1-\bar{p}} \leq p\log\frac{p}{q} + (1-p)\log\frac{10(1-p)}{9(1-q)} \\ &\leq D(p\|q) + (1-q)\log\frac{10}{9} \leq \frac{1}{6K}\log\frac{n}{K}, \end{aligned} \tag{51}$$

where the last inequality follows from (2) and (49). Equations (50) and (51) imply the assumption (37) in Lemma 23, and therefore the conclusion follows. ■

5.1.1 PROOF OF COROLLARY 3

The corollary is derived from Theorem 2 using the upper bound (35) on the KL divergence. In particular, condition (3) implies condition (2) in Theorem 2 in view of (35). Similarly, condition (4) implies condition (1) because $D(q\|p) \leq \frac{p}{1-p}$ in view of (35) and $p \leq \frac{1}{193}$. Finally, condition (5) implies condition (2) because $D(p\|q) \leq p\log\frac{p}{q}$ by definition of the KL divergence.

5.2 Proof of Theorem 4 and Corollary 5

Let $\langle X, Y\rangle := \mathrm{Tr}(X^\top Y)$ denote the trace inner product between two matrices. For each feasible solution $Y \in \mathcal{Y}$ of the optimization problem (7), we define $\Delta(Y) := \langle A, Y^* - Y\rangle$ and $d(Y) := \langle Y^*, Y^* - Y\rangle$. To prove the theorem, it suffices to show that $\Delta(Y) > 0$ for all feasible Y with $Y \neq Y^*$. For simplicity, in this proof we use a different convention that $Y_{ii}^* = 0$ and $Y_{ii} = 0$ for all

$i \in V$. Note that $\mathbb{E}[A] = qJ + (p-q)Y^* - qI$, where J is the $n \times n$ all-one matrix and I is the $n \times n$ identity matrix. We may decompose $\Delta(Y)$ into an expectation term and a fluctuation term:

$$\Delta(Y) = \langle \mathbb{E}[A], Y^* - Y \rangle + \langle A - \mathbb{E}[A], Y^* - Y \rangle = (p-q)d(Y) + \langle A - \mathbb{E}[A], Y^* - Y \rangle, \quad (52)$$

where the second equality follows from $\sum_{i,j} Y_{ij} = \sum_{i,j} Y^*_{ij}$ by feasibility of Y. For the second fluctuation term above, observe that

$$\langle A - \mathbb{E}[A], Y^* - Y \rangle = 2 \underbrace{\sum_{(i<j): \substack{Y^*_{ij}=1 \\ Y_{ij}=0}} (A_{ij} - p)}_{T_1(Y)} - 2 \underbrace{\sum_{(i<j): \substack{Y^*_{ij}=0 \\ Y_{ij}=1}} (A_{ij} - q)}_{T_2(Y)}.$$

Here each of $T_1(Y)$ and $T_2(Y)$ is the sum of $\frac{1}{2}d(Y)$ i.i.d. centered Bernoulli random variables with parameter p and q, respectively.

Using the Chernoff bound, we can bound the fluctuation for each fixed $Y \in \mathcal{Y}$:

$$\mathbb{P}\left\{T_1(Y) \le -\frac{p-q}{4}d(Y)\right\} \le \exp\left[-\frac{1}{2}d(Y)D\left(\frac{p+q}{2}\middle\|p\right)\right], \quad (53)$$

$$\mathbb{P}\left\{T_2(Y) \ge \frac{p-q}{4}d(Y)\right\} \le \exp\left[-\frac{1}{2}d(Y)D\left(\frac{p+q}{2}\middle\|q\right)\right]. \quad (54)$$

We need to control the fluctuation uniformly over $Y \in \mathcal{Y}$. Define the equivalence class $[Y] := \{Y' \in \mathcal{Y} : Y'_{ij} = Y_{ij}, \forall (i,j) \in \text{support}(Y^*)\}$, where $\text{support}(Y^*) := \{(i,j) : Y^*_{ij} = 1\}$. Obverse that all cluster matrices in the equivalence class $[Y]$ have the same value of $T_1(Y)$. The following combinatorial lemma upper bounds the number of Y's and $[Y]$'s such that $d(Y) = t$. Note that $2(K-1) \le d(Y) \le rK^2$ for all feasible $Y \ne Y^*$.

Lemma 26 *For each integer $t \in [K, rK^2]$, we have*

$$\left|\{Y \in \mathcal{Y} : d(Y) = t\}\right| \le \left(\frac{16t^2}{K^2}\right)^2 n^{32t/K},$$

$$\left|\{[Y] : d(Y) = t\}\right| \le \frac{16t^2}{K^2}(rK)^{16t/K}.$$

We prove this lemma in Appendix A. We also need the following lemma, which lower-bounds $D\left(\frac{p+q}{2}\|q\right)$ and $D\left(\frac{p+q}{2}\|p\right)$ using $D(p\|q)$ and $D(q\|p)$, respectively. The proof is given in Appendix B.

Lemma 27 *For any $0 \le p \le q \le 1$, we have*

$$D\left(\frac{p+q}{2}\middle\|q\right) \ge \frac{1}{36}D(p\|q), \quad (55)$$

$$D\left(\frac{p+q}{2}\middle\|p\right) \ge \frac{1}{36}D(q\|p). \quad (56)$$

Using the union bound, (53), Lemma 26 and Lemma 27, we obtain

$$\begin{aligned}
&\mathbb{P}\left\{\exists[Y] : Y \ne Y^*, T_1(Y) \le -\frac{p-q}{4}d(Y)\right\} \\
&\le \sum_{t=K}^{rK^2} \mathbb{P}\left\{\exists[Y] : d(Y) = t, T_1(Y) \le -\frac{p-q}{4}t\right\} \\
&\le \sum_{t=K}^{rK^2} \left|\{\exists[Y] : d(Y) = t\}\right| \cdot \mathbb{P}\left\{T_1(Y) \le -\frac{p-q}{4}t\right\} \\
&\le \sum_{t=K}^{rK^2} \frac{16t^2}{K^2}(rK)^{16t/K} \exp\left(-\frac{1}{72}tD(q\|p)\right) \\
&\overset{(a)}{\le} 16\sum_{t=K}^{rK^2}(rK)^2(\gamma rK)^{-5t/K} \le 16(\gamma rK)^{-1},
\end{aligned}$$

where (a) follows from the theorem assumption that $D(q\|p) \ge c_1 \log(\gamma rK)/K$ for a sufficiently large constant c_1. Similarly, using (54) we have

$$\begin{aligned}
&\mathbb{P}\left\{\exists Y \in \mathcal{Y} : Y \ne Y^*, T_2(Y) \ge \frac{p-q}{4}d(Y)\right\} \\
&\le \sum_{t=K}^{rK^2} \mathbb{P}\left\{\exists Y \in \mathcal{Y} : d(Y) = t, T_2(Y) \ge \frac{p-q}{4}t\right\} \\
&\le \sum_{t=K}^{rK^2} \left|\{Y \in \mathcal{Y} : d(Y) = t\}\right| \cdot \mathbb{P}\left\{T_2(Y) \ge \frac{p-q}{4}t\right\} \\
&\le \sum_{t=K}^{rK^2} \frac{256t^4}{K^4} n^{32t/K} \cdot \exp\left(-\frac{1}{72}tD(p\|q)\right) \overset{(b)}{\le} 256n^{-1},
\end{aligned}$$

where (b) follows from the theorem assumption that $D(p\|q) \ge c_1 \log n/K$ for a sufficiently large constant c_1. Combining the above two bounds with (52), we obtain

$$\mathbb{P}\{\exists Y \in \mathcal{Y} : \Delta(Y) \le 0\} \le 16(\gamma rK)^{-1} + 256n^{-1}.$$

Therefore Y^* is the unique optimal solution with the same probability. This proves the theorem.

5.2.1 PROOF OF COROLLARY 5

The corollary is derived from Theorem 4 using the lower bound (36) on the KL divergence. First assume $e^2q \ge p$. Then $K(p-q)^2 \gtrsim q(1-q)\log n$ implies condition (9) in view of (36). Next assume $e^2q < p$. It follows that $\log\frac{p}{q} \le 2\log\frac{p}{eq}$. By definition, $D(p\|q) \ge p\log\frac{p}{q} + (1-p)\log(1-p) \ge p\log\frac{p}{eq}$. Hence, $Kp\log\frac{p}{q} \gtrsim \log n$ implies $KD(p\|q) \gtrsim \log n$. Furthermore, $D(q\|p) \ge \frac{1}{2}(1-1/e^2)p$ in view of (36) and $p > e^2q$. Therefore, $Kp \gtrsim \log(rK)$ implies $KD(q\|p) \gtrsim \log(rK)$.

5.3 Proof of Theorem 6

We prove Theorem 6 and Theorem 17 (for submatrix localization) together in this section. Our proof relies only on two standard concentration results for the adjacency matrix A (Proposition 28 below).

We need some unified notation for the two models. For both models we use n_L and n_R to denote the problem dimensions, with the understanding that $n_L = n_R = n$ for planted clustering. Similarly, for planted clustering the left and right clusters are identical and $K_L = K_R = K$. Let $U \in \mathbb{R}^{n_L \times r}$ and $V \in \mathbb{R}^{n_R \times r}$ be the normalized characteristic matrices of the left and right clusters, respectively:

$$U_{ik} = \begin{cases} \frac{1}{\sqrt{K_L}}, & \text{if the left node } i \text{ is in the } k\text{-th left cluster,} \\ 0, & \text{otherwise,} \end{cases}$$

and similarly for V. Here $U = V$ for planted clustering. The true cluster matrix Y^* has the rank-r Singular Value Decomposition given by $Y^* = \sqrt{K_L K_R} U V^\top$. Define the projections $\mathcal{P}_T(M) = UU^\top M + MVV^\top - UU^\top MVV^\top$ and $\mathcal{P}_{T^\perp}(M) = M - \mathcal{P}_T(M)$. Several matrix norms will be used: the spectral norm $\|X\|$ (the largest singular value of X), the nuclear norm $\|X\|_*$ (the sum of the singular values), the ℓ_1 norm $\|X\|_1 = \sum_{i,j} |X_{ij}|$ and the ℓ_∞ norm $\|X\|_\infty = \max_{i,j} |X_{ij}|$.

We define a quantity $\nu > 0$ and a matrix $\bar{A} \in \mathbb{R}^{n_L \times n_R}$, which roughly correspond to the signal strength and the mean of A. For planted clustering, let $\nu := p - q$ and $\bar{A} := qJ + (p-q)Y^*$, where J is the all-one matrix. For submatrix localization, let $\nu := \mu$ and $\bar{A} := \mu Y^*$. The proof hinges on the following probabilistic property of the random matrix $A - \bar{A}$.

Proposition 28 *Under the condition (14) for planted clustering,* or *the condition (27) for submatrix localization, the following holds with probability at least* $1 - n^{-10}$*:*

$$\|A - \bar{A}\| \le \frac{1}{8}\nu\sqrt{K_L K_R}, \tag{57}$$

$$\|\mathcal{P}_T(A - \bar{A})\|_\infty \le \frac{1}{8}\nu. \tag{58}$$

We prove the proposition in Section 5.3.1 to follow. In the rest of the proof we assume the event that (57) and (58) hold. To establish the theorems, it suffices to show that $\langle Y^* - Y, A\rangle > 0$ for all feasible solution Y of the convex program with $Y \neq Y^*$. For any feasible Y, we may write

$$\begin{aligned}\langle Y^* - Y, A\rangle &= \langle \bar{A}, Y^* - Y\rangle + \langle A - \bar{A}, Y^* - Y\rangle \\ &= \nu\langle Y^*, Y^* - Y\rangle + \langle A - \bar{A}, Y^* - Y\rangle = \frac{\nu}{2}\|Y^* - Y\|_1 + \langle A - \bar{A}, Y^* - Y\rangle, \end{aligned} \tag{59}$$

where the second equality follows from the definition of $\bar{A}$, and the third equality holds because Y obeys the linear constraints $\sum_{i,j} Y_{ij} = \sum_{i,j} Y^*_{ij}$ and $Y_{ij} \in [0,1], \forall i,j$.

On the other hand, we have $\|Y^*\|_* \ge \|Y\|_*$ thanks to the constraint (12) or (25). Let $W := \frac{8(A-\bar{A})}{\nu\sqrt{K_L K_R}}$. By (57) we have $\|\mathcal{P}_{T^\perp}(W)\| \le \|W\| \le 1$, so $UV^\top + \mathcal{P}_{T^\perp}(W)$ is a subgradient of $f(X) := \|X\|_*$ at $X = Y^*$ (cf. Recht et al. 2010 for characterization of the subgradient of the nuclear norm). It follows that

$$0 \ge \|Y\|_* - \|Y^*\|_* \ge \left\langle UV^\top + \mathcal{P}_{T^\perp}(W), Y - Y^*\right\rangle = \langle W, Y - Y^*\rangle + \left\langle UV^\top - \mathcal{P}_T(W), Y - Y^*\right\rangle.$$

Rearranging terms and using the definition of W gives

$$\left\langle A - \bar{A}, Y^* - Y\right\rangle = \frac{\nu\sqrt{K_L K_R}}{8}\langle W, Y^* - Y\rangle \ge \frac{\nu\sqrt{K_L K_R}}{8}\left\langle -UV^\top + \mathcal{P}_T(W), Y^* - Y\right\rangle. \tag{60}$$

Assembling (59) and (60), we obtain that for any feasible Y,

$$\begin{aligned}\langle Y^* - Y, A\rangle &\ge \frac{\nu}{2}\|Y^* - Y\|_1 + \frac{\nu\sqrt{K_L K_R}}{8}\left\langle -UV^\top + \mathcal{P}_T(W), Y^* - Y\right\rangle \\ &\ge \left(\frac{\nu}{2} - \frac{\nu\sqrt{K_L K_R}}{8}\|UV^\top\|_\infty - \|\mathcal{P}_T(A - \bar{A})\|_\infty\right)\|Y^* - Y\|_1,\end{aligned}$$

where the last inequality follows from the duality between the ℓ_1 and ℓ_∞ norms. Using (58) and the fact that $\|UV^\top\|_\infty = 1/\sqrt{K_L K_R}$, we get

$$\langle Y^* - Y, A\rangle \ge \left(\frac{\nu}{2} - \frac{\nu}{8} - \frac{\nu}{8}\right)\|Y^* - Y\|_1 = \frac{\nu}{4}\|Y^* - Y\|_1,$$

where the R.H.S. is strictly positive for all $Y \neq Y^*$. This completes the proof of Theorems 6 and 17.

5.3.1 PROOF OF PROPOSITION 28

We first prove (58). By definition of $\mathcal{P}_T$, we have

$$\begin{aligned}\|\mathcal{P}_T(A - \bar{A})\|_\infty \le& \|UU^\top(A - \bar{A})\|_\infty + \|(A - \bar{A})VV^\top\|_\infty + \|UU^\top(A - \bar{A})VV^\top\|_\infty \\ \le& 3\max\left(\|UU^\top(A - \bar{A})\|_\infty, \|(A - \bar{A})VV^\top\|_\infty\right).\end{aligned} \tag{61}$$

Suppose the left node i belongs to the left cluster k. Then

$$(UU^\top(A - \bar{A}))_{ij} = \frac{1}{K_L}\sum_{l \in C_k^*}(A - \bar{A})_{lj} = \frac{1}{K_L}\sum_{l \in C_k^*}(A - \mathbb{E}A)_{lj} + \frac{1}{K_L}\sum_{l \in C_k^*}(\mathbb{E}A - \bar{A})_{lj}. \tag{62}$$

To proceed, we consider the two models separately.

Planted clustering: The entries of the matrix $A - \mathbb{E}A$ are centered Bernoulli random variables with variance bounded by $p(1-q)$ and mutually independent up to symmetry with respect to the diagonal. The first term of (62) is the average of K_L such random variables; by Bernstein's inequality (stated as Theorem 32 in Appendix C), we have with probability at least $1 - n^{-13}$ and for some universal constant c_2,

$$\left|\sum_{l \in C_k^*}(A - \mathbb{E}A)_{lj}\right| \le \sqrt{26p(1-q)K\log n} + 9\log n \le c_2\sqrt{p(1-q)K\log n},$$

where the last inequality follows because $Kp(1-q) > c_1 \log n$ in view of the condition (14). By definition of $\bar{A}$, $\mathbb{E}[A] - \bar{A}$ is a diagonal matrix with each diagonal entry equal to $-p$ or $-q$, so the second term of (62) has magnitude at most $1/K$. By the union bound over all (i,j) and substituting back to (61), we have with probability at least $1 - 2n^{-11}$,

$$\|\mathcal{P}_T(A - \bar{A})\|_\infty \le 3c_2\sqrt{p(1-q)\log n/K} + 3/K \le (p-q)/8 = \nu/8,$$

where the last inequality follows from the condition (14). This proves (58) in the proposition.

Submatrix localization: We have $\bar{A} = \mathbb{E}A$ by definition, so the second term of (62) is zero. The first term is the average of K_L independent centered random variables with unit sub-Gaussian norm. By a standard sub-Gaussian concentration inequality (e.g., Proposition 5.10 in Vershynin 2012), we have for some universal constant c_3 and with probability at least $1 - n^{-13}$,

$$\left|\sum_{l\in\mathcal{C}_k}(A - \mathbb{E}A)_{lj}\right| \le c_3\sqrt{K_L \log n}.$$

So $\|UU^\top(A-\mathbb{E}A)\|_\infty \le c_3\sqrt{\log n/K_L}$ with probability at least $1-n^{-11}$ by the union bound. Similarly, $\|(A-\mathbb{E}A)VV^\top\|_\infty \le c_2\sqrt{\log n/K_R}$ with the same probability. Combining with (61) gives

$$\|\mathcal{P}_T(A - \bar{A})\|_\infty \le \sqrt{\log n/\min\{K_L, K_R\}} \le \nu/8 = \mu/8,$$

where the last inequality holds under the condition (27). This proves (58) in the proposition.

We now turn to (57) in the proposition, and again consider the two models separately.

- *Planted clustering:* Note that $\|A - \bar{A}\| \le \|A - \mathbb{E}[A]\| + \|\bar{A} - \mathbb{E}[A]\| \le \|A - \mathbb{E}[A]\| + 1$. Under the condition (14), $Kp(1-q) \ge c_1 \log n$. We bound the spectral norm term in the lemma below.

  Lemma 29 *If $Kp(1-q) \ge c_1 \log n$, then there exists some universal constant c_4 such that $\|A - \mathbb{E}[A]\| \le c_4\sqrt{p(1-q)K\log n + q(1-q)n}$ with probability at least $1 - n^{-10}$.*

  We prove the lemma in Section 5.3.2 to follow. Applying the lemma, we obtain

  $$\|A - \bar{A}\| \le c_4\sqrt{p(1-q)K\log n + q(1-q)n} + 1 \le \frac{K(p-q)}{8} = \frac{K\nu}{8},$$

  where the second inequality holds under the condition (14).

- *Submatrix localization:* The matrix $A - \bar{A} = A - \mathbb{E}A$ has i.i.d. sub-Gaussian entries. Using a standard concentration bound for the spectral norm of such a matrix (e.g., Theorem 5.39 in Vershynin 2012), we get that for a universal constant c_5 and with probability at least $1 - n^{-10}$,

  $$\|A - \mathbb{E}A\| \le c_5\sqrt{n} \le \frac{\mu}{8}\sqrt{K_L K_R} = \frac{\nu}{8}\sqrt{K_L K_R},$$

  where the second inequality holds under the condition (27).

5.3.2 PROOF OF LEMMA 29

Let $R := \text{support}(Y^*)$ and $\mathcal{P}_R(\cdot) : \mathbb{R}^{n\times n} \to \mathbb{R}^{n\times n}$ be the operator that sets the entries outside R to zero. Set $B_1 := \mathcal{P}_R(A - \mathbb{E}[A])$ and $B_2 := A - \mathbb{E}[A] - B_1$. Then B_1 is a block-diagonal symmetric matrix with r blocks of size $K \times K$ and its upper-triangular entries are independent with zero mean and variance bounded by $p(1-q)$. Applying the matrix Bernstein inequality in Tropp (2012) and using the assumption that $Kp(1-q) \ge c_1 \log n$ in the lemma, we get that there exits some universal constant c_6 such that $\|B_1\| \le c_6\sqrt{p(1-q)K\log n}$ with probability at least $1 - n^{-11}$.

On the other hand, B_2 is symmetric and its upper-triangular entries are independent centered Bernoulli random variables with variance bounded by $\sigma^2 := \max\{q(1-q), c_7 \log n/n\}$ for any

universal constant c_7. If $\sigma^2 \ge \frac{\log^7 n}{n}$, then Theorem 8.4 in Chatterjee (2014) implies that $\|B_2\| \le 3\sigma\sqrt{n}$ with probability at least $1-n^{-11}$. If $c_7\frac{\log n}{n} \le \sigma^2 \le \frac{\log^7 n}{n}$ for a sufficiently large constant c_7, then Lemma 2 in Massoulié and Tomozei (2014) implies that $\|B_2\| \le c_8\sigma\sqrt{n}$ with probability at least $1 - n^{-11}$ for some universal constant c_8. (See Lemma 8 in Vu 2014 for a similar derivation.) Putting together, we conclude that with probability at least $1 - 2n^{-11}$,

$$\begin{aligned}\|A - \mathbb{E}[A]\| \le \|B_1\| + \|B_2\| &\le c_6\sqrt{p(1-q)K\log n} + c_8\max\{\sqrt{q(1-q)n}, \sqrt{\log n}\}\\ &\le c_4\sqrt{p(1-q)K\log n + q(1-q)n},\end{aligned}$$

where the last inequality holds because $Kp(1-q) \ge c_1 \log n$ by assumption. This proves the lemma.

5.4 Proof of Theorem 8

We first claim that $K(p-q) \le c_2\sqrt{Kp+qn}$ implies $K(p-q) \le c_2\sqrt{2qn}$ under the assumption that $K \le n/2$ and $qn \ge c_1 \log n$. In fact, if $Kp \le qn$, then the claim trivially holds. If $Kp > qn$, then $q < Kp/n \le p/2$. It follows that

$$Kp/2 < K(p-q) \le c_2\sqrt{Kp+qn} \le c_2\sqrt{2Kp}.$$

Therefore, we have $Kp < 8c_2^2$, which contradicts the assumption that $Kp > qn \ge c_1 \log n$. So $Kp > qn$ cannot hold. Consequently, it suffices to show that if $K(p-q) \le c_2\sqrt{2qn}$, then Y^* is not an optimal solution. We do this by deriving a contradiction assuming the optimality of Y^*.

Let J be the $n \times n$ all-ones matrix. Let $\mathcal{R} := \text{support}(Y^*)$ and $\mathcal{A} := \text{support}(A)$. Recall the cluster characteristic matrix U and the projection $\mathcal{P}_T(M) = UU^\top M + MUU^\top - UU^\top MUU^\top$ defined in Section 5.3, and that $Y^* = KUU^\top$ is the SVD of Y^*. Consider the Lagrangian

$$L(Y;\lambda,\mu,F,G) := -\langle A, Y\rangle + \lambda\left(\|Y\|_* - \|Y^*\|_*\right) + \eta\left(\langle J, Y\rangle - rK^2\right) - \langle F, Y\rangle + \langle G, Y - J\rangle,$$

where $\lambda, \eta \in \mathbb{R}$ and $F, G \in \mathbb{R}^{n\times n}$ are the Lagrangian multipliers. Since $Y = \frac{rK^2}{n^2}J$ is strictly feasible, strong duality holds by Slater's condition. Therefore, if Y^* is an optimal solution, then there must exist some $F, G \in \mathbb{R}^{n\times n}$ and λ for which the KKT conditions hold:

$$\left.\begin{aligned} 0 \in \frac{\partial L(Y;\lambda,\mu,F,G)}{\partial Y}\Big|_{Y=Y^*},\end{aligned}\right\}\text{Stationary condition}$$

$$\left.\begin{aligned} F_{ij} \ge 0, G_{ij} \ge 0, \forall(i,j),\\ \lambda \ge 0,\end{aligned}\right\}\text{Dual feasibility}$$

$$\left.\begin{aligned} F_{ij} = 0, \forall(i,j) \in \mathcal{R},\\ G_{ij} = 0, \forall(i,j) \in \mathcal{R}^c.\end{aligned}\right\}\text{Complementary slackness}$$

Recall that $M \in \mathbb{R}^{n\times n}$ is a sub-gradient of $\|X\|_*$ at $X = Y^*$ if and only if $\mathcal{P}_T(M) = UU^\top$ and $\|M - \mathcal{P}_T(M)\| \le 1$. Set $H = F - G$; then the KKT conditions imply that there exist some numbers $\lambda \ge 0, \eta \in \mathbb{R}$ and matrices W, H obeying

$$A - \lambda\left(UU^\top + W\right) - \eta J + H = 0; \tag{63}$$

$$\mathcal{P}_T W = 0; \qquad \|W\| \le 1; \tag{64}$$

$$H_{ij} \le 0, \ \forall(i,j) \in \mathcal{R}; \qquad H_{ij} \ge 0, \ \forall(i,j) \in \mathcal{R}^c. \tag{65}$$

Now observe that $UU^\top WUU^\top = 0$ by (64). We left and right multiply (63) by $UU^\top$ to obtain

$$\breve{A} - \lambda UU^\top - \eta J + \breve{H} = 0,$$

where for any $X \in \mathbb{R}^{n\times n}$, $\breve{X} := UU^\top XUU^\top$ is the matrix obtained by averaging each $K \times K$ block of X. Consider the last display equation on the entries in $\mathcal{R}$ and $\mathcal{R}^c$ respectively. Applying the Bernstein inequality (Theorem 32) on each entry $\breve{A}_{ij}$, we have with probability at least $1 - 2n^{-11}$,

$$p - \frac{\lambda}{K} - \eta + \breve{H}_{ij} \geq -\frac{c_3\sqrt{p(1-p)\log n}}{K} - \frac{c_4 \log n}{2K^2} \overset{(a)}{\geq} -\frac{\epsilon_0}{8}, \quad \forall (i,j) \in \mathcal{R}, \tag{66}$$

$$q - \eta + \breve{H}_{ij} \leq \frac{c_3\sqrt{q(1-q)\log n}}{K} + \frac{c_4 \log n}{2K^2} \overset{(b)}{\leq} \frac{\epsilon_0}{8}, \quad \forall (i,j) \in \mathcal{R}^c \tag{67}$$

for some universal constants $c_3, c_4 > 0$, where (a) and (b) follow from the assumption $K \geq c_1 \log n$ with a sufficiently large universal constant c_1. In the rest of the proof, we assume (66) and (67) hold. Using (65), we get that

$$\begin{aligned} \eta &\geq q - \frac{c_3\sqrt{q(1-q)\log n}}{K} - \frac{c_4 \log n}{2K^2} \geq q - \frac{\epsilon_0}{8}, \\ \eta &\leq p + \frac{c_3\sqrt{p(1-p)\log n}}{K} + \frac{c_4 \log n}{2K^2} - \frac{\lambda}{K} \leq p + \frac{\epsilon_0}{8} - \frac{\lambda}{K}. \end{aligned} \tag{68}$$

It follows that

$$\begin{aligned} \lambda &\leq K(p-q) + c_3(\sqrt{p(1-p)\log n} + \sqrt{q(1-q)\log n}) + \frac{c_4 \log n}{K} \\ &\leq 4\max\left\{K(p-q), c_3\sqrt{p(1-p)\log n}, c_3\sqrt{q(1-q)\log n}, \frac{c_4}{c_1}\right\}. \end{aligned} \tag{69}$$

On the other hand, the conditions (64) and (63) imply

$$\begin{aligned} \lambda^2 &= \left\|\lambda(UU^\top + W)\right\|^2 \geq \frac{1}{n}\left\|\lambda(UU^\top + W)\right\|_F^2 \\ &= \frac{1}{n}\left\|A - \eta J + H\right\|_F^2 \geq \frac{1}{n}\left\|A_{\mathcal{R}^c} - \eta J_{\mathcal{R}^c} + H_{\mathcal{R}^c}\right\|_F^2 \geq \frac{1}{n}\sum_{(i,j)\in\mathcal{R}^c}(1-\eta)^2 A_{ij}, \end{aligned}$$

where $X_{\mathcal{R}^c}$ denotes that matrix obtained from X by setting the entries outside $\mathcal{R}^c$ to zero. Using (68), $\lambda \geq 0$ and the assumption $p \leq 1 - \epsilon_0$, we obtain $\eta \leq 1 - \frac{7}{8}\epsilon_0$, and therefore

$$\lambda^2 \geq \frac{49}{64n}\epsilon_0^2 \sum_{(i,j)\in\mathcal{R}^c} A_{ij}. \tag{70}$$

Note that $\sum_{(i,j)\in\mathcal{R}^c} A_{ij}$ equals twice the sum of $\binom{n}{2} - r\binom{K}{2}$ i.i.d. Bernoulli random variables with parameter q. By the Chernoff bound of Binomial distributions and the assumption that $qn \geq c_1 \log n$, we have with probability at least $1 - n^{-11}$, $\sum_{(i<j)\in\mathcal{R}^c} A_{ij} \geq c_5 qn^2$ for some universal constant c_5. It follows from (70) that $\lambda^2 \geq \frac{1}{2}\epsilon_0^2 c_5 qn$. Combining with (69) and the assumption that $qn \geq c_1 \log n$, we conclude that with probability at least $1 - 3n^{-11}$, $K^2(p-q)^2 \geq \frac{1}{32}\epsilon^2 c_5 qn$. Choosing c_2 in the theorem assumption to be sufficiently small such that $2c_2^2 < \frac{1}{32}\epsilon^2 c_5$, we obtain $K(p-q) > c_2\sqrt{2qn}$, which leads to a contradiction. This completes the proof of the theorem.

5.5 Proof of Theorem 10

Define event

$$\mathcal{E}_1 = \left\{\min_{i\in V_1} d_i > \frac{(p-q)K}{2} + qn\right\} \cap \left\{\max_{i\in V_2} d_i < \frac{(p-q)K}{2} + qn\right\}.$$

Define $\mathcal{E}_2$ to be the event that $S_{ij} > \frac{(p-q)^2K}{3} + 2Kpq + q^2n$ for all nodes i, j from the same true cluster and $S_{ij} < \frac{(p-q)^2K}{3} + 2Kpq + q^2n$ for all pairs of nodes (i,j) from two different true clusters. On event $\mathcal{E}_1$, all nodes in V_1 are correctly declared to be non-isolated, and all nodes in V_2 are correctly declared to be isolated. One event $\mathcal{E}_1 \cap \mathcal{E}_2$, the counting algorithm correctly identifies all the true clusters. Hence, to prove the theorem, it suffices to show $\mathbb{P}\{\mathcal{E}_1^c\} \leq 2n^{-1}$ and $\mathbb{P}\{\mathcal{E}_2^c\} \leq 2n^{-1}$.

Let $\mathrm{Bin}(n,\alpha)$ denote the binomial distribution with n trials and success probability α. For each non-isolated node $i \in V_1$, its degree d_i is the sum of two independent binomial random variables distributed respectively as $\mathrm{Bin}(K-1,p)$ and $\mathrm{Bin}(n-K,q)$. For each isolated node $i \in V_2$, its degree d_i is distributed as $\mathrm{Bin}(n-1,q)$. It follows that $\mathbb{E}[d_i] = (n-1)q + (K-1)(p-q)$ if $i \in V_1$ and $\mathbb{E}[d_i] = (n-1)q$ if $i \in V_2$. Define $\sigma_1^2 := Kp(1-q) + nq(1-q)$, then $\mathrm{Var}[d_i] \leq \sigma_1^2$ for all i. Set $t_1 := \frac{1}{2}(K-1)(p-q)$. Since $p - q \leq p(1-q)$, it follows that $t_1 \leq \sigma_1^2$. Hence, Bernstein inequality (Theorem 32) gives

$$\mathbb{P}\{|d_i - \mathbb{E}[d_i]| \geq t_1\} \leq 2\exp\left(-\frac{t_1^2}{2\sigma_1^2 + 2t_1/3}\right) \leq 2\exp\left(-\frac{(K-1)^2(p-q)^2}{12\sigma_1^2}\right) \leq 2n^{-2},$$

where the last inequality follows from the assumption (17). By the union bound, we get that $\mathbb{P}\{\mathcal{E}_1^c\} \leq 2n^{-1}$.

For two nodes i and j in the same true cluster, the number of their common neighbors S_{ij} is the sum of two independent binomial random variables distributed respectively as $\mathrm{Bin}(K-2,p^2)$ and $\mathrm{Bin}(n-K,q^2)$. Similarly, for two nodes i, j in two different true clusters, S_{ij} is the sum of two independent binomial variables $\mathrm{Bin}(2(K-1),pq)$ and $\mathrm{Bin}(n-2K,q^2)$. Hence, $\mathbb{E}[S_{ij}]$ equals $(K-2)p^2 + (n-K)q^2$ if i and j are in the same true cluster and $2(K-1)pq + (n-2K)q^2$ if they are in two different true clusters. The difference of the expectations in two cases equals $K(p-q)^2 - 2p(p-q)$. Let $\sigma_2^2 := 2Kp^2(1-q^2) + nq^2(1-q^2)$, then $\mathrm{Var}[S_{ij}] \leq \sigma_2^2$. Set $t_2 := K(p-q)^2/3$. Since $p - q \leq p(1-q)$, it follows that $t_2 \leq \sigma_2^2$. Applying the Bernstein inequality (Theorem 32), we obtain that

$$\mathbb{P}\{|S_{ij} - \mathbb{E}[S_{ij}]| \geq t_2\} \leq 2\exp\left(-\frac{t_2^2}{2\sigma_2^2 + 2t_2/3}\right) \leq 2\exp\left(-\frac{K^2(p-q)^4}{24\sigma_2^2}\right) \leq 2n^{-3},$$

where the last inequality follows from the assumption (18). By the union bound, we get that $\mathbb{P}\{\mathcal{E}_2^c\} \leq 2n^{-1}$.

5.6 Proof of Theorem 12

For simplicity we assume K and n_2 are even numbers; the case where K or n_2 is odd can be proved similarly. We partition the non-isolated nodes V_1 into two equal-sized subsets V_{1+} and V_{1-} such that half of the nodes in each cluster are in V_{1+}. Similarly, the isolated nodes V_2 are partitioned into two equal-sized subsets V_{2+} and V_{2-}. The idea is to use the following large-deviation *lower* bound to the quantities d_i and S_{ij}.

Theorem 30 (Theorem 7.3.1 in Matoušek and Vondrák (2008)) *Let $X_1, \ldots, X_N$ be independent random variables such that $0 \le X_i \le 1$ for all i. Suppose $X = \sum_{i=1}^N X_i$ and $\sigma^2 := \sum_{i=1}^N Var[X_i] \ge 200$. Then for all $0 \le \tau \le \sigma^2/100$ and some universal constant $c_3 > 0$, we have*

$$\mathbb{P}\left[X \ge \mathbb{E}[X] + \tau\right] \ge c_3 e^{-\tau^2/(3\sigma^2)}.$$

The main hurdle is that the entries of the graph adjacency matrix A are not completely independent due to the symmetry of A, so we need to take into account the dependence among d_i's and the dependence among S_{ij}'s when applying Theorem 30.

We first argue that under the assumption (19), the simple counting algorithm fails to identify the isolated nodes with probability at least $1/4$. For each node i in $V_{1+} \cup V_{2+}$, let d_{i+} and d_{i-} be the numbers of its neighbors in $V_{1+} \cup V_{2+}$ and $V_{1-} \cup V_{2-}$, respectively, so its total degree is $d_i = d_{i+} + d_{i-}$. Let $\mathrm{Bin}(N, \alpha)$ denote the binomial distribution with N trials and success probability α. We consider the following two cases.

Case 1: $(Kp + (n-K)q)\log n_1 \ge nq \log n_2$. Recall that $n_1 = rK$ and $n_2 = n - n_1$. In this case, it follows from (19) that

$$(K-1)^2(p-q)^2 \le 2c_2(Kp + nq)\log n_1. \tag{71}$$

For each node $i \in V_{1+}$, the quantity d_{i-} is the sum of two independent Binomial random variables distributed as $\mathrm{Bin}(K/2, p)$ and $\mathrm{Bin}((n-K)/2, q)$, respectively. Define

$$\begin{aligned} t &:= (K-1)(p-q) + 2, \\ \gamma_d^- &:= \mathbb{E}[d_{i-}] - t = \frac{1}{2}nq + \frac{1}{2}K(p-q) - t, \\ \sigma_d^2 &:= \mathrm{Var}[d_{i-}] = \frac{1}{2}Kp(1-p) + \frac{1}{2}(n-K)q(1-q). \end{aligned}$$

By assumption of the theorem, we have $K \le n/2$, $q \le p \le 1 - c_0$ and thus $\sigma_d^2 \ge \frac{c_0}{4}(Kp + nq)$. Since $Kp^2 + nq^2 \ge c_1 \log n$ by assumption, it follows that $\sigma_d^2 \ge \frac{1}{4}c_0 c_1 \log n \ge 400$ by choosing the constant c_1 in the assumption sufficiently large. Furthermore, it follows from (71) that by choosing c_1 sufficiently large and c_2 sufficiently small, we have

$$\sigma_d^4 \ge \frac{1}{4}c_0(Kp+nq)\sigma_d^2 \ge \frac{c_0}{8c_2}\frac{(K-1)^2(p-q)^2}{\log n_1} \times \frac{1}{4}c_0 c_1 \log n \ge 200^2(K-1)^2(p-q)^2.$$

Moreover, we have shown that $\sigma_d^2 \ge 400$. Hence, we get that $\sigma_d^2 \ge 100t$. We can now apply Theorem 30 with (71) to get that

$$\mathbb{P}\left[d_{i-} \le \gamma_d^-\right] \ge c_3 \exp\left(-\frac{t^2}{3\sigma_d^2}\right) \ge c_3 n_1^{-c_4}$$

for some universal constant $c_4 > 0$ that can be made arbitrarily small by choosing c_2 in the assumption sufficiently small; the last inequality holds due to $\sigma_d^2 \ge \frac{c_0}{4}(Kp+nq)$, $\sigma_d^2 \ge 400$, and (71). Let $i^* := \arg\min_{i \in V_{1+}} d_{i-}$. Since the random variables $\{d_{i-} : i \in V_{1+}\}$ are mutually independent, we have

$$\mathbb{P}\left[d_{i^*-} > \gamma_d^-\right] = \prod_{i \in V_{1+}} \mathbb{P}\left[d_{i-} > \gamma_d^-\right] \le (1 - c_3 n_1^{-c_4})^{n_1/2} \le \exp\left(-c_3 n_1^{1-c_4}/2\right) \le 1/4,$$

where the last equality follows from letting c_4 sufficiently small and n_1 sufficiently large. Furthermore, for each $i \in V_{1+}$, the quantity d_{i+} is the sum of two independent Binomial random variables distributed as $\mathrm{Bin}(K/2-1, p)$ and $\mathrm{Bin}((n-K)/2, q)$, respectively. Since the median of $\mathrm{Bin}(N, \alpha)$ is at most $N\alpha + 1$, we know that with probability at least $1/2$, we have $d_{i+} \le \gamma_d^+ := nq/2 + K(p-q)/2 - p + 2$. Now observe that the two sets of random variables $\{d_{i+}, i \in V_{1+}\}$ and $\{d_{i-}, i \in V_{1+}\}$ are independent of each other, so d_{i+} is independent of i^* for each $i \in V_{1+}$. It follows that

$$\mathbb{P}\left[d_{i^*+} \le \gamma_d^+\right] = \sum_{i \in V_{1+}} \mathbb{P}\left[d_{i+} \le \gamma_d^+ | i^* = i\right]\mathbb{P}\left[i^* = i\right] = \sum_{i \in V_{1+}} \mathbb{P}\left[d_{i+} \le \gamma_d^+\right]\mathbb{P}\left[i^* = i\right] \ge \frac{1}{2}.$$

Combining the two display equations above with the union bound, we obtain that with probability at least $1/4$,

$$d_{i^*} = d_{i^*-} + d_{i^*+} \le \gamma_d^- + \gamma_d^+ = (n-1)q.$$

On this event the node i^* will be incorrectly declared as an isolated node.

Case 2: $(Kp+nq)\log n_1 \le nq \log n_2$. In this case we have $(K-1)^2(p-q)^2 \le 2c_2 nq \log n_2$ in view of (19). Set $i^* := \arg\max_{i \in V_{2+}} d_{i-}$. Following the same argument as in Case 1 and using the assumption $nq \ge c_1 \log n$, we can show that $d_{i^*} \ge nq + K(p-q)$ with probability at least $1/4$, and on this event node i^* will incorrectly be declared as a non-isolated node.

We next show that under the assumption (20), the simple algorithm fails to recover the clusters with probability at least $1/4$. For two nodes i and j in V_1, let S_{ij+} be the number of their common neighbors in $V_{1+} \cup V_{2+}$ and S_{ij-} the number of their common neighbors in $V_{1-} \cup V_{2-}$, so the total number of their common neighbors is $S_{ij} = S_{ij+} + S_{ij-}$.

For each pair of nodes (i, j) in V_{1+} from the same cluster, S_{ij-} is the sum of two independent Binomial random variables distributed as $\mathrm{Bin}(K/2, p^2)$ and $\mathrm{Bin}((n-K)/2, q^2)$, respectively. Define

$$\begin{aligned} t' &:= K(p-q)^2 + 4, \\ \gamma_S^- &:= \mathbb{E}[S_{ij-}] - t' = nq^2/2 + K(p^2-q^2)/2 - t', \\ \sigma_S^2 &:= \mathrm{Var}[S_{ij-}] = \frac{1}{2}Kp^2(1-p^2) + \frac{1}{2}(n-K)q^2(1-q^2). \end{aligned}$$

By assumption, we have $K \le n/2$, $q \le p \le 1 - c_0$ and hence $\sigma_S^2 \ge \frac{c_0}{4}(Kp^2 + nq^2)$. Since by assumption $Kp^2 + nq^2 \ge c_1 \log n$, it follows that $\sigma_S^2 \ge 200$ by choosing c_1 sufficiently large. Moreover, recall that condition (20) reads:

$$K^2(p-q)^4 < c_2(Kp^2 + nq^2)\log n_1.$$

Hence, by choosing the constant c_2 sufficiently small and c_1 sufficiently large, we have that $\sigma_S^2 \ge 100t'$. Theorem 30 with (20) then implies that

$$\mathbb{P}\left[S_{ij-} \le \gamma_S^-\right] \ge c_3 \exp\left(-\frac{(t')^2}{3\sigma_S^2}\right) \ge c_3 n_1^{-c_5},$$

where the universal constant $c_5 > 0$ can be made sufficiently small by choosing c_2 sufficiently small in (18); the last inequality holds due to $\sigma_S^2 \ge 200$, $\sigma_S^2 \ge \frac{c_0}{4}(Kp^2 + nq^2)$, and (20).

Without loss of generality, we may re-label the nodes such that $V_{1+} = \{1, 2, \ldots, n_1/2\}$ and for each $k = 1, \ldots, n_1/4$, the nodes $2k-1$ and $2k$ are in the same cluster. Note that the random variables $\{S_{(2k-1)(2k)-} : k = 1, 2, \ldots, n_1/4\}$ are mutually independent. Let $i^* := -1 + 2 \arg\min_{k=1,2,\ldots,n_1/4} S_{(2k-1)(2k)-}$ and $j^* := i^* + 1$. It follows that

$$\mathbb{P}\left[S_{i^*j^*-} \geq \gamma_S^-\right] \leq (1 - c_3 n_1^{-c_5})^{n_1/4} \leq \exp(-c_3 n_1^{1-c_5}/4) \leq 1/4.$$

Furthermore, notice that S_{ij+} is the sum of two independent Binomial random variables $\mathrm{Bin}(K/2-2, p^2)$ and $\mathrm{Bin}((n-K)/2, q^2)$. We use a median argument introduced in the first part of the proof to conclude that for all i, j, $S_{ij+} \leq \gamma_S^+ := nq^2/2 + K(p^2-q^2)/2 - 2p^2 + 2$ with probability at least $1/2$. Since $\{S_{ij+}, i, j \in V_{1+}\}$ only depends on the edges between V_{1+} and $V_{1+} \cup V_{2+}$, and (i^*, j^*) only depends on the edges between V_{1+} and $V_{1-} \cup V_{2-}$, it follows that $\{S_{ij+}, i, j \in V_{1+}\}$ and (i^*, j^*) are independent of each other. Therefore, $S_{i^*j^*+} \leq \gamma_S^+$ with probability at least $1/2$. Applying the union bound, we get that with probability at least $1/4$,

$$S_{i^*j^*} = S_{i^*j^*-} + S_{i^*j^*+} \leq \gamma_S^- + \gamma_S^+ = 2(K-1)pq + (n-2K)q^2.$$

On this event the nodes i^*, j^* will be incorrectly assigned to two different clusters.

6. Proofs for Submatrix Localization

In this section we prove the theoretical results in Section 3 for submatrix localization. Recall that $n := \max\{n_L, n_R\}$.

6.1 Proof of Theorem 15

We prove the theorem using Fano's inequality. Our arguments extend those used in Kolar et al. (2011). Recall that $\mathcal{Y}$ is the set of all valid bi-clustering matrices. Let $M = n_R - K_R$ and $\bar{\mathcal{Y}} = \{Y_0, Y_1, \ldots, Y_M\}$ be a subset of $\mathcal{Y}$ with cardinality $M+1$, which is specified later. Let $\mathbb{P}_{(Y^*,A)}$ denote the joint distribution of (Y^*, A) when Y^* is sampled from $\bar{\mathcal{Y}}$ uniformly at random and then A is generated according to the submatrix localization model with the true cluster matrix being Y^*. The minimax error probability can be bounded using the average error probability and Fano's inequality:

$$\inf_{\widehat{Y}} \sup_{Y^* \in \mathcal{Y}} \mathbb{P}\left[\widehat{Y} \neq Y^*\right] \geq \inf_{\widehat{Y}} \mathbb{P}_{(Y^*,A)}\left[\widehat{Y} \neq Y^*\right] \geq 1 - \frac{I(Y^*; A) + 1}{\log|\bar{\mathcal{Y}}|}, \tag{72}$$

where the mutual information is defined under the distribution $\mathbb{P}_{(Y^*,A)}$.

We construct $\bar{\mathcal{Y}}$ as follows. Let Y_0 be the bi-clustering matrix such that the left clusters $\{C_k\}_{k=1}^r$ are $C_k = \{(k-1)K_L + 1, \ldots, kK_L\}$ and the right clusters $\{D_l\}_{l=1}^r$ are $D_l = \{(l-1)K_R + 1, \ldots, lK_R\}$. Informally, each Y_i with $i \geq 1$ is obtained from Y_0 by keeping the left clusters and swapping two right nodes in two different right clusters. More specifically, for each $i \in [M]$: (1) Y_i has the same left clusters as Y_0; (2) if the right node $K_R + i \in D_l$ for Y_0, then Y_i has the same right clusters as Y_0 except that the first right cluster is $\{1, 2, \ldots, K_R - 1, K_R + i\}$ and the l-th right cluster is $D_l \setminus \{K_R + i\} \cup \{K_R\}$; (3) if the right node $K_R + i$ does not belong to any D_l for Y_0, then Y_i has the same right clusters as Y_0 except that the first right cluster is $\{1, 2, \ldots, K_R - 1, K_R + i\}$ instead.

Let $\mathbb{P}_i$ be the distribution of A conditioned on $Y^* = Y_i$, and $D(\mathbb{P}_i \| \mathbb{P}_{i'})$ the KL divergence between $\mathbb{P}_i$ and $\mathbb{P}_{i'}$. Since each $\mathbb{P}_i$ is a product of $n_L \times n_R$ Gaussian distributions, we have

$$\begin{aligned} I(Y^*; A) &\leq \frac{1}{(M+1)^2} \sum_{i,i'=0}^{M} D(\mathbb{P}_i \| \mathbb{P}_{i'}) \\ &\leq 3K_L \left[D\left(\mathcal{N}(\mu_1, \sigma^2) \| \mathcal{N}(\mu_2, \sigma^2)\right) + D\left(\mathcal{N}(\mu_2, \sigma^2) \| \mathcal{N}(\mu_1, \sigma^2)\right)\right] = 3K_L \frac{(\mu_1 - \mu_2)^2}{\sigma^2}, \end{aligned}$$

where we use the convexity of KL divergence in the first inequality, the definition of Y_i in the second inequality, and the expression for the KL divergence between two Gaussian distributions in the equality. If $(\mu_1 - \mu_2)^2 \leq \frac{\sigma^2 \log(n_R - K_R)}{12K_L}$, then $I(Y; A) \leq \frac{1}{2}\log(n_R - K_R) = \frac{1}{2}\log|\bar{\mathcal{Y}}|$. Since $\log(n_R - K_R) \geq \log(n_R/2) \geq 4$ if $n_R \geq 128$, it follows from (72) that the minimax error probability is at least $1/2$.

Alternatively, we can construct $Y_i, i \geq 1$ from Y_0 by keeping the right clusters and swapping two left nodes in two different left clusters. A similar argument shows that if $(\mu_1 - \mu_2)^2 \leq \frac{\sigma^2 \log(n_L - K_L)}{12K_R}$, the minimax error probability is at least $1/2$.

6.2 Proof of Theorem 16

Recall that $\langle X, Y\rangle := \mathrm{Tr}(X^\top Y)$ is the inner product between two matrices. For any feasible solution $Y \in \mathcal{Y}$ of (22), we define $\Delta(Y) := \langle A, Y^* - Y\rangle$ and $d(Y) := \langle Y^*, Y^* - Y\rangle$. To prove the theorem, it suffices to show that $\Delta(Y) > 0$ for all feasible Y with $Y \neq Y^*$. We may write

$$\Delta(Y) = \langle \mathbb{E}[A], Y^* - Y\rangle + \langle A - \mathbb{E}[A], Y^* - Y\rangle = \mu d(Y) + \langle A - \mathbb{E}[A], Y^* - Y\rangle \tag{73}$$

since $\mathbb{E}[A] = \mu Y^*$. The second term above can be written as

$$\langle A - \mathbb{E}[A], Y^* - Y\rangle = \underbrace{\sum_{(i,j): Y^*_{ij}=1, Y_{ij}=0} (A_{ij} - \mu)}_{T_1(Y)} + \underbrace{\sum_{(i,j): Y^*_{ij}=0, Y_{ij}=1} (-A_{ij})}_{T_2(Y)}.$$

Here each of $T_1(Y)$ and $T_2(Y)$ is the sum of $d(Y)$ i.i.d. centered sub-Gaussian random variables with parameter 1. By the sub-Gaussian concentration inequality given in Proposition 5.10 in Vershynin (2012), we obtained that for each $i = 1, 2$ and each fixed $Y \in \mathcal{Y}$,

$$\mathbb{P}\left\{T_i(Y) \leq -\frac{\mu}{2} d(Y)\right\} \leq e \exp\left(-C\mu^2 d(Y)\right),$$

where $C > 0$ is an absolute constant. Combining with the union bound and (73), we get

$$\mathbb{P}\left\{\Delta(Y) \leq 0\right\} \leq 2e \exp\left(-C\mu^2 d(Y)\right), \quad \text{for each } Y \in \mathcal{Y}. \tag{74}$$

Define the equivalence class $[Y] = \{Y' \in \mathcal{Y} : Y'_{ij} = Y_{ij}, \forall (i,j) \in \mathrm{support}(Y^*)$. The following combinatorial lemma (proved in Appendix A) upper-bounds the number of Y's and $[Y]$'s with a fixed value of $d(Y)$. Note that $K_L \wedge K_R \leq d(Y) \leq rK_LK_R$ for any feasible $Y \neq Y^*$.

Lemma 31 *For each integer $t \in [K_L \wedge K_R, rK_LK_R]$, we have*

$$\left|\{Y \in \mathcal{Y} : d(Y) = t\}\right| \le \left(\frac{16t^2}{K_LK_R}\right)^2 n_L^{16t/K_R} n_R^{16t/K_L}, \tag{75}$$

$$\left|\{[Y] : d(Y) = t\}\right| \le \frac{16t^2}{K_LK_R}(rK_L)^{8t/K_R}(rK_R)^{8t/K_L}. \tag{76}$$

Combining Lemma 31 with (74) and the union bound, we obtain

$$\begin{aligned}
&\mathbb{P}\left\{\exists Y \in \mathcal{Y} : Y \neq Y^*, \Delta(Y) \le 0\right\} \\
\le &\sum_{t=K_L\wedge K_R}^{rK_LK_R} \mathbb{P}\left\{\exists Y \in \mathcal{Y} : d(Y) = t, \Delta(Y) \le 0\right\} \\
\le &2e \sum_{t=K_L\wedge K_R}^{rK_LK_R} \left|\{Y \in \mathcal{Y} : d(Y) = t\}\right| \cdot \mathbb{P}\left\{d(Y) = t, \Delta(Y) \le 0\right\} \\
\le &2e \sum_{t=K_L\wedge K_R}^{rK_LK_R} \left(\frac{16t^2}{K_LK_R}\right)^2 n_L^{16t/K_R} n_R^{16t/K_L} \cdot \exp\left(-C\mu^2 t\right) \\
\overset{(a)}{\le} &2e \sum_{t=K_L\wedge K_R}^{rK_LK_R} 256 n^4 n^{-7t/(K_L\wedge K_R)} \le 512 e K_LK_R r n^{-3} \le 512 e n^{-1},
\end{aligned}$$

where (a) follows from the assumption that $\mu^2(K_L \wedge K_R) \ge C'\sigma^2 \log n$ for a sufficiently large constant C'. This means Y^* is the unique optimal solution to (22) with high probability.

6.3 Proof of Theorem 17

We have proved the theorem in Section 5.3.

6.4 Proof of Theorem 18

Note that the theorem assumes $n = n_L = n_R$ and $K = K_L = K_R$. Recall that J is the $n \times n$ all-one matrix, $\mathcal{R} := \text{support}(Y^*)$ and $\mathcal{A} := \text{support}(A)$, and $U, V \in \mathbb{R}^{n\times r}$ are the cluster characteristic matrices defined in Section 5.3, and $Y^* = KUV^\top$ is the SVD of Y^*. By relabeling the left nodes and right nodes, we can always make $U = V$ and thus we assume $U = V$ in the following proof.

Suppose Y^* is an optimal solution to the program. Then by the same argument used in the proof of Theorem 8, there must exist some $\lambda \ge 0$, η, W and H obeying the KKT conditions (63)–(65). Since $UU^\top WUU^\top = 0$ by (64), we can left and right multiply (63) by $UU^\top$ to obtain

$$\breve{A} - \lambda UU^\top - \eta J + \bar{H} = 0,$$

where for any matrix $X \in \mathbb{R}^{n\times n}$, we define the block-averaged matrix $\breve{X} := UU^\top XUU^\top$. Consider the last display equation on each entries in $\mathcal{R}$ and $\mathcal{R}^c$. By the Gaussian probability tail bound, there exists a universal constant $c_3 > 0$ such that with probability at least $1 - 2n^{-11}$,

$$\mu - \frac{\lambda}{K} - \eta + \bar{H}_{ij} \ge -\frac{c_3\sqrt{\log n}}{K}, \forall (i,j) \in \mathcal{R}, \tag{77}$$

$$-\eta + \bar{H}_{ij} \le \frac{c_3\sqrt{\log n}}{K}, \forall (i,j) \in \mathcal{R}^c. \tag{78}$$

Combining the last two display equations with (65), we get that

$$-\frac{c_3\sqrt{\log n}}{K} \le \eta \le \mu + \frac{c_3\sqrt{\log n}}{K} - \frac{\lambda}{K}.$$

It follows that

$$\lambda \le K\mu + 2c_3\sqrt{\log n} \le 4\max\left\{K\mu, c_3\sqrt{\log n}\right\}. \tag{79}$$

Furthermore, due to (77), (78) and $\lambda \ge 0$, we have

$$\bar{H}_{ij} \le \mu + \frac{2c_3\sqrt{\log n}}{K} \le \mu + \frac{1}{40}, \forall (i,j) \in \mathcal{R}^c, \tag{80}$$

where the last inequality holds when $K \ge c_1 \log n$.

On the other hand, the conditions (64) and (63) imply that

$$\begin{aligned}
\lambda^2 &= \left\|\lambda(UU^\top + W)\right\|^2 \ge \frac{1}{n}\left\|\lambda(UU^\top + W)\right\|_F^2 = \frac{1}{n}\left\|A - \eta J + H\right\|_F^2 \\
&= \frac{1}{n}\left(\left\|A_{\mathcal{R}} - \eta J_{\mathcal{R}} + H_{\mathcal{R}}\right\|_F^2 + \left\|A_{\mathcal{R}^c} - \eta J_{\mathcal{R}^c} + H_{\mathcal{R}^c}\right\|_F^2\right).
\end{aligned} \tag{81}$$

We now lower bound the RHS of (81). For each (i,j), define the Bernoulli random variables $\bar{b}_{ij} = \mathbf{1}(A_{ij} - \mathbb{E}A_{ij} \ge 1)$ and $\underline{b}_{ij} = \mathbf{1}(A_{ij} - \mathbb{E}A_{ij} \le -1)$, where $\mathbf{1}(\cdot)$ is the indicator function. By tail bounds of the standard Gaussian distribution, we have

$$\mathbb{P}\left(\bar{b}_{ij} = 1\right) = \mathbb{P}\left(\underline{b}_{ij} = 1\right) \ge \rho := \frac{1}{2\sqrt{2\pi}} e^{-1/2}.$$

Note that $\rho \ge \frac{1}{12}$. By Hoeffding's inequality, we know that with probability at least $1 - 2n^{-11}$,

$$\sum_{i,j\in\mathcal{R}^c} \bar{b}_{ij} \ge \frac{1}{2}\rho|\mathcal{R}^c| \quad \text{and} \quad \sum_{i,j\in\mathcal{R}^c} \underline{b}_{ij} \ge \frac{1}{2}\rho|\mathcal{R}^c|. \tag{82}$$

We consider two cases below.

- Case 1: $\eta \ge 40\mu$. By (80) and the Markov inequality, there is at most a fraction of $\frac{1}{30}$ of pairs (i,j) in $\mathcal{R}^c$ that satisfy $H_{ij} > 30\left(\mu + \frac{1}{40}\right)$. Let $\mathcal{D}$ denote the set of pairs (i,j) satisfying both $H_{ij} \le 30\left(\mu + \frac{1}{40}\right)$ and $A_{ij} \le -1$. In view of the second inequality in (82), we have $|\mathcal{D}|/|\mathcal{R}^c| \ge \rho/2 - 1/30 \ge 1/150$. Therefore, for $(i,j) \in \mathcal{D}$, we get that $-\eta + H_{\mathcal{R}^c} \le -10\mu + \frac{3}{4}$, and thus

$$\begin{aligned}
\left\|A_{\mathcal{R}^c} - \mu J_{\mathcal{R}^c} + H_{R^c}\right\|_F^2 &\ge \sum_{(i,j)\in\mathcal{D}} \left\|A_{\mathcal{R}^c} - \eta J_{\mathcal{R}^c} + H_{\mathcal{R}^c}\right\|_F^2 \\
&\ge \sum_{(i,j)\in\mathcal{D}} \left(-1 - 10\mu + \frac{3}{4}\right)^2 \ge \frac{1}{150}|\mathcal{R}^c| \cdot \frac{1}{16}.
\end{aligned}$$

- Case 2: $\eta \le 40\mu$. Since $\mu \le \frac{1}{100}$ by assumption, we have $\eta \le 1/2$. Therefore,

$$\|A_{\mathcal{R}^c} - \eta J_{\mathcal{R}^c} + H_{R^c}\|_F^2 \ge \sum_{(i,j)\in\mathcal{R}^c, \bar{b}_{ij}=1} \|A_{\mathcal{R}^c} - \eta J_{\mathcal{R}^c} + H_{\mathcal{R}^c}\|_F^2$$
$$\ge \sum_{(i,j)\in\mathcal{R}^c, \bar{b}_{ij}=1} (1-\eta)^2 \ge \frac{1}{2}\rho|\mathcal{R}^c| \cdot \frac{1}{4}.$$

Combining the two cases and substituting into (81), we obtain $\lambda^2 \ge c_4|\mathcal{R}^c|/n$ for some constant $c_4 > 0$. Since $|\mathcal{R}^c| = n^2 - rK^2 \ge n(n-K) \ge n^2/2$, we have $\lambda^2 \ge c_4 n/2$. It follows from (79) that

$$\max\left\{K\mu, c_3\sqrt{\log n}\right\} \ge \frac{\sqrt{c_4}}{4\sqrt{2}}\sqrt{n}.$$

Since $n \ge K \ge c_1 \log n$ with a sufficiently large constant c_1, we must have $K\mu \ge \frac{\sqrt{c_4}}{4\sqrt{2}}\sqrt{n}$. This violates the condition (28) in the theorem statement if we choose the universal constant c_2 sufficiently small. We conclude from this contradiction that Y^* is not an optimal solution of the convex program.

6.5 Proof of Theorem 20

We prove that with high probability, each of the three steps of the simple thresholding algorithm succeeds and thus Y^* is exactly recovered.

We first show that the simple thresholding algorithm correctly identifies all isolated nodes. Recall that $d_i = \sum_{j=1}^{n_R} A_{ij}$ is the row sum corresponding to the left node i. Observe that $d_i - \mathbb{E}[d_i]$ is the sum of n_R independent centered sub-Gaussian random variables with parameter 1. Moreover, $\mathbb{E}[d_i] = K_R\mu$ if node i is non-isolated; otherwise, $\mathbb{E}[d_i] = 0$. By Proposition 5.10 in Vershynin (2012), there exists a universal constant $c_3 > 0$ such that

$$\mathbb{P}\{|d_i - \mathbb{E}[d_i]| \ge K_R\mu/2\} \le e\exp\left(-\frac{c_3 K_R^2\mu^2}{n_R}\right) \le en_L^{-2},$$

where the last inequality follows from the assumption (29) by choosing the universal constant c_1 sufficiently large. By the union bound, we have with probability at least $1 - en_L^{-1}$, $d_i > \mu K_R/2$ for all non-isolated left nodes i and $d_i < \mu K_R/2$ for all isolated left nodes i. On this event, all isolated left nodes are correctly identified in Step 1 of the algorithm. A similar argument shows that all isolated right nodes are correctly identified with probability at least $1 - en_R^{-1}$. We use E_1 to denote the event that all the left and right isolated nodes are identified by the algorithm.

We first show that the simple thresholding algorithm correctly identifies all the left and right clusters. Recall that $S_{ii'} = \sum_{j=1}^{n_R} A_{ij}A_{i'j}$ is the inner product of two rows of A corresponding to the left nodes i and i'. If the two left nodes i, i' are in the same cluster, then $\mathbb{E}[S_{ii'}] = K_R\mu^2$; otherwise $\mathbb{E}[S_{ii'}] = 0$. Moreover, $A_{ij}A_{i'j}$ is the product of two independent sub-Gaussian random variables. We use $\|X\|_{\psi_2}$ and $\|X\|_{\psi_1}$ to denote the sub-Gaussian norm and sub-exponential norm[4]

4. The sub-exponential norm and sub-Gaussian norm of a random variable X are defined as $\|X\|_{\psi_i} = \sup_{p\ge 1} p^{-1/i}(\mathbb{E}|X|^p)^{1/p}$ for $i = 1, 2$, respectively (Vershynin, 2012).

It follows that

$$\left\|A_{ij}A_{i'j} - \mathbb{E}[A_{ij}]\mathbb{E}[A_{i'j}]\right\|_{\psi_1}$$
$$\overset{(a)}{\le} \left\|(A_{ij} - \mathbb{E}[A_{ij}])(A_{i'j} - \mathbb{E}[A_{i'j}])\right\|_{\psi_1} + \left\|(A_{ij} - \mathbb{E}[A_{ij}])\mathbb{E}[A_{i'j}]\right\|_{\psi_1} + \left\|(A_{ij} - \mathbb{E}[A_{ij}])\mathbb{E}[A_{i'j}]\right\|_{\psi_1}$$
$$\overset{(b)}{\le} 2\left\|A_{ij} - \mathbb{E}[A_{ij}]\right\|_{\psi_2}\left\|A_{i'j} - \mathbb{E}[A_{i'j}]\right\|_{\psi_2} + 2\mu\left\|A_{ij} - \mathbb{E}[A_{ij}]\right\|_{\psi_2} + 2\mu\left\|A_{i'j} - \mathbb{E}[A_{i'j}]\right\|_{\psi_2}$$
$$\overset{(c)}{\le} c'(4\mu + 2),$$

where (a) and (b) follow from $\|X+Y\|_{\psi_1} \le \|X\|_{\psi_1} + \|Y\|_{\psi_1}$ and $\|XY\|_{\psi_1} \le 2\|X\|_{\psi_2}\|Y\|_{\psi_2}$ for any random variables X, Y, and (c) holds for some universal constant $c' > 0$ because for each (i,j) $A_{ij} - \mathbb{E}[A_{ij}]$ is sub-Gaussian with parameter 1. By the Bernstein inequality for sub-exponential random variables given in Proposition 5.16 in Vershynin (2012), there exists some universal constant $c_4 > 0$ such that

$$\mathbb{P}\left\{|S_{ii'} - \mathbb{E}[S_{ii'}]| \ge K_R\mu^2/2\right\} \le e\exp\left[-c_4\min\left(\frac{K_R^2\mu^4}{n_R c'^2(4\mu+2)^2}, \frac{K_R\mu^2}{c'(4\mu+2)}\right)\right] \le e(rK_L)^{-3},$$

where the last inequality follows from the conditions (30) and (29). By the union bound, we get that with probability at least $1 - e(rK_L)^{-1}$, $S_{ii'} > \frac{\mu^2 K_R}{2}$ for all left nodes i, i' from the same left cluster and $S_{ii'} < \frac{\mu^2 K_R}{2}$ for all left nodes i, i' from two different left clusters. On the intersection of this event and the event E_1 defined above, Step 2 of the algorithm identifies the true left clusters. A similar argument shows that the algorithm also identifies the true right clusters with probability at least $1 - e(rK_R)^{-1}$. We use E_2 to denote that event that all the true left and right clusters are identified by the algorithm.

Finally, we show that the simple thresholding algorithm correctly associates all the left and right clusters. Let $B^*_{kl} := \sum_{i\in C_k^*, j\in D_l^*} A_{ij}$ be the block sum of A corresponding to the true let and right clusters C_k^* and D_l^*. By model assumptions, $B^*_{kl} - \mathbb{E}[B^*_{kl}]$ is a sum of $K_L K_R$ independent centered sub-Gaussian random variables with parameter 1. Moreover, $\mathbb{E}[B^*_{kl}] = \mu K_L K_R$ if $k = l$, and $\mathbb{E}[B^*_{kl}] = 0$ otherwise. By the standard sub-Gaussian concentration inequality given in Proposition 5.10 in Vershynin (2012), there exists some universal constant $c_5 > 0$ such that

$$\mathbb{P}\{|B^*_{kl} - \mathbb{E}[B^*_{kl}]| \ge \mu K_L K_R/2\} \le e\exp\left(-\frac{c_5\mu^2 K_L^2 K_R^2}{K_L K_R}\right) \le en^{-3},$$

where the last inequality holds because $\mu^2 K_L K_R \ge c_1 \log n$ in view of (29). By the union bound, we get that with probability at least $1 - en^{-1}$, $B^*_{kl} < \mu K_L K_R/2$ for all $k = l$ and $B^*_{kl} > \mu K_L K_R/2$ for all $k \ne l$. On the intersection of this event and the event E_2defined above, the quantities $\{B_{kl}\}$ used in Step 3 of the algorithm satisfy $B_{kl} = B^*_{kl}$, and the algorithm correctly associates the left and right clusters.

6.6 Proof of Theorem 21

We focus on identifying left isolated nodes and left clusters. The proof for the right nodes is identical. The main idea is to show that some of the d_i and $S_{ii'}$'s will have large deviation from their expectations.

Assume $rK_L \geq n_L/2$ first. We will show that if $K_R^2\mu^2 \leq c_1 n_R \log n_L$ for a sufficiently small universal constant c_1, then with high probability there exists a non-isolated left node i^* that is incorrectly declared as isolated. Recall that $d_i = \sum_{j=1}^{n_R} A_{ij}$ is the row sum corresponding to the left node i. If the left node i is non-isolated, then d_i is Gaussian with mean $K_R\mu$ and variance n_R. For a standard Gaussian random variable Z, its tail probability is lower bounded as $Q(t) := \mathbb{P}[Z \geq t] \geq \frac{1}{\sqrt{2\pi}}\frac{t}{t^2+1}\exp(-t^2/2)$. It follows that for a non-isolated left node i, there exist two positive universal constants c_3, c_4 such that

$$\mathbb{P}\left[d_i - \mathbb{E}[d_i] \leq K_R\mu/2\right] \geq c_3 \exp\left(-\frac{c_4 K_R^2\mu^2}{n_R}\right) \geq c_3 n_L^{-c_1 c_4}.$$

Let i^* be the non-isolated left node with the minimum d_i. Since $\{d_i\}_{i=1}^{n_L}$ are mutually independent, we have

$$\mathbb{P}\left[d_{i^*} > \frac{K_R\mu}{2}\right] \leq \left(1 - c_3 n_L^{-c_1 c_4}\right)^{rK_L} \leq \exp\left(-\frac{1}{2}c_3 n_L^{1-c_1 c_4}\right),$$

where the last inequality holds because $rK_L \geq n_L/2$. By choosing c_1 sufficiently small, we conclude that with high probability the non-isolated left node i^* will be incorrectly declared as an isolated node.

If $rK_L \leq n_L/2$, then we can similarly show that if $K_R^2\mu^2 \leq c_1 n_R \log n_L$ for a sufficiently small c_1, then with high probability there exists an isolated left node i^{**} incorrectly declared as non-isolated.

We next show that if

$$K_R^2\mu^4 \leq c_2 n_R \log(rK_L) \tag{83}$$

for a sufficiently small constant c_2, then there exist two left nodes i_1, i_2 in two different clusters that will be incorrectly assigned to the same cluster.

By the assumption that $n_R = \Omega(rK_L)$, the inequality (83) implies $K_R\mu^3 \leq c_2^{3/4} n_R$. Recall that $S_{ii'} = \sum_{j=1}^{n_R} A_{ij}A_{i'j}$. For two left nodes i, i' from two different clusters, we have

$$\mathbb{E}[S_{ii'}] = 0, \quad \mathrm{Var}[S_{ii'}] = 2K_R\mu^2 + n_R,$$
$$\sum_{j=1}^{n_R}\mathbb{E}[|A_{ij}A_{i'j}|^3] = \sum_{j=1}^{n_R}\mathbb{E}[|A_{ij}|^3]\mathbb{E}[|A_{i'j}|^3] \leq c_5(K_R\mu^3 + n_R) \leq c_5(c_2^{3/4}+1)n_R,$$

where c_5 is some universal positive constant. By the Berry-Esseen theorem, there exists a positive universal constant c_6 such that

$$\begin{aligned}
\mathbb{P}\left[S_{ii'} \geq \frac{\mu^2 K_R}{2}\right] &\geq Q\left(\frac{\mu^2 K_R}{2\sqrt{2K_R\mu^2 + n_R}}\right) - \frac{c_6(K_R\mu^3 + n_R)}{(2K_R\mu^2 + n_R)^{3/2}} \\
&\overset{(a)}{\geq} Q\left(\frac{\mu^2 K_R}{\sqrt{n_R}}\right) - \frac{c_6 c_5(c_2^{3/4}+1)}{\sqrt{n_R}} \\
&\overset{(b)}{\geq} Q\left(\sqrt{c_2\log(rK_L)}\right) - \frac{c_6 c_5(c_2^{3/4}+1)}{\sqrt{rK_L}} \\
&\overset{(c)}{\geq} c_3(rK_L)^{-c_4 c_2} - c_6 c_5(c_2^{3/4}+1)(rK_L)^{-1/2} \overset{(d)}{\geq} c_7(rK_L)^{-c_4 c_2},
\end{aligned}$$

where (a) holds because $Q(t)$ is non-increasing in t, (b) holds in view of (83) and the assumption that $n_R \geq rK_L$, (c) follows from $Q(t) \geq c_3\exp(-c_4 t^2)$, and (d) holds for some universal constant $c_7 > 0$ by choosing c_2 sufficiently small.

Set $(i_1, i_2) := \arg\max_{(i,i')\in W} S_{ii'}$, where W is a maximal set of node pairs (i, i') satisfying 1) i and i' are from two different clusters, and 2) for any $(i, i'), (j, j') \in W$, the nodes i, i', j, j' are all distinct. Then $|W| \geq rK_L/4$ and $\{S_{ii'} : (i, i') \in W\}$ are mutually independent. It follows that

$$\mathbb{P}\left[S_{i_1 i_2} < \frac{\mu^2 K_R}{2}\right] \leq \left(1 - c_7(rK_L)^{-c_4 c_2}\right)^{rK_L/4} \leq \exp\left(-\frac{1}{4}c_7(rK_L)^{1-c_4 c_2}\right).$$

Therefore, with probability at least $1 - \exp\left(-\frac{1}{4}c_7(rK_L)^{1-c_4 c_2}\right)$, we have $S_{i_1 i_2} \geq \frac{\mu^2 K_R}{2}$. On this event, (i_1, i_2) will be incorrectly assigned to the same cluster.

6.7 Proof of Theorem 22

We prove the first part of the theorem. Since A_{ij} are sub-Gaussian, there exists a universal constant $c_1 > 0$ such that $\mathbb{P}\left[|A_{ij} - \mathbb{E}A_{ij}| \leq \frac{1}{2}\sqrt{c_1\log n}\right] \geq 1 - n^{-12}$ for each (i, j). Recall that $\mathcal{R} := \mathrm{support}(Y^*)$. By the union bound over all (i, j), we obtain that with probability at least $1 - n^{-3}$,

$$\min_{(i,j)\in\mathcal{R}} A_{ij} > \mu - \frac{1}{2}\sqrt{c_1\log n} \overset{(a)}{>} \frac{1}{2}\mu \qquad \text{and} \qquad \max_{(i,j)\in\mathcal{R}^c} A_{ij} < \frac{1}{2}\sqrt{c_1\log n} \overset{(b)}{<} \frac{1}{2}\mu,$$

where (a) and (b) holds in view of the assumption (33). Therefore, the algorithm sets $\widehat{Y}_{ij} = 1$ for $(i, j) \in \mathcal{R}$ and $\widehat{Y}_{ij} = 0$ for $(i, j) \in \mathcal{R}^c$, which implies $\widehat{Y} = Y^*$.

For the second part of the theorem, note that $\{A_{ij}\}$ are Gaussian variables and thus

$$\mathbb{P}\left[A_{ij} \geq \mathbb{E}A_{ij} + \sqrt{2\log n}\right] = Q\left(\sqrt{2\log n}\right) \geq \frac{\sqrt{2\log n}}{\sqrt{2\pi}(2\log n + 1)n},$$
$$\mathbb{P}\left[A_{ij} \leq \mathbb{E}A_{ij} - \sqrt{2\log n}\right] = Q\left(\sqrt{2\log n}\right) \geq \frac{\sqrt{2\log n}}{\sqrt{2\pi}(2\log n + 1)n},$$

where the last inequality holds due to $Q(t) \geq \frac{1}{\sqrt{2\pi}}\frac{t}{t^2+1}\exp(-t^2/2)$. By independence of the entries of A, we obtain

$$\mathbb{P}\left[\max_{i,j\in\mathcal{R}^c} A_{ij} < \sqrt{2\log n}\right] \leq \left(1 - \frac{\sqrt{2\log n}}{\sqrt{2\pi}(2\log n+1)n}\right)^{|\mathcal{R}^c|} \leq \exp\left(-\frac{\sqrt{2\log n}|\mathcal{R}^c|}{\sqrt{2\pi}(2\log n+1)n}\right),$$
$$\mathbb{P}\left[\min_{i,j\in\mathcal{R}} A_{ij} > \mu - \sqrt{2\log n}\right] \leq \left(1 - \frac{\sqrt{2\log n}}{\sqrt{2\pi}(2\log n+1)n}\right)^{|\mathcal{R}|} \leq \exp\left(-\frac{\sqrt{2\log n}|\mathcal{R}|}{\sqrt{2\pi}(2\log n+1)n}\right),$$

Since $|\mathcal{R}| + |\mathcal{R}^c| = n^2$, we must have

$$\min\left\{\mathbb{P}\left[\max_{i,j\in\mathcal{R}^c} A_{ij} < \sqrt{2\log n}\right], \mathbb{P}\left[\min_{i,j\in\mathcal{R}} A_{ij} > \mu - \sqrt{2\log n}\right]\right\} \leq e^{-\Omega(n/\sqrt{\log n})}.$$

This inequality, together with the assumption (34), implies that either with probability at least $1 - e^{-\Omega(n/\sqrt{\log n})}$, at least one of the following must occur: $\max_{(i,j)\in\mathcal{R}^c} A_{ij} \geq \sqrt{2\log n} \geq \frac{3}{5}\mu$ and

$\min_{(i,j)\in R} A_{ij} \le \mu - \sqrt{2\log n} \le \frac{2}{5}\mu$. On this event, the output of the element-wise thresholding algorithm satisfies $\widehat{Y} \neq Y^*$.

Appendix A. Proof of Lemmas 26 and 31

Notice that Lemma 26 is a special case of Lemma 31 with $n_L = n_R$, $K_L = K_R$ and the left clusters identical to the right clusters. Hence we only need to prove Lemma 31.

Recall that $C_1^*, \ldots, C_r^*$ ($D_1^*, \ldots, D_r^*$, resp.) denote the true left (right, resp.) clusters associated with Y^*. The nodes in $V_L \setminus (\cup_{k=1}^r C_k^*)$ do not belong to any left clusters and are called isolated left nodes. Isolated right nodes are similarly defined.

Fix a $Y \in \mathcal{Y}$ with $d(Y) := \langle Y^*, Y - Y^* \rangle = t$. Based on Y, we construct a new ordered partition $(C_1, \ldots, C_{r+1})$ of V_L and a new ordered partition $(D_1, \ldots, D_{r+1})$ of V_R as follows.

1. Let $C_{r+1} := \{i : Y_{ij} = 0, \forall j\}$ and $D_{r+1} := \{j : Y_{ij} = 0, \forall i\}$.

2. The left nodes in $V_L \setminus C_{r+1}$ are further partitioned into r new left clusters of size K_L, such that the left nodes i and i' are in the same cluster if and only if the i-th and i'-th rows of Y are identical. Similarly, the right nodes in $V_R \setminus D_{r+1}$ are partitioned into r new right clusters of size K_R according to the columns of Y. We now define an ordering $C_1, \ldots, C_r$ of these r new left clusters and an ordering $D_1, \ldots, D_r$ for the new right clusters using the following procedure.

   (a) For each new left cluster C, if there exists a $k \in [r]$ such that $|C \cap C_k^*| > K_L/2$, then we label this new left cluster as C_k; this label is unique because the left cluster size is K_L. We associate C_k with the right cluster $\{j : Y_{ij} = 1, \forall i \in C_k\}$, which is labeled as D_k.

   (b) For each remaining unlabeled right cluster D, if there exists a $k \in [r]$ such that $|D \cap D_k^*| > K_R/2$, then we label this new right cluster as D_k; again this label is unique. We associate D_k with the left cluster $\{i : Y_{ij} = 1, \forall j \in D_k\}$, which is labeled as C_k.

   (c) The remaining unlabeled left clusters are labeled arbitrarily. For each remaining unlabeled right cluster, we label it according to $D_k := \{j : Y_{ij} = 1, \forall i \in C_k\}$.

For each $(k, k') \in [r] \times [r+1]$, we use $\alpha_{kk'} := |C_k^* \cap C_{k'}|$ and $\beta_{kk'} := |D_k^* \cap D_{k'}|$ to denote the sizes of intersections of the true and new clusters. We observe that the new clusters $(C_1, \ldots, C_{r+1}, D_1, \ldots, D_{r+1})$ have the following three properties:

(A0) $(C_1, \ldots, C_r, C_{r+1})$ is a partition of V_L with $|C_k| = K_L$ for each $k \in [r]$; $(D_1, \ldots, D_r, D_{r+1})$ is a partition of V_R with $|D_k| = K_R$ for each $k \in [r]$.

(A1) For each $k \in [r]$, exactly one of the following is true: (1) $\alpha_{kk} > K_L/2$; (2) $\alpha_{kk'} \le K_L/2$ for all $k' \in [r]$ and $\beta_{kk} > K_R/2$; (3) $\alpha_{kk'} \le K_L/2$ and $\beta_{kk'} \le K_R/2$ for all $k' \in [r]$.

(A2) We have

$$\sum_{k=1}^{r} \left(\alpha_{k(r+1)}\beta_{k(r+1)} + \sum_{k', k'' : k' \neq k''} \alpha_{kk'}\beta_{kk''} \right) = t;$$

here and henceforth, all summations involving k' or k'' (as the indices of the new clusters) are over the range $[r+1]$ unless defined otherwise.

Here, Property (A0) holds due to $Y \in \mathcal{Y}$, Property (A1) is direct consequence of how we label the new clusters, and Property (A2) follows from the following:

$$\begin{aligned} t = d(Y) &= \sum_{k=1}^{r} |\{(i,j) : (i,j) \in C_k^* \times D_k^*, Y_{ij} = 0\}| \\ &= \sum_{k=1}^{r} |\{(i,j) : (i,j) \in C_k^* \times D_k^*, (i,j) \in C_{r+1} \times D_{r+1}\}| \\ &\quad + \sum_{k=1}^{r} \sum_{(k',k'') : k' \neq k''} |\{(i,j) : (i,j) \in C_k^* \times D_k^*, (i,j) \in C_{k'} \times D_{k''}\}|. \end{aligned}$$

Since a different Y corresponds to a different ordered partition, and the ordered partition for any given Y with $d(Y) = t$ must satisfy the above three properties, we obtain the following bound on the cardinality of the set of interest:

$$|\{Y \in \mathcal{Y} : d(Y) = t\}| \le |\{(C_1, \ldots, C_{r+1}, D_1, \ldots, D_{r+1}) : \text{it satisfies (A0)–(A2)}\}|. \tag{84}$$

It remains to upper-bound the right hand side of (84).

Fix any ordered partition $(C_1, \ldots, C_r, C_{r+1}, D_1, \ldots, D_r, D_{r+1})$ with Properties (A0)–(A2). Consider the first true left cluster C_1^*. Define $m_1^{(L)} := \sum_{k' : k' \neq 1} \alpha_{1k'}$, which can be considered as the number of nodes in C_1^* that are misclassified by Y. Analogously define $m_1^{(R)} := \sum_{k'' : k'' \neq 1} \beta_{1k''}$. We consider the following two cases for the values of α_{11}.

- If $\alpha_{11} > K_L/4$, then

$$\sum_{(k',k'') : k' \neq k''} \alpha_{1k'}\beta_{1k''} \ge \alpha_{11} \sum_{k'' : k'' \neq 1} \beta_{1k''} > \frac{1}{4} m_1^{(R)} K_L.$$

- If $\alpha_{11} \le K_L/4$, then $m_1^{(L)} \ge 3K_L/4$, and we must also have $\alpha_{1k'} \le K_L/2$ for all $1 \le k' \le r$ by Property (A1). Hence,

$$\begin{aligned}&\sum_{(k',k''):k'\neq k''} \alpha_{1k'}\beta_{1k''} + \alpha_{1(r+1)}\beta_{1(r+1)}\\ \ge &\sum_{(k',k''):k'\neq k''} \mathbf{1}\left\{k' \neq 1\right\}\mathbf{1}\left\{k'' \neq 1\right\}\alpha_{1k'}\beta_{1k''} + \alpha_{1(r+1)}\beta_{1(r+1)}\\ =&m_1^{(L)}m_1^{(R)} - \sum_{2\le k'\le r}\alpha_{1k'}\beta_{1k'} \ge m_1^{(L)}m_1^{(R)} - \frac{1}{2}K_L m_1^{(R)} \ge \frac{1}{4}m_1^{(R)}K_L.\end{aligned}$$

  Similarly, we consider the following three cases for the values of β_{11}.

- If $\beta_{11} > K_R/4$, then

$$\sum_{(k',k''):k'\neq k''} \alpha_{1k'}\beta_{1k''} \ge \beta_{11}\sum_{k':k'\neq 1}\alpha_{1k'} > \frac{1}{4}m_1^{(L)}K_R.$$

- If $\beta_{11} \le K_R/4$ and $\beta_{1k''} \le K_L/2$ for all $1 < k'' \le r$, then, similarly to the second case for α_{11} above, we have

$$\sum_{(k',k''):k'\neq k''} \alpha_{1k'}\beta_{1k''} + \alpha_{1(r+1)}\beta_{1(r+1)} \ge \frac{1}{4}m_1^{(L)}K_R.$$

- If $\beta_{11} \le K_R/4$ and $\beta_{1k_0} > K_R/2$ for some $1 < k_0 \le r$, then by Property (A1) we must have $\alpha_{11} > K_L/2$. It follows that $m_1^{(L)} < K_L/2$ and

$$\sum_{(k',k''):k'\neq k''} \alpha_{1k'}\beta_{1k''} \ge \alpha_{11}\beta_{1k_0} > K_L K_R/4 \ge \frac{1}{2}m_1^{(L)}K_R.$$

Combining the above five cases, we conclude that the following is always true:

$$\sum_{(k',k''):k'\neq k''} \alpha_{1k'}\beta_{1k''} + \alpha_{1(r+1)}\beta_{1(r+1)} \ge \frac{1}{4}\left(m_1^{(L)}K_R \vee m_1^{(R)}K_L\right).$$

This inequality continues to hold if we replace $\alpha_{1k'}$, $\beta_{1k''}$, $m_1^{(L)}$ and $m_1^{(R)}$ respectively by $\alpha_{kk'}$, $\beta_{kk''}$, $m_k^{(L)}$ and $m_k^{(R)}$ (defined in a similar manner) for each $k \in [r]$. Summing these inequalities over $k \in [r]$ and using Property (A2), we obtain

$$t = \sum_{k=1}^r\left\{\alpha_{k(r+1)}\beta_{k(r+1)} + \sum_{(k',k''):k'\neq k''}\alpha_{kk'}\beta_{kk''}\right\} \ge \left(\frac{K_L}{4}\sum_{k=1}^r m_k^{(R)}\right) \vee \left(\frac{K_R}{4}\sum_{k=1}^r m_k^{(L)}\right).$$

Consequently, we have $\sum_{k\in[r]} m_k^{(L)} \le 4t/K_R$ and $\sum_{k\in[r]} m_k^{(R)} \le 4t/K_L$; i.e., the total number of misclassified non-isolated left (right, resp.) nodes is upper bounded by $4t/K_R$ ($4t/K_L$, resp.). This means that the total number of misclassified isolated left (right, resp.) nodes is also upper bounded

by $4t/K_R$ ($4t/K_L$, resp.), because by the cluster size constraint in Property (A0), one misclassified isolated node must produce one misclassified non-isolated node.

We can now upper-bound the right hand side of (84) using the above relation between the value of t and the misclassified nodes. For each Y with $d(Y) = t$, the pair

$$(\#\text{misclassified isolated left nodes},\ \ \#\text{misclassified non-isolated left nodes})$$

can take at most $(4t/K_R)^2$ different values. Similarly for the right nodes we have the bound $(4t/K_L)^2$. Given these numbers of misclassified nodes, there are at most $n_L^{8t/K_R}n_R^{8t/K_L}$ different ways to choose the identity of these misclassified nodes. Each misclassified non-isolated left node can then be assigned to one of $r-1 \le n_L$ different left clusters or left isolated, and each misclassified isolated left node can be assigned to one of $r \le n_L$ different left clusters; an analogous statement holds for the right nodes. Hence, the right hand side of (84) is upper bounded by $\left(\frac{16t^2}{K_L K_R}\right)^2 n_L^{16t/K_R}n_R^{16t/K_L}$. This proves the first part of the lemma.

To count the number of possible equivalence classes $[Y]$, we use a similar argument but only need to consider the misclassified *non-isolated* nodes. The number of misclassified non-isolated left (right, resp.) nodes can take at most $4t/K_R$ ($4t/K_L$, resp.) different values. Given these numbers, there are at most $(rK_L)^{4t/K_R}(rK_R)^{4t/K_L}$ different ways to choose the identity of the misclassified non-isolated nodes. Each misclassified non-isolated left (right, resp.) node can then be assigned to one of $r-1$ different left (right, resp.) clusters or left isolated. Therefore, the number of possible equivalence classes $[Y]$ with $d(Y) = t$ is upper bounded by $\frac{16t^2}{K_L K_R}(rK_L)^{8t/K_R}(rK_R)^{8t/K_L}$.

Appendix B. Proof of Lemma 27

The inequality (56) follows from (55) by replacing p with $1-q'$ and q with $1-p'$, so it suffices to prove (55). Note that for $1 \ge u \ge v \ge 0$, we have

$$D(u\|v) = u\log\frac{u}{v} + (1-u)\log\frac{1-u}{1-v} \le u\log\frac{u}{v}, \tag{85}$$

$$D(u\|v) \ge u\log\frac{u}{v} + (1-u)\log(1-u) \overset{(a)}{\ge} u\log\frac{u}{ev}, \tag{86}$$

where (a) follows from the inequality $x\log x \ge x-1, \forall x \in [0,1]$. We consider two cases:

Case 1: $p \le 8q$. In view of (35) and (36), we have $D(p\|q) \le \frac{(p-q)^2}{q(1-q)}$ and $D\left(\frac{p+q}{2}\|q\right) \ge \frac{(p-q)^2}{4(p+q)(1-q)}$. Since $p \le 8q$, it follows that $D\left(\frac{p+q}{2}\|q\right) \ge \frac{(p-q)^2}{36q(1-q)} \ge \frac{1}{36}D(p\|q)$.

Case 2: $p > 8q$. In view of (85) and (86), we have $D(p\|q) \le p\log\frac{p}{q}$ and $D\left(\frac{p+q}{2}\|q\right) \ge \frac{p+q}{2}\log\frac{p+q}{2eq}$. Since $p > 8q$ and $8 > (2e)^{(6/5)}$, we have $\log\frac{p}{q} > \frac{6}{5}\log(2e)$ and thus $\log\frac{p+q}{2eq} > \log\frac{p}{2eq} = \log\frac{p}{q} - \log(2e) > \frac{1}{6}\log\frac{p}{q}$. It follows that $D\left(\frac{p+q}{2}\|q\right) \ge \frac{p}{2}\cdot\frac{1}{6}\log\frac{p}{q} \ge \frac{1}{12}D(p\|q)$.

Appendix C. The Bernstein Inequality

Theorem 32 (Bernstein) *Let $X_1, \ldots, X_N$ be independent random variables such that $|X_i| \le M$ almost surely. Let $\sigma^2 = \sum_{i=1}^N Var(X_i)$. Then for any $t \ge 0$,*

$$\mathbb{P}\left[\sum_{i=1}^N X_i \ge t\right] \le \exp\left(\frac{-t^2}{2\sigma^2 + \frac{2}{3}Mt}\right).$$

A consequent of the above inequality is $\mathbb{P}\left[\sum_{i=1}^{N} X_i \geq \sqrt{2\sigma^2 u} + \frac{2Mu}{3}\right] \leq e^{-u}$ *for any* $u > 0$.

Abstract

We provide theoretical and empirical evidence for a type of asymmetry between causes and effects that is present when these are related via linear models contaminated with additive non-Gaussian noise. Assuming that the causes and the effects have the same distribution, we show that the distribution of the residuals of a linear fit in the anti-causal direction is closer to a Gaussian than the distribution of the residuals in the causal direction. This Gaussianization effect is characterized by reduction of the magnitude of the high-order cumulants and by an increment of the differential entropy of the residuals. The problem of non-linear causal inference is addressed by performing an embedding in an expanded feature space, in which the relation between causes and effects can be assumed to be linear. The effectiveness of a method to discriminate between causes and effects based on this type of asymmetry is illustrated in a variety of experiments using different measures of Gaussianity. The proposed method is shown to be competitive with state-of-the-art techniques for causal inference.

Keywords: causal inference, Gaussianity of the residuals, cause-effect pairs

1. Introduction

The inference of causal relationships from data is one of the current areas of interest in the artificial intelligence community, *e.g.* (Chen et al., 2014; Janzing et al., 2012; Morales-Mombiela et al., 2013). The reason for this surge of interest is that discovering the causal structure of a complex system provides an explicit description of the mechanisms that generate the data, and allows us to understand the consequences of interventions in the system (Pearl, 2000). More precisely, automatic causal inference can be used to determine how modifications of the value of certain relevant variables (the causes) influence the values of other related variables (the effects). Therefore, understanding cause-effect relations is of paramount importance to control the behavior of complex systems and has applications in industrial processes, medicine, genetics, economics, social sciences or meteorology.

Causal relations can be determined in complex systems in three different ways. First, they can be inferred from domain knowledge provided by an expert, and incorporated in an ad-hoc manner in the description of the system. Second, they can be discovered by performing interventions in the system. These are controlled experiments in which one or several variables of the system are forced to take particular values. Interventions constitute a primary tool for identifying causal relationships. However, in many situations they are unethical, expensive, or technically infeasible. Third, they can be estimated using causal discovery algorithms that use as input purely uncontrolled and static data.

This last approach for causal discovery has recently received much attention from the machine learning community (Shimizu et al., 2006; Hoyer et al., 2009; Zhang and Hyvärinen, 2009). These methods assume a particular model for the *mapping mechanisms* that link causes to effects. By specifying particular conditions on the mapping mechanism and the distributions of the cause and noise variables, the causal direction becomes identifiable Chen et al. (2014). For instance, Hoyer et al. (2009) assume that the effect is a non-linear transformation of the cause plus some independent additive noise. A potential drawback of these methods is that the assumptions made by the particular model considered could be unrealistic for the data under study.

In this paper we propose a general method for causal inference that belongs to the third of the categories described above. Specifically, we assume that the cause and the effect variables have the same distribution and are linked by a linear relationship contaminated with non-Gaussian noise. For the univariate case we prove that, under these assumptions, the magnitude of the cumulants of the residuals of order higher than two is smaller for the linear fit in the anti-causal direction than in the causal one. Since the Gaussian is the only distribution whose cumulants of order higher than 2 are zero, statistical tests based on measures of Gaussianity can be used for causal inference. An antecedent of this result is the observation that, when cause and effect have the same distribution, the residuals of a fit in the anti-causal direction have higher entropy than in the causal direction (Hyvärinen and Smith, 2013; Kpotufe et al., 2014). Since the residuals of the causal and anti-causal linear models have the same variance and the Gaussian is the distribution that maximizes the entropy for a fixed variance, this means that the distribution of the latter is more Gaussian than the former.

For multivariate cause-effect pairs that have the same distribution and are related by a linear model with additive non-Gaussian noise the proof given by Hyvärinen and Smith (2013) and Kpotufe et al. (2014) can be extended to show that the entropy of the vector of residuals of a linear fit in the anti-causal direction is larger than the corresponding residuals of a linear fit in the causal direction. We conjecture that also in this case there is a reduction of the magnitude of the tensor cumulants of the anti-causal multivariate residuals and provide some numerical evidence of this effect in two dimensions.

∗. The vast majority of the work was done while being at the Max Planck Institute for Intelligent Systems and at Cambridge University.

The problem of non-linear causal inference is addressed by embedding the original problem in an expanded feature space. We then make the assumption that the non-linear relation between causes and effects in the original space is linear in the expanded feature space. The computations required to make inference on the causal direction based on this embedding can be readily carried out using kernel methods.

In summary, the proposed method for causal inference proceeds by first making a transformation of the original variables so that causes and effects have the same distribution. Then we perform kernel ridge regression in both the causal and the anti-causal directions. The dependence between causes and effects, which is non-linear in the original space, is assumed to be linear in the kernel-induced feature space. A statistical test is then used to quantify the degree of similarity between the distributions of these residuals and a Gaussian distribution with the same variance. Finally, the direction in which the residuals are less Gaussian is identified as the causal one.

The performance of this method is evaluated in both synthetic and real-world cause-effect pairs. From the results obtained it is apparent that the anti-causal residuals of a linear fit in the expanded feature space are more Gaussian than the causal residuals. In general, it is difficult to estimate the entropy from a finite sample (Beirlant et al., 1997). Empirical estimators of high order cumulants involve high order moments, which means they often have large variance. As an alternative, we propose to use statistical tests based on the *energy distance* to characterize the Gaussianization effect for the residuals of linear fits in the causal and anti-causal directions. Tests based on the energy distance were analyzed in depth by Székely and Rizzo (2005). They have been shown to be related to homogeneity tests based on embeddings in a Reproducing Kernel Hilbert Space (Gretton et al., 2012). An advantage of energy distance-based statistics is that they can be readily estimated from a sample by computing expectations of pairwise Euclidean distances. The energy distance generally provides better results than the entropy or cumulant-based Gaussianity measures. In the problems investigated, the accuracy of the proposed method, using the energy distance to the Gaussian, is comparable to other state-of-the-art techniques for causal discovery.

The rest of the paper is organized as follows: Section 2 illustrates that, under certain conditions, the residuals of a linear regression fit are closer to a Gaussian in the anti-causal direction than in the causal one, based on a reduction of the high-order cumulants and on an increment of the entropy. This section considers both the univariate and multivariate cases. Section 3 adopts a kernel approach to carry out a feature expansion that can be used to detect non-linear causal relationships. We also show here how to compute the residuals in the expanded feature space, and how to choose the different hyper-parameters of the proposed method. Section 4 contains a detailed description of the implementation. In section 6 we present the results of an empirical assessment of the proposed method in both synthetic and real-world cause-effect data pairs. Finally, Section 7 summarizes the conclusions and puts forth some ideas for future research.

2. Asymmetry Based on the Non-Gaussianity of the Residuals of Linear Models

Let $\mathcal{X}$ and $\mathcal{Y}$ be two random variables that are causally related. The direction of the causal relation is not known. Our goal is to determine whether $\mathcal{X}$ causes $\mathcal{Y}$, *i.e.*, $\mathcal{X} \to \mathcal{Y}$ or,

alternatively $\mathcal{Y}$ causes $\mathcal{X}$, *i.e.*, $\mathcal{Y} \to \mathcal{X}$. For this purpose, we exploit an asymmetry between causes an effects. This type of asymmetry can be uncovered using statistical tests that measure the non-Gaussianity of the residuals of linear regression models obtained from fits in the causal and in the anti-causal direction.

To motivate the methodology that we have developed, we will proceed in stepwise manner. First we analyze a special case in one dimension: We assume that $\mathcal{X}$ and $\mathcal{Y}$ have the same distribution and are related via a linear model contaminated with additive i.i.d. non-Gaussian noise. The noise is independent of the cause. Under these assumptions we show that the distribution of the residuals of a linear fit in the incorrect (anti-causal) direction is closer to a Gaussian distribution than the distribution of the residuals in the correct (causal) direction. For this, we use an argument based on the reduction of the magnitude of the cumulants of order higher than 2. The cumulants are defined as the derivatives of the logarithm of the moment-generating function evaluated at zero (Cornish and Fisher, 1938; McCullagh, 1987).

The Gaussianization effect can be characterized also in terms of an increase of the entropy. The proof is based on the results of Hyvärinen and Smith (2013), which are extended in this paper to the multivariate case. In particular, we show that the entropy of the residuals of a linear fit in the anti-causal direction is larger or equal than the entropy of the residuals of a linear fit in the causal direction. Since the Gaussian it the distribution that has maximum entropy, given a particular covariance matrix, an increase of the entropy of the residuals means that their distribution becomes closer to the Gaussian.

Finally, we note that it is easy to guarantee that $\mathcal{X}$ and $\mathcal{Y}$ have the same distribution in the case that these variables are unidimensional and continuous. To this end we only have to transform one of the variables (typically the cause random variable) using the probability integral transform, as described in Section 4. However, after the data have been transformed, the relation between the variables will no longer be linear in general. Thus, to address non-linear cause-effect problems involving univariate random variables the linear model is formulated in an expanded feature space, where the multivariate analysis of the Gaussianization effect is also applicable. In this feature space all the computations required for causal inference can be formulated in terms of kernels. This can be used to detect non-linear causal relations in the original input space and allows for an efficient implementation of the method. The only assumption is that the non-linear relation in the original input space is linear in the expanded feature space induced by the selected kernel.

2.1 Analysis of the Univariate Case Based on Cumulants

Let $\mathcal{X}$ and $\mathcal{Y}$ be one-dimensional random variables that have the same distribution. Without further loss of generality, we will assume that they have zero mean and unit variance. Let $\mathbf{x} = (x_1, \ldots, x_N)^{\mathrm{T}}$ and $\mathbf{y} = (y_1, \ldots, y_N)^{\mathrm{T}}$ be N paired samples drawn i.i.d. from $P(\mathcal{X}, \mathcal{Y})$. Assume that the causal direction is $\mathcal{X} \to \mathcal{Y}$ and that the measurements are related by a linear model

$$y_i = w x_i + \epsilon_i \,, \quad \epsilon_i \perp x_i \,, \quad \forall i \,, \tag{1}$$

where $w = \mathrm{corr}(\mathcal{X}, \mathcal{Y}) \in [-1, 1]$ and ϵ_i is independent i.d. non-Gaussian additive noise.

A linear model in the opposite direction, *i.e.*, $\mathcal{Y} \to \mathcal{X}$, can be built using least squares

$$x_i = w y_i + \tilde{\epsilon}_i, \tag{2}$$

where $w = \text{corr}(\mathcal{Y}, \mathcal{X})$ is the same coefficient as in the previous model. The residuals of this reversed linear model are defined as $\tilde{\epsilon}_i = x_i - w y_i$.

Following an argument similar to that of Hernández-Lobato et al. (2011) we show that the residuals $\{\tilde{\epsilon}_i\}_{i=1}^N$ in the anti-causal direction are more Gaussian than the residuals $\{\epsilon_i\}_{i=1}^N$ in the actual causal direction $\mathcal{X} \to \mathcal{Y}$ based on a reduction of the magnitude of the cumulants. The proof is based on establishing a relation between the cumulants of the distribution of the residuals in both the causal and the anti-causal direction. First, we show that $\kappa_n(y_i)$, the n-th order cumulant of $\mathcal{Y}$, can be expressed in terms of $\kappa_n(\epsilon_i)$, the n-th order cumulant of the residuals:

$$\kappa_n(y_i) = w^n \kappa_n(x_i) + \kappa_n(\epsilon_i) = w^n \kappa_n(y_i) + \kappa_n(\epsilon_i) = \frac{1}{1 - w^n} \kappa_n(\epsilon_i)\,. \tag{3}$$

To derive this relation we have used (1), that x_i and y_i have the same distribution (and hence have the same cumulants), and standard properties of cumulants (Cornish and Fisher, 1938; McCullagh, 1987). Furthermore,

$$\begin{aligned}
\kappa_n(\tilde{\epsilon}_i) &= \kappa_n(x_i - w y_i) = \kappa_n(x_i - w^2 x_i - w\epsilon_i) = (1 - w^2)^n \kappa_n(x_i) + (-w)^n \kappa_n(\epsilon_i) \\
&= (1 - w^2)^n \kappa_n(y_i) + (-w)^n \kappa_n(\epsilon_i) = \frac{(1 - w^2)^n}{1 - w^n} \kappa_n(\epsilon_i) + (-w)^n \kappa_n(\epsilon_i) \\
&= c_n(w) \kappa_n(\epsilon_i)\,,
\end{aligned} \tag{4}$$

where we have used the definition of $\tilde{\epsilon}_i$ and (3) In Figure 1 the value of

$$c_n(w) = \frac{(1 - w^2)^n}{1 - w^n} + (-w)^n. \tag{5}$$

is displayed as a function of $w \in [-1, 1]$. Note that $c_1(w) = c_2(w) = 1$ independently of the value of w. This means that the mean and the variance of the residuals are the same in both the causal and anti-causal directions. For $n > 2$, $|c_n(w)| \leq 1$ with equality only for $w = 0$ and $w = \pm 1$. The result is that the high-order cumulants of the residuals in the anti-causal direction are smaller in magnitude that the corresponding cumulants in the causal direction. Using the observation that all the cumulants of the Gaussian distribution of order higher than two are zero (Marcinkiewicz, 1938), we conclude that the distribution of the residuals in the anti-causal direction is closer to the Gaussian distribution than in the causal direction.

In summary, we can infer the causal direction by (i) fitting a linear model in each possible direction, *i.e.*, $\mathcal{X} \to \mathcal{Y}$ and $\mathcal{Y} \to \mathcal{X}$, and (ii) carrying out statistical tests to detect the level of Gaussianity of the two corresponding residuals. The direction in which the residuals are less Gaussian is expected to be the correct one.

2.2 Analysis of the Multivariate Case Based on Cumulants

In this section we argue that the Gaussianization effect of the residuals in the anti-causal direction also takes place when the two random variables $\mathcal{X}$ and $\mathcal{Y}$ are multidimensional.

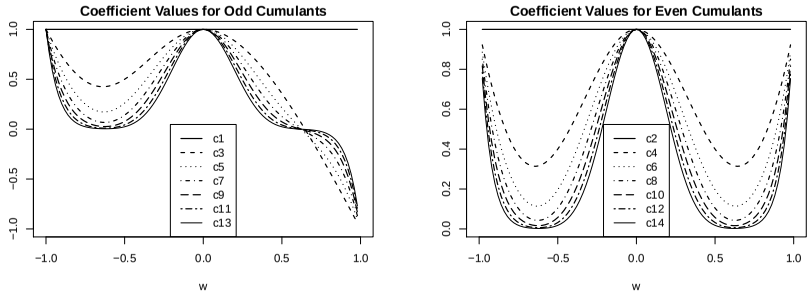

Figure 1: Values of the function $c_n(\cdot)$ as a function of w for each cumulant number n (odd in the left plot, even in the right plot). All values for $c_n(\cdot)$ lie in the interval $[-1, 1]$.

We will assume that these variables follow the same distribution and, without further loss of generality, that they have been whitened (*i.e.*, they have a zero mean vector and the identity matrix as the covariance matrix). Let $\mathbf{X} = (\mathbf{x}_1, \ldots, \mathbf{x}_N)^{\text{T}}$ and $\mathbf{Y} = (\mathbf{y}_1, \ldots, \mathbf{y}_N)^{\text{T}}$ be N paired samples drawn i.i.d. from $P(\mathcal{X}, \mathcal{Y})$. In this case, the model assumed for the actual causal relation is

$$\mathbf{y}_i = \mathbf{A}\mathbf{x}_i + \boldsymbol{\epsilon}_i\,, \quad \boldsymbol{\epsilon}_i \perp \mathbf{x}_i\,, \quad \forall i\,, \tag{6}$$

where $\mathbf{A} = \text{corr}(\mathcal{Y}, \mathcal{X})$ is a $d \times d$ matrix of model coefficients and $\boldsymbol{\epsilon}_i$ is i.i.d. non-Gaussian additive noise. The model in the anti-causal direction is the one that results from the least squares fit:

$$\mathbf{x}_i = \tilde{\mathbf{A}}\mathbf{y}_i + \tilde{\boldsymbol{\epsilon}}_i\,, \tag{7}$$

where we have defined $\tilde{\boldsymbol{\epsilon}}_i = \mathbf{x}_i - \tilde{\mathbf{A}}\mathbf{y}_i$ and $\tilde{\mathbf{A}} = \text{corr}(\mathcal{X}, \mathcal{Y}) = \mathbf{A}^{\text{T}}$.

As in the univariate case, we start by expressing the cumulants of $\mathcal{Y}$ in terms of the cumulants of the residuals. However, the cumulants are now tensors (McCullagh, 1987):

$$\kappa_n(\mathbf{y}_i) = \kappa_n(\mathbf{A}\mathbf{x}_i) + \kappa_n(\boldsymbol{\epsilon}_i)\,. \tag{8}$$

In what follows, the notation $\text{vect}(\cdot)$ stands for the vectorization of a tensor. For example, in the case of a tensor $\mathbf{T}$ with dimensions $d \times d \times d$

$$\text{vect}(\mathbf{T}) = (T_{1,1,1}, T_{2,1,1}, \cdots, T_{d,1,1}, T_{1,2,1}, \cdots, T_{d,d,d})^{\text{T}}.$$

Using this notation we obtain

$$\text{vect}(\kappa_n(\mathbf{y}_i)) = \mathbf{A}^n \text{vect}(\kappa_n(\mathbf{x}_i)) + \text{vect}(\kappa_n(\boldsymbol{\epsilon})) = (\mathbf{I} - \mathbf{A}^n)^{-1} \text{vect}(\kappa_n(\boldsymbol{\epsilon}))\,, \tag{9}$$

where $\mathbf{A}^n = \mathbf{A} \otimes \mathbf{A} \otimes \mathbf{A} \cdots \otimes \mathbf{A}$, n times, is computed using the Kronecker matrix product. To derive this expression we have used (6), the fact that $\mathcal{Y}$ and $\mathcal{X}$ are equally distributed and hence have the same cumulants. We also have used the properties of the tensor cumulants $\text{vect}(\kappa_n(\mathbf{A}\mathbf{x}_i)) = \mathbf{A}^n \text{vect}(\kappa_n(\mathbf{x}_i))$, where the powers of the matrix $\mathbf{A}$ are computed using the Kronecker product (McCullagh, 1987).

Similarly, for the reversed linear model

$$\begin{aligned}\kappa_n(\tilde{\boldsymbol{\epsilon}}_i) &= \kappa_n(\mathbf{x}_i - \mathbf{A}^{\mathrm{T}}\mathbf{y}_i) = \kappa_n(\mathbf{x}_i - \mathbf{A}^{\mathrm{T}}\mathbf{A}\mathbf{x}_i - \mathbf{A}^{\mathrm{T}}\boldsymbol{\epsilon}_i) = \kappa_n((\mathbf{I} - \mathbf{A}^{\mathrm{T}}\mathbf{A})\mathbf{x}_i - \mathbf{A}^{\mathrm{T}}\boldsymbol{\epsilon}_i) \\ &= \kappa_n((\mathbf{I} - \mathbf{A}^{\mathrm{T}}\mathbf{A})\mathbf{x}_i) + \kappa_n(-\mathbf{A}^{\mathrm{T}}\boldsymbol{\epsilon}_i)\,. \end{aligned} \tag{10}$$

Using again the notation for the vectorized tensor cumulants

$$\begin{aligned}\text{vect}(\kappa_n(\tilde{\boldsymbol{\epsilon}}_i)) &= (\mathbf{I} - \mathbf{A}^{\mathrm{T}}\mathbf{A})^n \text{vect}(\kappa_n(\mathbf{x}_i)) + (-1)^n (\mathbf{A}^{\mathrm{T}})^n \text{vect}(\kappa_n(\boldsymbol{\epsilon}_i)) \\ &= (\mathbf{I} - \mathbf{A}^{\mathrm{T}}\mathbf{A})^n (\mathbf{I} - \mathbf{A}^n)^{-1} \text{vect}(\kappa_n(\boldsymbol{\epsilon}_i)) + (-1)^n (\mathbf{A}^{\mathrm{T}})^n \text{vect}(\kappa_n(\boldsymbol{\epsilon}_i)) \\ &= \left((\mathbf{I} - \mathbf{A}^{\mathrm{T}}\mathbf{A})^n (\mathbf{I} - \mathbf{A}^n)^{-1} + (-1)^n (\mathbf{A}^{\mathrm{T}})^n\right) \text{vect}(\kappa_n(\boldsymbol{\epsilon}_i))\,, \end{aligned} \tag{11}$$

where the powers of matrices are computed using the Kronecker product as well, and where we have used (9) and that $\mathcal{Y}$ and $\mathcal{X}$ are equally distributed and have the same cumulants.

We now give some evidence to support that the magnitude of $\text{vect}(\kappa_n(\tilde{\boldsymbol{\epsilon}}_i))$ is smaller than the magnitude of $\text{vect}(\kappa_n(\boldsymbol{\epsilon}_i))$ in terms of the ℓ_2-norm, for cumulants of order higher than 2. That is, the tensors corresponding to high-order cumulants become closer to a tensor with all its components equal to zero. For this, we introduce the following definition:

Definition 1 *The operator norm of a matrix* $\mathbf{M}$ *induced by the* ℓ_p *vector norm is* $||\mathbf{M}||_{op} = min\{c \geq 0 : ||\mathbf{M}\mathbf{v}||_p \leq c||\mathbf{v}||_p, \forall \mathbf{v}\}$*, where* $||\cdot||_p$ *denotes the* ℓ_p*-norm for vectors.*

The consequence is that $||\mathbf{M}||_{\text{op}} \geq ||\mathbf{M}\mathbf{v}||_p / ||\mathbf{v}||_p$, $\forall \mathbf{v}$. This means that $||\mathbf{M}||_p$ can be understood as a measure of the size of the matrix $\mathbf{M}$. In the case of the ℓ_2-norm, the operator norm of a matrix $\mathbf{M}$ is equal to its largest singular value or, equivalently, to the square root of the largest eigenvalue of $\mathbf{M}^{\mathrm{T}}\mathbf{M}$. Let $\mathbf{M}_n = (\mathbf{I} - \mathbf{A}^{\mathrm{T}}\mathbf{A})^n (\mathbf{I} - \mathbf{A}^n)^{-1} + (-1)^n (\mathbf{A}^{\mathrm{T}})^n$. That is, $\mathbf{M}_n$ is the matrix that relates the cumulants of order n of the residuals in the causal and anti-causal directions in (11). We now evaluate $||\mathbf{M}_n||_{\text{op}}$, and show that in most cases its value is smaller than one for high-order cumulants $\kappa_n(\cdot)$, leading to a Gaussianization of the residuals in the anti-causal direction. From (11) and the definition given above, we know that $||\mathbf{M}_n||_{\text{op}} \geq ||\text{vect}(\kappa_n(\tilde{\boldsymbol{\epsilon}}_i))||_2 / ||\text{vect}(\kappa_n(\boldsymbol{\epsilon}_i))||_2$. This means that if $||\mathbf{M}_n||_{\text{op}} < 1$ the cumulants of the residuals in the incorrect causal direction are shrunk to the origin. Because the multivariate Gaussian distribution has all cumulants of order higher than two equal to zero (McCullagh, 1987), this translates into a distribution for the residuals in the anti-causal direction that is closer to the Gaussian distribution.

In the causal direction, we have that $\mathbb{E}[\mathbf{y}\mathbf{y}^T] = \mathbb{E}[(\mathbf{A}\mathbf{x}_i + \boldsymbol{\epsilon}_i)(\mathbf{A}\mathbf{x}_i + \boldsymbol{\epsilon}_i)^{\mathrm{T}}] = \mathbf{A}\mathbf{A}^T + \mathbf{C} = \mathbf{I}$, where $\mathbf{C}$ is the positive definite covariance matrix of the actual residuals[1]. Thus, $\mathbf{A}\mathbf{A}^T = \mathbf{I} - \mathbf{C}$ and hence the singular values of $\mathbf{A}$, denoted $\sigma_1, \ldots, \sigma_d$, satisfy $0 \leq \sigma_i = \sqrt{1 - \alpha_i} \leq 1$, where α_i is the corresponding positive eigenvalue of $\mathbf{C}$. Assume that $\mathbf{A}$ is symmetric (this

1. We assume such matrix exists and that it is positive definite.

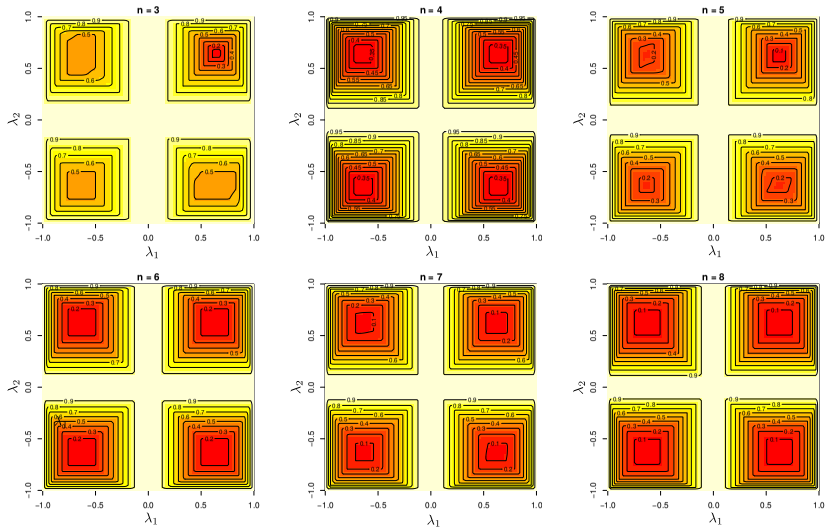

Figure 2: Contour curves of the values of $||\mathbf{M}_n||_{\text{op}}$ for $d = 2$ and for $n > 2$ as a function of λ_1 and λ_2, *i.e.*, the two eigenvalues of $\mathbf{A}$. $\mathbf{A}$ is assumed to be symmetric. Similar results are obtained for higher-order cumulants.

also means that $\mathbf{M}_n$ is symmetric). Denote by $\lambda_1, \ldots, \lambda_d$ to the eigenvalues of $\mathbf{A}$. That is, $\sigma_i = \sqrt{\lambda_i^2}$ and $0 \leq \lambda_i^2 \leq 1$, $i = 1, \ldots, d$. For a fixed cumulant of order n we have that

$$||\mathbf{M}_n||_{\text{op}} = \max_{\mathbf{v} \in \mathcal{S}} \left| \prod_{j=1}^{n} \frac{\left[1 - \lambda_{v_j}^2\right]}{1 - \prod_{i=1}^{n} \lambda_{v_i}} + (-1)^n \prod_{j=1}^{n} \lambda_{v_j} \right|, \tag{12}$$

where $\mathcal{S} = \{1, \ldots, d\}^n$, $|\cdot|$ denotes absolute value, and we have employed standard properties of the Kronecker product about eigenvalues and eigenvectors (Laub, 2004). Note that this expression does not depend on the eigenvectors of $\mathbf{A}$, but only on its eigenvalues.

Figure 2 shows, for symmetric $\mathbf{A}$, the value of $||\mathbf{M}_n||_{\text{op}}$ for $n = 3, \ldots, 8$, and $d = 2$ when the two eigenvalues of $\mathbf{A}$ range in the interval $(-1, 1)$. We observe that $||\mathbf{M}_n||_{\text{op}}$ is always smaller than one. As described before, this will lead to a reduction in the ℓ_2-norm of the cumulants in the anti-causal direction due to (11), and will in consequence produce a Gaussianization effect on the distribution of the residuals. For $n \leq 2$ it can be readily shown that $||\mathbf{M}_1||_{\text{op}} = ||\mathbf{M}_2||_{\text{op}} = 1$.

In general, the matrix $\mathbf{A}$ need not be symmetric. In this case, $||\mathbf{M}_1||_{\text{op}} = ||\mathbf{M}_2||_{\text{op}} = 1$ as well. However, the evaluation of $||\mathbf{M}_n||_{\text{op}}$ for $n > 2$ is more difficult, but feasible for small n.

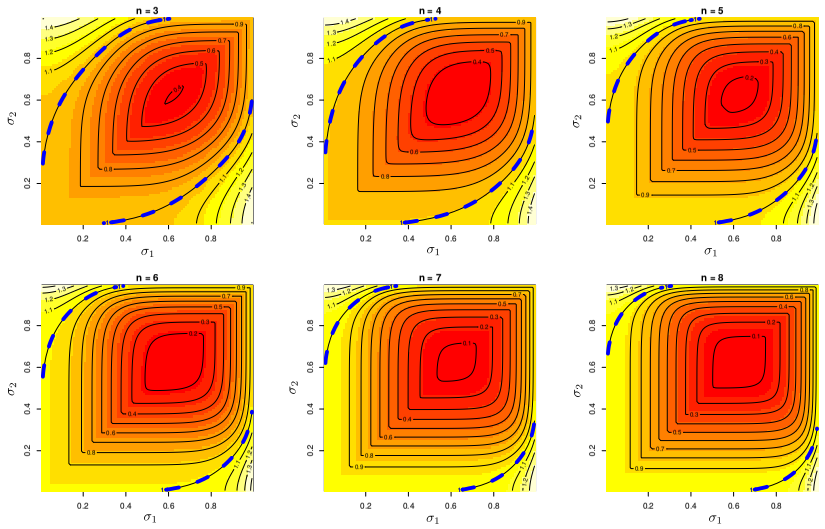

Figure 3: Contour curves of the values of $||\mathbf{M}_n||_{\text{op}}$ for $d = 2$ and for $n > 2$ as a function of σ_1 and σ_2, *i.e.*, the two singular values of $\mathbf{A}$. $\mathbf{A}$ is not assumed to be symmetric. The singular vectors of $\mathbf{A}$ are chosen at random. A dashed blue line highlights the boundary of the region where $||\mathbf{M}_n||_{\text{op}}$ is strictly smaller than one.

Figure 3 displays the values of $||\mathbf{M}_n||_{\text{op}}$, for $d = 2$, as the two singular values of $\mathbf{A}$, σ_1 and σ_2, vary in the interval $(0, 1)$. The left singular vectors and the right singular vectors of $\mathbf{A}$ are chosen at random. In this figure a dashed blue line highlights the boundary of the region where $||\mathbf{M}_n||_{\text{op}}$ is strictly smaller than one. We observe that for most values of σ_1 and σ_2, $||\mathbf{M}_n||_{\text{op}}$ is smaller than one, leading to a Gaussianization effect in the distribution of the residuals in the anti-causal direction. However, for some singular values, $||\mathbf{M}_n||_{\text{op}}$ is strictly larger than one. Of course, this does not mean that there is not such a Gaussianization effect also in those cases. The definition given for $||\mathbf{M}_n||_{\text{op}}$ assumes that all potential vectors $\mathbf{v}$ represent valid cumulants of a probability distribution, which need not be the case in practice. For example, it is well known that cumulants exhibit some form of symmetry (McCullagh, 1987). This can be seen in the second order cumulant, which is a covariance matrix. The consequence is that $||\mathbf{M}_n||_{\text{op}}$ is simply an upper bound on the reduction of the ℓ_2-norm of the cumulants in the anti-causal model. Thus, we also expect a Gaussianization effect to occur also for these cases. Furthermore, the numerical simulations presented in Section 6 provide evidence of this effect for asymmetric $\mathbf{A}$.

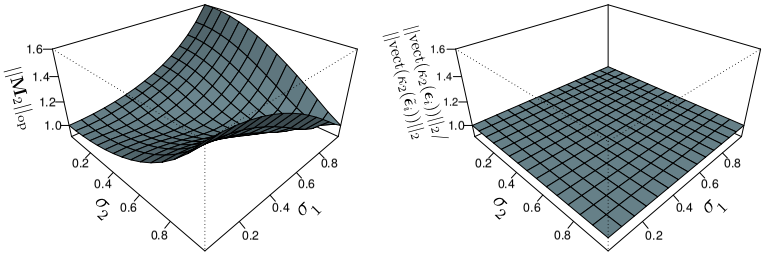

Figure 4: (left) Value of $||\mathbf{M}_2||_{\text{op}}$, for $d = 2$, as a function of σ_1 and σ_2, *i.e.*, the two singular values of $\mathbf{A}$. (right) Actual ratio between $||\text{vect}(\kappa_2(\boldsymbol{\epsilon}_i))||_2$ and $||\text{vect}(\kappa_2(\tilde{\boldsymbol{\epsilon}}_i))||_2$, for $d = 2$, as a function of σ_1 and σ_2. $\mathbf{A}$ is not assumed to be symmetric. The singular vectors of $\mathbf{A}$ are chosen at random.

The fact that $||\mathbf{M}_n||_{\text{op}}$ is only an upper bound is illustrated in Figure 4. This figure considers the particular case of the second cumulant $\kappa_2(\cdot)$, which can be analyzed in detail. On the left plot the value of $||\mathbf{M}_2||_{\text{op}}$ is displayed as a function of σ_1 and σ_2, the two singular values of $\mathbf{A}$. We observe that $||\mathbf{M}_2||_{\text{op}}$ takes values that are larger than one. In this case it is possible to evaluate in closed form the ℓ_2-norm of $\text{vect}(\kappa_2(\boldsymbol{\epsilon}_i))$ and $\text{vect}(\kappa_2(\tilde{\boldsymbol{\epsilon}}_i))$, *i.e.*, the vectors that contain the second order cumulant of the residuals in each direction. In particular, it is well known that the second order cumulant is equal to the covariance matrix (McCullagh, 1987). In the causal direction, the covariance matrix of the residuals is $\mathbf{C} = \mathbf{I} - \mathbf{A}\mathbf{A}^{\text{T}}$, as shown in the previous paragraphs. The covariance matrix of the residuals in the anti-causal direction, denoted by $\tilde{\mathbf{C}}$, can be computed similarly. Namely, $\tilde{\mathbf{C}} = \mathbf{I} - \mathbf{A}^{\text{T}}\mathbf{A}$. These two matrices, *i.e.*, $\mathbf{C}$ and $\tilde{\mathbf{C}}$, respectively give $k_2(\boldsymbol{\epsilon}_i)$ and $k_2(\tilde{\boldsymbol{\epsilon}}_i)$. Furthermore, they have the same singular values. This means that $||\text{vect}(k_2(\boldsymbol{\epsilon}_i))||_2 / ||\text{vect}(k_2(\tilde{\boldsymbol{\epsilon}}_i))||_2 = 1$, as illustrated by the right plot in Figure 4. Thus, $||\mathbf{M}_2||_{\text{op}}$ is simply an upper bound on the actual reduction of the ℓ_2-norm of the second order cumulant of the residuals in the anti-causal direction. The same behavior is expected for $||\mathbf{M}_n||_{\text{op}}$, with $n > 2$. In consequence, one should expect that the cumulants of the distribution of the residuals of a model fitted in the anti-causal direction are smaller in magnitude. This will lead to an increased level of Gaussianity measured in terms of a reduction of the magnitude of the high-order cumulants.

2.3 Analysis of the Multivariate Case Based on Information Theory

The analysis of the multivariate case carried out in the previous section is illustrative. Nevertheless, it does not prove that the distribution of the residuals in the anti-casual direction is more Gaussian based on a reduction of the magnitude of the cumulants. Further evidence of this increased level of Gaussianity can be obtained based on an increase of the entropy obtained by using information theory. In this case we also assume that the multi-dimensional variables $\mathcal{X}$ and $\mathcal{Y}$ follow the same distribution, but unlike in the previous

section, they need not be whitened, only centered. Here we closely follow Section 2.4 of the work by Hyvärinen and Smith (2013) and extend their results to the multivariate case.

Under the assumptions specified earlier, the model in the causal direction is $\mathbf{y}_i = \mathbf{A}\mathbf{x}_i + \boldsymbol{\epsilon}_i$, with $\mathbf{x}_i \perp \boldsymbol{\epsilon}_i$ and $\mathbf{A} = \text{Cov}(\mathcal{Y},\mathcal{X})\text{Cov}(\mathcal{X},\mathcal{X})^{-1}$. Similarly, the model in the anti-causal direction is $\mathbf{x}_i = \tilde{\mathbf{A}}\mathbf{y}_i + \tilde{\boldsymbol{\epsilon}}_i$ with $\tilde{\mathbf{A}} = \text{Cov}(\mathcal{X},\mathcal{Y})\text{Cov}(\mathcal{Y},\mathcal{Y})^{-1}$. By making use of the causal model it is possible to show that $\tilde{\boldsymbol{\epsilon}}_i = (\mathbf{I} - \tilde{\mathbf{A}}\mathbf{A})\mathbf{x}_i - \tilde{\mathbf{A}}\boldsymbol{\epsilon}_i$, where $\mathbf{I}$ is the identity matrix. Thus, the following equations are satisfied:

$$\begin{pmatrix} \mathbf{x}_i \\ \mathbf{y}_i \end{pmatrix} = \mathbf{P}\begin{pmatrix} \mathbf{x}_i \\ \boldsymbol{\epsilon}_i \end{pmatrix} = \begin{pmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{A} & \mathbf{I} \end{pmatrix}\begin{pmatrix} \mathbf{x}_i \\ \boldsymbol{\epsilon}_i \end{pmatrix}, \tag{13}$$

and

$$\begin{pmatrix} \mathbf{y}_i \\ \tilde{\boldsymbol{\epsilon}}_i \end{pmatrix} = \tilde{\mathbf{P}}\begin{pmatrix} \mathbf{x}_i \\ \boldsymbol{\epsilon}_i \end{pmatrix} = \begin{pmatrix} \mathbf{A} & \mathbf{I} \\ \mathbf{I} - \tilde{\mathbf{A}}\mathbf{A} & -\tilde{\mathbf{A}} \end{pmatrix}\begin{pmatrix} \mathbf{x}_i \\ \boldsymbol{\epsilon}_i \end{pmatrix}. \tag{14}$$

Let $H(\mathbf{x}_i, \mathbf{y}_i)$ be the entropy of the joint distribution of the two random variables associated with samples $\mathbf{x}_i$ and $\mathbf{y}_i$. Because (13) is a linear transformation, we can use the entropy transformation formula (Hyvärinen and Smith, 2013) to get that $H(\mathbf{x}_i, \mathbf{y}_i) = H(\mathbf{x}_i, \boldsymbol{\epsilon}_i) + \log|\text{det}\mathbf{P}|$, where $\text{det}\mathbf{P} = \text{det}\mathbf{I} = 1$. Thus, we have that $H(\mathbf{x}_i, \mathbf{y}_i) = H(\mathbf{x}_i, \boldsymbol{\epsilon}_i)$. Conversely, if we use (14) we have $H(\mathbf{y}_i, \boldsymbol{\epsilon}_i) = H(\mathbf{x}_i, \boldsymbol{\epsilon}_i) + \log|\text{det}\tilde{\mathbf{P}}|$, where $\text{det}\tilde{\mathbf{P}} = \text{det}\mathbf{A} \cdot \text{det}(-\tilde{\mathbf{A}} - (\mathbf{I} - \tilde{\mathbf{A}}\mathbf{A})\mathbf{A}^{-1}\mathbf{I}) = -\text{det}\mathbf{I} = -1$, under the assumption that $\mathbf{A}$ is invertible. The result is that $H(\mathbf{x}_i, \mathbf{y}_i) = H(\mathbf{y}_i, \boldsymbol{\epsilon}_i) = H(\mathbf{x}_i, \boldsymbol{\epsilon}_i)$.

Denote the mutual information between the cause and the noise with $I(\mathbf{x}_i, \boldsymbol{\epsilon}_i)$. Similarly, let $I(\mathbf{y}_i, \tilde{\boldsymbol{\epsilon}}_i)$ be the mutual information between the random variables corresponding to the observations $\mathbf{y}_i$ and $\tilde{\boldsymbol{\epsilon}}_i$. Then,

$$\begin{aligned} I(\mathbf{x}_i, \boldsymbol{\epsilon}_i) - I(\mathbf{y}_i, \tilde{\boldsymbol{\epsilon}}_i) &= H(\mathbf{x}_i) + H(\boldsymbol{\epsilon}_i) - H(\mathbf{x}_i, \boldsymbol{\epsilon}_i) - H(\mathbf{y}_i) - H(\tilde{\boldsymbol{\epsilon}}_i) + H(\mathbf{y}_i, \tilde{\boldsymbol{\epsilon}}_i) \\ &= H(\mathbf{x}_i) + H(\boldsymbol{\epsilon}_i) - H(\mathbf{y}_i) - H(\tilde{\boldsymbol{\epsilon}}_i)\,. \end{aligned} \tag{15}$$

Furthermore, from the actual causal model assumed we know that $I(\mathbf{x}_i, \boldsymbol{\epsilon}_i) = 0$. By contrast, we have that $I(\mathbf{y}_i, \tilde{\boldsymbol{\epsilon}}_i) \geq 0$, since both $\mathbf{y}_i$ and $\tilde{\boldsymbol{\epsilon}}_i$ depend on $\mathbf{x}_i$ and $\boldsymbol{\epsilon}_i$. We also know that $H(\mathbf{x}_i) = H(\mathbf{y}_i)$ because we have made the hypothesis that both $\mathcal{X}$ and $\mathcal{Y}$ follow the same distribution. The result is that:

$$H(\boldsymbol{\epsilon}_i) \leq H(\tilde{\boldsymbol{\epsilon}}_i)\,, \tag{16}$$

with equality iff the residuals are Gaussian. We note that an alternative but equivalent way to obtain this last result is to consider a multivariate version of Lemma 1 by Kpotufe et al. (2014), under the assumption of the same distribution for the cause and the effect. In particular, even though Kpotufe et al. (2014) assume univariate random variables, their work can be easily generalized to multiple variables.

Although the random variables corresponding to $\boldsymbol{\epsilon}_i$ and $\tilde{\boldsymbol{\epsilon}}_i$ have both zero mean, they need not have the same covariance matrix. Denote with $\text{Cov}(\boldsymbol{\epsilon}_i)$ and $\text{Cov}(\tilde{\boldsymbol{\epsilon}}_i)$ to these matrices and let $\hat{\boldsymbol{\epsilon}}_i$ and $\hat{\tilde{\boldsymbol{\epsilon}}}_i$ be the whitened residuals (*i.e.*, the residuals multiplied by the Cholesky factor of the inverse of the corresponding covariance matrix). Then,

$$H(\hat{\boldsymbol{\epsilon}}_i) \leq H(\hat{\tilde{\boldsymbol{\epsilon}}}_i) - \frac{1}{2}\log|\text{detCov}(\tilde{\boldsymbol{\epsilon}}_i)| + \frac{1}{2}\log|\text{detCov}(\boldsymbol{\epsilon}_i)|\,. \tag{17}$$

As shown in Appendix A, although not equal, the matrices $\text{Cov}(\boldsymbol{\epsilon}_i)$ and $\text{Cov}(\tilde{\boldsymbol{\epsilon}}_i)$ have the same determinant. Thus, the two determinants cancel in the equation above. This gives,

$$H(\hat{\boldsymbol{\epsilon}}_i) \leq H(\hat{\tilde{\boldsymbol{\epsilon}}}_i)\,. \tag{18}$$

The consequence is that the entropy of the whitened residuals in the anti-causal direction is expected to be higher or equal than the entropy of the whitened residuals in the causal direction. Because the Gaussian distribution is the continuous distribution with the highest entropy for a fixed covariance matrix, we conclude that the level of Gaussianity of the residuals in the anti-causal direction, measured in terms of differential entropy, has to be larger or equal to the level of Gaussianity of the residuals in the causal direction.

In summary, if the causal relation between the two identically distributed random variables $\mathcal{X}$ and $\mathcal{Y}$ is linear the residuals of a least squares fit in the anti-causal direction are more Gaussian than those of a linear fit in the causal direction. This Gaussianization can be characterized by a reduction of the magnitude of the corresponding high-order cumulants (although we have not formally proved this, we have provided some evidence that this is the case) and by an increase of the entropy (we have proved this in this section). A causal inference method can take advantage of this asymmetry to determine the causal direction. In particular, statistical tests based on measures of Gaussianity can be used for this purpose. However and importantly, these measures of Gaussianity need not be estimates of the differential entropy or the high-order cumulants. In particular, the entropy is a quantity that is particularly difficult to estimate in practice (Beirlant et al., 1997). The same occurs with the high-order cumulants. Their estimators involve high-order moments, and hence suffer from high variance.

When the distribution of the residuals in (6) is Gaussian, the causal direction cannot be identified. In this case, it is possible to show that the distribution of the reversed residuals $\tilde{\boldsymbol{\epsilon}}_i$, the cause $\mathbf{x}_i$, and the effect $\mathbf{y}_i$, is Gaussian as a consequence of (9) and (11). This non-identifiability agrees with the general result of Shimizu et al. (2006), which indicates that non-Gaussian distributions are strictly required in the disturbance variables to carry out causal inference in linear models with additive independent noise.

Finally, the fact that the Gaussianization effect is also expected in the multivariate case suggests a method to address causal inference problems in which the relationship between cause and effect is non-linear: It consists in mapping each observation x_i and y_i to a vector in an expanded feature space. One can them assume that the non-linear relation in the original input space is linear in the expanded feature space and compute the residuals of kernel ridge regressions in both directions. The direction in which the residuals are less Gaussian is identified as the causal one.

3. A Feature Expansion to Address Non-linear Causal Inference Problems

We now proceed to relax the assumption that the causal relationship between the unidimensional random variables $\mathcal{X}$ and $\mathcal{Y}$ is linear. For this purpose, instead of working in the original space in which the samples $\{(x_i, y_i)\}_{i=1}^N$ are observed, we will assume that the model is linear in some expanded feature space $\{(\phi(x_i), \phi(y_i))\}_{i=1}^N$ for some mapping function $\phi(\cdot) : \mathbb{R} \to \mathbb{R}^d$. Importantly, this map preserves the property that if x_i and y_i are

equally distributed, so will be $\phi(x_i)$ and $\phi(y_i)$. According to the analysis presented in the previous section, the residuals of a linear model in the expanded space should be more Gaussian in the anti-causal direction than the residuals of a linear model in the causal direction, based on an increment of the differential entropy and on a reduction of the magnitude of the cumulants. The assumption we make is that the non-linear relation between $\mathcal{X}$ and $\mathcal{Y}$ in the original input space is linear in the expanded feature space.

In this section we focus on obtaining the normalized residuals of linear models formulated in the expanded feature space. For this purpose, we assume that a kernel function $k(\cdot,\cdot)$ can be used to evaluate dot products in the expanded feature space. In particular, $k(x_i,x_j) = \phi(x_i)^{\mathrm{T}}\phi(x_j)$ and $k(y_i,y_j) = \phi(y_i)^{\mathrm{T}}\phi(y_j)$ for arbitrary x_i and x_j and y_i and y_j. Furthermore, we will not assume in general that $\phi(x_i)$ and $\phi(y_i)$ have been whitened, only centered. Whitening is a linear transformation which is not expected to affect to the level of Gaussianity of the residuals. However, once these residuals have been obtained they will be whitened in the expanded feature space. Later on we describe how to center the data in the expanded feature space. For now on, we will assume this step has already been done.

3.1 Non-linear Model Description and Fitting Process

Assume that the relation between $\mathcal{X}$ and $\mathcal{Y}$ is linear in an expanded feature space

$$\phi(y_i) = \mathbf{A}\phi(x_i) + \boldsymbol{\epsilon}_i\,, \quad \boldsymbol{\epsilon}_i \perp x_i, \tag{19}$$

where $\boldsymbol{\epsilon}_i$ is i.i.d. non-Gaussian additive noise.

Given N paired observations $\{(x_i,y_i)\}_{i=1}^N$ drawn i.i.d. from $P(\mathcal{X},\mathcal{Y})$, define the matrices $\boldsymbol{\Phi}_x = (\phi(x_1),\ldots,\phi(x_N))$ and $\boldsymbol{\Phi}_y = (\phi(y_1),\ldots,\phi(y_N))$ of size $d \times N$. The estimate of $\mathbf{A}$ that minimizes the sum of squared errors is $\hat{\mathbf{A}} = \boldsymbol{\Gamma}\boldsymbol{\Sigma}^{-1}$, where $\boldsymbol{\Gamma} = \boldsymbol{\Phi}_y\boldsymbol{\Phi}_x^{\mathrm{T}}$ and $\boldsymbol{\Sigma} = \boldsymbol{\Phi}_x\boldsymbol{\Phi}_x^{\mathrm{T}}$. Unfortunately, when $d > N$, where d is the number of variables in the feature expansion, the matrix $\boldsymbol{\Sigma}^{-1}$ does not exist and $\hat{\mathbf{A}}$ is not unique. This means that there is an infinite number of solutions for $\hat{\mathbf{A}}$ with zero squared error.

To avoid the indetermination described above and also to alleviate over-fitting, we propose a regularized estimator. Namely,

$$\mathcal{L}(\mathbf{A}) = \sum_{i=1}^{N} \frac{1}{2}||\phi(y_i) - \mathbf{A}\phi(x_i)||_2^2 + \tau\frac{1}{2}||\mathbf{A}||_{\mathcal{F}}^2\,, \tag{20}$$

where $||\cdot||_2$ denotes the ℓ_2-norm and $||\cdot||_{\mathcal{F}}$ denotes the Frobenius norm. In this last expression $\tau > 0$ is a parameter that controls the amount of regularization. The minimizer of (20) is $\hat{\mathbf{A}} = \boldsymbol{\Gamma}\boldsymbol{\Sigma}^{-1}$, where $\boldsymbol{\Gamma} = \boldsymbol{\Phi}_y\boldsymbol{\Phi}_x^{\mathrm{T}}$ and $\boldsymbol{\Sigma} = \tau\mathbf{I} + \boldsymbol{\Phi}_x\boldsymbol{\Phi}_x^{\mathrm{T}}$. The larger the value of τ, the closer the entries of $\hat{\mathbf{A}}$ are to zero. Furthermore, using the matrix inversion lemma we have that $\boldsymbol{\Sigma}^{-1} = \tau^{-1}\mathbf{I} - \tau^{-1}\boldsymbol{\Phi}_x\mathbf{V}^{-1}\boldsymbol{\Phi}_x^{\mathrm{T}}$, where $\mathbf{V} = (\tau\mathbf{I} + \mathbf{K}_{x,x})^{-1}$ and $\mathbf{K}_{x,x} = \boldsymbol{\Phi}_x^{\mathrm{T}}\boldsymbol{\Phi}_x$ is a kernel matrix whose entries are given by $k(x_i,x_j)$. After some algebra it is possible to show that

$$\hat{\mathbf{A}} = \boldsymbol{\Gamma}\boldsymbol{\Sigma}^{-1} = \boldsymbol{\Phi}_y\mathbf{V}\boldsymbol{\Phi}_x^{\mathrm{T}}\,, \tag{21}$$

which depends only on the matrix $\mathbf{V}$. This matrix be computed with cost $\mathcal{O}(N^3)$. We note that the estimate obtained in (21) coincides with the kernel conditional embedding operator described by Song et al. (2013) for mapping conditional distributions into infinite dimensional feature spaces using kernels.

3.2 Obtaining the Matrix of Inner Products of the Residuals

A first step towards obtaining the whitened residuals in feature space (which will be required for the estimation of their level of Gaussianity) is to compute the matrix of inner products of these residuals (kernel matrix). For this, we define $\boldsymbol{\epsilon}_i = \phi(y_i) - \hat{\mathbf{A}}\phi(x_i)$. Thus,

$$\begin{aligned}\boldsymbol{\epsilon}_i^{\mathrm{T}}\boldsymbol{\epsilon}_j &= \left[\phi(y_i) - \hat{\mathbf{A}}\phi(x_i)\right]^{\mathrm{T}}\left[\phi(y_j) - \hat{\mathbf{A}}\phi(x_j)\right] \\ &= \phi(y_i)^{\mathrm{T}}\phi(y_j) - \phi(y_i)^{\mathrm{T}}\hat{\mathbf{A}}\phi(x_j) - \phi(x_i)^{\mathrm{T}}\hat{\mathbf{A}}\phi(y_j) + \phi(x_i)^{\mathrm{T}}\hat{\mathbf{A}}\hat{\mathbf{A}}\phi(x_j)\,,\end{aligned} \tag{22}$$

for two arbitrary residuals $\boldsymbol{\epsilon}_i$ and $\boldsymbol{\epsilon}_j$ in feature space. In general, if we denote with $\mathbf{K}_\epsilon$ to the matrix whose entries are given by $\boldsymbol{\epsilon}_i^{\mathrm{T}}\boldsymbol{\epsilon}_j$ and define $\mathbf{K}_{y,y} = \boldsymbol{\Phi}_y^{\mathrm{T}}\boldsymbol{\Phi}_y$, we have that

$$\mathbf{K}_\epsilon = \mathbf{K}_{y,y} - \mathbf{K}_{y,y}\mathbf{V}\mathbf{K}_{x,x} - \mathbf{K}_{x,x}\mathbf{V}\mathbf{K}_{y,y} + \mathbf{K}_{x,x}\mathbf{V}\mathbf{K}_{y,y}\mathbf{V}\mathbf{K}_{x,x}\,, \tag{23}$$

where we have used the definition of $\hat{\mathbf{A}}$ in (21). This expression only depends on the kernel matrices $\mathbf{K}_{x,x}$ and $\mathbf{K}_{y,y}$ and the matrix $\mathbf{V}$, and can be computed with cost $\mathcal{O}(N^3)$.

3.3 Centering the Input Data and Centering and Whitening the Residuals

An assumption made in Section 2 was that the samples of the random variables $\mathcal{X}$ and $\mathcal{Y}$ are centered, *i.e.*, they have zero mean. In this section we show how to carry out this centering process in feature space. Furthermore, we also show how to center the residuals of the fitting process, which are also whitened. Whitening is a standard procedure in which the data are transformed to have the identity matrix as the covariance matrix. It also corresponds to projecting the data onto all the principal components, and scaling them to have unit standard deviation.

We show how to center the data in feature space. For this, we follow Schölkopf et al. (1997) and work with:

$$\tilde{\phi}(x_i) = \phi(x_i) - \frac{1}{N}\sum_{j=1}^{N}\phi(x_j)\,, \qquad \tilde{\phi}(y_i) = \phi(y_i) - \frac{1}{N}\sum_{j=1}^{N}\phi(y_j)\,. \tag{24}$$

The consequence is that now the kernel matrices $\mathbf{K}_{x,x}$ and $\mathbf{K}_{y,y}$ are replaced by

$$\begin{aligned}\tilde{\mathbf{K}}_{x,x} &= \mathbf{K}_{x,x} - \mathbf{1}_N\mathbf{K}_{x,x} - \mathbf{K}_{x,x}\mathbf{1}_N + \mathbf{1}_N\mathbf{K}_{x,x}\mathbf{1}_N\,, \\ \tilde{\mathbf{K}}_{y,y} &= \mathbf{K}_{y,y} - \mathbf{1}_N\mathbf{K}_{y,y} - \mathbf{K}_{y,y}\mathbf{1}_N + \mathbf{1}_N\mathbf{K}_{y,y}\mathbf{1}_N\,,\end{aligned} \tag{25}$$

where $\mathbf{1}_N$ is a $N \times N$ matrix with all entries equal to $1/N$. The residuals can be centered also in a similar way. Namely, $\tilde{\mathbf{K}}_\epsilon = \mathbf{K}_\epsilon - \mathbf{1}_N\mathbf{K}_\epsilon - \mathbf{K}_\epsilon\mathbf{1}_N + \mathbf{1}_N\mathbf{K}_\epsilon\mathbf{1}_N$.

We now explain the whitening of the residuals, which are now assumed to be centered. This process involves the computation of the eigenvalues and eigenvectors of the $d \times d$ covariance matrix $\mathbf{C}$ of the residuals. This is done as in kernel PCA (Schölkopf et al., 1997). Denote by $\tilde{\boldsymbol{\epsilon}}_i$ to the centered residuals. The covariance matrix is $\mathbf{C} = N^{-1}\sum_{i=1}^{N}\tilde{\boldsymbol{\epsilon}}_i\tilde{\boldsymbol{\epsilon}}_i^{\mathrm{T}}$. The eigenvector expansion implies that $\mathbf{C}\mathbf{v}_i = \lambda_i\mathbf{v}_i$, where $\mathbf{v}_i$ denotes the i-th eigenvector and λ_i the i-th eigenvalue. The consequence is that $N^{-1}\sum_{k=1}^{N}\tilde{\boldsymbol{\epsilon}}_k\tilde{\boldsymbol{\epsilon}}_k^{\mathrm{T}}\mathbf{v}_i = \lambda_i\mathbf{v}_i$. Thus, the eigenvectors can be expressed as a combination of the residuals. Namely, $\mathbf{v}_i = \sum_{j=1}^{N} b_{i,j}\tilde{\boldsymbol{\epsilon}}_j$,

where $b_{i,j} = N^{-1}\tilde{\boldsymbol{\epsilon}}_j^{\mathrm{T}}\mathbf{v}_i$. Substituting this result in the previous equation we have that $N^{-1}\sum_{k=1}^{N}\tilde{\boldsymbol{\epsilon}}_k\tilde{\boldsymbol{\epsilon}}_k^{\mathrm{T}}\sum_{j=1}^{N}b_{i,j}\tilde{\boldsymbol{\epsilon}}_j = \lambda_i\sum_{j=1}^{N}b_{i,j}\tilde{\boldsymbol{\epsilon}}_j$. When we multiply both sides by $\tilde{\boldsymbol{\epsilon}}_l^{\mathrm{T}}$ we obtain $N^{-1}\sum_{k=1}^{N}\tilde{\boldsymbol{\epsilon}}_l^{\mathrm{T}}\tilde{\boldsymbol{\epsilon}}_k\tilde{\boldsymbol{\epsilon}}_k^{\mathrm{T}}\sum_{j=1}^{N}b_{i,j}\tilde{\boldsymbol{\epsilon}}_j = \lambda_i\sum_{j=1}^{N}b_{i,j}\tilde{\boldsymbol{\epsilon}}_l^{\mathrm{T}}\tilde{\boldsymbol{\epsilon}}_j$, for $l = 1, \dots d$, which is written in terms of kernels as $\tilde{\mathbf{K}}_\epsilon\tilde{\mathbf{K}}_\epsilon\mathbf{b}_i = \lambda_i N\tilde{\mathbf{K}}_\epsilon\mathbf{b}_i$, where $\mathbf{b}_i = (b_{i,1}, \dots, b_{i,N})^{\mathrm{T}}$. A solution to this problem is found by solving the eigenvalue problem $\tilde{\mathbf{K}}_\epsilon\mathbf{b}_i = \lambda_i N\mathbf{b}_i$. We also require that the eigenvectors have unit norm. Thus, $1 = \mathbf{v}_i^{\mathrm{T}}\mathbf{v}_i = \sum_{j=1}^{N}\sum_{k=1}^{N}b_{i,j}b_{i,k}\tilde{\boldsymbol{\epsilon}}_j^{\mathrm{T}}\tilde{\boldsymbol{\epsilon}}_k = \mathbf{b}_i^{\mathrm{T}}\tilde{\mathbf{K}}_\epsilon\mathbf{b}_i = \lambda_i N\mathbf{b}_i^{\mathrm{T}}\mathbf{b}_i$, which means that $\mathbf{b}_i$ has norm $1/\sqrt{\lambda_i N}$. Consider now that $\tilde{\mathbf{b}}_i$ is one eigenvector of $\tilde{\mathbf{K}}_\epsilon$. Then, $\mathbf{b}_i = 1/\sqrt{\lambda_i N}\tilde{\mathbf{b}}_i$. Similarly, let $\tilde{\lambda}_i$ be an eigenvalue of $\tilde{\mathbf{K}}_\epsilon$. Then $\lambda_i = \tilde{\lambda}_i/N$. In summary, λ_i and $b_{i,j}$, with $i = 1, \dots, N$ and $j = 1, \dots, N$ can be found with cost $\mathcal{O}(N^3)$ by finding the eigendecomposition of $\tilde{\mathbf{K}}_\epsilon$.

The whitening process is carried out by projecting each residual $\tilde{\boldsymbol{\epsilon}}_k$ onto each eigenvector $\mathbf{v}_i$ and then multiplying by $1/\sqrt{\lambda_i}$. The corresponding i-th component for the k-th residual, denoted by $Z_{k,i}$, is $Z_{k,i} = 1/\sqrt{\lambda_i}\mathbf{v}_i^{\mathrm{T}}\tilde{\boldsymbol{\epsilon}}_k = 1/\sqrt{\lambda_i}\sum_{j=1}^{N}b_{i,j}\tilde{\boldsymbol{\epsilon}}_j^{\mathrm{T}}\tilde{\boldsymbol{\epsilon}}_k$, and in consequence, the whitened residuals are $\mathbf{Z} = \tilde{\mathbf{K}}_\epsilon\mathbf{B}\mathbf{D} = N\mathbf{B}\mathbf{D}^{-1} = \sqrt{N}\tilde{\mathbf{B}}$, where $\mathbf{B}$ is a matrix whose columns contain each $\mathbf{b}_i$, $\tilde{\mathbf{B}}$ is a matrix whose columns contain each $\tilde{b}_i$ and $\mathbf{D}$ is a diagonal matrix whose entries are equal to $1/\sqrt{\lambda_i}$. Each row of $\mathbf{Z}$ now contains the whitened residuals.

3.4 Inferring the Most Likely Causal Direction

After having trained the model and obtained the matrix of whitened residuals $\mathbf{Z}$ in each direction, a suitable Gaussianity test can be used to determine the correct causal relation between the variables $\mathcal{X}$ and $\mathcal{Y}$. Given the theoretical results of Section 2 one may be tempted to use tests based on entropy or cumulants estimation. Such tests may perform poorly in practice due to the difficulty of estimating high-order cumulants or differential entropy. In particular, the estimators of the cumulants involve high-order moments and hence, suffer from high variance. As a consequence, in our experiments we use a statistical test for Gaussianity based on the *energy distance* (Székely and Rizzo, 2005), which has good power, is robust to noise, and does not have any adjustable hyper-parameters. Furthermore, in Appendix B we motivate that in the anti-causal direction one should also expect a smaller energy distance to the Gaussian distribution.

Assume $\mathcal{X}$ and $\mathcal{Y}$ are two independent random variables whose probability distribution functions are $F(\cdot)$ and $G(\cdot)$. The energy distance between these distributions is defined as

$$D^2(F, G) = 2\mathbb{E}[||\mathcal{X} - \mathcal{Y}||] - \mathbb{E}[||\mathcal{X} - \mathcal{X}'||] - \mathbb{E}[||\mathcal{Y} - \mathcal{Y}'||]\,, \tag{26}$$

where $||\cdot||$ denotes some norm, typically the ℓ_2-norm; $\mathcal{X}$ and $\mathcal{X}'$ are independent and identically distributed (i.i.d.); $\mathcal{Y}$ and $\mathcal{Y}'$ are i.i.d; and $\mathbb{E}$ denotes expected value. The energy distance satisfies all axioms of a metric and hence characterizes the equality of distributions. Namely, $D^2(F, G) = 0$ if and only if $F = G$. Furthermore, in the case of univariate random variables the energy distance is twice the Cramér-von Mises distance given by $\int (F(x) - G(x))^2\, dx$.

Assume $\mathbf{X} = (\mathbf{x}_1, \dots, \mathbf{x}_N)^{\mathrm{T}}$ is a matrix that contains N random samples (one per each row of the matrix) from a d dimensional random variable with probability density f. The statistic described for testing for Gaussianity, *i.e.*, $\mathrm{H}_0 : f = \mathcal{N}(\cdot|\mathbf{0}, \mathbf{I})$ vs $\mathrm{H}_1 : f \neq \mathcal{N}(\cdot|\mathbf{0}, \mathbf{I})$,

that is described by Székely and Rizzo (2005) is:

$$\mathrm{Energy}(\mathbf{X}) = N\left(\frac{2}{N}\sum_{j=1}^{N}\mathbb{E}[||\mathbf{x}_j - \mathcal{Y}||] - \mathbb{E}[||\mathcal{Y} - \mathcal{Y}'||] - \frac{1}{N^2}\sum_{j,k=1}^{N}||\mathbf{x}_j - \mathbf{x}_k||\right), \tag{27}$$

where $\mathcal{Y}$ and $\mathcal{Y}'$ are independent random variables distributed as $\mathcal{N}(\cdot|\mathbf{0}, \mathbf{I})$ and $\mathbb{E}$ denotes expected value. Furthermore, the required expectations with respect to the Gaussian random variables $\mathcal{Y}$ and $\mathcal{Y}'$ can be efficiently computed as described by Székely and Rizzo (2005). The idea is that if f is similar to a Gaussian density $\mathcal{N}(\cdot|0, \mathbf{I})$, then $\mathrm{Energy}(\mathbf{X})$ is close to zero. Conversely, the null hypothesis H_0 is rejected for large values of $\mathrm{Energy}(\mathbf{X})$.

The data to test for Gaussianity is in our case $\mathbf{Z}$, *i.e.*, the matrix of whitened residuals, which has size $N \times N$. Thus, the whitened residuals have N dimensions. The direct introduction of these residuals into a statistical test for Gaussianity is not expected to provide meaningful results, as a consequence of the high dimensionality. Furthermore, in our experiments we have observed that it is often the case that a large part of the total variance is explained by the first principal component (see the supplementary material for evidence supporting this). That is, λ_i, *i.e.*, the eigenvalue associated to the i-th principal component, is almost negligible for $i \geq 2$. Additionally, we motivate in Appendix C that one should also obtain more Gaussian residuals, after projecting the data onto the first principal component, in terms of a reduction of the magnitude of the high-order cumulants. Thus, in practice, we consider only the first principal component of the estimated residuals in feature space. This is the component i with the largest associated eigenvalue λ_i. We denote such N-dimensional vector by $\mathbf{z}$.

Let $\mathbf{z}_{x\to y}$ be the vector of coefficients of the first principal component of the residuals in feature space when the linear fit is performed in the direction $\mathcal{X} \to \mathcal{Y}$. Let $\mathbf{z}_{y\to x}$ be the vector of coefficients of the first principal component of the residuals in feature space when the linear fit is carried out in the direction $\mathcal{Y} \to \mathcal{X}$. We define the measure of Gaussianization of the residuals as $\mathcal{G} = \mathrm{Energy}(\mathbf{z}_{x\to y})/N - \mathrm{Energy}(\mathbf{z}_{y\to x})/N$, where $\mathrm{Energy}(\cdot)$ computes the statistic of the energy distance test for Gaussianity described above. Note that we divide each statistic by N to cancel the corresponding factor that is considered in (27). Since in this test larger values for the statistic corresponds to larger deviations from Gaussianity, if $\mathcal{G} > 0$ the direction $\mathcal{X} \to \mathcal{Y}$ is expected to be more likely the causal direction. Otherwise, the direction $\mathcal{Y} \to \mathcal{X}$ is preferred.

The variance of $\mathcal{G}$ will depend on the sample size N. Thus, ideally one should use the difference between the p-values associated to each statistic as the confidence in the decision taken. Unfortunately, computing these p-values is expensive since the distribution of the statistic under the null hypothesis must be approximated via random sampling. In our experiments we measure the confidence of the decision in terms of the absolute value of $\mathcal{G}$, which is faster to obtain and we have found to perform well in practice.

3.5 Parameter Tuning and Error Evaluation

Assume that a squared exponential kernel is employed in the method described above. This means that $k(x_i, x_j) = \exp\left(-\gamma(x_i - x_j)^2\right)$, where $\gamma > 0$ is the bandwidth of the kernel. The same is assumed for $k(y_i, y_j)$. Therefore, two hyper-parameters require adjustment

in the method described. These are the ridge regression regularization parameter τ and the kernel bandwidth γ. They must be tuned in some way to produce the best possible fit in each direction. The method chosen to guarantee this is a grid search guided by a 10-fold cross-validation procedure, which requires computing the squared prediction error over unseen data. In this section we detail how to evaluate these errors.

Assume that M new paired data instances are available for validation. Let the two matrices $\mathbf{\Phi}_{y^{\text{new}}} = (\phi(y_1^{\text{new}}), \ldots, \phi(y_M^{\text{new}}))$ and $\mathbf{\Phi}_{x^{\text{new}}} = (\phi(x_1^{\text{new}}), \ldots, \phi(x_M^{\text{new}}))$ summarize these data. Define $\boldsymbol{\epsilon}_i^{\text{new}} = \phi(y_i^{\text{new}}) - \hat{\mathbf{A}}\phi(x_i^{\text{new}})$. After some algebra, it is possible to show that the sum of squared errors for the new instances is:

$$E = \sum_{i=1}^{M} (\boldsymbol{\epsilon}_i^{\text{new}})^{\text{T}} \boldsymbol{\epsilon}_i^{\text{new}} = \text{trace}\Big(\mathbf{K}_{y^{\text{new}},y^{\text{new}}} - \mathbf{K}_{y^{\text{new}},y}\mathbf{V}\mathbf{K}_{x^{\text{new}},x}^{\text{T}} - \mathbf{K}_{x^{\text{new}},x}\mathbf{V}\mathbf{K}_{y^{\text{new}},y}^{\text{T}} + \mathbf{K}_{x^{\text{new}},x}\mathbf{V}\mathbf{K}_{y,y}\mathbf{V}\mathbf{K}_{x^{\text{new}},x}^{\text{T}} \Big) . \quad (28)$$

where $\mathbf{K}_{y^{\text{new}},y^{\text{new}}} = \mathbf{\Phi}_{y^{\text{new}}}^{\text{T}}\mathbf{\Phi}_{y^{\text{new}}}$, $\mathbf{K}_{y^{\text{new}},y} = \mathbf{\Phi}_{y^{\text{new}}}^{\text{T}}\mathbf{\Phi}_{y}$ and $\mathbf{K}_{x,x^{\text{new}}} = \mathbf{\Phi}_{x}^{\text{T}}\mathbf{\Phi}_{x^{\text{new}}}$.

Of course, the new data must be centered before computing the error estimate. This process is similar to the one described in the previous section. In particular, centering can be simply carried out by working with the modified kernel matrices:

$$\begin{aligned}
\tilde{\mathbf{K}}_{x^{\text{new}},x} &= \mathbf{K}_{x^{\text{new}},x} - \mathbf{M}_N\mathbf{K}_{x,x} - \mathbf{K}_{x^{\text{new}},x}\mathbf{1}_N + \mathbf{M}_N\mathbf{K}_{x,x}\mathbf{1}_N \,, \\
\tilde{\mathbf{K}}_{y^{\text{new}},y} &= \mathbf{K}_{y^{\text{new}},y} - \mathbf{M}_N\mathbf{K}_{y,y} - \mathbf{K}_{y^{\text{new}},y}\mathbf{1}_N + \mathbf{M}_N\mathbf{K}_{y,y}\mathbf{1}_N \,, \\
\tilde{\mathbf{K}}_{y^{\text{new}},y^{\text{new}}} &= \mathbf{K}_{y^{\text{new}},y^{\text{new}}} - \mathbf{M}_N\mathbf{K}_{y,y^{\text{new}}} - \mathbf{K}_{y^{\text{new}},y}\mathbf{M}_N^{\text{T}} + \mathbf{M}_N\mathbf{K}_{y,y}\mathbf{M}_N^{\text{T}} \,, \quad (29)
\end{aligned}$$

where $\mathbf{M}_N$ is a matrix of size $M \times N$ with all components equal to $1/N$. In this process, the averages employed for the centering step are computed using only the observed data.

A disadvantage of the squared error is that it strongly depends on the kernel bandwidth parameter γ. This makes it difficult to choose this hyper-parameter in terms of such a performance measure. A better approach is to choose both γ and τ in terms of the explained variance by the model. This is obtained as follows: Explained-Variance $= 1 - \text{E}/M\text{Var}_{\text{ynew}}$, where E denotes the squared prediction error and Var_{ynew} the variance of the targets. The computation of the error E is done as described previously and Var_{ynew} is simply the average of the diagonal entries in $\tilde{\mathbf{K}}_{y^{\text{new}},y^{\text{new}}}$.

3.6 Finding Pre-images for Illustrative Purposes

The kernel method described above expresses its solution as feature maps of the original data points. Since the feature map $\phi(\cdot)$ is usually non-linear, we cannot guarantee the existence of a pre-image under $\phi(\cdot)$. That is, a point y such that $\phi(y) = \hat{\mathbf{A}}\phi(x)$, for some input point x. An alternative to amend this issue is to find approximate pre-images, which can be useful to make predictions or plotting results (Schölkopf and Smola, 2002). In this section we describe how to find this approximate pre-images.

Assume that we have a new data instance x_{new} for which we would like to know the associated target value y_{new}, after our kernel model has been fitted. The predicted value in

feature space is:

$$\phi(y_{\text{new}}) = \mathbf{\Phi}_y\mathbf{V}\mathbf{\Phi}_x^{\text{T}}\phi(x_{\text{new}}) = \mathbf{\Phi}_y\mathbf{V}\mathbf{k}_{x,x_{\text{new}}} = \sum_{i=1}^{n} \alpha_i\phi(y_i) \,, \quad (30)$$

where $\mathbf{k}_{x,x_{\text{new}}}$ contains the kernel evaluations between each entry in $\mathbf{x}$ (*i.e.*, the observed samples of the random variable $\mathcal{X}$) and the new instance. Finally, each α_i is given by a component of the vector $\mathbf{V}\mathbf{k}_{x,x_{\text{new}}}$. The approximate pre-image of $\phi(y_{\text{new}})$, y_{new}, is found by solving the following optimization problem:

$$y_{\text{new}} = \arg\min_u \; ||\phi(y_{\text{new}}) - \phi(u)||_2^2 = \arg\min_u \; -2\boldsymbol{\alpha}^{\text{T}}\mathbf{k}_{y,u} + k(u,u) \,, \quad (31)$$

where $\mathbf{k}_{y,u}$ is a vector with the kernel values between each y_i and u, and $k(u,u) = \phi(u)^{\text{T}}\phi(u)$. This is a non-linear optimization problem than can be solved approximately using standard techniques such as gradient descent. In particular, the computation of the gradient of $\mathbf{k}_{y,u}$ with respect to u is very simple in the case of the squared exponential kernel.

4. Data Transformation and Detailed Causal Inference Algorithm

The method for causal inference described in the previous section relies on the fact that both random variables $\mathcal{X}$ and $\mathcal{Y}$ are equally distributed. In particular, if this is the case, $\phi(x_i)$ and $\phi(y_i)$, *i.e.*, the maps of x_i and y_i in the expanded feature space, will also be equally distributed. This means that under such circumstances one should expect residuals that are more Gaussian in the anti-causal direction due to a reduction of the magnitude of the high order cumulants and an increment of the differential entropy. The requirement that $\mathcal{X}$ and $\mathcal{Y}$ are equally distributed can be easily fulfilled in the case of continuous univariate data by transforming $\mathbf{x}$, the samples of $\mathcal{X}$, to have the same empirical distribution as $\mathbf{y}$, the samples of $\mathcal{Y}$.

Consider $\mathbf{x} = (x_1, \ldots, x_N)^{\text{T}}$ and $\mathbf{y} = (y_1, \ldots, y_N)^{\text{T}}$ to be N paired samples of $\mathcal{X}$ and $\mathcal{Y}$, respectively. To guarantee the same distribution for these samples we only have to replace $\mathbf{x}$ by $\tilde{\mathbf{x}}$, where each component of $\tilde{\mathbf{x}}$, $\tilde{x}_i$, is given by $\tilde{x}_i = \hat{F}_y^{-1}(\hat{F}_x(x_i))$, with $\hat{F}_y^{-1}(\cdot)$ the empirical quantile distribution function of the random variable $\mathcal{Y}$, estimated using $\mathbf{y}$. Similarly, $\hat{F}_x(\cdot)$ is the empirical cumulative distribution function of $\mathcal{X}$, estimated using $\mathbf{x}$. This operation is known as the probability integral transform.

