Inspired by the centering trick proposed by LeCun et al. (1998), Tang and Sutskever (2011) have addressed the problem that RBMs perform differently on the *MNIST* and *1-MNIST* data set by changing the energy of the RBM in a way that the mean of the input data is removed. Montavon and Müller (2012) have extended the idea of centering to the visible and hidden variables of DBMs and have shown that centering improves the conditioning of the underlying optimization problem, leading to models with better discriminative properties for DBMs in general and better generative properties in the case of locally connected DBMs.

Following their line of thought, the energy for a centered binary RBM where the visible and hidden variables are shifted by the offset parameters $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_N)$ and $\boldsymbol{\lambda} = (\lambda_1, \ldots, \lambda_M)$, respectively, can be formulated as

$$E(\mathbf{x}, \mathbf{h}) = -(\mathbf{x} - \boldsymbol{\mu})^T \mathbf{b} - \mathbf{c}^T (\mathbf{h} - \boldsymbol{\lambda}) - (\mathbf{x} - \boldsymbol{\mu})^T \mathbf{W} (\mathbf{h} - \boldsymbol{\lambda}) \ . \tag{4}$$

By setting both offsets to zero one retains the normal binary RBM. Setting $\boldsymbol{\mu} = \langle \mathbf{x} \rangle_d$ and $\boldsymbol{\lambda} = \mathbf{0}$ leads to the model introduced by Tang and Sutskever (2011), and by setting $\boldsymbol{\mu} = \langle \mathbf{x} \rangle_d$ and $\boldsymbol{\lambda} = \langle \mathbf{h} \rangle_d$ we get a shallow variant of the centered DBM analyzed by Montavon and Müller (2012).

The conditional probabilities for a variable taking the value one are given by

$$p(x_i = 1|\mathbf{h}) = \sigma(\mathbf{w_{i*}} (\mathbf{h} - \boldsymbol{\lambda}) + b_i) \ , \tag{5}$$

$$p(h_j = 1|\mathbf{x}) = \sigma((\mathbf{x} - \boldsymbol{\mu})^T \mathbf{w_{*j}} + c_j) \ , \tag{6}$$

where $\sigma(\cdot)$ is the sigmoid function, $\mathbf{w_{i*}}$ represents the ith row, and $\mathbf{w_{*j}}$ the jth column of the weight matrix $\mathbf{W}$. The LL gradient now takes the form

$$\nabla \mathbf{W} = \langle (\mathbf{x} - \boldsymbol{\mu})(\mathbf{h} - \boldsymbol{\lambda})^T \rangle_d - \langle (\mathbf{x} - \boldsymbol{\mu})(\mathbf{h} - \boldsymbol{\lambda})^T \rangle_m \ , \tag{7}$$

$$\nabla \mathbf{b} = \langle \mathbf{x} - \boldsymbol{\mu} \rangle_d - \langle \mathbf{x} - \boldsymbol{\mu} \rangle_m = \langle \mathbf{x} \rangle_d - \langle \mathbf{x} \rangle_m \ , \tag{8}$$

$$\nabla \mathbf{c} = \langle \mathbf{h} - \boldsymbol{\lambda} \rangle_d - \langle \mathbf{h} - \boldsymbol{\lambda} \rangle_m = \langle \mathbf{h} \rangle_d - \langle \mathbf{h} \rangle_m \ . \tag{9}$$

$\nabla \mathbf{b}$ and $\nabla \mathbf{c}$ are independent of the choice of $\boldsymbol{\mu}$ and $\boldsymbol{\lambda}$ and thus centering only affects $\nabla \mathbf{W}$. It can be shown (see Appendix A) that the gradient of a centered BM is invariant to flip transformations if a flip of x_i to $1 - x_i$ implies a change of μ_i to $1 - \mu_i$, and in the case of RBMs a flip h_j to $1-h_j$ implies a change of λ_j to $1-\lambda_j$. This holds for $\mu_i = 0.5$, $\lambda_j = 0.5$ but remarkably also for the expectation values over x_i and h_j under any distribution. Moreover, if the offsets are set to the expectation values, centered RBMs get also invariant to shifts

Algorithm 1: Training centered RBMs

Initialize $\mathbf{W}$; /* *i.e.*, $\mathbf{W} \leftarrow \mathcal{N}(0, 0.01)^{N \times M}$ */

$\boldsymbol{\mu} \leftarrow \mathbf{0}$
$\boldsymbol{\lambda} \leftarrow \mathbf{0}$

of variables (see Section 4). Note that these properties of centered RBMs naturally extend to centered BMs and DBMs (see Section 3.2, Appendix A and B).

If we set $\boldsymbol{\mu}$ and $\boldsymbol{\lambda}$ to the expectation values of the variables, these values may depend on the RBM parameters (think for example about $\langle \mathbf{h} \rangle_d$) and thus they might change during training. Consequently, a learning algorithm for centered RBMs needs to update the offset values to match the expectations under the distribution that has changed through a parameter update. When updating the offsets one needs to transform the RBM parameters such that the modeled probability distribution stays the same. An RBM with offsets $\boldsymbol{\mu}$ and $\boldsymbol{\lambda}$ can be transformed to an RBM with offsets $\tilde{\boldsymbol{\mu}}$ and $\tilde{\boldsymbol{\lambda}}$ by

$$\tilde{\mathbf{W}} = \mathbf{W} \,, \tag{10}$$

$$\tilde{\mathbf{b}} = \mathbf{b} + \mathbf{W}\left(\tilde{\boldsymbol{\lambda}} - \boldsymbol{\lambda}\right) \,, \tag{11}$$

$$\tilde{\mathbf{c}} = \mathbf{c} + \mathbf{W}^T (\tilde{\boldsymbol{\mu}} - \boldsymbol{\mu}) \,, \tag{12}$$

such that $E(\mathbf{x}, \mathbf{h}|\boldsymbol{\theta}, \boldsymbol{\mu}, \boldsymbol{\lambda}) = E(\mathbf{x}, \mathbf{h}|\tilde{\boldsymbol{\theta}}, \tilde{\boldsymbol{\mu}}, \tilde{\boldsymbol{\lambda}}) + const$, is guaranteed (see Appendix B for a derivation for a more general BM). Obviously, this can also be used to transform a centered RBM to a normal RBM and *vice versa*, highlighting that centered and normal RBMs are just different parameterizations of the same model class.

If the intractable model mean is used for an offset, it has to be approximated by samples. Furthermore, when $\boldsymbol{\lambda}$ is chosen to be $\langle \mathbf{h} \rangle_d$ or $\langle \mathbf{h} \rangle_m$ or when $\boldsymbol{\mu}$ is chosen to be $\langle \mathbf{x} \rangle_m$ one could approximate the mean values either using the sampled states or the corresponding conditional probabilities. But due to the Rao-Blackwell theorem an estimation based on the probabilities has lower variance and therefore is the approximation of choice.[3]

Algorithm 1 shows pseudo code for training a centered binary RBM, where we use $\langle \cdot \rangle$ to denote the average over samples from the current batch. Thus, for example, we write $\langle \mathbf{x}_d \rangle$ for the average value of data samples $\mathbf{x}_d$ in the current batch, which is used as an approximation for the expectation of $\mathbf{x}$ under the data distribution, that is $\langle \mathbf{x} \rangle_d$. Similarly, $\langle \mathbf{h}_d \rangle = \langle p\left(\mathbf{h} = \mathbf{1}|\mathbf{x}_d\right) \rangle$ approximates $\langle \mathbf{h} \rangle_d$, where $p\left(\mathbf{x} = \mathbf{1}|\mathbf{h}\right)$ denotes the vector containing the elements $p\left(x_i = 1|\mathbf{h}\right)$. Note that in Algorithm 1 the update of the offsets is performed before the gradient is calculated, such that gradient and reparameterization both use the current samples. This is in contrast to the algorithm for centered DBMs proposed by Montavon and Müller (2012), where the update of the offsets and the reparameterization follows after the gradient update. Thus, while the gradient still uses the current samples the reparameterization is based on samples gained from the model of the previous iteration. However, the proposed DBM algorithm smooths the offset estimations by an exponentially moving average over the sample means from many iterations, so that the choice of the sample set used for the offset estimation should be less relevant.

In Algorithm 1 an exponentially moving average for the approximation of $\boldsymbol{\mu}$ is obtained if the corresponding sliding factor ν_μ is set to $0 < \nu_\mu < 1$ or prevented if $\nu_\mu = 1$ and equivalently for $\boldsymbol{\lambda}$ and ν_λ. The effects of using an exponentially moving average are empirically analyzed in Section 6.5.

3. This can be proven analogously to the proof of proposition 1 in the work of Swersky et al. (2010).

3.1 Centered Gradient

We now use the centering trick to derive a centered parameter update, which can replace the gradient during the training of normal RBMs. Similar to the derivation of the enhanced gradient we can transform a normal RBM to a centered RBM, perform a gradient update, and transform the RBM back (see Appendix B for a derivation for the more general BM). This yields the following parameter updates, which we refer to as centered gradient

$$\nabla_c \mathbf{W} = \langle (\mathbf{x}-\boldsymbol{\mu})(\mathbf{h}-\boldsymbol{\lambda})^T \rangle_d - \langle (\mathbf{x}-\boldsymbol{\mu})(\mathbf{h}-\boldsymbol{\lambda})^T \rangle_m \ , \tag{13}$$

$$\nabla_c \mathbf{b} = \langle \mathbf{x} \rangle_d - \langle \mathbf{x} \rangle_m - \nabla_c \mathbf{W} \boldsymbol{\lambda} \ , \tag{14}$$

$$\nabla_c \mathbf{c} = \langle \mathbf{h} \rangle_d - \langle \mathbf{h} \rangle_m - \nabla_c \mathbf{W}^T \boldsymbol{\mu} \ . \tag{15}$$

Note that by setting $\boldsymbol{\mu} = \frac{1}{2}\left(\langle \mathbf{x} \rangle_d + \langle \mathbf{x} \rangle_m\right)$ and $\boldsymbol{\lambda} = \frac{1}{2}\left(\langle \mathbf{h} \rangle_d + \langle \mathbf{h} \rangle_m\right)$ the centered gradient becomes equal to the enhanced gradient (see Appendix C). Thus, it becomes clear that the enhanced gradient is a special case of centering. This can also be concluded from the derivation of the enhanced gradient for Gaussian visible variables in (Cho et al., 2013a).

Algorithm 2: Training RBMs using the centered gradient

Initialize $\mathbf{W}$; /* *i.e.* $\mathbf{W} \leftarrow \mathcal{N}(0, 0.01)^{N \times M}$ */
Initialize $\boldsymbol{\mu}, \boldsymbol{\lambda}$; /* *i.e.* $\boldsymbol{\mu} \leftarrow \langle \texttt{data} \rangle, \boldsymbol{\lambda} \leftarrow \mathbf{0.5}$ */
Initialize $\mathbf{b}, \mathbf{c}$; /* *i.e.* $\mathbf{b} \leftarrow \sigma^{-1}(\boldsymbol{\mu}), \mathbf{c} \leftarrow \sigma^{-1}(\boldsymbol{\lambda})$ */
Initialize $\eta, \nu_\mu, \nu_\lambda$; /* *i.e.* $\eta, \nu_\mu, \nu_\lambda \in \{0.001, ..., 0.1\}$ */
repeat
  foreach batch **in** data **do**
    foreach sample $\mathbf{x}_d$ **in** batch **do**
      Calculate $\mathbf{h}_d = p(\mathbf{h} = \mathbf{1} | \mathbf{x}_d)$; /* ▷ Eq. (6) */
      Sample $\mathbf{x}_m$ *from RBM* ; /* *i.e.*, PCD-1, ▷ Eqs. (5), (6) */
      Calculate $\mathbf{h}_m = p(\mathbf{h} = \mathbf{1} | \mathbf{x}_m)$; /* ▷ Eq. (6) */
      Store $\mathbf{x}_m, \mathbf{h}_d, \mathbf{h}_m$
    Estimate $\boldsymbol{\mu}_{batch}$; /* *i.e.* $\boldsymbol{\mu}_{batch} \leftarrow \langle \mathbf{x}_d \rangle$ */
    Estimate $\boldsymbol{\lambda}_{batch}$; /* *i.e.* $\boldsymbol{\lambda}_{batch} \leftarrow \langle \mathbf{h}_d \rangle$ */
    /* Update offsets using exp. moving averages with sliding factors ν_μ and ν_λ */
    $\boldsymbol{\mu} \leftarrow (1 - \nu_\mu)\boldsymbol{\mu} + \nu_\mu \boldsymbol{\mu}_{batch}$
    $\boldsymbol{\lambda} \leftarrow (1 - \nu_\lambda)\boldsymbol{\lambda} + \nu_\lambda \boldsymbol{\lambda}_{batch}$
    /* Update parameters using the centered gradient with learning rate η */
    $\nabla_c \mathbf{W} \leftarrow \langle (\mathbf{x}_d - \boldsymbol{\mu})(\mathbf{h}_d - \boldsymbol{\lambda})^T \rangle - \langle (\mathbf{x}_m - \boldsymbol{\mu})(\mathbf{h}_m - \boldsymbol{\lambda})^T \rangle$; /* ▷ Eq. (13) */
    $\nabla_c \mathbf{b} \leftarrow \langle \mathbf{x}_d \rangle - \langle \mathbf{x}_m \rangle - \nabla_c \mathbf{W} \boldsymbol{\lambda}$; /* ▷ Eq. (14) */
    $\nabla_c \mathbf{c} \leftarrow \langle \mathbf{h}_d \rangle - \langle \mathbf{h}_m \rangle - \nabla_c \mathbf{W}^T \boldsymbol{\mu}$; /* ▷ Eq. (15) */
    $\mathbf{W} \leftarrow \mathbf{W} + \eta \nabla_c \mathbf{W}$
    $\mathbf{b} \leftarrow \mathbf{b} + \eta \nabla_c \mathbf{b}$
    $\mathbf{c} \leftarrow \mathbf{c} + \eta \nabla_c \mathbf{c}$
until *stopping criteria is met*;

The enhanced gradient has been designed such that the weight updates become the difference of the covariances between one visible and one hidden variable under the data and the model distribution. Interestingly, one gets the same weight update for two other choices of offset parameters, either $\boldsymbol{\mu} = \langle \mathbf{x} \rangle_d$ and $\boldsymbol{\lambda} = \langle \mathbf{h} \rangle_m$ or $\boldsymbol{\mu} = \langle \mathbf{x} \rangle_m$ and $\boldsymbol{\lambda} = \langle \mathbf{h} \rangle_d$. However, these offsets result in different update rules for the bias parameters.

Algorithm 2 shows pseudo code for training a normal binary RBM using the centered gradient, which is equivalent to training a centered binary RBM using Algorithm 1. Both algorithms can easily be extended to RBMs with other types of units, DBMs and BMs.

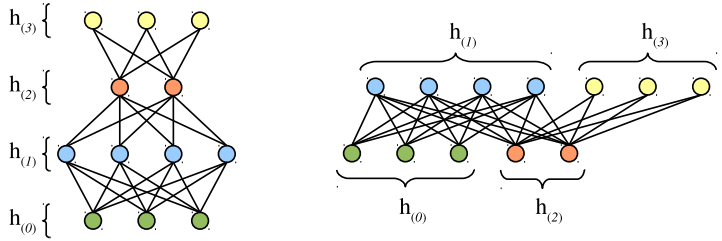
3.2 Centered Deep Boltzmann Machines

A DBM (Salakhutdinov and Hinton, 2009) is a deep undirected graphical model with several hidden layers where successive layers have a bipartite connectivity structure. Therefore, a DBM can be seen as a jointly trained stack of several RBMs and thus as a natural extension of RBMs. A centered binary DBM with L layers $\mathbf{h}_{(0)}, \cdots, \mathbf{h}_{(L)}$ (where $\mathbf{h}_{(0)}$ corresponds to the visible layer) represents a Gibbs distribution with energy

$$E\left(\mathbf{h}_{(0)}, \cdots, \mathbf{h}_{(L)}\right) = -\sum_{l=0}^{L} \left(\mathbf{h}_{(l)} - \boldsymbol{\lambda}_{(l)}\right)^T \mathbf{b}_{(l)} - \sum_{l=0}^{L-1} \left(\mathbf{h}_{(l)} - \boldsymbol{\lambda}_{(l)}\right)^T \mathbf{W}_{(l)} \left(\mathbf{h}_{(l+1)} - \boldsymbol{\lambda}_{(l+1)}\right),$$

where each layer l has a bias $\mathbf{b}_{(l)}$, an offset $\boldsymbol{\lambda}_{(l)}$ and is connected to layer $l+1$ by weight matrix $\mathbf{W}_l$.

The derivations, proofs and algorithms given in this work for RBMs/BMs automatically extend to DBMs since each DBM can be transformed to an RBM with restricted connections and partially unknown input data. This is illustrated for a DBM with four layers in Figure 1. As a consequence of this relation DBMs can essentially be trained in the same way as RBMs but also suffer from the same problems as described before. The major difference in DBM



(a) Deep network version. (b) Shallow network version.

Figure 1: Example for (a) a DBM or an ANN with four layers $h_{(0)}, \cdots, h_{(3)}$ and (b) the equivalent two layer shallow version of the same network with restricted connections and unknown input $h_{(2)}$.

training compared to RBM training is that the expectation under the data distribution in the LL gradient of DBMs gets intractable. Due to the partially missing input data the factorization trick used for the calculation of expectation under the data distribution in RBMs cannot be applied anymore. Instead the term is approximated by running a mean field estimation until convergence (Salakhutdinov and Hinton, 2009), which corresponds to approximating the gradient of the variational lower bound of the LL. Furthermore, it is common to pre-train DBMs in a greedy layer wise fashion using RBMs (Salakhutdinov and Hinton, 2009; Hinton and Salakhutdinov, 2012).

4. Centering in Artificial Neural Networks in General

Removing the mean from visible and hidden units was originally proposed for feed forward neural networks (LeCun et al., 1998; Schraudolph, 1998). When this idea was applied to the visible units of RBMs (Tang and Sutskever, 2011) the model was reparameterized such that the probability distribution defined by the normal and centered RBM stayed the same.

In this section we generalize this concept to show that centering is an alternative parameterization for arbitrary ANN architectures in general, if the network is reparameterized accordingly. Consider the centered artificial neuron model

$$o_j \quad = \quad \phi_j \left(\sum_i w_{ij} \left(a_i - \mu_i \right) + c_j \right), \tag{16}$$

where the output o_j of the jth neuron depends on its activation function ϕ_j, bias term c_j and weights w_{ij} with associated inputs a_i and their corresponding offsets μ_i. Such neurons can be used to construct arbitrary network architectures using undirected, directed and recurrent connections, which can then be optimized with respect to a chosen loss.

Two different ANNs that represent exactly the same functional input-output mapping can be considered as different parameterizations of the same model. Thus, a centered ANN is just a different parameterization of an uncentered ANN if we can show that their functional input-output mappings are the same. This can be guaranteed in general if all corresponding units in a centered and an uncentered ANN have the same mapping from inputs to outputs. If the offset μ_i is changed to $\tilde{\mu}_i = \mu_i + \nabla\mu_i$ then the output of the centered artificial neuron (16) becomes

$$\begin{aligned} \phi_j \left(\sum_i w_{ij} \left(a_i - \tilde{\mu}_i \right) + c_j \right) &= \phi_j \left(\sum_i w_{ij} \left(a_i - (\mu_i + \nabla\mu_i) \right) + c_j \right) \\ &= \phi_j \left(\sum_i w_{ij} \left(a_i - \mu_i \right) + c_j - \sum_i w_{ij} \nabla\mu_i \right), \end{aligned}$$

showing that the unit's output does not change when changing the offset μ_i to $\tilde{\mu}_i$ if the unit's bias parameter c_j is reparameterized to $\tilde{c}_j = c_j + \sum_i w_{ij} \nabla\mu_i$. This generalizes the reparameterization for RBMs given by Equations (10) – (12) to ANNs. Now, by setting μ_i or $\tilde{\mu}_i$ to zero it follows that for each normal ANN there exists a centered ANN and *vice versa* such that the output of each neuron and thus the functional mapping from input to output of the whole network stays the same. This holds independently of the chosen

activation functions, loss function and connection types including directed, undirected and recurrent connections.

Moreover, if we guarantee that a shift of a_i implies a shift of μ_i by the same value (that is, a shift of a_i to $a_i + \delta_i$ implies a shift of μ_i to $\mu_i + \delta_i$) the neuron's output o_j gets invariant to shifts of a_i. This is easy to see since δ_i cancels out in Equation (16) if the same shift is applied to both a_i and μ_i, which holds for example if we set the offsets to the mean values of the corresponding variables since $\langle a_i + \delta_i \rangle = \langle a_i \rangle + \delta_i$.

Note that, the original centering algorithm (LeCun et al., 1998; Schraudolph, 1998) did not reparameterize the network, which can cause instabilities especially if the learning rate is large.

4.1 Auto Encoders

An AE or auto-associator (Rumelhart et al., 1986b) is a type of ANN (and can thus be centered) that has originally been proposed for unsupervised dimensionality reduction. Like RBMs, AEs have also been used for unsupervised feature extraction and greedy layer-wise pre-training of deep neural networks (Bengio et al., 2007), and therefore fit well in this study for analyzing centering in ANNs.