One may wonder why should $\mathbf{x}$ be transformed instead of $\mathbf{y}$. The reason is that by transforming $\mathbf{x}$ the additive noise hypothesis made in (1) and (6) is preserved. In particular, we have that $y_i = f(\hat{F}_x^{-1}(\hat{F}_y(\tilde{x}_i))) + \epsilon_i$. On the other hand, if $\mathbf{y}$ is transformed instead, the additive noise model will generally not be valid anymore. More precisely, the transformation that computes $\tilde{\mathbf{y}}$ in such a way that it is distributed as $\mathbf{x}$ is $\tilde{y}_i = \hat{F}_x^{-1}(\hat{F}_y(y_i))$, $\forall i$. Thus, under this transformation we have that $\tilde{y}_i = \hat{F}_x^{-1}(\hat{F}_y(f(x_i) + \epsilon_i))$, which will lead to the violation of the additive noise model.

Of course, transforming $\mathbf{x}$ requires the knowledge of the causal direction. In practice, we will transform both $\mathbf{x}$ and $\mathbf{y}$ and consider that the correct transformation is the one that leads to the highest level of Gaussianization of the residuals in the feature space, after fitting the model in each direction. That is, the transformation that leads to the highest value of $\mathcal{G}$ is expected to be the correct one. We expect that when $\mathbf{y}$ is transformed instead

of $\mathbf{x}$, the Gaussianization effect of the residuals is not as high as when $\mathbf{x}$ is transformed, as a consequence of the violation of the additive noise model. This will allow to determine the causal direction. We do not have a theoretical result confirming this statement, but the good results obtained in Section 6.1 indicate that this is the case.

The details of the complete causal inference algorithm proposed are given in Algorithm 1. Besides a causal direction, *e.g.*, $\mathcal{X} \to \mathcal{Y}$ or $\mathcal{Y} \to \mathcal{X}$, this algorithm also outputs a confidence level in the decision made which is defined as $\max(|\mathcal{G}_{\tilde{x}}|, |\mathcal{G}_{\tilde{y}}|)$, where $\mathcal{G}_{\tilde{x}} = \text{Energy}(\mathbf{z}_{\tilde{x}\to y})/N - \text{Energy}(\mathbf{z}_{y\to\tilde{x}})/N$ denotes the estimated level of Gaussianization of the residuals when $\mathbf{x}$ is transformed to have the same distribution as $\mathbf{y}$. Similarly, $\mathcal{G}_{\tilde{y}} = \text{Energy}(\mathbf{z}_{\tilde{y}\to x})/N - \text{Energy}(\mathbf{z}_{\tilde{y}\to x})/N$ denotes the estimated level of Gaussianization of the residuals when $\mathbf{x}$ and $\mathbf{y}$ are swapped and $\mathbf{y}$ is transformed to have the same distribution as $\mathbf{x}$. Here $\mathbf{z}_{\tilde{x}\to y}$ contains the first principal component of the residuals in the expanded feature space when trying to predict $\mathbf{y}$ using $\tilde{\mathbf{x}}$. The same applies for $\mathbf{z}_{y\to\tilde{x}}$, $\mathbf{z}_{\tilde{y}\to x}$ and $\mathbf{z}_{x\to\tilde{y}}$. However, the residuals are obtained this time when trying to predict $\tilde{\mathbf{x}}$ using $\mathbf{y}$, when trying to predict $\mathbf{x}$ using $\tilde{\mathbf{y}}$ and when trying to predict $\tilde{\mathbf{y}}$ using $\mathbf{x}$, respectively. Recall that the reason for keeping only the first principal component of the residuals is described in Section 3.4.

Assume $|\mathcal{G}_{\tilde{x}}| > |\mathcal{G}_{\tilde{y}}|$. In this case we prefer the transformation of $\mathbf{x}$ to guarantee that the cause and the effect have the same distribution. The reason is that it leads to a higher level of Gaussianization of the residuals, as estimated by the energy statistical test. Now consider that $\mathcal{G}_{\tilde{x}} > 0$. We prefer the direction $\mathcal{X} \to \mathcal{Y}$ because the residuals of a fit in that direction are less Gaussian and hence have a higher value of the statistic of the energy test. By contrast, if $\mathcal{G}_{\tilde{x}} < 0$ we prefer the direction $\mathcal{Y} \to \mathcal{X}$ for the same reason. In the case that $|\mathcal{G}_{\tilde{x}}| < |\mathcal{G}_{\tilde{y}}|$ the reasoning is the same and we prefer the transformation of $\mathbf{y}$. However, because we have swapped $\mathbf{x}$ and $\mathbf{y}$ for computing $\mathcal{G}_{\tilde{y}}$, the decision is the opposite as the previous one. Namely, if $\mathcal{G}_{\tilde{y}} > 0$ we prefer the direction $\mathcal{Y} \to \mathcal{X}$ and otherwise we prefer the direction $\mathcal{X} \to \mathcal{Y}$. The confidence in the decision (*i.e.*, the estimated level of Gaussianization) is always measured by $\max(|\mathcal{G}_{\tilde{x}}|, |\mathcal{G}_{\tilde{y}}|)$.

The algorithm uses a squared exponential kernel with bandwidth parameter γ and the actual matrices $\hat{\mathbf{A}}_{\tilde{x}\to y}$ and $\hat{\mathbf{A}}_{y\to\tilde{x}}$, of potentially infinite dimensions, need not be evaluated in closed form in practice. As indicated in Section 3, all computations are carried out efficiently with cost $\mathcal{O}(N^3)$ using inner products, which are evaluated in terms of the corresponding kernel function. All hyper-parameters, *i.e.*, τ and γ, are chosen using a grid search method guided by a 10-fold cross-validation process. This search maximizes the explained variance of the left-out data and 10 potential values are considered for both τ and γ.

5. Related Work

The Gaussianity of residuals was first employed for causal inference by Hernández-Lobato et al. (2011). These authors analyze auto-regressive (AR) processes and show that a similar asymmetry as the one described in this paper can be used to determine the temporal direction of a time series in the presence of non-Gaussian noise. Namely, when fitting an AR process to a reversed time series, the residuals obtained follow a distribution that is closer to a Gaussian distribution. Nevertheless, unlike the work described here, the method proposed by Hernández-Lobato et al. (2011) cannot be used to tackle multidimensional or non-linear causal inference problems. In their work, Hernández-Lobato et al. (2011) show

Algorithm 1: Causal Inference Based on the Gaussianity of the Residuals (GR-AN)

Data: Paired samples $\mathbf{x}$ and $\mathbf{y}$ from the random variables $\mathcal{X}$ and $\mathcal{Y}$.
Result: An estimated causal direction alongside with a confidence level.

1 Standardize $\mathbf{x}$ and $\mathbf{y}$ to have zero mean and unit variance;
2 Transform $\mathbf{x}$ to compute $\tilde{\mathbf{x}}$; `// This guarantees that` $\tilde{\mathbf{x}}$ `is distributed as` $\mathbf{y}$.
3 $\hat{\mathbf{A}}_{\tilde{x}\to y} \leftarrow \text{FitModel}(\tilde{\mathbf{x}}, \mathbf{y})$; `// This also finds the hyper-parameters` τ `and` γ.
4 $\mathbf{z}_{\tilde{x}\to y} \leftarrow \text{ObtainResiduals}(\tilde{\mathbf{x}}, \mathbf{y}, \hat{\mathbf{A}}_{\tilde{x}\to y})$; `// First PCA component in feature space.`
5 $\hat{\mathbf{A}}_{y\to\tilde{x}} \leftarrow \text{FitModel}(\mathbf{y}, \tilde{\mathbf{x}})$; `// Fit the model in the other direction`
6 $\mathbf{z}_{y\to\tilde{x}} \leftarrow \text{ObtainResiduals}(\mathbf{y}, \tilde{\mathbf{x}}, \hat{\mathbf{A}}_{y\to\tilde{x}})$; `// First PCA component in feature space.`
7 $\mathcal{G}_{\tilde{x}} \leftarrow \text{Energy}(\mathbf{z}_{\tilde{x}\to y})/N - \text{Energy}(\mathbf{z}_{y\to\tilde{x}})/N$; `// Get the Gaussianization level.`
8 Swap $\mathbf{x}$ and $\mathbf{y}$ and repeat lines 2-7 of the algorithm to compute $\mathcal{G}_{\tilde{y}}$.

some advantages of using statistical tests based on measures of Gaussianity to determine the temporal direction of a time series, as a practical alternative to statistical tests based on the independence of the cause and the residual. The motivation for these advantages is that the former tests are one-sample tests while the later ones are two-sample tests.

The previous paper is extended by Morales-Mombiela et al. (2013) to consider multidimensional AR processes. However, this work lacks a theoretical result that guarantees that the residuals obtained when fitting a vectorial AR process in the reversed (anti-chronological) direction will follow a distribution closer to a Gaussian distribution. In spite of this issue, extensive experiments with simulated data suggest the validity of such conjecture. Furthermore, a series of experiments show the superior results of the proposed rule to determine the direction of time, which is based on measures of Gaussianity, and compared with other state-of-the-art methods based on tests of independence.

The problem of causal inference under continuous-valued data has also been analyzed by Shimizu et al. (2006). The authors propose a method called LINGAM that can identify the causal order of several variables when assuming that (a) the data generating process is linear, (b) there are no unobserved co-founders, and (c) the disturbance variables have non-Gaussian distributions with non-zero variances. These assumptions are required because LINGAM relies on the use of Independent Component Analysis (ICA). More specifically, let $\mathbf{x}$ denote a vector that contains the variables we would like to determine the causal

order of. LINGAM assumes that $\mathbf{x} = \mathbf{B}\mathbf{x} + \mathbf{e}$, where $\mathbf{B}$ is a matrix that can be permuted to strict lower triangularity if one knows the actual causal ordering in $\mathbf{x}$, and $\mathbf{e}$ is a vector of non-Gaussian independent disturbance variables. Solving for $\mathbf{x}$, one gets $\mathbf{x} = \mathbf{A}\mathbf{e}$, where $\mathbf{A} = (\mathbf{I} - \mathbf{B})^{-1}$. The $\mathbf{A}$ matrix can be inferred using ICA. Furthermore, given an estimate of $\mathbf{A}$, $\mathbf{B}$ can be obtained to find the corresponding connection strengths among the observed variables, which can then be used to determine the true causal ordering. LINGAM has been extended to consider linear relations among groups of variables (Entner and Hoyer, 2012; Kawahara et al., 2012).

In real-world data, causal relationships tend to be non-linear, a fact that questions the usefulness of linear methods. Hoyer et al. (2009) show that a basic linear framework for causal inference can be generalized to non-linear models. For non-linear models with additive noise, almost any non-linearities (invertible or not) will typically yield identifiable models. In particular, Hoyer et al. (2009) assume that $y_i = f(x_i) + \epsilon_i$, where $f(\cdot)$ is a possibly non-linear function, x_i is the cause variable, and ϵ_i is some independent and random noise. The proposed causal inference mechanism consists in performing a non-linear regression on the data to get an estimate of $f(\cdot)$, $\hat{f}(\cdot)$, and then calculate the corresponding residuals $\hat{\epsilon}_i = y_i - \hat{f}(x_i)$. Then, one may test whether $\hat{\epsilon}_i$ is independent of x_i or not. The same process is repeated in the other direction. The direction with the highest level of independence is chosen as the causal one. In practice, the estimate $\hat{f}(\cdot)$ is obtained using Gaussian processes for regression, and the HSIC test (Gretton et al., 2008) is used as the independence criterion. This method has obtained good performance results (Janzing et al., 2012) and it has been extended to address problems where the model is $y_i = h(f(x_i) + \epsilon_i)$, for some invertible function $h(\cdot)$ (Zhang and Hyvärinen, 2009). A practical difficulty is however that such a model is significantly harder to fit to the data.

In the work by Mooij et al. (2010), a method for causal inference is proposed based on a latent variable model, used to incorporate the effects of un-observed noise. In this context, it is considered that the effect variable is a function of the cause variable and an independent noise term, not necessarily additive, that is, $y_i = f(x_i, \epsilon_i)$, where x_i is the cause variable and ϵ_i is some independent and random noise. The causal direction is then inferred using standard Bayesian model selection. In particular, the preferred direction is the one under which the corresponding model has the largest marginal likelihood, where the marginal likelihood is understood as a proxy for the Kolmogorov complexity. This method suffers from several implementation difficulties, including the intractability of the marginal likelihood computation. However, it has shown encouraging results on synthetic and real-world data.

Janzing et al. (2010) consider the problem of inferring linear causal relations among multi-dimensional variables. The key point here is to use an asymmetry between the distributions of the cause and the effect that occurs if the covariance matrix of the cause and the matrix mapping the cause to the effect are independently chosen. This method exhibits the nice property that applies to both deterministic and stochastic causal relations, provided that the dimensionality of the involved random variables is sufficiently high. The method assumes that $\mathbf{y}_i = \mathbf{A}\mathbf{x}_i + \boldsymbol{\epsilon}_i$, where $\mathbf{x}_i$ is the cause and $\boldsymbol{\epsilon}_i$ is additive noise. Namely, denote with $\hat{\boldsymbol{\Sigma}}$ to the empirical covariance matrix of the variables in each $\mathbf{x}_i$. Given an estimate of $\mathbf{A}$, $\hat{\mathbf{A}}$, the method computes $\boldsymbol{\Delta}_{\mathbf{x}\to\mathbf{y}} = \log\text{trace}(\hat{\mathbf{A}}\hat{\boldsymbol{\Sigma}}\hat{\mathbf{A}}^{\mathrm{T}}) - \log\text{trace}(\hat{\boldsymbol{\Sigma}}) + \log\text{trace}(\hat{\mathbf{A}}\hat{\mathbf{A}}^{\mathrm{T}}) + d$, where d is the dimension of $\mathbf{x}_i$. This process is repeated to compute $\boldsymbol{\Delta}_{\mathbf{y}\to\mathbf{x}}$ where $\mathbf{x}_i$ and

$\mathbf{y}_i$ are swapped. The asymmetry described states that $\boldsymbol{\Delta}_{\mathbf{x}\to\mathbf{y}}$ should be close to zero while $\boldsymbol{\Delta}_{\mathbf{y}\to\mathbf{x}}$ should not. Thus, if $|\boldsymbol{\Delta}_{\mathbf{x}\to\mathbf{y}}| > |\boldsymbol{\Delta}_{\mathbf{y}\to\mathbf{x}}|$, $\mathbf{x}_i$ is expected to be the cause. Otherwise, the variables in $\mathbf{y}_i$ are predicted to be cause instead. Finally, a kernelized version of this method is also described by Chen et al. (2013).

Most of the methods introduced in this section assume some form of noise in the generative process of the effect. Thus, their use is not justified in the case of noiseless data. Janzing et al. (2012) describe a method to deal with these situations. In particular, the method makes use of information geometry to identify an asymmetry that can be used for causal inference. The asymmetry relies on the idea that the marginal distribution of the cause variable, denoted by $p(x)$, is expected to be chosen independently from the mapping mechanism producing the effect variable, denoted by the conditional distribution $p(y|x)$. Independence is defined here as orthogonality in the information space, which allows to describe a dependence that occurs between $p(y)$ and $p(x|y)$ in the anti-causal direction. This dependence can be then used to determine the causal order. A nice property of this method is that this asymmetry between the cause and the effect becomes very simple if both random variables are deterministically related. Remarkably, the method also performs very well in noisy scenarios, although no theoretical guarantees are provided in this case.

A similar method for causal inference to the last one is described by Chen et al. (2014). These authors also consider that $p(x)$ and $p(y|x)$ fulfill some sort of independence condition, and that this independence condition does not hold for the anti-causal direction. Based on this, they define an uncorrelatedness criterion between $p(x)$ and $p(y|x)$, and show an asymmetry between the cause and the effect in terms of a certain complexity metric on $p(x)$ and $p(y|x)$, which is less than the same complexity metric on $p(y)$ and $p(x|y)$. The complexity metric is calculated in terms of a reproducing kernel Hilbert space embedding (EMD) of probability distributions. Based on the complexity metric, the authors propose an efficient kernel-based algorithm for causal discovery.

In Section 2.3 we have shown that in the multivariate case one should expect higher entropies in the anti-causal direction. Similar results have been obtained in the case of non-linear relations and the univariate data case (Hyvärinen and Smith, 2013; Kpotufe et al., 2014). Assume $x, y \in \mathbb{R}$ and the actual causal model to be $y = f(x) + d$, with $x \perp d$ and $f(\cdot)$ an arbitrary function. Let e be the residual of a fit performed in the anti-causal direction. Section 5.2 of the work by Hyvärinen and Smith (2013) shows that the likelihood ratio R of each model (*i.e.*, the model fitted in the causal direction and the model fitted in the anti-causal direction) converges in the presence of infinite data to the difference between the sum of the entropies of the independent variable and the residual in each direction. Namely, $R \to -H(x) - H(d/\sigma_d) + H(y) + H(e/\sigma_e) + \log\sigma_d - \log\sigma_e$, where σ_d and σ_e denote the standard deviation of the errors in each direction. If $R > 0$, the causal direction is chosen. By contrast, if $R < 0$ the anti-causal direction is preferred. The process of evaluating R involves the estimation of the entropies of four univariate random variables, *i.e.*, x, d, y and e and the standard deviation of the errors d and e, which need not be equal. The non-linear functions are estimated as in the work by Hoyer et al. (2009) using a Gaussian process. The entropies are obtained using a maximum entropy approximation under the hypothesis that the distributions of these variables are not far from Gaussian (Hyvärinen, 1998). The resulting method is called non-linear maximum entropy (NLME). A practical difficulty is however that the estimation of the entropy is a very difficult task,

even in one dimension (Beirlant et al., 1997). Thus, the NLME method is adapted in an *ad-hoc* manner with the aim of obtaining better results in certain difficult situations with sparse residuals. More precisely, if $H(x)$ and $H(y)$ are ignored and Laplacian residuals are assumed $R \rightarrow \log \sigma_e - \log \sigma_d$. That is, the model with the minimum error is preferred. The errors are estimated however in terms of the absolute deviations (because of the Laplacian assumption). This method is called mean absolute deviation (MAD). Finally, Kpotufe et al. (2014) show the consistency of the noise additive model, give a formal proof for $R \geq 0$ (see Lemma 1), and propose to estimate $H(x)$, $H(y)$, $H(d)$ and $H(e)$ using kernel density estimators. Note that if x and y are equally distributed, $H(x) = H(y)$ and the condition $R \geq 0$ implies $H(e) \geq H(d)$. Nevertheless, σ_d and σ_e are in general different (see the supplementary material for an illustrative example). This means that in the approach of Hyvärinen and Smith (2013) and Kpotufe et al. (2014) it is not possible to make a decision directly on the basis of a Gaussianization effect on the residuals.

The proposed method GR-AN, introduced in Section 4, differs from the approaches described in the previous paragraph in that it does not have to deal with the estimation of four univariate entropies, which can be a particularly difficult task. By contrast, it relies on statistical tests of deviation from Gaussianity to infer the causal direction. Furthermore, the tests employed in our method need not be directly related to entropy estimation. This is particularly the case of the energy test suggested in Section 3.4. Not having to estimate differential entropies is an advantage of our method confirmed by the results that are obtained in the experiments section. In particular, we have empirically observed that that GR-AN performs better than the two methods for causal inference NLME and MAD that have been described in the previous paragraph. GR-AN also performs better than GR-ENT, a method that uses, instead of statistical tests of Gaussianity, a non-parametric estimator of the entropy (Singh et al., 2003).

6. Experiments

We carry out experiments to validate the method proposed in this paper, and empirically verify that the model residuals in the anti-causal direction are more Gaussian that the model residuals in the causal direction due to a reduction of the high-order cumulants and an increment of the differential entropy. From now on, we refer to our method as GR-AN (Gaussianity of the Residuals under Additive Noise). Furthermore, we compare the performance of GR-AN with four other approaches from the literature on causal inference, reviewed in Section 5. First, LINGAM (Shimizu et al., 2006), a method which assumes an additive noise model, but looks for independence between the cause and the residuals. Second, IR-AN (Independence of the Residuals under Additive Noise), by Hoyer et al. (2009). Third, a method based on information geometry, IGCI (Janzing et al., 2012). Fourth, a method based on Reproducing Kernel Hilbert Space Embeddings (EMD) of probability distributions (Chen et al., 2014). Fifth, the two methods for non-linear causal inference based on entropy estimation described by Hyvärinen and Smith (2013), NLME and MAD. Sixth, the same GR-AN method, but where we omit the transformation to guarantee that the random variables $\mathcal{X}$ and $\mathcal{Y}$ are equally distributed. This method is called GR-AN*. Last, we also compare results with two variants of GR-AN that are not based on the energy distance to measure the level of Gaussianity of the residuals. These are GR-K4, which uses

the empirical estimate of the fourth cumulant (kurtosis) to determine the causal direction (it chooses the direction with the largest estimated fourth cumulant); and GR-ENT, which uses a non-parametric estimator of the entropy (Singh et al., 2003) to determine the causal direction (the direction with the smallest entropy is preferred);

The hyper-parameters of the different methods are set as follows. In LINGAM, we use the parameters recommended by the implementation provided by the authors. In IR-AN, NLME and MAD we employ a Gaussian process whose hyper-parameters are found by type-II maximum likelihood. Furthermore, in IR-AN the HSIC test is used to assess independence between the causes and the residuals. In NLME the entropy estimator is the one described by Hyvärinen (1998). In IGCI, we test different normalizations (uniform and Gaussian) and different criteria (entropy or integral) and report the best observed result. In EMD and synthetic data, we follow Chen et al. (2014) to select the hyper-parameters. In EMD and real-world data, we evaluate different hyper-parameters and report the results for the best combination found. In GR-AN, GR-K4 and GR-ENT the hyper-parameters are found via cross-validation, as described in Section 4. The number of neighbors in the entropy estimator of GR-ENT is set to 10, a value that we have observed to give a good trade-off between bias and variance. Finally, in GR-AN, GR-K4, and GR-ENT we transform the data so that both variables are equally distributed, as indicated in Section 4.

The confidence in the decision is computed as indicated by Janzing et al. (2012). More precisely, in LINGAM the confidence is given by the maximum absolute value of the entries in the connection strength matrix $\mathbf{B}$. In IGCI we employ the absolute value of the difference between the corresponding estimates (entropy or integral) in each direction. In IR-AN the confidence level is obtained as the maximum of the two p-values of the HSIC test. In EMD we use the absolute value of the difference between the estimates of the corresponding complexity metric in each direction, as described in (Chen et al., 2014). In NLME and MAD the confidence level is given by the absolute value of the difference between the outputs of the entropy estimators in each direction (Hyvärinen and Smith, 2013). In GR-K4 we use the absolute difference between the estimated fourth cumulants. In GR-ENT we use the absolute difference between the estimates of the entropy. Finally, in GR-AN we follow the details given in Section 4 to estimate the confidence in the decision.

To guarantee the exact reproducibility of the different experiments described in this paper, the source-code for all methods and data sets is available in the public repository `https://bitbucket.org/dhernand/gr_causal_inference`.

6.1 Experiments with Synthetic Data

We carry out a first batch of experiments on synthetic data. In these experiments, we employ the four causal mechanisms that map $\mathcal{X}$ to $\mathcal{Y}$ described by Chen et al. (2014). They involve linear and non-linear functions, and additive and multiplicative noise effects:

- M_1: $y_i = 0.8x_i + \epsilon_i$.
- M_2: $y_i = x_i\epsilon_i$.
- M_3: $y_i = 0.3x_i^3 + \epsilon_i$.
- M_4: $y_i = \text{atan}(x_i)^3 + \epsilon_i$.

The noise ϵ_i can follow four different types of distributions: (i) A generalized Gaussian distribution with shape parameter equal to 10 (an example of a sub-Gaussian distribution); (ii) a Laplace distribution (an example of a super-Gaussian distribution); (iii) a Gaussian distribution; and (iv) a bimodal distribution with density $p(\epsilon_i) = 0.5\mathcal{N}(\epsilon_i|m, s)+0.5\mathcal{N}(\epsilon_i|-m, s)$, where $m = .63$ and $s = .1$. The Laplace distribution and the Gaussian distribution are adjusted to have the same variance as the generalized Gaussian distribution. The bimodal distribution already has the same variance as the generalized Gaussian distribution.

As indicated by Chen et al. (2014), in these experiments, the samples from the cause variable $\mathcal{X}$ are generated from three potential distributions:

- $p_1(x) = \frac{1}{\sqrt{2\pi}} \exp\{-x^2/2\}$.
- $p_2(x) = \frac{1}{2\sqrt{0.5\pi}} \exp\{-(x+1)^2/0.5\} + \frac{1}{2\sqrt{0.5\pi}} \exp\{-(x-1)^2/0.5\}$.
- $p_3(x) = \frac{1}{4\sqrt{0.5\pi}} \exp\{-(x+1.5)^2/0.5\}+\frac{1}{2\sqrt{0.5\pi}} \exp\{-x^2/0.5\}+\frac{1}{4\sqrt{0.5\pi}} \exp\{-(x-1.5)^2/0.5\}$.

These are unimodal, bimodal, and trimodal distributions, respectively.

Figure 5 displays a representative example of the plots of different combinations of distributions and mapping mechanisms when the noise follows a generalized Gaussian distribution with shape parameter equal to 10. The plots for Laplace, Gaussian or bimodal distributed noise look similar to these ones. The assumptions made by proposed method, *i.e.*, GR-AN, are valid in the case of all the causal mechanisms, except for M2, which considers multiplicative noise, and in the case of all cause distributions, p_1, p_2 and p_3. The only type of noise that violates the assumptions made by GR-AN is the case of Gaussian noise. In particular, under Gaussian noise GR-AN cannot infer the causal direction using Gaussianity measures because the actual residuals are already Gaussian.

The average results of each method on 100 repetitions of each potential causal mechanism, distribution for the effect, and noise distribution are displayed in Table 1. The size of each paired samples of $\mathcal{X}$ and $\mathcal{Y}$ is set to 500 in these experiments. We observe that when the assumptions made by the proposed method, GR-AN, are satisfied, it identifies the causal direction on a very high fraction of the 100 repetitions considered. However, when these assumptions are not valid, *e.g.*, in the case of the M2 causal mechanism, which has multiplicative noise, the performance worsens. The same happens when the distribution of the residuals is Gaussian. In these experiments, LINGAM tends to fail when the causal relation is strongly non-linear. This is the case of the causal mechanism M3. LINGAM also has problems when all the independent variables are Gaussian. Furthermore, all methods generally fail in the case of independent Gaussian variables that are linearly related. This corresponds to the causal mechanism M1, the distribution $p_1(x)$ for the cause, and the Gaussian distribution for the noise. The reason for this is that in this particular scenario the causal direction is not identifiable (Shimizu et al., 2006). IGCI and EMD sometimes fail in the case of the causal mechanism M1 and M4. However, they typically correctly identify the causal direction in the case of the mechanism M2, which has non-additive noise, and where the other methods tend to fail. Finally, IR-AN performs slightly better than GR-AN, especially in the case of additive Gaussian noise, where GR-AN is unable to identify the causal direction. MAD provides very bad results for some of the mechanism considered, *i.e.*, M1 and M4. Surprisingly this is the case even for Laplacian additive noise, which is

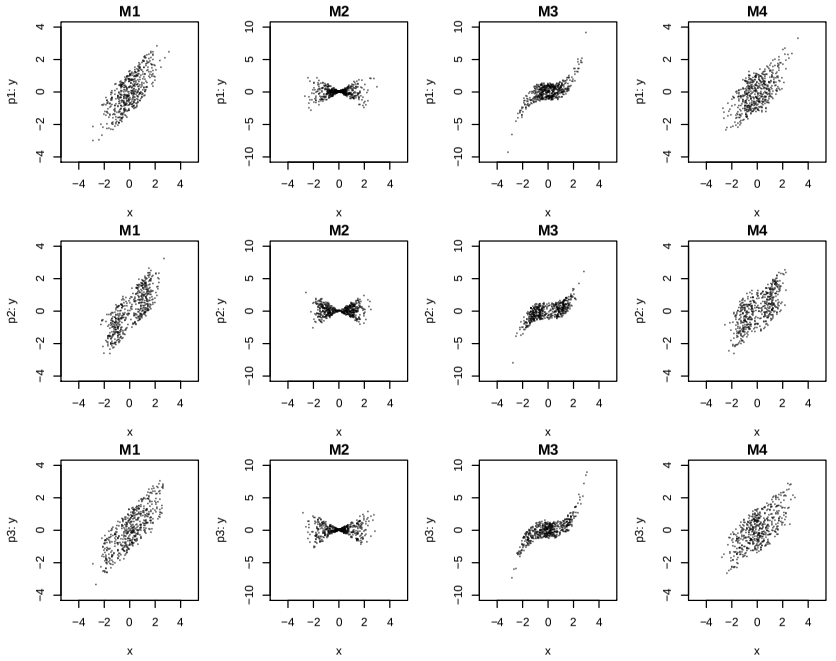

Figure 5: Plots of different distributions and mechanisms when the noise follows a generalized Gaussian distribution with shape parameter equal to 10.

the hypothesis made by MAD. This bad behavior is probably a consequence of ignoring the entropies of $\mathcal{X}$ and $\mathcal{Y}$ in this method. NLME and GR-ENT give worse results than GR-AN in some particular cases, *e.g.*, $p1$ and the causal mechanism M3. We believe this is related to the difficulty of estimating differential entropies in practice. GR-AN* performs very similar to GR-AN. This indicates that in practice one may ignore the transformation that guarantees that $\mathcal{X}$ and $\mathcal{Y}$ are equally distributed. GR-K4 also gives similar results to GR-AN, probably because in these experiments the tails of the residuals are not very heavy.

An overall comparison of the different methods evaluated is shown in Figure 6. This figure displays several radar charts that indicate the average accuracy of each method for the different types of noise considered and for each mechanism M1, M2, M3 and M4. In particular, for a given method and a given type of noise, the radius of each portion of the pie is proportional to the corresponding average accuracy of the method across the distributions p_1, p_2 and p_3 for the cause. The pie at the bottom corresponds to 100% accuracy for each causal mechanism. The conclusions derived from this figure are similar to the ones obtained

from Table 1. In particular, IR-AN performs very well, except for multiplicative noise (M3), closely followed by GR-AN, GR-AN*, and GR-K4, which give similar results. The methods perform very poorly in the case of additive Gaussian noise, since they cannot infer the actual causal direction in that situation. NLME and GR-ENT have problems in the case of the causal mechanism M3 and MAD in the case of the mechanisms M1 and M4. LINGAM also performs bad in the case of M3 and IGCI and EMD have problems in the case of the mechanisms M1 and M4. IGCI, EMD and MAD are the only methods performing well in the case of M2, the mechanism with non-additive noise.

We have repeated these experiments for other samples sizes, *e.g.*, 100, 200 300 and 1000. The results obtained are very similar to the ones reported here, except when the number of samples is small and equal to 100. In that case NLME performs slightly better than the proposed approach GR-AN, probably because with 100 samples it is very difficult to accurately estimate the non-linear transformation that is required to guarantee that $\mathcal{X}$ and $\mathcal{Y}$ are equally distributed. These results of these additional experiments are found in the supplementary material.

In summary, the good results provided by GR-AN and its variants in the experiments described indicate that (i) when the assumptions made by GR-AN are valid, the method has a good performance and (ii) there is indeed a Gaussianization effect in the residuals when the model is fitted under the anti-causal direction. Because GR-AN* also performs well in these experiments, this indicates that a Gaussianization of the residuals may happen even when $\mathcal{X}$ and $\mathcal{Y}$ do not follow the same distribution.

We give further evidence of the Gaussianization of the distribution of the residuals obtained when fitting the model under the anti-causal direction. For this, we analyze in detail three particular cases of GR-AN corresponding to the causal mechanism M3, the distribution $p_2(x)$ for the cause and each of the three types of additive noise considered. Namely, generalized Gaussian noise, Laplacian noise and bimodal noise. Figure 7 shows the predicted pre-images for new data instances when the model has been fitted in the causal ($\tilde{\mathcal{X}} \to \mathcal{Y}$) and the anti-causal ($\mathcal{Y} \to \tilde{\mathcal{X}}$) direction alongside with a histogram of the first principal component of the residuals in feature space. A Gaussian approximation is also displayed as a solid black line on top of the histogram. In this case $\mathbf{x}$, *i.e.*, the samples of $\mathcal{X}$, have been transformed to be equally distributed to $\mathbf{y}$, *i.e.*, the samples from $\mathcal{Y}$. We observe that the distribution of the residuals in the anti-causal direction ($\mathcal{Y} \to \tilde{\mathcal{X}}$) is more similar to a Gaussian distribution. Furthermore, for the direction $\tilde{\mathcal{X}} \to \mathcal{Y}$ the statistic of the energy based Gaussianity test for the first principal component of the residuals is respectively 4.02, 4.64 and 11.46, for generalized Gaussian, Laplacian and bimodal noise. Recall that the larger the value the larger the deviation from Gaussianity. In the case of the direction $\mathcal{Y} \to \tilde{\mathcal{X}}$, the energy statistic associated to the residuals is 0.97, 0.68 and 1.31, respectively. When $\mathbf{y}$ is transformed to have the same distribution as $\mathbf{x}$ similar results are observed (results not shown). However, the Gaussianization effect is not as strong as in this case, probably because it leads to the violation of the addtitive noise assumption. In summary, the figure displayed illustrates in detail the Gaussianization effect of the residuals when fitting the model in the anti-causal direction.

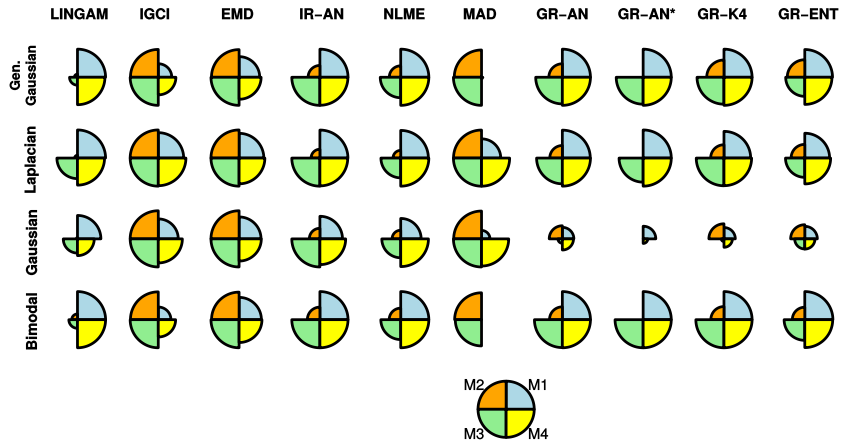

Figure 6: Radar charts showing the average accuracy of each method for the different types of noise considered and for each mechanism M1, M2, M3 and M4. For a particular method and type of noise, the radius of each portion of the pie is proportional to the corresponding average accuracy of the method across the distributions p_1, p_2 and p_3 for the cause. The pie at the bottom corresponds to 100% accuracy for each mechanism.

6.2 Experiments with Real Cause-effect Pairs

A second batch of experiments is performed on the cause-effect pairs from the ChaLearn challenge[2]. This challenge contains 8073 cause-effect data pairs with a labeled causal direction. From these pairs, we consider a subset for our experiments. In particular, we select the 184 pairs that have (i) at least 500 samples, and (ii) a fraction of repeated instances for each random variable of at most 1%. The first criterion guarantees that there is enough data to make a decision with high confidence. The second criterion removes the pairs with discrete random variables, motivated by the transformation required by the GR-AN method to guarantee the equal distribution of $\mathcal{X}$ and $\mathcal{Y}$. In particular, this transformation cannot be carried out on discrete data. Another advantage is that this filtering process of the data facilitates the experiments since several of the methods considered in the comparison (*i.e.*, GR-AN, GR-ENT, GR-K4, IR-AN, NLME, MAD and EMD) are computationally very expensive. More precisely, they have a cubic cost with respect to the number of samples and they require tuning several hyper-parameters. The consequence is that evaluating these methods on the 8073 pairs available is therefore not feasible.

2. See https://www.codalab.org/competitions/1381 for more information.

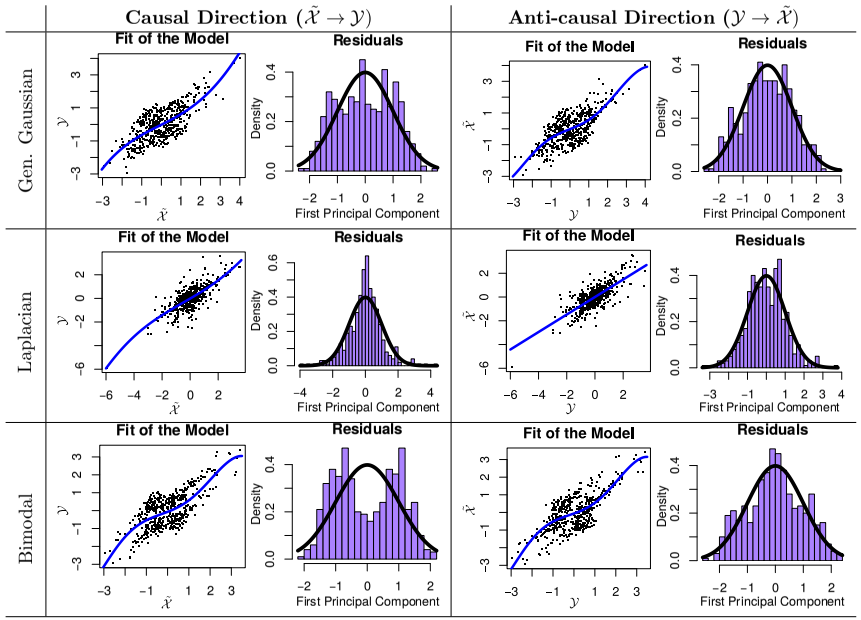

Figure 7: (left column) Predicted pre-images obtained in the casual direction $\tilde{\mathcal{X}} \to \mathcal{Y}$ alongside with a histogram of the first principal component of the residuals in feature space. A Gaussian fit is displayed as a solid black line. Results are shown for each type of additive noise considered. (right column) Same plots for the anti-causal direction $\mathcal{Y} \to \tilde{\mathcal{X}}$.

Using these 184 pairs we evaluate each of the methods considered in the previous section and report the corresponding accuracy as a function of the decisions made. In these experiments we sample at random 500 instances from each cause-effect pair. This is a standard number of samples that has been previously employed by other authors in their experiments with cause-effect pairs (Janzing et al., 2012). Furthermore, a threshold value is fixed and the obtained confidence in the decision by each method is compared to such threshold. Only if the confidence is above the threshold value, the cause-effect pair is considered in the evaluation of the accuracy of the corresponding method. A summary of the results is displayed in Figure 8. This figure shows for each method, as a fraction of the decisions made, the accuracy on the filtered data sets on which the confidence on the decision is above the threshold value. A gray area has been drawn to indicate accuracy values that are not statistically different from random guessing (accuracy equal to 50%) using a bino-

mial test (p-value above 5%). We observe that IR-AN obtains the best results, followed by GR-AN, GR-AN*, GR-K4, GR-ENT, IGCI, NLME and EMD. NLME, IGCI and EMD perform worse than GR-AN and GR-AN* when a high number of decisions are made. The differences in performance between IR-AN and GR-AN, when 100% of the decisions are made, are not statistically significant (a paired t-test returns a p-value equal to 25%). The fact that the performance of GR-AN* is similar to the performance of GR-AN also indicates that there is some Gaussianization of the residuals even though the two random variables $\mathcal{X}$ and $\mathcal{Y}$ are not equally distributed. We observe that the results of LINGAM and MAD are not statistically different from random guessing. This remarks the importance of non-linear models and questions the practical utility of the MAD method. In these experiments, GR-ENT and GR-K4 perform worse than GR-AN, which remarks the benefits of using the energy distance to estimate the deviation from the Gaussian distribution, as a practical alternative to entropy or cumulant based measures.

In summary, the results displayed in Figure 8 confirm that the level of Gaussianity of the residuals, estimated using statistical tests, is a useful metric that can be used to identify the causal order of two random variables. Furthermore, this figure also validates the theoretical results obtained in Section 2 which state that one should expect residuals whose distribution is closer to the Gaussian distribution when performing a fit in the anti-causal direction.

In the supplementary material we include additional results for other sample sizes. Namely, 100, 200 and 300 samples. The results obtained are similar to the ones reported in Figure 8. However, the differences between GR-ENT, NLME, GR-AN and GR-AN* are smaller. Furthermore, when the number of samples is small (*i.e.*, equal to 100) GR-AN performs worse than NLME, probably because with such a small number of samples it is difficult to estimate the non-linear transformation that guarantees that $\mathcal{X}$ and $\mathcal{Y}$ are equality distributed.

In this section we have also evaluated the different methods compared in the previous experiments on a random subset of 184 cause-effect pairs chosen across the 8073 pairs of the ChaLearn challenge (results not shown). In this case, the ranking of the curves obtained looks similar to the ranking displayed in Figure 8, *i.e.*, IR-AN performs best followed by GR-AN, GR-AN*, NLME and EMD. However, all methods obtain worse results in general and none of them, except IR-AN, perform significantly different from random guessing.

Finally, we also have evaluated the different methods in a subset of 82 cause-effect pairs extracted from the Tübingen cause-effect pairs[3]. We only considered those pairs with scalar cause and effect. The results obtained are displayed in Figure 9. In this case, the performance of the different methods is worse than the one displayed in Figure 8. Only IR-AN, IGCI and MAD perform significantly better than random guessing. Furthermore, GR-AN and GR-AN* do not perform well in this set of cause-effect pairs. This is also the case of NLME. We believe that the reason for this bad performance is that in most of these pairs some of the variables take discrete or repeated values. In the case of GR-AN this makes infeasible to transform the two random variables, $\mathcal{X}$ and $\mathcal{Y}$, so that they are equally distributed. Furthermore, the discrete random variables may have a strong impact in the tests for Gaussianity and in the estimation of the differential entropy. This could explain the bad performance of GR-AN*, NLME and GR-ENT.

3. See http://webdav.tuebingen.mpg.de/cause-effect/ for more details.

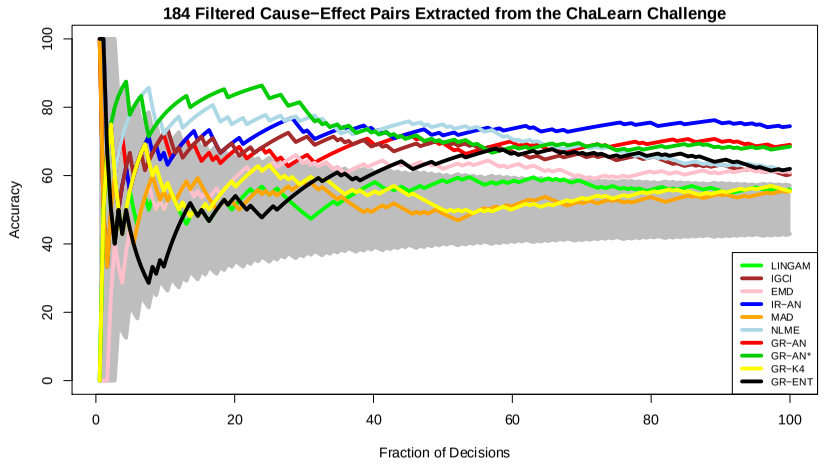

Figure 8: Accuracy of each method, as a fraction of the decisions made, on the 184 filtered cause-effect pairs extracted from the ChaLearn challenge. The number of samples of each pair is equal to 500. Best seen in color.

In summary, the results reported in this section have shown that in some cause-effect pairs, when the assumptions made by the proposed method are satisfied, there is indeed a Gaussianization effect in the residuals obtained when fitting the model in the anti-causal direction, and this asymmetry is useful to carry out causal inference on both synthetic and real inference problems. Our experiments also show that the transformation employed to guarantee that $\mathcal{X}$ and $\mathcal{Y}$ are equally distributed can be ignored in some cases without decreasing the performance. This indicates that our statement about the increased level of Gaussianity of the residuals, in terms of the increase of the entropy and the reduction of the high-order cumulants, may be true under more general assumptions.

7. Conclusions

In this paper we have shown that in the case of cause-effect pairs with additive non-Gaussian noise there is an asymmetry that can be used for causal inference. In particular, assuming that the cause and the effect are equally distributed random variables, that are linearly related, the residuals of a least squares fit in the anti-causal direction are more Gaussian than the residuals of a linear fit in the causal direction due a reduction of the magnitude of the high-order cumulants. Furthermore, by extending the results of Hyvärinen and Smith (2013) based on information theory, we have shown that this Gaussianization effect is also present when the two random variables are multivariate due to an increment of the

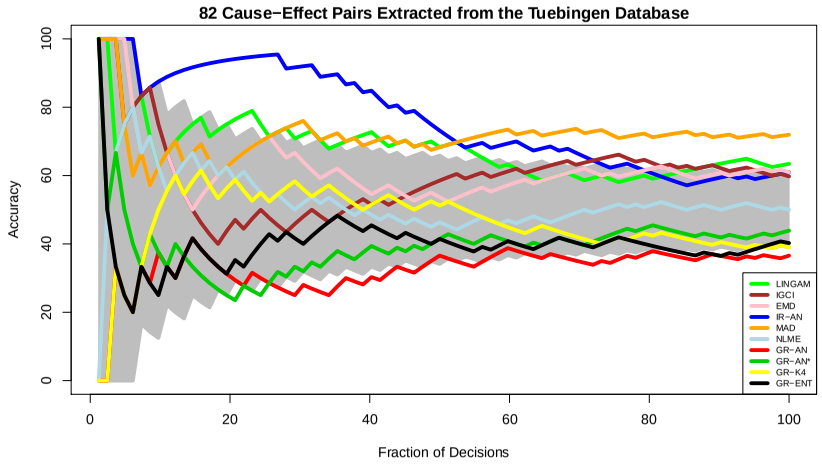

Figure 9: Accuracy of each method, as a fraction of the decisions made, on the 82 cause-effect pairs extracted from the Tuebingen database. Best seen in color.

differential entropy. This motivates the use of kernel methods to work in an expanded feature space. This enables addressing non-linear cause-effect inference problems using simple techniques. Specifically, kernel methods allow to fit a linear model in an expanded feature space which will be non-linear in the original input space.

Taking advantage of the asymmetry described, we have designed a method for non-linear causal inference, GR-AN (Gaussianity of the Residuals under Additive Noise). The method consists in computing the residuals of a linear model in an expanded feature space in both directions, *i.e.*, $\mathcal{X} \to \mathcal{Y}$ and $\mathcal{Y} \to \mathcal{X}$. The expected causal direction is the one in which the residuals appear to be more Gaussian (*i.e.*, the magnitude of the high-order cumulants is reduced and the entropy is increased). Thus, a suitable statistical test that measures the level of non-Gaussianity of the residuals can be used to determine the causal direction. In principle, one may be tempted to use statistical tests based on entropy or cumulant estimation. However, our experiments show that one can obtain better results by using a test based on an *energy distance* to quantify the Gaussianity of the residuals. In particular, entropy estimation is an arguably difficult task and the estimators of the cumulants involve high-order moments which can lead to high variance.

The effectiveness of the proposed method GR-AN has been illustrated in both synthetic and real-world causal inference problems. We have shown that in certain problems GR-AN is competitive with state-of-the-art methods and that it performs better than related methods based on entropy estimation (Hyvärinen and Smith, 2013). The entropy can be understood as a measure of non-Gaussianity. Nevertheless, it is very difficult to estimate

in practice. By contrast, the statistical test employed by GR-AR is not directly related to entropy estimation. This may explain the improvements observed. A limitation of the current formulation of GR-AN is that the distributions of the cause and the effect have to be equal. In the case of continuous univariate variables finding a transformation to make this possible is straightforward. Additionally, our experiments show that such a transformation can be side-stepped in some cases without a deterioration in performance. In any case, further research is needed to extend this analysis to remove this restriction.

Finally, the performance of GR-AN on cause-effect pairs with discretized values is rather poor. We believe this is due to the fact that in this case, finding a transformation so that the cause and the effect are equally distributed is infeasible. Furthermore, the discretization process probably has a strong impact on the Gaussianity tests. Further evidence that make these observations more plausible is the fact that discretization has also a strong negative impact in the performance of the methods based on entropy estimation.

Appendix A.

In this appendix we show that if $\mathcal{X}$ and $\mathcal{Y}$ follow the same distribution and they have been centered, then the determinant of the covariance matrix of the random variable corresponding to $\boldsymbol{\epsilon}_i$, denoted with $\mathrm{Cov}(\boldsymbol{\epsilon}_i)$, coincides with the determinant of the covariance matrix corresponding to the random variable $\tilde{\boldsymbol{\epsilon}}_i$, denoted with $\mathrm{Cov}(\tilde{\boldsymbol{\epsilon}}_i)$.

From the causal model, *i.e.*, $\mathbf{y}_i = \mathbf{A}\mathbf{x}_i + \boldsymbol{\epsilon}_i$, we have that:

$$\mathrm{Cov}(\mathcal{Y}) = \mathbf{A}\mathrm{Cov}(\mathcal{X})\mathbf{A}^{\mathrm{T}} + \mathrm{Cov}(\boldsymbol{\epsilon}_i)\,. \tag{32}$$

Since $\mathcal{X}$ and $\mathcal{Y}$ follow the same distribution we have that $\mathrm{Cov}(\mathcal{Y}) = \mathrm{Cov}(\mathcal{X})$. Furthermore, we know from the causal model that $\mathbf{A} = \mathrm{Cov}(\mathcal{Y}, \mathcal{X})\mathrm{Cov}(\mathcal{X})^{-1}$. Then,

$$\mathrm{Cov}(\boldsymbol{\epsilon}_i) = \mathrm{Cov}(\mathcal{X}) - \mathrm{Cov}(\mathcal{Y}, \mathcal{X})\mathrm{Cov}(\mathcal{X})^{-1}\mathrm{Cov}(\mathcal{X}, \mathcal{Y})\,. \tag{33}$$

In the case of $\tilde{\boldsymbol{\epsilon}}_i$ we know that the relation $\tilde{\boldsymbol{\epsilon}}_i = (\mathbf{I} - \tilde{\mathbf{A}}\mathbf{A})\mathbf{x}_i - \tilde{\mathbf{A}}\boldsymbol{\epsilon}_i$ must be satisfied, where $\tilde{\mathbf{A}} = \text{Cov}(\mathcal{X}, \mathcal{Y})\text{Cov}(\mathcal{Y})^{-1} = \text{Cov}(\mathcal{X}, \mathcal{Y})\text{Cov}(\mathcal{X})^{-1}$. Thus, we have that:

$$\begin{aligned}
\text{Cov}(\tilde{\boldsymbol{\epsilon}}_i) &= (\mathbf{I} - \tilde{\mathbf{A}}\mathbf{A})\text{Cov}(\mathcal{X})(\mathbf{I} - \mathbf{A}^{\text{T}}\tilde{\mathbf{A}}^{\text{T}}) + \tilde{\mathbf{A}}\text{Cov}(\boldsymbol{\epsilon}_i)\tilde{\mathbf{A}}^{\text{T}} \\
&= \text{Cov}(\mathcal{X}) - \text{Cov}(\mathcal{X})\mathbf{A}^{\text{T}}\tilde{\mathbf{A}}^{\text{T}} - \tilde{\mathbf{A}}\mathbf{A}\text{Cov}(\mathcal{X}) + \tilde{\mathbf{A}}\mathbf{A}\text{Cov}(\mathcal{X})\mathbf{A}^{\text{T}}\tilde{\mathbf{A}}^{\text{T}} \\
&\quad + \tilde{\mathbf{A}}\text{Cov}(\mathcal{X})\tilde{\mathbf{A}}^{\text{T}} - \tilde{\mathbf{A}}\text{Cov}(\mathcal{Y}, \mathcal{X})\text{Cov}(\mathcal{X})^{-1}\text{Cov}(\mathcal{X}, \mathcal{Y})\tilde{\mathbf{A}}^{\text{T}} \\
&= \text{Cov}(\mathcal{X}) - \text{Cov}(\mathcal{X})\mathbf{A}^{\text{T}}\tilde{\mathbf{A}}^{\text{T}} - \tilde{\mathbf{A}}\mathbf{A}\text{Cov}(\mathcal{X}) + \tilde{\mathbf{A}}\text{Cov}(\mathcal{X})\tilde{\mathbf{A}}^{\text{T}} \\
&= \text{Cov}(\mathcal{X}) - \text{Cov}(\mathcal{X}, \mathcal{Y})\text{Cov}\mathcal{X}^{-1}\text{Cov}(\mathcal{Y}, \mathcal{X}) - \text{Cov}(\mathcal{X}, \mathcal{Y})\text{Cov}\mathcal{X}^{-1}\text{Cov}(\mathcal{Y}, \mathcal{X}) \\
&\quad + \text{Cov}(\mathcal{X}, \mathcal{Y})\text{Cov}\mathcal{X}^{-1}\text{Cov}(\mathcal{Y}, \mathcal{X}) \\
&= \text{Cov}(\mathcal{X}) - \text{Cov}(\mathcal{X}, \mathcal{Y})\text{Cov}(\mathcal{X})^{-1}\text{Cov}(\mathcal{Y}, \mathcal{X})\,. \qquad (34)
\end{aligned}$$

By the matrix determinant theorem we have that $\text{detCov}(\tilde{\boldsymbol{\epsilon}}_i) = \text{detCov}(\boldsymbol{\epsilon}_i)$. See (Murphy, 2012, p. 117) for further details.

Appendix B.

In this Appendix we motivate that, if the distribution of the residuals is not Gaussian, but is close to Gaussian, one should also expected more Gaussian residuals in the anti-causal direction in terms of the energy distance described in Section 3.4. For simplicity we will consider the univariate case. We use the fact that the energy distance in the one-dimensional case is the squared distance between the cumulative distribution functions of the residuals and a Gaussian distribution (Székely and Rizzo, 2013). Thus,

$$\tilde{D}^2 = \int_{-\infty}^{\infty} \left[\tilde{F}(x) - \Phi(x)\right]^2 dx\,, \qquad D^2 = \int_{-\infty}^{\infty} \left[F(x) - \Phi(x)\right]^2 dx\,, \qquad (35)$$

where $\tilde{D}^2$ and D^2 are the energy distances to the Gaussian distribution in the anti-causal and the causal direction respectively; $\tilde{F}(x)$ and $F(x)$ are the c.d.f. of the residuals in the anti-causal and the causal direction, respectively; and finally, $\Phi(x)$ is the c.d.f. of a standard Gaussian.

One should expect that $\tilde{D}^2 \leq D^2$. To motivate this, we use the Gram-Charlier series and compute an expansion of $\tilde{F}(x)$ and $F(x)$ around the standard Gaussian distribution (Patel and Read, 1996). Such an expansion only converges in the case of distributions that are close to be Gaussian (see Section 17.6.6a of (Cramér, 1946) for further details). Namely,

$$\begin{aligned}
\tilde{F}(x) &= \Phi(x) - \phi(x)\left(\frac{\tilde{a}_3}{3!}H_2(x) + \frac{\tilde{a}_4}{4!}H_3(x) + \cdots\right)\,, \\
F(x) &= \Phi(x) - \phi(x)\left(\frac{a_3}{3!}H_2(x) + \frac{a_4}{4!}H_3(x) + \cdots\right)\,, \qquad (36)
\end{aligned}$$

where $\phi(x)$ is the p.d.f. of a standard Gaussian, $H_n(x)$ are Hermite polynomials and $\tilde{a}_n$ and a_n are coefficients that depend on the cumulants, *e.g.*, $a_3 = \kappa_3$, $a_4 = \kappa_4$, $\tilde{a}_3 = \tilde{\kappa}_3$, $\tilde{a}_4 = \tilde{\kappa}_4$. Note, however, that coefficients a_n and $\tilde{a}_n$ for $n > 5$ depend on combinations of

the cumulants. Using such an expansion we find:

$$\begin{aligned}
\tilde{D}^2 &= \int_{-\infty}^{\infty} \phi(x)^2 \left[-\sum_{n=3}^{\infty} \frac{\tilde{a}_n}{n!} H_{n-1}(x)\right]^2 dx \approx \int_{-\infty}^{\infty} \phi(x)^2 \left[-\sum_{n=3}^{4} \frac{\tilde{\kappa}_n}{n!} H_{n-1}(x)\right]^2 dx \\
&\approx \frac{\tilde{\kappa}_3^2}{36}\mathbb{E}[H_2(x)^2\phi(x)] + \frac{\tilde{\kappa}_4^2}{576}\mathbb{E}[H_3(x)^2\phi(x)]\,, \qquad (37)
\end{aligned}$$

where $\mathbb{E}[\cdot]$ denotes expectation with respect to a standard Gaussian and we have truncated the Gram-Charlier expansion after $n = 4$. Truncation of the Gram-Charlier expansion after $n = 4$ is a standard procedure that is often done in the ICA literature for entropy approximation. See for example Section 5.5.1 of (Hyvärinen et al., 2004). We have also used the fact that $\mathbb{E}[H_3(x)H_2(x)\phi(x)] = 0$. The same approach can be followed in the case of D^2, the energy distance in the causal direction. The consequence is that $D^2 \approx \kappa_3^2/36 \cdot \mathbb{E}[H_2(x)^2\phi(x)] + \kappa_4^2/576 \cdot \mathbb{E}[H_3(x)^2\phi(x)]$. Finally, the fact that one should expect $\tilde{D}^2 \leq D^2$ is obtained by noting that $\tilde{\kappa}_n = c_n\kappa_n$, where c_n is some constant that lies in the interval $(-1, 1)$, as indicated in Section 2.1. We expect that this result extends to the multivariate case.

Appendix C.

In this Appendix we motivate that one should expect also more Gaussian residuals in the anti-causal direction, based on a reduction of the cumulants, when the residuals in feature space are projected onto the first principal component. That is, when they are multiplied by the first eigenvector of the covariance matrix of the residuals, and scaled by the corresponding eigenvalue. Recall from Section 2.2 that these covariance matrices are $\mathbf{C} = \mathbf{I} - \mathbf{A}\mathbf{A}^{\text{T}}$ and $\tilde{\mathbf{C}} = \mathbf{I} - \mathbf{A}^{\text{T}}\mathbf{A}$, in the causal and anti-causal direction respectively. Note that both matrices have the same eigenvalues.

If $\mathbf{A}$ is symmetric we have that both $\mathbf{C}$ and $\tilde{\mathbf{C}}$ have the same matrix of eigenvectors $\mathbf{P}$. Let $\mathbf{p}_1^n$ be the first eigenvector multiplied n times using the Kronecker product. The cumulants in the anti-causal and the causal direction, after projecting the data onto the first eigenvector are $\tilde{\kappa}_n^{\text{proj}} = (\mathbf{p}_1^{\text{n}})^{\text{T}}\mathbf{M}_n\text{vect}(\tilde{\kappa}_n) = c(\mathbf{p}_1^{\text{n}})^{\text{T}}\text{vect}(\tilde{\kappa}_n)$ and $\kappa_n^{\text{proj}} = (\mathbf{p}_1^{\text{n}})^{\text{T}}\text{vect}(\kappa_n)$, respectively, where $\mathbf{M}_n$ is the matrix that relates the cumulants in the causal and the anti-causal direction (see Section 2.2) and c is one of the eigenvalues of $\mathbf{M}_n$. In particular, if $\mathbf{A}$ is symmetric, it is not difficult to show that $\mathbf{p}_1^{\text{n}}$ is one of the eigenvectors of $\mathbf{M}_n$. Furthermore, we also showed in that case that $||\mathbf{M}_n||_{\text{op}} < 1$ for $n \geq 3$ (see Section 2.2). The consequence is that $c \in (-1, 1)$, which combined with the fact that $||\mathbf{p}_1^n|| = 1$ leads to smaller cumulants in magnitude in the case of the projected residuals in the anti-causal direction.

If $\mathbf{A}$ is not symmetric we motivate that one should also expect more Gaussian residuals in the anti-causal direction due to a reduction in the magnitude of the cumulants. For this, we derive a smaller upper bound on their magnitude. This smaller upper bound is based on an argument that uses the operator norm of vectors.

Definition 2 *The operator norm of a vector* $\mathbf{w}$ *induced by the* ℓ_p *norm is* $||\mathbf{w}||_{op} = min\{c \geq 0 : ||\mathbf{w}^T\mathbf{v}||_p \leq c||\mathbf{v}||_p, \forall\mathbf{v}\}$.

The consequence is that $||\mathbf{w}||_{\text{op}} \geq ||\mathbf{w}^{\text{T}}\mathbf{v}||_p/||\mathbf{v}||_p$, $\forall\mathbf{v}$. Thus, the smallest the operator norm of $\mathbf{w}$, the smallest the expected value obtained when multiplying any vector by the

vector $\mathbf{w}$. Furthermore, it is clear that $||\mathbf{w}||_{\text{op}} = ||\mathbf{w}||_2$, in the case of the ℓ_2-norm. From the previous paragraph, in the anti-causal direction we have $||\tilde{\kappa}_n^{\text{proj}}||_2 = ||(\tilde{\mathbf{p}}_1^n)^{\text{T}}\mathbf{M}_n\text{vect}(\kappa_n)||_2$, where $\tilde{\mathbf{p}}_1$ is the first eigenvector of $\tilde{\mathbf{C}}$, while in the causal direction we have $||\kappa_n^{\text{proj}}||_2 = ||(\mathbf{p}_1^n)^{\text{T}}\text{vect}(\kappa_n)||_2$, where $\mathbf{p}_1$ is the first eigenvector of $\mathbf{C}$. Thus, because the norm of each vector $\tilde{\mathbf{p}}_1^n$ and $\mathbf{p}_1^n$ is one, we have that $||\mathbf{p}_1^n||_{\text{op}} = 1$. However, because we expect $\mathbf{M}_n$, to reduce the norm of $(\tilde{\mathbf{p}}_1^n)^{\text{T}}$, as motivated in Section 2.2, $||(\tilde{\mathbf{p}}_1^n)^{\text{T}}\mathbf{M}_n||_{\text{op}} < 1$ should follow. This is expected to lead to smaller cumulants in magnitude in the anti-causal direction.

Abstract

A popular approach for testing if two univariate random variables are statistically independent consists of partitioning the sample space into bins, and evaluating a test statistic on the binned data. The partition size matters, and the optimal partition size is data dependent. While for detecting simple relationships coarse partitions may be best, for detecting complex relationships a great gain in power can be achieved by considering finer partitions. We suggest novel consistent distribution-free tests that are based on summation or maximization aggregation of scores over all partitions of a fixed size. We show that our test statistics based on summation can serve as good estimators of the mutual information. Moreover, we suggest regularized tests that aggregate over all partition sizes, and prove those are consistent too. We provide polynomial-time algorithms, which are critical for computing the suggested test statistics efficiently. We show that the power of the regularized tests is excellent compared to existing tests, and almost as powerful as the tests based on the optimal (yet unknown in practice) partition size, in simulations as well as on a real data example.

Keywords: bivariate distribution, nonparametric test, statistical independence, mutual information, two-sample test, HHG R package

1. Introduction

Testing if two univariate random variables X and Y are independent of one another, given a random paired sample $(x_i, y_i)_{i=1}^N$, is a fundamental and extensively studied problem in statistics. Classical methods have focused on testing linear (Pearson's correlation coefficient) or monotone (Spearman's ρ, Kendall's τ) univariate dependence, and have little power to detect non-monotone relationships. Recently, there has been great interest in developing methods to capture complex dependencies between pairs of random variables. This interest follows from the recognition that in many modern applications, dependencies of interest may not be of simple forms, and therefore the classical methods cannot capture them. Moreover, in modern applications, thousands of variables are measured simultaneously, thus making it impossible to view the scatter-plots of all the potential pairs of variables of interest. For example, Steuer et al. (2002) searched for pairs of genes that are co-dependent, among thousands of genes measured, using the estimated mutual information as a dependence measure. Reshef et al. (2011) searched for any type of relationship, not just linear or monotone, in large data sets from global health, gene expression, major-league baseball, and the human gut microbiota. They proposed a novel criterion which generated much interest but has also been criticised for lacking power by Simon and Tibshirani (2011) and Gorfine et al. (2011), and for other theoretical grounds by Kinney and Atwal (2014).

A special important case is when X is categorical. In this case, the problem reduces to that of testing the equality of distributions, usually referred to as the K-sample problem (where K is the number of categories X can have). Jiang et al. (2014) searched for genes that are differentially expressed across two conditions (i.e., the 2-sample problem), using a novel test that has higher power over traditional methods such as Kolmogorov–Smirnov tests (Darling, 1957).

For modern applications, where all types of dependency are of interest, a desirable property for a test of independence is consistency against any alternative. A consistent test will have power increasing to one as the sample size increases, for any type of dependency between X and Y. Recently, several consistent tests of independence between univariate or multivariate random variables were proposed. Székely et al. (2007) suggested the distance covariance test statistic, that is the distance (in weighted L_2 norm) of the joint empirical characteristic function from the product of marginal characteristic functions. Gretton et al. (2008) and Gretton and Gyorfi (2010) considered a family of kernel based methods, and Sejdinovic et al. (2013) elegantly showed that the test of Székely et al. (2007) is a kernel based test with a particular choice of kernel. Heller et al. (2013) suggested a permutation test for independence between two random vectors X and Y, which uses as test statistics the sum over all pairs of points $(i, j), i \neq j$, of a score that tests for association between the two binary variables $I\{d(x_i, X) \leq d(x_i, x_j)\}$ and $I\{d(y_i, Y) \leq d(y_i, y_j)\}$, where $I(\cdot)$ is the indicator function and $d(\cdot, \cdot)$ is a distance metric, on the remaining $N-2$ sample points. Gretton and Gyorfi (2010) also considered dividing the underlying space into partitions that are refined with increasing sample size. For the K-sample problem, Székely and Rizzo (2004) suggested the energy test. This test was also proposed by Baringhaus and Franz (2004) and mentioned in Sejdinovic et al. (2013) to be related to the maximum mean discrepancy (MMD) test proposed in Gretton et al. (2007) and Gretton et al. (2012a). Harchaoui et al. (2008) adopted the kernel approach of Gretton et al. (2007) and incorporated the covariance into the test statistic by using the kernel Fisher discriminant.

The tests in the previous paragraph are not distribution-free, i.e., the null distribution of the test statistics depends on the marginal distributions of X and Y. Therefore, the significance of these

tests is typically computed by a permutation test. Another option is to try to estimate the null distribution, but this can be very difficult and can lead to over-conservative bounds. For example, Székely et al. (2007) suggested an asymptotically valid null bound for the significance which they showed was too conservative (see Sejdinovic et al. (2013) for suggestions on how to directly estimate the null distribution). The computational burden of applying the permutation tests to a large family of hypotheses may be great. For example, the yeast gene expression data set from Hughes et al. (2000) contained $N = 300$ expression levels for each of $6,325$ *Saccharomyces cerevisiae* genes. In order to test each pair of genes for co-expression, it is necessary to account for multiplicity of $M = 2 \times 10^7$ hypotheses. For the permutation tests of Heller et al. (2013) and Székely et al. (2007), the number of permutations required for deriving a p-value that is below $0.05/M$ is therefore of the order of 10^{10}. Since these test statistics are relatively costly to compute for each hypothesis, e.g., $O(N^2)$ in Székely et al. (2007), and $O(N^2 \log N)$ in Heller et al. (2013), applying them to the family of $M = 2 \times 10^7$ hypotheses is computationally very challenging, even with sophisticated re-sampling approaches such as that of Yu et al. (2011). Distribution-free tests have the advantage over non-distribution-free tests, that quantiles of the null distribution of the test statistic can be tabulated once per sample size, and repeating the test on new data for the same sample size will not require recomputing the null distribution. Therefore, the computational cost is only that of computing the test statistic for each of the hypotheses.

We note that for univariate random variables Székely and Rizzo (2009a) considered using the ranks of each random variable instead of the actual values in the test of distance covariance (Székely et al., 2007), resulting in a distribution-free test. Similarly, for the test of Heller et al. (2013) replacing data with ranks results in a distribution-free test. An earlier work by Feuerverger (1993) defined another test based on the empirical characteristic functions for univariate random variables. The test statistic of Feuerverger (1993) was based on a different distance metric of the joint empirical characteristic function from the product of marginal characteristic functions than that of Székely et al. (2007). Moreover, in Feuerverger's test the X's and Y's are first replaced by their normal scores, where the normal scores of the X's depend on the data only through their ranks among the X's, and similarly the normal scores of the Y's depend on the data only through their ranks among the Y's, thus making this test distribution-free. Pczos et al. (2012) suggested a kernel-based test which uses the MMD after transforming the data to ranks.

A popular approach for developing distribution-free tests of independence considers partitioning the sample space, and evaluating a test statistic on the binned data. A detailed review of distribution-free partition-based tests is provided in Section 1.1 for the independence problem, and in Section 1.2 for the K-sample problem. In 1.3 we describe our goals and the outline of the present paper.

1.1 Review of Distribution-Free Tests of Independence Based on Sample Space Partitions

For detecting any type of dependence between X and Y, the null hypothesis states that X and Y are independent, $H_0 : F_{XY} = F_X F_Y$, where the joint distribution of (X, Y) is denoted by F_{XY}, and the marginal distributions of X and Y, respectively, are denoted by F_X and F_Y. The alternative is that X and Y are dependent, $H_1 : F_{XY} \neq F_X F_Y$.

Figure 1 shows example partitions of the sample space based on the ranked observations, $rank(Y)$ versus $rank(X)$, where a $m \times m$ partition is based on $m - 1$ observations. We refer to such partitions as data derived partitions (DDP). The dependence in the data can be captured by many partitions, and some partitions are better than others.

Hoeffding (1948b) suggested a test based on summation of a score over all N 2×2 DDP of the sample space, which is consistent against any form of dependence if the bivariate density is continuous. Hoeffding's test statistic is

$$\iint N \left\{ \hat{F}_{XY}(x,y) - \hat{F}_X(x)\hat{F}_Y(y) \right\}^2 d\hat{F}_{XY}(x,y),$$

where $\hat{F}$ denotes the empirical cumulative distribution function. Blum et al. (1961) showed that Hoeffding's test statistic is asymptotically equivalent to $\sum_{i=1}^{N}(o^i_{1,1}o^i_{2,2} - o^i_{1,2}o^i_{2,1})^2/N^4$, where $o^i_{u,v}$, $u, v \in \{1, 2\}$, is the observed count of cell (u, v) in the 2×2 contingency table defined by the ith observation. Thas and Ottoy (2004) noted that by appropriately normalizing each term in the sum, the test statistic becomes the average of all Pearson statistics for independence applied to the contingency tables that are induced by 2×2 sample space partitions centered about observation $i \in \{1, \ldots, N\}$. They proved that the weighted version of Hoeffding's test statistic is still consistent.

Partitioning the sample space into finer partitions than the 2×2 quadrants of the classical tests, based on the observations, was also considered in Thas and Ottoy (2004). They suggested that the average of all Pearson statistics on finer partitions of fixed size $m \times m$ may improve the power, but did not provide a proof that the resulting tests are consistent. They examined in simulations only 3×3 and 4×4 partitions. Reshef et al. (2011) suggested the maximal information coefficient, which is a test statistic based on the maximum over dependence scores taken for partitions of various sizes, after normalization by the partition size, where the purpose of the normalization is equitability rather than power. Since computing the statistic exactly is often infeasible, they resort to a heuristic for selecting which partitions to include. Thus, in practice, their algorithm goes over only a small fraction of the partitions they set out to examine. In Section 4 we show that the power of this test is typically low.

1.2 Review of the K-Sample Problem

As in Section 1.1, we focus on consistent partition-based distribution-free tests. For testing equality of distributions, i.e., for a categorical X, one of the earliest and still very popular distribution-free consistent tests is the Kolmogorov–Smirnov test (Darling, 1957), which is based on the maximum score of all N partitions of the sample space based on an observed data point. Aggregation by summation over all N partitions has been considered by Cramer and von Mises (Darling, 1957), Pettitt (Pettitt, 1976) who constructed a test-statistic of the Anderson and Darling family (Anderson and Darling, 1952), and Scholz and Stephens (1987).

Thas and Ottoy (2007) suggested the following extension of the Anderson–Darling type test. For random samples of size N_1 and $N - N_1$, respectively, from two continuous densities, for a fixed m, they consider all possible partitions into m intervals of the sample space of the univariate continuous random variable. They compute Pearson's chi-square score for the observed versus expected (under the null hypothesis that the two samples come from the same distribution) counts, then aggregate by summation to get their test statistics. A permutation test is applied on the resulting test statistic, since under the null all $\binom{N}{N_1}$ assignments of the group labels are equally likely. They show that the suggested statistic for $m = 2$ is the Anderson–Darling test. They examined in simulations only partitions into $m \leq 4$ intervals.

Jiang et al. (2014) suggested a penalized score that aggregates by maximization the penalized log likelihood ratio statistic for testing equality of distributions, with a penalty for fine partitions.

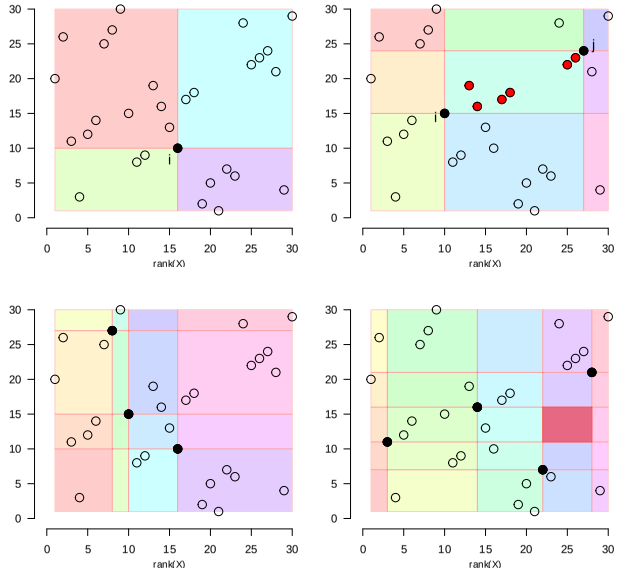

Figure 1: A visualization of the partitioning of the rank–rank plane which is at the basis of the data derived partitions (DDP) tests. Here, $N = 30$, and circles represent observed points. Full black circles represent those observations that were chosen to induce the partition, and different shades represent partition cells. With $m = 2$, all cells are corner cells (top-left); with $m = 3$, the center cell has two vertices which are observed sample points (top-right); with $m = 4$, all internal cells, i.e., cells that are not on the boundary, have at least one observed point vertex (bottom-left); only with $m \geq 5$, there exists at least one internal cell free of observed vertices (bottom-right, internal cell with no vertex which is a sample point is marked in red).

They developed an efficient dynamic programming algorithm to determine the optimal partition, and suggested a distribution-free permutation test to compute the p-value.

Although there are many additional tests for the two-sample problem, the list above contains the most common as well as the most recent developments in this field. Interestingly, when working with ranks, the energy test of Székely and Rizzo (2004) and the Cramer–von Mises test turn out to be equivalent.

1.3 Overview of This Paper

In this work, we suggest several novel distribution-free tests that are based on sample space partitions. The novelty of our approach lies in the fact that we consider aggregation of scores over all partitions of size $m \times m$ (or m for the K-sample case), where m can increase with sample size N, as well as consideration of all ms simultaneously without any assumptions on the underlying distributions. In Section 2 we present the new tests both for the independence problem and for the K-sample problem, with a focus on our regularized scores (that consider all ms) in Section 2.1. We prove that all suggested tests are consistent, including those presented in Thas and Ottoy (2004), and show the connection between our tests and mutual information (MI). In Section 3 we present innovative algorithms for the computation of the tests, which are essential for large m since the computational complexity of the naive algorithm is exponential in m. Simulations are presented in Section 4. Specifically, in Section 4.1 we show that for the two-sample problem for complex distributions there is a clear advantage for fine partitions, while for simple distributions rougher partitions have an advantage. In Section 4.2 we show that, for the independence problem, typically finer partitions have a clear advantage for complex non-monotone relationships. On the other hand, for simpler relationships, there is an advantage for rougher partitions. We further demonstrate the ability of our regularized method (which aggregates over all partitions) to adapt and find the best partition size. Moreover, in simulations we show that for complex relationships all these tests are more powerful than other existing distribution-free tests. In Section 5 we analyze the yeast gene expression data set from Hughes et al. (2000). With our distribution-free tests, we discover interesting non-linear relationships in this data set that could not have been detected by the classical tests, contrary to the conclusion in Steuer et al. (2002) that there are no non-monotone associations. Efficient implementations of all statistics and tests described herein are available in the R package *HHG*, which can be freely downloaded from the Comprehensive R Archive Network, `http://cran.r-project.org/`. Null tables can be downloaded from the first author's web site.

2. The Proposed Statistics

We assume that Y is a continuous random variable, and that X is either continuous or discrete. We have N independent realizations $(x_1, y_1), \ldots, (x_N, y_N)$ from the joint distribution of X and Y. Our test statistics will only depend on the marginal ranks, and therefore are distribution free, i.e., their null distributions are free of the marginal distributions F_X and F_Y.

Test statistics for the K-sample problem We first consider the case that X is categorical with $K \geq 2$ categories. In this case, a test of association is also a K-sample test of equality of distributions. For N observations, there are $\binom{N+1}{2}$ possible cells, and $\binom{N-1}{m-1}$ possible partitions of the observations into m cells, where a cell is an interval on the real line. Since the cell membership of

observations is the same regardless of whether the partition is defined on the original observations or on the ranked observations, and the statistics we suggest only depend on these cell memberships, we describe the proposed test statistics on the ranked observations, $rank(Y) \in \{1, ..., N\}$. Let Π_m denote the set of partitions into m cells. For any fixed partition $\mathcal{I} = \{i_1, \ldots, i_{m-1}\} \subset \{1.5, \ldots, N - 0.5\}$, $i_1 < i_2 < \ldots < i_{m-1}$, $\mathcal{C}(\mathcal{I})$ is the set of m cells defined by the partition. For a cell $C \in \mathcal{C}(\mathcal{I})$, let $o_C(g)$ and $e_C(g)$ be the observed and expected counts inside the cell for distribution $g \in \{1, \ldots, K\}$, respectively. The expected count $e_C(g)$ is the width of cell C based on ranks multiplied by N_g/N, where N_g is the total number observations from distribution g: $e_{[i_l, i_{l+1}]}(g) = (i_{l+1} - i_l) \times N_g/N$, where $l \in \{0, \ldots, m-1\}$, $i_0 = 0.5$ and $i_m = N + 0.5$. We consider either Pearson's score or the likelihood ratio score for a given cell C,

$$t_C \in \left\{ \sum_{g=1}^{K} \frac{[o_C(g) - e_C(g)]^2}{e_C(g)},\ \sum_{g=1}^{K} o_C(g) \log \frac{o_C(g)}{e_C(g)} \right\}. \tag{1}$$

For a given partition $\mathcal{I}$, the score is $T^{\mathcal{I}} = \sum_{C \in \mathcal{C}(\mathcal{I})} t_C$ (where if $t_C = \sum_{g=1}^{K} o_C(g) \log \frac{o_C(g)}{e_C(g)}$ then $T^{\mathcal{I}}$ is the likelihood ratio given the partition). Our test statistics aggregate over all partitions by summation (Cramer–von Mises-type statistics) and by maximization (Kolmogorov–Smirnov-type statistics):

$$S_m = \sum_{\mathcal{I} \in \Pi_m} T^{\mathcal{I}}, \quad M_m = \max_{\mathcal{I} \in \Pi_m} T^{\mathcal{I}}. \tag{2}$$

Tables of critical values for given sample sizes $N_1, \ldots, N_K$ can be obtained for (very) small sample sizes by generating all possible $N!/(\Pi_{g=1}^{K} N_g!)$ reassignments of ranks $\{1, \ldots, N\}$ to K groups of sizes $N_1, \ldots, N_K$ and computing the test statistic for each reassignment. The p-value is the fraction of reassignments for which the computed test statistics are at least as large as observed. When the number of possible reassignments is large, the null tables are obtained by large scale Monte Carlo simulations (we used $B = 10^6$ replicates for each given sample size $N_1, \ldots, N_K$). For each of the B reassignments selected at random from all possible reassignments, the test statistic is computed. Clearly, the B computations do not depend on the data, hence the tests based on these statistics are distribution free. Again, the p-value is the fraction of reassignments for which the computed test statistics are at least as large as the one observed, but here the fraction is computed out of the $B + 1$ assignments that include the B reassignments selected at random and the one observed assignment, see Chapter 15 in Lehmann and Romano (2005). The test based on each of these statistics is consistent:

Theorem 1 *Let Y be continuous, and X categorical with K categories. Let N_g be the total number of observations from distribution $g \in \{1, \ldots, K\}$, and $N = \sum_{g=1}^{K} N_g$. If the distribution of Y differs at a continuous density point y_0 across values of X in at least two categories, label these 1 and 2, $\lim_{N\to\infty} \frac{\min(N_1, N_2)}{N} > 0$, and m finite or $\lim_{N\to\infty} m/N = 0$, then the distribution-free permutation tests based on S_m and M_m are consistent.*

We omit the proof, since it is similar to (yet simpler than) the proof of Theorem 2 below.

Test statistics for the independence problem We now consider the case that X is continuous. For N pairs of observations, there are $\binom{N-1}{m-1} \times \binom{N-1}{m-1}$ partitions of the sample space into $m \times m$

cells, where a cell is a rectangular area in the plane. We refer to these partitions as the all derived partitions (ADP) and denote this set by Π_m^{ADP}. Since the cell membership of observations is the same regardless of whether the partition is defined on the original observations or on the ranked observations, and the statistics we suggest only depend on these cell memberships, we describe the proposed test statistics on the ranked observations, so the N pairs of observations are on the grid $\{1, \ldots, N\}^2$. For any fixed partition $\mathcal{I} = \{(i_1, j_1), \ldots, (i_{m-1}, j_{m-1})\} \subset \{1.5, \ldots, N - 0.5\}^2$, , $i_1 < i_2 < \ldots < i_{m-1}$, $j_1 < j_2 < \ldots < j_{m-1}$, $\mathcal{C}(\mathcal{I})$ is the set of $m \times m$ cells defined by the partition. For a cell $C \in \mathcal{C}(\mathcal{I})$, let o_C and e_C be the observed and expected counts inside the cell, respectively. The expected count in cell C with boundaries $[i_k, i_{k+1}] \times [j_l, j_{l+1}]$ is $e_C = (i_{k+1} - i_k) \times (j_{l+1} - j_l)/N$, where $k, l \in \{0, \ldots, m-1\}$, $i_0 = j_0 = 0.5, i_m = j_m = N + 0.5$. As with the K-sample problem, we consider either Pearson's score or the likelihood ratio score for a given cell C,

$$t_C \in \left\{ \frac{(o_C - e_C)^2}{e_C},\ o_C \log \frac{o_C}{e_C} \right\}. \tag{3}$$

For a given partition $\mathcal{I}$, the score is $T^{\mathcal{I}} = \sum_{C \in \mathcal{C}(\mathcal{I})} t_C$ (where if $t_C = o_C \log \frac{o_C}{e_C}$ then $T^{\mathcal{I}}$ is the likelihood ratio given the partition). As above, we consider as test statistics aggregation by summation and by maximization:

$$S_{m\times m}^{ADP} = \sum_{\mathcal{I} \in \Pi_m^{ADP}} T^{\mathcal{I}}, \quad M_{m\times m}^{ADP} = \max_{\mathcal{I} \in \Pi_m^{ADP}} T^{\mathcal{I}}. \tag{4}$$

We consider another test statistic based on DDP, where each set of $m - 1$ observed points in their turn define a partition (see Figure 1). This variant has a computational advantage over the ADP statistic for $m < 5$, see Remark 3.1. Since all observations have unique values, the remaining $N - (m-1)$ points are inside cells defined by the partition. There are $\binom{N}{m-1}$ partitions, denote this set of partitions by Π_m^{DDP}. As before, since the cell membership of observations is the same regardless of whether the partition is defined on the original observations or on the ranked observations, and the statistics we suggest only depend on these cell memberships, we describe the proposed test statistics on the ranked observations. For a cell $C \in \mathcal{C}(\mathcal{I})$, where $\mathcal{I} \in \Pi_m^{DDP}$, the boundaries of C are not necessarily defined by two sample points, as depicted at the bottom right panel of Figure 1. We refer to r_l and r_h as the lower and upper values of the ranks of X in C, and to s_l and s_h as the lower and upper values of the ranks of Y in C, where $r_l, r_h, s_l, s_h \in \{1, \ldots, N\}$. Let o_C and e_C be the observed and expected counts strictly inside the cell, respectively. The expected count in cell C with rank range $[r_l, r_h] \times [s_l, s_h]$ is $e_C = (r_h - r_l - 1)(s_h - s_l - 1)/[N - (m-1)]$. We consider Pearson's score or the likelihood ratio score for a given cell C, and define t_C as in (3). For a given partition $\mathcal{I}$, the score is $T^{\mathcal{I}} = \sum_{C \in \mathcal{C}(\mathcal{I})} t_C$, and similarly to (4) we define

$$S_{m\times m}^{DDP} = \sum_{\mathcal{I} \in \Pi_m^{DDP}} T^{\mathcal{I}}, \quad M_{m\times m}^{DDP} = \max_{\mathcal{I} \in \Pi_m^{DDP}} T^{\mathcal{I}}. \tag{5}$$

For each of the test statistics in (4) and (5), tables of exact critical values for a given sample size N can be obtained for small N by generating all possible $N!$ permutations of $\{1, \ldots, N\}$. For each permutation $(\pi(1), \ldots, \pi(N))$, the test statistic is computed for the reassigned pairs $(1, \pi(1)), \ldots, (N, \pi(N))$. Clearly, the computation of these null distributions does not depend on the data, hence the tests based on these statistics are distribution free. As in the case of the K-sample problem, the p-value is the fraction of permutations for which the computed test statistics

are at least as large as the one observed, and when the number of possible permutations is large, the critical values are obtained by large scale Monte Carlo simulations. The test based on each of these statistics is consistent:

Theorem 2 *Let the joint density of X and Y be $h(x,y)$, with marginal densities $f(x)$ and $g(y)$. If there exists a point (x_0,y_0) such that $h(x_0,y_0)$ is continuous and $h(x_0,y_0) \neq f(x_0)g(y_0)$, i.e., there is local dependence at a continuous density point, and if m is finite or $\lim_{N\to\infty} m/\sqrt{N} = 0$, then the distribution-free permutation tests based on the following test statistics are consistent:*

1. *The test statistics aggregated by summation: $S^{DDP}_{m\times m}$ and $S^{ADP}_{m\times m}$.*
2. *The test statistics aggregated by maximization: $M^{DDP}_{m\times m}$ and $M^{ADP}_{m\times m}$.*

A proof is given in Appendix A. For finite m, as $N\to\infty$, our test statistics converge to population measures of deviation from independence that are zero if and only if the independence hypothesis is true (see Hoeffding (1948a) for a discussion of a similar population quantity when $m=2$). For m growing with N, our test statistics estimate the mutual information, as detailed below.

We note that Thas and Ottoy suggested S_m with $t_C = \sum_{g=1}^{2} \frac{(o_C(g)-e_C(g))^2}{e_C(g)}$ in Thas and Ottoy (2007), and $S^{\mathrm{DDP}}_{m\times m}$ using Pearson's score for finite m in Thas and Ottoy (2004). However, they examined in simulations only $m \leq 4$. Thanks to the efficient algorithms we developed, detailed in Section 3, we are able to test for any $m \leq N$ in the K-sample problem, and for aggregation by summation in the test of independence. If the aggregation is by maximization in the test of independence, the algorithm, detailed in Section 3, is exponential in m and thus the computations are feasible only for $m \leq 4$.

We shall show in Section 4 that the power of the test based on a summation statistic can be different from the power of the test based on a maximization statistic, and which is more powerful depends on the joint distribution. However, for both aggregation methods, using $m > 3$ partitions improves power considerably for complex settings. Therefore, in complex settings our tests with $m > 3$ have a power advantage over the classical distribution-free tests, which focused on rough partitions, typically $m = 2$.

Connection to the MI An attractive feature of the statistics S_m and $S^{ADP}_{m\times m}$, for m large enough, is that they are directly associated with the MI ($I_{XY} = \int h(x,y)\log[h(x,y)/\{f(x)g(y)\}]dxdy$ for continuous X and Y). MI is a useful measure of statistical dependence. The variables X and Y are independent if and only if the MI is zero. Estimated MI is used in many applications to quantify the relationships between variables, see Steuer et al. (2002), Paninski (2003), Kinney and Atwal (2014) and references within. Although many works on MI estimation exist, no single one has been accepted as a state-of-the-art solution in all situations (Kinney and Atwal, 2014). A popular estimator among practitioners due to its simplicity and consistency is the *histogram* estimator, where the data are binned according to some scheme and the empirical mutual information of the resulting partition, i.e, the likelihood ratio score, is computed. Intuitively, one can expect that the statistic $S^{ADP}_{m\times m}$, properly normalized, can also serve as a consistent estimator of the mutual information, when the contingency tables are summarized by the likelihood ratio statistic, since it is the average of histogram estimators, over all partitions. This intuition is true despite the fact that the number of partitions goes to infinity, since we show that the convergence is uniform and that the fraction of "bad" partitions (i.e., partitions with cells that are too big or too small) is small, as long as m goes to infinity at a slow enough rate.

Theorem 3 *Suppose X is categorical with K categories and Y is continuous. Let N_g be the total number of observations from distribution $g \in \{1,\ldots,K\}$, and $N = \sum_{g=1}^{K} N_g$. If $\lim_{N\to\infty} \frac{N_g}{N} > 0$ for $g = 1,\ldots,K$, $\lim_{N\to\infty} \frac{m}{N} = 0$, and $\lim_{N\to\infty} m = \infty$, then $\frac{S_m}{N\binom{N-1}{m-1}}$ is a consistent estimator of the MI.*

Theorem 4 *Suppose the bivariate density of (X,Y) is continuous with bounded mutual information. If $\lim_{N\to\infty} m/\sqrt{N} = 0$, and $\lim_{N\to\infty} m = \infty$, then $\frac{S^{ADP}_{m\times m}}{N\binom{N-1}{m-1}\times\binom{N-1}{m-1}}$ is a consistent estimator of the MI.*

See Appendix B for a proof of Theorem 4. The proof of Theorem 3 is omitted since it is similar to that of Theorem 4. See Appendix D for a simulated example of MI estimation using $S^{DDP}_{m\times m}$, $S^{ADP}_{m\times m}$, and the histogram estimator. The ADP estimator is the least variable, as is intuitively expected since it is the average over many partitions.

Remark 2.1 *In this work we assume there are no ties among the continuous variables. In our software, tied data are broken randomly, so that our test remains distribution free. An alternative approach, which is no longer distribution free, is a permutation test on the ranks, with average ranks for ties. Then a tied observation, that falls on the border of a contingency table cell, receives equal weight in each of the cells it borders with.*

2.1 The Proposed Regularized Statistics

An important parameter of the statistics proposed above is m, the partition size. A poor choice of m may lead to substantial power loss: if m is too small or too large, it may lack power to discover complex non-monotone relationships. For example, consider the three simulation settings for the two-sample problem in the first row of Figure 2. The best partition for setting 1, "normal vs. normal with delta", for small sample sizes, is intuitively to divide the real line into three cells: until the start of the narrow peak, the support of the narrow peak, and after the peak ends. Moreover, the best aggregation method is by maximization, not summation, since there are very few good partitions that capture the peak and aggregation by summation using $m = 3$ will aggregate many bad partitions that miss the peak. Therefore, we expect that M_3 will be the most powerful test statistic for setting 1. For setting 2, "Mix. vs. Mix. 3 vs. 4 components", intuitively it seems best to partition into more than seven cells, and that many partitions will work well. For setting 3, "normal vs. normal with many deltas", it seems best to partition into many cells. Indeed, the power curves in Figure 3 show that for the first setting, M_m is optimal at value $m = 3$, yet if we use this value for the second setting, the test has 20% lower power than optimal power (which is 86% at $m = 10$), and if we use this value for the third setting, the test has 58% less power than the optimal power (which is 88% at $m = 34$). Since the optimal choice of m is unknown in practice, we suggest two types of regularizations which take into consideration the scores from all partition sizes.

The combined p-values statistic The first type of regularization we suggest is to combine the p-values from each m, so that the test statistic becomes the combined p-value. Specifically, let p_m be the p-value from a test statistic based on partition size m, be it S_m or M_m for the K-sample problem, or $S^{ADP}_{m\times m}$ or $S^{DDP}_{m\times m}$ for the independence problem. Due to the computational complexity, we do not consider a regularized score for $M_{m\times m}$. We consider as test statistics the minimum p-value,

$\min_{m\in\{2,\ldots,m_{\max}\}} p_m$, as well as the Fisher combined p-value, $-\sum_{m=2}^{m_{\max}} \log p_m$. These combined p-values are not p-values in themselves, but their null distribution can be easily obtained from the null distributions of the test statistics for fixed ms, as follows: (1) for each of B permutations, compute the test statistics for each $m \in \{2,\ldots,m_{\max}\}$; (2) compute the p-value of each of the resulting statistics, so for each permutation, we have a set of p-values $p_2,\ldots,p_{m_{\max}}$ to combine; (3) combine the p-values for each of the B permutations. Choose B to be large enough for the desired accuracy of approximation of the quantiles of the null distribution of the combined p-values used for testing. Obviously, since the combined p-values are based on the ranks of the data, they are distribution-free. Since they do not require fixing m in advance, they are a practical alternative to the tests that require m as input.

In order to examine how close this regularized score is to the optimal m (i.e., the m with highest power), we looked at the distribution of the ms with minimum p-values in 20,000 data samples from the above-mentioned three simulation settings. For these settings, using the aggregation by maximization statistic, the median m of the minimal p-value was: 3 for the first setting, 9 for the second setting, and 33 for the third setting. Moreover, the first and third quartiles were 3 to 5 for the first setting, 7 to 14 for the second setting, and 19 to 60 for the third setting. We conclude that for these examples, the m that achieves the minimum p-values in most runs was remarkably close to the optimal m (which was 3, 10, and 34 for settings 1,2, and 3, respectively), suggesting that the power of the minimum p-value statistic is close to that of the statistic with optimal m. Indeed, the power of the minimum p-values in settings 1-3 using aggregation by maximum was 0.825, 0.799, and 0.785, whereas the power using the (unknown in practice) optimal m in settings 1-3 was 0.894, 0.86, and 0.88, respectively. Further empirical investigations detailed in Section 4 give additional support to this regularization method.

An extensive numerical investigation, partially summarized in Appendix G, led us to choose the minimum p-value as the preferred regularization method. Between the two combining functions, we preferred the minimum over Fisher, since Fisher was far more sensitive to the choice of the range of m for combining (see Table 6). This regularized statistic is consistent, as the next theorems show.

Theorem 5 *Let Y be continuous, and X categorical. Let N_g be the total number of observations from distribution $g \in \{1,\ldots,K\}$, and $N = \sum_{g=1}^{K} N_g$. If the distribution of Y differs at a continuous density point y_0 across values of X in at least two categories, label these 1 and 2, $\lim_{N\to\infty} \frac{\min(N_1,N_2)}{N} > 0$, then the permutation test based on $\min_{m\in\{2,\ldots,m_{\max}\}} p_m$ is consistent, if:*

1. *it is based on $S_m, m \in \{2,\ldots,m_{\max}\}$, and $\lim_{N\to\infty} m_{\max}/\sqrt{N} = 0$ or $m_{\max}$ is finite.*

2. *it is based on $M_m, m \in \{2,\ldots,m_{\max}\}$ and $\lim_{N\to\infty} m_{\max}/N = 0$ or $m_{\max}$ is finite.*

Theorem 6 *Let the joint density of X and Y be $h(x,y)$, with marginal densities $f(x)$ and $g(y)$. If there exists a point (x_0,y_0) such that $h(x_0,y_0)$ is continuous and $h(x_0,y_0) \neq f(x_0)g(y_0)$, i.e., there is local dependence at a continuous density point, then the permutation test based on $\min_{m\in\{2,\ldots,m_{\max}\}} p_m$ is consistent, if*

1. *it is based on $S^{DDP}_{m\times m}$ or $S^{ADP}_{m\times m}$, and $\lim_{N\to\infty} m_{\max}/N^{1/3} = 0$ or $m_{\max}$ is finite.*

2. *it is based on $M^{DDP}_{m\times m}$ and $M^{ADP}_{m\times m}$, and $\lim_{N\to\infty} m_{\max}/\sqrt{N} = 0$ or $m_{\max}$ is finite.*

The proof of Theorem 6 follows in a straightforward way from the proofs of Theorem 2, see Appendix C for details. The proof of Theorem 5 follows similarly from the proof of Theorem 1, and it is omitted.

The penalized statistic The test statistic is the maximum (over all ms) of the statistic plus penalty. For the K-sample problem, Jiang et al. (2014) suggested assigning a prior on the partition scheme and they regularized the likelihood ratio score using this prior. Specifically, they assumed the partition size is Poisson and the conditional distribution on the m partition widths (normalized to sum to one) is $Dirichlet(1,\ldots,1)$. This led to their penalty term $-\lambda_0(\log N)(m-1)$, where $\lambda_0 > 0$ has to be fixed. We assume that the marginal distribution on the partition size is $\pi(m)$ (e.g., Poisson or Binomial), and that the prior probability of selecting $\mathcal{I}$ given m, $\pi(\mathcal{I}|m)$, is uniform. There is an important difference between our uniform discrete prior distribution on partitions of size m and the continuous Dirichlet uniform prior of Jiang et al. (2014). Our prior is uniform on all partitions that truly divide the sample space into m cells, i.e., we cannot have two partition lines between two consecutive samples, since this is actually an $m-1$ partition. Using the continuous Dirichlet prior results in practice in at most m partitions, but the partition size may also be strictly smaller than m if two partition points lie between two sample points. Therefore, their conditional distribution given the partition size parameter is not necessarily the true size of the partition. Their penalty translates to a conditional probability given a true partition size m of $\frac{(m-1)!}{(N-1)^{(m-1)}}$, compared to our $\pi(\mathcal{I}|m) = 1/\binom{N-1}{m-1}$. Therefore, their score penalizes more severely large ms, and their regularized test statistic has less power when the optimal m is large in our simulations.

For aggregation by maximum in the K-sample problem, we consider the regularized statistic,

$$\max_{m\in\{2,\ldots,m_{\max}\}} \{M_m + \log[\pi(\mathcal{I}|m)\pi(m)]\}, \tag{6}$$

where we use the likelihood ratio score per partition. Due to the computational complexity, we do not consider a regularized score for $M_{m\times m}$. For aggregation by summation, our efficient algorithms described in Section 3 enable us to consider the penalized average score per m,

$$\max_{m\in\{2,\ldots,m_{\max}\}} \{SLR_m\pi(\mathcal{I}|m) + \log\pi(m)\} \tag{7}$$

where $SLR_m\pi(\mathcal{I}|m)$ is S_m divided by the number of partitions of size m for the K-sample test, and $S^{ADP}_{m\times m}$ (or $S^{DDP}_{m\times m}$) divided by the number of partitions of size $m\times m$ for the test of independence, using the likelihood ratio score per partition. The null distribution of these regularized statistics is computed by a permutation test, and they are distribution free.

Regularization using priors was less effective than using combined p-values, except when the Poisson prior was used with parameter $\lambda = \sqrt{N}$ (see Table 7). We preferred the first type of regularization since it was at least as effective as regularizing by a Poisson prior, without requiring setting any additional parameters.

3. Efficient Algorithms

For computing the above test statistics for a given N and partition size m, the computational complexity of a naive implementation is exponential in m. We show in Section 3.1 more sophisticated algorithms for computing the aggregation by sum statistics for all $m \in \{2,\ldots,N\}$ at once that have complexity $O(N^2)$ for the K-sample problem, and $O(N^4)$ for the independence problem. This is

possible since instead of iterating over partitions, the algorithms iterate over cells. Moreover, the algorithms also enable calculating the regularized sum statistics of Section 2.1 in $O(N^2)$ and $O(N^4)$ for the K-sample and independence problems, respectively, since we just need to go over the list of m scores and for each score S_m check its p-value in our pre-calculated null tables, which requires just an additional $O(N\log(B))$, where B is the null-table size.

We show in Section 3.2 an algorithm with complexity $O(N^3)$ for the K-sample problem for computing the aggregation by maximum for all m at once. This algorithm also enables calculating the regularized maximum statistic of Section 2.1 in $O(N^3)$. The algorithms for aggregating by maximum in the independence problem are exponential in m, and therefore infeasible for modest N and $m > 4$. However, for $m = 3$ and $m = 4$ we provide efficient algorithms with $O(N^2)$ and $O(N^3)$ complexity, respectively, for the DDP test statistics.

3.1 Aggregation by Summation

The algorithms for aggregation by summation are efficient due to two key observations. First, the score per partition is a sum of contributions of individual cells, and the total number of cells is much smaller than the number of partitions (unless $m = 2$ in the K-sample problem, and $m \le 4$ when using DDP in the independence problem, see Remark 3.1 below). Therefore, we can interchange the order of summation between cells and partitions and thus achieve a big gain in computational efficiency, since it is easy to calculate in how many partitions each cell appears, see equations (8) and (11).

Second, because for a fixed m the number of partitions in which a specific cell appears depends only on the width (and for independence testing, also length) of the cell, the data-dependent computations do not depend on m: the test statistics are the sum of cell scores for every width for the K-sample test, and for every combination of width and length for the independence test, see equations (9) and (12). The complexity of the algorithm remains the same even when the scores are computed for all ms, since the complexity is determined by a preprocessing phase which is shared by all ms. Therefore, the complexity for the regularized scores is the same as the complexity for a single m.

3.1.1 Algorithm for the K-Sample Problem

For $g = 1,\dots,K$ (the categories of X) and $r = 1,\dots,N$ (the ranks of Y), we first compute in $O(N)$ A as follows:

$$A(g,r) = \sum_{i=1}^{r} I(g_i = g),$$

and let $A(g,0) = 0$. For a cell with rank range $[r_l, r_h]$, where $r_l, r_h \in \{1,\dots,N\}$, using A, the count of observations in category g that fall inside the cell can be computed in $O(1)$ operations as $o_C(g) = A(g,r_h) - A(g,r_l-1)$. Therefore, for each cell C the contribution of the cell, t_C, can be computed in $O(1)$ time.

Because the score per partition is a sum of contributions of individual cells, S_m is the sum over the score per cell, multiplied by the number of times the cell appears in a partition of size m.

Considering further summing cells of width 1 to N, we may write S_m as follows:

$$S_m = \sum_{\mathcal{I}\in\Pi_m} T^{\mathcal{I}} = \sum_{C\in\mathcal{C}} t_C \sum_{\mathcal{I}\in\Pi_m} I[C\in\mathcal{C}(\mathcal{I})] = \sum_{w=1}^{N}\sum_{C\in\mathcal{C}(w)} t_C n(w,m,C), \tag{8}$$

where $\mathcal{C}(w)$ is the collection of cells of width w and $n(w,m,C)$ is the number of partitions that include C. For computing $n(w,m,C)$, we differentiate between two possible types of cells: edge cells and internal cells. Edge cells differ from internal cells by having either $r_l = 1$ or $r_h = N$. The number of partitions of order m that include an edge cell of width $w = r_h - r_l + 1$ is given by $\binom{N-1-w}{m-2}$. The number of partitions including a similarly wide internal cell is $\binom{N-2-w}{m-3}$. Therefore, we may write S_m as follows:

$$S_m = \sum_{w=1}^{N}\binom{N-2-w}{m-3} T_i(w) + \sum_{w=1}^{N}\binom{N-1-w}{m-2} T_e(w), \tag{9}$$

where $T_i(w) = \sum_{\substack{C\in\mathcal{C}(w),\\ r_l\neq 1\cap r_h\neq N}} t_C$ and $T_e(w) = \sum_{\substack{C\in\mathcal{C}(w),\\ r_l=1\cup r_h=N}} t_C$. The algorithm proceeds as follows. First, in a preprocessing phase, we calculate $T_i(w)$ and $T_e(w)$ for all $w \in \{1,\dots,N\}$. Since t_C can be calculated in $O(1)$, as described above, the calculation of $T_i(w)$ and $T_e(w)$ for a fixed w takes $O(N)$. Since there are N values for w, we can compute and store all values of $T_i(w)$ and $T_e(w)$ in $O(N^2)$. Also in the preprocessing phase, for all $u, v \in \{0,\dots,N\}$ we calculate and store all $\binom{u}{v}$. This can be done in $O(N^2)$ using Pascal's triangle method.

Given $T_i(w), T_e(w), w = 1,\dots,N-1$ (which are independent of m!), and all $\binom{u}{v}$, we can clearly calculate S_m according to equation (9) for any m in $O(N)$ and therefore for all ms in $O(N^2)$, since $m < N$. Therefore the overall complexity of computing the scores for all ms is $O(N^2)$.

3.1.2 Algorithm for the Independence Problem

Let r_i be the rank of x_i among the observed x values, and s_i be the rank of y_i among the y values The algorithm first computes the empirical cumulative distribution in $O(N^2)$ time and space,

$$A(r,s) = \sum_{i=1}^{N} I(r_i \le r \text{ and } s_i \le s), \quad (r,s) \in \{0,1,\dots,N\}^2 \tag{10}$$

where $A(0,s) = 0, A(r,0) = 0$ and $\hat{F}(r,s) = A(r,s)/N$. First, let B be the $(N+1)\times(N+1)$ zero matrix, and initialize to one $B(r_i,s_i)$ for each observation $i = 1,\dots,N$. Next, go over the grid in s-major order, i.e., for every s go over all values of r, and compute:

1. $A(r,s) = B(r,s-1) + B(r-1,s) - B(r-1,s-1) + B(r,s)$, and
2. $B(r,s) = A(r,s)$.

We describe the algorithm for the ADP statistic, which selects partitions on the grid $\{1.5,\dots,N-0.5\}^2$ on ranked data. The main modifications for the DDP statistic are provided in Appendix E. The count of samples inside a cell with rank ranges $r \in [r_l, r_h]$ and $s \in [s_l, s_h]$ can be computed in $O(1)$ operations via the inclusion-exclusion principle:

$$o_C = A(r_h,s_h) - A(r_l-1,s_h) - A(r_h,s_l-1) + A(r_l-1,s_l-1).$$

Therefore, for each cell C the contribution of the cell t_C can be computed in $O(1)$ time. Because the score per partition is a sum of contributions of individual cells, we may write $S^{ADP}_{m\times m}$ as follows:

$$\sum_{\mathcal{I}\in\Pi^{ADP}_m} T^{\mathcal{I}} = \sum_{C\in\mathcal{C}} t_C \sum_{\mathcal{I}\in\Pi^{ADP}_m} I[C\in\mathcal{C}(\mathcal{I})] = \sum_{w=1}^{N-2}\sum_{l=1}^{N-2}\sum_{C\in\mathcal{C}(w,l)} t_C n(w,l,m,C), \qquad (11)$$

where $\mathcal{C}(w,l)$ is the collection of cells of width w and length l and $n(w,l,m,C)$ is the number of partitions that include C. As in the algorithm for the K-sample problem, $n(w,l,m,C)$ depends only on w,l,m, and whether the cell is an internal cell or an edge cell. For simplification, we discuss only the computation of the contribution of internal cells to the sum statistic, and non-internal cells can be handled similarly (as discussed in the algorithm for the K-sample problem). Therefore, our aim is to compute:

$$\sum_{w=1}^{N-2}\sum_{l=1}^{N-2} n(w,l,m)T(w,l), \qquad (12)$$

where $T(w,l)=\sum_{C\in\mathcal{C}(w,l)} t_C$ and $n(w,l,m)$ is the number of partitions that include an internal cell of width w and length l when the partition size is m and $\mathcal{C}(w,l)$ is relabelled to be the collection of internal cells of width w and length l.

The algorithm proceeds as follows. First in a preprocessing phase we perform two computations: 1) calculate and store $T(w,l)$ for all pairs $(w,l)\in\{1...N-2\}^2$. Since t_C can be calculated in $O(1)$, as described above, the calculation of $T(w,l)$ for a fixed (w,l) takes $O(N^2)$ and since there are $(N-2)^2$ pairs (w,l) the total preprocessing phase takes $O(N^4)$; 2) for all $u,v\in\{0,\ldots,N\}$ we calculate and store all $\binom{u}{v}$ in $O(N^2)$ steps using Pascal's triangle method.

Given $T(w,l)$, and all $\binom{u}{v}$, since $n(w,l,m)=\binom{N-2-w}{m-3}\binom{N-2-l}{m-3}$, we can clearly calculate equation (12) for a fixed m in $O(N^2)$ and therefore for all ms in $O(N^3)$. Due to the preprocessing phase the total complexity is $O(N^4)$.

Remark 3.1 *When it is desired to only compute the statistic for very small m, faster alternatives exist. For the two-sample problem, for $m=2$, the number of partitions is $O(N)$ and therefore an $O(N\log N)$ algorithm can be applied that aggregates over all partitions, and the complexity is dominated by the sorting of the N observations (for $m=3$, the number of partitions is already $O(N^2)$). Similarly, for the test of independence, the ADP statistic can be calculated in $O(N^2)$ steps for $m=2$, and the DDP statistic in $O(N^2)$ for $m=3$, and in $O(N^3)$ for $m=4$, since this is the order of the number of partitions. Per partition, the computation of the score for $m\le 4$ is computed in $O(1)$ time since the contribution of a cell can be computed in $O(1)$ time (as shown above). The DDP statistic for $m=2$ can be computed in $O(N\log N)$, using a similar sorting scheme as that detailed in Heller et al. (2013).*

3.2 Aggregation by Maximization

Algorithm for the K-sample problem Jiang et al. (2014) suggested an elegant and simple dynamic programming algorithm for calculating $\max_m\{M_m - m\lambda(N)\}$ for any function $\lambda(\cdot)$ in $O(N^2)$. We present a modification of their algorithm that enables us to calculate M_m for all ms in $O(N^3)$. As a first step, for all $i\le N$ and for all $j<i$ we calculate iteratively $M(i,j)$, the maximum score which partitions the first i samples into j partitions. We compute $M(i+1,j)$ from $M(a,j-1), a\le i$ using:

$$M(i+1,j)=\max_{a\in\{2,\ldots,i\}}\{M(a,j-1)+t_{[a+0.5,i+1+0.5]}\},$$

where $t_{[a+0.5,i+1+0.5]}$ is the score of the cell from $a+0.5$ to $i+1+0.5$. This calculation takes $O(N)$, and since we have $O(N^2)$ such items to calculate, this step takes $O(N^3)$. Since $M_m=M(N,m)$, the overall complexity for computing the scores for all ms is $O(N^3)$. Note that this algorithm enables us to calculate $\max_{m\in\{2,\ldots,m_{\max}\}}\{M_m+\log[\pi(\mathcal{I}|m)\pi(m)]\}$ in $O(N^3)$ for any function $\pi(m)$, thus the regularized test statistic in Section 2.1 can also be computed in $O(N^3)$.

Algorithm for the independence problem The algorithm is the same as described in Remark 3.1 for the ADP statistic for $m=2$ and for the DDP statistic for $m=3$ and $m=4$, with the difference that the aggregation is by maximization (not summation) over the scores per partition. We are not aware of a polynomial-time algorithm for arbitrary m. We discuss ways to reduce the computational complexity in Section 6.

Remark 3.2 *We show in Appendix F that for univariate data the test of Heller et al. (2013) with an arbitrary distance metric, with or without ties, can be computed in $O(N^2)$ in a similar fashion, thus improving their algorithm by a factor of $\log N$ when X and Y are univariate.*

4. Simulations

In simulations, we compared the power of our different test statistics in a wide range of scenarios. All tests were performed at the 0.05 significance level. Look-up tables of the quantiles of the null distributions of the test statistics for a given N were stored. Power was estimated by the fraction of test statistics that were at least as large as the 95th percentile of the null distribution. The null tables were based on 10^6 permutations.

The noise level was chosen separately for each configuration and sample size, so that the power is reasonable for at least some of the variants. This enables a clear comparison using a range of scenarios of interest. Since the power was very similar for the Pearson and likelihood ratio test statistics, only the results of the likelihood ratio test statistic are presented.

The simulations for the two-sample problem are detailed in 4.1, and for the independence problem in 4.2. The analysis was done with the R package *HHG*, now available on CRAN.

4.1 The Two-Sample Problem

We examined the power properties of the statistic aggregated by summation as well as by maximization for $m\in\{2,\ldots,N/2\}$, as well as the minimum p-value statistic, $\min_{m\in\{2,\ldots,m_{\max}\}} p_m$. We display here the results for $m_{\max}=149$ and $N=500$. However, the choice of $m_{\max}$ has little effect on power, see Appendix G for results with other values of $m_{\max}$. Also, see Appendix G for the results for $m_{\max}=29$ and $N=100$.

We compared these tests to six two-sample distribution-free tests suggested in the literature. We compared to Wilcoxon's rank sum test, since it is one of the most widely used tests to detect location shifts. We compared to two consistent tests suggested recently in the literature, the test of Jiang et al. (2014), referred to as DS, and the test of Heller et al. (2013) on ranks, referred to as HHG on ranks. Finally, we compared to the classical consistent tests of Kolmogorov and Smirnov,

referred to as KS, of Cramer and von Mises (which is equivalent to the energy test of Székely and Rizzo (2004) on ranks), referred to as CVM, and of Anderson and Darling, referred to as AD.

We examined the distributions depicted in Figure 2. The three scenarios in the third row were examined in Jiang et al. (2014). The remaining scenarios were chosen to have different numbers of intersections in the densities, ranging from 2 to 18, in order to examine the effect of partition size m on power when the optimal partition size increases, as well as verify that the regularized statistic has good power. The scenarios also differ by the range of support of where the differences in the distributions lie (specifically, in the first and third scenario in the first row the difference between the distributions is very local), since this makes the comparison between the two aggregation methods interesting. We considered symmetric as well as asymmetric distributions. Gaussian shift and scale setups were considered in Appendix G. Such setups are less interesting in the context of this work, because if the two distributions differ only in shift or scale then specialized tests such as Wilcoxon rank-sum for shift will be preferable, but it is important to know that the suggested tests do not break down in this case. We used 20,000 simulated data sets, in each of the configurations of Figure 2.

Table 1 and Figure 3 show the power for the setups in Figure 2. These results show that if the number of intersections of the two densities is at least four, tests statistics with $m \geq 4$ have an advantage. Since the classical competitors, KS, CVM and AD, are based on $m = 2$, they perform far worse in these setups. Moreover, although HHG and DS have better power than the classical tests, HHG is essentially an $m \leq 3$ test, and DS penalizes large ms severely, therefore their power is still too low when fine partitioning is advantageous. The minimum p-value statistic, which does not require to preset m, is remarkably efficient: in Figure 2 we see that in all settings considered, it is close to the power of the optimal m.

The choice of aggregation by maximization versus summation depends on how local the differences are between the distributions. In Figure 3 we see clearly that when the differences are in very local areas, maximization achieves the greatest power and the test based on minimum p-value has more power if the aggregation is by maximization rather than by summation (setups 1, 2, and 13), and aggregation by summation is better otherwise. Note that the optimal m for aggregation by summation is always larger than for aggregation by maximization. The reason is that in order to have a powerful statistic aggregated by maximization, it is enough to have one good partition (i.e., contain cells where the distributions clearly differ) for a fixed m, whereas by summation it is necessary to have a large fraction of good partitions among all partitions of size m.

4.2 The Independence Problem

We examined the power properties of the ADP and DDP statistics, aggregated by summation for $m \in \{1, \ldots, \sqrt{N}\}$, aggregated by maximization for $m \leq 4$, as well as the minimum p-value statistic $\min_{\{m \in 2,..,m_{max}\}} p_m$ based on aggregation by summation. We display here the results for $m_{\max} = 10$ and $N = 100$.

We compared these tests to seven tests of independence suggested in the literature. We compared to Spearman's ρ, since it is perhaps the most widely used test to detect monotone associations. We also compared to previous tests suggested in the literature with the same two important properties as our suggested tests, namely proven consistency and distribution-freeness, as well as an available implementation: the test of Hoeffding (1948b), referred to as Hoeffding; the tests of Székely et al. (2007) and Heller et al. (2013) that first transform the observations of each variable into ranks, referred to as dCov and HHG, respectively. We also compared to the test of Reshef et al. (2011),

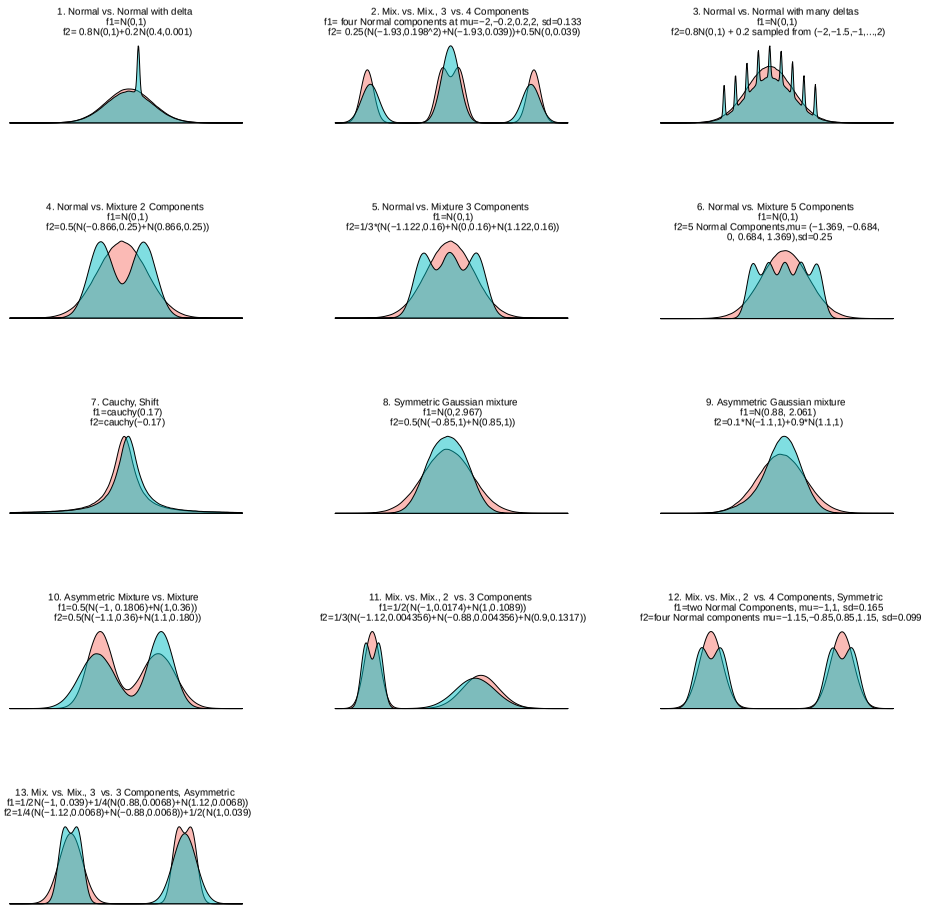

Figure 2: The two-sample problem in 13 different setups considered for $N = 500$, which differ in the number of intersections of the densities, the range of support where the differences lie, and whether they are symmetric or not.

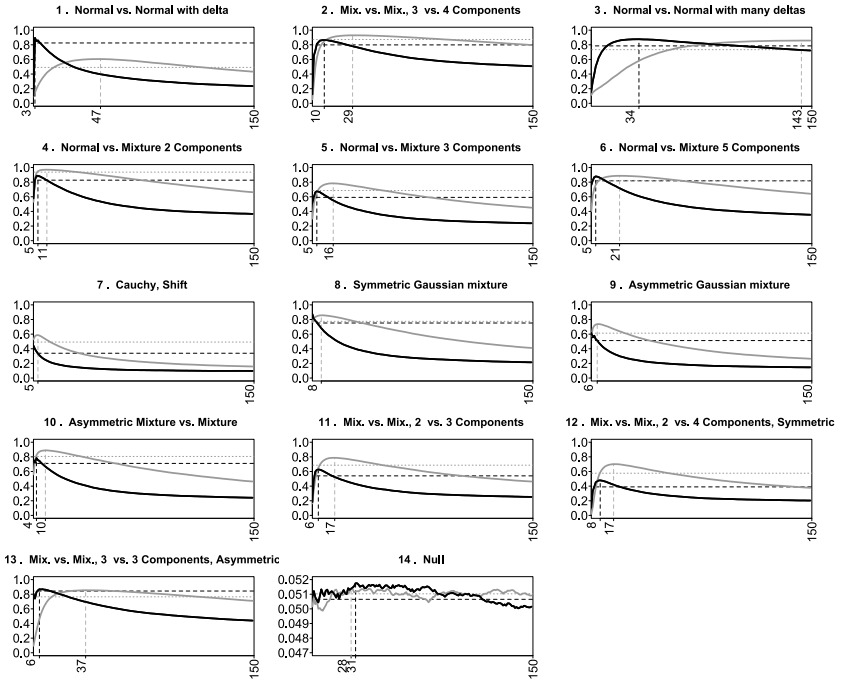

Figure 3: Estimated power with $N = 500$ sample points for the M_m (black) and S_m (grey) statistics for $m \in \{2, \ldots, 149\}$ for the setups of Figure 2. The score per partition was the likelihood ratio test statistic. The power of the minimum p-value is the horizontal dashed black line when it combines the p-values based on M_m, and the horizontal dotted grey line when it combines the p-values based on S_m. The vertical lines show the optimal m for M_m (black) and S_m (grey).

Table 1: Power of competitors (columns 4-9), along with the minimum p-value statistic using the M_m p-values (column 2) and the S_m p-values (column 3), for $N = 500$. The score per partition was the likelihood ratio test statistic. The standard error was at most 0.0035. The advantage of the test based on the minimum p-value is large when the number of intersections of the two densities is at least four (setups 2,3,4,5,6,10,11,12, and 13). The best competitors are HHG and DS, but HHG is essentially an $m \leq 3$ test, and DS penalizes large ms severely, therefore in setups where $m \geq 4$ partitions are better they can perform poorly. Among the two variants in columns 2 and 3, the better choice clearly depends on the range of support in which the differences in distributions occur: aggregation by maximum has better power when the difference between the distributions is very local (setups 1, 3, and 13), and aggregation by summation has better power otherwise. The highest power per row is underlined.

referred to as MIC, which is not consistent due to the computational shortcuts they have to use. We note that the power of the original dCov and HHG was fairly similar to the power of their distribution-free variants, see Appendix I.

We examine complex bivariate relationships depicted in Figure 4. Most of these scenarios were collected from the literature illustrating the performance of other methods. Specifically, the first two rows were examined in Newton (2009), the next two rows are similar to the relationships examined in Reshef et al. (2011), and the Heavisine and Doppler examples in the last row were used extensively in the literature on denoising, see e.g., Donoho and Johnstone (1995). In all but the 4 Independent Clouds setup, there is dependence. The 4 Independent Clouds setup allows us to verify that the tests maintain the nominal level. We used 2000 simulated data sets for $N = 100$ and $N = 300$, in each of the configurations of Figure 4. Monotone setups are presented in Appendix H in Figure 12. Monotone setups are less interesting in the context of this work, because if there is reason to believe that the dependence is monotone, specialized tests such as Spearman's ρ or Kendall's τ will be preferable, but it is important to know that the suggested tests have reasonable power, as demonstrated in the results in Appendix H, Figure 13 and Table 10.

Tables 2 and 3, and Figure 5 show the power for the settings depicted in Figure 4. We only considered the test based on the DDP minimum p-value statistic in Tables 2 and 3, since for the

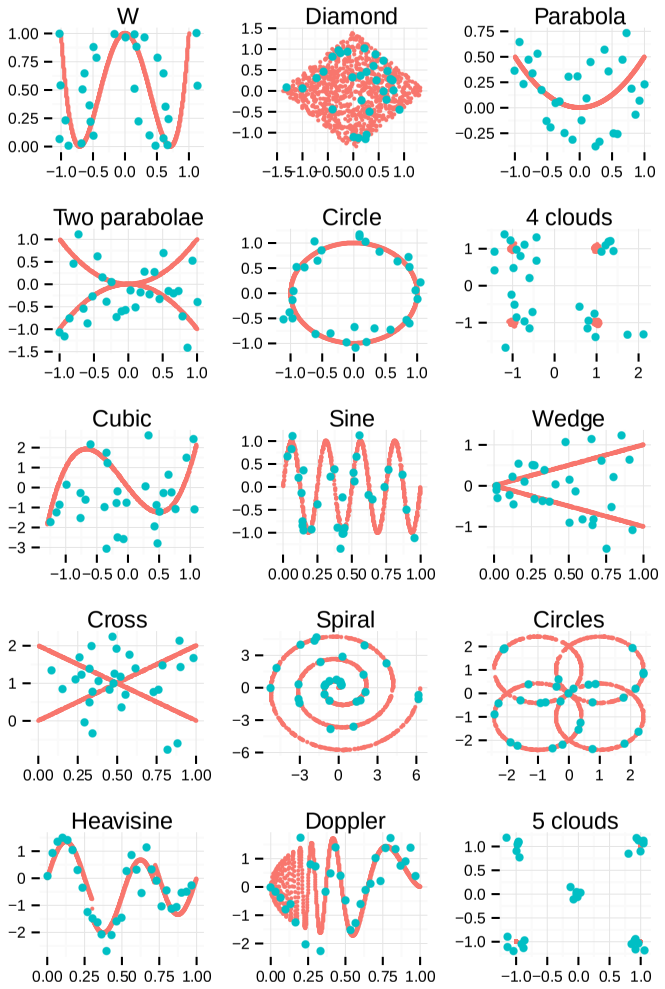

Figure 4: Bivariate relationships (in red), along with a sample $N = 100$ noisy observations (in blue). The "four clouds" relationship is a null relationship, where the two random variables are independent.

Table 2: Power of competitors (columns 3–7), along with the DDP minimum p-value statistic for $N = 100$. The standard error is at most 0.011. The score per partition was the likelihood ratio test statistic. The DDP minimum p-value statistic performs very well in comparison to the other tests. Although the competitors may have greater power in some examples, the advantage is usually small. By far the best competitor is HHG, yet it has a disadvantage when the relationship is more complex, thus benefiting from the finer partition of the minimum p-value test, especially in the Sine, Heavisine, Spiral and Circles examples. The highest power per row is underlined.

minimum p-value statistic the tests of ADP and DDP are almost identical. These results provide strong evidence that for non-monotone noisy dependencies our tests have excellent power properties. Specifically, $S^{DDP}_{m\times m}$ with $m \in \{3,\ldots,10\}$ is more powerful than all other tests in Table 2 in most settings. For example, it had greater power than all competitors in 9 settings with $m = 4$ and in 11 settings with $m = 5$, out of the 14 non-null settings. The test based on the minimum p-value has greater power than all competitors in 7 settings, and it is very close to the best competitor in most of the other settings. The MIC is best for the Sine example but performs poorly in all other examples. The minimum p-value statistic is a close second best in the Sine example, with a difference of only 0.005 from MIC, yet all other tests are more than 0.19 below MIC in power. Overall, the HHG test is the best competitor, but its power is lower than that of the minimum p-value statistic when the optimal m is greater than 4. Table 3 shows that when aggregating by maximization, the choice of m matters and the power is higher for $m > 2$. However, the minimum p-value statistic, which is aggregated by summation and considers finer partitions, is more powerful for most settings, and is a close second in the remaining settings.

5. Application to Real Data

We examine the co-dependence between pairs of genes on chromosome 1 in the yeast gene expression data set from Hughes et al. (2000), which contained $N = 300$ expression levels. After removing genes with missing values, we had 94 genes and a family of $\binom{94}{2} = 4371$ pairs to examine simultaneously. Each pair was tested for independence by the tests of Spearman, Hoeffding,

4Clouds	0.051	0.052	0.051	0.051	0.052

Table 3: The power of different variants aggregated by maximization (columns 3–6), along with the DDP minimum p-value statistic (column 2) for $N = 100$. The standard error is at most 0.011. The score per partition was the likelihood ratio test statistic. Although maximization is better than summation in some examples, the advantage is usually small. The advantage of the minimum p-value statistic, which is based on aggregation by summation, is large in the Cubic, Cross, Spiral, and Circles relationships. In most examples, power increases with m. The power differences between the ADP and DDP variants are small. We present only the maximum variants that take at most $O(N^3)$ to compute, therefore for ADP only results with $m = 2$ are presented. The highest power per row is underlined.

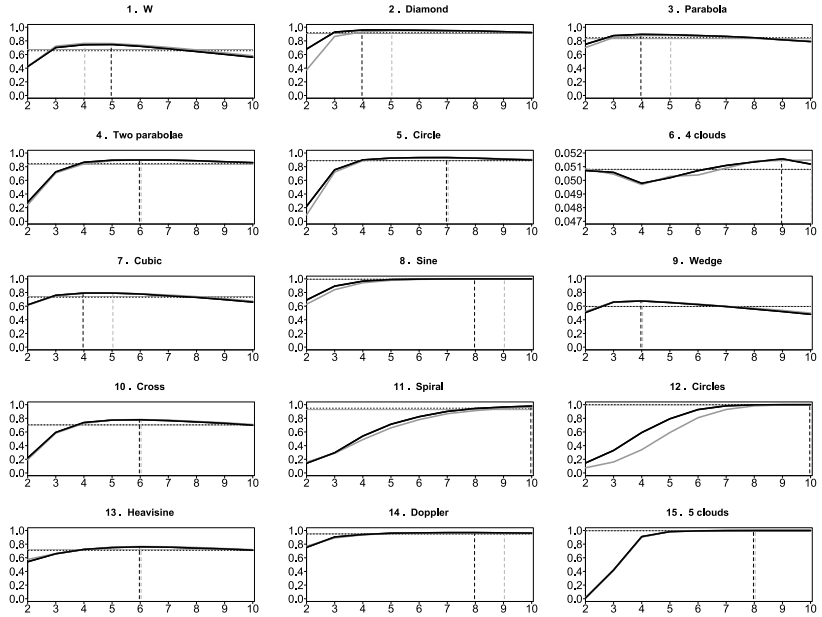

Figure 5: Estimated power as a function of partition size m, with $N = 100$ sample points, for the DDP (black) and ADP (grey) summation variants using the likelihood ratio score for the setups of Figure 4. The score per partition was the likelihood ratio test statistic. For DDP (black) and ADP (grey), the horizontal dashed line is the power of the minimum p-value statistic, and the vertical lines is the optimal m.

Test	Number of rejections	Number of intersections
Spearman	2488	2445
MIC	245	245
Hoeffding	2890	2844
HHG on ranks	3283	3199
dCov on ranks	2889	2845
minimum p-value based on ADP	3310	3294

Table 4: Benjamini–Hochberg rejections at level 0.05 for the gene expression problem of Hughes et al. (2000). For different test statistics (rows), the number of rejections (column 2), and their intersection with the rejections using the minimum p-value statistic on DDP (column 3). The minimum p-value statistic on DDP had the highest number of rejections, 3312.

MIC, dCov and HHG on ranks, as well as by our new tests with m ranging from 2 to $m_{\max} = 17$. The null tables were based on $20,000$ permutations for $N = 300$. The adjusted p-values from the Benjamini–Hochberg procedure (Benjamini and Hochberg, 1995) were computed for each test statistic.

Table 4 shows the pairwise agreements between the Benjamini–Hochberg procedure at level 0.05 using the different test statistics considered in each row, with the minimum p-value statistic based on DDP. Clearly, a large number of pairwise associations are missed when testing is performed with Spearman's ρ compared to the minimum p-value statistic, and only a small number of gene pairs detected with Spearman are missed by the minimum p-value statistic (row 1 in Table 4). These findings contradict an earlier examination of the data. Steuer et al. (2002) concluded that the most widely used approach for pairwise association testing, namely Spearman correlation, performs equivalently to a mutual information based testing approach. The authors speculated that actual dependencies, if any, are linear. The number of discoveries using MIC, Hoeffding, and dCov are much smaller than using the minimum p-value statistic. HHG on ranks also discovers less co-dependencies compared with the minimum p-value statistic. The agreement between the tests based on DDP and ADP was very high, as seen in the last row of Table 4 and in Figure 6, which shows the number of rejections for $S^{DDP}_{m\times m}$ and $S^{ADP}_{m\times m}$ for $m = 2,\ldots,17$. We conclude that in this data set there are many nonlinear associations, but powerful tests are necessary in order to detect such associations in light of the large number of simultaneous tests that have to be carried out, and that the suggested tests can be valuable tools for this task.

Note that the data had ties due to low precision of the documented expression levels. Ties were broken randomly, see remark 2.1. Repeated analysis with different seeds provided similar results.

6. Discussion

In this paper we proposed new partition-based test statistics for both the independence problem and the two-sample problem. We proved that the statistics are consistent for general alternatives and demonstrated in simulations that the power advantage of the tests based on finer partitions can be great. We further showed that the power of our regularized statistics is very close to that of the statistics based on the optimal partition size. We recommend the test using the minimum p-value statistic based on aggregation by summation, unless the alternative is suspected to be of very local nature. Specifically, in the K-sample problem if the difference between the distributions is on a

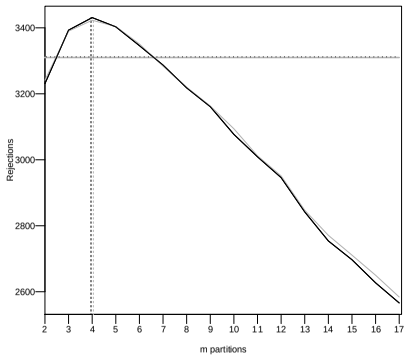

Figure 6: Number of discoveries of genes with associated expression patterns in the data of Hughes et al. (2000), by the Benjamini–Hochberg procedure at level 0.05 using $S^{DDP}_{m\times m}$ (black) and $S^{ADP}_{m\times m}$ (gray) for $m = 2,\ldots,17$. In addition, number of rejections using the minimum p-value statistic with $m_{\max} = 17$, using the DDP (black horizontal line) and the ADP (gray horizontal line).

very small range of the support, then the aggregation by maximization is preferred over aggregation by summation.

The algorithms described in Section 3.1 for the test of independence based on regularized scores for a range of $m \times m$ partitions can easily be generalized to include $m_x \times m_y$ partitions, where $m_x \neq m_y$, with the same complexity for the ADP statistic (for the DDP statistic $m_x = m_y$). Considering unequal partition sizes for X and Y is expected to improve power when the (unknown) optimal partition has an m_x value very different than the m_y value. Moreover, when the (unknown) optimal partition has $m_x \approx m_y$, the power loss from considering the minimum p-value over all $m_x \times m_y$ values instead of over all $m \times m$ values is expected to be small.

The algorithms we suggested for the K-sample problem are $O(N^2)$ and therefore are feasible even for large N. For the test of independence, even though the complexity of our suggested algorithms is $O(N^4)$, for small N these algorithms can be quite efficient in the following quite common multiple testing setting in modern studies. If M hypotheses are simultaneously examined with the same sample size, then the computational complexity of using our distribution-free tests is $O(M \times N^4)$ if null table is available for this N, or $\max\{O(M \times N^4), O(B \times N^4)\}$ if the null table is generated by the user using B Monte-Carlo replicates for the sample size N. If we needed to recompute the null distribution for every one of the M hypotheses (as required for permutation tests that are not distribution-free, such as dCov and HHG), then the computational complexity would have been $O(M \times B \times N^4)$, which may be infeasible in modern studies where the number of hypotheses tests simultaneously examined can be several thousands or hundreds of thousands. Since the null distribution needs to be generated only once in order to compute the significance

of all the M test statistics, due to the distribution-free property of our tests, they can be feasible with today's computing power even for a few thousands samples. However, computing $O(N^4)$ test statistics is unfeasible for larger sample sizes. To reduce the computational complexity when N is large, statistics which do not go over all partitions but rather just over a representative sample can be considered. This approach was used for example in Jiang (2014) for the K-sample problem. A simple way of doing this is to divide the data into $\sqrt{N} \times \sqrt{N}$ bins and only consider partitions that do not break up these bins. We expect such statistics to also be consistent and the algorithms that accompany them to be computable in $O(N^2)$.

If one expects relatively simple dependence structures, for large N, the $S_{3\times3}^{DDP}$ is recommended, since it is both distribution-free and computable in $O(N^2)$ (see Remark 3.1). In our simulations it was as powerful as HHG and more powerful than dCov, and it has the advantage of being distribution-free.

We focused our attention mainly on comparisons of distribution-free tests. We provided in Appendix I a comparison of our recommended tests with the non distribution-free HHG test of Heller et al. (2013) and the dCov test of Székely and Rizzo (2009b). These tests had less power than our novel distribution-free tests when there is advantage to finer partitions. It is of interest to examine how the extended α-distance dependence measure suggested in Székely and Rizzo (2009b) perform in these complex relationships. It is also of interest to compare to the non distribution-free kernel methods of Gretton et al. (2007) and Gretton et al. (2008). For this purpose, care must be taken in the choice of kernel bandwidth, see Gretton et al. (2012b).

In this work we restricted our attention to testing an independent sample from the joint distribution. If the paired observations are not independent, but are independent within blocks, we can easily modify our test by restricting the permutation tests to be within the blocks. When there is temporal dependence, an interesting work by Chwialkowski et al. (2014) suggested a bootstrap based approach for kernel based tests. How to modify our test in the face of temporal dependence is an open question.

A thorough investigation of the suggested mutual information estimator in Section 2 was outside the scope of this paper, but is of interest for future research. We suspect the asymptotic distribution of our mutual information estimator has a simple form. The bias of the estimator can be dealt with by modifying our estimator, and our algorithms accordingly, to only include partitions with cells of a minimum size, and by bias correction methods suggested in the literature, e.g., Vu et al. (2007). Although in this work we limited ourselves to a theoretical examination of the ADP summation statistic for mutual information estimation, we recognize that an estimator based only on the DDP may be useful, and we plan to explore it in the future.

Appendix A. Proof of Theorem 2

The proof for the DDP and ADP tests are given in Sections A.1 and A.2 respectively.

A.1 The DDP Test

Proof Denote $S_{m\times m} = S_{m\times m}^{DDP}$. For simplicity, we show the proof using Pearson's test statistic. The proof using the likelihood ratio test statistic is very similar and therefore omitted. We want to show that for an arbitrary fixed $\alpha \in (0,1)$, if H_0 is false, then $\lim_{N\to\infty} Pr(S_{m\times m} > S_{1-\alpha}^{tab}) = 1$, where $S_{1-\alpha}^{tab}$ denotes the $1-\alpha$ quantile of the null distribution of $S_{m\times m}$.

If H_0 is false, then without loss of generality $h(x_0,y_0) > f(x_0)g(y_0)$. Moreover, there exists a distance $R > 0$ such that $h(x,y) > f(x)g(y)$ for all points (x,y) in the set $\mathcal{A} = \{(x,y) : x_0 \le x \le x_0 + R, y_0 \le y \le y_0 + R\}$. The set $\mathcal{A}$ has positive probability, and moreover

$$\min_{\mathcal{A}}[h(x,y) - f(x)g(y)] > 0.$$

Denote this minimum by $c > 0$. Clearly, the following two subsets of $\mathcal{A}$ have positive probability as well:

$$\mathcal{A}_1 = \{(x,y) : x_0 \le x \le x_0 + R/4, y_0 \le y \le y_0 + R/4\}$$
$$\mathcal{A}_2 = \{(x,y) : x_0 + 3R/4 \le x \le x_0 + R, y_0 + 3R/4 \le y \le y_0 + R\}.$$

Denote the probabilities of $\mathcal{A}_1$ and $\mathcal{A}_2$ by f_1 and f_2, respectively.
Let $\Gamma\{(x_1,y_1),\ldots,(x_N,y_N)\}$ be the set of partitions of size m based on at least one sample point in $\mathcal{A}_1$ and on at least one sample point in $\mathcal{A}_2$. Let N_i denote the number of sample points in $\mathcal{A}_i, i \in \{1,2\}$. Let $\mathcal{I} \in \Gamma\{(x_1,y_1),\ldots,(x_N,y_N)\}$ be such a (arbitrary fixed) partition. So for $\mathcal{I}$ there exists $(i,j) \subseteq \mathcal{I}$ such that $(x_i,y_i) \in \mathcal{A}_1$ and $(x_j,y_j) \in \mathcal{A}_2$. Consider the cell C defined by the two points (i,j).

The fraction of observed counts in the cell C is a linear combination of empirical cumulative distribution functions

$$\frac{o_C}{N-(m-1)} = \hat{F}_{XY}(x_i,y_i) + \hat{F}_{XY}(x_j,y_j) - \hat{F}_{XY}(x_i,y_j) - \hat{F}_{XY}(x_j,y_i),$$

and the expected fraction under the null is a function of the marginal cumulative distributions

$$\frac{e_C}{N-(m-1)} = \{\hat{F}_X(x_j) - \hat{F}_X(x_i)\}\{\hat{F}_Y(y_j) - \hat{F}_Y(y_i)\}.$$

where $\hat{F}$ denotes the empirical distribution function based on $N-(m-1)$ sample points.

By the Glivenko-Cantelli theorem, uniformly almost surely,

$$\lim_{N\to\infty}\left(\frac{o_C}{N-(m-1)} - \int_{\{(x,y):x\in(x_i,x_j],y\in(y_i,y_j]\}} h(x,y)dxdy\right) = 0,$$
$$\lim_{N\to\infty}\left\{\frac{e_C}{N-(m-1)} - \left(\int_{\{x:x\in(x_i,x_j]\}} f(x)dx\right)\left(\int_{\{y:y\in(y_i,y_j]\}} g(y)dy\right)\right\} = 0. \tag{13}$$

It is important that the convergence be uniform in order to obtain a positive lower bound on the average over all partitions, see the discussion before equation (18).

Therefore, by Slutsky's theorem and the continuous mapping theorem, we have that uniformly almost surely

$$\begin{aligned}
&\lim_{N\to\infty} \frac{1}{N-(m-1)} \frac{(o_C - e_C)^2}{e_C} = \lim_{N\to\infty} \frac{\left(\frac{o_C}{N-(m-1)} - \frac{e_C}{N-(m-1)}\right)^2}{\frac{e_C}{N-(m-1)}} \\
&\geq \lim_{N\to\infty} \left(\frac{o_C}{N-(m-1)} - \frac{e_C}{N-(m-1)}\right)^2 \\
&= \lim_{N\to\infty} \left[\int_{\{(x,y):x\in(x_i,x_j],y\in(y_i,y_j]\}} \{h(x,y) - f(x)g(y)\}dxdy\right]^2, \qquad (14)
\end{aligned}$$

where the inequality follows from the fact that $\frac{e_C}{N-(m-1)} \leq 1$.

We shall show that this limit can be bounded from below by a positive constant that depends on (x_0, y_0) and R but not on $\mathcal{I}$. Since

$$\begin{aligned}
&\{(x,y) : x \in (x_0 + R/4, x_0 + 3R/4], y \in (y_0 + R/4, y_0 + 3R/4]\} \\
&\subseteq \{(x,y) : x \in (x_i, x_j], y \in (y_i, y_j]\},
\end{aligned}$$

a positive lower bound on expression (14) can be obtained:

$$\begin{aligned}
&\lim_{N\to\infty} \left[\int_{\{(x,y):x\in(x_i,x_j],y\in(y_i,y_j]\}} \{h(x,y) - f(x)g(y)\}dxdy\right]^2 \\
&\geq \left[\int_{\{(x,y):x\in(x_0+R/4,x_0+3R/4],y\in(y_0+R/4,y_0+3R/4]\}} \{h(x,y) - f(x)g(y)\}dxdy\right]^2 \\
&\geq c^2 \int_{\{(x,y):x\in(x_0+R/4,x_0+3R/4],y\in(y_0+R/4,y_0+3R/4]\}} dxdy = c^2R^2/4, \qquad (15)
\end{aligned}$$

where the first inequality follows since $h(x,y) - f(x)g(y) > 0$ in $\mathcal{A}$, and the second inequality follows since the minimum value is $c > 0$. Therefore, it follows that $\frac{1}{N-m+1}\frac{(o_C-e_C)^2}{e_C}$ converges uniformly almost surely to a positive constant greater than $c' = c^2R^2/4$,

$$Pr\left(\lim_{N\to\infty} \frac{1}{N-m+1}\frac{(o_C - e_C)^2}{e_C} \geq c'\right) = 1. \qquad (16)$$

The partition $\mathcal{I}$ either contains the cell C, or a group of cells that divide C. By Jensen's inequality, it follows that if the partition $\mathcal{I}$ contains a group of cells that divide C, the score is made larger, since for any partition of the cell C, $C = \cup_l C_l$,

$$\left(\frac{o_C - e_C}{e_C}\right)^2 = \left(\sum_l \frac{e_{C_l}\left(\frac{o_{C_l}}{e_{C_l}} - 1\right)}{\sum_h e_{C_h}}\right)^2 \leq \frac{\sum_l e_{C_l}\left(\frac{o_{C_l}}{e_{C_l}} - 1\right)^2}{\sum_l e_{C_l}} = \frac{\sum_l \frac{(o_{C_l}-e_{C_l})^2}{e_{C_l}}}{e_C},$$

and therefore

$$\frac{(o_C - e_C)^2}{e_C} \leq \sum_l \frac{(o_{C_l} - e_{C_l})^2}{e_{C_l}}. \qquad (17)$$

Since $\sum_l \frac{(o_{C_l}-e_{C_l})^2}{e_{C_l}}$ or $\frac{(o_C-e_C)^2}{e_C}$ is part of the sum that defines $T^{\mathcal{I}}$, it follows from equations (17) and (16) that $\frac{T^{\mathcal{I}}}{N-m+1}$ converges uniformly almost surely to a positive constant greater than c'.

Let $|\Gamma|$ denote the cardinality of $\Gamma\{(x_1,y_1),\ldots,(x_N,y_N)\}$. Since $\mathcal{I} \in \Gamma\{(x_1,y_1),\ldots,(x_N,y_N)\}$ was arbitrary fixed, and since the convergence for fixed $\mathcal{I}$ of $t_C/[N-(m-1)]$ to a limit bounded from below by a positive constant was uniform, it follows that $\frac{1}{|\Gamma|}\sum_{\mathcal{I}\in\Gamma}\frac{T^{\mathcal{I}}}{N-m+1}$ converges almost surely to a positive constant at least as large as c'. To see this, note that from the uniform convergence in equation (16), it follows that for an arbitrary fixed $\epsilon > 0$, there exists $N(\epsilon)$ (which does not depend on C) such that for all $N > N(\epsilon)$, $\frac{1}{N-(m-1)}\frac{(o_C-e_C)^2}{e_C} \geq c' - \epsilon$ for every C, and therefore that $\frac{1}{|\Gamma|}\sum_{\mathcal{I}\in\Gamma}\frac{T^{\mathcal{I}}}{N-m+1} \geq c' - \epsilon$ for all $N > N(\epsilon)$.

Since $S_{m\times m} \geq \sum_{\mathcal{I}\in\Gamma} T^{\mathcal{I}}$, it follows that almost surely

$$\lim_{N\to\infty} \frac{S_{m\times m}}{|\Gamma|(N-m+1)} > c'. \qquad (18)$$

We shall show that $\lim_{N\to\infty} |\Gamma|/\binom{N}{m-1}$ is bounded below by a positive constant. First, we shall consider the case where m is finite. Then, a subset of $\Gamma\{(x_1,y_1),\ldots,(x_N,y_N)\}$ is the set of all partitions with $m-2$ sample points in $\mathcal{A}_1$, and one sample point in $\mathcal{A}_2$. Therefore, $|\Gamma| \geq \binom{N_1}{m-2}N_2$. Simple algebraic manipulations lead to the following expression for $\frac{\binom{N_1}{m-2}N_2}{\binom{N}{m-1}}$:

$$(m-1)\frac{N_2}{N}\frac{N_1}{N-1}\cdots\frac{N_1-m+3}{N-m+2}.$$

Since N_1/N converges almost surely to f_1 , and similarly N_2/N converges almost surely to f_2, then for $m \geq 3$ finite it follows that $\frac{\binom{N_1}{m-2}N_2}{\binom{N}{m-1}}$ converges almost surely to a positive constant. Therefore, $|\Gamma|/\binom{N-1}{m-1}$ is bounded away from zero. Second, we shall consider the case that $m \to \infty$. The complement of Γ, Γ^C, is the set of contingency tables with no points in $\mathcal{A}_1$ or in $\mathcal{A}_2$. An upper bound for $|\Gamma^C|$ is

$$\binom{N-N_1}{m-1} + \binom{N-N_2}{m-1}.$$

Note that in order to show that $\lim_{N\to\infty} |\Gamma|/\binom{N}{m-1}$ is bounded below by a positive constant, since $|\Gamma| = \binom{N}{m-1} - |\Gamma^C|$, it is enough to show that $|\Gamma^C|/\binom{N}{m-1}$ converges to zero as $N \to \infty$. Simple algebraic manipulations lead to the following expression for $\frac{\binom{N-N_1}{m-1}}{\binom{N}{m-1}}$:

$$\left(1 - \frac{N_1}{N}\right)\cdots\left(1 - \frac{N_1}{N-(m-2)}\right) \leq \left(1 - \frac{N_1}{N}\right)^m.$$

Since N_1/N converges almost surely to $f_1 \in (0,1)$, it follows that $\frac{\binom{N-N_1}{m-1}}{\binom{N}{m-1}}$ converges almost surely to zero as $m \to \infty$. Similarly, since N_2/N converges almost surely to $f_2 \in (0,1)$, it follows that $\frac{\binom{N-N_2}{m-1}}{\binom{N}{m-1}}$ converges almost surely to zero. Therefore, $|\Gamma^C|/\binom{N}{m-1}$ converges to zero as $N \to \infty$.

Since $\lim_{N\to\infty} |\Gamma|/\binom{N}{m-1}$ is bounded below by a positive constant, it follows from (18) that almost surely

$$\lim_{N\to\infty} \frac{S_{m\times m}}{\binom{N}{m-1}(N-m+1)} \geq c'', \tag{19}$$

for some constant $c'' > 0$.

Consider now a random permutation $(\pi y_1), \ldots, (\pi y_N)$ of the y-values $y_1, \ldots, y_N$. Let $S^{\pi}_{m\times m}$ be the test statistic that is computed from the data $(x_1, \pi y_1), \ldots, (x_N, \pi y_N)$. Therefore, by Markov's inequality,

$$\begin{aligned} Pr\left(S^{\pi}_{m\times m} \geq c''\binom{N}{m-1}(N-m+1) \mid \vec{x}, \vec{y}\right) &\leq \frac{E(S^{\pi}_{m\times m}|\vec{x},\vec{y})}{c''\binom{N}{m-1}(N-m+1)} \\ \approx \quad \frac{\binom{N}{m-1}(m-1)^2}{c''\binom{N}{m-1}(N-m+1)}. \end{aligned} \tag{20}$$

where $\vec{x} = (x_1, \ldots, x_N)$ and $\vec{y} = (y_1, \ldots, y_N)$. The approximation in (20) becomes more accurate the larger N is, since each of the contingency tables is approximately χ^2 with $(m-1)^2$ degrees of freedom. The right hand side of equation (20) goes to 0 as $N \to \infty$, as long as $\lim_{N\to\infty} \frac{m}{\sqrt{N}} = 0$. Thus,

$$\lim_{N\to\infty, m/\sqrt{N}\to 0} Pr\left(S^{\pi}_{m\times m} \geq c''\binom{N}{m-1}(N-m+1) \mid \vec{x}, \vec{y}\right) = 0. \tag{21}$$

We now have all the necessary results to complete the proof. Specifically,

$$\lim_{N\to\infty} Pr(S_{m\times m} \leq S^{tab}_{1-\alpha}) \leq \lim_{N\to\infty} Pr\left\{S_{m\times m} \leq c''\binom{N}{m-1}(N-m+1)\right\} = 0,$$

where the inequality follows from (21), since $S^{tab}_{1-\alpha}$ is below $c''\binom{N}{m-1}(N-m+1)$ for N large enough, and the equality follows from (19), thus proving item 1 of Theorem 2.

To prove item 2, we will use the following inequality for chi-square distributions, which appears in equation (4.3) of Laurent and Massart (2000): for U a χ^2 statistic with D degrees of freedom, for any positive x, $Pr(U - D \geq 2\sqrt{Dx} + 2x) \leq e^{-x}$.

Let $\mathcal{I}$ be a fixed arbitrary partition of size m. Since for N large enough, under the null hypothesis, $T^{\mathcal{I}}$ is approximately a χ^2 statistic with $D = (m-1)^2$ degrees of freedom, it thus follows that for $x > D$,

$$Pr_{H_0}(T^{\mathcal{I}} - D \geq 4x) \leq e^{-x}. \tag{22}$$

Let $x = \frac{c'}{8}(N-m+1) - D/4$. Then for N large enough, $x > D$. It thus follows that

$$Pr_{H_0}(T^{\mathcal{I}} \geq \frac{c'}{2}(N-m+1)) \leq e^{-(\frac{c'}{8}(N-m+1)-D/4)} \leq e^{-(\frac{c'}{8}(N-m+1)-(m-1)^2/4)} \tag{23}$$

By Bonferroni's inequality,

$$\begin{aligned} Pr_{H_0}\left(M^{DDP}_{m\times m} \geq \frac{c'}{2}(N-m+1)\right) &\leq \sum_{\mathcal{I}\in\Pi^{DDP}_m} Pr_{H_0}\left(T^{\mathcal{I}} \geq \frac{c'}{2}(N-m+1)\right) \\ &\leq \binom{N}{m} e^{-(\frac{c'}{8}(N-m+1)-(m-1)^2/4)}, \end{aligned} \tag{24}$$

where the last inequality follows from (23). Since $\binom{N}{m}$ is at most $O(N^{\sqrt{N}})$, and since

$$e^{-(\frac{c'}{8}(N-m+1)-(m-1)^2/4)} = O(e^{-(\frac{c'}{8}N)}),$$

it follows that the expression in (24) goes to zero as $N \to \infty$.

Since we found contingency tables for which under the alternative the test statistic $\frac{T^{\mathcal{I}}}{N-m+1}$ converges uniformly almost surely to a positive constant greater than c' (16), it follows that $\frac{M^{DDP}_{m\times m}}{N-m+1}$ converges uniformly almost surely to a positive constant greater than c' when the null is false. From (24) it follows that as $N \to \infty$, with $\lim_{N\to\infty} \frac{m}{\sqrt{N}} = 0$, the probability that the test statistics $\frac{M^{DDP}_{m\times m}}{N-m+1}$ will be above $\frac{c'}{2}$ goes to zero when the null is true. It follows that the null hypothesis will be rejected with asymptotic probability one when it is false. ■

A.2 The ADP Test

Proof We want to show that if H_0 is false, then for an arbitrary fixed α, $\lim_{N\to\infty} Pr(S^{ADP}_{m\times m} > S^{tab}_{1-\alpha}) = 1$, where $S^{tab}_{1-\alpha}$ denotes the $1-\alpha$ quantile of the null distribution of $S^{ADP}_{m\times m}$. We use $\mathcal{A}, c, \mathcal{A}_1, \mathcal{A}_2, f_1, f_2$ as defined in the beginning of Appendix A of the main text.

For the ADP test, recall that the partitioning is based on selecting $m-1$ points from $1.5, \ldots, N-0.5$ for the partitions of the ranked x-values, and separately for the partitions of the ranked y-values. For a fixed rectangle, we say a grid point $(i+0.5, j+0.5)$ is in the rectangle if the two x-values with ranks i and $i+1$, and the two y-values with ranks j and $j+1$, are in the rectangle, for $(i,j) \in \{1, \ldots, N\}^2$. Let $\Gamma\{(x_1,y_1), \ldots, (x_N,y_N)\}$ be the set of partitions of size m with at least one grid point in $\mathcal{A}_1$ and at least one grid point in $\mathcal{A}_2$. Let N_{ix} be the number of x-coordinates of the grid points in $\mathcal{A}_i, i \in \{1,2\}$, and N_{iy} be the number of y-coordinates of the grid points in $\mathcal{A}_i, i \in \{1,2\}$.

Let $\mathcal{I} \in \Gamma\{(x_1,y_1), \ldots, (x_N,y_N)\}$ define an (arbitrary fixed) ADP partition in Γ. There exist two x-values in $\mathcal{A}_1$ that are separated by a grid point in $\mathcal{I}$, and two x-values in $\mathcal{A}_2$ that are separated by a grid point in $\mathcal{I}$, denote the average of these two x-values by x^*_1 and x^*_2. Let y^*_1 and y^*_2 be similarly defined for the y-values.

Let C be the cell defined by the points $(x^*_i, y^*_i), i = 1,2$. The fraction of observed counts in the cell C is a linear combination of empirical cumulative distribution functions

$$\frac{o_C}{N} = \hat{F}_{XY}(x^*_1, y^*_1) + \hat{F}_{XY}(x^*_2, y^*_2) - \hat{F}_{XY}(x^*_1, y^*_2) - \hat{F}_{XY}(x^*_2, y^*_1),$$

and the expected fraction under the null, is a function of the cumulative marginal distributions

$$\frac{e_C}{N} = \{\hat{F}_X(x^*_2) - \hat{F}_X(x^*_1)\}\{\hat{F}_Y(y^*_2) - \hat{F}_Y(y^*_1)\},$$

where $\hat{F}$ denotes the empirical cumulative distribution function based on N sample points.

By the Glivenko-Cantelli theorem, uniformly almost surely,

$$\lim_{N\to\infty}\left(\frac{o_C}{N}-\int_{\{(x,y):x\in(x_1^*,x_2^*],y\in(y_1^*,y_2^*]\}}h(x,y)dxdy\right)=0,$$
$$\lim_{N\to\infty}\left\{\frac{e_C}{N}-\left(\int_{\{x:x\in(x_1^*,x_2^*]\}}f(x)dx\right)\left(\int_{\{y:y\in(y_1^*,y_2^*]\}}g(y)dy\right)\right\}=0. \tag{25}$$

Therefore, by Slutsky's theorem and the continuous mapping theorem, we have that uniformly almost surely

$$\begin{aligned}&\lim_{N\to\infty}\frac{1}{N}\frac{(o_C-e_C)^2}{e_C}=\lim_{N\to\infty}\frac{\left(\frac{o_C}{N}-\frac{e_C}{N}\right)^2}{\frac{e_C}{N}}\\&\geq\lim_{N\to\infty}\left(\frac{o_C}{N}-\frac{e_C}{N}\right)^2\\&=\lim_{N\to\infty}\left[\int_{\{(x,y):x\in(x_1^*,x_2^*],y\in(y_1^*,y_2^*]\}}\{h(x,y)-f(x)g(y)\}dxdy\right]^2,\end{aligned} \tag{26}$$

where the inequality follows from the fact that $\frac{e_C}{N}\leq 1$.

We shall show that the limit (26) can be bounded from below by a positive constant that depends on (x_0,y_0) and R but not on $\mathcal{I}$. Since

$$\begin{aligned}&\{(x,y):x\in(x_0+R/4,x_0+3R/4],y\in(y_0+R/4,y_0+3R/4]\}\\&\subseteq\{(x,y):x\in(x_1^*,x_2^*],y\in(y_1^*,y_2^*]\},\end{aligned}$$

a positive lower bound can be obtained:

$$\begin{aligned}&\lim_{N\to\infty}\left[\int_{\{(x,y):x\in(x_1^*,x_2^*],y\in(y_1^*,y_2^*]\}}\{h(x,y)-f(x)g(y)\}dxdy\right]^2\\&\geq\left[\int_{\{(x,y):x\in(x_0+R/4,x_0+3R/4],y\in(y_0+R/4,y_0+3R/4]\}}\{h(x,y)-f(x)g(y)\}dxdy\right]^2\\&\geq c^2\int_{\{(x,y):x\in(x_0+R/4,x_0+3R/4],y\in(y_0+R/4,y_0+3R/4]\}}dxdy=c^2R^2/4,\end{aligned}$$

where the first inequality follows since $h(x,y)-f(x)g(y)>0$ in $\mathcal{A}$, and the second inequality follows since the minimum value is $c>0$. Therefore, it follows that $\frac{1}{N}\frac{(o_C-e_C)^2}{e_C}$ converges uniformly almost surely to a positive constant greater than $c'=c^2R^2/4$,

$$Pr\left(\lim_{N\to\infty}\frac{1}{N}\frac{(o_C-e_C)^2}{e_C}\geq c'\right)=1. \tag{27}$$

The partition $\mathcal{I}$ either contains the cell C, or a group of cells that divide C. By Jensen's inequality, it follows that in the latter case the score is made larger, see the arguments leading to expression

(17). It thus follows that the score $T^{\mathcal{I}}/N$ converges uniformly almost surely to a positive constant greater than c'.

Let $|\Gamma|$ denote the number of $\Gamma\{(x_1,y_1),\ldots,(x_N,y_N)\}$. Since $\mathcal{I}\in\Gamma\{(x_1,y_1),\ldots,(x_N,y_N)\}$ was arbitrarily fixed, it follows that $\frac{1}{|\Gamma|}\sum_{\mathcal{I}\in\Gamma}\frac{T^{\mathcal{I}}}{N}$ converges almost surely to a positive constant greater than $c'/2$. Since $S_{m\times m}\geq\sum_{\mathcal{I}\in\Gamma}T^{\mathcal{I}}$, it follows that almost surely,

$$\lim_{N\to\infty}\frac{S_{m\times m}}{|\Gamma|N}\geq\frac{c'}{2}. \tag{28}$$

We shall show that $\lim_{N\to\infty}|\Gamma|/\{\binom{N-1}{m-1}\binom{N-1}{m-1}\}$ is bounded below by a positive constant. First, we shall consider the case that m is finite. In this case, a subset of $\Gamma\{(x_1,y_1),\ldots,(x_N,y_N)\}$ is the set of all partitions with $m-2$ grid points in $\mathcal{A}_1$, and one grid point in $\mathcal{A}_2$, for both x-values and y-values. Therefore, $|\Gamma|\geq\binom{N_{1x}}{m-2}N_{2x}\binom{N_{1y}}{m-2}N_{2y}$. Simple algebraic manipulations lead to the following expression for $\frac{\binom{N_{1x}}{m-2}N_{2x}}{\binom{N-1}{m-1}}$:

$$(m-1)\frac{N_{2x}}{N-1}\frac{N_{1x}}{N-2}\cdots\frac{N_{1x}-m+3}{N-1-m+2}.$$

Since N_{1x}/N converges almost surely to $\int_{x_0}^{x_0+R/4}f(x)dx$, and similarly N_{2x}/N converges almost surely to $\int_{x_0+3R/4}^{x_0+R}f(x)dx$, then for $m\geq 3$ finite it follows that $\frac{\binom{N_{1x}}{m-2}N_{2x}}{\binom{N-1}{m-1}}$ converges almost surely to a positive constant. Similarly, $\frac{\binom{N_{1y}}{m-2}N_{2y}}{\binom{N-1}{m-1}}$ converges almost surely to a positive constant. Therefore, $|\Gamma|/\{\binom{N-1}{m-1}\binom{N-1}{m-1}\}$ is bounded away from zero.

Second, we shall consider the case that $m\to\infty$. The complement of Γ, Γ^C, is the set of contingency tables with no grid point in $\mathcal{A}_1$ or in $\mathcal{A}_2$. An upper bound for $|\Gamma^C|$ is:

$$\binom{N-1}{m-1}\left\{\binom{N-1-N_{1x}}{m-1}+\binom{N-1-N_{2x}}{m-1}+\binom{N-1-N_{1y}}{m-1}+\binom{N-1-N_{2y}}{m-1}\right\}$$

Note that since $|\Gamma|=\{\binom{N-1}{m-1}\binom{N-1}{m-1}\}-|\Gamma^C|$, it is enough to show that $|\Gamma^C|/\{\binom{N-1}{m-1}\binom{N-1}{m-1}\}$ converges to zero as $N\to\infty$. Simple algebraic manipulations lead to the following expression for $\frac{\binom{N-1-N_{1x}}{m-1}}{\binom{N-1}{m-1}}$:

$$\left(1-\frac{N_{1x}}{N-1}\right)\cdots\left(1-\frac{N_{1x}}{N-1-(m-2)}\right)\leq\left(1-\frac{N_{1x}}{N-1}\right)^m.$$

Since N_{1x}/N converges almost surely to a positive fraction $\int_{x_0}^{x_0+R/4}f(x)dx$, it follows that $\frac{\binom{N-1-N_{1x}}{m-1}}{\binom{N-1}{m-1}}$ converges almost surely to zero. Similarly, since N_{2x}/N, N_{1y}/N and N_{2y}/N converge almost surely to positive fractions, it follows that respectively, $\frac{\binom{N-1-N_{2x}}{m-1}}{\binom{N-1}{m-1}}$, $\frac{\binom{N-1-N_{1y}}{m-1}}{\binom{N-1}{m-1}}$, and $\frac{\binom{N-1-N_{2y}}{m-1}}{\binom{N-1}{m-1}}$ converge almost surely to zero. Thus $|\Gamma^C|/\{\binom{N-1}{m-1}\binom{N-1}{m-1}\}$ converges almost surely to zero.

Since $\lim_{N\to\infty} |\Gamma|/\{\binom{N-1}{m-1}\binom{N-1}{m-1}\}$ is bounded below by a positive constant, it follows from (28) that almost surely,

$$\lim_{N\to\infty} \frac{S_{m\times m}}{\binom{N-1}{m-1}\binom{N-1}{m-1}N} \geq c'', \tag{29}$$

for some constant $c'' > 0$.

Consider now a random permutation $(\pi y_1), \ldots, (\pi y_N)$ of the y-values $y_1, \ldots, y_N$. Let $S^{\pi}_{m\times m}$ be the test statistic that is computed from the data $(x_1, \pi y_1), \ldots, (x_N, \pi y_N)$. By Markov's inequality,

$$\begin{aligned} & Pr\left(S^{\pi}_{m\times m} \geq c''\binom{N-1}{m-1}\binom{N-1}{m-1}N \mid \vec{x}, \vec{y}\right) \leq \frac{E(S^{\pi}_{m\times m} \mid \vec{x}, \vec{y})}{c''\binom{N-1}{m-1}\binom{N-1}{m-1}N} \\ \approx & \frac{\binom{N-1}{m-1}\binom{N-1}{m-1}(m-1)^2}{c''\binom{N-1}{m-1}\binom{N-1}{m-1}N}, \end{aligned} \tag{30}$$

where $\vec{x} = (x_1, \ldots, x_N)$ and $\vec{y} = (y_1, \ldots, y_N)$. The approximation in (30) becomes more accurate the larger N is, since each of the contingency tables is approximately χ^2 with $(m-1)^2$ degrees of freedom. The right hand side of equation (30) goes to zero as $N \to \infty$, as long as $\lim_{N\to\infty} \frac{m}{\sqrt{N}} = 0$. Thus,

$$\lim_{N\to\infty, m/\sqrt{N}\to 0} Pr\left(S^{\pi}_{m\times m} \geq c''\binom{N-1}{m-1}\binom{N-1}{m-1}N \mid \vec{x}, \vec{y}\right) = 0. \tag{31}$$

We now have all the necessary results to complete the proof. Specifically,

$$\lim_{N\to\infty} Pr(S_{m\times m} \leq S^{tab}_{1-\alpha}) \leq Pr\left(S^{\pi}_{m\times m} \leq c''\binom{N-1}{m-1}\binom{N-1}{m-1}N\right) = 0, \tag{32}$$

where the inequality follows from (31), since $S^{tab}_{1-\alpha}$ is below $c''\binom{N-1}{m-1}\binom{N-1}{m-1}N$ for N large enough, and the equality follows from (29), thus proving item 1 of Theorem 1 for the ADP summation statistic.

■

Appendix B. Proof of Theorem 4

Proof We want to show that for all $\epsilon > 0, \lim_{N\to\infty} Pr\left(\left|\frac{S^{ADP}_{m\times m}(L)}{N|\Pi|} - I_{XY}\right| > \epsilon\right) = 0$ if $\lim_{N\to\infty} \frac{m}{\sqrt{N}} = 0$ and $\lim_{N\to\infty} m = \infty$, where $|\Pi| = \left(\binom{N-1}{m-1}\right)^2$ is the number of partitions.

For continuous marginals, the copula function of the joint distribution of (X, Y) is unique, denote it by $c(u, v)$. The mutual information is the negative copula entropy, $H_{UV} = -\int c(u, v) \log c(u, v) du dv$,

$$\begin{aligned} I_{XY} &= \int c(F_X(x), F_Y(y)) f(x) g(y) \log c(F_X(x), F_Y(y)) dx dy \\ &= \int c(u, v) \log c(u, v) du dv = -H_{UV}. \end{aligned} \tag{33}$$

Consider an arbitrary fixed partition $\mathcal{I} = \{(i_1, j_1), \ldots, (i_{m-1}, j_{m-1})\} \subset \{1.5, \ldots, N - 0.5\}^2$. Recall that $\mathcal{C}(\mathcal{I})$ is the set of $m \times m$ cells that are defined by the partition. For a cell C, let $r_l(C)$ and $r_h(C)$ be, respectively, the lowest and highest x-grid integer values in C. Similarly, let $s_l(C)$ and $s_h(C)$ be, respectively, the lowest and highest y-grid integer values in C.

The entropy of the partition $\mathcal{I}$ is

$$H^{\mathcal{I}}_{UV} = -\sum_{C\in\mathcal{C}(\mathcal{I})} Pr\left(\frac{r_l(C)}{N} \leq U \leq \frac{r_h(C)}{N}, \frac{s_l(C)}{N} \leq V \leq \frac{s_h(C)}{N}\right) \log\left\{Pr\left(\frac{r_l(C)}{N} \leq U \leq \frac{r_h(C)}{N}, \frac{s_l(C)}{N} \leq V \leq \frac{s_h(C)}{N}\right)\right\}.$$

The corresponding empirical (plug in) estimator is

$$\hat{H}^{\mathcal{I}}_{UV} = -\sum_{C\in\mathcal{C}(\mathcal{I})} \frac{o_C}{N} \log\left(\frac{o_C}{N}\right), \quad o_C = \sum_{i=1}^{N} I(r_l(C) \leq r_i \leq r_h(C), s_l(C) \leq s_i \leq s_h(C)).$$

Let $H^{\mathcal{I}}_U$ and $H^{\mathcal{I}}_V$ be the fixed marginal entropies of the partition $\mathcal{I}$:

$$\begin{aligned} H^{\mathcal{I}}_U &= -\sum_{C_x\in\mathcal{C}_x(\mathcal{I})} \frac{r_h(C_x) - r_l(C_x)}{N} \log\left(\frac{r_h(C_x) - r_l(C_x)}{N}\right), \\ H^{\mathcal{I}}_V &= -\sum_{C_y\in\mathcal{C}_y(\mathcal{I})} \frac{r_h(C_y) - r_l(C_y)}{N} \log\left(\frac{r_h(C_y) - r_l(C_y)}{N}\right), \end{aligned}$$

where $\mathcal{C}_x(\mathcal{I})$ and $\mathcal{C}_y(\mathcal{I})$ are the intervals induced by $\mathcal{I}$ in x and in y, respectively. Note that given $\mathcal{I}$, the observed and expected margins of the partitions are fixed, and therefore

$$H^{\mathcal{I}}_U = -\sum_{C\in\mathcal{C}(\mathcal{I})} o_C \log\left(\frac{r_h(C) - r_l(C)}{N}\right) \tag{34}$$

$$= -\sum_{C\in\mathcal{C}(\mathcal{I})} Pr(r_l(C) \leq U \leq r_h(C), s_l(C) \leq V \leq s_h(C)) \log\left(\frac{r_h(C) - r_l(C)}{N}\right) \tag{35}$$

$$H^{\mathcal{I}}_V = -\sum_{C\in\mathcal{C}(\mathcal{I})} o_C \log\left(\frac{s_h(C) - s_l(C)}{N}\right) \tag{36}$$

$$= -\sum_{C\in\mathcal{C}(\mathcal{I})} Pr(r_l(C) \leq U \leq r_h(C), s_l(C) \leq V \leq s_h(C)) \log\left(\frac{s_h(C) - s_l(C)}{N}\right) \tag{37}$$

The following simple derivation shows that the likelihood ratio score $T^{\mathcal{I}}$ is a linear combination of $\hat{H}^{\mathcal{I}}_{UV}, H^{\mathcal{I}}_U$ and $H^{\mathcal{I}}_V$:

$$\begin{aligned} T^{\mathcal{I}} &= \sum_{C\in\mathcal{C}(\mathcal{I})} o_C \log\frac{o_C}{e_C} \\ &= \sum_{C\in\mathcal{C}(\mathcal{I})} o_C \log\frac{o_C}{N} - \sum_{C\in\mathcal{C}(\mathcal{I})} o_C \log\frac{e_C}{N} \\ &= -N\hat{H}^{\mathcal{I}}_{UV} - \sum_{C\in\mathcal{C}(\mathcal{I})} o_C \log\left(N\frac{r_h(C) - r_l(C)}{N}\frac{s_h(C) - s_l(C)}{N}\frac{1}{N}\right) \\ &= -N\hat{H}^{\mathcal{I}}_{UV} + NH^{\mathcal{I}}_U + NH^{\mathcal{I}}_V, \end{aligned}$$

where the last equality follows from equations (34) and (36).

Let $E(\cdot)$ denote the expectation of a random variable. We bound from above our probability of interest by a sum of three probabilities as follows.

$$
\begin{aligned}
&Pr\left(\left|\frac{S^{ADP}_{m\times m}}{N|\Pi|} - I_{XY}\right| > \epsilon\right) = Pr\left(\left|\frac{\sum_{\mathcal{I}} T^{\mathcal{I}}_{m\times m}(L)}{N|\Pi|} - I_{XY}\right| > \epsilon\right)\\
&= Pr\left(\left|\frac{\sum_{\mathcal{I}}(H^{\mathcal{I}}_U + H^{\mathcal{I}}_V - \hat{H}^{\mathcal{I}}_{UV})}{|\Pi|} + H_{UV}\right| > \epsilon\right)\\
&= Pr(|\sum_{\mathcal{I}}(H^{\mathcal{I}}_U + H^{\mathcal{I}}_V - \hat{H}^{\mathcal{I}}_{UV} + H_{UV})| > |\Pi|\epsilon)\\
&= Pr(|\sum_{\mathcal{I}}(-\hat{H}^{\mathcal{I}}_{UV} + E(\hat{H}^{\mathcal{I}}_{UV})) + \sum_{\mathcal{I}}(-E(\hat{H}^{\mathcal{I}}_{UV}) + H^{\mathcal{I}}_{UV})\\
&+\sum_{\mathcal{I}}(-H^{\mathcal{I}}_{UV} + H^{\mathcal{I}}_U + H^{\mathcal{I}}_V + H_{UV})| > |\Pi|\epsilon)\\
&\le Pr(|\sum_{\mathcal{I}}(-\hat{H}^{\mathcal{I}}_{UV} + E(\hat{H}^{\mathcal{I}}_{UV}))| + |\sum_{\mathcal{I}}(-E(\hat{H}^{\mathcal{I}}_{UV}) + H^{\mathcal{I}}_{UV})|\\
&+|\sum_{\mathcal{I}}(-H^{\mathcal{I}}_{UV} + H^{\mathcal{I}}_U + H^{\mathcal{I}}_V + H_{UV})| > |\Pi|\epsilon)\\
&\le Pr(|\sum_{\mathcal{I}}(-\hat{H}^{\mathcal{I}}_{UV} + E(\hat{H}^{\mathcal{I}}_{UV}))| > |\Pi|\epsilon/3) \qquad (38)\\
&+Pr(|\sum_{\mathcal{I}}(-E(\hat{H}^{\mathcal{I}}_{UV}) + H^{\mathcal{I}}_{UV})| > |\Pi|\epsilon/3) \qquad (39)\\
&+Pr(|\sum_{\mathcal{I}}(-H^{\mathcal{I}}_{UV} + H^{\mathcal{I}}_U + H^{\mathcal{I}}_V + H_{UV})| > |\Pi|\epsilon/3), \qquad (40)
\end{aligned}
$$

where the last inequality follows from $\{|\sum_{\mathcal{I}}(-\hat{H}^{\mathcal{I}}_{UV} + E(\hat{H}^{\mathcal{I}}_{UV}))| + |\sum_{\mathcal{I}}(-E(\hat{H}^{\mathcal{I}}_{UV}) + H^{\mathcal{I}}_{UV})| + |\sum_{\mathcal{I}}(-H^{\mathcal{I}}_{UV} + H^{\mathcal{I}}_U + H^{\mathcal{I}}_V + H_{UV})| > |\Pi|\epsilon\} \subseteq \{(|\sum_{\mathcal{I}}(-\hat{H}^{\mathcal{I}}_{UV} + E(\hat{H}^{\mathcal{I}}_{UV}))| > |\Pi|\epsilon/3) \cup (|\sum_{\mathcal{I}}(-E(\hat{H}^{\mathcal{I}}_{UV}) + H^{\mathcal{I}}_{UV})| > |\Pi|\epsilon/3) \cup |\sum_{\mathcal{I}}(-H^{\mathcal{I}}_{UV} + H^{\mathcal{I}}_U + H^{\mathcal{I}}_V + H_{UV})| > |\Pi|\epsilon/3\}$ and Bonferroni's inequality.

We will show that the three probabilities (38)–(40) vanish as $N \to \infty, m \to \infty, \frac{m}{\sqrt{N}} \to 0$, thus proving the theorem.

The probability (38) can be upper-bounded as follows,

$$
\begin{aligned}
&Pr\left(|\sum_{\mathcal{I}}(\hat{H}^{\mathcal{I}}_{UV} - E(\hat{H}^{\mathcal{I}}_{UV}))| \ge |\Pi|\epsilon/3\right) \le \sum_{\mathcal{I}} Pr\left(|(\hat{H}^{\mathcal{I}}_{UV} - E(\hat{H}^{\mathcal{I}}_{UV}))| \ge \epsilon/3\right)\\
&\le |\Pi| 3e^{-\frac{N}{2}\epsilon^2/9\frac{1}{(\log N)^2}} \qquad (41)
\end{aligned}
$$

where the first inequality follows from the fact that $\{|\sum_{\mathcal{I}}(\hat{H}^{\mathcal{I}}_{UV} - E(\hat{H}^{\mathcal{I}}_{UV}))| \ge |\Pi|\epsilon/3\} \subseteq \{\cup_{\mathcal{I}\in\Pi}(\hat{H}^{\mathcal{I}}_{UV} - E(\hat{H}^{\mathcal{I}}_{UV})) \ge \epsilon/3\}$ and Bonferroni's inequality, and the second inequality follows from the upper bound (3.4) in Paninski (2003) for the plug in estimator for a given partition $\mathcal{I}$. This probability goes to zero as $N \to \infty$, since $|\Pi|$ is $O(N^{\sqrt{N}})$ and $\lim_{N\to\infty} O(N^{\sqrt{N}})e^{-\frac{N}{2}\epsilon^2/9\frac{1}{(\log N)^2}} = 0$.

The event in the second probability (39) is not random, so we need to show that $|\sum_{\mathcal{I}}(E(\hat{H}^{\mathcal{I}}_{UV}) - H^{\mathcal{I}}_{UV})| < |\Pi|\epsilon/3$ for N large enough. Proposition 1 in Paninski (2003) states that $0 \le (H^{\mathcal{I}}_{UV} - E(\hat{H}^{\mathcal{I}}_{UV})) \le \log(1 + \frac{(m-1)^2-1}{N})$. Therefore,

$$
|\sum_{\mathcal{I}}(E(\hat{H}^{\mathcal{I}}_{UV}) - H^{\mathcal{I}}_{UV})| \le |\Pi|\log(1 + \frac{(m-1)^2-1}{N})
$$

Clearly, the RHS is below $|\Pi|\epsilon/3$ for N large enough, if $\lim_{N\to\infty}\frac{m}{\sqrt{N}} = 0$.

It remains to show that (40) vanishes as $N \to \infty$. This event is not random, so we will show that

$$
\lim_{N\to\infty}\frac{|\sum_{\mathcal{I}}(-H^{\mathcal{I}}_{UV} + H^{\mathcal{I}}_U + H^{\mathcal{I}}_V + H_{UV})|}{|\Pi|} < \epsilon/3.
$$

By the mean value theorem, for cell C there exists a point (u_C, v_C) in C such that

$$
Pr(r_l(C) \le U \le r_h(C), s_l(C) \le V \le s_h(C)) = c(u_C, v_C)\frac{r_h(C) - r_l(C)}{N}\frac{s_h(C) - s_l(C)}{N}.
$$

Therefore,

$$
\begin{aligned}
&-H^{\mathcal{I}}_{UV}\\
&= \sum_{C\in\mathcal{C}(\mathcal{I})} c(u_C, v_C)\frac{r_h(C) - r_l(C)}{N}\frac{s_h(C) - s_l(C)}{N}\log\left(c(u_C, v_C)\frac{r_h(C) - r_l(C)}{N}\frac{s_h(C) - s_l(C)}{N}\right)\\
&= \sum_{C\in\mathcal{C}(\mathcal{I})}\frac{r_h(C) - r_l(C)}{N}\frac{s_h(C) - s_l(C)}{N}c(u_C, v_C)\log c(u_C, v_C) \qquad (42)\\
&+ \sum_{C\in\mathcal{C}(\mathcal{I})} Pr(r_l(C) \le U \le r_h(C), s_l(C) \le V \le s_h(C))\log\frac{r_h(C) - r_l(C)}{N}\\
&+ \sum_{C\in\mathcal{C}(\mathcal{I})} Pr(r_l(C) \le U \le r_h(C), s_l(C) \le V \le s_h(C))\log\frac{s_h(C) - s_l(C)}{N}\\
&= \sum_{C\in\mathcal{C}(\mathcal{I})}\frac{r_h(C) - r_l(C)}{N}\frac{s_h(C) - s_l(C)}{N}c(u_C, v_C)\log c(u_C, v_C) - H^{\mathcal{I}}_U - H^{\mathcal{I}}_V, \qquad (43)
\end{aligned}
$$

where the last equality follows from equations (35) and (37).

By the definition of the Riemann integral, expression (42) can be made arbitrarily close to $-H_{UV}$. Specifically, there exists a $0 < d(\epsilon) < 1$ such that if all cells satisfy $\frac{r_h(C)-r_l(C)}{N} < d$ and $\frac{s_h(C)-s_l(C)}{N} < d$, then

$$
|\sum_{C\in\mathcal{C}(\mathcal{I})}\frac{r_h(C) - r_l(C)}{N}\frac{s_h(C) - s_l(C)}{N}c(u_C, v_C)\log c(u_C, v_C) + H_{UV}| < \epsilon/3.
$$

Therefore, it follows that for any partition $\mathcal{I} \in \Pi$ for which all cells satisfy $\frac{r_h(C)-r_l(C)}{N} < d$ and $\frac{s_h(C)-s_l(C)}{N} < d$, then we have

$$
|(-H^{\mathcal{I}}_{UV} + H^{\mathcal{I}}_U + H^{\mathcal{I}}_V + H_{UV})| < \epsilon/3.
$$

It remains to show that the contribution of the fraction of partitions that do not satisfy $\frac{r_h(C)-r_l(C)}{N} < d$ and $\frac{s_h(C)-s_l(C)}{N} < d$ goes to zero as $N \to \infty$. Since the probability of selecting an x-value (or y-value) for a partition that will have a cell larger than d is $1-d$, the fraction of "bad" partitions is upper-bounded by

$$\frac{2m\binom{N(1-d)}{m-1}\binom{N}{m-1}}{\left(\binom{N-1}{m-1}\right)^2} \leq 2m(1-d)^{m-1}.$$

Since $m \to \infty$ the fraction of bad partitions goes to zero.

Note that $|(-H^{\mathcal{I}}_{UV} + H^{\mathcal{I}}_{U} + H^{\mathcal{I}}_{V} + H_{UV})|$ is at most $O(\log m^2)$ because by Jensen's inequality, $|H^{\mathcal{I}}_{UV}| \leq \log m^2, |H^{\mathcal{I}}_{U}| \leq \log m^2, |H^{\mathcal{I}}_{V}| \leq \log m^2$, and $|H_{UV}| = I_{XY}$ is assumed to be bounded. Therefore,

$$\frac{|\sum_{\mathcal{I}}(-H^{\mathcal{I}}_{UV} + H^{\mathcal{I}}_{U} + H^{\mathcal{I}}_{V} + H_{UV})|}{|\Pi|} \leq \epsilon/3 + O\left(\log m^2 m(1-d)^{m-1}\right).$$

Since the second term of the RHS goes to zero as $N \to \infty, m \to \infty, \frac{m}{\sqrt{N}} \to 0$, the proof is complete. ■

Appendix C. Proof of Theorem 6

Proof We shall prove items 1 and 2 for the DDP statistic only, since the proof for the ADP statistic is very similar. We shall use the notation of Section A.1. Let $\hat{m}$ be the value of m with minimum p-value,

$$\hat{m} = \arg \min_{m \in \{2,\ldots,m_{\max}\}} p_2, \ldots, p_m.$$

To prove item 1, we note that from equation (19) it follows that under the alternative,

$$\lim_{N\to\infty} \frac{S_{\hat{m}\times\hat{m}}}{\binom{N}{\hat{m}-1}(N-\hat{m}+1)} \geq c''.$$

Under the null,

$$\begin{aligned}
&Pr\left(S^{\pi}_{\hat{m}\times\hat{m}} \geq c''\binom{N}{\hat{m}-1}(N-\hat{m}+1) \mid \vec{x},\vec{y}\right) \\
&\leq \sum_{m=2}^{m_{\max}} Pr\left(S^{\pi}_{m\times m} \geq c''\binom{N}{m-1}(N-m+1) \mid \vec{x},\vec{y}\right) \\
&\leq m_{\max} \max_{m\in\{2,\ldots,m_{\max}\}} \frac{\binom{N}{m-1}(m-1)^2}{c''\binom{N}{m-1}(N-m+1)} \leq m_{\max}\frac{(m_{\max}-1)^2}{c''(N-m_{\max}+1)},
\end{aligned}$$

where the first inequality is the Bonferroni inequality, and the second inequality follows from equation (20). Since the last term goes to 0 as $N \to \infty$ if $\lim_{N\to\infty} m/N^{1/3} = 0$, the proof of item 1 is complete.

The proof of item 2 is very similar to the proof in Section A.1, the only modification is an additional application of Bonferroni's inequality under the null:

$$\begin{aligned}
&Pr_{H_0}\left(M^{DDP}_{\hat{m}\times\hat{m}} \geq \frac{c'}{2}(N-\hat{m}+1)\right) \leq \sum_{m=2}^{m_{\max}} Pr_{H_0}\left(M^{DDP}_{m\times m} \geq \frac{c'}{2}(N-m+1)\right) \\
&\leq m_{\max} \max_{m\in\{2,\ldots,m_{\max}\}} \binom{N}{m} e^{-(\frac{c'}{8}(N-m+1)-(m-1)^2/4)} \\
&\leq m_{\max}\binom{N}{m_{\max}} e^{-(\frac{c'}{8}(N-m_{\max}+1)-(m_{\max}-1)^2/4)},
\end{aligned}$$

where the first inequality in the last row follows from (24). Since $m_{\max}\binom{N}{m_{\max}}$ is at most $O(N \times N^{\sqrt{N}})$, and since

$$e^{-(\frac{c'}{8}(N-m_{\max}+1)-(m_{\max}-1)^2/4)} = O(e^{-(\frac{c'}{8}N)}),$$

it follows that the last expression goes to zero as $N \to \infty$. ■

Appendix D. An Example of Mutual Information Estimation

We examined our suggested estimator in the following setup. For $m = 15$ and $N \in \{300, 1000\}$ sample points drawn from a two–component Gaussian mixture, we simulated 50 data sets and computed the estimated mutual information using $S^{DDP}_{m\times m}$, $S^{ADP}_{m\times m}$, and the histogram estimator. The Gaussian mixture density was

$$0.8 \times f_{\mathcal{N}}\left(\begin{pmatrix}0.5\\0.5\end{pmatrix}, \begin{pmatrix}0.05 & 0.025\\0.025 & 0.05\end{pmatrix}\right) + 0.2 \times f_{\mathcal{N}}\left(\begin{pmatrix}0.125\\0.675\end{pmatrix}, \begin{pmatrix}0.01 & 0\\0 & 0.01\end{pmatrix}\right),$$

where $f_{\mathcal{N}}(\mu, \Sigma)$ is the bivariate normal distribution with mean μ and covariance matrix Σ. For each partition, we applied the Miller–Madow correction (Paninski, 2003), a simple and well-known modification that estimates the systematic error of the histogram estimators and improves the finite-sample properties of these estimators. We compared it to the histogram estimator, as well as to the estimator based on the DDP statistic that considers only a subset of all possible partitions. Table 5 shows that the variability and the bias decrease as N increases for all estimators, and that the ADP estimator is the least variable, as is intuitively expected since it is the average over many partitions. In practice, it is difficult to identify the optimal m: it should not be too small so that the local dependence structure is not missed, causing large bias, nor should it be too large so that the grid created is too sparse, causing large variance.

Appendix E. Algorithm for the DDP Statistic

For the DDP statistic, the algorithm is very similar to that for the ADP statistic, except that only DDP are considered on the grid of ranked data $\{1, \ldots, N\}^2$. The algorithm is slightly more complex because the number of partitions that include a cell C depends on the partition size m, on the data, and on the type of cell, with four possible types. Specifics follow for internal cells. The first type is a cell C for which there is a sample point that falls on the boundary of C but not on one of its

	$\mathbf{N = 300}$	$\mathbf{N = 1000}$
Histogram	0.3165 (0.0052)	0.1854 (0.0029)
Data derived partitions	0.3010 (0.0030)	0.1879 (0.0022)
All derived partitions	0.2954 (0.0028)	0.1860 (0.0021)

Table 5: The average (standard error) of the mutual information estimates using random samples of size 300 (column 2) and 1000 (column 3) from the two component Gaussian mixture, by the following methods: the naive histogram estimator that partitions each axis to 15 intervals of equal count, $S^{ADP}_{15\times15}/(N|\Pi^{ADP}_{15}|)$, and $S^{DDP}_{15\times15}/(N|\Pi^{DDP}_{15}|)$. The true mutual information value was 0.1784.

corners. Then no DDP can ever have C as a cell, and therefore the number of DDP that include C is zero. For example, in Figure 7 (middle panel), if the open circle is an observation, and therefore the filled circle with the same y value is not, since there are no ties, then any DDP with this y value will necessarily partition C at the x value of the open circle observation, and thus C cannot be a cell in any DDP. For the remaining three types of cells, if there are sample points that fall on the boundary of C they are necessarily on the corners of C. These types of cells differ by the number of observations that determine the cell. The second type is a cell C defined by two observed points. Then, the number of DDP that include C is the number of ways to choose $m-3$ points from the points in the four outer areas defined by $(0, r_l) \times (0, s_l)$, $(0, r_l) \times (s_h, N]$, $(r_h, N] \times (0, s_l)$, and $(r_h, N] \times (s_h, N]$, see Figure 7 (left panel) for illustration. The number of points in the four areas is calculable in $O(1)$ using A, as defined in equation (10). Specifically, the count of samples that fall strictly inside any cell with rank ranges $r \in [r_l, r_h]$ and $s \in [s_l, s_h]$ is:

$$o_C = A(r_h - 1, s_h - 1) - A(r_l, s_h - 1) - A(r_h - 1, s_l) + A(r_l, s_l).$$

The third and fourth type are cells defined by three or four observed points, respectively, see Figure 7 (middle and right panels). Now the number of DDP that include C is exactly the number of ways to choose $m-4$ and $m-5$ points, respectively, from the points in the four outer areas. Again, the number of points in the four outer areas is calculable in $O(1)$ using A. Since all cells are defined by two, three, or four points, there are no additional types of cells.

Let us denote the number of sample points in the four outer areas of a cell C by OUT. Further denote by $C(OUT)$ the group of all cells which have exactly OUT points in the outer areas. For the sake of brevity, lets consider only cells of type 2. Similarly to equation (12) for the ADP statistic, the contribution to the score $S^{DDP}_{m\times m}$ of internal cells of type 2 can be written as

$$\sum_{OUT=2}^{N-2} n(OUT, m) \sum_{C\in C(OUT)} t_C = \sum_{OUT=2}^{N-2} n(OUT, m) T(OUT). \tag{44}$$

The algorithm proceeds as follows. First in a preprocessing phase we perform two computations: 1)go over all cells and calculate t_C and OUT for each cell and update $T(OUT) = T(OUT) + t_C$. This stage takes $O(N^4)$; 2) for all $u, v \in \{0, \ldots, N\}$ we calculate and store all $\binom{u}{v}$ in $O(N^2)$ steps using Pascal's triangle method.

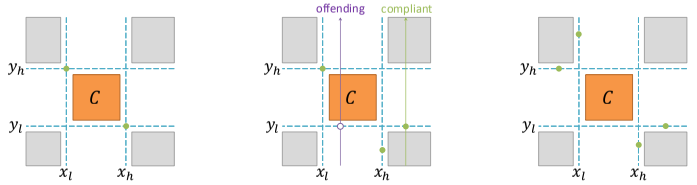

Figure 7: Inner cell example C (orange), and the sample points that define a partition where C is a cell (green). If any of the sample points ranked on a boundary column or row of C is not on the corner of C, then C can never be a DDP cell (offending point in purple, middle panel). An inner cell can be defined either by two data points (left), by three data points (middle), or by four data points (right).

Now for each m, since $n(OUT, m) = \binom{OUT}{m-3}$, given $T(OUT)$, clearly equation (44) can be calculated in $O(N)$ for a fixed m and in $O(N^2)$ for all ms. Therefore the total complexity is again $O(N^4)$ due to the preprocessing phase.

Appendix F. A Fast Algorithm for Computing the HHG Statistic

Here we describe a fast algorithm for computing the univariate original (distribution-dependent) HHG test statistic.

If $D_X(x_1, x_2)$ and $D_Y(y_1, y_2)$ are distance metrics in the variables tested for independence (for which, again, we have a paired sample with N i.i.d samples), the HHG test requires computing $N(N-1)$ different 2×2 contingency tables according to the following partitions of the distance-distance plane. For every "origin" sample i, and for every "radius" sample j, the remaining $N-2$ samples are classified according to whether their X and Y distances from i are both smaller than the X and Y distances from j to i, or if only X, only Y, or neither are smaller than the respective j to i distances. In the general case, generating contingency tables for all pairs can be done in $N^2 \log N$, as described in (Heller et al., 2013). In the univariate case, an $O(N^2)$ algorithm proceeds as follows.

Instead of working in the distance-distance plane, the algorithm is specified in terms of the (x, y), i.e., the sample plane. It is sufficient to consider the discrete grid expanded from unique X samples and unique Y samples actually observed (these can be identified in $O(N \log N)$). The double cumulative sum over this $N \times N$ grid is computed as in Section 3.1 of the main text, with the only difference being that after A is initialized to all zeros, it is updated sequentially with $A(r_i, s_i) = A(r_i, s_i) + 1$ for every sample of ranks in x and ranks in y, (r_i, s_i), $i = 1, 2, \ldots, N$, to account for possible ties.

Since, in the univariate case, $D_X(x_i, x_k) < D_X(x_i, x_j)$ is equivalent to $|x_k - x_i| < |x_j - x_i|$, and similarly for y, partition cells are simply axis-aligned rectangles, as in the distribution-free test. Here, however, only sample j is a vertex, and sample i is the center of mass. The diagonal-opposing vertex from j may not even be a point in the sample, and thus is not directly captured by A. Still, the appropriate point to sample A in, for computing the contingency table cell in $O(1)$, can be found in $O(1)$ additional amortized time, as follows:

1. Sort once the unique values of x, and do the same for y.

2. When traversing all pairs, first traverse i.

   (a) For every i, traverse the sorted values of x with two concurrent iterators starting from x_i, one moving right (i.e., from low to high x) and one advancing left.

   (b) Subsequently to each step taken with the right iterator, arriving at an x_j, advance the left iterator until a value is encountered which is farther from x_i than x_j is, and this is the opposing vertex x coordinate value for the rectangle for the pair i, j.

   The process, which is depicted in Figure 8, takes $O(N)$ time for N values, and is repeated for the y axis.

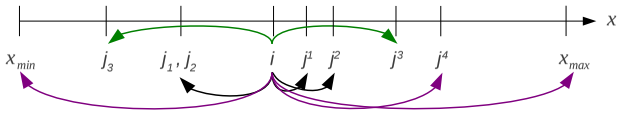

Figure 8: Finding the grid coordinates to sample for the $O(N^2)$ univariate (distribution-dependent) HHG algorithm.

Appendix G. Additional Simulations for the Two-Sample Problem

Table 6 shows a comparison of the performance of the minimum p-value and Fisher-combined test statistics. The variant with highest power in most setups (specifically, setups 2,4,5,6,8,9,10,11,12) is the Fisher-combined p-value using aggregation by summation and $m_{\max} = 50$. However, the Fisher-combined p-value test is sensitive to the choice of $m_{\max}$, which is unknown in practice. Since we view this as a significant weakness of the Fisher-combined statistic, and since the minimum p-value does not have this weakness and has very good power when compared with Fisher as well as when compared with other tests (with a large range of $m_{\max}$ values examined), we recommend the minimum p-value test statistic.

Table 7 shows the power using different priors for regularization. The priors are as follows: $\pi(m) = \sqrt{N}^m exp(-\sqrt{N})/m!$ for Poisson; $\pi(m) = \binom{N-1}{m-1} p^m (1-p)^{(N-m)}$ for Binomial, with $p = 0.119$ so that the penalty becomes that of the Akaike information criterion (i.e., $\log \pi(\mathcal{I}|m)\pi(m) = -2m$); $\pi(m) = 1/K$ for fixed K for Uniform. We also considered the prior in Jiang et al. (2014), resulting in the DS test with penalty $-\lambda_0 \log N(m-1)$. According to the recommendation in Jiang et al. (2014), we chose the value of λ_0 so that the level under the null is as close as possible to 0.05 from below, so $\lambda_0 = 1.11088$ for $N = 100$, and $\lambda_0 = 0.904$ for $N = 500$. The Poisson prior (with rate $\sqrt{N}$) was by far the best among all priors considered, and its power was comparable to that of the minimum p-value displayed in Table 6.

For sample size $N = 100$, we examined the distributions depicted in Figure 10, and we used 20,000 simulated data sets, in each of the configurations. Table 9 and Figure 11 show the power for

Table 6: Power of the minimum p-value test statistic (columns 2–5) as well as the Fisher-combined p-value test statistic (columns 6–9), using the different aggregation methods and two values of $m_{\max}$, for $N = 500$ and the setups of Figure 2. The difference between $m_{\max} = 50$ and $m_{\max} = 149$ is much larger for the Fisher-combined than for the minimum p-value test statistic when aggregated by summation (columns 8–9 versus columns 4–5). Moreover, the power is typically lower for the Fisher-combined that for the minimum p-value test statistic when the aggregation is by maximization (columns 6–7 versus columns 2–3).

Table 7: Power using different priors , for $N = 500$ and the setups of Figure 2.

the setups in Figure 10. These results concur with the results in Section 4.1 for $N = 500$, and show that if the number of intersections of the two distributions is at least four, tests statistics with $m \geq 4$ have an advantage.

Appendix H. Simulations of Monotone Relationships

Four monotone relationships are presented in Figure 12. Figure 13 shows that the differences for the summation variants between ADP and DDP are negligible, and that the power decreases with m for all of these variants. Similar conclusions hold for the maximum variants in Table 10. Table 10 further shows that for a linear relationship, Pearson, Spearman, Hoeffding and dCov are clearly

		Minimum p-value

Table 8: Power of competitors (columns 4–9), along with the minimum p-value using the M_m p-values (column 1) and the S_m p-values (column 2).

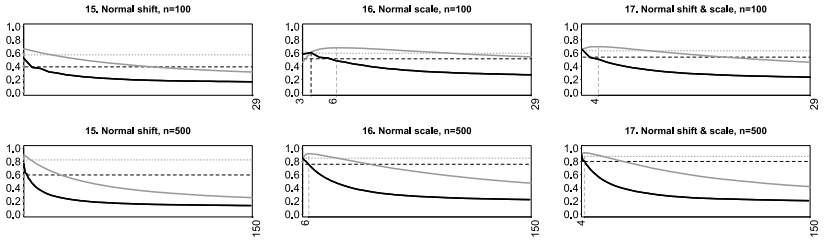

Figure 9: Estimated power for the M_m (black) and S_m (grey) statistics for $m \in \{2, \ldots, 149\}$ for the Gaussian shift difference (first column, $N(0,1)$ versus $N(0.5,1)$ for $N = 100$, and versus $N(0.3,1)$ for $N = 500$), Gaussian scale difference (second column, $N(0,1)$ versus $N(0, 0.6^2)$ for $N = 100$, and versus $N(0, 0.75^2)$ for $N = 500$), and for the Gaussian shift and scale difference (third column, $N(0,1)$ versus $N(0.36, 0.7^2)$ for $N = 100$, and versus $N(0.2, 0.8^2)$ for $N = 500$). The power of the minimum p-value is the horizontal dashed black line when it combines the p-values based on M_m, and the horizontal dotted grey line when it combines the p-values based on S_m. The vertical lines show the optimal m for M_m (grey) and S_m (black).

superior, but for the remaining three monotone relationships $\min_{m \in \{2,\ldots,m_{\max}\}} p_m$ has quite good power properties.

Appendix I. Comparisons of DCov/HHG on Ranks and on Data

In Section 4 we only considered distribution-free competitors. Therefore, we applied dCov and HHG on ranks rather than on data, even though they were designed as permutation tests on data. Usually, the computational advantage of performing the tests on $(rank(X), rank(Y))$ instead of on (X, Y), due to the distribution-free property of the tests on $(rank(X), rank(Y))$, comes at a cost of lower power, as noted by Székely et al. (2007). Table 11 shows a power comparison of these two permutation tests on ranks and on data. The power in most settings is indeed greater when the tests are used on data, and the maximal difference is almost 30% (in the Spiral setting for HHG) in favour of using the data. However, in some settings the power is actually larger for the test on ranks, e.g.,

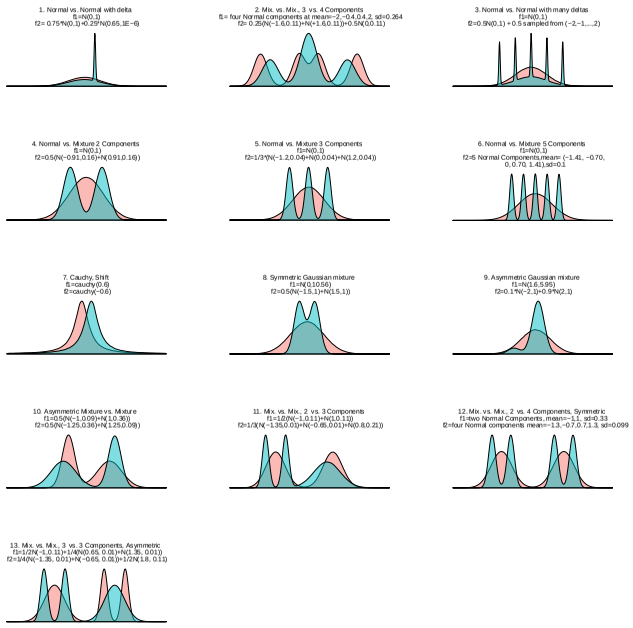

Figure 10: The two distributions in 13 different setups considered for $N = 100$, which differ in the number of intersections of the densities, the range of support where the differences lie, and the whether they are symmetric or not.

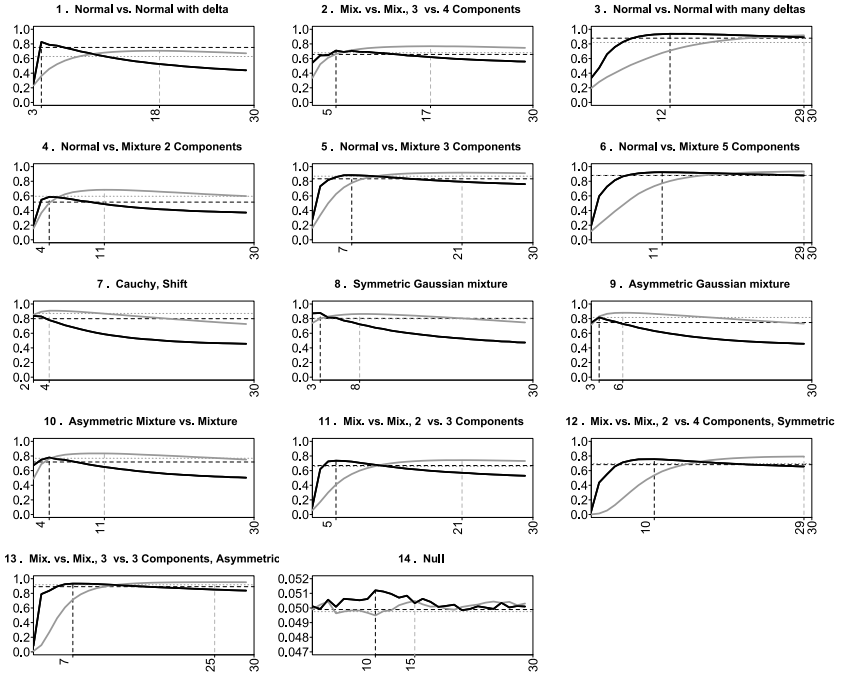

Figure 11: Estimated power with $N = 100$ sample points for the M_m (black) and S_m (grey) statistics for $m \in \{2, \ldots, 29\}$ for the setups of Figure 10. The power of the minimum p-value is the horizontal dashed black line when it combines the p-values based on M_m, and the horizontal dotted grey line when it combines the p-values based on S_m. The vertical lines show the optimal m for M_m (black) and S_m (grey).

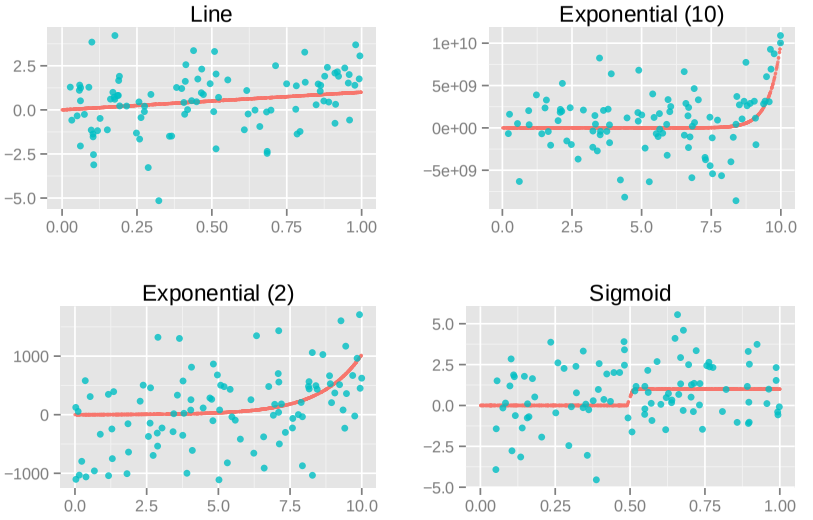

Figure 12: Bivariate monotone relationships (in red), along with a sample of $N = 100$ noisy observations (in blue).

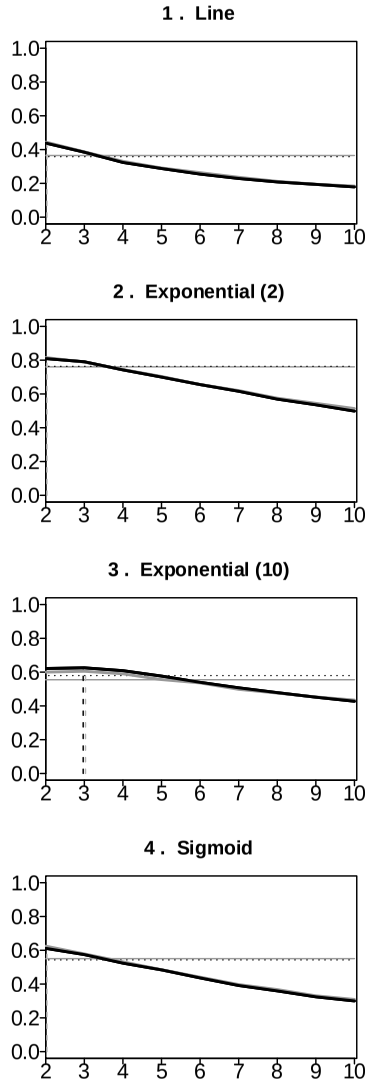

Figure 13: Estimated power for the DDP (black) and ADP (gray) summation variants, using the likelihood ratio score, for the setups from Figure 12, for a sample of size $N = 100$. The horizontal lines are the power of $\min_{m\in\{2,..,m_{\max}\}} p_m$ using DDP (dotted black) and using ADP (gray) .

Table 9: Power of competitors (columns 4–9), along with the minimum p-value statistic using the M_m p-values (column 1) and the S_m p-values (column 2), for $N = 100$. The standard error was at most 0.0035. The advantage of the test based on the minimum p-value is large when the number of intersections of the two densities is at least four (setups of rows 2,3, 4,5,6,10,11,12, and 13). The best competitors are HHG and DS, but HHG is essentially an $m \leq 3$ test, and DS penalizes large ms severely, therefore in setups where $m \geq 4$ partitions are better they can perform poorly. Among the two variants in columns 1 and 2, the better choice clearly depends on the range of support in which the differences in distributions occur: aggregation by maximum has better power when the difference between the distributions is very local (setups of rows 1 and 3), and aggregation by summation has better power otherwise. The highest power per row is underlined.

Test	Line	Exp2x	Exp10x	Sigmoid

Table 10: The power of competitors (rows 3–7), along with the minimum p-value statistic based on DDP (row 1) and on ADP (row 2) and the different maximum variants (rows 8–11), for $N = 100$. The standard error is at most 0.011.

in the Heavisine and 5Clouds settings for HHG, where the difference is 10% and 16%, respectively, in favour of using the ranked observations. Comparing the power of the HHG and dCov tests on data (in Table 11) to the power of our suggested minimum p-value statistic (in Table 2), we see that although dCov on data may have more power than dCov on ranks, it has far less power than HHG on data, and that HHG on data has less power than our test when the relationship is more complex, especially in the Sine, Heavisine, Spiral and Circles examples.

	dCov		HHG

Table 11: Power of the competitors dCov and HHG on ranks as well as on data for $N = 100$ (columns 2-4). The results on ranks are not identical numerically (though very close) to those of Table 2 due to the use of a different seed to generate the data for these same settings. The tests on data have greater power than on ranks in most, but not all, examples. HHG on data has the best power out of these four competitors, but like the HHG on ranks it has a disadvantage in comparison with our novel minimum p-value test when the relationship is more complex, especially in the Sine, Heavisine, Spiral, Circles, and 5Clouds examples (the power for this test was reproduced in column 6 here from Table 2 for convenience).

Abstract

We propose a Gibbs sampler for structure learning in directed acyclic graph (DAG) models. The standard Markov chain Monte Carlo algorithms used for learning DAGs are random-walk Metropolis-Hastings samplers. These samplers are guaranteed to converge asymptotically but often mix slowly when exploring the large graph spaces that arise in structure learning. In each step, the sampler we propose draws entire sets of parents for multiple nodes from the appropriate conditional distribution. This provides an efficient way to make large moves in graph space, permitting faster mixing whilst retaining asymptotic guarantees of convergence. The conditional distribution is related to variable selection with candidate parents playing the role of covariates or inputs. We empirically examine the performance of the sampler using several simulated and real data examples. The proposed method gives robust results in diverse settings, outperforming several existing Bayesian and frequentist methods. In addition, our empirical results shed some light on the relative merits of Bayesian and constraint-based methods for structure learning.

Keywords: structure learning, DAGs, Bayesian networks, Gibbs sampling, Markov chain Monte Carlo, variable selection

1. Introduction

We consider structure learning for graphical models based on directed acyclic graphs (DAGs). The basic structure learning task can be stated simply: given data $\mathbf{X}$ on p variables, assumed to be generated from a graphical model based on an unknown DAG G, the goal is to make inferences concerning the edge set of G (the vertex set is treated as fixed and known). Structure learning appears in a variety of applications (for an overview see Korb and Nicholson, 2011) and is a key subtask in many analyses involving graphical models, including causal inference.

In a Bayesian framework, structure learning is based on the posterior distribution $P(G \mid \mathbf{X})$ (Koller and Friedman, 2009). The domain of the distribution is the space $\mathcal{G}$ of all DAGs with p vertices. The size of the space grows super-exponentially with p, precluding exhaustive enumeration for all but the smallest problems. Markov chain Monte Carlo (MCMC) methods are widely used to sample DAGs and thereby approximate the posterior $P(G \mid \mathbf{X})$. Available methods include MC^3 (Madigan and York, 1995) and related samplers (Giudici and Castelo, 2003; Grzegorczyk and Husmeier, 2008) and algorithms that sample from the space of total orders (Friedman and Koller, 2003). Order-space sampling entails some restrictions on graph priors (Eaton and Murphy, 2007; Ellis and Wong, 2008), because the number of total orders with which a DAG is consistent is not constant. Order-space approaches have more recently led to exact methods based on dynamic programming (Koivisto and Sood, 2004; Parviainen and Koivisto, 2009; Tian and He, 2009; Tamada et al., 2011; Parviainen and Koivisto, 2013; Nikolova et al., 2013). These are currently feasible only in small domain settings (typically $p < 20$ but $p < 30$ is feasible on large cluster computers) and usually share the same restrictions on graph priors as order-space samplers. Frequentist constraint-based methods such as the PC-algorithm (Spirtes et al., 2000; Colombo and Maathuis, 2014) and the approach of Xie and Geng (2008) are an alternative. These methods make firm decisions about the DAG structure via a series of tests of conditional independence.

In this paper we propose a Gibbs sampler for structure learning of DAGs that ameliorates key deficiencies in existing samplers. Random-walk Metropolis-Hastings algorithms currently used for structure learning propose 'small' changes at each iteration, which can leave the algorithms unable to escape local modes. The Gibbs sampler proposed here considers the parents of a set of nodes as a single component (a so-called 'block'), sampling an entire parent set for each node in the block in one step. These 'large' moves are sampled from the appropriate conditional posterior distribution. This enables the sampler to efficiently locate and explore areas of significant posterior mass. The method is based on the simple heuristic that the parents of a node are similar to the covariates or inputs in variable selection, with the node as the output variable, but accounts for acyclicity exactly so that the equilibrium distribution is indeed the correct posterior distribution over DAGs. The sampler does not impose restrictions on priors or graph space beyond those (maximum in-degree, modular prior) common to most samplers for structure learning (e.g. Friedman and Koller, 2003; Ellis and Wong, 2008; Grzegorczyk and Husmeier, 2008). The maximum in-degree restriction formally precludes large-sample consistency in the general case, but facilitates effective and robust inference by reducing the size of the model space (see Discussion).

2. Notation and Model

Let G denote a DAG with vertex set $V(G) = \{1, \ldots, p\}$, and directed edge set $E(G) \subset V(G) \times V(G)$; often we will refer to vertex and edge sets simply as V and E respectively, leaving G implicit. The binary adjacency matrix corresponding to G is denoted A^G, with entries specified as $A^G_{uv} = 1 \iff (u, v) \in E(G)$ and diagonal entries equal to zero. For inference, G is treated as a latent graph in the space $\mathcal{G}$ of all possible DAGs with p vertices. When a DAG is used to define a probabilistic graphical model (a Bayesian network), each vertex (or node; we use both terms interchangeably) is associated with a component of a p-dimensional random vector $X = (X_1 \ldots X_p)^{\mathrm{T}}$. X_Z denotes the random variables (RVs) corresponding to variable indices $Z \subseteq \{1, \ldots, p\}$. We use bold type for the corresponding data; n samples are collected in the $n \times p$ matrix $\mathbf{X}$, with $\mathbf{X}_u$ denoting the column corresponding to variable u and $\mathbf{X}_Z$ the submatrix corresponding to variable index set $Z \subseteq \{1, \ldots, p\}$ (for notational simplicity we assume columns are ordered by increasing variable index).

A graph G

$$A^G = \begin{bmatrix} 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix}$$

$\mathrm{pa}_1^G = \emptyset$
$\mathrm{pa}_2^G = \{1\}$
$\mathrm{pa}_3^G = \{1, 2, 4\}$
$\mathrm{pa}_4^G = \emptyset$

Figure 1: Illustration of notation. A graph G, with vertex set $V = \{1, 2, 3, 4\}$, edge set $E = \{(1, 2), (1, 3), (2, 3), (4, 3)\}$ and adjacency matrix A^G as shown, can be specified using parent sets as $G = \langle \mathrm{pa}_1 = \emptyset, \mathrm{pa}_2 = \{1\}, \mathrm{pa}_3 = \{1, 2, 4\}, \mathrm{pa}_4 = \emptyset \rangle$ or abbreviated to $G = \langle \emptyset, \{1\}, \{1, 2, 4\}, \emptyset \rangle$ (see text for description of notation). For the vertex subset $Z = \{2, 4\}$, $\mathrm{pa}_Z^G = (\{1\}, \emptyset)$ and $\mathrm{pa}_{-Z}^G = (\emptyset, \{1, 2, 4\})$ and thus the graph can be specified as $G = \langle \mathrm{pa}_Z = \mathrm{pa}_Z^G, \mathrm{pa}_{-Z} = \mathrm{pa}_{-Z}^G \rangle$. We abbreviate this as $G = \langle \mathrm{pa}_Z^G, \mathrm{pa}_{-Z}^G \rangle$.

The proposed Gibbs sampler changes entire parent sets *en masse*, not just for one node but for a set of nodes, and so it will often be convenient and natural to specify a DAG G in terms of the parents of each node. Let $\mathrm{pa}_v^G = \{u : (u, v) \in E(G)\}$ denote the set of nodes that are parents of node v in G. A tuple of p parent sets $\langle \mathrm{pa}_1 = \mathrm{pa}_1^G, \ldots, \mathrm{pa}_p = \mathrm{pa}_p^G \rangle$ fully specifies the edge set E, since $u \in \mathrm{pa}_v^G \iff (u, v) \in E(G)$. Thus, structure learning can be viewed as inference of parent sets pa_v. The parent set pa_v takes values in the power set $\mathcal{P}(V \setminus \{v\})$ of nodes excluding node v, subject to acyclicity. We will usually suppress the labels, and simply write $\langle \mathrm{pa}_1^G, \ldots, \mathrm{pa}_p^G \rangle$ when specifying parent sets. Since pa_v^G is a subset of the variable indices, we can use $\mathbf{X}_{\mathrm{pa}_v^G}$ to denote the corresponding data submatrix.

We denote the tuple of parent sets of a set of nodes $Z = \{z_1, \ldots, z_s\} \subseteq V$ by $\mathrm{pa}_Z^G = (\mathrm{pa}_z^G)_{z \in Z}$. This is a tuple of s components (for notational convenience we take these to be ordered by increasing vertex index), each of which is the parent set for the corresponding node in G. We wish to make inferences about pa_Z, which takes values in $\mathcal{P}(V \setminus \{z_1\}) \times \ldots \times \mathcal{P}(V \setminus \{z_s\})$, subject to acyclicity. The tuple of parent sets for the complement $Z^{\mathsf{C}} = V \setminus Z$ is denoted $\mathrm{pa}_{-Z}^G = (\mathrm{pa}_z^G)_{z \in Z^{\mathsf{C}}}$. Clearly, a tuple $\langle \mathrm{pa}_{Z_1}^G, \ldots, \mathrm{pa}_{Z_s}^G \rangle$ of tuples of parent sets specifies the parents of *every* node in a graph whenever $\{Z_1, \ldots, Z_s\}$ forms a partition of V; the entire edge set can thus be specified by such a tuple. In particular, note that any graph G can be specified as $\langle \mathrm{pa}_Z^G, \mathrm{pa}_{-Z}^G \rangle$ for any $Z \subset V$. Some of the notation we use is illustrated in Figure 1.

Our statistical formulation for Bayesian networks is standard. We briefly summarize the main points and refer the reader to the references below for details. Given a DAG G, the joint distribution of X is $p(X \mid G, \{\theta_v\}) = \prod_{v \in V} p(X_v \mid X_{\mathrm{pa}_v^G}, \theta_v)$, i.e. the joint distribution factors over nodes, and each node is conditioned on its parents in G, parameterized by θ_v. For structural inference, interest focuses on the posterior distribution $P(G \mid \mathbf{X})$. This is proportional to the product of the marginal likelihood $p(\mathbf{X} \mid G)$ and a graph prior $\pi(G)$. Our sampler is compatible with essentially any specific model, but inherits computational costs associated with evaluation of the relevant quantities. In all examples we assume conjugate priors for θ_v, as well as local parameter independence and modularity; this leads to a closed-form marginal likelihood in both multinomial (Heckerman et al., 1995) and Gaussian

(Geiger and Heckerman, 1994) cases. Computations are simplified if the graph prior is modular (Friedman and Koller, 2003), meaning it factorises as $\pi(G) = \prod_{v \in V} \pi_v(\mathrm{pa}_v^G)$; we assume modular priors in all examples. Note that the prior is not specified over the space of orders and so is not subject to the restrictions this entails (Ellis and Wong, 2008; Eaton and Murphy, 2007). Under these assumptions, the posterior factorises across nodes as

$$\begin{aligned} P(G \mid \mathbf{X}) &= P(\mathrm{pa}_1 = \mathrm{pa}_1^G, \ldots, \mathrm{pa}_p = \mathrm{pa}_p^G \mid \mathbf{X}) \\ &\propto \prod_{v \in V} p(\mathbf{X}_v \mid \mathbf{X}_{\mathrm{pa}_v^G}) \pi_v(\mathrm{pa}_v^G), \end{aligned}$$

where $p(\mathbf{X}_v \mid \mathbf{X}_{\mathrm{pa}_v^G})$ is the marginal likelihood for node v given the graph $G = \langle \mathrm{pa}_1^G, \ldots, \mathrm{pa}_p^G \rangle$. The distribution $P(G \mid \mathbf{X})$ is the target distribution for our sampler.

3. A Gibbs Sampler for Structure Learning

In this section we provide a high-level description of the Gibbs sampler for structure learning. We first recall the standard random-walk Metropolis-Hastings sampler (known as MC^3) and then describe a naïve Gibbs sampler, which offers no gains over MC^3, but prepares the ground for the introduction of ideas from the Gibbs sampling literature. Specifically we discuss a strategy known as blocking that can improve mixing in Gibbs samplers and show how to use blocking for structure learning of DAGs. Several points relating to computation are central to developing a practical Gibbs sampler in this setting, but for clarity of exposition we defer discussion of computational aspects to Section 4.

3.1 MC^3 Sampler

The standard sampler for structure learning of DAGs is MC^3 (Madigan and York, 1995). This is a classical Metropolis-Hastings sampler with proposal G' drawn uniformly at random from the set $\mathrm{neigh}(G)$ of DAGs that differ from the current DAG G by the addition or removal of a single edge. The acceptance probability is $\min(1, r(G', G))$, where

$$r(G', G) = \min \left\{ 1, \frac{P(G' \mid \mathbf{X}) \, |\mathrm{neigh}(G')|^{-1}}{P(G \mid \mathbf{X}) \, |\mathrm{neigh}(G)|^{-1}} \right\}.$$

Variants of MC^3 include single-edge direction reversal proposals (Giudici and Castelo, 2003).

3.2 A Naïve (and Inefficient) Gibbs Sampler

Constructing a Gibbs sampler that is analogous to MC^3 is straightforward. The posterior distribution on DAGs is a joint distribution over the off-diagonal entries in the adjacency matrix A^G, i.e. over the $p(p-1)$ binary RVs A_{uv}^G, $u \neq v$. At each iteration, MC^3 can be thought of as proposing to toggle the value A_{uv}^G for some $u \neq v$, subject to the restriction that the resulting graph must be acyclic.

A simple Gibbs sampler works in a similar way. At each step, a move from graph G to a new graph G' is chosen by sampling from the conditional distribution of $A_{uv}^{G'}$ (for some $u \neq v$) given the rest of the graph. If $(u, v) \in E(G)$, define the graph $G^{(u,v)}$ to be identical to G, and $G^{-(u,v)}$ to be the graph that differs from G only in lacking an edge from u to

v; conversely, if $(u,v) \notin E(G)$, define $G^{-(u,v)}$ to be identical to G, and $G^{(u,v)}$ to be the graph that differs from G only in including an edge from u to v. If $G^{(u,v)}$ is cyclic, $G^{-(u,v)}$ is sampled as the new graph G' with probability 1. If $G^{(u,v)}$ is acyclic, the conditional distribution of $A^{G'}_{uv}$ is Bernoulli, i.e.

$$P(A^{G'}_{uv} = a \mid A^{G}_{-uv}) = \begin{cases} \dfrac{P(G^{-(u,v)} \mid \mathbf{X})}{P(G^{-(u,v)} \mid \mathbf{X}) + P(G^{(u,v)} \mid \mathbf{X})} & a = 0, \\ \dfrac{P(G^{(u,v)} \mid \mathbf{X})}{P(G^{-(u,v)} \mid \mathbf{X}) + P(G^{(u,v)} \mid \mathbf{X})} & a = 1. \end{cases}$$

The choice of u and v can either be made sequentially (systematically) or randomly (Roberts and Sahu, 1997); in this paper, random-scan Gibbs samplers are used throughout. We prove convergence of the Gibbs sampler to the target distribution in Appendix A.

3.3 Inefficiency in Gibbs Sampling

The mixing of Metropolis-Hastings samplers depends upon the proposal distribution, which for convenience is often chosen as a random-walk. In contrast, Gibbs samplers make moves according to conditional distributions that reflect local structure of the target distribution. Nonetheless, Gibbs sampling is not always efficient. In particular, correlation between the components being sampled can lead to inefficiency. To see this, consider a Gibbs sampler for a multivariate continuous distribution with highly correlated components. At each step, a single component is sampled according to its conditional distribution, but since it is strongly correlated with other component(s), the conditional is concentrated on only a small part of the support. This means the sampler is likely to make only small moves. Analogous issues arise with discrete distributions.

For graphical models based on DAGs, there may be strong dependence between the edge indicators A^G_{uv}, particularly for the collections of RVs corresponding to parent sets. For example, there may be RVs X_u and X_v that in combination score highly as parents of node w, but not individually. Then, A^G_{uw} and A^G_{vw} will be correlated. In addition, the acyclicity restriction may induce strong dependence. For example, suppose two RVs X_u and X_v are strongly correlated and both edges (u,v) and its reverse (v,u) have high posterior probability. If the edge (u,v) is present, the probability of it being removed is low, but its presence precludes the reversed edge (v,u) from being added. This possibility motivates the edge reversal move used in variants of MC^3 (Giudici and Castelo, 2003). Figure 2 shows a three node scenario. Here, both graphs (a) and (b) have high probability. Since reversing the edge (w,x) forms a cycle in (a), moves that consider the parents of only the pair w and x at the same time will not move between graphs (a) and (b) easily. Samplers that alter only a single edge indicator, such as MC^3, will also fail. In contrast, sampling the parents of all three nodes jointly would make it easy to move between graphs (a) and (b). Decorrelating transformations could alleviate such problems, but in general finding a suitable transformation is difficult, and for DAGs must of course encapsulate the requirement for acyclicity.

Figure 2: Illustrative scenario in which small local moves limit transitions between two regions of high probability. If both graphs (a) and (b) have high probability, the near-cyclic nature of the graphs makes transitions between (a) and (b) difficult.

3.4 A Gibbs Sampler with Blocking

We address the deficiencies of the naïve Gibbs sampler by grouping a number of the components together and sampling from their joint conditional distribution. In Gibbs sampling, this is known as *blocking*. Sampling from such a joint conditional can ameliorate difficulties caused by correlations between components because the joint conditional naturally accounts for the correlation structure. In the multivariate normal case, Roberts and Sahu (1997) have shown that blocking improves convergence for random-scan Gibbs sampling.

In principle, any group of components can be taken as a block, but for the algorithm to be useful in practice, sampling from a block's joint conditional distribution must be feasible, and ideally simple. The blocks that we consider correspond to groups (specifically tuples) of parent sets, so that the parent sets of several nodes are considered simultaneously. It is natural that each block is a tuple of parent sets because, as described in Section 2, we can specify a graph G using a tuple $\langle \mathrm{pa}^G_1, \ldots, \mathrm{pa}^G_p \rangle$ of parent sets. It is therefore convenient to describe the sampler using this alternative graph specification, in which $G = \langle \mathrm{pa}^G_1, \ldots, \mathrm{pa}^G_p \rangle$.

We denote the set of q nodes whose parent sets will be sampled together as a block by $W = \{w_1, \ldots, w_q\} \subseteq V$. Suppose the current graph is $G = \langle \mathrm{pa}^G_W, \mathrm{pa}^G_{-W} \rangle$ (recall that any graph can be written in this way with respect to any partition of the node set). A move to a new graph $G' = \langle \mathrm{pa}^{G'}_W, \mathrm{pa}^{G'}_{-W} \rangle$ is formed by changing the parents of the nodes in W from $\mathrm{pa}^G_W = (\mathrm{pa}^G_{w_1}, \ldots, \mathrm{pa}^G_{w_q})$ to $\mathrm{pa}^{G'}_W = (\mathrm{pa}^{G'}_{w_1}, \ldots, \mathrm{pa}^{G'}_{w_q})$ and setting $\mathrm{pa}^{G'}_{-W} = \mathrm{pa}^G_{-W}$ (i.e. leaving the parents of nodes not in W unchanged). We sample the tuple $\mathrm{pa}^{G'}_W$ of parent sets jointly, conditional on the tuple pa^G_{-W} of parent sets of nodes not in W (that remain unchanged). In terms of the adjacency matrix A^G, each block consists of the indicators specifying the parents of the nodes in W, i.e. A^G_{vw} for $v \in V, w \in W, v \neq w$.

To construct a Gibbs sampler using these blocks, we need to find the conditional posterior distribution on the tuple pa_W of parent sets, given that the remaining tuple pa_{-W} of parent sets is set to pa^G_{-W}. The conditional distribution depends on whether the graph G' formed using the proposed parent sets is acyclic. We therefore introduce $P\mathrm{a}^G_W$ to denote the set of permissible tuples, i.e. tuples $\mathrm{pa}^{G'}_W$ of parent sets such that $G' = \langle \mathrm{pa}^{G'}_W, \mathrm{pa}^G_{-W} \rangle$ is acyclic. For tuples $\mathrm{pa}^{G'}_W \notin P\mathrm{a}^G_W$, the conditional probability is 0. For $\mathrm{pa}^{G'}_W \in P\mathrm{a}^G_W$, the

Algorithm 1 A Gibbs sampler for learning DAGs, with blocks

Initialise starting point $G_0 = \langle \mathrm{pa}_1^{G_0}, \ldots, \mathrm{pa}_p^{G_0} \rangle$
for t in 1 to N **do**
  Sample q nodes uniformly at random from V, and call this set of nodes W
  Sample $\mathrm{pa}_W^{G'}$ from $P(\mathrm{pa}_W = \mathrm{pa}_W^{G'} \mid \mathrm{pa}_{-W}^{G_{t-1}}, \mathbf{X})$
  Set $G_t \leftarrow G = \langle \mathrm{pa}_W^{G'}, \mathrm{pa}_{-W}^{G_{t-1}} \rangle$
end for

conditional probability is

$$P(\mathrm{pa}_W = \mathrm{pa}_W^{G'} \mid \mathrm{pa}_{-W} = \mathrm{pa}_{-W}^{G}, \mathbf{X}) = \frac{P(\langle \mathrm{pa}_W^{G'}, \mathrm{pa}_{-W}^{G} \rangle \mid \mathbf{X})}{P(\mathrm{pa}_{-W}^{G} \mid \mathbf{X})} = \frac{P(G' \mid \mathbf{X})}{\sum_{\mathrm{pa}_W^{G''} \in Pa_W^G} P(\mathrm{pa}_W^{G''}, \mathrm{pa}_{-W}^{G} \mid \mathbf{X})}. \quad (1)$$

This is the conditional distribution needed to specify the blocked Gibbs sampler; Algorithm 1 outlines the procedure at a high level, with the set W of nodes chosen uniformly at random at each step. Asymptotic convergence follows from the argument in Appendix A (in fact the requirements on the graph prior will be weaker than in the naïve case).

3.5 Tuning Parameters

To reduce the computational costs of structure learning it is common to set a maximum in-degree (e.g. Friedman and Koller, 2003; Grzegorczyk and Husmeier, 2008). We set a maximum in-degree $\kappa = 3$ in all empirical examples, except where stated otherwise (Section 5). This facilitates sampling from the conditional distribution in Equation 1 by reducing the computational cost of evaluating the normalising constant. We set the block size $q = |W| = 3$. While q can be chosen freely in principle, evaluating the conditional distribution in Equation 1 becomes unmanageable when q is large. Thus, both κ and q act as tuning parameters (and are in addition to any hyper-parameters in the Bayesian formulation).

3.6 Structure Learning and Variable Selection

It is interesting to note that when $q = 1$ (and thus $W = w$ for some $w \in V$) if no choice of parent set induces a cycle then $Pa_W^G = \mathcal{P}(V \setminus \{w\})$, the power set of the remaining nodes. In this case, the conditional distribution in Equation 1 can be viewed as the posterior distribution of a variable selection problem with response or output variable w, and the other variables as covariates or inputs. If the addition of particular nodes introduces a cycle, we have a constrained problem. In particular, suppose adding any of the nodes $Z \subset V$ as parents of node w would create a cycle. Then $Pa_W^G = \mathcal{P}(V \setminus (\{w\} \cup Z))$ and the conditional distribution in Equation 1 is a constrained variable selection problem in which the nodes Z are excluded from the set of candidate inputs.

4. Computational Aspects

Designing a computationally efficient sampler is not straightforward in this setting. To see why, note that to sample from the conditional in Equation 1 we need to be able to identify the set Pa_W^G of tuples of parent sets that is permissible (in the sense of maintaining acyclicity). The cardinality of this set is typically large, and the interdependence between the parent sets of each node in W makes decomposing the problem into subproblems non-trivial. A simple but naïve approach would list all possible parent sets for each node in W and check each such combination for cyclicity, but this approach is slow and cumbersome.

We propose a partitioning scheme that leads to a two-stage sampler. The key idea is to choose the partition of Pa_W^G so that, conditional on a component of the partition, the parents of each node are independent. This enables an efficient two-stage sampling method that we describe in Section 4.3. Acyclicity constraints are met by an efficient dynamic algorithm.

4.1 A Partition on Permissible Tuples of Parent Sets

We partition the set Pa_W^G of permissible tuples of parent sets as $Pa_W^G = \{Pa_W^{G,H_1}, \ldots, Pa_W^{G,H_\eta}\}$. Each component Pa_W^{G,H_h} is a set of permissible tuples of parent sets for nodes in W. It is convenient to label the partition components using secondary (unrelated to G) DAGs $H_h \in \mathcal{H}$, where $\mathcal{H}$ is the space of DAGs with $q = |W|$ vertices; η is the cardinality of $\mathcal{H}$. We describe the relationship between each Pa_W^{G,H_h} and DAG H_h using the following elements, illustrated in Figure 3 and Table 1:

- The reduced graph $\overline{G} = \langle \mathrm{pa}_1^{\overline{G}}, \ldots, \mathrm{pa}_p^{\overline{G}} \rangle$, which is a function of the graph G, and is identical to G except that edges directed into nodes in W are removed.

$$\mathrm{pa}_w^{\overline{G}} = \begin{cases} \emptyset & w \in W, \\ \mathrm{pa}_w^G & w \notin W \end{cases}$$

- The (reflexive) transitive closure, which is the directed graph T^G on nodes V with edges E^{T}, where $(u, v) \in E^{\mathrm{T}}$ if and only if $u = v$ or a (directed) path from u to v exists in G (i.e. there exists a sequence of nodes $z_1, \ldots, z_s \in V(G)$, with $z_1 = u$ and $z_s = v$, such that $(z_1, z_2), (z_2, z_3), \ldots, (z_{s-1}, z_s) \in E(G)$).

- The descendant nodes $\mathrm{de}_w^{\overline{G}} = \{v \in V : \mathrm{T}_{wv}^{\overline{G}} = 1\}$ and the non-descendant nodes $\mathrm{nd}_w^{\overline{G}} = \{v \in V : \mathrm{T}_{wv}^{\overline{G}} = 0\}$ of $w \in W$ in the reduced graph $\overline{G}$. Note that $w \in \mathrm{de}_w^{\overline{G}}$ and $w \notin \mathrm{nd}_w^{\overline{G}}$ by definition.

- The nodes $\mathrm{nd}^{\overline{G}} = \bigcap_{w \in W} \mathrm{nd}_w^{\overline{G}}$ that are not descendants in the reduced graph $\overline{G}$ of any node in W.

- The nodes $\mathrm{de}_w^{\overline{G},H} = \bigcup_{x \in \mathrm{pa}_w^H} \mathrm{de}_x^{\overline{G}}$ that are descendants in the reduced graph $\overline{G}$ of any node $x \in \mathrm{pa}_w^H$, for a given node $w \in W$. Each node $x \in \mathrm{pa}_w^H$ is a parent node of the node w in the graph $H = \langle \mathrm{pa}_{w_1}^H, \ldots, \mathrm{pa}_{w_q}^H \rangle$.

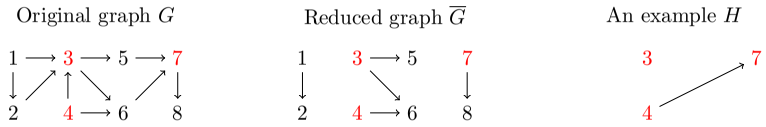

Figure 3: An illustrative example of the relevant graphs and sets, with $W = \{3, 4, 7\}$ shown in red. The edges into W are removed from the original graph G, to form $\overline{G}$. Here $\mathcal{H}$ is the set of all DAGs on the nodes $\{3, 4, 7\}$ and thus $\eta = |\mathcal{H}| = 25$. For H as shown, $\mathrm{nd}^{\overline{G}} = \{1, 2\}$.

	$\mathrm{de}_w^{\overline{G}}$	$\mathrm{nd}_w^{\overline{G}}$	$\mathrm{de}_w^{\overline{G},H}$	$\mathrm{de}_{-w}^{\overline{G},H}$	$Q_w^{\overline{G},H}$	Condition (B)
$w = 3$	$\{3, 5, 6\}$	$\{1, 2, 4, 7, 8\}$	$\emptyset$	$\{3, 4, 5, 6, 7, 8\}$	$\{1, 2\}$	No restriction
$w = 4$	$\{4, 6\}$	$\{1, 2, 3, 5, 7, 8\}$	$\emptyset$	$\{3, 4, 5, 6, 7, 8\}$	$\{1, 2\}$	No restriction
$w = 7$	$\{7, 8\}$	$\{1, 2, 3, 4, 5, 6\}$	$\{4, 6\}$	$\{3, 5, 6, 7, 8\}$	$\{1, 2, 4\}$	$\mathrm{pa}_7^{G'} \cap \{4\} \neq \emptyset$

Table 1: The relevant sets and requirements of conditions (A) and (B) for the illustrative graph G shown in Figure 3, with H as shown. Recall $\mathrm{nd}^{\overline{G}} = \{1, 2\}$. Condition (B) depends on $R_{7,4}^{\overline{G},H} = \{4\}$, but it imposes no restriction when $w \in \{3, 4\}$ because $\mathrm{pa}_3^H = \mathrm{pa}_4^H = \emptyset$. We find that $Pa_W^{G,H}$ contains all tuples of parent sets for which $\mathrm{pa}_3^{G'} \subseteq \{1, 2\}$, $\mathrm{pa}_4^{G'} \subseteq \{1, 2\}$ and $\mathrm{pa}_7^{G'} = \{4\} \cap Z$ where $Z \subseteq \{1, 2\}$.

- The nodes $\mathrm{de}_{-w}^{\overline{G},H} = \bigcup_{x \in W \setminus \mathrm{pa}_w^H} \mathrm{de}_x^{\overline{G}}$ that are descendants in the reduced graph $\overline{G}$ of any node $x \in W \setminus \mathrm{pa}_w^H$, for a given node $w \in W$. Each node $x \in W \setminus \mathrm{pa}_w^H$ is not a parent node of w in the graph $H = \langle \mathrm{pa}_{w_1}^H, \ldots, \mathrm{pa}_{w_q}^H \rangle$.

Using this notation, we define $Pa_w^{G,H}$, for given $G \in \mathcal{G}$, $W \subseteq V$, $w \in W$ and $H = \langle \mathrm{pa}_{w_1}^H, \ldots, \mathrm{pa}_{w_q}^H \rangle \in \mathcal{H}$, as the set of parent sets $\mathrm{pa}_w^{G'}$ that satisfy the following conditions.

(A) $\mathrm{pa}_w^{G'} \subseteq Q_w^{\overline{G},H} = \left(\mathrm{nd}^{\overline{G}} \cup \mathrm{de}_w^{\overline{G},H} \right) \setminus \mathrm{de}_{-w}^{\overline{G},H}$

(B) $\mathrm{pa}_w^{G'} \cap R_{w,x}^{\overline{G},H} \neq \emptyset$ for all nodes $x \in \mathrm{pa}_w^H$, with $R_{w,x}^{\overline{G},H} = \mathrm{de}_x^{\overline{G}} \setminus \mathrm{de}_{-w}^{\overline{G},H}$.

Note that (B) depends on $\mathrm{de}_x^{\overline{G}}$ not $\mathrm{de}_x^{\overline{G},H}$. We define $Pa_W^{G,H}$ as the set of tuples formed by the Cartesian product of the sets $Pa_w^{G,H}$ of parent sets for $w \in W$; in other words $\mathrm{pa}_W^{G'} = (\mathrm{pa}_{w_1}^{G'}, \ldots, \mathrm{pa}_{w_q}^{G'}) \in Pa_W^{G,H}$ if and only if $\mathrm{pa}_{w_1}^{G'} \in Pa_{w_1}^{G,H}, \ldots, \mathrm{pa}_{w_q}^{G'} \in Pa_{w_q}^{G,H}$.

Lemma 1 *$\{Pa_W^{G,H_1}, \ldots, Pa_W^{G,H_\eta}\}$ is a partition of Pa_W^G.*

Proof See Appendix B. ■

Condition (A) ensures all graphs $G' = \langle \mathrm{pa}_W^{G'}, \mathrm{pa}_{-W}^G \rangle$, with parents $\mathrm{pa}_W^{G'} \in Pa_W^{G,H}$, are acyclic. It requires that all parents of $w \in W$ are either not descendants in the reduced graph $\overline{G}$ of any node in W, or a node whose ancestors in the reduced graph $\overline{G}$ are all parents in the graph H of node w. In particular, no descendant of w is added as an ancestor of w.

Condition (B) ensures each DAG G' is a member of $Pa_W^{G,H}$ for only a single $H \in \mathcal{H}$ for any given $G \in \mathcal{G}$ and thus that $\{Pa_W^{G,H_1}, \ldots, Pa_W^{G,H_\eta}\}$ is a partition of the set of permissible tuples of parent sets. The condition checks that each edge in the graph H is 'used' i.e. that $\mathrm{pa}_W^{G'} = (\mathrm{pa}_{w_1}^{G'}, \ldots, \mathrm{pa}_{w_q}^{G'}) \in Pa_W^{G,H}$ would not be allowed under any $H' \neq H$, $H' \in \mathcal{H}$. Specifically, it ensures that each parent set $\mathrm{pa}_w^{G'}$ contains at least one descendant node $v \in V$ of each parent pa_w^H of node w in the graph H, and that v is not a descendant in $\overline{G}$ of any node $x \in W$ that is not a parent in H of $w \in W$. To see why this condition is required, consider a graph G' in which all nodes in W have no parents. Then $\mathrm{pa}_w^{G'} = \emptyset$ for all nodes $w \in W$ and so condition (A) holds for all $H \in \mathcal{H}$. Thus if condition (B) is disregarded, $\mathrm{pa}_W^{G'} \in Pa_W^{G,H}$ for all $H \in \mathcal{H}$, implying that $\{Pa_W^{G,H_1}, \ldots, Pa_W^{G,H_\eta}\}$ is not a partition of Pa_W^G.

4.2 Fast Identification of Partition Components

Parent sets in each set $Pa_w^{G,H}$ can be identified easily using simple set operations, and consequently the partition components $Pa_W^{G,H}$ can be easily identified via Cartesian products of these sets. Let $Pa_w^{\mathrm{all}} = \mathcal{P}(V \setminus \{w\})$ denote the set of all possible parent sets of node w, subject to maximum in-degree κ, and $Pa_w^{\mathrm{all}}(v) = Pa_w^{\mathrm{all}} \setminus \mathcal{P}(V \setminus \{w, v\})$ denote the subset of Pa_w^{all} containing only parent sets that contain node $v \in V$. Parent sets in $Pa_w^{G,H}$ must (A) not include any nodes *not* in $Q_w^{\overline{G},H}$, and (B) include at least one node in $R_{w,x}^{\overline{G},H}$ for each $x \in \mathrm{pa}_w^H$, and thus

$$Pa_w^{G,H} = \begin{cases} Pa_w^{(B)} \setminus Pa_w^{(A)} & \text{if } \mathrm{pa}_w^H \neq \emptyset \\ Pa_w^{\mathrm{all}} \setminus Pa_w^{(A)} & \text{if } \mathrm{pa}_w^H = \emptyset \,, \end{cases}$$

where $Pa_w^{(A)} = \bigcup_{v \notin Q_w^{\overline{G},H}} Pa_w^{\mathrm{all}}(v)$ and $Pa_w^{(B)} = \bigcap_{x \in \mathrm{pa}_w^H} \bigcup_{r \in R_{w,x}^{\overline{G},H}} Pa_w^{\mathrm{all}}(r)$.

We fix $q = |W|$ as a small constant for all p and set a maximum in-degree κ. This means permissible tuples of parents sets can be identified in $\mathcal{O}(p^{\kappa+1})$ time by storing the 'lookup tables' $Pa_w^{\mathrm{all}}(v)$ as bit maps, assuming that $\mathcal{O}(1)$ querying of the descendants and non-descendants is available.

This can be achieved using a dynamic algorithm that provides access to the transitive closure. Giudici and Castelo (2003) previously used a similar approach. For a graph with transitive closure T^G with edges E^{T}, the descendants and non-descendants of node u are $\{v : (u, v) \in E^{\mathrm{T}}\}$ and $\{v : (u, v) \notin E^{\mathrm{T}}\}$ respectively. Thus, the descendants and non-descendants of a node can be identified in $\mathcal{O}(1)$ time when the transitive closure is known. The transitive closure for an arbitrary directed graph with p vertices can be determined in $\mathcal{O}(p^\omega)$ time (Munro, 1971), where ω is the best known exponent for matrix multiplication (Coppersmith and Winograd, 1990, show $\omega < 2.376$). However, in the present setting only incremental changes are made to the current state G of the sampler, so it is not necessary to use an offline algorithm at each iteration. Instead, we can use a fully dynamic transitive closure algorithm (Demetrescu et al., 2010) that provides procedures both for querying the

transitive closure, and for incrementally updating it when an edge is added or removed from the graph. We choose to implement the algorithm introduced by King and Sagert (2002), which performs queries in $\mathcal{O}(1)$ time, and updates in $\mathcal{O}(p^2)$ worst-case time (see reference for details of required assumptions). A trade-off exists between the performance of these two operations, but this bound for updates is thought to be the best possible whilst retaining $\mathcal{O}(1)$ queries (Demetrescu and Italiano, 2005) and the algorithm is simple to implement.

The algorithm maintains a $p \times p$ path count matrix C^G whose elements C^G_{uv} are the number of distinct paths from node u to node v in the graph G for $u \neq v$, and $C^G_{uv} = 1$ for $u = v$. The transitive closure can be derived from the path count matrix by noting that $\mathrm{T}^G_{uv} = 1$ if and only if $C^G_{uv} > 0$. Thus query operations are performed in $\mathcal{O}(1)$ by simply checking whether the relevant component of C^G is positive. When an edge is added or removed C^G is updated as follows. First consider adding an edge (u, v) to a graph G to form a new graph G'. The increase in the number of distinct paths between any two nodes x and y is given by the (x, y) element of $C^G_{*u} \otimes C^G_{v*}$, where C^G_{*u} denotes the u^{th} column of C^G, C^G_{v*} denotes the v^{th} row and $\otimes$ denotes the outer product. Thus, the path count matrix is updated simply as $C^{G'} = C^G + C^G_{*u} \otimes C^G_{v*}$. Similarly, when an edge (u, v) is removed from the graph the update is $C^{G'} = C^G - C^G_{*u} \otimes C^G_{v*}$.

4.3 Two-stage Sampling Method

We draw a new graph $G' = \langle \mathrm{pa}^{G'}_W, \mathrm{pa}^G_{-W} \rangle$ starting from a graph G using a two-stage method: we sample first a component $Pa^{G,H'}_W$ of the partition of permissible tuples of parent sets and then a tuple $\mathrm{pa}^{G'}_W$ of parent sets from the selected partition component.

In the first stage, $Pa^{G,H'}_W$ is drawn from the conditional distribution, given the tuple of parent sets of nodes not in W.

$$\begin{aligned} P(Pa^{G,H'}_W \mid \mathrm{pa}^G_{-W}, \mathbf{X}) &= \frac{P(Pa^{G,H'}_W, \mathrm{pa}^G_{-W} \mid \mathbf{X})}{P(\mathrm{pa}^G_{-W} \mid \mathbf{X})} \\ &= \frac{\sum_{\mathrm{pa}^{G'}_W \in Pa^{G,H'}_W} \prod_{w \in W} p(\mathbf{X}_w \mid \mathbf{X}_{\mathrm{pa}^{G'}_w}) \pi_w(\mathrm{pa}^{G'}_w)}{\sum_{H'' \in \mathcal{H}} \sum_{\mathrm{pa}^{G''}_W \in Pa^{G,H''}_W} \prod_{w \in W} p(\mathbf{X}_w \mid \mathbf{X}_{\mathrm{pa}^{G''}_w}) \pi_w(\mathrm{pa}^{G''}_w)} \\ &= \frac{\prod_{w \in W} \sum_{\mathrm{pa}^{G'}_w \in Pa^{G,H'}_w} p(\mathbf{X}_w \mid \mathbf{X}_{\mathrm{pa}^{G'}_w}) \pi_w(\mathrm{pa}^{G'}_w)}{\sum_{H'' \in \mathcal{H}} \prod_{w \in W} \sum_{\mathrm{pa}^{G''}_w \in Pa^{G,H''}_w} p(\mathbf{X}_w \mid \mathbf{X}_{\mathrm{pa}^{G''}_w}) \pi_w(\mathrm{pa}^{G''}_w)} \end{aligned}$$

The final equality follows by an interchange of sum and product that is proved in Lemma 2. This makes evaluation more efficient by allowing the sums to be evaluated separately for each node. Friedman and Koller (2003) used a similar interchange.

Lemma 2 *The following identity holds for any $H \in \mathcal{H}$, $W \subseteq V$ and $G \in \mathcal{G}$.*

$$\sum_{\mathrm{pa}_W \in Pa^{G,H}_W} \prod_{w \in W} p(\mathbf{X}_w \mid \mathbf{X}_{\mathrm{pa}_w}) \pi_w(\mathrm{pa}_w) = \prod_{w \in W} \sum_{\mathrm{pa}_w \in Pa^{G,H}_w} p(\mathbf{X}_w \mid \mathbf{X}_{\mathrm{pa}_w}) \pi_w(\mathrm{pa}_w)$$

Proof See Appendix C. ■

Algorithm 2 A Gibbs sampler for learning DAGs, with general blocks

Initialise starting point $G_0 = \langle \mathrm{pa}^{G_0}_1, \ldots, \mathrm{pa}^{G_0}_p \rangle$
Compute initial path count matrix C^{G_0}
for t in 1 to N **do**
  Sample q nodes uniformly at random from V, and call this set of nodes W
  Let $G = G_{t-1}$
  Form $\overline{G}$ as defined in Section 4.1
  Evaluate $C^{\overline{G}}$ from C^G as described in Section 4.2
  for $w \in W$ **do**
    Evaluate $\mathrm{de}^{\overline{G}}_w = \{v : C^{\overline{G}}_{wv} \geq 1\}$
    Evaluate $\mathrm{nd}^{\overline{G}}_w = \{v : C^{\overline{G}}_{wv} = 0\}$
  end for
  for $H \in \mathcal{H}$ **do**
    for $w \in W$ **do**
      Evaluate $Pa^{G,H}_w$ as described in Section 4.2
      Let $K^H_w = \sum_{\mathrm{pa}^{G'}_w \in Pa^{G,H}_w} p(\mathbf{X}_w \mid \mathbf{X}_{\mathrm{pa}^{G'}_w}) \pi_w(\mathrm{pa}^{G'}_w)$
    end for
    Let $K^H = \prod_{w \in W} K^H_w$
  end for
  Sample $Pa^{G,H'}_W$ according to $P(Pa^{G,H'}_W \mid \mathrm{pa}^G_{-W}, \mathbf{X}) = \frac{K^{H'}}{\sum_{H'' \in \mathcal{H}} K^{H''}}$
  for $w \in W$ **do**
    Sample $\mathrm{pa}^{G'}_w$ according to $P(\mathrm{pa}^{G'}_w \mid Pa^{G,H'}_W, \mathrm{pa}^G_{-W}, \mathbf{X})$
  end for
  Set $G_t \leftarrow G = \langle \mathrm{pa}^{G'}_W, \mathrm{pa}^{G_{t-1}}_{-W} \rangle$
  Update C^{G_t}
end for

In the second stage, we sample new parents $\mathrm{pa}^{G'}_W$ from the selected partition component, and form the new graph $G' = \langle \mathrm{pa}^{G'}_W, \mathrm{pa}^G_{-W} \rangle$. The parents of each node $w \in W$, conditional on H', are independent, and so can be sampled separately from the following conditional distribution:

$$P(\mathrm{pa}^{G'}_w \mid Pa^{G,H'}_W, \mathrm{pa}^G_{-W}, \mathbf{X}) = \frac{p(\mathbf{X}_w \mid \mathbf{X}_{\mathrm{pa}^{G'}_w}) \pi_w(\mathrm{pa}^{G'}_w)}{\sum_{\mathrm{pa}^{G''}_w \in Pa^{G,H'}_w} p(\mathbf{X}_w \mid \mathbf{X}_{\mathrm{pa}^{G''}_w}) \pi_w(\mathrm{pa}^{G''}_w)}.$$

This step is straightforward because this distribution is simply the posterior distribution of a constrained variable selection with response w and $Pa^{G,H'}_w$ as the set of possible active sets (i.e. selected covariates).

Algorithm 2 outlines the complete algorithm. The methods in Sections 4.2 enable fast identification of each partition component. Run-time is a function of p, maximum in-degree κ, and the number q of nodes in the block. We choose a small, fixed q for all p, so the run-time is determined by the evaluation of $Pa^{G,H}_w$, which is $\mathcal{O}(p^{\kappa+1})$.

5. Results

In this section, we empirically assess the performance of the proposed sampler, comparing it with existing samplers as well as frequentist methods for structure learning of DAGs.

5.1 Evaluation Setup

We compare the Gibbs sampler with the MC^3 sampler (Madigan and York, 1995) and the REV sampler (Grzegorczyk and Husmeier, 2008), a variant of MC^3 that uses a more extensive edge reversal move. We also compare with two frequentist constraint-based methods: the PC-algorithm (Spirtes et al., 2000), and the Xie and Geng (2008) method, that is shown by its authors to outperform the PC-algorithm in some settings.

Tuning parameters for each method were set as follows. For the constraint-based methods, the significance level was $\alpha = 0.05$ by default, but we also show some results for $\alpha = 0.00005, 0.0001, 0.0005, 0.001, 0.005, 0.01, 0.1$. The Gibbs sampler we use is a random-scan sampler, with $q = 3$ (i.e. the parent sets of three nodes are sampled jointly at each iteration). To permit a fair comparison, for MC^3 we use the same fast online transitive closure algorithm (Section 4.2), and pre-computation and caching of local marginal likelihoods used in the Gibbs sampler (REV uses a similar pre-computation and caching scheme). We constrain all of the samplers to maximum in-degree $\kappa = 3$ and set the graph prior as $\pi(G) \propto 1$. We use conjugate formulations throughout, specifically multinomial-Dirichlet (Heckerman et al., 1995) for discrete data and Normal with a g-prior (with $g = n$) (Geiger and Heckerman, 1994; Zellner, 1986) for continuous data.

We consider six examples: a small domain example, where comparison with the exact posterior (Tian and He, 2009) is possible; data simulated from the ALARM network and from randomly-generated networks of varying sparsity; data sets from social science and biology; and a pathological 4-node example designed to highlight a failure case for our method.

In practical use samplers can only be run for a finite number of iterations (depending on available time and computational resources). We set the maximum number of iterations as follows. In total, we drew 10^6 iterations of REV (retaining only every 10^{th} iteration to reduce storage requirements). Following Grzegorczyk and Husmeier (2008), 85% of proposals within REV were MC^3 proposals (without MC^3 proposals, the REV sampler is not irreducible). In our implementation, the computational costs of the Gibbs sampler are an order of magnitude lower than REV's (accounting for MC^3 moves), but we nevertheless treated the computational costs as the same for the purposes of comparison and drew 10^6 iterations of the Gibbs sampler (again retaining every 10^{th} iteration). The computational costs of our implementation of MC^3 are roughly 1/10 of a Gibbs iteration, and so we performed 10^7 iterations of MC^3 (retaining every 100^{th}).

For each sampler, 10 independent runs starting from different initial graphs were performed. We discarded the first 1/4 of samples, but as an additional filter we considered trace plots (log marginal likelihood versus iteration) for each run of each sampler and discarded further samples if they appeared to be from a pre-convergent phase. Specifically, if there was a clear 'step change' in the trace for a certain run we discarded all samples in that run drawn prior to the highest 'step' being reached. We note that this simple filter cannot be regarded as detecting convergence because the highest 'step' may correspond to a region

near a local rather than a global mode. We therefore also study convergence in detail via other metrics.

5.2 Evaluation Metrics

Each sampler gives an estimated posterior distribution over DAGs. From this we obtain a point estimate either as the **maximum a posteriori** (MAP) graph G^{MAP}, or as a **thesholded graph** G_τ formed by including all directed edges whose marginal posterior edge probabilities are at least τ (note that G_τ need not be acyclic). When $\tau = 0.5$ we get the **median probability model** G^{med} (for normal linear models Barbieri and Berger, 2004, show that in some settings this is the optimal model for prediction). We also consider thresholding to match sparsity levels seen in frequentist point estimates, i.e. setting τ such that $|E(G_\tau)| = |E(\hat{G})|$ for a point estimate $\hat{G}$. By G_τ^{PC} and G_τ^{Xie} we denote thresholded graphs whose sparsity is matched to the PC and Xie-Geng estimates respectively.

We use the structural Hamming distance (SHD) to quantify differences between DAGs. This is the minimum number of edge insertions and deletions needed to transform one graph into another. Comparisons are made using completed partially directed acyclic graphs (Chickering, 2002a). To show the behaviour of the samplers at shorter MCMC run lengths some metrics are shown against iteration t. These are based on the final 3/4 of samples drawn up to t (except for log marginal likelihoods), and so may incorporate some samples drawn before convergence.

We assess convergence and stability via the following metrics:

- **Trace plots** of log marginal likelihood against iteration t.
- Between-run agreement between **posterior edge probabilities**. These are visualized as scatter plots. When edge probabilities agree between a pair of runs, all points in the plot will lie close to the $y = x$ line. We show two variants: a hexagonally-binned version, to avoid over-plotting (Carr et al., 1987); and a panelled plot, in which each panel shows one pair of runs. We also consider the number of edges with estimated posterior probability greater than 0.9 in one run, and less than 0.1 in another run. Such **'major discrepancies'** represent serious Monte Carlo artefacts.
- **Potential scale reduction factor (PSRF)** is a multiple-chain convergence diagnostic, developed by Gelman and Rubin (1992), that compares within- and between-chain means and variances of a suitable summary statistic. PSRF < 1.1 is often taken to indicate that a sampler has run sufficiently long. The natural summary statistics in this context are the posterior edge probabilities. However, we find that the resulting PSRF is not a reliable indicator of convergence. In simulations (not shown) using a 20 node network for which we could calculate true posterior edge probabilities (Tian and He, 2009), we found little association between single-edge PSRF and the (absolute) error in posterior edge probability. In particular, the diagnostic appeared to be very conservative for edges with true posterior probability near 0 or 1. We therefore suggest that a reasonable use of PSRF in this context may be to assess relative convergence between different samplers, rather than as an absolute indicator of convergence. Below, we compare samplers in terms of the proportion of edges with PSRF < 1.1 (a larger proportion suggests better mixing). To calculate PSRF we consider the 10 runs

of each sampler as a collection of 5 pairs of runs and calculate PSRF separately for each edge using the final three quarters of the samples drawn up to that point.

- For the real data, we assess **stability under resampling** ("shaking the data") by comparing estimates across bootstrap samples.

For experiments in which the true data-generating graph G^* is known we use the following metrics to assess accuracy:

- **Structural Hamming distance** (SHD) between G^* and the estimated graphs.
- **Receiver-operating characteristic (ROC) curves**. These show agreement between G^* and an estimate G_τ by plotting true positive against false positive rates parameterized by threshold τ. We consider also the **area under the ROC curve** (AUROC), focusing in particular on the small false positive rate region of the curve that is often of interest in applications.

Finally, when the posterior edge probabilities can be computed exactly (Tian and He, 2009) (i.e. in small p settings) we also consider the **maximum and average absolute error in posterior edge probability**, calculated across the set of all possible edges.

We note that while SHD and ROC scores are useful in assessing performance, they are not convergence measures, as they do not assess accuracy of the posterior distribution *per se* (to see why, consider a degenerate sampler that samples only G^*, giving perfect scores on SHD and ROC, but an incorrect posterior distribution).

5.3 Small Domain Comparison to Exact Posterior

We applied the methods to the Zoo data set (Newman et al., 1998) that records $p = 17$ (discrete) characteristics of $n = 101$ animals. The maximum log marginal likelihood found by the Gibbs and REV samplers was consistent across runs, but less so for the MC^3 sampler, and the Gibbs sampler reached a plateau of high probability after the fewest iterations (Figure A13a). REV required about ten times as many iterations as Gibbs to achieve the same proportion of edges with PSRF < 1.1 while MC^3 needed about 100 times as many (Figure A14a). The estimated edge probabilities given by the Gibbs sampler were stable between runs (Figure A15a). The results from the REV sampler were also stable, but MC^3 less so, with major disparities between some runs. Figure 4 shows the error in posterior edge probabilities as a function of iterations. Convergence was quickest for the Gibbs sampler, followed by REV and then MC^3. All runs of the Gibbs sampler reached a point at which the maximum absolute error was 0.05 (after 67,000 iterations on average). In contrast, only 5/10 runs of REV and 6/10 runs of MC^3 reached the same level of accuracy in their complete run. Similarly, the Gibbs sampler achieved an average absolute error of less than 0.01 in the fewest iterations.

5.4 The ALARM Network

The ALARM network (Beinlich et al., 1989) consists of 37 discrete nodes and 46 edges and has been widely used in studying structure learning (e.g. Friedman and Koller, 2003; Grzegorczyk and Husmeier, 2008). We simulated data sets from ALARM with sample sizes

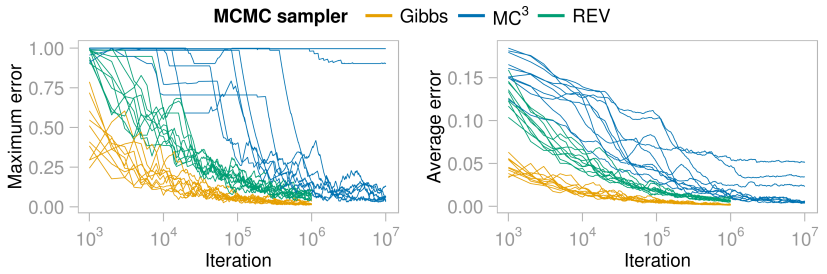

Figure 4: For the Zoo data set, maximum and average (across all possible 272 edges) error in posterior edge probabilities versus iteration number (on a $\log_{10}$ scale). For each MCMC algorithm, 10 independent runs, initialised at disparate initial values, are shown.

$n = 100$, 500, 1000, 2500, 5000. Figure 5 shows trace plots for the $n = 1000$ case as an illustrative example. The maximum log marginal likelihood found by the Gibbs sampler across runs was $-10{,}608.20 \pm 0.8$ (mean $\pm$ standard deviation), whereas for REV it was $-10{,}627.2 \pm 40.4$ and for MC^3 $-11{,}176.9 \pm 273.7$. The highest scoring graph discovered by any of the 10 runs of the MC^3 sampler had log marginal likelihood $-10{,}856.6$, far below the Gibbs maximum, suggesting non-convergence in all 10 runs. REV appeared to reach convergence in all but two runs (runs 9 and 10). The Gibbs sampler consistently (and rapidly) reached a high scoring plateau and appeared to have converged in all 10 runs. PSRF results were in line with these findings (Figure A14b); more than 10 times as many iterations of REV were needed to give the same proportion of edges with PSRF < 1.1 as the Gibbs sampler.

Figure 6 compares pairs of runs for $n = 1000$; this pair of runs is typical of all 10 runs (except for runs 9 and 10 of REV which disagree considerably; all runs shown in Figure A15b). There were no major between-run discrepancies (as defined in Section 5.2) for the Gibbs sampler at any sample size. The mean number of major discrepancies (across pairs of runs) increased from 0 ($n = 100$) to 8 and 91 for MC^3 and REV respectively (when $n = 5000$).

Figure 7 shows ROC curves for false positive rates < 0.05. The Gibbs sampler performs better and with less variability than the other methods. Sample size is influential. For small n the Bayesian methods outperform the constraint-based methods. However, counter to the increase in statistical information, REV and MC^3 perform less well with larger n: e.g. at $n = 100$ for a false positive rate (FPR) of 0, the Gibbs sampler found 21.9 ± 1.9 (mean $\pm$ standard deviation) true edges; REV 20.1 ± 1.4; and MC^3 21.7 ± 2.1. But at $n = 5000$, for the same FPR, Gibbs found 43.0 ± 0.0 true edges; REV 13.2 ± 21.3; and MC^3 did not find any true edges (the true graph has 46 edges). The constraint-based methods performed well for large sample sizes, as anticipated by the asymptotic consistency of the PC-algorithm (Kalisch and Bühlmann, 2007). The Xie-Geng method performed particularly well for $n = 5000$. Figure 8 shows AUROC as a function of iterations; the Gibbs sampler performed

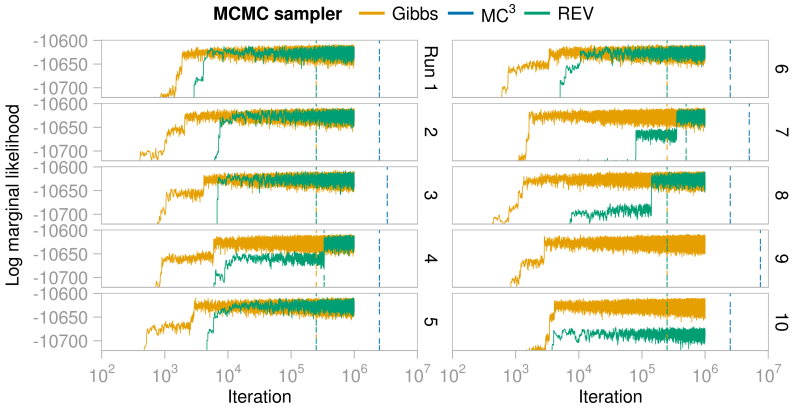

Figure 5: Log marginal likelihood of the graphs visited by the three MCMC samplers in 10 independent runs, initialised at disparate initial conditions, on the ALARM data, with data sample size $n = 1000$. Iteration number is displayed on a $\log_{10}$ scale. The dashed lines indicate where the burn-in phase ended. In all cases the log marginal likelihood of the graphs reached by the MC^3 sampler are below the displayed range.

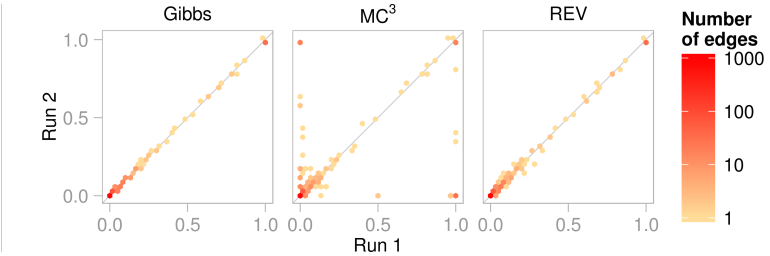

Figure 6: Convergence diagnostic plots for each MCMC sampler for the ALARM data, with $n = 1000$. The posterior edge probabilities given by two independent MCMC runs are plotted against each other, binned into hexagonal areas to avoid over-plotting. When the edge probabilities of the two runs agree, all of the points in the plot will lie close to the $y = x$ line; strongly off-diagonal points indicate extreme discrepancies between the runs.

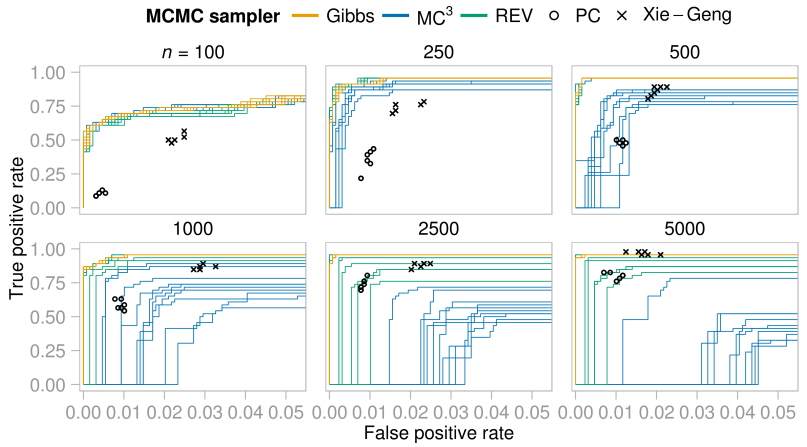

Figure 7: ALARM data, receiver operating characteristic (ROC) curves for each of 10 independent MCMC runs for each MCMC sampler, and point estimates for the constraint-based methods. Note that the horizontal axis shows only false positives rates < 0.05, corresponding to the case in which interest focuses on high-ranked edges (the complete curves are shown in Figures A16). Point estimates from Xie-Geng's constraint-based method and the PC-algorithm are also shown for all 8 significance levels considered.

best after all run lengths and sample sizes considered. These results are supported by SHDs between point estimates and the true graph (Table A2).

5.5 Networks of Varying Sparseness

Sparsity can be used to statistical and computational advantage but in practice it may be hard to know what level of sparsity is reasonable for a given application. We therefore sought to investigate the effect of varying network sparsity, including scenarios where the data-generating graph can violate the in-degree constraint we impose. We simulated data following a procedure described in Kalisch and Bühlmann (2007) that we outline below. We first generated a DAG G via its adjacency matrix A^G, by drawing entries as $A^G_{uv} \sim$ Bernoulli(ρ), where $\rho \in (0, 1)$ is a parameter controlling sparsity. Entries were drawn independently for each $u < v$, with $A^G_{uv} = 0$ otherwise. Larger ρ gives a denser graph and the expected number of neighbours (parents or immediate children) of a node is $\rho(p-1)$. We set $p = 25, n = 1000$ and considered 5 values of the sparseness parameter ρ (corresponding to expected neighbourhood sizes 2, 3, 4, 5 and 6). For each ρ we drew 10 DAGs, simulating a data set from each DAG by ancestral sampling using a Normal linear model (see Kalisch and Bühlmann, 2007, for full details).

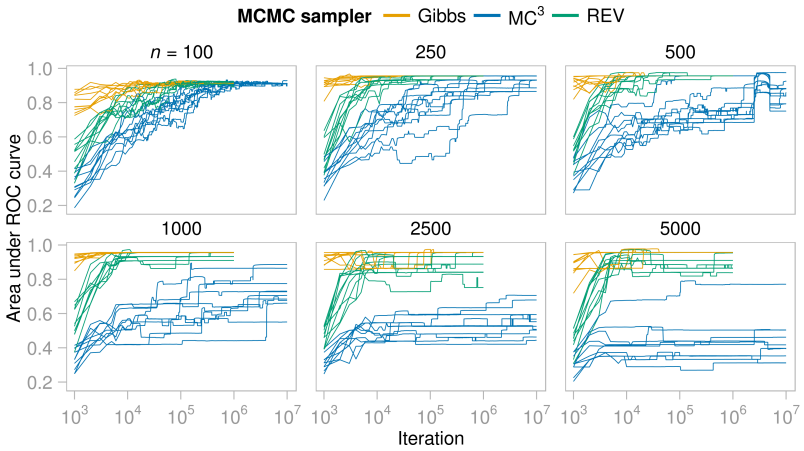

Figure 8: ALARM data, area under the receiver operating characteristic curve (AUROC) against iteration number ($\log_{10}$ scale) for each of the 10 independent runs for each MCMC algorithm. Each panel shows results for a particular sample size $n = 100, \ldots, 5000$.

Figure 9 shows boxplots over SHDs. We see that accuracy decreases with increasing density, echoing results in Kalisch and Bühlmann (2007) for the PC algorithm. As throughout, all the samplers had an in-degree constraint (maximum in-degree $\kappa = 3$), while the frequentist methods did not. Nevertheless, the performance of the Bayesian methods did not appear to deteriorate any more rapidly than the frequentist methods. At all ρ's, the median probability graph G^{med} outperformed the frequentist methods which in turn outperformed the MAP graph. In this context, we draw attention to a difference between the median probability and MAP graphs: the former, although obtained by averaging over DAGs satisfying the in-degree constraint, may itself have in-degree greater than κ, while the latter is necessarily subject to the constraint.

5.6 Survey Data

The publicly available Behavioral Risk Factor Surveillance System Survey (BRFSS) (Centers for Disease Control and Prevention, 2008) is a household-level random-digit telephone survey, collected by the U.S. National Center for Chronic Disease Prevention and Health, that has been conducted throughout the United States since 1984. We considered (discrete) responses to $p = 24$ questions (see Appendix D), spanning most of the topics covered in the survey. We considered the responses from New York in the 2008 survey, removing samples for respondents who refused or were unsure of their response, or whose response was

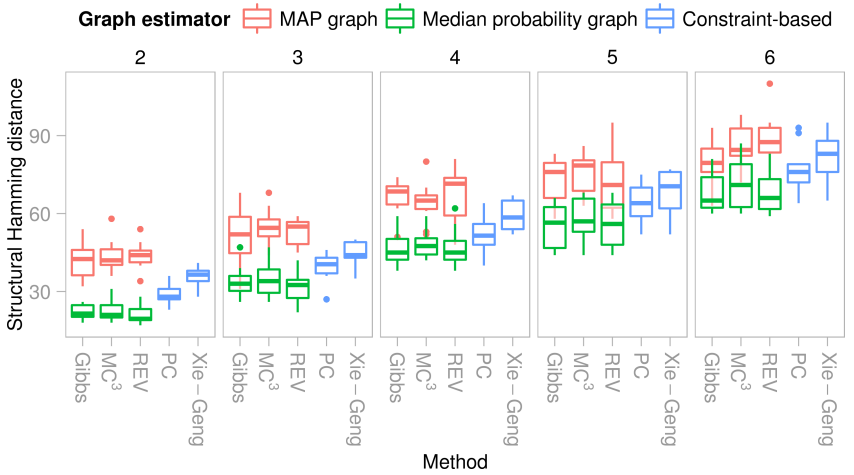

Figure 9: Synthetic data, accuracy of estimation for networks with different levels of sparsity. The panels correspond to simulations in which the expected number of neighbours for each node in the data-generating graph is respectively 2, 3, 4, 5, and 6. Accuracy is quantified by structural Hamming distance (SHD) between estimates and data generating graphs (smaller SHDs correspond to more accurate estimates). Box plots are over the 10 independent networks/data sets simulated for each sparsity level. For MCMC methods, results from the MAP graph G^{MAP} and median probability model G^{med} are shown.

missing, to any of the 24 questions. The resulting sample size was $n = 4,197$. The median probability graph G^{med} estimated by the Gibbs sampler is shown in Figure A17a.

Figure 10 shows between-run agreement. The Gibbs runs showed better agreement than the REV runs and the MC^3 runs disagreed considerably (these pairs of runs were typical; all runs shown in Figure A18a). Indeed there were no major between-run discrepancies (in the sense of Section 5.2) for the Gibbs sampler, whereas there were on average 2.4 major discrepancies for REV and 10.9 for MC^3. The Gibbs sampler also had the highest proportion of edges with PSRF < 1.1 (Figure A14c).

The maximum log marginal likelihoods found by each of the three samplers differed considerably as did the number of iterations needed to reach a plateau (Figure A13b). The Gibbs sampler typically reached a plateau after around 500 samples (although in one run 10^3 samples were needed). REV took longer to reach a (usually lower) plateau. MC^3 appeared to become stuck in a region with even lower log marginal likelihood.

To investigate stability under resampling of the data we applied the methods to 10 bootstrap resamples of the data set. The Gibbs and REV samplers were more stable than the frequentist methods as well as than MC^3. For example, using G^{PC}_{τ} as a point estimate

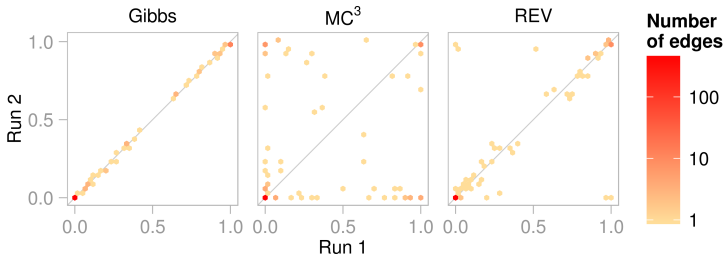

Figure 10: Convergence diagnostic plots for each MCMC sampler for the survey data. The posterior edge probabilities given by two independent MCMC runs are plotted against each other, binned into hexagonal areas to avoid over-plotting. When the two runs give the same estimates of the posterior edge probabilities all of the points appear on the line $y = x$; strongly off-diagonal points indicate extreme discrepancies between the runs. This pair of runs was typical of all pairs.

for the Bayesian methods (i.e. thresholding to give the same number of edges as PC), the mean SHD between results from pairs of bootstrap data sets was 21.7 (Gibbs), 22.3 (REV), 33.4 (MC^3) and 30.8 (PC-algorithm). Results for G^{MAP} and G^{Xie}_{τ} are shown in Figure A19a.

5.7 Large-sample, Single-cell Molecular Data

We used single-cell molecular data from Bendall et al. (2011) with $p = 34$ continuous variables (see Appendix D) and $n = 21,691$. The median probability graph G^{med} estimated by the Gibbs sampler is shown in Figure A17b.

Figure 11 shows between-run agreement for the samplers for a typical pair of runs; the Gibbs sampler shows better agreement than REV or MC^3. All but one of the 10 runs of the Gibbs sampler were consistent with each other (Figure A18b) and the one inconsistent run nonetheless showed better agreement with the other Gibbs runs than any pair of runs of the other samplers. The Gibbs sampler had no major discrepancies (as defined in Section 5.2) between any pairs of runs, while there were on average 26 and 87 major discrepancies for REV and MC^3 respectively. Smaller discrepancies followed a similar pattern: the average number of edges differing by 0.1 or more in posterior probability between runs were 6.4 (Gibbs sampler), 56.6 (REV), and 151.8 (MC^3). The Gibbs sampler also had the highest proportion of edges with PSRF < 1.1 after any run length (Figure A14d). Trace plots are shown in Figure A13c. The Gibbs sampler found a region of higher log marginal likelihood than the other samplers and did so consistently. Indeed, the maximum log marginal likelihood achieved across all REV runs was exceeded in every Gibbs run and after only around 5000 iterations. Finally, we considered stability under resampling of the data (Figure A19b), including also the frequentist point estimators for comparison. The mean SHD between PC estimates from pairs of bootstrap samples was 214.6; the corresponding mean SHDs for the samplers (using G^{PC}_{τ} point estimates) were 128.8 (Gibbs), 140.1 (REV) and 225.2 (MC^3). We note that the SHDs are particularly high here because the PC-algorithm estimates a

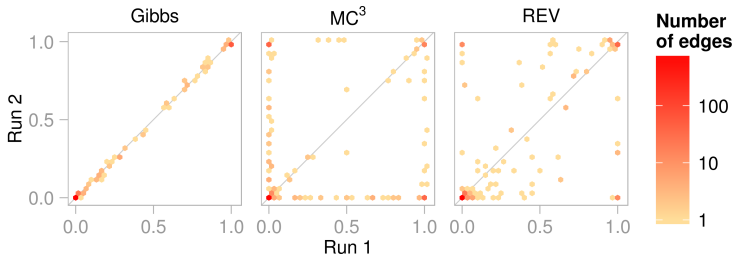

Figure 11: Convergence diagnostic plots for each MCMC sampler for the single-cell molecular data. The posterior edge probabilities given by two independent MCMC runs are plotted against each other, binned into hexagonal areas to avoid over-plotting. When the two runs give the same estimates of the posterior edge probabilities all of the points appear on the line $y = x$; strongly off-diagonal points indicate extreme discrepancies between the runs. This pair of runs was typical of all pairs of runs.

network with a high density (recall that under G^{PC}_{τ} all methods choose the same number of edges as PC).

5.8 A Pathological 4-node Example

Our final example demonstrates the potential sensitivity of the Gibbs sampler to choice of $q = |W|$ (the number of nodes whose parent sets are sampled together in a single iteration). The example was constructed to highlight a situation in which the sampler can become stuck in a local mode unless q is large enough, potentially leading to extremely slow convergence.

We used as data 10^5 simulated samples from a 4-node network in which the parents of node 2 were nodes 1 and 4; the parents of node 3 were nodes 1 and 2; and nodes 1 and 4 had no parents. Each node was Bernoulli distributed. The probability of success was 0.6 for nodes 1 and 4, while nodes 2 and 3 were noisy XORs with probability of success 0.9 when either parent (but not both) was 'true' and 0.1 otherwise.

For the purposes of demonstration, we set $q = 2$. As shown in Figure 12, after 10^6 iterations the maximum error in edge probability for the Gibbs sampler was 0.016 ± 0.015 (mean $\pm$ standard deviation across 10 runs). Given that there are only 543 DAGs with $p = 4$ nodes, this magnitude of error is unexpectedly large. The slow convergence is due to the concentration of posterior mass on two graphs that the sampler cannot easily move between. The MAP graph (posterior probability 0.61) is the graph in which the parents of node 2 are nodes 1 and 3; the parents of node 4 are nodes 1 and 2; and nodes 1 and 3 have no parents. The data-generating graph has posterior probability 0.38. The graphs differ in the parents of 3 nodes, and so with $q = 2$ the sampler cannot move between them in a single step. At the same time, the large sample size leads to all other graphs having low posterior probability (< 0.002), making multi-step transitions between the two graphs unlikely. Thus, the sampler becomes stuck on one of the two graphs. In this example,

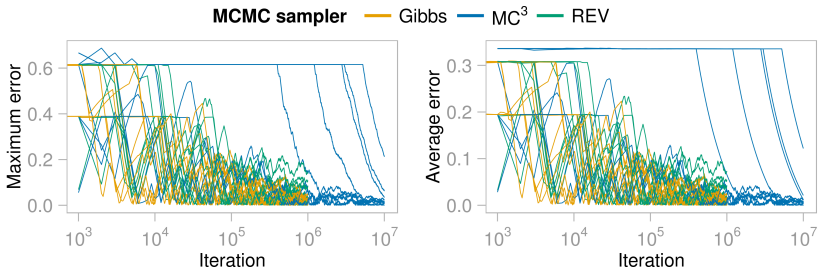

Figure 12: For the pathological 4-node example, maximum and average (across all possible 12 edges) error in posterior edge probabilities by iteration number (on a $\log_{10}$ scale). For each MCMC algorithm, 10 independent runs, initialised at disparate initial values, are shown.

setting $q = 3$ improved convergence (maximum error 0.0011 ± 0.0009 after 10^6 iterations), but in real-world examples it is difficult to rule out the possibility that analogous issues may arise.

6. Discussion

We introduced a Gibbs sampler for structure learning of DAGs that can converge more easily than existing samplers due to its ability to efficiently make large moves in DAG space. We showed that it provides often substantial gains in accuracy and stability in comparison with existing (Bayesian and frequentist) methods in a range of settings.

The formulation of the sampler develops and exploits the connection between variable selection and structure learning. This connection has been widely studied for undirected graphs (e.g. Meinshausen and Bühlmann, 2006), but for DAGs is complicated by the acyclicity requirement. Our approach accounts for acyclicity but further work in this area may ease the adaptation of results and methods from Bayesian variable selection to the case of DAGs. In the proposed sampler, existing variable selection methods could be of direct utility in sampling from the conditional distribution $P(\mathrm{pa}_W \mid \mathrm{pa}^G_{-W}, \mathbf{X})$. When this sampling step is difficult, a Metropolis-within-Gibbs approach (i.e. substituting a Metropolis step in place of the Gibbs step) could be considered. With $q = |W| = 1$, the conditional $P(\mathrm{pa}_W \mid \mathrm{pa}^G_{-W}, \mathbf{X})$ is identical to the posterior of the corresponding variable selection problem. Then, a Metropolis-within-Gibbs move could directly exploit existing variable selection methods.

In common with most of the structure learning literature, we used an in-degree constraint. This gives a smaller DAG space and in addition controls the number of parameters needed to specify conditional distributions. However, it is a strong constraint and a natural concern is whether it excludes higher in-degree models that could be appropriate for the data. This possibility cannot be ruled out, but the use of model averaging and marginal posterior summaries may ameliorate the concern to some extent, because even when the

true number of parents of a node exceeds the restriction, important candidate parents may still have high edge scores (and appear in a summary graph). For example, suppose the true in-degree of a node is 4, but at most 3 incoming edges are permitted. In this case, although no model including all 4 parents can be considered, provided the signal can be detected considering only 3 nodes at a time, the posterior probability of all 4 edges may nonetheless be high.

In our empirical examples the REV sampler of Grzegorczyk and Husmeier (2008) showed impressive gains over MC^3. The Gibbs sampler generally seemed to outperform both. The use of conditional distributions in REV is a point of similarity with the Gibbs sampler proposed here. The performance gains of Gibbs could be explained by two key differences from REV. First, REV does not use the natural conditional distribution and requires an accept-reject step. Second, REV must include at least some MC^3 proposals (otherwise the sampler is not irreducible), and these steps are not tailored to the shape of the posterior distribution (Grzegorczyk and Husmeier, 2008, make REV proposals with probability 1/15 and so most steps are based on MC^3 proposals).

If there is strong correlation between the parent sets of more than $q = |W|$ nodes, the Gibbs sampler may not mix well. In this situation, constraint-based methods may be useful. Alternatively, q could be chosen at each step according to some distribution, so that a mixture of different block sizes is used. This would in particular allow larger blocks to be used without increasing the computational demands of the algorithm excessively. In this paper we fixed $q = 3$, and found this simple choice gave a well-behaved and effective sampler. But there is a trade-off: increasing q increases the time taken to evaluate $P(\mathrm{pa}_W \mid \mathrm{pa}^G_{-W}, \mathbf{X})$, but also increases move size, with the potential to improve convergence.

Practical use of the Gibbs sampler in the form described here requires exact sampling from the conditional $P(\mathrm{pa}_W \mid \mathrm{pa}^G_{-W}, \mathbf{X})$ and there are situations related to this requirement in which other methods may be more suitable. First, when an appropriate maximum in-degree cannot be set, MC^3 or a variant could be more appropriate (although convergence could be very slow). Alternatively, search procedures such as GES (Chickering, 2002b) or HCMC (Castelo and Kočka, 2003) could be used. Second, exact sampling from the conditional distribution is challenging in settings with thousands of nodes. In this case, efficient constraint-based methods (such as the PC-algorithm) may be a better choice, particularly in the large sample setting. As noted by a referee, an interesting area for future research would be combining the Gibbs sampler with some aspects of other methods—such as PC—that are relatively well suited to the truly high-dimensional setting.

Acknowledgments

The authors are grateful to Karen Sachs for providing the single-cell molecular data; to Marco Grzegorczyk and Dirk Husmeier for their inspiring work in this area and for providing their implementation of the REV sampler; to the referees for numerous suggestions that improved the article; and to Frances Griffiths, David Lunn and Paul Newcombe for helpful discussions. Part of this work was carried out while the authors were at the University of Warwick—whose excellent scientific environment the authors warmly acknowledge—and

Appendix A. Convergence Conditions for Gibbs Samplers

Convergence of a Gibbs sampler for DAGs does not follow from the usual justification of Gibbs sampling that relies on the Hammersley-Clifford theorem (Besag, 1974). The theorem gives a positivity condition that is sufficient to prove that the univariate conditional distributions used by the Gibbs sampler uniquely define the joint distribution. The required condition is that the support of the joint distribution is given by the Cartesian product of the supports of the marginal distributions. An example of when this condition does not hold is the joint density $p(x, y)$ for a pair of random variables X and Y with support only on $[0,1] \times [0,1]$ and $[2,3] \times [2,3]$. Clearly $p(x)$ and $p(y)$ are both positive on $[0,1]$ and $[2,3]$ but neither $[0,1] \times [2,3]$ or $[2,3] \times [0,1]$ are in the support of the joint distribution (Hobert et al., 1997).

In the DAG setting, the acyclicity requirement means that this positivity condition is not satisfied. Consider a DAG consisting of two correlated random variables $\mathbf{X}_1$ and $\mathbf{X}_2$. The correlation means that both the graph with a single edge $(1,2)$ and the graph with a single edge $(2,1)$ have positive posterior probability. Thus $P(A^G_{12} = 1 \mid \mathbf{X}) > 0$ and $P(A^G_{21} = 1 \mid \mathbf{X}) > 0$ in the posterior marginal distributions. However, in the joint posterior distribution $P(A^G_{12} = 1, A^G_{21} = 1 \mid \mathbf{X}) = 0$ because the corresponding graph (the complete graph) is cyclic. The complete graph is thus not in the support of the joint distribution but is in the Cartesian product of the supports of the marginal distributions.

An alternative sufficient condition for uniqueness of the joint distribution and convergence of the Gibbs sampler when positivity is not satisfied is given by Besag (1994), which was extended for continuous settings by Hobert et al. (1997). In the present context, the condition requires that for every pair $G', G'' \in \mathcal{G}$ of DAGs with p nodes there exists a finite sequence $G_1, \ldots, G_N$, with $G_1 = G'$, $G_N = G''$ and $N \in \mathbb{N}$, and such that G_t and G_{t-1} differ in only a single component (in this context, a single edge), and that the joint posterior distribution $P(G_t \mid \mathbf{X}) > 0$ for all $t = 0, \ldots N$. When the graph prior $\pi(G) > 0$ for all $G \in \mathcal{G}$, this condition is clearly satisfied: as an example, one such finite sequence removes every edge of G', one at a time, and then adds every edge of G'', one at a time. Each graph in the sequence is clearly acyclic, since the sequence is composed of subgraphs of the acyclic G' and G'', and so has positive probability in the joint distribution when the graph prior is positive everywhere in $\mathcal{G}$. A similar proof follows if the graph prior has support on all subgraphs of graphs with support in the graph prior, as is true for most widely used priors.

Appendix B. Proof of Lemma 1

Lemma 1 $\{Pa^{G,H_1}_W, \ldots Pa^{G,H_\eta}_W\}$ *is a partition of* Pa^G_W.

Proof. We show: (i) $\bigcup_{h=1,\ldots\eta} Pa^{G,H_h}_W \subseteq Pa^G_W$; (ii) $\bigcup_{h=1,\ldots\eta} Pa^{G,H_h}_W \supseteq Pa^G_W$; and (iii) $Pa^{G,H_{h_1}}_W \cap Pa^{G,H_{h_2}}_W = \emptyset$ for $H_{h_1} \neq H_{h_2}$, $H_{h_1}, H_{h_2} \in \mathcal{H}$.

(i) We prove the relationship by showing that $Pa^{G,H_h}_W \subseteq Pa^G_W$ for each $h = 1, \ldots, \eta$. By the definition of Pa^G_W in Section 3.4 we need to show that $G' = \langle \mathrm{pa}^{G'}_W, \mathrm{pa}^G_{-W} \rangle$ is acyclic for all tuples $\mathrm{pa}^{G'}_W \in Pa^{G,H_h}_W$ of parent sets, for all $h = 1, \ldots, \eta$.

We proceed by contradiction. Suppose some graph $G' = \langle \mathrm{pa}^{G'}_W, \mathrm{pa}^G_{-W} \rangle$ with $\mathrm{pa}^{G'}_W \in Pa^{G,H_h}_W$ is cyclic. First note that $\overline{G}$ is acyclic because $\overline{G}$ is a subgraph of the acyclic G. Since the graph G' differs from the acyclic graph $\overline{G}$ only in the parents of nodes in W, each cycle in G' must include at least one node in W. Denote by $x_1 \rightsquigarrow x_2$ the existence of a path (that obeys the edge directions) in the graph G' from node $x_1 \in W$ to node $x_2 \in W$ that does not include any nodes in W (except x_1 and x_2). Let $w_1, \ldots, w_r \in W$ be the (minimal) complete set of nodes in W included in some cycle in G'. Without loss of generality suppose that $w_1 \rightsquigarrow w_2 \rightsquigarrow \ldots \rightsquigarrow w_r$ in G'. Note that since $w_1, \ldots, w_r$ is the complete set of nodes in W in the cycle, no node between w_i and w_{i+1} in the path can be in W, $i \in \{1, \ldots, r-1\}$.

We now show that for $x_1, x_2 \in W$, $x_1 \rightsquigarrow x_2$ only if an edge (x_1, x_2) links node x_1 to x_2 in the graph H_h. Since $x_1 \rightsquigarrow x_2$, there must exist a node $v \in V$ that is a parent of x_2 in G' such that v is a descendant in G' of x_1. Note that if the edge (x_1, x_2) is in the graph G' then $v = x_1$. Since v is a parent of node x_2 in the graph G' and $x_2 \in W$, then $v \in \left(\mathrm{nd}^{\overline{G}} \cup \mathrm{de}^{\overline{G},H_h}_{x_2}\right) \setminus \mathrm{de}^{\overline{G},H_h}_{-x_2}$ by condition (A). Also since $x_1 \rightsquigarrow x_2$ does not include any nodes in W, v is also a descendant in $\overline{G}$ of x_1 because G' and $\overline{G}$ differ only in which nodes are parents of nodes in W. We proceed by contradiction. Suppose no edge (x_1, x_2) exists in H_h. Then v is a descendant of x_1 in the graph $\overline{G}$, but x_1 is not a parent of x_2 in the graph H_h. So $v \in \mathrm{de}^{\overline{G},H_h}_{-x_2}$, which by condition (A) is a contradiction. Thus $x_1 \rightsquigarrow x_2$ only if (x_1, x_2) is present in H_h, for $x_1, x_2 \in W$.

Now, recall that $w_1 \rightsquigarrow w_2 \rightsquigarrow \ldots \rightsquigarrow w_r$. Since a cycle is formed we must in addition have a path in G' from node w_r to node w_1. Since $w_1, \ldots, w_r$ is the complete set of nodes in W involved in the cycle, no node on the path from w_r to w_1 can be in W. Thus $w_r \rightsquigarrow w_1$. However, this implies that the edges $(w_1, w_2), (w_2, w_3), \ldots, (w_{r-1}, w_r)$, (w_r, w_1) are all in H_h, which implies H_h is cyclic. But H_h is acyclic by assumption, and so we have a contradiction.

(ii) Suppose we start from a graph $G = \langle \mathrm{pa}^G_W, \mathrm{pa}^G_{-W} \rangle$. We want to show that for each DAG $G' = \langle \mathrm{pa}^{G'}_W, \mathrm{pa}^G_{-W} \rangle$ there is some $H' \in \mathcal{H}$ such that $\mathrm{pa}^{G'}_W \in Pa^{G,H'}_W$. We will show that $\mathrm{pa}^{G'}_W \in Pa^{G,H'}_W$, where $H' = \langle \mathrm{pa}^{H'}_1, \ldots, \mathrm{pa}^{H'}_q \rangle \in \mathcal{H}$ is a DAG on nodes in W and $\mathrm{pa}^{H'}_w = \{x \in W : \text{there exists some } v \in \mathrm{pa}^{G'}_w \text{ such that } v \in \mathrm{de}^{\overline{G}}_x\}$. As usual, $\mathrm{pa}^{G'}_w$ is the parent set in the graph G' of the node w; and $\mathrm{de}^{\overline{G}}_x$ is the descendants in $\overline{G}$ of the node x. Note that H' is a subgraph (on the nodes in W) of the transitive closure $\mathrm{T}^{G'}$. By definition, G' is a DAG, so $\mathrm{T}^{G'}$ is also a DAG, and thus H' is a DAG.

We show that $\mathrm{pa}^{G'}_W \in Pa^{G,H'}_W$ by showing that for each node $w \in W$, both conditions (A) and (B) that specify membership of $Pa^{G,H'}_w$ are satisfied.

For (A) we need $\mathrm{pa}_w^{G'} \subseteq \left(\mathrm{nd}^{\overline{G}} \cup \mathrm{de}_w^{\overline{G},H'}\right) \setminus \mathrm{de}_{-w}^{\overline{G},H'}$. Let $v \in \mathrm{pa}_w^{G'}$ meaning that v is a parent of the node w in the graph G'. First we show that $v \notin \mathrm{de}_{-w}^{\overline{G},H'}$, and then show that $v \in \mathrm{nd}^{\overline{G}} \cup \mathrm{de}_w^{\overline{G},H'}$.

To show that $v \notin \mathrm{de}_{-w}^{\overline{G},H'}$, note that if $v \in \mathrm{de}_{-w}^{\overline{G},H'}$ then v must be a descendant in $\overline{G}$ of some node $y \in W$ that is not in $\mathrm{pa}_w^{H'}$. However, every such y is in $\mathrm{pa}_w^{H'}$ by the definition of $\mathrm{pa}_w^{H'}$, thus $v \notin \mathrm{de}_{-w}^{\overline{G},H'}$.

To show that $v \in \mathrm{nd}^{\overline{G}} \cup \mathrm{de}_w^{\overline{G},H'}$, we suppose $v \notin \mathrm{nd}^{\overline{G}}$ and show this implies that $v \in \mathrm{de}_w^{\overline{G},H'}$. This follows because if $v \notin \mathrm{nd}^{\overline{G}}$ then it must be the descendant in $\overline{G}$ of some node $y \in W$. Then $y \in \mathrm{pa}_w^{H'}$ by definition of H'. Therefore $v \in \mathrm{de}_w^{\overline{G},H'}$, as required.

For (B), we need $\mathrm{pa}_w^{G'} \cap \left(\mathrm{de}_x^{\overline{G}} \setminus \mathrm{de}_{-w}^{\overline{G},H'}\right) \neq \emptyset$ for all $x \in \mathrm{pa}_w^{H'}$. Consider $x \in \mathrm{pa}_w^{H'}$. By the definition of $\mathrm{pa}_w^{H'}$, this means that there exists some node $v \in \mathrm{pa}_w^{G'}$ such that $v \in \mathrm{de}_x^{\overline{G}}$. Additionally, any $y \in W$ for which $v \in \mathrm{de}_y^{\overline{G}}$ is such that $y \in \mathrm{pa}_w^{H'}$, by definition of $\mathrm{pa}_w^{H'}$. Thus v is not a descendant in $\overline{G}$ of any node in W that is not in $\mathrm{pa}_w^{H'}$. Then $v \in \mathrm{pa}_w^{G'} \cap \left(\mathrm{de}_x^{\overline{G}} \setminus \mathrm{de}_{-w}^{\overline{G},H'}\right)$, and thus the condition is satisfied.

(iii) Since $H_{h_1} \neq H_{h_2}$, at least one node has different parents in H_{h_1} and H_{h_2}. Suppose that the node $w \in W$ is such a node, and that $x \in W$ is a parent of w in H_{h_1} but not in H_{h_2}. Consider a parent set $\mathrm{pa}_w^{G_1} \in Pa_w^{G,H_{h_1}}$. We will prove that $\mathrm{pa}_w^{G_1} \notin Pa_w^{G,H_{h_2}}$, and the result follows.

By condition (B), there must exist some $v \in \mathrm{de}_x^{\overline{G}} \setminus \mathrm{de}_{-w}^{\overline{G},H_{h_1}}$ such that $v \in \mathrm{pa}_w^{G_1}$. We will show that $v \notin \mathrm{pa}_w^{G_2}$ for every parent set $\mathrm{pa}_w^{G_2} \in Pa_w^{G,H_{h_2}}$. This follows because $v \in \mathrm{de}_x^{\overline{G}}$ and so is a descendant in $\overline{G}$ of x, which is not a parent of w in H_{h_2}. Thus $v \in \mathrm{de}_{-w}^{H_{h_2}}$, and so $v \notin \left(\mathrm{nd}^{\overline{G}} \cup \mathrm{de}_w^{\overline{G},H_{h_2}}\right) \setminus \mathrm{de}_{-w}^{\overline{G},H_{h_2}}$. Therefore v cannot be a parent of w in G_2. ■

Appendix C. Proof of Lemma 2

Lemma 2 *The following identity holds for any $H \in \mathcal{H}$, $W \subseteq V$ and $G \in \mathcal{G}$.*

$$\sum_{\mathrm{pa}_W \in Pa_W^{G,H}} \prod_{w \in W} p(\mathbf{X}_w \mid \mathbf{X}_{\mathrm{pa}_w}) \pi_w(\mathrm{pa}_w) = \prod_{w \in W} \sum_{\mathrm{pa}_w \in Pa_w^{G,H}} p(\mathbf{X}_w \mid \mathbf{X}_{\mathrm{pa}_w}) \pi_w(\mathrm{pa}_w)$$

Proof. Define $\lambda_w^{(i)} = p(X_w \mid \mathbf{X}_{\mathrm{pa}_w^{(i)}}) \pi_w(\mathrm{pa}_w^{(i)})$, $i \in \{1, \dots \mathbb{P}\}$, where $\mathbb{P}$ is the cardinality of $Pa_W^{G,H}$, and where $\mathrm{pa}_w^{(i)}$ is the parent set of node w for the i^{th} member of $Pa_W^{G,H}$ i.e. we have that $Pa_W^{G,H} = \left\{(\mathrm{pa}_{w_1}^{(1)}, \dots, \mathrm{pa}_{w_q}^{(1)}), \dots, (\mathrm{pa}_{w_1}^{(\mathbb{P})}, \dots, \mathrm{pa}_{w_q}^{(\mathbb{P})})\right\}$. Similarly, define $Pa_w^{G,H} = \left\{\mathrm{pa}_w^{(1)}, \dots, \mathrm{pa}_w^{(\mathbb{P}_w)}\right\}$, and thus $\mathbb{P}_w$ is the number of tuples of parent sets in $Pa_w^{G,H}$. Recall that $Pa_W^{G,H}$ is the Cartesian product of the sets $Pa_w^{G,H}$ of parent sets for $w \in W$, thus

$$\begin{aligned}
\prod_{w \in W} \sum_{\mathrm{pa}_w^{(i)} \in Pa_w^{G,H}} \lambda_w^{(i)} &= \prod_{w \in W} \left(\lambda_w^{(1)} + \dots + \lambda_w^{(\mathbb{P}_w)}\right) \\
&= \sum_{i_1 \in \{1,\dots,\mathbb{P}_1\}, \dots, i_q \in \{1,\dots,\mathbb{P}_q\}} \lambda_{w_1}^{(i_1)} \dots \lambda_{w_q}^{(i_q)} \\
&= \sum_{(\mathrm{pa}_{w_1}^{(i)}, \dots, \mathrm{pa}_{w_q}^{(i)}) \in Pa_W^{G,H}} \lambda_{w_1}^{(i)} \dots \lambda_{w_q}^{(i)} \\
&= \sum_{(\mathrm{pa}_{w_1}^{(i)}, \dots, \mathrm{pa}_{w_q}^{(i)}) \in Pa_W^{G,H}} \prod_{w \in W} \lambda_w^{(i)} .
\end{aligned}$$

■

Appendix D. Details of Data Analysed

We included in our analysis the following variables from the survey data (Centers for Disease Control and Prevention, 2008): `SEX`, `_AGE_G`, `_RACEGR2`, `MARITAL`, `_CHLDCNT`, `_INCOMG`, `USEEQUIP`, `_HCVU65`, `MEDCOST`, `_SMOKER3`, `_ASTHMST`, `_RFDRHV3`, `_RFBING4`, `QLREST2`, `_RFSEAT3`, `_TOTINDA`, `_BMI4CAT`, `DIABETE2`, `EMTSUPRT`, `LSATISFY`, `_EXTETH2`, `_AIDTST2`, `_DENVST1`, `IMONTH`. In our analysis of the single-cell molecular data (Bendall et al., 2011) we included the following quantities, including the binding of antibodies, viability and DNA content: `191-DNA`, `193-DNA`, `103-Viability`, `115-CD45`, `139-CD45RA`, `141-pPLCgamma2`, `142-CD19`, `144-CD11b`, `145-CD4`, `146-CD8`, `148-CD34`, `150-pSTAT5`, `147-CD20`, `152-Ki67`, `154-pSHP2`, `151-pERK1/2`, `153-pMAPKAPK2`, `156-pMAPKAPK2AP70/Syk`, `158-CD33`, `160-CD123`, `159-pSTAT3`, `164-pSLP-76`, `165-pNFkB`, `166-IkBalpha`, `167-CD38`, `168-pH3`, `170-CD90`, `169-pP38`, `171-pBtk/Itk`, `172-pS6`, `174-pSrcFK`, `176-pCREB`, `175-pCrkL`, `110_114-CD3`.

Table A2: ALARM data, structural Hamming distances (SHD) between estimated graphs and the true data-generating graph. For Bayesian methods we compare to both the *maximum a posteriori* (top line) and the median probability graph (bottom line), and report mean SHD over 10 independent Monte Carlo runs, along with the corresponding standard deviation. For constraint-based methods, we report results for $\alpha = 0.05$.

Appendix F. Additional Figures

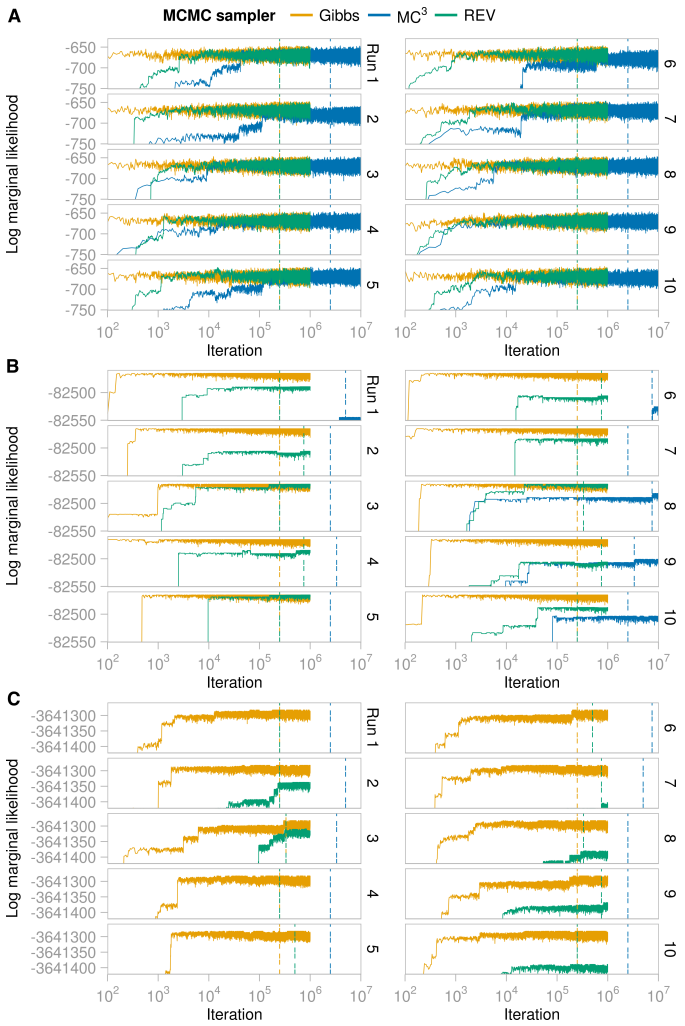

Figure A13: Log marginal likelihood of the graphs visited by the three MCMC samplers in 10 independent runs, initialised at disparate initial conditions. In (A) Zoo data; (B) survey data; (C) single-cell molecular data. Iteration number is displayed on a $\log_{10}$ scale. The dashed lines indicate where the burn-in phase ended.

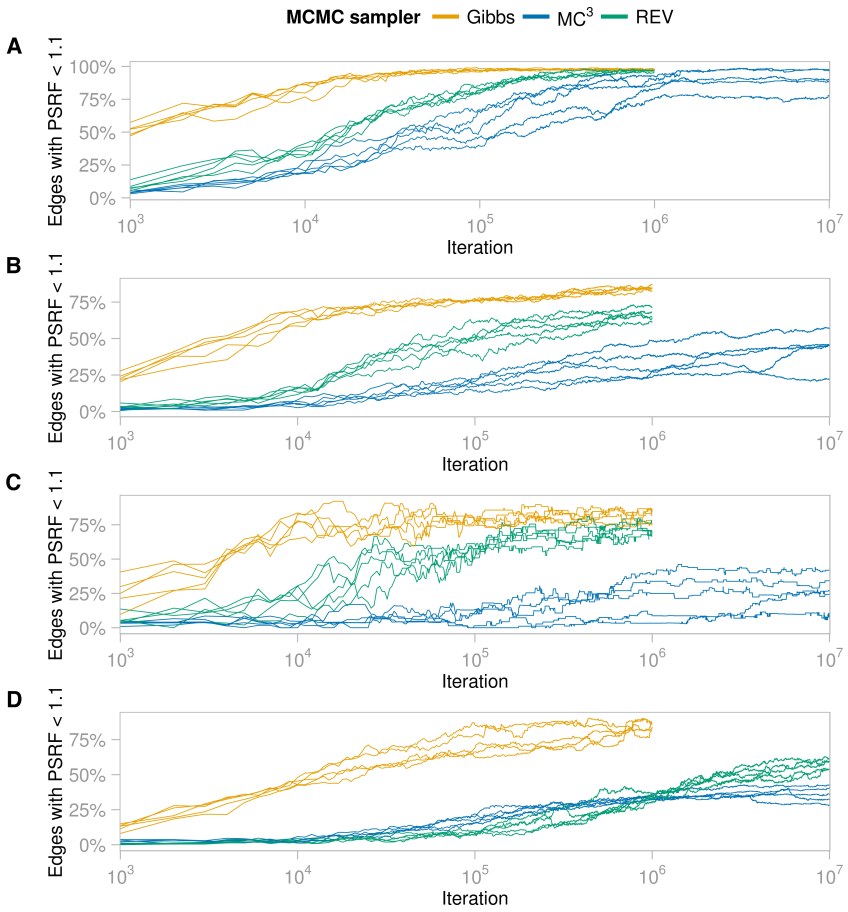

Figure A14: Proportion of edges with PSRF < 1.1 against iteration number. (A) Zoo data; (B) ALARM data, $n = 1000$; (C) survey data; (D) single-cell molecular data.

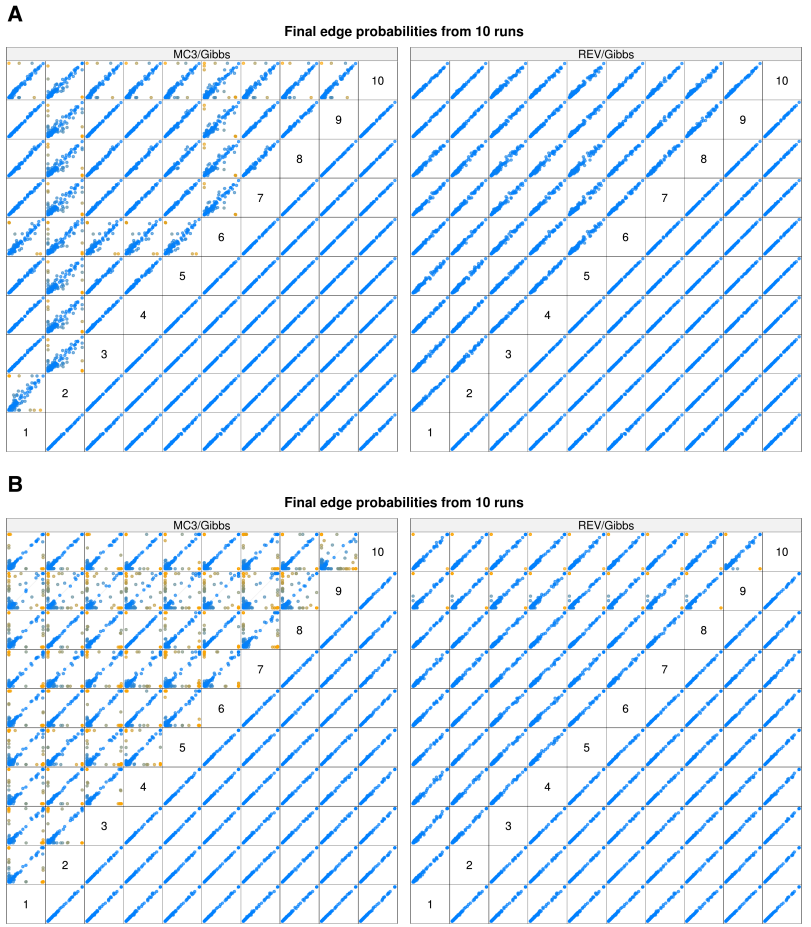

Figure A15: Convergence diagnostic plots for all pairs of 10 independent MCMC runs for each sampler for (A) Zoo data and (B) ALARM data, $n = 1000$. In each cell, the posterior edge probabilities given by two independent runs are plotted against each other. Each point represents a single edge. The lower half of both panels compares runs of the Gibbs sampler; the upper half compares runs of the MC^3 and the REV sampler respectively. When the two runs give the same estimates of the posterior edge probabilities, all of the points appear on the line $y = x$. The blue to orange colour scale represents the distance from this line, with orange points the furthest away.

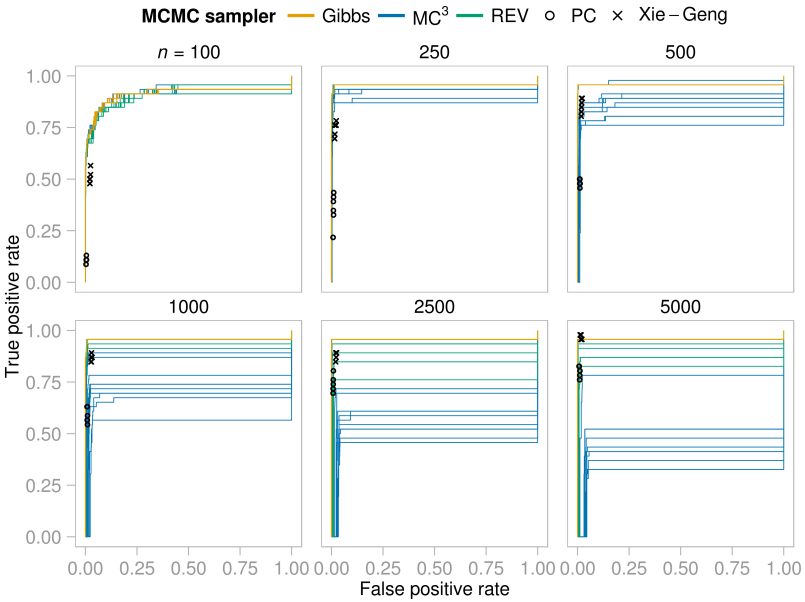

Figure A16: ALARM data, receiver operating characteristic (ROC) curves for each of 10 independent MCMC runs for each MCMC sampler, and point estimates for the constraint-based methods. Point estimates from Xie-Geng's constraint-based method and the PC-algorithm are also shown for all 8 significance levels.

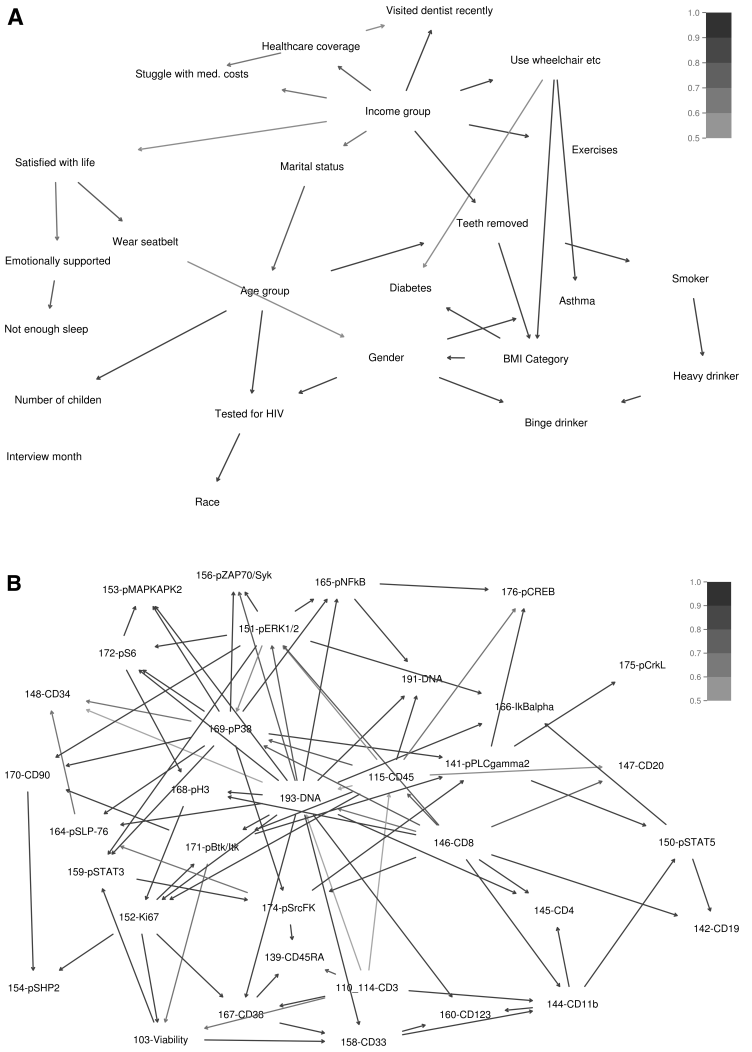

Figure A17: The median probability model G^{med} estimated by the Gibbs sampler, for (A) survey data and (B) single-cell molecular data. Darker shading indicates higher posterior edge probability. Note that no hard constraints were specified to ensure, for example, an in-degree of 0 for 'Age Group' in (A); such constraints were omitted to keep the implementations of the various methods simple.

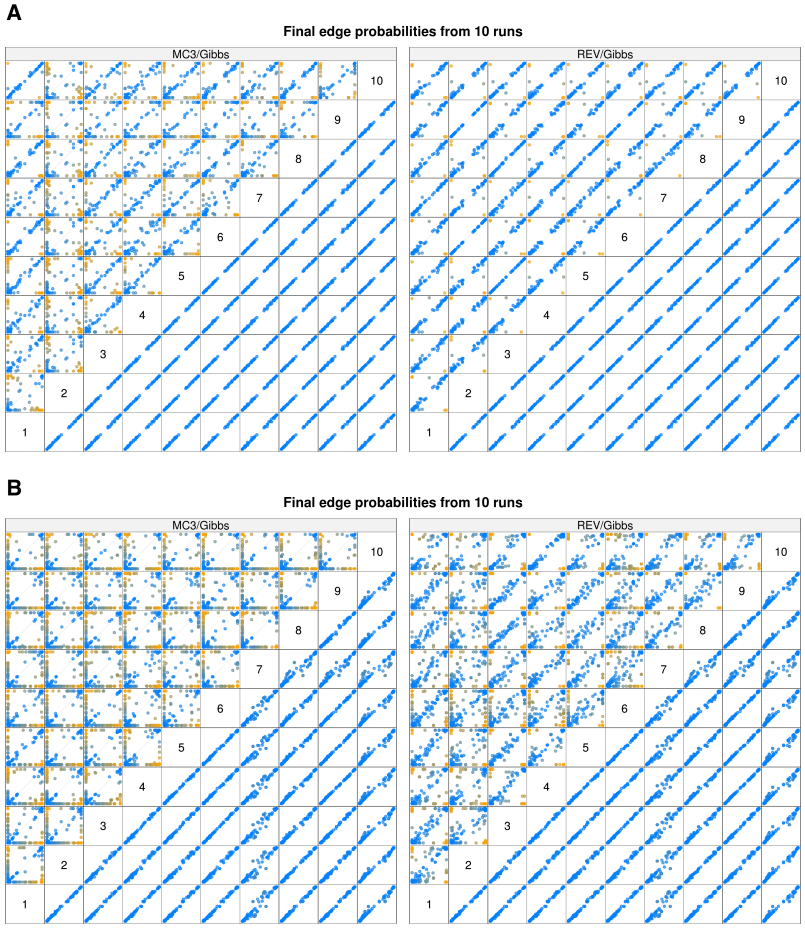

Figure A18: Convergence diagnostic plots for all pairs of 10 independent MCMC runs for each sampler for (A) survey data and (B) single-cell molecular data. In each cell, the posterior edge probabilities given by two independent runs are plotted against each other. Each point represents a single edge. The lower half of both panels compares runs of the Gibbs sampler; the upper half compares runs of the MC^3 and the REV sampler respectively. When the two runs give the same estimates of the posterior edge probabilities, all of the points appear on the line $y = x$. The blue to orange colour scale represents the distance from this line, with orange points the furthest away.

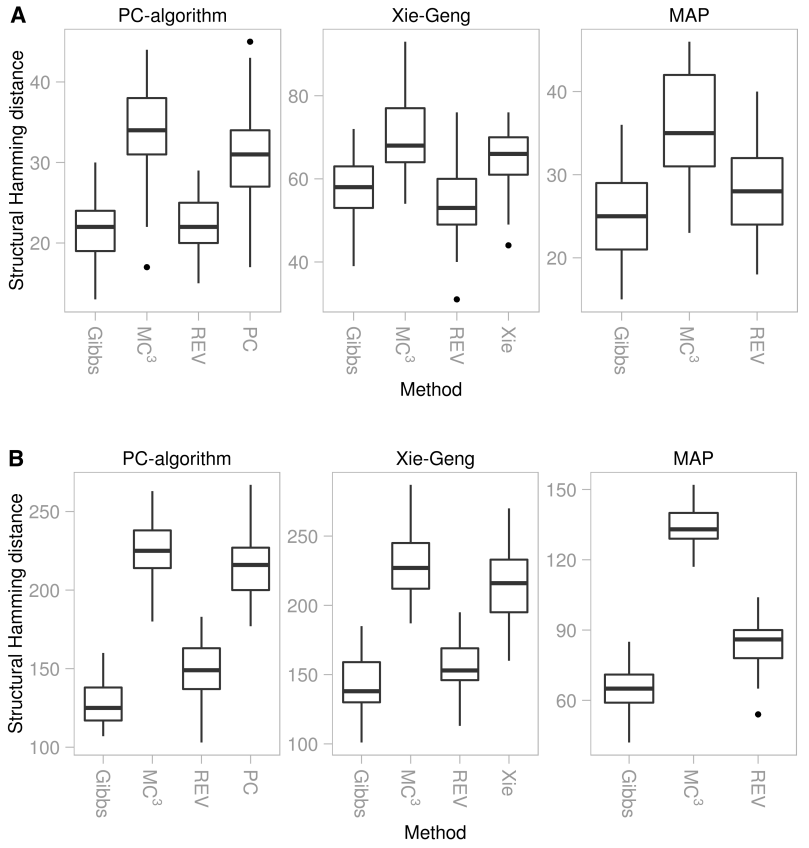

Figure A19: Stability of estimators under bootstrapping, as quantified by structural Hamming distance (SHD) between estimates obtained from pairs of bootstrap iterations for (A) survey data and (B) single-cell molecular data. In each case 10 bootstrap data sets were drawn and each estimator was run on each bootstrap data set. Smaller SHDs indicate stable estimation in the sense of graph estimates that are robust to resampling. Boxplots are shown over all pairs of bootstrap iterations. The edge probabilities were thresholded so that the resulting graphs had the same number of edges as the graph indicated in the panel title: G_τ^{PC} (the graph estimated by the PC-algorithm), G_τ^{Xie} (Xie-Geng method), or G^{MAP} (MAP graph).

Abstract

Learning probabilistic models over strings is an important issue for many applications. Spectral methods propose elegant solutions to the problem of inferring weighted automata from finite samples of variable-length strings drawn from an unknown target distribution p. These methods rely on a singular value decomposition of a matrix $\mathbf{H}_S$, called the empirical Hankel matrix, that records the frequencies of (some of) the observed strings S. The accuracy of the learned distribution depends both on the quantity of information embedded in $\mathbf{H}_S$ and on the distance between $\mathbf{H}_S$ and its mean $\mathbf{H}_p$. Existing concentration bounds seem to indicate that the concentration over $\mathbf{H}_p$ gets looser with its dimensions, suggesting that it might be necessary to bound the dimensions of $\mathbf{H}_S$ for learning. We prove new *dimension-free* concentration bounds for classical Hankel matrices and several variants, based on prefixes or factors of strings, that are useful for learning. Experiments demonstrate that these bounds are tight and that they significantly improve existing (dimension-dependent) bounds. One consequence of these results is that the spectral learning approach remains consistent even if all the observations are recorded within the empirical matrix.

Keywords: Hankel matrices, Matrix Bernstein bounds, Probabilistic Grammatical Inference, Rational series, Spectral learning

1. Introduction

Many applications in natural language processing, text analysis or computational biology require learning probabilistic models over finite variable-size strings such as probabilistic automata, Hidden Markov Models (HMM), or more generally, weighted automata. Weighted automata exactly model the class of rational series, and their algebraic properties have been widely studied in that context (Droste et al., 2009). In particular, they admit algebraic representations that can be characterized by a set of finite-dimensional linear operators whose ranks are closely linked to the minimum number of states needed to define the automaton. From a machine learning perspective, the objective is then to infer good estimates of these linear operators from finite samples. In this paper, we consider the problem of learning the linear representation of a weighted automaton, from a finite sample, composed of variable-size strings i.i.d. from an unknown target distribution.

Recently, the seminal papers of (Hsu et al., 2009) for learning HMM and (Bailly et al., 2009) for weighted automata, have defined a new category of approaches - the so-called *spectral methods* - for learning distributions over strings represented by finite state models (Siddiqi et al., 2010; Song et al., 2010; Balle et al., 2012; Balle and Mohri, 2012). Extensions to probabilistic models for tree-structured data (Bailly et al., 2010; Parikh et al., 2011; Cohen et al., 2012), transductions (Balle et al., 2011) or other graphical models (Anandkumar et al., 2012c,b,a; Luque et al., 2012) have also attracted a lot of interest.

Spectral methods suppose that the main parameters of a model can be expressed as the spectrum of a linear operator and estimated from the spectral decomposition of a matrix that sums up the observations. Given a rational series r, the values taken by r can be arranged in a matrix $\mathbf{H}_r$ whose rows and columns are indexed by strings, such that the linear operators defining r can be recovered directly from the right singular vectors of $\mathbf{H}_r$. This matrix is called the Hankel matrix of r.

In a learning context, given a learning sample S drawn from a target distribution p, an empirical estimate $\mathbf{H}_S$ of $\mathbf{H}_p$ is built and then, a rational series $\tilde{p}$ is inferred from the right singular vectors of $\mathbf{H}_S$. However, the size of $\mathbf{H}_S$ increases drastically with the size of S and state of the art approaches consider smaller matrices $\mathbf{H}_S^{U,V}$ indexed by limited subset of strings U and V. It can be shown that the above learning scheme, or slight variants of it, are consistent as soon as the matrix $\mathbf{H}_S^{U,V}$ has full rank (Hsu et al., 2009; Bailly, 2011; Balle et al., 2012) and that the accuracy of the inferred series is directly connected to the concentration distance $\|\mathbf{H}_S^{U,V} - \mathbf{H}_p^{U,V}\|_2$ between the empirical Hankel matrix and its mean (Hsu et al., 2009; Bailly, 2011).

On the one hand, limiting the size of the Hankel matrix avoids prohibitive calculations. Moreover, most existing concentration bounds on sum of random matrices depend on their size and suggest that $\|\mathbf{H}_S^{U,V} - \mathbf{H}_p^{U,V}\|_2$ may become significantly looser with the size of U and V, compromising the accuracy of the inferred model.

On the other hand, limiting the size of the Hankel matrix implies a drastic loss of information: only the strings of S compatible with U and V will be considered. In order to limit the loss of information when dealing with restricted sets U and V, a general trend is to work with other functions than the target p, such as the *prefix* function $\overline{p}(u) \coloneqq \sum_{v\in\Sigma^*} p(uv)$ or the *factor* function $\widehat{p} \coloneqq \sum_{v,w\in\Sigma^*} p(vuw)$ (Balle et al., 2013; Luque et al., 2012). These functions are rational, they have the same rank as p, a representation of p can easily be derived from representations of $\overline{p}$ or $\widehat{p}$ and they allow a better use of the information contained in the learning sample.

A first contribution of this paper is to provide a *dimension free* concentration inequality for $\|\mathbf{H}_S^{U,V} - \mathbf{H}_p^{U,V}\|_2$, by using recent results on tail inequalities for sum of random matrices (Tropp, 2012), and in particular a dimension-free Matrix Bernstein Bound Theorem stated in (Hsu et al., 2011). As a consequence, the spectral learning approach is consistent whatever sets U and V are chosen, and even if they are set to Σ^*, showing that restricting the dimensions of $\mathbf{H}$ is not mandatory.

However, this Matrix Bernstein Bound Theorem cannot be directly applied as such to the prefix and factor series, since the norm of the corresponding random matrices is unbounded. A second contribution of the paper is then to define two classes of parametrized functions,

$\overline{p}_\eta$ and $\widehat{p}_\eta$, that constitute continuous intermediates between p and $\overline{p}$ (resp. p and $\widehat{p}$), and to provide analogous dimension-free concentration bounds for these two classes. Lastly, we adapt a Matrix Bernstein bound theorem for subexponential matrices from (Tropp, 2012) to the dimension free case, using a technique similar as the one used in (Hsu et al., 2011) and we apply it to the prefix Hankel matrices.

These bounds are evaluated on a benchmark made of 11 problems extracted from the PAutomaC challenge (Verwer et al., 2012). These experiments show that the bounds derived from our theoretical results for bounded random matrices are quite tight - compared to the exact values - and that they significantly improve existing bounds, even on matrices of fixed dimensions. By contrast, the bounds obtained in the subexponential case are somewhat loose.

Our theoretical results entail that spectral learning is consistent whatever dimensions of the Hankel matrix are chosen but they give no indication on what should be done in practical cases. We have computed the distance between the spaces spanned by the first right singular vectors of $\mathbf{H}_S^{U,V}$ and $\mathbf{H}_p^{U,V}$ for various sizes of U and V, for each target of our benchmark. These experiments seem to indicate that the best results are obtained by limiting one dimension and taking the other as large as possible but a theoretical justification remains to be provided.

The paper is organized as follows. Section 2 introduces the main notations, definitions and concepts. Section 3 provides some Matrix Berstein bounds that will be used to prove the different results of the paper. Section 4.1 presents a first dimension free-concentration inequality for the standard Hankel matrices. Then, we introduce the prefix and the factor variants and provide analogous concentration results in Sections 4.3 and 4.5 respectively. Section 6 describes some experiments before the conclusion presented in Section 7. The Appendix contains the proof of an original result, which states that the series $u \mapsto p(\Sigma^* u \Sigma^*)$, i.e. the probability that a random string contains a substring u as a factor, may be not rational even if p is rational, explaining why we have considered the less natural series $\widehat{p}$. It also contains two small proofs of known results, in order to keep the paper self-contained.

2. Preliminaries

We first present some preliminary definitions and results about matrices, rational languages, Hankel matrices and spectral learning algorithms for the inference of rational stochastic languages.