In general, an AE consists of a deterministic encoder $encode(\mathbf{x})$, which maps the input $\mathbf{x} = (x_1, ..., x_N)$ to a hidden representation $\mathbf{h} = (h_1, ..., h_M)$ and a deterministic decoder $decode(\mathbf{h})$, which maps the hidden representation to the reconstructed input representation $\tilde{\mathbf{x}}$. The network is optimized such that the reconstructed input $\tilde{\mathbf{x}}$ gets as close as possible to the original input $\mathbf{x}$ measured by a chosen loss $\mathcal{L}(\mathbf{x}, \tilde{\mathbf{x}})$. Common choices for the loss are the mean squared error $\langle \sum_{i=1}^{N} (x_i - \tilde{x}_i)^2 \rangle_d$ for arbitrary input and the average cross entropy $\langle -\sum_{i=1}^{N} x_i \log \tilde{x}_i + (1 - x_i) \log(1 - \tilde{x}_i) \rangle_d$ for binary data. AEs are usually trained via back-propagation (Kelley, 1960; Rumelhart et al., 1986a) and they can be seen as feed-forward neural networks where the input patterns are also the desired output patterns. We can therefore define a centered AE by centering the encoder and decoder, which for a centered three layer AE corresponds to

$$\begin{aligned} encode(\mathbf{x}) &= \phi^{enc} \left(\mathbf{W}' \left(\mathbf{x} - \boldsymbol{\mu} \right) + \mathbf{c} \right) &= \mathbf{h}, \\ decode(\mathbf{h}) &= \phi^{dec} \left(\mathbf{W} \left(\mathbf{h} - \boldsymbol{\lambda} \right) + \mathbf{b} \right) &= \tilde{\mathbf{x}}, \end{aligned}$$

with encoder matrix $\mathbf{W}'$, decoder matrix $\mathbf{W}$, encoder bias $\mathbf{c}$, decoder bias $\mathbf{b}$, encoder offset $\boldsymbol{\mu}$, decoder offset $\boldsymbol{\lambda}$, encoder activation function ϕ^{enc} and decoder activation function ϕ^{dec}. It is common to assume tied weights, which means that the encoder matrix is just the transpose of the decoder matrix ($\mathbf{W}' = \mathbf{W}^T$). Although this reduces the number of free parameters AEs can still learn trivial representations if the number of hidden units is not chosen to be much smaller than the number of input dimensions or if the network is not regularized. Common regularized variants of AEs are denoising AEs (Vincent et al., 2008), sparse AEs (Olshausen et al., 1996; Poultney et al., 2006; Ng, 2011) and contractive AEs (Bishop, 1995; Rifai et al., 2011).

When choosing the activation functions for the encoder and decoder (that are sigmoid, tangens-hyperbolicus, radial-basis, linear, linear-rectifier, ...), we have to ensure that the encoder activation function is appropriate for the input data (for example a sigmoid cannot represent negative values). It is worth mentioning that when using the sigmoid function

for ϕ^{enc} and ϕ^{dec} and tied weights, the encoder becomes equivalent to Equation (5) and the decoder becomes equivalent to Equation (6). The network structure therefore becomes equivalent to an RBM such that the only difference is the training objective (that is the loss function).

4.2 Initialization of the Model Parameters

It is a common way to initialize the weight matrix of ANNs to small random values to break the symmetry. The bias parameters are often initialized to zero. However, we argue that there exists a more reasonable initialization for the bias parameters.

Hinton (2010) has proposed to initialize the RBM's visible bias parameter b_i to $\ln(p_i/(1-p_i))$, where p_i is the proportion of the data points in which unit i is on (that is $p_i = \langle x_i \rangle_d$). He has stated that if this is not done, the hidden units are used to activate the ith visible unit with a probability of approximately p_i in the early stage of training.

We argue that this initialization is in fact reasonable since it corresponds to the Maximum Likelihood Estimate (MLE) of the visible bias given the data for an RBM with zero weight matrix, given by

$$\mathbf{b}^* = \ln\left(\frac{\langle \mathbf{x} \rangle_d}{\mathbf{1} - \langle \mathbf{x} \rangle_d}\right) = -\ln\left(\frac{\mathbf{1}}{\langle \mathbf{x} \rangle_d} - \mathbf{1}\right) = \sigma^{-1}(\langle \mathbf{x} \rangle_d) \ , \tag{17}$$

where σ^{-1} is the inverse sigmoid function. Note that the MLE of the visible bias for an RBM with zero weights is the same whether the RBM is centered or not. The conditional probability of the visible variables of an RBM with this initialization is then given by $p(\mathbf{x} = \mathbf{1}|\mathbf{h}) = \sigma(\sigma^{-1}(\langle \mathbf{x} \rangle_d)) = \langle \mathbf{x} \rangle_d$, where $p(\mathbf{x} = \mathbf{1}|\mathbf{h})$ denotes the vector containing the elements $p(x_i = 1|\mathbf{h})$. Thus, the mean of the data is initially modeled only by the bias values and the weights are free to model higher order statistics in the beginning of training. For the unknown hidden variables it is reasonable to assume an initial mean of 0.5 so that the MLE of the hidden bias for an RBM with zero weights is given by $\mathbf{c}^* = \sigma^{-1}(0.5) = 0.0$. These considerations still hold approximately if the weights are not zero but initialized to small random values. For bigger initial weight values the model can be initially centered by using the inverse sigmoid of the average hidden activity given the data ($\mathbf{c}^* = \sigma^{-1}(\langle p(\mathbf{h} = \mathbf{1}|\mathbf{x}) \rangle_d)$) for the hidden biases.

Montavon and Müller (2012) have suggested to initialize the bias parameters of centered DBMs to the inverse sigmoid of the initial offset parameters. They have argued that this initialization leads to a good starting point, because it guarantees that the Boltzmann machine is initially centered. Actually, if the initial offsets are set to $\mu_i = \langle x_i \rangle_d$ and $\lambda_j = 0.5$ the initialization suggested by Montavon and Müller (2012) is equal to the initialization to the MLEs as follows from Equation (17).

Note that this initialization is not restricted to RBMs or the sigmoid activation function. Independently of the initial weight matrix we can always set the bias in ANNs to the inverse activation function of the corresponding mean value.

5. Methods

As shown in Section 3 the algorithms described by Cho et al. (2011), Tang and Sutskever (2011) and Montavon and Müller (2012) can all be viewed as different ways of applying

the centering trick. They differ in the choice of the offset parameters and in the way of approximating them, either based on the samples gained from the model in the previous learning step or from the current one, using an exponentially moving average or not. The question arises, how RBMs should be centered to achieve the best performance in terms of the LL. In Section 5 we therefore empirically analyze the different ways of centering and try to achieve a deeper understanding of why centering is beneficial.

For simplicity we introduce the following shorthand notation. The letter d denotes the data mean $\langle \cdot \rangle_d$, m denotes the model mean $\langle \cdot \rangle_m$, a denotes the average of the means $\frac{1}{2}\langle \cdot \rangle_d + \frac{1}{2}\langle \cdot \rangle_m$, and 0 is used if the offsets are set to zero. We indicate the choice of $\boldsymbol{\mu}$ in the first and the choice of $\boldsymbol{\lambda}$ in the second place, for example dm translates to $\boldsymbol{\mu} = \langle \mathbf{x} \rangle_d$ and $\boldsymbol{\lambda} = \langle \mathbf{h} \rangle_m$. We add a superscribed b (before) or l (later/after) to denote whether the reparameterization is performed before or after the gradient update. If the sliding factor in Algorithm 1 or 2 is set to a value smaller than one and thus an exponentially moving average is used, a subscript s (sliding) is added. Thus, we represent the variant of Cho

Abbr.	μ	λ	Description
00	$\mathbf{0}$	$\mathbf{0}$	Normal binary RBM (Smolensky, 1986)
$d0$	$\langle \mathbf{x} \rangle_d$	$\mathbf{0}$	Data Normalization RBM (Tang and Sutskever, 2011)
dd_s^l	$\langle \mathbf{x} \rangle_d$	$\langle \mathbf{h} \rangle_d$	Original Centered RBM (Montavon and Müller, 2012) reparam. after gradient update, use of an exp. moving average
aa^b	$0.5\,(\langle \mathbf{x} \rangle_d + \langle \mathbf{x} \rangle_m)$	$0.5\,(\langle \mathbf{h} \rangle_d + \langle \mathbf{h} \rangle_m)$	Enhanced gradient RBM (Cho et al., 2011) reparam. before gradient update, no use of an exp. moving average
dd_s^b	$\langle \mathbf{x} \rangle_d$	$\langle \mathbf{h} \rangle_d$	Centering using the data mean, reparam. before gradient update, use of an exp. moving average
mm_s^b	$\langle \mathbf{x} \rangle_m$	$\langle \mathbf{h} \rangle_m$	Centering using the model mean, reparam. before gradient update, use of an exp. moving average
dm_s^b	$\langle \mathbf{x} \rangle_d$	$\langle \mathbf{h} \rangle_m$	Centering using the data mean for the visible and the model mean for hidden units, reparam. before gradient update, use of an exp. moving average

Table 1: Look-up table: Abbreviations for the most frequently used algorithms.

et al. (2011) by aa^b, the one of Montavon and Müller (2012) by dd^l_s, the data normalization of Tang and Sutskever (2011) by *d0*, and the normal binary RBM simply by *00*. Table 1 summarizes the abbreviations most frequently used in this paper.

We begin our analysis with experiments on RBMs, where one layer is small enough to guarantee that the exact LL is still tractable. In a first set of experiments we analyze the four algorithms described above in terms of the evolution of the LL during training. In a second set of experiments we analyze the effect of the initializations described in Section 4.2. We proceed with a comparison of the effects of estimating offset values and reparameterizing the parameters before or after the gradient update. Afterwards we analyze the effects of using an exponentially moving average to approximate the offset values in the different algorithms and of choosing other offset values. We then compare the normal and the centered gradient with the natural gradient. Finally, to verify whether the results scale to more realistic problem sizes we compare RBMs, DBMs and AE on ten large data sets.

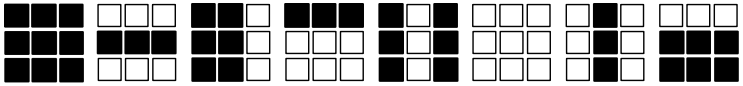
5.1 Benchmark Problems

We consider twelve different benchmark problems in our detailed analysis, see also Figure 2. The ***Bars & Stripes*** (MacKay, 2003) data set consists of patterns of size $D \times D$ that can be generated as follows. First, for each row of a pattern all corresponding pixels are either set to zero or to one with equal probability. Second, with a probability of 0.5 the pattern is rotated by 90 degrees. This leads to $N = 2^{D+1}$ patterns where the completely uniform patterns occur twice as often as the others. The data set is symmetric in terms of the amount of zeros and ones and thus the flipped and unflipped problems are equivalent. An upper bound of the LL is given by $(N-4)\ln\left(\frac{1}{N}\right) + 4\ln\left(\frac{2}{N}\right)$. For our experiments we used $D = 3$ or $D = 2$ (only in Section 6.9) leading to an upper bound of -41.59 and -13.86, respectively.

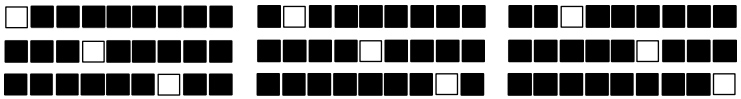
The ***Shifting Bar*** data set is an artificial benchmark problem we have designed to be asymmetric in terms of the amount of zeros and ones in the data. The data set consists of vectors of size N where a set of B successive pixels with cyclic boundary conditions are set to one, the 'bar', and the others are set to zero. More formally the data set can be generated as follows, beginning with a vector where all pixels are set to zero, an index $0 \leq i < N$ is chosen uniformly at random. The pixel with index i and the following $B-1$ pixels, which underly cyclic boundary conditions are set to one (that is the pixels with indices $\{i,\ (i+1) \mod N, \ldots, (i+B-1) \mod N\}$ are set to one). This leads to N different patterns with equal probability, and an upper bound of the LL of $N\ln\left(\frac{1}{N}\right)$, the percentage of ones in the data set is $\frac{B}{N}$. For our experiments we used $N = 9$, $B = 1$ and its flipped version ***Flipped Shifting Bar***, which we get for $N = 9$, $B = 8$, both having an upper LL bound of -19.78.

The ***MNIST*** (LeCun et al., 1998) data set of handwritten digits has become a standard benchmark problem for RBMs. It consists of $60,000$ training and $10,000$ testing examples of gray value handwritten digits of size 28×28. Usually, in a first preprocessing step the values are normalized to lie in $[0, 1]$. Across different studies the normalized values are then either used directly as input, or the data set is binarized using a threshold of 0.5 or by sampling according to the normalized values that are treated as probabilities.[4] In this study

4. In Appendix D we give a an comparison of normal and centered RBMs on the different *MNIST* versions.



(a) 8 out of 16 patterns from the *Bars & Stripes* data set.



(b) All patterns of the *Shifting Bar* data set with $N = 9$ and $B = 1$.

(c) Example patterns from the *MNIST* data set after binarization.

(d) Example patterns from the *Caltech 101 Silhouette* data set.

Figure 2: Some patterns from the different benchmark problems.

we binarized *MNIST* with a threshold of 0.5. The data set contains 13.3% ones, similar to the *Shifting Bar* problem, which for our choice of N and B contains 11.1% ones. We refer to the data set where each bit of *MNIST* is flipped (that is each one is replaced by a zero and *vice versa*) as ***1-MNIST***.

The ***CalTech 101 Silhouettes*** (Marlin et al., 2010) data set consists of 4100 training, 2307 validation, and 2264 testing examples of binary object silhouettes of size 28×28. The data set contains 55.1% ones, and thus (like in the *Bars & Stripes problem*) the amount of zeros and ones is almost the same. The background pixels take the value one, which is in contrast to *MNIST* where the background pixels are set to zero.

In some experiments we also considered the eight ***UCI binary*** (Larochelle et al., 2010; Larochelle and Murray, 2011) data sets from different domains comprising biological, image, text and game-related data. The data sets differ in dimensionality (112 to 500) and size (a few hundred to several thousand examples) and have been separated into training, validation, and test sets. All *UCI binary* data sets contain less ones than zeros, where the percentage of ones lies between 3.9% and 36.8%.

6. Results

For all models in this work the weight matrices were initialized with random values sampled from a Gaussian with zero mean and a standard deviation of 0.01. If not stated otherwise the visible biases, hidden biases, and offsets were initialized as described in Section 4.2.

We began our analysis with experiments on small RBMs where the LL can be calculated exactly, where we used 4 hidden units when modeling *Bars & Stripes* and *Shifting Bar* and 16 hidden units when modeling *MNIST*. For training we used CD-1, PCD-1 and PT_c (with $c = 10$ or $c = 20$) where the c temperatures were distributed uniformly from 0 to 1. For *Bars & Stripes* and *Shifting Bar* full-batch training was performed for 50,000 gradient updates, where the LL was evaluated every 50th gradient update. For modeling *MNIST* mini-batch training with a batch size of 100 was performed for 100 epochs, each consisting of 600 gradient updates and the exact LL was evaluated after each epoch. Note that in order to get an unbiased comparison of the different models, we did not use any additional modifications of the update rule like a momentum term, weight decay or an annealing learning rate.

The tables in this work show the maximum average LL and the corresponding standard deviation reached during training averaged over 25 trials. In addition the final average LL reached at the end of training is given in parenthesis to indicate a potential divergence of the LL. For some computational expensive experiments we used only 10 trials, which will be mentioned explicitly. For reasons of readability, the LL values for the big data sets were normalized to the number of training samples. In order to check if the result of the best method within one row differs significantly from the others we performed pairwise signed Wilcoxon rank-sum tests (with $p = 0.05$). The best results are highlighted in bold. This can be more than one value if the significance test between these values was negative.

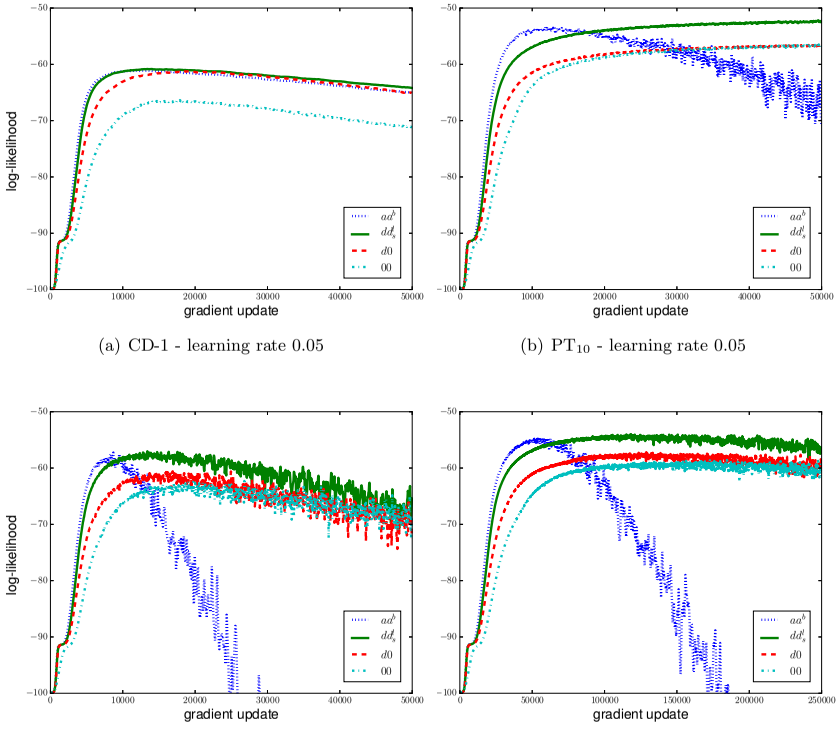
6.1 Comparison of the Standard Methods

The comparison of the learning performance of the previously described algorithms dd_s^l, aa^b, *d0*, and *00* (using their originally proposed initializations) shows that training a centered RBM leads to significantly higher LL values than training a normal binary RBM (see Table 2 for the results on *Bars & Stripes* and *MNIST* and Table 3 for the results on *Shifting Bar* and *Flipped Shifting Bar*).

Figure 3 illustrates on the *Bars & Stripes* data set that centering (aa^b, dd_s^l, and *d0*) leads to faster learning and higher LL values than normal RBMs (*00*). This differs from the observations made for DBMs by Montavon and Müller (2012), who have found a better generative performance of centering only in the case of locally connected DBMs. Furthermore, Figure 3 shows that centering both the visible and the hidden variables (dd_s^l and aa^b) compared to centering only the visible variables (*d0*) accelerates learning and leads to a higher LL. This is different from the observations made for RBMs by Tang and Sutskever (2011), who have stated that centering only the visible variables leads to a performance similar to that of the enhanced gradient. Thus centered RBMs where visible and hidden variables are centered can form more accurate models of the data distribution than normal RBMs and centered RBMs where only the visible variables are centered.

It can also be seen from Figure 3 that all methods show divergence in combination with CD and PCD (as described before by Fischer and Igel, 2010, for normal RBMs), which

is prevented for dd_s^l, *d0*, and *00* when using PT as shown in Figure 3(b). This can be explained by the fact that PT leads to faster mixing Markov chains and thus less biased gradient approximations. The *aa* algorithm however suffers from severe divergence of the LL when PCD or PT is used, which is even worse than with CD. This divergence problem does occur independently of the choice of the learning rate as indicated by the LL values reached at the end of training (given in parentheses) in Table 2 and Table 3, and which can



(a) CD-1 - learning rate 0.05

(b) PT_{10} - learning rate 0.05

(c) PCD-1 - learning rate 0.05

(d) PCD-1 - learning rate 0.01

Figure 3: Evolution of the average LL on the training data for models with 4 hidden units on the *Bars & Stripes* data set for the standard centering methods. (a) CD-1 with a learning rate of $\eta = 0.05$, (b) PT_{10} with a learning rate of $\eta = 0.05$, (c) PCD-1 with a learning rate of $\eta = 0.05$, and (d) PCD-1 with a learning rate of $\eta = 0.01$.

also be seen by comparing Figure 3(c) and Figure 3(d). The divergence occurs earlier and is more severe for bigger learning rates, while for the other algorithms we never observed divergence in combination with PT even for very big learning rates and long training time. The reasons for this divergence are discussed in detail in Section 6.4.

The results in Table 3 also demonstrate the flip invariance of the centered RBMs on the *Shifting Bar* data set empirically. Whereas *00* fails to model the flipped version of the data set correctly, dd_s^l, aa^b, and *d0* have approximately the same performance on the flipped and unflipped data set.

6.2 Initialization

The experiments in this section were done to analyze the effects of different initializations of the parameters as discussed in Section 4.2. First, we trained normal binary RBMs (that is *00*) where the visible bias was initialized to zero or to the inverse sigmoid of the data mean. In both cases the hidden bias was initialized to zero. Table 4 shows the results for normal binary RBMs trained on the *Flipped Shifting Bar* data set, where RBMs with zero initialization failed to learn the distribution accurately. The RBMs using the inverse sigmoid initialization achieved better performance and therefore seem to be less sensitive

Table 5: Maximum average LL on the training data for centered RBMs (dd_s^l) with 4 hidden units on the *Flipped Shifting Bar* data set, where the visible bias is initialized to zero or to the inverse sigmoid of the data mean.

to the 'difficulty' of the data representation. However, the results are not as good as the results of the centered RBMs shown in Table 3. The same observations can be made when training RBMs on the *MNIST* data set (see Table 4 bottom). The RBMs with inverse sigmoid initialization achieved significantly better results than RBMs initialized to zero in the case of PCD and PT, but still worse compared to the centered RBMs. Furthermore, using the inverse sigmoid initialization allows us to achieve similar performance on *MNIST* and *1-MNIST*, while the RBM with zero initialization failed to learn the distribution for *1-MNIST* at all (results not shown). A visual comparison of the filters of normal RBMs trained on *MNIST* and *1-MNIST* has already been given by Cho et al. (2011) and Tang and Sutskever (2011).