2.1 Matrices

The identity matrix of size n is denoted by $\mathbf{I}_n$, or simply by $\mathbf{I}$. Let $\mathbf{M} \in \mathbb{R}^{m \times n}$ be a $m \times n$ real matrix. The *singular values* of $\mathbf{M}$ are the square roots of the eigenvalues of the matrix $\mathbf{M}^\top\mathbf{M}$, where $\mathbf{M}^\top$ denotes the transpose of $\mathbf{M}$: $\sigma_{\max}(\mathbf{M})$ and $\sigma_{\min}(\mathbf{M})$ denote the largest and smallest singular value of $\mathbf{M}$, respectively. The *spectral radius* $\rho(\mathbf{M})$ of a square matrix $\mathbf{M}$ is the supremum among the modulus of the eigenvalues of $\mathbf{M}$. If $\mathbf{M}$ is symmetric, $\sigma_{\max}(\mathbf{M})$ coincides with $\rho(\mathbf{M})$.

Every rank-d matrix $\mathbf{M} \in \mathbb{R}^{m \times n}$ admits a factorization of the form $\mathbf{M} = \mathbf{U}\mathbf{D}\mathbf{V}^\top$, called a *reduced singular value decomposition* (SVD), where $\mathbf{U} \in \mathbb{R}^{m \times d}$ and $\mathbf{U}^\top\mathbf{U} = \mathbf{I}_d$, $\mathbf{V} \in \mathbb{R}^{n \times d}$ and $\mathbf{V}^\top\mathbf{V} = \mathbf{I}_d$ and $\mathbf{D}$ is a diagonal matrix whose diagonal elements, listed in descending order,

are the singular values of $\mathbf{M}$. The columns of $\mathbf{U}$ (resp. of $\mathbf{V}$) are called the right-singular vectors of $\mathbf{M}$ (resp. left-singular vectors of $\mathbf{M}$).

The notion of singular values, singular vectors and singular value decomposition can be extended to infinite matrices via the notion of *Hilbert spaces compact operators* (see (Stein and Shakarchi, 2005) for example). Let $(e_i)_{i \in \mathbb{N}}$ be an orthonormal basis of a separable Hilbert space $\mathcal{H}$. A bounded operator $\mathbf{T}$ on $\mathcal{H}$ can be represented by the matrix $(\langle \mathbf{T}(e_i), e_j \rangle_{\mathcal{H}})_{i,j \in \mathbb{N}}$. Compact operators are the closure of finite-rank operators in the uniform operator topology: $\max_{\|x\|=1} \|\mathbf{T}_n(x) - \mathbf{T}(x)\| \to 0$. A sufficient condition for a matrix $\mathbf{M}$ to represent a compact operator is that it has a finite Frobenius norm: $\sum_{i,j \in \mathbb{N}} M[i,j]^2 < \infty$. The matrix of any compact operator admits a reduced SVD. In particular, if $\mathbf{M}$ is the matrix of a finite rank bounded operator, it admits a reduced singular value decomposition $\mathbf{M} = \mathbf{U}\mathbf{D}\mathbf{V}^\top$.

The *operator norm* $\|\cdot\|_k$ induced by the corresponding vector norm on $\mathbb{R}^n$ is defined by $\|\mathbf{M}\|_k \coloneqq \max_{x \neq 0} \frac{\|\mathbf{M}x\|_k}{\|x\|_k}$. It can be shown that

$$\|\mathbf{M}\|_1 = \max_{1 \leq j \leq n} \sum_{i=1}^{m} |\mathbf{M}[i,j]|, \|\mathbf{M}\|_\infty = \max_{1 \leq i \leq m} \sum_{j=1}^{n} |\mathbf{M}[i,j]| \text{ and } \|\mathbf{M}\|_2 = \sigma_{\max}(\mathbf{M}).$$

We will mainly use the *spectral norm* $\|\cdot\|_2$ and we will omit the sub index 2 for the sake of simplicity. It can be shown that

$$\|\mathbf{M}\| \leq \sqrt{\|\mathbf{M}\|_1 \|\mathbf{M}\|_\infty} \tag{1}$$

These norms can be extended, under certain conditions, to infinite matrices. For example, the previous inequality remains true (with possibly infinite right-hand side term) if $\mathbf{M}$ represents the matrix of a compact operator in an orthonormal basis of a separable Hilbert space.

A symmetric matrix $\mathbf{M} \in \mathbb{R}^{n \times n}$ is *positive semidefinite* if $u^\top \mathbf{M} u \geq 0$ for all vectors $u \in \mathbb{R}^n$. Let $\preccurlyeq$ denotes the *positive semidefinite ordering* (or *Löwner ordering*) on symmetric matrices: $\mathbf{A} \preccurlyeq \mathbf{B}$ means that $\mathbf{B} - \mathbf{A}$ is positive semidefinite. The family of positive semidefinite matrices in $\mathbb{R}^{n \times n}$ forms a convex closed cone.

Any real valued function can be extended to symmetric matrices by the following method: let $\mathbf{A} = \mathbf{U}^\top \mathrm{diag}(\lambda_1, \ldots, \lambda_n)\mathbf{U}$ where $\mathrm{diag}(x_1, \ldots, x_n)$ is the diagonal matrix built over $x_1, \ldots, x_n$ and where $\mathbf{U} \in \mathbb{R}^{n \times n}$ is unitary, i.e. $\mathbf{U}^\top\mathbf{U} = \mathbf{U}\mathbf{U}^\top = \mathbf{I}$; define the matrix $f(\mathbf{A})$ by $f(\mathbf{A}) \coloneqq \mathbf{U}^\top \mathrm{diag}(f(\lambda_1), \ldots, f(\lambda_n))\mathbf{U}$. It can be shown that this definition is independent of the chosen eigenvalue decomposition. The *transfer rule* states that $f \leq g$ implies that $f(\mathbf{A}) \preccurlyeq g(\mathbf{A})$ for any symmetric matrix $\mathbf{A}$. The definition above can be used to define the exponential $e^{\mathbf{A}}$ of a symmetric matrix $\mathbf{A}$ and the logarithm $\log \mathbf{B}$ of a positive semidefinite matrix $\mathbf{B}$. It can be shown that the logarithm preserves the semidefinite order: $\mathbf{0} \preccurlyeq \mathbf{A} \preccurlyeq \mathbf{B}$ implies $\log \mathbf{A} \preccurlyeq \log \mathbf{B}$. See (Tropp, 2012) for a short overview of matrix properties.

2.2 Rational stochastic languages and Hankel matrices

Most classical results on rational series can be found in one of the following references (Berstel and Reutenauer, 1988; Salomaa and Soittola, 1978). Let Σ be a finite alphabet. The set of all finite strings over Σ is denoted by Σ^*, the empty string is denoted by ϵ, the length of

string w is denoted by $|w|$ and Σ^n (resp. $\Sigma^{\leq n}$, resp. $\Sigma^{\geq n}$) denotes the set of all strings of length n (resp. $\leq n$, resp. $\geq n$). For any string w, let $\text{Pref}(w) \coloneqq \{u \in \Sigma^* | \exists v \in \Sigma^* \quad w = uv\}$ and $\text{Suff}(w) \coloneqq \{v \in \Sigma^* | \exists u \in \Sigma^* \quad w = uv\}$.

A *series* is a mapping $r : \Sigma^* \to \mathbb{R}$. The *support* of the series r is the set $\text{supp}(r) = \{u \in \Sigma^* : r(u) \neq 0\}$. A series r is *non negative* if it takes only non negative values. A non negative series r is *convergent* if the sum $\sum_{u\in\Sigma^*} r(u)$ is bounded: for any $A \subseteq \Sigma^*$, let us denote $r(A) \coloneqq \sum_{u\in A} r(u)$. A *stochastic language* p is a probability distribution over Σ^*, i.e. a non negative series p satisfying $p(\Sigma^*) = 1$.

Let $n \geq 1$ and $\mathbf{M}$ be a morphism defined from Σ^* to $\mathbb{M}_n$, the set of square $n \times n$ matrices with real coefficients. For all $u \in \Sigma^*$, let us denote $\mathbf{M}(u)$ by $\mathbf{M}_u$ and $\Sigma_{x\in\Sigma}\mathbf{M}_x$ by $\mathbf{M}_\Sigma$. A series r over Σ is *rational* if there exists an integer $n \geq 1$, two vectors $I, T \in \mathbb{R}^n$ and a morphism $\mathbf{M} : \Sigma^* \to \mathbb{M}_n$ such that for all $u \in \Sigma^*$, $r(u) = I^\top \mathbf{M}_u T$. The triplet $\langle I, \mathbf{M}, T\rangle$ is called an n-dimensional *linear representation* of r. The vector I can be interpreted as a vector of initial weights, T as a vector of terminal weights and the morphism $\mathbf{M}$ as a set of matrix parameters associated with the letters of Σ. A *rational stochastic language* is thus a stochastic language admitting a linear representation.

Let $U, V \subseteq \Sigma^*$, the *Hankel matrix* $\mathbf{H}_r^{U,V}$, associated with a series r, is the matrix indexed by $U \times V$ and defined by $\mathbf{H}_r^{U,V}[u, v] \coloneqq r(uv)$, for any $(u, v) \in U \times V$. If $U = V = \Sigma^*$, $\mathbf{H}_r^{U,V}$, simply denoted by $\mathbf{H}_r$, is a bi-infinite matrix. In the following, we always assume that $\epsilon \in U \cap V$ and that U and V are ordered in quasi-lexicographic order: strings are first ordered by increasing length and then, according to the lexicographic order. It can be shown that a series r is rational if and only if the rank of the matrix $\mathbf{H}_r$ is finite. The rank of $\mathbf{H}_r$ is equal to the minimal dimension of a linear representation of r: it is called the rank of r. The Hankel matrix $\mathbf{H}_r$ represents a bounded operator if and only if $\sum_{u\in\Sigma^*} r^2(u) < \infty$; in particular, if r is a non negative convergent rational series, then $\mathbf{H}_r$ represents a compact operator, which admits a reduced singular value decomposition.

Let r be a non negative convergent rational series and let $\langle I, \mathbf{M}, T\rangle$ be a minimal d-dimensional linear representation of r. Then, the matrix $\mathbf{I}_d - \mathbf{M}_\Sigma$ is invertible and the sum $\mathbf{I}_d + \mathbf{M}_\Sigma + \ldots + \mathbf{M}_\Sigma^n + \ldots$ converges to $(\mathbf{I}_d - \mathbf{M}_\Sigma)^{-1}$. For any ρ_r such that $\rho(\mathbf{M}_\Sigma) < \rho_r < 1$, there exists a constant $C_r > 0$ such that $r(\Sigma^{\geq n}) \leq C_r \rho_r^n$ for any integer n (we show in Section 6.1 how such constants can be computed in pratical cases). For any integer $k \geq 1$, let us define the moments $S_r^{(k)} \coloneqq \sum_{u_1 u_2 \ldots u_k \in \Sigma^*} r(u_1 u_2 \ldots u_k)$. It can easily be shown that

$$S_r^{(k)} = I^\top (\mathbf{I}_d - \mathbf{M}_\Sigma)^{-k} T. \tag{2}$$

Several rational series can be naturally associated with a rational non negative convergent series r (see (Balle et al., 2014) for example):

- $\overline{r}$, defined by $\overline{r}(u) \coloneqq \sum_{v\in\Sigma^*} r(uv) = r(u\Sigma^*)$, associated with the *prefixes* of the support of r,
- $\widehat{r}$, defined by $\hat{r}(u) \coloneqq \sum_{v,w\in\Sigma^*} r(vuw)$, associated with the *factors* of the support of r.

If p is a stochastic language, it can be noticed that $\overline{p}(u)$ is the probability that a string begins with u and that $\widehat{p}(u) = \mathbb{E}_{v\sim p}|v|_u$, where $|v|_u = \sum_{x,y\in\Sigma^*} \mathbf{1}_{xuy=v}$. We have $\widehat{p}(u) \geq p(\Sigma^* u \Sigma^*)$, the probability that a string contains u as a substring. The function $u \mapsto p(\Sigma^* u \Sigma^*)$ has a

simpler probabilistic interpretation than $\widehat{p}$. However, this function is not rational in general and cannot easily be used in a learning context.

Proposition 1 *There exists a rational stochastic language p of rank one and built on a two-letter alphabet Σ such that the series $u \mapsto p(\Sigma^* u \Sigma^*)$ is not rational.*

Proof See Appendix. ■

If $\langle I, \mathbf{M}, T\rangle$ is a minimal d-dimensional linear representation of r, then $\langle I, \mathbf{M}, (\mathbf{I}_d - \mathbf{M}_\Sigma)^{-1}T\rangle$ (resp. $\langle [I^\top(\mathbf{I}_d - \mathbf{M}_\Sigma)^{-1}]^\top, \mathbf{M}, (I_d - \mathbf{M}_\Sigma)^{-1}T\rangle$) is a minimal linear representation of $\overline{r}$ (resp. of $\widehat{r}$). Conversely, a linear representation of r can be deduced from any linear representation of $\overline{r}$ or of $\widehat{r}$. Clearly,

$$r(\Sigma^*) = S_r^{(1)}, \overline{r}(\Sigma^*) = S_r^{(2)} \text{ and } \widehat{r}(\Sigma^*) = S_r^{(3)}.$$

Let $U, V \subseteq \Sigma^*$. For any string $w \in \Sigma^*$, let us define the matrices $\mathbf{H}_w^{U,V}$, $\overline{\mathbf{H}}_w^{U,V}$ and $\widehat{\mathbf{H}}_w^{U,V}$ by

$$\mathbf{H}_w^{U,V}[u, v] \coloneqq \mathbf{1}_{uv=w}, \overline{\mathbf{H}}_w^{U,V}[u, v] \coloneqq \mathbf{1}_{uv\in\text{Pref}(w)} \text{ and } \widehat{\mathbf{H}}_w^{U,V}[u, v] \coloneqq \sum_{x,y\in\Sigma^*} \mathbf{1}_{xuvy=w}$$

for any $(u, v) \in U \times V$.

For any non empty multiset of strings S, let us define the matrices $\mathbf{H}_S^{U,V}$, $\overline{\mathbf{H}}_S^{U,V}$ and $\widehat{\mathbf{H}}_S^{U,V}$ by

$$\mathbf{H}_S^{U,V} \coloneqq \frac{1}{|S|}\sum_{w\in S} \mathbf{H}_w^{U,V}, \overline{\mathbf{H}}_S^{U,V} \coloneqq \frac{1}{|S|}\sum_{w\in S} \overline{\mathbf{H}}_w^{U,V} \text{ and } \widehat{\mathbf{H}}_S^{U,V} \coloneqq \frac{1}{|S|}\sum_{w\in S} \widehat{\mathbf{H}}_w^{U,V}.$$

Let p_S be the empirical stochastic language associated with S, defined by $p_S(u) \coloneqq \frac{|\{u\in S\}|}{|S|}$. We have

$$\mathbf{H}_{p_S}^{U,V} = \mathbf{H}_S^{U,V}, \mathbf{H}_{\overline{p_S}}^{U,V} = \overline{\mathbf{H}}_S^{U,V} \text{ and } \mathbf{H}_{\widehat{p_S}}^{U,V} = \widehat{\mathbf{H}}_S^{U,V}.$$

For example, let $S = \{a, ab\}$, $U = V = \{\epsilon, a, b\}$. We have

$$\mathbf{H}_S^{U,V} = \begin{pmatrix} 0 & 1/2 & 0 \\ 1/2 & 0 & 1/2 \\ 0 & 0 & 0 \end{pmatrix}, \quad \overline{\mathbf{H}}_S^{U,V} = \begin{pmatrix} 1 & 1 & 0 \\ 1 & 0 & 1/2 \\ 0 & 0 & 0 \end{pmatrix} \text{ and } \widehat{\mathbf{H}}_S^{U,V} = \begin{pmatrix} 5/2 & 1 & 1/2 \\ 1 & 0 & 1/2 \\ 1/2 & 0 & 0 \end{pmatrix}.$$

2.3 Spectral Algorithm for Learning Rational Stochastic Languages

Rational series admit *canonical linear representations* determined by their Hankel matrix. Let r be a rational series of rank d and $U \subset \Sigma^*$ such that the matrix $\mathbf{H}_r^{U\times\Sigma^*}$ (denoted by $\mathbf{H}$ in the following) has rank d. Moreover, suppose that $\sum_{u\in\Sigma^*} r(u)^2 < \infty$.

- For any string s, let $\mathbf{T}_s$ be the constant matrix whose rows and columns are indexed by Σ^* and defined by $\mathbf{T}_s[u, v] \coloneqq 1$ if $v = us$ and 0 otherwise.
- Let E be a vector indexed by Σ^* whose coordinates are all zero except the first one equals to 1: $E[u] = \mathbf{1}_{u=\epsilon}$ and let P be the vector indexed by Σ^* defined by $P[u] \coloneqq r(u)$.

- Let $\mathbf{H} = \mathbf{L}\mathbf{D}\mathbf{R}^\top$ be a reduced singular value decomposition of $\mathbf{H}$: $\mathbf{R}$ (resp. $\mathbf{L}$) is a matrix whose columns form a set of orthonormal vectors - the right (resp. left) singular vectors of $\mathbf{H}$ - and $\mathbf{D}$ is a $d \times d$ diagonal matrix, composed of the singular values of $\mathbf{H}$.

Then, $\langle \mathbf{R}^\top E, (\mathbf{R}^\top \mathbf{T}_x \mathbf{R})_{x\in\Sigma}, \mathbf{R}^\top P\rangle$ is a linear representation of r (Bailly et al., 2009; Hsu et al., 2009; Bailly, 2011; Balle et al., 2012).

Proposition 2 *$\langle \mathbf{R}^\top E, (\mathbf{R}^\top \mathbf{T}_x \mathbf{R})_{x\in\Sigma}, \mathbf{R}^\top P\rangle$ is a linear representation of r*

Proof See Appendix. ■

The basic spectral algorithm for learning rational stochastic languages aims at identifying the canonical linear representation of the target p determined by its Hankel matrix $\mathbf{H}_p$.

Let S be a sample independently drawn according to p:

- choose sets $U, V \subseteq \Sigma^\star$ and build the Hankel matrix $\mathbf{H}_S^{U\times V}$,
- choose a rank d, compute a SVD of $\mathbf{H}_S^{U\times V}$, and consider the d right singular vectors $\mathbf{R}_S$ associated with the d largest singular values,
- build the canonical linear representation $\langle \mathbf{R}_S^\top E, (\mathbf{R}_S^\top \mathbf{T}_x \mathbf{R}_S)_{x\in\Sigma}, \mathbf{R}_S^\top P_S\rangle$ where E and P are the vectors indexed by V s.t. $E[v] = \mathbf{1}_{v=\epsilon}$ and $P[v] \coloneqq p_S(v)$.

Alternative learning strategies consist in learning $\overline{p}$ or $\widehat{p}$, using the same algorithm, and then to compute an estimate of p. In all cases, the accuracy of the learned representation mainly depends on the estimation of $\mathbf{R}$. The Stewart formula (Stewart, 1990) bounds the principle angle θ between the spaces spanned by the right singular vectors of $\mathbf{R}$ and $\mathbf{R}_S$:

$$|\sin(\theta)| \leq \frac{\left\|\mathbf{H}_S^{U\times V} - \mathbf{H}_r^{U\times V}\right\|}{\sigma_{\min}(\mathbf{H}_r^{U\times V})}.$$

According to this formula, the concentration of the Hankel matrix around its mean is critical and the question of limiting the sizes of U and V naturally arises. Note that the Stewart inequality does not give any clear indication on the impact or on the interest of limiting these sets. Indeed, it can be shown that both the numerator and the denominator of the right part of the inequality increase with U and V (see Appendix).

3. Matrix Bernstein bounds

Let p be a rational stochastic language over $\Sigma^\star$, let ξ be a random variable distributed according to p, let $U, V \subseteq \Sigma^\star$ and let $\mathbf{Z}(\xi) \in \mathbb{R}^{|U|\times|V|}$ be a random matrix. For instance, $\mathbf{Z}(\xi)$ may be equal to $\mathbf{H}_\xi^{U,V}$, $\overline{\mathbf{H}}_\xi^{U,V}$ or $\widehat{\mathbf{H}}_\xi^{U,V}$ (ξ will be often omitted for the sake of simplicity). Let S be sample of strings drawn independently according to p.

Concentration bounds for sum of random matrices can be used to estimate the spectral distance between the empirical matrix $\mathbf{Z}_S$ computed on the sample S and its mean.

However, most of classical inequalities depend on the dimensions of the matrices. For eample, the following result describes a simple matrix Bernstein inequality on sum of random matrices (Ahlswede and Winter, 2002; Tropp, 2012).

Suppose that $\mathbb{E}\mathbf{Z}(\xi) = 0$ and let $\nu(\mathbf{Z}) = \max\{\|\mathbb{E}\mathbf{Z}\mathbf{Z}^\top\|, \|\mathbb{E}\mathbf{Z}^\top\mathbf{Z}\|\}$. Then,

$$\Pr\left(\|\mathbf{Z}_S\| \geq \frac{t}{N}\right) \leq (d_1 + d_2)\ \exp\left(-\frac{t^2}{2N\nu(\mathbf{Z}) + 2Mt/3}\right) \tag{3}$$

where N is the size of S, d_1 and d_2 are the dimensions of the matrix $\mathbf{Z}$ and $\|\mathbf{Z}\| \leq M$ almost surely.

We would like to apply this result to $\mathbf{Z} = \mathbf{H}_\xi^{U,V} - \mathbb{E}\mathbf{H}_\xi^{U,V}$, $\mathbf{Z} = \overline{\mathbf{H}}_\xi^{U,V} - \mathbb{E}\overline{\mathbf{H}}_\xi^{U,V}$ and $\mathbf{Z} = \widehat{\mathbf{H}}_\xi^{U,V} - \mathbb{E}\widehat{\mathbf{H}}_\xi^{U,V}$. However, we will see that while $\left\|\mathbf{H}_\xi^{U,V}\right\|$ is bound, $\left\|\overline{\mathbf{H}}_\xi^{U,V}\right\| = \Omega(\max(|U|^{1/2}, |V|^{1/2}))$ in the worst case, and $\left\|\widehat{\mathbf{H}}_\xi^{U,V}\right\|$may be unbounded even for fixed U and V.

These concentration bounds get worse with both sizes of the matrices. Coming back to the discussion at the end of Section 2, they suggest to limit the size of the sets U and V, and therefore, to design strategies to choose optimal sets. However, dimension-free bounds can be obtained.

3.1 A dimension-free Matrix Bernstein bound theorem

We then use recent results from (Tropp, 2012; Hsu et al., 2012) to obtain dimension-free concentration bounds for Hankel matrices.

Theorem 3 *(Hsu et al., 2012). Let $\xi_1, \ldots, \xi_N$ be random variables, and for each $i = 1, \ldots, N$, let $\mathbf{X}_i(\xi_i)$ be a symmetric matrix-valued functional of ξ_i[1]. For any $\eta \in \mathbb{R}$ and any $t > 0$,*

$$Pr\left[\left\|\eta \sum_{i=1}^N \mathbf{X}_i - \sum_{i=1}^N \log \mathbb{E}[\exp(\eta \mathbf{X}_i)]\right\| > t\right] \leq \operatorname{Tr}\left(\mathbb{E}\left[-\eta \sum_{i=1}^N \mathbf{X}_i + \sum_{i=1}^N \log \mathbb{E}[\exp(\eta \mathbf{X}_i)]\right]\right) \cdot (e^t - t - 1)^{-1}.$$

A matrix Bernstein bound can be derived from previous Theorem.

Theorem 4 *(Hsu et al., 2012). If there exists $b > 0, \sigma > 0, k > 0$ s.t. for all $i = 1, \ldots, N$, $\mathbb{E}_i[\mathbf{X}_i] = 0$, $\|\mathbf{X}_i\| \leq b$, $\left\|\frac{1}{N}\sum_{i=1}^N \mathbb{E}_i(\mathbf{X}_i^2)\right\| \leq \sigma^2$ and $\mathbb{E}\left[\operatorname{Tr}\left(\frac{1}{N}\sum_{i=1}^N \mathbb{E}_i(\mathbf{X}_i^2)\right)\right] \leq \sigma^2 k$ almost surely, then for all $t > 0$,*

$$Pr\left[\left\|\frac{1}{N}\sum_{i=1}^N \mathbf{X}_i\right\| > \sqrt{\frac{2\sigma^2 t}{N}} + \frac{bt}{3N}\right] \leq k \cdot t(e^t - t - 1)^{-1}.$$

1. (Hsu et al., 2011) consider the more general case, where $\mathbf{X}_i$ be a symmetric matrix-valued functional of $\xi_1, \ldots, \xi_i$.

Previous theorem is valid for symmetric matrices, but it can be extended to general real-valued matrices thanks to the principle of dilation.

Let $\mathbf{Z}$ be a matrix, the *dilation* of $\mathbf{Z}$ is the symmetric matrix $\mathbf{X}$ defined by

$$\mathbf{X} = \begin{bmatrix} 0 & \mathbf{Z} \\ \mathbf{Z}^T & 0 \end{bmatrix}. \text{ Then } \mathbf{X}^2 = \begin{bmatrix} \mathbf{Z}\mathbf{Z}^T & 0 \\ 0 & \mathbf{Z}^T\mathbf{Z} \end{bmatrix}$$

and $\|\mathbf{X}\| = \|\mathbf{Z}\|$, $\mathrm{Tr}(\mathbf{X}^2) = \mathrm{Tr}(\mathbf{Z}\mathbf{Z}^T) + \mathrm{Tr}(\mathbf{Z}^T\mathbf{Z})$ and $\left\|\mathbf{X}^2\right\| \leq \max(\left\|\mathbf{Z}\mathbf{Z}^T\right\|, \left\|\mathbf{Z}^T\mathbf{Z}\right\|)$.

We can then reformulate previous theorem as follows.

Theorem 5 *Let $\xi_1, \ldots, \xi_N$ be i.i.d. random variables, and for $i = 1, \ldots, N$, let $\mathbf{Z}_i = \mathbf{Z}(\xi_i)$ be i.i.d. matrices and $\mathbf{X}_i$ the dilation of $\mathbf{Z}_i$. If there exists $b > 0, \sigma > 0$, and $k > 0$ such that $\mathbb{E}[\mathbf{X}_1] = 0$, $\|\mathbf{X}_1\| \leq b$, $\left\|\mathbb{E}(\mathbf{X}_1^2)\right\| \leq \sigma^2$ and $\mathrm{Tr}(\mathbb{E}(\mathbf{X}_1^2)) \leq \sigma^2 k$ almost surely, then for all $t > 0$,*

$$Pr\left[\left\|\frac{1}{N}\sum_{i=1}^{N}\mathbf{X}_i\right\| > \sqrt{\frac{2\sigma^2 t}{N}} + \frac{bt}{3N}\right] \leq k \cdot t(e^t - t - 1)^{-1}.$$

We will then make use of this theorem to derive our new concentration bounds. Section 4.1 deals with the standard case, Section 4.3 with the prefix case and Section 4.5 with the factor case.

3.2 The subexponential case

Theorem 5 needs that the random matrices are bounded. However, the norm of $\overline{\mathbf{H}}_{\xi}^{U,V}$ depends on the size of U and V and $\widehat{\mathbf{H}}_{\xi}^{U,V}$ may be unbounded even in U and V are finite. Fortunately, Bernstein inequalities for subexponential random variables have been extended to unbounded random matrices whose moments grow at a limited rate [Th. 6.2 in (Tropp, 2012)]. We adapt this result to the dimension-free case in a similar way as what has been done in (Hsu et al., 2012) for Theorem 4.

Theorem 6 *[Matrix Bernstein bound: subexponential case.] If there exist $k > 0$, $R > 0$, and a symmetric matrix $\mathbf{A}$ such that for all $i = 1, \ldots, N$, $\mathbb{E}\mathbf{X}_i = 0$, $\mathbb{E}\mathbf{X}_i^p \preccurlyeq \frac{p!}{2}R^{p-2}\mathbf{A}^2$ for any integer $p \geq 2$, $\mathrm{Tr}(\mathbf{A}^2) \leq k\sigma^2$ where $\sigma^2 = \left\|\mathbf{A}^2\right\|$, then for any $t > 0$,*

$$Pr\left[\left\|\frac{1}{N}\sum_{i=1}^{N}\mathbf{X}_i\right\| > \frac{Rt}{N} + \sqrt{\frac{2\sigma^2 t}{N}}\right] \leq k \cdot t(e^t - t - 1)^{-1}.$$

Proof Let $0 < \eta < 1/R$. We have

$$\mathbb{E}e^{\eta\mathbf{X}_i} = \mathbb{E}\sum_{p\geq 0}\frac{1}{p!}\eta^p\mathbf{X}_i^p = \mathbf{I} + \sum_{p\geq 2}\frac{1}{p!}\eta^p\mathbb{E}\mathbf{X}_i^p \preccurlyeq \mathbf{I} + \frac{\eta^2}{2(1-\eta R)}\mathbf{A}^2.$$

Hence, by using the monotonicity of the logarithm function and the transfer rule applied to the inequality $\log(1+x) \leq x$,

$$\log\mathbb{E}e^{\eta\mathbf{X}_i} \preccurlyeq \frac{\eta^2}{2(1-\eta R)}\mathbf{A}^2.$$

Now, let η and t such that

$$\left\|\eta\sum_{i=1}^{N}\mathbf{X}_i - \sum_{i=1}^{N}\log\mathbb{E}e^{\eta\mathbf{X}_i}\right\| \leq t.$$

Then,

$$\left\|\eta\sum_{i=1}^{N}\mathbf{X}_i\right\| \leq t + \left\|\sum_{i=1}^{N}\log\mathbb{E}e^{\eta\mathbf{X}_i}\right\| \leq t + N\frac{\eta^2}{2(1-\eta R)}\left\|\mathbf{A}^2\right\|$$

and

$$\left\|\frac{1}{N}\sum_{i=1}^{N}\mathbf{X}_i\right\| \leq \frac{t}{N\eta} + \frac{\eta}{2(1-\eta R)}\sigma^2.$$

Moreover,

$$\mathrm{Tr}\left(\mathbb{E}\left[-\eta\sum_{i=1}^{N}\mathbf{X}_i + \sum_{i=1}^{N}\log\mathbb{E}e^{\eta\mathbf{X}_i}\right]\right) \leq \frac{N\eta^2}{2(1-\eta R)}k\sigma^2.$$

Hence,

$$\begin{aligned}\Pr\left[\left\|\frac{1}{N}\sum_{i=1}^{N}\mathbf{X}_i\right\| > \frac{t}{N\eta} + \frac{\eta}{2(1-\eta R)}\sigma^2\right] &\leq \Pr\left[\left\|\eta\sum_{i=1}^{N}\mathbf{X}_i - \sum_{i=1}^{N}\log\mathbb{E}e^{\eta\mathbf{X}_i}\right\| > t\right] \\ &\leq \frac{N\eta^2}{2(1-\eta R)}k\sigma^2(e^t - t - 1)^{-1} \text{from Theorem 3.}\end{aligned}$$

It can easily be checked that $\frac{t}{N\eta} + \frac{\eta}{2(1-\eta R)}\sigma^2$ takes its minimal positive value m at

$$\eta_{\min} = \frac{\sqrt{\frac{2t}{N\sigma^2}}}{1 + R\sqrt{\frac{2t}{N\sigma^2}}} \text{ and that } m = \frac{Rt}{N} + \sqrt{\frac{2\sigma^2 t}{N}}.$$

We have also

$$\frac{\eta_{\min}^2}{1 - R\eta_{\min}} \leq \left(\frac{\eta_{\min}}{1 - R\eta_{\min}}\right)^2 = \frac{2t}{N\sigma^2}$$

which entails the theorem. ■

4. Concentration bounds for Hankel matrices: main results

In this section, we present the main results of the paper. All proofs are reported in Section 5.

Let p be a rational stochastic language over Σ^*, let S be a sample independently drawn according to p, and let $U, V \subseteq \Sigma^*$ be finite set of strings.

4.1 Concentration Bound for the Hankel Matrix $\mathbf{H}_p^{U,V}$

We first describe a bound on $\|\mathbf{H}_S^{U,V} - \mathbf{H}_p^{U,V}\|$, independent from the sizes of U and V.

Let ξ be a random variable distributed according to p, let $\mathbf{Z}(\xi) = \mathbf{H}_{\xi}^{U,V} - \mathbf{H}_p^{U,V}$ be the random matrix defined by $\mathbf{Z}[u,v] = \mathbf{1}_{\xi=uv} - p(uv)$ and let $\mathbf{X}$ be the dilation of $\mathbf{Z}$.

Clearly, $\mathbb{E}\,\mathbf{X} = 0$. In order to apply Theorem 5, it is necessary to compute the parameters b, σ and k. We show in Lemma 14 that $\|\mathbf{X}\| \leq 2$, $\mathbb{E}\,Tr(\mathbf{X}^2) \leq 2S_p^{(2)}$ and $\left\|\mathbb{E}\,\mathbf{X}^2\right\| \leq S_p^{(2)}$ which entails that 4 conditions of Theorem 5 are fulfilled with $b = 2, \sigma^2 = S_p^{(2)}$ and $k = 2$.

Theorem 7 *Let p be a rational stochastic language and let S be a sample of N strings drawn i.i.d. from p. For all $t > 0$,*

$$Pr\left[\left\|\mathbf{H}_S^{U,V} - \mathbf{H}_p^{U,V}\right\| > \sqrt{\frac{2S_p^{(2)}t}{N}} + \frac{2t}{3N}\right] \leq 2t(e^t - t - 1)^{-1}.$$

This bound is independent from U and V. It can be noticed that the proof of Lemma 14 also provides a dimension dependent bound by replacing $S_p^{(2)}$ with $\sum_{(u,v)\in U\times V} p(uv)$, which may result in a significative improvement if U or V are small.

The moment $S_p^{(2)}$ is generally unknown. However, it can be estimated from S. Indeed, $S_p^{(2)} = \sum_{u,v\in\Sigma^*} p(uv) = \sum_{w\in\Sigma^*}(|w|+1)p(w) = \mathbb{E}|\xi|+1$ and $\frac{1}{N}\sum_{w\in S}|w|+1$ is an natural estimate for $S_p^{(2)}$.The random variable $|\xi|$ is sub-exponential and its concentration around its mean can be estimated using Bernstein-type inequalities (see (Vershynin, 2012) for example). Thus, Theorem 7 can easily be reformulated replacing $S_p^{(2)}$ by its estimate.

4.2 Concentration Bound for the smoothed prefix Hankel Matrix $H_{\overline{p}_\eta}^{U,V}$

The random matrix $\overline{\mathbf{Z}}(\xi) = \overline{\mathbf{H}}_\xi^{U,V} - \mathbf{H}_{\overline{p}}^{U,V}$ is defined by $\overline{\mathbf{Z}}[u,v] = \mathbf{1}_{uv\in Pref(\xi)} - \overline{p}(uv)$, where references to U and V are omitted for the sake of readability. It can easily be shown that $\left\|\overline{\mathbf{Z}}\right\|$ may be unbounded if U or V are unbounded. For example, consider the stochastic language defined on a one-letter alphabet $\Sigma = \{a\}$ by $p(a^n) = (1-\rho)\rho^n$. If $U = V = \Sigma^{\leq n}$, $\overline{\mathbf{Z}}$ may be equal to the $(n+1)\times(n+1)$ upper triangular all-ones matrix whose norm is $\Theta(n)$. Hence, Theorem 5 cannot be directly applied to obtain dimension-free bounds. This suggests that the concentration of $\overline{\mathbf{Z}}$ around its mean could be far weaker than the concentration of $\mathbf{Z}$.

For any $\eta \in [0,1]$, we define a smoothed variant[2] of $\overline{p}$ by

$$\overline{p}_\eta(u) \coloneqq \sum_{x\in\Sigma^*} \eta^{|x|} p(ux) = \sum_{n\geq 0} \eta^n p(u\Sigma^n). \tag{4}$$

Note that $\overline{p}_1 = \overline{p}$, $\overline{p}_0 = p$ and that $p(u) \leq \overline{p}_\eta(u) \leq \overline{p}(u)$ for every string u: the functions $\overline{p}_\eta$ are natural intermediates between p and $\overline{p}$.

Any function $\overline{p}_\eta$ can be used to compute p:

$$p(u) = \overline{p}_\eta(u) - \eta\overline{p}_\eta(u\Sigma). \tag{5}$$

Moreover, when p is rational, each $\overline{p}_\eta$ is also rational and a linear representation of p can be derived from any linear representation of $\overline{p}_\eta$. More precisely,

2. Note that our *smoothed variant* can also be interpreted as a *discounted variant* since the parameter η helps to reduce the impact of long strings.

Proposition 8 *Let p be a rational stochastic language, let $\langle I, (\mathbf{M}_x)_{x\in\Sigma}, T\rangle$ be a minimal linear representation of p and let $\overline{T}_\eta = (\mathbf{I}_d - \eta\mathbf{M}_\Sigma)^{-1}T$. Then, $\langle I, (\mathbf{M}_x)_{x\in\Sigma}, \overline{T}_\eta\rangle$ is a linear representation of $\overline{p}_\eta$. Hence, $S_{\overline{p}_\eta}^{(k)} = I^T(\mathbf{I}_d - \mathbf{M}_\Sigma)^{-k}(\mathbf{I}_d - \eta\mathbf{M}_\Sigma)^{-1}T$. In particular, $S_{\overline{p}}^{(k)} = S_p^{(k+1)}$.*

Therefore, it is a consistent learning strategy to learn $\overline{p}_\eta$ from the data, for some η, and next, to derive p. A theoretical study that would guide the choice of the parameter η remains to be done. In the absence of such indications, its value can be set by cross validation.

For any $0 \leq \eta \leq 1$, let $\overline{\mathbf{Z}}_\eta(\xi)$ be the random matrix defined by

$$\overline{\mathbf{Z}}_\eta[u,v] \coloneqq \sum_{x\in\Sigma^*} \eta^{|x|}\mathbf{1}_{\xi=uvx} - \overline{p}_\eta(uv) = \sum_{x\in\Sigma^*} \eta^{|x|}(\mathbf{1}_{\xi=uvx} - p(uvx)).$$

for any $(u,v) \in U\times V$. It is clear that $\mathbb{E}\,\overline{\mathbf{Z}}_\eta = 0$. We show that $\left\|\overline{\mathbf{Z}}_\eta\right\|$ is bounded by $\frac{1}{1-\eta} + S_{\overline{p}_\eta}^{(1)}$ if $\eta < 1$ (Lemma 15), that $\left\|\mathbb{E}\,\overline{\mathbf{X}}_\eta^2\right\| \leq S_{\overline{p}_\eta}^{(2)}$ and $\mathbb{E}\,Tr(\overline{\mathbf{X}}_\eta^2) \leq 2S_{\overline{p}_\eta}^{(2)}$. (Lemma 17).

Therefore, we can apply Theorem 5 with $b = \frac{1}{1-\eta} + S_{\overline{p}_\eta}^{(1)}, \sigma^2 = S_{\overline{p}_\eta}^{(2)}$ and $k = 2$.

Theorem 9 *Let p be a rational stochastic language, let S be a sample of N strings drawn i.i.d. from p and let $0 \leq \eta < 1$. For all $t > 0$,*

$$Pr\left[\left\|\overline{\mathbf{H}}_{\eta,S}^{U,V} - \mathbf{H}_{\overline{p}_\eta}^{U,V}\right\|_2 > \sqrt{\frac{2S_{\overline{p}_\eta}^{(2)}t}{N}} + \frac{t}{3N}\left[\frac{1}{1-\eta} + S_{\overline{p}_\eta}^{(1)}\right]\right] \leq 2t(e^t - t - 1)^{-1}.$$

Remark that when $\eta = 0$ we find back the concentration bound of Theorem 7. When U and V are finite, a careful examination of the proof of Lemma 15 shows that $S_{\overline{p}_\eta}^{(2)}$ can be replaced with $\sum_{(u,v)\in U\times V}\overline{p}_\eta(uv)$, which may provide a significant better bound if U and V are small. Moreover, Inequality 8 can be used to provide a finite bound depending on the sizes of U and V, when $\eta = 1$.

As for Theorem 7, the moment $S_{\overline{p}_\eta}^{(2)}$ is generally unknown but it can be estimated from S, with controled accuracy, providing a reformulation of the theorem that would not depend on this parameter.

4.3 Concentration Bound for the prefix Hankel Matrix $H_{\overline{p}}^{U,V}$

Theorem 9 does not provide a dimension-free bound for the prefix Hankel matrices $\overline{\mathbf{H}}_S^{U,V}$. However, we show that $\overline{\mathbf{Z}}(\xi)$ is a subexponential random matrix (Lemma 21), and that Theorem 6 can be used to provide a bound in this case.

More precisely, let $\mathbf{X}(\xi)$ be the dilation of the matrix $\overline{\mathbf{Z}}(\xi)$, let $C_p > 0$ and $0 < \rho_p < 1$ be such that $p(\Sigma^n) \leq C_p\rho_p^n$ for any integer n.

For any $0 < \beta < -\ln\rho_p$, we show in Lemma 21 the existence of a symmetric matrix $\mathbf{A}^2$ satisfying $\left\|\mathbf{A}^2\right\| \leq K(1-\rho_p e^\beta)^{-1}, \mathrm{Tr}(\mathbf{A}^2) \leq 2K(1-\rho_p e^\beta)^{-2}$and such that for any $k \geq 0$,

$\mathbb{E}\mathbf{X}^k \preccurlyeq \frac{k!}{2} R^{k-2}\mathbf{A}^2$ where $R = e^{1/e}\beta^{-1}$ and $K = 2e^{3/e}\beta^{-3}C_p S_p^{(3)} e^{\beta S_p^{(2)}}$ is a constant that only depends on p and β.

Hence, we can apply Theorem 6 to obtain the following dimension free bound:

Theorem 10 *Let p be a rational stochastic language and let S be a sample of N strings drawn i.i.d. from p. For all $t > 0$,*

$$Pr\left[\left\|\overline{\mathbf{H}}_S^{U,V} - \mathbf{H}_{\overline{p}}^{U,V}\right\|_2 > \frac{e^{1/e}t}{N\beta} + \sqrt{\frac{2\sigma^2 t}{N}}\right] \leq \frac{2}{1-\rho_p e^{\beta}} \cdot t(e^t - t - 1)^{-1}$$

where $\sigma^2 = K(1-\rho_p e^{\beta})^{-2}$, $K = \beta^{-2}C_p S_p^{(3)} e^{\beta S_p^{(2)}}$ and $0 < \beta < -\ln \rho_p$.

Note that β can be set to $1-\rho_p$ but depending on the particular values of the terms, β can be adjusted to obtain better bounds.

Thus, Theorem 10 describes a dimension free concentration bound for the prefix Hankel matrix. However, the constants K and σ that occur in this bound can be very large, which makes it impossible to use it in practical cases, such as those we consider in Section 6.

4.4 Concentration Bound for the smoothed factor Hankel Matrix $H_{\widehat{p}_\eta}^{U,V}$

The random matrix $\widehat{\mathbf{Z}}(\xi) = \widehat{\mathbf{H}}_{\xi}^{U,V} - \mathbf{H}_{\widehat{p}^{U,V}}$ is defined by

$$\widehat{\mathbf{Z}}[u,v] = \sum_{x,y\in\Sigma^*} \mathbf{1}_{\xi=xuvy} - \widehat{p}(uv),$$

where references to U and V are omitted for the sake of readability. $\left\|\widehat{\mathbf{Z}}\right\|$ is unbounded if the support of p is unbounded. Indeed, $\widehat{\mathbf{Z}}[\epsilon,\epsilon] = |\xi| + 1 - \widehat{p}(\epsilon)$. Hence, Theorem 5 cannot be directly applied either.

We can also define smoothed variants $\widehat{p}_\eta$ of $\widehat{p}$, for any $\eta \in [0,1]$ by

$$\widehat{p}_\eta(u) = \sum_{x,y\in\Sigma^*} \eta^{|xy|} p(xuy) = \sum_{m,n\geq 0} \eta^{m+n} p(\Sigma^m u \Sigma^n)$$

which have properties similar to functions $\overline{p}_\eta$:

- $p \leq \widehat{p}_\eta \leq \widehat{p}$, $\widehat{p}_1 = \widehat{p}$ and $\widehat{p}_0 = p$,
- when p is rational, each $\widehat{p}_\eta$ is also rational,
- if $\langle I, (\mathbf{M}_x)_{x\in\Sigma}, T\rangle$ be a minimal linear representation of p then $\langle \widehat{I}_\eta, (\mathbf{M}_x)_{x\in\Sigma}, \overline{T}_\eta\rangle$ is a linear representation of $\hat{p}_\eta$, where $\widehat{I}_\eta = (I_d - \eta\mathbf{M}_\Sigma^{\mathrm{T}})^{-1} I$,
- I and T can be computed from $\widehat{I}_\eta$ and $\widehat{T}_\eta$ when η and $\mathbf{M}_\Sigma$ are known:

$$T = (\mathbf{I}_d - \eta\mathbf{M}_\Sigma)\widehat{T}_\eta, I = (\mathbf{I}_d - \eta\mathbf{M}_\Sigma)\widehat{I}_\eta \text{ and} \tag{6}$$

$$p(u) = \widehat{p}_\eta(u) - \eta\widehat{p}_\eta(u\Sigma) - \eta\widehat{p}_\eta(\Sigma u) + \eta^2\widehat{p}_\eta(\Sigma u\Sigma) \tag{7}$$

- therefore, it is a consistent learning strategy to learn $\widehat{p}_\eta$ from the data, for some η, and next, to derive p.

For $\eta \in [0,1]$, let $\widehat{\mathbf{Z}}_\eta(\xi)$ be the random matrix defined by

$$\widehat{\mathbf{Z}}_\eta[u,v] = \sum_{x,y\in\Sigma^*} \eta^{|xy|}\mathbf{1}_{\xi=xuvy} - \widehat{p}_\eta(uv) = \sum_{x,y\in\Sigma^*} \eta^{|xy|}(\mathbf{1}_{\xi=xuvy} - p(xuvy))$$

for any $(u,v) \in U\times V$. Clearly, $\mathbb{E}\,\widehat{\mathbf{Z}}_\eta = 0$. We show that $\left\|\widehat{\mathbf{Z}}_\eta\right\|$ is bounded by $(1-\eta)^{-2} + S_{\widehat{p}_\eta}^{(1)}$ if $\eta < 1$ (lemma 24).

While $\overline{p}$ is bounded by 1, a property which is often used in the proofs, $\widehat{p}$ is unbounded when η converges to 1. Let us introduce a new constant K_η defined by

$$K_\eta = \begin{cases} 1 & \text{if } \eta \leq e^{-1} \\ (-e\eta\ln\eta)^{-1} & \text{otherwise.} \end{cases}$$

We show in Lemma 26 that

$$\left\|\mathbb{E}\widehat{\mathbf{X}}_\eta^2\right\| \leq K_\eta S_{\widehat{p}_\eta}^{(2)} \text{ and } Tr(\mathbb{E}(\widehat{\mathbf{X}}_\eta^2)) \leq 2K_\eta S_{\widehat{p}_\eta}^{(2)}.$$

Eventually, we can apply Theorem 5 with $b = (1-\eta)^{-2} + S_{\widehat{p}_\eta}^{(1)}, \sigma^2 = K_\eta S_{\widehat{p}_\eta}^{(2)}$ and $k = 2$.

Theorem 11 *Let p be a rational stochastic language, let S be a sample of N strings drawn i.i.d. from p and let $0 \leq \eta < 1$. For all $t > 0$,*

$$Pr\left[\|\widehat{\mathbf{H}}_{\eta,S}^{U,V} - \mathbf{H}_{\widehat{p}_\eta}^{U,V}\|_2 > \sqrt{\frac{2K_\eta S_{\widehat{p}_\eta}^{(2)} t}{N}} + \frac{t}{3N}\left[\frac{1}{(1-\eta)^2} + S_{\widehat{p}_\eta}^{(1)}\right]\right] \leq 2t(e^t - t - 1)^{-1}.$$

Remark that when $\eta = 0$ we find back the concentration bound of Theorem 7. As in the previous cases, $S_{\widehat{p}_\eta}^{(2)}$ can be replaced with $\sum_{(u,v)\in U\times V}\widehat{p}_\eta(uv)$, which may provide a significant better bound if U and V are small. However, it not possible to use these results to obtain a bound, even depending on U and V, when $\eta = 1$.

As for the previous theorems, the moment $S_{\widehat{p}_\eta}^{(2)}$ can be estimated from S in order to provide a reformulation of the theorem that would not depend on this parameter.

4.5 Concentration Bound for the factor Hankel Matrix $H_{\widehat{p}}^{U,V}$

$\widehat{\mathbf{Z}}(\xi)$ is not a subexponential random matrix, and therefore, Theorem 6 cannot be used to provide a bound in this case. This suggests that the concentration of $\widehat{\mathbf{Z}}(\xi)$ around its mean is quite loose.

5. Proofs of all concentration bounds results

In this section, we detail the proofs of all the results stated in Section 4, keeping the titles of all subsections and the notations that have been introduced in the corresponding subsection.

5.1 Concentration Bound for the Hankel Matrix $\mathbf{H}_p^{U,V}$: proofs

Recall that $\mathbf{X}$ is the dilation of the random matrix $\mathbf{Z}(\xi) = \mathbf{H}_\xi^{U,V} - \mathbf{H}_p^{U,V}$.

Clearly, $\mathbb{E}\,\mathbf{X} = 0$. We need technical lemmas in order to obtains bound on $\mathbb{E}\,\mathbf{X}^2$ and $\mathbb{E}\,Tr(\mathbf{X}^2)$ and apply Theorem 5.

Lemma 12 *Let X and Y be two random variables such that $0 \leq X, Y \leq M$. Then,*

$$|\mathbb{E}\,(X - \mathbb{E}\,X)(Y - \mathbb{E}\,Y)| \leq M \min\{\mathbb{E}\,X, \mathbb{E}\,Y\}.$$

Proof Indeed, $0 \leq \mathbb{E}\,XY \leq M \min\{\mathbb{E}\,X, \mathbb{E}\,Y\}$ and $0 \leq \mathbb{E}\,X\mathbb{E}\,Y \leq M \min\{\mathbb{E}\,X, \mathbb{E}\,Y\}$, which entails the lemma. ■

Lemma 13 *For any $u, u' \in U$, $v, v' \in V$,*

$$|\mathbb{E}\,\mathbf{Z}[u,v]\mathbf{Z}[u',v']| \leq \min\{p(uv), p(u'v')\}.$$

Proof This a corollary of Lemma 12 with $X \coloneqq \mathbf{1}_{\xi=uv}$, $Y \coloneqq \mathbf{1}_{\xi=u'v'}$ and $M = 1$. ■

Lemma 14 *$\|\mathbf{X}\| \leq 2$, $\mathbb{E}\,Tr(\mathbf{X}^2) \leq 2S_p^{(2)}$ and $\left\|\mathbb{E}\,\mathbf{X}^2\right\| \leq S_p^{(2)}$.*

Proof

1. $\forall u \in U$, $\sum_{v\in V} |\mathbf{Z}[u,v]| = \sum_{v\in V} |\mathbf{1}_{\xi=uv} - p(uv)| \leq 1 + p(u\Sigma^*) \leq 2$. Therefore, $\|\mathbf{Z}\|_\infty \leq 2$. In a similar way, it can be shown that $\|\mathbf{Z}\|_1 \leq 2$. Hence,

$$\|\mathbf{X}\| = \|\mathbf{Z}\| \leq \sqrt{\|\mathbf{Z}\|_\infty \|\mathbf{Z}\|_1} \leq 2.$$

2. For all $(u,u') \in U^2$: $\mathbf{Z}\mathbf{Z}^T[u,u'] = \sum_{v\in V} \mathbf{Z}[u,v]\mathbf{Z}_{u',v}$. Therefore,

$$\mathbb{E}\,Tr(\mathbf{Z}\mathbf{Z}^T) = \mathbb{E}\sum_{u\in U} \mathbf{Z}\mathbf{Z}^T[u,u] = \mathbb{E}\sum_{u\in U, v\in V} \mathbf{Z}[u,v]\mathbf{Z}[u,v] \leq \sum_{u,v\in\Sigma^*} \mathbb{E}\,\mathbf{Z}[u,v]^2 \leq \sum_{u,v\in\Sigma^*} p(uv) \leq S_p^{(2)}.$$

In a similar way, it can be proved that $\mathbb{E}\,Tr(\mathbf{Z}^T\mathbf{Z}) \leq S_p^{(2)}$. Therefore, $\mathbb{E}\,Tr(\mathbf{X}^2) \leq 2S_p^{(2)}$.

3. For any $u \in U$,

$$\sum_{u'\in U} |\mathbb{E}\,\mathbf{Z}\mathbf{Z}^T[u,u']| \leq \sum_{u'\in U, v\in V} |\mathbb{E}\,\mathbf{Z}[u,v]\mathbf{Z}[u',v]| \leq \sum_{u'\in U, v\in V} p(u'v) \leq S_p^{(2)}.$$

Hence, $\left\|\mathbf{Z}\mathbf{Z}^T\right\|_\infty \leq S_p^{(2)}$. It can be proved, in a similar way, that $\left\|\mathbf{Z}^T\mathbf{Z}\right\|_\infty \leq S_p^{(2)}$, $\left\|\mathbf{Z}\mathbf{Z}^T\right\|_1 \leq S_p^{(2)}$ and $\left\|\mathbf{Z}^T\mathbf{Z}\right\|_1 \leq S_p^{(2)}$. Therefore, $\left\|\mathbf{X}^2\right\| \leq S_p^{(2)}$. ■

5.2 Concentration Bound for the smoothed prefix Hankel Matrix $H_{\overline{p}_\eta}^{U,V}$: proofs

Proof (Proposition 8.)

For every string u, $\overline{p}_\eta(u) = \sum_{n\geq 0} I^T\mathbf{M}_u\eta^n\mathbf{M}_\Sigma^n T = I^T\mathbf{M}_u(\sum_{n\geq 0}\eta^n\mathbf{M}_\Sigma^n)T = I^T\mathbf{M}_u\overline{T}_\eta$. The expression of $S_{\overline{p}_\eta}^{(k)}$ comes directly from Equation 2. ■

Lemma 15 *For any $U, V \subseteq \Sigma^*$,*

$$\left\|\overline{\mathbf{Z}}_\eta\right\| \leq \frac{1}{1-\eta} + S_{\overline{p}_\eta}^{(1)}.$$

Proof Indeed, let $u \in U$.

$$\begin{aligned}\sum_{v\in V} |\overline{\mathbf{Z}}_\eta[u,v]| &\leq \sum_{v,x\in\Sigma^*} \eta^{|x|}\mathbf{1}_{\xi=uvx} + \sum_{v\in\Sigma^*} \overline{p}_\eta(uv)\\ &\leq (1 + \eta + \ldots + \eta^{|\xi|-|u|}) + S_{\overline{p}_\eta}^{(1)}\\ &\leq \frac{1}{1-\eta} + S_{\overline{p}_\eta}^{(1)}.\end{aligned}$$

Hence, $\left\|\overline{\mathbf{Z}}_\eta\right\|_\infty \leq \frac{1}{1-\eta} + S_{\overline{p}_\eta}^{(1)}$. Similarly, $\left\|\overline{\mathbf{Z}}_\eta\right\|_1 \leq \frac{1}{1-\eta} + S_{\overline{p}_\eta}^{(1)}$, which completes the proof. ■

When U and V are bounded, let l be the maximal length of a string in $U \cup V$. It can easily be shown that $\left\|\overline{\mathbf{Z}}_\eta\right\| \leq l + 1 + S_{\overline{p}_\eta}^{(1)}$ and therefore, in that case,

$$\left\|\overline{\mathbf{Z}}_\eta\right\| \leq Min(l+1, \frac{1}{1-\eta}) + S_{\overline{p}_\eta}^{(1)} \tag{8}$$

which holds even if $\eta = 1$.

Lemma 16 *$|\mathbb{E}(\overline{\mathbf{Z}}_\eta[u,v]\overline{\mathbf{Z}}_\eta[u',v'])| \leq \min\{\overline{p}_\eta(uv), \overline{p}_\eta(u'v')\}$, for any $u, u' \in U$ and $v, v' \in V$.*

Proof This a corollary of Lemma 12 with $X \coloneqq \sum_{x\in\Sigma^*} \eta^{|x|}\mathbf{1}_{\xi=uvx}$, $Y \coloneqq \sum_{x\in\Sigma^*} \eta^{|x|}\mathbf{1}_{\xi=u'v'x}$ and $M = 1$. ■

Let $\overline{\mathbf{X}}_\eta$ be the dilation of $\overline{\mathbf{Z}}_\eta$. We can now propose bounds for $\mathbb{E}\,\overline{\mathbf{X}}_\eta^2$ and $\mathbb{E}\,Tr(\overline{\mathbf{X}}_\eta^2)$.

Lemma 17

$$\left\|\mathbb{E}\,\overline{\mathbf{X}}_\eta^2\right\| \leq S_{\overline{p}_\eta}^{(2)} \text{ and } \mathbb{E}\,Tr(\overline{\mathbf{X}}_\eta^2) \leq 2S_{\overline{p}_\eta}^{(2)}.$$

Proof Indeed,

$$\left\|\mathbb{E}\,\overline{\mathbf{Z}}_\eta\overline{\mathbf{Z}}_\eta^T\right\|_\infty \leq \max_{u\in\Sigma^*} \sum_{u',v\in\Sigma^*} |\mathbb{E}\,\overline{\mathbf{Z}}_\eta[u,v]\overline{\mathbf{Z}}_\eta[u',v]| \leq \sum_{u',v} \overline{p}_\eta(u'v) \leq S_{\overline{p}_\eta}^{(2)}.$$

We have also

$$\left\|\mathbb{E}\,\overline{\mathbf{Z}}_\eta\overline{\mathbf{Z}}_\eta^T\right\|_1 \leq S_{\overline{p}_\eta}^{(2)} \text{ and therefore } \left\|\mathbb{E}\,\overline{\mathbf{Z}}_\eta\ \overline{\mathbf{Z}}_\eta^T\right\| \leq S_{\overline{p}_\eta}^{(2)}.$$

Similar computations provide all the inequalities. ■

5.3 Concentration Bound for the prefix Hankel Matrix $H_{\overline{p}}^{U,V}$: proofs

Let $\mathbf{X}(\xi)$ be the dilation of the matrix $\overline{\mathbf{Z}}(\xi)$. It can easily be shown that

$$\mathbf{X}^{2k+1} = \begin{bmatrix} 0 & \left(\overline{\mathbf{Z}}\cdot\overline{\mathbf{Z}}^\top\right)^k\overline{\mathbf{Z}} \\ \overline{\mathbf{Z}}^\top\left(\overline{\mathbf{Z}}\cdot\overline{\mathbf{Z}}^\top\right)^k & 0 \end{bmatrix} \text{ and } \mathbf{X}^{2k} = \begin{bmatrix} \left(\overline{\mathbf{Z}}\cdot\overline{\mathbf{Z}}^\top\right)^k & 0 \\ 0 & \left(\overline{\mathbf{Z}}^\top\cdot\overline{\mathbf{Z}}\right)^k \end{bmatrix}.$$

Let $t \in \Sigma^*$ be a realization of ξ.

Lemma 18 *For any strings $u, v, t \in \Sigma^*$ and any stochastic language p,*

$$\sum_{v\in V}|\overline{\mathbf{Z}}[u,v]| \le |t| + \overline{p}(u\Sigma^*),\ \sum_{u\in U}|\overline{\mathbf{Z}}[u,v]| \le |t| + \overline{p}(\Sigma^* u)$$

and

$$\sum_{u\in U, v\in V}|\overline{\mathbf{Z}}[u,v]| \le \frac{|t|(|t|+3)}{2} + S_p^{(3)}.$$

Proof We have $\sum_{v\in V}|\overline{\mathbf{Z}}[u,v]| \le \sum_{w\in\Sigma^*, uw\in \mathrm{Pref}(t)}|1-\overline{p}(uw)| + \overline{p}(u\Sigma^*)$. Moreover, if $u = w = \epsilon$, $\overline{p}(uw) = 1$. Hence, there are at most $|t|$ strings w such that $uw \in \mathrm{Pref}(t)$ and $|1-\overline{p}(uw)| \neq 0$, which proves the first inequality. The second one is proved in a similar way. A similar argument proves that there are at most $(|t|+1)(|t|+2)/2 - 1 = |t|(|t|+3)/2$ pairs of words u, w such that $uw \in \mathrm{Pref}(t)$ and $|1-\overline{p}(uw)| \neq 0$, which entails the third inequality. ■

Lemma 19 *Let $\mathbf{M}$ be a matrix of the form $(\overline{\mathbf{Z}}^\top)^e(\overline{\mathbf{Z}}\cdot\overline{\mathbf{Z}}^\top)^k\overline{\mathbf{Z}}^f$, where $k \in \mathbb{N}$ and $e, f \in \{0,1\}$. Then, for any strings $u, v \in \Sigma^*$, $|\mathbf{M}[u,v]| \le (|t| + S_p^{(2)})^h$ where $h = e + 2k + f$. Moreover, $\sum_{u\in U}|\mathbf{M}[u,v]|$ and $\sum_{v\in V}|\mathbf{M}[u,v]|$ are bounded by $S_p^{(3)}(|t|+1)(|t|+S_p^{(2)})^h$.*

Proof By induction on $h = e + 2k + f$. The inequality is obvious if $h = 0$. Let $\mathbf{M} = \overline{\mathbf{Z}}\mathbf{N}$.

$$|\mathbf{M}[u,v]| \le \sum_{w\in V}|\overline{\mathbf{Z}}[u,w]\mathbf{N}[w,v]| \le (|t| + S_p^{(2)})^{h-1}\sum_{w\in V}|\overline{\mathbf{Z}}[u,w]| \text{ by induction hypothesis.}$$

By Lemma 18, we have

$$|\mathbf{M}[u,v]| \le (|t| + S_p^{(2)})^h \text{ since } \overline{p}(u\Sigma^*) \le S_p^{(2)}$$

and

$$\sum_{u\in U}|\mathbf{M}[u,v]| \le (|t| + S_p^{(2)})^{h-1}\left(\frac{|t|(|t|+3)}{2} + S_p^{(3)}\right) \le S_p^{(3)}(|t|+1)(|t|+S_p^{(2)})^h$$

since $1 \le S_p^{(3)}$ and $(\frac{|t|(|t|+3)}{2} + 1) \le (|t|+1)(|t|+S_p^{(2)})$.

The other cases are proved in a similar way. ■

Corollary 20 *For any integer k, $\left\|\mathbf{X}^k\right\| \le S_p^{(3)}(|t|+1)(|t|+S_p^{(2)})^k$.*

Proof Indeed, it can easily be shown that for any $k \in \mathbb{N}$ and $e \in \{0,1\}$, $\left\|\mathbf{X}^{2k+e}\right\| = \left\|\left(\overline{\mathbf{Z}}\cdot\overline{\mathbf{Z}}^\top\right)^k\overline{\mathbf{Z}}^e\right\|$. The result is a consequence of Lemma 19. ■

Let $C_p > 0$ and $0 < \rho_p < 1$ be such that $p(\Sigma^n) \le C_p\rho_p^n$.

Let $\mathbf{X}^k(t) = \mathbf{U}_t^\top diag(\lambda_1, \ldots, \lambda_r, 0, \ldots, 0)\mathbf{U}_t$ be an eigenvalue decomposition of $\mathbf{X}^k$, where $\lambda_1, \lambda_2, \ldots, \lambda_r$ are the non zero eigenvalues of $\mathbf{X}^k(t)$, and let $\mathbf{J}_t = diag(1, \ldots, 1, 0, \ldots, 0)$ the matrix whose coefficients are all equal to 0 but the r upper diagonal elements which are equal to 1. We have

$$\mathbf{X}^k \preccurlyeq \mathbf{U}^\top diag(|\lambda_1|, \ldots, |\lambda_r|, 0, \ldots, 0)\mathbf{U} \preccurlyeq \left\|\mathbf{X}_t^k\right\|\mathbf{U}_t^\top\mathbf{J}_t\mathbf{U}_t. \tag{9}$$

For any $n \in \mathbb{N}$, let

$$\mathbf{M}_n = \sum_{t\in\Sigma^n}\frac{p(t)}{p(\Sigma^n)}\mathbf{U}_t^\top\mathbf{J}_t\mathbf{U}_t \text{ if } p(\Sigma^n) \neq 0 \text{ and } \mathbf{M}_n = 0 \text{ otherwise.}$$

We can remark that $\|\mathbf{M}_n\| \le 1$ and $0 \preccurlyeq \mathbf{M}_n$.

Let $\mathbf{A}$ be the symmetric matrix such that

$$\mathbf{A}^2 = K\sum_{n\ge 0}\rho_p^n e^{\beta n}\mathbf{M}_n$$

where $K = 2e^{3/e}\beta^{-3}C_pS_p^{(3)}e^{\beta S_p^{(2)}}$ and $0 < \beta < -\ln\rho_p$. For example, β can be taken equal to $1-\rho_p$.

Since $\rho_p e^\beta < 1$ and $\|\mathbf{M}_n\| \le 1$, $\mathbf{A}$ is well defined. Moreover, $0 \preccurlyeq \mathbf{A}^2$.

Lemma 21 *We have $\left\|\mathbf{A}^2\right\| \le K(1-\rho_p e^\beta)^{-1}, \mathrm{Tr}(\mathbf{A}^2) \le 2K(1-\rho_p e^\beta)^{-2}$ and for any $k \ge 0$, $\mathbb{E}\mathbf{X}^k \preccurlyeq \frac{k!}{2}R^{k-2}\mathbf{A}^2$ where $R = e^{1/e}\beta^{-1}$.*

Proof The bound on $\|\mathbf{A}\|$ is straightforward.

The rank of $\mathbf{X}^k$, equal to the rank of $\mathbf{J}_t$, is bounded by $2(|t|+1)$ and hence, $\mathrm{Tr}(\mathbf{M}_n) \le 2(n+1)$. The bound on $\mathrm{Tr}(\mathbf{A}^2)$ comes from the following classical equality: if $|x| < 1$ then, $\sum_{n\ge 0}(n+1)x^n = (1-x)^{-2}$.

We have

$$\begin{aligned}
\mathbb{E}\mathbf{X}^k &\preccurlyeq \sum_t p(t) S_p^{(3)} (|t|+1)(|t|+S_p^{(2)})^k \mathbf{U}_t^\top \mathbf{J}_t \mathbf{U}_t && \text{from } Eq\ 9 \text{ and } Cor.\ 20 \\
&\preccurlyeq \sum_t p(t) S_p^{(3)} (|t|+S_p^{(2)})^{k+1} \mathbf{U}_t^\top \mathbf{J}_t \mathbf{U}_t && \text{since } S_p^{(2)} \geq 1 \\
&= S_p^{(3)} \sum_{n\geq 0} p(\Sigma^n)(n+S_p^{(2)})^{k+1} \mathbf{M}_n \\
&\preccurlyeq C_p S_p^{(3)} \sum_{n\geq 0} \rho_p^n \frac{[(n+S_p^{(2)})\beta]^{k+1}}{(k+1)!} \frac{(k+1)!}{\beta^{k+1}} \mathbf{M}_n && \text{since } p(\Sigma^n) \leq C_p \rho_p^n \\
&\preccurlyeq C_p S_p^{(3)} \sum_{n\geq 0} \rho_p^n e^{(n+S_p^{(2)})\beta} \frac{(k+1)!}{\beta^{k+1}} \mathbf{M}_n && \text{since } x^k/k! \leq e^x \\
&\preccurlyeq k! \left(\frac{e^{1/e}}{\beta}\right)^k \frac{e^{1/e}}{\beta} C_p S_p^{(3)} e^{S_p^{(2)}\beta} \sum_{n\geq 0} (\rho_p e^\beta)^n \mathbf{M}_n && \text{since } k+1 \leq e^{(k+1)/e} \\
&= \frac{k!}{2} R^{k-2} \mathbf{A}^2.
\end{aligned}$$

■

5.4 Concentration Bound for the smoothed factor Hankel Matrix $H_{\widehat{p}_\eta}^{U,V}$: proofs

Lemma 22 *Let $0 < \eta \leq 1$. For any integer n, $(n+1)\eta^n \leq K_\eta$.*

Proof Let $f(x) = (x+1)\eta^x$. We have $f'(x) = \eta^x(1+(x+1)\ln\eta)$ and f takes its maximum for $x_M = -1 - 1/\ln\eta$, which is positive if and only if $\eta > 1/e$. We have $f(x_M) = (-e\eta\ln\eta)^{-1}$. ■

Lemma 23 *Let $w, u \in \Sigma^*$. Then,*

$$\sum_{x,y\in\Sigma^*} \eta^{|xy|} \mathbf{1}_{w=xuy} \leq K_\eta \text{ and } \widehat{p}(u) \leq K_\eta p(\Sigma^* u \Sigma^*).$$

Proof Indeed, if $w = xuy$, then $|xy| = |w| - |u|$ and u appears at most $|w| - |u| + 1$ times as a factor of w. Therefore, $\sum_{x,y\in\Sigma^*} \eta^{|xy|}\mathbf{1}_{w=xuy} \leq (|w|-|u|+1)\eta^{|w|-|u|} \leq K_\eta$. Moreover,

$$\widehat{p}(u) = \sum_{x,y\in\Sigma^*} \eta^{|xy|} p(xuy) = \sum_{w\in\Sigma^* u \Sigma^*} p(w) \sum_{x,y\in\Sigma^*} \eta^{|xy|} \mathbf{1}_{w=xuvy} \leq K_\eta p(\Sigma^* u \Sigma^*).$$

■

For $\eta \in [0,1]$, let $\widehat{\mathbf{Z}}_\eta(\xi)$ be the random matrix defined by

$$\widehat{\mathbf{Z}}_\eta[u,v] = \sum_{x,y\in\Sigma^*} \eta^{|xy|} \mathbf{1}_{\xi=xuvy} - \widehat{p}_\eta(uv) = \sum_{x,y\epsilon\Sigma^*} \eta^{|xy|} (\mathbf{1}_{\xi=xuvy} - p(xuvy))$$

for any $(u,v) \in U \times V$. Clearly, $\mathbb{E}\,\widehat{\mathbf{Z}}_\eta = 0$. We show below that $\left\|\widehat{\mathbf{Z}}_\eta\right\|$ is bounded if $\eta < 1$.

The moments $S_{\widehat{p}_\eta}^{(k)}$ satisfy $S_{\widehat{p}_\eta}^{(k)} = I^\top (I_d - \eta\mathbf{M}_\Sigma)^{-1}(I_d - \mathbf{M}_\Sigma)^{-k}(I_d - \eta\mathbf{M}_\Sigma)^{-1} T$, $S_{\widehat{p}_0}^{(k)} = S_p^{(k)}$ and $S_{\widehat{p}_1}^{(k)} = S_p^{(k+2)}$.

Lemma 24

$$\left\|\widehat{\mathbf{Z}}_\eta\right\| \leq (1-\eta)^{-2} + S_{\widehat{p}_\eta}^{(1)}.$$

Proof Indeed, for all u,

$$\sum_{v\in V} |\widehat{\mathbf{Z}}_\eta[u,v]| \leq \sum_{v,x,y\in\Sigma^*} [\eta^{|xy|}\mathbf{1}_{\xi=xuvy} + \hat{p}_\eta(uv)] \leq \sum_{x,y\in\Sigma^*} \eta^{|xy|}\mathbf{1}_{\xi\epsilon x\Sigma^* y} + S_{\hat{p}_\eta}^{(1)} \leq (1-\eta)^{-2} + S_{\widehat{p}_\eta}^{(1)}.$$

Hence, $\left\|\widehat{\mathbf{Z}}_\eta\right\|_\infty \leq (1-\eta)^{-2} + S_{\hat{p}_\eta}^{(1)}$. Similarly, $\left\|\overline{\mathbf{Z}}_\eta\right\|_1 \leq (1-\eta)^{-2} + S_{\hat{p}_\eta}^{(1)}$, which completes the proof. ■

Lemma 25 *For any $u, u', v, v' \in \Sigma^*$, $|\mathbb{E}(\widehat{\mathbf{Z}}_\eta[u,v]\widehat{\mathbf{Z}}_\eta[u',v'])| \leq K_\eta \min\{\widehat{p}(uv), \widehat{p}(u'v')\}$.*

Proof This a corollary of Lemmas 12 and 23 with $X \coloneqq \sum_{x,y\in\Sigma^*} \eta^{|xy|}\mathbf{1}_{\xi=xuvy}$, $Y \coloneqq \sum_{x,y\in\Sigma^*} \eta^{|xy|}\mathbf{1}_{\xi=xu'v'y}$ and $M = K_\eta$. ■

Let $\widehat{\mathbf{X}}_\eta$ be the dilation of $\widehat{\mathbf{Z}}_\eta$. We can now propose bounds for $\mathbb{E}\,\widehat{\mathbf{X}}_\eta^2$ and $\mathbb{E}\,Tr(\widehat{\mathbf{X}}_\eta^2)$.

Lemma 26

$$\left\|\mathbb{E}\widehat{\mathbf{X}}_\eta^2\right\| \leq K_\eta S_{\widehat{p}_\eta}^{(2)} \text{ and } Tr(\mathbb{E}(\widehat{\mathbf{X}}_\eta^2)) \leq 2K_\eta S_{\widehat{p}_\eta}^{(2)}.$$

Proof Indeed,

$$||\mathbb{E}(\widehat{\mathbf{Z}}\widehat{\mathbf{Z}}^\top)||_\infty \leq \max_u \sum_{u',v} |\mathbb{E}(\widehat{\mathbf{Z}}_\eta[u,v]\widehat{\mathbf{Z}}_\eta[u',v])| \leq K_\eta \sum_{u',v} \widehat{p}(u'v) \leq K_\eta S_{\widehat{p}_\eta}^{(2)}.$$

We have also

$$||\mathbb{E}(\widehat{\mathbf{Z}}\widehat{\mathbf{Z}}^\top)||_1 \leq K_\eta S_{\widehat{p}_\eta}^{(2)} \text{ and therefore } ||\mathbb{E}(\widehat{\mathbf{Z}}\widehat{\mathbf{Z}}^\top)|| \leq K_\eta S_{\widehat{p}_\eta}^{(2)}.$$

Similar computations provide all inequalities. ■

5.5 The factor Hankel Matrix $H_{\widehat{p}}^{U,V}$ is not subexponential: proof

$\widehat{\mathbf{Z}}(\xi)$ can be not a subexponential random matrix. Let $\Sigma = \{a\}$ be a one-letter alphabet and let p be the rational stochastic language defined by $p(a^n) = 2^{-(n+1)}$. When $\xi = a^n$, $\widehat{\mathbf{H}}_\xi$ is the matrix defined by $\widehat{\mathbf{H}}_\xi[i,j] = n+1-(i+j)$ if $i+j \leq n$ and 0 otherwise. Let $\widehat{\mathbf{H}}_n \in \mathbb{R}^{n\times n}$ be the nonnegative symmetric matrix defined by

$$\widehat{\mathbf{H}}_n = \begin{pmatrix} n & n-1 & \cdots & \cdots & 1 \\ n-1 & n-2 & \cdots & 1 & 0 \\ \vdots & \vdots & \iddots & & \vdots \\ \vdots & 1 & & & \\ 1 & 0 & \cdots & & 0 \end{pmatrix}$$

It can easily be deduced from the definition of a subexponential random matrix that if $\widehat{\mathbf{Z}}(\xi)$ were subexponential then, there would exist constants $C, R > 0$ such that for every integer k,

$$\max_{n\geq 0} 2^{-n}\|\widehat{\mathbf{H}}_n^k\| \leq \|\sum_{n\geq 0} 2^{-n}\widehat{\mathbf{H}}_n^k\| \leq Ck!R^k.$$

Proposition 27 *$\widehat{\mathbf{Z}}(\xi)$ is not subexponential.*

We need the following Lemma.

Lemma 28 *Bo (2000) Let A be a $n \times n$ nonnegative symmetric matrix with positive row sums $d_1, \ldots, d_n$. Then, the spectral radius of A satisfies $\rho(A) \geq n^{-1/2}\sqrt{\sum_{i=1}^n d_i^2}$.*

Proof (of Proposition 27) Lemma 28 applied to the matrix $\widehat{\mathbf{H}}_n$ gives that $\rho(\widehat{\mathbf{H}}_n) = \Omega(n^2)$. Indeed, we have the row sums d_i satisfy $d_i \geq (n+1-i)^2/2$ and $\sum_{i=1}^n d_i^2 = \Theta(n^5)$. Hence, for every integer k, $\|\widehat{\mathbf{H}}_n^k\| \geq n^{2k}$. Now, taking $n = k$, we should have $2^{-k}k^{2k} \leq CR^k k! \leq CR^k k^k$ for every integer k, which is false. ■

6. Experiments

The theoretical bounds described in the previous Sections have been evaluated on the benchmark of PAutomaC (Verwer et al., 2012).

6.1 Presentation of the benchmark

The benchmark of PAutomaC provides samples of strings generated from probabilistic automata and designed to evaluate probabilistic automata learning. We have selected eleven problems from that benchmark, for which the sparsity of the Hankel matrices makes the use of standard SVD algorithms available from `NumPy` or `SciPy` possible. Table 1 provides some information about the selected problems.

- Target models are of different types: non deterministic probabilistic automata (PA), deterministic probabilistic automata (DPA) and hidden Markov models (HMM). Each target is a rational stochastic language. We display the size of the corresponding alphabet, its 2nd and 3rd moments and the spectral radius ρ of $\mathbf{M}_\Sigma$[3], for a minimal representation $\langle I, \mathbf{M}, T\rangle$ of p. We display the number of states of the target automaton and the rank of the corresponding Hankel matrix computed using `NumPy`: the true rank of the target lies between these two values. We also provide constants C_p and ρ_p satisfying $p(\Sigma^n) \leq C_p\rho_p^n$ for any integer n[4].

3. Since the matrices $\mathbf{M}_\Sigma$ corresponding to two minimal representations are similar, the spectral radius ρ only depends on the underlying rational series.
4. From Gelfand's formula, $\|\mathbf{M}_\Sigma^k\|^{1/k}$ converges to ρ when $k \to \infty$. For any k satisfying $\|\mathbf{M}_\Sigma^k\|^{1/k} < 1$, we can take $\rho_p = \|\mathbf{M}_\Sigma^k\|^{1/k}$ and $C_p = \max_{0\leq r<k} \min_{0\leq s\leq r} \|I^T\mathbf{M}^s\| \cdot \|\mathbf{M}^{r-s}T\|$. We have noted in practice that when k increases, ρ_p decreases to ρ while C_p increases very slowly. We have uniformly taken the values computed for $k = 100$.

- Each problem comprises a sample S of strings independently drawn from the target. We provide the cardinal of S, the maximal length and the average length of strings in S.
- The empirical Hankel matrices are built on the prefixes, suffixes or factors of elements of S. We provide their size computed as the product of the number of non null rows by the number of non null columns. Almost all their cells are null: we provide the sparsity ratio.

Table 1: The 11 selected problems. The size of the Hankel matrices matrices is expressed in billions, where 1 g stands for 10^9. Sparsity indicates the ratio of non zero entries in the matrix: for example, there are $5.3 \times 1.9\ 10^4$ non empty cells in $\mathbf{H}_S$ for pb 3.

Figure 1 shows the typical behavior of $S_{\overline{p}_\eta}^{(1)}$ and $S_{\widehat{p}_\eta}^{(1)}$, similar for all the problems.

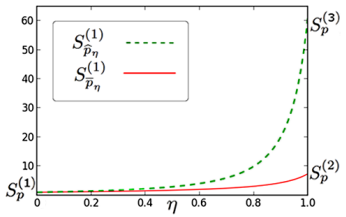

Figure 1: Behavior of $S_{\overline{p}_\eta}^{(1)}$ and $S_{\widehat{p}_\eta}^{(1)}$ for $\eta \in [0;1]$.

6.2 Accuracy of the bounds

For each problem, the exact value of $\|\mathbf{H}_S^{U,V} - \mathbf{H}_p^{U,V}\|_2$ is computed for sets U and V of the form $\Sigma^{\leq l}$, where we have maximized l according to our computing resources. This value is compared to the bounds provided by Theorem 7 and Equation (3), with $\delta = 0.05$ (Table 2). The optimized bound ("opt."), refers to the case where σ^2 has been calculated over $U \times V$ rather than $\Sigma^* \times \Sigma^*$ (see the remark at the end of Section 4.1). Tables 3 and 4 show analog comparisons for the prefix and the factor cases with different values of η. We can remark that our dimension-free bounds are significantly more accurate than the one provided by Equation (3). Similar results have been obtained for all the problems of PautomaC.

We have not reported experimental results based on Theorem 10, as for all the problems we consider, the constant σ is extremely large. For example, on Problem 3, with $\beta = 1 - \rho_p$, and using the parameters of Table 1, we have $\sigma \simeq 5308$, which would provide non significant accuracy values.

6.3 Implication for learning

The theoretical results of the last sections show that $\left\|\mathbf{H}_S^{U,V} - \mathbf{H}^{U,V}\right\|$, and similar expressions for other variants of the Hankel matrices, are bounded by a term that converges to 0 as the size of S increases, and is independent from U and V. This entails that the spectral learning

Table 4: Concentration bounds for $\|\widehat{\mathbf{H}}_S^{U,V} - \mathbf{H}_{\widehat{p},\eta}^{U,V}\|$ (factor case) where $U = V = \Sigma^{\leq l}$ and $\eta = 1/e$.

algorithm is consistent, whatever sets U and V are chosen, as soon as the rank of $\mathbf{H}^{U,V}$ is equal to the rank of the target, and even if we set $U = V = \Sigma^*$. But these concentration bounds give no indication of what should be done in pratical cases.

The spectral learning algorithm first computes the r-first right singular vectors $R_S^{U,V}$ of $\mathbf{H}_S^{U,V}$ and then build a linear representation from $R_S^{U,V}$. Since an exact linear representation of the target can be computed from the r-first right singular vectors $R^{U,V}$ of $\mathbf{H}^{U,V}$, where r is the rank of the target, the distance between the linear spaces spanned by $R_S^{U,V}$ and $R^{U,V}$ seems to be a relevant measure to evaluate the impact on learning of the choice of U and V.

There are several ways to measure the distance between two linear spaces. Most of them are based on the principal angles $\theta_1 \geq \theta_2 \geq \ldots \geq \theta_r$ between them. The largest principal angle θ_1 is a harsh measure since, even if the two spaces coincide along the last $r-1$ principal angles, the distance between the two spaces can be large. We have considered the following measure

$$d(span(R^{U,V}), span(R_S^{U,V})) = 1 - \frac{1}{r}\sum_{i=1}^{r} \cos\theta_i \tag{10}$$

which is equal to 0 if the spaces coincide and 1 if they are completely orthogonal, and which takes into account all the principal angles.

The tables 5 to 9 show the distance between $span(R^{U,V})$ and $span(R_S^{U,V})$ for p, $\overline{p}_{1/2}$, $\overline{p}$, $\widehat{p}_{1/2}$ and $\widehat{p}$, and for matrices having 100 columns and a variable number of rows, from 100 to 20,000 (i.e. $|V| = 100$ and $100 \leq |U| \leq 20,000$).

These tables show that

- the distance between the empirical and true singular vector spaces is smaller for the factor variant than for the prefix variant, and smaller for the prefix variant than for the classical Hankel matrices
- for both the prefix and factor variants, the distance is smaller for $\eta = 1$ than for $\eta = 1/2$ (and $\eta = 0$)
- in most cases, the distance computed for $|U| = 20,000$ is either minimal or not very far from the minimum.

We have run similar experiences for increasing values of $|V|$, from 100 to 20,000. The tables are very similar but the distances systematically increase with V. Table 10 shows the

Table 5: Distance between the spaces spanned by the r first right singular vectors of $\mathbf{H}^{U,V}$ and $\mathbf{H}_S^{U,V}$ for $|V| = 100$ and $100 \leq |U| \leq 20,000$. Entries must be scaled by 10^{-1}.

results for $d(span(\mathbf{H}^{U,V}), span(\mathbf{H}_S^{U,V}))$ computed on problem 3 - the behavior is similar for all the problems and all other variants.

These experiments call for the following recommendations that remain to be confirmed by further theoretical studies.

- use the data to infer first the factor variant of p, rather than the prefix variant or p itself,
- use a small number of columns,
- use as many rows as available, unless a specific information on the domain indicate to bound their number.

7. Conclusion

We have provided dimension-free concentration inequalities for Hankel matrices in the context of spectral learning of rational stochastic languages. These bounds cover 3 cases, each one corresponding to a specific way to exploit the strings under observation, paying attention to the strings themselves, to their prefixes or to their factors. For the last two cases, we introduced parametrized variants which allow a trade-off between the rate of the concentration and the exploitation of the information contained in data.

Experiments on the PAutomaC benchmark show that our dimension-free bounds are quite tight (except the subexponential bound for the prefix variant) and significantly more accurate than the bounds provided by classically used dimension-dependent bounds.

A consequence of these dimension-free inequalities is that the spectral learning algorithm is consistent, even if the whole empirical Hankel matrix is used, suggesting that the choice of relevant sets of rows and columns is maybe not critical. However, they do not provide any indication on what should be done in pratical cases. Experiments indicate that the singular vector spaces computed from the empirical Hankel matrices converge more quickly to the true singular vector spaces for the factor variant of the Hankel matrix - which is consistent with the experiments in (Balle et al., 2014), a small number of columns and a large number of rows. It would be interesting to obtain concentration results which confirm these practice. Another research direction would be to link up the prefix and factor cases to concentration bounds for sum of random tensors and to generalize the results to the case where a fixed number ≥ 1 of factors is considered for each string.

8. Appendix

8.1 Proof of Proposition 1

On a one-letter alphabet, for any non negative rational convergent series r, the series $u \mapsto r(\Sigma^* u \Sigma^*)$ is rational. Indeed, $r(\Sigma^* u \Sigma^*) = r(u\Sigma^*) = \overline{r}(u)$ and $\overline{r}$ is rational. On the other hand, this property may be false as soon as the alphabet contains at least two letters.

Proposition 1 *There exists a rational stochastic language p of rank 1 and built over a two-letter alphabet such that the series $u \mapsto p(\Sigma^* u \Sigma^*)$ is not rational.*

Proof Let $\Sigma = \{a, b\}$ and p be the rational stochastic language defined by $p(u) \coloneqq \alpha^{|u|_a}\beta^{|u|_b}\gamma$ where $\alpha, \beta, \gamma > 0$, $\alpha + \beta + \gamma = 1$ and where $|u|_x$ denotes the number of occurrences of the letter $x \in \Sigma$ in u. We have

$$p(\Sigma^*) = \sum_{u \in \Sigma^*} \alpha^{|u|_a}\beta^{|u|_b}\gamma = \gamma \sum_{n=0}^{\infty} \sum_{m=0}^{n} \binom{n}{m} \alpha^m \beta^{n-m} = \gamma \sum_{n=0}^{\infty} (\alpha+\beta)^n = \frac{\gamma}{1-\alpha-\beta} = 1.$$

Let f be the series defined by $f(u) \coloneqq p(\Sigma^* u \Sigma^*)$. Let us compute $f(a^n)$ for any integer n. Clearly, $f(\varepsilon) = 1$. Let $n \geq 1$. We can write

$$\Sigma^* = \bigcup_{m=0}^{n-1} \{a^m\} \cup a^n\Sigma^* \cup \bigcup_{m=0}^{n-1} a^m b \Sigma^*$$

and

$$\begin{aligned} f(a^n) &= p(a^n\Sigma^*) + \sum_{m=0}^{n-1} p(a^m b \Sigma^* a^n \Sigma^*) \\ &= \alpha^n + \sum_{m=0}^{n-1} \alpha^m \beta p(\Sigma^* a^n \Sigma^*) \\ &= \alpha^n + \frac{1-\alpha^n}{1-\alpha}\beta f(a^n) \end{aligned}$$

and therefore,

$$f(a^n) = (1-\alpha)\frac{\alpha^n}{\gamma + \beta\alpha^n}.$$

Suppose that f is rational. Then, every submatrix of the Hankel matrix of f is of finite rank. In particular, there exists an index k and real coefficients $\lambda_0, \lambda_1, \ldots, \lambda_{k-1}$ such that for any integer p,

$$f(a^{k+p}) = \sum_{i=0}^{k-1} \lambda_i f(a^{i+p})$$

which is equivalent to

$$\sum_{i=0}^{k-1} \lambda_i \alpha^{i-k} \frac{\gamma + \beta\alpha^{k+p}}{\gamma + \beta\alpha^{i+p}} = 1.$$

Let $g(z)$ be the complex function defined by

$$g(z) \coloneqq \left(\sum_{i=0}^{k-1} \mu_i \frac{\delta + \alpha^k z}{\delta + \alpha^i z}\right) - 1$$

where $\delta = \gamma/\beta$ and $\mu_i = \lambda_i \alpha^{i-k}$ for $0 \leq i \leq k-1$.

The function g as poles at $-\delta\alpha^{-i}$ and hence, is analytic on a neighborhood V of 0. Since $g(\alpha^p) = 0$ for any integer p, the principle of permanence shows that g is uniformly equal to 0 on V, i.e.

$$\sum_{i=0}^{k-1} \mu_i (\delta + \alpha^i z)^{-1} = (\delta + \alpha^k z)^{-1}, \forall z \in V.$$

In particular, these two functions and all their derivatives are equal for $z = 0$: we obtain the system

$$\sum_{i=0}^{k-1} \mu_i \alpha^{ih} = \alpha^{kh} \text{ for every } h \geq 0. \tag{11}$$

The Vandermonde matrix

$$\begin{pmatrix} 1 & 1 & 1 & \dots & 1 \\ 1 & \alpha & \alpha^2 & \dots & \alpha^k \\ 1 & \alpha^2 & \alpha^4 & \dots & \alpha^{2k} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & \alpha^k & \alpha^{2k} & \dots & \alpha^{k^2} \end{pmatrix}$$

has a non zero determinant since $\alpha^i \neq \alpha^j$ for $i \neq j$ and therefore, the unique solution of the system $\sum_{i=0}^{k} \mu_i \alpha^{ih} = 0$ for $0 \leq h \leq k$ is $\mu_0 = \mu_1 = \dots = \mu_k = 0$ and the system (11) has no solution. ■

8.2 Proof of Proposition 2

From the definition of $\mathbf{T}_s$, it can easily be shown that the mapping $s \mapsto \mathbf{T}_s$ is a morphism: $\mathbf{T}_{s_1}\mathbf{T}_{s_2}[u,v] = \sum_{w\in\Sigma^*} \mathbf{T}_{s_1}[u,w]\mathbf{T}_{s_2}[w,v] = 1$ iff $v = us_1s_2$ and 0 otherwise.
If $\mathbf{X}$ is a matrix whose rows are indexed by Σ^*, we have $\mathbf{T}_s\mathbf{X}[u,v] = \sum_w \mathbf{T}_s[u,w]\mathbf{X}[w,v] = \mathbf{X}[us,v]$: i.e. the rows of $\mathbf{T}_S\mathbf{X}$ are included in the set of rows of $\mathbf{X}$. Then, it follows from the definition of E that $E^\top\mathbf{T}_s$ is equal to the first row of $\mathbf{T}_s$ (indexed by ϵ) with all coordinates equal to zero except the one indexed by s which equal 1.

Now, from the reduced singular value decomposition of $\mathbf{H} = \mathbf{L}\mathbf{D}\mathbf{R}^\top$ at rank d, $\mathbf{R}$ is a matrix of dimension $\infty \times d$ whose columns form a set of orthonormal vectors - the right singular vectors of $\mathbf{H}$ - such that $\mathbf{R}^\top\mathbf{R} = \mathbf{I}_d$ and $\mathbf{R}\mathbf{R}^\top\mathbf{H}^\top = \mathbf{H}^\top$ ($\mathbf{R}\mathbf{R}^\top$ is the orthogonal projection on the subspace spanned by the rows of $\mathbf{H}$).
One can easily deduce, by a recurrence over n, that for every string $u = x_1 \dots x_n$,

$$(\mathbf{R}^\top\mathbf{T}_{x_1}\mathbf{R}) \circ \dots \circ (\mathbf{R}^\top\mathbf{T}_{x_n}\mathbf{R})\mathbf{R}^\top\mathbf{H}^\top = \mathbf{R}^\top\mathbf{T}_u\mathbf{H}^\top.$$

Indeed, the inequality is trivially true for $n = 0$ since $\mathbf{T}_\epsilon = \mathbf{I}_d$. Then, we have that $\mathbf{R}^\top\mathbf{T}_x\mathbf{R}\mathbf{R}^\top\mathbf{T}_u\mathbf{H}^\top = \mathbf{R}^\top\mathbf{T}_x\mathbf{T}_u\mathbf{H}^\top = \mathbf{R}^\top\mathbf{T}_{xu}\mathbf{H}^\top$ since the columns of $\mathbf{T}_u\mathbf{H}^\top$ are rows of $\mathbf{H}$ and $\mathbf{T}$ is a morphism.

If $P^\top$ is the first row of $\mathbf{H}$ then: $E^\top\mathbf{R}(\mathbf{R}^\top\mathbf{T}_{x_1}\mathbf{R}) \circ \dots \circ (\mathbf{R}^\top\mathbf{T}_{x_n}\mathbf{R})\mathbf{R}^\top P = E^\top\mathbf{T}_u P = r(u)$. Thus, $\langle \mathbf{R}^\top E, (\mathbf{R}^\top\mathbf{T}_x\mathbf{R})_{x\in\Sigma}, \mathbf{R}^\top P\rangle$ is a linear representation of r of dimension d.

8.3 Monotonicity in Stewart formula.

Let us first recall the min – max characterization of singular values derived from the Courant-Fischer Theorem: for any matrix $\mathbf{A} \in \mathbb{R}^{m\times n}$,

$$\sigma_k(\mathbf{A}) = \min_{u_1,..,u_{k-1}\in\mathbb{R}^n} \max_{x\in\mathbb{R}^n, \|x\|=1, x\in[u_1,..,u_{k-1}]^\perp} \|\mathbf{A}x\|.$$

Let $\mathbf{B}$ be the result obtained by replacing all elements in the last column of $\mathbf{A}$ with 0 and let $u_k \in \mathbb{R}^n$ be defined by $u_k[i] = \mathbf{1}_{i=n}$.

$$\begin{aligned}\sigma_k(\mathbf{A}) &\geq \min_{u_1,..,u_{k-1}\in\mathbb{R}^n} \max_{x\in\mathbb{R}^n, \|x\|=1, x\in[u_1,..,u_k]^\perp} \|\mathbf{A}x\| \\ &= \min_{u_1,..,u_{k-1}\in\mathbb{R}^n} \max_{x\in\mathbb{R}^n, \|x\|=1, x\in[u_1,..,u_{k-1}]^\perp} \|\mathbf{B}x\| = \sigma_k(\mathbf{B}).\end{aligned}$$

A similar argument holds if we delete a row of $\mathbf{A}$. Then, it can easily be shown by induction that if $\mathbf{B}$ is obtained by deleting some rows and columns in $\mathbf{A}$, then $\sigma_k(\mathbf{A}) \geq \sigma_k(\mathbf{B})$ (as far as $\sigma_k(\mathbf{B})$ is defined).

Therefore, if $U \subseteq U'$ and $V \subseteq V'$, then $\left\|\mathbf{H}_S^{U\times V} - \mathbf{H}_r^{U\times V}\right\| \leq \left\|\mathbf{H}_S^{U'\times V'} - \mathbf{H}_r^{U'\times V'}\right\|$ and $\sigma_{\min}(\mathbf{H}_r^{U\times V}) \leq \sigma_{\min}(\mathbf{H}_r^{U'\times V'})$.

Abstract

The discovery of causal relationships from purely observational data is a fundamental problem in science. The most elementary form of such a causal discovery problem is to decide whether X causes Y or, alternatively, Y causes X, given joint observations of two variables X, Y. An example is to decide whether altitude causes temperature, or vice versa, given only joint measurements of both variables. Even under the simplifying assumptions of no confounding, no feedback loops, and no selection bias, such bivariate causal discovery problems are challenging. Nevertheless, several approaches for addressing those problems have been proposed in recent years. We review two families of such methods: methods based on Additive Noise Models (ANMs) and Information Geometric Causal Inference (IGCI). We present the benchmark CauseEffectPairs that consists of data for 100 different cause-effect pairs selected from 37 data sets from various domains (e.g., meteorology, biology, medicine, engineering, economy, etc.) and motivate our decisions regarding the "ground truth" causal directions of all pairs. We evaluate the performance of several bivariate causal discovery methods on these real-world benchmark data and in addition on artificially simulated data. Our empirical results on real-world data indicate that certain methods are indeed able to distinguish cause from effect using only purely observational data, although more benchmark data would be needed to obtain statistically significant conclusions. One of the best performing methods overall is the method based on Additive Noise Models that has originally been proposed by Hoyer et al. (2009), which obtains an accuracy of 63 ± 10 % and an AUC of 0.74 ± 0.05 on the real-world benchmark. As the main theoretical contribution of this work we prove the consistency of that method.

Keywords: Causal discovery, additive noise, information-geometric causal inference, cause-effect pairs, benchmarks

1. Introduction

An advantage of having knowledge about causal relationships rather than statistical associations is that the former enables prediction of the effects of actions that perturb the observed system. Knowledge of cause and effect can also have implications on the applicability of semi-supervised learning and covariate shift adaptation (Schölkopf et al., 2012). While the gold standard for identifying causal relationships is controlled experimentation, in many cases, the required experiments are too expensive, unethical, or technically impossible to perform. The development of methods to identify causal relationships from purely observational data therefore constitutes an important field of research.

An observed statistical dependence between two variables X, Y can be explained by a causal influence from X to Y, a causal influence from Y to X, a possibly unobserved common cause that influences both X and Y ("confounding", see e.g., Pearl, 2000), a possibly unobserved common effect of X and Y that is conditioned upon in data acquisition ("selection bias", see e.g., Pearl, 2000), or combinations of these. Most state-of-the-art causal discovery algorithms that attempt to distinguish these cases based on observational data require that X and Y are part of a larger set of observed random variables influencing each other. For example, in that case, and under a genericity condition called "faithfulness", conditional independences between subsets of observed variables allow one to draw partial conclusions regarding their causal relationships (Spirtes et al., 2000; Pearl, 2000; Richardson and Spirtes, 2002; Zhang, 2008).

In this article, we focus on the *bivariate* case, assuming that only two variables, say X and Y, have been observed. We simplify the causal discovery problem considerably by assuming no confounding, no selection bias and no feedback. We study how to distinguish X causing Y from Y causing X using only purely observational data, i.e., a finite i.i.d. sample drawn from the joint distribution $\mathbb{P}_{X,Y}$.[1] As an example, consider the data visualized in Figure 1. The question is: does X cause Y, or does Y cause X? The true answer is "X causes Y", as here X is the altitude of weather stations and Y is the mean temperature measured at these weather stations (both in arbitrary units). In the absence of knowledge about the measurement procedures that the variables correspond with, one can try to exploit the subtle statistical patterns in the data in order to find the causal direction. This challenge of distinguishing cause from effect using only observational data has attracted increasing interest recently (Mooij and Janzing, 2010; Guyon et al., 2010, 2016). Approaches to causal discovery based on conditional independences do not work here, as X and Y are typically dependent, and there are no other observed variables to condition on.

1. We denote probability distributions by $\mathbb{P}$ and probability densities (typically with respect to Lebesgue measure on $\mathbb{R}^d$) by p.

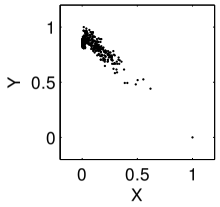

Figure 1: Example of a bivariate causal discovery task: decide whether X causes Y, or Y causes X, using only the observed data (visualized here as a scatter plot).

A variety of causal discovery methods has been proposed in recent years (Friedman and Nachman, 2000; Kano and Shimizu, 2003; Shimizu et al., 2006; Sun et al., 2006, 2008; Hoyer et al., 2009; Mooij et al., 2009; Zhang and Hyvärinen, 2009; Janzing et al., 2010; Mooij et al., 2010; Daniušis et al., 2010; Mooij et al., 2011; Shimizu et al., 2011; Janzing et al., 2012; Hyvärinen and Smith, 2013; Peters and Bühlmann, 2014; Kpotufe et al., 2014; Nowzohour and Bühlmann, 2015; Sgouritsa et al., 2015) that were claimed to be able to solve this task under certain assumptions. All these approaches exploit the *complexity* of the marginal and conditional probability distributions, in one way or the other. On an intuitive level, the idea is that the factorization of the joint density $p_{C,E}(c,e)$ of cause C and effect E into $p_C(c)p_{E\,|\,C}(e\,|\,c)$ typically yields models of lower total complexity than the alternative factorization into $p_E(e)p_{C\,|\,E}(c\,|\,e)$. Although this idea is intuitively appealing, it is not clear how to define complexity. If "complexity" and "information" are measured by Kolmogorov complexity and algorithmic information, respectively (Janzing and Schölkopf, 2010; Lemeire and Janzing, 2013), one can show that the statement "p_C contains no information about $p_{E\,|\,C}$" implies that the sum of the complexities of p_C and $p_{E\,|\,C}$ cannot be greater than the sum of the complexities of p_E and $p_{C\,|\,E}$. Some approaches, instead, define certain classes of "simple" conditionals, e.g., Additive Noise Models (Hoyer et al., 2009) and second-order exponential models (Sun et al., 2006; Janzing et al., 2009), and infer X to be the cause of Y whenever $\mathbb{P}_{Y\,|\,X}$ is from this class (and $\mathbb{P}_{X\,|\,Y}$ is not). Another approach that employs complexity in a more implicit way postulates that $\mathbb{P}_C$ contains no information about $\mathbb{P}_{E\,|\,C}$ (Janzing et al., 2012).

Despite the large number of methods for bivariate causal discovery that has been proposed over the last few years, their practical performance has not been studied very systematically, although some domain-specific studies have been performed (Smith et al., 2011; Statnikov et al., 2012). The present work attempts to address this by presenting benchmark data and reporting extensive empirical results on the performance of various bivariate causal discovery methods. Our main contributions are fourfold:

- We review two families of bivariate causal discovery methods, methods based on *Additive Noise Models (ANMs)* (originally proposed by Hoyer et al., 2009), and *Information Geometric Causal Inference (IGCI)* (originally proposed by Daniušis et al., 2010).

- We present a detailed description of the benchmark CauseEffectPairs that we collected over the years for the purpose of evaluating bivariate causal discovery methods. It currently consists of data for 100 different cause-effect pairs selected from 37 data sets from various domains (e.g., meteorology, biology, medicine, engineering, economy, etc.).

- We report the results of extensive empirical evaluations of the performance of several members of the ANM and IGCI families, both on artificially simulated data as well as on the CauseEffectPairs benchmark.

- We prove the consistency of the original implementation of ANM that was proposed by Hoyer et al. (2009).

The CauseEffectPairs benchmark data are provided on our website (Mooij et al., 2014). The synthetic benchmark data are provided as an online appendix for reproducibility purposes. In addition, all the code (including the code to run the experiments and create the figures) is provided both as an online appendix and on the first author's homepage[2] under an open source license to allow others to reproduce and build on our work.

The structure of this article is somewhat unconventional, as it partially consists of a review of existing methods, but it also contains new theoretical and empirical results. We will start in the next subsection by giving a more rigorous definition of the causal discovery task we consider in this article. In Section 2 we give a review of ANM, an approach based on the assumed additivity of the noise, and describe various ways of implementing this idea for bivariate causal discovery. In Appendix A we provide a proof for the consistency of the original ANM implementation that was proposed by Hoyer et al. (2009). In Section 3, we review IGCI, a method that exploits the independence of the distribution of the cause and the functional relationship between cause and effect. This method is designed for the deterministic (noise-free) case, but has been reported to work on noisy data as well. Section 4 gives more details on the experiments that we have performed, the results of which are reported in Section 5. Appendix D describes the CauseEffectPairs benchmark data set that we used for assessing the accuracy of various methods. We conclude in Section 6.

1.1 Problem Setting

In this subsection, we formulate the problem of interest central to this work. We tried to make this section as self-contained as possible and hope that it also appeals to readers who are not familiar with the terminology in the field of causality. For more details, we refer the reader to Pearl (2000).

Suppose that X, Y are two random variables with joint distribution $\mathbb{P}_{X,Y}$. This observational distribution corresponds to measurements of X and Y in an experiment in which X and Y are both (passively) observed. If an external intervention (i.e., from outside the system under consideration) changes some aspect of the system, then in general, this may lead to a change in the joint distribution of X and Y. In particular, we will consider a

2. http://www.jorismooij.nl/

perfect intervention[3] "do(x)" (or more explicitly: "do($X = x$)") that forces the variable X to have the value x, and leaves the rest of the system untouched. We denote the resulting interventional distribution of Y as $\mathbb{P}_{Y\,|\,\mathrm{do}(x)}$, a notation inspired by Pearl (2000). This interventional distribution corresponds to the distribution of Y in an experiment in which X has been set to the value x by the experimenter, after which Y is measured. Similarly, we may consider a perfect intervention do(y) that forces Y to have the value y, leading to the interventional distribution $\mathbb{P}_{X\,|\,\mathrm{do}(y)}$ of X.

For example, X and Y could be binary variables corresponding to whether the battery of a car is empty, and whether the start engine of the car is broken. Measuring these variables in many cars, we get an estimate of the joint distribution $\mathbb{P}_{X,Y}$. The marginal distribution $\mathbb{P}_X$, which only considers the distribution of X, can be obtained by integrating the joint distribution over Y. The conditional distribution $\mathbb{P}_{X\,|\,Y=0}$ corresponds with the distribution of X for the cars with a broken start engine (i.e., those cars for which we observe that $Y = 0$). The interventional distribution $\mathbb{P}_{X\,|\,\mathrm{do}(Y=0)}$, on the other hand, corresponds with the distribution of X after destroying the start engines of all cars (i.e., after actively setting $Y = 0$). Note that the distributions $\mathbb{P}_X, \mathbb{P}_{X\,|\,Y=0}, \mathbb{P}_{X\,|\,\mathrm{do}(Y=0)}$ may all be different.

In the absence of selection bias, we define:[4]

Definition 1 *We say that X **causes** Y if $\mathbb{P}_{Y\,|\,\mathrm{do}(x)} \neq \mathbb{P}_{Y\,|\,\mathrm{do}(x')}$ for some x, x'.*

Causal relations can be *cyclic*, i.e., X causes Y and Y also causes X. For example, an increase of the global temperature causes sea ice to melt, which causes the temperature to rise further (because ice reflects more sun light).

In the context of multiple variables $X_1, \ldots, X_p$ with $p \geq 2$, we define *direct* causation in the absence of selection bias as follows:

Definition 2 *X_i is a **direct cause** of X_j with respect to $X_1, \ldots, X_p$ if*

$$\mathbb{P}_{X_j\,|\,\mathrm{do}(X_i=x, \boldsymbol{X}_{\setminus ij}=\boldsymbol{c})} \neq \mathbb{P}_{X_j\,|\,\mathrm{do}(X_i=x', \boldsymbol{X}_{\setminus ij}=\boldsymbol{c})}$$

for some x, x' and some $\boldsymbol{c}$, where $\boldsymbol{X}_{\setminus ij} := X_{\{1,\ldots,p\}\setminus\{i,j\}}$ are all other variables besides X_i, X_j.

In words: X is a direct cause of Y with respect to a set of variables under consideration if Y depends on the value we force X to have in a perfect intervention, while fixing all other variables. The intuition is that a direct causal relation of X on Y is not mediated via the other variables. The more variables one considers, the harder it becomes experimentally to distinguish direct from indirect causation, as one has to keep more variables fixed.[5]

We may visualize direct causal relations in a *causal graph*:

3. Different types of "imperfect" interventions can be considered as well, see e.g., Eberhardt and Scheines (2007); Eaton and Murphy (2007); Mooij and Heskes (2013). In this paper we only consider perfect interventions.
4. In the presence of selection bias, one has to be careful when linking causal relations to interventional distributions. Indeed, if one would (incorrectly) apply Definition 1 to the conditional interventional distributions $\mathbb{P}_{Y\,|\,\mathrm{do}(X=x),S=s}$ instead of to the unconditional interventional distributions $\mathbb{P}_{Y\,|\,\mathrm{do}(X=x)}$ (e.g., because one is not aware of the fact that the data has been conditioned on S), one may obtain incorrect conclusions regarding causal relations.
5. For the special case $p = 2$ that is of interest in this work, we do not need to distinguish indirect from direct causality, as they are equivalent in that special case. However, we introduce this concept in order to define causal graphs on more than two variables, which we use to explain the concepts of confounding and selection bias.

Definition 3 *The **causal graph** $\mathcal{G}$ has variables $X_1, \ldots, X_p$ as nodes, and a directed edge from X_i to X_j if and only if X_i is a direct cause of X_j with respect to $X_1, \ldots, X_p$.*

Note that this definition allows for cyclic causal relations. In contrast with the typical assumption in the causal discovery literature, we do not assume here that the causal graph is necessarily a Directed Acyclic Graph (DAG).

If X causes Y, we generically have that $\mathbb{P}_{Y\,|\,\mathrm{do}(x)} \neq \mathbb{P}_Y$. Figure 2 illustrates how various causal relationships between X and Y (and at most one other variable) generically give rise to different (in)equalities between marginal, conditional, and interventional distributions involving X and Y. Note that the list of possibilities in Figure 2 is not exhaustive, as (i) feedback relationships with a latent variable were not considered; (ii) combinations of the cases shown are possible as well, e.g., (d) can be considered to be the combination of (a) and (b), and both (e) and (f) can be combined with all other cases; (iii) more than one latent variable could be present.

Returning to the example of the empty batteries (X) and broken start engines (Y), it seems reasonable to assume that these two variables are not causally related and case (c) in Figure 2 would apply, and therefore X and Y must be statistically independent.

In order to illustrate case (f), let us introduce a third binary variable, S, which measures whether the car starts or not. If the data acquisition is done by a car mechanic who only considers cars that do not start ($S = 0$), then we are in case (f): conditioning on the common effect S of X and Y leads to selection bias, i.e., X and Y are statistically dependent when conditioning on S (even though they are not directly causally related). Indeed, if we know that a car doesn't start, then learning that the battery is not empty makes it much more likely that the start engine is broken.

Another way in which two variables that are not directly causally related can still be statistically dependent is case (e), i.e., if they have a common cause. As an example, take for X the number of stork breeding pairs (per year) and for Y the number of human births (per year) in a country. Data has been collected for different countries and shows a significant correlation between X and Y (Matthews, 2000). Few people nowadays believe that storks deliver babies, or the other way around, and therefore it seems reasonable to assume that X and Y are not directly causally related. One obvious confounder (Z in Figure 2e) that may explain the observed dependence between X and Y is land area.

When data from all (observational and interventional) distributions are available, it becomes straightforward in principle to distinguish the six cases in Figure 2 simply by checking which (in)equalities in Figure 2 hold. In practice, however, we often only have data from the observational distribution $\mathbb{P}_{X,Y}$ (for example, because intervening on stork population or human birth rate is impractical). Can we then still infer the causal relationship between X and Y? If, under certain assumptions, we can decide upon the causal direction, we say that the causal direction is *identifiable* from the observational distribution (and our assumptions).

In this work, we will simplify matters considerably by considering only (a) and (b) in Figure 2 as possibilities. In other words, we assume that X and Y are dependent (i.e.,

6. Here, we assume that the intervention is performed *before* the conditioning. Since conditioning and intervening do not commute in general, one has to be careful when modeling causal processes in the presence of selection bias to take into account the actual ordering of these events.

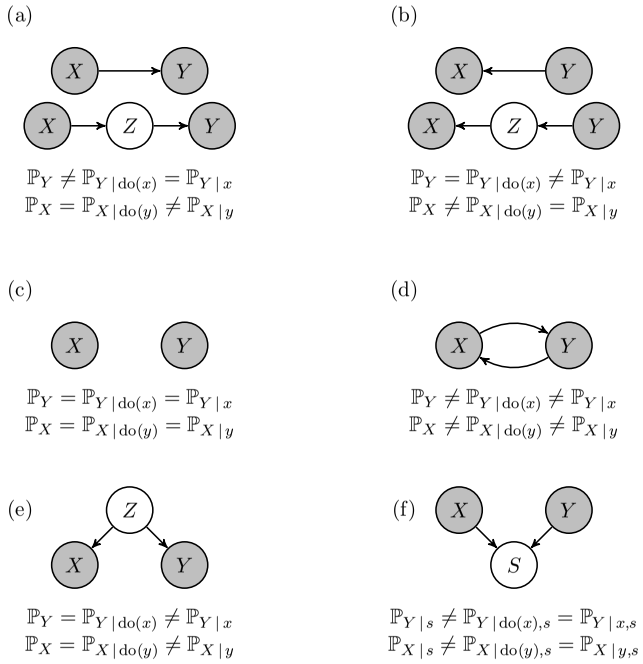

Figure 2: Several possible causal relationships between two observed variables X, Y and a single latent variable: (a) X causes Y; (b) Y causes X; (c) X, Y are not causally related; (d) feedback relationship, i.e., X causes Y and Y causes X; (e) a hidden confounder Z explains the observed dependence; (f) conditioning on a hidden selection variable S explains the observed dependence.[6] We used shorthand notation regarding quantifiers: equalities are generally valid, inequalities not necessarily. For example, "$\mathbb{P}_X = \mathbb{P}_{X\,|\,y}$" means "$\forall y : \mathbb{P}_X = \mathbb{P}_{X\,|\,y}$", whereas "$\mathbb{P}_X \neq \mathbb{P}_{X\,|\,y}$" means "$\exists y : \mathbb{P}_X \neq \mathbb{P}_{X\,|\,y}$". In all situations except (c), X and Y are (generically) dependent, i.e., $\mathbb{P}_{X,Y} \neq \mathbb{P}_X \mathbb{P}_Y$. The basic task we consider in this article is deciding between (a) and (b), using only data from $\mathbb{P}_{X,Y}$.

$\mathbb{P}_{X,Y} \neq \mathbb{P}_X \mathbb{P}_Y$), there is no confounding (common cause of X and Y), no selection bias (common effect of X and Y that is implicitly conditioned on), and no feedback between X and Y (a two-way causal relationship between X and Y). Inferring the causal direction between X and Y, i.e., deciding which of the two cases (a) and (b) holds, using *only the observational distribution* $\mathbb{P}_{X,Y}$ is the challenging task that we consider in this work.[7]

7. Note that this is a different question from the one often faced in problems in epidemiology, economics and other disciplines where causal considerations play an important role. There, the causal direction is often known *a priori*, i.e., one can exclude case (b), but the challenge is to distinguish case (a) from case (e) or

2. Additive Noise Models

In this section, we review a family of causal discovery methods that exploits *additivity* of the noise. We only consider the bivariate case here. More details and extensions to the multivariate case can be found in Hoyer et al. (2009); Peters et al. (2014).

2.1 Theory

There is an extensive body of literature on causal modeling and causal discovery that assumes that effects are linear functions of their causes plus independent, Gaussian noise. These models are known as *Structural Equation Models* (SEM) (Wright, 1921; Bollen, 1989) and are popular in econometrics, sociology, psychology and other fields. Although the assumptions of linearity and Gaussianity are mathematically convenient, they are not always realistic. More generally, one can define *Functional Models*, also known as *Structural Causal Models* (SCM) or *Non-Parametric Structural Equation Models* (NP-SEM), in which effects are modeled as (possibly nonlinear) functions of their causes and latent noise variables (Pearl, 2000).

2.1.1 Bivariate Structural Causal Models

In general, if $Y \in \mathbb{R}$ is a direct effect of a cause $X \in \mathbb{R}$ and m latent causes $\boldsymbol{U} = (U_1, \ldots, U_m) \in \mathbb{R}^m$, then it is intuitively reasonable to model this relationship as

$$\begin{cases} Y = f(X, U_1, \ldots, U_m), \\ X \perp\!\!\!\perp \boldsymbol{U}, \quad X \sim p_X(x), \quad \boldsymbol{U} \sim p_{\boldsymbol{U}}(u_1, \ldots, u_m), \end{cases} \tag{1}$$

where $f : \mathbb{R} \times \mathbb{R}^m \to \mathbb{R}$ is a possibly nonlinear function (measurable with respect to the Borel sets of $\mathbb{R} \times \mathbb{R}^m$ and $\mathbb{R}$), and $p_X(x)$ and $p_{\boldsymbol{U}}(u_1, \ldots, u_m)$ are the joint densities of the observed cause X and latent causes $\boldsymbol{U}$ (with respect to Lebesgue measure on $\mathbb{R}$ and $\mathbb{R}^m$, respectively). The assumption that X and $\boldsymbol{U}$ are independent ("$X \perp\!\!\!\perp \boldsymbol{U}$") is justified by the assumption that there is no confounding, no selection bias, and no feedback between X and Y.[8] We will denote the observational distribution corresponding to (1) by $\mathbb{P}^{(1)}_{X,Y}$. By making use of the semantics of SCMs (Pearl, 2000), (1) also induces interventional distributions $\mathbb{P}^{(1)}_{X\,|\,\mathrm{do}(y)} = \mathbb{P}^{(1)}_X$ and $\mathbb{P}^{(1)}_{Y\,|\,\mathrm{do}(x)} = \mathbb{P}^{(1)}_{Y\,|\,x}$.

As the latent causes $\boldsymbol{U}$ are unobserved anyway, we can summarize their influence by a single "effective" *noise* variable $E_Y \in \mathbb{R}$ (also known as "disturbance term"):

$$\begin{cases} Y = f_Y(X, E_Y) \\ X \perp\!\!\!\perp E_Y, \quad X \sim p_X(x), \quad E_Y \sim p_{E_Y}(e_Y). \end{cases} \tag{2}$$

This simpler model can be constructed in such a way that it induces the same (observational and interventional) distributions as (1):

a combination of both. Even though our empirical results indicate that some methods for distinguishing case (a) from case (b) still perform reasonably well when their assumption of no confounding is violated by adding a latent confounder as in (e), we do not claim that these methods can be used to distinguish case (e) from case (a).

8. Another assumption that we have made here is that there is no *measurement noise*, i.e., noise added by the measurement apparatus. Measurement noise would mean that instead of measuring X itself, we observe a noisy version $\tilde{X}$, but Y is still a function of X, the (latent) variable X that is not corrupted by measurement noise.

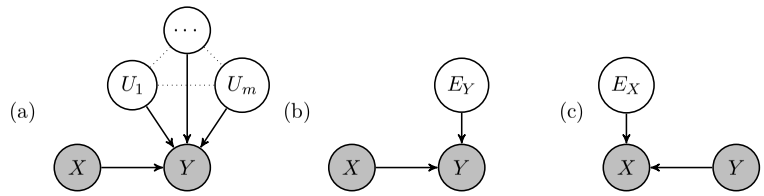

Figure 3: Causal graphs of Structural Causal Models (1), (2) and (3), respectively. (a) and (b) are interventionally equivalent, (b) and (c) are only observationally equivalent in general.

Proposition 4 *Given a model of the form (1) for which the observational distribution has a positive density with respect to Lebesgue measure, there exists a model of the form (2) that is* ***interventionally equivalent****, i.e., it induces the same observational distribution* $\mathbb{P}_{X,Y}$ *and the same interventional distributions* $\mathbb{P}_{X\,|\,\mathrm{do}(y)}$, $\mathbb{P}_{Y\,|\,\mathrm{do}(x)}$.

Proof Denote by $\mathbb{P}^{(1)}_{X,Y}$ the observational distribution induced by model (1). One possible way to construct E_Y and f_Y is to define the conditional cumulative density function $F_{Y\,|\,x}(y) := \mathbb{P}^{(1)}(Y \leq y\,|\,X = x)$ and its inverse with respect to y for fixed x, $F^{-1}_{Y\,|\,x}$. Then, one can define E_Y as the random variable

$$E_Y := F_{Y\,|\,X}(Y),$$

(where now the fixed value x is substituted with the random variable X) and the function f_Y by[9]

$$f_Y(x, e) := F^{-1}_{Y\,|\,x}(e).$$

Now consider the change-of-variables $(X, Y) \mapsto (X, E_Y)$. The corresponding joint densities transform as

$$p^{(1)}_{X,Y}(x, y) = p_{X,E_Y}\left(x, F_{Y\,|\,x}(y)\right)\left|\frac{\partial F_{Y\,|\,x}}{\partial y}(x, y)\right| = p_{X,E_Y}\left(x, F_{Y\,|\,x}(y)\right)p^{(1)}_{Y\,|\,X}(y\,|\,x),$$

and therefore

$$p^{(1)}_X(x) = p_{X,E_Y}\left(x, F_{Y\,|\,x}(y)\right)$$

for all x, y. This implies that $E_Y \perp\!\!\!\perp X$ and that $p_{E_Y} = \mathbf{1}_{(0,1)}$.

This establishes that $\mathbb{P}^{(2)}_{X,Y} = \mathbb{P}^{(1)}_{X,Y}$. The identity of the interventional distributions follows directly, because

$$\mathbb{P}^{(1)}_{X\,|\,\mathrm{do}(y)} = \mathbb{P}^{(1)}_X = \mathbb{P}^{(2)}_X = \mathbb{P}^{(2)}_{X\,|\,\mathrm{do}(y)}$$

and

$$\mathbb{P}^{(1)}_{Y\,|\,\mathrm{do}(x)} = \mathbb{P}^{(1)}_{Y\,|\,x} = \mathbb{P}^{(2)}_{Y\,|\,x} = \mathbb{P}^{(2)}_{Y\,|\,\mathrm{do}(x)}.$$

■

9. Note that we denote probability densities with the symbol p, so we can safely use the symbol f for a function without risking any confusion.

A similar construction of an effective noise variable can be performed in the other direction as well, at least to obtain a model that induces the same observational distribution. More precisely, we can construct a function f_X and a random variable E_X such that

$$\begin{cases} X = f_X(Y, E_X) \\ Y \perp\!\!\!\perp E_X, \quad Y \sim p_Y(y), \quad E_X \sim p_{E_X}(e_X) \end{cases} \tag{3}$$

induces the same observational distribution $\mathbb{P}^{(3)}_{X,Y} = \mathbb{P}^{(2)}_{X,Y}$ as (2) and the original (1). A well-known example is the linear-Gaussian case:

Example 1 *Let*

$$\begin{cases} Y = \alpha X + E_Y & X \sim \mathcal{N}(\mu_X, \sigma^2_X) \\ E_Y \perp\!\!\!\perp X & E_Y \sim \mathcal{N}(\mu_{E_Y}, \sigma^2_{E_Y}). \end{cases}$$

The model

$$\begin{cases} X = \beta Y + E_X & Y \sim \mathcal{N}(\mu_Y, \sigma^2_Y) \\ E_X \perp\!\!\!\perp Y & E_X \sim \mathcal{N}(\mu_{E_X}, \sigma^2_{E_X}) \end{cases}$$

with

$$\beta = \frac{\alpha\sigma^2_X}{\alpha^2\sigma^2_X + \sigma^2_{E_Y}},$$
$$\mu_Y = \alpha\mu_X + \mu_{E_Y}, \quad \sigma^2_Y = \alpha^2\sigma^2_X + \sigma^2_{E_Y},$$
$$\mu_{E_X} = (1 - \alpha\beta)\mu_X - \beta\mu_{E_Y}, \quad \sigma^2_{E_X} = (1 - \alpha\beta)^2\sigma^2_X + \beta^2\sigma^2_{E_Y}$$

induces the same joint distribution on X, Y.

However, in general the interventional distributions induced by (3) will be different from those of (2) and the original model (1). For example, in general

$$\mathbb{P}^{(3)}_{X\,|\,\mathrm{do}(y)} = \mathbb{P}^{(3)}_{X\,|\,y} = \mathbb{P}^{(2)}_{X\,|\,y} \neq \mathbb{P}^{(2)}_X = \mathbb{P}^{(2)}_{X\,|\,\mathrm{do}(y)}.$$

This means that whenever we can model an observational distribution $\mathbb{P}_{X,Y}$ with a model of the form (3), we can also model it using (2), and therefore the causal relationship between X and Y is not identifiable from the observational distribution without making additional assumptions. In other words: (1) and (2) are interventionally equivalent, but (2) and (3) are only observationally equivalent. Without having access to the interventional distributions, this symmetry prevents us from drawing any conclusions regarding the direction of the causal relationship between X and Y if we only have access to the observational distribution $\mathbb{P}_{X,Y}$.

2.1.2 Breaking the Symmetry

By *restricting* the models (2) and (3) to have lower complexity, asymmetries can be introduced. The work of Kano and Shimizu (2003); Shimizu et al. (2006) showed that for *linear* models (i.e., where the functions f_X and f_Y are restricted to be linear), *non-Gaussianity* of the input and noise distributions actually allows one to distinguish the directionality of such functional models. Peters and Bühlmann (2014) recently proved that for linear

models, Gaussian noise variables with *equal variances* also lead to identifiability. For high-dimensional variables, the structure of the covariance matrices can be exploited to achieve asymmetries (Janzing et al., 2010; Zscheischler et al., 2011).

Hoyer et al. (2009) showed that also *nonlinearity* of the functional relationships aids in identifying the causal direction, as long as the influence of the noise is additive. More precisely, they consider the following class of models:

Definition 5 *A tuple (p_X, p_{E_Y}, f_Y) consisting of a density p_X, a density p_{E_Y} with finite mean, and a Borel-measurable function $f_Y : \mathbb{R} \to \mathbb{R}$, defines a* ***bivariate Additive Noise Model (ANM)*** *$X \to Y$*

$$\begin{cases} Y = f_Y(X) + E_Y \\ X \perp\!\!\!\perp E_Y, \quad X \sim p_X, \quad E_Y \sim p_{E_Y}. \end{cases}$$

If the induced distribution $\mathbb{P}_{X,Y}$ has a density with respect to Lebesgue measure, the induced density $p(x, y)$ is said to satisfy an Additive Noise Model $X \to Y$.

Note that an ANM is a special case of model (2) where the influence of the noise on Y is restricted to be additive.

We are especially interested in cases for which the additivity requirement introduces an asymmetry between X and Y:

Definition 6 *If the joint density $p(x, y)$ satisfies an Additive Noise Model $X \to Y$, but does not satisfy any Additive Noise Model $Y \to X$, then we call the ANM $X \to Y$* ***identifiable*** *(from the observational distribution).*

Hoyer et al. (2009) proved that Additive Noise Models are generically identifiable. The intuition behind this result is that if $p(x, y)$ satisfies an Additive Noise Model $X \to Y$, then $p(y \,|\, x)$ depends on x only through its mean, and all other aspects of this conditional distribution do not depend on x. On the other hand, $p(x \,|\, y)$ will typically depend in a more complicated way on y (see also Figure 4). Only for very specific choices of the parameters of an ANM one obtains a non-identifiable ANM. We have already seen an example of such a non-identifiable ANM: the linear-Gaussian case (Example 1). A more exotic example with non-Gaussian distributions is described in Peters et al. (2014, Example 25). Zhang and Hyvärinen (2009) proved that non-identifiable ANMs necessarily fall into one out of five classes. In particular, their result implies something that we might expect intuitively: if f is not injective,[10] the ANM is identifiable.

Mooij et al. (2011) showed that bivariate identifiability even holds generically when feedback is allowed (i.e., if both $X \to Y$ *and* $Y \to X$), at least when assuming noise and input distributions to be Gaussian. Peters et al. (2011) provide an extension of the acyclic model for discrete variables. Zhang and Hyvärinen (2009) give an extension of the identifiability results allowing for an additional bijective[11] transformation of the data, i.e., using a functional model of the form $Y = \phi\big(f_Y(X) + E_Y\big)$, with $E_Y \perp\!\!\!\perp X$, and $\phi : \mathbb{R} \to \mathbb{R}$

10. A mapping is said to be *injective* if it does not map distinct elements of its domain to the same element of its codomain.
11. A mapping is said to be *surjective* if every element in its codomain is mapped to by at least one element of its domain. It is called *bijective* if it is surjective and injective.

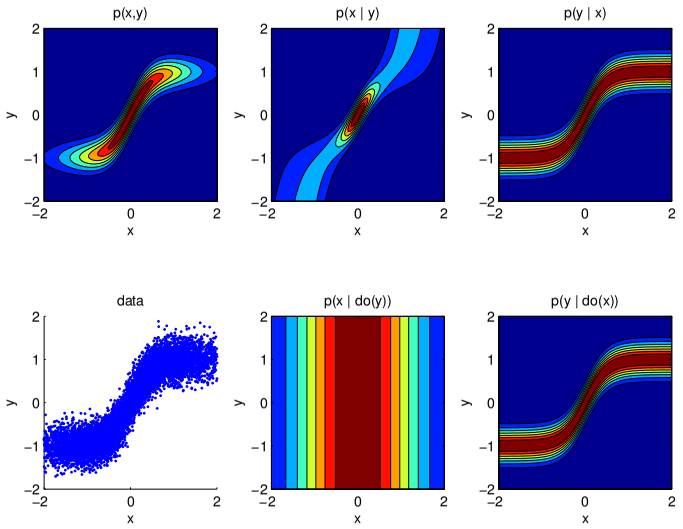

Figure 4: Identifiable ANM with $Y = \tanh(X) + E$, where $X \sim \mathcal{N}(0, 1)$ and $E \sim \mathcal{N}(0, 0.5^2)$. Shown are contours of the joint and conditional distributions, and a scatter plot of data sampled from the model distribution. Note that the contour lines of $p(y \,|\, x)$ only shift as x changes. On the other hand, $p(x \,|\, y)$ differs by more than just its mean for different values of y.

bijective, which they call the Post-NonLinear (PNL) model. The results on identifiability of Additive Noise Models can be extended to the multivariate case if there are no hidden variables and no feedback loops (Peters et al., 2014). This extension can be applied to nonlinear ANMs (Hoyer et al., 2009; Bühlmann et al., 2014), linear non-Gaussian models (Shimizu et al., 2011), the model of equal error variances (Peters and Bühlmann, 2014) or to the case of discrete variables (Peters et al., 2011). Full identifiability in the presence of hidden variables for the acyclic case has only been established for linear non-Gaussian models (Hoyer et al., 2008).

2.1.3 Additive Noise Principle

Following Hoyer et al. (2009), we hypothesize that:

Principle 1 *Suppose we are given a joint density $p(x, y)$ and we know that the causal structure is either that of (a) or (b) in Figure 2. If $p(x, y)$ satisfies an* identifiable *Additive Noise Model $X \to Y$, then it is likely that we are in case (a), i.e., X causes Y.*

This principle should not be regarded as a rigorous statement, but rather as an empirical assumption: we cannot exactly quantify *how likely* the conclusion that X causes Y is, as there is always a possibility that Y causes X while $p_{X,Y}$ happens to satisfy an identifiable

Additive Noise Model $X \to Y$. In general, that would require a special choice of the distribution of X and the conditional distribution of Y given X, which is unlikely. In this sense, we can regard this principle as a special case of Occam's Razor.

In the next subsection, we will discuss various ways of operationalizing this principle. In Section 4, we provide empirical evidence supporting this principle.

2.2 Estimation Methods

The following Lemma is helpful to test whether a density satisfies a bivariate Additive Noise Model:

Lemma 7 *Given a joint density $p(x,y)$ of two random variables X,Y such that the conditional expectation $\mathbb{E}(Y \mid X = x)$ is well-defined for all x and measurable. Then, $p(x,y)$ satisfies a bivariate Additive Noise Model $X \to Y$ if and only if $E_Y := Y - \mathbb{E}(Y \mid X)$ has finite mean and is independent of X.*

Proof Suppose that $p(x,y)$ is induced by (p_X, p_U, f), say $Y = f(X) + U$ with $X \perp\!\!\!\perp U$, $X \sim p_X$, $U \sim p_U$. Then $\mathbb{E}(Y \mid X = x) = f(x) + \nu$, with $\nu = \mathbb{E}(U)$. Therefore, $E_Y = Y - \mathbb{E}(Y \mid X) = Y - (f(X) + \nu) = U - \nu$ is independent of X. Conversely, if E_Y is independent of X, $p(x,y)$ is induced by the bivariate Additive Noise Model $(p_X, p_{E_Y}, x \mapsto \mathbb{E}(Y \mid X = x))$. ■

In practice, we usually do not have the density $p(x,y)$, but rather a finite sample of it. In that case, we can use the same idea for testing whether this sample comes from a density that satisfies an Additive Noise Model: we estimate the conditional expectation $\mathbb{E}(Y \mid X)$ by regression, and then test the independence of the residuals $Y - \mathbb{E}(Y \mid X)$ and X.

Suppose we have two data sets, a *training* data set $\mathcal{D}_N := \{(x_n, y_n)\}_{n=1}^N$ (for estimating the function) and a *test* data set $\mathcal{D}'_N := \{(x'_n, y'_n)\}_{n=1}^N$ (for testing independence of residuals), both consisting of i.i.d. samples distributed according to $p(x,y)$. We will write $\boldsymbol{x} = (x_1, \ldots, x_N)$, $\boldsymbol{y} = (y_1, \ldots, y_N)$, $\boldsymbol{x}' = (x'_1, \ldots, x'_N)$ and $\boldsymbol{y}' = (y'_1, \ldots, y'_N)$. We will consider two scenarios: the "data splitting" scenario where training and test set are independent (typically achieved by splitting a bigger data set into two parts), and the "data recycling" scenario in which the training and test data are identical (where we use the same data twice for different purposes: regression and independence testing).[12]

Hoyer et al. (2009) suggested the following procedure to test whether the data come from a density that satisfies an Additive Noise Model.[13] By regressing Y on X using the training data $\mathcal{D}_N$, an estimate $\hat{f}_Y$ for the regression function $x \mapsto \mathbb{E}(Y \mid X = x)$ is obtained. Then, an independence test is used to estimate whether the predicted residuals are independent of the input, i.e., whether $(Y - \hat{f}_Y(X)) \perp\!\!\!\perp X$, using test data $(\boldsymbol{x}', \boldsymbol{y}')$. If the null hypothesis of independence is not rejected, one concludes that $p(x,y)$ satisfies an Additive Noise Model $X \to Y$. The regression procedure and the independence test can be freely chosen.

There is a caveat, however: under the null hypothesis that $p(x,y)$ indeed satisfies an ANM, the error in the estimated residuals may introduce a dependence between the predicted residuals $\hat{\boldsymbol{e}}'_Y := \boldsymbol{y}' - \hat{f}_Y(\boldsymbol{x}')$ and $\boldsymbol{x}'$ even if the true residuals $\boldsymbol{y}' - \mathbb{E}(Y \mid X = \boldsymbol{x}')$ are

12. Kpotufe et al. (2014) refer to these scenarios as "decoupled estimation" and "coupled estimation", respectively.
13. They only considered the data recycling scenario, but the same idea can be applied to the data splitting scenario.

independent of $\boldsymbol{x}'$. Therefore, the threshold for the independence test statistic has to be chosen with care: the standard threshold that would ensure consistency of the independence test on its own may be too tight. As far as we know, there are no theoretical results on the choice of that threshold that would lead to a consistent way to test whether $p(x,y)$ satisfies an ANM $X \to Y$.

We circumvent this problem by assuming *a priori* that $p(x,y)$ either satisfies an ANM $X \to Y$, or an ANM $Y \to X$, but not both. In that sense, the test statistics of the independence test can be directly compared, and no threshold needs to be chosen. This leads us to Algorithm 1 as a general scheme for identifying the direction of the ANM. In order to decide whether $p(x,y)$ satisfies an Additive Noise Model $X \to Y$, or an Additive Noise Model $Y \to X$, we simply estimate the regression functions in both directions, calculate the corresponding residuals, estimate the dependence of the residuals with respect to the input by some dependence measure $\hat{C}$, and output the direction that has the lowest dependence.

In principle, any consistent regression method can be used in Algorithm 1. Likewise, in principle any consistent measure of dependence can be used in Algorithm 1 as score function. In the next subsections, we will consider in more detail some possible choices for the score function. Originally, Hoyer et al. (2009) proposed to use the p-value of the Hilbert Schmidt Independence Criterion (HSIC), a kernel-based non-parametric independence test. Alternatively, one can also use the HSIC statistic itself as a score, and we will show that this leads to a consistent procedure. Other dependence measures could be used instead, e.g., the measure proposed by Reshef et al. (2011). Kpotufe et al. (2014); Nowzohour and Bühlmann (2015) proposed to use as a score the sum of the estimated differential entropies of inputs and residuals and proved consistency of that procedure. For the Gaussian case, that is equivalent to the score considered in a high-dimensional context that was shown to be consistent by Bühlmann et al. (2014). This Gaussian score is also strongly related to an empirical-Bayes score originally proposed by Friedman and Nachman (2000). Finally, we will briefly discuss a Minimum Message Length score that was considered by Mooij et al. (2010) and another idea (based on minimizing a dependence measure directly) proposed by Mooij et al. (2009).

2.2.1 HSIC-based Scores

One possibility, first considered by Hoyer et al. (2009), is to use the Hilbert-Schmidt Independence Criterion (HSIC) (Gretton et al., 2005) for testing the independence of the estimated residuals with the inputs. See Appendix A.1 for a definition and basic properties of the HSIC independence test.

As proposed by Hoyer et al. (2009), one can use the p-value of the HSIC statistic under the null hypothesis of independence. This amounts to the following score function for measuring dependence:

$$\hat{C}(\boldsymbol{u}, \boldsymbol{v}) := -\log \hat{p}_{\mathrm{HSIC}_{\kappa_{\hat{\ell}(\boldsymbol{u})}, \kappa_{\hat{\ell}(\boldsymbol{v})}}}(\boldsymbol{u}, \boldsymbol{v}). \tag{4}$$

Here, κ_ℓ is a kernel with parameters ℓ, that are estimated from the data. $\boldsymbol{u}$ and $\boldsymbol{v}$ are either inputs or estimated residuals (see also Algorithm 1). A low HSIC p-value indicates that we should reject the null hypothesis of independence. Another possibility is to use the HSIC

Algorithm 1 General procedure to decide whether $p(x, y)$ satisfies an Additive Noise Model $X \to Y$ or $Y \to X$.

Input:

1. I.i.d. sample $\mathcal{D}_N := \{(x_i, y_i)\}_{i=1}^N$ of X and Y ("training data");
2. I.i.d. sample $\mathcal{D}'_N := \{(x'_i, y'_i)\}_{i=1}^N$ of X and Y ("test data");
3. Regression method;
4. Score estimator $\hat{C} : \mathbb{R}^N \times \mathbb{R}^N \to \mathbb{R}$.

Output: $\hat{C}_{X\to Y}$, $\hat{C}_{Y\to X}$, `dir`.

1. Use the regression method to obtain estimates:
   (a) $\hat{f}_Y$ of the regression function $x \mapsto \mathbb{E}(Y \,|\, X = x)$,
   (b) $\hat{f}_X$ of the regression function $y \mapsto \mathbb{E}(X \,|\, Y = y)$
   using the training data $\mathcal{D}_N$;
2. Use the estimated regression functions to predict residuals:
   (a) $\hat{\boldsymbol{e}}'_Y := \boldsymbol{y}' - \hat{f}_Y(\boldsymbol{x}')$
   (b) $\hat{\boldsymbol{e}}'_X := \boldsymbol{x}' - \hat{f}_X(\boldsymbol{y}')$
   from the test data $\mathcal{D}'_N$.
3. Calculate the scores to measure dependence of inputs and estimated residuals on the test data $\mathcal{D}'_N$:
   (a) $\hat{C}_{X\to Y} := \hat{C}(\boldsymbol{x}', \hat{\boldsymbol{e}}'_Y)$;
   (b) $\hat{C}_{Y\to X} := \hat{C}(\boldsymbol{y}', \hat{\boldsymbol{e}}'_X)$;
4. Output $\hat{C}_{X\to Y}, \hat{C}_{Y\to X}$ and

$$\texttt{dir} := \begin{cases} X \to Y & \text{if } \hat{C}_{X\to Y} < \hat{C}_{Y\to X}, \\ Y \to X & \text{if } \hat{C}_{X\to Y} > \hat{C}_{Y\to X}, \\ ? & \text{if } \hat{C}_{X\to Y} = \hat{C}_{Y\to X}. \end{cases}$$

value itself (instead of its p-value):

$$\hat{C}(\boldsymbol{u}, \boldsymbol{v}) := \widehat{\mathrm{HSIC}}_{\kappa_{\hat{\ell}(\boldsymbol{u})}, \kappa_{\hat{\ell}(\boldsymbol{v})}}(\boldsymbol{u}, \boldsymbol{v}). \tag{5}$$

An even simpler option is to use a fixed kernel k:

$$\hat{C}(\boldsymbol{u}, \boldsymbol{v}) := \widehat{\mathrm{HSIC}}_{k,k}(\boldsymbol{u}, \boldsymbol{v}). \tag{6}$$

In Appendix A, we prove that under certain technical assumptions, Algorithm 1 with score function (6) is a consistent procedure for inferring the direction of the ANM. In particular, the product kernel $k \cdot k$ should be characteristic in order for HSIC to detect all possible independences, and the regression method should satisfy the following condition:

Definition 8 *Let X, Y be two real-valued random variables with joint distribution $\mathbb{P}_{X,Y}$. Suppose we are given sequences of training data sets $\mathcal{D}_N = \{X_1, X_2, \ldots, X_N\}$ and test data sets $\mathcal{D}'_N = \{X'_1, X'_2, \ldots, X'_N\}$ (in either the data splitting or the data recycling scenario). We call a regression method **suitable** for regressing Y on X if the mean squared error between true and estimated regression function, evaluated on the test data, vanishes asymptotically in expectation, i.e.,*

$$\lim_{N\to\infty} \mathbb{E}_{\mathcal{D}_N, \mathcal{D}'_N} \left(\frac{1}{N} \sum_{n=1}^{N} \left| \hat{f}_Y(X'_n; \mathcal{D}_N) - \mathbb{E}(Y \,|\, X = X'_n) \right|^2 \right) = 0. \tag{7}$$

Here, the expectation is taken over both training data $\mathcal{D}_N$ and test data $\mathcal{D}'_N$.

The consistency result then reads as follows:

Theorem 9 *Let X, Y be two real-valued random variables with joint distribution $\mathbb{P}_{X,Y}$ that either satisfies an Additive Noise Model $X \to Y$, or $Y \to X$, but not both. Suppose we are given sequences of training data sets $\mathcal{D}_N$ and test data sets $\mathcal{D}'_N$ (in either the data splitting or the data recycling scenario). Let $k : \mathbb{R} \times \mathbb{R} \to \mathbb{R}$ be a bounded non-negative Lipschitz-continuous kernel such that the product $k \cdot k$ is characteristic. If the regression procedure used in Algorithm 1 is suitable for both $\mathbb{P}_{X,Y}$ and $\mathbb{P}_{Y,X}$, then Algorithm 1 with score (6) is a consistent procedure for estimating the direction of the Additive Noise Model.*

Proof See Appendix A (where a slightly more general result is shown, allowing for two different kernels k, l to be used). The main technical difficulty consists of the fact that the error in the estimated regression function introduces a dependency between the cause and the estimated residuals. We overcome this difficulty by showing that the dependence is so weak that its influence on the test statistic vanishes asymptotically. ■

In the data splitting case, weakly universally consistent regression methods (Györfi et al., 2002) are suitable. In the data recycling scenario, any regression method that satisfies (7) is suitable. An example of a kernel k that satisfies the conditions of Theorem 9 is the Gaussian kernel.

2.2.2 Entropy-based Scores

Instead of explicitly testing for independence of residuals and inputs, one can use the sum of their differential entropies as a score function (e.g., Kpotufe et al., 2014; Nowzohour and Bühlmann, 2015). This can easily be seen using Lemma 1 of Kpotufe et al. (2014), which we reproduce here because it is very instructive:

Lemma 10 *Consider a joint distribution of X, Y with density $p(x, y)$. For arbitrary functions $f, g : \mathbb{R} \to \mathbb{R}$ we have:*

$$H(X) + H\big(Y - f(X)\big) = H(Y) + H\big(X - g(Y)\big) - I\big(X - g(Y), Y\big) + I\big(Y - f(X), X\big),$$

where $H(\cdot)$ denotes differential Shannon entropy, and $I(\cdot,\cdot)$ denotes differential mutual information (Cover and Thomas, 2006). ■

The proof is a simple application of the chain rule of differential entropy. If $p(x,y)$ satisfies an identifiable Additive Noise Model $X \to Y$, then there exists a function f with $I(Y - f(X), X) = 0$ (e.g., the regression function $x \mapsto \mathbb{E}(Y \mid X = x)$), but $I(X - g(Y), Y) > 0$ for any function g. Therefore, one can use Algorithm 1 with score function

$$\hat{C}(\boldsymbol{u}, \boldsymbol{v}) := \hat{H}(\boldsymbol{u}) + \hat{H}(\boldsymbol{v}) \tag{8}$$

in order to estimate the causal direction, using any estimator $\hat{H}(\cdot)$ of the differential Shannon entropy. Kpotufe et al. (2014); Nowzohour and Bühlmann (2015) prove that this approach to estimating the direction of Additive Noise Models is consistent under certain technical assumptions.

Kpotufe et al. (2014) note that the advantage of score (8) (based on marginal entropies) over score (5) (based on dependence) is that marginal entropies are cheaper to estimate than dependence (or mutual information). This is certainly true when considering computation time. However, as we will see later, a disadvantage of relying on differential entropy estimators is that these can be quite sensitive to discretization effects.

2.2.3 Gaussian Score

The differential entropy of a random variable X can be upper bounded in terms of its variance (see e.g., Cover and Thomas, 2006, Theorem 8.6.6):

$$H(X) \leq \frac{1}{2}\log(2\pi e) + \frac{1}{2}\log \mathbb{V}\mathrm{ar}(X), \tag{9}$$

where identity holds in case X has a Gaussian distribution. Assuming that $p(x,y)$ satisfies an identifiable Gaussian Additive Noise Model $X \to Y$ with Gaussian input and Gaussian noise distributions, we therefore conclude from Lemma 10 that

$$\begin{aligned}\log \mathbb{V}\mathrm{ar}(X) + \log \mathbb{V}\mathrm{ar}(Y - \hat{f}(X)) &= 2H(X) + 2H(Y - \hat{f}(X)) - 2\log(2\pi e)\\ &< 2H(Y) + 2H(X - \hat{g}(Y)) - 2\log(2\pi e)\\ &\leq \log \mathbb{V}\mathrm{ar}Y + \log \mathbb{V}\mathrm{ar}(X - \hat{g}(Y))\end{aligned}$$

for any function g. In that case, we can therefore use Algorithm 1 with score function

$$\hat{C}(\boldsymbol{u}, \boldsymbol{v}) := \log \widehat{\mathbb{V}\mathrm{ar}}(\boldsymbol{u}) + \log \widehat{\mathbb{V}\mathrm{ar}}(\boldsymbol{v}). \tag{10}$$

This score was also considered recently by Bühlmann et al. (2014) and shown to lead to a consistent estimation procedure under certain assumptions.

2.2.4 Empirical-Bayes Scores

Deciding the direction of the ANM can also be done by applying model selection using empirical Bayes. As an example, for the ANM $X \to Y$, one can consider a generative model that models X as a Gaussian, and Y as a Gaussian Process (Rasmussen and Williams, 2006) conditional on X. For the ANM $Y \to X$, one considers a similar model with the roles

Algorithm 2 Procedure to decide whether $p(x,y)$ satisfies an Additive Noise Model $X \to Y$ or $Y \to X$ suitable for empirical-Bayes or MML model selection.

Input:

1. I.i.d. sample $\mathcal{D}_N := \{(x_i, y_i)\}_{i=1}^N$ of X and Y ("data");
2. Score function $\hat{C} : \mathbb{R}^N \times \mathbb{R}^N \to \mathbb{R}$ for measuring model fit and model complexity.

Output: $\hat{C}_{X\to Y}$, $\hat{C}_{Y\to X}$, `dir`.

1. (a) calculate $\hat{C}_{X\to Y} = \hat{C}(\boldsymbol{x}, \boldsymbol{y})$
   (b) calculate $\hat{C}_{Y\to X} = \hat{C}(\boldsymbol{y}, \boldsymbol{x})$
2. Output $\hat{C}_{X\to Y}, \hat{C}_{Y\to X}$ and

$$\texttt{dir} := \begin{cases} X \to Y & \text{if } \hat{C}_{X\to Y} < \hat{C}_{Y\to X},\\ Y \to X & \text{if } \hat{C}_{X\to Y} > \hat{C}_{Y\to X},\\ ? & \text{if } \hat{C}_{X\to Y} = \hat{C}_{Y\to X}. \end{cases}$$

of X and Y reversed. Empirical-Bayes model selection is performed by calculating the maximum evidences (marginal likelihoods) of these two models when optimizing over the hyperparameters, and preferring the model with larger maximum evidence. This is actually a special case (the bivariate case) of an approach proposed by Friedman and Nachman (2000).[14] Considering the negative log marginal likelihoods leads to the following score for the ANM $X \to Y$:

$$\hat{C}_{X\to Y}(\boldsymbol{x}, \boldsymbol{y}) := \min_{\mu,\tau^2,\boldsymbol{\theta},\sigma^2} \left(-\log \mathcal{N}(\boldsymbol{x} \mid \mu\mathbf{1}, \tau^2\boldsymbol{I}) - \log \mathcal{N}(\boldsymbol{y} \mid \mathbf{0}, \boldsymbol{K}_{\boldsymbol{\theta}}(\boldsymbol{x}) + \sigma^2\boldsymbol{I})\right), \tag{11}$$

and a similar expression for $\hat{C}_{Y\to X}$, the score of the ANM $Y \to X$. Here, $\boldsymbol{K}_{\boldsymbol{\theta}}(\boldsymbol{x})$ is the $N \times N$ kernel matrix $K_{ij} = k_{\boldsymbol{\theta}}(x_i, x_j)$ for a kernel with parameters $\boldsymbol{\theta}$ and $\mathcal{N}(\cdot \mid \boldsymbol{\mu}, \boldsymbol{\Sigma})$ denotes the density of a multivariate normal distribution with mean $\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Sigma}$. If one would put a prior distribution on the hyperparameters and integrate them out, this would correspond to Bayesian model selection. In practice, one typically uses "empirical Bayes", which means that the hyperparameters $(\mu, \tau, \boldsymbol{\theta}, \sigma)$ are optimized over instead for computational reasons. Note that this method skips the explicit regression step, instead it (implicitly) integrates over all possible regression functions (Rasmussen and Williams, 2006). Also, it does not distinguish the data splitting and data recycling scenarios, instead it uses the data directly to calculate the (maximum) marginal likelihood. Therefore, the structure of the algorithm is slightly different, see Algorithm 2. In Appendix B we show that this score is actually closely related to the Gaussian score considered in Section 2.2.3.

14. Friedman and Nachman (2000) even hint at using this method for inferring causal relationships, although it seems that they only thought of cases where the functional dependence of the effect on the cause was not injective.

2.2.5 Minimum Message Length Scores

In a similar vein as (empirical) Bayesian marginal likelihoods can be interpreted as measuring likelihood in combination with a complexity penalty, Minimum Message Length (MML) techniques can be used to construct scores that incorporate a trade-off between model fit (likelihood) and model complexity (Grünwald, 2007). Asymptotically, as the number of data points tends to infinity, one would expect the model fit to outweigh the model complexity, and therefore by Lemma 10, simple comparison of MML scores should be enough to identify the direction of an identifiable Additive Noise Model.

A particular MML score was considered by Mooij et al. (2010). This is a special case (referred to in Mooij et al. (2010) as "AN-MML") of their more general framework that allows for non-additive noise. Like (11), the score is a sum of two terms, one corresponding to the marginal density $p(x)$ and the other to the conditional density $p(y\,|\,x)$:

$$\hat{C}_{X\to Y}(\boldsymbol{x},\boldsymbol{y}) := \mathcal{L}(\boldsymbol{x}) + \min_{\boldsymbol{\theta},\sigma^2}\left(-\log \mathcal{N}(\boldsymbol{y}\,|\,0, \boldsymbol{K}_\theta(\boldsymbol{x}) + \sigma^2 \boldsymbol{I})\right). \tag{12}$$

The second term is an MML score for the conditional density $p(y\,|\,x)$, and is identical to the conditional density term in (11). The MML score $\mathcal{L}(\boldsymbol{x})$ for the marginal density $p(x)$ is derived as an asymptotic expansion based on the Minimum Message Length principle for a mixture-of-Gaussians model (Figueiredo and Jain, 2002):

$$\mathcal{L}(\boldsymbol{x}) = \min_{\boldsymbol{\eta}}\left(\sum_{j=1}^{k}\log\left(\frac{N\alpha_j}{12}\right) + \frac{k}{2}\log\frac{N}{12} + \frac{3k}{2} - \log p(\boldsymbol{x}\,|\,\boldsymbol{\eta})\right), \tag{13}$$

where $p(\boldsymbol{x}\,|\,\boldsymbol{\eta})$ is a Gaussian mixture model: $p(x_i\,|\,\boldsymbol{\eta}) = \sum_{j=1}^{k}\alpha_j \mathcal{N}(x_i\,|\,\mu_j,\sigma_j^2)$ with $\boldsymbol{\eta} = (\alpha_i,\mu_i,\sigma_i^2)_{i=1}^k$. The optimization problem (13) is solved numerically by means of the algorithm proposed by Figueiredo and Jain (2002), using a small but nonzero value (10^{-4}) of the regularization parameter.

Comparing this score with the empirical-Bayes score (11), the main conceptual difference is that the former uses a more complicated mixture-of-Gaussians model for the marginal density, whereas (11) uses a simple Gaussian model. We can use (12) in combination with Algorithm 2 in order to estimate the direction of an identifiable Additive Noise Model.

2.2.6 Minimizing HSIC Directly

One can try to apply the idea of combining regression and independence testing into a single procedure (as achieved with the empirical-Bayes score described in Section 2.2.4, for example) more generally. Indeed, a score that measures the dependence between the residuals $\boldsymbol{y}' - f_Y(\boldsymbol{x}')$ and the inputs $\boldsymbol{x}'$ can be minimized with respect to the function f_Y. Mooij et al. (2009) proposed to minimize $\widehat{\mathrm{HSIC}}\big(\boldsymbol{x},\boldsymbol{y}-f(\boldsymbol{x})\big)$ with respect to the function f. However, the optimization problem with respect to f turns out to be a challenging non-convex optimization problem with multiple local minima, and there are no guarantees to find the global minimum. In addition, the performance depends strongly on the selection of suitable kernel bandwidths, for which no suitable automatic procedure is known in this context. Finally, proving consistency of such a method might be challenging, as the minimization may introduce strong dependences between the residuals. Therefore, we do not discuss or evaluate this method in more detail here.

3. Information-Geometric Causal Inference

In this section, we review a class of causal discovery methods that exploits independence of the distribution of the cause and the conditional distribution of the effect given the cause. It nicely complements causal inference based on additive noise by employing asymmetries between cause and effect that have nothing to do with noise.

3.1 Theory

Information-Geometric Causal Inference (IGCI) is an approach that builds upon the assumption that for $X \to Y$ the marginal distribution $\mathbb{P}_X$ contains no information about the conditional[15] $\mathbb{P}_{Y\,|\,X}$ and vice versa, since they represent independent mechanisms. As Janzing and Schölkopf (2010) illustrated for several toy examples, the conditional and marginal distributions $\mathbb{P}_Y, \mathbb{P}_{X\,|\,Y}$ may then contain information about each other, but it is hard to formalize in what sense this is the case for scenarios that go beyond simple toy models. IGCI is based on the strong assumption that X and Y are deterministically related by a bijective function f, that is, $Y = f(X)$ and $X = f^{-1}(Y)$. Although its practical applicability is limited to causal relations with sufficiently small noise and sufficiently high non-linearity, IGCI provides a setting in which the independence of $\mathbb{P}_X$ and $\mathbb{P}_{Y\,|\,X}$ provably implies well-defined dependences between $\mathbb{P}_Y$ and $\mathbb{P}_{X\,|\,Y}$ in a sense described below.

To introduce IGCI, note that the deterministic relation $Y = f(X)$ implies that the conditional $\mathbb{P}_{Y\,|\,X}$ has no density $p(y\,|\,x)$, but it can be represented using f via

$$\mathbb{P}(Y = y\,|\,X = x) = \begin{cases} 1 & \text{if } y = f(x) \\ 0 & \text{otherwise.} \end{cases}$$

The fact that $\mathbb{P}_X$ and $\mathbb{P}_{Y\,|\,X}$ contain no information about each other then translates into the statement that $\mathbb{P}_X$ and f contain no information about each other.

Before sketching a more general formulation of IGCI (Daniušis et al., 2010; Janzing et al., 2012), we begin with the most intuitive case where f is a strictly monotonically increasing differentiable bijection of $[0,1]$. We then assume that the following equality is approximately satisfied:

$$\int_0^1 \log f'(x) p(x)\,dx = \int_0^1 \log f'(x)\,dx, \tag{14}$$

where f' is the derivative of f. To see why (14) is an independence between function f and input density p_X, we interpret $x \mapsto \log f'(x)$ and $x \mapsto p(x)$ as random variables[16] on the probability space $[0,1]$. Then the difference between the two sides of (14) is the covariance of these two random variables with respect to the uniform distribution on $[0,1]$:

$$\begin{aligned}\mathbb{C}\mathrm{ov}(\log f', p_X) &= \mathbb{E}(\log f' \cdot p_X) - \mathbb{E}(\log f')\mathbb{E}(p_X) \\ &= \int \log f'(x)\cdot p(x)dx - \int \log f'(x)dx \int p(x)dx\,.\end{aligned}$$

15. Note that $\mathbb{P}_{Y\,|\,X}$ represents the whole family of distributions $x \mapsto \mathbb{P}_{Y\,|\,X=x}$.
16. Note that random variables are formally defined as maps from a probability space to the real numbers.

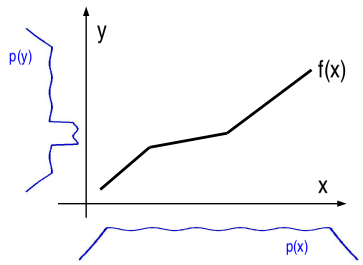

Figure 5: Illustration of the basic intuition behind IGCI. If the density p_X of the cause X is not correlated with the slope of f, then the density p_Y tends to be high in regions where f is flat (and f^{-1} is steep). Source: Janzing et al. (2012).

As shown in Section 2 in Daniušis et al. (2010), p_Y is then related to the inverse function f^{-1} in the sense that

$$\int_0^1 \log(f^{-1})'(y) \cdot p(y)\, dy \geq \int_0^1 \log(f^{-1})'(y)\, dy\,,$$

with equality if and only if f' is constant. Hence, $\log(f^{-1})'$ and p_Y are positively correlated due to

$$\mathbb{E}\big(\log(f^{-1})' \cdot p_Y\big) - \mathbb{E}\big(\log(f^{-1})'\big)\mathbb{E}(p_Y) > 0\,.$$

Intuitively, this is because the density p_Y tends to be high in regions where f is flat, or equivalently, f^{-1} is steep (see also Figure 5). Hence, we have shown that $\mathbb{P}_Y$ contains information about f^{-1} and hence about $\mathbb{P}_{X\,|\,Y}$ whenever $\mathbb{P}_X$ does not contain information about $\mathbb{P}_{Y\,|\,X}$ (in the sense that (14) is satisfied), except for the trivial case where f is linear.

To employ this asymmetry, Daniušis et al. (2010) introduce the expressions

$$C_{X\to Y} := \int_0^1 \log f'(x) p(x) dx \tag{15}$$

$$C_{Y\to X} := \int_0^1 \log(f^{-1})'(y) p(y) dy = -C_{X\to Y}\,. \tag{16}$$

Since the right hand side of (14) is smaller than zero due to $\int_0^1 \log f'(x) dx \leq \log \int_0^1 f'(x) dx = 0$ by concavity of the logarithm (exactly zero only for constant f), IGCI infers $X \to Y$ whenever $C_{X\to Y}$ is negative. Section 3.5 in Daniušis et al. (2010) also shows that

$$C_{X\to Y} = H(Y) - H(X)\,,$$

i.e., the decision rule considers the variable with lower differential entropy as the effect. The idea is that the function introduces new irregularities to a distribution rather than smoothing the irregularities of the distribution of the cause.

Generalization to other reference measures: In the above version of IGCI the uniform distribution on $[0,1]$ plays a special role because it is the distribution with respect to which uncorrelatedness between p_X and $\log f'$ is defined. The idea can be generalized to other reference distributions. How to choose the right one for a particular inference problem is a difficult question which goes beyond the scope of this article. From a high-level perspective, it is comparable to the question of choosing the right kernel for kernel-based machine learning algorithms; it also is an *a priori* structure of the range of X and Y without which the inference problem is not well-defined.

Let u_X and u_Y be densities of X and Y, respectively, that we call "reference densities". For example, uniform or Gaussian distributions would be reasonable choices. Let u_f be the image of u_X under f and $u_{f^{-1}}$ be the image of u_Y under f^{-1}. Then we hypothesize the following generalization of (14):

Principle 2 *If X causes Y via a deterministic bijective function f such that $u_{f^{-1}}$ has a density with respect to Lebesgue measure, then*

$$\int \log \frac{u_{f^{-1}}(x)}{u_X(x)} p(x)\, dx \approx \int \log \frac{u_{f^{-1}}(x)}{u_X(x)} u_X(x)\, dx\,. \tag{17}$$

In analogy to the remarks above, this can also be interpreted as uncorrelatedness of the functions $\log(u_{f^{-1}}/u_X)$ and p_X/u_X with respect to the measure given by the density of u_X with respect to the Lebesgue measure. Again, we hypothesize this because the former expression is a property of the function f alone (and the reference densities) and should thus be unrelated to the marginal density p_X. The special case (14) can be obtained by taking the uniform distribution on $[0,1]$ for u_X and u_Y.

As generalization of (15,16) we define:[17]

$$\begin{aligned} C_{X\to Y} &:= \int \log \frac{u_{f^{-1}}(x)}{u_X(x)} p(x) dx \\ C_{Y\to X} &:= \int \log \frac{u_f(y)}{u_Y(y)} p(y) dy = \int \log \frac{u_X(x)}{u_{f^{-1}}(x)} p(x) dx = -C_{Y\to X}\,, \end{aligned} \tag{18}$$

where the second equality in (18) follows by substitution of variables. Again, the hypothesized independence implies $C_{X\to Y} \leq 0$ since the right hand side of (17) coincides with $-D(u_X \| u_{f^{-1}})$ where $D(\cdot\|\cdot)$ denotes Kullback-Leibler divergence. Hence, we also infer $X \to Y$ whenever $C_{X\to Y} < 0$. Note also that

$$C_{X\to Y} = D(p_X \| u_X) - D(p_X \| u_{f^{-1}}) = D(p_X \| u_X) - D(p_Y \| u_Y)\,,$$

where we have only used the fact that relative entropy is preserved under bijections. Hence, our decision rule amounts to inferring that the density of the cause is closer to its reference density. This decision rule gets quite simple, for instance, if u_X and u_Y are Gaussians with the same mean and variance as p_X and p_Y, respectively. Then it again amounts to inferring $X \to Y$ whenever X has larger entropy than Y after rescaling both X and Y to have the same variance.

17. Note that the formulation in Section 2.3 in Daniušis et al. (2010) is more general because it uses *manifolds* of reference densities instead of a single density.

3.2 Estimation Methods

The specification of the reference measure is essential for IGCI. We describe the implementation for two different choices:

1. *Uniform distribution:* scale and shift X and Y such that extrema are mapped onto 0 and 1.
2. *Gaussian distribution:* scale X and Y to variance 1.

Given this preprocessing step, there are different options for estimating $C_{X\to Y}$ and $C_{Y\to X}$ from empirical data (see Section 3.5 in Daniušis et al., 2010):

1. *Slope-based estimator:*

$$\hat{C}_{X\to Y} := \frac{1}{N-1}\sum_{j=1}^{N-1} \log \frac{|y_{j+1}-y_j|}{x_{j+1}-x_j}\,, \tag{19}$$

   where we assumed the pairs $\{(x_i,y_i)\}$ to be ordered ascendingly according to x_i. Since empirical data are noisy, the y-values need not be in the same order. $\hat{C}_{Y\to X}$ is given by exchanging the roles of X and Y.

2. *Entropy-based estimator:*

$$\hat{C}_{X\to Y} := \hat{H}(Y) - \hat{H}(X)\,, \tag{20}$$

   where $\hat{H}(\cdot)$ denotes some differential entropy estimator.

The theoretical equivalence between these estimators breaks down on empirical data not only due to finite sample effects but also because of noise. For the slope based estimator, we even have

$$\hat{C}_{X\to Y} \neq -\hat{C}_{Y\to X}\,,$$

and thus need to compute both terms separately.

Note that the IGCI implementations discussed here make sense only for continuous variables with a density with respect to Lebesgue measure. This is because the difference quotients are undefined if a value occurs twice. In many empirical data sets, however, the discretization (e.g., due to rounding to some number of digits) is not fine enough to guarantee this. A very preliminary heuristic that was employed in earlier work (Daniušis et al., 2010) removes repeated occurrences by removing data points, but a conceptually cleaner solution would be, for instance, the following procedure: Let $\tilde{x}_j$ with $1\le j\le \tilde{N}$ be the ordered values after removing repetitions and let $\tilde{y}_j$ denote the corresponding y-values. Then we replace (19) with

$$\hat{C}_{X\to Y} := \frac{1}{\sum_{j=1}^{\tilde{N}-1} n_j}\sum_{j=1}^{\tilde{N}-1} n_j \log \frac{|\tilde{y}_{j+1}-\tilde{y}_j|}{\tilde{x}_{j+1}-\tilde{x}_j}\,, \tag{21}$$

where n_j denotes the number of occurrences of $\tilde{x}_j$ in the original data set. Here we have ignored the problem of repetitions of y-values since they are less likely, because they are not

Algorithm 3 General procedure to decide whether $\mathbb{P}_{X,Y}$ is generated by a deterministic monotonic bijective function from X to Y or from Y to X.

Input:

1. I.i.d. sample $\mathcal{D}_N := \{(x_i,y_i)\}_{i=1}^N$ of X and Y ("data");
2. Normalization procedure $\nu : \mathbb{R}^N \to \mathbb{R}^N$;
3. IGCI score estimator $\hat{C} : \mathbb{R}^N \times \mathbb{R}^N \to \mathbb{R}$.