We then trained models using the centering versions *dd*, *aa*, and *d0* comparing the initialization suggested in Section 4.2 against the initialization to zero. In most cases the results showed no significant difference in terms of the maximum LL reached in trials with different initializations, or slightly better results were found when using the inverse sigmoid in combination with a small learning rate. This can be explained by the better starting point yielded by this initialization. See Table 5 for the results for dd_s^l on the *Flipped Shifting Bar* data set as an example. We therefore used the inverse sigmoid initialization in the following experiments since it was beneficial for normal RBMs.

6.3 Reparameterization

To investigate the effects of performing the reparameterization before or after the gradient update during training of centered RBMs , we analyzed the learning behavior of dd_s^b (the algorithm suggested here) and dd_s^l (the algorithm suggested by Montavon and Müller, 2012) on all data sets. The results for RBMs trained on the *Bars & Stripes* data set and the *MNIST* data set are given in Table 6 (top). No significant difference between the two versions can be observed and the same result (not shown) was obtained for the *Shifting Bar*

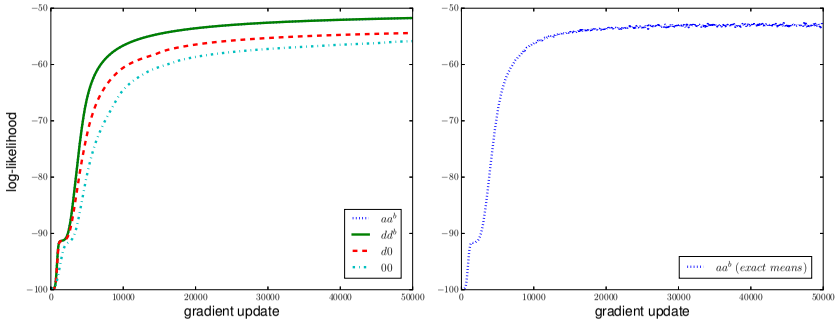
Table 6: Maximum average LL on the training data for RBMs (top) with 4 hidden units on the *Bars & Stripes* data set and (bottom) with 16 hidden units on the *MNIST* data set, using the reparameterization before (dd_s^b) and after (dd_s^l) the gradient update.

and the *Flipped Shifting Bar* data set. We therefore reparameterize the RBMs before the gradient update in the remainder of this work. This is also motivated by the fact that the enhanced gradient is only equivalent to centering using the average of model and data mean for visible and hidden offsets if the model is reparameterized before it is updated (that is, the enhanced gradient is equivalent to aa^b but not to aa^l).

6.4 Analyzing the Model-Mean-Related Divergence Effect

The severe divergence problem observed when using the enhanced gradient in combination with PCD or PT raises the question whether the problem is induced by setting the offsets to $0.5(\langle \mathbf{x} \rangle_d + \langle \mathbf{x} \rangle_m)$ and $0.5(\langle \mathbf{h} \rangle_d + \langle \mathbf{h} \rangle_m)$ or by bad sampling based estimates of gradient and offsets. We therefore trained centered RBMs with 9 visible and 4 hidden units on the *Bars & Stripes* data set using either the exact gradient where only $\langle \mathbf{x} \rangle_m$ and $\langle \mathbf{h} \rangle_m$ were approximated by samples or using PT_{10} estimates of the gradient while $\langle \mathbf{x} \rangle_m$ and $\langle \mathbf{h} \rangle_m$ were calculated exactly. Figure 4(a) shows that if the exact gradient is used but the offsets are estimated, no divergence for aa in combination with PT is observed and the performance of aa and dd become almost equivalent. Interestingly, the divergence is also prevented if the gradient is estimated using PT but the offsets are calculated exactly as shown in Figure 4(b).



(a) Exact gradient with approximated offsets (b) PT_{10} with exact means

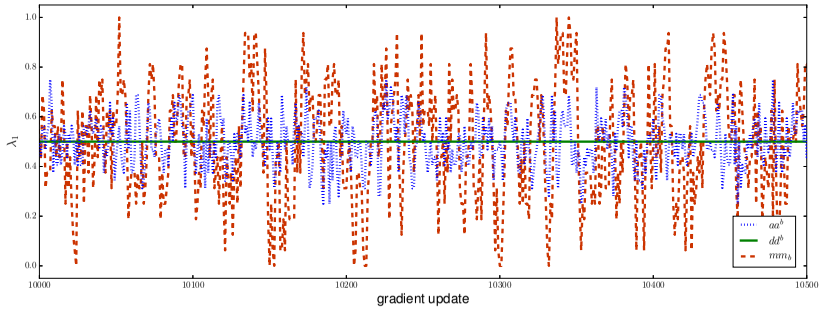
Figure 4: Evolution of the average LL on the training data for RBMs with 4 hidden units on the *Bars & Stripes* data set for the standard centering methods. (a) When the exact gradient is used but the offsets are estimated using PT_{10} and (b) when PT_{10} is used for estimating the gradient but the offsets are calculated exactly. In both cases the learning rate was $\eta = 0.05$.

Thus, the divergence behavior must be induced by approximating both, gradient and offsets. The fact that the mean under the data distribution can always be calculated exactly might explain why we do not observe divergence for dd in combination with PT.

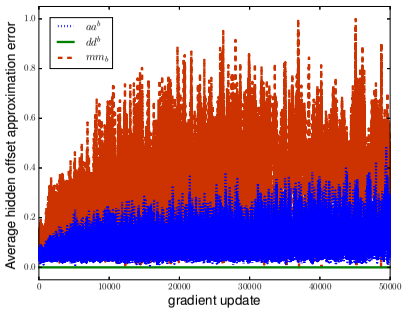
To further deepen the understanding of the divergence effect we investigated the parameter evolution during training of RBMs with different offsets. We observed that the change of the offset values between two gradient updates gets extremely large during training when using the model mean. Figure 5(a) shows in an exemplary manner the evolution of the first hidden offset λ_1 for a single trial, where the approximated offset for dd^b is almost constant while it is rather large for aa^b and even bigger for mm^b (the centering variant that uses the mean of hidden and visible variables under the model distribution as offsets). In each iteration we calculated the exact offsets to estimate the approximation error shown in Figure 5(b). Obviously, there is no approximation error for dd while the error for aa quickly gets large and the error for mm gets even twice as big. In combination with the gradient approximation error this causes the weight matrices for aa and mm to grow extremely big as shown in Figure 5(c). Consistent with the even larger approximation error for the offset estimate of mm, the divergence for mm becomes even worse than that for aa, as shown in Figure 6.

To further confirm that the divergence is not just caused by the additional sampling noise introduced by approximating the offsets, we trained a centered RBM using PT for the gradient approximation while we set the offsets to uniform random values between zero and one in each iteration. The results are shown in Figure 6(a) and demonstrate that even random offset values do not lead to the divergence problems. Thus, the divergence cannot

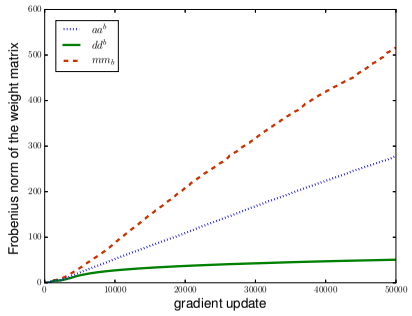
be caused by additional sampling noise but rather by the correlated errors of gradient and offset approximations. To test this hypothesis we investigated mm^b where the samples for offset and gradient approximations were taken from different PT sampling processes. The results are shown in Figure 6(b) where no divergence can be observed anymore. While creating two sets of samples for gradient and offset approximations prevents the LL from diverging it almost doubles the computational cost and can therefore not be considered as a reasonable solution in practice. Moreover, using the model mean as offset still leads to



(a) Close up of the offset evolution for λ_1

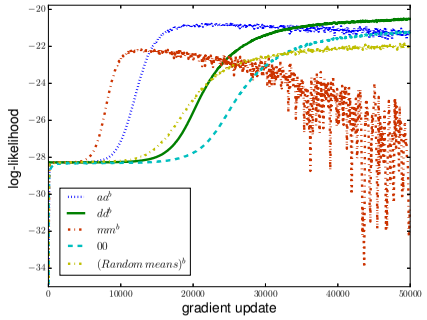


(b) Evolution of the offset approximation error

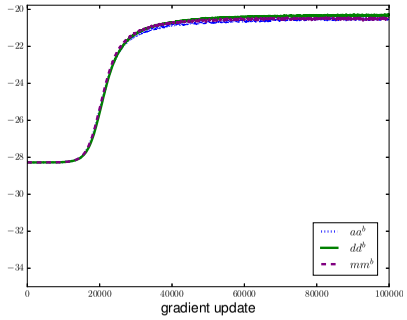


(c) Evolution of the weight norm

Figure 5: Evolution of the offsets and weights of different centered variants for RBMs with 4 hidden units during training on *Bars & Stripes* using PT_{10}. For clearness a single trial is shown, but the experiments were repeated 25 times and all trials showed qualitatively the same results. (a) Close up of the evolution of offset λ_1 over 500 gradient updates. (b) The evolution of the absolute difference between exact and approximated hidden offset averaged over all hidden units. (c) The evolution of the Frobenius norm of the weight matrices.



(a) Random offsets



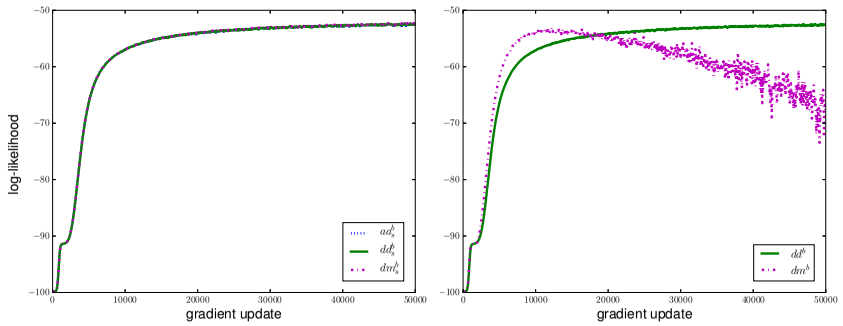
(b) Independent approximations

Figure 6: Evolution of the average LL on the training data for RBMs with 4 hidden units on the *Shifting Bars* data set using PT_{10} with a learning rate of $\eta = 0.1$. (a) Normal RBMs, centered RBMs, and centered RBMs with random offset values (denoted by *Random means*^{b}). (b) Centered RBMs when the samples for the offset approximations come from a different Markov chain than the samples used for the gradient approximation.

slightly worse final LL values than using the mean under the data distribution. This might be explained by the fact that the additional approximation of the model mean introduces noise while the data mean can be estimated exactly. Note, that the divergence also occurs if either only visible or hidden offsets are set to the PT-approximated model mean, which can be seen for example for dm in Figure 7(b).

Interestingly, the observed initially faster learning speed of mm and aa, which can be seen in Figure 6(a), does not occur anymore when offset and gradient approximation are based on different sample sets. This observation can also be made when the exact gradient is used (see Figure 4a). Thus, the initially faster learning speed seems also be caused by the correlated approximations of gradient and offsets and could be explained by the rapidly growing norm of the weight matrix shown in Figure 5(c), which effectively leads to a bigger step size in the parameter updates.

Note, that divergence can either be caused by using the expectation under the model distribution for the offset approximations as described in this section or by the bias of the gradient approximation introduced by using only a few steps of Gibbs sampling (Fischer and Igel, 2010; Schulz et al., 2010; Fischer and Igel, 2011). The latter can occur for all methods when CD or PCD is used for training. Furthermore, the LL can also decrease on the test data due to overfitting to the training data, which is not divergence in the proper sense.



(a) With exponentially moving average (b) Without exponentially moving average

Figure 7: Evolution of the average LL on the training data for RBMs with 4 hidden units on *Bars & Stripes* with different centering variants, using PT_{10} and a learning rate of $\eta = 0.05$. (a) Using an exponentially moving average with a sliding factor of 0.01 (the curves are almost equivalent) and (b) without exponentially moving average (see also Figure 3b for aa^b)

6.5 Usage of an Exponentially Moving Average

The approximation of the mean values of the variables using just a few samples might be too inaccurate or biased by the samples in the current batch. This is in particular the case when the model mean is used as shown in Section 6.4, but also when the data mean is used with a small batch size. Therefore, an exponentially moving average can be used to smooth the approximation of the offsets between parameter updates, which stabilizes the approximations when small batch sizes are used as well as when the model mean is used for the offsets.

We analyzed the impact of using an exponentially moving average with a sliding factor of 0.01 for the estimation of the offset parameters. Figure 7(a) illustrates on the *Bars& Stripes* data set that the learning curves of the different models become almost equivalent and that the divergence problem when using the model mean does not occur anymore when an exponentially moving average is used. However, the maximum LL values reached are the same whether an exponentially moving average is used or not. This can be seen by comparing Figure 7(a) and Figure 7(b) and also by comparing the results in Table 2 and Table 3 with those in Table 7. As discussed in Section 6.4, this problem is caused by the correlation between the approximation error of gradient and offsets. When using an exponential moving average the current offsets contain only a small fraction of the current mean such that the correlation is highly reduced.

In our experiments, *dd* does not suffer from the divergence problem when PT is used for sampling, even without exponentially moving average as can be seen in Figure 7(b) for

example or in the case of mini-batch learning (results not shown). Thus, *dd* seems to be generally more stable than the other centering variants, which is also true for big models as will be shown at the end of Section 6.7.

In the previous experiments an exponentially moving average was used for the approximation of visible and hidden offsets as originally suggested by Montavon and Müller (2012). Note however, that in batch learning when $\langle \mathbf{x} \rangle_d$ is used for the visible offsets, these values stay constant such that an exponentially moving average has no effect. More generally

Table 7: Maximum average LL on the training data for RBMs with 4 hidden units on (top) *Bars & Stripes*, and (middle) *Flipped Shifting Bar*, and (bottom) RBMs with 16 hidden units on *MNIST* when using an exponentially moving average with a sliding factor of 0.01.

if the training data and thus $\langle \mathbf{x} \rangle_d$ is known in advance the visible offsets should be fixed to this value independent of whether batch or mini-batch learning is used. However, the use of an exponentially moving average for approximating $\langle \mathbf{x} \rangle_d$ is reasonable if the training data is not known in advance, as well as for the approximation of the mean of the hidden representation $\langle \mathbf{h} \rangle_d$. We therefore used an exponentially moving average for the following experiments on the big data sets.

6.6 Control Experiments: Other Choices for the Offsets

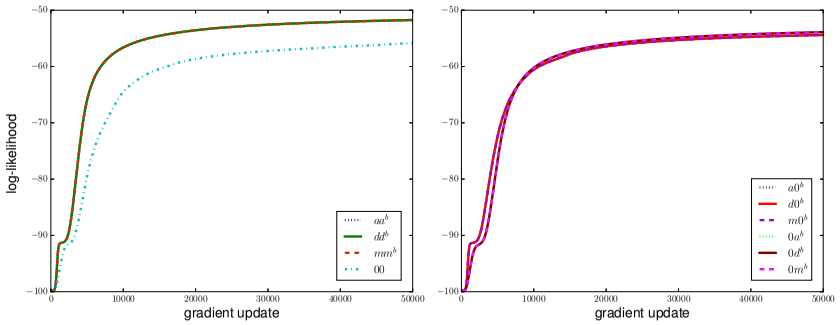
As discussed in Section 3, any offset value between 0 and 1 guarantees the flip invariance property as long as it is flipped simultaneously with the data. An intuitive and constant choice is to set the offsets to 0.5, which has also been proposed by Ollivier et al. (2011) and results in a symmetric variant of the energy of RBMs. This leads to comparable LL values on flipped and unflipped data sets. However, if the data set is unbalanced in the amount of zeros and ones like *MNIST*, we found that the performance is always worse compared to that of a normal RBM on the version of the data set that has fewer ones than zeros. Therefore, fixing the offset values to 0.5 cannot be considered as an alternative for centering using expectation values over the data or model distribution.

In Section 3.1, we mentioned that using either $\boldsymbol{\mu} = \langle \mathbf{x} \rangle_d$ and $\boldsymbol{\lambda} = \langle \mathbf{h} \rangle_m$ or $\boldsymbol{\mu} = \langle \mathbf{x} \rangle_m$ and $\boldsymbol{\lambda} = \langle \mathbf{h} \rangle_d$ as offsets both lead to the same updates for the weights as the enhanced gradient. Using $\boldsymbol{\mu} = \langle \mathbf{x} \rangle_d$ and $\boldsymbol{\lambda} = \langle \mathbf{h} \rangle_m$ seems reasonable since the data mean is usually known in advance. As mentioned above we refer to centering with this choice of offsets as *dm*. We trained RBMs with dm_s^b using a sliding factor of 0.01. The results are shown in Table 7 and suggest that there is no significant difference between dm_s^b, aa_s^b, and dd_s^b. However, without an exponentially moving average dm^b has the same divergence problems as aa^b when PT_c is used for sampling, as shown in Figure 7(b).

We further tried variants like *mm*, *m*0, 0*d*, *m*0, etc., but did not find better performance than that of *dd*. The variants that subtract an offset from both, visible and hidden variables outperformed or achieved the same performance as the variants that only subtract an offset from either visible or hidden variables. When the model expectation was used without an exponentially moving average either for $\boldsymbol{\mu}$ or $\boldsymbol{\lambda}$, or for both offsets we always observed the divergence when PT_c was used for sampling (results not shown).

Interestingly, if the exact gradient and offsets are used for training, no significant difference can be observed in terms of the LL evolution whether data mean, model mean or the average of both is used for the offsets, as shown in Figure 8. But centering both visible and hidden units still leads to better results than centering only one. Furthermore, the results illustrate that centered RBMs outperform normal binary RBMs also if the exact gradient is used for training both models. This further emphasizes that the worse performance of normal binary RBMs is caused by the properties of the gradient rather than by the gradient approximation.

The control experiments confirm our findings that centering both visible and hidden units is important and that the performance of *dd*, *aa*, and *mm* become similar when an exponentially moving average is used.



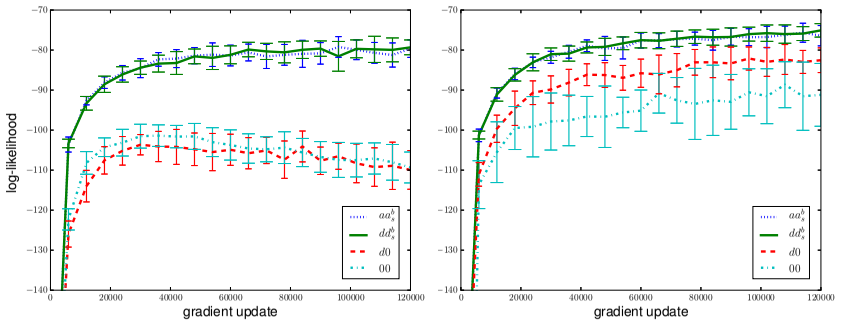
(a) Visible and hidden units centered (b) Visible or hidden units centered

Figure 8: Evolution of the average LL on the training data for RBMs with 4 hidden units on the *Bars & Stripes* data set for the various centering methods when the exact gradient is used with the exact offsets and a learning rate of $\eta = 0.05$. The plots for aa^b, dd^b and mm^b overlay each other and so do $a0^b$, $d0^b$, $m0^b$, and also $0a^b$, $0d^b$ and $0m^b$. In (b) the plots for $a0^b$, $d0^b$, $m0^b$ can be distinguished from the plots for $a0^b$, $d0^b$, $m0^b$ in that they are initially slower and later lower.

6.7 Experiments with Big RBMs

For the experiments in Section 6.1-6.6 we trained small models in order to be able to run many experiments and to evaluate the LL exactly. In this section we want to show that the results we observed on the toy problems and *MNIST* with RBMs having 16 hidden units carry over to more realistic settings. Furthermore, we want to investigate the generalization performance of the different models. In a first set of experiments we therefore trained the models *00*, *d0*, dd_s^b, and aa_s^b with 500 hidden units on *MNIST* and *Caltech*. The weight matrices were initialized with random values sampled from a Gaussian with zero mean and a standard deviation of 0.01, and visible and hidden biases and offsets were initialized as described in Section 4.2. The LL was estimated using Annealed Importance Sampling (AIS), where we used the same setup as described in the analysis of Salakhutdinov and Murray (2008).

Figure 9 shows the evolution of the average LL on the test data of *MNIST* over 25 trials for PCD-1 and PT_{20} for different centering versions. The models were trained for 200 epochs, each consisting of 600 gradient updates with a batch size of 100 and the LL was estimated every 10th epoch using AIS. Both variants dd_s^b and aa_s^b reach significantly higher LL values than *00* and *d0*. Also the standard deviation over the 25 trials indicated by the error bars is smaller for dd_s^b and aa_s^b than for *00* and *d0*, especially when PT_{20} is used for sampling. Furthermore, *00* and *d0* show divergence already after 30000 gradient updates when PCD-1 is used, while no divergence can be observed for dd_s^b and aa_s^b up to 120000



(a) PCD-1 (b) PT_{20}

Figure 9: Evolution of the average LL on the test data of *MNIST* during training of different centering variants with 500 hidden units, using a learning rate of $\eta = 0.01$, and a sliding factor of 0.01. (a) When using PCD-1 and (b) when using PT_{20} for training. The error bars indicate the standard deviation of the LL over the 25 trials.

gradient updates. The evolution of the LL on the training data is not shown, since it is almost equivalent to the evolution on the test data. The superiority of centering over normal RBMs can also be observed for the other variants of *MNIST* as shown in Appendix D.

Figure 10 shows the evolution of the average LL on training and test data of the *Caltech* data set over 25 trials for different centering versions using PCD-1 with a batch size of 100 and either a learning rate of 0.001 or 0.01. The LL was estimated every 5000th gradient update using AIS. The results show that dd_s^b, aa_s^b and *d0* reach higher LL values than *00* for both learning rates and on training and test data. While dd_s^b and aa_s^b perform only slightly better than *d0* when a small learning rate is used, the difference becomes more prominent for a big learning rate. Figure 10(c) and (d) show that all models overfit to the training data. Nevertheless, dd_s^b and aa_s^b reach higher LL values on the test data and thus lead to a better generalization. The final average LL on the test data for dd_s^b and aa_s^b shown in Figure 10(b) is around -118. This is consistent with the reported performance of -120.0 for a normal RBM with 500 hidden units trained with PCD-1 (Marlin et al., 2010) and -114.75 when PT sampling is used in combination with the enhanced gradient (Cho et al., 2013b).

In a second set of experiments we extended our analysis to the eight *UCI binary* data sets used by Larochelle et al. (2010). The four different models *00*, *d0*, dd_s^b, and aa_s^b were trained with the same setup as before using PCD-1, a learning rate of 0.01, a batch size of 100 and a total number of 5000 epochs. All experiments were repeated 25 times and we trained either RBMs with 16 hidden units and calculated the LL exactly or RBMs with 200 hidden units using AIS for estimating the LL. Additionally we trained RBMs with 200 hidden variables with a smaller learning rate of 0.001 for 30000 epochs. Due to the long

training time these experiments were repeated only 10 times. The maximum average LL for the test data is shown in Table 8. On seven out of eight data sets dd_s^b or aa_s^b reached the best result independent of whether 16 or 200 hidden units, or a learning rate of 0.01 or 0.001 were used. Whenever aa_s^b reached the highest value it was not significantly different from that of dd_s^b. Note that when training RBMs with 16 hidden units *d0* reached comparable results to

(c) Training data - learning rate 0.01 (d) Test data - learning rate 0.01

Figure 10: Evolution of the average LL on *Caltech* data set with different centering variants with 500 hidden units. The results on training and test data for a learning rate of $\eta = 0.001$ are shown in sub-figures (a) and (b), respectively, and for a learning rate of $\eta = 0.01$ in sub-figures (c) and (d), respectively. In both cases a sliding factor of 0.01 and PCD-1 was used. The error bars indicate the standard deviation of the LL over the 25 trials.

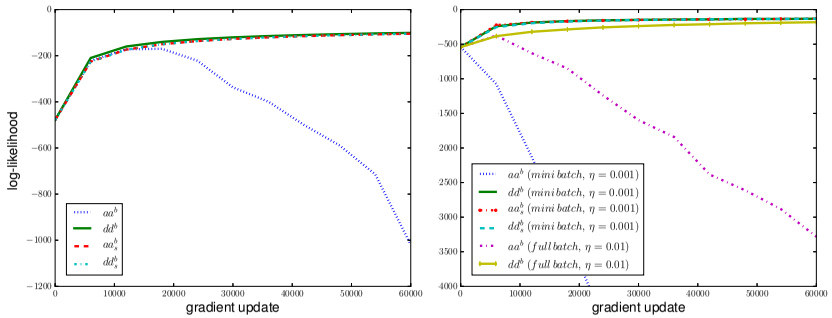
.



(a) MNIST LL on test data

(b) Caltech LL on test data

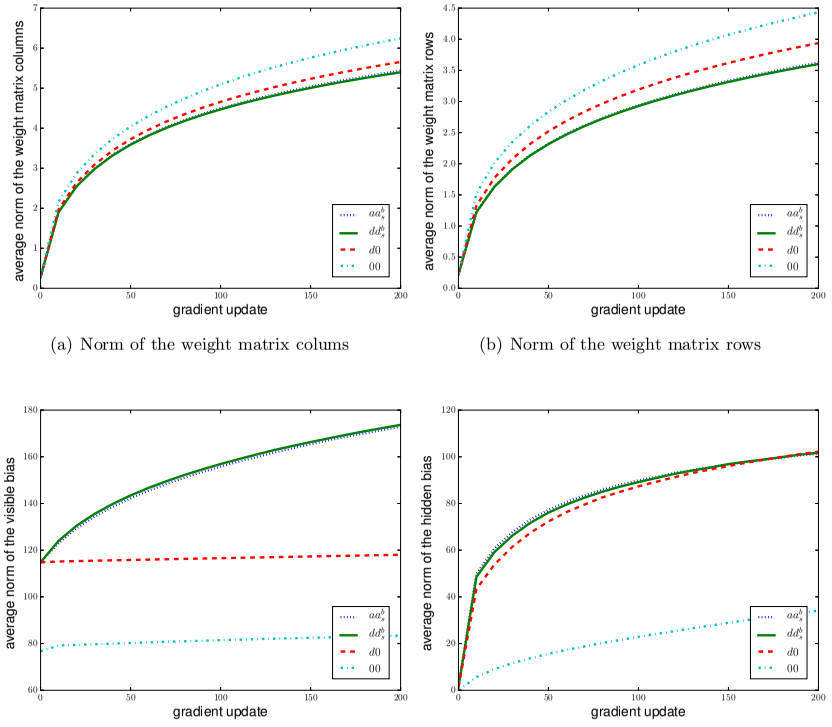
Figure 11: Evolution of the LL of exemplary trials for the different centering variants aa^b, dd^b, aa^b_s and dd^b_s on (a) *MNIST* and (b) *Caltech* during training using PT_{20} with a batch size of 100, 500 hidden units and a learning rate of 0.001. For *Caltech* aa^b and dd^b were also trained in full batch mode with PT_{20} and a learning rate of 0.01.

dd^b_s on some data sets. Only on the *RCV1* data set, 00 lead to better LL values than the centered RBMs for both 16 and 200 hidden units. It seems that the convergence rate on the *RCV1*, *OCR* and *WEB* data set is rather low for all models since the difference between the highest and the final LL values is rather small, indicating that no divergence or overfitting has happened so far. This can also be observed on the training data shown in Table 9. The *DNA* data set and the *NIPS* data set overfitted to the training data as indicated by the fact that the LL only decreased for the test data. In contrast, on the remaining three data sets *ADULT*, *CONNECT-4* and *MUSHROOM* the divergence can be observed on training and test data. Finally note that all eight data sets contain more zeros than ones in the current representation as mentioned in Section 5.1. Thus, the performance of the normal RBM would be even worse on the flipped data sets while for the centering variants it would stay the same (results not shown). Consistent with the experiments on small models, the results from nine of the ten real world data sets clearly support the superiority of centered over normal RBMs, show that centering visible and hidden units in RBMs is important for yielding good models and that averaged over all data sets dd^b_s performs better than aa^b_s.

To emphasize that the divergence problems induced by using the model means as offsets also occurs for big models when no moving average is used, we trained RBMs with 500 hidden units on *MNIST* and *Caltech* using PT_{20} with a learning rate of 0.001 and a batch size of 100. In addition, we trained aa^b and dd^b on *Caltech* using full batch learning and a learning rate of 0.01. Figure 11 shows that aa^b diverges while dd^b and the corresponding centering versions using a moving average, aa^b_s and dd^b_s, show no divergence. The divergence for aa^b even occurs in full batch training as shown in Figure 11(b).

6.8 Investigating the Effect of Centering on the Model Parameters

One explanation why centering works has already been given by Montavon and Müller (2012), who found that centering leads to a better conditioned optimization problem. Furthermore, Cho et al. (2011) have shown that when the enhanced gradient is used for training the update directions for the weights are less correlated than when the standard gradient is used, which allows to learn more meaningful features. From our analysis in Section 3 we know that centered RBMs and normal RBMs belong to the same model class and therefore the reason why centered RBMs outperform normal RBMs can indeed only be due to the optimization procedure. Furthermore, one has to keep in mind that in centered RBMs



(a) Norm of the weight matrix colums

(b) Norm of the weight matrix rows

(c) Norm of the visible bias vector

(d) Norm of the hidden bias vector

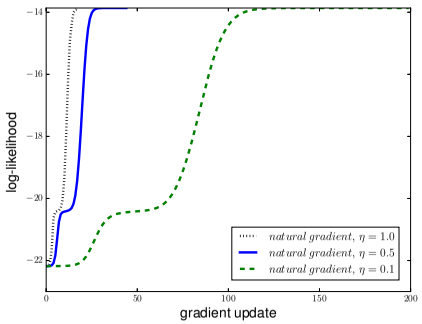
Figure 12: Evolution of the average Euclidean norm of the parameters of the RBMs with 500 hidden units trained on *MNIST*.

the variables mean values are explicitly stored in the corresponding offset parameters, or if the centered gradient is used for training normal RBMs the mean values are transferred to the corresponding bias parameters. This allows the weights to model second and higher order statistics right from the start, which is in contrast to normal binary RBMs where weights usually capture parts of the mean values. To support this statement empirically, we calculated the average weight and bias norms during training of the RBMs with 500 hidden units on *MNIST* using the standard and the centered gradient. The results are shown in Figure 12, where it can be seen that the row and column norms (see Figure 12a and 12b) of the weight matrix for dd_s^b, aa_s^b, and *d0* are consistently smaller than for *00*. At the same time the bias values (see Figure 12c and 12d) for dd_s^b, aa_s^b, and *d0* are much bigger than for *00*, indicating that the weight vectors of *00* model information that could potentially be modeled by the bias values. Interestingly, the curves for all parameters of dd_s^b and aa_s^b show the same logarithmic shape, while for *d0* and *00* the visible bias norm does not change significantly. It seems that the bias values did not adapt properly during training. Comparing, *d0* with dd_s^b and aa_s^b, the weight norms are slightly bigger and the visible bias is much smaller for *d0*, indicating that it is not sufficient to center only the visible variables and that visible and hidden bias influence each other. This dependence between the mean of the hidden variables and the bias of the visible variables can also be seen from Equation (11) where the transformation of the visible bias depends on the offset of the hidden variables.

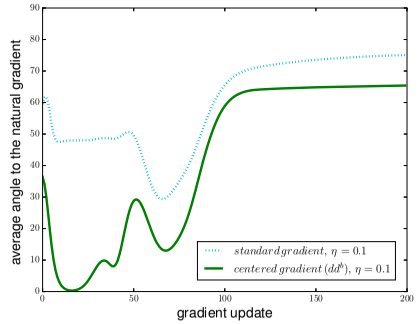
6.9 Comparision with the Natural Gradient

The results in Section 6.7 indicate that one explanation for the better performance of centering and thus the centered gradient compared to the standard gradient is the decoupling of the bias and weight parameters. As described in Section 2.2 the natural gradient is independent of the parameterization of the model distribution. Thus, it is also independent of how the mean information is stored in the parameters and should not suffer from the described bias-weight coupling problem. For the same reason it is also invariant under changes of the representation of the data distribution (for example variable flipping). That is why we expect the direction of the centered gradient to be closer to the direction of the natural gradient than the direction of the standard gradient.

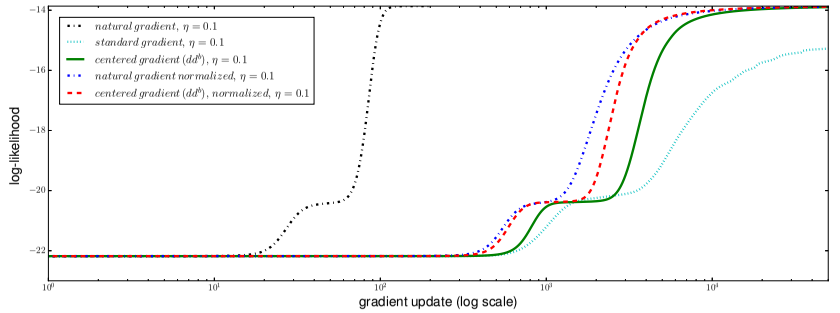
To verify this hypothesis empirically, we trained small RBMs with 4 visible and 4 hidden units using the exact natural gradient on the 2×2 *Bars & Stripes* data set. After each gradient update the different exact gradients were calculated and the angle between the centered and the natural gradient as well as the angle between the standard and the natural gradient were calculated. The results are shown in Figure 13 where Figure 13(a) shows the evolution of the average LL when the exact natural gradient is used for training with different learning rates. Figure 13(b) shows the average angles between the different gradients during training when the natural gradient is used for training with a learning rate of 0.1. The angle between centered and natural gradient is consistently much smaller than the angle between standard and natural gradient. Comparable results can also be observed for the *Shifting Bar* data set and when the standard or centered gradient is used for training (results not shown).



(a) LL evolution of the natural gradient



(b) Angle between standard natural gradient



(c) Comparision of the LL evolution of standard, natural and centered gradient

Figure 13: Comparison of the centered gradient, standard gradient, and natural gradient for RBMs with 4 visible and 4 hidden units trained on *Bars & Stripes* 2×2. (a) The average LL evolution on the training data over 25 trials when the natural gradient is used for training with different learning rates, (b) the average angle over 25 trials between the natural and standard gradient as well as natural and centered gradient when a learning rate of 0.1 is used, and (c) average LL evolution on the training data over 25 trials when either the natural gradient, standard gradient, or centered gradient is used for training.

Note how fast the natural gradient reached a value very close to the theoretical LL upper bound of -13.86 even for a learning rate of 0.1. This verifies empirically the theoretical statement that the natural gradient is clearly the update direction of choice, which should be used if it is tractable. To further emphasize how quickly the natural gradient converges, we compared the average LL evolution for the standard, centered and natural gradient, as shown in Figure 13(c). Although much slower than the natural gradient, the centered gradient reached the theoretical upper bound of the LL. The standard gradient seems to saturate on a much smaller value, showing again the inferiority of the standard gradient even if it is calculated exactly and not only approximated.

To verify that the better performance of natural and centered gradient is not only due to larger gradients resulting in bigger step sizes, we also analyzed the LL evolution for the natural and centered gradient when they are scaled to the norm of the standard gradient before updating the parameters. The results are shown in Figure 13(c). The natural gradient still outperforms the other methods but it becomes significantly slower than when used with its original norm. The reason why the norm of the natural gradient is somehow optimal can be explained by the fact that it ensures constant progress regardless of the curvature of the manifold of probability distributions as explained in (Desjardins et al., 2013). Like a Newton step the Fisher metric results in an automatic local step size adaption such that even a learning rate of 1.0 can be used as illustrated in Figure 13(a).

Interestingly, if the length of the natural gradient and the centered gradient are normalized to the length of the standard gradient and therefore the optimal step size is ignored, the centered gradient becomes almost as fast as the natural gradient. The fact that the normalization of the centered gradient increases the resulting learning speed shows that the norm of the centered gradient is smaller than the norm of the standard gradient. Therefore, the worse performance of the standard gradient does not result from the length but the direction of the gradient.

To conclude, these results support our assumption that the centered gradient is closer to the natural gradient and that it is therefore preferable over the standard gradient (Melchior et al., 2013; Fischer, 2014), which has recently also been confirmed by Grosse and Salakhudinov (2015).

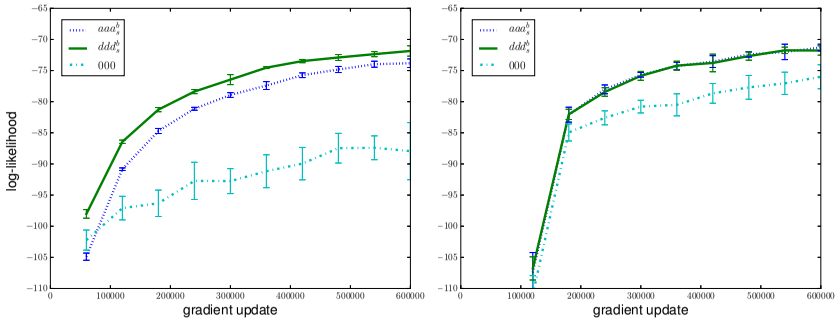
6.10 Experiments with DBMs

When centering was first applied to DBMs by Montavon and Müller (2012) the authors have only seen an improvement via centering for locally connected DBMs. Due to our observations for RBMs and the structural similarity between RBMs and DBMs (a DBM is an RBM with restricted connections and partially unknown input data as discussed in Section 3.2) we expect that the observed benefit of centering also carries over to fully connected DBMs. To verify this assumption and empirically investigate the different centering variants for DBMs we performed extensive experiments on the big data sets listed in Section 5.1.

Training the models and evaluating the lower bound of the LL was performed as originally proposed for normal DBMs by Salakhutdinov and Hinton (2009). The authors have also proposed to pre-train DBMs in a layer-wise fashion based on RBMs (Hinton and Salakhutdinov, 2012). In our experiments we trained all models with and without pre-training to investigate the effect of pre-training in both normal and centered DBMs. For

pre-training we used the same learning rate and the same offset type as in the final DBM models. Note that we keep using the term "average LL" although it is precisely speaking only the lower bound of the average LL, which has been shown to be rather tied (Salakhutdinov and Hinton, 2009). For the estimation of the partition function we again used AIS where we doubled the number of intermediate temperatures compared to the setting in the RBM experiments to 29.000. We continue using the shorthand notations introduced for RBMs also for DBMs with the only difference that we add a third letter to indicate the offset used in the second hidden layer, such that 000 corresponds to the normal binary DBM, and ddd^b_s and aaa^b_s correspond to the centered DBMs using the data mean and the average of data and model mean as offset, respectively. Due to the large number of experiments and the high computational cost (especially for estimating the LL) the experiments were repeated only 10 times and we focused our analysis on normal DBMs (000) and fully centered DBMs (ddd^b_s, aaa^b_s) only.

Again, we begin our analysis with the *MNIST* data set on which we trained normal and centered DBMs with 500 hidden units in the first and 500 units in the second hidden layer. Training was done using PCD-1 with a batch size of 100, a learning rate of 0.001 and in case of centering a sliding factor of 0.01 for the extensive amount of 1.000 epochs (600000

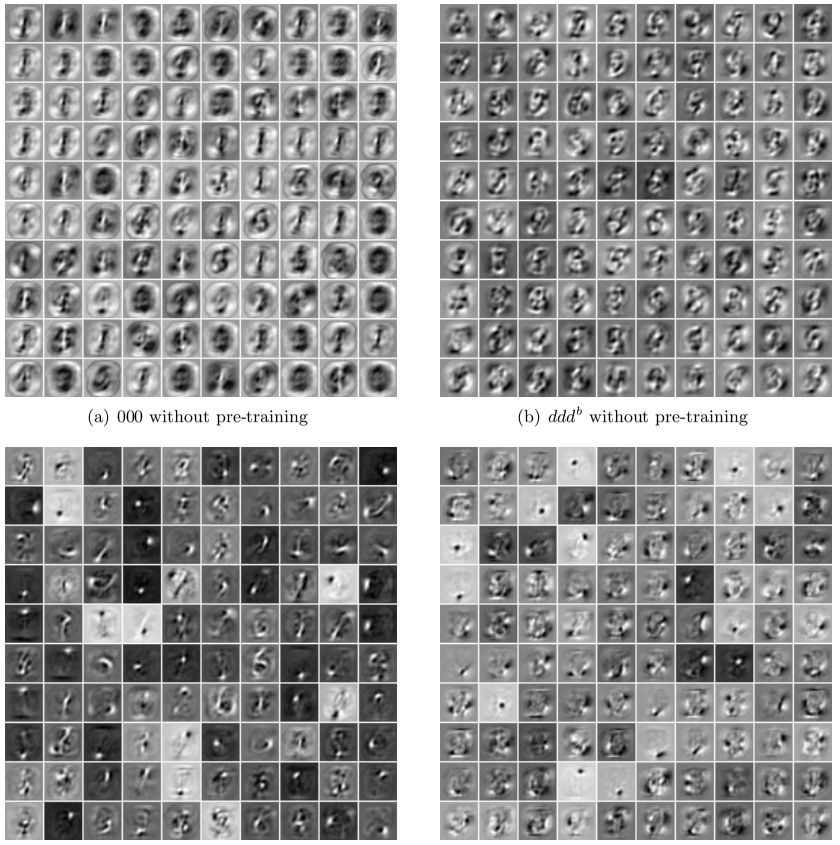


(a) Without pre-training (b) With pre-training

Figure 14: Evolution of the average LL on the test data of the *MNIST* data set for DBMs with 500 hidden units on the first and second layer. The different variants aaa^b_s, ddd^b_s and 000 were either trained (a) without pre-training or (b) with pre-training each DBM layer for 120000 gradient updates (200 epochs). In both cases PCD-1 with a learning rate of $\eta = 0.001$ and for centering a sliding factor of 0.01 was used. The error bars indicate the standard deviation of the average LL over the 10 trials. We skipped evaluating the initial model in (a) and started the LL evaluation in (b) after the 200 epochs of pre-training to roughly account for the computation overhead of pre-training

gradient updates). The evolution of the average LL on the test data without pre-training is shown in Figure 14(a), while the evolution of the average LL on the training data is not shown since it is almost equivalent. Both centered DBMs reach significantly higher LL values with a much smaller standard deviation between the trials than normal DBMs (as indicated by the error bars) and ddd_s^b performs slightly better than aaa_s^b. These findings are different to the observations of Montavon and Müller (2012) who reported an improvement of the model quality in terms of LL through centering only for locally connected DBMs. This might be due to the different training setup (for example a different learning rate, batch size, shorter training time, using ddd_s^l instead of ddd_s^b, or approximation of the data dependent part of the LL gradient by Gibbs sampling instead of optimizing the lower bound of the LL). Figure 14(b) shows the evolution of the average LL on the test data for the same models with pre-training for 120000 gradient updates (200 epochs). The evolution of the average LL on the training data was again almost equivalent and is thus not shown. It can be seen that ddd_s^b has approximately the same performance with and without pre-training but the performance of aaa_s^b improves by pre-training such that a similar LL level as for ddd_s^b is reached. Pre-training allows 000 to reach better LL than without pre-training, however it is still significantly worse compared to the centered DBMs with or without pre-training. By comparing these results with the results for RBMs with 500 hidden units trained on *MNIST* shown in Figure 9(a) we see that all DBMs reach higher LL values than the corresponding RBM models.