Output: $\hat{C}_{X\to Y}$, $\hat{C}_{Y\to X}$, `dir`.

1. Normalization:
   (a) calculate $\tilde{\boldsymbol{x}} = \nu(\boldsymbol{x})$
   (b) calculate $\tilde{\boldsymbol{y}} = \nu(\boldsymbol{y})$
2. Estimation of scores:
   (a) calculate $\hat{C}_{X\to Y} = \hat{C}(\tilde{\boldsymbol{x}},\tilde{\boldsymbol{y}})$
   (b) calculate $\hat{C}_{Y\to X} = \hat{C}(\tilde{\boldsymbol{y}},\tilde{\boldsymbol{x}})$
3. Output $\hat{C}_{X\to Y}, \hat{C}_{Y\to X}$ and

$$\texttt{dir} := \begin{cases} X\to Y & \text{if } \hat{C}_{X\to Y} < \hat{C}_{Y\to X}, \\ Y\to X & \text{if } \hat{C}_{X\to Y} > \hat{C}_{Y\to X}, \\ ? & \text{if } \hat{C}_{X\to Y} = \hat{C}_{Y\to X}. \end{cases}$$

ordered if the relation between X and Y is noisy (and for bijective deterministic relations, they only occur together with repetitions of x anyway).

Finally, let us mention one simple case where IGCI with estimator (19) provably works asymptotically, even though its assumptions are violated. This happens if the effect is a non-injective function of the cause. More precisely, assume $Y = f(X)$ where $f : [0,1] \to [0,1]$ is continuously differentiable and non-injective, and moreover, that p_X is strictly positive and bounded away from zero. To argue that $\hat{C}_{Y\to X} > \hat{C}_{X\to Y}$ asymptotically for $N\to\infty$ we first observe that the mean value theorem implies

$$\frac{|f(x_2)-f(x_1)|}{|x_2-x_1|} \le \max_{x\in[0,1]} |f'(x)| =: s_{\max} \tag{22}$$

for any pair x_1, x_2. Thus, for any sample size N we have $\hat{C}_{X\to Y} \le \log s_{\max}$. On the other hand, $\hat{C}_{Y\to X} \to \infty$ for $N\to\infty$. To see this, note that all terms in the sum (19) are bounded from below by $-\log s_{\max}$ due to (22), while there is no *upper* bound for the summands because adjacent y-values may be from different branches of the non-injective function f and then the corresponding x-values may not be close. Indeed, this will happen for a constant fraction of adjacent pairs. For those, the gaps between the y-values decrease

with $\mathcal{O}(1/N)$ while the distances of the corresponding x-values remain of $\mathcal{O}(1)$. Thus, the overall sum (19) diverges. It should be emphasized, however, that one can have opposite effects for any finite N. To see this, consider the function $x \mapsto 2|x - 1/2|$ and modify it locally around $x = 1/2$ to obtain a continuously differentiable function f. Assume that the probability density in $[1/2, 1]$ is so low that almost all points are contained in $[0, 1/2]$. Then, $\hat{C}_{X\to Y} \approx \log 2$ while $\hat{C}_{Y\to X} \approx -\log 2$ and IGCI with estimator (19) decides (incorrectly) on $Y \to X$. For sufficiently large N, however, a constant (though possibly very small) fraction of y-values come from different branches of f and thus $\hat{C}_{Y\to X}$ diverges (while $\hat{C}_{X\to Y}$ remains bounded from above).

4. Experiments

In this section we describe the data that we used for evaluation, implementation details for various methods, and our evaluation criteria. The results of the empirical study will be presented in Section 5.

4.1 Implementation Details

The complete source code to reproduce our experiments is available online as open source under the FreeBSD license, both as an online appendix and on the homepage of the first author.[18] We used `MatLab` on a `Linux` platform, and made use of external libraries `GPML` v3.5 (2014-12-08) (Rasmussen and Nickisch, 2010) for GP regression and `ITE` v0.61 (Szabó, 2014) for entropy estimation. For parallelization, we used the convenient command line tool `GNU parallel` (Tange, 2011).

4.1.1 Regression

We used standard Gaussian Process (GP) Regression (Rasmussen and Williams, 2006) for nonparametric regression, using the `GPML` implementation (Rasmussen and Nickisch, 2010). We used a squared exponential covariance function, constant mean function, and an additive Gaussian noise likelihood. We used the FITC approximation (Quiñonero-Candela and Rasmussen, 2005) as an approximation for exact GP regression in order to reduce computation time. We found that 100 FITC points distributed on a linearly spaced grid greatly reduce computation time without introducing a noticeable approximation error. Therefore, we used this setting as a default for the GP regression. The computation time of this method scales as $\mathcal{O}(Nm^2T)$, where N is the number of data points, $m = 100$ is the number of FITC points, and T is the number of iterations necessary to optimize the marginal likelihood with respect to the hyperparameters. In practice, this yields considerable speedups compared with exact GP inference, which scales as $\mathcal{O}(N^3T)$.

Table 1: Entropy estimation methods. "ITE" refers to the Information Theoretical Estimators Toolbox (Szabó, 2014). The first group of entropy estimators is nonparametric, the second group makes additional parametric assumptions on the distribution of the data.

4.1.2 Entropy Estimation

We tried many different empirical entropy estimators, see Table 1. The first method, `1sp`, uses a so-called "1-spacing" estimate (see e.g., Kraskov et al., 2004):

$$\hat{H}(\boldsymbol{x}) := \psi(N) - \psi(1) + \frac{1}{N-1}\sum_{i=1}^{N-1} \log|x_{i+1} - x_i| \,, \tag{23}$$

where the x-values should be ordered ascendingly, i.e., $x_i \leq x_{i+1}$, and ψ is the digamma function (i.e., the logarithmic derivative of the gamma function: $\psi(x) = d/dx \log\Gamma(x)$, which behaves as $\log x$ asymptotically for $x \to \infty$). As this estimator would become $-\infty$ if a value occurs more than once, we first remove duplicate values from the data before applying (23). There should be better ways of dealing with discretization effects, but we nevertheless include this particular estimator for comparison, as it was also used in previous implementations of the entropy-based IGCI method (Daniušis et al., 2010; Janzing et al., 2012). These estimators can be implemented in $\mathcal{O}(N \ln N)$ complexity, as they only need to sort the data and then calculate a sum over data points.

We also made use of various entropy estimators implemented in the Information Theoretical Estimators (ITE) Toolbox (Szabó, 2014). The method `3NN` is based on k-nearest neighbors with $k = 3$, all `sp*` methods use Vasicek's spacing method with various corrections, `KDP` uses k-d partitioning, `PSD` uses the power spectral density representation and Szego's theorem, `ME1` and `ME2` use the maximum entropy distribution method, and `EdE` uses the Edgeworth expansion. For more details, see the documentation of the ITE toolbox (Szabó, 2014).

4.1.3 Independence Testing: HSIC

As covariance function for HSIC, we use the popular Gaussian kernel:

$$\kappa_\ell : (x, x') \mapsto \exp\left(-\frac{(x-x')^2}{\ell^2}\right),$$

with bandwidths selected by the median heuristic (Schölkopf and Smola, 2002), i.e., we take

$$\hat{\ell}(\boldsymbol{u}) := \text{median}\{\|u_i - u_j\| : 1 \le i < j \le N, \|u_i - u_j\| \neq 0\},$$

and similarly for $\hat{\ell}(\boldsymbol{v})$. We also compare with a fixed bandwidth of 0.5. As the product of two Gaussian kernels is characteristic, HSIC with such kernels will detect any dependence asymptotically (see also Lemma 12 in Appendix A), at least when the bandwidths are fixed.

The p-value can either be estimated by using permutation, or can be approximated by a Gamma approximation, as the mean and variance of the HSIC value under the null hypothesis can also be estimated in closed form (Gretton et al., 2008). In this work, we use the Gamma approximation for the HSIC p-value.

The computation time of our naïve implementation of HSIC scales as $\mathcal{O}(N^2)$. Using incomplete Cholesky decompositions, one can obtain an accurate approximation in only $\mathcal{O}(N)$ (Jegelka and Gretton, 2007). However, the naïve implementation was fast enough for our purpose.

4.2 Data Sets

We will use both real-world and simulated data in order to evaluate the methods. Here we give short descriptions and refer the reader to Appendix C and Appendix D for details.

4.2.1 Real-world Benchmark Data

The CauseEffectPairs (CEP) benchmark data set that we propose in this work consists of different "cause-effect pairs", each one consisting of samples of a pair of statistically dependent random variables, where one variable is known to cause the other one. It is an extension of the collection of the eight data sets that formed the "CauseEffectPairs" task in the *Causality Challenge #2: Pot-Luck* competition (Mooij and Janzing, 2010) which was performed as part of the NIPS 2008 Workshop on Causality (Guyon et al., 2010). Version 1.0 of the CauseEffectPairs collection that we present here consists of 100 pairs, taken from 37 different data sets from various domains. The CEP data are publicly available at Mooij et al. (2014). Appendix D contains a detailed description of each cause-effect pair and a justification of what we believe to be the ground truth causal relations. Scatter plots of the pairs are shown in Figure 6. In our experiments, we only considered the 95 out of 100 pairs that have one-dimensional variables, i.e., we left out pairs 52–55 and 71.

4.2.2 Simulated Data

As collecting real-world benchmark data is a tedious process (mostly because the ground truths are unknown, and acquiring the necessary understanding of the data-generating process in order to decide about the ground truth is not straightforward), we also studied

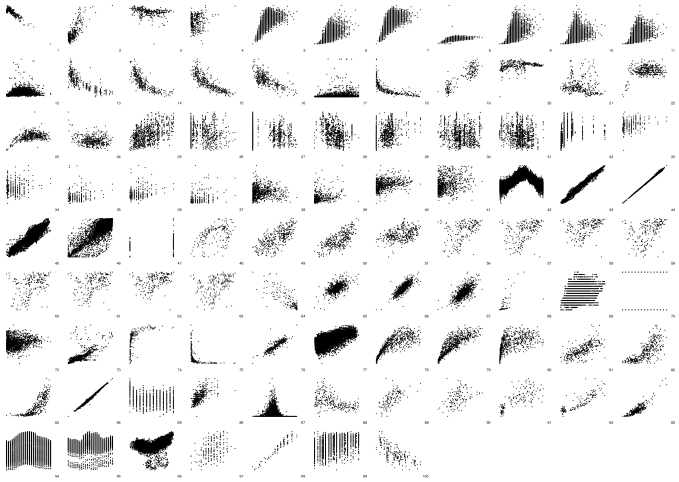

Figure 6: Scatter plots of the cause-effect pairs in the CauseEffectPairs benchmark data. We only show the pairs for which both variables are one-dimensional.

the performance of methods on simulated data where we can control the data-generating process, and therefore can be certain about the ground truth.

Simulating data can be done in many ways. It is not straightforward to simulate data in a "realistic" way, e.g., in such a way that scatter plots of simulated data look similar to those of the real-world data (see Figure 6). For reproducibility, we describe in Appendix C in detail how the simulations were done. Here, we will just sketch the main ideas.

We sample data from the following structural equation models. If we do not want to model a confounder, we use:

$$\begin{aligned} &E_X \sim p_{E_X},\, E_Y \sim p_{E_Y} \\ &X = f_X(E_X) \\ &Y = f_Y(X, E_Y), \end{aligned}$$

and if we do want to include a confounder Z, we use:

$$\begin{aligned} &E_X \sim p_{E_X},\, E_Y \sim p_{E_Y},\, E_Z \sim p_{E_Z} \\ &Z = f_Z(E_Z) \\ &X = f_X(E_X, E_Z) \\ &Y = f_Y(X, E_Y, E_Z). \end{aligned}$$

Here, the noise distributions $p_{E_X}, p_{E_Y}, p_{E_Z}$ are randomly generated distributions, and the causal mechanisms f_Z, f_X, f_Y are randomly generated functions. Sampling the random

distributions for a noise variable E_X (and similarly for E_Y and E_Z) is done by mapping a standard-normal distribution through a random function, which we sample from a Gaussian Process. The causal mechanism f_X (and similarly f_Y and f_Z) is drawn from a Gaussian Process as well. After sampling the noise distributions and the functional relations, we generate data for X, Y, Z. Finally, Gaussian measurement noise is added to both X and Y.

By controlling various hyperparameters, we can control certain aspects of the data generation process. We considered four different scenarios. `SIM` is the default scenario without confounders. `SIM-c` includes a one-dimensional confounder, whose influences on X and Y are typically equally strong as the influence of X on Y. The setting `SIM-ln` has low noise levels, and we would expect IGCI to work well in this scenario. Finally, `SIM-G` has approximate Gaussian distributions for the cause X and approximately additive Gaussian noise (on top of a nonlinear relationship between cause and effect); we expect that methods which make these Gaussianity assumptions will work well in this scenario. Scatter plots of the simulated data are shown in Figures 7–10.

4.3 Preprocessing and Perturbations

The following preprocessing was applied to each pair (X, Y). Both variables X and Y were standardized (i.e., an affine transformation is applied on both variables such that their empirical mean becomes 0, and their empirical standard deviation becomes 1). In order to study the effect of discretization and other small perturbations of the data, one of these four perturbations was applied:

unperturbed : No perturbation is applied.

discretized : Discretize the variable that has the most unique values such that after discretization, it has as many unique values as the other variable. The discretization procedure repeatedly merges those values for which the sum of the absolute error that would be caused by the merge is minimized.

undiscretized : "Undiscretize" both variables X and Y. The undiscretization procedure adds noise to each data point z, drawn uniformly from the interval $[0, z' - z]$, where z' is the smallest value $z' > z$ that occurs in the data.

small noise : Add tiny independent Gaussian noise to both X and Y (with mean 0 and standard deviation 10^{-9}).

Ideally, a causal discovery method should be robust against these and other small perturbations of the data.

4.4 Evaluation Measures

We evaluate the performance of the methods in two different ways:

forced-decision : given a sample of a pair (X, Y) the methods have to decide either $X \to Y$ or $Y \to X$; in this setting we evaluate the accuracy of these decisions;

ranked-decision : we used the scores $\hat{C}_{X\to Y}$ and $\hat{C}_{Y\to X}$ to construct heuristic confidence estimates that are used to rank the decisions; we then produced receiver-operating

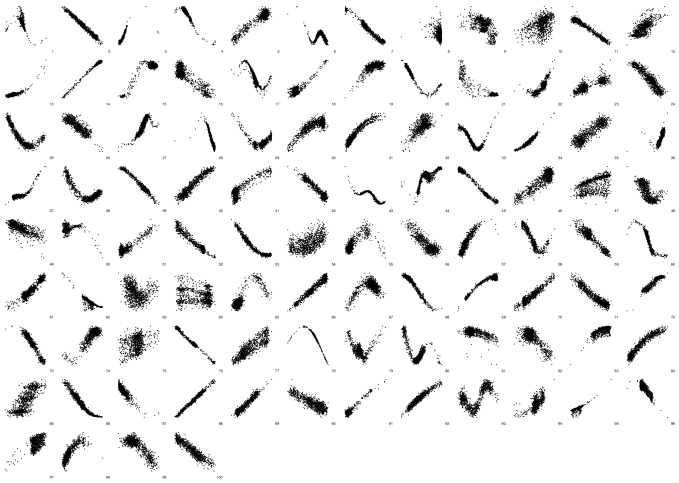

Figure 7: Scatter plots of the cause-effect pairs in simulation scenario `SIM`.

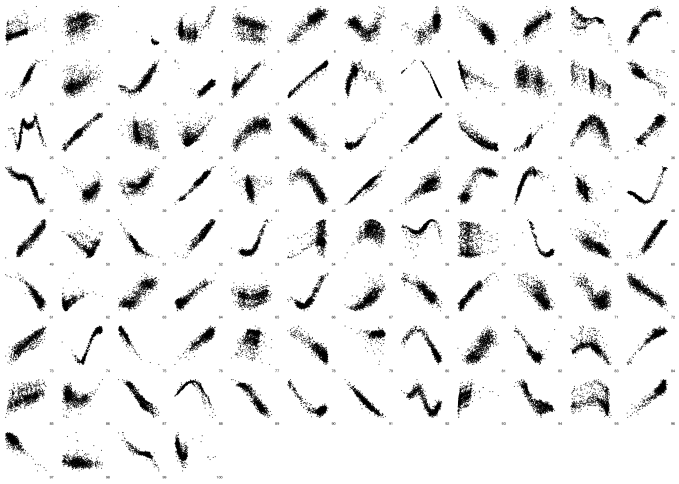

Figure 8: Scatter plots of the cause-effect pairs in simulation scenario `SIM-c`.

Figure 9: Scatter plots of the cause-effect pairs in simulation scenario `SIM-ln`.

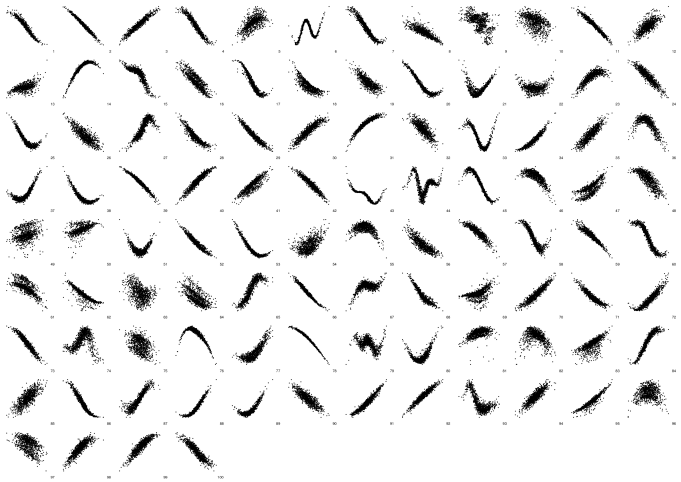

Figure 10: Scatter plots of the cause-effect pairs in simulation scenario `SIM-G`.

characteristic (ROC) curves and used the area under the curve (AUC) as performance measure.

Some methods have an advantage in the second setting, as the scores on which their decisions are based yield a reasonably accurate ranking of the decisions. By only taking the most confident (highest ranked) decisions, the accuracy of these decisions increases, and this leads to a higher AUC than for random confidence estimates. Which of the two evaluation measures (accuracy or AUC) is the most relevant depends on the application.[19]

4.4.1 Weights

For the CEP data, we cannot always consider pairs that come from the same data set as independent. For example, in the case of the `Abalone` data set (Bache and Lichman, 2013; Nash et al., 1994), the variables "whole weight", "shucked weight", "viscera weight", "shell weight" are strongly correlated. Considering the four pairs (age, whole weight), (age, shucked weight), etc., as independent could introduce a bias. We (conservatively) correct for that bias by downweighting these pairs. In general, we chose the weights such that the weights of all pairs from the same data set are equal and sum to one. For the real-world cause-effect pairs, the weights are specified in Table 4. For the simulated pairs, we do not use weighting.

4.4.2 Forced-decision: Evaluation of Accuracy

In the "forced-decision" setting, we calculate the weighted accuracy of a method in the following way:

$$\text{accuracy} = \frac{\sum_{m=1}^{M} w_m \delta_{\hat{d}_m, d_m}}{\sum_{m=1}^{M} w_m},$$

where d_m is the true causal direction for the m'th pair (either "$\leftarrow$" or "$\rightarrow$"), $\hat{d}_m$ is the estimated direction (one of "$\leftarrow$", "$\rightarrow$", and "?"), and w_m is the *weight* of the pair. Note that we are only awarding correct decisions, i.e., if no estimate is given (d_m = "?"), this will negatively affect the accuracy. We calculate confidence intervals assuming a binomial distribution using the method by Clopper and Pearson (1934).

4.4.3 Ranked-decision: Evaluation of AUC

To construct an ROC curve, we need to rank the decisions based on some heuristic estimate of confidence. For most methods we simply use

$$\hat{S} := -\hat{C}_{X \to Y} + \hat{C}_{Y \to X}. \tag{24}$$

19. In earlier work, we have reported accuracy-decision rate curves instead of ROC curves. However, it is easy to visually overinterpret the significance of such a curve in the low decision-rate region. In addition, AUC was used as the evaluation measure by Guyon et al. (2016). A slight disadvantage of ROC curves is that they introduce an asymmetry between "positives" and "negatives", whereas for our task, there is no such asymmetry: we can easily transform a positive into a negative and vice versa by swapping the variables X and Y. Therefore, "accuracy" is a more natural measure than "precision" in our setting. We mitigate this problem by balancing the class labels by swapping X and Y variables for a subset of the pairs.

The interpretation is that the higher $\hat{S}$, the more likely $X \to Y$, and the lower $\hat{S}$, the more likely $Y \to X$. For `ANM-pHSIC`, we use a different heuristic:

$$\hat{S} := \begin{cases} \frac{-1}{\min\{\hat{C}_{X\to Y}, \hat{C}_{Y\to X}\}} & \text{if } \hat{C}_{X\to Y} < \hat{C}_{Y\to X} \\ \frac{1}{\min\{\hat{C}_{X\to Y}, \hat{C}_{Y\to X}\}} & \text{if } \hat{C}_{X\to Y} > \hat{C}_{Y\to X}, \end{cases} \tag{25}$$

and for `ANM-HSIC`, we use:

$$\hat{S} := \begin{cases} \frac{-1}{1-\min\{\hat{C}_{X\to Y}, \hat{C}_{Y\to X}\}} & \text{if } \hat{C}_{X\to Y} < \hat{C}_{Y\to X} \\ \frac{1}{1-\min\{\hat{C}_{X\to Y}, \hat{C}_{Y\to X}\}} & \text{if } \hat{C}_{X\to Y} > \hat{C}_{Y\to X}. \end{cases} \tag{26}$$

In the "ranked-decision" setting, we also use weights to calculate weighted recall (depending on a threshold θ):

$$\text{recall}(\theta) = \frac{\sum_{m=1}^{M} w_m \mathbf{1}_{\hat{S}_m > \theta} \delta_{d_m,\to}}{\sum_{m=1}^{M} w_m \delta_{d_m,\to}},$$

where $\hat{S}_m$ is the heuristic score of the m'th pair (high values indicating high likelihood that $d_m = \ \to$, low values indicating high likelihood that $d_m = \ \leftarrow$), and the weighted precision (also depending on θ):

$$\text{precision}(\theta) = \frac{\sum_{m=1}^{M} w_m \mathbf{1}_{\hat{S}_m > \theta} \delta_{d_m,\to}}{\sum_{m=1}^{M} w_m \mathbf{1}_{\hat{S}_m > \theta}}.$$

We use the `MatLab` routine `perfcurve` to produce (weighted) ROC curves and to estimate weighted AUC and confidence intervals for the weighted AUC by bootstrapping.[20]

5. Results

In this section, we report the results of the experiments that we carried out in order to evaluate the performance of various methods. We plot the accuracies and AUCs as box plots, indicating the estimated (weighted) accuracy or AUC, the corresponding 68% confidence interval, and the 95% confidence interval. If there were pairs for which no decision was taken because of some failure, the number of nondecisions is indicated on the corresponding box plot. The methods that we evaluated are listed in Table 2. Computation times are reported in Appendix E.

5.1 Additive Noise Models

We start by reporting the results for methods that exploit additivity of the noise. Figure 11 shows the performance of all ANM methods on different unperturbed data sets, i.e., the CEP benchmark and various simulated data sets. Figure 12 shows the performance of the same methods on different perturbations of the CEP benchmark data. The six variants `sp1`,...,`sp6` of the spacing estimators perform very similarly, so we show only the results for `ANM-ent-sp1`. For the "undiscretized" perturbed version of the CEP benchmark data, GP regression failed in one case because of a numerical problem, which explains the failures across all methods in Figure 12 for that case.

20. We used the "percentile method" (`BootType = 'per'`) as the default method ("bias corrected and accelerated percentile method") sometimes yielded an estimated AUC that fell outside the estimated 95% confidence interval of the AUC.

Name	Algorithm	Score	Heuristic	Details
`ANM-pHSIC`	1	(4)	(25)	DR, adaptive kernel bandwidth
`ANM-HSIC`	1	(5)	(26)	DR, adaptive kernel bandwidth
`ANM-HSIC-ds`	1	(5)	(26)	DS, adaptive kernel bandwidth
`ANM-HSIC-fk`	1	(5)	(26)	DR, fixed kernel bandwidth (0.5)
`ANM-HSIC-ds-fk`	1	(5)	(26)	DS, fixed kernel bandwidth (0.5)
`ANM-ent-...`	1	(8)	(24)	DR, entropy estimators from Table 1
`ANM-Gauss`	1	(10)	(24)	DR
`ANM-FN`	2	(11)	(24)	
`ANM-MML`	2	(12)	(24)	
`IGCI-slope`	3	(19)	(24)	
`IGCI-slope++`	3	(21)	(24)	
`IGCI-ent-...`	3	(20)	(24)	Entropy estimators from Table 1

Table 2: The methods that are evaluated in this work. DS = Data Splitting, DR = Data Recycling.

5.1.1 HSIC-based Scores

As we see in Figure 11 and Figure 12, the ANM methods that use HSIC perform reasonably well on all data sets, obtaining accuracies between 63% and 85%. Note that the simulated data (and also the real-world data) deviate in at least three ways from the assumptions made by the additive noise method: (i) the noise is not additive, (ii) a confounder can be present, and (iii) additional measurement noise was added to both cause and effect. Moreover, the results turn out to be robust against small perturbations of the data. This shows that the additive noise method can perform reasonably well, even in case of model misspecification.

The results of `ANM-pHSIC` and `ANM-HSIC` are very similar. The influence of various implementation details on performance is small. On the CEP benchmark, data-splitting (`ANM-HSIC-ds`) slightly increases accuracy, whereas using a fixed kernel (`ANM-HSIC-fk`, `ANM-HSIC-ds-fk`) slightly lowers AUC. Generally, the differences in performance are small and not statistically significant. The variant `ANM-HSIC-ds-fk` is proved to be consistent in Appendix A. If standard GP regression satisfies the property in (32), then `ANM-HSIC-fk` is also consistent.

5.1.2 Entropy-based Scores

For the entropy-based score (8), we see in Figure 11 and Figure 12 that the results depend strongly on which entropy estimator is used.

All (nonparametric) entropy estimators (`1sp`, `3NN`, `spi`, `KDP`, `PSD`) perform well on simulated data, with the exception of `EdE`. On the CEP benchmark on the other hand, the performance varies greatly over estimators. One of the reasons for this are discretization

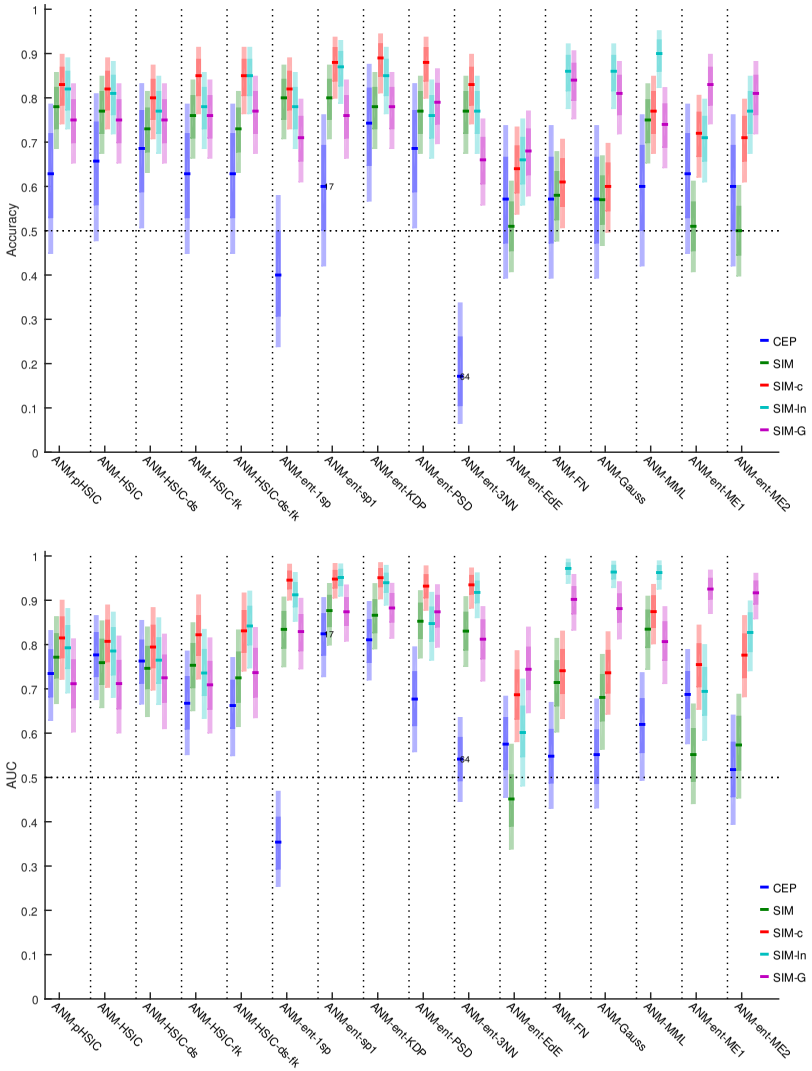

Figure 11: Accuracies (top) and AUCs (bottom) of various ANM methods on different (unperturbed) data sets. For the variants of the spacing estimator, only the results for `sp1` are shown, as results for `sp2`,...,`sp6` were similar.

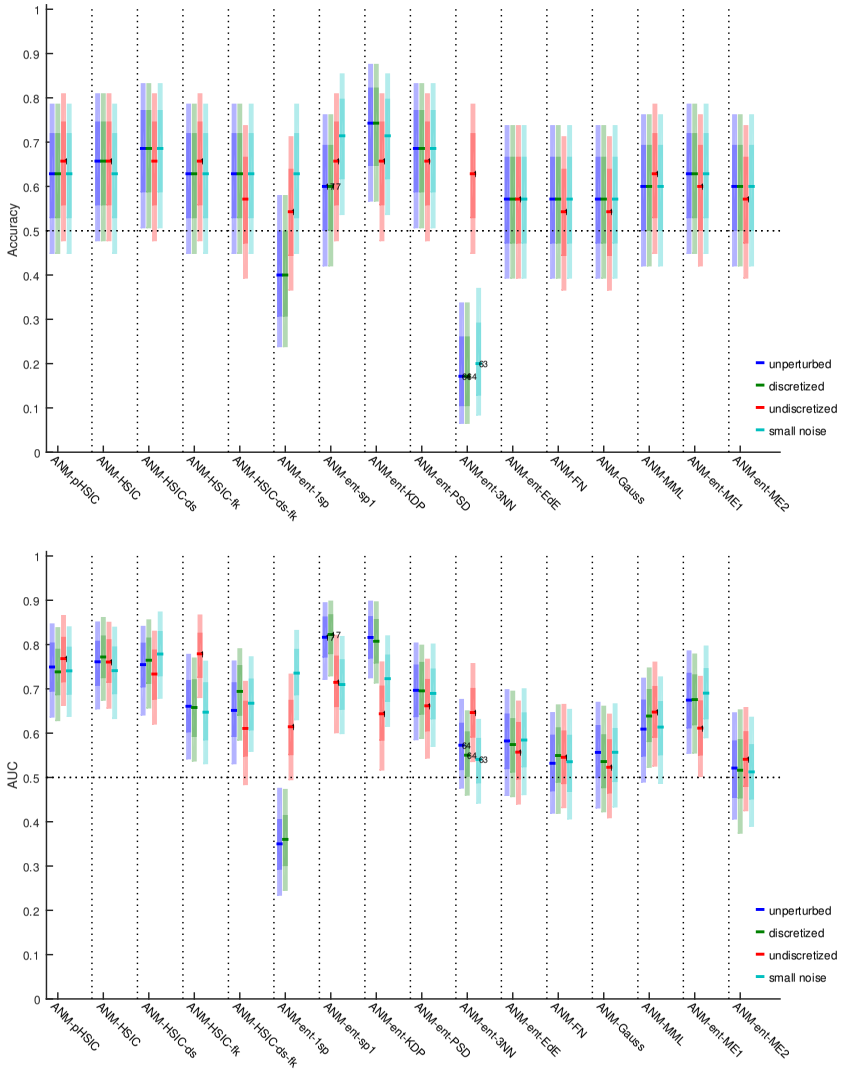

Figure 12: Accuracies (top) and AUCs (bottom) of various ANM methods on different perturbations of the CEP benchmark data. For the variants of the spacing estimator, only the results for `sp1` are shown, as results for `sp2`,...,`sp6` were similar.

effects. Indeed, the differential entropy of a variable that can take only a finite number of values is $-\infty$. The way in which differential entropy estimators treat values that occur multiple times differs, and this can have a large influence on the estimated entropy. For example, `1sp` simply ignores values that occur more than once, which leads to a performance that is below chance level on the CEP data. `3NN` returns $-\infty$ (for both $\hat{C}_{X\to Y}$ and $\hat{C}_{Y\to X}$) in the majority of the pairs in the CEP benchmark and therefore often cannot decide. The spacing estimators `sp`i also return $-\infty$ in quite a few cases. The only (non-parametric) entropy-based ANM methods that perform well on both the CEP benchmark data and the simulated data are `ANM-ent-KDP` and `ANM-ent-PSD`. Of these two methods, `ANM-ent-PSD` seems more robust under perturbations than `ANM-ent-KDP`, and can compete with the HSIC-based methods.

5.1.3 Other Scores

Consider now the results for the parametric entropy estimators (`ANM-Gauss`, `ANM-ent-ME1`, `ANM-ent-ME2`), the empirical-Bayes method `ANM-FN`, and the MML method `ANM-MML`.

First, note that `ANM-Gauss` and `ANM-FN` perform very similarly. This means that the difference between these two scores (i.e., the complexity measure of the regression function, see also Appendix B) does not outweigh the common part (the likelihood) of these two scores. Both these scores do not perform much better than chance on the CEP data, probably because the Gaussianity assumption is typically violated in real data. They do obtain high accuracies and AUCs for the `SIM-ln` and `SIM-G` scenarios. For `SIM-G` this is to be expected, as the assumption that the cause has a Gaussian distribution is satisfied in that scenario. For `SIM-ln` it is not evident why these scores perform so well—it could be that the noise is close to additive and Gaussian in that scenario.

The related score `ANM-MML`, which employs a more sophisticated complexity measure for the distribution of the cause, performs better on the two simulation settings `SIM` and `SIM-c`. However, `ANM-MML` performs worse in the `SIM-G` scenario, which is probably due to a higher variance of the MML complexity measure compared with the simple Gaussian entropy measure. This is in line with expectations. However, performance of `ANM-MML` is hardly better than chance on the CEP data. In particular, the AUC of `ANM-MML` is worse than that of `ANM-pHSIC`.

The parametric entropy estimators `ME1` and `ME2` do not perform very well on the `SIM` data, although their performance on the other simulated data sets (in particular `SIM-G`) is good. The reasons for this behaviour are not understood; we speculate that the parametric assumptions made by these estimators match the actual distribution of the data in these particular simulation settings quite well. The accuracy and AUC of `ANM-ent-ME1` and `ANM-ent-ME2` on the CEP data are lower than those of `ANM-pHSIC`.

5.2 Information Geometric Causal Inference

Here we report the results of the evaluation of different IGCI variants. Figure 13 shows the performance of all the IGCI variants on different (unperturbed) data sets, the CEP benchmark and four different simulation settings, using the uniform base measure. Figure 14 shows the same for the Gaussian base measure. Figure 15 shows the performance of the IGCI methods on different perturbations of the CEP benchmark, using the uniform base measure,

and Figure 16 for the Gaussian base measure. Again, the six variants `sp1`,...,`sp6` of the spacing estimators perform very similarly, so we show only the results for `IGCI-ent-sp1`.

Let us first look at the performance on simulated data. Note that none of the IGCI methods performs well on the simulated data when using the uniform base measure. A very different picture emerges when using the Gaussian base measure: here the performance covers a wide spectrum, from lower than chance level on the `SIM` data to accuracies higher than 90% on `SIM-G`. The choice of the base measure clearly has a larger influence on the performance than the choice of the estimation method.

As IGCI was designed for the bijective deterministic case, one would expect that IGCI would work best on `SIM-ln` (without depending too strongly on the reference measure), because in that scenario the noise is relatively small. Surprisingly, this does not turn out to be the case. To understand this unexpected behavior, we inspect the scatter plots in Figure 9 and observe that the functions in `SIM-ln` are either non-injective or relatively close to linear. Both can spoil the performance despite having low noise (see also the remarks at the end of Subsection 3.2 on finite sample effects).

For the more noisy settings, earlier experiments showed that `IGCI-slope` and `IGCI-1sp` can perform surprisingly well on simulated data (Janzing et al., 2012). Here, however, we see that the performance of all IGCI variants on noisy data depends strongly on characteristics of the data generation process and on the chosen base measure. IGCI seems to pick up certain features in the data that turn out to be correlated with the causal direction in some settings, but can be anticorrelated with the causal direction in other settings. In addition, our results suggest that if the distribution of the cause is close to the base measure used in IGCI, then also for noisy data the method may work well (as in the `SIM-G` setting). However, for causal relations that are not sufficiently non-linear, performance can drop significantly (even below chance level) in case of a discrepancy between the actual distribution of the cause and the base measure assumed by IGCI.

Even though the performance of all IGCI variants with uniform base measure is close to chance level on the simulated data, most methods perform better than chance on the CEP data (with the exception of `IGCI-ent-sp1` and `IGCI-ent-3NN`). When using the Gaussian base measure, performance of IGCI methods on CEP data varies considerably depending on implementation details. For some IGCI variants the performance on CEP data is robust to small perturbations (most notably the parametric entropy estimators), but for most non-parametric entropy estimators and for `IGCI-slope`, there is a strong dependence and sometimes even an inversion of the accuracy when perturbing the data slightly. We do not have a good explanation for these observations.

5.2.1 Original Implementations

Let us now take a closer look at the accuracies of the original methods `IGCI-slope` and `IGCI-ent-1sp` that were proposed by Daniušis et al. (2010); Janzing et al. (2012), and at the newly introduced `IGCI-slope++` that is closely related to `IGCI-slope`. The IGCI variants `slope`, `slope++` and `ent-1sp` perform very similar on all data sets. For both uniform and Gaussian base measures, the performance is better than chance level on the CEP benchmark, but not as much as in previous evaluations on earlier versions of the benchmark. The discrepancy with the accuracies of around 80% reported by Janzing et al.

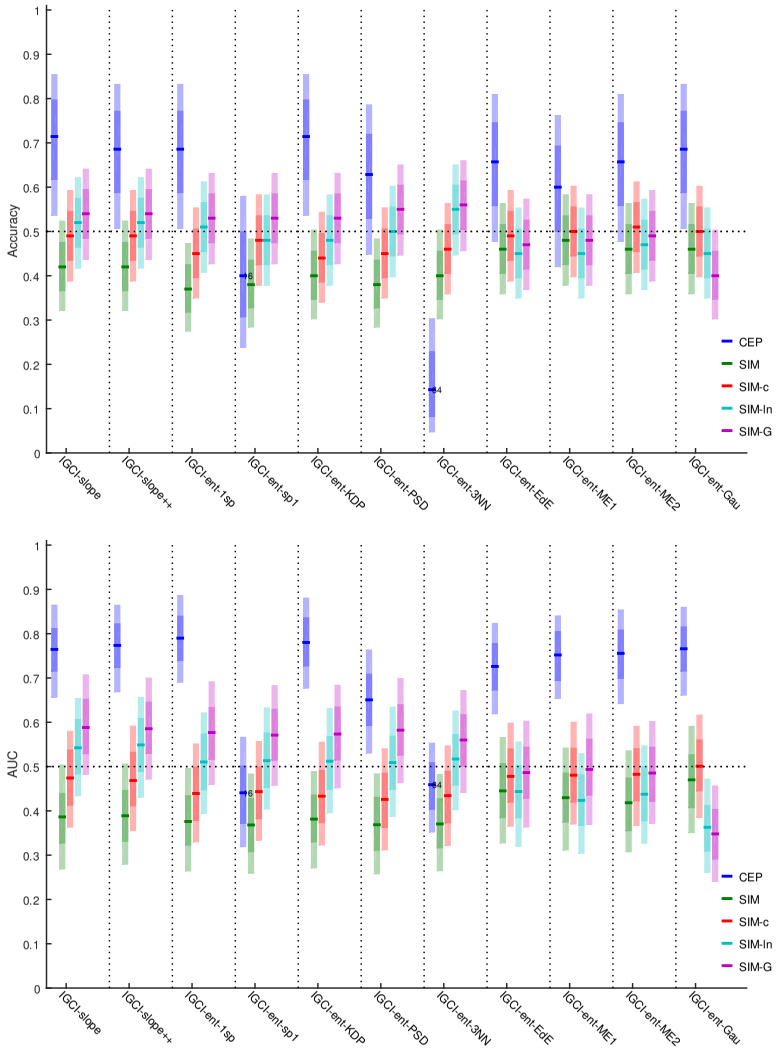

Figure 13: Accuracies (top) and AUCs (bottom) for various IGCI methods using the uniform base measure on different (unperturbed) data sets.

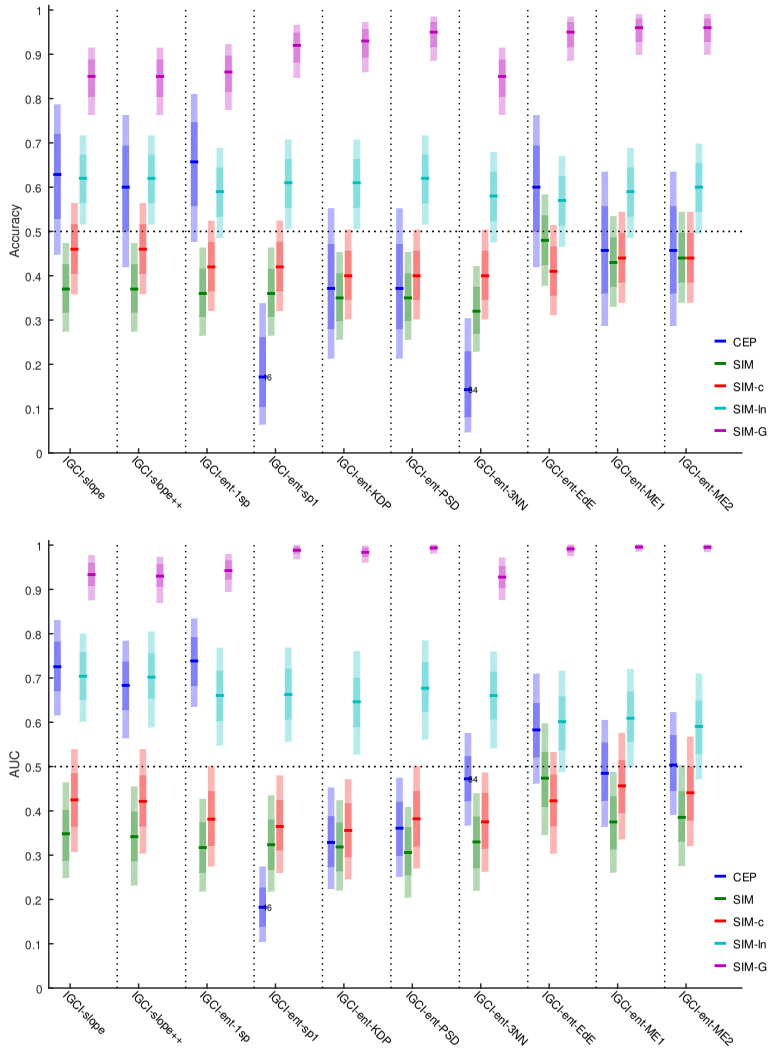

Figure 14: Accuracies (top) and AUCs (bottom) for various IGCI methods using the Gaussian base measure on different (unperturbed) data sets.

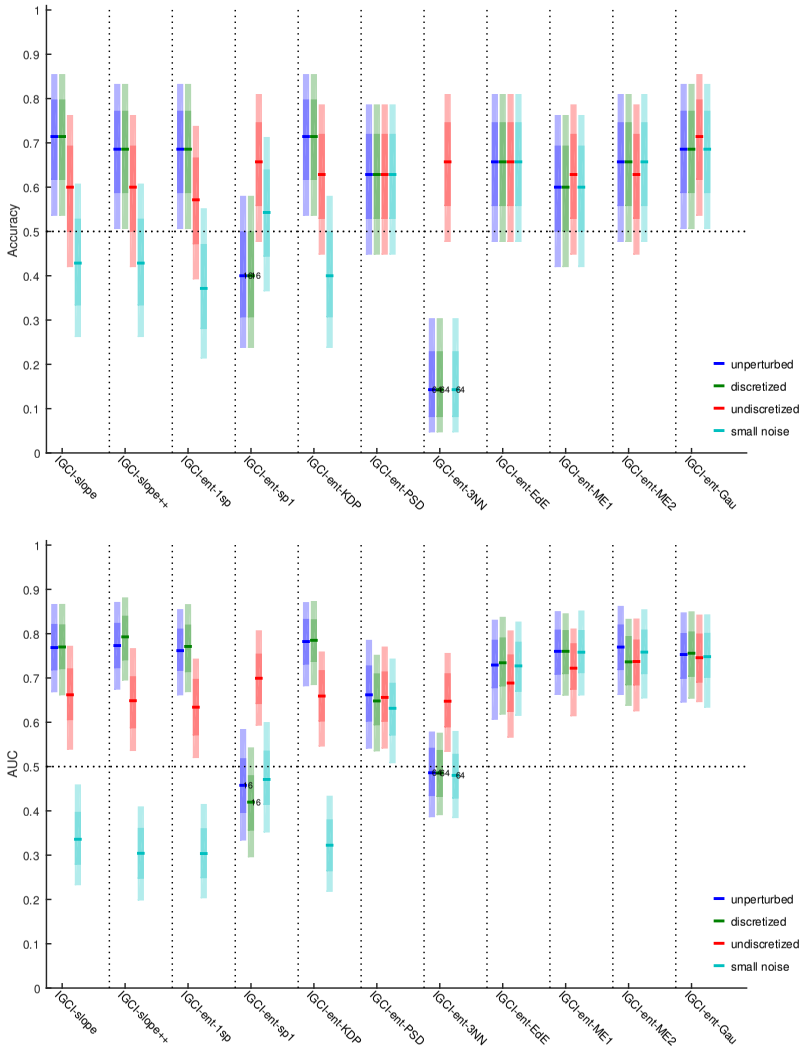

Figure 15: Accuracies (top) and AUCs (bottom) for various IGCI methods using the uniform base measure on different perturbations of the CEP benchmark data.

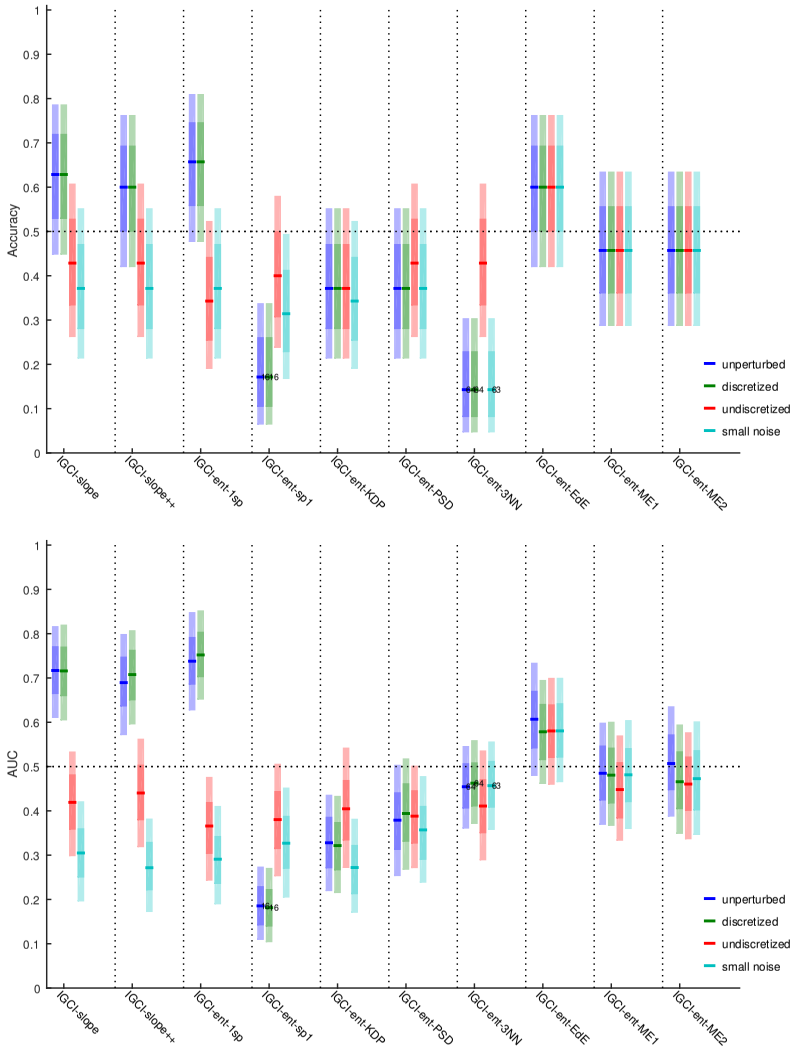

Figure 16: Accuracies (top) and AUCs (bottom) for various IGCI methods using the Gaussian base measure on different perturbations of the CEP benchmark data.

(2012) could be explained by the fact that here we evaluate on a larger set of cause-effect pairs, and we chose the weights more conservatively.

It is also interesting to look at the behavior under perturbations of the CEP data. When using the uniform base measure, the accuracy of both `IGCI-slope` and `IGCI-ent-1sp` drops back to chance level if small noise is added, whereas AUC even becomes worse than chance level. For the Gaussian base measure, both accuracy and AUC become worse than random guessing on certain perturbations of the CEP data, although discretization does not affect performance. This observation motivated the introduction of the slope-based estimator `IGCI-slope++` that uses (21) instead of (19) in order to deal better with repetitions of values. However, as we can see, this estimator does not perform better in practice than the original estimator `IGCI-slope`.

5.2.2 Nonparametric Entropy Estimators

It is clear that discretization effects play an important role in the performance of the nonparametric entropy estimators. For example, the closely related estimators `1sp` and `sp`i perform comparably on simulated data, but on the CEP data, the `sp`i estimators perform worse because of nondecisions due to repeated values. Similarly, the bad performance of `IGCI-ent-3NN` on the CEP data is related to discretization effects. This is in line with our observations on the behavior of these entropy estimators when using them for entropy-based ANM methods.

Further, note that the performance of `IGCI-ent-KDP` is qualitatively similar to that of `IGCI-ent-PSD`, but in contrast with the `PSD` estimator, the results of the `KDP` estimator are not robust under perturbations when using the uniform base measure. The only nonparametric entropy estimators that give results that are robust to small perturbations of the data (for both base measures) are `PSD` and `EdE`. The performance of `IGCI-ent-PSD` on the CEP benchmark depends on the chosen base measure: for the uniform base it is better than chance level, for the Gaussian base measure it is worse than chance level. Interestingly, the `EdE` estimator that performed poorly for ANM gives consistently good results on the CEP benchmark when used for IGCI: it is the only nonparametric entropy estimator that yields results that are better than chance for both base measures and irrespective of whether the data were perturbed or not.

Apparently, implementation details of entropy estimators can result in huge differences in performance, often in ways that we do not understand well.

5.2.3 Parametric Entropy Estimators

Let us finally consider the performance of entropy-based IGCI methods that use parametric entropy estimators, which make additional assumptions on the distribution. As expected, these estimators are robust to small perturbations of the data.

Interestingly, `IGCI-ent-Gau` with uniform base measure turns out to be one of the best IGCI methods on the CEP benchmark, in the sense that it obtains good accuracy and AUC and in addition is robust to perturbations. Note that the performance of `IGCI-ent-Gau` on the CEP benchmark is comparable with that of the original implementation `IGCI-slope` and the newer version `IGCI-slope++`, but that only `IGCI-ent-Gau` is robust to small perturbations of the data. This estimator simply estimates entropy by assuming a Gaussian

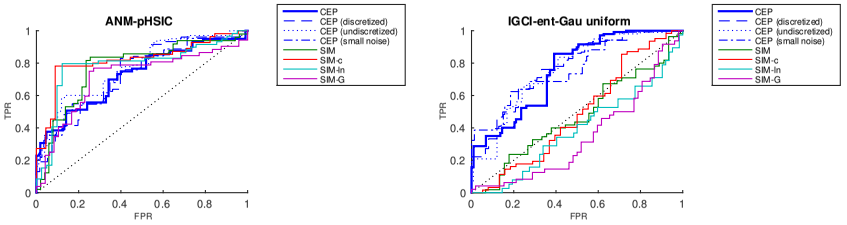

Figure 17: ROC curves for two of the best-performing methods (`ANM-pHSIC` and `IGCI-ent-Gau`). Both methods work well on the CEP benchmark and keep performing well under small perturbations of the data, but only `ANM-pHSIC` also performs well on the simulated data.

distribution. In other words, it uses:

$$\hat{C}_{X\to Y} := \frac{1}{2}\log\widehat{\mathbb{V}\mathrm{ar}}(\tilde{\boldsymbol{y}}) - \frac{1}{2}\log\widehat{\mathbb{V}\mathrm{ar}}(\tilde{\boldsymbol{x}}) = \log\left(\frac{\sqrt{\widehat{\mathbb{V}\mathrm{ar}}(\boldsymbol{y})}}{\max(\boldsymbol{y})-\min(\boldsymbol{y})}\Big/\frac{\sqrt{\widehat{\mathbb{V}\mathrm{ar}}(\boldsymbol{x})}}{\max(\boldsymbol{x})-\min(\boldsymbol{x})}\right).$$

Apparently, the ratio of the size of the support of the distribution and its standard deviation is already quite informative on the causal direction for the CEP data. This might also explain the relatively good performance on this benchmark of `IGCI-ent-ME1` and `IGCI-ent-ME2` when using the uniform base measure, as these estimate entropy by fitting a parametric distribution to the data (which includes Gaussian distributions as a special case). On the other hand, these methods do not work better than chance on the simulated data.

Now let us look at the results when using the Gaussian base measure. `IGCI-ent-Gau` makes no sense in combination with the Gaussian base measure. `IGCI-ent-ME1` and `IGCI-ent-ME2` on the CEP data do not perform better than chance. On simulated data, they only do (extremely) well for the `SIM-G` scenario which uses a Gaussian distribution of the cause measure, i.e., for which the chosen base measure exactly corresponds with the distribution of the cause.

6. Discussion and Conclusion

In this work, we considered a challenging bivariate causal discovery problem, where the task is to decide whether X causes Y or vice versa, using only a sample of purely observational data. We reviewed two families of methods that can be applied to this task: methods based on Additive Noise Models (ANMs) and Information Geometric Causal Inference (IGCI) methods. We discussed various possible implementations of these methods and how they are related.

In addition, we have proposed the CauseEffectPairs benchmark data set consisting of 100 real-world cause-effect pairs and we provided our justifications for the ground truths. We have used this benchmark data in combination with several simulated data sets in order

to evaluate various bivariate causal discovery methods. Our main conclusions (illustrated in Figure 17) are twofold:

1. The ANM methods that use HSIC perform reasonably well on all data sets (including the perturbed versions of the CEP benchmark and all simulation settings), obtaining accuracies between 63% and 85% (see Figures 11 and 12). In particular, the original `ANM-pHSIC` method obtains an accuracy of 63 ± 10 % and an AUC of 0.74 ± 0.05 on the CEP benchmark. The only other ANM method that performs well on all data sets is `ANM-ent-PSD`. It obtains a higher accuracy ($69 \pm 10\%$) than `ANM-pHSIC` on the CEP benchmark, but a lower AUC (0.68 ± 0.06), but these differences are not statistically significant.

2. The performance of IGCI-based methods varies greatly depending on implementation details, perturbations of the data and certain characteristics of the data, in ways that we do not fully understand (see Figures 13, 14, 15, 16). In many cases, causal relations seem to be too linear for IGCI to work well. None of the IGCI implementations performed well on *all* data sets that we considered, and the apparent better-than-chance performance of some of these methods on the CEP benchmark remains somewhat of a mystery.

The former conclusion about the performance of `ANM-pHSIC` is in line with earlier reports, but the latter conclusion is surprising, considering that good performance of `IGCI-slope` and `IGCI-ent-1sp` has been reported on several occasions in earlier work (Daniušis et al., 2010; Mooij et al., 2010; Janzing et al., 2012; Statnikov et al., 2012; Sgouritsa et al., 2015). One possible explanation that the performance of IGCI on simulated data here differs from earlier reports is that earlier simulations used considerably smoother distributions of the cause variable.

Ironically, the original ANM method `ANM-pHSIC` proposed by Hoyer et al. (2009) turned out to be one of the best methods overall, despite the recent research efforts aimed at developing better methods. This observation motivated the consistency proof of HSIC-based ANM methods, the major theoretical contribution of this work. We expect that extending this consistency result to the multivariate case (see also Peters et al., 2014) should be straightforward.

One reason for the disappointing performance of several methods (in particular, the slope-based IGCI estimators and methods that make use of certain nonparametric differential entropy estimators) is discretization. When dealing with real-world data on a computer, variables of a continuous nature are usually discretized because they have to be represented as floating point numbers. Often, additional rounding is applied, for example because only the most significant digits are recorded. We found that for many methods, especially for those that use differential entropy estimators, (coarse) discretization of the data causes problems. This suggests that performance of several methods can still be improved, e.g., by using entropy estimators that are more robust to such discretization effects. The HSIC independence measure (and its p-value) and the `PSD` entropy estimator were found to be robust against small perturbations of the data, including discretization.

Since we compared many different implementations (which turned out to have quite different performance characteristics), we need to use a strong correction for multiple testing

if we would like to conclude that one of these methods performs significantly better than chance. Although it seems unlikely that the good performance of `ANM-pHSIC` on both CEP data *and* all simulated data is due to chance alone, eventually we are most interested in the performance on real-world data alone. Unfortunately, the CEP benchmark turned out to be too small to warrant significant conclusions for any of the tested methods.

A rough estimate how large the CauseEffectPairs benchmark should have been in order to obtain significant results can easily be made. Using a standard (conservative) Bonferroni correction, taking into account that we compared 37 methods, we would need about 120 (weighted) pairs for an accuracy of 65% to be considered significant (with two-sided testing and 5% significance threshold). This is about four times as much as the current number of 37 (weighted) pairs in the CauseEffectPairs benchmark. Therefore, we suggest that at this point, the highest priority regarding future work should be to obtain more validation data, rather than developing additional methods or optimizing computation time of existing methods. We hope that our publication of the CauseEffectPairs benchmark data inspires researchers to collaborate on this important task and we invite everybody to contribute pairs to the CauseEffectPairs benchmark data.

Concluding, our results provide some evidence that distinguishing cause from effect is indeed possible from purely observational real-world data by exploiting certain statistical patterns in the data. However, the performance of current state-of-the-art bivariate causal discovery methods still has to be improved further in order to enable practical applications, and more validation data are needed in order to obtain statistically significant conclusions. Furthermore, it is not clear at this stage under what assumptions current methods could be extended to deal with possible confounding variables, an important issue in practice.

Acknowledgments

JMM was supported by NWO, the Netherlands Organization for Scientific Research (VIDI grant 639.072.410). JP received funding from the People Programme (Marie Curie Actions) of the European Union's Seventh Framework Programme (FP7/2007-2013) under REA grant agreement no 326496. The authors thank Stefan Harmeling for fruitful discussions and providing the code to create Figure 6. We also thank S. Armagan Tarim and Steve Prestwich for contributing cause-effect pairs `pair0094`, `pair0095`, and `pair0096`. Finally, we thank several anonymous reviewers for their comments that helped us to improve the drafts.

Appendix A. Consistency Proof of `ANM-HSIC`

In this Appendix, we prove the consistency of Algorithm 1 with score (6), which is closely related to the algorithm originally proposed by Hoyer et al. (2009) that uses score (4). The main difference is that the original implementation uses the HSIC p-value, whereas here, we use the HSIC value itself as a score. Also, we consider the option of splitting the data set into one part for regression and another part for independence testing. Finally, we fix the HSIC kernel instead of letting its bandwidth be chosen by a heuristic that depends on

the data. The reason that we make these small modifications is that they lead to an easier proof of consistency of the method.

We start with recapitulating the definition and basic properties of the Hilbert Schmidt Independence Criterion (HSIC) in Section A.1. Then, we discuss asymptotic properties of non-parametric regression methods in Section A.2. Finally, we combine these ingredients in Section A.3.

A.1 Consistency of HSIC

We recapitulate the definitions and some asymptotic properties of the Hilbert Schmidt Independence Criterion (HSIC), following mostly the notations and terminology in Gretton et al. (2005). The HSIC estimator that we use here is the original biased estimator proposed by Gretton et al. (2005).

Definition 11 *Given two random variables $X \in \mathcal{X}$ and $Y \in \mathcal{Y}$ with joint distribution $\mathbb{P}_{X,Y}$, and bounded kernels $k : \mathcal{X}^2 \to \mathbb{R}$ and $l : \mathcal{Y}^2 \to \mathbb{R}$, we define the* ***population HSIC*** *of X and Y as*

$$\begin{aligned}\mathrm{HSIC}_{k,l}(X,Y) :=& \mathbb{E}\big(k(X,X')l(Y,Y')\big) + \mathbb{E}\big(k(X,X')\big)\mathbb{E}\big(l(Y,Y')\big) \\ &- 2\mathbb{E}\Big(\mathbb{E}\big(k(X,X')\,|\,X\big)\mathbb{E}\big(l(Y,Y')\,|\,Y\big)\Big).\end{aligned}$$

Here, (X,Y) and (X',Y') are two independent random variables distributed according to $\mathbb{P}_{X,Y}$.

When k and l are clear from the context, we will typically suppress the dependence of the population HSIC on the choice of the kernels k and l, simply writing $\mathrm{HSIC}(X,Y)$ instead. The justification for the name "independence criterion" stems from the following important result (Fukumizu et al., 2008, Theorem 3):

Lemma 12 *Whenever the product kernel $k \cdot l$ is characteristic (in the sense of Fukumizu et al. (2008); Sriperumbudur et al. (2010)): $\mathrm{HSIC}_{k,l}(X,Y) = 0$ if and only if $X \perp\!\!\!\perp Y$ (i.e., X and Y are independent).* ■

A special case of this lemma, assuming that X and Y have compact domain, was proved originally in Gretton et al. (2005). Recently, Gretton (2015) showed that a similar result also holds if both kernels k and l are characteristic and satisfy some other conditions as well. Intuitively, a characteristic kernel leads to an injective embedding of probability measures into the corresponding Reproducible Kernel Hilbert Space (RKHS). The HSIC is the squared RKHS distance between the embedded joint distribution and the embedded product of the marginals. Given that the embedding is injective, this distance is zero if and only if the variables are independent. Examples of characteristic kernels are Gaussian RBF kernels and Laplace kernels. For more details on the notion of characteristic kernel (see Sriperumbudur et al., 2010). We will use the following (biased) estimator of the population HSIC (Gretton et al., 2005):

Definition 13 *Given two N-tuples (with $N \geq 2$) $\boldsymbol{x} = (x_1, \ldots, x_N) \in \mathcal{X}^N$ and $\boldsymbol{y} = (y_1, \ldots, y_N) \in \mathcal{Y}^N$, and bounded kernels $k : \mathcal{X}^2 \to \mathbb{R}$ and $l : \mathcal{Y}^2 \to \mathbb{R}$, we define*

$$\widehat{\mathrm{HSIC}}_{k,l}(\boldsymbol{x},\boldsymbol{y}) := (N-1)^{-2}\mathrm{tr}(KHLH) = (N-1)^{-2}\sum_{i,j=1}^{N} \bar{K}_{ij}L_{ij}, \tag{27}$$

where $K_{ij} = k(x_i, x_j)$, $L_{ij} = l(y_i, y_j)$ are Gram matrices and $H_{ij} = \delta_{ij} - N^{-1}$ is a centering matrix, and we write $\bar{K} := HKH$ for the centered Gram matrix K. Given an i.i.d. sample $\mathcal{D}_N = \{(x_n, y_n)\}_{n=1}^N$ from $\mathbb{P}_{X,Y}$, we define the ***empirical HSIC*** *of X and Y estimated from $\mathcal{D}_N$ as*

$$\widehat{\mathrm{HSIC}}_{k,l}(X,Y;\mathcal{D}_N) := \widehat{\mathrm{HSIC}}_{k,l}(\boldsymbol{x},\boldsymbol{y}).$$

Again, when k and l are clear from the context, we will typically suppress the dependence of the empirical HSIC on the choice of the kernels k and l. Unbiased estimators of the population HSIC were proposed in later work (Song et al., 2012), but we will not consider those here. A large deviation result for this empirical HSIC estimator is given by Gretton et al. (2005, Theorem 3):

Lemma 14 *Assume that kernels k and l are bounded almost everywhere by 1, and are non-negative. Suppose that the data set $\mathcal{D}_N$ consists of N i.i.d. samples from some joint probability distribution $\mathbb{P}_{X,Y}$. Then, for $N \geq 2$ and all $\delta > 0$, with probability at least $1 - \delta$:*

$$\left|\mathrm{HSIC}_{k,l}(X,Y) - \widehat{\mathrm{HSIC}}_{k,l}(X,Y;\mathcal{D}_N)\right| \leq \sqrt{\frac{\log(6/\delta)}{\alpha^2 N}} + \frac{c}{N},$$

where $\alpha^2 > 0.24$ and c are constants. ■

This directly implies the consistency of the empirical HSIC estimator:[21]

Corollary 15 *Let $(X_1,Y_1),(X_2,Y_2),\ldots$ be i.i.d. according to $\mathbb{P}_{X,Y}$. Defining the sequence of data sets $\mathcal{D}_N = \{(X_n,Y_n)\}_{n=1}^N$ for $N = 2,3,\ldots$, we have for non-negative bounded kernels k,l that, as $N \to \infty$:*

$$\widehat{\mathrm{HSIC}}_{k,l}(X,Y;\mathcal{D}_N) \xrightarrow{P} \mathrm{HSIC}_{k,l}(X,Y).$$

■

We do not know of any results for consistency of HSIC when using adaptive kernel parameters (i.e., when estimating the kernel from the data). This is why we only present a consistency result for fixed kernels here.

For the special case that $\mathcal{Y} = \mathbb{R}$, we will use the following continuity property of the empirical HSIC estimator. It shows that for a Lipschitz-continuous kernel l, the empirical HSIC is also Lipschitz-continuous in the corresponding argument, but with a Lipschitz constant that scales at least as $N^{-1/2}$ for $N \to \infty$. This novel technical result will be the key to our consistency proof of Algorithm 1 with score (6).

Lemma 16 *For all $N \geq 2$, for all $\boldsymbol{x} \in \mathcal{X}^N$, for all $\boldsymbol{y}, \boldsymbol{y}' \in \mathbb{R}^N$, for all bounded kernels $k : \mathcal{X}^2 \to \mathbb{R}$, and for all bounded and Lipschitz-continuous kernels $l : \mathbb{R}^2 \to \mathbb{R}$:*

$$\left|\widehat{\mathrm{HSIC}}(\boldsymbol{x},\boldsymbol{y}) - \widehat{\mathrm{HSIC}}(\boldsymbol{x},\boldsymbol{y}')\right| \leq \frac{32\lambda C}{\sqrt{N}}\left\|\boldsymbol{y} - \boldsymbol{y}'\right\|,$$

where $|k(\xi,\xi')| \leq C$ for all $\xi,\xi' \in \mathcal{X}$ and λ is the Lipschitz constant of l.

21. Let $X_1, X_2, \ldots$ be a sequence of random variables and let X be another random variable. We say that X_n converges to X **in probability**, written $X_n \xrightarrow{P} X$, if

$$\forall \epsilon > 0 : \qquad \lim_{n\to\infty} \mathbb{P}(|X_n - X| > \epsilon) = 0.$$

Proof From (27) it follows that:

$$\left|\widehat{\mathrm{HSIC}}(\boldsymbol{x},\boldsymbol{y}) - \widehat{\mathrm{HSIC}}(\boldsymbol{x},\boldsymbol{y}')\right| = (N-1)^{-2}\left|\sum_{i,j=1}^{N}\bar{K}_{ij}(L_{ij}-L'_{ij})\right|,$$

where $K_{ij} = k(x_i, x_j)$, $L_{ij} = l(y_i, y_j)$, $L'_{ij} = l(y'_i, y'_j)$ and $\bar{K} := HKH$ with $H_{ij} = \delta_{ij} - N^{-1}$. First, note that $|K_{ij}| \leq C$ implies that $\left|\bar{K}_{ij}\right| \leq 4C$:

$$\begin{aligned}\left|\bar{K}_{ij}\right| &= \left|K_{ij} - \frac{1}{N}\sum_{i'=1}^{N}K_{i'j} - \frac{1}{N}\sum_{j'=1}^{N}K_{ij'} + \frac{1}{N^2}\sum_{i',j'=1}^{N}K_{i'j'}\right| \\ &\leq |K_{ij}| + \frac{1}{N}\sum_{i'=1}^{N}\left|K_{i'j}\right| + \frac{1}{N}\sum_{j'=1}^{N}\left|K_{ij'}\right| + \frac{1}{N^2}\sum_{i',j'=1}^{N}\left|K_{i'j'}\right| \leq 4C.\end{aligned}$$

Now starting from the definition and using the triangle inequality:

$$\left|\sum_{i,j=1}^{N}\bar{K}_{ij}(L_{ij}-L'_{ij})\right| \leq \left|\sum_{i,j=1}^{N}\bar{K}_{ij}\big(l(y'_i,y'_j)-l(y'_i,y_j)\big)\right| + \left|\sum_{i,j=1}^{N}\bar{K}_{ij}\big(l(y'_i,y_j)-l(y_i,y_j)\big)\right|.$$

For the first term, using Cauchy-Schwartz (in $\mathbb{R}^{N^2}$) and the Lipschitz property of l:

$$\begin{aligned}\left|\sum_{i,j=1}^{N}\bar{K}_{ij}\big(l(y'_i,y'_j)-l(y'_i,y_j)\big)\right|^2 &\leq \left(\sum_{i,j=1}^{N}\left|\bar{K}_{ij}\right|^2\right)\left(\sum_{i,j=1}^{N}\left|l(y'_i,y'_j)-l(y'_i,y_j)\right|^2\right) \\ &\leq 16N^2C^2\cdot\lambda^2 N\sum_{j=1}^{N}\left|y'_j-y_j\right|^2 \\ &= 16N^3C^2\lambda^2\left\|\boldsymbol{y}'-\boldsymbol{y}\right\|^2.\end{aligned}$$

The second term is similar. The result now follows (using that $\frac{N}{N-1} \leq 2$ for $N \geq 2$). ■

A.2 Consistency of Nonparametric Regression

From now on, we will assume that both X and Y take values in $\mathbb{R}$. Györfi et al. (2002) provide consistency results for several nonparametric regression methods. Here we briefly discuss the main property ("weak universal consistency") that is of particular interest in our setting.

Given a distribution $\mathbb{P}_{X,Y}$, one defines the **regression function** of Y on X as the conditional expectation

$$f(x) := \mathbb{E}(Y \mid X = x).$$

Given an i.i.d. sample of data points $\mathcal{D}_N = \{(x_n, y_n)\}_{n=1}^N$ (the "training" data), a regression method provides an estimate of the regression function $\hat{f}(\,\cdot\,;\mathcal{D}_N)$. The **mean squared error on the training data** (also called "training error") is defined as:

$$\frac{1}{N}\sum_{n=1}^{N}\left|f(x_n)-\hat{f}(x_n;\mathcal{D}_N)\right|^2.$$

The **risk** (also called "generalization error"), i.e., the expected L_2 error on an independent test datum, is defined as:

$$\mathbb{E}_X\left|f(X)-\hat{f}(X;\mathcal{D}_N)\right|^2 = \int\left|f(x)-\hat{f}(x;\mathcal{D}_N)\right|^2 d\mathbb{P}_X(x).$$

Note that the risk is a random variable that depends on the training data $\mathcal{D}_N$.

If the expected risk converges to zero as the number of training points increases, the regression method is called "weakly consistent". More precisely, following Györfi et al. (2002):

Definition 17 *Let $(X_1,Y_1),(X_2,Y_2),\ldots$ be i.i.d. according to $\mathbb{P}_{X,Y}$. Defining training data sets $\mathcal{D}_N = \{(X_n,Y_n)\}_{n=1}^N$ for $N = 2,3,\ldots$, and writing $\mathbb{E}_{\mathcal{D}_N}$ for the expectation value when averaging over $\mathcal{D}_N$, a sequence of estimated regression functions $\hat{f}(\cdot;\mathcal{D}_N)$ is called **weakly consistent for a certain distribution** $\mathbb{P}_{X,Y}$ if*

$$\lim_{N\to\infty}\mathbb{E}_{\mathcal{D}_N}\left(\mathbb{E}_X\left|f(X)-\hat{f}(X;\mathcal{D}_N)\right|^2\right) = 0. \tag{28}$$

*A regression method is called **weakly universally consistent** if it is weakly consistent for all distributions $\mathbb{P}_{X,Y}$ with finite second moment of Y, i.e., with $\mathbb{E}_Y(Y^2) < \infty$.*

Many popular nonparametric regression methods have been shown to be weakly universally consistent (see e.g., Györfi et al., 2002). One might expect naïvely that if the expected risk goes to zero, then also the expected training error should vanish asymptotically:

$$\lim_{N\to\infty}\mathbb{E}_{\mathcal{D}_N}\left(\frac{1}{N}\sum_{n=1}^{N}\left|f(X_n)-\hat{f}(X_n;\mathcal{D}_N)\right|^2\right) = 0. \tag{29}$$

However, property (29) does not necessarily follow from (28).[22] One would expect that asymptotic results on the training error would actually be easier to obtain than results on

22. Here is a counterexample. Suppose that regression method $\hat{f}$ satisfies properties (29) and (28) and that X has bounded density. Given a smooth function $\phi : \mathbb{R} \to \mathbb{R}$ with support $\subset [-1,1]$, $0 \leq \phi(x) \leq 1$, and $\phi(0) = 1$, we now construct a modified sequence of estimated regression functions $\tilde{f}(\,\cdot\,;\mathcal{D}_N)$ that is defined as follows:

$$\tilde{f}(x;\mathcal{D}_N) := \hat{f}(x;\mathcal{D}_N) + \sum_{i=1}^{N}\phi\left(\frac{x-X_i}{\Delta_i^{(N)}}\right),$$

where the $\Delta_i^{(N)}$ should be chosen such that $\Delta_i^{(N)} \leq N^{-2}$ and that the intervals $[X_i - \Delta_i^{(N)}, X_i + \Delta_i^{(N)}]$ are disjoint. Then, we have that

$$\lim_{N\to\infty}\mathbb{E}_{\mathcal{D}_N}\left(\mathbb{E}_X\left|f(X)-\tilde{f}(X;\mathcal{D}_N)\right|^2\right) = 0,$$

but on the other hand,

$$\lim_{N\to\infty}\mathbb{E}_{\mathcal{D}_N}\frac{1}{N}\sum_{n=1}^{N}\left|f(X_n)-\tilde{f}(X_n;\mathcal{D}_N)\right|^2 = 1.$$

generalization error. One result that we found in the literature is Lemma 5 in Kpotufe et al. (2014), which states that a certain box kernel regression method satisfies (29) under certain assumptions on the distribution $\mathbb{P}_{X,Y}$. The reason that we bring this up at this point is that property (29) allows to prove consistency even when one uses the same data for both regression and independence testing (see also Lemma 19).

From now on, we will always consider the following setting. Let $(\tilde{X}_1, \tilde{Y}_1)$, $(\tilde{X}_2, \tilde{Y}_2)$, ... be i.i.d. according to some joint distribution $\mathbb{P}_{X,Y}$. We distinguish two different scenarios:

- "Data splitting": using half of the data for training, and the other half of the data for testing. In particular, we define $X_n := \tilde{X}_{2n-1}$, $Y_n := \tilde{Y}_{2n-1}$, $X'_n := \tilde{X}_{2n}$ and $Y'_n := \tilde{Y}_{2n}$ for $n = 1, 2, \ldots$.

- "Data recycling": using the same data both for regression and for testing. In particular, we define $X_n := \tilde{X}_n$, $Y_n := \tilde{Y}_n$, $X'_n := \tilde{X}_n$ and $Y'_n := \tilde{Y}_n$ for $n = 1, 2, \ldots$.

In both scenarios, for $N = 1, 2, \ldots$, we define a sequence of training data sets $\mathcal{D}_N := \{(X_n, Y_n)\}_{n=1}^N$ (for the regression) and a sequence of test data sets $\mathcal{D}'_N := \{(X'_n, Y'_n)\}_{n=1}^N$ (for testing independence of residuals). Note that in the data recycling scenario, training and test data are identical, whereas in the data splitting scenario, training and test data are independent.

Define a random variable (the "residual")

$$E := Y - f(X) = Y - \mathbb{E}(Y \mid X), \tag{30}$$

and its vector-valued versions on the test data:

$$\boldsymbol{E}'_{\ldots N} := \big(Y'_1 - f(X'_1), \ldots, Y'_N - f(X'_N)\big),$$

called the **true residuals**. Using a regression method, we obtain an estimate $\hat{f}(x; \mathcal{D}_N)$ for the regression function $f(x) = \mathbb{E}(Y \mid X = x)$ from the training data $\mathcal{D}_N$. We then define an estimate of the vector-valued version of E on the test data:

$$\hat{\boldsymbol{E}}'_{\ldots N} := \big(Y'_1 - \hat{f}(X'_1; \mathcal{D}_N), \ldots, Y'_N - \hat{f}(X'_N; \mathcal{D}_N)\big), \tag{31}$$

called the **predicted residuals**.

Definition 18 *We call the regression method **suitable** for regressing Y on X if the mean squared error between true and predicted residuals vanishes asymptotically in expectation:*

$$\lim_{N\to\infty} \mathbb{E}_{\mathcal{D}_N, \mathcal{D}'_N} \left(\frac{1}{N} \left\| \hat{\boldsymbol{E}}'_{\ldots N} - \boldsymbol{E}'_{\ldots N} \right\|^2 \right) = 0. \tag{32}$$

Here, the expectation is taken over both training data $\mathcal{D}_N$ and test data $\mathcal{D}'_N$.

Lemma 19 *In the data splitting case, any regression method that is weakly consistent for $\mathbb{P}_{X,Y}$ is suitable. In the data recycling case, any regression method satisfying property (29) is suitable.*

Proof Simply rewriting:

$$\lim_{N\to\infty} \mathbb{E} \left(\frac{1}{N} \left\| \hat{\boldsymbol{E}}'_{\ldots N} - \boldsymbol{E}'_{\ldots N} \right\|^2 \right) =$$
$$\lim_{N\to\infty} \mathbb{E} \left(\frac{1}{N} \sum_{n=1}^N \left| \big(Y'_n - \hat{f}(X'_n; \mathcal{D}_N)\big) - \big(Y'_n - f(X'_n)\big) \right|^2 \right) =$$
$$\lim_{N\to\infty} \mathbb{E}_{\mathcal{D}_N, \mathcal{D}'_N} \left(\frac{1}{N} \sum_{n=1}^N \left| \hat{f}(X'_n; \mathcal{D}_N) - f(X'_n) \right|^2 \right).$$

Therefore, (32) reduces to (28) in the data splitting scenario (where each X'_n is an independent copy of X), and reduces to (29) in the data recycling scenario (where $X'_n = X_n$). ■

In particular, if $\mathbb{E}(X^2) < \infty$ and $\mathbb{E}(Y^2) < \infty$, any weakly universally consistent regression method is suitable both for regressing X on Y and Y on X in the data splitting scenario.

A.3 Consistency of `ANM-HSIC`

We can now prove our main result, stating that the empirical HSIC calculated from the test set inputs and the predicted residuals on the test set (using the regression function estimated from the training set) converges in probability to the population HSIC of the true inputs and the true residuals:

Theorem 20 *Let $X, Y \in \mathbb{R}$ be two random variables with joint distribution $\mathbb{P}_{X,Y}$. Let $k, l : \mathbb{R} \times \mathbb{R} \to \mathbb{R}$ be two bounded non-negative kernels and assume that l is Lipschitz continuous. Suppose we are given sequences of training data sets $\mathcal{D}_N$ and test data sets $\mathcal{D}'_N$ (in either the data splitting or the data recycling scenario described above). Suppose we use a suitable regression procedure (c.f. Lemma 19), to obtain a sequence $\hat{f}(x; \mathcal{D}_N)$ of estimates of the regression function $\mathbb{E}(Y \mid X = x)$ from the training data. Defining the true residual E by (30), and the predicted residuals $\hat{\boldsymbol{E}}'_{\ldots N}$ on the test data as in (31), then, for $N \to \infty$:*

$$\widehat{\mathrm{HSIC}}_{k,l}(\boldsymbol{X}'_{\ldots N}, \hat{\boldsymbol{E}}'_{\ldots N}) \xrightarrow{P} \mathrm{HSIC}_{k,l}(X, E).$$

Proof We start by applying Lemma 16:

$$\left| \widehat{\mathrm{HSIC}}(\boldsymbol{X}'_{\ldots N}, \hat{\boldsymbol{E}}'_{\ldots N}) - \widehat{\mathrm{HSIC}}(\boldsymbol{X}'_{\ldots N}, \boldsymbol{E}'_{\ldots N}) \right|^2 \leq \left(\frac{32\lambda C}{\sqrt{N}} \right)^2 \left\| \hat{\boldsymbol{E}}'_{\ldots N} - \boldsymbol{E}'_{\ldots N} \right\|^2,$$

where λ and C are constants. From the suitability of the regression method, (32), it therefore follows that

$$\lim_{N\to\infty} \mathbb{E}_{\mathcal{D}_N, \mathcal{D}'_N} \left| \widehat{\mathrm{HSIC}}(\boldsymbol{X}'_{\ldots N}, \hat{\boldsymbol{E}}'_{\ldots N}) - \widehat{\mathrm{HSIC}}(\boldsymbol{X}'_{\ldots N}, \boldsymbol{E}'_{\ldots N}) \right|^2 = 0,$$

i.e.,

$$\widehat{\mathrm{HSIC}}(\boldsymbol{X}'_{\ldots N}, \hat{\boldsymbol{E}}'_{\ldots N}) - \widehat{\mathrm{HSIC}}(\boldsymbol{X}'_{\ldots N}, \boldsymbol{E}'_{\ldots N}) \xrightarrow{L_2} 0.$$

As convergence in L_2 implies convergence in probability (see, e.g, Wasserman, 2004),

$$\widehat{\mathrm{HSIC}}(\boldsymbol{X}'_{\ldots N}, \hat{\boldsymbol{E}}'_{\ldots N}) - \widehat{\mathrm{HSIC}}(\boldsymbol{X}'_{\ldots N}, \boldsymbol{E}'_{\ldots N}) \xrightarrow{P} 0.$$

From the consistency of the empirical HSIC, Corollary 15:

$$\widehat{\mathrm{HSIC}}(\boldsymbol{X}'_{\ldots N}, \boldsymbol{E}'_{\ldots N}) \xrightarrow{P} \mathrm{HSIC}(X, E).$$

Hence, by taking sums (see e.g., Theorem 5.5 in Wasserman, 2004), we arrive at the desired statement. ■

We are now ready to show that Algorithm 1 with score (6) (which is the special case $k = l$) is consistent.

Corollary 21 *Let X, Y be two real-valued random variables with joint distribution $\mathbb{P}_{X,Y}$ that either satisfies an Additive Noise Model $X \to Y$, or $Y \to X$, but not both. Suppose we are given sequences of training data sets $\mathcal{D}_N$ and test data sets $\mathcal{D}'_N$ (in either the data splitting or the data recycling scenario). Let $k, l : \mathbb{R} \times \mathbb{R} \to \mathbb{R}$ be two bounded non-negative Lipschitz-continuous kernels such that their product $k \cdot l$ is characteristic. If the regression procedure used in Algorithm 1 is suitable for both $\mathbb{P}_{X,Y}$ and $\mathbb{P}_{Y,X}$, then Algorithm 1 with score (6) is a consistent procedure for estimating the direction of the Additive Noise Model.*

Proof Define "population residuals" $E_Y := Y - \mathbb{E}(Y \,|\, X)$ and $E_X := X - \mathbb{E}(X \,|\, Y)$. Note that $\mathbb{P}_{X,Y}$ satisfies a bivariate Additive Noise Model $X \to Y$ if and only if $E_Y \perp\!\!\!\perp X$ (c.f. Lemma 7). Further, by Lemma 12, we have $\mathrm{HSIC}_{k,l}(X, E_Y) = 0$ if and only if $X \perp\!\!\!\perp E_Y$. Similarly, $\mathbb{P}_{X,Y}$ satisfies a bivariate Additive Noise Model $Y \to X$ if and only if $\mathrm{HSIC}_{l,k}(Y, E_X) = 0$.

Now, by Theorem 20,

$$\hat{C}_{X\to Y} := \widehat{\mathrm{HSIC}}_{k,l}(\boldsymbol{X}'_{\ldots N}, \hat{\boldsymbol{E}}_Y(\mathcal{D}'_N; \mathcal{D}_N)) \xrightarrow{P} \mathrm{HSIC}_{k,l}(X, E_Y),$$

and similarly

$$\hat{C}_{Y\to X} := \widehat{\mathrm{HSIC}}_{l,k}(\boldsymbol{Y}'_{\ldots N}, \hat{\boldsymbol{E}}_X(\mathcal{D}'_N; \mathcal{D}_N)) \xrightarrow{P} \mathrm{HSIC}_{l,k}(Y, E_X),$$

where the predicted residuals are defined by

$$\hat{\boldsymbol{E}}_Y(\mathcal{D}'_N; \mathcal{D}_N) := \big(Y'_1 - \hat{f}_Y(X'_1; \mathcal{D}_N), \ldots, Y'_N - \hat{f}_Y(X'_N; \mathcal{D}_N)\big),$$
$$\hat{\boldsymbol{E}}_X(\mathcal{D}'_N; \mathcal{D}_N) := \big(X'_1 - \hat{f}_X(Y'_1; \mathcal{D}_N), \ldots, X'_N - \hat{f}_X(Y'_N; \mathcal{D}_N)\big),$$

with estimates $\hat{f}_Y(x; \mathcal{D}_N), \hat{f}_X(y; \mathcal{D}_N)$ of the regression functions $\mathbb{E}(Y \,|\, X = x), \mathbb{E}(X \,|\, Y = y)$ from the training data $\mathcal{D}_N$.

Because $\mathbb{P}_{X,Y}$ satisfies an Additive Noise Model only in one of the two directions, this implies that either $\mathrm{HSIC}_{k,l}(X, E_Y) = 0$ and $\mathrm{HSIC}_{l,k}(Y, E_X) > 0$ (corresponding with $X \to Y$), or $\mathrm{HSIC}_{k,l}(X, E_Y) > 0$ and $\mathrm{HSIC}_{l,k}(Y, E_X) = 0$ (corresponding with $Y \to X$). Therefore the test procedure is consistent. ■

Appendix B. Relationship Between Scores (10) and (11)

For the special case of an Additive Noise Model $X \to Y$, the empirical-Bayes score proposed by Friedman and Nachman (2000) is given in (11):

$$\hat{C}_{X\to Y} = \min_{\mu,\tau^2,\boldsymbol{\theta},\sigma^2} \big(-\log \mathcal{N}(\boldsymbol{x} \,|\, \mu\mathbf{1}, \tau^2\boldsymbol{I}) - \log \mathcal{N}(\boldsymbol{y} \,|\, \mathbf{0}, \boldsymbol{K}_{\boldsymbol{\theta}}(\boldsymbol{x}) + \sigma^2\boldsymbol{I})\big).$$

It is a sum of the negative log likelihood of a Gaussian model for the inputs:

$$\begin{aligned} &\min_{\mu,\tau^2} \big(-\log \mathcal{N}(\boldsymbol{x} \,|\, \mu\mathbf{1}, \tau^2\boldsymbol{I})\big) \\ &= \min_{\mu,\tau^2} \left(\frac{N}{2}\log(2\pi\tau^2) + \frac{1}{2\tau^2}\sum_{i=1}^N (x_i - \mu)^2\right) \\ &= \frac{N}{2}\log(2\pi e) + \frac{N}{2}\log\left(\frac{1}{N}\sum_{i=1}^N (x_i - \bar{x})^2\right) \end{aligned} \tag{33}$$

with $\bar{x} := \frac{1}{N}\sum_{i=1}^N x_i$, and the negative log marginal likelihood of a GP model for the outputs, given the inputs:

$$\begin{aligned} &\min_{\boldsymbol{\theta},\sigma^2} \big(-\log \mathcal{N}(\boldsymbol{y} \,|\, 0, \boldsymbol{K}_{\boldsymbol{\theta}}(\boldsymbol{x}) + \sigma^2\boldsymbol{I})\big) \\ &= \min_{\boldsymbol{\theta},\sigma^2} \left(\frac{N}{2}\log(2\pi) + \frac{1}{2}\log|\det(\boldsymbol{K}_{\boldsymbol{\theta}}(\boldsymbol{x}) + \sigma^2\boldsymbol{I})| + \boldsymbol{y}^T(\boldsymbol{K}_{\boldsymbol{\theta}}(\boldsymbol{x}) + \sigma^2\boldsymbol{I})^{-1}\boldsymbol{y}\right). \end{aligned} \tag{34}$$

Note that (33) is an empirical estimator of the entropy of a Gaussian with variance $\mathbb{V}\mathrm{ar}(X)$, up to a factor N:

$$H(X) = \frac{1}{2}\log(2\pi e) + \frac{1}{2}\log \mathbb{V}\mathrm{ar}(X).$$

We will show that (34) is closely related to an empirical estimator of the entropy of the residuals $Y - \mathbb{E}(Y \,|\, X)$:

$$H(Y - \mathbb{E}(Y \,|\, X)) = \frac{1}{2}\log(2\pi e) + \frac{1}{2}\log \mathbb{V}\mathrm{ar}(Y - \mathbb{E}(Y \,|\, X)).$$

This means that the score (11) considered by Friedman and Nachman (2000) is closely related to the Gaussian score (10) for $X \to Y$:

$$\hat{C}_{X\to Y} = \log \mathbb{V}\mathrm{ar}(X) + \log \mathbb{V}\mathrm{ar}(Y - \hat{f}_Y(X)).$$

The following Lemma shows that standard Gaussian Process regression can be interpreted as a penalized maximum likelihood optimization.

Lemma 22 *Let $\boldsymbol{K}_{\boldsymbol{\theta}}(\boldsymbol{x})$ be the kernel matrix (abbreviated as $\boldsymbol{K}$) and define a negative penalized log-likelihood as:*

$$-\log \mathcal{L}(\boldsymbol{f}, \sigma^2; \boldsymbol{y}, \boldsymbol{K}) := \underbrace{\frac{N}{2}\log(2\pi\sigma^2) + \frac{1}{2\sigma^2}\sum_{i=1}^N (y_i - f_i)^2}_{\textit{Likelihood}} + \underbrace{\frac{1}{2}\boldsymbol{f}^T\boldsymbol{K}^{-1}\boldsymbol{f} + \frac{1}{2}\log\left|\det\left(\boldsymbol{I} + \sigma^{-2}\boldsymbol{K}\right)\right|}_{\textit{Penalty}}. \tag{35}$$

Minimizing with respect to $\boldsymbol{f}$ yields a minimum at

$$\hat{\boldsymbol{f}}_{\sigma,\boldsymbol{\theta}} = \operatorname*{argmin}_{\boldsymbol{f}} \left(-\log \mathcal{L}(\boldsymbol{f}, \sigma^2; \boldsymbol{y}, \boldsymbol{K}_{\boldsymbol{\theta}})\right) = \boldsymbol{K}_{\boldsymbol{\theta}}(\boldsymbol{K}_{\boldsymbol{\theta}} + \sigma^2 \boldsymbol{I})^{-1}\boldsymbol{y}, \tag{36}$$

and the value at the minimum is given by

$$\min_{\boldsymbol{f}} \left(-\log \mathcal{L}(\boldsymbol{f}, \sigma^2; \boldsymbol{y}, \boldsymbol{K}_{\boldsymbol{\theta}})\right) = -\log \mathcal{L}(\hat{\boldsymbol{f}}_{\sigma,\boldsymbol{\theta}}, \sigma^2; \boldsymbol{y}, \boldsymbol{K}_{\boldsymbol{\theta}}) = -\log \mathcal{N}(\boldsymbol{y} \,|\, \boldsymbol{0}, \boldsymbol{K}_{\boldsymbol{\theta}} + \sigma^2 \boldsymbol{I}). \tag{37}$$

Proof Because $\boldsymbol{B}(\boldsymbol{A}^{-1} + \boldsymbol{B}^{-1})\boldsymbol{A} = \boldsymbol{A} + \boldsymbol{B}$ for invertible (equally-sized square) matrices $\boldsymbol{A}, \boldsymbol{B}$, the following identity holds:

$$(\boldsymbol{A}^{-1} + \boldsymbol{B}^{-1})^{-1} = \boldsymbol{A}(\boldsymbol{A} + \boldsymbol{B})^{-1}\boldsymbol{B}.$$

Substituting $\boldsymbol{A} = \boldsymbol{K}$ and $\boldsymbol{B} = \sigma^2 \boldsymbol{I}$, we obtain directly that

$$(\boldsymbol{K}^{-1} + \sigma^{-2}\boldsymbol{I})^{-1} = \boldsymbol{K}(\boldsymbol{K} + \sigma^2 \boldsymbol{I})^{-1}\sigma^2. \tag{38}$$

By taking log-determinants, it also follows that

$$\log|\det \boldsymbol{K}| + \log|\det(\boldsymbol{K}^{-1} + \sigma^{-2}\boldsymbol{I})| = \log|\det\left(\boldsymbol{I} + \sigma^{-2}\boldsymbol{K}\right)|.$$

Therefore, we can rewrite (35) as follows:

$$\mathcal{L}(\boldsymbol{f}, \sigma^2; \boldsymbol{y}, \boldsymbol{K}) = \mathcal{N}(\boldsymbol{f}|\boldsymbol{0}, \boldsymbol{K})\mathcal{N}(\boldsymbol{y} - \boldsymbol{f}|\boldsymbol{0}, \sigma^2\boldsymbol{I}) \left|\det\left(\boldsymbol{K}^{-1} + \sigma^{-2}\boldsymbol{I}\right)\right|^{-1/2} (2\pi)^{N/2}. \tag{39}$$

Equation (A.7) in Rasmussen and Williams (2006) for the product of two Gaussians states that

$$\mathcal{N}(\boldsymbol{x}|\boldsymbol{a}, \boldsymbol{A})\mathcal{N}(\boldsymbol{x}|\boldsymbol{b}, \boldsymbol{B}) = \mathcal{N}(\boldsymbol{a}|\boldsymbol{b}, \boldsymbol{A} + \boldsymbol{B})\mathcal{N}(\boldsymbol{x}|\boldsymbol{c}, \boldsymbol{C}),$$

where $\boldsymbol{C} = (\boldsymbol{A}^{-1} + \boldsymbol{B}^{-1})^{-1}$ and $\boldsymbol{c} = \boldsymbol{C}(\boldsymbol{A}^{-1}\boldsymbol{a} + \boldsymbol{B}^{-1}\boldsymbol{b})$. Substituting $\boldsymbol{x} = \boldsymbol{f}$, $\boldsymbol{a} = \boldsymbol{0}$, $\boldsymbol{A} = \boldsymbol{K}$, $\boldsymbol{b} = \boldsymbol{y}$, and $\boldsymbol{B} = \sigma^2\boldsymbol{I}$, and using (38), this gives:

$$\mathcal{N}(\boldsymbol{f}|\boldsymbol{0}, \boldsymbol{K})\mathcal{N}(\boldsymbol{y} - \boldsymbol{f}|\boldsymbol{0}, \sigma^2\boldsymbol{I}) = \mathcal{N}(\boldsymbol{y} \,|\, \boldsymbol{0}, \boldsymbol{K} + \sigma^2\boldsymbol{I})\mathcal{N}(\boldsymbol{f}|\hat{\boldsymbol{f}}, (\boldsymbol{K}^{-1} + \sigma^{-2}\boldsymbol{I})^{-1}),$$

where

$$\hat{\boldsymbol{f}}_{\sigma,\boldsymbol{\theta}} := \boldsymbol{K}_{\boldsymbol{\theta}}(\boldsymbol{K}_{\boldsymbol{\theta}} + \sigma^2\boldsymbol{I})^{-1}\boldsymbol{y}.$$

Therefore, we can rewrite (39) as:

$$\begin{aligned}&\mathcal{L}(\boldsymbol{f}, \sigma^2; \boldsymbol{y}, \boldsymbol{K}) \\ &\quad = \mathcal{N}(\boldsymbol{y} \,|\, \boldsymbol{0}, \boldsymbol{K} + \sigma^2\boldsymbol{I})\mathcal{N}(\boldsymbol{f}|\hat{\boldsymbol{f}}, (\boldsymbol{K}^{-1} + \sigma^{-2}\boldsymbol{I})^{-1}) \left|\det\left(\boldsymbol{K}^{-1} + \sigma^{-2}\boldsymbol{I}\right)\right|^{-1/2} (2\pi)^{N/2}.\end{aligned}$$

It is now obvious that the penalized likelihood is maximized for $\boldsymbol{f} = \hat{\boldsymbol{f}}_{\sigma,\boldsymbol{\theta}}$ (for fixed hyperparameters $\sigma, \boldsymbol{\theta}$) and that at the maximum, it has the value

$$\mathcal{L}(\hat{\boldsymbol{f}}_{\sigma,\boldsymbol{\theta}}, \sigma^2; \boldsymbol{y}, \boldsymbol{K}_{\boldsymbol{\theta}}) = \mathcal{N}(\boldsymbol{y} \,|\, \boldsymbol{0}, \boldsymbol{K}_{\boldsymbol{\theta}} + \sigma^2\boldsymbol{I}).$$

■

Note that the estimated function (36) is identical to the mean posterior GP, and the value (37) is identical to the negative logarithm of the marginal likelihood (evidence) of the data according to the GP model (Rasmussen and Williams, 2006).

Making use of Lemma 22, the conditional part (34) in score (11) can be rewritten as:

$$\begin{aligned}&\min_{\sigma^2,\boldsymbol{\theta}} \left(-\log \mathcal{N}(\boldsymbol{y} \,|\, \boldsymbol{0}, \boldsymbol{K}_{\boldsymbol{\theta}} + \sigma^2\boldsymbol{I})\right) \\ &= \min_{\sigma^2,\boldsymbol{\theta}} \frac{1}{2}\left(N\log(2\pi\sigma^2) + \frac{1}{\sigma^2}\sum_{i=1}^{N}(y_i - (\hat{\boldsymbol{f}}_{\sigma,\boldsymbol{\theta}})_i)^2 + \hat{\boldsymbol{f}}_{\sigma,\boldsymbol{\theta}}^T \boldsymbol{K}_{\boldsymbol{\theta}}^{-1}\hat{\boldsymbol{f}}_{\sigma,\boldsymbol{\theta}} + \log|\det\left(\boldsymbol{I} + \sigma^{-2}\boldsymbol{K}_{\boldsymbol{\theta}}\right)|\right) \\ &= \underbrace{\frac{N}{2}\log(2\pi\hat{\sigma}^2) + \frac{1}{2\hat{\sigma}^2}\sum_{i=1}^{N}(y_i - (\hat{\boldsymbol{f}})_i)^2}_{\text{Likelihood term}} + \underbrace{\frac{1}{2}\hat{\boldsymbol{f}}^T\boldsymbol{K}_{\hat{\boldsymbol{\theta}}}^{-1}\hat{\boldsymbol{f}} + \frac{1}{2}\log|\det\left(\boldsymbol{I} + \hat{\sigma}^{-2}\boldsymbol{K}_{\hat{\boldsymbol{\theta}}}\right)|}_{\text{Complexity penalty}},\end{aligned}$$

where $\hat{\boldsymbol{f}} := \hat{\boldsymbol{f}}_{\hat{\sigma},\hat{\boldsymbol{\theta}}}$ for the minimizing $(\hat{\sigma}, \hat{\boldsymbol{\theta}})$. If the complexity penalty is small compared to the likelihood term around the optimal values $(\hat{\sigma}, \hat{\boldsymbol{\theta}})$, we can approximate:

$$\begin{aligned}&\min_{\sigma^2,\boldsymbol{\theta}} \left(-\log \mathcal{N}(\boldsymbol{y} \,|\, \boldsymbol{0}, \boldsymbol{K}_{\boldsymbol{\theta}} + \sigma^2\boldsymbol{I})\right) \\ &\approx \frac{N}{2}\log(2\pi\hat{\sigma}^2) + \frac{1}{2\hat{\sigma}^2}\sum_{i=1}^{N}(y_i - \hat{f}_i)^2 \\ &\approx \min_{\sigma^2}\left(\frac{N}{2}\log(2\pi\sigma^2) + \frac{1}{2\sigma^2}\sum_{i=1}^{N}(y_i - \hat{f}_i)^2\right) \\ &= \frac{N}{2}\log(2\pi e) + \frac{N}{2}\log\left(\frac{1}{N}\sum_{i=1}^{N}(y_i - \hat{f}_i)^2\right).\end{aligned}$$

This shows that there is a close relationship between the two scores (11) and (10).

Appendix C. Details on the Simulated Data

Here we give more details on how the data were simulated. The simulated data itself is provided as supplementary material on the first author's website.

C.1 Sampling from a Random Density

We first describe how we sample from a random density. First, we sample $\boldsymbol{X} \in \mathbb{R}^N$ from a standard-normal distribution:

$$\boldsymbol{X} \sim \mathcal{N}(\boldsymbol{0}_N, \boldsymbol{I}_N),$$

and define $\overrightarrow{\boldsymbol{X}}$ to be the vector that is obtained by sorting $\boldsymbol{X}$ in ascending order. Then, we sample a realization $\boldsymbol{F}$ of a Gaussian Process with inputs $\overrightarrow{\boldsymbol{X}}$, using a kernel with hyperparameters $\boldsymbol{\theta}$ and white noise with standard deviation σ:

$$\boldsymbol{F} \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{K}_{\boldsymbol{\theta}}(\overrightarrow{\boldsymbol{X}}) + \sigma^2\boldsymbol{I}),$$

where $\boldsymbol{K}_{\boldsymbol{\theta}}(\overrightarrow{\boldsymbol{X}})$ is the Gram matrix for $\overrightarrow{\boldsymbol{X}}$ using kernel $k_{\boldsymbol{\theta}}$. We use the trapezoidal rule to calculate the cumulative integral of the function $e^F : \mathbb{R} \to \mathbb{R}$ that linearly interpolates the points $(\overrightarrow{\boldsymbol{X}}, \exp(\boldsymbol{F}))$. In this way, we obtain a vector $\boldsymbol{G} \in \mathbb{R}^N$ where each element G_i corresponds to $\int_{\overrightarrow{X}_1}^{\overrightarrow{X}_i} e^F(x)\,dx$. As covariance function, we used the Gaussian kernel:

$$k_{\boldsymbol{\theta}}(\boldsymbol{x}, \boldsymbol{x}') = \exp\left(-\sum_{i=1}^{D} \frac{(x_i - x_i')^2}{\theta_i^2}\right).$$

We will denote this whole sampling procedure by:

$$\boldsymbol{G} \sim \mathcal{RD}(\boldsymbol{\theta}, \sigma).$$

C.2 Sampling Cause-Effect Pairs

We simulate cause-effect pairs as follows. First, we sample three noise variables:

$$\begin{aligned} W_{E_X} &\sim \Gamma(a_{W_{E_X}}, b_{W_{E_X}}) & \boldsymbol{E}_X &\sim \mathcal{RD}(W_{E_X}, \tau) \\ W_{E_Y} &\sim \Gamma(a_{W_{E_Y}}, b_{W_{E_Y}}) & \boldsymbol{E}_Y &\sim \mathcal{RD}(W_{E_X}, \tau) \\ W_{E_Z} &\sim \Gamma(a_{W_{E_Z}}, b_{W_{E_Z}}) & \boldsymbol{E}_Z &\sim \mathcal{RD}(W_{E_Z}, \tau) \end{aligned}$$

where each noise variable has a random characteristic length scale. We then standardize each noise sample $\boldsymbol{E}_X$, $\boldsymbol{E}_Y$ and $\boldsymbol{E}_Z$.

If there is no confounder, we sample $\boldsymbol{X}$ from a GP with inputs $\boldsymbol{E}_X$:

$$\begin{aligned} S_{E_X} &\sim \Gamma(a_{S_{E_X}}, b_{S_{E_X}}) \\ \boldsymbol{X} &\sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{K}_{S_{E_X}}(\boldsymbol{E}_X) + \tau^2 \boldsymbol{I}) \end{aligned}$$

and then we standardize $\boldsymbol{X}$. Then, we sample $\boldsymbol{Y}$ from a GP with inputs $(\boldsymbol{X}, \boldsymbol{E}_Y) \in \mathbb{R}^{N \times 2}$:

$$\begin{aligned} S_X &\sim \Gamma(a_{S_X}, b_{S_X}) \\ S_{E_Y} &\sim \Gamma(a_{S_{E_Y}}, b_{S_{E_Y}}) \\ \boldsymbol{Y} &\sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{K}_{(S_X, S_{E_Y})}((\boldsymbol{X}, \boldsymbol{E}_Y)) + \tau^2 \boldsymbol{I}) \end{aligned}$$

and then we standardize $\boldsymbol{Y}$.

If there is a confounder, we sample $\boldsymbol{X}$ from a GP with inputs $(\boldsymbol{E}_X, \boldsymbol{E}_Z) \in \mathbb{R}^{N \times 2}$:

$$\begin{aligned} S_{E_X} &\sim \Gamma(a_{S_{E_X}}, b_{S_{E_X}}) \\ S_{E_Z} &\sim \Gamma(a_{S_{E_Z}}, b_{S_{E_Z}}) \\ \boldsymbol{X} &\sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{K}_{(S_{E_X}, S_{E_Z})}((\boldsymbol{E}_X, \boldsymbol{E}_Z)) + \tau^2 \boldsymbol{I}) \end{aligned}$$

and then we standardize $\boldsymbol{X}$. Then, we sample $\boldsymbol{Y}$ from a GP with inputs $(\boldsymbol{X}, \boldsymbol{E}_Y, \boldsymbol{E}_Z) \in \mathbb{R}^{N \times 3}$:

$$\begin{aligned} S_X &\sim \Gamma(a_{S_X}, b_{S_X}) \\ S_{E_Y} &\sim \Gamma(a_{S_{E_Y}}, b_{S_{E_Y}}) \\ S_{E_Z} &\sim \Gamma(a_{S_{E_Z}}, b_{S_{E_Z}}) \\ \boldsymbol{Y} &\sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{K}_{(S_X, S_{E_Y}, S_{E_Z})}((\boldsymbol{X}, \boldsymbol{E}_Y, \boldsymbol{E}_Z)) + \tau^2 \boldsymbol{I}) \end{aligned}$$

Scenario	$(a_{W_{E_X}}, b_{W_{E_X}})$	$(a_{S_{E_X}}, b_{S_{E_X}})$	$(a_{S_{E_Y}}, b_{S_{E_Y}})$	$(a_{S_{M_X}}, b_{S_{M_X}})$	$(a_{S_{M_Y}}, b_{S_{M_Y}})$
`SIM`	$(5, 0.1)$	$(2, 1.5)$	$(2, 15)$	$(2, 0.1)$	$(2, 0.1)$
`SIM-c`	$(5, 0.1)$	$(2, 1.5)$	$(2, 15)$	$(2, 0.1)$	$(2, 0.1)$
`SIM-ln`	$(5, 0.1)$	$(2, 1.5)$	$(2, 300)$	$(2, 0.01)$	$(2, 0.01)$
`SIM-G`	$(10^6, 10^{-3})$	$(10^6, 10^{-3})$	$(2, 15)$	$(2, 0.1)$	$(2, 0.1)$

Table 3: Parameter settings used to simulate cause-effect pairs for four scenarios. `SIM-c` has a confounder, the other scenarios have no confounders. The common parameters for the four scenarios are: $\tau = 10^{-4}$, $(a_{WnE_Y}, b_{W_{E_Y}}) = (5, 0.1)$, $(a_{W_{E_Z}}, b_{W_{E_Z}}) = (5, 0.1)$, $(a_{S_{E_Z}}, b_{S_{E_Z}}) = (2, 15)$, $(a_{S_X}, b_{S_X}) = (2, 15)$.

and then we standardize $\boldsymbol{Y}$.

Finally, we add measurement noise:

$$\begin{aligned} S_{M_X} &\sim \Gamma(a_{S_{M_X}}, b_{S_{M_X}}) \\ \boldsymbol{M}_X &\sim \mathcal{N}(\boldsymbol{0}, S_{M_X}^2 \boldsymbol{I}) \\ \boldsymbol{X} &\leftarrow \boldsymbol{X} + \boldsymbol{M}_X \\ S_{M_Y} &\sim \Gamma(a_{S_{M_Y}}, b_{S_{M_Y}}) \\ \boldsymbol{M}_Y &\sim \mathcal{N}(\boldsymbol{0}, S_{M_Y}^2 \boldsymbol{I}) \\ \boldsymbol{Y} &\leftarrow \boldsymbol{Y} + \boldsymbol{M}_Y \end{aligned}$$

We considered the four scenarios in Table 3: `SIM`, a scenario without confounders; `SIM-c`, a similar scenario but with one confounder; `SIM-ln`, a scenario with low noise levels (for which we expect IGCI to perform well); `SIM-G`, a scenario with a distribution of X that is almost Gaussian. We used $N = 1000$ samples for each pair, and simulated 100 cause-effect pairs for each scenario.

Appendix D. Description of the CauseEffectPairs Benchmark

The CauseEffectPairs benchmark set described here is an extension of the collection of the eight data sets that formed the CauseEffectPairs task in the *Causality Challenge #2: Pot-Luck* competition (Mooij and Janzing, 2010) that was performed as part of the NIPS 2008 Workshop on Causality (Guyon et al., 2010).[23] Here we describe version 1.0 of the CauseEffectPairs benchmark, which consists of 100 "cause-effect pairs", each one consisting of samples of a pair of statistically dependent random variables, where one variable is known to cause the other one. The task is to identify for each pair which of the two variables is the cause and which one the effect, using the observed samples only. The data are publicly available at Mooij et al. (2014).

The data sets were selected such that we expect common agreement on the ground truth. For example, the first pair consists of measurements of altitude and mean annual temperature of more than 300 weather stations in Germany. It should be obvious that altitude causes temperature rather than the other way around. Even though part of the

23. The introduction of this section and the descriptions of these 8 pairs are heavily based on Mooij and Janzing (2010).

statistical dependences may also be due to hidden common causes and selection bias, we expect that there is a significant cause-effect relation between the two variables in each pair, based on our understanding of the data generating process.

The best way to decide upon the ground truth of the causal relationships in the systems that generated the data would be by performing interventions on one of the variables and observing whether the intervention changes the distribution of the other variable. Unfortunately, these interventions cannot be performed in practice for many of the existing pairs because the original data-generating system is no longer available, or because of other practical reasons. Therefore, we have selected data sets in which the causal direction should be clear from the meanings of the variables and the way in which the data were generated. Unfortunately, for many data sets that are publicly available, it is not always clearly documented exactly how the variables are defined and measured.

In selecting the cause-effect pair data sets, we applied the following criteria:

- The minimum number of samples per pair should be a few hundred;
- The variables should have values in $\mathbb{R}^d$ for some $d = 1, 2, 3, \ldots$;
- There should be a significant cause–effect relationship between the two variables;
- The direction of the causal relationship should be known or obvious from the meaning of the variables.

Version 1.0 of the CauseEffectPairs collection consists of 100 pairs satisfying these criteria, taken from 37 different data sets from different domains. We refer to these pairs as `pair0001`, ..., `pair00100`. Table 4 gives an overview of the cause-effect pairs. In the following subsections, we describe the cause-effect pairs in detail, and motivate our decisions on the causal relationships present in the pairs. We provide a scatter plot for each pair, where the horizontal axis corresponds with the cause, and the vertical axis with the effect. For completeness, we describe all the pairs in the data set, including those that have been described before in Mooij and Janzing (2010).

Pair	Variable 1	Variable 2	Data Set	Ground Truth	Weight
pair0001	Altitude	Temperature	D.1	→	1/6
pair0002	Altitude	Precipitation	D.1	→	1/6
pair0003	Longitude	Temperature	D.1	→	1/6
pair0004	Altitude	Sunshine hours	D.1	→	1/6
pair0005	Age	Length	D.2	→	1/7

Table 4: Overview of the pairs in version 1.0 of the CauseEffectPairs benchmark.

D.1 DWD

The DWD climate data were provided by the Deutscher Wetterdienst (DWD). We downloaded the data from http://www.dwd.de and merged several of the original data sets to obtain data for 349 weather stations in Germany, selecting only those weather stations without missing data. After merging the data sets, we selected the following six variables: altitude, latitude, longitude, and annual mean values (over the years 1961–1990) of sunshine duration, temperature and precipitation. We converted the latitude and longitude variables from sexagesimal to decimal notation. Out of these six variables, we selected six different pairs with "obvious" causal relationships: altitude–temperature (pair0001), altitude–precipitation (pair0002), longitude–temperature (pair0003), altitude–sunshine hours (pair0004), latitude–temperature (pair0020), longitude–precipitation (pair0021).

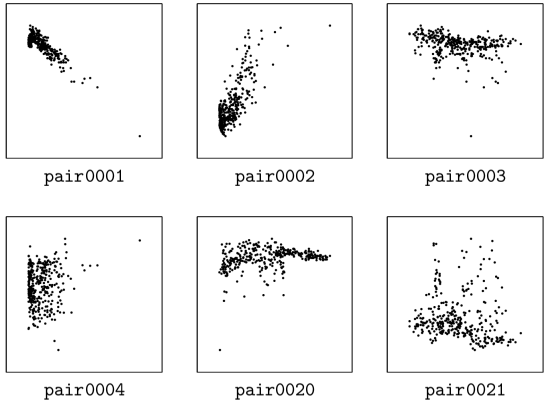

Figure 18: Scatter plots of pairs from D.1. pair0001: altitude → temperature, pair0002: altitude → precipitation, pair0003: longitude → temperature, pair0004: altitude → sunshine hours, pair0020: latitude → temperature, pair0021: longitude → precipitation.

pair0001: Altitude → Temperature

As an elementary fact of meteorology, places with higher altitude tend to be colder than those that are closer to sea level (roughly 1 centigrade per 100 meter). There is no doubt that altitude is the cause and temperature the effect: one could easily think of an intervention where the thermometer is lifted (e.g., by using a balloon) to measure the temperature at a higher point of the same longitude and latitude. On the other hand, heating or cooling a location usually does not change its altitude (except perhaps if the location happens to be the space enclosed by a hot air balloon, but let us assume that the thermometers used to gather this data were fixed to the ground). The altitudes in the DWD data set range from 0 m to 2960 m, which is sufficiently large to detect significant statistical dependences.

One potential confounder is latitude, since all mountains are in the south and far from the sea, which is also an important factor for the local climate. The places with the highest average temperatures are therefore those with low altitude but lying far in the south. Hence this confounder should induce positive correlations between altitude and temperature as opposed to the negative correlation between altitude and temperature that is observed empirically. This suggests that the direct causal relation between altitude and temperature dominates over the confounder.

pair0002: Altitude → Precipitation

It is known that altitude is also an important factor for precipitation since rain often occurs when air is forced to rise over a mountain range and the air becomes over-saturated with water due to the lower temperature (orographic rainfall). This effect defines an indirect causal influence of altitude on precipitation via temperature. These causal relations are, however, less simple than the causal influence from altitude to temperature because gradients of the altitude with respect to the main direction of the wind are more relevant than the altitude itself. A hypothetical intervention that would allow us to validate the causal relation could be to build artificial mountains and observe orographic rainfall.

pair0003: Longitude → Temperature

To detect the causal relation between longitude and temperature, a hypothetical intervention could be to move a thermometer between West and East. Even if one would adjust for altitude and latitude, it is unlikely that temperature would remain the same since the climate in the West is more oceanic and less continental than in the East of Germany. Therefore, longitude causes temperature.

pair0004: Altitude → Sunshine Hours

Sunshine duration and altitude are slightly positively correlated. Possible explanations are that higher weather stations are sometimes above low-hanging clouds. Cities in valleys, especially if they are close to rivers or lakes, typically have more misty days. Moving a sunshine sensor above the clouds clearly increases the sunshine duration whereas installing an artificial sun would not change the altitude. The causal influence from altitude to sunshine duration can be confounded, for instance, by the fact that there is a simple statistical dependence between altitude and longitude in Germany as explained earlier.

pair0020: Latitude → Temperature

Moving a thermometer towards the equator will generally result in an increased mean annual temperature. Changing the temperature, on the other hand, does not necessarily result in a north-south movement of the thermometer. The obvious ground truth of latitude causing temperature might be somewhat "confounded" by longitude, in combination with the selection bias that arises from only including weather stations in Germany.

pair0021: Longitude → Precipitation

As the climate in the West is more oceanic and less continental than in the East of Germany, we expect there to be a relationship between longitude and precipitation. Changing longitude by moving in East-West direction may therefore change precipitation, even if one would adjust for altitude and latitude. On the other hand, making it rain locally (e.g., by cloud seeding) will not result in a change in longitude.

D.2 Abalone

The Abalone data set (Nash et al., 1994) in the UCI Machine Learning Repository (Bache and Lichman, 2013) contains 4177 measurements of several variables concerning the sea snail *Abalone*. We downloaded the data from https://archive.ics.uci.edu/ml/datasets/Abalone. The original data set contains the nine variables sex, length, diameter, height, whole weight, shucked weight, viscera weight, shell weight and number of rings. The number of rings in the shell is directly related to the age of the snail: adding 1.5 to the number of rings gives the age in years. Of these variables, we selected six pairs with obvious cause-effect relationships: age–length (pair0005), age–shell weight (pair0006), age–diameter (pair0007), age–height (pair0008), age–whole weight (pair0009), age–shucked weight (pair0010), age–viscera weight (pair0011).

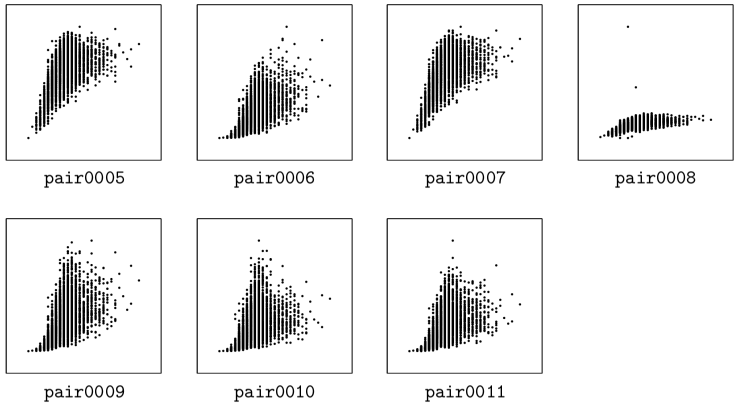

Figure 19: Scatter plots of pairs from D.2. pair0005: age → length, pair0006: age → shell weight, pair0007: age → diameter, pair0008: age → height, pair0009: age → whole weight, pair0010: age → shucked weight, pair0011: age → viscera weight.

pair0005–pair0011: Age → {Length, Shell Weight, Diameter, Height, Whole/Shucked/Viscera Weight}

For the variable "age" it is not obvious what a reasonable intervention would be since there is no possibility to change the time. However, waiting and observing how variables

change over time can be considered as equivalent to the hypothetical intervention on age (provided that the relevant background conditions do not change too much). Clearly, this "intervention" would change the probability distribution of the length, whereas changing the length of snails (by surgery) would not change the distribution of age (assuming that the surgery does not take years). Regardless of the difficulties of defining interventions, we expect common agreement on the ground truth: age causes all the other variables related to length, diameter height and weight.

There is one subtlety that has to do with how age is measured for these shells: this is done by counting the rings. For the variable "number of rings" however, changing the length of the snail may actually change the number of rings. We here presume that all snails have undergone their natural growing process so that the number of rings is a good proxy for the variable age.

D.3 Census Income KDD

The Census Income (KDD) data set (U.S. Department of Commerce, 1994) in the UCI Machine Learning Repository (Bache and Lichman, 2013) has been extracted from the 1984 and 1985 U.S. Census studies. We downloaded the data from https://archive.ics.uci.edu/ml/datasets/Census-Income+(KDD). We have selected the following variables: AAGE (age), AHRSPAY (wage per hour) and DIVVAL (dividends from stocks).

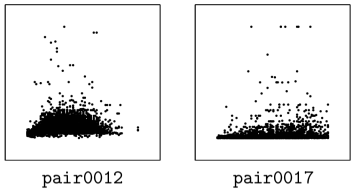

Figure 20: Scatter plots of pairs from D.3. pair0012: age → wage per hour, pair0017: age → dividends from stocks.

pair0012: Age → Wage Per Hour

We only used the first 5000 instances for which wage per hour was not equal to zero. The data clearly shows an increase of wage up to about 45 and a decrease for higher age.

As already argued for the Abalone data, interventions on the variable "age" are difficult to define. Compared to the discussion in the context of the Abalone data set, it seems more problematic to consider waiting as a reasonable "intervention" here, since the relevant (economical) background conditions change rapidly compared to the length of the human life: If someone's salary is higher than the salary of a 20 year younger colleague *because* of his/her longer job experience, we cannot conclude that the younger colleague will earn the same money 20 years later as the older colleague earns now. Possibly, the factory or even the branch of industry he/she was working in does not exist any more and his/her job experience is no longer appreciated. However, we know that employees sometimes indeed do get a higher income because of their longer job experience. Pretending longer job experience

by a fake certificate of employment would be a possible intervention. On the other hand, changing the wage per hour is an intervention that is easy to imagine (though difficult for us to perform) and this would certainly not change the age.

pair0017: Age → Dividends from Stocks

We only used the first 5000 instances for which dividends from stocks was not equal to zero. Similar considerations apply as for age vs. wage per hour. Doing an intervention on age is not practical, but companies could theoretically intervene on the dividends from stocks, and that would not result in a change of age, obviously. On the other hand, age influences income, and thereby over time, the amount of money that people can invest in stocks, and thereby, the amount of dividends they earn from stocks. This causal relation is a very indirect one, though, and the dependence between age and dividends from stock is less pronounced than that between age and wage per hour.

D.4 Auto-MPG

The Auto-MPG data set in the UCI Machine Learning Repository (Bache and Lichman, 2013) concerns city-cycle fuel consumption in miles per gallon (MPG), i.e., the number of miles a car can drive on one gallon of gasoline, and contains several other attributes, like displacement, horsepower, weight, and acceleration. The original data set comes from the StatLib library (Meyer and Vlachos, 2014) and was used in the 1983 American Statistical Association Exposition. We downloaded the data from http://archive.ics.uci.edu/ml/datasets/Auto+MPG and selected only instances without missing data, thereby obtaining 392 samples.

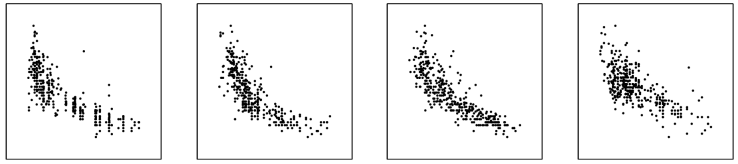

Figure 21: Scatter plots of pairs from D.4. pair0013: displacement → fuel consumption, pair0014: horse power → fuel consumption, pair0015: weight → fuel consumption, pair0016: horsepower → acceleration, pair0054: (displacement,horsepower,weight) → (MPG,acceleration)

pair0013: Displacement → Fuel Consumption

Displacement is the total volume of air/fuel mixture an engine can draw in during one complete engine cycle. The larger the displacement, the more fuel the engine can consume with every turn. Intervening on displacement (e.g., by increasing the cylinder bore) changes the fuel consumption. Changing the fuel consumption (e.g., by increasing the weight of the

car, or changing its air resistance, or by using another gear) will not change the displacement, though.

pair0014: Horse power → Fuel Consumption

Horse power measures the amount of power an engine can deliver. There are various ways to define horsepower and different standards to measure horse power of vehicles. In general, though, it should be obvious that fuel consumption depends on various factors, including horse power. Changing horsepower (e.g., by adding more cylinders to an engine, or adding a second engine to the car) would lead to a change in fuel consumption. On the other hand, changing fuel consumption does not necessarily change horse power.

pair0015: Weight → Fuel Consumption

There is a strong selection bias here, as car designers use a more powerful motor (with higher fuel consumption) for a heavier car. Nevertheless, the causal relationship between weight and fuel consumption should be obvious: if we intervene on weight, then fuel consumption will change, but not necessarily vice versa.

pair0016: Horsepower → Acceleration

Horsepower is one one of the factors that cause acceleration. Other factors are wheel size, the gear used, and air resistance. Intervening on acceleration does not necessarily change horsepower.

pair0054: (Displacement,Horsepower,Weight) → (MPG,Acceleration)

This pair consists of two multivariate variables that are combinations of the variables we have considered before. The multivariate variable consisting of the three components displacement, horsepower and weight can be considered to cause the multivariate variable comprised of fuel consumption and acceleration.

D.5 GAGurine

This data concerns the concentration of the chemical compound Glycosaminoglycan (GAG) in the urine of 314 children aged from zero to seventeen years. This is the GAGurine data set supplied with the MASS package of the computing language R (Venables and Ripley, 2002).

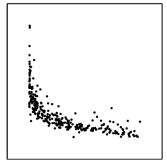

Figure 22: Scatter plots of pairs from D.5. pair0018: age → concentration GAG.

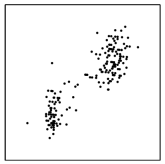
pair0018: Age → Concentration GAG

Obviously, GAG concentration does not cause age, but it could be the other way around, considering the strong dependence between the two variables.

D.6 Old Faithful

This is the geyser data set supplied with the MASS package of the computing language R (Venables and Ripley, 2002). It is originally described in (Azzalini and Bowman, 1990) and contains data about the duration of an eruption and the time interval between subsequent eruptions of the Old Faithful geyser in Yellowstone National Park, USA. The data consists of 194 samples and was collected in a single continuous measurement from August 1 to August 15, 1985.



pair0019

Figure 23: Scatter plots of pairs from D.6. pair0019: current duration → next interval.

pair0019: Current Duration → Next Interval

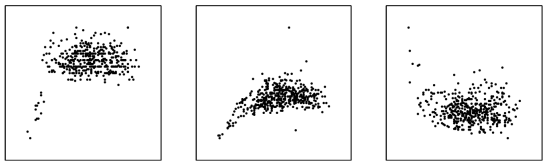
The chronological ordering of events implicates that the time interval between the current and the next eruption is an effect of the duration of the current eruption.

D.7 Arrhythmia

The Arrhythmia data set (Guvenir et al., 1997) from the UCI Machine Learning Repository (Bache and Lichman, 2013) concerns cardiac arrhythmia. It consists of 452 patient records and contains many different variables. We downloaded the data from https://archive.ics.uci.edu/ml/datasets/Arrhythmia and only used the variables for which the causal relationships should be evident. We removed two instances from the data set, corresponding with patient lengths of 680 and 780 cm, respectively.

pair0022–pair0024: Age → {Height, Weight, Heart Rate}

As discussed before, "interventions" on age (for example, waiting a few years) may affect height of persons. On the other hand, we know that height does not cause age. The same holds for age and weight and for age and heart rate. It is important to note here that age is simply measured in years since the birth of a person. Indeed, weight, height and also heart rate might influence "biological aging", the gradual deterioration of function of the human body.



pair0022 pair0023 pair0024

Figure 24: Scatter plots of pairs from D.7. pair0022: age → height, pair0023: age → weight, pair0024: age → heart rate.

D.8 Concrete Compressive Strength

This data set, available at the UCI Machine Learning Repository (Bache and Lichman, 2013), concerns a systematic study (Yeh, 1998) regarding concrete compressive strength as a function of ingredients and age. Citing Yeh (1998): "High-performance concrete (HPC) is a new terminology used in the concrete construction industry. In addition to the three basic ingredients in conventional concrete, i.e., Portland cement, fine and coarse aggregates, and water, the making of HPC needs to incorporate supplementary cementitious materials, such as fly ash and blast furnace slag, and chemical admixture, such as superplasticizer 1 and 2. Several studies independently have shown that concrete strength development is determined not only by the water-to-cement ratio, but that it also is influenced by the content of other concrete ingredients." Compressive strength is measured in units of MPa, age in days, and the other variables are measured in kilograms per cubic metre of concrete mixture. The data set was downloaded from https://archive.ics.uci.edu/ml/datasets/Concrete+Compressive+Strength and contains 1030 measurements.

pair0025–pair0032: {Cement, Blast Furnace Slag, Fly Ash, Water, Superplasticizer, Coarse Aggregate, Fine Aggregate, Age} → Compressive Strength

It should be obvious that compressive strength is the effect, and the other variables are its causes. Note, however, that in practice one cannot easily intervene on the mixture components without simultaneously changing the other mixture components. For example, if one adds more water to the mixture, then as a result, all other components will decrease, as they are measured in kilograms per cubic metre of concrete mixture. Nevertheless, we expect that we can see these interventions as reasonable approximations of "perfect interventions" on a single variable.

D.9 Liver Disorders

This data set, available at the UCI Machine Learning Repository (Bache and Lichman, 2013), was collected by BUPA Medical Research Ltd. It consists of several blood test results, which are all thought to be indicative for liver disorders that may arise from excessive alcohol consumption. Each of the 345 instances constitutes the record of a single male individual. Daily alcohol consumption is measured in number of half-pint equivalents of

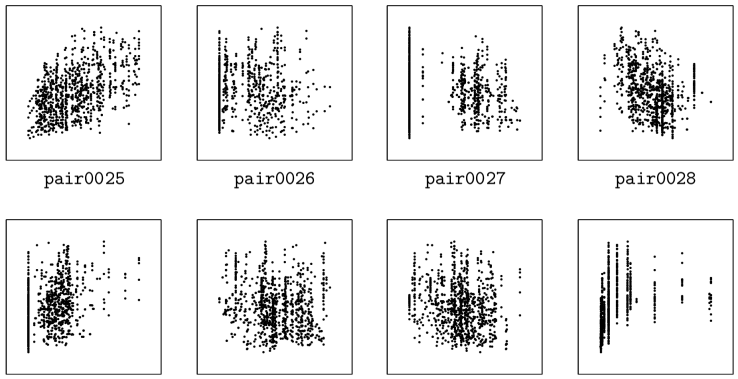


Figure 25: Scatter plots of pairs from D.8. `pair0025`: cement → compressive strength, `pair0026`: blast furnace slag → compressive strength, `pair0027`: fly ash → compressive strength, `pair0028`: water → compressive strength, `pair0029`: superplasticizer → compressive strength, `pair0030`: coarse aggregate → compressive strength, `pair0031`: fine aggregate → compressive strength, `pair0032`: age → compressive strength.

alcoholic beverages drunk per day. The blood test results are mean corpuscular volume (MCV), alkaline phosphotase (ALP), alanine aminotransferase (ALT), aspartate aminotransferase (AST), and gamma-glutamyl transpeptidase (GGT). The data is available at `https://archive.ics.uci.edu/ml/datasets/Liver+Disorders`.

Although one would expect that daily alcohol consumption is the cause, and the blood test results are the effects, this is not necessarily the case. Indeed, citing Baynes and Dominiczak (1999): "[...] increased plasma concentrations of acetaldehyde after the ingestion of alcohol [...] causes the individual to experience unpleasant flushing and sweating, which discourages alcohol abuse. Disulfiram, a drug that inhibits ALDH, also leads to these symptoms when alcohol is taken, and may be given to reinforce abstinence from alcohol." This means that *a priori*, a reverse causation of the chemical whose concentration is measured in one of these blood tests on daily alcohol consumption cannot be excluded with certainty. Nevertheless, we consider this to be unlikely, as the medical literature describes how these particular blood tests can be used to diagnose liver disorders, but we did not find any evidence that these chemicals can be used to *treat* excessive alcohol consumption.

`pair0033`: Alcohol Consumption → Mean Corpuscular Volume

The mean corpuscular volume (MCV) is the average volume of a red blood cell. An elevated MCV has been associated with alcoholism (Tønnesen et al., 1986), but there are many other factors also associated with MCV.

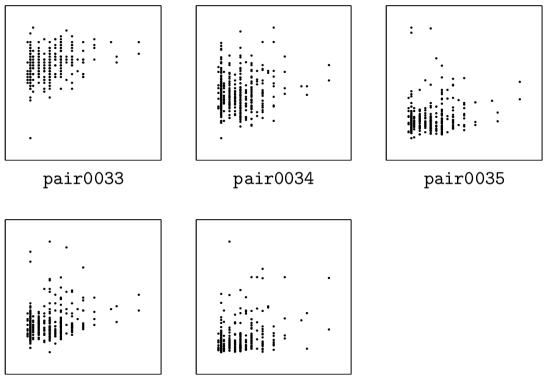

Figure 26: Scatter plots of pairs from D.9. `pair0033`: alcohol consumption → mean corpuscular volume, `pair0034`: alcohol consumption → alkaline phosphotase, `pair0035`: alcohol consumption → alanine aminotransferase, `pair0036`: alcohol consumption → aspartate aminotransferase, `pair0037`: alcohol consumption → gamma-glutamyl transpeptidase.

`pair0034`: Alcohol Consumption → Alkaline Phosphotase

Alkaline phosphatase (ALP) is an enzyme that is predominantly abundant in liver cells, but is also present in bone and placental tissue. Elevated ALP levels in blood can be due to many different liver diseases and also bone diseases, but also occur during pregnancy (Braunwald et al., 2001).

`pair0035`: Alcohol Consumption → Alanine Aminotransferase

Alanine Aminotransferase (ALT) is an enzyme that is found primarily in the liver cells. It is released into the blood in greater amounts when there is damage to the liver cells, for example due to a viral hepatitis or bile duct problems. ALT levels are often normal in alcoholic liver disease (Braunwald et al., 2001).

`pair0036`: Alcohol Consumption → Aspartate Aminotransferase

Aspartate aminotransferase (AST) is an enzyme that is found in the liver, but also in many other bodily tissues, for example the heart and skeletal muscles. Similar to ALT, the AST levels raise in acute liver damage. Elevated AST levels are not specific to the liver, but can also be caused by other diseases, for example by pancreatitis. An AST:ALT ratio of more than 3:1 is highly suggestive of alcoholic liver disease (Braunwald et al., 2001).

pair0037: Alcohol Consumption → Gamma-Glutamyl Transpeptidase

Gamma-Glutamyl Transpeptidase (GGT) GGT is another enzyme that is primarily found in liver cells. It is rarely elevated in conditions other than liver disease. High GGT levels have been associated with alcohol use (Braunwald et al., 2001).

D.10 Pima Indians Diabetes

This data set, available at the UCI Machine Learning Repository (Bache and Lichman, 2013), was collected by the National Institute of Diabetes and Digestive and Kidney Diseases in the USA to forecast the onset of diabetes mellitus in a high risk population of Pima Indians near Phoenix, Arizona. Cases in this data set were selected according to several criteria, in particular being female, at least 21 years of age and of Pima Indian heritage. This means that there could be selection bias on age.

We downloaded the data from `https://archive.ics.uci.edu/ml/datasets/Pima+Indians+Diabetes`. We only selected the instances with nonzero values, as it seems likely that zero values encode missing data. This yielded 768 samples.

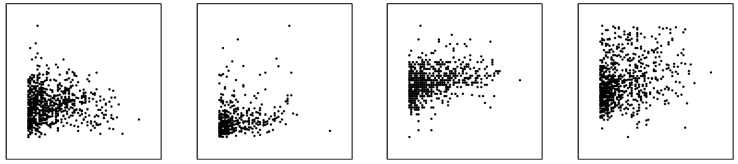

Figure 27: Scatter plots of pairs from D.10. `pair0038`: age → body mass index, `pair0039`: age → serum insulin, `pair0040`: age → diastolic blood pressure, `pair0041`: age → plasma glucose concentration.

pair0038: Age → Body Mass Index

Body mass index (BMI) is defined as the ratio between weight (kg) and the square of height (m). Obviously, age is not caused by body mass index, but as age is a cause of both height and weight, age causes BMI.

pair0039: Age → Serum Insulin

2-Hour serum insulin (μU/ml), measured 2 hours after the ingestion of a standard dose of glucose, in an oral glucose tolerance test. We can exclude that serum insulin causes age, and there could be an effect of age on serum insulin. Another explanation for the observed dependence could be the selection bias.

pair0040: Age → Diastolic Blood Pressure

Diastolic blood pressure (mm Hg). It seems obvious that blood pressure does not cause age. The other causal direction seems plausible, but again, an alternative explanation for the dependence could be selection bias.

pair0041: Age → Plasma Glucose Concentration

Plasma glucose concentration, measured 2 hours after the ingestion of a standard dose of glucose, in an oral glucose tolerance test. Similar reasoning as before: we do not believe that plasma glucose concentration causes ages, but it could be the other way around, and there may be selection bias.

D.11 B. Janzing's Meteo Data

This data set is from a private weather station, owned by Bernward Janzing, located in Furtwangen (Black Forest), Germany at an altitude of 956 m. The measurements include temperature, precipitation, and snow height (since 1979), as well as solar radiation (since 1986). The data have been archived by Bernward Janzing, statistical evaluations have been published in Janzing (2004), monthly summaries of the weather are published in local newspapers since 1981.

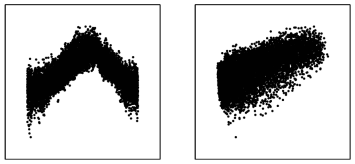

Figure 28: Scatter plots of pairs from D.11. `pair0042`: day of the year → temperature, `pair0077`: solar radiation → temperature.

pair0042: Day of the Year → Temperature

This data set shows the dependence between season and temperature over 25 years plus one month, namely the time range 01/01/1979–01/31/2004. It consists of 9162 measurements.

One variable is the day of the year, represented by an integer from 1 to 365 (or 366 for leap years). The information about the year has been dropped. Y is the mean temperature of the respective day, calculated according to the following definition:

$$T_{mean} := \frac{T_{morning} + T_{midday} + 2T_{evening}}{4},$$

where morning, midday, and evening are measured at 7:00 am, 14:00 pm, and 21:00 pm (MEZ), respectively (without daylight saving time). Double counting of the evening value is official standard of the German authority "Deutscher Wetterdienst". It has been defined at a time where no electronic data loggers were available and thermometers had to be read

out by humans. Weighting the evening value twice has been considered a useful heuristics to account for the missing values at night.

We consider day of the year as the cause, since it can be seen as expressing the angular position on its orbit around the sun. Although true interventions are infeasible, it is commonly agreed that changing the position of the earth would result in temperature changes at a fixed location due to the different solar incidence angle.

`pair0077`: Solar Radiation → Temperature

This data set shows the relation between solar radiation and temperature over 23 years, namely the interval 01/01/1986–12/31/2008. It consists of 8401 measurements.

Solar radiation is measured per area in W/m^2 averaged over one day on a horizontal surface. Temperature is the averaged daily, as in `pair0042`. The original data has been processed by us to extract the common time interval. We assume that radiation causes temperature. High solar radiation increases the temperature of the air already at a scale of hours. Interventions are easy to implement: Creating artificial shade on a large enough surface would decrease the air temperature. On longer time scales there might also be an influence from temperature to radiation via the generation of clouds through evaporation in more humid environments. This should, however, not play a role for daily averages.

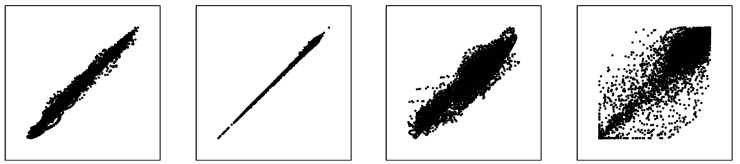
D.12 NCEP-NCAR Reanalysis

This data set, available from the NOAA (National Oceanic and Atmospheric Administration) Earth System Research Laboratory website at `http://www.esrl.noaa.gov/psd/data/gridded/data.ncep.reanalysis.surface.html`, is a subset of a reanalysis data set, incorporating observations and numerical weather prediction model output from 1948 to date (Kalnay et al., 1996). The reanalysis data set was produced by the National Center for Environmental Prediction (NCEP) and the National Center for Atmospheric Research (NCAR). Reanalysis data products aim for a realistic representation of all relevant climatological variables on a spatiotemporal grid. We collected four variables from a global grid of 144×73 cells: air temperature (in K, `pair0043`), surface pressure (in Pascal, `pair0044`), sea level pressure (in Pascal, `pair0045`) and relative humidity (in %, `pair0045`) on two consecutive days, day 50 and day 51 of the year 2000 (i.e., Feb 19th and 20th). Each data pair consists of $144 \times 73 - 143 = 10369$ data points, distributed across the globe. 143 data points were subtracted because at the north pole values are repeated across all longitudes.

Each data point is the daily average over an area that covers $2.5^\circ \times 2.5^\circ$ (approximately 250 km × 250 km at the equator). Because causal influence cannot propagate backwards in time, temperature, pressure and humidity in a certain area are partly affected by their value the day before in the same area.

`pair0043`: Temperature at t → Temperature at t+1

Due to heat storage, mean daily air temperature near surface at any day largely impact daily air temperature at the following day. We assume there is no causation backwards in time, hence the correlation between temperatures at two consecutive days must be driven by confounders (such as large-scale weather patterns) or a causal influence from the first day to the second.



pair0043 pair0044 pair0045 pair0046

Figure 29: Scatter plots of pairs from D.12. `pair0043`: temperature at t → temperature at t+1, `pair0044`: surface pressure at t → surface pressure at t+1, `pair0045`: sea level pressure at t → sea level pressure at t+1, `pair0046`: relative humidity at t → relative humidity at t+1, `pair0052`: (temp, press, slp, rh) at t → (temp, press, slp, rh) at t+1.

`pair0044`: Surface Pressure at t → Surface Pressure at t+1

Pressure patterns near the earth's surface are mostly driven by large-scale weather patterns. However, large-scale weather patterns are also driven by local pressure gradients and hence, some of the correlation between surface pressure at two consecutive days stems from a direct causal link between the first and the second day, as we assume there is no causation in time.

`pair0045`: Sea Level Pressure at t → Sea Level Pressure at t+1

Similar reasoning as in `pair0044`.

`pair0046`: Relative Humidity at t → Relative Humidity at t+1

Humidity of the air at one day affects the humidity of the following day because if no air movement takes place and no drying or moistening occurs, it will approximately stay the same. Furthermore, as reasoned above, because there is no causation backwards in time, relative humidity at day $t+1$ cannot affect humidity at day t. Note that relative humidity has values between 0 and 100. Values can be saturated in very humid places such as tropical rainforest and approach 0 in deserts. For this reason, the scatter plot looks as if the data were clipped.

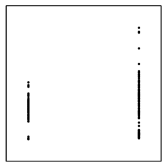
`pair0052`: (Temp, Press, SLP, RH) at t → (Temp, Press, SLP, RH) at t+1

The pairs `pair0043`–`pair0046` were combined to a 4-dimensional vector. From the reasoning above it follows that the vector of temperature, near surface pressure, sea level pressure and relative humidity at day t has a causal influence on the vector of the same variables at time $t+1$.

D.13 Traffic

This data set has been extracted from `http://www.b30-oberschwaben.de/html/tabelle.html`, a website containing various kinds of information about the national highway B30. This is a road in the federal state Baden-Württemberg, Germany, which provides an impor-

tant connection of the region around Ulm (in the North) with the Lake Constance region (in the South). After extraction, the data set contains 254 samples.



pair0047

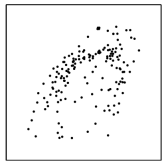
Figure 30: Scatter plots of pairs from D.13. pair0047: type of day → number of cars.

pair0047: Type of Day → Number of Cars

One variable is the number of cars per day, the other denotes the type of the respective day, with "1" indicating Sundays and holidays and "2" indicating working days. The type of day causes the number of cars per day. Indeed, introducing an additional holiday by a political decision would certainly change the amount of traffic on that day, while changing the amount of traffic by instructing a large number of drivers to drive or not to drive at a certain day would certainly not change the type of that day.

D.14 Hipel & McLeod

This data set contains 168 measurements of indoor and outdoor temperatures. It was taken from a book by Hipel and McLeod (1994) and can be downloaded from http://www.stats.uwo.ca/faculty/mcleod/epubs/mhsets/readme-mhsets.html.



pair0048

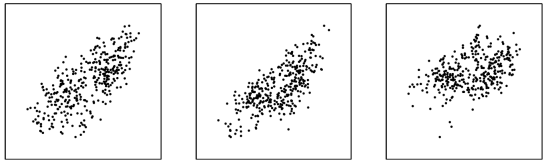
Figure 31: Scatter plots of pairs from D.14. pair0048: outdoor temperature → indoor temperature.

pair0048: Outdoor Temperature → Indoor Temperature

Outdoor temperatures can have a strong impact on indoor temperatures, in particular when indoor temperatures are not adjusted by air conditioning or heating. Contrarily, indoor temperatures will have little or no effect on outdoor temperatures, because the outside environment has a much larger heat capacity.

D.15 Bafu

This data set deals with the relationship between daily ozone concentration in the air and temperature. It was downloaded from http://www.bafu.admin.ch/luft/luftbelastung/blick_zurueck/datenabfrage/index.html. Lower atmosphere ozone (O_3) is a secondary pollutant that is produced by the photochemical oxidation of carbon monoxide (CO), methane (CH_4), and non-methane volatile organic compounds (NMVOCs) by OH in the presence of nitrogen oxides (NO_x, NO + NO_2) (Rasmussen et al., 2012). It is known that ozone concentration strongly correlates with surface temperature (Bloomer et al., 2009). Several explanations are given in the literature (see e.g., Rasmussen et al., 2012). Without going into details of the complex underlying chemical processes, we mention that the crucial chemical reactions are stronger at higher temperatures. For instance, isoprene emissions of plants increase with increasing temperature and isoprene can play a similar role in the generation of O_3 as NO_x (Rasmussen et al., 2012). Apart from this, air pollution may be influenced indirectly by temperature, e.g., via increasing traffic at 'good' weather conditions or an increased occurrence rate of wildfires. All these explanations state a causal path from temperature to ozone. Note that the phenomenon of ozone pollution in the lower atmosphere discussed here should not be confused with the 'ozone hole', which is a lack of ozone in the higher atmosphere. Close to the surface, ozone concentration does not have an impact on temperatures. For all three data sets, ozone is measured in $\mu g/m^3$ and temperature in °C.



pair0049 pair0050 pair0051

Figure 32: Scatter plots of pairs from D.15. pair0049: temperature → ozone concentration, pair0050: temperature → ozone concentration, pair0051: temperature → ozone concentration, pair0055: radiation → ozone concentration.

pair0049: Temperature → Ozone Concentration

365 daily mean values of ozone and temperature of year 2009 in Lausanne-César-Roux, Switzerland.

pair0050: Temperature → Ozone Concentration

365 daily mean values of ozone and temperature of year 2009 in Chaumont, Switzerland.

pair0051: Temperature → Ozone Concentration

365 daily mean values of ozone and temperature of year 2009 in Davos-See, Switzerland.

pair0055: Radiation → Ozone Concentration

72 daily mean values of ozone concentrations and radiation in the last 83 days of 2009 at 16 different places in Switzerland (11 days were deleted due to missing data). Solar radiation and surface ozone concentration are correlated (Feister and Balzer, 1991). The deposition of ozone is driven by complex micro-meteorological processes including wind direction, air temperature, and global radiation (Stockwell et al., 1997). For instance, solar radiation affects the height of the planetary boundary layer and cloud formation and thus indirectly influences ozone concentrations. In contrast, global radiation is not driven by ozone concentrations close to the surface.

Ozone is given in $\mu g/m^3$, radiation in W/m^2. The 16 different places are: 1: Bern-Bollwerk, 2: Magadino-Cadenazzo, 3: Lausanne-César-Roux, 4: Payerne, 5: Lugano-Universita, 6: Taenikon, 7: Zuerich-Kaserne, 8: Laegeren, 9: Basel-Binningen, 10: Chaumont, 11: Duebendorf, 12: Rigi-Seebodenalp, 13: Haerkingen, 14: Davos-See, 15: Sion-Aéroport, 16: Jungfraujoch.

D.16 Environmental

We downloaded ozone concentration, wind speed, radiation and temperature from http://www.mathe.tu-freiberg.de/Stoyan/umwdat.html, discussed in Stoyan et al. (1997). The data consist of 989 daily values over the time period from 05/01/1989 to 10/31/1994 observed in Heilbronn, Germany.

pair0053: (Wind Speed, Radiation, Temperature) → Ozone Concentration

As we have argued above in Section D.15, wind direction (and speed), air temperature, and global radiation influence local ozone concentrations. Wind can influence ozone concentrations for example in the following way. No wind will keep the the concentration of ozone in a given air parcel constant if no lateral or vertical sources or sinks are prevalent. In contrast, winds can move and disperse and hence mix air with different ozone concentrations. Ozone concentration is given in $\mu g/m^3$, wind speed in m/s, global radiation in W/m^2 and temperature in °C.

D.17 UNdata

The following data were taken from the "UNdata" database of the United Nations Statistics Division at http://data.un.org.

pair0056–pair0059: Latitude of Capital → Female Life Expectancy

Pairs pair0056–pair0059 consist of female life expectancy (in years) at birth versus latitude of the country's capital, for various countries (China, Russia and Canada were removed). The four pairs correspond with measurements over the periods 2000–2005, 1995–2000, 1990–1995, 1985–1990, respectively. The data were downloaded from http://data.un.org/Data.aspx?d=GenderStat&f=inID%3a37.

The location of a country (encoded in the latitude of its capital) has an influence on how poor or rich a country is, hence affecting the quality of the health care system and ultimately life expectancy. This influence could stem from abundance of natural resources within

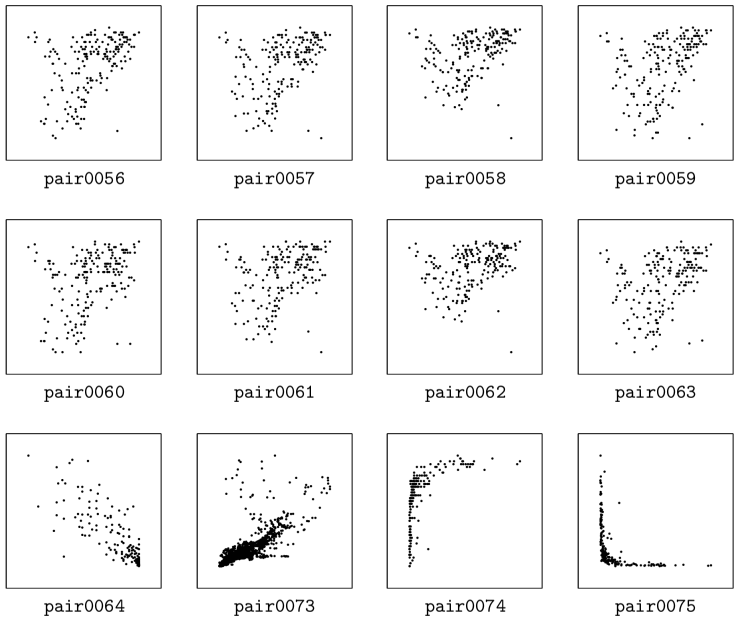


Figure 33: Scatter plots of pairs from D.17. pair0056–pair0059: latitude of capital → female life expectancy, pair0060–pair0063: latitude of capital → male life expectancy, pair0064: drinking water access → infant mortality, pair0073: energy use → CO_2 emissions, pair0074: GNI per capita → life expectancy, pair0075: GNI per capita → under-5 mortality rate.

the country's borders or the influence neighboring countries have on its economic welfare. Furthermore, the latitude can influence life expectancy via climatic factors. For instance, life expectancy might be smaller if a country frequently experiences climatic extremes. In contrast, it is clear that life expectancy does not have any effect on latitude.

pair0060–pair0063: Latitude of Capital → Male Life Expectancy

Pairs pair0060–pair0063 are similar, but concern male life expectancy. The same reasoning as for female life expectancy applies here.

pair0064: Drinking Water Access → Infant Mortality

Here, one variable describes the percentage of population with sustainable access to improved drinking water sources in 2006, whereas the other variable denotes the infant mortality rate (per 1000 live births) for both sexes. The data were downloaded from http://

data.un.org/Data.aspx?d=WHO&f=inID%3aMBD10 and http://data.un.org/Data.aspx?d=WHO&f=inID%3aRF03, respectively, and consist of 163 samples.

Clean drinking water is a primary requirement for health, in particular for infants (Esrey et al., 1991). Changing the percentage of people with access to clean water will directly change the mortality rate of infants, since infants are particularly susceptible to diseases (Lee et al., 1997). There may be some feedback, because if infant mortality is high in a poor country, development aid may be directed towards increasing the access to clean drinking water.

pair0073: Energy Use → CO_2 Emissions

This data set contains energy use (in kg of oil equivalent per capita) and CO_2 emission data from 152 countries between 1960 and 2005, yielding together 5084 samples. Considering the current energy mix across the world, the use of energy clearly results in CO_2 emissions (although in varying amounts across energy sources). Contrarily, a hypothetical change in CO_2 emissions will not affect the energy use of a country on the short term. On the longer term, if CO_2 emissions increase, this may cause energy use to decrease because of fear for climate change.

pair0074: GNI per Capita → Life Expectancy

We collected the Gross National Income (GNI, in USD) per capita and the life expectancy at birth (in years) for 194 different countries. GNI can be seen as an index of wealth of a country. In general, richer countries have a better health care system than poor countries an thus can take better care of their citizens when they are ill. Reversely, we believe that the life expectancy of humans has a smaller impact on how wealthy a country is than vice versa.

pair0075: GNI per Capita → Under-5 Mortality Rate

Here we collected the Gross National Income (GNI, in USD) per capita and the under-5 mortality rate (deaths per 1000 live births) for 205 different countries. The reasoning is similar as in pair0074. GNI as an index of wealth influences the quality of the health care system, which in turn determines whether young children will or will not die from minor diseases. As children typically do not contribute much to GNI per capita, we do not expect the reverse causal relation to be very strong.

D.18 Yahoo database

These data denote stock return values and were downloaded from http://finance.yahoo.com. We collected 1331 samples from the following stocks between January 4th, 2000 and June 17, 2005: Hang Seng Bank (0011.HK), HSBC Hldgs (0005.HK), Hutchison (0013.HK), Cheung kong (0001.HK), and Sun Hung Kai Prop. (0016.HK). Subsequently, the following preprocessing was applied, which is common in financial data processing:

1. Extract the dividend/split adjusted closing price data from the Yahoo Finance data base.

2. For the few days when the price is not available, we use simple linear interpolation to estimate the price.

3. For each stock, denote the closing price on day t by P_t, and the corresponding return is calculated as $X_t = (P_t - P_{t-1})/P_{t-1}$.

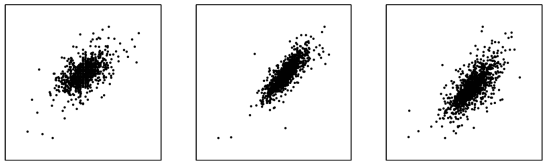

Figure 34: Scatter plots of pairs from D.18. pair0065: Stock Return of Hang Seng Bank → Stock Return of HSBC Hldgs, pair0066: Stock Return of Hutchison → Stock Return of Cheung kong, pair0067: Stock Return of Cheung kong → Stock Return of Sun Hung Kai Prop.

pair0065: Stock Return of Hang Seng Bank → Stock Return of HSBC Hldgs

HSBC owns 60% of Hang Seng Bank. Consequently, if stock returns of Hang Seng Bank change, this should have an influence on stock returns of HSBC Hldgs, whereas causation in the other direction would be expected to be less strong.

pair0066: Stock Return of Hutchison → Stock Return of Cheung kong

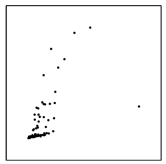
Cheung kong owns about 50% of Hutchison. Same reasoning as in pair0065.

pair0067: Stock Return of Cheung kong → Stock Return of Sun Hung Kai Prop.

Sun Hung Kai Prop. is a typical stock in the Hang Seng Property subindex, and is believed to depend on other major stocks, including Cheung kong.

D.19 Internet Traffic Data

This data set has been created from the log-files of a http-server of the Max Planck Institute for Intelligent Systems in Tübingen, Germany. The variable Internet connections counts the number of times an internal website of the institute has been accessed during a time interval of 1 minute (more precisely, it counts the number of URL requests). Requests for non-existing websites are not counted. The variable Byte transferred counts the total number of bytes sent for all those accesses during the same time interval. The values $(x_1, y_1), \ldots, (x_{498}, y_{498})$ refer to 498 time intervals. To avoid too strong dependence between the measurements, the time intervals are not adjacent but have a distance of 20 minutes.



pair0068

Figure 35: Scatter plots of pairs from D.19. pair0068: internet connections → bytes transferred.

pair0068: Internet Connections → Bytes Transferred

Internet connections causes Bytes transferred because an additional access of the website raises the transfer of data, while transferring more data does not create an additional website access. Note that not every access yields data transfer because the website may still be cached. However, this fact does not spoil the causal relation, it only makes it less deterministic.

D.20 Inside and Outside Temperature

This bivariate time-series data consists of measurements of inside room temperature (°C) and outside temperature (°C), where measurements were taken every 5 minutes for a period of about 56 days, yielding a total of 16382 measurements. The outside thermometer was located on a spot that was exposed to direct sunlight, which explains the large fluctuations. The data were collected by Joris M. Mooij.

pair0069

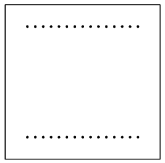
Figure 36: Scatter plots of pairs from D.20. pair0069: outside temperature → inside temperature.

pair0069: Outside Temperature → Inside Temperature

Although there is a causal relationship in both directions, we expect that the strongest effect is from outside temperature on inside temperature, as the heat capacity of the inside of a house is much smaller than that of its surroundings. See also the reasoning for pair0048.

D.21 Armann & Bülthoff

This data set is taken from a psychological experiment that artificially generates images of human faces that interpolate between male and female, taking real faces as basis (Armann and Bülthoff, 2012). The interpolation is done via principal component analysis after representing true face images as vectors in an appropriate high-dimensional space. Human subjects are instructed to label the faces as male or female. The variable "parameter" runs between 0 and 14 and describes the transition from female to male. It is chosen by the experimenter. The binary variable "answer" indicates the answers 'female' and 'male', respectively. The data set consists of 4499 samples.



pair0070

Figure 37: Scatter plots of pairs from D.21. pair0070: parameter → answer.

pair0070: Parameter → Answer

Certainly parameter causes answer. We do not have to talk about *hypothetical* interventions. Instead, we have a true intervention, since "parameter" has been set by the experimenter.

D.22 Acute Inflammations

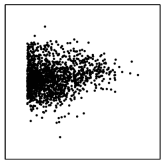
This data set is part of the UCI Machine Learning Repository (Bache and Lichman, 2013) and is available at https://archive.ics.uci.edu/ml/datasets/Acute+Inflammations. It was collected in order to create a computer expert system that decides whether a patient suffers from two different diseases of urinary system (Czerniak and Zarzycki, 2003). The two possible diseases are acute inflammations of urinary bladder and acute nephritises of renal pelvis origin. As it is also possible to chose none of those, the class variable takes values in $\{0,1\}^2$. The decision is based on six symptoms: temperature of patient (e.g. 35.9), occurrence of nausea ("yes" or "no"), lumbar pain ("yes" or "no"), urine pushing ("yes" or "no"), micturition pains ("yes" or "no") and burning of urethra, itch, swelling of urethra outlet ("yes" or "no"). These are grouped together in a six-dimensional vector "symptoms".

pair0071: Symptoms → Classification of Disease

One would think that the disease is causing the symptoms but this data set was created artificially. The description on the UCI homepage says: "The data was created by a medical expert as a data set to test the expert system, which will perform the presumptive diagnosis of two diseases of urinary system. (...) Each instance represents an potential patient." We thus consider the symptoms as the cause for the expert's decision.

D.23 Sunspots

The data set consists of 1632 monthly values between May 1874 and April 2010 and therefore contains 1632 data points. The temperature data have been taken from http://www.cru.uea.ac.uk/cru/data/temperature/ and have been collected by Climatic Research Unit (University of East Anglia) in conjunction with the Hadley Centre (at the UK Met Office) (Morice et al., 2012). The temperature data is expressed in deviations from the 1961–90 mean global temperature of the Earth (i.e., monthly anomalies). The sunspot data (Hathaway, 2010) are taken from the National Aeronautics and Space Administration and were downloaded from http://solarscience.msfc.nasa.gov/SunspotCycle.shtml. According to the description on that website, "sunspot number is calculated by first counting the number of sunspot groups and then the number of individual sunspots. The sunspot number is then given by the sum of the number of individual sunspots and ten times the number of groups. Since most sunspot groups have, on average, about ten spots, this formula for counting sunspots gives reliable numbers even when the observing conditions are less than ideal and small spots are hard to see."



pair0072

Figure 38: Scatter plots of pairs from D.23. pair0072: sunspots → global mean temperature.

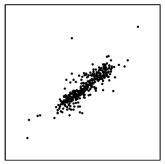
pair0072: Sunspots → Global Mean Temperature

Sunspots are phenomena that appear temporarily on the sun's surface. Although the causes of sunspots are not entirely understood, there is a significant dependence between the number of sunspots and the global mean temperature anomalies (p-value for zero correlation is less than 10^{-4}). There is evidence that the Earth's climate heats and cools as solar activity rises and falls (Haigh, 2007), and the sunspot number can be seen as a proxy for solar activity. Also, we do not believe that the Earth's surface temperature (or changes of the Earth's atmosphere) has an influence on the activity of the sun. We therefore consider number of sunspots causing temperature as the ground truth.

D.24 Food and Agriculture Organization of the UN

The data set has been collected by Food and Agriculture Organization of the UN (http://www.fao.org/economic/ess/ess-fs/en/) and is accessible at http://www.docstoc.com/docs/102679223/Food-consumption-and-population-growth---FAO. It covers 174 countries or areas during the period from 1990–92 to 1995–97 and the period from 1995–97 to 2000–02. As one entry is missing, this gives 347 data points. We selected two variables:

population growth and food consumption. The first variable indicates the average annual rate of change of population (in %), the second one describes the average annual rate of change of total dietary consumption for total population (kcal/day) (also in %).



pair0076

Figure 39: Scatter plots of pairs from D.24. pair0076: population growth → food consumption growth.

pair0076: Population Growth → Food Consumption Growth

We regard population growth to cause food consumption growth, mainly because more people eat more. Both variables are most likely also confounded by the availability of food, driven for instance by advances in agriculture and subsequently increasing yields, but also by national and international conflicts, the global food market and other economic factors. However, for the short time period considered here, confounders which mainly influence the variables on a temporal scale can probably be neglected. Their might also be a causal link from food consumption growth to population growth, for instance one could imagine that if people are well fed, they also reproduce more. However, we assume this link only plays a minor role here.

D.25 Light Response

The filtered version of the light response data was obtained from Moffat (2012). It consists of 721 measurements of Net Ecosystem Productivity (NEP) and three different measures of the Photosynthetic Photon Flux Density (PPFD): the direct, diffuse, and total PPFD. NEP is a measure of the net CO_2 flux between the biosphere and the atmosphere, mainly driven by biotic activity. It is defined as the photosynthetic carbon uptake minus the carbon release by respiration, and depends on the available light. NEP is measured in units of μmol CO_2 m^{-2} s^{-1}. PPFD measures light intensity in terms of photons that are available for photosynthesis, i.e., with wavelength between 400 nm and 700 nm (visible light). More precisely, PPFD is defined as the number of photons with wavelength of 400–700 nm falling on a certain area per time interval, measured in units of μmol photons m^{-2} s^{-1}. The total PPFD is the sum of PPFDdif, which measures only diffusive photons, and PPFDdir, which measures only direct (solar light) photons. The data was measured over several hectare of a forest in Hainich, Germany (site name DE-Hai, latitude: 51.08°N, longitude: 10.45°E), and is available from http://fluxnet.ornl.gov.

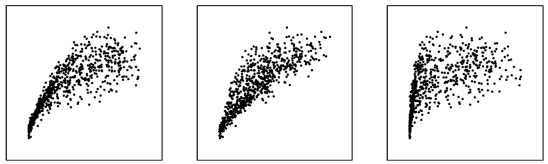


Figure 40: Scatter plots of pairs from D.25. pair0078: PPFD → NEP, pair0079: PPFDdif → NEP, pair0080: PPFDdir → NEP.

pair0078–pair0080: {PPFD,PPFDdif,PPFDdir} → NEP

Net Ecosystem Productivity is known to be driven by both the direct and the diffuse Photosynthetic Photon Flux Density, and hence also by their sum, the total PPFD.

D.26 FLUXNET

The data set contains measurements of net CO_2 exchanges between atmosphere and biosphere aggregated over night, and the corresponding temperature. It is taken from the FLUXNET network (Baldocchi et al., 2001), available at http://fluxnet.ornl.gov (see also Section D.25). The data have been collected at a 10 Hz rate and was aggregated to one value per day over one year (365 values) and at three different sites (BE-Bra, DE-Har, US-PFa). CO_2 exchange measurements typically have a footprint of about 1km^2. The data set contains further information on the quality of the data ("1" means that the value is credible, "NaN" means that the data point has been filled in).

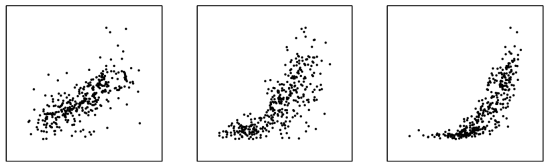

Figure 41: Scatter plots of pairs from D.26. pair0081 (BE-Bra): temperature → local CO_2 flux, pair0082 (DE-Har): temperature → local CO_2 flux, pair0083 (US-PFa): temperature → local CO_2 flux.

pair0081–pair0083: Temperature → Local CO_2 Flux

Because of lack of sunlight, CO_2 exchange at night approximates ecosystem respiration (carbon release from the biosphere to the atmosphere), which is largely dependent on temperature (see, e.g., Mahecha et al., 2010). The CO_2 flux is mostly generated by microbial decomposition in soils and maintenance respiration from plants and does not have a direct effect on temperature. We thus consider temperature causing CO_2 flux as the ground truth.

The three pairs pair0081–pair0083 correspond with sites BE-Bra, DE-Har, US-PFa, respectively.

D.27 US County-Level Growth

The data set from Wheeler (2003) is available at http://www.spatial-econometrics.com/data/contents.html. It contains both employment and population information for 3102 counties in the US in 1980. We selected columns eight and nine in the file "countyg.dat". Column eight contains the natural logarithm of the number of employed people, while column nine contains the natural logarithm of the total number of people living in this county, and is therefore always larger than the number in column eight.

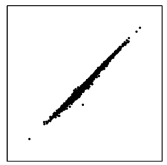

Figure 42: Scatter plots of pairs from D.27. pair0084: population → employment.

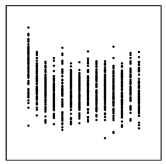
pair0084: Population → Employment

It seems reasonable that the total population causes the employment and not vice versa. If we increase the number of people living in an area, this has a direct effect on the number of employed people. We believe that the decision to move into an economically strong area is rather based on the employment rate rather than the absolute number of employed people. There might be an effect that the employment status influences the decision to get children but we regard this effect to be less relevant.

D.28 Milk Protein Trial

This data set is extracted from that for the milk protein trial used by Verbyla and Cullis (1990). The original data set consists of assayed protein content of milk samples taken weekly from each of 79 cows. The cows were randomly allocated to one of three diets: barley, mixed barley-lupins, and lupins, with 25, 27 and 27 cows in the three groups, respectively. Measurements were taken for up to 19 weeks but there were 38 drop-outs from week 15 onwards, corresponding to cows who stopped producing milk before the end of the experiment. We removed the missing values (drop-outs) in the data set: we did not consider the measurements from week 15 onwards, which contain many drop-outs, and we discarded the cows with drop-outs before week 15. Finally, the data set contains 71 cows and 14 weeks, i.e., 994 samples in total. Furthermore, we re-organized the data set to see the relationship between the milk protein and the time to take the measurement. We selected two variables: the time to take weekly measurements (from 1 to 14), and the protein content of the milk produced by each cow at that time.



pair0085

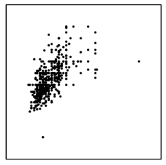
Figure 43: Scatter plots of pairs from D.28. pair0085: time of measurement → protein content of milk.

pair0085: Time of Measurement → Protein Content of Milk

Clearly, the time of the measurement causes the protein content and not vice versa. We do not consider the effect of the diets on the protein content.

D.29 kamernet.nl

This data was collected by Joris M. Mooij from http://www.kamernet.nl, a Dutch website for matching supply and demand of rooms and apartments for students, in 2007. The variables of interest are the size of the apartment or room (in m^2) and the monthly rent in EUR. Two outliers (one with size $0\,m^2$, the other with rent of 1 EUR per month) were removed, after which 666 samples remained.



pair0086

Figure 44: Scatter plots of pairs from D.29. pair0086: size of apartment → monthly rent.

pair0086: Size of Apartment → Monthly Rent

Obviously, the size causes the rent, and not vice versa.

D.30 Whistler Daily Snowfall

The Whistler daily snowfall data is one of the data sets on http://www.mldata.org, and was originally obtained from http://www.climate.weatheroffice.ec.gc.ca/ (Whistler Roundhouse station, identifier 1108906). We downloaded it from http://www.mldata.org/repository/data/viewslug/whistler-daily-snowfall. It concerns historical daily snowfall data in Whistler, BC, Canada, over the period July 1, 1972 to December 31, 2009. It was measured at the top of the Whistler Gondola (Latitude: 50°04′04.000″ N, Longitude:

122°56′50.000″ W, Elevation: 1835 m). We selected two attributes, mean temperature (°C) and total snow (cm). The data consists of 7753 measurements of these two attributes.

pair0087

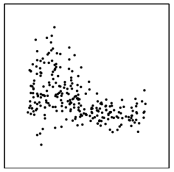
Figure 45: Scatter plots of pairs from D.30. pair0087: temperature → total snow.

pair0087: Temperature → Total Snow

Common sense tells us that the mean temperature is one of the causes of the total amount of snow, although there may be a small feedback effect of the amount of snow on temperature. Confounders are expected to be present (e.g., whether there are clouds).

D.31 Bone Mineral Density

This data set comes from the R package ElemStatLearn, and contains measurements of the age and the relative change of the bone mineral density of 261 adolescents. Each value is the difference in the spinal bone mineral density taken on two consecutive visits, divided by the average. The age is the average age over the two visits. We preprocessed the data by taking only the first measurement for each adolescent, as each adolescent has 1–3 measurements.



pair0088

Figure 46: Scatter plots of pairs from D.31. pair0088: age → relative bone mineral density.

pair0088: Age → Bone Mineral Density

Age must be the cause, bone mineral density the effect.

D.32 Soil Properties

These data were collected within the Biodiversity Exploratories project, see http://www.biodiversity-exploratories.de. We used data set 14686 (soil texture) and 16666 (root decomposition). With the goal to study fine root decomposition rates, Solly et al. (2014)

placed litterbags containing fine roots in 150 forest and 150 grassland sites along a climate gradient across Germany. Besides the decomposition rates, a range of other relevant variables were measured, including soil properties such as clay content, soil organic carbon content and soil moisture. We deleted sites with missing values and separated grasslands and forests.

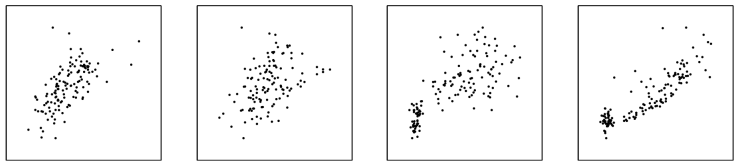


Figure 47: Scatter plots of pairs from D.32. `pair0089`: Root decomposition in April → Root decomposition in October (Forests), `pair0090`: Root decomposition in April → Root decomposition in October (Grasslands), `pair0091`: Clay content in soil → Soil moisture (forests), `pair0092`: Clay content in soil → Organic carbon content (forests).

`pair0089`–`pair0090`: Root Decomposition in April → Root Decomposition in October

Root decomposition happens monotonously in time. Hence the amount decomposed in April directly affects the amount decomposed in October in the same year.

`pair0091`: Clay Content in Soil → Soil Moisture

The amount of water that can be stored in soils depends on its texture. The clay content of a soil influences whether precipitation is stored longer in soils or runs off immediately. In contrast, it is clear that wetness of a soil does not affect its clay content.

`pair0092`: Clay Content in Soil → Organic Carbon Content

How much carbon an ecosystem stores in its soil depends on multiple factors, including the land cover type, climate and soil texture. Higher amounts of clay are favorable for storage of organic carbon (Solly et al., 2014). Soil organic carbon, on the other hand, does not alter the texture of a soil.

D.33 Runoff

This data set comes from the MOPEX data base (`http://www.nws.noaa.gov/ohd/mopex/mo_datasets.htm` and can be downloaded directly from `ftp://hydrology.nws.noaa.gov/pub/gcip/mopex/US_Data/Us_438_Daily/`. It contains precipitation and runoff data from over 400 river catchments in the USA on a daily resolution from 1948 to 2004. We computed yearly averages of precipitation and runoff for each catchment.

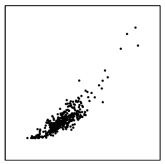

Figure 48: Scatter plots of pairs from D.33. `pair0093`: Precipitation → Runoff.

`pair0093`: Precipitation → Runoff

Precipitation is by far the largest driver for runoff in a given river catchment. There might be a very small feedback from runoff that evaporates and generates new precipitation. This is, however, negligible if the catchment does not span over full continents.

D.34 Electricity Load

This data set comes from a regional energy distributor in Turkey. It contains three variables, the hour of the day, temperature in degree Celsius and electricity consumption (load) in MW per hour. We thank S. Armagan Tarim and Steve Prestwich for providing the data.

Figure 49: Scatter plots of pairs from D.34. `pair0094`: Hour of the day → Temperature, `pair0095`: Hour of the day → Electricity consumption, `pair0096`: Temperature → Electricity consumption.

`pair0094`: Hour of the Day → Temperature

We consider hour of the day as the cause, since it can be seen as expressing the angular position of the sun. Although true interventions are unfeasible, it is commonly agreed that changing the position of the sun would result in temperature changes at a fixed location due to the different solar incidence angle.

`pair0095`: Hour of the Day → Electricity Consumption

The hour of the day constrains in many ways what people do and thus also their use of electricity. Consequently, we consider hour of the day as cause and electricity consumption as effect.

pair0096: Temperature → Electricity Consumption

Changes in temperature can prompt people to use certain electric devices, e.g., an electric heating when it is gets very cold or the usage of a fan or air conditioning when it gets very hot. Furthermore, certain machines such as computers have to be cooled more if temperatures rise. Hence we consider temperature as cause and electricity consumption as effect.

D.35 Ball Track

The data has been recorded by D. Janzing using a ball track that has been equipped with two pairs of light barriers. The first pair measures the initial speed and the second pair the speed of a ball at some later position of the track. The units are arbitrary and differ for both measurements since they are obtained by inverting the time the ball needed to pass the distance between two light barriers of one pair.

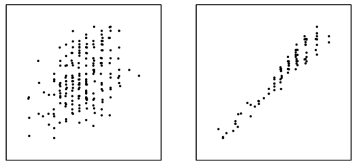

Figure 50: Scatter plots of pairs from D.35. pair0097: Initial speed → Final speed, pair0098: Initial speed → Final speed.

The initial part of the track has large slope. The initial speed is strongly determined by the exact position where the ball is put on the track. For part of the runs, the position of the ball has been chosen by D. Janzing, the other part by a 4-year old child. This should avoid that the variation of the initial position is done in a too systematic way.

Two similar experiments have been performed, using different ball track setups. For pair0098 the ball track had a longer acceleration zone than for pair0097, which allows for larger variations in initial speed.

pair0097: Initial Speed → Final Speed

These data consists of 202 measurements. Obviously, the initial speed of the ball causes the final speed.

pair0098: Initial Speed → Final Speed

These data consist of 94 measurements. Again, the initial speed of the ball causes the final speed.

D.36 Nlschools

This is data set nlschools from the R package MASS. The data were used by Snijders and Bosker (1999) as a running example and are about a study of 2287 eighth-grade pupils (aged about 11) in 132 classes in 131 schools in the Netherlands. We used two variables: lang, a language test score, and SES, the social-economic status of the pupil's family.

Figure 51: Scatter plots of pairs from D.36. pair0099: Social-economic status of family → Language test score.

pair0099: Social-Economic Status of Family → Language Test Score

We consider the social-economic status of the pupil's family to be the cause of the language test score of the pupil. However, note that selection bias may be present via the choice of the schools to include in the study.

D.37 CPUs

This is data set cpus from the R package MASS, and concerns characteristics of 209 CPUs (Ein-Dor and Feldmesser, 1987). We used two variables: syct, cycle time in nanoseconds, and perf, the published performance on a benchmark mix relative to an IBM 370/158-3, and took the logarithms of the original values.

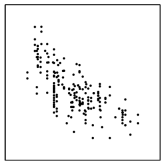

Figure 52: Scatter plots of pairs from D.37. pair0100: CPU cycle time → Performance.

pair0100: CPU Cycle Time → Performance

It should be obvious that CPU cycle time causes its performance.

Appendix E. Computation Time

We report the total computation time for each benchmark set and for each of our implementations of various methods in Figures 53 and 54. We used a machine with `Intel Xeon CPU E5-2680 v2 @ 2.80GHz` processors, 40 cores, and 125 GB of RAM. The measured computation time measures the total time spent (i.e., the sum of the computation times of individual cores). We did not spend much effort on optimizing the implementations, so the reported computation times should be seen as upper bounds on what is achievable. We only report results for the unperturbed data, as the preprocessing does not affect computation time significantly.

In general, for the ANM implementations, most time is taken by the Gaussian Process regression. The HSIC test and entropy estimators are relatively quick compared to that. A notable outlier is `ANM-MML` which spends much time on estimating the MML of the marginal distribution using the algorithm by Figueiredo and Jain (2002). IGCI implementations are much faster than ANM (about two orders of magnitude in our setting), as non-parametric regression is not required. One notable outlier for the IGCI implementations is `IGCI-ent-PSD`, which shows that the `ent-PSD` estimator is slower than the other entropy estimators in the `ITE` toolbox. Interestingly, this is also the only non-parametric entropy estimator that turned out to be robust to perturbations of the data.

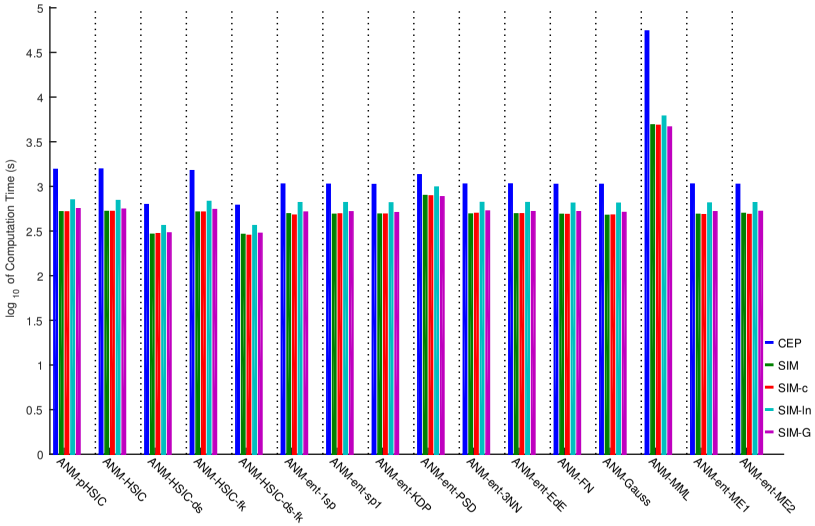

Figure 53: Computation times of various ANM methods on different (unperturbed) data sets. For the variants of the spacing estimator, only the results for `sp1` are shown, as results for `sp2`,...,`sp6` were similar.

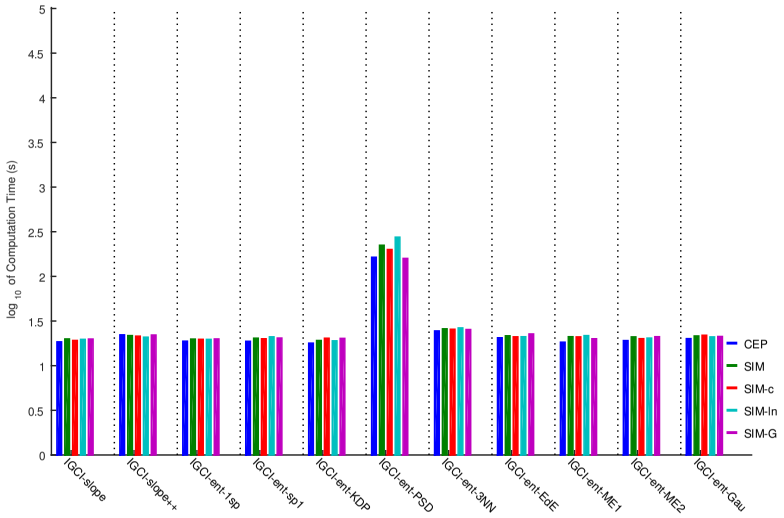

Figure 54: Computation times of various IGCI methods on different (unperturbed) data sets. For the variants of the spacing estimator, only the results for `sp1` are shown, as results for `sp2`,...,`sp6` were similar. We only show results for the uniform base measure as those for the Gaussian base measure are similar.

Abstract

Multi-task learning (MTL) aims to improve generalization performance by learning multiple related tasks simultaneously. While sometimes the underlying task relationship structure is known, often the structure needs to be estimated from data at hand. In this paper, we present a novel family of models for MTL, applicable to regression and classification problems, capable of learning the structure of tasks relationship. In particular, we consider a joint estimation problem of the tasks relationship structure and the individual task parameters, which is solved using alternating minimization. The task relationship revealed by structure learning is founded on recent advances in Gaussian graphical models endowed with sparse estimators of the precision (inverse covariance) matrix. An extension to include flexible Gaussian copula models that relaxes the Gaussian marginal assumption is also proposed. We illustrate the effectiveness of the proposed model on a variety of synthetic and benchmark data sets for regression and classification. We also consider the problem of combining Earth System Model (ESM) outputs for better projections of future climate, with focus on projections of temperature by combining ESMs in South and North America, and show that the proposed model outperforms several existing methods for the problem.

Keywords: multi-task learning, structure learning, Gaussian copula, probabilistic graphical model, sparse modeling

1. Introduction

In multi-task learning (MTL) one can benefit from the knowledge of the underlying structure relating the learning tasks while carrying them out simultaneously. In situations where some tasks might be highly dependent on each other, the strategy of isolating each task will not be helpful in exploiting the potential information one might acquire from other related tasks. The last few years experienced an increase of activity in this area where new methods and applications have been proposed. From the methods perspective, there have been contributions devoted to novel formulations to describe task structure and to incorporate them into the learning framework (Evgeniou and Pontil, 2004; Ji and Ye, 2009; Kim and Xing, 2010; Kumar and Daume III, 2012; Yang et al., 2013). Meanwhile MTL has been applied to problems ranging from object detection in computer vision, going through web image and video search (Wang et al., 2009), and achieving multiple microarray data set integration in computational biology (Widmer and Rätsch, 2012).

Much of the existing work in MTL assumes the existence of a priori knowledge about the task relationship structure (see Section 2). However, in many problems there is only a high level understanding of those relationships, and hence the structure of the task relationship needs to be estimated from the data. Recently, there have been attempts to explicitly model the relationship and incorporate it into the learning process (Zhang and Yeung, 2010; Zhang and Schneider, 2010; Yang et al., 2013). In the majority of these methods, the tasks dependencies are represented as unknown hyper-parameters in hierarchical Bayesian models and are estimated from the data. As will be discussed in Section 2, many of these methods are either computationally expensive or restrictive on dependence structure complexity.

In *structure learning*, we estimate the (conditional) dependence structures between random variables in a high-dimensional distribution, and major advances have been achieved in the past few years (Banerjee et al., 2008; Friedman et al., 2008; Cai et al., 2011; Wang et al., 2013). In particular, assuming sparsity in the conditional dependence structure, i.e., each variable is dependent only on a few others, there are estimators based on convex (sparse) optimization which are guaranteed to recover the correct dependence structure with high probability, even when the number of samples is small compared to the number of variables.

In this paper, we present a family of models for MTL, for regression and classification problems, which are capable of learning the structure of task relationships and parameters for individual tasks. The problem is posed as a joint estimation where parameters of the tasks and relationship structure are learned using alternating minimization. This paper is an extension of our early work (Gonçalves et al., 2014), as it further includes improvements on the task relationship modeling and can now handle a wider spectrum of problems.

The relationship structure is modeled by either imposing a prior over the features across tasks (Section 3.3) or assuming correlated residuals (Section 3.7). We can use of a variety of methods from the structure learning literature to estimate the relationships. The formulation can be extended to Gaussian copula models (Liu et al., 2009; Xue and Zou, 2012), which are more flexible as it does not rely on strict Gaussian assumptions and has shown to be more robust to outliers. The resulting estimation problems are solved using suitable first order methods, including proximal updates (Beck and Teboulle, 2009) and alternating direction method of multipliers (Boyd et al., 2011). Based on our modeling, we show that MTL can benefit from advances in the structure learning area. Moreover, any future development in the area can be readily used in the context of MTL.

The proposed Multi-task Sparse Structure Learning (MSSL) approach has important practical implications: given a set of tasks, one can just feed the data from all the tasks without any knowledge or guidance on task relationship, and MSSL will figure out which tasks are related and will also estimate task specific parameters. Through experiments on a wide variety of data sets for multi-task regression and classification, we illustrate that MSSL is competitive with and usually outperforms several baselines from the existing MTL literature. Furthermore, the task relationships learned by MSSL are found to be accurate and consistent with domain knowledge on the problem.

In addition to evaluation on synthetic and benchmark data sets, we consider the problem of predicting air surface temperature in South and North America. The goal here is to combine outputs from Earth System Models (ESMs) reported by various countries to the Intergovernmental Panel on Climate Change (IPCC), where the regression problem at each geographical location forms a task. The weight on each model at each location forms the "skill" of that model, and the hope is that outputs from skillful models in each region can be more reliable for future projections of temperature. MSSL is able to identify geographically nearby regions as related tasks, which is meaningful for temperature prediction, without any previous knowledge of the spatial location of the tasks, and outperforms baseline approaches.

The remainder of the paper is structured as follows. Section 2 briefly discusses the related work in multi-task learning. Section 3 presents an overview and gentle introduction to the proposed multi-task sparse structure learning (MSSL) approach. Section 3.3 discusses a specific form of MSSL where the task structure dependence is learned based on the task coefficients. The MSSL is extended to the Gaussian copula MSSL in Section 3.6. Section 3.7 discusses another specific form of MSSL where the task structure dependence is learned based on the task residuals. Section 4 presents experimental results on regression and classification using synthetic, benchmark, and climate data sets. We conclude in Section 5.

Notation. We denote by m the number of tasks, d the problem dimension, supposed to be the same for all learning tasks, and n_k the number of samples for the k-th task. $\mathbf{X}_k \in \mathbb{R}^{n_k \times d}$ and $\mathbf{y}_k \in \mathbb{R}^{n_k \times 1}$ are the input and output data for the k-th task. Let $\mathbf{W} \in \mathbb{R}^{d \times m}$ be the parameter matrix, where columns are vector parameters $\mathbf{w}_k \in \mathbb{R}^d$, $k = 1, ..., m$, for the tasks. $(x)_+ = \max(0, x)$. Let $\mathcal{S}_+^p$ be the set of $p \times p$ positive semidefinite matrices. For any matrix $\mathbf{A}$, $\mathrm{tr}(\mathbf{A})$ is the trace operator, $\|\mathbf{A}\|_1$ and $\|\mathbf{A}\|_F$ are the ℓ_1-norm and Frobenius norm of $\mathbf{A}$, respectively. $\mathbf{A} \circ \mathbf{B}$ denotes the Hadamard (element-wise) product of the matrices $\mathbf{A}$ and $\mathbf{B}$. $\mathbf{I}_p$ is the $p \times p$ identity matrix and $\mathbf{0}_{p \times p}$ is a matrix full of zeros. For an m-variate random variable $V = (V_1, ..., V_m)$, we denote by $V_{\setminus\{i,j\}}$ the set of marginals except i and j.

2. Related Work

MTL has attracted a great deal of attention in the past few years and consequently many algorithms have been proposed (Evgeniou and Pontil, 2004; Argyriou et al., 2007; Xue et al., 2007; Jacob et al., 2008; Obozinski et al., 2010; Zhou et al., 2011b; Zhang and Yeung, 2010; Yang et al., 2013; Gonçalves et al., 2014). We will present a general view of the methods and discuss in more details those that are more related to ours.

The majority of the proposed methods fall into the class of regularized multi-task learning, which has the form

$$\min_{\mathbf{W}} \sum_{k=1}^{m} \left(\sum_{i=1}^{n_k} \ell\left(f(\mathbf{x}_k^i, \mathbf{w}_k), y_k^i\right) \right) + \mathcal{R}(\mathbf{W}),$$

where $\ell(\cdot)$ is the loss function such as squared, logistic, and hinge loss; $\mathcal{R}(\mathbf{W})$ is a regularization function for $\mathbf{W}$ that can be designed to enforce some sharing of information between tasks. In such a context, the goal of MTL is to estimate the tasks parameters $\mathbf{W} = [\mathbf{w}_1, ..., \mathbf{w}_m]$, while taking into account the underlying relationship among tasks.

The existing methods basically differ in the way the regularization $\mathcal{R}(\mathbf{W})$ is designed, including the structural constraints imposed to matrix $\mathbf{W}$ and the relationship among the

tasks. Some methods assume a fixed structure a priori, while others try to estimate it from the data. In the following we present a representative set of methods from these categories.

2.1 MTL with All Tasks Related

One class of MTL methods assumes that all tasks are related and the information about tasks are selectively shared among all tasks, with the hypothesized structure of the parameter matrix $\mathbf{W}$ controlling how the information is shared.

Evgeniou and Pontil (2004) considered the scenario that all tasks are related in a way that the model parameters are close to some mean model. Motivated by the sparsity inducing property of the ℓ_1-norm (Tibshirani, 1996), the idea of structured sparsity has been widely explored in MTL algorithms. Argyriou et al. (2007) assumed that there exists a subset of features that is shared for all the tasks and imposed an $\ell_{2,1}-$norm penalization on the matrix $\mathbf{W}$ to select such set of features. In the dirty-model proposed in Jalali et al. (2010) the matrix $\mathbf{W}$ is modeled as the sum of a group sparse and an element-wise sparse matrix. The sparsity pattern is imposed by ℓ_q and ℓ_1-norm regularizations. Similar decomposition was assumed in Chen et al. (2010), but there $\mathbf{W}$ is a sum of an element-wise sparse (ℓ_1) and a low-rank (nuclear norm) matrix. The assumption that a low-dimensional subspace is shared by all tasks is explored in Ando et al. (2005), Chen et al. (2009), and Obozinski et al. (2010). For example, in Obozinski et al. (2010) a trace norm regularization on $\mathbf{W}$ was used to select the common low-dimensional subspace.

2.2 MTL with Cluster Assumption

Another class of MTL methods assumes that not all tasks are related, but instead the relatedness is in a group (cluster) structure, that is, mutually related tasks are in the same cluster, while unrelated tasks belong to different clusters. Information is shared only by those tasks belonging to the same cluster. The problem then involves estimating the number of clusters and the matrix encoding the assignment cluster information.

In Bakker and Heskes (2003) task clustering was enforced by considering a mixture of Gaussians as a prior over task parameters. Evgeniou et al. (2005) proposed a task clustering regularization to encode cluster information in the MTL formulation. Xue et al. (2007) employed a Dirichlet process prior over the task coefficients to encourage task clustering and the number of clusters was someway automatically determined by the prior.

2.3 MTL with Dependence Structure Learning

Recently, there have been some proposals to estimate and incorporate the dependence among the tasks into the learning process. These methods are the most related to ours.

A matrix-variate normal distribution was used as a prior for $\mathbf{W}$ matrix in Zhang and Yeung (2010). The hyper-parameter for such a prior distribution captures the covariance matrix ($\mathbf{\Sigma}$) among all task coefficients. The resulting non-convex maximum a posteriori problem is relaxed by restricting the model complexity. It has a positive side of making the whole problem convex, but has the downside of significantly restricting the flexibility of the task relatedness structure. Also, in Zhang and Yeung (2010), the task relationship is modeled by the covariance among tasks, but uses the inverse (precision matrix, $\mathbf{\Sigma}^{-1} = \mathbf{\Omega}$)

in the task parameter learning step, therefore, the inverse of the covariance matrix needed to be computed at every iteration. We, on the other hand, do not constrain the complexity of our model and also learn the inverse of the covariance matrix directly, which tends to be more stable than computing covariance and then inverting it.

Zhang and Schneider (2010) also used a matrix-variate normal prior over $\mathbf{W}$. The two matrix hyper-parameters explicitly represent the covariance among the features (assuming the same feature relationships in all tasks) and covariance among the tasks, respectively. Sparse inducing penalization on the inverse covariance $\mathbf{\Omega}$ of both is added into the formulation. Unlike Zhang and Yeung (2010), both matrices are learned in an alternating minimization algorithm and can be computationally prohibitive in high dimensional problems due to the cost of modeling and estimating the feature covariance.

Yang et al. (2013) also assumed a matrix normal prior for $\mathbf{W}$. However, the row and column covariance hyperparameters have a Matrix Generalized Inverse Gaussian (MGIG) prior distribution. The mean of matrix $\mathbf{W}$ is factorized as the product of two matrices that also has matrix-variate normal distribution as a prior. The model inference is done via a variational Expectation Maximization (EM) algorithm. Due to the lack of a closed form expression to compute statistics of the MGIG distribution, the method resort to the use of sampling techniques, which can be slow for high-dimensional problems.

Rothman et al. (2010) also enforced sparsity on both $\mathbf{W}$ and $\mathbf{\Omega}$. Similar to our residual-based MSSL formulation, it differs in two aspects: (i) our formulation allows a richer class of conditional distribution $p(y|\mathbf{x})$, namely distributions in the exponential family, rather than simply Gaussian; and (ii) we employ a semiparametric Gaussian copula model to capture task relationship, which does not rely of Gaussian assumption on the marginals and have shown to be more robust to outliers (Liu et al., 2012), then traditional Gaussian model used in Rothman et al. (2010). As will be seen in the experiments, the MSSL method with copula models produced more accurate predictions. Rai et al. (2012) extended the formulation in Rothman et al. (2010) to model feature dependence, additionally to the task dependence modeling. However, it is computationally prohibitive for high-dimensional problems, due to the cost of estimating another precision matrix for feature dependence.

Zhou and Tao (2014) used copula as a richer class of conditional marginal distributions $p(y_k|\mathbf{x})$. As copula models express the joint distribution $p(\mathbf{y}|\mathbf{x})$ from the set of marginal distributions, this formulation allows marginals to have arbitrary continuous distributions. Output correlation is exploited via the sparse inverse covariance in the copula function, which is estimated by a procedure based on proximal algorithms. Our method also covers a rich class of conditional distributions, the exponential family that includes Gaussian, Bernoulli, Multinomial, Poisson, and Dirichlet, among others. We use Gaussian copula models to capture tasks dependence, instead of explicitly modeling marginal distributions.

3. Multi-task Sparse Structure Learning

In this section we describe our multi-task Sparse Structure Learning (MSSL) method. As our modeling is founded on structure estimation in Gaussian graphical models, we first introduce the associated problem before presenting the proposed method.

3.1 Structure Estimation in Gaussian Graphical Models

Here we describe the undirected graphical model used to capture the underlying linear dependence structure of our multi-task learning framework.

Let $V = (V_1, \ldots, V_m)$ be an m-variate random vector with joint distribution $p(V)$. Such distribution can be characterized by an undirected graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where the vertex set $\mathcal{V}$ represents the m covariates of V and edge set $\mathcal{E}$ represents the conditional dependence relations between the covariates of V. If V_i is conditionally independent of V_j given the other variables, then the edge (i, j) is not in $\mathcal{E}$. Assuming $V \sim \mathcal{N}(\mathbf{0}, \mathbf{\Sigma})$, the missing edges correspond to zeros in the inverse covariance matrix or *precision* matrix given by $\mathbf{\Sigma}^{-1} = \mathbf{\Omega}$, i.e., $(\mathbf{\Sigma}^{-1})_{ij} = 0 \; \forall (i, j) \notin E$ (Lauritzen, 1996).

Classical estimation approaches (Dempster, 1972) work well when m is small. Given, that we have n i.i.d. samples $v_1, \ldots, v_n$ from the distribution, the empirical covariance matrix is $\hat{\mathbf{\Sigma}} = \frac{1}{n}\sum_{i=1}^{n}(v_i - \bar{v})^\top(v_i - \bar{v})$, where $\bar{v} = \frac{1}{n}\sum_{i=1}^{n} v_i$. However, when $m > n$, $\hat{\mathbf{\Sigma}}$ is rank-deficient and its inverse cannot be used to estimate the precision matrix $\mathbf{\Omega}$. Nonetheless, for a sparse graph, i.e. most of the entries in the precision matrix are zero, several methods exist to estimate $\mathbf{\Omega}$ (Friedman et al., 2008; Boyd et al., 2011).

3.2 MSSL Formulation

For ease of exposition, let us consider a simple linear model for each task: $\mathbf{y}_k = \mathbf{X}_k\mathbf{w}_k + \boldsymbol{\xi}_k$ where $\mathbf{w}_k$ is the parameter vector for task k and $\boldsymbol{\xi}_k$ denotes the residual error. The proposed MSSL method estimates both the task parameters $\mathbf{w}_k$ for all tasks and the structure dependence, based on some information from each task. Further, the dependence structure is used as inductive bias in the $\mathbf{w}_k$ learning process, aiming at improving the generalization capability of the tasks.

We investigate and formalize two ways of learning the relationship structure (a graph indicating the relationship among the tasks), represented by $\mathbf{\Omega}$: (a) modeling $\mathbf{\Omega}$ from the task specific parameters $\mathbf{w}_k, \forall k = 1, ..., m$ and (b) modeling $\mathbf{\Omega}$ from the residual errors $\boldsymbol{\xi}_k, \forall k = 1, ..., m$. Based on how we model $\mathbf{\Omega}$, we propose p-MSSL (from tasks parameters) and r-MSSL (from residual error). Both models are discussed in the following sections.

At a high level, the estimation problem in such MSSL approaches takes the form:

$$\min_{\mathbf{W}, \mathbf{\Omega} \succ 0} \; \mathcal{L}((\mathbf{Y}, \mathbf{X}), \mathbf{W}) + \mathcal{B}(\mathbf{W}, \mathbf{\Omega}) + \mathcal{R}_1(\mathbf{W}) + \mathcal{R}_2(\mathbf{\Omega}), \tag{1}$$

where $\mathcal{L}(\cdot)$ denotes suitable task specific loss function, $\mathcal{B}(\cdot)$ is the inductive bias term, and $\mathcal{R}_1(\cdot)$ and $\mathcal{R}_2(\cdot)$ are suitable sparsity inducing regularization terms. The interaction between parameters $\mathbf{w}_k$ and the relationship matrix $\mathbf{\Omega}$ is captured by the $\mathcal{B}(\cdot)$ term. Notably, when $\mathbf{\Omega}_{k,k'} = 0$, the parameters $\mathbf{w}_k$ and $\mathbf{w}_{k'}$ have no influence on each other. Sections 3.3 to 3.7 delineate the modeling details behind MSSL algorithms and how it leads to the solution of the optimization problem in (1).

3.3 Parameter Precision Structure

If the tasks are unrelated, one can learn the columns of the coefficient matrix $\mathbf{W}$ independently for each of the m tasks. However, when there exist relationships among the m tasks, learning the columns of $\mathbf{W}$ independently fails to capture these dependencies. In such a

scenario, we propose to use the precision matrix $\mathbf{\Omega} \in \mathbb{R}^{m \times m}$ in order to capture pairwise partial correlations between tasks.

In the parameter precision structure based MSSL (p-MSSL) model we assume that features across tasks (*rows* $\hat{\mathbf{w}}_j$ of the matrix $\mathbf{W}$) follows a multivariate Gaussian distribution with zero mean and covariance matrix $\mathbf{\Sigma}$, i.e., $\hat{\mathbf{w}}_j \sim \mathcal{N}(\mathbf{0}, \mathbf{\Sigma})\ \forall j = 1, ..., d$, where $\mathbf{\Sigma}^{-1}$=$\mathbf{\Omega}$. The problem of interest is to estimate both the parameters $\mathbf{w}_1, \ldots, \mathbf{w}_m$ and the precision matrix $\mathbf{\Omega}$. By imposing such a prior over the *rows* of $\mathbf{W}$, we are capable of explicitly estimating the dependency structure among the tasks via the precision matrix $\mathbf{\Omega}$.

With a multivariate Gaussian prior over the *rows* of $\mathbf{W}$, its posterior can be written as

$$p\left(\mathbf{W}|(\mathbf{X}, \mathbf{Y}), \mathbf{\Omega}\right) \propto \prod_{k=1}^{m} \prod_{i=1}^{n_k} p\left(y_k^i | \mathbf{x}_k^i, \mathbf{w}_k^\top\right) \prod_{j=1}^{d} p\left(\hat{\mathbf{w}}_j | \mathbf{\Omega}\right), \tag{2}$$

where the first term in the right hand side denotes the conditional distribution of the response given the input and parameters, and the second term denotes the prior over *rows* of $\mathbf{W}$. In this paper, we consider the *penalized* maximization of (2), assuming that the parameter matrix $\mathbf{W}$ and the precision matrix $\mathbf{\Omega}$ are sparse, i.e., contain few non-zero elements. In the following, we provide two specific instantiations of this model. First, we consider a Gaussian conditional distribution, wherein we obtain the well known least squares regression problem (Section 3.3.1). Second, for discrete labeled data, choosing a Bernoulli conditional distribution leads to a logistic regression problem (Section 3.3.2).

3.3.1 Least Squares Regression

Assume that

$$p\left(y_k^i \middle| \mathbf{x}_k^i, \mathbf{w}_k\right) = \mathcal{N}_1\left(y_k^i \middle| \mathbf{w}_k^\top \mathbf{x}_k^i, \sigma_k^2\right),$$

where it is considered for ease of exposition that the variance of the residuals $\sigma_k^2 = 1, \forall k = 1, ..., m$, though it can be incorporated in the model and learned from the data. We can write this optimization problem as minimization of the negative logarithm of (2), which corresponds to a regularized linear regression problem

$$\min_{\mathbf{W}, \mathbf{\Omega} \succ 0} \quad \frac{1}{2} \sum_{k=1}^{m} \sum_{i=1}^{n_k} \left(\mathbf{w}_k^\top \mathbf{x}_k^i - y_k^i\right)^2 - \frac{d}{2} \log |\mathbf{\Omega}| + \frac{1}{2} \mathrm{tr}(\mathbf{W} \mathbf{\Omega} \mathbf{W}^\top).$$

Further, assuming that $\mathbf{\Omega}$ and $\mathbf{W}$ are sparse, we add ℓ_1-norm regularizers over both parameters. In the case one task has a much larger number of samples compared to the others, it may dominate the empirical loss term. To avoid such bias we modify the cost function and compute the weighted average of the empirical losses of the form

$$\min_{\mathbf{W}, \mathbf{\Omega} \succ 0} \quad \sum_{k=1}^{m} \frac{1}{n_k} \sum_{i=1}^{n_k} \left(\mathbf{w}_k^\top \mathbf{x}_k^i - y_k^i\right)^2 - d \log |\mathbf{\Omega}| + \lambda_0 \mathrm{tr}(\mathbf{W} \mathbf{\Omega} \mathbf{W}^\top) + \lambda_1 \|\mathbf{W}\|_1 + \lambda_2 \|\mathbf{\Omega}\|_1, \tag{3}$$

where λ_0, λ_1, and $\lambda_2 > 0$ are penalty parameters. The sparsity assumption on $\mathbf{W}$ is motivated by the fact that maybe some features are not relevant for discriminative purposes and can then be dropped out from the model. Precision matrix $\mathbf{\Omega}$ plays an important role in Gaussian graphical models because its zero entries precisely capture the conditional

independence, that is, $\mathbf{\Omega}_{ij} = 0$ if and only if $\mathbf{w}_i \perp\!\!\!\perp \mathbf{w}_j | \mathbf{W}_{\setminus\{i,j\}}$. Then, enforcing sparsity on $\mathbf{\Omega}$ will highlight the conditional independence among tasks parameters.

In this formulation, the term involving the trace of the outer product $\mathrm{tr}(\mathbf{W} \mathbf{\Omega} \mathbf{W}^\top)$ affects the *rows* of $\mathbf{W}$, such that if $\mathbf{\Omega}_{ij} \neq 0$, then $\mathbf{w}_i$ and $\mathbf{w}_j$ are constrained to be similar.

Although the problem is not jointly convex on $\mathbf{W}$ and $\mathbf{\Omega}$, it is in fact biconvex, that is, fixing $\mathbf{\Omega}$ the problem is convex on $\mathbf{W}$, and vice-versa. So, the associated biconvex function in problem (3) is split into two convex functions exhibited in (4a) and (4b). Then, one can use an alternating optimization procedure that updates $\mathbf{W}$ and $\mathbf{\Omega}$ by fixing one of them and solving the corresponding convex optimization problem (Gorski et al., 2007), given by

$$f_{\mathbf{\Omega}}(\mathbf{W}; \mathbf{X}, \mathbf{Y}, \lambda_0, \lambda_1) = \sum_{k=1}^{m} \frac{1}{n_k} \sum_{i=1}^{n_k} (\mathbf{w}_k^\top \mathbf{x}_k^i - y_k^i)^2 + \lambda_0 \mathrm{tr}(\mathbf{W} \mathbf{\Omega} \mathbf{W}^\top) + \lambda_1 \|\mathbf{W}\|_1, \tag{4a}$$

$$f_{\mathbf{W}}(\mathbf{\Omega}; \mathbf{X}, \mathbf{Y}, \lambda_0, \lambda_2) = \lambda_0 \mathrm{tr}(\mathbf{W} \mathbf{\Omega} \mathbf{W}^\top) - d \log |\mathbf{\Omega}| + \lambda_2 \|\mathbf{\Omega}\|_1. \tag{4b}$$

The alternating minimization algorithm proceeds as described in Algorithm 1. The procedure is guaranteed to converge to a *partial optimum* Gorski et al. (2007), since the original problem (3) is biconvex and convex in each argument $\mathbf{\Omega}$ and $\mathbf{W}$.

Algorithm 1: Multitask Sparse Structure Learning (MSSL) algorithm

```
Data: {X_k, y_k}_{k=1}^m.                          // training data for all tasks
Input: λ0, λ1, λ2 > 0.   // penalty parameters chosen by cross-validation
Result: W, Ω.                                      // estimated parameters
begin
    /* Ω^0 is initialized with identity matrix and                      */
    /* W^0 with random numbers in [-0.5,0.5].                           */
    Initialize Ω^0 and W^0
    t = 1
    repeat
        W^(t+1) = argmin_W f_Ω(t)(W)                // optimize W with Ω fixed
        Ω^(t+1) = argmin_Ω f_W(t+1)(Ω)              // optimize Ω with W fixed
        t = t + 1
    until stopping condition met
end
```

Update for W: The update step involving (4a) is an ℓ_1-regularized quadratic problem. Thus the problem is an ℓ_1-penalized quadratic optimization program, which we solve using established proximal gradient descent methods such as FISTA (Beck and Teboulle, 2009). The $\mathbf{W}$-step can be seen as a general case of the formulation in Subbian and Banerjee (2013) in the context of climate model combination, where in our proposal $\mathbf{\Omega}$ is any positive definite precision matrix, rather than a fixed Laplacian matrix as in Subbian and Banerjee (2013).

In the class of proximal gradient methods the cost function $h(x)$ is decomposed as $h(x) = f(x) + g(x)$, where $f(x)$ is a convex and smooth function and $g(x)$ is convex and

typically non-smooth. The accelerated proximal gradient iterates as follows

$$\begin{aligned} \mathbf{z}^{t+1} &:= \mathbf{w}_k^t + \omega^t \left(\mathbf{w}_k^t - \mathbf{w}_k^{t-1}\right) \\ \mathbf{w}_k^{t+1} &:= \mathbf{prox}_{\rho^t g}\left(\mathbf{z}^{t+1} - \rho^t \nabla f\left(\mathbf{z}^{t+1}\right)\right), \end{aligned} \tag{5}$$

where $\omega^t \in [0, 1)$ is an extrapolation parameter and ρ^t is the step size. The ω^t parameter is chosen as $\omega^t = (\eta_t - 1)/\eta_{t+1}$, with $\eta_{t+1} = (1 + \sqrt{1 + 4\eta_t^2})/2$ as done in Beck and Teboulle (2009) and ρ^t can be computed by a line search. The proximal operator associated with the ℓ_1-norm is the soft-thresholding operator

$$\mathbf{prox}_{\rho^t}(\mathbf{x})_i = (|x_i| - \rho^t)_+ \text{sign}(x_i) \tag{6}$$

The convergence rate of the algorithm is $\mathcal{O}(1/t^2)$ (Beck and Teboulle, 2009). Considering the squared loss, the gradient for the weights of the k-th task is computed as

$$\nabla f\left(\mathbf{w}_k\right) = \frac{1}{n_k}(\mathbf{X}_k^\top \mathbf{X}_k \mathbf{w}_k - \mathbf{X}_k^\top \mathbf{y}_k) + \lambda_0 \boldsymbol{\psi}_k, \tag{7}$$

where $\boldsymbol{\psi}_k$ is the k-th column of matrix $\boldsymbol{\Psi} = 2\mathbf{W}\boldsymbol{\Omega} = \frac{\partial}{\partial \mathbf{W}} \text{tr}(\mathbf{W}\boldsymbol{\Omega}\mathbf{W}^\top)$. Note that the first two terms of the gradient, which come from the loss function, are independent for each task and then can be computed in parallel.

Update for $\boldsymbol{\Omega}$: The update step for $\boldsymbol{\Omega}$ involving (4b) is known as the *sparse inverse covariance selection problem* and efficient methods have been proposed recently (Banerjee et al., 2008; Friedman et al., 2008; Boyd et al., 2011; Cai et al., 2011; Wang et al., 2013). Re-writing (4b) in terms of the sample covariance matrix $\mathbf{S}$, the minimization problem is

$$\min_{\boldsymbol{\Omega} \succ 0} \ \lambda_0 \text{tr}(\mathbf{S}\boldsymbol{\Omega}) - \log|\boldsymbol{\Omega}| + \frac{\lambda_2}{d}\|\boldsymbol{\Omega}\|_1, \tag{8}$$

where $\mathbf{S} = \frac{1}{d}\mathbf{W}^\top \mathbf{W}$. This formulation will be useful to connect to the Gaussian copula extension in the next section. As λ_2 is a user defined parameter, the factor $\frac{1}{d}$ can be incorporated into λ_2.

To solve the minimization problem (8) we use an efficient Alternating Direction Method of Multiplies (ADMM) algorithm (Boyd et al., 2011). ADMM is a strategy that is intended to blend the benefits of dual decomposition and augmented Lagrangian methods for constrained optimization. It takes the form of a *decomposition-coordination* procedure, in which the solutions to small local problems are coordinated to find a solution to a large global problem. We refer interested readers to Boyd et al. (2011) in its Section 6.5 for details on the derivation of the updates.

In ADMM, we start by forming the augmented Lagrangian function of the problem (8)

$$L_\rho(\boldsymbol{\Theta}, \mathbf{Z}, \mathbf{U}) = \lambda_0 \text{tr}(\mathbf{S}\boldsymbol{\Theta}) - \log|\boldsymbol{\Theta}| + \lambda_2\|\mathbf{Z}\|_1 + \frac{\rho}{2}\|\boldsymbol{\Theta} - \mathbf{Z} + \mathbf{U}\|_F^2 - \frac{\rho}{2}\|\mathbf{U}\|_F^2, \tag{9}$$

where $\mathbf{U}$ is the scaled dual variable. Note that the non-smooth convex function (8) is split in two functions by adding an auxiliary variable $\mathbf{Z}$, besides a linear constraint $\boldsymbol{\Theta} - \mathbf{Z} = 0$.

Given the matrix $\mathbf{S}^{(t+1)} = \frac{1}{d}(\mathbf{W}^{(t+1)})^\top \mathbf{W}^{(t+1)}$ and setting $\boldsymbol{\Theta}^0 = \boldsymbol{\Omega}^{(t)}$, $\mathbf{Z}^0 = \mathbf{0}_{m\times m}$, and $\mathbf{U}^0 = \mathbf{0}_{m\times m}$, the ADMM for the problem (8) consists of the iterations:

$$\boldsymbol{\Theta}^{l+1} = \underset{\boldsymbol{\Theta}\succ 0}{\text{argmin}} \ \ \lambda_0 \text{tr}(\mathbf{S}^{l+1}\boldsymbol{\Theta}) - \log|\boldsymbol{\Theta}| + \frac{\rho}{2}\|\boldsymbol{\Theta} - \mathbf{Z}^l + \mathbf{U}^l\|_F^2 \tag{10a}$$

$$\mathbf{Z}^{l+1} = \underset{\mathbf{Z}}{\text{argmin}} \ \ \lambda_2\|\mathbf{Z}\|_1 + \frac{\rho}{2}\|\boldsymbol{\Theta}^{l+1} - \mathbf{Z} + \mathbf{U}^l\|_F^2 \tag{10b}$$

$$\mathbf{U}^{l+1} = \mathbf{U}^l + \boldsymbol{\Theta}^{l+1} - \mathbf{Z}^{l+1}. \tag{10c}$$

The output of the ADMM is $\boldsymbol{\Omega}^{t+1} = \boldsymbol{\Theta}^L$, where L is the number of steps for convergence.

Each ADMM step can be solved efficiently. For the $\boldsymbol{\Theta}$-update, we can observe, from the first order optimality condition of (10a) and the implicit constraint $\boldsymbol{\Theta} \succ 0$, that the solution consists basically of a singular value decomposion.

The $\mathbf{Z}$-update (10b) can be computed in closed form, as follows

$$\mathbf{Z}^{l+1} = S_{\lambda_2/\rho}\Big(\boldsymbol{\Theta}^{l+1} + \mathbf{U}^l\Big), \tag{11}$$

where $S_{\lambda_2/\rho}(\cdot)$ is an element-wise soft-thresholding operator (Boyd et al., 2011). Finally, the updates for $\mathbf{U}$ in (10c) are already in closed form.

3.3.2 Log Linear Models

As described previously, our model can also be applied to classification. Let us assume that

$$p\left(y_k^i \middle| \mathbf{x}_k^i, \mathbf{w}_k\right) = \text{Be}\left(y_k^i \middle| h\left(\mathbf{w}_k^\top \mathbf{x}_k^i\right)\right),$$

where $h(\cdot)$ is the sigmoid function, and $\text{Be}(p)$ is a Bernoulli distribution. Therefore, following the same construction as in Section 3.3.1, parameters $\mathbf{W}$ and $\boldsymbol{\Omega}$ can be obtained by solving the following minimization problem:

$$\min_{\mathbf{W},\boldsymbol{\Omega}\succ 0} \sum_{k=1}^m \frac{1}{n_k} \sum_{i=1}^{n_k} \left(y_k^i \mathbf{w}_k^\top \mathbf{x}_k^i - \log(1 + e^{\mathbf{w}_k^\top \mathbf{x}_k^i})\right) + \lambda_0 \text{tr}(\mathbf{W}\boldsymbol{\Omega}\mathbf{W}^\top) - d\log|\boldsymbol{\Omega}| + \lambda_1\|\mathbf{W}\|_1 + \lambda_2\|\boldsymbol{\Omega}\|_1. \tag{12}$$

The loss function is the logistic loss, where we have considered a 2-class classification setting. In general, we can consider any generalized linear model (GLM) (Nelder and Baker, 1972), with different link functions $h(\cdot)$, and therefore different probability densities, such as Poisson, Multinomial, and Gamma, for the conditional distribution. For any such model, our framework requires the optimization of an objective function of the form

$$\min_{\mathbf{W},\boldsymbol{\Omega}\succ 0} \ \sum_{k=1}^m \mathcal{L}(\mathbf{y}_k, \mathbf{X}_k\mathbf{w}_k) + \lambda_0 \text{tr}(\mathbf{W}\boldsymbol{\Omega}\mathbf{W}^\top) - d\log|\boldsymbol{\Omega}| + \lambda_1\|\mathbf{W}\|_1 + \lambda_2\|\boldsymbol{\Omega}\|_1, \tag{13}$$

where $\mathcal{L}(\cdot)$ is a convex loss function obtained from a GLM.

Note that the objective function in (12) is similar to the one obtained for multi-task learning with linear regression in (3) in Section 3.3.1. Therefore, we use the same alternating minimization algorithm described in Section 3.3.1 to solve the problem in (12).

3.4 p-MSSL Interpretation as Using a Product of Distributions as Prior

From a probabilistic perspective, sparsity can be enforced using the so-called sparsity promoting priors, such as the Laplacian-like (double exponential) prior (Park and Casella, 2008). Accordingly, instead of exclusively assuming a multivariate Gaussian distribution as a prior for the rows of tasks parameter matrix $\mathbf{W}$, we can consider an improper prior which consists of the product of multivariate Gaussian and Laplacian distributions, of the form

$$p_{GL}\Big(\hat{\mathbf{w}}_j|\boldsymbol{\mu},\boldsymbol{\Omega},\lambda_0,\lambda_1\Big) \propto |\boldsymbol{\Omega}|^{1/2}\exp\left\{-\frac{\lambda_0}{2}(\hat{\mathbf{w}}_j-\boldsymbol{\mu})^\top\boldsymbol{\Omega}(\hat{\mathbf{w}}_j-\boldsymbol{\mu})\right\}\exp\left\{-\frac{\lambda_1}{2}\|\hat{\mathbf{w}}_j\|_1\right\}, \quad (14)$$

where we introduced the λ_0 parameter to control the strength of the Gaussian prior. By changing λ_0 and λ_1, we alter the relative effect of the two component priors in the product. Setting λ_0 to one and λ_1 to zero, we return to the exclusive Gaussian prior as in (2). Hence, p-MSSL formulation in (3) can be seen exactly (assuming sparse precision matrix in Gaussian prior) as a MAP inference of the conditional posterior distribution (with $\boldsymbol{\mu}=0$)

$$p\Big(\mathbf{W}|(\mathbf{X},\mathbf{Y}),\boldsymbol{\Omega}\Big) \propto \prod_{k=1}^{K}\prod_{i=1}^{N_k}\mathcal{N}\Big(y_k^i|\mathbf{w}_k^\top\mathbf{x}_k^i,\sigma^2\Big)\prod_{j=1}^{D}p_{GL}\Big(\hat{\mathbf{w}}_j|\boldsymbol{\Omega},\lambda_0,\lambda_1\Big). \quad (15)$$

Equivalently, the p-MSSL with GLM formulation as in (13) can be obtained by replacing the conditional Gaussian in (15) by another distribution in the exponential family.

3.5 Adding New Tasks

Suppose now that, after estimating all the tasks parameters and the precision matrix, a new task arrives and needs to be trained. This is known as the *asymmetric* MTL problem (Xue et al., 2007). Clearly, it will be computationally prohibitive in real applications to re-run the MSSL every time a new task arrives. Fortunately, MSSL can easily incorporate the new learning task into the framework using the information from the previous trained tasks.

After the arrival of the new task $\tilde{m}$, where $\tilde{m}=m+1$, the extended sample covariance matrix $\tilde{\mathbf{S}}$, computed from the parameter matrix $\mathbf{W}$, and the precision matrix $\tilde{\boldsymbol{\Omega}}$ are partitioned in the following form

$$\tilde{\boldsymbol{\Omega}}=\begin{pmatrix}\boldsymbol{\Omega}_{11} & \boldsymbol{\omega}_{12}\\ \boldsymbol{\omega}_{12}^\top & \omega_{22}\end{pmatrix} \qquad \tilde{\mathbf{S}}=\begin{pmatrix}\mathbf{S}_{11} & \mathbf{s}_{12}\\ \mathbf{s}_{12}^\top & s_{22}\end{pmatrix}$$

where $\mathbf{S}_{11}$ and $\boldsymbol{\Omega}_{11}$ are the sample covariance and precision matrix, respectively, corresponding to the previous tasks, which have already been trained and will be kept fixed during the estimation of the parameters associated with the new task.

Let $\mathbf{w}_{\tilde{m}}$ be the set of parameters associated with the new task $\tilde{m}$ and $\tilde{\mathbf{W}}=[\mathbf{W}_m\ \mathbf{w}_{\tilde{m}}]_{d\times\tilde{m}}$, where $\mathbf{W}_m$ is the matrix with the task parameters of all previous m tasks. For the learning of $\mathbf{w}_{\tilde{m}}$, we modify problem (4a) to include only those terms on which $\mathbf{w}_{\tilde{m}}$ depends

$$f_{\tilde{\boldsymbol{\Omega}}}(\mathbf{w}_{\tilde{m}};\mathbf{X}_{\tilde{m}},\mathbf{y}_{\tilde{m}},\lambda_0,\lambda_1)=\frac{1}{n_{\tilde{m}}}\sum_{i=1}^{n_{\tilde{m}}}(\mathbf{w}_{\tilde{m}}^\top\mathbf{x}_{\tilde{m}}^i-y_{\tilde{m}}^i)^2+\lambda_0\mathrm{tr}(\tilde{\mathbf{W}}\tilde{\boldsymbol{\Omega}}\tilde{\mathbf{W}}^\top)+\lambda_1\|\mathbf{w}_{\tilde{m}}\|_1, \quad (16)$$

and the same optimization methods for (4a) can be applied.

Recall that the task dependence learning problem (8) is equivalent to solving a graphical Lasso problem. Based on Banerjee et al. (2008), Friedman et al. (2008) proposed a block coordinate descent method which updates one column (and the corresponding row) of the matrix $\tilde{\boldsymbol{\Omega}}$ per iteration. They show that if $\tilde{\boldsymbol{\Omega}}$ is initialized with a positive semidefinite matrix, then the final (estimated) $\hat{\tilde{\boldsymbol{\Omega}}}$ matrix will be positive semidefinite, even if $d>m$. Setting initial values of $\boldsymbol{\omega}_{12}$ as zero and ω_{22} as one (the new task is supposed to be conditionally independent on all other previous tasks), the extended precision matrix $\tilde{\boldsymbol{\Omega}}$ is assured to be positive semidefinite. From Friedman et al. (2008), $\boldsymbol{\omega}_{12}$ and ω_{22} are obtained as:

$$\boldsymbol{\omega}_{12}=-\hat{\boldsymbol{\beta}}\theta_{22} \quad (17a)$$

$$\omega_{22}=1/(\theta_{22}-\boldsymbol{\theta}_{12}^\top\hat{\boldsymbol{\beta}}), \quad (17b)$$

where $\hat{\boldsymbol{\beta}}$ is computed from

$$\hat{\boldsymbol{\beta}}:=\arg\min_{\boldsymbol{\alpha}}\ \Big\{\frac{1}{2}\|\tilde{\boldsymbol{\Omega}}_m^{1/2}\boldsymbol{\alpha}-\tilde{\boldsymbol{\Omega}}_m^{-1/2}\mathbf{s}_{12}\|_2^2+\delta\|\boldsymbol{\alpha}\|_1\Big\}, \quad (18)$$

where $\eta>0$ and $\delta>0$ are sparsity regularization parameters; and $\boldsymbol{\theta}_{12}^\top=\tilde{\boldsymbol{\Omega}}_{11}^{-1}\hat{\boldsymbol{\beta}}$ and $\theta_{22}=s_{22}+\delta$. See Friedman et al. (2008) for further details. The problem (18) is a simple Lasso formulation for which efficient algorithms have been proposed (Beck and Teboulle, 2009; Boyd et al., 2011). Then to learn the coefficients for the new task $\tilde{m}$ and its relationship with the previous tasks, we iterate over solving (16) and (17) until convergence.

3.6 MSSL with Gaussian Copula Models

In the Gaussian graphical model associated with the problem (4b) the rows of the weight matrix $\mathbf{W}$ are assumed to be normally distributed. As such assumption may not hold in some cases, we need a more flexible model. A promising candidate is the copula model.

Copulas are class of flexible multivariate distributions that are expressed by its univariate marginals and a copula function that describes the dependence structure between the variables. Consequently, copulas decompose a multivariate distribution into its marginal distributions and the copula function connecting them. Copulas are founded on Sklar (1959) theorem which states that: *any m-variate distribution $f(V_1,...,V_m)$ with continuous marginal functions $f_1,...,f_m$ can be expressed as its copula function $C(\cdot)$ evaluated at its marginals, that is, $f(V_1,...,V_m)=C(f_1(V_1),...,f_m(V_m))$* and, conversely, *any copula function $C(\cdot)$ with marginal distributions $f_1,...,f_m$ defines a multivariate distribution.* Several copulas have been described, which typically exhibit different dependence properties. Here, we focus on the Gaussian copula that adopts a balanced combination of flexibility and interpretability that has attracted a lot of attention (Xue and Zou, 2012).

3.6.1 Gaussian Copula Distributions

The Gaussian copula $C_{\boldsymbol{\Sigma}^0}$ is the copula of an m-variate Gaussian distribution $\mathcal{N}_m(0,\ \boldsymbol{\Sigma}^0)$ with $m\times m$ positive definite correlation matrix $\boldsymbol{\Sigma}^0$

$$C(V_1,...,V_m;\boldsymbol{\Sigma}^0)=\Phi_{\boldsymbol{\Sigma}^0}\Big(\Phi^{-1}(V_1),...,\Phi^{-1}(V_m)\Big), \quad (19)$$

where Φ^{-1} is the inverse of a standard normal distribution function and $\Phi_{\mathbf{\Sigma}^0}$ is the joint distribution function of a multivariate normal distribution with mean vector zero and covariance matrix equal to the correlation matrix $\mathbf{\Sigma}^0$. Note that without loss of generality, the covariance matrix $\mathbf{\Sigma}^0$ can be viewed as a correlation matrix, as observations can be replaced by their normal-scores. Therefore, Sklar's theorem allows to construct a multivariate distribution with non-Normal marginal distributions and the Gaussian copula.

A more general formulation of the Gaussian copula is the semiparametric Gaussian copulas (Liu et al., 2009; Xue and Zou, 2012), which allows the marginals to follow any non-parametric distribution.

Definition 1 (Semiparametric Gaussian copula models) *Let $f = \{f_1, ..., f_m\}$ be a set of continuous monotone and differentiable univariate functions. An m-dimensional random variable $V = (V_1, ..., V_m)$ has a semiparametric Gaussian Copula distribution if the joint distribution of the transformed variable $f(V)$ follows a multivariate Gaussian distribution with correlation matrix $\mathbf{\Sigma}^0$, that is, $f(V) = (f_1(V_1), ..., f_m(V_m))^\top \sim \mathcal{N}_m(0, \mathbf{\Sigma}^0)$.*

From the definition we notice that the copula does not have requirements on the marginal distributions as long the monotone continuous functions $f_1, ..., f_m$ exist.

The semiparametric Gaussian copula model is completely characterized by two unknown parameters: the correlation matrix $\mathbf{\Sigma}^0$ (or its inverse, the precision matrix $\mathbf{\Omega}^0 = (\mathbf{\Sigma}^0)^{-1}$) and the marginal transformation functions $f_1, ..., f_m$. The unknown marginal distributions can be estimated by existing nonparametric methods. However, as will be seen next, when estimating the dependence parameter is the ultimate aim, one can directly estimate $\mathbf{\Omega}^0$ without explicitly computing the functions.

Let $Z = (Z_1, ..., Z_m) = (f(V_1), ..., f(V_m))$ be a set of latent variables. By the assumption of joint normality of Z, we know that $\mathbf{\Omega}^0_{ij} = 0 \iff Z_i \perp\!\!\!\perp Z_j | Z_{\setminus\{i,j\}}$. Interestingly, Liu et al. (2009) showed that $Z_i \perp\!\!\!\perp Z_j | Z_{\setminus\{i,j\}} \iff V_i \perp\!\!\!\perp V_j | V_{\setminus\{i,j\}}$, that is, variables V and Z share exactly the same conditional dependence graph. As we focus on sparse precision matrix, to estimate the parameter $\mathbf{\Omega}^0$ we can resort to the ℓ_1-penalized maximum likelihood method, the graphical Lasso problem (8).

Let $r_{1i}, ..., r_{ni}$ be the rank of the samples from variable V_i and the sample mean $\bar{r}_j = \frac{1}{n}\sum_{i=1}^n r_{ij} = \frac{n+1}{2}$. We start by reviewing the Spearman's ρ and Kendal's τ statistics:

$$\text{(Spearman's } \rho) \quad \hat{\rho}_{ij} = \frac{\sum_{t=1}^n (r_{ti} - \bar{r}_i)(r_{tj} - \bar{r}_j)}{\sqrt{\sum_{t=1}^n (r_{ti} - \bar{r}_i)^2 \cdot \sum_{t=1}^n (r_{tj} - \bar{r}_j)^2}}, \tag{20a}$$

$$\text{(Kendall's } \tau) \quad \hat{\tau}_{ij} = \frac{2}{n(n-1)} \sum_{1 \le t \le t' \le n} \text{sign}\Big((v_{ti} - v_{t'i})(v_{tj} - v_{t'j})\Big). \tag{20b}$$

We observe that Spearman's rho is computed from the ranks of the samples and Kendall's correlation is based on the concept of concordance of pairs, which in turn is also computed from the ranks r_i. Therefore, both measures are invariant to monotone transformation of the original samples and rank-based correlations such as Spearman's ρ and Kendal's τ of the observed variables V and the latent variables Z are identical. In other words, if we are only interested in estimating the precision matrix $\mathbf{\Omega}^0$, we can treat the observed variable V as the unknown variable Z, thus avoiding estimating the transformation functions $f_1, ..., f_m$.

To connect Spearman's ρ and Kendal's τ rank-based correlation to the underlying Pearson correlation in the graphical Lasso formulation (8) of the inverse covariance selection problem, for Gaussian random variables a result due to Kendall (1948) is used:

$$\hat{\mathbf{S}}^\rho_{ij} = \begin{cases} 2\sin\left(\frac{\pi}{6}\hat{\rho}_{ij}\right), & i \neq j \\ 1 & , \ i = j \end{cases}, \qquad \hat{\mathbf{S}}^\tau_{ij} = \begin{cases} \sin\left(\frac{\pi}{2}\hat{\tau}_{ij}\right), & i \neq j \\ 1 & , \ i = j. \end{cases}$$

We then replace $\mathbf{S}$ in (8) by $\hat{\mathbf{S}}^\rho$ or $\hat{\mathbf{S}}^\tau$ and the same ADMM proposed in Section 3.3.1 is applied. The MSSL algorithms with Gaussian copula models are called p-MSSL$_{\text{cop}}$ and r-MSSL$_{\text{cop}}$, for the parameter and residual-based versions, respectively.

Liu et al. (2012) suggested that the SGC models can be used as a safe replacement of the popular Gaussian graphical models, even when the data are truly Gaussian. Compared with the Gaussian graphical model (8), the only additional cost of the SGC model is the computation of the $m(m-1)/2$ pairs of Spearman's ρ or Kendal's τ statistics, for which efficient algorithms have complexity $O(m \log m)$.

Other copula distributions also exist, such as the Archimedean class of copulas (McNeil and Nešlehová, 2009), which are useful to model tail dependence. Nevertheless, Gaussian copula is a compelling distribution for expressing the intricate dependency graph structure.

3.7 Residual Precision Structure

In the residual structure based MSSL, called r-MSSL, the relationship among tasks will be modeled in terms of partial correlations among the errors $\boldsymbol{\xi} = (\xi_1, \ldots, \xi_m)^\top$, instead of considering explicit dependencies between the coefficients $\mathbf{w}_1, \ldots, \mathbf{w}_m$ for the different tasks. To illustrate this idea, let us consider the regression scenario where $\mathbf{Y} = (\mathbf{y}_1, \ldots, \mathbf{y}_m)$ is a vector of desired outputs for each task, and $\mathbf{X} = (\mathbf{X}_1, \ldots, \mathbf{X}_m)^\top$ are the covariates for the m tasks. The assumed linear model can be denoted by

$$\mathbf{Y} = \mathbf{X}\mathbf{W} + \boldsymbol{\xi}, \tag{21}$$

where $\boldsymbol{\xi} = \mathbf{Y} - \mathbf{X}\mathbf{W} \sim \mathcal{N}(\mathbf{0}, \mathbf{\Sigma}^0)$. In this model, the errors are not assumed to be i.i.d., but vary jointly over the tasks following a Gaussian distribution with precision matrix $\mathbf{\Omega} = (\mathbf{\Sigma}^0)^{-1}$. Finding the dependence structure among the tasks now amounts to estimating the precision matrix $\mathbf{\Omega}$. Such models are commonly used in spatial statistics (Mardia and Marshall, 1984) in order to capture spatial autocorrelation between geographical locations. We adopt the framework in order to capture "loose coupling" between the tasks by means of a dependence in the error distribution. For example, in domains such as climate or remote sensing, there often exist noise autocorrelations over the spatial domain under consideration. Incorporating this dependence by means of the residual precision matrix is therefore more interpretable than the explicit dependence among the coefficients in $\mathbf{W}$.

Following the above definition, the multi-task learning framework can be modified to incorporate the relationship between the errors $\boldsymbol{\xi}$. We assume that the coefficient matrix $\mathbf{W}$ is fixed, but unknown. Since $\boldsymbol{\xi}$ follows a Gaussian distribution, maximizing the likelihood of the data, penalized with a sparse regularizer over $\mathbf{\Omega}$, reduces to the optimization problem

$$\min_{\mathbf{W}, \mathbf{\Omega} \succ 0} \left(\sum_{k=1}^m \frac{1}{n_k} \|\mathbf{y}_k - \mathbf{X}_k \mathbf{w}_k\|_2^2 \right) - d \log |\mathbf{\Omega}| + \lambda_0 \text{tr}\Big((\mathbf{Y} - \mathbf{X}\mathbf{W})\mathbf{\Omega}(\mathbf{Y} - \mathbf{X}\mathbf{W})^\top\Big) + \lambda_1 \|\mathbf{W}\|_1 + \lambda_2 \|\mathbf{\Omega}\|_1. \tag{22}$$

We use the alternating minimization scheme illustrated in previous sections to solve the problem in (22). Since the cost function is biconvex and convex in each of its arguments $\mathbf{W}$

and $\mathbf{\Omega}$, thus a *partial optimum* will be found (Gorski et al., 2007). Fixing $\mathbf{W}$, the problem of estimating $\mathbf{\Omega}$ is exactly the same as (8), but with the interpretation of capturing the conditional dependence among the residuals instead of the coefficients. The problem of estimating the tasks coefficients $\mathbf{W}$ will be slightly modified due to the change in the trace term, but the algorithms presented in Section 3.3.1 can still be used. Further, the model can be extended to losses other than the squared loss, used here due to the fact that $\boldsymbol{\xi}$ follows a Gaussian distribution.

Two instances of MSSL have been provided, p-MSSL and r-MSSL, along with their Gaussian copula versions, p-MSSL$_{\text{cop}}$ and r-MSSL$_{\text{cop}}$. In summary, p-MSSL and p-MSSL$_{\text{cop}}$ can be applied to both regression and classification problems. On the other hand, r-MSSL and r-MSSL$_{\text{cop}}$, can only be applied to regression problems, as the residual error of a classification problem is clearly non-Gaussian.

3.8 Complexity Analysis

The complexity of an iteration of the MSSL algorithms can be measured in terms of the complexity of its $\mathbf{W}$-step and $\mathbf{\Omega}$-step. Each iteration of the FISTA algorithm in the $\mathbf{W}$-step involves the element-wise operations, for both the $\mathbf{z}$-update and the proximal operator, which takes $\mathcal{O}(md)$ operations each. Gradient computation of the squared loss with trace penalization involves matrices multiplication which costs $\mathcal{O}(\max(mn^2d, dm^2))$ operations for dense matrix $\mathbf{W}$ and $\mathbf{\Omega}$, but can be reduced as both matrices are sparse. We are assuming that all tasks have the same number of samples n.

In an ADMM iteration, the dominating operation is clearly the SVD decomposition when solving the subproblem (10a). It costs $\mathcal{O}(m^3)$ operations. The other two steps amount to element-wise operations which costs $\mathcal{O}(m^2)$ operations. As mentioned previously, the copula-based MSSL algorithms have the additional cost of $\mathcal{O}(m\log(m))$ for computing Kendal's τ or Spearman's ρ statistics.

The memory requirements include $\mathcal{O}(md)$ for the $\mathbf{z}$ and previous weight matrix $\mathbf{W}^{(t-1)}$ in the $\mathbf{W}$-step and $\mathcal{O}(m^2)$ for the dual variable $\mathbf{U}$ and the auxiliary matrix $\mathbf{Z}$ in the ADMM for the $\mathbf{\Omega}$-step. We should mention that the complexity is evidently associated with the optimization algorithms used for solving problems 4a and 4b.

4. Experimental Results

In this section we provide experimental results to show the effectiveness of the proposed framework for both regression and classification problems.

4.1 Regression

We start with experiments on synthetic data and then move to the problem of predicting land air temperature in South and North America by the use of multi-model ensemble.

To select the penalty parameters λ_1 and λ_2 we use a stability selection procedure described in Meinshausen and Bühlmann (2010). It is a sub-sampling approach that provides a way to find stable structures and hence a principle to choose a proper amount of regularization for structure estimation. The parameter λ_0 was set to one in all experiments.

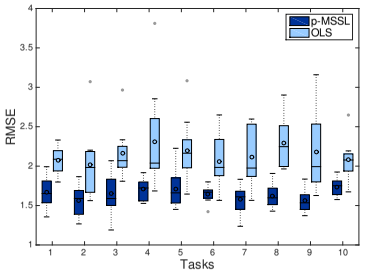

Figure 1: RMSE per task comparison between p-MSSL and Ordinary Least Square over 30 independent runs. p-MSSL gives better performance on related tasks (1-4 and 5-10).

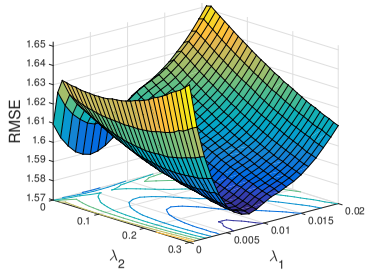

Figure 2: Average RMSE error on the test set of synthetic data for all tasks varying parameters λ_2 (controls sparsity on $\mathbf{\Omega}$) and λ_1 (controls sparsity on $\mathbf{W}$).

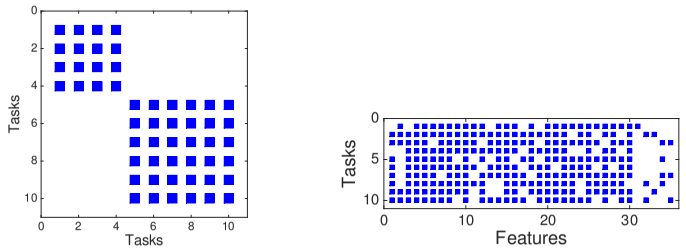
4.1.1 Synthetic Data set

We created a synthetic data set with 10 linear regression tasks of dimension $D = D_r + D_u$, where D_r and D_u are the number of relevant and non-relevant (unnecessary) variables, respectively. This is to evaluate the ability of the algorithm to discard non-relevant features. We used $D_r = 30$ and $D_u = 5$. For each task, the relevant input variables $\mathbf{X}'_k$ are generated i.i.d. from a multivariate normal distribution, $\mathbf{X}'_k \sim \mathcal{N}(\mathbf{0}, \mathbf{I}_{D_r})$. The corresponding output variable is generated as $\mathbf{y}_k = \mathbf{X}'_k\mathbf{w}_k + \boldsymbol{\xi}$ where $\xi_i \sim \mathcal{N}(0,1), \forall i = 1, ..., n_k$. Unnecessary variables are generated as $\mathbf{X}''_k \sim \mathcal{N}(\mathbf{0}, \mathbf{I}_{D_u})$. Hence, the total synthetic input data of the k-th task is formed as the concatenation of both set of variables, $\mathbf{X}_k = [\mathbf{X}'_k\ \mathbf{X}''_k]$. Note that only the relevant variables are used to produce the output variable $\mathbf{y}_k$. The parameter vectors for all tasks are chosen so that tasks 1 to 4 and 5 to 10 form two groups. Parameters for tasks 1-4 were generated as: $\mathbf{w}_k = \mathbf{w}_a \odot \mathbf{b}_k + \boldsymbol{\xi}$, where $\odot$ is the element-wise Hadamard product; and for tasks 5-10: $\mathbf{w}_k = \mathbf{w}_b \odot \mathbf{b}_k + \boldsymbol{\xi}$, where $\boldsymbol{\xi} = \mathcal{N}(\mathbf{0}, 0.2\mathbf{I}_{D_r})$. Vectors $\mathbf{w}_a$ and $\mathbf{w}_b$ are generated from $\mathcal{N}(\mathbf{0}, \mathbf{I}_{D_r})$, while $\mathbf{b}_k \sim \mathcal{U}(0,1)$ are uniformly distributed D_r-dimensional random vectors. In summary, we have two clusters of mutually related tasks. We train the p-MSSL model with 50 data instances and test it on 100 data instances.

Figure 1 shows the RMSE error for p-MSSL and for the case where Ordinary Least Squares (OLS) was applied individually for each task. As expected, sharing information among related tasks improves prediction accuracy. p-MSSL does well on related tasks 1 to 4 and 5 to 10. Figures 3a and 3b depict the sparsity pattern of the task parameters $\mathbf{W}$ and the precision matrix $\mathbf{\Omega}$ estimated by the p-MSSL algorithm. As can be seen, our model is able to recover the true dependence structure among tasks. The two clusters of tasks were clearly revealed, indicated by the filled squares, meaning non-zero entries in the precision matrix, and then, relationship among tasks. Additionally, p-MSSL was able to discard most of the irrelevant features (last five) intentionally added into the synthetic data set.

Sensitivity analysis of p-MSSL sparsity parameters λ_1 (controls sparsity on $\mathbf{W}$) and λ_2 (controls sparsity on $\mathbf{\Omega}$) on the synthetic data is presented in Figure 2. We observe that the smallest RMSE was found with a value of $\lambda_1 > 0$, which implies that a reduced set of variables is more representative than the full set, as it is indeed the case for the synthetic



(a) (b)

Figure 3: Sparsity pattern of the p-MSSL estimated parameters on the synthetic data set: (a) precision matrix $\mathbf{\Omega}$; (b) weight matrix $\mathbf{W}$. The algorithm identified the true task relationship in (a) and removed most of the non-relevant features (last five columns) in (b).

data set. The best solution is with a sparse precision matrix, as we can see in Figure 2 (smallest RMSE with $\lambda_2 > 0$). We should mention that as we increase λ_1 we encourage sparsity on $\mathbf{W}$ and, as a consequence, it becomes harder for p-MSSL to capture the true relationship among the column vectors (tasks parameters), since it learns $\mathbf{\Omega}$ from $\mathbf{W}$. This drawback is overcome in the r-MSSL algorithm, in which the precision matrix is estimated from the residuals instead of being estimated from the task parameters directly.

4.1.2 Combining Earth System Models

An Earth System Model (ESM) is a complex mathematical representation of the major climate system components (atmosphere, land surface, ocean, and sea ice), and their interactions. They are run as computer simulations, to predict climate variables such as temperature, pressure, and precipitation over multiple centuries. Several ESMs have been proposed by climate science institutes from different countries around the world.

The forecasts of future climate variables as predicted by these models have high variability, which in turn introduces uncertainty in analysis based on these predictions. One of the reasons for such uncertainty in the response of the ESMs comes from the model variability due to the fact that ESMs implements certain climatic process in different ways. Then, suitably combining outputs from multiple ESMs can greatly reduce the variability. Another equally important source of uncertainty is due to initial conditions. As ESMs are non-linear dynamic systems, changes in initial conditions can lead to different realizations of climate. In this work we focus only on the model variability. Modeling uncertainty from initial conditions is an ongoing work.

We consider the problem of combining ESM outputs for land surface temperature prediction in both South and North America, which are the world's fourth and third-largest continents, respectively, and jointly cover approximately one third of the Earth's land area. The climate is very diversified in those areas. In South America, the Amazon River basin in the north has the typical hot wet climate suitable for the growth of rain forests. The Andes Mountains, on the other hand, remain cold throughout the year. The desert regions of Chile are the driest part of South America. As for North America, the subartic climate in North

Table 1: Description of the Earth System Models used in the experiments.

Canada contrasts with the semi-arid climate in western United States and Mexico's central area. The Rocky Mountains have a large impact in land's climate, and temperature significantly varies due to topographic effects (elevation and slope) (Kinel et al., 2002). Southeast of the United States is characterized by its subtropical humid climate with relatively high temperatures and an evenly distributed precipitation throughout the year.

For the experiments we use 10 ESMs from the CMIP5 data set (Taylor et al., 2012). Details about the ESMs data sets are listed in Table 1. The global observation data for surface temperature is obtained from the Climate Research Unit (CRU) at the University of East Anglia. Both, ESM outputs and observed data are the raw temperatures (not anomalies) measured in degree Celsius. We align the data from the ESMs and CRU observations to have the same spatial and temporal resolution, using publicly available climate data operators (CDO). For all the experiments, we used a $2.5^o \times 2.5^o$ grid over latitudes and longitudes in South and North America, and monthly mean temperature data for 100 years, 1901-2000, with records starting from January 16, 1901. In other words, we have two data sets: (1) South America with 250 spatial locations; and (2) North America with 490 spatial locations over land. Data sets and code are available at: `bitbucket.org/andreric/mssl-code`. For the MTL framework, each geographical location represents a task (regression problem).

From an MTL perspective, the two data sets have different levels of difficulty. North America data set has almost twice the number of tasks as compared to South America, so that we discuss the performance of MSSL in problems with high number of tasks. It brings new challenges to MTL methods. On the other hand, South America has a more diverse climate, which makes task dependence structure more complex. Preliminary results on South America were published in Gonçalves et al. (2015) employing a high-level description format.

Baselines and Evaluation: We consider the following eight baselines for comparison and evaluation of MSSL performance for the ESM combination problem. The first two baselines (MMA and Best-ESM) are commonly used in climate sciences due to their stability and simple interpretation. We will refer to these baselines and MSSL as the "models" in the sequel and the constituent ESMs as "submodels". Four well known MTL methods were also added in the comparison. The eight baselines are:

1. **Multi-model Average (MMA)**: is the current technique used by Intergovernmental Panel on Climate Change (IPCC). It gives equal weight to all ESMs at every location.

2. **Best-ESM**: uses the predicted outputs of the best ESM in the training phase (lowest RMSE). This baseline is not a combination of submodels, but a single ESM instead.

3. **Ordinary Least Squares (OLS)**: performs an ordinary least squares regression for each geographic location, independently of the others.

4. **Spatial Smoothing Multi Model Regression (S^2M^2R)**: proposed by Subbian and Banerjee (2013) to deal with ESM outputs combination, can be seen as a special case of MSSL with the pre-defined dependence matrix $\mathbf{\Omega}$ equal to the Laplacian matrix.

5. **MTL-FEAT** (Argyriou et al., 2007): all the tasks are assumed to be related and share a low-dimensional feature subspace. The following two methods, 6 and 7, can be seen as relaxations of this assumption. We used the code provided in MALSAR package (Zhou et al., 2011a).

6. **Group-MTL** (Kang et al., 2011): groups of related tasks are assumed and tasks belonging to the same group share a common feature representation. The code was taken from the author's homepage: `http://www-scf.usc.edu/~zkang/GoupMTLCode.zip`.

7. **GO-MTL** (Kumar and Daume III, 2012): founded on a relaxation of the group idea in Kang et al. (2011) by allowing subspaces shared by each group to overlap between them. We obtained the code directly from the authors.

8. **MTRL** (Zhang and Yeung, 2010): the covariance matrix among tasks coefficients is captured by imposing a matrix-variate normal prior over the coefficient matrix $\mathbf{W}$. The non-convex MAP problem is relaxed and an alternating minimization procedure is proposed to solve the convex problem. The code was taken from author's homepage: `http://www.comp.hkbu.edu.hk/~yuzhang/codes/MTRL.zip`.

Methodology

We assume here that sub-models skills are stationary, that is, the coefficient associated with each sub-model does not change over time. To have an overall measure of the capability of the method, we considered scenarios with different amount of data available for training. For each scenario, the same number of training data (columns of Table 2) are used for all tasks, and the remaining data is used for test. Starting from one year of temperature measures (12 samples), we increase till ten years of data for training. The remained data was used as test set. For each scenario 30 independent runs are performed. Therefore, the results are reported as the average and standard deviation of RMSE for all scenarios.

Results

Table 2 report the average and standard deviation RMSE for all locations in South and North America. In South America, except for the smallest training sample (12 months) the average model (MMA) has the highest RMSE for all training sample size. Best-ESM presented a better temperature future projection compared to MMA. Generally speaking, the MTL methods performed significantly better than non-MTL ones, particularly when a small number of samples are available for training. As the spatial smoothness assumption is true for temperature, S^2M^2R obtained results comparable with those yielded by MTL methods. However, this assumption does not hold for other climate variables, such as

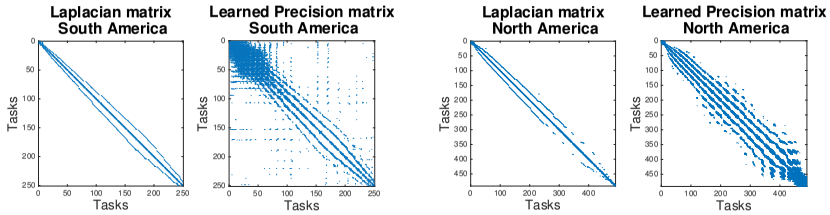

Figure 4: Laplacian matrix (on grid graph) assumed by S^2M^2R and the precision matrix learned by r-MSSL$_{\text{cop}}$ on both South and North America. r-MSSL$_{\text{cop}}$ can capture spatial relations beyond immediate neighbors. While South America is densely connected in the Amazon forest area (corresponding to top left corner) along with many spurious connections, North America is more spatially smooth.

precipitation and S^2M^2R may not succeed in those problems. On the other hand, MTL methods are general enough and in principle can be used for any climate variable. In the realm of MTL methods, all the four MSSL instantiations outperform the four other MTL contenders. It is worth observing that the two MSSL methods based on Gaussian Copula models provided smaller RMSE than the two with Gaussian models, particularly for problems with small training sample size. As Gaussian Copula models are more flexible, it is able to capture a wider range of task dependences than ordinary Gaussian models.

Similar behavior is observed in North America data set, except for the fact that MMA does much better than Best-ESM for all training sample settings. Again, all the four MSSL instantiations provided better future temperature projection. We also note that the residual-based structure dependence modeling with Gaussian Copula, r-MSSL$_{\text{cop}}$, produced slightly better results than the other three MSSL instantiations. As will be left clear in Figures 4 and 6, residual-based MSSL coherently captures related geographical locations, indicating that it can be used as an alternative to parameter-based task dependence modeling.

Figure 4 shows the precision matrix estimated by the r-MSSL$_{\text{cop}}$ algorithm and the Laplacian matrix assumed by S^2M^2R in both South and North America. Blue dots means negative entries in the matrix, while red, positive. Interpreting the entries of the matrix in terms of partial correlation, $\mathbf{\Omega}_{ij} < 0$ means positive partial correlation between $\mathbf{w}_i$ and $\mathbf{w}_j$, while $\mathbf{\Omega}_{ij} > 0$ means negative partial correlation. Not only is the precision matrix for r-MSSL$_{\text{cop}}$ able to capture the relationship among a geographical locations' immediate neighbors (as in a grid graph) but it also recovers relationships between locations that are not immediate neighbors. The plots also provide an information of the range of neighborhood influence, which can be useful in spatial statistics analysis.

The RMSE per geographical location for r-MSSL$_{\text{cop}}$ and three common approaches used in climate sciences, MMA, Best-ESM, and OLS, are shown in Figures 5. As previously mentioned, South and North America have a diverse climate and not all of the ESMs are designed to take into account and capture this scenario. Hence, averaging the model outputs, as done by MMA, reduces prediction accuracy. On the other hand r-MSSL$_{\text{cop}}$

Table 2: Mean and standard deviation over 30 independent runs for several amounts of monthly data used for training. The symbol "*" indicates statistically significant (t-test, P < 0.05) improvement when compared to the best contender. MSSL with Gaussian copula provides better prediction accuracy.

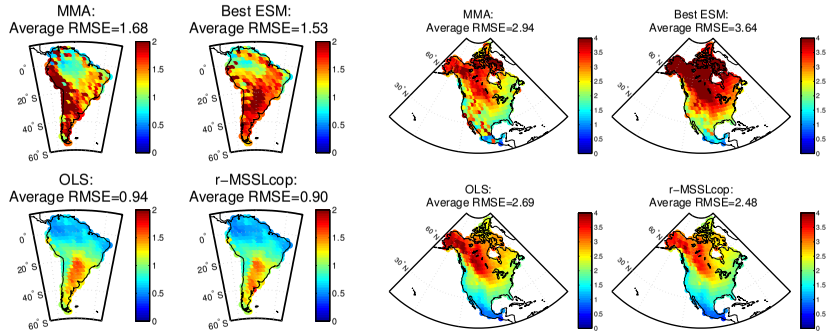

Figure 5: [Best viewed in color] RMSE per location for r-MSSL$_{\text{cop}}$ and three common methods in climate sciences, computed using 60 monthly temperature measures for training. It shows that r-MSSL$_{\text{cop}}$ substantially reduces RMSE, particularly in Northern South America and Northwestern North America.

performs better because it learns a more appropriate weight combination on the model outputs and incorporates spatial smoothing by learning the task relationship.

Figure 6 presents the dependence structure estimated by r-MSSL$_{\text{cop}}$ for South and North America data sets. Blue connections indicate dependent regions.

We immediately observe that locations in the northwest part of South America are densely connected. This area has a typical tropical climate and comprises the Amazon rainforest which is known for having hot and humid climate throughout the year with low temperature variation (Ramos, 2014). The cold climates which occur in the southernmost parts of Argentina and Chile are clearly highlighted. Such areas have low temperatures throughout the year, but there are large daily variations (Ramos, 2014). An important observation can be made about South America west cost, ranging from central Chile to Venezuela passing through Peru which has one of the driest deserts in the world. These areas are located to the left side of Andes Mountains and are known for arid climate. The average model is not performing well on this region compared to r-MSSL$_{\text{cop}}$. We can see the long lines connecting these coastal regions, which probably explains the improvement in terms of RMSE reduction achieved by r-MSSL$_{\text{cop}}$. The algorithm uses information from related locations to enhance its performance on these areas.

In the structure learned for North America, a densely connected area is also observed in the northeast part of North America, particularly the regions of Nunavut and North Quebec, which are characterized by their polar climate, with extremely severe winters and cold summers. Long connections between Alaska and regions from Northwestern Canada, which share similar climate patterns, can also be seen. Again, the r-MSSL$_{\text{cop}}$ algorithm had no access to the latitude and longitude of the locations during the training phase. r-MSSL$_{\text{cop}}$ also identified related regions, in terms of model skills, in the Gulf of Mexico. We hypothesize that no more connections were seen due to the high variability in air and sea

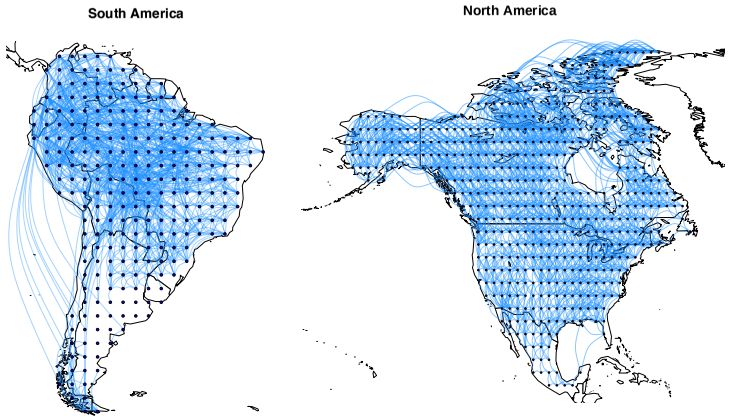

Figure 6: Relationships between geographical locations estimated by the r-MSSL$_{\text{cop}}$ algorithm using 120 months of data for training. The blue lines indicate that connected locations are conditionally dependent on each other. As expected, temperature is very spatially smooth, as we can see by the high neighborhood connectivity, although some long range connections are also observed.

surface temperature in these area (Twilley, 2001), that in turn has a strong impact on Gulf of Mexico costal regions.

4.1.3 MSSL sensitivity to initial values of $\mathbf{W}$

As discussed earlier, the MSSL algorithms may be susceptible to the choice of initial values of the parameters $\mathbf{\Omega}$ and $\mathbf{W}$, as the optimization function (3) is not jointly convex on $\mathbf{\Omega}$ and $\mathbf{W}$. In this section we analyze the impact of different parameter initializations on the RMSE and the number of non-zero entries in the estimated $\mathbf{\Omega}$ and $\mathbf{W}$ parameters.

Table 3 shows the mean and standard deviation over 10 independent runs with random initialization of $\mathbf{W}$ in the interval [-0.5,0.5] for the South America data set. For the $\mathbf{\Omega}$ matrix we started with an identity matrix, as it is reasonable to assume tasks independence beforehand. The results showed that the solutions are not sensitive to initial values of $\mathbf{W}$. The largest variation was found in the number of non-zero entries in the $\mathbf{\Omega}$ matrix for North America data set. However, it corresponds to 0.07% of the average number of non-zero entries and was not enough to significantly alter the RMSE of the solutions. Figure 7 shows the convergence of p-MSSL for several random initializations of $\mathbf{W}$. We note that in all runs the cost function decreases smoothly and similarly to each other, showing the stability of the method.

	Synt.	South America	North America
RMSE	1.14 (2e-6)	0.86 (0)	2.46 (1.6e-4)
# nz $\mathbf{W}$	345 (0)	2341 (0.32)	4758 (2.87)
# nz $\mathbf{\Omega}$	55(0)	4954 (0.63)	73520 (504.4)

Table 3: p-MSSL sensitivity to initial values of $\mathbf{W}$ in terms of RMSE, mean and standard deviation, and number of non-zero entries in $\mathbf{W}$ and $\mathbf{\Omega}$.

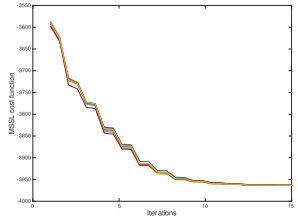

Figure 7: Convergence behavior of p-MSSL for distinct initializations of the weight matrix $\mathbf{W}$.

4.2 Classification

We test the performance of the p-MSSL on five data sets (six problems) described below. Recall that r-MSSL can not be applied for classification problems, once it relies on a Gaussian assumption of the residuals. This is currently the subject of an ongoing work. All data sets were standardized, then all features have zero mean and standard deviation one.

- **Landmine Detection:** Data from 19 landmine fields were collected, which have distinct characteristics. Each object in a given data set is represented by a 9-dimensional feature vector and the corresponding binary label (1 for landmine and 0 for clutter) (Xue et al., 2007). The feature vectors are extracted from radar images, concatenating four moment-based features, three correlation-based features, one energy ratio feature and one spatial variance feature. The goal is to classify between mine or clutter.

- **Spam Detection:** E-mail spam data set from ECML 2006 discovery challenge. It consists of two problems: Problem A with e-mails from 3 different users (2500 e-mails per user); and Problem B with e-mails from 15 distinct users (400 e-mails per user). We performed feature selection to get the 500 most informative variables using the Laplacian score feature selection algorithm (He et al., 2006). The goal is to classify between spam vs. ham. For both problems, we create different tasks for different users. This data set can be found at `http://www.ecmlpkdd2006.org/challenge.html`.

- **MNIST** data set consists of 28×28-size images of hand-written digits from 0 through 9. We transform this multiclass classification problem by applying the all-versus-all decomposition, leading to 45 binary classification problems (tasks). When a new test sample arrives, a voting scheme is performed among the classifiers. The number of samples for each classification problem is about 15000. This data set can be found at `http://yann.lecun.com/exdb/mnist/`.

- **Letter:** The handwritten letter data set consists of eight tasks, with each one being a binary classification of two letters: a/g, a/o, c/e, f/t, g/y, h/n, m/n and i/j. The input for each data point consists of 128 features representing the pixel values of the handwritten letter. The number of data points for each task varies from 3057 to 7931. This data set can be found at `http://ai.stanford.edu/~btaskar/ocr/`.

- **Yale-faces**: The face recognition data set contains 165 grayscale images with dimension 32x32 pixels of 15 individuals. Similar to MNIST, the problem is also transformed by all-versus-all decomposition, totalling 105 binary classification problems (tasks). For each task only 22 samples are available. This data set can be found at `http://vision.ucsd.edu/content/yale-face-database`.

Baseline algorithms: Four baseline algorithms were considered in the experiments and the regularization parameters for all algorithms were selected using cross-validation from the set $\{0.01, 0.1, 1, 10, 100\}$. The algorithms are:

1. **Logistic Regression (LR)**: learns separate logistic regression models for each task.
2. **MTL-FEAT** (Argyriou et al., 2007): employs an $\ell_{2,1}$-norm regularization term to capture the task relationship from multiple related tasks constraining all models to share a common set of features.
3. **CMTL** (Zhou et al., 2011b): incorporates a regularization term to induce clustering between tasks and then share information only to tasks belonging to the same cluster.
4. **Low rank MTL** (Abernethy et al., 2006): assumes that related tasks share a low dimensional subspace and applies a trace regularization norm to capture that relation.

Results: Table 4 shows the results of each algorithm for all data sets. It was obtained over 10 independent runs using a holdout cross-validation (2/3 for training and 1/3 for test). The performance of each run is measured by the average of the performance of all tasks.

MTL-FEAT	6.16 (0.31)	3.33 (0.43)	7.03 (0.67)	2.61 (0.08)	11.66 (0.29)	7.15 (1.60)
Trace	5.75 (0.28)	2.65 (0.32)	5.40 (0.54)	2.27 (0.09)	5.90 (0.21)	7.49 (1.72)
p-MSSL	**5.68** (**0.37**)	1.90* (0.27)	6.55 (0.68)	1.96* (0.08)	5.34* (0.19)	9.58 (0.91)
p-MSSL$_{\text{cop}}$	**5.68** (**0.35**)	**1.77*** (**0.29**)	**5.32** (**0.45**)	**1.95*** (**0.08**)	**5.29*** (**0.19**)	**5.28*** (**0.45**)

Table 4: Average classification error rates and standard deviation over 10 independent runs for all methods and data sets considered. Bold values indicate the best value and the symbol "*" means significant statistical improvement of the MSSL algorithm in relation to the contenders determined by t-test with $\mathrm{P} < 0.05$.

For all data sets p-MSSL$_{\text{cop}}$ presented statistically significant better results than the contenders for the most of the data sets. The three MTL methods presume the structure of the matrix $\mathbf{W}$, which may not be a proper choice for some problems. Such disagreement in the structure of the problem might explains the poor results in some data sets.

Focusing the analysis on p-MSSL and the copula version, p-MSSL$_{\text{cop}}$, their results are relatively similar for most of the data set, except for *Yale-faces*, where the difference is quite large. The two algorithms differ only in the way the inverse covariance matrix $\mathbf{\Omega}$ is computed. One hyphotesis for p-MSSL$_{\text{cop}}$ superiority on *Yale-faces* data set is that it may have captured hidden important dependencies among tasks, as the Copula Gaussian model can capture a wider class of dependencies than traditional Gaussian graphical models.

For the *Yale-faces* data set, which contains the smallest number of data available for training, all the MTL algorithms obtained considerable improvement compared to the traditional single task learning approach (LR), corroborating with the assertion that MTL approaches are particularly suitable for problems with few data samples.

5. Conclusion

We proposed a framework for multi-task structure learning. Our framework simultaneously learns the tasks and their relationship, with the task dependences defined as edges in an undirected graphical model. The formulation allows the direct extension of the graphical model to the recently developed semiparametric Gaussian copula models. As such model does not rely on the Gaussian assumption of task parameters, it gives more flexibility to capture hidden task conditional independence, thus helping to improve prediction accuracy. The problem formulation leads to a bi-convex optimization problem which can be efficiently solved using alternating minimization. We show that the proposed framework is general enough to be specialized to Gaussian models and generalized linear models. Extensive experiments on benchmark and climate data sets for regression tasks and real-world data sets for classification tasks illustrate that structure learning not only improves multi-task prediction performance, but also captures relevant qualitative behaviors among tasks.

Acknowledgments

We thank the AE and the three anonymous reviewers for their valuable comments and suggestions. The research was supported by NSF grants IIS-1029711, IIS-0916750, IIS-0953274, CNS-1314560, IIS-1422557, CCF-1451986, IIS-1447566, and by NASA grant NNX12AQ39A. Abstract

Apache Spark is a popular open-source platform for large-scale data processing that is well-suited for iterative machine learning tasks. In this paper we present MLlib, Spark's open-source distributed machine learning library. MLlib provides efficient functionality for a wide range of learning settings and includes several underlying statistical, optimization, and linear algebra primitives. Shipped with Spark, MLlib supports several languages and provides a high-level API that leverages Spark's rich ecosystem to simplify the development of end-to-end machine learning pipelines. MLlib has experienced a rapid growth due to its vibrant open-source community of over 140 contributors, and includes extensive documentation to support further growth and to let users quickly get up to speed.

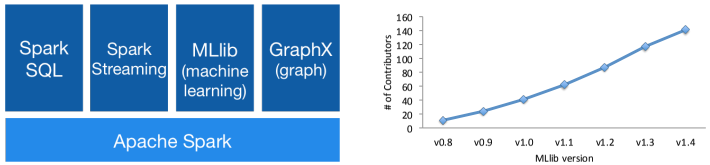
Keywords: scalable machine learning, distributed algorithms, apache spark

1. Introduction

Modern datasets are rapidly growing in size and complexity, and there is a pressing need to develop solutions to harness this wealth of data using statistical methods. Several 'next generation' data flow engines that generalize MapReduce (Dean and Ghemawat, 2004) have been developed for large-scale data processing, and building machine learning functionality on these engines is a problem of great interest. In particular, Apache Spark (Zaharia et al., 2012) has emerged as a widely used open-source engine. Spark is a fault-tolerant and general-purpose cluster computing system providing APIs in Java, Scala, Python, and R, along with an optimized engine that supports general execution graphs. Moreover, Spark is efficient at iterative computations and is thus well-suited for the development of large-scale machine learning applications.

In this work we present MLlib, Spark's distributed machine learning library, and the largest such library. The library targets large-scale learning settings that benefit from data-parallelism or model-parallelism to store and operate on data or models. MLlib consists of fast and scalable implementations of standard learning algorithms for common learning settings including classification, regression, collaborative filtering, clustering, and dimensionality reduction. It also provides a variety of underlying statistics, linear algebra, and optimization primitives. Written in Scala and using native (`C++` based) linear algebra libraries on each node, MLlib includes Java, Scala, and Python APIs, and is released as part of the Spark project under the Apache 2.0 license.

MLlib's tight integration with Spark results in several benefits. First, since Spark is designed with iterative computation in mind, it enables the development of efficient implementations of large-scale machine learning algorithms since they are typically iterative in nature. Improvements in low-level components of Spark often translate into performance gains in MLlib, without any direct changes to the library itself. Second, Spark's vibrant open-source community has led to rapid growth and adoption of MLlib, including contributions from over 140 people. Third, MLlib is one of several high-level libraries built on top of Spark, as shown in Figure 1(a). As part of Spark's rich ecosystem, and in part due to MLlib's `spark.ml` API for pipeline development, MLlib provides developers with a wide range of tools to simplify the development of machine learning pipelines in practice.



(a) (b)

Figure 1: (a) Apache Spark ecosytem. (b). Growth in MLlib contributors.

2. History and Growth

Spark was started in the UC Berkeley AMPLab and open-sourced in 2010. Spark is designed for efficient iterative computation and starting with early releases has been packaged with example machine learning algorithms. However, it lacked a suite of robust and scalable learning algorithms until the creation of MLlib. Development of MLlib began in 2012 as part of the MLbase project (Kraska et al., 2013), and MLlib was open-sourced in September 2013. From its inception, MLlib has been packaged with Spark, with the initial release of MLlib included in the Spark 0.8 release. As an Apache project, Spark (and consequently MLlib) is open-sourced under the Apache 2.0 license. Moreover, as of Spark version 1.0, Spark and MLlib are on a 3-month release cycle.

The original version of MLlib was developed at UC Berkeley by 11 contributors, and provided a limited set of standard machine learning methods. Since this original release, MLlib has experienced dramatic growth in terms of contributors. Less than two years later, as of the Spark 1.4 release, MLlib has over 140 contributors from over 50 organizations. Figure 1(b) demonstrates the growth in MLlib's open source community as a function of release version. The strength of this open-source community has spurred the development of a wide range of additional functionality.

3. Core Features

In this section we highlight the core features of MLlib; we refer the reader to the MLlib user guide for additional details (MLlib, 2015).

Supported Methods and Utilities. MLlib provides fast, distributed implementations of common learning algorithms, including (but not limited to): various linear models, naive Bayes, and ensembles of decision trees for classification and regression problems; alternating least squares with explicit and implicit feedback for collaborative filtering; and k-means clustering and principal component analysis for clustering and dimensionality reduction. The library also provides a number of low-level primitives and basic utilities for convex optimization, distributed linear algebra, statistical analysis, and feature extraction, and supports various I/O formats, including native support for LIBSVM format, data integration via Spark SQL (Armbrust et al., 2015), as well as PMML (Guazzelli et al., 2009) and MLlib's internal format for model export.

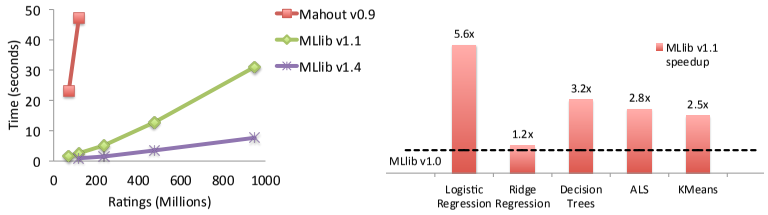
Algorithmic Optimizations. MLlib includes many optimizations to support efficient distributed learning and prediction. We highlight a few cases here. The ALS algorithm for

recommendation makes careful use of blocking to reduce JVM garbage collection overhead and to leverage higher-level linear algebra operations. Decision trees use many ideas from the PLANET project (Panda et al., 2009), such as data-dependent feature discretization to reduce communication costs, and tree ensembles parallelize learning both within trees and across trees. Generalized linear models are learned via optimization algorithms which parallelize gradient computation, using fast `C++`-based linear algebra libraries for worker computations. Many algorithms benefit from efficient communication primitives; in particular tree-structured aggregation prevents the driver from being a bottleneck, and Spark broadcast quickly distributes large models to workers.

Pipeline API. Practical machine learning pipelines often involve a sequence of data preprocessing, feature extraction, model fitting, and validation stages. Most machine learning libraries do not provide native support for the diverse set of functionality required for pipeline construction. Especially when dealing with large-scale datasets, the process of cobbling together an end-to-end pipeline is both labor-intensive and expensive in terms of network overhead. Leveraging Spark's rich ecosystem and inspired by previous work (Pedregosa et al., 2011; Buitinck et al., 2013; Sparks et al., 2013, 2015), MLlib includes a package aimed to address these concerns. This package, called `spark.ml`, simplifies the development and tuning of multi-stage learning pipelines by providing a uniform set of high-level APIs (Meng et al., 2015), including APIs that enable users to swap out a standard learning approach in place of their own specialized algorithms.

Spark Integration. MLlib benefits from the various components within the Spark ecosystem. At the lowest level, Spark core provides a general execution engine with over 80 operators for transforming data, e.g., for data cleaning and featurization. MLlib also leverages the other high-level libraries packaged with Spark. Spark SQL provides data integration functionality, SQL and structured data processing which can simplify data cleaning and preprocessing, and also supports the DataFrame abstraction which is fundamental to the `spark.ml` package. GraphX (Gonzalez et al., 2014) supports large-scale graph processing and provides a powerful API for implementing learning algorithms that can naturally be viewed as large, sparse graph problems, e.g., LDA (Blei et al., 2003; Bradley, 2015). Additionally, Spark Streaming (Zaharia et al., 2013) allows users to process live data streams and thus enables the development of online learning algorithms, as in Freeman (2015). Moreover, performance improvements in Spark core and these high-level libraries lead to corresponding improvements in MLlib.

Documentation, Community, and Dependencies. The MLlib user guide provides extensive documentation; it describes all supported methods and utilities and includes several code examples along with API docs for all supported languages (MLlib, 2015). The user guide also lists MLlib's code dependencies, which as of version 1.4 are the following open-source libraries: Breeze, netlib-java, and (in Python) NumPy (Breeze, 2015; Halliday, 2015; Braun, 2015; NumPy, 2015). Moreover, as part of the Spark ecosystem, MLlib has active community mailing lists, frequent meetup events, and JIRA issue tracking to facilitate open-source contributions (Community, 2015). To further encourage community contributions, Spark Packages (Packages, 2015) provides a community package index to track the growing number of open source packages and libraries that work with Spark. To date, several of the contributed packages consist of machine learning functionality that builds on MLlib.



(a) (b)

Figure 2: (a) Benchmarking results for ALS. (b) MLlib speedup between versions.

Finally, a massive open online course has been created to describe the core algorithmic concepts used to develop the distributed implementations within MLlib (Talwalkar, 2015).

4. Performance and Scalability

In this section we briefly demonstrate the speed, scalability, and continued improvements in MLlib over time. We first look at scalability by considering ALS, a commonly used collaborative filtering approach. For this benchmark, we worked with scaled copies of the Amazon Reviews dataset (McAuley and Leskovec, 2013), where we duplicated user information as necessary to increase the size of the data. We ran 5 iterations of MLlib's ALS for various scaled copies of the dataset, running on a 16 node EC2 cluster with m3.2xlarge instances using MLlib versions 1.1 and 1.4. For comparison purposes, we ran the same experiment using Apache Mahout version 0.9 (Mahout, 2014), which runs on Hadoop MapReduce. Benchmarking results, presented in Figure 2(a), demonstrate that MapReduce's scheduling overhead and lack of support for iterative computation substantially slow down its performance on moderately sized datasets. In contrast, MLlib exhibits excellent performance and scalability, and in fact can scale to much larger problems.

Next, we compare MLlib versions 1.0 and 1.1 to evaluate improvement over time. We measure the performance of common machine learning methods in MLlib, with all experiments performed on EC2 using m3.2xlarge instances with 16 worker nodes and synthetic datasets from the spark-perf package (`https://github.com/databricks/spark-perf`). The results are presented in Figure 2(b), and show a 3× speedup on average across all algorithms. These results are due to specific algorithmic improvements (as in the case of ALS and decision trees) as well as to general improvements to communication protocols in Spark and MLlib in version 1.1 (Yavuz and Meng, 2014).

5. Conclusion

MLlib is in active development, and the following link provides details on how to contribute: `https://cwiki.apache.org/confluence/display/SPARK/Contributing+to+Spark`. Moreover, we would like to acknowledge all MLlib contributors. The list of Spark contributors can be found at `https://github.com/apache/spark`, and the `git log` command can be used to identify MLlib contributors.

Abstract

On-line portfolio selection is a practical financial engineering problem, which aims to sequentially allocate capital among a set of assets in order to maximize long-term return. In recent years, a variety of machine learning algorithms have been proposed to address this challenging problem, but no comprehensive open-source toolbox has been released for various reasons. This article presents the first open-source toolbox for "On-Line Portfolio Selection" (OLPS), which implements a collection of classical and state-of-the-art strategies powered by machine learning algorithms. We hope that OLPS can facilitate the development of new learning methods and enable the performance benchmarking and comparisons of different strategies. OLPS is an open-source project released under Apache License (version 2.0), which is available at `https://github.com/OLPS/` or `http://OLPS.stevenhoi.org/`.

Keywords: On-line portfolio selection, online learning, trading system, simulation.

1. Introduction

In recent years, machine learning has been applied to various applications in finance (Györfi et al., 2012), including On-line Portfolio Selection, which aims to sequentially allocate capital among a set of assets, such that the investment return can be maximized in the long run (Kelly, 1956). It has attracted increasing attention from both academia and industry, and several machine learning algorithms have been proposed (Li and Hoi, 2014), including traditional algorithms (Cover, 1991; Helmbold et al., 1998; Agarwal et al., 2006; Borodin et al., 2004; Györfi et al., 2006, 2008), and recent state-of-the-art online learning algorithms (Li et al., 2011, 2012, 2013, 2015). Unlike other application domains in machine learning where various open-source packages are available, very few open-source toolkits[1] exist for on-line portfolio selection, primarily due to the confidential nature of financial industry. Consequently, it is difficult for researchers to evaluate new algorithms for comprehensive comparisons with existing ones.

This article introduces an open-source toolkit named "On-Line Portfolio Selection" (OLPS), which consists of a family of classical and state-of-the-art on-line portfolio selection algorithms. To the best of our knowledge, OLPS is the first comprehensive open-source package for this problem, which includes various strategies, and a set of preprocessing, postprocessing and visualization tools in an integrated platform. The open-source nature of OLPS makes it easy for a third party to develop new algorithms, and facilitates the comparisons with many built-in algorithms on real datasets.

1. Some repositories contain public datasets, such as `http://www.cs.technion.ac.il/~rani/portfolios` and `http://www.szit.bme.hu/~oti/portfolio`, but no public code was released.

2. Overview and Implementation

OLPS implements a framework for backtesting various algorithms for on-line portfolio selection in both Matlab and Octave (the GUI is only available in Matlab) under Windows, Linux, and Mac OS. Figure 1 gives an overview of the OLPS toolkit with three main modules: (i) data preprocessing: it loads a dataset and initializes the backtesting environments, e.g., preparing log file handles, etc; (ii) algorithms: it calls selected algorithms, and simulates the trading process based on the chosen data from the first module; and (iii) post-processing: it analyzes statistical significance of the results from the second module, e.g., some risk-adjusted returns.

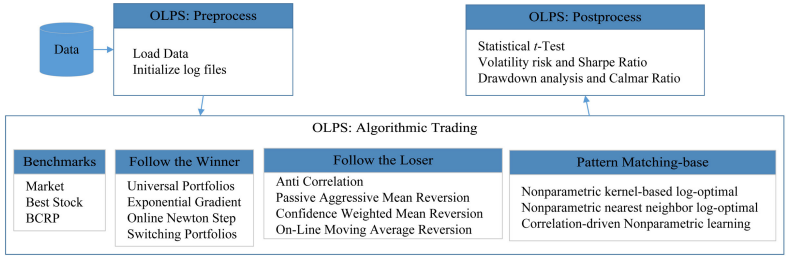

Figure 1: Structure of the OLPS toolbox.

2.1 Pre-processing

Datasets	Markets	Regions	Time Frames	# Periods	# Assets	File Names (.mat)
NYSE (O)	Stock	US	07/03/1962 - 12/31/1962	5651	36	`nyse-o`
NYSE (N)	Stock	US	01/01/1985 - 06/30/2010	6431	23	`nyse-n`
TSE	Stock	CA	01/04/1994 - 12/31/1998	1259	88	`tse`
SP500	Stock	US	01/02/1998 - 01/31/2003	1276	25	`sp500`
MSCI	Index	Global	04/01/2006 - 03/31/2010	1043	24	`msci`
DJIA	Stock	US	01/14/2001 - 01/14/2003	507	30	`djia`

Table 1: Summary of the six datasets from real markets.

The main functionality of this step is to initialize the trading environment. OLPS supports all types of datasets that Matlab/Octave accepts, and all existing datasets are in MAT-file. A typical dataset contains an $n \times m$ matrix of price relatives, where n denotes the number of trading periods, and m refers to the number of assets. It can be further adapted to incorporate real market data feeds, such that the toolkit can handle real time data and conduct paper trading or real trading[2]. Table 1

2. For example, Interactive Brokers (`http://www.interactivebrokers.com`) provides free APIs. Paper and real trading both require to implement order submission, while back test does not.

summarizes several representative public datasets included in the toolbox[3]. Users are free to collect up-to-date data from various sources, such as the CRSP database, Quandl.com, etc.

2.2 Algorithmic Trading

This step conducts simulation based on historical market data. Table 2 summarizes the families of algorithms implemented in the OLPS toolbox. In our framework, implementing a new strategy generally requires four files, i.e., an entry file, a run file, a kernel file and an expert file. The entry file extracts parameters and call the corresponding run file. The run file simulates a whole trading process, and calls its kernel file to construct a portfolio for each period, which is used for rebalancing. The kernel file outputs a portfolio, while it facilitates the development of meta algorithms, which combine multiple experts' portfolios outputted by expert files that output one portfolio. In case of only one expert, the kernel file is not necessary and directly enters the expert file. Developing new strategies involves writing a kernel file, which aims to output portfolio.

	T0	`t0.m`	Borodin et al. (2000)

Table 2: Summary of the implemented algorithms.

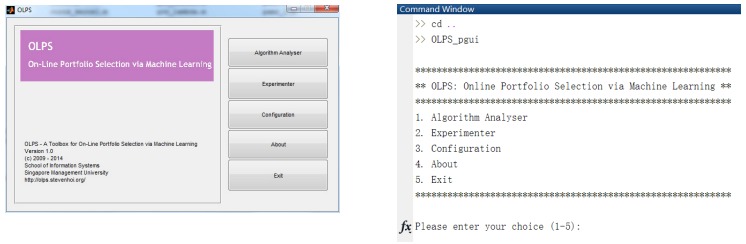
2.3 Post-processing

After the algorithmic trading simulation, the last step is to post-process the portfolio's return series for performance analysis by summarizing the following performance metrics:

- Cumulative Return: the most widely used performance metric in related studies;
- Volatility and Sharpe Ratio: measures volatility risk and related risk-adjusted return;
- Drawdown and Calmar Ratio: measures downside risk and risk-adjusted return;
- *T*-test statistics (Grinold and Kahn, 1999): tests if a strategy's return is significantly different from the market.

3. More datasets and their details, including the components, can be found at the project website.

3. Usage



(a) GUI mode (b) Pseudo GUI mode

Figure 2: GUI mode and Pseudo GUI mode.

We provide three interfaces to run simulations in the toolbox. As shown in Figure 2, the toolbox has two types of Graphical User Interfaces (GUIs), including a GUI implemented in Matlab and a Pseudo GUI in command line, which is thus available in both Matlab and Octave. The other interface is a Command Line Interface (CLI), and is also available in both Matlab and Octave.

While a GUI is straightforward to use, in the CLI mode, we generalize a *manager* function so as to control the running of all algorithms.Suppose we are going to simulate the PAMR algorithm on the NYSE (O) dataset. The commands can be listed as follows:

```
1: >> opts.quiet_mode=1; opts.display_interval=500; opts.progress=0;
2: >> opts.analyze_mode=1; opts.log_mode=1; opts.mat_mode=1;
3: >> manager('pamr', 'nyse-o', {0.5, 0}, opts);
```

Line 1 and 2 set some variables that are used to control the display and file storage. Line 3 calls the manager function to execute the "pamr" strategy on the "nyse-o" dataset with the parameters equaling "{0.5, 0}". During the simulation, the toolbox will output information periodically. After the simulation, the algorithm will analyze the returns and output the cumulative return, risk adjusted returns and statistical test statistics. Corresponding running details and results will be automatically stored in the Log folder.

4. Summary

This article presented OLPS — an open-source On-Line Portfolio Selection toolbox to facilitate the related research in machine learning and computational finance. This is the first open-source project in the area, which not only facilitates researchers to develop new strategies, but also allows them to easily benchmark their performance with existing strategies. Besides, the toolbox supports a large collection of classical and state-of-the-art on-line portfolio selection strategies. The toolbox offers a user-friendly GUI in Matlab, a Pseudo GUI and a CLI mode in both Octave and Matlab. We hope that the open-source nature of the software would encourage researchers to extend the toolkit and share their algorithms through the OLPS platform.

Abstract

Max-convolution is an important problem closely resembling standard convolution; as such, max-convolution occurs frequently across many fields. Here we extend the method with fastest known worst-case runtime, which can be applied to nonnegative vectors by numerically approximating the Chebyshev norm $\|\cdot\|_\infty$, and use this approach to derive two numerically stable methods based on the idea of computing p-norms via fast convolution: The first method proposed, with runtime in $O(k\log(k)\log(\log(k)))$ (which is less than $18k\log(k)$ for any vectors that can be practically realized), uses the p-norm as a direct approximation of the Chebyshev norm. The second approach proposed, with runtime in $O(k\log(k))$ (although in practice both perform similarly), uses a novel null space projection method, which extracts information from a sequence of p-norms to estimate the maximum value in the vector (this is equivalent to querying a small number of moments from a distribution of bounded support in order to estimate the maximum). The p-norm approaches are compared to one another and are shown to compute an approximation of the Viterbi path in a hidden Markov model where the transition matrix is a Toeplitz matrix; the runtime of approximating the Viterbi path is thus reduced from $O(nk^2)$ steps to $O(nk\log(k))$ steps in practice, and is demonstrated by inferring the U.S. unemployment rate from the S&P 500 stock index.

Keywords: Bayesian inference, *maximum a posteriori*, fast Fourier transform, max-convolution, p-norm, L_p space, hidden Markov model, null space projection, polynomial matrix

1. Introduction

Max-convolution occurs frequently in signal processing and Bayesian inference: it is used in image analysis (Ritter and Wilson, 2000), in network calculus (Boyer et al., 2013), in economic equilibrium analysis (Sun and Yang, 2002), and in a probabilistic variant of combinatoric generating functions, wherein information on a sum of values into their most probable constituent parts (*e.g.*, identifying proteins from mass spectrometry (Serang et al., 2010; Serang, 2014)). Max-convolution operates on the semi-ring $(max, \times)$, meaning that it behaves identically to a standard convolution, except it employs a max operation in lieu of the + operation in standard convolution (max-convolution is also equivalent to min-convolution, also called infimal convolution, which operates on the tropical semi-ring $(min, +)$). Due to the importance and ubiquity of max-convolution, substantial effort has been invested into highly optimized implementations (*e.g.*, implementations of the quadratic method on GPUs; Zach et al., 2008).

Max-convolution can be defined using vectors (or discrete random variables, whose probability mass functions are analogous to nonnegative vectors) with the relationship $M = L + R$. Given the target sum $M = m$, the max-convolution finds the largest value $L[\ell] \times R[r]$ for which $m = \ell + r$.

$$\begin{aligned} M[m] &= \max_{\ell, r:\, m=\ell+r} L[\ell]R[r] \\ &= \max_{\ell} L[\ell]R[m-\ell] \\ &= (L \ *_{\max} \ R)[m] \end{aligned}$$

where $*_{\max}$ denotes the max-convolution operator. In probabilistic terms, this is equivalent to finding the highest probability of the joint events $\Pr(L = \ell, R = r)$ that would produce each possible value of the sum $M = L + R$ (note that in the probabilistic version, the vector M would subsequently need to be normalized so that its sum is 1).

Although applications of max-convolution are numerous, only a small number of methods exist for solving it (Serang, 2015). These methods fall into two main categories, each with their own drawbacks: The first category consists of very accurate methods that are have worst-case runtimes either quadratic (Bussieck et al., 1994) or slightly more efficient than quadratic in the worst-case (Bremner et al., 2006). Conversely, the second type of method computes a numerical approximation to the desired result, but in $O(k\log_2(k))$ steps; however, no bound for the numerical accuracy of this method has been derived (Serang, 2015).

While the two approaches from the first category of methods for solving max-convolution do so by either using complicated sorting routines or by creating a bijection to an optimization problem, the numerical approach solves max-convolution by showing an equivalence between $*_{\max}$ and the process of first generating a vector $u^{(m)}$ for each index m of the result (where $u^{(m)}[\ell] = L[\ell]R[m-\ell]$ for all in-bounds indices) and subsequently computing the maximum $M[m] = \max_\ell u^{(m)}[\ell]$. When L and R are nonnegative, the maximization over the vector $u^{(m)}$ can be computed exactly via the Chebyshev norm

$$\begin{aligned} M[m] &= \max_{\ell} u^{(m)}[\ell] \\ &= \lim_{p\to\infty} \|u^{(m)}\|_p \end{aligned}$$

but requires $O(k^2)$ steps (where k is the length of vectors L and R). However, once a fixed p^*-norm is chosen, the approximation corresponding to that p^* can be computed by expanding the p^*-norm to yield

$$\begin{aligned} \lim_{p\to\infty} \|u^{(m)}\|_p &= \lim_{p\to\infty} \left(\sum_\ell \left(u^{(m)}[\ell] \right)^p \right)^{\frac{1}{p}} \\ &\approx \left(\sum_\ell \left(u^{(m)}[\ell] \right)^{p^*} \right)^{\frac{1}{p^*}} \\ &= \left(\sum_\ell L[\ell]^{p^*} \ R[m-\ell]^{p^*} \right)^{\frac{1}{p^*}} \\ &= \left(\sum_\ell \left(L^{p^*} \right)[\ell] \ \left(R^{p^*} \right)[m-\ell] \right)^{\frac{1}{p^*}} \\ &= \left(L^{p^*} \ * \ R^{p^*} \right)^{\frac{1}{p^*}}[m] \end{aligned}$$

where $L^{p^*} = \langle (L[0])^{p^*}, (L[1])^{p^*}, \ldots, (L[k-1])^{p^*} \rangle$ and $*$ denotes standard convolution. The standard convolution can be done via fast Fourier transform (FFT) in $O(k \log_2(k))$ steps, which is substantially more efficient than the $O(k^2)$ required by the naive method (**Algorithm 1**).

To date, the numerical method has demonstrated the best speed-accuracy trade-off on Bayesian inference tasks, and can be generalized to multiple dimensions (*i.e.*, tensors). In particular, they have been used with probabilistic convolution trees (Serang, 2014) to efficiently compute the most probable values of discrete random variables $X_0, X_1, \ldots X_{n-1}$ for which the sum is known $X_0 + X_1 + \ldots X_{n-1} = y$ (Serang, 2014). The one-dimensional variant of this problem (*i.e.*, where each X_i is a one-dimensional vector) solves the probabilistic generalization of the subset sum problem, while the two-dimensional variant (*i.e.*, where each X_i is a one-dimensional matrix) solves the generalization of the knapsack problem (note that these problems are not NP-hard in this specific case, because we assume an evenly-spaced discretization of the possible values of the random variables).

However, despite the practical performance that has been demonstrated by the numerical method, only cursory analysis has been performed to formalize the influence of the value of p^* on the accuracy of the result and to bound the error of the p^*-norm approximation. Optimizing the choice of p^* is non-trivial: Larger values of p^* more closely resemble a true maximization under the p^*-norm, but result in underflow (note that in **Algorithm 1**, the maximum values of both L and R can be divided out and then multiplied back in after max-convolution so that overflow is not an issue). Conversely, smaller values of p^* suffer less underflow, but compute a norm with less resemblance to maximization. Here we perform an in-depth analysis of the influence of p^* on the accuracy of numerical max-convolution, and from that analysis we construct a modified piecewise algorithm, on which we demonstrate bounds on the worst-case absolute error. This modified algorithm, which runs in $O(k \log(k) \log(\log(k)))$ steps, is demonstrated using a hidden Markov model describing the relationship between U.S. unemployment and the S&P 500 stock index.

We then extend the modified algorithm and introduce a second modified algorithm, which not only uses a single p-norm as a means of approximating the Chebyshev norm, but instead uses a sequence of p-norms and assembles them using a projection as a means to approximate the Chebyshev norm. Using numerical simulations as evidence, we make a conjecture regarding the relative error of the null space projection method. In practice, this null space projection algorithm is shown to have similar runtime and higher accuracy when compared with the piecewise algorithm.

2. Methods

We begin by outlining and comparing three numerical methods for max-convolution. By analyzing the benefits and deficits of each of these methods, we create improved variants. All of these methods will make use of the basic numerical max-convolution idea summarized in the introduction, and as such we first declare a method for computing the numerical max-convolution estimate for a given p^* as `numericalMaxConvolveGivenPStar` (**Algorithm 1**).

Algorithm 1 Numerical max-convolution given a fixed p^*, a numerical method to estimate the max-convolution of two PMFs or nonnegative vectors. The parameters are two nonnegative vectors L' and R' (both scaled so that they have maximal element 1) and the numerical value p^* used for computation. The return value is a numerical estimate of the max-convolution $L' *_{\max} R'$.

procedure numericalMaxConvolveGivenPStar(L', R', p^*)
  $\forall \ell,\ vL[\ell] \leftarrow L[\ell]^{p^*}$
  $\forall r,\ vR[r] \leftarrow R[r]^{p^*}$
  $vM \leftarrow vL * vR$ ▷ Standard FFT convolution is used here
  $\forall m,\ M'[m] \leftarrow vM[m]^{\frac{1}{p^*}}$
  return M'
end procedure

2.1 Fixed Low-Value $p^* = 8$ Method:

The effects of underflow will be minimal (as it is not very far from standard FFT convolution, an operation with high numerical stability), but it can still be imprecise due to numerical "bleed-in" (*i.e.*, error due to contributions from non-maximal terms for a given $u^{(m)}$ because the p^*-norm is not identical to the Chebyshev norm). Overall, this will perform well on indices where the exact value of the result is small, but perform poorly when the exact value of the result is large.

2.2 Fixed High-Value $p^* = 64$ Method:

As noted above, will offer the converse pros and cons compared to using a low p^*: numerical artifacts due to bleed-in will be smaller (thus achieving greater performance on indices where the exact values of the result are larger), but underflow may be significant (and therefore, indices where the exact results of the max-convolution are small will be inaccurate).

2.3 Higher-Order Piecewise Method:

The higher-order piecewise method formalizes the empirical cutoff values found in Serang 2015; previously, numerical stability boundaries were found for each p^* by computing both the exact max-convolution (via the naive $O(k^2)$ method) and via the numerical method using the ascribed value of p^*, and finding the value below which the numerical values experienced a high increase in relative absolute error.

Those previously observed empirical numerical stability boundaries can be formalized by using the fact that the employed `numpy` implementation of FFT convolution has high accuracy on indices where the result has a value $\geq \tau$ relative to the maximum value; therefore, if the arguments L and R are both normalized so that each has a maximum value of 1, the fast max-convolution approximation is numerically stable for any index m where the result of the FFT convolution, *i.e.*, $vM[m]$, is $\geq \tau$. The `numpy` documentation defines a conservative numeric tolerance for underflow $\tau = 10^{-12}$, which is a conservative estimate of the numerical stability boundary demonstrated in **Figure 1** (those boundary points occur very close to the true machine precision $\epsilon \approx 10^{-15}$).

Because Cooley-Tukey implementations of FFT-based convolution (*e.g.*, the `numpy` implementation) are widely applied to large problems with extremely small error, we will make a simplification and assume that, when constraining the FFT result to reach a value higher than machine epsilon (+ tolerance threshold), the error from the FFT is negligible in comparison to the error introduced by the p^*-norm approximation. This is firstly because the only source of numerical error during FFT (assuming an FFT implementation with numerically precise twiddle factors) on vectors in $[0, 1]^k$ will be the result of underflow from repeated addition and subtraction (neglecting the non-influencing multiplication with twiddle factors, which each have magnitude 1). The numerically imprecise routines are thus limited to $(x + y) - x$; when $x >> y$ (*i.e.*, $\frac{y}{x} < \epsilon \approx 10^{-15}$, the machine precision), then $(x + y) - x$ will return 0 instead of y. To recover at least one bit of the significand, the intermediate results of the FFT must surpass machine precision ϵ (since the worst case addition initially happens with the maximum $x = 1.0$).

The maximum sum of any values from a list of k such elements can never exceed k; for this reason, a conservative estimate of the numerical tolerance (with regard to underflow) of a DFT (discrete Fourier transform) will be the smallest value of y for which $\frac{y}{k} > \epsilon$; thus, $y > \epsilon k$. This yields a conservative estimate of the minimum value in one index at the result of an DFT convolution: when the result at some index m is $> \epsilon k$, then the result should be numerically stable. We emphasize on the very conservative nature of this estimate for a minimum stable value that is derived under the assumption of a simple, naive implementation of a DFT. In general however, FFT (a special case of DFT algorithms) implementations (especially well-proven implementations of the Cooley-Tukey algorithm) tend to follow error bounds logarithmic in k (Schatzman, 1996), due to their divide-and-conquer strategies, which perform fewer arithmetic operations. In practice, even for longer vectors

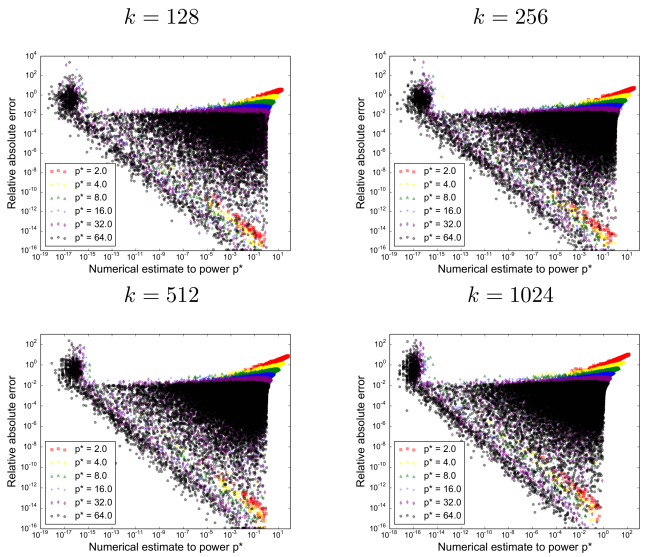

Figure 1: **Empirical estimate of τ to construct a piecewise method.** For each $k \in \{128, 256, 512, 1024\}$, 32 replicate max-convolutions (on vectors filled with uniform values) are performed. Error from two sources can be seen: error due to underflow is depicted in the sharp left mode, whereas error due to imperfect approximation, where $\|\cdot\|_{p^*} > \|\cdot\|_\infty$ can be seen in the gradual mode on the right. Error due to p^*-norm approximation is significantly smaller when p^* is larger (thereby flattening the right mode), but larger p^* values are more susceptible to underflow, pushing more indices into the left mode. Regardless of the value of k, error due to underflow occurs when $(\|\cdot\|_{p^*})^{p^*}$ goes below $\approx 10^{-15}$; this is approximately the numerical tolerance for τ described by the `numpy` documentation. Therefore, at each index m we can construct a piecewise method that uses the largest value of p^* for which the FFT convolution result is not close to the machine precision (*i.e.*, $(\|u^{(m)}\|_{p^*})^{p^*} \geq \tau$ for some $\tau > 10^{-15}$).

(*e.g.*, $k = 1024$ as shown in **Figure 1**), it is empirically demonstrated that the influence of the length on the τ threshold is negligible. By using a numerical tolerance $\tau = 10^{-12}$, we ensure that the vast majority of numerical error for the numerical max-convolution algorithm is due to the p^*-norm approximation (*i.e.*, employing $\|u^{(m)}\|_{p^*}$ instead of $\|u^{(m)}\|_\infty$) and not due to the long-used and numerically performant FFT result. Furthermore, in practice the mean squared error due to FFT will be much smaller than the conservative worst-case outlined here, because it is difficult for the largest intermediate summed value (in this case x) to be consistently large when many such very small values (in this case y) are encountered in the same list. Although τ could be chosen specifically for a problem of size k, note that this simple derivation is very conservative and thus it would be better to use a tighter bound for choosing τ. Regardless, for an FFT implementation that isn't as performant (*e.g.*, because it uses `float` types instead of `double`), increasing τ slightly would suffice.

Therefore, from this point forward we consider that the dominant cause of error to come from the max-convolution approximation. Using larger p^* values will provide a closer approximation; however, using a larger value of p^* may also drive values to zero (because the inputs L and R will be normalized within **Algorithm 1** so that the maximum of each is 1 when convolved via FFT), limiting the applicability of large p^* to indices m for which $vM[m] \geq \tau$.

Through this lens, the choice of p^* can be characterized by two opposing sources of error: higher p^* values better approximate $\|u^{(m)}\|_{p^*}$ but will be numerically unstable for many indices; lower p^* values provide worse approximations of $\|u^{(m)}\|_{p^*}$ but will be numerically unstable for only few indices. These opposing sources of error pose a natural method for improving the accuracy of this max-convolution approximation. By considering a small collection of p^* values, we can compute the full numerical estimate (at all indices) with each p^* using **Algorithm 1**; computing the full result at a given p^* is $\in O(k \log_2(k))$, so doing so on some small number c of p^* values considered, then the overall runtime will be $\in O(ck \log_2(k))$. Then, a final estimate is computed at each index by using the largest p^* that is stable (with respect to underflow) at that index. Choosing the largest p^* (of those that are stable with respect to underflow) corresponds to minimizing the bleed-in error, because the larger p^* becomes, the more muted the non-maximal terms in the norm become (and thus the closer the p^*-norm becomes to the true maximum).

Here we introduce this piecewise method and compare it to the simpler low-value $p^* = 8$ and high-value $p^* = 64$ methods and analyze the worst-case error of the piecewise method.

3. Results

This section derives theoretical error bounds as well as a practical comparison on an example for the standard piecewise method. Furthermore the development of an improvement with affine scaling is shown. Eventually, an evaluation of the latter is performed on a larger problem. Therefore we applied our technique to compute the Viterbi path for a hidden Markov model (HMM) to assess runtime and the level of error propagation.

3.1 Error and Runtime Analysis of the Piecewise Method

We first analyze the error for a particular underflow-stable p^* and then use that to generalize to the piecewise method, which seeks to use the highest underflow-stable p^*.

3.1.1 Error Analysis for a Fixed Underflow-Stable p^*:

We first scale L and R into L' and R' respectively, where the maximum elements of both L' and R' are 1; the absolute error can be found by unscaling the absolute error of the scaled problem:

$$|exact(L, R)[m] - numeric(L', R')[m]| = \max_\ell L[\ell] \max_r R[r] \, |exact(L', R')[m] - numeric(L', R')[m]|.$$

Algorithm 2 Piecewise numerical max-convolution , a numerical method to estimate the max-convolution of nonnegative vectors (revised to reduce bleed-in error). This procedure uses a p^* close to the largest possible stable value at each result index. The return value is a numerical estimate of the max-convolution $L *_{\max} R$. The runtime is in $O(k \log_2(k) \log_2(p^*_{\max}))$.

procedure numericalMaxConvolvePiecewise(L, R, $p^*_{\max}$)
  $\ell_{\max} \leftarrow \text{argmax}_\ell\, L[\ell]$
  $r_{\max} \leftarrow \text{argmax}_r\, R[r]$
  $L' \leftarrow \frac{L}{L[\ell_{\max}]}$
  $R' \leftarrow \frac{R}{R[r_{\max}]}$ ▷ Scale to a proportional problem on L', R'
  $allPStar \leftarrow [2^0, 2^1, \ldots, 2^{\lceil \log_2(p^*_{\max}) \rceil}]$
  for $i \in \{0, 1, \ldots len(allPStar)\}$ **do**
    $resForAllPStar[i] \leftarrow$ `fftNonnegMaxConvolveGivenPStar`(L', R', $allPStar[i]$)
  end for
  for $m \in \{0, 1, \ldots len(L) + len(R) - 1\}$ **do**
    $maxStablePStarIndex[m] \leftarrow \max\{i : (resForAllPStar[i][m])^{\text{allPStar}[i]} \geq \tau)\}$
  end for
  for $m \in \{0, 1, \ldots len(L) + len(R) - 1\}$ **do**
    $i \leftarrow maxStablePStarIndex[m]$
    $result[m] \leftarrow resForAllPStar[i][m]$
  end for
  return $L[\ell_{\max}] \times R[r_{\max}] \times result$ ▷ Undo previous scaling
end procedure

We first derive an error bound for the scaled problem on L', R' (any mention of a vector $u^{(m)}$ refers to the scaled problem), and then reverse the scaling to demonstrate the error bound on the original problem on L, R.

For any particular "underflow-stable" p^* (*i.e.*, any value of p^* for which $\left(\|u^{(m)}\|_{p^*}\right)^{p^*} \geq \tau$), the absolute error for the numerical method for fast max-convolution can be bound fairly easily by factoring out the maximum element of $u^{(m)}$ (this maximum element is equivalent to the Chebyshev norm) from the p^*-norm:

$$\begin{aligned}
& |exact(L', R')[m] - numeric(L', R')[m]| \\
= \;& |\|u^{(m)}\|_{p^*} - \|u^{(m)}\|_\infty| \\
= \;& \|u^{(m)}\|_{p^*} - \|u^{(m)}\|_\infty \\
= \;& \|u^{(m)}\|_\infty \left(\frac{\|u^{(m)}\|_{p^*}}{\|u^{(m)}\|_\infty} - 1 \right) \\
= \;& \|u^{(m)}\|_\infty \left(\| \frac{u^{(m)}}{\|u^{(m)}\|_\infty} \|_{p^*} - 1 \right) \\
= \;& \|u^{(m)}\|_\infty \left(\|v^{(m)}\|_{p^*} - 1 \right)
\end{aligned}$$

where $v^{(m)}$ is a nonnegative vector of the same length as $u^{(m)}$ (this length is denoted k_m) where $v^{(m)}$ contains one element equal to 1 (because the maximum element of $u^{(m)}$ must, by definition, be contained within $u^{(m)}$) and where no element of $v^{(m)}$ is greater than 1 (also provided by the definition of the maximum). These observations result in the equation

$$\begin{aligned}
\|v^{(m)}\|_{p^*} &\leq \|(1, 1, \ldots 1)\|_{p^*} \\
&= \left(\sum_i^{k_m} 1^{p^*} \right)^{\frac{1}{p^*}} \\
&= k_m{}^{\frac{1}{p^*}}.
\end{aligned}$$

Thus, since $\|v^{(m)}\|_{p^*} \geq 1$, the error is bounded:

$$\begin{aligned}
& |exact(L', R')[m] - numeric(L', R')[m]| \\
= \;& \|u^{(m)}\|_\infty \left(\|v^{(m)}\|_{p^*} - 1 \right) \\
\leq \;& \|v^{(m)}\|_{p^*} - 1 \\
\leq \;& k_m^{\frac{1}{p^*}} - 1,
\end{aligned}$$

because $\forall m,\ \|u^{(m)}\|_\infty \leq 1$ for a scaled problem on L', R'.

3.1.2 Error Analysis of Piecewise Method

However, the bounds derived above are only applicable for p^* where $\|u^{(m)}\|_{p^*}^{p^*} \geq \tau$. The piecewise method is slightly more complicated, and can be partitioned into two cases: In the first case, the top contour is used (*i.e.*, when $p^*_{\max}$ is underflow-stable). Conversely, in the second case, a middle contour is used (*i.e.*, when $p^*_{\max}$ is not underflow-stable). In this context, in general a contour comprises of a set of indices m with the same maximum stable p^*.

In the first case, when we use the top contour $p^* = p^*_{\max}$, we know that $p^*_{\max}$ must be underflow-stable, and thus we can reuse the bound given an underflow-stable p^*.

In the second case, because the p^* used is $< p^*_{\max}$, it follows that the next higher contour (using $2p^*$) must not be underflow-stable (because the highest underflow-stable p^* is used and because the p^* are searched in log-space). The bound derived above that demonstrated

$$\|u^{(m)}\|_{p^*} \leq \|u^{(m)}\|_\infty k_m^{\frac{1}{p^*}}$$

can be combined with the property that $\|\cdot\|_{p^*} \geq \|\cdot\|_\infty$ for any $p^* \geq 1$ to show that

$$\|u^{(m)}\|_\infty \in \left[\frac{\|u^{(m)}\|_{p^*}}{k_m^{\frac{1}{p^*}}}, \|u^{(m)}\|_{p^*} \right].$$

Thus the absolute error can also be shown to be bounded using the fact that we are in a middle contour:

$$\begin{aligned}
&= \|u^{(m)}\|_{p^*} - \|u^{(m)}\|_\infty \\
&= \|u^{(m)}\|_{p^*} \left(1 - \frac{\|u^{(m)}\|_\infty}{\|u^{(m)}\|_{p^*}} \right) \\
&\leq \|u^{(m)}\|_{p^*} \left(1 - k_m^{\frac{-1}{p^*}} \right) \\
&< \tau^{\frac{1}{2p^*}} \left(1 - k_m^{\frac{-1}{p^*}} \right).
\end{aligned}$$

The absolute error from middle contours will be quite small when $p^* = 1$ is the maximum underflow-stable value of p^* at index m, because $\tau^{\frac{1}{2p^*}}$, the first factor in the error bound, will become $\sqrt{\tau} \approx 10^{-6}$, and $1 - k_m^{\frac{-1}{p^*}} < 1$ (qualitatively, this indicates that a small p^* is only used when the result is very close to zero, leaving little room for absolute error). Likewise, when a very large p^* is used, then $1 - k_m^{\frac{-1}{p^*}}$ becomes very small, while $\tau^{\frac{1}{2p^*}} < 1$ (qualitatively, this indicates that when a large p^* is used, the $\|\cdot\|_{p^*} \approx \|\cdot\|_\infty$, and thus there is little absolute error). Thus for the extreme values of p^*, middle contours will produce fairly small absolute errors. The unique mode p^*_{mode} can be found by finding the value that solves

$$\frac{\partial}{\partial p^*_{mode}} \left(\tau^{\frac{1}{2p^*_{mode}}} \left(1 - k_m^{\frac{-1}{p^*_{mode}}} \right) \right) = 0,$$

which yields

$$p^*_{mode} = \frac{\log_2(k_m)}{\log_2(-\frac{2\log_2(k) - \log_2(\tau)}{\log_2(\tau)})}.$$

An appropriate choice of $p^*_{\max}$ should be $> p^*_{mode}$ so that the error for any contour (both middle contours and the top contour) is smaller than the error achieved at p^*_{mode}, allowing us to use a single bound for both. Choosing $p^*_{\max} = p^*_{mode}$ would guarantee that all contours are no worse than the middle-contour error at p^*_{mode}; however, using $p^*_{\max} = p^*_{mode}$ is still quite liberal, because it would mean that for indices in the highest contour (there must be a nonempty set of such indices, because the scaling on L' and R' guarantees that the maximum index will have an exact value of 1, meaning that the approximation endures no underflow and is underflow-stable for every p^*), a better error *could* be achieved by increasing $p^*_{\max}$. For this reason, we choose $p^*_{\max}$ so that the top-contour error produced at $p^*_{\max}$ is not substantially larger than all errors produced for p^* before the mode (*i.e.*, for $p^* < p^*_{mode}$).

Choosing any value of $p^*_{\max} > p^*_{mode}$ guarantees the worst-case absolute error bound derived here; however, increasing $p^*_{\max}$ further over p^*_{mode} may possibly improve the mean squared error in practice (because it is possible that many indices in the result would be numerically stable with p^* values substantially larger than p^*_{mode}). However, increasing $p^*_{\max} >> p^*_{mode}$ will produce diminishing returns and generally benefit only a very small number of indices in the result, which have exact values very close to 1. In order to balance these two aims (increasing $p^*_{\max}$ enough over p^*_{mode} but not excessively so), we make a qualitative assumption that a non-trivial number of indices require us to use a p^* below p^*_{mode}; therefore, increasing $p^*_{\max}$ to produce an error significantly smaller than the lowest worst-case error for contours below the mode (*i.e.*, $p^* < p^*_{mode}$) will increase the runtime without significantly decreasing the mean squared error (which will become dominated by the errors from indices that use $p^* < p^*_{mode}$). The lowest worst-case error contour below the mode is $p^* = 1$ (because the absolute error function is unimodal, and thus must be increasing until p^*_{mode} and decreasing afterward); therefore, we heuristically specify that $p^*_{\max}$ should produce a worst-case error on a similar order of magnitude to the worst-case error produced with $p^* = 1$. In practice, specifying the errors at $p^*_{\max}$ and $p^* = 1$ should be equal is very conservative (it produces very large estimates of $p^*_{\max}$, which sometimes benefit only one or two indices in the result); for this reason, we heuristically choose that the worst-case error at $p^*_{\max}$ should be no worse than square root of the worst case error at $p^* = 1$ (this makes the choice of $p^*_{\max}$ less conservative because the errors at $p^* = 1$ are very close to zero, and thus their square root is larger). The square root was chosen because it produced, for the applications described in this paper, the smallest value of $p^*_{\max}$ for which the mean squared error was significantly lower than using $p^*_{\max} = p^*_{mode}$ (the lowest value of $p^*_{\max}$ guaranteed to produce the absolute error bound). This heuristic does satisfy the worst-case bound outlined here (because, again, $p^*_{\max} > p^*_{mode}$), but it could be substantially improved if an expected distribution of magnitudes in the result vector were known ahead of time: prior knowledge

regarding the number of points stable at each p^* considered would enable a well-motivated choice of $p^*_{\max}$ that truly optimizes the expected mean squared error.

From this heuristic choice of $p^*_{\max}$, solving

$$\sqrt{\sqrt{\tau}\left(1 - \frac{1}{k}\right)} = k^{\frac{1}{p^*_{\max}}} - 1$$

(with the square root of the worst-case at $p^* = 1$ on the left and the worst-case error at $p^*_{\max}$ on the right) yields

$$\begin{aligned} p^*_{\max} &= \frac{\log_2(k)}{\log_2(1 + \sqrt{\sqrt{\tau}\left(1 - \frac{1}{k}\right)})} \\ &\approx \frac{\log_2(k)}{\log_2(1 + \sqrt{\sqrt{\tau}})} \end{aligned}$$

for any non-trivial problem (*i.e.*, when $k >> 1$), and thus

$$p^*_{\max} \approx \log_{1+\tau^{\frac{1}{4}}}(k),$$

indicating that the absolute error at the top contour will be roughly equal to the fourth root of τ.

3.1.3 Worst-case Absolute Error

By setting $p^*_{\max}$ in this manner, we guarantee that the absolute error at any index of any unscaled problem on L, R is less than

$$\max_\ell L[\ell] \ \max_r R[r] \ \tau^{\frac{1}{2p^*_{mode}}} \left(1 - k_m^{\frac{-1}{p^*_{mode}}}\right)$$

where p^*_{mode} is defined above. The full formula for the middle-contour error at this value of p^*_{mode} does not simplify and is therefore quite large; for this reason, it is not reported here, but this gives a numeric bound of the worst case middle-contour error that is bound in terms of the variable k (and with no other free variables).

3.1.4 Runtime Analysis

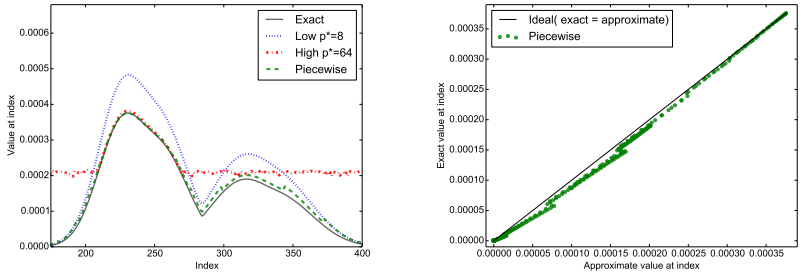
The piecewise method clearly performs $\log_2(p^*_{\max})$ FFTs (each requiring $O(k\log_2(k))$ steps); therefore, since $p^*_{\max}$ is chosen to be $\log_{1+\tau^{\frac{1}{4}}}(k)$ (to achieve the desired error bound), the total runtime is thus

$$O(k\log_2(k)\log_2(\log_{1+\tau^{\frac{1}{4}}}(k)).$$

For any practically sized problem, the $\log_2(\log_{1+\tau^{\frac{1}{4}}}(k))$ factor is essentially a constant; even when k is chosen to be the number of particles in the observable universe ($\approx 2^{270}$; Eddington, 1923), the $\log_2(\log_{1+\tau^{\frac{1}{4}}}(k))$ is ≈ 18, meaning that for any problem of practical size, the full piecewise method is no more expensive than computing between 1 and 18 FFTs.

3.2 Comparison of Low-Value $p^* = 8$, High-value $p^* = 64$, and Piecewise Method

We first use an example max-convolution problem to compare the results from the low-value $p^* = 8$, the high-value $p^* = 64$ and piecewise methods. At every index, these various approximation results are compared to the exact values, as computed by the naive quadratic method (**Figure 2a**).



(a) (b)

Figure 2: **The accuracy of numerical fast max-convolution methods. (a)** Different approximations for a sample max-convolution problem. The low-p^* method is underflow-stable, but overestimates the result. The high-p^* method is accurate when underflow-stable, but experiences underflow at many indices. The piecewise method stitches together approximations from different p^* to maintain underflow-stability. **(b)** Exact vs. piecewise approximation at various indices of the same problem. A clear banding pattern is observed with one tight, elliptical cluster for each contour. The slope of the clusters deviates more for the contours using lower p^* values.

3.3 Improved Affine Piecewise Method

Figure 2b depicts a scatter plot of the exact result vs. the piecewise approximation at every index (using the same problem from **Figure 2a**). It shows a clear banding pattern: the exact and approximate results are clearly correlated, but each contour (*i.e.*, each collection of indices that use a specific p^*) has a different average slope between the exact and approximate values, with higher p^* contours showing a generally larger slope and smaller p^* contours showing greater spread and lower slopes. This intuitively makes sense, because the bounds on $\|u^{(m)}\|_\infty \in [\|u^{(m)}\|_{p^*} k_m^{\frac{-1}{p^*}}, \|u^{(m)}\|_{p^*}]$ derived above constrain the scatter plot points inside a quadrilateral envelope (**Figure 3**).

The correlations within each contour can be exploited to correct biases that emerge for smaller p^* values. In order to do this, $\|u^{(m)}\|_\infty$ must be computed for at least two points m_1 and m_2 within the contour, so that a mapping $\|u^{(m)}\|_{p^*} \approx f(\|u^{(m)}\|_{p^*}) = a\|u^{(m)}\|_{p^*} + b$ can be constructed. Fortunately, a single $\|u^{(m)}\|_\infty$ can be computed exactly in $O(k)$ (by actually computing a single $u^{(m)}$ and computing its max, which is equivalent to computing a single index result via the naive quadratic method). As long as the exact value $\|u^{(m)}\|_\infty$ is computed for only a small number of indices, the order of the runtime will not change (each contour already costs $O(k \log_2(k))$, so adding a small number of $O(k)$ steps for each contour will not change the asymptotic runtime).

If the two indices chosen are

$$m_{\min} = \operatorname*{argmin}_{m \in contour(p^*)} \|u^{(m)}\|_{p^*}$$

and

$$m_{\max} = \operatorname*{argmax}_{m \in contour(p^*)} \|u^{(m)}\|_{p^*},$$

then we are guaranteed that the affine function f can be written as a convex combination of the exact values at those extreme points (using barycentric coordinates):

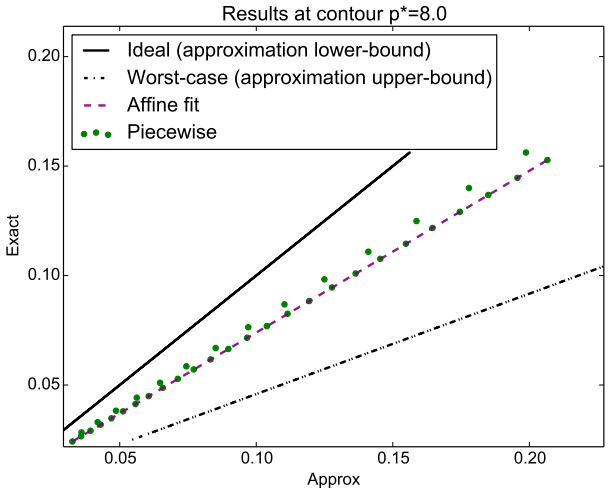


Figure 3: **A single contour from the piecewise approximation.** The cluster of points (one point for each index in the previous figure) is bounded by the exact value (ideal approximation) and the approximation upper-bound for $p^* = 8$ (worst-case approximation). The points are well described by an affine function fit using the left-most and right-most points.

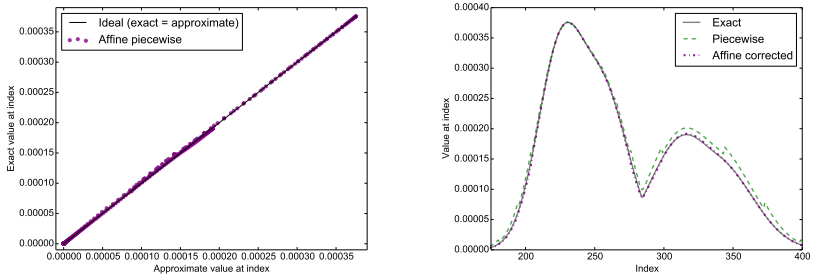

(a)

(b)

Figure 4: **Piecewise method with affine contour fitting.** The approximate values at each index of the max-convolution problem are almost identical to the exact result at the same index.

Algorithm 3 Improved affine piecewise numerical max-convolution, a numerical method to estimate the max-convolution nonnegative vectors (further revised to reduce numerical error). This procedure uses a p^* close to the largest possible stable value at each result index. The return value is a numerical estimate of the max-convolution $L *_{\max} R$. The runtime is in $O(k \log_2(k) \log_2(p^*_{\max}))$.

procedure NUMERICALMAXCONVOLVEPIECEWISEAFFINE(L, R, $p^*_{\max}$)
  $\ell_{\max} \leftarrow \operatorname{argmax}_\ell L[\ell]$
  $r_{\max} \leftarrow \operatorname{argmax}_r R[r]$
  $L' \leftarrow \frac{L}{L[\ell_{\max}]}$
  $R' \leftarrow \frac{R}{R[r_{\max}]}$ ▷ Scale to a proportional problem on L', R'
  $allPStar \leftarrow [2^0, 2^1, \ldots, 2^{\lceil \log_2(p^*_{\max}) \rceil}]$
  for $i \in \{0, 1, \ldots len(allPStar)\}$ **do**
    $resForAllPStar[i] \leftarrow$ `fftNonnegMaxConvolveGivenPStar`$(L', R', allPStar[i])$
  end for
  for $m \in \{0, 1, \ldots len(L) + len(R) - 1\}$ **do**
    $maxStablePStarIndex[m] \leftarrow \max\{i : (resForAllPStar[i][m])^{\text{allPStar}[i]} \geq \tau)\}$
  end for
  $result \leftarrow$ `affineCorrect`$(resForAllPStar, maxStablePStarIndex)$
  return $L[\ell_{\max}] \times R[r_{\max}] \times result$ ▷ Undo previous scaling
end procedure

$$f(\|u^{(m)}\|_{p^*}) = \lambda_m \|u^{(m_{\max})}\|_\infty + (1 - \lambda_m) \|u^{(m_{\min})}\|_\infty$$

$$\lambda_m = \frac{\|u^{(m)}\|_{p^*} - \|u^{(m_{\min})}\|_{p^*}}{\|u^{(m_{\max})}\|_{p^*} - \|u^{(m_{\min})}\|_{p^*}} \in [0, 1]$$

Thus, by computing $\|u^{(m_{\min})}\|_\infty$ and $\|u^{(m_{\max})}\|_\infty$ (each in $O(k)$ steps), we can compute an affine function f to correct contour-specific trends (**Algorithm 3**).

3.3.1 Error Analysis of Improved Affine Piecewise Method

By exploiting the convex combination used to define f, the absolute error of the affine piecewise method can also be bound. Qualitatively, this is because, by fitting on the extrema in the contour, we

Algorithm 4 Subroutine for correcting errors in a contour, with an affine transformation based on exact boundary points. It needs the results of the evaluation of the different p-norms as well as the (index of the) maximum stable values of p^* at every index.

procedure AFFINECORRECT($resForAllPStar$, $maxStablePStarIndex$)
  $\forall i, slope[i] \leftarrow 1$
  $\forall i, bias[i] \leftarrow 0$
  $usedPStar \leftarrow set(maxStablePStarIndex)$
  for $i \in usedPStar$ **do**
    $contour \leftarrow \{m : maxStablePStarIndex[m] = i\}$
    $mMin \leftarrow argmin_{m \in contour} resForAllPStar[i][m]$
    $mMax \leftarrow argmax_{m \in contour} resForAllPStar[i][m]$
    $xMin \leftarrow resForAllPStar[i][mMin]$
    $xMax \leftarrow resForAllPStar[i][mMax]$
    $yMin \leftarrow$ `maxConvolutionAtIndex`$(mMin)$
    $yMax \leftarrow$ `maxConvolutionAtIndex`$(mMax)$
    if $xMax > xMin$ **then**
      $slope[i] \leftarrow \frac{yMax - yMin}{xMax - xMin}$
      $bias[i] \leftarrow yMin - slope[i] \times xMin$
    else
      $slope[i] \leftarrow \frac{yMax}{xMax}$
    end if
  end for
  for $m \in \{0, 1, \ldots len(L) + len(R) - 1\}$ **do**
    $i \leftarrow maxStablePStarIndex[m]$
    $result[m] \leftarrow resForAllPStar[i][m] \times slope[i] + bias[i]$
  end for
  return $result$
end procedure

are now interpolating. If the two points used to determine the parameters of the affine function were not chosen in this manner to fit the affine function, then it would be possible to choose two points with very close x-values (*i.e.*, similar approximate values) and disparate y-values (*i.e.*, different exact values), and extrapolating to other points could propagate a large slope over a large distance; using the extreme points forces the affine function to be a convex combination of the extrema, thereby avoiding this problem.

$$
\begin{aligned}
& f(\|u^{(m)}\|_{p^*}) = \lambda_m \|u^{(m_{\max})}\|_\infty + (1-\lambda_m)\,\|u^{(m_{\min})}\|_\infty \\
\in & \left[\lambda_m \frac{\|u^{(m_{\max})}\|_{p^*}}{k_{m_{\max}}^{\frac{1}{p^*}}} + (1-\lambda_m)\,\frac{\|u^{(m_{\min})}\|_{p^*}}{k_{m_{\min}}^{\frac{1}{p^*}}},\right. \\
& \qquad \left. \lambda_m \|u^{(m_{\max})}\|_{p^*} + (1-\lambda_m)\,\|u^{(m_{\min})}\|_{p^*}\right] \\
\subseteq & \left[\lambda_m \frac{\|u^{(m_{\max})}\|_{p^*}}{k^{\frac{1}{p^*}}} + (1-\lambda_m)\,\frac{\|u^{(m_{\min})}\|_{p^*}}{k^{\frac{1}{p^*}}},\right. \\
& \qquad \left. \lambda_m \|u^{(m_{\max})}\|_{p^*} + (1-\lambda_m)\,\|u^{(m_{\min})}\|_{p^*}\right] \\
= & \left[k^{\frac{-1}{p^*}}\left(\lambda_m \|u^{(m_{\max})}\|_{p^*} + (1-\lambda_m)\,\|u^{(m_{\min})}\|_{p^*}\right),\right. \\
& \qquad \left. \lambda_m \|u^{(m_{\max})}\|_{p^*} + (1-\lambda_m)\,\|u^{(m_{\min})}\|_{p^*}\right] \\
= & \left[k^{\frac{-1}{p^*}}\|u^{(m)}\|_{p^*}, \|u^{(m)}\|_{p^*}\right]
\end{aligned}
$$

The worst-case absolute error of the scaled problem on L', R' can be defined as

$$\max_m |\ f(\|u^{(m)}\|_{p^*}) - \|u^{(m)}\|_\infty\ |.$$

Because the function $f(\|u^{(m)}\|_{p^*}) - \|u^{(m)}\|_\infty$ is affine, it's derivative can never be zero, and thus Lagrangian theory states that the maximum must occur at a boundary point. Therefore, the worst-case absolute error is

$$
\begin{aligned}
\leq & \quad \max\{\|u^{(m)}\|_{p^*} - \|u^{(m)}\|_\infty, \|u^{(m)}\|_\infty - \|u^{(m)}\|_{p^*} k^{\frac{-1}{p^*}}\} \\
= & \quad \|u^{(m)}\|_{p^*} - \|u^{(m)}\|_\infty,
\end{aligned}
$$

which is identical to the worst-case error bound before applying the affine transformation f. Thus applying the affine transformation can dramatically improve error, but will not make it worse than the original worst-case.

3.4 An Improved Approximation of the Chebyshev Norm

In order to improve the error of the piecewise numerical method, we consider the worst-case, when $\frac{u^{(m)}}{\|u^{(m)}\|_\infty} = (1, 1, \ldots 1)$. In this case, computing any two norms of $u^{(m)}$ (at p_1^* and p_2^*) would be sufficient to solve exactly for $\|u^{(m)}\|_\infty$, because

$$
\begin{aligned}
\|u^{(m)}\|_{p_1^*}^{p_1^*} & \propto \|u^{(m)}\|_\infty^{p_1^*} \\
\|u^{(m)}\|_{p_2^*}^{p_2^*} & \propto \|u^{(m)}\|_\infty^{p_2^*},
\end{aligned}
$$

where the proportionality constant is $k_m = len(u^{(m)})$.

Thus we see that although the p^*-norm approximation of the Chebyshev norm is a good approximation, the curve of the norms (at various different p^*) values holds far more information than a simple point estimate would. Therefore, we derive an improved algorithm by proceeding as follows: First, we note that, rather than computing the p^*-norm of a vector $u^{(m)}$ by summing all elements of $u^{(m)}$ taken to the power p^*, it is possible to equivalently sum over only the unique values of $u^{(m)}$ (here denoted in $\beta_1, \beta_2, \ldots$) taken to the p^* where each term in the sum is weighted by the number of occurrences of each (denoted $h_1, h_2, \ldots$, respectively). For this reason, we can then use a sequence of norms to compute a (potentially smaller) collection of approximate unique values $\alpha_1, \alpha_2, \ldots \alpha_r$, where once again, the p^*-norm is equal to the sum over those unique values to the p^*, where each term in the sum is weighted by numbers of occurrences $n_1, n_2, \ldots n_r$. Therefore, given $2r$ different norms of $u^{(m)}$, it is possible to project and estimate r unique α_i values. The maximum of those $\alpha_1, \alpha_2, \ldots \alpha_r$ values, (the $\alpha_1, \alpha_2, \ldots \alpha_r$ values can be thought of as projections of the true unique values $\beta_1, \beta_2, \ldots$) can then be used as an estimate of the true maximum element in $u^{(m)}$, which we will now demonstrate.

Specifically, where k_m is the length of $u^{(m)}$ and where there are $e_m \leq k_m$ unique values (β_i) in $u^{(m)}$, we can model the norms perfectly with

$$\|u^{(m)}\|_{p^*}^{p^*} = \sum_i^{e_m} h_i \beta_i^{p^*}$$

where h_i is an integer that indicates the number of times β_i occurs in $u^{(m)}$ (and where $\sum_i h_i = k_m = len(u^{(m)})$). This multi-set view of the vector $u^{(m)}$ can be used to project it down to a dimension r:

$$
\begin{bmatrix}
\alpha_1^{p^*} & \alpha_2^{p^*} & \cdots & \alpha_r^{p^*} \\
\alpha_1^{2p^*} & \alpha_2^{2p^*} & \cdots & \alpha_r^{2p^*} \\
\alpha_1^{3p^*} & \alpha_2^{3p^*} & \cdots & \alpha_r^{3p^*} \\
\vdots & \vdots & & \vdots \\
\alpha_1^{\ell p^*} & \alpha_2^{\ell p^*} & \cdots & \alpha_r^{\ell p^*}
\end{bmatrix}
\cdot
\begin{bmatrix} n_1 \\ n_2 \\ n_3 \\ \vdots \\ n_r \end{bmatrix}
=
\begin{bmatrix}
\|u^{(m)}\|_{p^*}^{p^*} \\
\|u^{(m)}\|_{2p^*}^{2p^*} \\
\|u^{(m)}\|_{3p^*}^{3p^*} \\
\vdots \\
\|u^{(m)}\|_{\ell p^*}^{\ell p^*}
\end{bmatrix}.
$$

By solving the above system of equations for all α_i, the maximum $\hat{\alpha} = \max_i \alpha_i$ can be used to approximate the true maximum $\max_i \beta_i = \|u^{(m)}\|_\infty$. This projection can be thought of as querying distinct moments of the distribution $\text{pmf}_{U^{(m)}}$ that corresponds to some unknown vector $u^{(m)}$, and then assembling the moments into a model in order to predict the unknown maximum value in $u^{(m)}$. Of course, when r, the number of terms in our model, is sufficiently large, then computing r norms of $u^{(m)}$ will result in an exact result, but it could result in $O(k_m)$ execution time, meaning that our numerical max-convolution algorithm becomes quadratic; therefore, we must consider that a small number of distinct moments are queried in order to estimate the maximum value in $u^{(m)}$. Regardless, the system of equations above is quite difficult to solve directly via elimination for even very small values of r, because the symbolic expressions become quite large and because symbolic polynomial roots cannot be reliably computed when the degree of the polynomial is > 5. Even in cases when it can be solved directly, it will be far too inefficient.