The higher layer representations in DBMs highly depend on the data driven lower layer representations. Therefore, we expect to see a qualitative difference between the second layer receptive fields or filters, given by the columns of the weight matrices in centered and normal DBMs. We did not visualize the filters of the first layer since all models showed the well known stroke like structure, which can be seen for RBMs in the review paper by Fischer and Igel (2014) for example. We visualized the receptive fields of the second layer by the linear back-projection of the second layer filters into the input space given by the matrix product of first and second layer weight matrix. The corresponding back projected second layer filters of 000 and ddd_s^b are shown Figure 15(a) and (b), respectively. It can be seen that many second layer filters of 000 are roughly the same and thus highly correlated. Moreover, they seem to represent some kind of mean information. Whereas the filters for ddd_s^b have much more diverse and less correlated structures than the filters of the normal DBM. When pre-training is used the filters of 000 become more diverse and the filters of both 000 and ddd_s^b become more selective as can be seen in Figure 15(c) and (d), respectively. The differences in selectivity of the filters between the different DBM variants can also be seen from the average mean field activation of the variables in the second hidden layer. As shown in Figure 16(a) without pre-training the average activation given the training data is approximately 0.5 for all hidden units of ddd_s^b while for aaa_s^b it is a bit less balanced and for 000 the units tend to be either active or inactive all the time. The results in Figure 16(b) illustrate that the average activities for all models become less balanced when pre-training is used, which also reflects the higher selectivity of the filters as shown in Figure 15(c) and (d). While the second layer hidden activities of ddd_s^b and aaa_s^b stay in a reasonable range, they become extremely selective for 000 where 300 out of 500 units are inactive most of the time. Therefore, the filters, the average activation and the evolution of the LL indicate that normal RBMs have difficulties in making use of the second hidden layer.



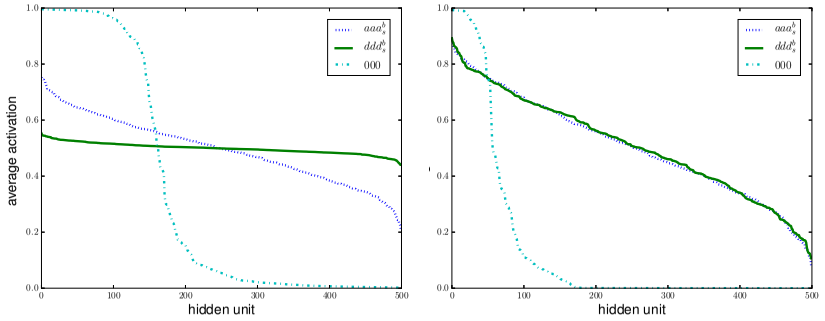
(a) 000 without pre-training

(b) ddd^b without pre-training

(c) 000 with pre-training

(d) ddd^b with pre-training

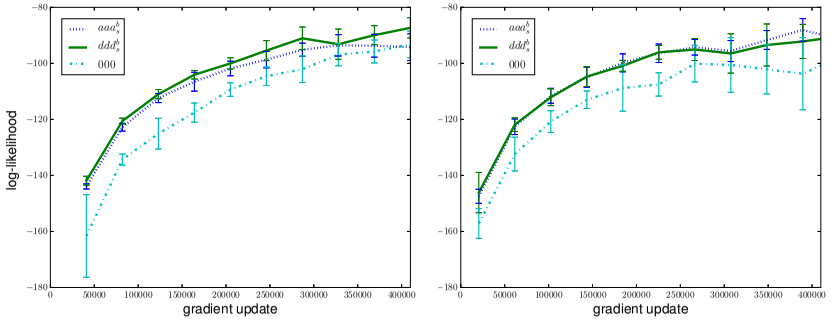
Figure 15: Random selection of 100 linearly projected filters of the second hidden layer for (a) 000 and (b) ddd^b without pre-training and (c) 000 and (d) ddd^b without 200 epochs pre-training. The filters have been normalized independently such that the structure can be seen better.



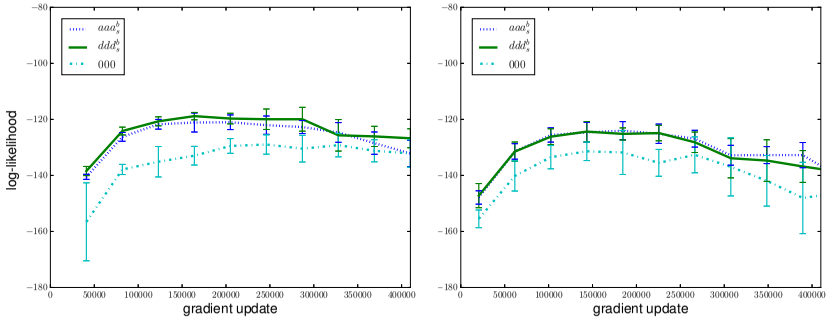
(a) Without pre-training (b) With pre-training

Figure 16: Ordered average mean field activation of the 500 hidden units in the second layer of the different DBMs given the training data (a) without pre-training and (b) with pre-training. Sampling the states or using the conditional probabilities of the variables instead of taking the mean field activation leads to almost equivalent results.

We continue our analysis with experiments on the *Caltech* data set on which we again trained normal and centered DBMs with 500 hidden units on the first and 500 hidden units on the second hidden layer. Training was also done using PCD-1 with a batch size of 100, a learning rate of 0.001 and in case of centering a sliding factor of 0.01. Since the training data has only 41 batches the models were trained for the extensive amount of 10000 epochs (410000 gradient updates). Figure 17 shows the average LL on the test data (c) without and (d) with 500 epochs pre-training. In addition, Figure 17(a) and (b) show the corresponding average LL on the training data demonstrating that all models overfitted to the training data of the *Caltech* data set. The results are consistent with the results on *MNIST*. 000 performs worse than centering on training and test data independently of whether pre-training is used or not. Furthermore, aaa_s^b seems to perform slightly worse than ddd_s^b without pre-training, while the performance becomes equivalent if pre-training is used. But in contrast to the results for *MNIST*, on the *Caltech* data set all methods perform worse with pre-training. This negative effect of pre-training becomes even worse when the number of pre-training epochs is increased. In the case of 2.000 epochs of pre-training for example, ddd_s^b and aaa_s^b still perform better than 000 but the maximal average LL among all models, which was reached by ddd_s^b was only -98.1 for the training data and -141.4 for the test data, compared to -90.4 and -124.0 when 500 epochs of pre-training were used, and -87.3 and -118.8 when no pre-training was used. Without pre-training the LL values are comparable to the results when an RBM with 500 hidden units is trained on *Caltech* as shown in Figure 10, illustrating that in terms of the LL a DBM does not necessarily perform better than an RBM. We also examined the filters and the average hidden activities for the



(a) LL on the training data without pre-training (b) LL on the training data with pre-training



(c) LL on the test data without pre-training (d) LL on the test data with pre-training

Figure 17: Evolution of the average LL on the *Caltech* data set for different DBMs (aaa_s^b, ddd_s^b, and 000) with 500 units in the first and 500 units in second hidden layer. LL on (a) the training data and (c) the test data without pre-training and the LL on (b) the training data and (d) the test data with 500 epochs (20500 gradients updates) of pre-training. The models were trained using PCD-1 with a batch size of 100, a sliding factor of 0.01 and a learning rate of $\eta = 0.001$. The error bars indicate the standard deviation of the LL over the 10 trials. We skipped evaluating the initial model and (a) and (c) start after the 500 epochs of pre-training to roughly account for the computation overhead of pre-training.

training data of *Caltech*. Both led to the same conclusions as the results for *MNIST* and are therefore not shown here.

Finally, we also performed experiments on the eight *UCI binary* data sets described in Section 5.1 using the same training setup as for the corresponding RBM experiments. That is, the DBMs with 200 hidden units on the first and 200 hidden units on the second hidden layer were trained for 5.000 epochs with PCD-1, a batch size of 100, a learning rate of 0.01, and in the case of centering a sliding factor of 0.01. The LL was evaluated every 50th epoch and in the case of pre-training the models were pre-trained for 200 epochs. Table 10 shows the maximum average LL on the test data with and without pre-training. Without pre-training the results are consistent with the findings for RBMs. ddd^b performs better than 000 on all data sets except for RCV1 where 000 performs slightly better. The LL values for the DBMs are comparable but not necessarily better than the corresponding LL values for RBMs, which are shown in Table 8. In the case of the *WEB* data set for example the DBMs even perform worse than the RBMs . When pre-training is used the performance of all models, centered or normal, is worse than the performance of the corresponding DBMs without pre-training. For completeness Table 11 shows the maximum average LL on the training data leading to the same conclusions as the results on test data.

To summarize, the experiments described in this section show that centered DBMs reach higher LL values than normal DBMs. While pre-training leads to more selective filters in general, it is often even harmful for the model performance in terms of the LL.

6.11 Experiments with Auto Encoders

The benefit of centering in feed forward neural networks for supervised tasks has already been shown by Schraudolph (1998). In this section we analyze centering in a special kind of unsupervised feed forward neural networks, namely centered AEs as introduced in Section 4.1. We therefore trained normal and centered three layer AEs on the ten big data sets described in Section 5.1. To avoid trivial solutions we used tied weights and the number of output dimensions was 50 percent of the number of input/data dimensions. Since the data sets are binary we used the sigmoid non-linearity in encoder and decoder and the cross entropy cost function. Training was done using standard back propagation for 5000 epochs without any further modification. As for the RBM and DBM experiments, the weight matrices were initialized with random values sampled from a Gaussian with zero mean and standard deviation 0.01, and the biases and offsets were initialized as described in Section 4.2. The batch size was 100, the sliding factor 0.01 and we used a default learning rate

Table 12: Average minimal reached cost value with standard deviation on test and training data of *MNIST*, *Caltech* and the eight*UCI binary* data sets for centered and normal three layer AEs with sigmoid units, cross entropy cost function, and the number of hidden units set to 50 percent of the number of input units (data dimensions). The average number of epochs needed to reach the minimal cost value is given in brackets, and (5000) indicates that convergence was not achieved during training.

of 0.1 for all experiments. Each experiment was repeated 10 times and we calculated the average minimal cost value, the corresponding standard deviation and the average number of epochs needed to reach the minimal cost value. A second set of experiments was performed with a learning rate of 0.5 when the average number of epochs needed to reach the minimal cost value on the test data was close or equal to 5000 epochs, or with a learning rate of 0.01 when the average number of epochs needed to reach the minimal cost value on the test data was less than 500 epochs. The results are given by Table 12, showing that (except for the RCV1 data set) centered AEs perform clearly better in terms of the average minimal cost value on the test data than normal AEs. On the training data normal AEs only perform slightly better on data sets where both models reached very small cost values anyway. We did not show the results for the validation sets since they are almost equivalent to the results for test data.

Interestingly, the result that centering only performs worse on the RCV1 data set is fully consistent with the findings for RBMs and DBMs. We inspected the RCV1 data set and its first and second order statistics but did not find anything conspicuous compared to the other data sets that might have explained why for this particular data set centering is not beneficial. However, learning is much slower for this data set when centering is used, which can also be seen by comparing the results for learning rate 0.1 an 0.5 in Table 12.

7. Conclusion

This work discussed centering in RBMs and DBMs, where centering is done by subtracting offset parameters from visible and hidden variables. Our theoretical analysis has yielded the following results:

1. Centered BMs/RBMs/DBMs and normal BMs/RBMs/DBMs are different parameterizations of the same model class (Section 3), such that any normal BM/RBM/DBM can be transformed to an equivalent centered BM/RBM/DBM an *vice versa*. This equivalence generalizes to ANNs in general, which justifies the use of centering in arbitrary ANNs (Section 4).

2. The LL gradient of centered binary BMs and thus of centered binary RBMs/DBMs is invariant under simultaneous flip of data and offsets, for any offset value in the range of zero to one. This leads to the desired invariance of the LL performance of the model under changes of data representation (Section 3 and Appendix A).

3. Training a centered BM/RBM/DBM can be reformulated as training a normal BM/RBM/DBM with a new parameter update, which we refer to as centered gradient (Section 3.1 and Appendix B).

4. From this new formulation follows that the enhanced gradient is a particular form of centering. That is, the centered gradient becomes equivalent to the enhanced gradient by setting the visible and hidden offsets to the average over model and data mean of the corresponding variable (Section 3.1 and Appendix C).

Our numerical analysis has yielded the following results:

1. Optimal performance of centered binary RBMs/DBMs is achieved when both, visible and hidden variables, are centered and the offsets are set to the expectations of the corresponding variable under data or model distribution (Section 6.1, 6.6 and 6.7).

2. Centered binary RBMs/DBMs reach significantly higher LL values than normal binary RBMs/DBMs (Section 6.7 and 6.10). As an example, centered binary RBMs with 500 hidden units achieved an average LL on the test data of *MNIST* around -75 compared to -88 for normal binary RBMs (Figure 9).

3. Initializing the bias parameters such that the RBM/DBM/AE is initially centered (that is $b_i = \sigma^{-1}(\langle x_i \rangle)$) can already improve the performance of a normal binary RBM. However, this initialization leads to a performance still worse than the performance of a centered binary RBM (Section 6.2) and is therefore no alternative to centering.

4. Using the model expectation (as for the enhanced gradient for example) can lead to a severe divergence of the LL when PCD or PT_c is used for sampling. This is caused by the correlation of offset and gradient approximation (Section 6.4).

5. The divergence can be prevented when an exponentially moving average for the approximations of the offset values is used (Section 6.5), which also stabilizes the training for other centering variants especially when the mini batch size is small.

6. Training centered binary RBMs/DBMs leads to smaller weight norms and larger bias norms compared to normal binary RBMs/DBMs. This supports the hypothesis that when using the standard gradient the mean value is modeled by both weights and biases, while when using the centered gradient the mean values are explicitly modeled by the bias parameters (Section 6.9).

7. The direction of the centered gradient is closer to the natural gradient than that of the standard gradient and the natural gradient is extremely efficient for training RBMs if tractable (Section 6.9).

8. Centered binary DBMs reach higher LL values than normal binary DBMs independently of whether pre-training is used or not. Thus pre-training cannot be considered as an alternative to centering (Section 6.10).

9. While pre-training slightly helps normal binary DBMs on *MNIST* we did not observe an improvement through pre-training for centered binary DBMs. Furthermore, on all data sets other than *MNIST* pre-training led to lower LL values and the results became worse as longer pre-training was performed for normal and centered binary DBMs (Section 6.10).

10. The visual inspection of the learned filters, the average second hidden layer activities and the reached LL values suggest that normal binary DBMs have difficulties in making use of the third and higher layers (Section 6.10).

11. Centering also improves the performance in terms of the optimized loss for AEs, which supports our assumption that centering is beneficial not only for probabilistic models like RBMs and DBMs but also for ANNs in general (Section 6.11).

Based on our results we recommend to center all units in the network using the data mean and to use an exponentially moving average if the mini-batch size is rather small (< 100 for stochastic models and < 10 for deterministic models). Furthermore, we do not recommend to use pre-training for DBMs since it often deteriorates the results.

All results clearly support the superiority of centered RBMs/DBMs and AEs, which we believe will also extend to other models. Future work might focus on centering in BMs and also other probabilistic models such as the neural auto-regressive distribution estimator (Larochelle and Murray, 2011) or in recurrent neural networks such as long short-term memory (Hochreiter and Schmidhuber, 1997). An extension to also normalizing the variance of the units and a comparison to the recently proposed batch normalization (Ioffe and Szegedy, 2015) would also be of interest.

The implementation of the algorithms proposed and analyzed in this work are part of the Python library PyDeep publicly available at `https://github.com/MelJan/PyDeep`.

Acknowledgments

We would like to thank Nan Wang for helpful discussions, Tobias Glasmachers for his suggestions on the natural gradient part, and Alberto Escalante for his valuable corrections. We also like to thank the anonymous reviewers for helpful suggestions. Furthermore, Asja Fischer was supported by the German Federal Ministry of Education and Research within the National Network Computational Neuroscience under grant number 01GQ0951 (Bernstein Fokus Learning behavioral models: From human experiment to technical assistance).

Appendix A. Proof of Invariance for the Centered Gradient

In the following we show that the LL gradient of centered binary BMs and thus the LL gradient for centered binary RBMs and DBMs is invariant to flips of the variables if the corresponding offset parameters flip as well (see Melchior et al., 2013, for a proof specifically for RBMs). Since training a normal binary BM using the centered gradient (see Appendix B) is equivalent to training a centered binary BM, the proof also holds for the centered gradient.

In contrast to an RBM or DBM a BM is a fully connected graphical model and the energy for a centered BM and binary values $\mathbf{x} = (x_1, ..., x_N)$ is given by

$$E(\mathbf{x}) = -\sum_i (x_i - \mu_i)\, b_i - \sum_{i,j>i} (x_i - \mu_i)\, w_{ij}\, (x_j - \mu_j) \quad , \tag{18}$$

and the corresponding LL gradient w.r.t. the parameters w_{ij} and b_i is given by

$$\nabla w_{ij} = \langle (x_i - \mu_i)(x_j - \mu_j) \rangle_d - \langle (x_i - \mu_i)(x_j - \mu_j) \rangle_m \quad , \tag{19}$$

$$\nabla b_i = \langle (x_i - \mu_i) \rangle_d - \langle (x_i - \mu_i) \rangle_m = \langle x_i \rangle_d - \langle x_i \rangle_m \quad . \tag{20}$$

In the following $\boldsymbol{\theta}$ and $\nabla\boldsymbol{\theta}$ is used to jointly denote all parameters w_{ij} and b_i and their derivatives ∇w_{ij} and ∇b_i, respectively .

We begin by formalizing the invariance property for the energy.

Definition 1 *Let there be a binary random variable X_i. The variable X_i' is called 'flipped' or 'flip of X_i' if it takes the values $x_i' = 1 - x_i$ for any given state x_i of X_i.*

Definition 2 *Let there be a centered binary BM with parameters $\boldsymbol{\theta}$, offsets $\boldsymbol{\mu}$, binary random variables $\mathbf{X} = (X_1, \ldots, X_N)$, and energy $E(\mathbf{x})$, and a second centered binary BM with parameters $\tilde{\boldsymbol{\theta}}$, offsets $\tilde{\boldsymbol{\mu}}$, binary random variables $\tilde{\mathbf{X}} = (\tilde{X}_1, \ldots, \tilde{X}_N)$ and energy $\tilde{E}(\tilde{\mathbf{x}})$, where in the latter BM an arbitrary number of variables have been flipped. The energies $E(\mathbf{x})$ and $\tilde{E}(\tilde{\mathbf{x}})$ are called 'flip-invariant' or 'invariant to flips of variables' if $E(\mathbf{x}) = \tilde{E}(\tilde{\mathbf{x}})$ holds.*

Theorem 3 *Let the binary parameter f_i take the value -1 if the corresponding variable X_i, has been flipped and 1 otherwise. The energies $E(\mathbf{x})$ and $\tilde{E}(\tilde{\mathbf{x}})$ are 'flip-invariant' according to Definition 2 if the offsets flip simultaneously with the variables, compactly denoted by*

$$\tilde{x}_i = \frac{1-f_i}{2} + f_i x_i \ , \tag{21}$$

$$\tilde{\mu}_i = \frac{1-f_i}{2} + f_i \mu_i \ , \tag{22}$$

and if the parameters of the models are related in the following way

$$\tilde{w}_{ij} = f_i w_{ij} f_j \ , \tag{23}$$

$$\tilde{b}_i = f_i b_i \ . \tag{24}$$

Proof First note that

$$\begin{aligned} (\tilde{x}_i - \tilde{\mu}_i) &\overset{(21,22)}{=} \left(\frac{1-f_i}{2} + f_i x_i\right) - \left(\frac{1-f_i}{2} + f_i \mu_i\right) \\ &= \frac{1-f_i}{2} + f_i x_i - \frac{1-f_i}{2} - f_i \mu_i \\ &= (x_i - \mu_i) f_i = f_i (x_i - \mu_i) \ , \end{aligned} \tag{25}$$

so that

$$\begin{aligned} \tilde{E}(\tilde{\mathbf{x}}) &\overset{(18)}{=} -\sum_i (\tilde{x}_i - \tilde{\mu}_i)\, \tilde{b}_i - \sum_{i,j>i} (\tilde{x}_i - \tilde{\mu}_i)\, \tilde{w}_{ij}\, (\tilde{x}_j - \tilde{\mu}_j) \\ &\overset{(23,24,25)}{=} -\sum_i (x_i - \mu_i) \underbrace{f_i f_i}_{=1} b_i - \sum_{i,j>i} (x_i - \mu_i) \underbrace{f_i f_i}_{=1} w_{ij} \underbrace{f_j f_j}_{=1} (x_j - \mu_j) \\ &\overset{(18)}{=} E(\mathbf{x}) \ . \end{aligned}$$

■

Definition 4 *Let there be two BMs with 'flip-invariant' energies according to Definition 2. The gradient of the LL ($\nabla\boldsymbol{\theta}$ or $\nabla\tilde{\boldsymbol{\theta}}$ respectively) are called 'flip-invariant' or 'invariant to flips of variables' if $E(\mathbf{x}) = \tilde{E}(\tilde{\mathbf{x}})$ still holds after updating $\boldsymbol{\theta}$ and $\tilde{\boldsymbol{\theta}}$ to $\boldsymbol{\theta} + \eta\nabla\boldsymbol{\theta}$ and $\tilde{\boldsymbol{\theta}} + \eta\nabla\tilde{\boldsymbol{\theta}}$, respectively, for any learning rate η.*

We can now state the following theorem for the parameter updates.