For this reason, we solve for the α_i values using an exact, alternative approach: If we define a polynomial $\gamma(x) = \left(x - \alpha_1^{p^*}\right)\left(x - \alpha_2^{p^*}\right)\cdots\left(x - \alpha_r^{p^*}\right)$, then $x \in \{\alpha_1^{p^*}, \alpha_2^{p^*}, \ldots \alpha_r^{p^*}\} \Leftrightarrow \gamma(x) = 0$. We can expand $\gamma(x) = \gamma_0 + \gamma_1 x + \gamma_2 x^2 + \cdots + \gamma_r x^r$, and then write

$$\begin{bmatrix} \gamma_0 & \gamma_1 & \gamma_2 & \cdots & \gamma_r \end{bmatrix} \cdot \begin{bmatrix} \alpha_1^{p^*} & \alpha_2^{p^*} & & \alpha_r^{p^*} \\ \alpha_1^{2p^*} & \alpha_2^{2p^*} & \cdots & \alpha_r^{2p^*} \\ \alpha_1^{3p^*} & \alpha_2^{3p^*} & & \alpha_r^{3p^*} \\ \vdots & \vdots & & \vdots \\ \alpha_1^{\ell p^*} & \alpha_2^{\ell p^*} & & \alpha_r^{\ell p^*} \end{bmatrix} \cdot \begin{bmatrix} n_1 \\ n_2 \\ n_3 \\ \vdots \\ n_r \end{bmatrix} =$$

$$\begin{bmatrix} \alpha_1^{p^*}\gamma(\alpha_1^{p^*}) & \alpha_2^{p^*}\gamma(\alpha_2^{p^*}) & \alpha_3^{p^*}\gamma(\alpha_3^{p^*}) & \cdots & \alpha_r^{p^*}\gamma(\alpha_r^{p^*}) \end{bmatrix} \cdot \begin{bmatrix} n_1 \\ n_2 \\ n_3 \\ \vdots \\ n_r \end{bmatrix} =$$

$$\begin{bmatrix} 0 & 0 & 0 & \cdots & 0 \end{bmatrix} \cdot \begin{bmatrix} n_1 \\ n_2 \\ n_3 \\ \vdots \\ n_r \end{bmatrix} = 0,$$

which indicates that

$$\begin{bmatrix} \gamma_0 & \gamma_1 & \gamma_2 & \cdots & \gamma_r \end{bmatrix} \cdot \begin{bmatrix} \|u^{(m)}\|_{p^*}^{p^*} \\ \|u^{(m)}\|_{2p^*}^{2p^*} \\ \|u^{(m)}\|_{3p^*}^{3p^*} \\ \vdots \\ \|u^{(m)}\|_{\ell p^*}^{\ell p^*} \end{bmatrix} = 0.$$

Furthermore, $\gamma(x) = 0, x \neq 0 \Leftrightarrow x^i\gamma(x) = 0, i \in \mathbb{N}$; therefore we can write

$$\begin{bmatrix} \gamma_0 & \gamma_1 & \gamma_2 & \cdots & \gamma_r & 0 & 0 & \cdots & 0 \\ 0 & \gamma_0 & \gamma_1 & \gamma_2 & \cdots & \gamma_r & 0 & \cdots & 0 \\ 0 & 0 & \gamma_0 & \gamma_1 & \gamma_2 & \cdots & \gamma_r & \cdots & 0 \\ & & & & \vdots & & & & \\ 0 & 0 & \cdots & 0 & \gamma_0 & \gamma_1 & \gamma_2 & \cdots & \gamma_r \end{bmatrix} \cdot \begin{bmatrix} \|u^{(m)}\|_{p^*}^{p^*} \\ \|u^{(m)}\|_{2p^*}^{2p^*} \\ \|u^{(m)}\|_{3p^*}^{3p^*} \\ \vdots \\ \|u^{(m)}\|_{\ell p^*}^{\ell p^*} \end{bmatrix} =$$

$$\begin{bmatrix} \|u^{(m)}\|_{p^*}^{p^*} & \|u^{(m)}\|_{2p^*}^{2p^*} & \|u^{(m)}\|_{3p^*}^{3p^*} & \cdots & \|u^{(m)}\|_{(r+1)p^*}^{(r+1)p^*} \\ \|u^{(m)}\|_{2p^*}^{2p^*} & \|u^{(m)}\|_{3p^*}^{3p^*} & \|u^{(m)}\|_{4p^*}^{4p^*} & \cdots & \|u^{(m)}\|_{(r+2)p^*}^{(r+2)p^*} \\ \|u^{(m)}\|_{3p^*}^{3p^*} & \|u^{(m)}\|_{4p^*}^{4p^*} & \|u^{(m)}\|_{5p^*}^{5p^*} & \cdots & \|u^{(m)}\|_{(r+3)p^*}^{(r+3)p^*} \\ \vdots & \vdots & \vdots & & \vdots \\ \|u^{(m)}\|_{(\ell-r)p^*}^{(\ell-r)p^*} & \|u^{(m)}\|_{(\ell-r+1)p^*}^{(\ell-r+1)p^*} & \|u^{(m)}\|_{(\ell-r+2)p^*}^{(\ell-r+2)p^*} & \cdots & \|u^{(m)}\|_{\ell p^*}^{\ell p^*} \end{bmatrix} \cdot \begin{bmatrix} \gamma_0 \\ \gamma_1 \\ \gamma_2 \\ \vdots \\ \gamma_r \end{bmatrix} = 0.$$

Therefore,

$$\begin{bmatrix} \gamma_0 \\ \gamma_1 \\ \gamma_2 \\ \vdots \\ \gamma_r \end{bmatrix} \in null\left(\begin{bmatrix} \|u^{(m)}\|_{p^*}^{p^*} & \|u^{(m)}\|_{2p^*}^{2p^*} & \|u^{(m)}\|_{3p^*}^{3p^*} & \cdots & \|u^{(m)}\|_{(r+1)p^*}^{(r+1)p^*} \\ \|u^{(m)}\|_{2p^*}^{2p^*} & \|u^{(m)}\|_{3p^*}^{3p^*} & \|u^{(m)}\|_{4p^*}^{4p^*} & \cdots & \|u^{(m)}\|_{(r+2)p^*}^{(r+2)p^*} \\ \|u^{(m)}\|_{3p^*}^{3p^*} & \|u^{(m)}\|_{4p^*}^{4p^*} & \|u^{(m)}\|_{5p^*}^{5p^*} & \cdots & \|u^{(m)}\|_{(r+3)p^*}^{(r+3)p^*} \\ \vdots & \vdots & \vdots & & \vdots \\ \|u^{(m)}\|_{(\ell-r)p^*}^{(\ell-r)p^*} & \|u^{(m)}\|_{(\ell-r+1)p^*}^{(\ell-r+1)p^*} & \|u^{(m)}\|_{(\ell-r+2)p^*}^{(\ell-r+2)p^*} & \cdots & \|u^{(m)}\|_{\ell p^*}^{\ell p^*} \end{bmatrix}\right).$$

Because the columns of

$$\begin{bmatrix} \alpha_1^{p^*} & \alpha_2^{p^*} & & \alpha_r^{p^*} \\ \alpha_1^{2p^*} & \alpha_2^{2p^*} & \cdots & \alpha_r^{2p^*} \\ \alpha_1^{3p^*} & \alpha_2^{3p^*} & & \alpha_r^{3p^*} \\ \vdots & \vdots & & \vdots \\ \alpha_1^{\ell p^*} & \alpha_2^{\ell p^*} & & \alpha_r^{\ell p^*} \end{bmatrix}$$

must be linearly independent when $\alpha_1, \alpha_2, \ldots$ are distinct (which is the case by the definition of our multiset formulation of the norm), then $r = \frac{\ell}{2}$ will determine a unique solution; thus the null space above is computed from a matrix with $r + 1$ columns and r rows, yielding a single vector for $(\gamma_0, \gamma_1, \ldots \gamma_r)$. This vector can then be used to compute the roots of the polynomial $\gamma_0 + \gamma_1 x + \gamma_2 x^2 + \cdots + \gamma_r x^r$, which will determine the values $\{\alpha_1^{p^*}, \alpha_2^{p^*}, \ldots \alpha_r^{p^*}\}$, which can each be taken to the $\frac{1}{p^*}$ power to compute $\{\alpha_1, \alpha_2, \ldots, \alpha_r\}$; the largest of those α_i values is used as the estimate of the maximum element in $u^{(m)}$. When $u^{(m)}$ contains at least r distinct values (*i.e.*, $e_m \geq r$), then the problem will be well-defined; thus, if the roots of the null space spanning vector are not well-defined, then a smaller r can be used (and should be able to compute an exact estimate of the maximum, since $u^{(m)}$ can be projected exactly when r is the precise number of unique elements found in $u^{(m)}$).

To summarize, the null space projection method is performed as follows: First, standard FFT-based convolution is used for each p^* to compute the different norms at every index m. Then those norms are used to populate and compute the null space of a matrix. Finally the roots of the polynomial whose coefficients are given by the null space vector are computed to estimate the different $\alpha_1, \alpha_2, \ldots$. Note that this projection method is valid for any sequence of norms with even spacing: $\|u^{(m)}\|_{p_0+p^*}^{p_0+p^*}, \|u^{(m)}\|_{p_0+2p^*}^{p_0+2p^*}, \|u^{(m)}\|_{p_0+3p^*}^{p_0+3p^*}, \ldots \|u^{(m)}\|_{p_0+\ell p^*}^{p_0+\ell p^*}$.

The null space projection method can therefore be computed for an arbitrary r (*i.e.*, it can be used to project to an arbitrary number of unique elements in $u^{(m)}$) by using linear algebra to compute the null space and to compute the roots of the polynomial (for instance, using the `numpy.roots` command in Python). For greater efficiency, setting r to a small constant allows us to precompute closed-form solutions of both the null space and the polynomial roots. For instance, using $r = 2$ (which is equivalent to projecting each vector $u^{(m)}$ to two unique values) results in a $\mathbb{R}^{3\times 2}$ null space computation and computing roots of a quadratic polynomial, both of which can be done in closed form **Algorithm 5**. Details of this $r = 2$ case can be found in **Appendix 5**. In this case, it is possible to construct a series of powers of two with interleaved points, which guarantees that 4 evenly spaced p^* values exist (when the highest numerically stable p^* is higher than 2), meaning that the number of FFT calls is only $2\times$ what would be used by the original piecewise method (rather than $4\times$ the calls, which would be necessary if 4 evenly spaced points were placed at each considered p^* in a naive scheme). From algebraic and empirical evidence, we conjecture that the relative error of this $r = 2$ null space projection is bounded above by $1 - 0.7^{\frac{4}{p^*}}$, where p^* is the highest numerically stable p^* value.

This relative error is superior to the worst-case relative error when using a single p^*-norm estimate of the maximum. The relative error using the null space projection decreases rapidly as p^* is increased, meaning that the same procedure can be used to achieve an absolute error bound:

$$\hat{\alpha} - \|u^{(m)}\|_\infty < \tau^{\frac{1}{2p^*}}\left(1 - 0.7^{\frac{4}{p^*}}\right),$$

which achieves a unique maximum at

$$p^*_{mode} = \frac{1.4267 * \log(\tau) - 4.07094}{(\log(\tau) - 2.8534)\left(\log(1 - \frac{2.8534}{\log(\tau)})\right)} \approx 14.52.$$

Algorithm 5 Piecewise numerical max-convolution with projection, a numerical method to estimate the max-convolution of two PMFs or nonnegative vectors. This method uses a nullspace projection to achieve a closer estimate of the true maximum. Depending on the number of stable estimates, linear or quadratic projection is used. The parameters are two nonnegative vectors L' and R' (both scaled so that they have maximal element 1). The return value is a numerical estimate of the max-convolution $L' *_{\max} R'$.

procedure numericalMaxConvolvePiecewiseProjectionAffine(L', R', p^*)
  $\ell_{\max} \leftarrow \text{argmax}_\ell L[\ell]$
  $r_{\max} \leftarrow \text{argmax}_r R[r]$
  $L' \leftarrow \frac{L}{L[\ell_{\max}]}$
  $R' \leftarrow \frac{R}{R[r_{\max}]}$ ▷ Scale to a proportional problem on L', R'
  $allPStar \leftarrow [2^{-1}, 2^0, 2^1, \ldots, 2 + 2^{\left\lfloor \log_2(p^*_{\max}) \right\rfloor}]$

  for $p \in \{0, 1, \ldots len(maxStablePStarIndex)\}$ **do**
    $maxP \leftarrow allPStarInterleaved[maxStablePStarIndex[p]]$
    $spacing \leftarrow 0.25 * maxP$
    $est_4 \leftarrow resForAllPStar[maxStablePStarIndex[p]]$
    $est_3 \leftarrow resForAllPStar[maxStablePStarIndex[p] - 1]$
    if $maxStablePStarIndex[p] < 5$ **then** ▷ Need 5 p^* in sequence to get 4 evenly spaced
      $resForAllPStar[p] \leftarrow$ `maxLin`(est_3, est_4)
    else
      $est_2 \leftarrow resForAllPStar[maxStablePStarIndex[p] - 2]$
      $est_1 \leftarrow resForAllPStar[maxStablePStarIndex[p] - 4]$ ▷ Index - 4 is the next evenly spaced point
      $resForAllPStar[p] \leftarrow$ `maxQuad`$(est_1, est_2, est_3, est_4, spacing)$
    end if
  end for
  $result \leftarrow$ `affineCorrect`$(resForAllPStar, maxStablePStarIndex)$
  return $L[\ell_{\max}] \times R[r_{\max}] \times result$ ▷ Undo previous scaling
end procedure

As before, the worst-case absolute error of the unscaled problem will be found by simply scaling the absolute error at p^*_{mode}:

$$\max_\ell L[\ell] \max_r R[r] \tau^{\frac{1}{2p^*_{mode}}} \left(1 - 0.7^{\frac{4}{p^*_{mode}}}\right).$$

Because p^*_{mode} (the value of p^* producing the worst-case absolute error) for the null space projection method it is invariant to the length of the list k (enabling us to compute a numeric value), and because its numeric value is so small, even a fairly small choice of $p^*_{\max}$ will suffice (now $p^*_{\max} \in O(1)$ rather than in $O(\log(k))$ as it was with the original piecewise method).

The one caveat of this worst-case absolute error bound is that it presumes at least four evenly spaced, stable p^* can be found (which may not be the case by choosing p^* from the sequence 2^i in cases when $\|u^{(m)}\|_\infty \approx 0$); however, assuming standard fast convolution can be performed (a reasonable assumption given it is one of the essential numeric algorithms), then four evenly spaced p^* values could be chosen very close to 1; therefore, these values of p^* could be added to the sequence so that the algorithm is slightly slower, but essentially always yield this worst-case absolute error bound.

In practice, we can demonstrate that the null space projection method is very accurate. First we show the impact of using the quadratic (*i.e.*, $r = 2$) projection method on unscaled single $u^{(m)}$ vectors. The projection method was tested on vectors of different lengths drawn from different types of Beta distributions and are compared with the results of the p-norms with the highest stable p (**Figure 5**). The relative errors between the original piecewise method and the null space projection method are compared using a max-convolution on two randomly created input PMFs of lengths 1024 (**Figure 6**). Note that the null space projection can also be paired with affine scaling on the back end, just as the original piecewise method can be. In practice, the null space projection increases the accuracy demonstrably on a variety of different problems, although the original piecewise method also performs well.

Although the worst-case runtime of the null space projection method is roughly 2× that of the original piecewise method, the error bound no longer depends on the length of the result k. Thus, for a given relative error bound on the top contour (*i.e.*, the equivalent of the derivation of $p^*_{\max}$ in the original piecewise algorithm), the value of $p^*_{\max}$ is fixed and no longer $\in O(\log(k))$. For example, achieving a 0.5% relative error in the top contour would require

$$1 - 0.7^{\frac{4}{p^*_{\max}}} \leq 0.005 \rightarrow p^*_{\max} \geq 4\frac{\log(0.7)}{\log(0.995)} \approx 284.62,$$

meaning that choosing $p^*_{\max} = 512$ would achieve a very high accuracy, but while only performing 2×9 FFTs. For very large vectors, this will not be substantially more expensive than the original piecewise algorithm, which uses a higher value of $p^*_{\max}$ (in this case, $p^*_{\max} = \log_{1.005}(k)$, which continues to grow as k does) to keep the error lower in practice. As a result, the runtime of the null space projection approximation is $\in O(k \log(k))$ rather than $O(k \log(k) \log(\log(k)))$, despite the similar runtime in practice to the original piecewise method (the null space projection method uses 2× as many FFTs performed per p^* value, but requires slightly fewer p^* values).

3.5 Practical Runtime Comparison

To compare the actual runtimes of the final algorithm developed in this manuscript with a naive max-convolution and a previously proposed method from Bussieck et al. (1994), all methods were run on vectors of different random (uniform in $[0, 1]$) composition and length (k). The first and second input vector were generated seperately but are always of same length. **Table 1** shows the result of this experiment. All methods were implemented in Python, using `numpy` where applicable (*e.g.*, to vectorize). A non-vectorized version of naive max-convolution was included to estimate the effects of vectorization. The approach from Bussieck et al. ran as a reimplementation based on the

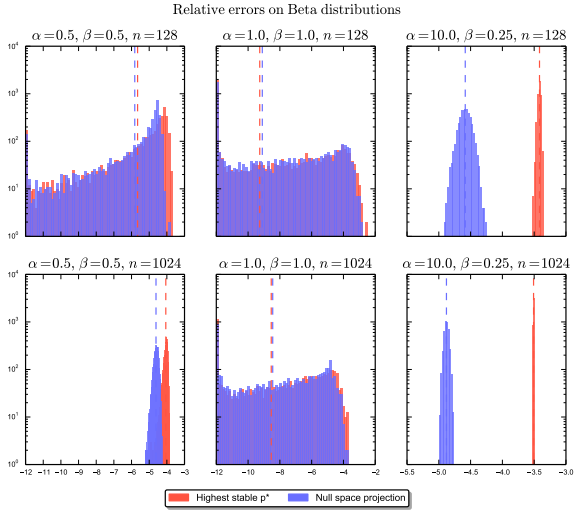

Figure 5: **Relative errors on random vectors with and without null space projection.** For the two approximation methods (using the highest stable p^*-norm with the heuristically chosen $p^*_{\max}$ or using the null space projection with $p^*_{\max} = 64$), vectors of different lengths are sampled (2^{12} repetitions) from a variety of Beta distributions. The settings for the parameters (α, β) of the Beta distribution that were used, as well as the lengths of the generated vectors are shown in the titles of the subplots: $\alpha = 0.5, \beta = 0.5$ (bimodal with modes near zero and one); $\alpha = 0.1, \beta = 0.1$ (uniform distribution); $\alpha = 10, \beta = 0.25$ (with a strong mode near one). The red area depicts the frequencies (y-axis) of the different magnitudes of (relative) error (x-axis) when using the highest stable p^*-norm is used as an approximation of the Chebyshev norm ($p = \infty$). The blue area shows the errors with the method that performs a projection (either quadratic or linear depending on how many numerically stable p^* are available) to estimate the Chebyshev norm.

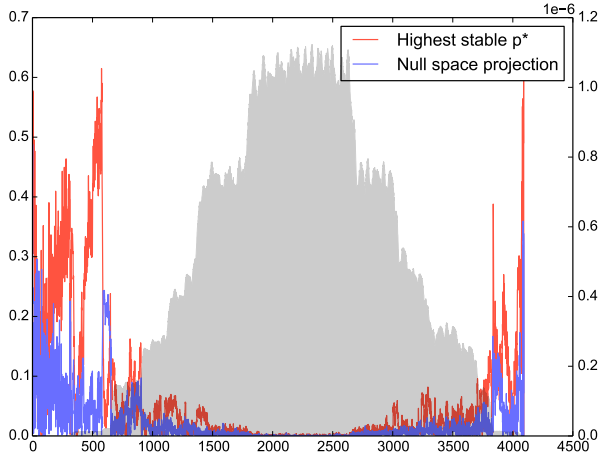

Figure 6: **Relative errors on large max-convolution with and without null space projection.** Max-convolution between two randomly generated vectors (both uniform vectors convolved with narrow Gaussians with uniform noise added afterward), performed with the highest stable p^*-norm (using the heuristic choice of $p^*_{\max}$ for problems of this size) and with null space projection (using $p^*_{\max} = 64$). The left y-axis shows the relative error at index m. Associated with that, you can see the red and blue curve depicting the errors from the two different methods: Red describes the max-norm estimation using only the highest stable p^* while purple was generated using quadratic projection at the four highest stable p^* values (when at least four evenly spaced values are numerically stable) and linear projection at the two highest stable p^* values (when only two p^* are numerically stable). The results of both approaches are corrected with the affine transformation method proposed in this manuscript. In the background the gray shaded curve shows the exact result of the max-convolution at every index (to be used with the second y-axis on the right).

k	2^6	2^7	2^8	2^9	2^{10}	2^{11}	2^{12}
Naive	**0.0142**	0.0530	0.192	0.767	3.03	12.1	48.2
Naive (vectorized)	0.0175	0.0381	0.0908	0.251	0.790	2.75	10.1
FILL1 (Bussieck et al., 1994)	0.0866	1.09	7.21	19.4	457	—	—
Max. stable p^*, affine corrected	0.0277	0.0353	0.0533	0.0848	0.149	0.274	0.537
Projection, affine corrected	0.0236	**0.0307**	**0.0467**	**0.0760**	**0.137**	**0.258**	**0.520**

Table 1: **Runtimes of different methods for max-convolution on uniform vectors of length k.** The runtimes were gathered using the `timeit` package in Python. They include all preprocessing steps necessary for the algorithm (*e.g.*, sorting prior to the FILL1 approach). The values are total runtimes (in seconds) to run 5 repetitions on different, randomly generated vectors. FILL1 was not run on larger problems, because it ran substantially longer than the non-vectorized naive approach. On the two approximation methods presented in this manuscript, the highest stable p^*-norm approximation was run with the heuristically chosen $p^*_{\max}$ for problems of the appropriate size and the null space projection was run with $p^*_{\max} = 64$.

pseudocode in their manuscript. From their variants of proposed methods, FILL1 was chosen because of its use in their corresponding benchmark and its recommendation by the authors for having a lower runtime constant in practice compared to other methods they proposed. The method is based on sorting the input vectors and traversing the (implicitly) resulting partially ordered matrix of products in a way that not all entries need to be evaluated, while only keeping track of the so-called cover of maximal elements. FILL1 already includes some more sophisticated checks to keep the cover small and thereby reducing the overhead per iteration. Unfortunately, although we observed that the FILL1 method requires between $O(n \log(n))$ and $O(n^2)$ iterations in practice, this per-iteration overhead results in a worst-case cost of $\log(n)$ per iteration, yielding an overall runtime in practice between $O(n \log(n) \log(n))$ and $O(n^2 \log(n))$. As the authors state, this overhead is due to the expense of storing the cover, which can be implemented *e.g.*, using a binary heap (recommended by the authors and used in this reimplementation). Additionally, due to the fairly sophisticated datastructures needed for this algorithm it had a higher runtime constant than the other methods presented here, and furthermore we saw no means to vectorize it to improve the efficiency. For this reason, it is not truly fair to compare the raw runtimes to the other vectorized algorithms (and it is not likely that this Python reimplementation is as efficient as the original version, which Bussieck et al., 1994 implemented in ANSI-C); however, comparing a non-vectorized implementation of the naive $O(n^2)$ approach with its vectorized counterpart gives an estimated $\approx 5\times$ speedup from vectorization, suggesting that it is not substantially faster than the naive approach on these problems (it should be noted that whereas the methods presented here have tight runtime bounds but produce approximate results, the FILL1 algorithm is exact, but its runtime depends on the data processed). During investigation of these runtimes, we found that on the given problems, the proposed average case of $O(n \log(n))$ iterations was rarely reached. A reason might be an unrecognized violation of the assumptions of the theory behind this theoretical average runtime in how the input vectors were generated.

In contrast to the exact method from Bussieck et al. (1994), the herein proposed approximate procedure are faster whenever the input vectors are at least 128 elements long (shorter vectors are most efficiently processed with the naive approach). The null space projection method is the fastest method presented here (because it can use a lower $p^*_{\max}$), although the higher density of p^* values it uses (and thus, additional FFTs) make the runtimes nearly identical for both approximation methods.

3.6 Demonstration on Hidden Markov Model With Toeplitz Transition Matrix

One example that profits from fast max-convolution of non-negative vectors is computing the Viterbi path using a hidden Markov model (HMM) (*i.e.*, the *maximum a posteriori* states) with an additive transition function satisfying $\Pr(X_{i+1} = a | X_i = b) \propto \delta(a - b)$ for some arbitrary function δ (δ can be represented as a table, because we are considering all possible discrete functions). This additivity constraint is equivalent to the transition matrix being a "Toeplitz matrix": the transition matrix $T_{a,b} = \Pr(X_{i+1} = a | X_i = b)$ is a Toeplitz matrix when all cells diagonal from each other (to the upper left and lower right) have identical values (*i.e.*, $\forall a, \forall b,\ T_{a,b} = T_{a+1,b+1}$). Because of the Markov property of the chain, we only need to max-marginalize out the latent variable at time i to compute the distribution for the next latent variable X_{i+1} and all observed values of the data variables $D_0 \dots D_{i+1}$. This procedure, called the Viterbi algorithm, is continued inductively:

$$\max_{x_0, x_1, \dots x_{i-1}} \Pr(D_0, D_1, \dots D_{i-1}, X_0 = x_0, X_1 = x_1, \dots, X_i = x_i) =$$

$$\max_{x_{i-1}} \max_{x_0, x_1, \dots x_{i-2}} \Pr(D_0, D_1, \dots D_{i-2}, X_0 = x_0, X_1 = x_1, \dots, X_{i-1} = x_{i-1}) \Pr(D_{i-1} | X_{i-1} = x_{i-1}) \Pr(X_i = x_i | X_{i-1} = x_{i-1})$$

and continuing by exploiting the self-similarity on a smaller problem to proceed inductively with variable $fromLeft$, revealing a max-convolution (for this specialized HMM with additive transitions):

$$\max_{x_0, x_1, \dots x_{i-1}} \Pr(D_0, D_1, \dots D_{i-1}, X_0 = x_0, X_1 = x_1, \dots, X_i = x_i) =$$
$$\max_{x_{i-1}} fromLeft[i-1] \Pr(D_{i-1} | X_{i-1} = x_{i-1}) \delta[x_i - x_{i-1}] =$$
$$(fromLeft[i-1]\ likelihood[D_{i-1}])\ *_{\max}\ \delta[x_i - x_{i-1}].$$

After computing this left-to-right pass (which consisted of $n-1$ max-convolutions and vector multiplications), we can find the *maximum a posteriori* configuration of the latent variables $X_0, \dots X_{n-1} = x^*_0, \dots x^*_{n-1}$ backtracking right-to-left, which can be done by finding the variable value x_i that maximizes $fromLeft[i][x_i] \times \delta[x^*_{i+1} - x_i]$ (thus defining x^*_i and enabling induction on the right-to-left pass). The right-to-left pass thus requires $O(nk)$ steps (**Algorithm 6**). Note that the full max-marginal distributions on each latent variable X_i can be computed via a small modification, which would perform a more complex right-to-left pass that is nearly identical to the left-to-right pass, but which performs subtraction instead of addition (*i.e.*, by reversing the vector representation of the PMF of the subtracted argument before it is max-convolved; Serang, 2014).

We apply this HMM with additive transition probabilities to a data analysis problem from economics. It is known for example, that the current figures of unemployment in a country have (among others) impact on prices of commodities like oil. If one could predict unemployment figures before the usual weekly or monthly release by the responsible government bureaus, this would lead to an information advantage and an opportunity for short-term arbitrage. The close relation of economic indicators like market prices and stock market indices (especially of indices combining several stocks of different industries) to unemployment statistics can be used to tackle this problem.

In the following demonstration of our method, we create a simple HMM with additive transitions and use it to infer the *maximum a posteriori* unemployment statistics given past history (*i.e.*, how often unemployment is low and high, as well as how often unemployment goes down or up in a

Algorithm 6 Viterbi for models with additive transitions, which accepts the length k vector *prior*, a list of n binned observations *data*, a $a \times k$ matrix of likelihoods (where a is the number of bins used to discretize the data) *likelihoods*, and a length $2k-1$ vector δ that describes the transition probabilities. The algorithm returns a Viterbi path of length n, where each element in the path is a valid state $\in \{0, 1, \ldots k-1\}$.

end procedure

short amount of time) and current stock market prices (the observed data). We discretized random variables for the observed data (S&P 500, adjusted closing prices ; retrieved from YAHOO! historical stock prices: `http://data.bls.gov/cgi-bin/surveymost?blsseriesCUUR0000SA0`), and "latent" variables (unemployment insurance claims, seasonally adjusted, were retrieved from the U.S. Department of Labor: `https://www.oui.doleta.gov/unemploy/claims.asp`). Stock prices were additionally inflation adjusted by (*i.e.*, divided by) the consumer price index (CPI) (retrieved from the U.S. Bureau of Labor Statistics: `https://finance.yahoo.com/q?s=^GSPC`). The intersection of both "latent" and observed data was available weekly from week 4 in 1967 to week 52 in 2014, resulting in 2500 data points for each type of variable.

To investigate the influence of overfitting, we partition the data in two parts, before June 2005 and after June 2005, so that we are effectively training on $\frac{2000 \times 100}{2500} = 80\%$ of the data points, and then demonstrate the Viterbi path on the entirety of the data (both the 80% training data and the 20% of the data withheld from empirical parameter estimation). Unemployment insurance claims were discretized into 512 and stock prices were discretized into 128 bins. Simple empirical models of the prior distribution for unemployment, the likelihood of unemployment given stock prices, and the transition probability of unemployment were built as follows: The initial or prior distribution for unemployment claims at $i = 0$ was calculated by marginalizing the time series of training data for the claims (*i.e.*, counting the number of times any particular unemployment value was reached over all possible bins). Our transition function (the conditional probability $\Pr(X_{i+1}|X_i)$) similarly counts the number of times each possible change $X_{i+1} - X_i \in \{-511, -510, \ldots 511\}$ occurred over all available time points. Interestingly, the resulting transition distribution roughly resembles a Gaussian (but is not an exact Gaussian). This underscores a great quality of working with discrete distributions: while continuous distributions may have closed-forms for max-convolution (which can be computed quickly), discrete distributions have the distinct advantage that they can accurately approximate any smooth distribution. Lastly, the likelihoods of observing a stock price given the unemployment at the same time were trained using an empirical joint distribution (essentially a heatmap), which is displayed in **Figure 7**.

We compute the Viterbi path two times: First we use naive, exact max-convolution, which requires a total of $O(nk^2)$ steps. Second, we use fast numerical max-convolution, which requires $O(n\, k \log(k) \log(\log(k))$ steps. Despite the simplicity of the model, the exact Viterbi path (computed via exact max-convolution) is highly informative for predicting the value of unemployment, even for the 20% of the data that were not used to estimate the empirical prior, likelihood, and transition distributions. Also, the numerical max-convolution method is nearly identical to the exact max-convolution method at every index (**Figure 8**). Even with a fairly rough discretization (*i.e.*, $k = 512$), the fast numerical method (via the original, simpler piecewise algorithm with $p^*_{\max} = 8192$) used 141.4 seconds compared to the 292.3 seconds required by the naive approach. The higher-precision projection algorithm (which uses a smaller $p^*_{\max}$, but calls FFT twice for each power of two p^*) computes nearly identical result using $p^*_{\max} = 64$ for this problem in 136.6 seconds. The speedup of both fast numerical algorithms relative to the naive quadratic max-convolution algorithm will increase dramatically as k is increased.

4. Discussion

Both piecewise numerical max-convolution methods are highly accurate in practice and achieve a substantial speedup over both the naive approach and the approach proposed by Bussieck et al. (1994). This is particularly true for large problems: For the original piecewise method presented here, the $\log_2(\log_{1+\tau^{\frac{1}{4}}}(k))$ multiplier may never be small, but it grows so slowly with k that it will be < 18 even when k is on the same order of magnitude as the number of particles in the observable universe. This means that, for all practical purposes, the method behaves asymptotically as a slightly slower $O(k \log_2(k))$ method, which means the speedup relative to the naive method

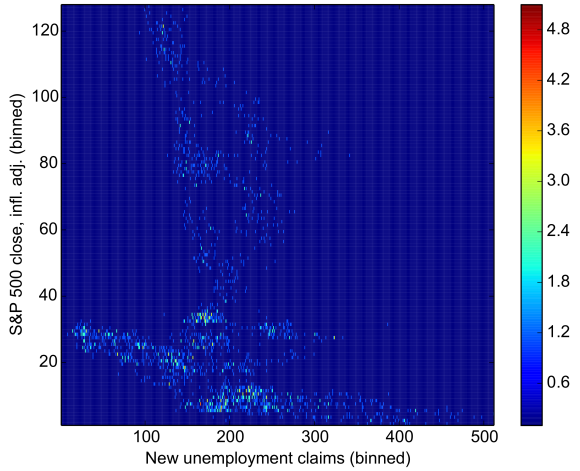

Figure 7: **Heatmap for trained likelihood matrix.** This heatmap depicts a joint empirical distribution between the S&P 500 index and new unemployment claims, which share a tenuous inverse relationship. Given D_i, the discretized stock index value at time i, row D_i contains the likelihood table $\Pr(D_i|X_i)$, which is denoted $likelihood[data[i]]$ in the code.

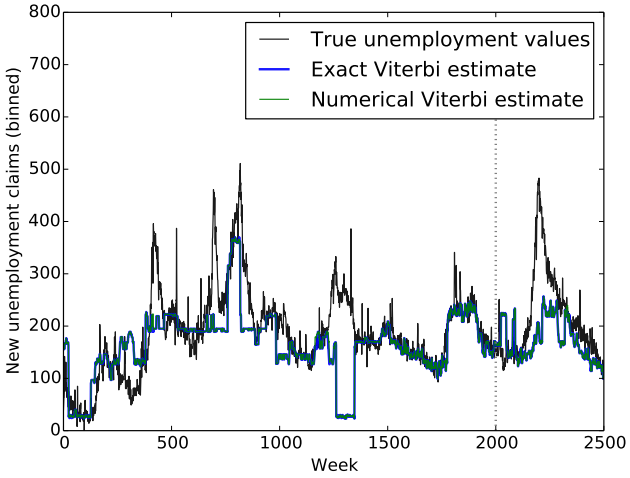

Figure 8: **Viterbi analysis of employment given stock index values.** The Viterbi path corresponding to the *maximum a posteriori* prediction of the number of new unemployment insurance claims is produced for a model where the state transition probabilities are additive. The exact Viterbi estimate tracks well with the true unemployment values. Training parameters were taken from only the true unemployment data to the left of the vertical dotted line; however, the Viterbi paths to the right of the dotted line (where unemployment data were withheld from the likelihood, prior, and transition parameters) also track well with the true unemployment statistics. The Viterbi path computed with fast numerical max-convolution (via the null space projection piecewise approach) is nearly identical to the result computed with the slower exact approach. Note that for this problem, the original, simpler piecewise approach also produces very similar results.

becomes more pronounced as k becomes large. For the second method presented (the null space projection), the runtime for a given relative error bound will be in $O(k \log_2(k))$. In practice, both methods have similar runtime on moderate or large problems.

The basic motivation of the first approach described—*i.e.*, the idea of approximating the Chebyshev norm with the largest p^*-norm that can be computed accurately, and then convolving according to this norm using FFT—also suggests further possible avenues of research. For instance, it may be possible to compute a single FFT (rather than an FFT at each of several contours) on a more precise implementation of complex numbers. Such an implementation of complex values could store not only the real and imaginary components, but also other much smaller real and imaginary components that have been accumulated through + operations, even those which have small enough magnitudes that they are dwarfed by other summands. With such an approach it would be possible to numerically approximate the max-convolution result in the same overall runtime as long as only a bounded "history" of such summands was recorded (*i.e.*, if the top few magnitude summands—whether that be the top 7 or the top $\log_2(\log_{1+\tau^{\frac{1}{4}}}(k))$—was stored and operated on). In a similar vein, it would be interesting to investigate the utility of complex values that use rational numbers (rather than fixed-precision floating point values), which will be highly precise, but will increase in precision (and therefore, computational complexity of each arithmetic operation) as the dynamic range between the smallest and largest nonzero values in L and R increases (because taking L' to a large power p^* may produce a very small value). Other simpler improvements could include optimizing the error vs. runtime trade-off between the log-base of the contour search: the method currently searches $\log_2(p^*_{\max})$ contours, but a smaller or larger log-base could be used in order to optimize the trade-off between error and runtime.

It is likely that the best trade-off will occur by performing the fast p^*-norm convolution with a number type that sums values over vast dynamic ranges by appending them in a short (*i.e.*, bounded or constant size) list or tree and sums values within the same dynamic range by querying the list or tree and then summing in at the appropriate magnitude. This is reminiscent of the fast multipole algorithm (Rokhlin, 1985). This would permit the method to use a single large p^* rather than a piecewise approach, by moving the complexity into operations on a single number rather than by performing multiple FFTs with simple floating-point numbers.

The basic motivation of the second approach described—*i.e.*, using the *sequence* of p^*-norms (each computed via FFT) to estimate the maximum value—generalizes the p^*-norm fast convolution numerical approach into an interesting theoretical problem in its own right: given an oracle that delivers a small number of norms (the number of norms retrieved must be $c \in o(k)$ to significantly outperform the naive quadratic approach) about each vector $u^{(m)}$, amalgamate these norms in an efficient manner to estimate the maximum value in each $u^{(m)}$. This method may be applicable to other problems, such as databases where the maximum values of some combinatorial operation (in this case the *maximum a posteriori* distribution of the sum of two random variables $X+Y$) is desired but where caching all possible queries and their maxima would be time or space prohibitive. In a manner reminiscent of how we employ FFT, it may be possible to retrieve moments of the result of some combinatoric combination between distributions on the fly, and then use these moments to approximate true maximum (or, in general, other sought quantities describing the distribution of interest).

In practice, the worst-case relative error of our quadratic approximation is quite low. For example, when $p^* = 8$ is stable, then the relative error is less than 2.3%, regardless of the lengths of the vectors being max-convolved. In contrast, the worst-case relative error using the original piecewise method would be $\leq k^{\frac{1}{16}} - 1$, where k is the length of the max-convolution result (when $n = 1024$, the relative error of the original piecewise method would be $\approx 54\%$).

Of course, the use of the null space projection method is predicated on the existence of at least four sequential p^* points, but it would be possible to use finer spacing between p^* values (*e.g.*, $p^* \in (1, 1.01, 1.02, 1.03)$ to guarantee that this will essentially be the case as long as FFT (*i.e.*, $p^* = 1$) is stable. But more generally, the problem of estimating extrema from p^*-norms (or,

equivalently, from the p^*-th roots of the p^*-th moments of a distribution with bounded support), will undoubtedly permit many more possible approaches that we have not yet considered. One that would be compelling is to relate the Fourier transform of the sequential moments to the maximum value in the distribution; such an approach could permit all stable p^* at any index m to be used to efficiently approximate the maximum value (by computing the FFT of the sequence of norms). Such new adaptations of the method could permit low worst-case error without any noticable runtime increase.

4.1 Multidimensional Numerical Max-Convolution

The fast numerical piecewise method for max-convolution (and the affine piecewise modification) are both applicable to matrices as well as vectors (and, most generally, to tensors of any dimension). This is because the p^*-norm (as well as the derived error bounds as an approximation of the Chebyshev norm) can likewise approximate the maximum element in the tensor $u^{(m_1,m_2,\ldots)}$ generated to find the max-convolution result at index $m_1, m_2, \ldots$ of a multidimensional problem, because the sum

$$\sum_{i_1,i_2,\ldots} \left(u^{(m_1,m_2,\ldots)}_{i_1,i_2,\ldots}\right)^{p^*}$$

computed by convolution corresponds to the Frobenius norm (*i.e.*, the "entrywise norm") of the tensor, and after taking the result of the sum to the power $\frac{1}{p^*}$, will converge to the maximum value in the tensor (if p^* is large enough).

This means that the fast numerical approximation, including the affine piecewise modification, can be used without modification by invoking standard multidimensional convolution (*i.e.*, $*$). Matrix (and, in general, tensor) convolution is likewise possible for any dimension via the row-column algorithm, which transforms the FFT of a matrix into sequential FFTs on each row and column. The accompanying Python code demonstrates the fast numerical max-convolution method on matrices, and the code can be run on tensors of any dimension (without requiring any modification).

The speedup of FFT tensor convolution (relative to naive convolution) becomes considerably higher as the dimension of the tensors increases; for this reason, the speedup of fast numerical max-convolution becomes even more pronounced as the dimension increases. For a tensor of dimension d and width k (*i.e.*, where the index bounds of every dimension are $\in \{0, 1, \ldots k-1\}$), the cost of naive max-convolution will be in $O(k^{2d})$, whereas the cost of numerical max-convolution is $O(k^d \log_2(k))$ (ignoring the $\log_2(\log_{1+\tau^{\frac{1}{4}}}(k)) \leq 18$ multiplier), meaning that there is an $O(\frac{k^d}{d \log_2(k)})$ speedup from the numerical approach. Examples of such tensor problems include graph theory, where adjacency matrix representation can be used to describe respective distances between nodes in a network.

As a concrete example, the demonstration Python code computes the max-convolution between two 256×256 matrices. The naive method required 494 seconds, but the numerical result with the original piecewise method was computed in 3.18 seconds (yielding a maximum absolute error of 0.0173 and a maximum relative error of 0.0511) and the numerical result with the null space projection method was computed in 3.99 seconds (using $p^*_{\max} = 512$, which corresponds to a relative error of $< 0.1\%$ in the top contour, yielding a maximum absolute error of 0.0141 and a maximum relative error of 0.0227) and in 3.05 seconds (using $p^*_{\max} = 64$, which corresponds to a relative error of $< 2.5\%$ in the top contour, yielding a maximum absolute error of 0.0667 and a maximum relative error of 0.067). Not only does the speedup of the proposed methods relative to naive max-convolution increase significantly as the dimension of the tensor is increased, no other faster-than-naive algorithms exist for max-convolution of matrices or tensors.

Multidimensional max-convolution can likewise be applied to hidden Markov models with additive transitions over multidimensional variables (*e.g.*, allowing the latent variable to be a two-dimensional joint distribution of American and German unemployment with a two-dimensional joint transition probability).

4.2 Max-Deconvolution

The same p^*-norm approximation can also be applied to the problem of max-deconvolution (*i.e.*, solving $M = L *_{\max} R$ for R when given M and L). This can be accomplished by computing the ratio of $FFT(M^{p^*})$ to $FFT(L^{p^*})$ (assuming L has already been properly zero-padded), and then computing the inverse FFT of the result to approximate R^{p^*}; however, it should be noted that deconvolution methods are typically less stable than the corresponding convolution methods, computing a ratio is less stable than computing a product (particularly when the denominator is close to zero).

4.3 Amortized Argument for Low MSE of the Affine Piecewise Method

Although the largest absolute error of the affine piecewise method is the same as the largest absolute error of the original piecewise method, the mean squared error (MSE) of the affine piecewise method will be lower than the square of the worst-case absolute error.

To achieve the worst-case absolute error for a given contour the affine correction must be negligible; therefore, there must be two nearly vertical points on the scatter plot of $\|u^{(m_1)}\|_\infty$ vs. $\|u^{(m_1)}\|_{p^*}$, which are both extremes of the bounding envelope from **Figure 3**. Thus, there must exist two different indices m_1 and m_2 with vectors where $\|u^{(m_1)}\|_{p^*} \approx \|u^{(m_1)}\|_\infty$ and where

$$\|u^{(m_2)}\|_{p^*} \approx \|u^{(m_2)}\|_\infty k_{m_2}^{\frac{1}{p^*}}$$

(creating two vertical points on the scatter plot, and forcing that both cannot simultaneously be corrected by a single affine mapping). In order to do this, it is required to have $u^{(m_1)}$ filled with a single nonzero value and for the remaining elements of $u^{(m_1)}$ to equal zero. Conversely, $u^{(m_2)}$ must be filled entirely with large, nonzero values (the largest values possible that would still use the same contour p^*). Together, these two arguments place strong constraints on the vectors L' and R' (and transitively, also constrains the unscaled vectors L and R): On one hand, filling $u^{(m_1)}$ with $k_{m_1} - 1$ zeros requires that $k_{m_1} - 1$ elements from either L or R must be zero (because at least one factor must be zero to achieve a product of zero). On the other hand, filling $u^{(m_2)}$ with all large-value nonzeros requires that k_{m_2} elements of *both* L and R are nonzero. Together, these requirements stipulate that both $k_{m_1} - 1 + k_{m_2} \leq k$, because entries of L and R cannot simultaneously be zero and nonzero. Therefore, in order to have many such vertical points, constrains the lengths of the $u^{(m_1)}, u^{(m_2)}, u^{(m_3)}, \ldots$ vectors corresponding to those points. While the worst-case absolute error bound presumes that an individual vector $u^{(m)}$ may have length k, this will not be possible for many vectors corresponding to vertical points on the scatter plot. For this reason, the MSE will be significantly lower than the square of the worst-case absolute error, because making a high affine-corrected absolute error on one index necessitates that the absolute errors at another index cannot be the worst-case absolute error (if the sizes of L and R are fixed).

5. Availability

Code for exact max-convolution and the fast numerical method (which includes both $\|\cdot\|_{p^*}$ and null space projection methods) is implemented in Python and available at `https://bitbucket.org/orserang/fast-numerical-max-convolution`. All included code works for `numpy` arrays of any dimension, *i.e.*, tensors).

Appendix A. Details on the Projection Method

This appendix establishes a closed-form equation for finding the maximum via the projection method as it is used in the implementation of the algorithm and proves/conjectures an upper/lower bound of its relative error.

A.1 Closed-Form Projection Method for $r = 2$

In general, the computation of both the null space spanning vector $(\gamma_0, \gamma_1, \ldots \gamma_r)$ and of machine-precision approximations for the roots of the polynomial $\gamma_0 + \gamma_1 x + \gamma_2 x^2 + \cdots + \gamma_r x^r$ (which can be approximated by constructing a matrix with that characteristic polynomial and performing eigen-decomposition; Horn and Johnson, 1999) are both in $O(r^3)$ for each index m in the result; however, by using a small $r = 2$, we can compute a closed form solution of both the null space spanning vector and of the resulting quadratic roots. This enables faster exploitation of the curve of norms for estimating the maximum value of $u^{(m)}$ (although it doesn't achieve the high accuracy possible with a much larger $r \approx e$). This is equivalent to approximating $\|u^{(m)}\|_{p^*}^{p^*} \approx h_1 \alpha_1^{p^*} + h_2 \alpha_2^{p^*}$, where $h_1 + h_2 = k_m = len(u^{(m)})$.

In this case, the single spanning vector of the null space of

$$\begin{bmatrix} \|u^{(m)}\|_{p^*}^{p^*} & \|u^{(m)}\|_{2p^*}^{2p^*} & \|u^{(m)}\|_{3p^*}^{3p^*} \\ \|u^{(m)}\|_{2p^*}^{2p^*} & \|u^{(m)}\|_{3p^*}^{3p^*} & \|u^{(m)}\|_{4p^*}^{4p^*} \end{bmatrix}$$

will be

$$\begin{bmatrix} \gamma_0 \\ \gamma_1 \\ \gamma_2 \end{bmatrix} = \begin{bmatrix} \|u^{(m)}\|_{2p^*}^{2p^*} \|u^{(m)}\|_{4p^*}^{4p^*} - \left(\|u^{(m)}\|_{3p^*}^{3p^*}\right)^2 \\ \|u^{(m)}\|_{2p^*}^{2p^*} \|u^{(m)}\|_{3p^*}^{3p^*} - \|u^{(m)}\|_{p^*}^{p^*} \|u^{(m)}\|_{4p^*}^{4p^*} \\ \|u^{(m)}\|_{p^*}^{p^*} \|u^{(m)}\|_{3p^*}^{3p^*} - \left(\|u^{(m)}\|_{2p^*}^{2p^*}\right)^2 \end{bmatrix}$$

and thus $\hat{\alpha} \approx \|u^{(m)}\|_\infty$ can be computed by using the quadratic formula to solve $\gamma_0 + \gamma_1 x + \gamma_2 x^2 = 0$ for x, and computing $\hat{\alpha}$ using the maximum of those zeros: $\hat{\alpha} = x_{\max}^{\frac{1}{p^*}}$. When the quadratic is not well defined, then this indicates that the number of unique elements in $u^{(m)}$ is less than 2, and thus cannot be projected uniquely (*i.e.*, $e_m < r$); in this case, the closed-form linear solution can be used rather than a closed-form quadratic solution:

$$\hat{\alpha} = \left(\frac{\|u^{(m)}\|_{4p^*}^{4p^*}}{\|u^{(m)}\|_{3p^*}^{3p^*}}\right)^{\frac{1}{p^*}}.$$

When the closed-form linear solution is not numerically stable (due to division by a value close to zero), then the p^*-norm approximation can likewise be used.

A.2 Adapted Piecewise Algorithm Using Interleaved p^* Points

Because the norms must have evenly spaced p^* values in order to use the projection method described above, the exponential sequence of p^* values used in the original piecewise algorithm will not contain four evenly spaced points (which are necessary to solve the quadratic formulation, *i.e.*, $r = 2$). One possible solution would be to take the maximal stable value of p^* for any index (which will be a power of two found using the original piecewise method), and then also computing norms (via the FFT, as before) for $p^* - 3\delta, p^* - 2\delta, p^* - \delta, p^*$; however, this will result in a $4\times$ slowdown in the

algorithm, because for every p^*-norm computed via FFT before, now four must be computed. An alternative approach reuses existing values in the 2^i sequence of p^*: for p^* sufficiently large, then the exponential sequence is guaranteed to include these stable p^* values: $\frac{p^*}{4}, \frac{p^*}{2}, p^*$. By considering $\frac{3p^*}{4}$ in p^* candidates, then we can be guaranteed to have four evenly spaced and stable p^* values. This can be achieved easily by noting that

$$\frac{3p^*}{4} = \frac{\frac{p^*}{2} + p^*}{2},$$

meaning that we can insert all possible necessary p^* values for evenly spaced sequences of length four by first computing the exponential sequence of p^* values and then inserting the averages between every pair of adjacent powers of two (and inserting them in a way that maintains the sorted order): $1, 2, 4, 8, 16, \ldots$ becomes $1, 1.5, 2, 3, 4, 6, 8, 12, 16, \ldots$. Thus, if (for some index m) 16 is the highest stable p^* that is a power of two (*i.e.*, the p^* value that would be used by the original piecewise algorithm), then we are guaranteed to use the evenly spaced sequence $4, 8, 12, 16$. By interleaving the powers of two with the averages from the following powers of two, we reduce the number of FFTs to $2\times$ that used by the original piecewise algorithm. For small values of r (such as the $r = 2$ used here), the estimation of the maximum from each sequence of four norms is in $O(4k)$, meaning the total time will still be $k\log(k)\log(\log(k) + 4k \in O(k\log(k)\log(\log(k)))$, which is the same as before. Because the spacing in this formulation is $\frac{p^*}{4}$, and given the maximal root of the quadratic polynomial $\gamma(x_{\max}) = 0$, then $\hat{\alpha} = x_{\max}^{\frac{4}{p^*}}$ (taking the maximal root $x_{\max}$ to the power $\frac{4}{p^*}$ instead of $\frac{1}{p^*}$, which had been the spacing used in the description of the projection method). The null space projection method is shown in **Algorithm 5**.

Algorithm 7 Linear projection of the maximum, using previously computed values est_3, est_4 for two p^* with a difference of *spacing* (estimates given in ascending order of their corresponding p's used). The naming of the variables follows the scheme $est_i = \|u^{(m)}\|_{\frac{i}{4}maxP}$. To prevent numeric instabilities, the algorithm checks for division by zero within a tolerance $\tau_{\text{Div}} = 10^{-10}$ (again, a conservative estimate of the machine precision). The return value is a new estimate of the real maximum.

```
1: procedure MAXLIN(est_3, est_4, spacing)
2:     if |est_3| > τ_Div then
3:         result ← est_4 / est_3
4:     else
5:         result ← est_4
6:     end if
7:     return result^(1.0/spacing)
8: end procedure
```

A.3 Accuracy of the $r = 2$ Projection-Based Method

The full closed-form of the quadratic roots used above (which solve the projection when $r = 2$) will be