Theorem 5 *The gradient of centered binary BMs with flip invariant energies according to Definition 2, is also invariant to flips of arbitrary variables if the corresponding offset parameters flip as well, that is if a flipped variable $\tilde{x}_i = 1 - x_i$ implies $\tilde{\mu}_i = 1 - \mu_i$.*

Proof

$$\begin{aligned} \nabla\tilde{w}_{ij} &\overset{(19)}{=} \langle(\tilde{x}_i - \tilde{\mu}_i)(\tilde{x}_j - \tilde{\mu}_j)\rangle_d - \langle(\tilde{x}_i - \tilde{\mu}_i)(\tilde{x}_j - \tilde{\mu}_j)\rangle_m \\ &\overset{(25)}{=} \langle f_i(x_i - \mu_i)(x_j - \mu_j) f_j\rangle_d - \langle f_i(x_i - \mu_i)(x_j - \mu_j) f_j\rangle_m \\ &\overset{(19)}{=} f_i \nabla w_{ij} f_j \ , \\ \nabla\tilde{b}_i &\overset{(20)}{=} \langle(\tilde{x}_i - \tilde{\mu}_i)\rangle_d - \langle(\tilde{x}_i - \tilde{\mu}_i)\rangle_m \\ &\overset{(25)}{=} \langle f_i(x_i - \mu_i)\rangle_d - \langle f_i(x_i - \mu_i)\rangle_m, \\ &\overset{(20)}{=} f_i \nabla b_i \ . \end{aligned}$$

Comparing these results with Equations (23) – (24) shows that the gradient underlies the same sign changes under variable flips as the parameters. Thus, it holds for the updated parameters $\tilde{\boldsymbol{\theta}} + \eta\nabla\tilde{\boldsymbol{\theta}}$ and $\boldsymbol{\theta} + \eta\nabla\boldsymbol{\theta}$ that

$$\begin{aligned} \tilde{w}_{ij} + \eta\nabla\tilde{w}_{ij} &= f_i\,(w_{ij} + \eta\nabla w_{ij})\, f_j \ , \\ \tilde{b}_i + \eta\nabla\tilde{b}_i &= f_i\,(b_i + \eta\nabla b_i) \ , \end{aligned}$$

showing that $E(\mathbf{x}) = \tilde{E}(\tilde{\mathbf{x}})$ is still guaranteed as follows from Theorem 3 and thus that the gradient of centered RBMs is flip-invariant according to Definition 4. ■

Theorem 3 and Theorem 5 hold for any value from zero to one for μ_i, if it is guaranteed that the offsets flip simultaneously with the corresponding variables. In practice one wants the model to perform equivalently on any flipped version of the data set without knowing which version is presented. This holds if we set the offsets to the expectation value of the corresponding variables under any distribution $p^*(x_i)$, since when $\mu_i = \sum_{x_i} p^*(x_i)\, x_i$, flipping X_i leads to $\tilde{\mu}_i = \sum_{x_i} p^*(x_i)\,(1 - x_i) = 1 - \sum_{x_i} p^*(x_i)\, x_i = 1 - \mu_i$.

Appendix B. Derivation of the Centered Gradient

In the following we show that the gradient of centered BMs can be reformulated as an alternative update for the parameters of a normal binary BM, which we name 'centered gradient'.

We first show that the parameter transformation

$$w_{ij} = \hat{w}_{ij} \ , \tag{26}$$

$$b_i = \hat{b}_i + \sum_{j \neq i} \hat{w}_{ij} \mu_j \ , \tag{27}$$

allows to transform a normal binary BM with energy $\hat{E}(\mathbf{x}) = -\sum_i x_i \hat{b}_i - \sum_{i,j>i} x_i \hat{w}_{ij} x_j$ into a centered binary BM with energy $E(\mathbf{x}) = -\sum_i (x_i - \mu_i)\, b_i - \sum_{i,j>i} (x_i - \mu_i)\, w_{ij}\, (x_j - \mu_j)$

and *vice versa* such that $E(\mathbf{x}) = \hat{E}(\mathbf{x}) + const$ is guaranteed for all $\mathbf{x} \in \{0,1\}^n$ and thus that the modeled distribution stays the same.

$$
\begin{aligned}
E(\mathbf{x}) &= -\sum_i (x_i - \mu_i)\, b_i - \sum_{i,j>i} (x_i - \mu_i)\, w_{ij}\, (x_j - \mu_j) \\
&\overset{(26,27)}{=} -\sum_i (x_i - \mu_i) \left(\hat{b}_i + \sum_{j \neq i} \hat{w}_{ij} \mu_j \right) - \sum_{i,j>i} (x_i - \mu_i)\, \hat{w}_{ij}\, (x_j - \mu_j) \\
&= -\sum_i x_i \hat{b}_i - \sum_i x_i \sum_{j \neq i} \hat{w}_{ij} \mu_j + \sum_i \mu_i \hat{b}_i + \mu_i \sum_{j \neq i} \hat{w}_{ij} \mu_j \\
&\quad - \sum_{i,j>i} x_i \hat{w}_{ij} x_j + \sum_{i,j>i} x_i \hat{w}_{ij} \mu_j + \sum_{i,j>i} \mu_i \hat{w}_{ij} x_j - \sum_{i,j>i} \mu_i \hat{w}_{ij} \mu_j \\
&= \underbrace{-\sum_i x_i \hat{b}_i - \sum_{i,j>i} x_i \hat{w}_{ij} x_j}_{\hat{E}(\mathbf{x})} + \underbrace{\sum_i \mu_i \hat{b}_i + \mu_i \sum_{j \neq i} \hat{w}_{ij} \mu_j - \sum_{i,j>i} \mu_i \hat{w}_{ij} \mu_j}_{const} \\
&\quad - \sum_i x_i \sum_{j \neq i} \hat{w}_{ij} \mu_j + \sum_{i,j>i} x_i \hat{w}_{ij} \mu_j + \sum_{i,j>i} \mu_i \hat{w}_{ij} x_j \\
&= \hat{E}(\mathbf{x}) + const - \sum_i x_i \sum_{j \neq i} \hat{w}_{ij} \mu_j + \sum_{i,j>i} x_i \hat{w}_{ij} \mu_j + \sum_{j,i>j} \mu_j \hat{w}_{ij} x_i \\
&= \hat{E}(\mathbf{x}) + const - \sum_i x_i \sum_{j \neq i} \hat{w}_{ij} \mu_j + \sum_{i,j \neq i} x_i \hat{w}_{ij} \mu_j \\
&= \hat{E}(\mathbf{x}) + const \ .
\end{aligned}
$$

Updating the parameters of the centered BM according to Equations (19) – (20) with a learning rate η leads to an updated set of parameters w'_{ij}, b'_i, given by

$$
\begin{aligned}
w'_{ij} &\overset{(19)}{=} w_{ij} + \eta(\langle (x_i - \mu_i)(x_j - \mu_j) \rangle_d - \langle (x_i - \mu_i)(x_j - \mu_j) \rangle_m) \ , &(28)\\
b'_i &\overset{(20)}{=} b_i + \eta(\langle x_i \rangle_d - \langle x_i \rangle_m) \ . &(29)
\end{aligned}
$$

One can now transform the updated centered BM back to a normal BM by applying the inverse transformation to the updated parameters, which finally leads to the centered gradient.

$$
\begin{aligned}
\hat{w}'_{ij} &\overset{(26)}{=} w'_{ij} \\
&\overset{(26,28)}{=} \hat{w}_{ij} + \eta \underbrace{\left(\langle (x_i - \mu_i)(x_j - \mu_j) \rangle_d - \langle (x_i - \mu_i)(x_j - \mu_j) \rangle_m \right)}_{= \nabla_c \hat{w}_{ij}} \ , &(30)
\end{aligned}
$$

$$
\begin{aligned}
\hat{b}'_i &\overset{(27)}{=} b'_i - \sum_{j \neq i} \hat{w}'_{ij} \mu_j \\
&\overset{(29,30)}{=} b_i + \eta(\langle x_i \rangle_d - \langle x_i \rangle_m) - \sum_{j \neq i} (\hat{w}_{ij} + \eta \nabla_c \hat{w}_{ij}) \mu_j \\
&\overset{(27)}{=} \hat{b}_i + \sum_{j \neq i} \hat{w}_{ij} \mu_j + \eta(\langle x_i \rangle_d - \langle x_i \rangle_m) - \sum_{j \neq i} \hat{w}_{ij} \mu_j - \sum_{j \neq i} \eta \nabla_c \hat{w}_{ij} \mu_j \\
&= \hat{b}_i + \underbrace{\eta(\langle x_i \rangle_d - \langle x_i \rangle_m - \sum_{j \neq i} \nabla_c \hat{w}_{ij} \mu_j)}_{\overset{(14)}{=} \nabla_c \hat{b}_i} \ . &(31)
\end{aligned}
$$

In case of an RBM the visible units are only connected to hidden units and *vice versa* such that the sum in Equation (31) either sums over all visible units or all hidden units leading to the centered gradient for RBMs given by Equations (13) – (15) (see Melchior et al., 2013, for a detailed derivation for RBMs).

Appendix C. Enhanced Gradient as a Special Case of the Centered Gradient

In the following we show that the enhanced gradient can be derived as a special case of the centered gradient. We show the equivalence for RBMs since the enhanced gradient was originally proposed for RBMs. However, the derivations for BMs and DBMs are analogous.

By setting $\boldsymbol{\mu} = \frac{1}{2}(\langle \mathbf{x} \rangle_d + \langle \mathbf{x} \rangle_m)$ and $\boldsymbol{\lambda} = \frac{1}{2}(\langle \mathbf{h} \rangle_d + \langle \mathbf{h} \rangle_m)$ we get

$$
\begin{aligned}
\nabla_c \mathbf{W} &\overset{(13)}{=} \langle (\mathbf{x} - \boldsymbol{\mu})(\mathbf{h} - \boldsymbol{\lambda})^T \rangle_d - \langle (\mathbf{x} - \boldsymbol{\mu})(\mathbf{h} - \boldsymbol{\lambda})^T \rangle_m \\
&= \langle \mathbf{x}\mathbf{h}^T \rangle_d - \langle \mathbf{x} \rangle_d \boldsymbol{\lambda}^T - \boldsymbol{\mu} \langle \mathbf{h}^T \rangle_d + \boldsymbol{\mu}\boldsymbol{\lambda}^T - \langle \mathbf{x}\mathbf{h}^T \rangle_m + \langle \mathbf{x} \rangle_m \boldsymbol{\lambda}^T + \boldsymbol{\mu} \langle \mathbf{h}^T \rangle_m - \boldsymbol{\mu}\boldsymbol{\lambda}^T \\
&= \langle \mathbf{x}\mathbf{h}^T \rangle_d - \frac{1}{2} \langle \mathbf{x} \rangle_d (\langle \mathbf{h} \rangle_d + \langle \mathbf{h} \rangle_m)^T - \frac{1}{2} (\langle \mathbf{x} \rangle_d + \langle \mathbf{x} \rangle_m) \langle \mathbf{h}^T \rangle_d \\
&\quad - \langle \mathbf{x}\mathbf{h}^T \rangle_m + \frac{1}{2} \langle \mathbf{x} \rangle_m (\langle \mathbf{h} \rangle_d + \langle \mathbf{h} \rangle_m)^T + \frac{1}{2} (\langle \mathbf{x} \rangle_d + \langle \mathbf{x} \rangle_m) \langle \mathbf{h}^T \rangle_m \\
&= \langle \mathbf{x}\mathbf{h}^T \rangle_d - \frac{1}{2} \langle \mathbf{x} \rangle_d \langle \mathbf{h}^T \rangle_d - \frac{1}{2} \langle \mathbf{x} \rangle_d \langle \mathbf{h}^T \rangle_m - \frac{1}{2} \langle \mathbf{x} \rangle_d \langle \mathbf{h}^T \rangle_d - \frac{1}{2} \langle \mathbf{x} \rangle_m \langle \mathbf{h}^T \rangle_d \\
&\quad - \langle \mathbf{x}\mathbf{h}^T \rangle_m + \frac{1}{2} \langle \mathbf{x} \rangle_m \langle \mathbf{h}^T \rangle_d + \frac{1}{2} \langle \mathbf{x} \rangle_m \langle \mathbf{h}^T \rangle_m + \frac{1}{2} \langle \mathbf{x} \rangle_d \langle \mathbf{h}^T \rangle_m + \frac{1}{2} \langle \mathbf{x} \rangle_m \langle \mathbf{h}^T \rangle_m \\
&= \langle \mathbf{x}\mathbf{h}^T \rangle_d - \langle \mathbf{x} \rangle_d \langle \mathbf{h}^T \rangle_d - \langle \mathbf{x}\mathbf{h}^T \rangle_m + \langle \mathbf{x} \rangle_m \langle \mathbf{h}^T \rangle_m \\
&= \langle (\mathbf{x} - \langle \mathbf{x} \rangle_d)(\mathbf{h} - \langle \mathbf{h} \rangle_d)^T \rangle_d - \langle (\mathbf{x} - \langle \mathbf{x} \rangle_m)(\mathbf{h} - \langle \mathbf{h} \rangle_m)^T \rangle_m \\
&\overset{(1)}{=} \nabla_e \mathbf{W} \ , &(32)
\end{aligned}
$$

and for the derivatives with respect to the bias parameters follows directly that

$$
\begin{aligned}
\nabla_c \mathbf{b} &\overset{(14,32)}{=} \langle \mathbf{x} \rangle_d - \langle \mathbf{x} \rangle_m - \nabla_e \mathbf{W} \boldsymbol{\lambda} \\
&= \langle \mathbf{x} \rangle_d - \langle \mathbf{x} \rangle_m - \nabla_e \mathbf{W} \frac{1}{2} (\langle \mathbf{h} \rangle_d + \langle \mathbf{h} \rangle_m) \\
&\overset{(2)}{=} \nabla_e \mathbf{b} \ ,
\end{aligned}
$$

$$\begin{aligned}\nabla_c \mathbf{c} &\overset{(15,32)}{=} \langle \mathbf{h} \rangle_d - \langle \mathbf{h} \rangle_m - \nabla_e \mathbf{W}^T \boldsymbol{\mu} \\ &= \langle \mathbf{h} \rangle_d - \langle \mathbf{h} \rangle_m - \nabla_e \mathbf{W}^T \frac{1}{2} \left(\langle \mathbf{x} \rangle_d + \langle \mathbf{x} \rangle_m \right) \\ &\overset{(3)}{=} \nabla_e \mathbf{c} \ .\end{aligned}$$

Appendix D. Comparison of the Different MNIST Variants

In this section we compare the performance of normal and centered RBMs on different variants of the *MNIST* data set (LeCun et al., 1998). The data set is provided at `http://yann.lecun.com/exdb/mnist/` and consists of pixel values in the range of 0 to 255.

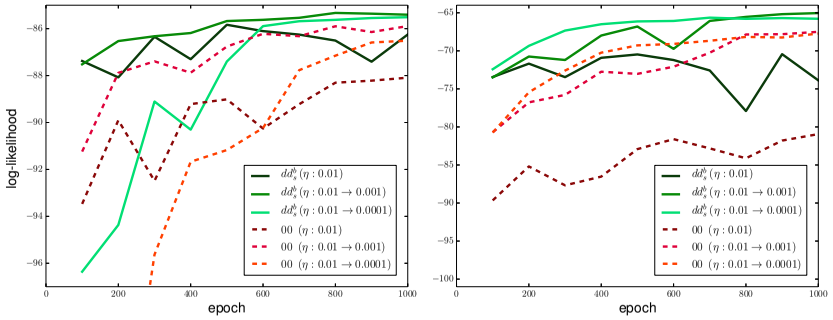
Since the data set is not binary it has to be preprocessed when used with binary RBMs. In a first step the values are usually normalized to lie in $[0, 1]$. In different studies the normalized values are then either used directly as input, or the data set is binarized using a threshold of 0.5 or by sampling according to the normalized values (which are treated as the probabilities for the variables being in state 1). Here, we refer to these three different binarized variants of *MNIST* as *MNIST-Probabilities*, *MNIST-Threshold*, and *MNIST-Sampled*, respectively.

Since it is often not mentioned how the data set is binarized it is hard to compare the LL values reported for *MNIST* experiments across studies. Furthermore, since the results are mainly given for big models the LL is usually approximated using AIS, which easily overestimates the LL if the setup is not chosen properly. In our experience using a reasonable base partition function such as one that is based on the MLE for zero weights (Salakhutdinov and Murray, 2008) is crucial for AIS not to dramatically overestimate the LL for RBMs/DBMs. In this work, we ensured that when given the same pseudo random number generator, our AIS implementation and the *MNIST-Sampled* data set were the same as used by Salakhutdinov and Murray (2008).

As a baseline we trained normal and centered RBMs with 16 hidden units on the three different *MNIST* variants for 100 epochs using the setup described in Section 6. The maximum average of the exact LL values for the test data for dd_s^b and 00 are given in Table 13. Although the maximum reached values are quite different for the different *MNIST* variants, centered RBMs outperformed normal RBMs on all three data sets.

We continued by training normal and centered RBMs with 500 hidden units on the three different data sets for 200 epochs. The setup for training and evaluating the models was



(a) *MNIST-Sampled* (b) *MNIST-Threshold*

Figure 18: Evolution of the LL of single trials on the test data of (a) *MNIST-Sampled* and (b) *MNIST-Threshold* for dd_s^b and 00 with 500 hidden units. The models were trained for 1000 epochs with a weight decay of 0.0002 and a momentum of 0.9 that was reduced to 0.5 after 5 epochs. The learning rate was either fixed to 0.01, decayed from 0.01 to 0.001 or from 0.01 to 0.0001 over 1000 epochs.

the same as described in Section 6. The maximum average LL values are given in Table 14, showing again that the reached LL on the different *MNIST* variants is quite different and that centered RBMs reach better values than normal RBMs on all three data sets.

In our experience the use of weight decay, momentum and an annealing learning rate is crucial to reach a LL that is comparable to the value of -86.34 reported by Salakhutdinov and Murray (2008). We therefore trained centered RBMs (dd_s^b) and normal RBMs (00) using PCD-25 for the extensive amount of 1000 epochs (600000 gradient updates). In addition a weight decay of 0.0002, and a momentum of 0.9 that was set to 0.5 after 5 epochs was used. The learning rate was fixed to 0.01 or either decayed from 0.01 to 0.001 or from 0.01 to 0.0001 over 1000 epochs.

The average LL on the test data of *MNIST-Sampled* for single trials are shown in Figure 18(a). It can be seen that a decaying learning rate is crucial for 00, which only reaches a value of -88.0 without decaying learning rate but -85.9 with a learning rate that decayed from 0.01 to 0.001. dd_s^b reaches a LL value of -86.2 without and -85.5 with a learning rate that decayed from 0.01 to 0.001. Although the difference between normal and centered RBMs become smaller with weight decay, dd_s^b still reaches a higher LL, seems to be less depended on the learning rate schedule and allows faster learning. We performed the same experiments also for the *MNIST-Threshold* data set. The results are shown in Figure 18(b), which show qualitatively the same results. The difference between 00 and dd_s^b is more prominent on the *MNIST-Threshold* where 00 reaches a LL value of -67.5 and dd_s^b reaches -65.0, which can also be seen from Table 14.

Abstract

The instrumental variable method consistently estimates the effect of a treatment when there is unmeasured confounding and a valid instrumental variable. A valid instrumental variable is a variable that is independent of unmeasured confounders and affects the treatment but does not have a direct effect on the outcome beyond its effect on the treatment. Two commonly used estimators for using an instrumental variable to estimate a treatment effect are the two stage least squares estimator and the control function estimator. For linear causal effect models, these two estimators are equivalent, but for nonlinear causal effect models, the estimators are different. We provide a systematic comparison of these two estimators for nonlinear causal effect models and develop an approach to combing the two estimators that generally performs better than either one alone. We show that the control function estimator is a two stage least squares estimator with an augmented set of instrumental variables. If these augmented instrumental variables are valid, then the control function estimator can be much more efficient than usual two stage least squares without the augmented instrumental variables while if the augmented instrumental variables are not valid, then the control function estimator may be inconsistent while the usual two stage least squares remains consistent. We apply the Hausman test to test whether the augmented instrumental variables are valid and construct a pretest estimator based on this test. The pretest estimator is shown to work well in a simulation study. An application to the effect of exposure to violence on time preference is considered.

Keywords: Causal Inference, Control Function Estimator,Endogenous Variable, Instrumental Variable Method, Two Stage Least Squares Estimator, Pretest Estimator.

1. Introduction

Randomized controlled studies are the gold standard to estimate the treatment effect. Unfortunately, randomized controlled studies are often not feasible because of cost or ethical constraints. When randomized studies are not feasible, observational studies provide an alternative source of data for estimating the treatment effect. Since treatments were not randomly assigned, a major concern in observational studies is the possible presence of unmeasured confounders that affect both the treatment and the outcome. The instrumental variable method is designed to estimate the effects of treatments when there are unmeasured confounders. The method requires a valid instrumental variable which is a variable that (1) is associated with the treatment conditioning on the measured covariates; (2) is independent of the unmeasured confounders conditioning on the measured covariates; (3) has no direct effect on the outcome beyond its effect on the treatment. The definition of an instrumental variable is illustrated in Figure 1, where the arrows represent the causal relationship. The lack of an arrow between the instrumental variable and unmeasured confounding represents assumption (2); The lack of an arrow between the instrumental variable and outcome represents assumption (3). The existence of an arrow between the treatment and instruments represents assumption (1) when the instrumental variable causes the treatment. Note that assumption (1) is also satisfied when the instrumental variable is associated with the treatment, but does not cause the treatment, see Hernan & Robins (2006). See Holland (1988), Angrist et al. (1996), Tan (2006), Cheng et al. (2009), Brookhart et al. (2009), Baiocchi et al. (2014) and Imbens (2014) for good discussions of instrumental variable methods.

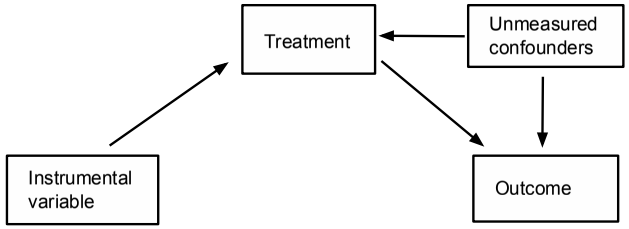

Figure 1: The directed acyclic graph for the relationship between the instrumental variable, treatment, unmeasured confounders and outcome.

Two commonly used methods for using an instrumental variable to estimate the treatment effect are the two stage least squares method and the control function method. Both of these methods are implemented in two stages. In the first stage of the two stage least squares method, we regress the treatment on the instruments and baseline covariates. In the second stage, the outcome is regressed on the predicted value from the first stage and baseline covariates and the coefficients of the second stage regression are taken as the two stage least squares estimates. Compared to the ordinary least squares method, the second stage of the two stage least squares method replaces the treatment with the corresponding predicted value from the first stage. The basic idea of the two stage least squares method is to extract variation in the treatment that is independent of the unmeasured confounders and use this variation to estimate the treatment effect. In contrast to two stage least squares, the control function method uses the instrumental variable to split the unmeasured confounders into two parts: one part that is correlated with the treatment and the other part that is uncorrelated with the treatment. The first stage of the control function method is similar

to that of the two stage least square method. In the second stage of the control function method, the outcome is regressed on the treatment, baseline covariates and the residual of the first stage regression and the coefficients of the second stage regression are taken as the control function estimates. Intuitively, the residual of the first stage regression accounts for the unmeasured confounders. The method is called the control function method because the effect of the unmeasured confounders is controlled for via the inclusion of the control function (residual of the first stage regression) in the second stage regression. The control function method has been developed in econometrics (Heckman (1976); Ahn & Powell (2004); Andrews & Schafgans (1998); Blundell & Powell (2004); Imbens & Wooldridge (2007)) and also in biostatistics and health services research (Nagelkerke et al (2000) and Terza et al. (2008)), where the method has been called the two stage residual inclusion method.

When the treatment has a linear effect on the outcome, then the control function method and two stage least squares produce identical estimates. However, when the treatment has a nonlinear effect on the outcome, then the methods produce different estimates. Settings in which the treatment is thought to have a nonlinear effect on the outcome are common; examples include the effect of the concentration of a drug in a person's body on the body's response (Nedelman et al, 2007), the effect of education on earnings (Card, 1994), the effect of a bank's financial capital on its costs (Hughes & Mester, 1998) and the effect of industry lobbying on government tariff policy (Gawande & Bandyopadhyay , 2000).

Imbens & Wooldridge (2007) conjectured that the control function estimator, while less robust than two stage least squares, might be much more precise because it keeps the treatment variables in the second stage. However, Imbens and Wooldridge note that a systematic comparison had not been done between the two estimators. The goal of this paper is to provide such a systematic comparison of the control function method to two stage least squares for nonlinear causal effect models.

We illuminate the relationship between control function and two stage least squares estimators by showing that the control function estimator is equivalent to a two stage least squares estimator with an augmented set of instrumental variables. When these augmented instrumental variables are valid, the control function method is more efficient than usual two stage least squares. For example, in the setting (1) of Table 1, the control function estimator is considerably more efficient than two stage least squares, sometimes more than 10 times more efficient. However, when the augmented instrumental variables are invalid, the control function method is inconsistent. Thus, the key issue for deciding whether to use the control function estimator vs. usual two stage least squares is whether the augmented instrumental variables are valid. The validity of the augmented instrumental variables can be tested using the Hausman test (Hausman, 1978). We develop a pretest estimator based on this test and show that it performs well in simulation studies, being close to the control function estimator when the augmented instrumental variables are valid and close to two stage least squares when the augmented instrumental variable are invalid. The pretest estimator combines the strengths of the control function and two stage least squares estimators.

Our paper is organized as follows. In section 2, we describe the set up of our model and how to implement the two stage least squares method and the control function method. In section 3, we describe how the control function method is equivalent to two stage least

squares with an augmented set of instrumental variables. In section 4, we describe the Hausman test for the validity of the augmented instrumental variables and formulate a pretest estimator. In section 5 , we present simulation studies comparing the control function method to the usual two stage least squares method. In section 6, we apply our methods to a study of the effect of exposure of violence on time preference. In section 7, we present discussions about more generalized models. In section 8, we conclude the paper. The proof of theorems, more simulation studies and two additional data analysis are presented in the Appendix.

2. Set up of model and description of methods

In this section, we introduce the model and describe the control function and the two stage least squares method. In Section 2.1, the model is introduced; In Section 2.2 and 2.3, we describe the two stage least squares method and the control function method, respectively. In Section 2.4, we discuss the assumptions for the control function method.

2.1 Set up of model

In this paper, our focus is on a model where the outcome variable is a non-linear function of the treatment variable. Let y_1 denote the outcome variable and y_2 denote the treatment variable. Let z_1 denote a vector of measured pre-treatment covariates and z_2 denote a vector of instrumental variables and $z = (z_1, z_2)$. In the following discussion, we assume both z_1 and z_2 are one dimensional. In section 3.4, we will extend the method to allow z_1 and z_2 to be vectors.

For defining the causal effect of the treatment, we use the potential outcome approach (Rubin (1974) and Neyman (1923)). Let $y_1^{(y_2^*)}$ denote the outcome that would be observed if the unit is assigned treatment level $y_2 = y_2^*$. An additive, non-linear causal effect model for the potential outcomes (similar to the linear causal effect model in Holland (1988)) is

$$y_1^{(y_2^*)} = y_1^{(0)} + \beta_1 g_1(y_2^*) + \beta_2 g_2(y_2^*) + \cdots + \beta_k g_k(y_2^*), \tag{1}$$

where $g_1(y_2^*) = y_2^*$ and $g_1, \cdots, g_k$ are linearly independent functions. Since g_1 is linear, $g_2, \cdots, g_k$ are non-linear functions. The causal effect of increasing y_2 from y_2^* to $y_2^* + 1$ is

$$(\beta_1(y_2^* + 1) + \beta_2 g_2(y_2^* + 1) + \cdots + \beta_k g_k(y_2^* + 1)) - (\beta_1 y_2^* + \beta_2 g_2(y_2^*) + \cdots + \beta_k g_k(y_2^*)).$$

We assume that the pretreatment covariate z_1 has a linear effect on potential outcomes, $E\left(y_1^{(0)}|z_1\right) = \beta_0 + \beta_{k+1} z_1$ and denote the residual by $u_1 = y_1^{(0)} - E(y_1^{(0)}|z_1)$. The model for the observed data is

$$y_1 = \beta_0 + \beta_1 g_1(y_2) + \beta_2 g_2(y_2) + \cdots + \beta_k g_k(y_2) + \beta_{k+1} z_1 + u_1, \tag{2}$$

where y_2 is the observed value of the treatment variable and $g_1(y_2) = y_2$. For identifiability, we assume that $g_i(0) = 0$ for $2 \le i \le k$. We also assume that y_2's expectation given z_1 and z_2 is linear in parameters but possibly nonlinear in z_1 and z_2,i.e.,

$$y_2 = \alpha_0 + \alpha_1^T \mathbf{J}(z_1) + \alpha_2^T \mathbf{H}(z_2) + v_2, \tag{3}$$

where $\alpha_2 \neq \mathbf{0}$, z_1 and z_2 are independent of u_1 and v_2, u_1 and v_2 are potentially correlated, and $\mathbf{H} = (z_2, h_2(z_2), \cdots, h_k(z_2))$ is a known vector of linearly independent functions of z_2. $\mathbf{J}$ is a known vector of functions, which can be a nonlinear function, for simplicity of notation, we will assume a linear effect of z_1 henceforth,

$$y_2 = \alpha_0 + \alpha_1 z_1 + \alpha_2^T \mathbf{H}(z_2) + v_2, \tag{4}$$

We say that $I(z_2) = (z_2, h_2(z_2) \cdots, h_k(z_2))$ are valid instrumental variables if $I(z_2)$ satisfies the following two assumptions (Stock (2002), White (1984)(p.8) and Wooldridge (2010)(p.99)):

Assumption 1 (***Relevance***) *The instruments are correlated with the endogenous variables* $W = (g_1(y_2), \cdots, g_k(y_2))$ *given* z_1*, that is,* $E\left(WI(z_2)^T | z_1\right)$ *is of full column rank.*

Assumption 2 (***Exogeneity***) *The instruments are uncorrelated with the error in (2), that is,*

$$E(I(z_2)u_1) = 0.$$

To ensure assumption 1, we need to have at least k valid instrument variables for $g_1(y_2), \cdots, g_k(y_2)$. This requires that the instrument z_2 has at least k different values. Otherwise, we cannot construct k linearly independent functions of z_2 to be instruments for $g_1(y_2), \cdots, g_k(y_2)$.

Remark 1 *In econometric terminology,* y_2 *is called an endogenous variable,* z_1 *are called included exogenous variables and* $I(z_2) = (z_2, h_2(z_2) \cdots, h_k(z_2))$ *is called an excluded exogenous variable. Sometimes* $z_1, z_2, h_2(z_2), \cdots, h_k(z_2)$ *together are referred to as the instrumental variables (i.e., both the included and excluded exogenous variables), but we will just refer to* $I(z_2) = (z_2, h_2(z_2) \cdots, h_k(z_2))$ *(the excluded exogenous variable) as the instruments. Assumption 1 is called the rank condition in the econometric literature while* $r \geq k$ *is called the order condition. As discussed in Wooldridge (2010)(p.99), the order condition is necessary for the rank condition.*

Remark 2 *Sufficient conditions for Assumption 2 to hold are that (i)* I *is independent of the potential outcome* $y_1^{(0)}$ *after controlling for the measured confounders* z_1*, that is* I *is independent of unmeasured confounders and (ii)* I *has no direct effect on* y_1 *and only affects* y_1 *through* y_2*. These conditions are discussed by Holland (1988).*

2.2 Description of two stage least squares method

In the following, we will describe the two stage least squares (2SLS) method briefly. Let $y \sim x_1 + x_2$ denote linear regression of y on x_1, x_2 and an intercept. Following Kelejian (1971), the usual two stage least squares estimator is introduced as Algorithm 1.

We will refer to this as the usual two stage least squares method as we will show in section 3 that the control function method can be viewed as a two stage least squares method with an augmented set of instruments.

Let $L(y|x)$ denote the best linear projection $\gamma^T x$ of y onto x where $\gamma = \arg\min_\tau E\left((y - \tau^T x)^2\right)$. Let $Z = \{1, z_1, z_2, h_2(z_2), \cdots, h_k(z_2)\}$ denote the exogenous variables. The linear projection

Algorithm 1 Two stage least squares estimator (2SLS)

Input: i.i.d observations of pre-treatment covariates z_1, instrumental variables $(z_2, h_2(z_2) \cdots, h_k(z_2))$, the treatment variable y_2 and outcome variable y_1.

Output: The two stage least squares estimator $\widehat{\beta}^{\text{2SLS}}$ of treatment effects $\beta = (\beta_1, \beta_2, \cdots, \beta_k)$ in (2).

1: Implement the regression

$$\begin{aligned} y_2 &\sim z_1 + z_2 + h_2(z_2) + \cdots + h_k(z_2), \\ &\vdots \\ g_k(y_2) &\sim z_1 + z_2 + h_2(z_2) + \cdots + h_k(z_2), \end{aligned} \tag{5}$$

and obtain the corresponding predicted values as $\left(\widehat{y_2}, \widehat{g_2(y_2)}, \cdots, \widehat{g_k(y_2)}\right)$.

2: Implement the regression:

$$y_1 \sim \widehat{y_2} + \cdots + \widehat{g_k(y_2)} + z_1. \tag{6}$$

The two stage least squares estimates are the coefficient estimates on $y_2, g_2(y_2), \cdots, g_k(y_2)$ from (6).

of y_1 onto $1, L(g_1(y_2)|Z), \cdots, L(g_k(y_2)|Z), z_1$ is

$$L(y_1|1, L(g_1(y_2)|Z), \cdots, L(g_k(y_2)|Z), z_1) = \beta_0 + \sum_{i=1}^{k} \beta_i L(g_i(y_2)|Z) + \beta_{k+1} z_1.$$

Thus, if we know $L = \{L(g_1(y_2)|Z), \cdots, L(g_k(y_2)|Z)\}$, then the least squares estimate of y on $1, L(g_1(y_2)|Z), \cdots, L(g_k(y_2)|Z), z_1$ will provide an unbiased estimate of β. Even though L is unknown, we can obtain a consistent estimate of L. Substituting this estimate into the second stage regression provides a consistent estimate of β under regularity conditions. See White (1984)(p21, p32) for the details.

2.3 Description of the control function method

We introduce the control function (CF) method in Algorithm 2.

2.4 Additional assumptions of control function

The consistency of control function estimators requires stronger assumptions than $I(z_2)$ satisfying Assumptions 1 and 2, that is, stronger than $I(z_2)$ being valid instrumental variables. The control function method is consistent under the following additional assumptions in addition to Assumptions 1 and 2 (Imbens & Wooldridge , 2007):

Assumption 3 u_1 *and* v_2 *are independent of* $z = (z_1, z_2)$.

Assumption 4 $E(u_1|v_2) = L(u_1|v_2)$ *where* $L(u_1|v_2) = \rho v_2$ *and* $\rho = \frac{E(u_1 v_2)}{E(v_2^2)}$.

Algorithm 2 Control function estimator (CF)

Input: i.i.d observations of pre-treatment covariates z_1, instrumental variables $(z_2, h_2(z_2)\cdots, h_k(z_2))$, the treatment variable y_2 and outcome variable y_1.

Output: The control function estimator $\widehat{\beta}^{\text{CF}}$ of treatment effects $\beta = (\beta_1, \beta_2, \cdots, \beta_k)$ in (2).

1: Implement the regression

$$y_2 \sim z_1 + z_2 + h_2(z_2) + \cdots + h_k(z_2) \tag{7}$$

and obtain the predicted value $\widehat{y_2}$ and the residual $e_1 = y_2 - \widehat{y_2}$.

2: Implement the regression

$$y_1 \sim y_2 + \cdots + g_k(y_2) + z_1 + e_1. \tag{8}$$

The control function estimates are the coefficient estimates on $y_2, g_2(y_2), \cdots, g_k(y_2)$ from the above regression (8).

Remark 3 *We only assume $z = (z_1, I(z_2))$ is uncorrelated with u_1 in Assumption 2. Two stage least squares does not make assumptions about v_2 but the control function method relies on assumptions about v_2. If (u_1, v_2) follow bivariate normal distribution, Assumption 4 is satisfied automatically.*

Model (29) is an example where $I(z_2) = \left(z_2, z_2^2\right)$ are valid instrumental variables that satisfy Assumptions 1 and 2 but not Assumption 3 and 4. The simulation results in Table 1 show that the control function estimate for model (29) is biased.

Assumptions 3 and 4 are sufficient but not necessary conditions for the control function method to be consistent. To investigate the consistency of the control function method, we can express (2) as

$$y_1 = \beta_0 + \beta_1 g_1(y_2) + \beta_2 g_2(y_2) + \cdots + \beta_k g_k(y_2) + \beta_{k+1} z_1 + \rho v_1 + e, \tag{9}$$

where e is $u_1 - \rho v_2$. Under some regularity conditions (Wooldridge (2010) p.56), one sufficient condition for the control function method to be consistent is that the new error e in (9) is uncorrelated with $g_i(y_2)$:

$$E\left(g_i(y_2)e\right) = 0 \quad \text{for} \quad i = 1, \cdots, k. \tag{10}$$

Assumptions 1,2, 3 and 4 lead to $E\left(f(y_2)e\right) = 0$ for all f, which is stronger than the sufficient condition (10). In Section 4, we develop a test for the consistency of the control function method that can help to decide whether the control function estimator should be used.

3. Relation between control function and two stage least squares

In this section, we compare the control function and the two stage least squares estimator. To better understand the control function method, we will first focus on the case $k = 2$

$$y_1 = \beta_0 + \beta_1 y_2 + \beta_2 g_2(y_2) + \beta_3 z_1 + u_1;$$

$$y_2 = \alpha_0 + \alpha_1 z_1 + \alpha_2 z_2 + \alpha_3 h_2(z_2) + v_2.$$

For example, a common model has $g_2(y_2) = y_2^2$ and $h_2(z_2) = z_2^2$.

3.1 Loss of information for the control function method and comparison to two stage least squares

Two stage least squares regresses y_1 on $\widehat{y_2} = LS\left(y_2|1, z_1, z_2, h_2(z_2)\right)$, $\widehat{g_2(y_2)} = LS\left(g_2(y_2)|1, z_1, z_2, h_2(z_2)\right)$ and z_1 where $LS(A|B)$ denotes the least square estimate of the linear projection of A onto span(B). The control function estimator regresses y_1 on $y_2, g_2(y_2), z_1$ and $e_1 = y_2 - \widehat{y_2}$. Intuitively, it seems that the control function method is better than two stage least squares since it keeps y_2 and $g_2(y_2)$ in the second stage regression rather than losing information by replacing y_2 and $g_2(y_2)$ by projections as two stage least squares does. However, the control function method also loses information as explained in the following theorem.

Theorem 1 *The following regression*

$$y_1 \sim z_1 + \widetilde{y_2} + \widetilde{g_2(y_2)},$$

will have the same estimates of the corresponding coefficients as the second stage regression of the control function method:

$$y_1 \sim z_1 + y_2 + g_2(y_2) + e_1,$$

where e_1 is the residual of the regression $y_2 \sim z_1 + z_2 + h_2(z_2)$ and $\widetilde{y_2}$ is the residual of the regression $y_2 \sim e_1$ and $\widetilde{g_2(y_2)}$ is the residual of the regression $g_2(y_2) \sim e_1$. *By the property of OLS, $\widetilde{y_2}$ differs from $\hat{y}_2$ only by a constant.*

Proof In appendix B. ■

From Theorem 1, the control function method can be viewed as a two stage estimator similar to two stage least squares: in the first stage, the exogenous part of the endogenous variables, $\widetilde{y_2}$ and $\widetilde{g_2(y_2)}$, are obtained by taking residuals from regressing y_2 and $g_2(y_2)$ on the variable e_1 respectively and in the second stage, the endogenous variables in the regression are replaced by the exogenous parts.

Although both the control function method and two stage least squares lose information by projecting $g_2(y_2)$ and y_2 to subspaces, the control function method does preserve more information. Let $(\text{span}\{e_1\})^{\perp}$ denote the orthogonal complement of the space spanned by the vector e_1 and span$\{1, z_1, z_2, h_2(z_2)\}$ denote the space spanned by the vectors $1, z_1, z_2, h_2(z_2)$. The control function method projects $g_2(y_2)$ and y_2 to $(\text{span}\{e_1\})^{\perp}$ while two stage least squares projects $g_2(y_2)$ and y_2 to span$\{1, z_1, z_2, h_2(z_2)\}$, which is a subspace of $(\text{span}\{e_1\})^{\perp}$. We will now show that the control function method is equivalent to two stage least squares with an augmented set of instrumental variables.

3.2 Equivalence of control function to two stage least squares with an augmented set of instrumental variables

In section 3.1, we showed that the first stage projection space of the control function estimator is larger than that of the two stage least squares estimator. One natural question

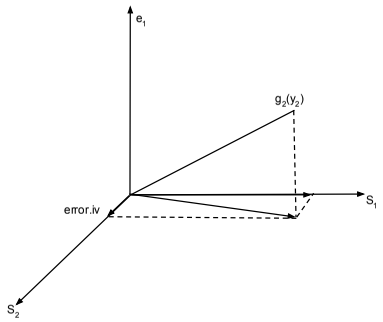

Figure 2: Projection and Decomposition of the control function Estimator. $S_1 = \text{span}\{1, z_1, z_2, h_2(z_2)\}$ and $S_2 = \text{span}\{error.iv\}$ is defined as the orthogonal complement of S_1 in the subspace $\text{span}\{e_1\}^{\perp}$.

is what is the extra part of the control function first stage projection space. The following theorem explains the extra part.