Algorithm 8 Quadratic projection of the maximum, using previously computed estimates $est_1, est_2, est_3, est_4$ for four equally spaced p in steps of *spacing* (estimates given in ascending order of their corresponding p's used). The naming of the variables follows the scheme $est_i = \|u^{(m)}\|_{\frac{i}{4}maxP}$. To prevent numeric instabilities, the algorithm checks for division by zero within a tolerance $\tau_{\text{Div}} = 10^{-10}$. The return value is a new estimate of the real maximum.

```
1: procedure MAXQUAD(est_1, est_2, est_3, est_4, spacing)

&\quad \div 2(\|v^{(m)}\|_{2p^*}^{2p^*{}^2} - \|v^{(m)}\|_{1p^*}^{1p^*}\|v^{(m)}\|_{3p^*}^{3p^*})\Big)^{\frac{1}{p^*}}\Big) \\
&= \|u^{(m)}\|_{\infty}\max\Big(\Big(\Big(\|v^{(m)}\|_{2p^*}^{2p^*}\|v^{(m)}\|_{3p^*}^{3p^*} - \|v^{(m)}\|_{1p^*}^{1p^*}\|v^{(m)}\|_{4p^*}^{4p^*} \\
&\quad \pm \Big((\|v^{(m)}\|_{2p^*}^{2p^*}\|v^{(m)}\|_{3p^*}^{3p^*} - \|v^{(m)}\|_{1p^*}^{1p^*}\|v^{(m)}\|_{4p^*}^{4p^*})^2 \\
&\quad - 4\ (\|v^{(m)}\|_{1p^*}^{1p^*}\|v^{(m)}\|_{3p^*}^{3p^*} - \|v^{(m)}\|_{2p^*}^{2p^*{}^2})(\|v^{(m)}\|_{2p^*}^{2p^*}\|v^{(m)}\|_{4p^*}^{4p^*} - \|v^{(m)}\|_{3p^*}^{3p^*{}^2})\Big)^{0.5}\Big) \\
&\quad \div 2(\|v^{(m)}\|_{2p^*}^{2p^*{}^2} - \|v^{(m)}\|_{1p^*}^{1p^*}\|v^{(m)}\|_{3p^*}^{3p^*})\Big)^{\frac{1}{p^*}}\Big)
\end{aligned}
$$

where $p^* = \frac{maxP}{4}$ in the pseudocode (*i.e.*, the maximum numerically stable p^* used by the piecewise algorithm at that index). Note that $\|u^{(m)}\|_{\infty}^{p^*}$ can be factored out because the exponents in every term

in the numerator will be $5p^*$ (*i.e.*, $10p^*$ in the square root). Similarly the terms in the denominator each contain $\|u^{(m)}\|_\infty^{4p^*}$. Factoring out the maximum value is then the same as operating on scaled vectors v (instead of u) with the maximum entry being 1, and at least one element of value 1.

Furthermore, the denominator $2\gamma_2 \geq 0$; even though the terms summed to compute γ_2 are not exclusively nonnegative, symmetry can be used to demonstrate that every negative term is outweighed by a unique corresponding term:

$$\begin{aligned}
\gamma_2 &= \|v^{(m)}\|_1\|v^{(m)}\|_3^3 - \left(\|u^{(m)}\|_{2p^*}^{2p^*}\right)^2 \\
&= \left(\sum_i v_i^{(m)}\right)\left(\sum_i {v_i^{(m)}}^3\right) - \left(\sum_i {v_i^{(m)}}^2\right)^2 \\
&= \sum_{i,j} v_i^{(m)} {v_j^{(m)}}^3 - \sum_{i,j} {v_i^{(m)}}^2 {v_j^{(m)}}^2 \\
&= \sum_{i,j} v_i^{(m)} {v_j^{(m)}}^2 \left(v_j^{(m)} - v_i^{(m)}\right) \\
&= \sum_i v_i^{(m)} {v_i^{(m)}}^2 \left(v_i^{(m)} - v_i^{(m)}\right) + \sum_{i<j} v_i^{(m)} {v_j^{(m)}}^2 \left(v_j^{(m)} - v_i^{(m)}\right) + v_j^{(m)} {v_i^{(m)}}^2 \left(v_i^{(m)} - v_j^{(m)}\right) \\
&= 0 + \sum_{i<j} v_i^{(m)} v_j^{(m)} \left(v_j^{(m)} - v_i^{(m)}\right)\left(v_j^{(m)} - v_i^{(m)}\right) \\
&= \sum_{i<j} v_i^{(m)} v_j^{(m)} \left(v_j^{(m)} - v_i^{(m)}\right)^2 \\
&\geq 0.
\end{aligned}$$

Thus, for well-defined problems (*i.e.*, when $\gamma_2 \neq 0$), the denominator $2\gamma_2 > 0$, and therefore, the maximum root of the quadratic polynomial will correspond to the term that adds (rather than subtracts) the square root term:

$$\begin{aligned}
\hat{\alpha} = \|u^{(m)}\|_\infty \Big(&\Big(\|v^{(m)}\|_{2p^*}^{2p^*} \|v^{(m)}\|_{3p^*}^{3p^*} - \|v^{(m)}\|_{1p^*}^{1p^*} \|v^{(m)}\|_{4p^*}^{4p^*} \\
&+ \Big((\|v^{(m)}\|_{2p^*}^{2p^*} \|v^{(m)}\|_{3p^*}^{3p^*} - \|v^{(m)}\|_{1p^*}^{1p^*} \|v^{(m)}\|_{4p^*}^{4p^*})^2 \\
&- 4 \ (\|v^{(m)}\|_{1p^*}^{1p^*} \|v^{(m)}\|_{3p^*}^{3p^*} - \|v^{(m)}\|_{2p^*}^{2p^{*2}}) (\|v^{(m)}\|_{2p^*}^{2p^*} \|v^{(m)}\|_{4p^*}^{4p^*} - \|v^{(m)}\|_{3p^*}^{3p^{*2}}) \Big)^{0.5} \Big) \\
&\div 2(\|v^{(m)}\|_{2p^*}^{2p^{*2}} - \|v^{(m)}\|_{1p^*}^{1p^*} \|v^{(m)}\|_{3p^*}^{3p^*}) \Big)^{\frac{1}{p^*}} \Big).
\end{aligned}$$

The relative absolute error is defined as $|\frac{\hat{\alpha} - \|u^{(m)}\|_\infty}{\|u^{(m)}\|_\infty}| = |\frac{\hat{\alpha}}{\|u^{(m)}\|_\infty} - 1|$; therefore, a bound on the relative error of the projection method can be established by bounding

$$\begin{aligned}
s(p^*, k_m) = &\frac{\hat{\alpha}}{\|u^{(m)}\|_\infty} \\
= &\Big(\Big(\|v^{(m)}\|_{2p^*}^{2p^*} \|v^{(m)}\|_{3p^*}^{3p^*} - \|v^{(m)}\|_{1p^*}^{1p^*} \|v^{(m)}\|_{4p^*}^{4p^*} \\
&+ \Big((\|v^{(m)}\|_{2p^*}^{2p^*} \|v^{(m)}\|_{3p^*}^{3p^*} - \|v^{(m)}\|_{1p^*}^{1p^*} \|v^{(m)}\|_{4p^*}^{4p^*})^2 \\
&- 4 \ (\|v^{(m)}\|_{1p^*}^{1p^*} \|v^{(m)}\|_{3p^*}^{3p^*} - \|v^{(m)}\|_{2p^*}^{2p^{*2}}) (\|v^{(m)}\|_{2p^*}^{2p^*} \|v^{(m)}\|_{4p^*}^{4p^*} - \|v^{(m)}\|_{3p^*}^{3p^{*2}}) \Big)^{0.5} \Big) \\
&\div 2(\|v^{(m)}\|_{2p^*}^{2p^{*2}} - \|v^{(m)}\|_{1p^*}^{1p^*} \|v^{(m)}\|_{3p^*}^{3p^*}) \Big)^{\frac{1}{p^*}}.
\end{aligned}$$

where the length of the $u^{(m)}$ (respectively $v^{(m)}$) is k_m. Using this reformulation, $s = 1$ indicates a zero-error approximation. This can be rewritten to bound its value before taking to the power $\frac{1}{p^*}$:

$$s(p^*, k_m) = t(p^*, k_m)^{\frac{1}{p^*}}$$

where

$$\begin{aligned}
t(p^*, k_m) = &\Big(\|v^{(m)}\|_{2p^*}^{2p^*} \|v^{(m)}\|_{3p^*}^{3p^*} - \|v^{(m)}\|_{1p^*}^{1p^*} \|v^{(m)}\|_{4p^*}^{4p^*} \\
&+ \Big((\|v^{(m)}\|_{2p^*}^{2p^*} \|v^{(m)}\|_{3p^*}^{3p^*} - \|v^{(m)}\|_{1p^*}^{1p^*} \|v^{(m)}\|_{4p^*}^{4p^*})^2 \\
&- 4 \ (\|v^{(m)}\|_{1p^*}^{1p^*} \|v^{(m)}\|_{3p^*}^{3p^*} - \|v^{(m)}\|_{2p^*}^{2p^{*2}}) (\|v^{(m)}\|_{2p^*}^{2p^*} \|v^{(m)}\|_{4p^*}^{4p^*} - \|v^{(m)}\|_{3p^*}^{3p^{*2}}) \Big)^{0.5} \Big) \\
&\div 2(\|v^{(m)}\|_{2p^*}^{2p^{*2}} - \|v^{(m)}\|_{1p^*}^{1p^*} \|v^{(m)}\|_{3p^*}^{3p^*}).
\end{aligned}$$

The extreme values of $t(p^*, k_m)$ can be found by minimizing and maximizing over the possible values of $v^{(m)} \in V = \{v : [0,1]^{k_m} : \exists i, v_i = 1, \exists j, v_j \in (0,1)\}$. The final constraint on v_j in (0,1) is because any v containing only one unique value (which must be 1 in this case since dividing by the maximum element in $u^{(m)}$ to compute $v^{(m)}$ has divided the value at that index by itself ($\exists i, v_i = 1$) will lead to instabilities. When values in v are identical to one another, using $r = 1$ yields an exact solution, and thus solving with $r = 2$ is not well-defined because $\gamma_2 = 0$. Because all elements ${v^{(m)}}^{p^*} \in [0,1]$ and $p^* \geq 1$, we can perform a change of variables $v_i^{(m)} = {v^{(m)}}_i^{p^*}$, thereby eliminating references to p^*:

$$\begin{aligned}
t(k_m) \geq \min_{v \in \mathbb{R}^{k_m} : \exists i, v_i = 1, \exists j, v_j \in (0,1)} &\Big(\|v^{(m)}\|_2^2 \|v^{(m)}\|_3^3 - \|v^{(m)}\|_1^1 \|v^{(m)}\|_4^4 \\
&+ \Big((\|v^{(m)}\|_2^2 \|v^{(m)}\|_3^3 - \|v^{(m)}\|_1^1 \|v^{(m)}\|_4^4)^2 \\
&- 4 \ (\|v^{(m)}\|_1^1 \|v^{(m)}\|_3^3 - \|v^{(m)}\|_2^{2^2}) (\|v^{(m)}\|_2^2 \|v^{(m)}\|_4^4 - \|v^{(m)}\|_3^{3^2}) \Big)^{0.5} \Big) \\
&\div 2(\|v^{(m)}\|_2^{2^2} - \|v^{(m)}\|_1^1 \|v^{(m)}\|_3^3).
\end{aligned}$$

k_m	3	4	5	6	7
Minimum	0.935537	0.902161	0.895671	0.880487	0.85343
Maximum	1	1	1	1	1

Table 2: **Exact bounds of $t(k_m)$ for short vectors of length k_m.** This table shows the results of numerical minimization techniques performed on the symbolic closed-form of $t(k_m)$ in Mathematica (using `NMinimize`). All $k_m - 1$ entries (excluding the first that was set to 1.0) were left symbolic and constrained to $[0, 1]$, with restriction that the denominator of $t(k_m)$ was nonzero.

k_m	4	64	1024
Minimum ($k_m - 1$ d.o.f.)	0.90221268	0.74942834	0.81858283
Maximum ($k_m - 1$ d.o.f.)	0.99999986	0.92482416	0.86795636
Minimum (vectors of form $(1, a, b, \dots b)$, 2 d.o.f.)	0.90216688	0.75455478	0.71695386
Maximum (vectors of form $(1, a, b, \dots b)$, 2 d.o.f.)	1.00000000	1.0000000	1.00000000

Table 3: **Bounds via random sampling for vectors different in size and type.** This table shows the minimal and maximal values resulting from the evaluation of $t(k_m)$ on 10^5 randomly generated vectors (uniform distribution in $[0, 1]$). The first part shows the result for vectors of potentially unconstrained composition, besides one (w.l.o.g. the first) being set to 1.0. The values in the second half were obtained based on vectors of (supposedly) worst-case composition (*i.e.*, of form $(1, a, b, \dots b)$).

$$
\begin{aligned}
t(k_m) \leq \max_{v \in \mathbb{R}^{k_m} : \exists i, v_i = 1, \exists j, v_j \in (0,1)} & \Big(\|v^{(m)}\|_2^2 \|v^{(m)}\|_3^3 - \|v^{(m)}\|_1^1 \|v^{(m)}\|_4^4 \\
& + \Big((\|v^{(m)}\|_2^2 \|v^{(m)}\|_3^3 - \|v^{(m)}\|_1^1 \|v^{(m)}\|_4^4)^2 \\
& - 4 \ (\|v^{(m)}\|_1^1 \|v^{(m)}\|_3^3 - \|v^{(m)}\|_2^{2^2}) (\|v^{(m)}\|_2^2 \|v^{(m)}\|_4^4 - \|v^{(m)}\|_3^{3^2}) \Big)^{0.5} \Big) \\
& \div 2(\|v^{(m)}\|_2^{2^2} - \|v^{(m)}\|_1^1 \|v^{(m)}\|_3^3).
\end{aligned}
$$

For small vector lengths, the exact bounds of $t(k_m)$ are shown in **Table 2**. Notice that the upper bound is fixed, but the lower bound grows monotonically smaller as k_m, the length of the vector considered, increases. For larger vectors, Mathematica does not find optima in a matter of hours, and for arbitrary-length vectors, the Karush-Kuhn-Tucker criteria do not easily yield minima or maxima; however, we do observe that all maxima are achieved by vectors that are permutations (order does not influence the result) of $v = (1, 1, \dots 1, b, b, \dots b)$ (again, when only two unique values are found in v, the approximation is exact and thus $\frac{\hat{\alpha}}{\|u^{(m)}\|_\infty} = 1$). Likewise, the minima are achieved by permutations of $v = (1, a, b, b, \dots b)$. For this reason, we perform further empirical estimation of the bound by randomly sampling vectors of the form $(1, v_2, v_3, \dots v_{k_m})$ with $k_m - 1$ degrees of freedom (d.o.f.) and sampling vectors of the form $v = (1, a, b, b, \dots b)$ (with 2 d.o.f.), whose extrema are shown in **Table 3**.

At length 64 we see that due to an extreme value scenario, an unconstrained vector scores slightly lower than a vector holding the worst-case pattern $(1, a, b, \dots b)$, because both forms of sampling approach the true lower bound, but one of the unconstrained $k_m - 2$ d.o.f. is slightly closer.

From these results, we conjecture that t is bounded above ≤ 1 (this is achievable at any length k_m by letting v contain exactly two distinct values). In this manner, we achieve our predicted upper bound of 1 regardless of the length k_m. Likewise, we conjecture that at any k_m (not simply the lengths investigated, where this principle is true), the lower bound is given by vectors of the form $(1, a, b, b, \dots b)$. Qualitatively, this conjecture stems from the fact that since the estimate is perfect when v contains exactly two distinct elements, then the worst-case lower bound when v contains three distinct values will concentrate the points at some value far from the other two distinct values. When four distinct values are permitted, then we conjecture that the optimal choice (for minimizing t) of the fourth value will equal the choice for the third distinct value, since that was already determined to be the best point for deceiving the quadratic approximation. From this conjecture, we can then use the fact that the bounds should only grow more extreme as k_m increases, since $\mathbb{R}^1 \subset \mathbb{R}^2 \subset \cdots$ (*i.e.*, lower-dimensional solutions can always be reached in a higher dimension by setting some of the values to 0). Thus the minimum for any possible vector should be conservatively bounded below on vectors of the form $(1, a, b, b, \dots b)$ and is achieved by letting k_m approach ∞:

$$
\lim_{k_m \to \infty} t(k_m) = \frac{a^4 b - a^3 b^2 - a^2 b^3 + \sqrt{b^2 \left(-a^4 + 3a^3 b - 3a^2 b^2 + ab^3 + (b-1)^3\right)^2} + ab^4 + b^4 - b^3 - b^2 + b}{2b\left(a^3 - 2a^2 b + ab^2 + (b-1)^2\right)}.
$$

The minimum value of this expression over all $a \in [0, 1], b \in [0, 1]$ is 0.704 (computed again with Mathematica). Overall, assuming our conjecture regarding the forms of the vectors achieving the minima and maxima, then it follows that $t \in (0.7, 1]$, and the worst-case relative error at the $p^*_{\max}$ contour will be bounded by

$$
|t^{\frac{1}{p^*_{\max}}} - 1| < 1 - 0.7^{\frac{4}{p^*_{\max}}}.
$$

Abstract

In this paper, we propose a novel model for high-dimensional data, called the *Hybrid Orthogonal Projection and Estimation (HOPE)* model, which combines a linear orthogonal projection and a finite mixture model under a unified generative modeling framework. The HOPE model itself can be learned unsupervised from unlabelled data based on the maximum likelihood estimation as well as discriminatively from labelled data. More interestingly, we have shown the proposed HOPE models are closely related to neural networks (NNs) in a sense that each hidden layer can be reformulated as a HOPE model. As a result, the HOPE framework can be used as a novel tool to probe why and how NNs work, more importantly, to learn NNs in either supervised or unsupervised ways. In this work, we have investigated the HOPE framework to learn NNs for several standard tasks, including image recognition on MNIST and speech recognition on TIMIT. Experimental results have shown that the HOPE framework yields significant performance gains over the current state-of-the-art methods in various types of NN learning problems, including unsupervised feature learning, supervised or semi-supervised learning.

Keywords: Orthogonal Projection, PCA, Mixture Models, Neural Networks, Unsupervised Learning, von Mises-Fisher (vMF) model

1. Introduction

Machine learning systems normally consist of several distinct steps in design, namely feature extraction and data modeling. In feature extraction, some engineering tricks are used to pre-process raw data to extract useful and representative features for the underlying data sets. As a result, this stage is sometimes called *feature engineering*. For high-dimensional data, the feature extraction stage needs to distill "good" features that are representative enough to discriminate different data samples but also it has to perform effective dimensionality reduction to generate less correlated features that can be easily modeled in a lower dimensional space. In data modeling, an appropriate model is selected to model data in the lower-dimensional feature space. There are a wide range of models available for this purpose, such as k-Nearest-Neighbours (kNN) methods, decision trees, linear discriminant models, neural networks, statistical models from the exponential family, or mixtures of the exponential family distributions, and so on. Subsequently, all unknown model parameters are estimated from available training samples based on certain learning criterion, such as maximum likelihood estimation (MLE) or discriminative learning.

In many traditional machine learning methods, feature extraction and data modeling are normally conducted independently in two loosely-coupled stages, where feature extraction parameters and model parameters are separately optimized based on rather different criteria. Particularly, feature extraction is normally regarded as a pre-processing stage, where feature extraction parameters are estimated under some quite loose conditions, such as the assumption that data is normally distributed in a high-dimensional space as implied in linear discriminant analysis (LDA) and principal component analysis (PCA). On the other hand, neural networks (NNs) favor an end-to-end learning process, which is normally considered as one exception to the above paradigm. In practice, it has been widely observed that NNs are capable of dealing with almost any type of raw data directly without any explicit feature engineering. In the recent resurgence of NNs in "deep learning", more and more empirical results have demonstrated that deep neural networks (DNNs) can effectively de-correlate high-dimensional raw data and automatically learn useful features from large training sets, without being disturbed by "the curse of dimensionality". However, it still remains as an open question why NNs can handle it and what mechanism is used by NNs to de-correlate high-dimensional raw data to learn good feature representations for many complicated real-world tasks.

In this paper, we first propose a novel data modeling framework for high-dimensional data, namely Hybrid Orthogonal Projection and Estimation (HOPE)(Zhang and Jiang, 2015; Zhang et al., 2015). The key argument for the HOPE framework is that feature extraction and data modeling should not be decoupled into two separate stages in learning since a good feature extraction module can not be learned based on some over-simplified and unrealistic modeling assumptions. The feature extraction and data modeling must be jointly learned and optimized by considering the complex nature of data distributions. This is particularly important in coping with high-dimensional data arising from most real-world applications, such as image, video and speech signals. In the HOPE framework, we propose to model high-dimensional data by combining a relatively simple feature extraction model, namely a linear orthogonal projection, with a powerful statistical model for data modeling, namely a finite mixture model of the exponential family distributions, under a unified generative modeling framework. In this paper, we consider two possible choices for the mixture models, namely Gaussian mixture models (GMMs) and mixtures of the von Mises-Fisher (movMFs) distributions. First of all, an orthogonal linear projection is used in feature extraction to ensure that the highly-correlated high-dimensional raw data is first projected onto a lower-dimensional latent feature space, where all feature dimensions are largely de-correlated. This will facilitate data modeling in this feature space over the original data space. Secondly, in the HOPE framework, we propose to use a powerful model to represent data in the lower-dimensional feature space, rather than using any over-simplified models for computational convenience. This is very important since any real-world data tend to follow a rather complex distribution, which can always be approximated by a finite mixture model

up to any arbitrary precision. Thirdly, the most important argument in HOPE is that both the orthogonal projection and the mixture model must be learned jointly according to a single unified criterion. In this paper, we first study how to learn HOPE in an unsupervised manner based on the conventional maximum likelihood (ML) criterion and also explain that the HOPE models can also be learned in a supervised way based on any discriminative learning criterion.

Another important finding in this work is that the proposed HOPE models are closely related to neural networks (NNs) currently widely used in deep learning. As we will show, any single hidden layer in the most popular rectified linear (ReLU) NNs can always be reformulated as a HOPE model consisting of a linear orthogonal projection and a mixture of von Mises-Fisher distributions (movMFs). This formulation helps to explain how NNs actually deal with high-dimensional data and why NNs can de-correlate almost any types of high-dimensional data to generate good feature representations. More importantly, this formulation may open up new possibilities to learn NNs more effectively. For example, both supervised and unsupervised learning algorithms for the HOPE models can be easily applied to learning NNs. By imposing an explicit orthogonal constraint on the feature extraction layer, we will show that the HOPE methods are very effective in learning NNs for both supervised and unsupervised learning. In unsupervised learning, we have shown that the maximum likelihood (ML) based HOPE learning algorithms can serve as a very effective unsupervised learning method to learn NNs from unlabelled data. Our experimental results have shown that the ML-based HOPE learning algorithm can learn good feature representations in an unsupervised way without using any data labels. These unsupervised learned features may be fed to some simple post-stage classifiers, such as linear SVM, to yield comparable performance as deep NNs supervised learned end-to-end using data labels. Our proposed unsupervised learning algorithms significantly outperform the previous methods based on the Restricted Boltzmann Machine (RBM) (Hinton et al., 2006) and the autoencoder variants (Bengio et al., 2007; Vincent et al., 2008). Moreover, in supervised learning, relying on the HOPE models, we have managed to learn some shallow NNs from scratch, which perform comparably with the state-of-the-art deep neural networks (DNNs), as opposed to learning shallow NNs to mimic a pre-trained deep neural network as in Ba and Caruana (2014). Finally, the HOPE models can also be used to train deep neural networks and it normally provides significant performance gain over the standard NN learning methods. These results have suggested that the orthogonal constraint in HOPE may serve as a good model regularization in learning of NNs.

2. Related Work

Dimensionality reduction in feature space is a well-studied topic in machine learning. Among many, PCA is the most popular technique in this category. PCA is defined as the orthogonal projection of the high-dimensional data onto a lower dimensional linear space, known as the principal subspace, such that the variance of the projected data is maximized (Bishop, 2006). The nice property of PCA is that it can be formulated as an eigenvector problem of the data covariance matrix, where a simple closed-form solution exists. Moreover, in the probabilistic PCA (Tipping and Bishop, 1999a; Roweis, 1998), PCA can be expressed as the maximum likelihood solution to a probabilistic latent variable model. In this case, if

the projected data are assumed to follow a zero-mean unit-covariance Gaussian distribution in the principal subspace, the probabilistic PCA can also be solved by an exact closed-form solution related to the eigenvectors of the data covariance matrix. The major limitation of PCA is that it is constrained to learn a linear subspace. Many approaches have been proposed to perform nonlinear dimension reduction to learn possible nonlinear manifolds embedded within a high dimensional data space. One way to model the nonlinear structure is through a combination of linear models, so that we make a piece-wise linear approximation to the manifold. This can be obtained by a clustering technique to partition the data set into local groups with standard PCA applied to each group. (see Hinton et al., 1997; Kambhatla and Leen, 1997; Tipping and Bishop, 1999b). In mixtures of probabilistic PCA (Tipping and Bishop, 1999b), the high-dimensional raw data is assumed to follow a mixture model, where each component may perform its own maximum likelihood PCA in a local region. However, in these methods, it may be quite challenging to perform effective clustering or estimate good mixture models for high-dimensional data due to the strong correlation in various data dimensions. Alternatively, a flexible nonlinear method is proposed to reduce feature dimension based on a deep auto-associative neural network (Hinton and Salakhutdinov, 2006).

Similar to PCA, the Fisher's linear discriminant analysis (LDA) can also be viewed as a linear dimensionality reduction technique. However, PCA is unsupervised in the sense that PCA depends only on the data while Fisher's LDA is supervised since it uses both data and class-label information. The high-dimensional data are linearly projected to a subspace where various classes are best distinguished as measured by the Fisher criterion. Moreover, the so-called heteroscedastic discriminant analysis (HLDA) (Kumar and Andreou, 1998) is proposed to extend LDA to deal with high-dimensional data with heteroscedastic covariance, where a linear projection can be learned from data and class labels based on the maximum likelihood criterion. On the other hand, in the independent component analysis (ICA) methods (Hyvarinen and Oja, 2000), it assumes the latent features follow a fully factorized non-Gaussian distribution, where non-Gaussianity is critical to distinguish independent components in the latent space based on the mixed observations from the original data space. In this paper, we make a more general assumption on the distributions in the latent feature space, which are only factorized between the signal and noise components.

Recently, many deep learning approaches have been proposed to capture complex data distributions, such as Restricted Boltzmann Machine (RBM) (Hinton et al., 2006) and the autoencoder variants (Bengio et al., 2007; Vincent et al., 2008). In the so-called independent factor analysis (Attias, 1999) and variational auto-encoders (Kingma and Welling, 2014; Rezende et al., 2014), a variational Bayes approach is adopted to model the joint distribution of the observed data and latent features, leading to a variational lower-bound of the data likelihood function, which can be maximized in model learning. On the contrary, in this paper, we take a rather different approach to model the data distribution, where the observed data and the latent features are viewed as two sets of random variables that are linked by a deterministic transformation. In this way, we may derive a much simpler formulation that allows us to directly maximize the data likelihood function without using sampling and variational approximation. A simple case of two classes was studied for a one-dimension feature space in an earlier work (Hinton and Nowlan, 1990). Moreover, relying on an orthogonal constraint, we may further simplify the computation of the underlying

Jacobian matrix. Note that a different trick, namely the triangular structure constraint, is used to simplify the way to compute the determinants of the Jacobian matrices (see Dinh et al., 2015; Oord and Dambre, 2015).

3. Hybrid Orthogonal Projection and Estimation (HOPE)

Consider a standard PCA setting, where each data sample is represented as a high-dimensional vector $\mathbf{x}$ with dimensionality D. Our goal is to learn a linear projection, represented as a matrix $\mathbf{U}$, to map each data sample onto a space having dimensionality $M < D$, which is called the latent feature space hereafter in this paper. Our proposed HOPE model is essentially a generative model in nature but it may also be viewed as a generalization to extend the probabilistic PCA in Tipping and Bishop (1999a) to consider a complex data distribution that has to be modeled by a finite mixture model in the latent feature space. This setting is very different from Tipping and Bishop (1999b), where the original data $\mathbf{x}$ is modeled by mixture models in the original higher D-dimensional raw data space.

3.1 HOPE: Combining Generalized PCA with Generative Model

Assume we have a full-size $D \times D$ orthogonal matrix $\hat{\mathbf{U}}$, satisfying $\hat{\mathbf{U}}^T\hat{\mathbf{U}} = \hat{\mathbf{U}}\hat{\mathbf{U}}^T = \mathbf{I}$, each data sample $\mathbf{x}$ in the original D-dimensional data space can be decomposed based on all orthogonal row vectors of $\hat{\mathbf{U}}$, denoted as $\mathbf{u}_i$ with $i = 1, \cdots, D$, as follows:

$$\mathbf{x} = \sum_{i=1}^{D} (\mathbf{x} \cdot \mathbf{u}_i)\, \mathbf{u}_i. \tag{1}$$

As shown in PCA, each high-dimensional data $\mathbf{x}$ can normally be represented fairly precisely in a lower-dimensional principal subspace and the contributions from the remaining dimensions may be viewed as random residual noises that have sufficiently small variances. Therefore, we have

$$\mathbf{x} = \underbrace{(\mathbf{x} \cdot \mathbf{u}_1)\, \mathbf{u}_1 + \cdots + (\mathbf{x} \cdot \mathbf{u}_M)\, \mathbf{u}_M}_{signal\ \ component\ \ \tilde{\mathbf{x}}} + \underbrace{(\mathbf{x} \cdot \mathbf{u}_{M+1})\, \mathbf{u}_{M+1} + \cdots + (\mathbf{x} \cdot \mathbf{u}_D)\, \mathbf{u}_D}_{noise\ \ component\ \ \bar{\mathbf{x}}} \tag{2}$$

Here we are interested in learning an $M \times D$ projection matrix, denoted as $\mathbf{U}$, to extract the signal component $\tilde{\mathbf{x}}$. First of all, if M ($M < D$) is selected properly, the projection may serve as an effective feature extraction for signals as well as a mechanism to eliminate unwanted noises from the higher dimensional raw data. This may make the subsequent learning process more robust and less prone to overfitting. Secondly, all M row vectors $\mathbf{u}_i$ with $i = 1, \cdots, M$ are learned to represent signals well in a lower M-dimension space. Furthermore, since all $\mathbf{u}_i$ are orthogonal, it implies the latent features are largely de-correlated. This will significantly simplify the following learning problem as well.

In this case, each D-dimension data sample, $\mathbf{x}$, is linearly projected onto an M-dimension vector $\mathbf{z}$ as $\mathbf{z} = \mathbf{U}\mathbf{x}$, where $\mathbf{U}$ is an orthogonal matrix, satisfying $\mathbf{U}\mathbf{U}^T = \mathbf{I}$. Meanwhile, we denote the projection of the unwanted noise component $\bar{\mathbf{x}}$ as $\mathbf{n}$, and $\mathbf{n}$ can be similarly computed as $\mathbf{n} = \mathbf{V}\mathbf{x}$, where $\mathbf{V}$ is another orthogonal matrix corresponding to all noise dimensions, satisfying $\mathbf{V}\mathbf{V}^T = \mathbf{I}$. Moreover, $\mathbf{V}$ is orthogonal to $\mathbf{U}$, i.e. $\mathbf{V}\mathbf{U}^T = \mathbf{0}$. In overall, we may represent the above projection as follows:

$$\big[\mathbf{z};\ \mathbf{n}\big] = \big[\mathbf{U};\ \mathbf{V}\big]\mathbf{x} = \hat{\mathbf{U}}\mathbf{x} \tag{3}$$

where $\hat{\mathbf{U}}$ is the above-mentioned $D \times D$ orthogonal projection matrix.

Moreover, it is straightforward to show that the signal component $\tilde{\mathbf{x}}$ and the residual noise $\bar{\mathbf{x}}$ in the original data space can be easily computed from the above projections as follows:

$$\tilde{\mathbf{x}} = \mathbf{U}^T\mathbf{z} = \mathbf{U}^T\mathbf{U}\mathbf{x} \tag{4}$$

$$\bar{\mathbf{x}} = \mathbf{x} - \tilde{\mathbf{x}} = (\mathbf{I} - \mathbf{U}^T\mathbf{U})\mathbf{x} \tag{5}$$

In the following, we consider how to learn the projection matrix $\mathbf{U}$ to represent D-dimensional data well in a lower M-dimension feature space. If this projection is learned properly, we may assume the above signal projection, $\mathbf{z}$, and the residual noise projection, $\mathbf{n}$, are independent in the latent feature space. Therefore, we may derive the probability distribution of the original data as follows:

$$p(\mathbf{x}) = |\hat{\mathbf{U}}^{-1}| \cdot p(\mathbf{z}) \cdot p(\mathbf{n}) \tag{6}$$

where $\hat{\mathbf{U}}^{-1}$ denotes the Jacobian matrix to linearly map the data from the projected space back to the original data space. If $\hat{\mathbf{U}}$ is orthonormal, the above Jacobian term equals to one. In this work, we follow Tipping and Bishop (1999a) to assume the residual noise projection $\mathbf{n}$ follows an isotropic covariance Gaussian distribution in the (D-M)-dimensional space, i.e. $p(\mathbf{n}) \sim \mathcal{N}(\mathbf{n} \mid \mathbf{0}, \sigma^2\mathbf{I})$, [1] where σ^2 is a variance parameter to be learned from data. As for the signal projection $\mathbf{z}$, we adopt a quite different approach, as described below in detail.

In all previous works, the signal projection $\mathbf{z}$ is assumed to follow a simple distribution in the M-dimension space. For example, $\mathbf{z}$ is assumed to follow a zero-mean unit-covariance Gaussian distribution in probabilistic PCA (Tipping and Bishop, 1999a; Roweis, 1998). The advantage of this assumption is that an exact closed-form solution may be derived to calculate the projection matrix $\mathbf{U}$ using the spectral methods based on the data covariance matrix.

However, in most real-world applications, $\mathbf{z}$ is still located in a very high-dimensional space even after the linear projection, it does not make sense to assume $\mathbf{z}$ follows a simple unimodal distribution. As widely reported in the literature, it is empirically observed that real-world data normally do not follow a unimodal distribution in a high-dimensional space and they usually appear only in multiple concentrated regions in the high-dimensional space. More realistically, it is better to assume that $\mathbf{z}$ follows a finite mixture model in the M-dimension feature space because a finite mixture model may theoretically approximate any arbitrary statistical distribution as long as a sufficiently large number of mixture components are used. For simplicity, we may assume $\mathbf{z}$ follows a finite mixture of some exponential family distributions:

$$p(\mathbf{z}) = \sum_{k=1}^{K} \pi_k \cdot f_k(\mathbf{z}|\boldsymbol{\theta}_k) \tag{7}$$

1. Without losing generality, we may simply normalize the training data to ensure that the residual noises have zero mean.

where π_k denotes mixture weights with $\sum_{k=1}^{K} \pi_k = 1$, and $f_k(\mathbf{z}|\boldsymbol{\theta}_k)$ stands for a unimodal distribution from the exponential family with model parameters $\boldsymbol{\theta}_k$. We use $\boldsymbol{\Theta}$ to denote all model parameters in the mixture model, i.e., $\boldsymbol{\Theta} = \{\boldsymbol{\theta}_k, \pi_k \mid k = 1, \cdots, K\}$. In practice, $f_k(\mathbf{z}|\boldsymbol{\theta}_k)$ is chosen from the exponential family based on the nature of data. In this paper, we consider two possible choices for high-dimensional continuous data, namely the multivariate Gaussian distributions and the von Mises-Fisher (vMF) distributions. The learning algorithm can be easily extended to other models in the exponential family.

For example, if we choose the multivariate Gaussian distribution, then $\mathbf{z}$ follows a Gaussian mixture model (GMM) as follows:

$$p(\mathbf{z}) = \sum_{k=1}^{K} \pi_k \cdot f_k(\mathbf{z}|\boldsymbol{\theta}_k) = \sum_{k=1}^{K} \pi_k \cdot \mathcal{N}(\mathbf{z} \mid \boldsymbol{\mu}_k, \Sigma_k) \tag{8}$$

where $\mathcal{N}(\mathbf{z} \mid \boldsymbol{\mu}_k, \Sigma_k)$ denotes a multivariate Gaussian distribution with the mean vector $\boldsymbol{\mu}_k$ and the covariance matrix Σ_k. Since the projection matrix $\mathbf{U}$ is orthogonal, all dimensions in $\mathbf{z}$ are highly de-correlated. Therefore, it is reasonable to assume each Gaussian component has a diagonal covariance matrix Σ_k. This may significantly simplify the model estimation of GMMs.

Alternatively, we may select a less popular model, i.e., the von Mises-Fisher (vMF) distribution.[2] The vMF distribution may be viewed as a generalized normal distribution defined on a high-dimensional spherical surface. In this case, $\mathbf{z}$ follows a mixture of the von Mises-Fisher (movMF) distributions as follows:

$$p(\mathbf{z}) = \sum_{k=1}^{K} \pi_k \cdot f_k(\mathbf{z}|\boldsymbol{\theta}_k) = \sum_{k=1}^{K} \pi_k \cdot \mathcal{C}_M(|\boldsymbol{\mu}_k|) \cdot e^{\mathbf{z} \cdot \boldsymbol{\mu}_k} \tag{9}$$

where $\mathbf{z}$ is located on the surface of an M-dimensional sphere, i.e., $|\mathbf{z}| = 1$, $\boldsymbol{\mu}_k$ denotes all model parameters of the k-th vMF component and it is an M-dimensional vector in this case, and $\mathcal{C}_M(\kappa)$ is the probability normalization term of the k-th vMF component defined as:

$$\mathcal{C}_M(\kappa) = \frac{\kappa^{M/2-1}}{(2\pi)^{M/2} I_{M/2-1}(\kappa)} \tag{10}$$

where $I_v(\cdot)$ denotes the modified Bessel function of the first kind at order v.

4. Unsupervised Learning of HOPE Models

Obviously, the HOPE model is essentially a generative model that combines feature extraction and data modelling together, and thus its model parameters, including both the projection matrix and the mixture model, can be estimated based on the maximum likelihood (ML) criterion, just like normal generative models as well as the probabilistic PCA in Tipping and Bishop (1999a). However, since $\mathbf{z}$ follows a mixture distribution, no closed-form solution is available to derive either the projection matrix or the mixture model. In

2. The main reason why we are interested in the von Mises-Fisher (vMF) distributions is that the choice of the vMF model can strictly link our HOPE model to regular neural networks in deep learning. We will elucidate this later in this paper.

this case, some iterative optimization algorithms, such as stochastic gradient descent (SGD) (Bottou, 2004), may be used to jointly estimate both the projection matrix $\mathbf{U}$ and the underlying mixture model altogether to maximize a joint likelihood function. In this section, we assume the projection matrices, not only $\mathbf{U}$ but also the whole $\hat{\mathbf{U}}$, are all orthonormal. As a result, the Jacobian term in eq.(6) disappears since it equals to one. Refer to Appendix A for the case where $\mathbf{U}$ is not orthonormal.

Given a training set as $\mathbf{X} = \{\mathbf{x}_n \mid n = 1, \cdots, N\}$, assume that all $\mathbf{x}_n$ are normalized to be of unit length as $|\mathbf{x}_n| = 1$, the joint log-likelihood function related to all HOPE parameters, including the projection matrix $\mathbf{U}$, the mixture model $\boldsymbol{\Theta} = \{\boldsymbol{\theta}_k | k = 1, \cdots, K\}$ and residual noise variance σ, can be expressed as follows:

$$\begin{aligned} \mathcal{L}(\mathbf{U}, \boldsymbol{\Theta}, \sigma \mid \mathbf{X}) &= \sum_{n=1}^{N} \ln \Pr(\mathbf{x}_n) = \sum_{n=1}^{N} \Big[\ln \Pr(\mathbf{z}_n) + \ln \Pr(\mathbf{n}_n) \Big] \\ &= \underbrace{\sum_{n=1}^{N} \ln \left(\sum_{k=1}^{K} \pi_k \cdot f_k(\mathbf{U}\mathbf{x}_n|\boldsymbol{\theta}_k) \right)}_{\mathcal{L}_1(\mathbf{U},\boldsymbol{\Theta})} + \underbrace{\sum_{n=1}^{N} \ln \Big(\mathcal{N}\big(\mathbf{n}_n \,|\, \mathbf{0}, \sigma^2 \mathbf{I}\big) \Big)}_{\mathcal{L}_2(\mathbf{U},\sigma)} \end{aligned} \tag{11}$$

The HOPE parameters, including $\mathbf{U}$, $\boldsymbol{\Theta}$ and σ, can all be estimated by maximizing the above likelihood function as:

$$\{\mathbf{U}^*, \boldsymbol{\Theta}^*, \sigma^*\} = \arg\max_{\mathbf{U},\boldsymbol{\Theta},\sigma} \quad \mathcal{L}(\mathbf{U}, \boldsymbol{\Theta}, \sigma \mid \mathbf{X}) \tag{12}$$

subject to the orthogonal constraint:

$$\mathbf{U}\mathbf{U}^T = \mathbf{I}. \tag{13}$$

There are many methods to enforce the above orthogonal constraint in the optimization. For example, we may periodically apply the Gram-Schmidt process in linear algebra to orthogonalize $\mathbf{U}$ during the optimization process. In this work, for computational efficiency, we follow Bao et al. (2013, 2012) to cast the orthogonal constraint condition in eq.(13) as a penalty term in the objective function to convert the above constrained optimization problem into an unconstrained one as follows:

$$\{\mathbf{U}^*, \boldsymbol{\Theta}^*, \sigma^*\} = \arg\max_{\mathbf{U},\boldsymbol{\Theta},\sigma} \quad \Big[\mathcal{L}(\mathbf{U}, \boldsymbol{\Theta}, \sigma \mid \mathbf{X}) - \beta \cdot \mathcal{D}(\mathbf{U}) \Big] \tag{14}$$

where β ($\beta > 0$) is a control parameter to balance the contribution of the penalty term, and the penalty term $\mathcal{D}(\mathbf{U})$ is a differentiable function as:

$$\mathcal{D}(\mathbf{U}) = \sum_{i=1}^{M} \sum_{j=i+1}^{M} \frac{|\mathbf{u}_i \cdot \mathbf{u}_j|}{|\mathbf{u}_i| \cdot |\mathbf{u}_j|} \tag{15}$$

with $\mathbf{u}_i$ denoting the i-th row vector of the projection matrix $\mathbf{U}$, and $\mathbf{u}_i \cdot \mathbf{u}_j$ representing the inner product of $\mathbf{u}_i$ and $\mathbf{u}_j$. The norms of all row vectors of $\mathbf{U}$ need to be normalized to one after each update.

In this work, we propose to use the stochastic gradient descent (SGD) method to optimize the objective function in eq.(14). In this case, given any training data or a mini-batch of them, we calculate the gradients of the objective function with respect to the projection matrix, $\mathbf{U}$, and the parameters of the mixture model, $\mathbf{\Theta}$, and then update them iteratively until the objective function converges. The gradients of $\mathcal{L}_1(\mathbf{U}, \mathbf{\Theta})$ depends on the mixture model to be used. In the following, we first consider how to compute the derivatives of $\mathcal{D}(\mathbf{U})$ and $\mathcal{L}_2(\mathbf{U}, \sigma)$, which are general for all HOPE models. After that, as two examples, we will show how to calculate the derivatives of $\mathcal{L}_1(\mathbf{U}, \mathbf{\Theta})$ for GMMs and movMFs.

4.1 Dealing with the Penalty Term $\mathcal{D}(\mathbf{U})$

Following Bao et al. (2013), the gradients of the penalty term $\mathcal{D}(\mathbf{U})$ with respect to each row vector, $\mathbf{u}_i$ $(i = 1, \cdots, M)$, can be easily derived as follows:

$$\frac{\partial \mathcal{D}(\mathbf{U})}{\partial \mathbf{u}_i} = \sum_{j=1}^{M} \; g_{ij} \cdot \left[\frac{\mathbf{u}_j}{\mathbf{u}_i \cdot \mathbf{u}_j} - \frac{\mathbf{u}_i}{\mathbf{u}_i \cdot \mathbf{u}_i} \right] \tag{16}$$

where g_{ij} denotes the absolute cosine value of the angle between two row vectors, $\mathbf{u}_i$ and $\mathbf{u}_j$, computed as follows:

$$g_{ij} = \frac{|\mathbf{u}_i \cdot \mathbf{u}_j|}{|\mathbf{u}_i| \cdot |\mathbf{u}_j|}. \tag{17}$$

The above derivatives can be equivalently represented as the following matrix form:

$$\frac{\partial \mathcal{D}(\mathbf{U})}{\partial \mathbf{U}} = (\mathbf{D} - \mathbf{B})\mathbf{U} \tag{18}$$

where $\mathbf{D}$ is an $M \times M$ matrix, with its elements computed as $d_{ij} = \frac{\text{sign}(\mathbf{u}_i \cdot \mathbf{u}_j)}{|\mathbf{u}_i| \cdot |\mathbf{u}_j|}$ $(1 \leq i, j \leq M)$, and $\mathbf{B}$ is an $M \times M$ diagonal matrix, with its diagonal elements computed as $b_{ii} = \frac{\sum_{j=1} g_{ij}}{\mathbf{u}_i \cdot \mathbf{u}_i}$ $(1 \leq i \leq M)$.

4.2 Dealing with the Noise Model Term $\mathcal{L}_2$

The log-likelihood function related to the noise model, $\mathcal{L}_2(\mathbf{U}, \sigma)$, can be expressed as:

$$\mathcal{L}_2(\mathbf{U}, \sigma) = -\frac{N(D-M)}{2} \ln(\sigma^2) - \frac{1}{2\sigma^2} \sum_{n=1}^{N} \mathbf{n}_n^T \mathbf{n}_n. \tag{19}$$

And we have:

$$\begin{aligned} \mathbf{n}_n^T \mathbf{n}_n &= (\mathbf{x}_n - \mathbf{U}^T \mathbf{z}_n)^T (\mathbf{x}_n - \mathbf{U}^T \mathbf{z}_n) = (\mathbf{x}_n - \mathbf{U}^T \mathbf{U} \mathbf{x}_n)^T (\mathbf{x}_n - \mathbf{U}^T \mathbf{U} \mathbf{x}_n) \\ &= \mathbf{x}_n^T \mathbf{x}_n - 2\mathbf{x}_n^T \mathbf{U}^T \mathbf{U} \mathbf{x}_n + \mathbf{x}_n^T \mathbf{U}^T \mathbf{U} \mathbf{U}^T \mathbf{U} \mathbf{x}_n \end{aligned} \tag{20}$$

Therefore, $\mathcal{L}_2(\mathbf{U}, \sigma)$ can be expressed as:

$$\mathcal{L}_2(\mathbf{U}, \sigma) = -\frac{N(D-M)}{2} \ln(\sigma^2) - \frac{1}{2\sigma^2} \sum_{n=1}^{N} \left[\mathbf{x}_n^T \mathbf{x}_n - 2\mathbf{x}_n^T \mathbf{U}^T \mathbf{U} \mathbf{x}_n + \mathbf{x}_n^T \mathbf{U}^T \mathbf{U} \mathbf{U}^T \mathbf{U} \mathbf{x}_n \right] \tag{21}$$

The gradient with respect to $\mathbf{U}$ [3] can be derived as follows:

$$\begin{aligned} \frac{\partial \mathcal{L}_2(\mathbf{U}, \sigma)}{\partial \mathbf{U}} &= \frac{1}{\sigma^2} \sum_{n=1}^{N} \left[2\mathbf{U}\mathbf{x}_n\mathbf{x}_n^T - \mathbf{U}\mathbf{U}^T\mathbf{U}\mathbf{x}_n\mathbf{x}_n^T - \mathbf{U}\mathbf{x}_n\mathbf{x}_n^T\mathbf{U}^T\mathbf{U} \right] \\ &= \frac{1}{\sigma^2} \sum_{n=1}^{N} \mathbf{U} \left[\mathbf{x}_n(\bar{\mathbf{x}}_n)^T + \bar{\mathbf{x}}_n(\mathbf{x}_n)^T \right]. \end{aligned} \tag{22}$$

For the noise variance σ^2, we can easily derive the following closed-form update formula by vanishing its derivative to zero:

$$\sigma^2 = \frac{1}{N(D-M)} \sum_{n=1}^{N} \mathbf{n}_n^T \mathbf{n}_n \tag{23}$$

As long as the learned noise variance σ^2 is small enough, maximizing the above term $\mathcal{L}_2$ will force all signal dimensions into the projection matrix $\mathbf{U}$ and only the residual noises will be modelled by $\mathcal{L}_2$.

4.3 Computing $\mathcal{L}_1$ for GMMs

In this section, we consider how to compute the partial derivatives of $\mathcal{L}_1(\mathbf{U}, \mathbf{\Theta})$ for GMMs. Assume each mini-batch $\mathbf{X}$ consists of a small subset of randomly selected training samples, $\mathbf{X} = \{\mathbf{x}_n \mid n = 1, \cdots, N\}$, the log likelihood function of HOPE models with GMMs can be represented as follows:

$$\mathcal{L}_1(\mathbf{U}, \mathbf{\Theta}) = \sum_{n=1}^{N} \; \ln \left[\sum_{k=1}^{K} \pi_k \cdot \mathcal{N}(\mathbf{U}\mathbf{x}_n \mid \boldsymbol{\mu}_k, \Sigma_k) \right] \tag{24}$$

The partial derivative of $\mathcal{L}_1(\mathbf{U}, \mathbf{\Theta})$ w.r.t the mean vector, $\boldsymbol{\mu}_k$, of the k-th Gaussian component can be calculated as follows:

$$\frac{\partial \mathcal{L}_1(\mathbf{U}, \mathbf{\Theta})}{\partial \boldsymbol{\mu}_k} = \sum_{n=1}^{N} \gamma_k(\mathbf{z}_n) \cdot \Sigma_k^{-1}(\mathbf{z}_n - \boldsymbol{\mu}_k) \tag{25}$$

where $\mathbf{z}_n = \mathbf{U}\mathbf{x}_n$, and $\gamma_k(\mathbf{z}_n)$ denotes the so-called occupancy statistics of the k-th Gaussian component, computed as $\gamma_k(\mathbf{z}_n) = \frac{\pi_k \mathcal{N}(\mathbf{z}_n | \boldsymbol{\mu}_k, \Sigma_k)}{\sum_{j=1}^{K} \pi_j \mathcal{N}(\mathbf{z}_n | \boldsymbol{\mu}_j, \Sigma_j)}$.

The partial derivative of $\mathcal{L}_1(\mathbf{U}, \mathbf{\Theta})$ w.r.t π_k can be simply derived as follows:

$$\frac{\partial \mathcal{L}_1(\mathbf{U}, \mathbf{\Theta})}{\partial \pi_k} = \sum_{n=1}^{N} \; \frac{\gamma_k(\mathbf{z}_n)}{\pi_k} \tag{26}$$

3. We may use the constraint $\mathbf{U}\mathbf{U}^T = \mathbf{I}$ to significantly simplify the above derivation. However, that leads to a gradient computation strongly relying on the orthogonal constraint. Since we use SGD to iteratively optimize all model parameters, including $\mathbf{U}$. We can not ensure $\mathbf{U}\mathbf{U}^T = \mathbf{I}$ strictly holds anytime in the SGD process. Therefore, the simplified gradient usually yields poor convergence performance.

The partial derivative of $\mathcal{L}_1(\mathbf{U}, \boldsymbol{\Theta})$ w.r.t the Σ_k is computed as follows:

$$\frac{\partial \mathcal{L}_1(\mathbf{U}, \boldsymbol{\Theta})}{\partial \Sigma_k} = -\frac{1}{2} \sum_{n=1}^{N} \gamma_k(\mathbf{z}_n) \Big[\Sigma_k^{-1} - \Sigma_k^{-1} (\mathbf{z}_n - \boldsymbol{\mu}_k)(\mathbf{z}_n - \boldsymbol{\mu}_k)^T \Sigma_k^{-1} \Big]. \tag{27}$$

When we use the above gradients to update Gaussian covariance matrices in SGD, we have to impose additional constraints to ensure all covariance matrices are positive semidefinite. However, if we adopt diagonal covariance matrices for all Gaussian components, these constraints can be implemented in a fairly simple way.

Finally, the partial derivative of $\mathcal{L}_1(\mathbf{U}, \boldsymbol{\Theta})$ w.r.t the projection matrix $\mathbf{U}$ is computed as:

$$\frac{\partial \mathcal{L}_1(\mathbf{U}, \boldsymbol{\Theta})}{\partial \mathbf{U}} = \sum_{n=1}^{N} \sum_{k=1}^{K} \gamma_k(\mathbf{z}_n) \cdot \Sigma_k^{-1} (\boldsymbol{\mu}_k - \mathbf{z}_n) \mathbf{x}_n^T. \tag{28}$$

4.4 Computing $\mathcal{L}_1$ for movMFs

Similarly, we derive all partial derivatives of $\mathcal{L}_1(\mathbf{U}, \boldsymbol{\Theta})$ for a mixture of vMFs (movMFs). In this case, given a mini-batch of training samples, $\mathbf{X} = \{\mathbf{x}_n \mid n = 1, \cdots, N\}$, the log-likelihood function of the HOPE model with movMFs can be expressed as follows:

$$\mathcal{L}_1(\mathbf{U}, \boldsymbol{\Theta}) = \sum_{n=1}^{N} \ \ln \left[\sum_{k=1}^{K} \pi_k \cdot \mathcal{C}_M(|\boldsymbol{\mu}_k|) \cdot e^{\mathbf{z}_n \cdot \boldsymbol{\mu}_k} \right] \tag{29}$$

where each $\mathbf{z}_n$ must be normalized to be of unit length [4] as required by the vMF distribution as:

$$\tilde{\mathbf{z}}_n = \mathbf{U}\mathbf{x}_n, \quad \mathbf{z}_n = \frac{\tilde{\mathbf{z}}_n}{|\tilde{\mathbf{z}}_n|}. \tag{30}$$

Similar to the HOPE models with GMMs, we first define an occupancy statistic for k-th vMF component as:

$$\gamma_k(\mathbf{z}_n) = \frac{\pi_k \cdot \mathcal{C}_M(|\boldsymbol{\mu}_k|) \cdot e^{\mathbf{z}_n \cdot \boldsymbol{\mu}_k}}{\sum_{j=1}^{K} \pi_j \cdot \mathcal{C}_M(|\boldsymbol{\mu}_j|) \cdot e^{\mathbf{z}_n \cdot \boldsymbol{\mu}_j}}. \tag{31}$$

In a similar way, we can derive the partial derivatives of $\mathcal{L}_1(\mathbf{U}, \boldsymbol{\Theta})$ with respect to π_k, $\boldsymbol{\mu}_k$ and $\mathbf{U}$ as follows:

$$\frac{\partial \mathcal{L}_1(\mathbf{U}, \boldsymbol{\Theta})}{\partial \pi_k} = \sum_{n=1}^{N} \frac{\gamma_k(\mathbf{z}_n)}{\pi_k} \tag{32}$$

$$\frac{\partial \mathcal{L}_1(\mathbf{U}, \boldsymbol{\Theta})}{\partial \boldsymbol{\mu}_k} = \sum_{n=1}^{N} \ \gamma_k(\mathbf{z}_n) \cdot \left[\mathbf{z}_n - \frac{\boldsymbol{\mu}_k}{|\boldsymbol{\mu}_k|} \cdot \frac{I_{M/2}(|\boldsymbol{\mu}_k|)}{I_{M/2-1}(|\boldsymbol{\mu}_k|)} \right] \tag{33}$$

4. In practice, we usually normalize all original data, $\mathbf{x}_n$, to be of unit length: $|\mathbf{x}_n| = 1$, prior to the HOPE model. In this case, as long as M is properly chosen (e.g., to be large enough), the projection matrix $\mathbf{U}$ is always learned to extract from $\mathbf{x}_n$ as much energy as possible. Therefore, this normalization step may be skipped because the norm of the projected $\mathbf{z}_n$ is always very close to one even without normalization in this stage, i.e., $|\mathbf{z}_n| = |\tilde{\mathbf{z}}_n| \approx 1$.

Refer to Appendix B for all details on how to derive the above derivatives for the movMF distributions. Moreover, when movMFs are used, we need some special treatments to compute the Bessel functions in vMFs, i.e, $I_v(\cdot)$, as shown in eqs.(31) and (33). In this work, we adopt the numerical method in Abramowitz and Stegun (2006) to approximate the Bessel functions, refer to the Appendix C for the numerical details on this.

4.5 The SGD-based Learning Algorithm

Because all mixture weights, π_k $(k = 1, \cdots K)$, and all row vectors, $\mathbf{u}_i$ $(i = 1, \cdots, M)$ of the projection matrix satisfy the constraints: $\sum_k^K \pi_k = 1$ and $|\mathbf{u}_j| = 1$ $(\forall j)$. During the SGD learning process, π_k and $\mathbf{u}_i$ must be normalized after each update as follows:

$$\pi_k \leftarrow \frac{\pi_k}{\sum_j \pi_j} \tag{35}$$

$$\mathbf{u}_i \leftarrow \frac{\mathbf{u}_i}{|\mathbf{u}_i|}. \tag{36}$$

Finally, we summarize the SGD algorithm to learn the HOPE models based on the maximum likelihood (ML) criterion in Algorithm 1.

5. Learning Neural Networks as HOPE

As described above, the HOPE model may be used as a novel model for high-dimensional data. The HOPE model itself can be efficiently learned in an unsupervised manner from unlabelled data based on the above-mentioned maximum likelihood criterion. Moreover, if data labels are available, a variety of discriminative training methods (see Jiang, 2010; Jiang and Li, 2010; Jiang et al., 2015) may be used to learn the HOPE model in a supervised way based on some other discriminative learning criteria.

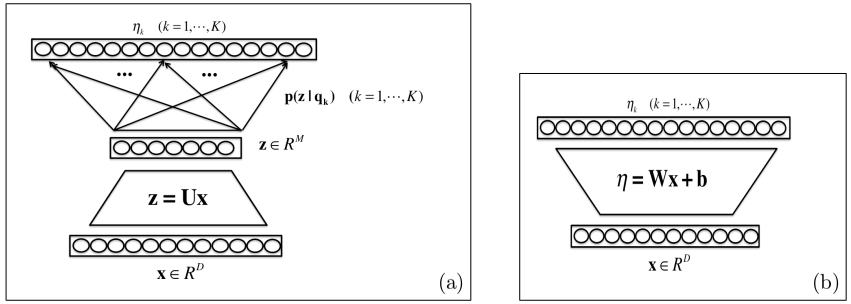

Figure 1: Illustration of a HOPE model as a layered network structure in (a). It may be equivalently reformulated as a hidden layer in neural nets shown in (b).

More interestingly, as we will elucidate here, there exists strong relationship between the HOPE models and neural networks (NNs). First of all, we will show that the HOPE models may be used as a new tool to probe the mechanism why NNs work so well in practice. Under the new HOPE framework, we may explain why NNs can almost universally excel on a variety of data types and how NNs handle various types of highly-correlated high-dimensional data, which may be quite challenging to many other machine learning models. Secondly, more importantly, the HOPE framework provides us with some new approaches to learn NNs: (i) Unsupervised learning: the maximum likelihood estimation of HOPE may be directly applied to learn NNs from unlabelled data; (ii) Supervised learning: the HOPE framework can be incorporated into the normal supervised learning of NNs by explicitly imposing some orthogonal constraints in learning. This may improve the learning of NNs and yield better and more compact models.

5.1 Linking HOPE to Neural Networks

A HOPE model normally consists of two stages: i) a linear orthogonal projection from the raw data space to the latent feature space; ii) a generative model defined as a finite mixture model in the latent feature. As a result, we may depict every HOPE model as a two-layer network: a linear projection layer and a nonlinear model layer, as shown in Figure 1 (a). The first layer represents the linear orthogonal projection from $\mathbf{x}$ ($\mathbf{x} \in \mathbf{R}^D$) to $\mathbf{z}$ ($\mathbf{z} \in \mathbf{R}^M$): $\mathbf{z} = \mathbf{U}\mathbf{x}$. The second layer represents the underlying finite mixture model in the feature space. Taking movMFs as an example, each node in the model layer represents the log-likelihood contribution from one mixture component as follows:

$$\phi_k = \ln\left(\pi_k \cdot f_k(\mathbf{z}|\boldsymbol{\theta}_k)\right) = \ln \pi_k + \ln \mathcal{C}_M(|\boldsymbol{\mu}_k|) + \mathbf{z} \cdot \boldsymbol{\mu}_k. \tag{37}$$

Given an input $\mathbf{x}$ (assuming $\mathbf{x}$ is projected to $\mathbf{z}$ in the latent feature space), if we know all ϕ_k ($1 \le k \le K$) in the model layer, we can easily compute the log-likelihood value of $\mathbf{x}$

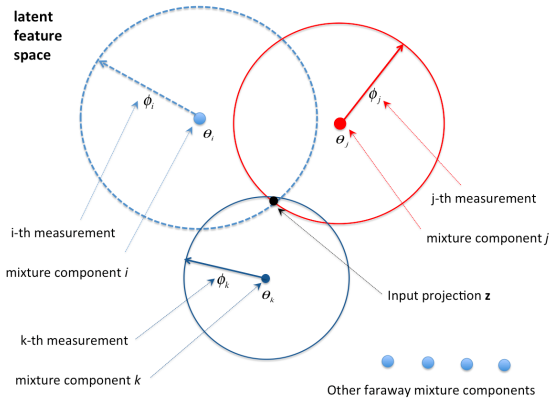

Figure 2: Illustration of the HOPE features as trilateration in the latent feature space.

from the HOPE model in eq.(9) as follows:

$$\ln p(\mathbf{z}) = \ln \sum_{k=1}^{K} \exp(\phi_k). \tag{38}$$

Moreover, all ϕ_k ($1 \le k \le K$) may be used as a set of distance measurements to locate the input projection, $\mathbf{z}$, in the latent space as *trilateration*, shown in Figure 2. Therefore, all ϕ_k ($1 \le k \le K$) may be viewed as a set of features to distinctly represent the original input $\mathbf{x}$.

Furthermore, we may use a preset threshold ε to prune the raw measurements, ϕ_k ($1 \le k \le K$), as follows:

$$\eta_k = \max(0, \phi_k - \varepsilon) \tag{39}$$

to eliminate those small log likelihood values from some faraway mixture components. Pruning small log-likelihood values as above may result in several benefits. Firstly, this pruning operation does not affect the total likelihood from the mixture model because it is always dominated by only a few top components. Therefore, we have:

$$\ln p(\mathbf{z}) \approx \varepsilon + \ln \sum_{k=1}^{K} \exp(\eta_k).$$

Secondly, this pruning step does not affect the trilateration problem in Figure 2. This is similar to the Global Positioning System (GPS) where the weak signals from faraway satellites are not used for localization. More importantly, the above pruning operation may improve robustness of the features since these small log-likelihood values may become very noisy. Note that the above pruning operation is similar to the rectified linear nonlinearity

in regular ReLU neural networks. Here we give a more intuitive explanation for the popular ReLU operation under the HOPE framework.

In this way, as shown in Figure 1 (a), all rectified log likelihood values in the model layer, i.e., η_k $(1 \leq k \leq K)$, may be viewed as a sensory map to measure each input, $\mathbf{x}$, in the latent feature space using all mixture components as the probers. Each pixel in the map, i.e., a pruned measurement η_k, roughly tells the distance between the centroid of a mixture component and the input projection $\mathbf{z}$ in the latent feature space. Under some condition (e.g., $K \gg M$), the input projection can be precisely located based on these pruned η_k values as a trilateration problem in the M-dimensional feature space, as shown in Figure 2. Therefore, this sensory map may be viewed as a feature representation learned to represent the input $\mathbf{x}$, which may be fed to a *softmax* classifier to form a normal shallow neural network, or to another HOPE model to form a deep neural network.

Moreover, since the projection layer is linear, it can be mathematically combined with the upper model layer to generate a single layer structure, as shown in Figure 1 (b). If movMFs are used in HOPE, it is equivalent to a hidden layer in normal rectified linear (ReLU) neural networks.[5] And the weight matrix in the merged layer can be simply derived from the HOPE model parameters, $\mathbf{U}$ and $\mathbf{\Theta}$. It is simple to show that the weight vectors for each hidden node k $(1 \leq k \leq K)$ in Figure 1 (b) may be derived as

$$\mathbf{w}_k = \mathbf{U}^T \boldsymbol{\mu}_k$$

and its bias is computed as

$$b_k = \ln \pi_k + \ln \mathcal{C}_M(|\boldsymbol{\mu}_k|) - \varepsilon.$$

Even though the linear projection layer may be merged with the model layer after all model parameters are learned, it may be beneficial to keep them separate during the model learning process. In this way, the model capacity may be controlled by two distinct control parameters: i) M can be selected properly to filter out noise components as in eq.(2) to prevent overfitting in learning; ii) K may be chosen independently to ensure the model is complex enough to model very big data sets for more difficult tasks. Moreover, we may enforce the orthogonal constraint, i.e., $\mathbf{U}\mathbf{U}^T = \mathbf{I}$, during the model learning to ensure that all dimensions of $\mathbf{z}$ are mostly de-correlated in the latent feature space, which may significantly simplify the density estimation in the feature space using a finite mixture model.

The formulation in Figure 1 (a) helps to explain the underlying mechanism of how neural networks work. Under the HOPE framework, it becomes clear that each hidden layer in neural networks may actually perform two different tasks implicitly, namely feature extraction and data modeling. This may shed some light on why neural nets can directly deal with various types of highly-correlated high-dimensional data (Pan et al., 2012) without any explicit dimensionality reduction and feature de-correlation steps.

Based on the above discussion, a HOPE model is mathematically equivalent to a hidden layer in neural networks. For example, each movMF HOPE model can be collapsed into a single weight matrix, same as a hidden layer of ReLU NNs. On the contrary, any weight

5. On the other hand, if GMMs are used in HOPE, it can be similarly shown that it is equivalent to a hidden layer in Radial basis function (RBF) networks (Park and Sandberg, 1991).

matrix in ReLU NNs may be decomposed as a product of two matrices as in Figure 1 (a) as long as M is not less than the rank of the weight matrix. In practice, we may deliberately choose a smaller value for M to regularize the models. Under this formulation, it is clear that neural networks may be trained under the HOPE framework. There are several advantages to learn neural networks under the HOPE framework. First of all, the modelling capacity of neural networks may be explicitly controlled by selecting proper values for M and K, each of which is chosen for a different purpose. Secondly, we can easily apply the maximum likelihood estimation of HOPE models in section 4 to unsupervised or semi-supervised learning to learn NNs from unlabelled data. Thirdly, the useful orthogonal constraints may be incorporated into the normal back-propagation process to learn better NN models in supervised learning as well.

5.2 Unsupervised Learning of Neural Networks as HOPE

The maximum likelihood estimation method for HOPE in section 4 can be used to learn neural networks layer by layer in an unsupervised learning mode. All HOPE model parameters in Figure 1 (a) are first estimated based on the maximum likelihood criterion as in section 4. Next, the two layers in the HOPE model are merged to form a regular NN hidden layer as in Figure 1 (b). In this case, class labels are not required to learn all network weights and neural networks can be learned from unlabelled data under a theoretically solid framework. This is similar to the Hebbian style learning (Rolls and Treves, 1998) but it has a well-founded and converging objective function in learning. As described above, the rectified log-likelihood values from the HOPE model, i.e., η_k $(1 \leq k \leq K)$, may be viewed as a sensory map using all mixture components as the probers in the latent feature space, which may serve as a good feature representation for the original data. At the end, a small amount of labelled data may be used to learn a simple classifier, either a *softmax* layer or a linear support vector machine (SVM), on the top of the HOPE layers, which takes the sensory map as input for final classification or prediction.

In unsupervised learning, the learned orthogonal projection matrix $\mathbf{U}$ may be viewed as a generalized PCA, which performs dimensionality reduction by considering the complex distribution modeled by a finite mixture model in the latent feature space.

5.3 Supervised Learning of Neural Networks as HOPE

The HOPE framework can also be applied to the supervised learning of neural networks when data labels are available. Let us take ReLU neural networks as example, each hidden layer in a ReLU neural network, as shown in Figure 1 (b), may be viewed as a HOPE model and thus it can be decomposed as a combination of a projection layer and a model layer, as shown in Figure 1 (a). In this case, M needs to be chosen properly to avoid overfitting. In other words, each hidden layer in ReLU NNs is represented as two layers during learning, namely a linear projection layer and a nonlinear model layer. If data labels are available, as in Jiang and Li (2010); Jiang et al. (2015), instead of using the maximum likelihood criterion, we may use other discriminative training criteria (Jiang, 2010) to form the objective function to learn all network parameters. Let us take the popular minimum cross-entropy error criterion as an example, given a training set of the input data and the class labels, i.e., $\mathbf{X} = \{\mathbf{x}_t, l_t \mid 1 \leq t \leq T\}$, we may use the HOPE outputs, i.e., all η_k in

eq.(39) to form the cross-entropy objective function as follows:

$$\mathcal{F}_{CE}(\mathbf{U}, \boldsymbol{\mu}_k, b_k \mid \mathbf{X}) = -\sum_{t=1}^{T} \log \left[\frac{\exp\left(\eta_{l_t}(\mathbf{x}_t)\right)}{\sum_{k=1}^{K} \exp\left(\eta_k(\mathbf{x}_t)\right)} \right] \tag{40}$$

Obviously, the standard back-propagation algorithm may be used to optimize the above objective function to learn all decomposed HOPE model parameters end-to-end, including $\mathbf{U}$, $\{\boldsymbol{\mu}_k, b_k \mid 1 \leq k \leq K\}$ from all HOPE layers. The only difference is that the orthogonal constraints, as in eq.(13), must be imposed for all projection layers during training, where the derivatives in eq.(18) must be incorporated in the standard back-propagation process to update each projection matrix $\mathbf{U}$ to ensure it is orthonormal. Note that in the supervised learning based on a discriminative training criterion, the unit-length normalization of the data projections in eq.(30) can be relaxed for computational simplicity since this normalization is only important for computing the likelihood for pure probabilistic models. After the learning, each pair of projection and model layers may be merged into a single hidden layer. After merging, the resultant network remains the exactly same network structure as normal ReLU neural networks. This learning method is related to the well-known low-rank matrix factorization method used for training deep NNs in speech recognition (Sainath et al., 2013; Xue et al., 2013). However, since we impose the orthogonal constraints for all projection matrices during the training process, it may lead to more compact models and/or better performance.

In supervised learning, the learned orthogonal projection matrix $\mathbf{U}$ may be viewed as a generalized LDA or HLDA (Kumar and Andreou, 1998), which optimizes the data projection to maximize (or minimize) the underlying discriminative learning criterion.

5.4 HOPE for Deep Learning

As above, the HOPE framework can be used to learn rather strong shallow NN models. However, this does not hinder HOPE from building deeper models for deep learning. As shown in Figure 3, we may have two different structures to learn very deep neural networks under the HOPE framework. In Figure 3 (a), one HOPE model is used as the first layer primarily for feature extraction and a deep neural network is concatenated on top of it as a powerful classifier to form a deep structure. The deep model in Figure 3 (a) may be learned in either supervised or semi-unsupervised mode. In semi-unsupervised learning, the HOPE model is learned based on the maximum likelihood estimation and the upper deep NN is learned in a supervised way. Alternatively, if we have enough labelled data, we may jointly learn both HOPE and DNN in a supervised mode. In Figure 3 (b), we may even stack multiple HOPE models to form another deep model structure. In this case, each HOPE model generates a sensory feature map in each HOPE layer. Just like all pixels in a normal image, all thresholded log-likelihood values in the sensory feature map are also highly correlated, especially for those mixture components locating relatively close by in the feature space. Thus, it makes sense to add another HOPE model on top of it to de-correlate features and perform data modeling at a finer granularity. The deep HOPE model structures in Figure 3 (b) can also be learned in an either supervised or unsupervised mode. In unsupervised learning, these HOPE layers are learned layer-wise using the maximum likelihood estimation. In supervised learning, all HOPE layers are

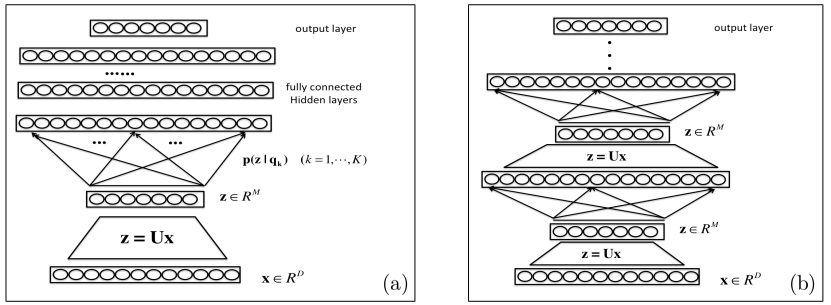

Figure 3: Two structures to learn deep networks with HOPE: (a) Stacking a DNN on top of one HOPE layer; (b) Stacking multiple HOPE layers.

learned by back-propagation with orthonormal constraints being imposed on all projection layers.

6. Experiments

In this section, we will investigate the proposed HOPE framework in learning neural networks for several standard image and speech recognition tasks under several different learning conditions: i) unsupervised feature learning; ii) supervised learning; iii) semi-supervised learning. The examined tasks include the image recognition tasks using the MNIST data set, and the speech recognition task using the TIMIT data set.

6.1 MNIST: Image Recognition

The MNIST data set (LeCun et al., 1998) consists of 28×28 pixel greyscale images of handwritten digits 0-9, with 60,000 training and 10,000 test examples. In our experiments, we first evaluate the performance of unsupervised feature learning using the HOPE model with movMFs. Secondly, we investigate the performance of supervised learning of DNNs under the HOPE framework, and further study the effect of the orthogonal constraint in the HOPE framework. Finally, we consider a semi-supervised learning scenario with the HOPE models, where all training samples (without labels) are used to learn feature representation unsupervised and then a portion of training data (along with labels) is used to learn post-stage classification models in a supervised way. [6]

6.1.1 Unsupervised Feature Learning on MNIST

In this experiment, we first randomly extract many small patches from the original unlabelled training images on MNIST. Each patch is of 6-by-6 in dimension, represented as a vector in $\mathbb{R}^D$, with $D = 36$. In this work, we randomly extract 400,000 patches in total

6. Matlab codes are available at `https://wiki.eecs.yorku.ca/lab/MLL/projects:hope:start` for readers to reproduce all MNIST results reported in this paper.

from the MNIST training set for unsupervised feature learning. Moreover, every patch is normalized by subtracting the mean and being divided by the standard deviation of its elements.

In unsupervised feature learning, we follow the same experimental setting in Coates et al. (2011), where an unsupervised learning algorithm is used to learn a "black box" feature extractor to map each input vector in $\mathbb{R}^D$ to another K-dimension feature vector. In this work, we have examined several different unsupervised learning algorithms for feature learning: (i) kmeans clustering; (ii) spherical kmeans (spkmeans) clustering; (iii) mixture of vMF (movMF), (iv) PCA based dimension reduction plus movMF (PCA-movMF); and (v) the HOPE model with movMFs (HOPE-movMF). As for *kmeans* and *spkmeans*, the only difference is that different distance measures are used in clustering: *kmeans* uses the Euclidean distance while *spkmeans* uses the cosine distance. As for the movMF model, we can use the expectation maximization (EM) algorithm for estimation, as described in Banerjee et al. (2005). In the following, we briefly summarize the experimental details for these feature extractors.

1. **kmeans**: We first apply the k-means clustering method to learn K centroids $\boldsymbol{\mu}_k$ from all extracted patch input vectors. For each learned centroid $\boldsymbol{\mu}_k$, we use a soft threshold function to compute each feature as: $f_k(x) = \max(0, |\mathbf{x} - \boldsymbol{\mu}^k| - \varepsilon)$, where ε is a pre-set threshold. In this way, we may generate a K-dimension feature vector for each patch.

2. **spkmeans**: As for the spk-means clustering, we need to normalize all input patch vectors to be of unit length before clustering them into K different centroids based on the cosine distance measure. Given each learned centroid $\boldsymbol{\mu}_k$, we can compute each feature as $f_k(x) = \max(0, \mathbf{x}^T \boldsymbol{\mu}_k - \varepsilon)$.

3. **movMF**: We also need to normalize all input patch vectors to be of unit length. We use the EM algorithm to learn all model parameters $\boldsymbol{\mu}_k$. For each learned centroid $\boldsymbol{\mu}_k$ of the movMF model, we compute one feature as $f_k(x) = \max\big(0, \ln(\pi_k) + \ln(\mathcal{C}_N(|\boldsymbol{\mu}_k|)) + \mathbf{x}^T \boldsymbol{\mu}_k - \varepsilon\big)$.

4. **PCA-movMF**: Comparing to movMF, the only difference is that we first use PCA for dimensionality reduction, reducing all input patch vectors from $\mathbb{R}^D$ to $\mathbb{R}^M$. Then, we use the same method to estimate an movMF model for the reduced D-dimension feature vectors. In this experiment, we set $M = 20$ to reserve 99.5% of the total sum of all eigenvalues in PCA. For each learned vMF model $\boldsymbol{\mu}_k$, we compute one feature as $f_k(x) = \max\big(0, \ln(\pi_k) + \ln(\mathcal{C}_N(|\boldsymbol{\mu}_k|)) + \mathbf{z}^T \boldsymbol{\mu}_k - \varepsilon\big)$.

5. **HOPE-movMF**: We use the maximum likelihood estimation method described in section 4 to learn a HOPE model with movMFs. For each learned vMF component, we can compute one feature as $f_k(x) = \max(0, \ln(\pi_k) + \ln(\mathcal{C}_M(|\boldsymbol{\mu}_k|)) + \tilde{\mathbf{z}} \cdot \boldsymbol{\mu}_k - \varepsilon)$. Similar to PCA-movMF, we also set $M = 20$ here.

Furthermore, since HOPE-movMF is learned using SGD, we need to tune some hyper-parameters for HOPE, such as the learning rate, mini-batch size, β and σ^2. In this work, the learning rate is set to 0.002, minibatch size is set to 100, we set $\beta = 1.0$, and the noise variance is manually set to $\sigma^2 = 0.1$ for convenience.

model / K=	400	800	1200	1600
kmeans	1.41	1.31	1.16	1.13
spkmeans	1.09	0.90	0.86	0.81
movMF	0.89	0.82	0.81	0.84
PCA-movMF	0.87	0.75	0.73	0.74
HOPE-movMF	0.76	0.71	**0.64**	0.67

Table 1: Classification error rates (in %) on the MNIST test set using supervised learned linear SVMs as classifiers and unsupervised learned features (4K-dimension) from different models.

After learning the above models, they are used as feature extractors. We use the same method as described in Coates et al. (2011) to generate a feature representation for each MNIST image, where each feature extractor is convolving over an MNIST image to obtain the feature representations for all local patches in the image. Next, we split the image into four equally-sized quadrants and the feature vectors in each quadrant are all summed up to pool as one feature vector. In this way, we can get a $4K$-dimensional feature vector for each MNIST image, where K is the number of all learned features for each patch. Finally, we use these pooled $4K$-dimension feature vectors for all training images, along with the labels, to estimate a simple linear SVM as a post-stage classifier for image classification. The experimental results are shown in Table 1. We can see that *spkmeans* and *movMF* can achieve much better performance than *kmeans*. The PCA-based dimension reduction leads to further performance gain. Finally, the jointly trained HOPE model with movMFs yields the best performance, e.g., 0.64% in classification error rate when $K = 1200$. This is a very strong performance for unsupervised feature learning on MNIST.

6.1.2 Supervised Learning of Neural Networks as HOPE on MNIST

In this experiment, we use the MNIST data set to examine the supervised learning of rectified linear (ReLU) neural networks under the HOPE framework, as discussed in section 5.3.

Here we follow the normalized initialization in Glorot and Bengio (2010) to randomly initialize all NN weights, without using pre-training. We adopt a small modification to the method in Glorot and Bengio (2010) by adding a factor to control the dynamic range of initial weights as follows:

$$W_i \sim \left[-\gamma \cdot \frac{\sqrt{6}}{\sqrt{n_i + n_{i+1}}}, \gamma \cdot \frac{\sqrt{6}}{\sqrt{n_i + n_{i+1}}} \right] \tag{41}$$

where n_i denotes the number of units in the i-th layer. For the ReLU units, due to the unbounded behavior of the activation function, activations of ReLU units might grow unbounded. To handle this numerical problem, we shrink the dynamic range of initial weights by using a small factor γ ($\gamma = 0.5$), which is equivalent to scaling the activations.

We use SGD to train ReLU neural networks using the following learning schedule:

$$\epsilon^t = \epsilon_0 \cdot \alpha^t \tag{42}$$

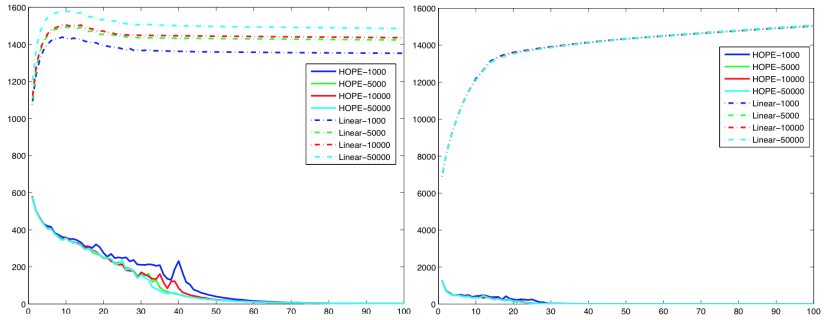

Figure 4: The learning curves of the total sum of correlation coefficients of the linear projection and orthogonal HOPE projection matrices, respectively. left: M=200, K=1k,5k,10k,50k; right: M=400, K=1k,5k,10k,50k.

$$m^t = \begin{cases} \frac{t}{T} m_f + (1 - \frac{t}{T}) m_i & t < T \\ m_f & t \geq T \end{cases} \tag{43}$$

where ϵ^t and m^t denote the learning rate and momentum for the t-th epoch, and we set all control parameters as $m_i = 0.5, m_f = 0.99, \alpha = 0.998$. In total, we run $T = 50$ epochs for learning without dropout and run $T = 500$ epochs for learning with dropout. Moreover, the weight decay is used here and it is set to 0.00001. Furthermore, for the HOPE model, the control parameter for the orthogonal constraint, β, is set to 0.01 in all experiments. In this work, we do not use any data augmentation method.

Under the HOPE framework, we decompose each ReLU hidden layer into two layers as in Figure 1 (a). In this experiment, we first examine the supervised learning of NNs with or without imposing the orthogonal constraints to all projection layers. Firstly, we investigate the performance of a neural network containing only a single hidden layer, decomposed into a pair of a linear projection layer and a nonlinear model layer. Here we evaluate neural networks with a different number of hidden units (K) and a varying size of the projection layer (M). From the experimental results shown in Table. 2, we can see that the HOPE-trained NN can achieve much better performance than the baseline NN, especially when smaller values are used for M. This supports that the projection layer may eliminate residual noises in data to avoid over-fitting when M is properly set. However, after we relax the orthogonal constraint in the HOPE model, as shown in Table 2, the performance of the models using only linear projection layers gets much worse than those of the HOPE models as well as that of the baseline NN. These results verify that orthogonal projection layers are critical in the HOPE models. Furthermore, in Figure. 4, we have plotted the learning curves of the total sum of all correlation coefficients among all row vectors in the learned projection matrix $\mathbf{U}$, i.e., $\sum_{i \neq j} \frac{|\mathbf{u}_i \cdot \mathbf{u}_j|}{|\mathbf{u}_i||\mathbf{u}_j|}$. We can see that all projection vectors tend

Linear3: 784-(400-K)-10	1.53	1.52	1.49	1.52	1.49

Table 2: Classification error rates (in %) on the MNIST test set using a shallow NN with one hidden layer of different hidden units. Neither dropout nor data augmentation is used here for a quick turnaround. Two numbers in brackets, $[M, K]$, indicate a HOPE model with the orthogonal constraint in the projection, and two number in parentheses, (M, K), indicate the same model structure without imposing the orthogonal constraint in the projection.

to get strongly correlated (especially when M is large) in the linear projection matrix as the learning proceeds. On the other hand, the orthogonal constraint can effectively de-correlate all the projection vectors. Moreover, we show all correlation coefficients, i.e., $\frac{|\mathbf{u}_i \cdot \mathbf{u}_j|}{|\mathbf{u}_i||\mathbf{u}_j|}$, of the linear projection matrix and the HOPE orthogonal projection matrix as two images in Figure 5, which clearly shows that the linear projection matrix has many strongly correlated dimensions and the HOPE projection matrix is (as expected) orthogonal.

As the MNIST training set is very small, we use the dropout technique (Hinton et al., 2012; Srivastava et al., 2014) to improve the model learning on the MNIST task. In this experiment, the visible dropout probability is set to 20% and the hidden layer dropout

Net Architecture / K=	1k	2k	5k
NN baseline: 784-K-10	1.05	1.01	1.01
HOPE1: 784-[200-K]-10	0.99	**0.85**	0.89
HOPE2: 784-[400-K]-10	0.86	0.86	**0.85**

Table 3: Comparison of classification error rates (in %) on the MNIST test set between a shallow NN and two HOPE-trained NNs with the same model structure. Dropout is used in this experiment.

model	Net Architecture	without dropout	with dropout
DNN baseline	784-1200-1200-10	1.25	0.92
HOPE + NN	784-[400-1200]-1200-10	0.99	0.82
HOPE*2	784-[400-1200]-[400-1200]-10	0.97	**0.81**

Table 4: Comparison of classification error rates (in %) on the MNIST test set between a 2-hidden-layer DNN and two HOPE-trained DNNs with similar model structures, with or without using dropout.

probability is set to 30%. In Table 3, we compare a 1-hidden-layer shallow NN with two HOPE models (M=200,400). The results show that the HOPE framework can significantly improve supervised learning of NNs. Under the HOPE framework, we can train very simple shallow neural networks from scratch, which can yield comparable performance as deep models. For example, on the MNIST task, as shown in Table 3, we may achieve 0.85% in classification error rate using a shallow neural network (with only one hidden layer of 2000 nodes) trained under the HOPE framework. Furthermore, we consider building even deeper models (two-hidden-layer NNs) under the HOPE framework. Using the two different structures in Figure 3, we can further improve the classification error rate to 0.81%, as shown in Table. 4. This is a very strong result reported on MNIST without using CNNs and data augmentation.

6.1.3 Semi-supervised Learning on MNIST

In this experiment, we combine the unsupervised feature learning with supervised model learning and examine the classification performance when only limited labelled data is available. Here we also list the results using convolutional deep belief networks (CDBN) (Lee et al., 2009) and ladder networks (Rasmus et al., 2015) as two baseline systems for comparison. In our experiments, we use the raw pixel features and unsupervised learned (USL) features in section 6.1.1. As example, we choose the unsupervised learned features from the HOPE-movMF model ($K = 800$) in Table 1.[7] Next, we concatenate the features to a post-stage classifier, which is supervised trained using only a portion of the training data, ranging from 1000 to 60000 (all). We consider many different types of classifiers here,

7. For the HOPE-movMF model with $K = 800$, there are 115 empty clusters. Thus, the unsupervised learned features are of 2740 in dimension.

labeled training samples	1000	2000	5000	10000	20000	60000(ALL)
CDBN(Lee et al., 2009)	2.62	2.13	1.59	-	-	0.82
Ladder network (Rasmus et al., 2015)	1.07	-	-	-	-	0.61
Raw feature+DNN1	8.32	4.71	3.2	2.15	1.48	0.92
Raw feature+HOPE-DNN1	8.22	4.53	2.92	2.04	1.34	0.86
Raw feature+HOPE-DNN2	7.21	4.02	2.60	1.83	1.30	0.82
USL feature+linear SVM	2.91	2.38	1.47	1.13	0.90	0.71
USL feature+DNN2	2.83	1.99	1.03	0.88	0.70	0.43
USL feature+HOPE-DNN3	2.50	1.78	0.95	0.87	0.67	0.42
USL feature+HOPE-DNN4	2.46	1.70	0.90	0.79	0.66	**0.40**

Table 5: Classification error rates (in %) on the MNIST test set using raw pixel features or unsupervised learned features, along with different post-stage classifiers trained separately by limited labeled data. Here USL denotes the unsupervised learned features from HOPE-movMF ($K = 800$). All used classifiers include: DNN1 (784-1200-1200-10); HOPE-DNN1 (784-[400-1200]-10); HOPE-DNN2 (784-[400-1200]-1200-10); DNN2 (2740-1200-1200-10); HOPE-DNN3 (2740-[400-1200]-10); HOPE-DNN4 (784-[400-1200]-1200-10).

including linear SVM, regular DNNs and HOPE-trained DNNs. Note that all classifiers are trained separately from the feature learning. All results are summarized in Table 5. It shows that we can achieve the best performance when we combine the HOPE-trained USL features with HOPE-trained post-stage classifiers. The gains are quite dramatic no matter how much labelled data is used. For example, when only 5000 labelled samples are used, our method can achieve 0.90% in error rate, which significantly outperforms all other methods including CDBN in Lee et al. (2009). The ladder network in (Rasmus et al., 2015) yields better performance when only 1000 labels are used. However, Rasmus et al. (2015) adopts a much larger model than ours. It involves three different modules of distortion, denoising and classification. Each module uses a 6-hidden-layer structure. Moreover, in our semi-supervised experiments, we do not fine-tune the feature extraction module with any supervision signals from labels. Finally, as we use all training data for the HOPE model, we can achieve 0.40% in error rate, which significantly outperforms both CDBN and ladder networks. To the best of our knowledge, this is one of the best results reported on MNIST without using CNNs and data augmentation. Furthermore, our best system uses a quite simple model structure, consisting of a HOPE-trained feature extraction layer of 800 nodes and a HOPE-trained NN of two hidden layers (1200 node in each layer), which is much smaller and simpler than those top-performing systems on MNIST.

6.2 TIMIT: Speech Recognition

In this experiment, we examine the supervised learning of shallow and deep neural networks under the HOPE framework for a standard speech recognition task using the TIMIT data set. The HOPE-based supervised learning method is compared with the regular back-propagation training method. We use the minimum cross-entropy learning criterion here.

The TIMIT speech corpus consists of a training set of 462 speakers, a separate development set of 50 speakers for cross-validation, and a core test set of 24 speakers. All results are reported on the 24-speaker core test set. The speech waveform data is analyzed using a 25-ms Hamming window with a 10-ms fixed frame rate. The speech feature vector is generated by a Fourier-transform-based filter-banks that include 40 coefficients distributed on the Mel scale and energy, along with their first and second temporal derivatives. This leads to a 123-dimension feature vector per speech frame. We further concatenate 15 consecutive frames within a long context window of (7+1+7) to feed to the models, as 1845-dimension input vectors (Xue et al., 2014). All speech data are normalized by subtracting the mean of the training set and being divided by the standard deviation of the training set on each dimension so that all input vectors have zero mean and unit variance. We use 183 target class labels (i.e., 3 states for each of the 61 phones) for the DNN training. After decoding, these 61 phone classes are mapped to a set of 39 classes for the final scoring as in Lee and Hon (1989). In our experiments, a bi-gram language model at phone level, estimated from all transcripts in the training set, is used for speech recognition.

We first train ReLUs based shallow and deep neural networks as our baseline systems. The networks are trained using the back-propagation algorithm, with a mini-batch size of 100. The initial learn rate is set to 0.004 and it is kept unchanged if the error rate on the development set is still decreasing. Afterwards, the learning rate is halved after every epoch, and the whole training procedure is stopped when the error reduction on the development set is less than 0.1% in two consecutive iterations. In our experiments, we also use momentum and weight decay, which are set to 0.9 and 0.0001, respectively. When we use the mini-batch SGD to train neural networks under the HOPE framework, the control parameter for the orthogonal constraints, i.e. β, is set to be 0.01.

In our experiments, we compare the standard NNs with the HOPE-trained NNs for two fully-connected network architectures, one shallow network with one hidden layer of 10240 hidden nodes and one deep network with 3 hidden layers of 2048 nodes. The performance comparison between them is shown in Table. 6. Our results are comparable with Xue et al. (2014) and another recent work (Ba and Caruana, 2014), using deep neural networks on TIMIT. From the results, we can see that the HOPE-trained NNs can consistently outperform the regular NNs by an about 0.8% absolute reduction in phone recognition error rates. Moreover, the HOPE-trained neural networks are much smaller than their counterpart DNNs in number of model parameters if the HOPE layers are not merged. After merging, they have exactly the same model structure as their counterpart NNs.

7. Conclusions

In this paper, we have proposed a novel model, called hybrid orthogonal projection and estimation (HOPE), for high-dimensional data. The HOPE model combines feature extraction and data modeling under a unified generative modeling framework so that both feature extractor and data model can be jointly learned in either supervised or unsupervised ways. More interestingly, we have shown that the HOPE models are closely related to neural networks in a way that each hidden layer in NNs can be reformulated as a HOPE model. Therefore, the proposed HOPE related learning algorithms can be easily applied to perform either supervised or unsupervised learning for neural networks. We have evaluated the proposed HOPE models in learning NNs on several standard tasks, including image recognition on MNIST and speech recognition on TIMIT. Experimental results have strongly supported that the HOPE models can provide a very effective unsupervised learning method for NNs. Meanwhile, the supervised learning of NNs can also be conducted under the HOPE framework, which normally yields better performance and more compact models.

As the future work, we will investigate the HOPE model to learn convolution neural networks (CNNs) for more challenging image recognition tasks, such as CIFAR and ImageNet. Moreover, we are also examining the HOPE-based unsupervised learning for various natural language processing (NLP) tasks.

model	Net Architecture	FACC (%)	PER (%)
NN	1845-10240-183	61.45	23.85
HOPE-NN	1845-[256-10240]-183	62.11	**23.04**

Appendix A. Learning HOPE when $\hat{\mathbf{U}}$ is not orthonormal

In some tasks, in additional to dimension reduction, we may want to use the projection matrix $\mathbf{U}$ to perform signal whitening to ensure the signal projection $\mathbf{z}$ has roughly the same variance along all dimensions. This has been shown to be quite important for many image recognition and speech recognition tasks. In this case, we may still want to impose the orthogonal constraints among all row vectors of $\mathbf{U}$, i.e., $\mathbf{u}_i \cdot \mathbf{u}_j = 0 \ \ (i, j = 1, \cdots, M, \ i \neq j)$, but these row vectors may not be of unit length, i.e., $|\mathbf{u}_i| \geq 1 \ \ (i = 1, \cdots, M)$. Moreover, it is better not to whiten the residual noises in the remaining $D - M$ dimensions to unnecessarily amplify them. Therefore, we still enforce the unit-length constraints for the matrix $\mathbf{V}$, i.e., $|\mathbf{u}_i| = 1$ $(i = M + 1, \cdots, D)$. Because $\mathbf{U}$ is not orthonormal anymore, when we compute the likelihood function of the original data in eq.(11) for HOPE, we have to include the Jacobian term as follows:

$$\begin{aligned}\mathcal{L}(\mathbf{U},\mathbf{\Theta},\sigma \mid \mathbf{X}) &= \sum_{n=1}^{N} \ln \Pr(\mathbf{x}_n) = \sum_{n=1}^{N} \Big[\ln|\hat{\mathbf{U}}^{-1}| + \ln \Pr(\mathbf{z}_n) + \ln \Pr(\mathbf{n}_n) \Big] \\ = \underbrace{N \cdot \ln|\hat{\mathbf{U}}^{-1}|}_{\mathcal{J}(\mathbf{U})} &+ \underbrace{\sum_{n=1}^{N} \ln\left(\sum_{k=1}^{K} \pi_k \cdot f_k(\mathbf{U}\mathbf{x}_n|\boldsymbol{\theta}_k) \right)}_{\mathcal{L}_1(\mathbf{U},\mathbf{\Theta})} + \underbrace{\sum_{n=1}^{N} \ln\Big(\mathcal{N}\big(\mathbf{n}_n \,|\, \mathbf{0}, \sigma^2\mathbf{I}\big) \Big)}_{\mathcal{L}_2(\mathbf{U},\sigma)}\end{aligned} \tag{44}$$

Because $\mathbf{U}\mathbf{U}^T \neq \mathbf{I}$ here, we have

$$\mathbf{x}_n = \mathbf{U}^T(\mathbf{U}\mathbf{U}^T)^{-1}\mathbf{z}_n + \mathbf{V}^T\mathbf{n}_n \tag{45}$$

and then we have

$$\begin{aligned}\mathbf{x}_n^T\mathbf{x}_n &= \Big(\mathbf{n}_n^T\mathbf{V} + \mathbf{z}_n^T(\mathbf{U}\mathbf{U}^T)^{-1}\mathbf{U}\Big)\Big(\mathbf{V}^T\mathbf{n}_n + \mathbf{U}^T(\mathbf{U}\mathbf{U}^T)^{-1}\mathbf{z}_n\Big) \\ &= \mathbf{n}_n^T\mathbf{n}_n + \mathbf{z}_n^T(\mathbf{U}\mathbf{U}^T)^{-1}\mathbf{z}_n = \mathbf{n}_n^T\mathbf{n}_n + \mathbf{x}_n^T\mathbf{U}^T(\mathbf{U}\mathbf{U}^T)^{-1}\mathbf{U}\mathbf{x}_n\end{aligned} \tag{46}$$

Therefore, we may derive the residual noise energy as:

$$\begin{aligned}\mathbf{n}_n^T\mathbf{n}_n &= \mathbf{x}_n^T\mathbf{x}_n - \mathbf{x}_n^T\mathbf{U}^T(\mathbf{U}\mathbf{U}^T)^{-1}\mathbf{U}\mathbf{x}_n \\ &= \mathbf{x}_n^T\Big[\mathbf{I} - \mathbf{U}^T(\mathbf{U}\mathbf{U}^T)^{-1}\mathbf{U}\Big]\mathbf{x}_n\end{aligned} \tag{47}$$

In this case, $\mathcal{L}_2(\mathbf{U},\sigma)$ can be expressed as:

$$\mathcal{L}_2(\mathbf{U},\sigma) = -\frac{N}{2}\ln(\sigma^2) - \frac{1}{2\sigma^2}\sum_{n=1}^{N}\Big[\mathbf{x}_n^T\mathbf{x}_n - \mathbf{x}_n^T\mathbf{U}^T(\mathbf{U}\mathbf{U}^T)^{-1}\mathbf{U}\mathbf{x}_n\Big] \tag{48}$$

Therefore, its gradient with respect to $\mathbf{U}$, can be derived as follows:

$$\begin{aligned}\frac{\partial\mathcal{L}_2(\mathbf{U},\sigma)}{\partial\mathbf{U}} &= \frac{1}{\sigma^2}\sum_{n=1}^{N}\Big[(\mathbf{U}\mathbf{U}^T)^{-1}\mathbf{U}\mathbf{x}_n\mathbf{x}_n^T - (\mathbf{U}\mathbf{U}^T)^{-1}\mathbf{U}\mathbf{x}_n\mathbf{x}_n^T\mathbf{U}^T(\mathbf{U}\mathbf{U}^T)^{-1}\mathbf{U}\Big] \\ &= \frac{1}{\sigma^2}\sum_{n=1}^{N}(\mathbf{U}\mathbf{U}^T)^{-1}\mathbf{U}\mathbf{x}_n\mathbf{x}_n^T\Big[\mathbf{I} - \mathbf{U}^T(\mathbf{U}\mathbf{U}^T)^{-1}\mathbf{U}\Big]\end{aligned} \tag{49}$$

Next, we consider the Jacobian term, $\mathcal{J}(\mathbf{U})$, which can be computed as follows:

$$\mathcal{J}(\mathbf{U}) = N\cdot\ln|\hat{\mathbf{U}}^{-1}| = -N\sum_{i=1}^{M}\ln|\mathbf{u}_i| \tag{50}$$

Because of $\frac{\partial\mathcal{J}(\mathbf{U})}{\partial\mathbf{u}_i} = -\frac{N\cdot\mathbf{u}_i}{|\mathbf{u}_i|^2}$ $(i=1,\cdots,M)$, it is easy to show that its derivative with respect to $\mathbf{U}$ can be derived as:

$$\frac{\partial\mathcal{J}(\mathbf{U})}{\partial\mathbf{U}} = -N\cdot\big(\mathbf{U}\mathbf{U}^T\big)^{-1}\mathbf{U}. \tag{51}$$

Similarly, the HOPE parameters, i.e., $\mathbf{U}$, $\mathbf{\Theta}$ and σ, can be estimated by maximizing the above likelihood function as follows:

$$\{\mathbf{U}^*,\mathbf{\Theta}^*,\sigma^*\} = \arg\max_{\mathbf{U},\mathbf{\Theta},\sigma}\ \ \mathcal{L}(\mathbf{U},\mathbf{\Theta},\sigma \mid \mathbf{X}) \tag{52}$$

subject to an orthogonal constraint:

$$\mathbf{U}\mathbf{U}^T = \mathbf{\Phi}, \tag{53}$$

where $\mathbf{\Phi}$ is a diagonal matrix. The above constraint can also be implemented as an penalty term similar to eq.(15). However, the norm of each row vector is relaxed as follows:

$$|\mathbf{u}_i| \geq 1 \quad (i=1,\cdots,M) \tag{54}$$

The log-likelihood function related to the signal model, $\mathcal{L}_1(\mathbf{U},\mathbf{\Theta})$, and signal variance, σ^2, are calculated in the same way as before.

Appendix B. Derivatives of movMFs

The partial derivatives of the objective function in eq.(29) w.r.t all $\boldsymbol{\mu}_k$ can be computed as follows:

$$\frac{\partial\mathcal{L}_1(\mathbf{U},\mathbf{\Theta})}{\partial\boldsymbol{\mu}_k} = \sum_{n=1}^{N}\frac{\pi_k\cdot\Big(\mathcal{C}_M'(|\boldsymbol{\mu}_k|)\frac{\partial\kappa_k}{\boldsymbol{\mu}_k}\cdot e^{\mathbf{z}_n^T\cdot\boldsymbol{\mu}_k} + \mathcal{C}_M(|\boldsymbol{\mu}_k|)\cdot e^{\mathbf{z}_n^T\cdot\boldsymbol{\mu}_k}\cdot\mathbf{z}_n\Big)}{\sum_{j=1}^{K}\pi_j\cdot\mathcal{C}_M(|\boldsymbol{\mu}_j|)\cdot e^{\mathbf{z}\cdot\boldsymbol{\mu}_j}} \tag{55}$$

where we have

$$\frac{\partial\,|\boldsymbol{\mu}_k|}{\partial\boldsymbol{\mu}_k} = \frac{\boldsymbol{\mu}_k}{|\boldsymbol{\mu}_k|}. \tag{56}$$

As to $\mathcal{C}_M'(\kappa)$, for brevity, let us denote $s=\frac{M}{2}-1$, and $\xi=(2\pi)^{s+1}$.

$$\begin{aligned}\mathcal{C}_M'(\kappa) &= \frac{s\cdot\kappa^{s-1}}{\xi I_s(\kappa)} - \frac{\kappa^s\cdot I'_s(\kappa)}{\xi {I_s}^2(\kappa)} = \frac{\kappa^s}{\xi I_s(\kappa)}\left(\frac{s}{\kappa} - \frac{I'_s(\kappa)}{I_s(\kappa)}\right) \\ &= \mathcal{C}_M(\kappa)\cdot\left(\frac{s}{\kappa} - \frac{I'_s(\kappa)}{I_s(\kappa)}\right)\end{aligned} \tag{57}$$

where $I_v(\cdot)$ denotes the Bessel function of the first kind at the order v. Because we have

$$\kappa I_{s+1}(\kappa) = \kappa I'_s(\kappa) - sI_s(\kappa) \Rightarrow \frac{s}{\kappa} - \frac{I'_s(\kappa)}{I_s(\kappa)} = -\frac{I_{s+1}(\kappa)}{I_s(\kappa)}$$

Thus, we may derive

$$\mathcal{C}_M'(\kappa) = -\mathcal{C}_M(\kappa)\cdot\frac{I_{s+1}(\kappa)}{I_s(\kappa)} \tag{58}$$

Substituting eq. (56) and eq. (58) into eq. (55), we obtain the partial derivative of the objective function in eq. (29) w.r.t $\boldsymbol{\mu}_k$ as follows:

$$\begin{aligned}\frac{\partial\mathcal{L}_1(\mathbf{U},\mathbf{\Theta})}{\partial\boldsymbol{\mu}_k} &= \sum_{n=1}^{N}\frac{\pi_k\cdot\mathcal{C}_M(|\boldsymbol{\mu}_k|)\cdot e^{\mathbf{z}_n\cdot\boldsymbol{\mu}_k}\left(\mathbf{z}_n - \frac{\boldsymbol{\mu}_k}{|\boldsymbol{\mu}_k|}\cdot\frac{I_{M/2}(|\boldsymbol{\mu}_k|)}{I_{M/2-1}(|\boldsymbol{\mu}_k|)}\right)}{\sum_{j=1}^{K}\pi_j\cdot\mathcal{C}_{\mathcal{M}}(|\boldsymbol{\mu}_j|)\cdot e^{\mathbf{z}_n\cdot\boldsymbol{\mu}_j}} \\ &= \sum_{n=1}^{N}\gamma(z_{nk})\cdot\left(\mathbf{z}_n - \frac{\boldsymbol{\mu}_k}{|\boldsymbol{\mu}_k|}\cdot\frac{I_{M/2}(|\boldsymbol{\mu}_k|)}{I_{M/2-1}(|\boldsymbol{\mu}_k|)}\right)\end{aligned} \tag{59}$$

where $\gamma(z_{nk}) = \frac{\pi_k \cdot \mathcal{C}_M(|\boldsymbol{\mu}_k|) \cdot e^{\mathbf{z}_n \cdot \boldsymbol{\mu}_k}}{\sum_{j=1}^K \pi_j \cdot \mathcal{C}_M(|\boldsymbol{\mu}_j|) \cdot e^{\mathbf{z}_n \cdot \boldsymbol{\mu}_j}}$ is the occupancy statistics of k-th component of $\mathbf{z}_n$.

Next, let us consider the partial derivative of the objective function in eq.(29) w.r.t $\mathbf{U}$. Based on the chain rule, we have

$$\frac{\partial \mathcal{L}_1(\mathbf{U}, \boldsymbol{\Theta})}{\partial \mathbf{U}} = \frac{\partial \mathcal{L}_1(\mathbf{U}, \boldsymbol{\Theta})}{\partial \widetilde{\mathbf{z}}_n} \cdot \frac{\partial \widetilde{\mathbf{z}}_n}{\partial \mathbf{U}} = \left(\frac{\partial \mathbf{z}_n^T}{\partial \widetilde{\mathbf{z}}_n} \cdot \frac{\partial \mathcal{L}_1(\mathbf{U}, \boldsymbol{\Theta})}{\partial \mathbf{z}_n} \right) \cdot \frac{\partial \widetilde{\mathbf{z}}_n}{\partial \mathbf{U}} \tag{60}$$

Furthermore, we may derive

$$\frac{\partial \mathcal{L}_1(\mathbf{U}, \boldsymbol{\Theta})}{\partial \mathbf{z}_n} = \sum_{n=1}^N \sum_{k=1}^K \frac{\pi_k \cdot \mathcal{C}_M(|\boldsymbol{\mu}_k|) \cdot e^{\mathbf{z}_n \cdot \boldsymbol{\mu}_k}}{\sum_{j=1}^K \pi_j \cdot \mathcal{C}_M(|\boldsymbol{\mu}_j|) \cdot e^{\mathbf{z}_n \cdot \boldsymbol{\mu}_j}} \cdot \boldsymbol{\mu}_k = \sum_{n=1}^N \sum_{k=1}^K \gamma(z_{nk}) \cdot \boldsymbol{\mu}_k \tag{61}$$

$$\begin{aligned} \frac{\partial \mathbf{z}_n^T}{\partial \tilde{\mathbf{z}}_n} &= \frac{\partial (\tilde{\mathbf{z}}_n^T / |\tilde{\mathbf{z}}_n|)}{\partial \tilde{\mathbf{z}}_n} = \frac{1}{|\tilde{\mathbf{z}}_n|^2} \left(\frac{\partial \tilde{\mathbf{z}}_n^T}{\partial \tilde{\mathbf{z}}_n} |\tilde{\mathbf{z}}_n| - \frac{\partial |\tilde{\mathbf{z}}_n|}{\partial \tilde{\mathbf{z}}_n} \tilde{\mathbf{z}}_n^T \right) \\ &= \frac{1}{|\tilde{\mathbf{z}}_n|} \left(\mathbf{I} - \frac{\tilde{\mathbf{z}}_n \tilde{\mathbf{z}}_n^T}{|\tilde{\mathbf{z}}_n|^2} \right) = \frac{1}{|\tilde{\mathbf{z}}_n|} \left(\mathbf{I} - \mathbf{z}_n \mathbf{z}_n^T \right) \end{aligned} \tag{62}$$

Substituting eq.(61) and eq. (62) into eq. (60), we can obtain

$$\frac{\partial \mathcal{L}_1(\mathbf{U}, \boldsymbol{\Theta})}{\partial \mathbf{U}} = \sum_{n=1}^N \sum_{k=1}^K \frac{\gamma(z_{nk})}{|\tilde{\mathbf{z}}_n|} (\mathbf{I} - \mathbf{z}_n \mathbf{z}_n^T) \boldsymbol{\mu}_k \mathbf{x}_n^T \tag{63}$$

Appendix C. Numerical Methods for $I_v(\cdot)$

In the learning algorithm for movMFs, we may need to compute the Bessel functions, $I_v(\cdot)$, in several places. First of all, we need to compute the normalization term $\mathcal{C}_M(\kappa)$ when calculating the likelihood function of a vMF distribution as in eq.(9). Secondly, we need to calculate the rations of the modified Bessel functions, $A_d(\kappa) = \frac{I_{M/2}(\kappa)}{I_{M/2-1}(\kappa)}$, in eq.(59). As we know, the modified Bessel functions of the first kind take the following form:

$$I_d(\kappa) = \sum_{k \geq 0} \frac{1}{\Gamma(d+1+k)k!} (\frac{\kappa}{2})^{2k+d}, \tag{64}$$

From eq. (64), we can see that when $\kappa \gg d$, $I_d(\kappa)$ overflows quite rapidly. Meanwhile, when $\kappa = o(d)$ and $d \to \infty$, $I_d(\kappa)$ underflows quite rapidly. In this work, we use the approximation strategy in eq. (9.7.7) on page 378 of Abramowitz and Stegun (2006) as follows:

$$I_d(\kappa) \sim \frac{1}{\sqrt{2\pi d}} \cdot \frac{e^{d\eta}}{(1 + (\frac{\kappa}{d})^2)^{1/4}} \cdot \left[1 + \sum_{k=1}^{\infty} \frac{u_k(t)}{d^k} \right] \tag{65}$$

where we have

$$t = \frac{1}{\sqrt{1 + (\kappa/d)^2}} \tag{66}$$

$$\eta = \sqrt{1 + (\kappa/d)^2} + \ln \frac{\kappa/d}{1 + \sqrt{1 + (\kappa/d)^2}} \tag{67}$$

with the functions $u_k(t)$ taking the following forms:

$$\begin{aligned} u_0(t) &= 1 \\ u_1(t) &= (3t - 5t^3)/24 \\ u_2(t) &= (81t^2 - 462t^4 + 385t^6)/1152 \end{aligned}$$

Refer to page 366 in Abramowitz and Stegun (2006) for other higher orders $u_k(t)$.

Usually, the sum of the term $[1 + \sum_{k=1}^{\infty} \frac{u_k(t)}{d^k}]$ in eq.(65) is very small and it is safe to eliminate it from evaluation in most cases. Then, after substituting eq.(66) and eq.(67) into eq.(65), the logarithm of the approximated modified Bessel function is finally computed as follows:

$$\ln I_d(\kappa) = -\ln \sqrt{2\pi d} + d \cdot \left(\sqrt{1 + (\kappa/d)^2} + \ln \frac{\kappa}{d} - \ln \left(1 + \sqrt{1 + (\kappa/d)^2} \right) \right) - \frac{1}{4} \ln \left(1 + (\frac{\kappa}{d})^2 \right) \tag{68}$$

In this work, the approximation in eq.(68) is used to compute all Bessel functions in the learning algorithms for movMFs.

The Optimal Sample Complexity of PAC Learning

Steve Hanneke STEVE.HANNEKE@GMAIL.COM

Editor: John Shawe-Taylor

Abstract

This work establishes a new upper bound on the number of samples sufficient for PAC learning in the realizable case. The bound matches known lower bounds up to numerical constant factors. This solves a long-standing open problem on the sample complexity of PAC learning. The technique and analysis build on a recent breakthrough by Hans Simon.

Keywords: sample complexity, PAC learning, statistical learning theory, minimax analysis, learning algorithm

1. Introduction

Probably approximately correct learning (or *PAC* learning; Valiant, 1984) is a classic criterion for supervised learning, which has been the focus of much research in the past three decades. The objective in PAC learning is to produce a classifier that, with probability at least $1-\delta$, has error rate at most ε. To qualify as a PAC learning algorithm, it must satisfy this guarantee for all possible target concepts in a given family, under all possible data distributions. To achieve this objective, the learning algorithm is supplied with a number m of i.i.d. training samples (data points), along with the corresponding correct classifications. One of the central questions in the study of PAC learning is determining the minimum number $\mathcal{M}(\varepsilon,\delta)$ of training samples necessary and sufficient such that there exists a PAC learning algorithm requiring at most $\mathcal{M}(\varepsilon,\delta)$ samples (for any given ε and δ). This quantity $\mathcal{M}(\varepsilon,\delta)$ is known as the *sample complexity*.

Determining the sample complexity of PAC learning is a long-standing open problem. There have been upper and lower bounds established for decades, but they differ by a logarithmic factor. It has been widely believed that this logarithmic factor can be removed for certain well-designed learning algorithms, and attempting to prove this has been the subject of much effort. Simon (2015) has very recently made an enormous leap forward toward resolving this issue. That work proposed an algorithm that classifies points based on a majority vote among classifiers trained on independent data sets. Simon proves that this algorithm achieves a sample complexity that reduces the logarithmic factor in the upper bound down to a very slowly-growing function. However, that work does not quite completely resolve the gap, so that determining the optimal sample complexity remains open.

The present work resolves this problem by completely eliminating the logarithmic factor. The algorithm achieving this new bound is also based on a majority vote of classifiers. However, unlike Simon's algorithm, here the voting classifiers are trained on data subsets specified by a recursive algorithm, with substantial overlaps among the data subsets the classifiers are trained on.

2. Notation

We begin by introducing some basic notation essential to the discussion. Fix a nonempty set $\mathcal{X}$, called the *instance space*; we suppose $\mathcal{X}$ is equipped with a σ-algebra, defining the measurable subsets of $\mathcal{X}$. Also denote $\mathcal{Y}=\{-1,+1\}$, called the *label space*. A *classifier* is any measurable function $h:\mathcal{X}\to\mathcal{Y}$. Fix a nonempty set $\mathbb{C}$ of classifiers, called the *concept space*. To focus the discussion on nontrivial cases,[1] we suppose $|\mathbb{C}|\geq 3$; other than this, the results in this article will be valid for *any* choice of $\mathbb{C}$.

In the learning problem, there is a probability measure $\mathcal{P}$ over $\mathcal{X}$, called the *data distribution*, and a sequence $X_1(\mathcal{P}), X_2(\mathcal{P}),\ldots$ of independent $\mathcal{P}$-distributed random variables, called the *unlabeled data*; for $m\in\mathbb{N}$, also define $\mathbb{X}_{1:m}(\mathcal{P})=\{X_1(\mathcal{P}),\ldots,X_m(\mathcal{P})\}$, and for completeness denote $\mathbb{X}_{1:0}(\mathcal{P})=\{\}$. There is also a special element of $\mathbb{C}$, denoted $f^\star$, called the *target function*. For any sequence $S_x=\{x_1,\ldots,x_k\}$ in $\mathcal{X}$, denote by $(S_x,f^\star(S_x))=\{(x_1,f^\star(x_1)),\ldots,(x_k,f^\star(x_k))\}$. For any probability measure P over $\mathcal{X}$, and any classifier h, denote by $\mathrm{er}_P(h;f^\star)=P(x:h(x)\neq f^\star(x))$. A *learning algorithm* $\mathcal{A}$ is a map,[2] mapping any sequence $\{(x_1,y_1),\ldots,(x_m,y_m)\}$ in $\mathcal{X}\times\mathcal{Y}$ (called a *data set*), of any length $m\in\mathbb{N}\cup\{0\}$, to a classifier $h:\mathcal{X}\to\mathcal{Y}$ (not necessarily in $\mathbb{C}$).

Definition 1 *For any $\varepsilon,\delta\in(0,1)$, the* sample complexity of (ε,δ)-PAC learning, *denoted $\mathcal{M}(\varepsilon,\delta)$, is defined as the smallest $m\in\mathbb{N}\cup\{0\}$ for which there exists a learning algorithm $\mathcal{A}$ such that, for every possible data distribution $\mathcal{P}$, $\forall f^\star\in\mathbb{C}$, denoting $\hat{h}=\mathcal{A}((\mathbb{X}_{1:m}(\mathcal{P}),f^\star(\mathbb{X}_{1:m}(\mathcal{P}))))$,*

$$\mathbb{P}\left(\mathrm{er}_{\mathcal{P}}\left(\hat{h};f^\star\right)\leq\varepsilon\right)\geq 1-\delta.$$

If no such m exists, define $\mathcal{M}(\varepsilon,\delta)=\infty$.

The sample complexity is our primary object of study in this work. We require a few additional definitions before proceeding. Throughout, we use a natural extension of set notation to sequences: for any finite sequences $\{a_i\}_{i=1}^k,\{b_i\}_{i=1}^{k'}$, we denote by $\{a_i\}_{i=1}^k\cup\{b_i\}_{i=1}^{k'}$ the concatenated sequence $\{a_1,\ldots,a_k,b_1,\ldots,b_{k'}\}$. For any set A, we denote by $\{a_i\}_{i=1}^k\cap A$ the subsequence comprised of all a_i for which $a_i\in A$. Additionally, we write $b\in\{b_i\}_{i=1}^{k'}$ to indicate $\exists i\leq k'$ s.t. $b_i=b$, and we write $\{a_i\}_{i=1}^k\subseteq\{b_i\}_{i=1}^{k'}$ or $\{b_i\}_{i=1}^{k'}\supseteq\{a_i\}_{i=1}^k$ to express that $a_j\in\{b_i\}_{i=1}^{k'}$ for every $j\leq k$. We also denote $|\{a_i\}_{i=1}^k|=k$ (the length of the sequence). For any $k\in\mathbb{N}\cup\{0\}$ and any sequence $S=\{(x_1,y_1),\ldots,(x_k,y_k)\}$ of points in $\mathcal{X}\times\mathcal{Y}$, denote $\mathbb{C}[S]=\{h\in\mathbb{C}:\forall(x,y)\in S,h(x)=y\}$, referred to as the set of classifiers *consistent* with S.

Following Vapnik and Chervonenkis (1971), we say a sequence $\{x_1,\ldots,x_k\}$ of points in $\mathcal{X}$ is *shattered* by $\mathbb{C}$ if $\forall y_1,\ldots,y_k\in\mathcal{Y}$, $\exists h\in\mathbb{C}$ such that $\forall i\in\{1,\ldots,k\}$, $h(x_i)=y_i$: that is, there are 2^k distinct classifications of $\{x_1,\ldots,x_k\}$ realized by classifiers in $\mathbb{C}$. The Vapnik-Chervonenkis dimension (or *VC dimension*) of $\mathbb{C}$ is then defined as the largest

1. The sample complexities for $|\mathbb{C}|=1$ and $|\mathbb{C}|=2$ are already quite well understood in the literature, the former having sample complexity 0, and the latter having sample complexity either 1 or $\Theta(\frac{1}{\varepsilon}\ln\frac{1}{\delta})$ (depending on whether the two classifiers are exact complements or not).
2. We also admit randomized algorithms $\mathcal{A}$, where the "internal randomness" of $\mathcal{A}$ is assumed to be independent of the data. Formally, there is a random variable R independent of $\{X_i(P)\}_{i,P}$ such that the value $\mathcal{A}(S)$ is determined by the input data S and the value of R.

integer k for which there exists a sequence $\{x_1, \ldots, x_k\}$ in $\mathcal{X}$ shattered by $\mathbb{C}$; if no such largest k exists, the VC dimension is said to be infinite. We denote by d the VC dimension of $\mathbb{C}$. This quantity is of fundamental importance in characterizing the sample complexity of PAC learning. In particular, it is well known that the sample complexity is finite for any $\varepsilon, \delta \in (0,1)$ if and only if $d < \infty$ (Vapnik, 1982; Blumer, Ehrenfeucht, Haussler, and Warmuth, 1989; Ehrenfeucht, Haussler, Kearns, and Valiant, 1989). For simplicity of notation, for the remainder of this article we suppose $d < \infty$; furthermore, note that our assumption of $|\mathbb{C}| \geq 3$ implies $d \geq 1$.

We adopt a common variation on big-O asymptotic notation, used in much of the learning theory literature. Specifically, for functions $f, g : (0,1)^2 \to [0,\infty)$, we let $f(\varepsilon,\delta) = O(g(\varepsilon,\delta))$ denote the assertion that $\exists \varepsilon_0, \delta_0 \in (0,1)$ and $c_0 \in (0,\infty)$ such that, $\forall \varepsilon \in (0,\varepsilon_0)$, $\forall \delta \in (0,\delta_0)$, $f(\varepsilon,\delta) \leq c_0 g(\varepsilon,\delta)$; however, we also require that the values $\varepsilon_0, \delta_0, c_0$ in this definition be *numerical constants*, meaning that they are *independent of* $\mathbb{C}$ *and* $\mathcal{X}$. For instance, this means c_0 cannot depend on d. We equivalently write $f(\varepsilon,\delta) = \Omega(g(\varepsilon,\delta))$ to assert that $g(\varepsilon,\delta) = O(f(\varepsilon,\delta))$. Finally, we write $f(\varepsilon,\delta) = \Theta(g(\varepsilon,\delta))$ to assert that both $f(\varepsilon,\delta) = O(g(\varepsilon,\delta))$ and $f(\varepsilon,\delta) = \Omega(g(\varepsilon,\delta))$ hold. We also sometimes write $O(g(\varepsilon,\delta))$ in an expression, as a place-holder for some function $f(\varepsilon,\delta)$ satisfying $f(\varepsilon,\delta) = O(g(\varepsilon,\delta))$: for instance, the statement $N(\varepsilon,\delta) \leq d + O(\log(1/\delta))$ expresses that $\exists f(\varepsilon,\delta) = O(\log(1/\delta))$ for which $N(\varepsilon,\delta) \leq d + f(\varepsilon,\delta)$. Also, for any value $z \geq 0$, define $\mathrm{Log}(z) = \ln(\max\{z, e\})$ and similarly $\mathrm{Log}_2(z) = \log_2(\max\{z, 2\})$.

As is commonly required in the learning theory literature, we adopt the assumption that the events appearing in probability claims below are indeed measurable. For our purposes, this comes into effect only in the application of classic generalization bounds for sample-consistent classifiers (Lemma 4 below). See Blumer, Ehrenfeucht, Haussler, and Warmuth (1989) and van der Vaart and Wellner (1996) for discussion of conditions on $\mathbb{C}$ sufficient for this measurability assumption to hold.

3. Background

Our objective in this work is to establish *sharp* sample complexity bounds. As such, we should first review the known *lower bounds* on $\mathcal{M}(\varepsilon,\delta)$. A basic lower bound of $\frac{1-\varepsilon}{\varepsilon}\ln\left(\frac{1}{\delta}\right)$ was established by Blumer, Ehrenfeucht, Haussler, and Warmuth (1989) for $0 < \varepsilon < 1/2$ and $0 < \delta < 1$. A second lower bound of $\frac{d-1}{32\varepsilon}$ was supplied by Ehrenfeucht, Haussler, Kearns, and Valiant (1989), for $0 < \varepsilon \leq 1/8$ and $0 < \delta \leq 1/100$. Taken together, these results imply that, for any $\varepsilon \in (0, 1/8]$ and $\delta \in (0, 1/100]$,

$$\mathcal{M}(\varepsilon,\delta) \geq \max\left\{\frac{d-1}{32\varepsilon}, \frac{1-\varepsilon}{\varepsilon}\ln\left(\frac{1}{\delta}\right)\right\} = \Omega\left(\frac{1}{\varepsilon}\left(d + \mathrm{Log}\left(\frac{1}{\delta}\right)\right)\right). \tag{1}$$

This lower bound is complemented by classic *upper bounds* on the sample complexity. In particular, Vapnik (1982) and Blumer, Ehrenfeucht, Haussler, and Warmuth (1989) established an upper bound of

$$\mathcal{M}(\varepsilon,\delta) = O\left(\frac{1}{\varepsilon}\left(d\mathrm{Log}\left(\frac{1}{\varepsilon}\right) + \mathrm{Log}\left(\frac{1}{\delta}\right)\right)\right). \tag{2}$$

They proved that this sample complexity bound is in fact achieved by any algorithm that returns a classifier $h \in \mathbb{C}[(\mathbb{X}_{1:m}(\mathcal{P}), f^\star(\mathbb{X}_{1:m}(\mathcal{P})))]$, also known as a *sample-consistent learning algorithm* (or *empirical risk minimization* algorithm). A sometimes-better upper bound was established by Haussler, Littlestone, and Warmuth (1994):

$$\mathcal{M}(\varepsilon,\delta) = O\left(\frac{d}{\varepsilon}\mathrm{Log}\left(\frac{1}{\delta}\right)\right). \tag{3}$$

This bound is achieved by a modified variant of the *one-inclusion graph prediction algorithm*, a learning algorithm also proposed by Haussler, Littlestone, and Warmuth (1994), which has been conjectured to achieve the optimal sample complexity (Warmuth, 2004).

In very recent work, Simon (2015) produced a breakthrough insight. Specifically, by analyzing a learning algorithm based on a simple majority vote among classifiers consistent with distinct subsets of the training data, Simon (2015) established that, for any $K \in \mathbb{N}$,

$$\mathcal{M}(\varepsilon,\delta) = O\left(\frac{2^{2K}\sqrt{K}}{\varepsilon}\left(d\log^{(K)}\left(\frac{1}{\varepsilon}\right) + K + \mathrm{Log}\left(\frac{1}{\delta}\right)\right)\right), \tag{4}$$

where $\log^{(K)}(x)$ is the K-times iterated logarithm: $\log^{(0)}(x) = \max\{x, 1\}$ and $\log^{(K)}(x) = \max\{\log_2(\log^{(K-1)}(x)), 1\}$. In particular, one natural choice would be $K \approx \log^*\left(\frac{1}{\varepsilon}\right)$,[3] which (one can show) optimizes the asymptotic dependence on ε in the bound, yielding

$$\mathcal{M}(\varepsilon,\delta) = O\left(\frac{1}{\varepsilon}2^{O(\log^*(1/\varepsilon))}\left(d + \mathrm{Log}\left(\frac{1}{\delta}\right)\right)\right).$$

In general, the entire form of the bound (4) is optimized (up to numerical constant factors) by choosing $K = \max\left\{\log^*\left(\frac{1}{\varepsilon}\right) - \log^*\left(\frac{1}{d}\mathrm{Log}\left(\frac{1}{\delta}\right)\right) + 1, 1\right\}$. Note that, with either of these choices of K, there is a range of ε, δ, and d values for which the bound (4) is strictly smaller than both (2) and (3): for instance, for small ε, it suffices to have $\mathrm{Log}(1/\delta) \ll d\mathrm{Log}(1/\varepsilon)/(2^{2\log^*(1/\varepsilon)}\sqrt{\log^*(1/\varepsilon)})$ while $2^{2\log^*(1/\varepsilon)}\sqrt{\log^*(1/\varepsilon)} \ll \min\{\mathrm{Log}(1/\delta), d\}$. However, this bound still does not quite match the form of the lower bound (1).

There have also been many special-case analyses, studying restricted types of concept spaces $\mathbb{C}$ for which the above gaps can be closed (e.g., Auer and Ortner, 2007; Darnstädt, 2015; Hanneke, 2015). However, these special conditions do not include many of the most-commonly studied concept spaces, such as linear separators and multilayer neural networks. There have also been a variety of studies that, in addition to restricting to specific concept spaces $\mathbb{C}$, also introduce strong restrictions on the data distribution $\mathcal{P}$, and establish an upper bound of the same form as the lower bound (1) under these restrictions (e.g., Long, 2003; Giné and Koltchinskii, 2006; Bshouty, Li, and Long, 2009; Hanneke, 2009, 2015; Balcan and Long, 2013). However, there are many interesting classes $\mathbb{C}$ and distributions $\mathcal{P}$ for which these results do not imply any improvements over (2). Thus, in the present literature, there persists a gap between the lower bound (1) and the minimum of all of the known upper bounds (2), (3), and (4) applicable to the *general* case of an arbitrary concept space of a given VC dimension d (under arbitrary data distributions).

In the present work, we establish a new upper bound for a novel learning algorithm, which holds for *any* concept space $\mathbb{C}$, and which improves over all of the above general

3. The function $\log^*(x)$ is the iterated logarithm: the smallest $K \in \mathbb{N} \cup \{0\}$ for which $\log^{(K)}(x) \leq 1$. It is an extremely slowly growing function of x.

upper bounds in its joint dependence on ε, δ, and d. In particular, it is *optimal*, in the sense that it matches the lower bound (1) up to numerical constant factors. This work thus solves a long-standing open problem, by determining the precise form of the optimal sample complexity, up to numerical constant factors.

4. Main Result

This section presents the main contributions of this work: a novel learning algorithm, and a proof that it achieves the optimal sample complexity.

4.1 Sketch of the Approach

The general approach used here builds on an argument of Simon (2015), which itself has roots in the analysis of sample-consistent learning algorithms by Hanneke (2009, Section 2.9.1). The essential idea from Simon (2015) is that, if we have two classifiers, $\hat{h}$ and $\hat{g}$, the latter of which is an element of $\mathbb{C}$ consistent with an i.i.d. data set $\tilde{S}$ *independent* from $\hat{h}$, then we can analyze the probability that they *both* make a mistake on a random point by bounding the error rate of $\hat{h}$ under the distribution $\mathcal{P}$, and bounding the error rate of $\hat{g}$ under the *conditional* distribution given that $\hat{h}$ makes a mistake. In particular, it will either be the case that $\hat{h}$ itself has small error rate, or else (if $\hat{h}$ has error rate larger than our desired bound) with high probability, the number of points in $\tilde{S}$ contained in the error region of $\hat{h}$ will be at least some number $\propto \mathrm{er}_{\mathcal{P}}(\hat{h}; f^\star)|\tilde{S}|$; in the latter case, we can bound the conditional error rate of $\hat{g}$ in terms of the number of such points via a classic generalization bound for sample-consistent classifiers (Lemma 4 below). Multiplying this bound on the conditional error rate of $\hat{g}$ by the error rate of $\hat{h}$ results in a bound on the probability they both make a mistake. More specifically, this argument yields a bound of the following form: for an appropriate numerical constant $\tilde{c} \in (0, \infty)$, with probability at least $1-\delta$, $\forall \hat{g} \in \mathbb{C}[\tilde{S}]$,

$$\mathcal{P}\left(x : \hat{h}(x) = \hat{g}(x) \neq f^\star(x)\right) \leq \frac{\tilde{c}}{|\tilde{S}|}\left(d\mathrm{Log}\left(\frac{\mathrm{er}_{\mathcal{P}}(\hat{h}; f^\star)|\tilde{S}|}{d}\right) + \mathrm{Log}\left(\frac{1}{\delta}\right)\right).$$

The original analysis of Simon (2015) applied this reasoning repeatedly, in an inductive argument, thereby bounding the probability that K classifiers, each consistent with one of K independent training sets, all make a mistake on a random point. He then reasoned that the error rate of the majority vote of $2K-1$ such classifiers can be bounded by the sum of these bounds for all subsets of K of these classifiers, since the majority vote classifier agrees with at least K of the constituent classifiers.

In the present work, we also consider a simple majority vote of a number of classifiers, but we alter the way the data is split up, allowing significant overlaps among the subsamples. In particular, each classifier is trained on considerably more data this way. We construct these subsamples recursively, motivated by an inductive analysis of the sample complexity. At each stage, we have a working set S of i.i.d. data points, and another sequence T of data points, referred to as the *partially-constructed subsample*. As a terminal case, if $|S|$ is smaller than a certain cutoff size, we generate a subsample $S \cup T$, on which we will train a classifier $\hat{g} \in \mathbb{C}[S \cup T]$. Otherwise (for the nonterminal case), we use (roughly) a constant fraction of the points in S to form a subsequence S_0, and make three recursive calls to the

algorithm, using S_0 as the working set in each call. By an inductive hypothesis, for each of these three recursive calls, with probability $1-\delta'$, the majority vote of the classifiers trained on subsamples generated by that call has error rate at most $\frac{c}{|S_0|}(d + \mathrm{Log}(1/\delta'))$, for an appropriate numerical constant c. These three majority vote classifiers, denoted h_1, h_2, h_3, will each play the role of $\hat{h}$ in the argument above.

With the remaining constant fraction of data points in S (i.e., those not used to form S_0), we divide them into three independent subsequences S_1, S_2, S_3. Then for each of the three recursive calls, we provide as its partially-constructed subsample (i.e., the "T" argument) a sequence $S_i \cup S_j \cup T$ with $i \neq j$; specifically, for the k^{th} recursive call ($k \in \{1,2,3\}$), we take $\{i,j\} = \{1,2,3\} \setminus \{k\}$. Since the argument T is retained within the partially-constructed subsample passed to each recursive call, a simple inductive argument reveals that, for each $i \in \{1,2,3\}$, $\forall k \in \{1,2,3\} \setminus \{i\}$, all of the classifiers $\hat{g}$ trained on subsamples generated in the k^{th} recursive call are contained in $\mathbb{C}[S_i]$. Furthermore, since S_i is not included in the argument to the i^{th} recursive call, h_i and S_i are independent. Thus, by the argument discussed above, applied with $\hat{h} = h_i$ and $\tilde{S} = S_i$, we have that with probability at least $1-\delta'$, for any $\hat{g}$ trained on a subsample generated in recursive calls $k \in \{1,2,3\} \setminus \{i\}$, the probability that *both* h_i *and* $\hat{g}$ make a mistake on a random point is at most $\frac{\tilde{c}}{|S_i|}\left(d\mathrm{Log}\left(\frac{\mathrm{er}_{\mathcal{P}}(h_i; f^\star)|S_i|}{d}\right) + \mathrm{Log}\left(\frac{1}{\delta'}\right)\right)$. Composing this with the aforementioned inductive hypothesis, recalling that $|S_i| \propto |S|$ and $|S_0| \propto |S|$, and simplifying by a bit of calculus, this is at most $\frac{c'}{|S|}\left(d\mathrm{Log}(c) + \mathrm{Log}\left(\frac{1}{\delta'}\right)\right)$, for an appropriate numerical constant c'. By choosing $\delta' \propto \delta$ appropriately, the union bound implies that, with probability at least $1-\delta$, this holds for all choices of $i \in \{1,2,3\}$. Furthermore, by choosing c sufficiently large, this bound is at most $\frac{c}{12|S|}\left(d + \mathrm{Log}\left(\frac{1}{\delta}\right)\right)$.

To complete the inductive argument, we then note that on any point x, the majority vote of all of the classifiers (from all three recursive calls) must agree with at least one of the three classifiers h_i, and must agree with at least $1/4$ of the classifiers $\hat{g}$ trained on subsamples generated in recursive calls $k \in \{1,2,3\} \setminus \{i\}$. Therefore, on any point x for which the majority vote makes a mistake, with probability at least $1/12$, a uniform random choice of $i \in \{1,2,3\}$, and of $\hat{g}$ from recursive calls $k \in \{1,2,3\} \setminus \{i\}$, results in h_i and $\hat{g}$ that both make a mistake on x. Applying this fact to a *random* point $X \sim \mathcal{P}$ (and invoking Fubini's theorem), this implies that the error rate of the majority vote is at most 12 times the average (over choices of i and $\hat{g}$) of the probabilities that h_i and $\hat{g}$ both make a mistake on X. Combined with the above bound, this is at most $\frac{c}{|S|}\left(d + \mathrm{Log}\left(\frac{1}{\delta}\right)\right)$. The formal details are provided below.

4.2 Formal Details

For any $k \in \mathbb{N} \cup \{0\}$, and any $S \in (\mathcal{X} \times \mathcal{Y})^k$ with $\mathbb{C}[S] \neq \emptyset$, let $L(S)$ denote an arbitrary classifier h in $\mathbb{C}[S]$, entirely determined by S: that is, $L(\cdot)$ is a fixed sample-consistent learning algorithm (i.e., empirical risk minimizer). For any $k \in \mathbb{N}$ and sequence of data sets $\{S_1, \ldots, S_k\}$, denote $L(\{S_1, \ldots, S_k\}) = \{L(S_1), \ldots, L(S_k)\}$. Also, for any values $y_1, \ldots, y_k \in \mathcal{Y}$, define the majority function: $\mathrm{Majority}(y_1, \ldots, y_k) = \mathrm{sign}\left(\sum_{i=1}^k y_i\right) = 2\mathbb{1}\left[\sum_{i=1}^k y_i \geq 0\right] - 1$. We also overload this notation, defining the *majority classifier* $\mathrm{Majority}(h_1, \ldots, h_k)(x) = \mathrm{Majority}(h_1(x), \ldots, h_k(x))$, for any classifiers $h_1, \ldots, h_k$.

Now consider the following recursive algorithm, which takes as input two finite data sets, S and T, satisfying $\mathbb{C}[S \cup T] \neq \emptyset$, and returns a *finite sequence of data sets* (referred to as *subsamples* of $S \cup T$). The classifier used to achieve the new sample complexity bound below is simply the majority vote of the classifiers obtained by applying L to these subsamples.

Algorithm: $\mathbb{A}(S;T)$
0. If $|S| \leq 3$
1. Return $\{S \cup T\}$
2. Let S_0 denote the first $|S| - 3\lfloor |S|/4 \rfloor$ elements of S, S_1 the next $\lfloor |S|/4 \rfloor$ elements, S_2 the next $\lfloor |S|/4 \rfloor$ elements, and S_3 the remaining $\lfloor |S|/4 \rfloor$ elements after that
3. Return $\mathbb{A}(S_0; S_2 \cup S_3 \cup T) \cup \mathbb{A}(S_0; S_1 \cup S_3 \cup T) \cup \mathbb{A}(S_0; S_1 \cup S_2 \cup T)$

Theorem 2

$$\mathcal{M}(\varepsilon, \delta) = O\left(\frac{1}{\varepsilon}\left(d + \mathrm{Log}\left(\frac{1}{\delta}\right)\right)\right).$$

In particular, a sample complexity of the form expressed on the right hand side is achieved by the algorithm that returns the classifier $\mathrm{Majority}(L(\mathbb{A}(S;\emptyset)))$*, given any data set* S*.*

Combined with (1), this immediately implies the following corollary.

Corollary 3

$$\mathcal{M}(\varepsilon, \delta) = \Theta\left(\frac{1}{\varepsilon}\left(d + \mathrm{Log}\left(\frac{1}{\delta}\right)\right)\right).$$

The algorithm $\mathbb{A}$ is expressed above as a recursive method for constructing a sequence of subsamples, as this form is most suitable for the arguments in the proof below. However, it should be noted that one can equivalently describe these constructed subsamples *directly*, as the selection of which data points should be included in which subsamples can be expressed as a simple function of the indices. To illustrate this, consider the simplest case in which $S = \{(x_0, y_0), \ldots, (x_{m-1}, y_{m-1})\}$ with $m = 4^\ell$ for some $\ell \in \mathbb{N}$: that is, $|S|$ is a power of 4. In this case, let $\{T_0, \ldots, T_{n-1}\}$ denote the sequence of labeled data sets returned by $\mathbb{A}(S;\emptyset)$, and note that since each recursive call reduces $|S|$ by a factor of 4 while making 3 recursive calls, we have $n = 3^\ell$. First, note that (x_0, y_0) is contained in *every* subsample T_i. For the rest, consider any $i \in \{1, \ldots, m-1\}$ and $j \in \{0, \ldots, n-1\}$, and let us express i in its base-4 representation as $i = \sum_{t=0}^{\ell-1} i_t 4^t$, where each $i_t \in \{0,1,2,3\}$, and express j in its base-3 representation as $j = \sum_{t=0}^{\ell-1} j_t 3^t$, where each $j_t \in \{0,1,2\}$. Then it holds that $(x_i, y_i) \in T_j$ if and only if the largest $t \in \{0, \ldots, \ell-1\}$ with $i_t \neq 0$ satisfies $i_t - 1 \neq j_t$. This kind of direct description of the subsamples is also possible when $|S|$ is not a power of 4, though a bit more complicated to express.

4.3 Proof of Theorem 2

The following classic result will be needed in the proof. A bound of this type is implied by a theorem of Vapnik (1982); the version stated here features slightly smaller constant factors, obtained by Blumer, Ehrenfeucht, Haussler, and Warmuth (1989).[4]

4. Specifically, it follows by combining their Theorem A2.1 and Proposition A2.1, setting the resulting expression equal to δ and solving for ε.

Lemma 4 *For any* $\delta \in (0,1)$*,* $m \in \mathbb{N}$*,* $f^\star \in \mathbb{C}$*, and any probability measure* P *over* $\mathcal{X}$*, letting* $Z_1, \ldots, Z_m$ *be independent* P*-distributed random variables, with probability at least* $1 - \delta$*, every* $h \in \mathbb{C}[\{(Z_i, f^\star(Z_i))\}_{i=1}^m]$ *satisfies*

$$\mathrm{er}_P(h; f^\star) \leq \frac{2}{m}\left(d\mathrm{Log}_2\left(\frac{2em}{d}\right) + \mathrm{Log}_2\left(\frac{2}{\delta}\right)\right).$$

We are now ready for the proof of Theorem 2.

Proof of Theorem 2 Fix any $f^\star \in \mathbb{C}$ and probability measure $\mathcal{P}$ over $\mathcal{X}$, and for brevity, denote $\mathbb{S}_{1:m} = (\mathbb{X}_{1:m}(\mathcal{P}), f^\star(\mathbb{X}_{1:m}(\mathcal{P})))$, for each $m \in \mathbb{N}$. Also, for any classifier h, define $\mathrm{ER}(h) = \{x \in \mathcal{X} : h(x) \neq f^\star(x)\}$.

We begin by noting that, for any finite sequences S and T of points in $\mathcal{X} \times \mathcal{Y}$, a straightforward inductive argument reveals that all of the subsamples $\hat{S}$ in the sequence returned by $\mathbb{A}(S;T)$ satisfy $\hat{S} \subseteq S \cup T$ (since no additional data points are ever introduced in any step). Thus, if $f^\star \in \mathbb{C}[S]$ and $f^\star \in \mathbb{C}[T]$, then $f^\star \in \mathbb{C}[S] \cap \mathbb{C}[T] = \mathbb{C}[S \cup T] \subseteq \mathbb{C}[\hat{S}]$, so that $\mathbb{C}[\hat{S}] \neq \emptyset$. In particular, this means that, in this case, each of these subsamples $\hat{S}$ is a valid input to $L(\cdot)$, and thus $L(\mathbb{A}(S;T))$ is a well-defined sequence of classifiers. Furthermore, since the recursive calls all have T as a subsequence of their second arguments, and the terminal case (i.e., Step 1) includes this second argument in the constructed subsample, another straightforward inductive argument implies that every subsample $\hat{S}$ returned by $\mathbb{A}(S;T)$ satisfies $\hat{S} \supseteq T$. Thus, in the case that $f^\star \in \mathbb{C}[S]$ and $f^\star \in \mathbb{C}[T]$, by definition of L, we also have that every classifier h in the sequence $L(\mathbb{A}(S;T))$ satisfies $h \in \mathbb{C}[T]$.

Fix a numerical constant $c = 1800$. We will prove by induction that, for any $m' \in \mathbb{N}$, for every $\delta' \in (0,1)$, and every finite sequence T' of points in $\mathcal{X} \times \mathcal{Y}$ with $f^\star \in \mathbb{C}[T']$, with probability at least $1 - \delta'$, the classifier $\hat{h}_{m',T'} = \mathrm{Majority}\left(L\left(\mathbb{A}(\mathbb{S}_{1:m'}; T')\right)\right)$ satisfies

$$\mathrm{er}_{\mathcal{P}}(\hat{h}_{m',T'}; f^\star) \leq \frac{c}{m'+1}\left(d + \ln\left(\frac{18}{\delta'}\right)\right). \tag{5}$$

First, as a base case, consider any $m' \in \mathbb{N}$ with $m' \leq c\ln(18e) - 1$. In this case, fix any $\delta' \in (0,1)$ and any sequence T' with $f^\star \in \mathbb{C}[T']$. Also note that $f^\star \in \mathbb{C}[\mathbb{S}_{1:m'}]$. Thus, as discussed above, $\hat{h}_{m',T'}$ is a well-defined classifier. We then trivially have

$$\mathrm{er}_{\mathcal{P}}(\hat{h}_{m',T'}; f^\star) \leq 1 \leq \frac{c}{m'+1}(1 + \ln(18)) < \frac{c}{m'+1}\left(d + \ln\left(\frac{18}{\delta'}\right)\right),$$

so that (5) holds.

Now take as an inductive hypothesis that, for some $m \in \mathbb{N}$ with $m > c\ln(18e) - 1$, for every $m' \in \mathbb{N}$ with $m' < m$, we have that for every $\delta' \in (0,1)$ and every finite sequence T' in $\mathcal{X} \times \mathcal{Y}$ with $f^\star \in \mathbb{C}[T']$, with probability at least $1 - \delta'$, (5) is satisfied. To complete the inductive proof, we aim to establish that this remains the case with $m' = m$ as well. Fix any $\delta \in (0,1)$ and any finite sequence T of points in $\mathcal{X} \times \mathcal{Y}$ with $f^\star \in \mathbb{C}[T]$. Note that $c\ln(18e) - 1 \geq 3$, so that (since $|\mathbb{S}_{1:m}| = m > c\ln(18e) - 1$) we have $|\mathbb{S}_{1:m}| \geq 4$, and hence the execution of $\mathbb{A}(\mathbb{S}_{1:m}; T)$ returns in Step 3 (not Step 1). Let S_0, S_1, S_2, S_3 be as in the definition of $\mathbb{A}(S;T)$, with $S = \mathbb{S}_{1:m}$. Also denote $T_1 = S_2 \cup S_3 \cup T$, $T_2 = S_1 \cup S_3 \cup T$, $T_3 = S_1 \cup S_2 \cup T$, and for each $i \in \{1,2,3\}$, denote $h_i = \mathrm{Majority}\left(L\left(\mathbb{A}(S_0; T_i)\right)\right)$, corresponding to

the majority votes of classifiers trained on the subsamples from each of the three recursive calls in the algorithm.

Note that $S_0 = \mathbb{S}_{1:(m-3\lfloor m/4 \rfloor)}$. Furthermore, since $m \geq 4$, we have $1 \leq m - 3\lfloor m/4 \rfloor < m$. Also note that $f^\star \in \mathbb{C}[S_i]$ for each $i \in \{1,2,3\}$, which, together with the fact that $f^\star \in \mathbb{C}[T]$, implies $f^\star \in \mathbb{C}[T] \cap \bigcap_{j \in \{1,2,3\} \setminus \{i\}} \mathbb{C}[S_j] = \mathbb{C}[T_i]$ for each $i \in \{1,2,3\}$. Thus, since $f^\star \in \mathbb{C}[S_0]$ as well, for each $i \in \{1,2,3\}$, $L\left(\mathbb{A}(S_0;T_i)\right)$ is a well-defined sequence of classifiers (as discussed above), so that h_i is also well-defined. In particular, note that $h_i = \hat{h}_{(m-3\lfloor m/4 \rfloor), T_i}$. Therefore, by the inductive hypothesis (applied under the conditional distribution given S_1, S_2, S_3, which are independent of S_0), combined with the law of total probability, for each $i \in \{1,2,3\}$, there is an event E_i of probability at least $1 - \delta/9$, on which

$$\mathcal{P}(\mathrm{ER}(h_i)) \leq \frac{c}{|S_0|+1}\left(d + \ln\left(\frac{9 \cdot 18}{\delta}\right)\right) \leq \frac{4c}{m}\left(d + \ln\left(\frac{9 \cdot 18}{\delta}\right)\right). \tag{6}$$

Next, fix any $i \in \{1,2,3\}$, and denote by $\{(Z_{i,1}, f^\star(Z_{i,1})), \ldots, (Z_{i,N_i}, f^\star(Z_{i,N_i}))\} = S_i \cap (\mathrm{ER}(h_i) \times \mathcal{Y})$, where $N_i = |S_i \cap (\mathrm{ER}(h_i) \times \mathcal{Y})|$: that is, $\{(Z_{i,t}, f^\star(Z_{i,t}))\}_{t=1}^{N_i}$ is the subsequence of elements (x,y) in S_i for which $x \in \mathrm{ER}(h_i)$. Note that, since h_i and S_i are independent, $Z_{i,1}, \ldots, Z_{i,N_i}$ are conditionally independent given h_i and N_i, each with conditional distribution $\mathcal{P}(\cdot|\mathrm{ER}(h_i))$ (if $N_i > 0$). Thus, applying Lemma 4 under the conditional distribution given h_i and N_i, combined with the law of total probability, we have that on an event E_i' of probability at least $1 - \delta/9$, if $N_i > 0$, then every $h \in \mathbb{C}\left[\{(Z_{i,t}, f^\star(Z_{i,t}))\}_{t=1}^{N_i}\right]$ satisfies

$$\mathrm{er}_{\mathcal{P}(\cdot|\mathrm{ER}(h_i))}(h; f^\star) \leq \frac{2}{N_i}\left(d\mathrm{Log}_2\left(\frac{2eN_i}{d}\right) + \mathrm{Log}_2\left(\frac{18}{\delta}\right)\right).$$

Furthermore, as discussed above, each $j \in \{1,2,3\} \setminus \{i\}$ and $h \in L\left(\mathbb{A}(S_0;T_j)\right)$ have $h \in \mathbb{C}[T_j]$, and $T_j \supseteq S_i \supseteq \{(Z_{i,t}, f^\star(Z_{i,t}))\}_{t=1}^{N_i}$, so that $\mathbb{C}[T_j] \subseteq \mathbb{C}\left[\{(Z_{i,t}, f^\star(Z_{i,t}))\}_{t=1}^{N_i}\right]$. It follows that every $h \in \bigcup_{j \in \{1,2,3\} \setminus \{i\}} L\left(\mathbb{A}(S_0;T_j)\right)$ has $h \in \mathbb{C}\left[\{(Z_{i,t}, f^\star(Z_{i,t}))\}_{t=1}^{N_i}\right]$. Thus, on the event E_i', if $N_i > 0$, $\forall h \in \bigcup_{j \in \{1,2,3\} \setminus \{i\}} L(\mathbb{A}(S_0;T_j))$,

$$\begin{aligned}
&\mathcal{P}(\mathrm{ER}(h_i) \cap \mathrm{ER}(h)) = \mathcal{P}(\mathrm{ER}(h_i))\mathcal{P}(\mathrm{ER}(h)|\mathrm{ER}(h_i)) \\
&= \mathcal{P}(\mathrm{ER}(h_i))\mathrm{er}_{\mathcal{P}(\cdot|\mathrm{ER}(h_i))}(h; f^\star) \leq \mathcal{P}(\mathrm{ER}(h_i))\frac{2}{N_i}\left(d\mathrm{Log}_2\left(\frac{2eN_i}{d}\right) + \mathrm{Log}_2\left(\frac{18}{\delta}\right)\right).
\end{aligned} \tag{7}$$

Additionally, since h_i and S_i are independent, by a Chernoff bound (applied under the conditional distribution given h_i) and the law of total probability, there is an event E_i'' of probability at least $1 - \delta/9$, on which, if $\mathcal{P}(\mathrm{ER}(h_i)) \geq \frac{23}{\lfloor m/4 \rfloor}\ln\left(\frac{9}{\delta}\right) \geq \frac{2(10/3)^2}{\lfloor m/4 \rfloor}\ln\left(\frac{9}{\delta}\right)$, then

$$N_i \geq (7/10)\mathcal{P}(\mathrm{ER}(h_i))|S_i| = (7/10)\mathcal{P}(\mathrm{ER}(h_i))\lfloor m/4 \rfloor.$$

In particular, on E_i'', if $\mathcal{P}(\mathrm{ER}(h_i)) \geq \frac{23}{\lfloor m/4 \rfloor}\ln\left(\frac{9}{\delta}\right)$, then the above inequality implies $N_i > 0$.

Combining this with (6) and (7), and noting that $\mathrm{Log}_2(x) \leq \mathrm{Log}(x)/\ln(2)$ and $x \mapsto \frac{1}{x}\mathrm{Log}(c'x)$ is nonincreasing on $(0,\infty)$ (for any fixed $c' > 0$), we have that on $E_i \cap E_i' \cap E_i''$,

if $\mathcal{P}(\mathrm{ER}(h_i)) \geq \frac{23}{\lfloor m/4 \rfloor}\ln\left(\frac{9}{\delta}\right)$, then every $h \in \bigcup_{j \in \{1,2,3\} \setminus \{i\}} L(\mathbb{A}(S_0;T_j))$ has

$$\begin{aligned}
\mathcal{P}(\mathrm{ER}(h_i) \cap \mathrm{ER}(h)) &\leq \frac{20}{7\ln(2)\lfloor m/4 \rfloor}\left(d\mathrm{Log}\left(\frac{2e(7/10)\mathcal{P}(\mathrm{ER}(h_i))\lfloor m/4 \rfloor}{d}\right) + \mathrm{Log}\left(\frac{18}{\delta}\right)\right) \\
&\leq \frac{20}{7\ln(2)\lfloor m/4 \rfloor}\left(d\mathrm{Log}\left(\frac{(7/5)ec\left(d + \ln\left(\frac{9 \cdot 18}{\delta}\right)\right)}{d}\right) + \mathrm{Log}\left(\frac{18}{\delta}\right)\right) \\
&\leq \frac{20}{7\ln(2)\lfloor m/4 \rfloor}\left(d\mathrm{Log}\left((2/5)c\left((7/2)e + \frac{7e}{d}\ln\left(\frac{18}{\delta}\right)\right)\right) + \mathrm{Log}\left(\frac{18}{\delta}\right)\right) \\
&\leq \frac{20}{7\ln(2)\lfloor m/4 \rfloor}\left(d\ln((9/5)ec) + 8\ln\left(\frac{18}{\delta}\right)\right),
\end{aligned} \tag{8}$$

where this last inequality is due to Lemma 5 in Appendix A. Since $m > c\ln(18e) - 1 > 3200$, we have $\lfloor m/4 \rfloor > (m-4)/4 > \frac{799}{800}\frac{m}{4} > \frac{799}{800}\frac{3200}{3201}\frac{m+1}{4}$. Plugging this relaxation into the above bound, combined with numerical calculation of the logarithmic factor (with c as defined above), we find that the expression in (8) is less than

$$\frac{150}{m+1}\left(d + \ln\left(\frac{18}{\delta}\right)\right).$$

Additionally, if $\mathcal{P}(\mathrm{ER}(h_i)) < \frac{23}{\lfloor m/4 \rfloor}\ln\left(\frac{9}{\delta}\right)$, then monotonicity of measures implies

$$\mathcal{P}(\mathrm{ER}(h_i) \cap \mathrm{ER}(h)) \leq \mathcal{P}(\mathrm{ER}(h_i)) < \frac{23}{\lfloor m/4 \rfloor}\ln\left(\frac{9}{\delta}\right) < \frac{150}{m+1}\left(d + \ln\left(\frac{18}{\delta}\right)\right),$$

again using the above lower bound on $\lfloor m/4 \rfloor$ for this last inequality. Thus, regardless of the value of $\mathcal{P}(\mathrm{ER}(h_i))$, on the event $E_i \cap E_i' \cap E_i''$, we have $\forall h \in \bigcup_{j \in \{1,2,3\} \setminus \{i\}} L(\mathbb{A}(S_0;T_j))$,

$$\mathcal{P}(\mathrm{ER}(h_i) \cap \mathrm{ER}(h)) < \frac{150}{m+1}\left(d + \ln\left(\frac{18}{\delta}\right)\right).$$

Now denote $h_{\mathrm{maj}} = \hat{h}_{m,T} = \mathrm{Majority}\left(L(\mathbb{A}(S;T))\right)$, again with $S = \mathbb{S}_{1:m}$. By definition of Majority$(\cdot)$, for any $x \in \mathcal{X}$, at least $1/2$ of the classifiers h in the sequence $L(\mathbb{A}(S;T))$ have $h(x) = h_{\mathrm{maj}}(x)$. From this fact, the strong form of the pigeonhole principle implies that at least one $i \in \{1,2,3\}$ has $h_i(x) = h_{\mathrm{maj}}(x)$ (i.e., the majority vote must agree with the majority of classifiers in at least one of the three subsequences of classifiers). Furthermore, since each $\mathbb{A}(S_0;T_j)$ (with $j \in \{1,2,3\}$) supplies an equal number of entries to the sequence $\mathbb{A}(S;T)$ (by a straightforward inductive argument), for each $i \in \{1,2,3\}$, at least $1/4$ of the classifiers h in $\cup_{j \in \{1,2,3\} \setminus \{i\}} L(\mathbb{A}(S_0;T_j))$ have $h(x) = h_{\mathrm{maj}}(x)$: that is, since $|L(\mathbb{A}(S_0;T_i))| = (1/3)|L(\mathbb{A}(S;T))|$, we must have at least $(1/6)|L(\mathbb{A}(S;T))| = (1/4)\left|\bigcup_{j \in \{1,2,3\} \setminus \{i\}} L(\mathbb{A}(S_0;T_j))\right|$ classifiers h in $\bigcup_{j \in \{1,2,3\} \setminus \{i\}} L(S_0;T_j)$ with $h(x) = h_{\mathrm{maj}}(x)$ in order to meet the total of at least $(1/2)|L(\mathbb{A}(S;T))|$ classifiers $h \in L(\mathbb{A}(S;T))$ with $h(x) = h_{\mathrm{maj}}(x)$. In particular, letting I be a random variable uniformly distributed on $\{1,2,3\}$ (independent of the data), and letting $\tilde{h}$ be a random variable conditionally (given I and S) uniformly distributed on the classifiers $\cup_{j \in \{1,2,3\} \setminus \{I\}} L(\mathbb{A}(S_0;T_j))$, this implies that for any fixed $x \in \mathrm{ER}(h_{\mathrm{maj}})$, with conditional (given S) probability at least $1/12$,

$h_I(x) = \tilde{h}(x) = h_{\text{maj}}(x)$, so that $x \in \text{ER}(h_I) \cap \text{ER}(\tilde{h})$ as well. Thus, for a random variable $X \sim \mathcal{P}$ (independent of the data and I,$\tilde{h}$), the law of total probability and monotonicity of conditional expectations imply

$$\begin{aligned}
&\mathbb{E}\left[\mathcal{P}\left(\text{ER}(h_I) \cap \text{ER}(\tilde{h})\right)\middle|S\right] = \mathbb{E}\left[\mathbb{P}\left(X \in \text{ER}(h_I) \cap \text{ER}(\tilde{h})\middle|I, \tilde{h}, S\right)\middle|S\right] \\
&= \mathbb{E}\left[\mathbb{1}\left[X \in \text{ER}(h_I) \cap \text{ER}(\tilde{h})\right]\middle|S\right] = \mathbb{E}\left[\mathbb{P}\left(X \in \text{ER}(h_I) \cap \text{ER}(\tilde{h})\middle|S, X\right)\middle|S\right] \\
&\geq \mathbb{E}\left[\mathbb{P}\left(X \in \text{ER}(h_I) \cap \text{ER}(\tilde{h})\middle|S, X\right)\mathbb{1}\left[X \in \text{ER}(h_{\text{maj}})\right]\middle|S\right] \\
&\geq \mathbb{E}\left[(1/12)\mathbb{1}\left[X \in \text{ER}(h_{\text{maj}})\right]|S\right] = (1/12)\text{er}_{\mathcal{P}}(h_{\text{maj}}; f^\star).
\end{aligned}$$

Thus, on the event $\bigcap_{i\in\{1,2,3\}} E_i \cap E_i' \cap E_i''$,

$$\begin{aligned}
\text{er}_{\mathcal{P}}(h_{\text{maj}}; f^\star) &\leq 12\mathbb{E}\left[\mathcal{P}\left(\text{ER}(h_I) \cap \text{ER}(\tilde{h})\right)\middle|S\right] \\
&\leq 12 \max_{i\in\{1,2,3\}} \max_{j\in\{1,2,3\}\setminus\{i\}} \max_{h\in L(\mathbb{A}(S_0;T_j))} \mathcal{P}(\text{ER}(h_i) \cap \text{ER}(h)) \\
&< \frac{1800}{m+1}\left(d + \ln\left(\frac{18}{\delta}\right)\right) = \frac{c}{m+1}\left(d + \ln\left(\frac{18}{\delta}\right)\right).
\end{aligned}$$

Furthermore, by the union bound, the event $\bigcap_{i\in\{1,2,3\}} E_i \cap E_i' \cap E_i''$ has probability at least $1-\delta$. Thus, since this argument holds for any $\delta \in (0,1)$ and any finite sequence T with $f^\star \in \mathbb{C}[T]$, we have succeeded in extending the inductive hypothesis to include $m' = m$.

By the principle of induction, we have established the claim that, $\forall m \in \mathbb{N}$, $\forall \delta \in (0,1)$, for every finite sequence T of points in $\mathcal{X} \times \mathcal{Y}$ with $f^\star \in \mathbb{C}[T]$, with probability at least $1-\delta$,

$$\text{er}_{\mathcal{P}}(\hat{h}_{m,T}; f^\star) \leq \frac{c}{m+1}\left(d + \ln\left(\frac{18}{\delta}\right)\right). \tag{9}$$

To complete the proof, we simply take $T = \emptyset$ (the empty sequence), and note that, for any $\varepsilon, \delta \in (0,1)$, for any value $m \in \mathbb{N}$ of size at least

$$\left\lfloor \frac{c}{\varepsilon}\left(d + \ln\left(\frac{18}{\delta}\right)\right)\right\rfloor, \tag{10}$$

the right hand side of (9) is less than ε, so that Majority$(L(\mathbb{A}(\cdot;\emptyset)))$ achieves a sample complexity equal the expression in (10). In particular, this implies

$$\mathcal{M}(\varepsilon, \delta) \leq \frac{c}{\varepsilon}\left(d + \ln\left(\frac{18}{\delta}\right)\right) = O\left(\frac{1}{\varepsilon}\left(d + \text{Log}\left(\frac{1}{\delta}\right)\right)\right).$$

■

5. Remarks

On the issue of computational complexity, we note that the construction of subsamples by $\mathbb{A}$ can be quite efficient. Since the branching factor is 3, while $|S_0|$ is reduced by roughly

a factor of 4 with each recursive call, the total number of subsamples returned by $\mathbb{A}(S;\emptyset)$ is a sublinear function of $|S|$. Furthermore, with appropriate data structures, the operations within each node of the recursion tree can be performed in constant time. Indeed, as discussed above, one can directly determine which data points to include in each subsample via a simple function of the indices, so that construction of these subsamples truly is computationally easy.

The only remaining significant computational issue in the learning algorithm is then the efficiency of the sample-consistent base learner L. The existence of such an algorithm L, with running time polynomial in the size of the input sequence and d, has been the subject of much investigation for a variety of concept spaces $\mathbb{C}$ (e.g., Khachiyan, 1979; Karmarkar, 1984; Valiant, 1984; Pitt and Valiant, 1988; Helmbold, Sloan, and Warmuth, 1990). For instance, the commonly-used concept space of *linear separators* admits such an algorithm (where $L(S)$ may be expressed as a solution of a system of linear inequalities). One can easily extend Theorem 2 to admit base learners L that are *improper* (i.e., which may return classifiers not contained in $\mathbb{C}$), as long as they are guaranteed to return a sample-consistent classifier in *some* hypothesis space $\mathcal{H}$ of VC dimension $O(d)$. Furthermore, as discussed by Pitt and Valiant (1988) and Haussler, Kearns, Littlestone, and Warmuth (1991), there is a simple technique for efficiently converting *any* efficient PAC learning algorithm for $\mathbb{C}$, returning classifiers in $\mathcal{H}$, into an efficient algorithm L for finding (with probability $1-\delta'$) a classifier in $\mathcal{H}$ consistent with a given data set S with $\mathbb{C}[S] \neq \emptyset$. Additionally, though the analysis above takes L to be deterministic, this merely serves to simplify the notation in the proof, and it is straightforward to generalize the proof to allow randomized base learners L, including those that fail to return a sample-consistent classifier with some probability δ' taken sufficiently small (e.g., $\delta' = \delta/(2|\mathbb{A}(S;\emptyset)|)$). Composing these facts, we may conclude that, for any concept space $\mathbb{C}$ that is efficiently PAC learnable using a hypothesis space $\mathcal{H}$ of VC dimension $O(d)$, there exists an efficient PAC learning algorithm for $\mathbb{C}$ with optimal sample complexity (up to numerical constant factors).

We conclude by noting that the constant factors obtained in the above proof are quite large. Some small refinements are possible within the current approach: for instance, by choosing the S_i subsequences slightly larger (e.g., $(3/10)|S|$), or using a tighter form of the Chernoff bound when lower-bounding N_i. However, there are inherent limitations to the approach used here, so that reducing the constant factors by more than, say, one order of magnitude, may require significant changes to some part of the analysis, and perhaps the algorithm itself. For this reason, it seems the next step in the study of $\mathcal{M}(\varepsilon,\delta)$ should be to search for strategies yielding refined constant factors. In particular, Warmuth (2004) has conjectured that the one-inclusion graph prediction algorithm also achieves a sample complexity of the optimal form. This conjecture remains open at this time. The one-inclusion graph predictor is known to achieve the optimal sample complexity in the closely-related *prediction model* of learning (where the objective is to achieve *expected* error rate at most ε), with a numerical constant factor very close to optimal (Haussler, Littlestone, and Warmuth, 1994). It therefore seems likely that a (positive) resolution of Warmuth's one-inclusion graph conjecture may also lead to improvements in constant factors compared to the bound on $\mathcal{M}(\varepsilon,\delta)$ established in the present work.

Acknowledgments

I would like to express my sincere thanks to Hans Simon and Amit Daniely for helpful comments on a preliminary attempt at a solution.

Appendix A. A Technical Lemma

The following basic lemma is useful in the proof of Theorem 2.[5]

Lemma 5 *For any $a, b, c_1 \in [1, \infty)$ and $c_2 \in [0, \infty)$,*

$$a \ln\left(c_1\left(c_2 + \frac{b}{a}\right)\right) \leq a \ln\left(c_1(c_2 + e)\right) + \frac{1}{e}b.$$

Proof If $\frac{b}{a} \leq e$, then monotonicity of $\ln(\cdot)$ implies

$$a \ln\left(c_1\left(c_2 + \frac{b}{a}\right)\right) \leq a \ln(c_1(c_2 + e)) \leq a \ln(c_1(c_2 + e)) + \frac{1}{e}b.$$

On the other hand, if $\frac{b}{a} > e$, then

$$a \ln\left(c_1\left(c_2 + \frac{b}{a}\right)\right) \leq a \ln\left(c_1 \max\{c_2, 2\}\frac{b}{a}\right) = a \ln\left(c_1 \max\{c_2, 2\}\right) + a \ln\left(\frac{b}{a}\right).$$

The first term in the rightmost expression is at most $a \ln(c_1(c_2+2)) \leq a \ln(c_1(c_2+e))$. The second term in the rightmost expression can be rewritten as $b\frac{\ln(b/a)}{b/a}$. Since $x \mapsto \ln(x)/x$ is nonincreasing on (e, ∞), in the case $\frac{b}{a} > e$, this is at most $\frac{1}{e}b$. Together, we have that

$$a \ln\left(c_1\left(c_2 + \frac{b}{a}\right)\right) \leq a \ln(c_1(c_2 + e)) + \frac{1}{e}b$$

in this case as well. ■

Abstract

Policy search methods can allow robots to learn control policies for a wide range of tasks, but practical applications of policy search often require hand-engineered components for perception, state estimation, and low-level control. In this paper, we aim to answer the following question: does training the perception and control systems jointly end-to-end provide better performance than training each component separately? To this end, we develop a method that can be used to learn policies that map raw image observations directly to torques at the robot's motors. The policies are represented by deep convolutional neural networks (CNNs) with 92,000 parameters, and are trained using a guided policy search method, which transforms policy search into supervised learning, with supervision provided by a simple trajectory-centric reinforcement learning method. We evaluate our method on a range of real-world manipulation tasks that require close coordination between vision and control, such as screwing a cap onto a bottle, and present simulated comparisons to a range of prior policy search methods.

Keywords: Reinforcement Learning, Optimal Control, Vision, Neural Networks

1. Introduction

Robots can perform impressive tasks under human control, including surgery (Lanfranco et al., 2004) and household chores (Wyrobek et al., 2008). However, designing the perception and control software for autonomous operation remains a major challenge, even for basic tasks. Policy search methods hold the promise of allowing robots to automatically learn new behaviors through experience (Kober et al., 2010b; Deisenroth et al., 2011; Kalakrishnan et al., 2011; Deisenroth et al., 2013). However, policies learned using such methods often rely on a number of hand-engineered components for perception and control, so as to present the policy with a more manageable and low-dimensional representation of observations and actions. The vision system in particular can be complex and prone to errors, and it is typically not improved during policy training, nor adapted to the goal of the task.

In this article, we aim to answer the following question: can we acquire more effective policies for sensorimotor control if the perception system is trained jointly with the control policy, rather than separately? In order to represent a policy that performs both

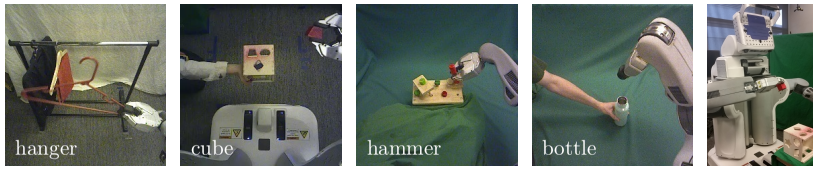

Figure 1: Our method learns visuomotor policies that directly use camera image observations (left) to set motor torques on a PR2 robot (right).

perception and control, we use deep neural networks. Deep neural network representations have recently seen widespread success in a variety of domains, such as computer vision and speech recognition, and even playing video games. However, using deep neural networks for real-world sensorimotor policies, such as robotic controllers that map image pixels and joint angles to motor torques, presents a number of unique challenges. Successful applications of deep neural networks typically rely on large amounts of data and direct supervision of the output, neither of which is available in robotic control. Real-world robot interaction data is scarce, and task completion is defined at a high level by means of a cost function, which means that the learning algorithm must determine on its own which action to take at each point. From the control perspective, a further complication is that observations from the robot's sensors do not provide us with the full state of the system. Instead, important state information, such as the positions of task-relevant objects, must be inferred from inputs such as camera images.

We address these challenges by developing a guided policy search algorithm for sensorimotor deep learning, as well as a novel CNN architecture designed for robotic control. Guided policy search converts policy search into supervised learning, by iteratively constructing the training data using an efficient model-free trajectory optimization procedure. We show that this can be formalized as an instance of Bregman ADMM (BADMM) (Wang and Banerjee, 2014), which can be used to show that the algorithm converges to a locally optimal solution. In our method, the full state of the system is observable at training time, but not at test time. For most tasks, providing the full state simply requires positioning objects in one of several known positions for each trial during training. At test time, the learned CNN policy can handle novel, unknown configurations, and no longer requires full state information. Since the policy is optimized with supervised learning, we can use standard methods like stochastic gradient descent for training. Our CNNs have 92,000 parameters and 7 layers, including a novel spatial feature point transformation that provides accurate spatial reasoning and reduces overfitting. This allows us to train our policies with relatively modest amounts of data and only tens of minutes of real-world interaction time.

We evaluate our method by learning policies for inserting a block into a shape sorting cube, screwing a cap onto a bottle, fitting the claw of a toy hammer under a nail with various grasps, and placing a coat hanger on a rack with a PR2 robot (see Figure 1). These tasks require localization, visual tracking, and handling complex contact dynamics. Our results demonstrate improvements in consistency and generalization from training visuomotor policies end-to-end, when compared to training the vision and control components separately. We also present simulated comparisons that show that guided policy search outperforms a

number of prior methods when training high-dimensional neural network policies. Some of the material in this article has previously appeared in two conference papers (Levine and Abbeel, 2014; Levine et al., 2015), which we extend to introduce visual input into the policy.

2. Related Work

Reinforcement learning and policy search methods (Gullapalli, 1990; Williams, 1992) have been applied in robotics for playing games such as table tennis (Kober et al., 2010b), object manipulation (Gullapalli, 1995; Peters and Schaal, 2008; Kober et al., 2010a; Deisenroth et al., 2011; Kalakrishnan et al., 2011), locomotion (Benbrahim and Franklin, 1997; Kohl and Stone, 2004; Tedrake et al., 2004; Geng et al., 2006; Endo et al., 2008), and flight (Ng et al., 2004). Several recent papers provide surveys of policy search in robotics (Deisenroth et al., 2013; Kober et al., 2013). Such methods are typically applied to one component of the robot control pipeline, which often sits on top of a hand-designed controller, such as a PD controller, and accepts processed input, for example from an existing vision pipeline (Kalakrishnan et al., 2011). Our method learns policies that map visual input and joint encoder readings directly to the torques at the robot's joints. By learning the entire mapping from perception to control, the perception layers can be adapted to optimize task performance, and the motor control layers can be adapted to imperfect perception.

We represent our policies with convolutional neural networks (CNNs). CNNs have a long history in computer vision and deep learning (Fukushima, 1980; LeCun et al., 1989; Schmidhuber, 2015), and have recently gained prominence due to excellent results on a number of vision benchmarks (Ciresan et al., 2011; Krizhevsky et al., 2012; Ciresan et al., 2012; Girshick et al., 2014a; Tompson et al., 2014; LeCun et al., 2015; He et al., 2015). Most applications of CNNs focus on classification, where locational information is discarded by means of successive pooling layers to provide for invariance (Lee et al., 2009). Applications to localization typically either use a sliding window (Girshick et al., 2014a) or object proposals (Endres and Hoiem, 2010; Uijlings et al., 2013; Girshick et al., 2014b) to localize the object, reducing the task to classification, perform regression to a heatmap of manually labeled keypoints (Tompson et al., 2014), requiring precise knowledge of the object position in the image and camera calibration, or use 3D models to localize previously scanned objects (Pepik et al., 2012; Savarese and Fei-Fei, 2007). Many prior robotic applications of CNNs do not directly consider control, but employ CNNs for the perception component of a larger robotic system (Hadsell et al., 2009; Sung et al., 2015; Lenz et al., 2015b; Pinto and Gupta, 2015). We use a novel CNN architecture for our policies that automatically learn feature points that capture spatial information about the scene, without any supervision beyond the information from the robot's encoders and camera.

Applications of deep learning in robotic control have been less prevalent in recent years than in visual recognition. Backpropagation through the dynamics and the image formation process is typically impractical, since they are often non-differentiable, and such long-range backpropagation can lead to extreme numerical instability, since the linearization of a suboptimal policy is likely to be unstable. This issue has also been observed in the related context of recurrent neural networks (Hochreiter et al., 2001; Pascanu and Bengio, 2012). The high dimensionality of the network also makes reinforcement learning difficult (Deisenroth et al., 2013). Pioneering early work on neural network control used

small, simple networks (Pomerleau, 1989; Hunt et al., 1992; Bekey and Goldberg, 1992; Lewis et al., 1998; Bakker et al., 2003; Mayer et al., 2006), and has largely been supplanted by methods that use carefully designed policies that can be learned efficiently with reinforcement learning (Kober et al., 2013). More recent work on sensorimotor deep learning has tackled simple task-space motions (Lenz et al., 2015a; Lampe and Riedmiller, 2013) and used unsupervised learning to obtain low-dimensional state spaces from images (Lange et al., 2012). Such methods have been demonstrated on tasks with a low-dimensional underlying structure: Lenz et al. (2015a) controls the end-effector in 2D space, while Lange et al. (2012) controls a 2-dimensional slot car with 1-dimensional actions. Our experiments include full torque control of 7-DoF robotic arms interacting with objects, with 30-40 state dimensions. In simple synthetic environments, control from images has been addressed with image features (Jodogne and Piater, 2007), nonparametric methods (van Hoof et al., 2015), and unsupervised state-space learning (Böhmer et al., 2013; Jonschkowski and Brock, 2014). CNNs have also been trained to play video games with Q-learning, Monte Carlo tree search, and stochastic search (Mnih et al., 2013; Koutník et al., 2013; Guo et al., 2014), and have been applied to simple simulated control tasks (Watter et al., 2015; Lillicrap et al., 2015). However, such methods have only been demonstrated on synthetic domains that lack the visual complexity of the real world, and require an impractical number of samples for real-world robotic learning. Our method is sample efficient, requiring only minutes of interaction time. To the best of our knowledge, this is the first method that can train deep visuomotor policies for complex, high-dimensional manipulation skills with direct torque control.

Learning visuomotor policies on a real robot requires handling complex observations and high dimensional policy representations. We tackle these challenges using guided policy search. In guided policy search, the policy is optimized using supervised learning, which scales gracefully with the dimensionality of the policy. The training set for supervised learning can be constructed using trajectory optimization under known dynamics (Levine and Koltun, 2013a,b, 2014; Mordatch and Todorov, 2014) and trajectory-centric reinforcement learning methods that operate under unknown dynamics (Levine and Abbeel, 2014; Levine et al., 2015), which is the approach taken in this work. In both cases, the supervision is adapted to the policy, to ensure that the final policy can reproduce the training data. The use of supervised learning in the inner loop of iterative policy search has also been proposed in the context of imitation learning (Ross et al., 2011, 2013). However, such methods typically do not address the question of how the supervision should be adapted to the policy.

The goal of our approach is also similar to visual servoing, which performs feedback control on feature points in a camera image (Espiau et al., 1992; Mohta et al., 2014; Wilson et al., 1996). However, our visuomotor policies are entirely learned from real-world data, and do not require feature points or feedback controllers to be specified by hand. This allows our method much more flexibility in choosing how to use the visual signal. Our approach also does not require any sort of camera calibration, in contrast to many visual servoing methods (though not all – see e.g. Jägersand et al. (1997); Yoshimi and Allen (1994)).

3. Background and Overview

In this section, we define the visuomotor policy learning problem and present an overview of our approach. The core component of our approach is a guided policy search algorithm

that separates the problem of learning visuomotor policies into separate supervised learning and trajectory learning phases, each of which is easier than optimizing the policy directly. We also discuss a policy architecture suitable for end-to-end learning of vision and control, and a training setup that allows our method to be applied to real robotic platforms.

3.1 Definitions and Problem Formulation

In policy search, the goal is to learn a policy $\pi_\theta(\mathbf{u}_t|\mathbf{o}_t)$ that allows an agent to choose actions $\mathbf{u}_t$ in response to observations $\mathbf{o}_t$ to control a dynamical system, such as a robot. The policy comes from some parametric class parameterized by θ, which could be, for example, the weights of a neural network. The system is defined by states $\mathbf{x}_t$, actions $\mathbf{u}_t$, and observations $\mathbf{o}_t$. For example, $\mathbf{x}_t$ might include the joint angles of the robot, the positions of objects in the world, and their time derivatives, $\mathbf{u}_t$ might consist of motor torque commands, and $\mathbf{o}_t$ might include an image from the robot's onboard camera. In this paper, we address finite horizon episodic tasks with $t \in [1, \ldots, T]$. The states evolve in time according to the system dynamics $p(\mathbf{x}_{t+1}|\mathbf{x}_t, \mathbf{u}_t)$, and the observations are, in general, a stochastic consequence of the states, according to $p(\mathbf{o}_t|\mathbf{x}_t)$. Neither the dynamics nor the observation distribution are assumed to be known in general. For notational convenience, we will use $\pi_\theta(\mathbf{u}_t|\mathbf{x}_t)$ to denote the distribution over actions under the policy conditioned on the state. However, since the policy is conditioned on the observation $\mathbf{o}_t$, this distribution is in fact given by $\pi_\theta(\mathbf{u}_t|\mathbf{x}_t) = \int \pi_\theta(\mathbf{u}_t|\mathbf{o}_t)p(\mathbf{o}_t|\mathbf{x}_t)d\mathbf{o}_t$. The dynamics and $\pi_\theta(\mathbf{u}_t|\mathbf{x}_t)$ together induce a distribution over trajectories $\tau = \{\mathbf{x}_1, \mathbf{u}_1, \mathbf{x}_2, \mathbf{u}_2, \ldots, \mathbf{x}_T, \mathbf{u}_T\}$:

$$\pi_\theta(\tau) = p(\mathbf{x}_1) \prod_{t=1}^{T} \pi_\theta(\mathbf{u}_t|\mathbf{x}_t) p(\mathbf{x}_{t+1}|\mathbf{x}_t, \mathbf{u}_t).$$

The goal of a task is given by a cost function $\ell(\mathbf{x}_t, \mathbf{u}_t)$, and the objective in policy search is to minimize the expectation $E_{\pi_\theta(\tau)}[\sum_{t=1}^{T} \ell(\mathbf{x}_t, \mathbf{u}_t)]$, which we will abbreviate as $E_{\pi_\theta(\tau)}[\ell(\tau)]$. A summary of the notation used in the paper is provided in Table 1.

3.2 Approach Summary

Our methods consists of two main components, which are illustrated in Figure 3. The first is a supervised learning algorithm that trains policies of the form $\pi_\theta(\mathbf{u}_t|\mathbf{o}_t) = \mathcal{N}(\mu^\pi(\mathbf{o}_t), \Sigma^\pi(\mathbf{o}_t))$, where both $\mu^\pi(\mathbf{o}_t)$ and $\Sigma^\pi(\mathbf{o}_t)$ are general nonlinear functions. In our implementation, $\mu^\pi(\mathbf{o}_t)$ is a deep convolutional neural network, while $\Sigma^\pi(\mathbf{o}_t)$ is an observation-independent learned covariance, though other representations are possible. The second component is a trajectory-centric reinforcement learning (RL) algorithm that generates guiding distributions $p_i(\mathbf{u}_t|\mathbf{x}_t)$ that provide the supervision used to train the policy. These two components form a policy search algorithm that can be used to learn complex robotic tasks using only a high-level cost function $\ell(\mathbf{x}_t, \mathbf{u}_t)$. During training, only samples from the guiding distributions $p_i(\mathbf{u}_t|\mathbf{x}_t)$ are generated by running rollouts on the physical system, which avoids the need to execute partially trained neural network policies on physical hardware.

Supervised learning will not, in general, produce a policy with good long-horizon performance, since a small mistake on the part of the policy will place the system into states that are outside the distribution in the training data, causing compounding errors. To

symbol	definition	example/details
$\mathbf{x}_t$	Markovian system state at time step $t \in [1, T]$	joint angles, end-effector pose, object positions, and their velocities; dimensionality: 14 to 32
$\mathbf{u}_t$	control or action at time step $t \in [1, T]$	joint motor torque commands; dimensionality: 7 (for the PR2 robot)
$\mathbf{o}_t$	observation at time step $t \in [1, T]$	RGB camera image, joint encoder readings & velocities, end-effector pose; dimensionality: around 200,000
τ	trajectory: $\tau = \{\mathbf{x}_1, \mathbf{u}_1, \mathbf{x}_2, \mathbf{u}_2, \ldots, \mathbf{x}_T, \mathbf{u}_T\}$	notational shorthand for a sequence of states and actions
$\ell(\mathbf{x}_t, \mathbf{x}_t)$	cost function that defines the goal of the task	distance between an object in the gripper and the target
$p(\mathbf{x}_{t+1}\|\mathbf{x}_t, \mathbf{u}_t)$	unknown system dynamics	physics that govern the robot and any objects it interacts with
$p(\mathbf{o}_t\|\mathbf{x}_t)$	unknown observation distribution	stochastic process that produces camera images from system state
$\pi_\theta(\mathbf{u}_t\|\mathbf{o}_t)$	learned nonlinear global policy parameterized by weights θ	convolutional neural network, such as the one in Figure 2
$\pi_\theta(\mathbf{u}_t\|\mathbf{x}_t)$	$\int \pi_\theta(\mathbf{u}_t\|\mathbf{o}_t)p(\mathbf{o}_t\|\mathbf{x}_t)d\mathbf{o}_t$	notational shorthand for observation-based policy conditioned on state
$p_i(\mathbf{u}_t\|\mathbf{x}_t)$	learned local time-varying linear-Gaussian controller for initial state $\mathbf{x}_1^i$	time-varying linear-Gaussian controller has form $\mathcal{N}(\mathbf{K}_{ti}\mathbf{x}_t + \mathbf{k}_{ti}, \mathbf{C}_{ti})$
$\pi_\theta(\tau)$	trajectory distribution for $\pi_\theta(\mathbf{u}_t\|\mathbf{x}_t)$: $p(\mathbf{x}_1)\prod_{t=1}^{T} \pi_\theta(\mathbf{u}_t\|\mathbf{x}_t)p(\mathbf{x}_{t+1}\|\mathbf{x}_t, \mathbf{u}_t)$	notational shorthand for trajectory distribution induced by a policy

Table 1: Summary of the notation frequently used in this article.

avoid this issue, the training data must come from the policy's own state distribution (Ross et al., 2011). We achieve this by alternating between trajectory-centric RL and supervised learning. The RL stage adapts to the current policy $\pi_\theta(\mathbf{u}_t|\mathbf{o}_t)$, providing supervision at states that are iteratively brought closer to the states visited by the policy. This is formalized as a variant of the BADMM algorithm (Wang and Banerjee, 2014) for constrained optimization, which can be used to show that, at convergence, the policy $\pi_\theta(\mathbf{u}_t|\mathbf{o}_t)$ and the guiding distributions $p_i(\mathbf{u}_t|\mathbf{x}_t)$ will exhibit the same behavior. This algorithm is derived in Section 4. The guiding distributions are substantially easier to optimize than learning the policy parameters directly (e.g., using model-free reinforcement learning), because they use the full state of the system $\mathbf{x}_t$, while the policy $\pi_\theta(\mathbf{u}_t|\mathbf{o}_t)$ only uses the observations. This means that the method requires the full state to be known during training, but not at test time. This makes it possible to efficiently learn complex visuomotor policies, but imposes additional assumptions on the observability of $\mathbf{x}_t$ during training that we discuss in Section 4.

When learning visuomotor tasks, the policy $\pi_\theta(\mathbf{u}_t|\mathbf{o}_t)$ is represented by a novel convolutional neural network (CNN) architecture, which we describe in Section 5.2. CNNs have enjoyed considerable success in computer vision (LeCun et al., 2015), but the most popular

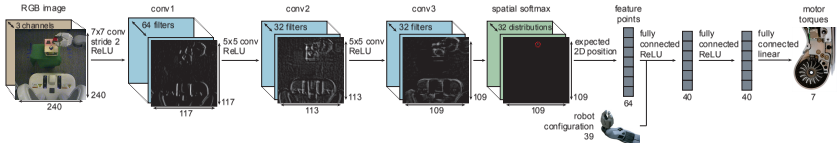

Figure 2: Visuomotor policy architecture. The network contains three convolutional layers, followed by a spatial softmax and an expected position layer that converts pixel-wise features to feature points, which are better suited for spatial computations. The points are concatenated with the robot configuration, then passed through three fully connected layers to produce the torques.

architectures rely on large datasets and focus on semantic tasks such as classification, often intentionally discarding spatial information. Our architecture, illustrated in Figure 2, uses a fixed transformation from the last convolutional layer to a set of spatial feature points, which form a concise representation of the visual scene suitable for feedback control. Our network has 7 layers and around 92,000 parameters, which presents a major challenge for standard policy search methods (Deisenroth et al., 2013).

To reduce the amount of experience needed to train visuomotor policies, we also introduce a pretraining scheme that allows us to train effective policies with a relatively small number of iterations. The pretraining steps are illustrated in Figure 3. The intuition behind our pretraining is that, although we ultimately seek to obtain sensorimotor policies that combine both vision and control, low-level aspects of vision can be initialized independently. To that end, we pretrain the convolutional layers of our network by predicting elements of $\mathbf{x}_t$ that are not provided in the observation $\mathbf{o}_t$, such as the positions of objects in the scene. We also initially train the guiding trajectory distributions $p_i(\mathbf{u}_t|\mathbf{x}_t)$ independently of the convolutional network until the trajectories achieve a basic level of competence at the task, and then switch to full guided policy search with end-to-end training of $\pi_\theta(\mathbf{u}_t|\mathbf{o}_t)$. In our implementation, we also initialize the first layer filters from the model of Szegedy et al. (2014), which is trained on ImageNet (Deng et al., 2009) classification. The initialization and pretraining scheme is described in Section 5.2.

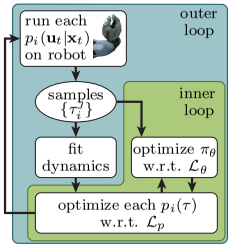
4. Guided Policy Search with BADMM

Guided policy search transforms policy search into a supervised learning problem, where the training set is generated by a simple trajectory-centric RL algorithm. This algorithm

optimizes linear-Gaussian controllers $p_i(\mathbf{u}_t|\mathbf{x}_t)$, and is described in Section 4.2. We refer to the trajectory distribution induced by $p_i(\mathbf{u}_t|\mathbf{x}_t)$ as $p_i(\tau)$. Each $p_i(\mathbf{u}_t|\mathbf{x}_t)$ succeeds from different initial states. For example, in the task of placing a cap on a bottle, these initial states correspond to different positions of the bottle. By training on trajectories for multiple bottle positions, the final CNN policy can succeed from all initial states, and can generalize to other states from the same distribution.

The final policy $\pi_\theta(\mathbf{u}_t|\mathbf{o}_t)$ learned with guided policy search is only provided with observations $\mathbf{o}_t$ of the full state $\mathbf{x}_t$, and the dynamics are assumed to be unknown. A diagram of this method, which corresponds to an expanded version of the guided policy search box in Figure 3, is shown on the right. In the outer loop, we draw sample trajectories $\{\tau_i^j\}$ for each initial state on the physical system by running the corresponding controller $p_i(\mathbf{u}_t|\mathbf{x}_t)$. The samples are used to fit the dynamics $p_i(\mathbf{x}_{t+1}|\mathbf{x}_t, \mathbf{u}_t)$ that are used to improve $p_i(\mathbf{u}_t|\mathbf{x}_t)$, and serve as training data for the policy. The inner loop alternates between optimizing each $p_i(\tau)$ and optimizing the policy to match these trajectory distributions. The policy is trained to predict the actions along each trajectory from the observations $\mathbf{o}_t$, rather than the full state $\mathbf{x}_t$. This allows the policy to directly use raw observations at test time. This alternating optimization can be framed as an instance of the BADMM algorithm (Wang and Banerjee, 2014), which converges to a solution where the trajectory distributions and the policy have the same state distribution. This allows greedy supervised training of the policy to produce a policy with good long-horizon performance.



4.1 Algorithm Derivation

Policy search methods minimize the expected cost $E_{\pi_\theta}[\ell(\tau)]$, where $\tau = \{\mathbf{x}_1, \mathbf{u}_1, \ldots, \mathbf{x}_T, \mathbf{u}_T\}$ is a trajectory, and $\ell(\tau) = \sum_{t=1}^{T} \ell(\mathbf{x}_t, \mathbf{u}_t)$ is the cost of an episode. In the fully observed case, the expectation is taken under $\pi_\theta(\tau) = p(\mathbf{x}_1) \prod_{t=1}^{T} \pi_\theta(\mathbf{u}_t|\mathbf{x}_t) p(\mathbf{x}_{t+1}|\mathbf{x}_t, \mathbf{u}_t)$. The final policy $\pi_\theta(\mathbf{u}_t|\mathbf{o}_t)$ is conditioned on the observations $\mathbf{o}_t$, but $\pi_\theta(\mathbf{u}_t|\mathbf{x}_t)$ can be recovered as $\pi_\theta(\mathbf{u}_t|\mathbf{x}_t) = \int \pi_\theta(\mathbf{u}_t|\mathbf{o}_t) p(\mathbf{o}_t|\mathbf{x}_t) d\mathbf{o}_t$. We will present the derivation in this section for $\pi_\theta(\mathbf{u}_t|\mathbf{x}_t)$, but we do not require knowledge of $p(\mathbf{o}_t|\mathbf{x}_t)$ in the final algorithm. As discussed in Section 4.3, the integral will be evaluated with samples from the real system, which include both $\mathbf{x}_t$ and $\mathbf{o}_t$. We begin by rewriting the expected cost minimization as a constrained problem:

$$\min_{p, \pi_\theta} E_p[\ell(\tau)] \text{ s.t. } p(\mathbf{u}_t|\mathbf{x}_t) = \pi_\theta(\mathbf{u}_t|\mathbf{x}_t) \; \forall \, \mathbf{x}_t, \mathbf{u}_t, t, \tag{1}$$

where we will refer to $p(\tau)$ as a guiding distribution. This formulation is equivalent to the original problem, since the constraint forces the two distributions to be identical. However, if we approximate the initial state distribution $p(\mathbf{x}_1)$ with samples $\mathbf{x}_1^i$, we can choose $p(\tau)$ to be a class of distributions that is much easier to optimize than π_θ, as we will show later. This will allow us to use simple local learning methods for $p(\tau)$, without needing to train the complex neural network policy $\pi_\theta(\mathbf{u}_t|\mathbf{o}_t)$ directly with reinforcement learning, which would require a prohibitive amount of experience on real physical systems.

The constrained problem can be solved by a dual descent method, which alternates between minimizing the Lagrangian with respect to the primal variables, and incrementing

the Lagrange multipliers by their subgradient. Minimization of the Lagrangian with respect to $p(\tau)$ and θ is done in alternating fashion: minimizing with respect to θ corresponds to supervised learning (making π_θ match $p(\tau)$), and minimizing with respect to $p(\tau)$ consists of one or more trajectory optimization problems. The dual descent method we use is based on BADMM (Wang and Banerjee, 2014), a variant of ADMM (Boyd et al., 2011) that augments the Lagrangian with a Bregman divergence between the constrained variables. We use the KL-divergence as the Bregman constraint, which is particularly convenient for working with probability distributions. We will also modify the constraint $p(\mathbf{u}_t|\mathbf{x}_t) = \pi_\theta(\mathbf{u}_t|\mathbf{x}_t)$ by multiplying both sides by $p(\mathbf{x}_t)$, to get $p(\mathbf{u}_t|\mathbf{x}_t)p(\mathbf{x}_t) = \pi_\theta(\mathbf{u}_t|\mathbf{x}_t)p(\mathbf{x}_t)$. This constraint is equivalent, but has the convenient property that we can express the Lagrangian in terms of expectations. The BADMM augmented Lagrangians for θ and p are therefore given by

$$\mathcal{L}_\theta(\theta, p) = \sum_{t=1}^{T} E_{p(\mathbf{x}_t,\mathbf{u}_t)}[\ell(\mathbf{x}_t, \mathbf{u}_t)] + E_{p(\mathbf{x}_t)\pi_\theta(\mathbf{u}_t|\mathbf{x}_t)}[\lambda_{\mathbf{x}_t,\mathbf{u}_t}] - E_{p(\mathbf{x}_t,\mathbf{u}_t)}[\lambda_{\mathbf{x}_t,\mathbf{u}_t}] + \nu_t \phi_t^\theta(\theta, p)$$
$$\mathcal{L}_p(p, \theta) = \sum_{t=1}^{T} E_{p(\mathbf{x}_t,\mathbf{u}_t)}[\ell(\mathbf{x}_t, \mathbf{u}_t)] + E_{p(\mathbf{x}_t)\pi_\theta(\mathbf{u}_t|\mathbf{x}_t)}[\lambda_{\mathbf{x}_t,\mathbf{u}_t}] - E_{p(\mathbf{x}_t,\mathbf{u}_t)}[\lambda_{\mathbf{x}_t,\mathbf{u}_t}] + \nu_t \phi_t^p(\theta, p),$$

where $\lambda_{\mathbf{x}_t,\mathbf{u}_t}$ is the Lagrange multiplier for state $\mathbf{x}_t$ and action $\mathbf{u}_t$ at time t, and $\phi_t^\theta(\theta, p)$ are $\phi_t^p(\theta, p)$ are expectations of the KL-divergences:

$$\phi_t^p(p, \theta) = E_{p(\mathbf{x}_t)}[D_{\mathrm{KL}}(p(\mathbf{u}_t|\mathbf{x}_t)\|\pi_\theta(\mathbf{u}_t|\mathbf{x}_t))]$$
$$\phi_t^\theta(\theta, p) = E_{p(\mathbf{x}_t)}[D_{\mathrm{KL}}(\pi_\theta(\mathbf{u}_t|\mathbf{x}_t))\|p(\mathbf{u}_t|\mathbf{x}_t)].$$

Dual descent with alternating primal minimization is then described by the following steps:

$$\theta \leftarrow \arg\min_\theta \sum_{t=1}^{T} E_{p(\mathbf{x}_t)\pi_\theta(\mathbf{u}_t|\mathbf{x}_t)}[\lambda_{\mathbf{x}_t,\mathbf{u}_t}] + \nu_t \phi_t^\theta(\theta, p)$$
$$p \leftarrow \arg\min_p \sum_{t=1}^{T} E_{p(\mathbf{x}_t,\mathbf{u}_t)}[\ell(\mathbf{x}_t, \mathbf{u}_t) - \lambda_{\mathbf{x}_t,\mathbf{u}_t}] + \nu_t \phi_t^p(p, \theta)$$
$$\lambda_{\mathbf{x}_t,\mathbf{u}_t} \leftarrow \lambda_{\mathbf{x}_t,\mathbf{u}_t} + \alpha\nu_t(\pi_\theta(\mathbf{u}_t|\mathbf{x}_t)p(\mathbf{x}_t) - p(\mathbf{u}_t|\mathbf{x}_t)p(\mathbf{x}_t)).$$

This procedure is an instance of BADMM, and therefore inherits its convergence guarantees. Note that we drop terms that are independent of the optimization variables on each line. The parameter α is a step size. As with most augmented Lagrangian methods, the weight ν_t is set heuristically, as described in Appendix A.1.

The dynamics only affect the optimization with respect to $p(\tau)$. In order to make this optimization efficient, we choose $p(\tau)$ to be a mixture of N Gaussians $p_i(\tau)$, one for each initial state sample $\mathbf{x}_1^i$. This makes the action conditionals $p_i(\mathbf{u}_t|\mathbf{x}_t)$ and the dynamics $p_i(\mathbf{x}_{t+1}|\mathbf{x}_t, \mathbf{u}_t)$ linear-Gaussian, as discussed in Section 4.2. This is a reasonable choice when the system is deterministic, or the noise is Gaussian or small, and we found that this approach is sufficiently tolerant to noise for use on real physical systems. Our choice of p also assumes that the policy $\pi_\theta(\mathbf{u}_t|\mathbf{o}_t)$ is conditionally Gaussian. This is also reasonable, since the mean and covariance of $\pi_\theta(\mathbf{u}_t|\mathbf{o}_t)$ can be any nonlinear function of the observations

$\mathbf{o}_t$, which themselves are a function of the unobserved state $\mathbf{x}_t$. In Section 4.2, we show how these assumptions enable each $p_i(\tau)$ to be optimized very efficiently. We will refer to $p_i(\tau)$ as guiding distributions, since they serve to focus the policy on good, low-cost behaviors.

Aside from learning $p_i(\tau)$, we must choose a tractable way to represent the infinite set of constraints $p(\mathbf{u}_t|\mathbf{x}_t)p(\mathbf{x}_t) = \pi_\theta(\mathbf{u}_t|\mathbf{x}_t)p(\mathbf{x}_t)$. One approximate approach proposed in prior work is to replace the exact constraints with expectations of features (Peters et al., 2010). When the features consist of linear, quadratic, or higher order monomial functions of the random variable, this can be viewed as a constraint on the moments of the distributions. If we only use the first moment, we get a constraint on the expected action: $E_{p(\mathbf{u}_t|\mathbf{x}_t)p(\mathbf{x}_t)}[\mathbf{u}_t] = E_{\pi_\theta(\mathbf{u}_t|\mathbf{x}_t)p(\mathbf{x}_t)}[\mathbf{u}_t]$. If the stochasticity in the dynamics is low, as we assumed previously, the optimal solution for each $p_i(\tau)$ will have low entropy, making this first moment constraint a reasonable approximation. The KL-divergence terms in the augmented Lagrangians will still serve to softly enforce agreement between the higher moments. While this simplification is quite drastic, we found that it was more stable in practice than including higher moments, likely because these higher moments are harder to estimate accurately with a limited number of samples. The alternating optimization is now given by

$$\theta \leftarrow \arg\min_\theta \sum_{t=1}^{T} E_{p(\mathbf{x}_t)\pi_\theta(\mathbf{u}_t|\mathbf{x}_t)}[\mathbf{u}_t^{\mathrm{T}}\lambda_{\mu t}] + \nu_t \phi_t^\theta(\theta, p) \tag{2}$$
$$p \leftarrow \arg\min_p \sum_{t=1}^{T} E_{p(\mathbf{x}_t,\mathbf{u}_t)}[\ell(\mathbf{x}_t, \mathbf{u}_t) - \mathbf{u}_t^{\mathrm{T}}\lambda_{\mu t}] + \nu_t \phi_t^p(p, \theta) \tag{3}$$
$$\lambda_{\mu t} \leftarrow \lambda_{\mu t} + \alpha\nu_t(E_{\pi_\theta(\mathbf{u}_t|\mathbf{x}_t)p(\mathbf{x}_t)}[\mathbf{u}_t] - E_{p(\mathbf{u}_t|\mathbf{x}_t)p(\mathbf{x}_t)}[\mathbf{u}_t]),$$

where $\lambda_{\mu t}$ is the Lagrange multiplier on the expected action at time t. In the rest of the paper, we will use $\mathcal{L}_\theta(\theta, p)$ and $\mathcal{L}_p(p, \theta)$ to denote the two augmented Lagrangians in Equations (2) and (3), respectively. In the next two sections, we will describe how $\mathcal{L}_p(p, \theta)$ can be optimized with respect to p under unknown dynamics, and how $\mathcal{L}_\theta(\theta, p)$ can be optimized for complex, high-dimensional policies. Implementation details of the BADMM optimization are presented in Appendix A.1.

4.2 Trajectory Optimization under Unknown Dynamics

Since the Lagrangian $\mathcal{L}_p(p, \theta)$ in the previous section factorizes over the mixture elements in $p(\tau) = \sum_i p_i(\tau)$, we describe the trajectory optimization method for a single Gaussian $p(\tau)$. When there are multiple mixture elements, this procedure is applied in parallel to each $p_i(\tau)$. Since $p(\tau)$ is Gaussian, the conditionals $p(\mathbf{x}_{t+1}|\mathbf{x}_t, \mathbf{u}_t)$ and $p(\mathbf{u}_t|\mathbf{x}_t)$, which correspond to the dynamics and the controller, are time-varying linear-Gaussian, and given by

$$p(\mathbf{u}_t|\mathbf{x}_t) = \mathcal{N}(\mathbf{K}_t\mathbf{x}_t + \mathbf{k}_t, \mathbf{C}_t) \qquad p(\mathbf{x}_{t+1}|\mathbf{x}_t, \mathbf{u}_t) = \mathcal{N}(f_{\mathbf{x}t}\mathbf{x}_t + f_{\mathbf{u}t}\mathbf{u}_t + f_{ct}, \mathbf{F}_t).$$

This type of controller can be learned efficiently with a small number of real-world samples, making it a good choice for optimizing the guiding distributions. Since a different set of time-varying linear-Gaussian dynamics is fitted for each initial state, this dynamics representation can model any continuous deterministic system that can be locally linearized. Stochastic dynamics can violate the local linearity assumption in principle, but we found that in practice this representation was well suited for a wide variety of noisy real-world tasks.

The dynamics are determined by the environment. If they are known, $p(\mathbf{u}_t|\mathbf{x}_t)$ can be optimized with a variant of the iterative linear-quadratic-Gaussian regulator (iLQG) (Li and Todorov, 2004; Levine and Koltun, 2013a), which is a variant of DDP (Jacobson and Mayne, 1970). In the case of unknown dynamics, we can fit $p(\mathbf{x}_{t+1}|\mathbf{x}_t, \mathbf{u}_t)$ to sample trajectories sampled from the trajectory distribution at the previous iteration, denoted $\hat{p}(\tau)$. If $\hat{p}(\tau)$ is too different from $p(\tau)$, these samples will not give a good estimate of $p(\mathbf{x}_{t+1}|\mathbf{x}_t, \mathbf{u}_t)$, and the optimization will diverge. To avoid this, we can bound the change from $\hat{p}(\tau)$ to $p(\tau)$ in terms of their KL-divergence by a step size ϵ, producing the following constrained problem:

$$\min_{p(\tau)\in\mathcal{N}(\tau)} \mathcal{L}_p(p, \theta) \text{ s.t. } D_{\mathrm{KL}}(p(\tau)\|\hat{p}(\tau)) \leq \epsilon.$$

This type of policy update has previously been proposed by several authors in the context of policy search (Bagnell and Schneider, 2003; Peters and Schaal, 2008; Peters et al., 2010; Levine and Abbeel, 2014). In the case when $p(\tau)$ is Gaussian, this problem can be solved efficiently using dual gradient descent, while the dynamics $p(\mathbf{x}_{t+1}|\mathbf{x}_t, \mathbf{u}_t)$ are fitted to samples gathered by running the previous controller $\hat{p}(\mathbf{u}_t|\mathbf{x}_t)$ on the robot. Fitting a global Gaussian mixture model to tuples $(\mathbf{x}_t, \mathbf{u}_t, \mathbf{x}_{t+1})$ and using it as a prior for fitting the dynamics $p(\mathbf{x}_{t+1}|\mathbf{x}_t, \mathbf{u}_t)$ serves to greatly reduce the sample complexity. We describe the dynamics fitting procedure in detail in Appendix A.3.

Note that the trajectory optimization cost function $\mathcal{L}_p(p, \theta)$ also depends on the policy $\pi_\theta(\mathbf{u}_t|\mathbf{x}_t)$, while we only have access to $\pi_\theta(\mathbf{u}_t|\mathbf{o}_t)$. In order to compute a local quadratic expansion of the KL-divergence term $D_{\mathrm{KL}}(p(\mathbf{u}_t|\mathbf{x}_t)\|\pi_\theta(\mathbf{u}_t|\mathbf{x}_t))$ inside $\mathcal{L}_p(p, \theta)$ for iLQG, we also estimate a linearization of the mean of the conditionally Gaussian policy $\pi_\theta(\mathbf{u}_t|\mathbf{o}_t)$ with respect to the state $\mathbf{x}_t$, using the same procedure that we use to linearize the dynamics. The data for this estimation consists of tuples $\{\mathbf{x}_t^i, E_{\pi_\theta(\mathbf{u}_t|\mathbf{o}_t^i)}[\mathbf{u}_t]\}$, which we can obtain because both the states $\mathbf{x}_t^i$ and the observations $\mathbf{o}_t^i$ are available for all of the samples evaluated on the real physical system.

This constrained optimization is performed in the "inner loop" of the optimization described in the previous section, and the KL-divergence constraint $D_{\mathrm{KL}}(p(\tau)\|\hat{p}(\tau)) \leq \epsilon$ imposes a step size on the trajectory update. The overall algorithm then becomes an instance of generalized BADMM (Wang and Banerjee, 2014). Note that the augmented Lagrangian $\mathcal{L}_p(p, \theta)$ consists of an expectation under $p(\tau)$ of a quantity that is independent of p. We can locally approximate this quantity with a quadratic by using a quadratic expansion of $\ell(\mathbf{x}_t, \mathbf{u}_t)$, and fitting a linear-Gaussian to $\pi_\theta(\mathbf{u}_t|\mathbf{x}_t)$ with the same method we used for the dynamics. We can then solve the primal optimization in the dual gradient descent procedure with a standard LQR backward pass. This is significantly simpler and much faster than the forward-backward dynamic programming procedure employed in previous work (Levine and Abbeel, 2014; Levine and Koltun, 2014). This improvement is enabled by the use of BADMM, which allows us to always formulate the KL-divergence term in the Lagrangian with the distribution being optimized as the first argument. Since the KL-divergence is convex in its first argument, this makes the corresponding optimization significantly easier. The details of this LQR-based dual gradient descent algorithm are derived in Appendix A.4.

We can further improve the efficiency of the method by allowing samples from multiple trajectories $p_i(\tau)$ to be used to fit a shared dynamics $p(\mathbf{x}_{t+1}|\mathbf{x}_t, \mathbf{u}_t)$, while the controllers $p_i(\mathbf{u}_t|\mathbf{x}_t)$ are allowed to vary. This makes sense when the initial states of these trajectories

are similar, and they therefore visit similar regions. This allows us to draw just a single sample from each $p_i(\tau)$ at each iteration, allowing us to handle many more initial states.

4.3 Supervised Policy Optimization

Since the policy parameters θ participate only in the constraints of the optimization problem in Equation (1), optimizing the policy corresponds to minimizing the KL-divergence between the policy and trajectory distribution, as well as the expectation of $\lambda_{\mu t}^{\mathrm{T}}\mathbf{u}_t$. For a conditional Gaussian policy of the form $\pi_\theta(\mathbf{u}_t|\mathbf{o}_t) = \mathcal{N}(\mu^\pi(\mathbf{o}_t), \Sigma^\pi(\mathbf{o}_t))$, the objective is

$$\begin{aligned}\mathcal{L}_\theta(\theta, p) = &\frac{1}{2N}\sum_{i=1}^{N}\sum_{t=1}^{T} E_{p_i(\mathbf{x}_t,\mathbf{o}_t)}\big[\mathrm{tr}[\mathbf{C}_{ti}^{-1}\Sigma^\pi(\mathbf{o}_t)] - \log|\Sigma^\pi(\mathbf{o}_t)| \\ &+(\mu^\pi(\mathbf{o}_t) - \mu_{ti}^p(\mathbf{x}_t))\mathbf{C}_{ti}^{-1}(\mu^\pi(\mathbf{o}_t) - \mu_{ti}^p(\mathbf{x}_t)) + 2\lambda_{\mu t}^{\mathrm{T}}\mu^\pi(\mathbf{o}_t)\big],\end{aligned}$$

where $\mu_{ti}^p(\mathbf{x}_t)$ is the mean of $p_i(\mathbf{u}_t|\mathbf{x}_t)$ and $\mathbf{C}_{ti}$ is the covariance, and the expectation is evaluated using samples from each $p_i(\tau)$ with corresponding observations $\mathbf{o}_t$. The observations are sampled from $p(\mathbf{o}_t|\mathbf{x}_t)$ by recording camera images on the real system. Since the input to $\mu^\pi(\mathbf{o}_t)$ and $\Sigma^\pi(\mathbf{o}_t)$ is not the state $\mathbf{x}_t$, but only an observation $\mathbf{o}_t$, we can train the policy to directly use raw observations. Note that $\mathcal{L}_\theta(\theta, p)$ is simply a weighted quadratic loss on the difference between the policy mean and the mean action of the trajectory distribution, offset by the Lagrange multiplier. The weighting is the precision matrix of the conditional in the trajectory distribution, which is equal to the curvature of its cost-to-go function (Levine and Koltun, 2013a). This has an intuitive interpretation: $\mathcal{L}_\theta(\theta, p)$ penalizes deviation from the trajectory distribution, with a penalty that is locally proportional to its cost-to-go. At convergence, when the policy $\pi_\theta(\mathbf{u}_t|\mathbf{o}_t)$ takes the same actions as $p_i(\mathbf{u}_t|\mathbf{x}_t)$, their Q-functions are equal, and the supervised policy objective becomes equivalent to the policy iteration objective (Levine and Koltun, 2014)

In this work, we optimize $\mathcal{L}_\theta(\theta, p)$ with respect to θ using stochastic gradient descent (SGD), a standard method for neural network training. The covariance of the Gaussian policy does not depend on the observation in our implementation, though adding this dependence would be straightforward. Since training complex neural networks requires a substantial number of samples, we found it beneficial to include sampled observations from previous iterations into the policy optimization, evaluating the action $\mu_{ti}^p(\mathbf{x}_t)$ at their corresponding states using the current trajectory distributions. Since these samples come from the wrong state distribution, we use importance sampling and weight them according to the ratio of their probability under the current distribution $p(\mathbf{x}_t)$ and the one they were sampled from, which is straightforward to evaluate under the estimated linear-Gaussian dynamics (Levine and Koltun, 2013b).

4.4 Comparison with Prior Guided Policy Search Methods

We presented a guided policy search method where the policy is trained on observations, while the trajectories are trained on the full state. The BADMM formulation of guided policy search is new to this work, though several prior guided policy search methods based on constrained optimization have been proposed. Levine and Koltun (2014) proposed a formulation similar to Equation (1), but with a constraint on the KL-divergence between

$p(\tau)$ and π_θ. This results in a more complex, non-convex forward-backward trajectory optimization phase. Since the BADMM formulation solves a convex problem during the trajectory optimization phase, it is substantially faster and easier to implement and use, especially when the number of trajectories $p_i(\tau)$ is large.

The use of ADMM for guided policy search was also proposed by Mordatch and Todorov (2014) for deterministic policies under known dynamics. This approach requires known, deterministic dynamics and trains deterministic policies. Furthermore, because this approach uses a simple quadratic augmented Lagrangian term, it further requires penalty terms on the gradient of the policy to account for local feedback. Our approach enforces this feedback behavior due to the higher moments included in the KL-divergence term, but does not require computing the second derivative of the policy.

5. End-to-End Visuomotor Policies

Guided policy search allows us to optimize complex, high-dimensional policies with raw observations, such as when the input to the policy consists of images from a robot's onboard camera. However, leveraging this capability to directly learn policies for visuomotor control requires designing a policy representation that is both data-efficient and capable of learning complex control strategies directly from raw visual inputs. In this section, we describe a deep convolutional neural network (CNN) model that is uniquely suited to this task. Our approach combines a novel spatial soft-argmax layer with a pretraining procedure that provides for flexibility and data-efficiency.

5.1 Visuomotor Policy Architecture

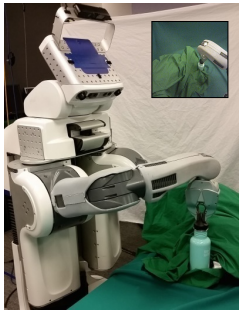
Our visuomotor policy runs at 20 Hz on the robot, mapping monocular RGB images and the robot configurations to joint torques on a 7 DoF arm. The configuration includes the angles of the joints and the pose of the end-effector (defined by 3 points in the space of the end-effector), as well as their velocities, but does not include the position of the target object or goal, which must be determined from the image. CNNs often use pooling to discard the locational information that is necessary to determine positions, since it is an irrelevant distractor for tasks such as object classification (Lee et al., 2009). Because locational information is important for control, our policy does not use pooling. Additionally, CNNs built for spatial tasks such as human pose estimation often also rely on the availability of location labels in image-space, such as hand-labeled keypoints (Tompson et al., 2014). We propose a novel CNN architecture capable of estimating spatial information from an image without direct supervision in image space. Our pose estimation experiments, discussed in Section 5.2, show that this network can learn useful visual features using only 3D position information provided by the robot, and no camera calibration. Further training the network with guided policy search to directly output motor torques causes it to acquire *task-specific* visual features. Our experiments in Section 6.4 show that this improves performance beyond the level achieved with features trained only for pose estimation.

Our network architecture is shown in Figure 2. The visual processing layers of the network consist of three convolutional layers, each of which learns a bank of filters that are applied to patches centered on every pixel of its input. These filters form a hierarchy of local image features. Each convolutional layer is followed by a rectifying nonlinearity of

the form $a_{cij} = \max(0, z_{cij})$ for each channel c and each pixel coordinate (i, j). The third convolutional layer contains 32 response maps with resolution 109×109. These response maps are passed through a spatial softmax function of the form $s_{cij} = e^{a_{cij}} / \sum_{i'j'} e^{a_{ci'j'}}$. Each output channel of the softmax is a probability distribution over the location of a feature in the image. To convert from this distribution to a coordinate representation (f_{cx}, f_{cy}), the network calculates the expected image position of each feature, yielding a 2D coordinate for each channel: $f_{cx} = \sum_{ij} s_{cij} x_{ij}$ and $f_{cy} = \sum_{ij} s_{cij} y_{ij}$, where (x_{ij}, y_{ij}) is the image-space position of the point (i, j) in the response map. Since this is a linear operation, it corresponds to a fixed, sparse fully connected layer with weights $W_{cix} = x_{ij}$ and $W_{cjy} = y_{ij}$. The combination of the spatial softmax and expectation operator implement a kind of soft-argmax. The spatial feature points (f_{cx}, f_{cy}) are concatenated with the robot's configuration and fed into two fully connected layers, each with 40 rectified units, followed by linear connections to the torques. The full network contains about 92,000 parameters, of which 86,000 are in the convolutional layers.

The spatial softmax and the expected position computation serve to convert pixel-wise representations in the convolutional layers to spatial coordinate representations, which can be manipulated by the fully connected layers into 3D positions or motor torques. The softmax also provides lateral inhibition, which suppresses low, erroneous activations, only keeping strong activations that are more likely to be accurate. This makes our policy more robust to distractors, providing generalization to novel visual variation. We compare our architecture with more standard alternatives in Section 6.3 and evaluate robustness to visual distractors in Section 6.4. However, the proposed architecture is also in some sense more specialized for visuomotor control, in contrast to more general standard convolutional networks. For example, not all perception tasks require information that can be coherently summarized by a set of spatial locations.

5.2 Visuomotor Policy Training

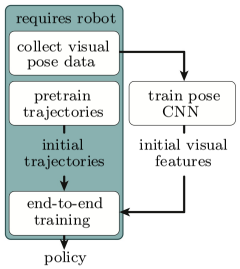


The guided policy search trajectory optimization phase uses the full state of the system, though the final policy only uses the observations. This type of instrumented training is a natural choice for many robotics tasks, where the robot is trained under controlled conditions, but must then act intelligently in uncontrolled, real-world situations. In our tasks, the unobserved variables are the pose of a target object (e.g. the bottle on which a cap must be placed). During training, this target object is typically held in the robot's left gripper, while the robot's right arm performs the task, as shown to the right. This allows the robot to move the target through a range of known positions. The final visuomotor policy does not receive this position as input, but must instead use the camera images. Due to the modest amount of training data, distractors that are correlated with task-relevant variables can hamper generalization. For this reason, the left arm is covered with cloth to prevent the policy from associating its appearance with the object's position.

While we can train the visuomotor policy entirely from scratch, the algorithm would spend a large number of iterations learning basic visual features and arm motions that can more efficiently be learned by themselves, before being incorporated into the policy. To speed up learning, we initialize both the vision layers in the policy and the trajectory distributions for guided policy search by leveraging the fully observed training setup. To initialize the vision layers, the robot moves the target object through a range of random positions, recording camera images and the object's pose, which is computed automatically from the pose of the gripper. This dataset is used to train a pose regression CNN, which consists of the same vision layers as the policy, followed by a fully connected layer that outputs the 3D points that define the target. Since the training set is still small (we use 1000 images collected from random arm motions), we initialize the filters in the first layer with weights from the model of Szegedy et al. (2014), which is trained on ImageNet (Deng et al., 2009) classification. After training on pose regression, the weights in the convolutional layers are transferred to the policy CNN. This enables the robot to learn the appearance of the objects prior to learning the behavior.

To initialize the linear-Gaussian controllers for each of the initial states, we take 15 iterations of guided policy search without optimizing the visuomotor policy. This allows for much faster training in the early iterations, when the trajectories are not yet successful, and optimizing the full visuomotor policy is unnecessarily time consuming. Since we still want the trajectories to arrive at compatible strategies for each target position, we replace the visuomotor policy during these iterations with a small network that receives the full state, which consisted of two layers with 40 rectified linear hidden units in our experiments. This network serves only to constrain the trajectories and avoid divergent behaviors from emerging for similar initial states, which would make subsequent policy learning difficult.

After initialization, we train the full visuomotor policy with guided policy search. During the supervised policy optimization phase, the fully connected motor control layers are first optimized by themselves, since they are not initialized with pretraining. This can be done very quickly because these layers are small. Then, the entire network is further optimized end-to-end. We found that first training the upper layers before end-to-end optimization prevented the convolutional layers from forgetting useful features learning during pretraining, when the error signal due to the untrained upper layers is very large. The entire pretraining scheme is summarized in the diagram on the right. Note that the trajectories can be pretrained in parallel with the vision layer pretraining, which does not require access to the physical system. Furthermore, the entire initialization procedure does not use any additional information that is not already available from the robot.



6. Experimental Evaluation

In this section, we present a series of experiments aimed at evaluating our approach and answering the following questions:

1. How does the guided policy search algorithm compare to other policy search methods for training complex, high-dimensional policies, such as neural networks?
2. Does our trajectory optimization algorithm work on a real robotic platform with unknown dynamics, for a range of different tasks?
3. How does our spatial softmax architecture compare to other, more standard convolutional neural network architectures?
4. Does training the perception and control systems in a visuomotor policy jointly end-to-end provide better performance than training each component separately?

Evaluating a wide range of policy search algorithms on a real robot would be extremely time consuming, particularly for methods that require a large number of samples. We therefore answer question (1) by using a physical simulator and simpler policies that do not use vision. This also allows us to test the generality of guided policy search on tasks that include manipulation, walking, and swimming. To answer question (2), we present a wide range of experiments on a PR2 robot. These experiments allow us to evaluate the sample efficiency of our trajectory optimization algorithm. To address question (3), we compare a range of different policy architectures on the task of localizing a target object (the cube in the shape sorting cube task). Since localizing the target object is a prerequisite for completing the shape sorting cube task, this serves as a good proxy for evaluating different architectures. Finally, we answer the last and most important question (4) by training visuomotor policies for hanging a coat hanger on a clothes rack, inserting a block into a shape sorting cube, fitting the claw of a toy hammer under a nail with various grasps, and screwing on a bottle cap. These tasks are illustrated in Figure 8.

6.1 Simulated Comparisons to Prior Policy Search Methods

In this section, we compare our method against prior policy search techniques on a range of simulated robotic control tasks. These results previously appeared in our conference paper that introduced the trajectory optimization procedure with local linear models (Levine and Abbeel, 2014). In these tasks, the state $\mathbf{x}_t$ consists of the joint angles and velocities of each robot, and the actions $\mathbf{u}_t$ consist of the torques at each joint. The neural network policies used one hidden layer and soft rectifier nonlinearities of the form $a = \log(1+\exp(z))$. Since these policies use the state as input, they only have a few hundred parameters, far fewer than our visuomotor policies. However, even this number of parameters can pose a major challenge for prior policy search methods (Deisenroth et al., 2013).

Experimental tasks. We simulated 2D and 3D peg insertion, octopus arm control, and planar swimming and walking. The difficulty in the peg insertion tasks stems from the need to align the peg with the slot and the complex contacts between the peg and the walls, which result in discontinuous dynamics. Octopus arm control involves moving the tip of a flexible arm to a goal position (Engel et al., 2005). The challenge in this task stems from its high dimensionality: the arm has 25 degrees of freedom, corresponding to 50 state dimensions. The swimming task requires controlling a three-link snake, and the walking task requires a seven-link biped to maintain a target velocity. The challenge in these tasks comes from underactuation. Details of the simulation and cost for each task are in Appendix B.1.

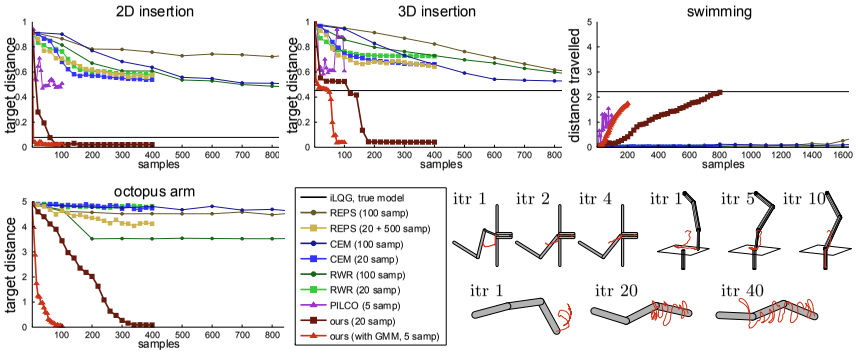


Figure 4: Results for learning linear-Gaussian controllers for 2D and 3D insertion, octopus arm, and swimming. Our approach uses fewer samples and finds better solutions than prior methods, and the GMM further reduces the required sample count. Images in the lower-right show the last time step for each system at several iterations of our method, with red lines indicating end effector trajectories.

Prior methods. We compare to REPS (Peters et al., 2010), reward-weighted regression (RWR) (Peters and Schaal, 2007; Kober and Peters, 2009), the cross-entropy method (CEM) (Rubinstein and Kroese, 2004), and PILCO (Deisenroth and Rasmussen, 2011). We also use iLQG (Li and Todorov, 2004) with a known model as a baseline, shown as a black horizontal line in all plots. REPS is a model-free method that, like our approach, enforces a KL-divergence constraint between the new and old policy. We compare to a variant of REPS that also fits linear dynamics to generate 500 pseudo-samples (Lioutikov et al., 2014), which we label "REPS (20 + 500)." RWR is an EM algorithm that fits the policy to previous samples weighted by the exponential of their reward, and CEM fits the policy to the best samples in each batch. With Gaussian trajectories, CEM and RWR only differ in the weights. These methods represent a class of RL algorithms that fit the policy to weighted samples, including PoWER and PI2 (Kober and Peters, 2009; Theodorou et al., 2010; Stulp and Sigaud, 2012). PILCO is a model-based method that uses a Gaussian process to learn a global dynamics model that is used to optimize the policy. We used the open-source implementation of PILCO provided by the authors. Both REPS and PILCO require solving large nonlinear optimizations at each iteration, while our method does not. Our method used 5 rollouts with the Gaussian mixture model prior, and 20 without. Due to its computational cost, PILCO was provided with 5 rollouts per iteration, while other prior methods used 20 and 100. For all prior methods with free hyperparameters (such as the fraction of elites for CEM), we performed hyperparameter sweeps and chose the most successful settings for the comparison.

Gaussian trajectory distributions. In the first set of comparisons, we evaluate only the trajectory optimization procedure for training linear-Gaussian controllers under unknown dynamics to determine its sample-efficiency and applicability to complex, high-dimensional problems. The results of this comparison for the peg insertion, octopus arm, and swimming

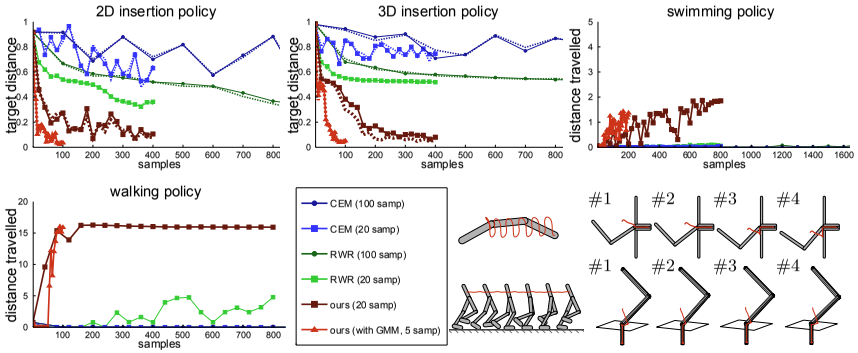

Figure 5: Comparison on neural network policies. For insertion, the policy was trained to search for an unknown slot position on four slot positions (shown above). Generalization to new positions is graphed with dashed lines. Note how the end effector (red) follows the surface to find the slot, and how the swimming gait is smoother due to the stationary policy.

tasks appears in Figure 4. The horizontal axis shows the total number of samples, and the vertical axis shows the minimum distance between the end of the peg and the bottom of the slot, the distance to the target for the octopus arm, or the total distance travelled by the swimmer. Since the peg is 0.5 units long, distances above this amount correspond to controllers that cannot perform an insertion. Our method learned much more effective controllers with fewer samples, especially when using the Gaussian mixture model prior. On 3D insertion, it outperformed the iLQG baseline, which used a known model. Contact discontinuities cause problems for derivative-based methods like iLQG, as well as methods like PILCO that learn a smooth global dynamics model. We use a time-varying local model, which preserves more detail, and fitting the model to samples has a smoothing effect that mitigates discontinuity issues. Prior policy search methods could servo to the hole, but were unable to insert the peg. On the octopus arm, our method succeeded despite the high dimensionality of the state and action spaces.[1] Our method also successfully learned a swimming gait, while prior model-free methods could not initiate forward motion. PILCO also learned an effective gait due to the smooth dynamics of this task, but its GP-based optimization required orders of magnitude more computation time than our method, taking about 50 minutes per iteration. In the case of prior model-free methods, the high dimensionality of the time-varying linear-Gaussian controllers likely caused considerable difficulty (Deisenroth et al., 2013), while our approach exploits the structure of linear-Gaussian controllers for efficient learning.

1. The high dimensionality of the octopus arm made it difficult to run PILCO, though in principle, such methods should perform well on this task given the arm's smooth dynamics.

Neural network policies. In the second set of comparisons, shown in Figure 5, we compare guided policy search to RWR and CEM[2] on the challenging task of training high-dimensional neural network policies for the peg insertion and locomotion tasks. The variant of guided policy search used in this comparison differs somewhat from the version described in Section 4, in that it used a simpler dual gradient descent formulation, rather than BADMM. In practice, we found the performance of these methods to be very similar, though the BADMM variant was substantially faster and easier to implement.

On swimming, our method achieved similar performance to the linear-Gaussian case, but since the neural network policy was stationary, the resulting gait was much smoother. Previous methods could only solve this task with 100 samples per iteration, with RWR eventually obtaining a distance of 0.5m after 4000 samples, and CEM reaching 2.1m after 3000. Our method was able to reach such distances with many fewer samples. Following prior work (Levine and Koltun, 2013a), the walker trajectory was initialized from a demonstration, which was stabilized with simple linear feedback. The RWR and CEM policies were initialized with samples from this controller to provide a fair comparison. The graph shows the average distance travelled on rollouts that did not fall, and shows that only our method was able to learn walking policies that succeeded consistently.

On peg insertion, the neural network was trained to insert the peg without precise knowledge of the position of the hole, resulting in a partially observed problem. The holes were placed in a region of radius 0.2 units in 2D and 0.1 units in 3D. The policies were trained on four different hole positions, and then tested on four new hole positions to evaluate generalization. The hole position was not provided to the neural network, and the policies therefore had to search for the hole, with only joint angles and velocities as input. Only our method could acquire a successful strategy to locate both the training and test holes, although RWR was eventually able to insert the peg into one of the four holes in 2D.

These comparisons show that training even medium-sized neural network policies for continuous control tasks with a limited number of samples is very difficult for many prior policy search algorithms. Indeed, it is generally known that model-free policy search methods struggle with policies that have over 100 parameters (Deisenroth et al., 2013). In subsequent sections, we will evaluate our method on real robotic tasks, showing that it can scale from these simulated tasks all the way up to end-to-end learning of visuomotor control.

6.2 Learning Linear-Gaussian Controllers on a PR2 Robot

In this section, we demonstrate the range of manipulation tasks that can be learned using our trajectory optimization algorithm on a real PR2 robot. These experiments previously appeared in our conference paper on guided policy search (Levine et al., 2015). Since performing trajectory optimization is a prerequisite for guided policy search to learn effective visuomotor policies, it is important to evaluate that our trajectory optimization can learn a wide variety of robotic manipulation tasks under unknown dynamics. The tasks in these experiments are shown in Figure 6, while Figure 7 shows the learning curves for each task. For all robotic experiments in this article, the tasks were learned entirely from scratch,

2. PILCO cannot optimize neural network policies, and we could not obtain reasonable results with REPS. Prior applications of REPS generally focus on simpler, lower-dimensional policy classes (Peters et al., 2010; Lioutikov et al., 2014).

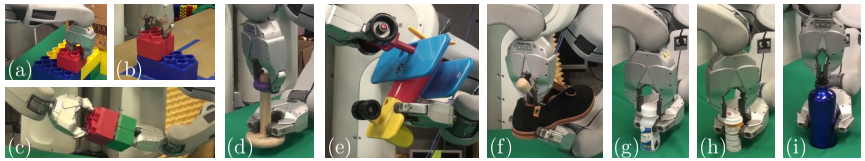

Figure 6: Tasks for linear-Gaussian controller evaluation: (a) stacking lego blocks on a fixed base, (b) onto a free-standing block, (c) held in both gripper; (d) threading wooden rings onto a peg; (e) attaching the wheels to a toy airplane; (f) inserting a shoe tree into a shoe; (g,h) screwing caps onto pill bottles and (i) onto a water bottle.

with the initialization of the controllers $p(\mathbf{u}_t|\mathbf{x}_t)$ described in Appendix B.2. The number of samples required to learn each controller is around 20-25, substantially lower than many prior policy search methods in the literature (Peters and Schaal, 2008; Kober et al., 2010b; Theodorou et al., 2010; Deisenroth et al., 2013). Total learning time was about ten minutes for each task, of which only 3-4 minutes involved system interaction. The rest of the time was spent resetting the robot to the initial state and on computation.

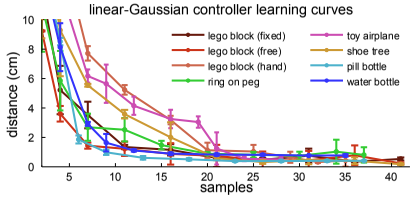

Figure 7: Distance to target point during training of linear-Gaussian controllers. The actual target may differ due to perturbations. Error bars indicate one standard deviation.

The linear-Gaussian controllers are optimized for a specific condition – e.g., a specific position of the target lego block. To evaluate their robustness to errors in the specified target position, we conducted experiments on the lego block and ring tasks where the target object (the lower block and the peg) was perturbed at each trial during training, and then tested with various perturbations. For each task, controllers were trained with Gaussian perturbations with standard deviations of 0, 1, and 2 cm in the position of the target object, and each controller was tested with perturbations of radius 0, 1, 2, and 3 cm. Note that with a radius of 2 cm, the peg would be placed about one ring-width away from the expected position. The results are shown in Table 2. All controllers were robust to perturbations of 1 cm, and would often succeed at 2 cm. Robustness increased slightly when more noise was injected during training, but even controllers trained without noise exhibited considerable robustness, since the linear-Gaussian controllers themselves add noise during sampling. We also evaluated a kinematic baseline for each perturbation level, which planned a straight path from a point 5 cm above the target to the expected (unperturbed) target location. This baseline was only able to place the lego block in the absence of perturbations. The rounded top of the peg provided an easier condition for the baseline, with occasional successes at higher perturbation levels. Our controllers outperformed the baseline by a wide margin.

All of the robotic experiments discussed in this section may be viewed in the corresponding supplementary video, available online: `http://rll.berkeley.edu/icra2015gps`. A video illustration of the visuomotor policies, discussed in the following sections, is also available: `http://sites.google.com/site/visuomotorpolicy`.

		test perturbation							
		lego block				ring on peg			
		0 cm	1 cm	2 cm	3 cm	0 cm	1 cm	2 cm	3 cm
training perturb.	0 cm	5/5	5/5	3/5	2/5	5/5	5/5	0/5	0/5
	1 cm	5/5	5/5	3/5	2/5	5/5	5/5	3/5	0/5
	2 cm	5/5	5/5	5/5	3/5	5/5	5/5	3/5	0/5
	kinematic baseline	5/5	0/5	0/5	0/5	5/5	3/5	0/5	0/5

Table 2: Success rates of linear-Gaussian controllers under target object perturbation.

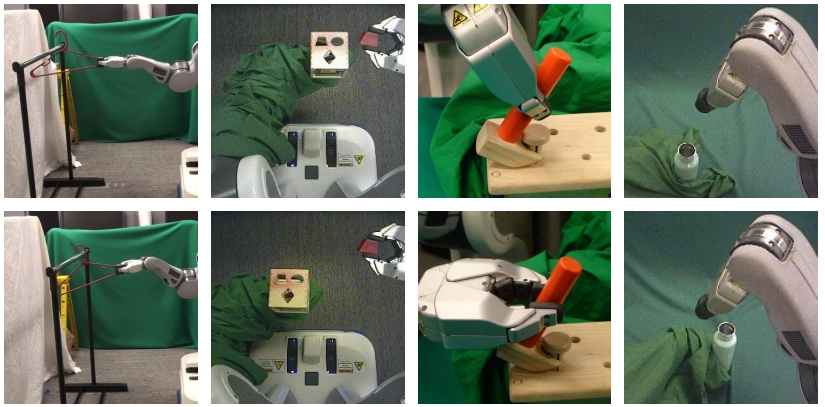
6.3 Spatial Softmax CNN Architecture Evaluation

In this section, we evaluate the neural network architecture that we propose in Section 5.1 in comparison to more standard convolutional networks. To isolate the architectures from other confounding factors, we measure their accuracy on the pose estimation pretraining task described in Section 5.2. This is a reasonable proxy for evaluating how well the network can overcome two major challenges in visuomotor learning: the ability to handle relatively small datasets without overfitting, and the capability to learn tasks that are inherently spatial. We compare to a network where the expectation operator after the softmax is replaced with a learned fully connected layer, as is standard in the literature, a network where both the softmax and the expectation operators are replaced with a fully connected layer, and a version of this network that also uses 3×3 max pooling with stride 2 at the first two layers. These alternative architectures have many more parameters, since the fully connected layer takes the entire bank of response maps from the third convolutional layer as input. Pooling helps to reduce the number of parameters, but not to the same degree as the spatial softmax and expectation operators in our architecture.

The results in Table 3 indicate that using the softmax and expectation operators improves pose estimation accuracy substantially. Our network is able to outperform the more standard architectures because it is forced by the softmax and expectation operators to learn feature points, which provide a concise representation suitable for spatial inference. Since most of the parameters in this architecture are in the convolutional layers, which benefit from extensive weight sharing, overfitting is also greatly reduced. By removing pooling, our network also maintains higher resolution in the convolutional layers, improving spatial accuracy. Although we did attempt to regularize the larger standard architectures with higher weight decay and dropout, we did not observe a significant improvement on this dataset. We also did not extensively optimize the parameters of this network, such as filter size and number of channels, and investigating these design decisions further would be valuable to investigate in future work.

network architecture	test error (cm)
softmax + feature points (**ours**)	**1.30 ± 0.73**
softmax + fully connected layer	2.59 ± 1.19
fully connected layer	4.75 ± 2.29
max-pooling + fully connected	3.71 ± 1.73

Table 3: Average pose estimation accuracy and standard deviation with various architectures, measured as average Euclidean error for the three target points in 3D, with ground truth determined by forward kinematics from the left arm.



(a) hanger (b) cube (c) hammer (d) bottle

Figure 8: Illustration of the tasks in our visuomotor policy experiments, showing the variation in the position of the target for the hanger, cube, and bottle tasks, as well as two of the three grasps for the hammer, which also included variation in position (not shown).

6.4 Deep Visuomotor Policy Evaluation

In this section, we present an evaluation of our full visuomotor policy training algorithm on a PR2 robot. The aim of this evaluation is to answer the following question: does training the perception and control systems in a visuomotor policy jointly end-to-end provide better performance than training each component separately?

Experimental tasks. We trained policies for hanging a coat hanger on a clothes rack, inserting a block into a shape sorting cube, fitting the claw of a toy hammer under a nail with various grasps, and screwing on a bottle cap. The cost function for these tasks encourages low distance between three points on the end-effector and corresponding target points, low torques, and, for the bottle task, spinning the wrist. The equations for these cost functions and the details of each task are presented in Appendix B.2. The tasks are illustrated in Figure 8. Each task involved variation of 10-20 cm in each direction in the position of the target object (the rack, shape sorting cube, nail, and bottle). In addition, the coat hanger and hammer tasks were trained with two and three grasps, respectively. The current angle of the grasp was not provided to the policy, but had to be inferred from observing the robot's gripper in the camera images. All tasks used the same policy architecture and model parameters.

Experimental conditions. We evaluated the visuomotor policies in three conditions: (1) the training target positions and grasps, (2) new target positions not seen during training and, for the hammer, new grasps (spatial test), and (3) training positions with visual distractors (visual test). A selection of these experiments is shown in the supplementary video.[3] For the visual test, the shape sorting cube was placed on a table rather than held in

3. The video can be viewed at `http://sites.google.com/site/visuomotorpolicy`

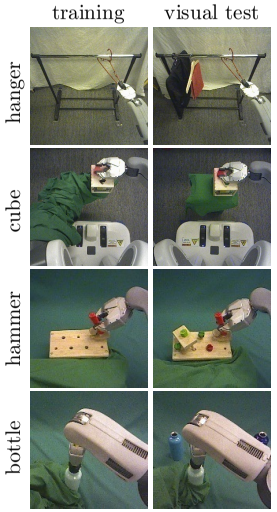
the gripper, the coat hanger was placed on a rack with clothes, and the bottle and hammer tasks were done in the presence of clutter. Illustrations of this test are shown in Figure 9.

Comparison. The success rates for each test are shown in Figure 9. We compared to two baselines, both of which train the vision layers in advance for pose prediction, instead of training the entire policy end-to-end. The features baseline discards the last layer of the pose predictor and uses the feature points, resulting in the same architecture as our policy, while the prediction baseline feeds the predicted pose into the control layers. The pose prediction baseline is analogous to a standard modular approach to policy learning, where the vision system is first trained to localize the target, and the policy is trained on top of it. This variant achieves poor performance. As discussed in Section 6.3, the pose estimate is accurate to about 1 cm. However, unlike the tasks in Section 6.2, where robust controllers could succeed even with inaccurate perception, many of these tasks have tolerances of just a few millimeters. In fact, the pose prediction baseline is only successful on the coat hanger, which requires comparatively little accuracy. Millimeter accuracy is difficult to achieve even with calibrated cameras and checkerboards. Indeed, prior work has reported that the PR2 can maintain a camera to end effector accuracy of about 2 cm during open loop motion (Meeussen et al., 2010). This suggests that the failure of this baseline is not atypical, and that our visuomotor policies are learning visual features and control strategies that improve the robot's accuracy. When provided with pose estimation features, the policy has more freedom in how it uses the visual information, and achieves somewhat higher success rates. However, full end-to-end training performs significantly better, achieving high accuracy even on the challenging bottle task, and successfully adapting to the variety of grasps on the hammer task. This suggests that, although the vision layer pretraining is clearly beneficial for reducing computation time, it is not sufficient by itself for discovering good features for visuomotor policies.

Visual distractors. The policies exhibit moderate tolerance to distractors that are visually separated from the target object. This is enabled in part by the spatial softmax, which has a lateral inhibition effect that suppresses non-maximal activations. Since distractors are unlikely to activate each feature as much as the true object, their activations are therefore suppressed. However, as expected, the learned policies tend to perform poorly under drastic changes to the backdrop, or when the distractors are adjacent to or occluding the manipulated objects, as shown in the supplementary video. A standard solution to this issue to expose the policy to a greater variety of visual situations during training. This issue could also be mitigated by artificially augmenting the image samples with synthetic transformations, as discussed in prior work in computer vision (Simard et al., 2003), or even incorporating ideas from transfer and semi-supervised learning.

6.5 Features Learned with End-to-End Training

The visual processing layers of our architecture automatically learn features points using the spatial softmax and expectation operators. These feature points encapsulate all of the visual information received by the motor layers of the policy. In Figure 10, we show the features points discovered by our visuomotor policy through guided policy search. Each policy learns features on the target object and the robot manipulator, both clearly relevant



coat hanger	training (18)	spatial test (24)	visual test (18)
end-to-end	**100%**	**100%**	**100%**
pose features	88.9%	87.5%	83.3%
pose prediction	55.6%	58.3%	66.7%
shape cube	training (27)	spatial test (36)	visual test (40)
end-to-end	**96.3%**	**91.7%**	**87.5%**
pose features	70.4%	83.3%	40%
pose prediction	0%	0%	n/a
toy hammer	training (45)	spatial test (60)	visual test (60)
end-to-end	**91.1%**	**86.7%**	**78.3%**
pose features	62.2%	75.0%	53.3%
pose prediction	8.9%	18.3%	n/a
bottle cap	training (27)	spatial test (12)	visual test (40)
end-to-end	**88.9%**	**83.3%**	**62.5%**
pose features	55.6%	58.3%	27.5%

Success rates on training positions, on novel test positions, and in the presence of visual distractors. The number of trials per test is shown in parentheses.

Figure 9: Training and visual test scenes as seen by the policy (left), and experimental results (right). The hammer and bottle images were cropped for visualization only.

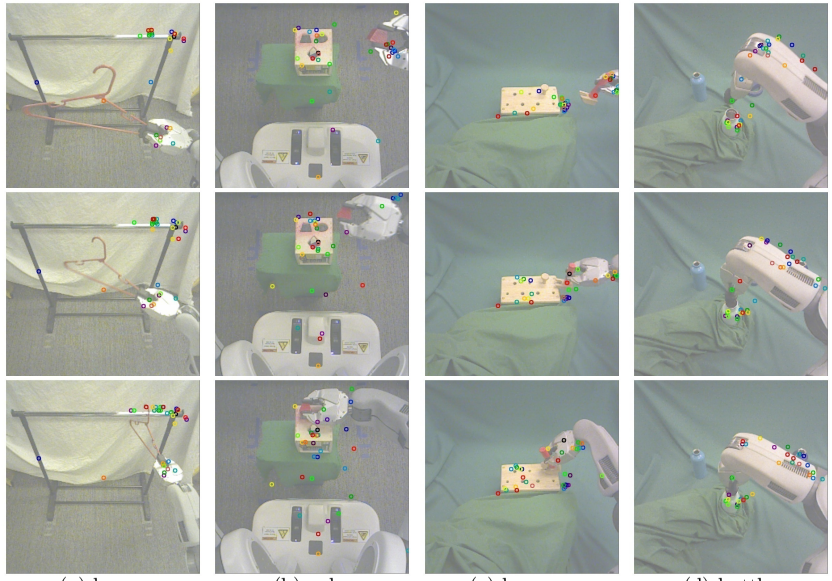
to task execution. The policy tends to pick out robust, distinctive features on the objects, such as the left pole of the clothes rack, the left corners of the shape-sorting cube and the bottom-left corner of the toy tool bench. In the bottle task, the end-to-end trained policy outputs points on both sides of the bottle, including one on the cap, while the pose prediction network only finds points on the right edge of the bottle.

In Figure 11, we compare the feature points learned through guided policy search to those learned by a CNN trained for pose prediction. After end-to-end training, the policy acquired a distinctly different set of feature points compared to the pose prediction CNN used for initialization. The end-to-end trained model finds more feature points on task-relevant objects and fewer points on background objects. This suggests that the policy improves its performance by acquiring *goal-driven* visual features that differ from those learned for object localization.

The feature point representation is very simple, since it assumes that the learned features are present at all times, and only one instance of each feature is ever present in the image. While this is a drastic simplification, both the pose predictor and the policy still achieve good results. A more flexible architecture that still learns a concise feature point representation could further improve policy performance. We hope to explore this in future work.

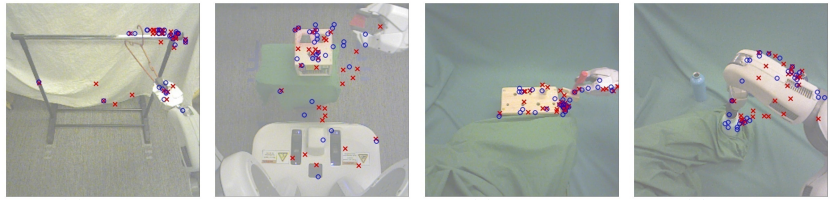
6.6 Computational Performance and Sample Efficiency

We used the Caffe deep learning library (Jia et al., 2014) for CNN training. Each visuomotor policy required a total of 3-4 hours of training time: 20-30 minutes for the pose prediction data collection on the robot, 40-60 minutes for the fully observed trajectory pretraining on



(a) hanger (b) cube (c) hammer (d) bottle

Figure 10: Feature points tracked by the policy during task execution for each of the four tasks. Each feature point is displayed in a different random color, with consistent coloring across images. The policy finds features on the target object and the robot gripper and arm. In the bottle cap task, note that the policy correctly ignores the distractor bottle in the background, even though it was not present during training.



(a) hanger (b) cube (c) hammer (d) bottle

Figure 11: Feature points learned for each task. For each input image, the feature points produced by the policy are shown in blue, while the feature points of the pose prediction network are shown in red. The end-to-end trained policy tends to discover more feature points on the target object and the robot arm than the pose prediction network.

the robot and offline pose pretraining (which can be done in parallel), and between 1.5 and 2.5 hours for end-to-end training with guided policy search. The coat hanger task required two iterations of guided policy search, the shape sorting cube and the hammer required three, and the bottle task required four. Only about 15 minutes of the training time consisted of executing trials on the robot. Since training was dominated by computation, we expect significant speedup from a more efficient implementation. The number of samples for training each policy is shown in Table 4. Each trial was five seconds in length, and the numbers do not include the time needed to collect about 1000 images for pretraining the visual processing layers of the policy.

	number of trials		
task	trajectory pretraining	end-to-end training	total
coat hanger	120	36	156
shape cube	90	81	171
toy hammer	150	90	240
bottle cap	180	108	288

Table 4: Total number of trials used for learning each visuomotor policy.

7. Discussion and Future Work

In this paper, we presented a method for learning robotic control policies that use raw input from a monocular camera. These policies are represented by a novel convolutional neural network architecture, and can be trained end-to-end using our guided policy search algorithm, which decomposes the policy search problem in a trajectory optimization phase that uses full state information and a supervised learning phase that only uses the observations. This decomposition allows us to leverage state-of-the-art tools from supervised learning, making it straightforward to optimize extremely high-dimensional policies. Our experimental results show that our method can execute complex manipulation skills, and that end-to-end training produces significant improvements in policy performance compared to using fixed vision layers trained for pose prediction.

Although we demonstrate moderate generalization over variations in the scene, our current method does not generalize to dramatically different settings, especially when visual distractors occlude the manipulated object or break up its silhouette in ways that differ from the training. The success of CNNs on exceedingly challenging vision tasks suggests that this class of models is capable of learning invariance to irrelevant distractor features (LeCun et al., 2015), and in principle this issue can be addressed by training the policy in a variety of environments, though this poses certain logistical challenges. More practical alternatives that could be explored in future work include simultaneously training the policy on multiple robots, each of which is located in a different environment, developing more sophisticated regularization and pretraining techniques to avoid overfitting, and introducing artificial data augmentation to encourage the policy to be invariant to irrelevant clutter. However, even without these improvements, our method has numerous applications in, for example, an industrial setting where the robot must repeatedly and efficiently perform a task that requires visual feedback under moderate variation in background and clutter conditions.

Our method takes advantage of a known, fully observed state space during training. This is both a weakness and a strength. It allows us to train linear-Gaussian controllers

for guided policy search using a very small number of samples, far more efficiently than standard policy search methods. However, the requirement to observe the full state during training limits the tasks to which the method can be applied. In many cases, this limitation is minor, and the only "instrumentation" required at training is to position the objects in the scene at consistent positions. However, tasks that require, for example, manipulating freely moving objects require more extensive instrumentation, such as motion capture. A promising direction for addressing this limitation is to combine our method with unsupervised state-space learning, as proposed in several recent works, including our own (Lange et al., 2012; Watter et al., 2015; Finn et al., 2015).

In future work, we hope to explore more complex policy architectures, such as recurrent policies that can deal with extensive occlusions by keeping a memory of past observations. We also hope to extend our method to a wider range of tasks that can benefit from visual input, as well as a variety of other rich sensory modalities, including haptic input from pressure sensors and auditory input. With a wider range of sensory modalities, end-to-end training of sensorimotor policies will become increasingly important: while it is often straightforward to imagine how vision might help to localize the position of an object in the scene, it is much less apparent how sound can be integrated into robotic control. A learned sensorimotor policy would be able to naturally integrate a wide range of modalities and utilize them to directly aid in control.

Appendix A. Guided Policy Search Algorithm Details

In this appendix, we describe a number of implementation details of our BADMM-based guided policy search algorithm and our linear-Gaussian controller optimization method.

A.1 BADMM Dual Variables and Weight Adjustment

Recall that the inner loop alternating optimization is given by

$$\theta \leftarrow \arg\min_\theta \sum_{t=1}^{T} E_{p(\mathbf{x}_t)\pi_\theta(\mathbf{u}_t|\mathbf{x}_t)}[\mathbf{u}_t^\mathrm{T}\lambda_{\mu t}] + \nu_t \phi_t^\theta(\theta, p)$$

$$p \leftarrow \arg\min_p \sum_{t=1}^{T} E_{p(\mathbf{x}_t,\mathbf{u}_t)}[\ell(\mathbf{x}_t,\mathbf{u}_t) - \mathbf{u}_t^\mathrm{T}\lambda_{\mu t}] + \nu_t \phi_t^p(p,\theta)$$

$$\lambda_{\mu t} \leftarrow \lambda_{\mu t} + \alpha\nu_t(E_{\pi_\theta(\mathbf{u}_t|\mathbf{x}_t)p(\mathbf{x}_t)}[\mathbf{u}_t] - E_{p(\mathbf{u}_t|\mathbf{x}_t)p(\mathbf{x}_t)}[\mathbf{u}_t]).$$

We use a step size of $\alpha = 0.1$ in all of our experiments, which we found to be more stable than $\alpha = 1.0$. The weights ν_t are initialized to 0.01 and incremented based on the following schedule: at every iteration, we compute the average KL-divergence between $p(\mathbf{u}_t|\mathbf{x}_t)$ and $\pi_\theta(\mathbf{u}_t|\mathbf{x}_t)$ at each time step, as well as its standard deviation over time steps.

The weights ν_t corresponding to time steps where the KL-divergence is higher than the average are increased by a factor of 2, and the weights corresponding to time steps where the KL-divergence is two standard deviations or more below the average are decreased by a factor of 2. The rationale behind this schedule is to adjust the KL-divergence penalty to keep the policy and trajectory in agreement by roughly the same amount at all time steps. Increasing ν_t too quickly can lead to the policy and trajectory becoming "locked" together, which makes it difficult for the trajectory to decrease its cost, while leaving it too low requires more iterations for convergence. We found this schedule to work well across all tasks, both during trajectory pretraining and while training the visuomotor policy.

To update the dual variables $\lambda_{\mu t}$, we evaluate the expectations over $p(\mathbf{x}_t)$ by using the latest batch of sampled trajectories. For each state $\{\mathbf{x}_t^i\}$ along these sampled trajectories, we evaluate the expectations over $\mathbf{u}_t$ under $\pi_\theta(\mathbf{u}_t|\mathbf{x}_t)$ and $p(\mathbf{u}_t|\mathbf{x}_t)$, which correspond simply to the means of these conditional Gaussian distributions, in closed form.

A.2 Policy Variance Optimization

As discussed in Section 4, the variance of the Gaussian policy $\pi_\theta(\mathbf{u}_t|\mathbf{o}_t)$ does not depend on the observation, though this dependence would be straightforward to add. Analyzing the objective $\mathcal{L}_\theta(\theta, p)$, we can write out only the terms that depend on Σ^π:

$$\mathcal{L}_\theta(\theta, p) = \frac{1}{2N}\sum_{i=1}^{N}\sum_{t=1}^{T} E_{p_i(\mathbf{x}_t,\mathbf{o}_t)}\left[\mathrm{tr}[\mathbf{C}_{ti}^{-1}\Sigma^\pi] - \log|\Sigma^\pi|\right].$$

Differentiating and setting the derivative to zero, we obtain the following equation for Σ^π:

$$\Sigma^\pi = \left[\frac{1}{NT}\sum_{i=1}^{N}\sum_{t=1}^{T}\mathbf{C}_{ti}^{-1}\right]^{-1},$$

where the expectation under $p_i(\mathbf{x}_t)$ is omitted, since $\mathbf{C}_{ti}$ does not depend on $\mathbf{x}_t$.

A.3 Dynamics Fitting

Optimizing the linear-Gaussian controllers $p_i(\mathbf{u}_t|\mathbf{x}_t)$ that induce the trajectory distributions $p_i(\tau)$ requires fitting the system dynamics $p_i(\mathbf{x}_{t+1}|\mathbf{x}_t, \mathbf{u}_t)$ at each iteration to samples generated on the physical system from the previous controller $\hat{p}_i(\mathbf{u}_t|\mathbf{x}_t)$. In this section, we describe how these dynamics are fitted. As in Section 4, we drop the subscript i, since the dynamics are fitted the same way for all of the trajectory distributions.

The linear-Gaussian dynamics are defined as $p(\mathbf{x}_{t+1}|\mathbf{x}_t, \mathbf{u}_t) = \mathcal{N}(f_{\mathbf{x}t}\mathbf{x}_t + f_{\mathbf{u}t}\mathbf{u}_t + f_{ct}, \mathbf{F}_t)$, and the data that we obtain from the robot can be viewed as tuples $\{\mathbf{x}_t^i, \mathbf{u}_t^i, \mathbf{x}_{t+1}^i\}$. A simple way to fit these linear-Gaussian dynamics is to use linear regression to determine $f_\mathbf{x}$, $f_\mathbf{u}$, and f_c, and fit $\mathbf{F}_t$ based on the errors. However, the sample complexity of linear regression scales with the dimensionality of $\mathbf{x}_t$. For a high-dimensional robotic system, we might need an impractically large number of samples at each iteration to obtain a good fit. However, we can observe that the dynamics at nearby time steps are strongly correlated, and we can dramatically reduce the sample complexity of the dynamics fitting by bringing in information from other time steps, and even prior iterations. We will bring in this

information by fitting a global model to all of the transitions $\{\mathbf{x}_t^i, \mathbf{u}_t^i, \mathbf{x}_{t+1}^i\}$ for all t and all tuples from several prior iterations (we use three prior iterations in our implementation), and then use this model as a prior for fitting the dynamics at each time step. Note that this global model does not itself need to be a good forward dynamics model – it just needs to serve as a good prior to reduce the sample complexity of linear regression.

To make it more convenient to incorporate a data-driven prior, we will first reformulate this linear regression fit and view it as fitting a Gaussian model to the dataset $\{\mathbf{x}_t^i, \mathbf{u}_t^i, \mathbf{x}_{t+1}^i\}$ at each time step t, and then conditioning this Gaussian to obtain $p(\mathbf{x}_{t+1}|\mathbf{x}_t, \mathbf{u}_t)$. While this is equivalent to linear regression, it allows us to easily incorporate a normal-inverse-Wishart prior on this Gaussian in order to bring in prior information. Let $\hat{\Sigma}$ be the empirical covariance of our dataset, and let $\hat{\mu}$ be the empirical mean. The normal-inverse-Wishart prior is defined by prior parameters $\mathbf{\Phi}$, μ_0, m, and n_0. Under this prior, the maximum a posteriori estimates for the covariance Σ and mean μ are given by

$$\Sigma = \frac{\mathbf{\Phi} + N\hat{\Sigma} + \frac{Nm}{N+m}(\hat{\mu} - \mu_0)(\hat{\mu} - \mu_0)^{\mathrm{T}}}{N + n_0} \qquad \mu = \frac{m\mu_0 + n_0\hat{\mu}}{m + n_0}.$$

Having obtained Σ and μ, we can obtain an estimate of the dynamics $p(\mathbf{x}_{t+1}|\mathbf{x}_t, \mathbf{u}_t)$ by conditioning the distribution $\mathcal{N}(\mu, \Sigma)$ on $[\mathbf{x}_t; \mathbf{u}_t]$, which produces linear-Gaussian dynamics $p(\mathbf{x}_{t+1}|\mathbf{x}_t, \mathbf{u}_t) = \mathcal{N}(f_{\mathbf{x}t}\mathbf{x}_t + f_{\mathbf{u}t}\mathbf{u}_t + f_{ct}, \mathbf{F}_t)$. The parameters of the normal-inverse-Wishart prior are obtained from the global model of the dynamics which, as described previously, is fitted to all available tuples $\{\mathbf{x}_t^i, \mathbf{u}_t^i, \mathbf{x}_{t+1}^i\}$.

The simplest prior can be obtained by fitting a Gaussian distribution to vectors $[\mathbf{x}; \mathbf{u}; \mathbf{x}']$. If the mean and covariance of this data are given by $\bar{\mu}$ and $\bar{\Sigma}$, the prior is given by $\mathbf{\Phi} = n_0\bar{\Sigma}$ and $\mu_0 = \bar{\mu}$, while n_0 and m should be set to the number of data points in the datasets. In practice, settings n_0 and m to 1 tends to produce better results, since the prior is fitted to many more samples than are available for linear regression at each time step. While this prior is simple, we can obtain a better prior by employing a nonlinear model.

The particular global model we use in this work is a Gaussian mixture model over vectors $[\mathbf{x}; \mathbf{u}; \mathbf{x}']$. Systems of articulated rigid bodies undergoing contact dynamics, such as robots interacting with their environment, can be coarsely modeled as having piecewise linear dynamics. The Gaussian mixture model provides a good approximation for such piecewise linear systems, with each mixture element corresponding to a different linear mode (Khansari-Zadeh and Billard, 2010). Under this model, the state transition tuple is assumed to come from a distribution that depends on some hidden state h, which corresponds to the mixture element identity. In practice, this hidden state might correspond to the type of contact profile experienced by a robotic arm at step i. The prior for the dynamics fit at time step t is then obtained by inferring the hidden state distribution for the transition dataset $\{\mathbf{x}_t^i, \mathbf{u}_t^i, \mathbf{x}_{t+1}^i\}$, and using the mean and covariance of the corresponding mixture elements (weighted by their probabilities) to obtain $\bar{\mu}$ and $\bar{\Sigma}$. The prior parameters can then be obtained as described above.

In our experiments, we set the number of mixture elements for the Gaussian mixture model prior such that there were at least 40 samples per mixture element, or 20 total mixture elements, whichever was lower. In general, we did not find the performance of the method to be sensitive to this parameter, though overfitting did tend to occur in the early iterations when the number of samples is low, if the number of mixtures was too high.

A.4 Trajectory Optimization

In this section, we show how the LQR backward pass can be used to optimize the constrained objective in Section 4.2. The constrained trajectory optimization problem is given by

$$\min_{p(\tau)\in\mathcal{N}(\tau)} \mathcal{L}_p(p, \theta) \text{ s.t. } D_{\mathrm{KL}}(p(\tau)\|\hat{p}(\tau)) \leq \epsilon.$$

The augmented Lagrangian $\mathcal{L}_p(p, \theta)$ consists of an entropy term and an expectation under $p(\tau)$ of a quantity that is independent of p. We can locally approximate this quantity with a quadratic by using a quadratic expansion of $\ell(\mathbf{x}_t, \mathbf{u}_t)$, and fitting a linear Gaussian to $\pi_\theta(\mathbf{u}_t|\mathbf{x}_t)$ with the same method we used for the dynamics. We can then solve the primal optimization in the dual gradient descent procedure with a standard LQR backward pass. As discussed in Section 4, $\mathcal{L}_p(p, \theta)$ can be written as the expectation of some function $c(\tau)$ that is independent of p, such that $\mathcal{L}_p(p, \theta) = E_{p(\tau)}[c(\tau)] - \nu_t\mathcal{H}(p(\tau))$. Specifically,

$$c(\mathbf{x}_t, \mathbf{u}_t) = \ell(\mathbf{x}_t, \mathbf{u}_t) - \mathbf{u}_t^{\mathrm{T}}\lambda_{\mu t} - \nu_t \log \pi_\theta(\mathbf{u}_t|\mathbf{x}_t)$$

Writing the Lagrangian of the constrained optimization, we have

$$\mathcal{L}(p) = E_{p(\tau)}[c(\tau) - \eta \log \hat{p}(\tau)] - (\eta + \nu_t)\mathcal{H}(p(\tau)) - \eta\epsilon,$$

where η is the Lagrange multiplier. Note that $\mathcal{L}(p)$ is the Lagrangian of the constrained trajectory optimization, which is not related to the augmented Lagrangian $\mathcal{L}_p(\tau, \theta)$. Grouping the terms in the expectation and omitting constants, we can rewrite the minimization of the Lagrangian with respect to the primal variables as

$$\min_{p(\tau)\in\mathcal{N}(\tau)} E_{p(\tau)}\left[\frac{1}{\eta + \nu_t}c(\tau) - \frac{\eta}{\eta + \nu_t}\log \hat{p}(\tau)\right] - \mathcal{H}(p(\tau)). \tag{4}$$

Let $\tilde{c}(\tau) = \frac{1}{\eta+\nu_t}c(\tau) - \frac{\eta}{\eta+\nu_t}\log \hat{p}(\tau)$. The above optimization corresponds to minimizing $E_{p(\tau)}[\tilde{c}(\tau)] - \mathcal{H}(p(\tau))$. This type of maximum entropy problem can be solved using the LQR algorithm, and the solution is given by

$$p(\mathbf{u}_t|\mathbf{x}_t) = \mathcal{N}(\mathbf{K}_t\mathbf{x}_t + \mathbf{k}_t; Q_{\mathbf{u},\mathbf{u}t}^{-1}),$$

where $\mathbf{K}_t$ and $\mathbf{k}_t$ are the feedback and open loop terms of the optimal linear feedback controller corresponding to the cost $\tilde{c}(\mathbf{x}_t, \mathbf{u}_t)$ and the dynamics $p(\mathbf{x}_{t+1}|\mathbf{x}_t, \mathbf{u}_t)$, and $Q_{\mathbf{u},\mathbf{u}t}$ is the quadratic term in the Q-function at time step t. All of these terms can be obtained from a standard LQR backward pass (Li and Todorov, 2004), which we summarize below.

Recall that the estimated linear-Gaussian dynamics have the form $p(\mathbf{x}_{t+1}|\mathbf{x}_t, \mathbf{u}_t) = \mathcal{N}(f_{\mathbf{x}t}\mathbf{x}_t + f_{\mathbf{u}t}\mathbf{u}_t + f_{ct}, \mathbf{F}_t)$. The quadratic cost approximation has the form

$$\tilde{c}(\mathbf{x}_t, \mathbf{u}_t) \approx \frac{1}{2}[\mathbf{x}_t; \mathbf{u}_t]^{\mathrm{T}}\tilde{c}_{\mathbf{xu},\mathbf{xu}t}[\mathbf{x}_t; \mathbf{u}_t] + [\mathbf{x}_t; \mathbf{u}_t]^{\mathrm{T}}\tilde{c}_{\mathbf{xu}t} + \text{const},$$

where subscripts denote derivatives, e.g. $\tilde{c}_{\mathbf{xu}t}$ is the gradient of $\tilde{c}$ with respect to $[\mathbf{x}_t; \mathbf{u}_t]$, while $\tilde{c}_{\mathbf{xu},\mathbf{xu}t}$ is the Hessian.[4] Under this model of the dynamics and cost function, the

4. We assume that all Taylor expansions here are recentered around zero. Otherwise, the point around which the derivatives are computed must be subtracted from $\mathbf{x}_t$ and $\mathbf{u}_t$ in all of these equations.

optimal controller can be computed by recursively computing the quadratic Q-function and value function, starting with the last time step. These functions are given by

$$V(\mathbf{x}_t) = \frac{1}{2}\mathbf{x}_t^{\mathrm{T}} V_{\mathbf{x},\mathbf{x}t}\mathbf{x}_t + \mathbf{x}_t^{\mathrm{T}} V_{\mathbf{x}t} + \text{const}$$
$$Q(\mathbf{x}_t, \mathbf{u}_t) = \frac{1}{2}[\mathbf{x}_t; \mathbf{u}_t]^{\mathrm{T}} Q_{\mathbf{xu},\mathbf{xu}t}[\mathbf{x}_t; \mathbf{u}_t] + [\mathbf{x}_t; \mathbf{u}_t]^{\mathrm{T}} Q_{\mathbf{xu}t} + \text{const}$$

We can express them with the following recurrence, which is computed starting at the last time step $t = T$ and moving backward through time:

$$\begin{aligned}
Q_{\mathbf{xu},\mathbf{xu}t} &= \tilde{c}_{\mathbf{xu},\mathbf{xu}t} + f_{\mathbf{xu}t}^{\mathrm{T}} V_{\mathbf{x},\mathbf{x}t+1} f_{\mathbf{xu}t} \\
Q_{\mathbf{xu}t} &= \tilde{c}_{\mathbf{xu}t} + f_{\mathbf{xu}t}^{\mathrm{T}} V_{\mathbf{x}t+1} + f_{\mathbf{xu}t}^{\mathrm{T}} V_{\mathbf{x},\mathbf{x}t+1} f_{ct} \\
V_{\mathbf{x},\mathbf{x}t} &= Q_{\mathbf{x},\mathbf{x}t} - Q_{\mathbf{u},\mathbf{x}t}^{\mathrm{T}} Q_{\mathbf{u},\mathbf{u}t}^{-1} Q_{\mathbf{u},\mathbf{x}t} \\
V_{\mathbf{x}t} &= Q_{\mathbf{x}t} - Q_{\mathbf{u},\mathbf{x}t}^{\mathrm{T}} Q_{\mathbf{u},\mathbf{u}t}^{-1} Q_{\mathbf{u}t},
\end{aligned}$$

and the optimal control law is then given by $g(\mathbf{x}_t) = \mathbf{K}_t\mathbf{x}_t + \mathbf{k}_t$, where $\mathbf{K}_t = -Q_{\mathbf{u},\mathbf{u}t}^{-1} Q_{\mathbf{u},\mathbf{x}t}$ and $\mathbf{k}_t = -Q_{\mathbf{u},\mathbf{u}t}^{-1} Q_{\mathbf{u}t}$. If, instead of simply minimizing the expected cost, we instead wish to optimize the maximum entropy objective in Equation (4), the optimal controller is instead linear-Gaussian, with the solution given by $p(\mathbf{u}_t|\mathbf{x}_t) = \mathcal{N}(\mathbf{K}_t\mathbf{x}_t + \mathbf{k}_t; Q_{\mathbf{u},\mathbf{u}t}^{-1})$, as shown in prior work (Levine and Koltun, 2013a).

Appendix B. Experimental Setup Details

In this appendix, we present a detailed summary of the experimental setup for our simulated and real-world experiments.

B.1 Simulated Experiment Details

All of the simulated experiments used the MuJoCo simulation package (Todorov et al., 2012), with simulated frictional contacts and torque motors at the joints used for actuation. Although no control or state noise was added during simulation, noise was injected naturally by the linear-Gaussian controllers. The linear-Gaussian controllers $p_i(\mathbf{u}_t|\mathbf{x}_t)$ were initialized to stay near the initial state $\mathbf{x}_1$ using linear feedback based on a proportional-derivative control law for all tasks, except for the octopus arm, where $p_i(\mathbf{u}_t|\mathbf{x}_t)$ was initialized to be zero mean with a fixed spherical covariance, and the walker, which was initialized to track a demonstration trajectory with proportional-derivative feedback. The walker was the only task that used a demonstration, as described previously. We describe the details of each system below.

Peg insertion: The 2D peg insertion task has 6 state dimensions (joint angles and angular velocities) and 2 action dimensions. The 3D version of the task has 12 state dimensions, since the arm has 3 degrees of freedom at the shoulder, 1 at the elbow, and 2 at the wrist. Trials were 8 seconds in length and simulated at 100 Hz, resulting in 800 time steps per rollout. The cost function is given by

$$\ell(\mathbf{x}_t, \mathbf{u}_t) = \frac{1}{2} w_{\mathbf{u}} \|\mathbf{u}_t\|^2 + w_{\mathbf{p}} \ell_{12}(\mathbf{p}_{\mathbf{x}_t} - \mathbf{p}^\star),$$

where $\mathbf{p}_{\mathbf{x}_t}$ is the position of the end effector for state $\mathbf{x}_t$, $\mathbf{p}^\star$ is the desired end effector position at the bottom of the slot, and the norm $\ell_{12}(z)$ is given by $\frac{1}{2}\|z\|^2 + \sqrt{\alpha + z^2}$, which corresponds to the sum of an ℓ_2 and soft ℓ_1 norm. We use this norm to encourage the peg to precisely reach the target position at the bottom of the hole, but to also receive a larger penalty when far away. The task also works well in 2D with a simple ℓ_2 penalty, though we found that the 3D version of the task takes longer to insert the peg all the way into the hole without the ℓ_1-like square root term. The weights were set to $w_{\mathbf{u}} = 10^{-6}$ and $w_{\mathbf{p}} = 1$. Initial states were chosen by moving the shoulder of the arm relative to the hole, with four equally spaced starting states in a 20 cm region for the 2D arm, and four random starting states in a 10 cm radius for the 3D arm.

Octopus arm: The octopus arm consists of six four-sided chambers. Each edge of each chamber is a simulated muscle, and actions correspond to contracting or relaxing the muscle. The state space consists of the positions and velocities of the chamber vertices. The midpoint of one edge of the first chamber is fixed, resulting in a total of 25 degrees of freedom: the 2D positions of the 12 unconstrained points, and the orientation of the first edge. Including velocities, the total dimensionality of the state space is 50. The cost function depends on the activation of the muscles and distance between the tip of the arm and the target point, in the same way as for peg insertion. The weights are set to $w_{\mathbf{u}} = 10^{-3}$ and $w_{\mathbf{p}} = 1$.

Swimmer: The swimmer consists of 3 links and 5 degrees of freedom, including the global position and orientation which, together with the velocities, produces a 10 dimensional state space. The swimmer has 2 action dimensions corresponding to the torques between joints. The simulation applied drag on each link of the swimmer to roughly simulate a fluid, allowing it to propel itself. The rollouts were 20 seconds in length at 20 Hz, resulting in 400 time steps per rollout. The cost function for the swimmer is given by

$$\ell(\mathbf{x}_t, \mathbf{u}_t) = \frac{1}{2} w_{\mathbf{u}} \|\mathbf{u}_t\|^t + \frac{1}{2} w_v \|v_{x\mathbf{x}_t} - v_x^\star\|^2$$

where $v_{x\mathbf{x}_t}$ is the horizontal velocity, $v_x^\star = 2.0\text{m/s}$, and the weights were $w_{\mathbf{u}} = 2 \cdot 10^{-5}$ and $w_v = 1$.

Walker: The bipedal walker consists of a torso and two legs, each with three links, for a total of 9 degrees of freedom and 18 dimensions, with velocity, and 6 action dimensions. The simulation ran for 5 seconds at 100 Hz, for a total of 500 time steps. The cost function is given by

$$\ell(\mathbf{x}_t, \mathbf{u}_t) = \frac{1}{2} w_{\mathbf{u}} \|\mathbf{u}_t\|^t + \frac{1}{2} w_v \|v_{x\mathbf{x}_t} - v_x^\star\|^2 + \frac{1}{2} w_h \|p_{y_{\mathbf{x}_t}} - p_y^\star\|^2$$

where $v_{x\mathbf{x}_t}$ is again the horizontal velocity, $p_{y_{\mathbf{x}_t}}$ is the vertical position of the root, $v_x^\star = 2.1\text{m/s}$, $p_y^\star = 1.1\text{m}$, and the weights were set to $w_{\mathbf{u}} = 10^{-4}$, $w_v = 1$, and $w_h = 1$.

B.2 Robotic Experiment Details

All of the robotic experiments were conducted on a PR2 robot. The robot was controlled at 20 Hz via direct effort control,[5] and camera images were recorded using the RGB camera on a PrimeSense Carmine sensor. The images were downsampled to $240 \times 240 \times 3$. The learned policies controlled one 7 DoF arm of the robot, while the other arm was used to move objects in the scene to automatically vary the initial conditions. The camera was kept fixed in each experiment. Each episode was 5 seconds in length. For each task, the cost function required placing the object held in the gripper at a particular location (which might require, for example, to insert a shape into a shape sorting cube). The cost was given by the following equation:

$$\ell(\mathbf{x}_t, \mathbf{u}_t) = w_{\ell_2} d_t^2 + w_{\log} \log(d_t^2 + \alpha) + w_{\mathbf{u}} \|\mathbf{u}_t\|^2,$$

where d_t is the distance between three points in the space of the end-effector and their target positions,[6], and the weights are set to $w_{\ell_2} = 10^{-3}$, $w_{\log} = 1.0$, and $w_{\mathbf{u}} = 10^{-2}$. The quadratic term encourages moving the end-effector toward the target when it is far, while the logarithm term encourages placing it precisely at the target location, as discussed in prior work (Levine et al., 2015). The bottle cap task used an additional cost term consisting of a quadratic penalty on the difference between the wrist angular velocity and a target velocity.

For all of the tasks, we initialized all of the linear-Gaussian controllers $p_i(\mathbf{u}_t|\mathbf{x}_t)$ to stay near the initial state $\mathbf{x}_1$, with a diagonal noise covariance. The covariance of the noise was chosen to be proportional to a diagonal approximation of the inverse effective mass at each joint, as provided by the manufacturer of the PR2 robot, and the feedback controller was constructed using LQR, with an approximate linear model obtained from the same diagonal inverse mass matrix. The role of this initial controller was primarily to avoid dangerous actions during the first iteration. We discuss the particular setup for each experiment below:

Coat hanger: The coat hanger task required the robot to hang a coat hanger on a clothes rack. The coat hanger was grasped at one of two angles, about 35° apart, and the rack was positioned at three different distances from the robot during training, with differences of about 10 cm between each position. The rack was moved manually between these positions during training. A trial was considered successful if, when the coat hanger was released, it remained hanging on the rack rather than dropping to the ground.

Shape sorting cube: The shape sorting cube task required the robot to insert a red trapezoid into a trapezoidal hole on a shape sorting cube. During training, the cube was positioned at nine different positions, situated at the corners, edges, and middle of a rectangular region 16 cm × 10 cm in size. During training, the shape sorting cube was moved through the training positions by using the left arm. A trial was considered successful if the bottom face of the trapezoid was completely inside the shape sorting cube, such that if the robot were to release the trapezoid, it would fall inside the cube.

5. The PR2 robot does not provide for closed loop torque control, but instead supports an effort control interface that directly sets feedforward motor voltages. In practice, these voltages are roughly proportional to feedforward torques, but are also affected by friction and damping.
6. Three points fully define the pose of the end-effector. For the bottle cap task, which is radially symmetric, we use only two points.

Toy hammer: The hammer task required the robot to insert the claw of a toy hammer underneath a toy plastic nail, placing the claw around the base of the nail. The hammer was grasped at one of three angles, each 22.5° apart, for a total variation of 45° degrees, and the nail was positioned at five positions, at the corners and center of a rectangular region 10 cm × 7 cm in size. During training, the toy tool bench containing the nail was moved using the left arm. A trial was considered successful if the tip of the claw of the hammer was at least under the centerline of the nail.

Bottle cap: The bottle cap task required the robot to screw a cap onto a bottle at various positions. The bottle was located at nine different positions, situated at the corners, edges, and middle of a rectangular region 16 cm × 10 cm in size, and the left arm was used to move the bottle through the training positions. A trial was considered successful if, after completion, the cap could not be removed from bottle simply by pulling vertically.