Theorem 2 *The following two regressions give the same estimates of corresponding coefficients*

$$g_2(y_2) \sim z_1 + z_2 + h_2(z_2);$$
$$\widetilde{g_2(y_2)} \sim z_1 + z_2 + h_2(z_2).$$

Proof In appendix B. ■

Theorem 2 implies that regressing the control function first stage estimate of $g_2(y_2)$, $\widetilde{g_2(y_2)}$ on $\{1, z_1, z_2, h_2(z_2)\}$ produces the same predicted value for $g_2(y_2)$ as that of the first stage of two stage least squares. Consequently, the control function method first stage estimate $\widetilde{g_2(y_2)}$ can be decomposed into two orthogonal parts: one part is the same with the two stage least squares first stage estimate and the other part is denoted as $error.iv$. Letting $\gamma_0, \gamma_1, \gamma_2, \gamma_3$ denote the coefficients in $g_2(y_2) \sim z_1 + z_2 + h_2(z_2)$, we define

$$error.iv = \widetilde{g_2(y_2)} - (\gamma_0 + \gamma_1 z_1 + \gamma_2 z_2 + \gamma_3 h_2(z_2)). \tag{11}$$

The decomposition is shown in Figure 2. Let $S_1 = \text{span}\{1, z_1, z_2, h_2(z_2)\}$ and $S_2 = \text{span}\{error.iv\}$. The projection of $g_2(y_2)$ to the space $S_1 \cup S_2$ is the control function first stage predicted value $\widetilde{g_2(y_2)}$ while the projection of $g_2(y_2)$ to the space S_1 is the two stage least squares first stage predicted value $\widehat{g_2(y_2)}$. The projection along the direction of $error.iv$ represents the extra part of the control function projection.

Since $\widetilde{g_2(y_2)}$ is the residual of the regression $g_2(y_2) \sim e_1$, the first stage regression of control function estimation can be written as

$$\begin{aligned} g_2(y_2) &= \gamma_c + \gamma e_1 + \widetilde{g_2(y_2)} \\ &= \gamma_c + \gamma e_1 + \gamma_0 + \gamma_1 z_1 + \gamma_2 z_2 + \gamma_3 h_2(z_2) + error.iv \end{aligned} \tag{12}$$

where the column vector e_1 is orthogonal to the column vectors $z_2, h_2(z_2), error.iv$ and $error.iv$ is orthogonal to z_1, z_2 and $h_2(z_2)$ by the property of OLS. The following theorem shows the equivalence of the control function estimator to the two stage least squares method with an augmented set of instruments.

Theorem 3 *The control function estimator with instruments $z_1, z_2, h_2(z_2)$ in the first stage is equivalent to the two stage least squares estimator with instruments $z_1, z_2, h_2(z_2), error.iv$ in the first stage.*

Proof In appendix B. ■

We now show that if Assumptions 3 and 4 do hold, the extra instrument $error.iv$ is a valid instrumental variable, that is, $error.iv$ satisfies Assumptions 1 and 2. Recall the definition $e = u_1 - \rho v_2$. By Assumptions 3 and 4, $E(g_2(y_2)\, e) = 0$ and the population version of $error.iv$ is

$$g_2(y_2) - L(g_2(y_2) | v_2, z_1, z_2, h_2(z_2))$$

where L means the linear projection. Since v_2 and $z_1, z_2, h_2(z_2)$ are uncorrelated with e,

$$E(error.iv \times e) = E((g_2(y_2) - L(g_2(y_2) | v_2, z_1, , h_2(z_2)))\, e) = 0.$$

3.3 Equivalence of control function with two stage least squares with augmented instruments for general nonlinear model

In the last section, we showed the equivalence of control function with two stage least squares for $k = 2$. In this section, we will show the results hold for $k \geq 3$ and present an algorithm to find the augmented set of instrumental variables for the general model. This will help us understand the control function estimator's properties since two stage least squares' properties are well understood (See Remarks 2 and section 3.5 below).

We will first consider $k = 3$ in our general model (2) and then it will be straightforward to generalize to $k > 3$. The model for $k = 3$ is

$$y_1 = \beta_0 + \beta_1 y_2 + \beta_2 g_2(y_2) + \beta_3 g_3(y_2) + \beta_4 z_1 + u_1.$$

Let $I = \{z_2, h_2(z_2), h_3(z_2)\}$ be valid instrumental variables for $y_2, g_2(y_2), g_3(y_2)$. As in the case of $k = 2$, we can find the extra instrument $error.iv_1$ for $g_2(y_2)$. If we do the same thing for $g_3(y_2)$, we will obtain the extra instrumental variable, $error.iv_2.prime$. However, there exists the problem that the error instrument $error.iv_2.prime$ is not orthogonal to $error.iv_1$. This will make $error.iv_2.prime$ have a non-zero coefficient when we treat $error.iv_2.prime$ as one of the instrumental variables for $g_2(y_2)$. The non-zero coefficient will lead to the estimate of $g_2(y_2)$ being different from what is used in the second stage of control function. To remove the correlation, we do the regression

$$error.iv_2.prime \sim error.iv_1,$$

and treat the residual of this regression as $error.iv_2$.

Theorem 4 *If we regress y_2 on $z_1, z_2, h_2(z_2), h_3(z_2)$ in the first stage, then the control function estimator is equivalent to two stage least squares with the augmented set of instrumental variables $z_1, z_2, h_2(z_2), h_3(z_2), error.iv_1, error.iv_2$.*

Proof In appendix B. ■

Remark 4 *Since the control function method is the same as two stage least squares with an augmented set of instrumental variables, we can calculate the variance of control function estimators with the help of the known variance formula for two stage least squares (Wooldridge (2010), page 102).*

This generalizes to the general $k > 3$ model. The following is an algorithm to identify the augmented set of instrumental variables for which the control function estimator is equivalent to two stage least squares with the augmented set of instrumental variables. Recall that e_1 denotes the residual of the regression $y_2 \sim z_1 + z_2 + h_2(z_2) + h_3(z_2)$ and $\widetilde{g_i(y_2)} = resid(g_i(y_2) \sim e_1)$. Set the control function projection space $S_1 = \text{span}\{z_1, z_2, h_2(z_2), h_3(z_2)\}$ for y_2. Regress $\widetilde{g_2(y_2)}$ on the space S_1 to obtain the residual $error.iv_1$ and set the control function projection space $S_2 = S_1 \oplus \text{span}\{error.iv_1\}$, where $\oplus$ denotes the direct sum of two subspaces. For $g_j(y_2), j = 3, \cdots, k$, regress $\widetilde{g_j(y_2)}$ on S_{j-1} to obtain the extra instrument $error.iv_j$, and set the control function projection space $S_j = S_{j-1} \oplus \text{span}\{error.iv_j\}$. This algorithm will produce the corresponding set of instrumental variables for the control function method. Each nonlinear function of endogenous variables will contribute one extra instrumental variable.

We can generalize Theorem 4 to models with $k > 3$.

Theorem 5 *If we regress y_2 on $z_1, z_2, h_2(z_2), \cdots, h_k(z_2)$ in the first stage, then the control function estimator is equivalent to two stage least squares with the augmented set of instrumental variables $z_1, z_2, h_2(z_2), \cdots, h_k(z_2), error.iv_1, error.iv_2, \cdots, error.iv_{k-1}$.*

The proof of Theorem 4 applies to this generalized theorem.

3.4 General nonlinear model of multidimensional instruments $\mathbf{z}_2$

In this section, we extend our results to allow $\mathbf{z}_1$ and $\mathbf{z}_2$ to be vectors. In the vector case, the first stage model is extended as

$$y_2 = \alpha_0 + \alpha_1^T \mathbf{J}(\mathbf{z}_1) + \alpha_2^T \mathbf{H}(\mathbf{z}_2) + v_2, \tag{13}$$

where $\mathbf{J}$ is a known vector of functions of $\mathbf{z}_1$ and $\mathbf{H} = (\mathbf{z}_2, h_2(\mathbf{z}_2), \cdots, h_k(\mathbf{z}_2))$ is a known vector of linearly independent functions of $\mathbf{z}_2$.

The first stage of two stage least squares is extended as

$$\begin{aligned} y_2 &\sim \mathbf{J}(\mathbf{z}_1) + \mathbf{z}_2 + h_2(\mathbf{z}_2) + \cdots + h_k(\mathbf{z}_2), \\ &\vdots \\ g_k(y_2) &\sim \mathbf{J}(\mathbf{z}_1) + \mathbf{z}_2 + h_2(\mathbf{z}_2) + \cdots + h_k(\mathbf{z}_2), \end{aligned} \tag{14}$$

where the notation $y \sim \mathbf{x}$, where $\mathbf{x} = (\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_s)$ denotes linear regression of y on $\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_s$ and an intercept. From these k first stage regression, we obtain the predicted values of k first stage regressions as $\left(\widehat{y_2}, \widehat{g_2(y_2)}, \cdots, \widehat{g_k(y_2)}\right)$. In the second stage, we do the following regression:

$$y_1 \sim \widehat{y_2} + \cdots + \widehat{g_k(y_2)} + \mathbf{z}_1. \tag{15}$$

The first stage of the control function method is

$$\begin{aligned} &y_2 \sim \mathbf{J}(\mathbf{z}_1) + \mathbf{z}_2 + h_2(\mathbf{z}_2) + \cdots + h_k(\mathbf{z}_2); \\ &e_1 = y_2 - \widehat{y_2}. \end{aligned} \tag{16}$$

In the second stage, we do the following linear regression:

$$y_1 \sim y_2 + \cdots + g_k(y_2) + \mathbf{z}_1 + e_1. \tag{17}$$

The generalization of Theorem 4 and Theorem 5 is as follows:

Theorem 6 *If we regress y_2 on $\mathbf{J}(\mathbf{z}_1), \mathbf{z}_2, h_2(\mathbf{z}_2), \cdots, h_k(\mathbf{z}_2)$ in the first stage, then the control function estimator is equivalent to two stage least squares with the augmented set of instrumental variables $\mathbf{J}(\mathbf{z}_1), \mathbf{z}_2, h_2(\mathbf{z}_2), \cdots, h_k(\mathbf{z}_2), error.iv_1, error.iv_2, \cdots, error.iv_{k-1}$.*

The proof of Theorem 4 applies to this generalized theorem.

3.5 Control function bias formula

To ensure consistency of the control function estimation, the Assumptions 1 and 2 of $z_2, h_2(z_2), \cdots, h_k(z_2)$ being valid instruments are not enough and extra assumptions are needed, such as Assumptions 3 and 4. We will present a formula for the asymptotic bias of the control function method when the extra assumptions of control function are not satisfied. Since we have shown that the control function estimator is a two stage least squares estimator with augmented instrumental variables (Sections 3.2 and 3.3), we could make use of the bias formula of two stage least squares with invalid instrumental variables given in Small (2007).

Let Y_N denote the vector of the outcome variable y_1, W_N denote the matrix whose columns are the endogenous variable $y_2, g_2(y_2), \cdots, g_k(y_2)$, X_N denote the matrix whose columns are the included exogenous variables z_1 and Z_N denote the matrix whose columns are the instrumental variables $z_2, h_2(z_2), \cdots, h_k(z_2)$ for W_N. Let $C_N = [W_N, X_N]$ and $D_N = [Z_N, X_N]$. In the second stage, we will replace C_N by the first stage predicted values $\widehat{C_N} = D_N\left(D_N^T D_N\right)^{-1} D_N^T C_N$. The two stage least squares estimator is $\left(\widehat{C_N}^T \widehat{C_N}\right)^{-1} \widehat{C_N}^T Y_N$. When the instrumental variables are not valid, there exists asymptotic bias for the estimator given in the second stage. For the model

$$y_1 = \beta_0 + \beta_1 g_1(y_2) + \cdots + \beta_k g_k(y_2) + \beta_{k+1} z_1 + u_1 \tag{18}$$

we could write u_1 as

$$u_1 = LP(u_1|Z) + u_1 - LP(u_1|Z) \tag{19}$$

where Z denote the instrumental variables and and $u_1 - LP(u_1|Z)$ is uncorrelated with Z by the property of OLS. Plugging (19) into (18):

$$y_1 = \beta_0 + \beta_1 y_2 + \beta_2 y_2^2 + \beta_3 z_1 + LP(u_1|Z) + u_1 - LP(u_1|Z)$$

$$y_1 - LP(u_1|Z) = \beta_0 + \beta_1 y_2 + \beta_2 y_2^2 + \beta_3 z_1 + u_1 - LP(u_1|Z) \tag{20}$$

For (20), we could make use of the two stage least squares method with the outcome variable $y_1 - LP(u_1|Z)$ to obtain the consistent estimate $\left(\widehat{C_N}^T \widehat{C_N}\right)^{-1} \widehat{C_N}^T \left[Y_N - LP(U_N|Z_N)\right]$, where U_N denotes the vector of error u_1 in the second stage. Hence a consistent estimator of the asymptotic bias from using the control function method is

$$\left(\widehat{C_N}^T \widehat{C_N}\right)^{-1} \widehat{C_N}^T LP(U_N|Z_N) \tag{21}$$

The control function bias formula (21) shows that in order for the control function estimator to be asymptotically unbiased, all augmented instruments are required to be uncorrelated with the error of the second stage. It is possible that the augmented instruments are correlated with the second stage error even when Z_N are valid instrumental variables. See the simulation study in section 5.3 for an example. In Section 4, we develop a test for whether the augmented instruments are correlated with the error of the second stage.

3.6 Comparison between usual two stage least squares and control function

In this section, we compare usual two stage least squares (i.e., without any augmented instruments) to the control function method under the assumptions 1 and 2 of valid instruments and the additional assumptions 3 and 4 of the control function method. For $k = 3$, $X = (y_2, g_2(y_2), g_3(y_2))$ denote the endogenous variables and $Z_1 = (z_1, z_2, h_2(z_2), h_3(z_2))$ denote the instrumental variables. $Z_2 = (error.iv_1, error.iv_2)$ denote the augmented instruments and $\widetilde{X} = (e_1, \delta_0 e_1 + error.iv_1, \delta_1 e_1 + \delta_2 error.iv_1 + error.iv_2)$ denote the residual of regressing X on Z_1. According to White (1984), the asymptotic variance of a two stage least squares estimator will not increase when adding extra valid instruments and will decrease as long as the extra valid instruments are correlated with the endogenous variables given the current instruments. In our setting, adding Z_2 to the list of instrumental variables will decrease the asymptotic variance if Z_2 is correlated with $\widetilde{X}$. Since $E(e_1 \times error.iv) = 0$, we have $E(error.iv_1 \widetilde{X}) = \left(0, E(error.iv_1^2), \delta_2 E(error.iv_1^2)\right)$ and $E(error.iv_2 \widetilde{X}) = \left(0, 0, E(error.iv_1^2)\right)$. Assume

$$g_2(y_2) \text{ is not a linear combination of } \quad 1, e_1, z_1, z_2 \text{ and } h_2(z_2) \quad \text{almost surely,} \tag{22}$$

we have $E(error.iv_1^2) > 0$ and $E(error.iv_1 \widetilde{X}) \neq 0$ and $E(error.iv_2 \widetilde{X}) \neq 0$. Hence, it follows that the control function estimator is strictly better than two stage least squares under the assumptions 1 and 2 of valid instruments, the additional assumptions 3 and 4 of the control function method and the functional assumption (22). Since e_1 is a linear function of y_2, the functional assumption (22) is saying that the nonlinear functional $g_2(y_2)$ cannot be expressed as a linear combination of linear functions of y_2 and the other variables

$1, z_1, z_2, h_2(z_2)$. For example, assuming the first stage model (13) and $g_2(y_2) = y_2^2$ and $h_2(z_2) = z_2^2$, the functional assumption (22) is automatically satisfied.

We have shown that the control function estimator is equivalent to the two stage least squares estimator with an augmented set of instrumental variables and certain assumptions will make the control function estimator consistent and more efficient than the two stage least squares estimator. Just as we can view the control function estimator as one type of two stage least squares estimator, we can view the usual two stage least squares estimator without the augmented instruments as one type of control function estimator. For $k = 3$, if we include e_1, e_2 and e_3, which are the residuals of the regression $y_2 \sim z_1 + z_2 + h_2(z_2) + h_3(z_2)$, $g_2(y_2) \sim z_1 + z_2 + h_2(z_2) + h_3(z_2)$ and $g_3(y_2) \sim z_1 + z_2 + h_2(z_2) + h_3(z_2)$ respectively, in the second stage regression, this control function estimator is the same as the usual two stage least squares estimator without the augmented instruments.

4. A pretest estimator

We will explain how to test the validity of the augmented instrumental variables the control function method uses for $k = 2$; it is straightforward to extend the test to the more general model. Recall the instruments for the usual two stage least squares estimator: $Z_1 = (1, z_1, z_2, h_2(z_2))$; As we have shown (Sections 3.2 and 3.3), the control function estimator is a two-stage estimator with the instruments $Z = (Z_1, error.iv)$, where $error.iv$ is the augmented instrumental variable. We use $\widehat{\beta}^{\text{2SLS}}$ to denote the usual two stage least squares estimator with instruments Z_1 and use $\widehat{\beta}^{\text{CF}}$ to denote the two stage least squares estimator with the augmented set of instruments Z. Under the null hypothesis that the augmented instrumental variable $error.iv$ is valid, the two estimators are consistent and $\widehat{\beta}^{\text{CF}}$ is efficient. Under the alternative hypothesis that the augmented instrumental variable $error.iv$ is invalid, $\widehat{\beta}^{\text{2SLS}}$ is consistent while $\widehat{\beta}^{\text{CF}}$ is not consistent.

The Hausman test (Hausman (1978)) provides a test for the validity of the augmented instrumental variable $error.iv$. The test statistic $H(\widehat{\beta}^{\text{CF}}, \widehat{\beta}^{\text{2SLS}})$ is defined as

$$H(\widehat{\beta}^{\text{CF}}, \widehat{\beta}^{\text{2SLS}}) = \left(\widehat{\beta}^{\text{CF}} - \widehat{\beta}^{\text{2SLS}}\right)^T \left[Cov\left(\widehat{\beta}^{\text{2SLS}}\right) - Cov\left(\widehat{\beta}^{\text{CF}}\right)\right]^- \left(\widehat{\beta}^{\text{CF}} - \widehat{\beta}^{\text{2SLS}}\right), \tag{23}$$

where $Cov\left(\widehat{\beta}^{\text{CF}}\right)$ and $Cov\left(\widehat{\beta}^{\text{2SLS}}\right)$ are the covariance matrices of $\widehat{\beta}^{\text{CF}}$ and $\widehat{\beta}^{\text{2SLS}}$ and A^- denote the Moore-Penrose pseudoinverse. Under the null hypothesis where the augmented instrument $error.iv$ is valid, the test statistic $H(\widehat{\beta}^{\text{CF}}, \widehat{\beta}^{\text{2SLS}})$ is asymptotically χ_1^2.

Based on the statistic $H(\widehat{\beta}^{\text{CF}}, \widehat{\beta}^{\text{2SLS}})$, we introduce a pretest estimator in Algorithm 3, which uses the control function estimator if there is not evidence that it is inconsistent and otherwise uses the usual two stage least squares estimator.

For the rest of the paper, we will use $\alpha = 0.05$ in Algorithm 3. If the p-value of the test statistic $H(\widehat{\beta}^{\text{CF}}, \widehat{\beta}^{\text{2SLS}})$ is less than 0.05, then there is evidence that the control function estimator is inconsistent and the usual two stage least squares estimator is used; otherwise, the control function estimator is used.

Algorithm 3 Pretest estimator

Input: i.i.d observations of pre-treatment covariates z_1, instrumental variables $(z_2, h_2(z_2) \cdots, h_k(z_2))$, the treatment variable y_2, outcome variable y_1 and level α.

Output: The pretest estimator of treatment effects $\beta = (\beta_1, \beta_2, \cdots, \beta_k)$ in (2).

1: Implement Algorithm 1 and obtain the estimator $\widehat{\beta}^{\text{2SLS}}$ and the corresponding covariance structure $Cov\left(\widehat{\beta}^{\text{2SLS}}\right)$. Implement Algorithm 2 and obtain the estimator $\widehat{\beta}^{\text{CF}}$ and the corresponding covariance structure $Cov\left(\widehat{\beta}^{\text{CF}}\right)$.

2: Calculate the test statistic $H(\widehat{\beta}^{\text{CF}}, \widehat{\beta}^{\text{2SLS}})$ as (23) and define the p-value $p = P\left(\chi^2(1) \geq H(\widehat{\beta}^{\text{CF}}, \widehat{\beta}^{\text{2SLS}})\right)$. The level α pretest estimator is defined as

$$\widehat{\beta}^{\text{Pretest}} = \begin{cases} \widehat{\beta}^{\text{CF}} & \text{if } p > \alpha \\ \widehat{\beta}^{\text{2SLS}} & \text{if } p \leq \alpha \ . \end{cases} \tag{24}$$

5. Simulation study

Our simulation study compares the usual two stage least squares (2SLS) estimator, the control function (CF) estimator and the pretest estimator. We will consider several different model settings where the assumptions of the control function estimator are satisfied, moderately violated (two settings) and drastically violated and we will also investigate the sensitivity of the control function estimator to different joint distributions of errors. The sample size is 10,000 and we implement 10,000 simulations for each setting. We report the winsorized sample mean of the estimators (WMEAN) and the winsorized root mean square error (WRMSE). The non-winsorized sample mean of the estimators (NWEAN) and the non-winsorized root mean square error (NRMSE) are reported in the appendix C. The winsorized statistics are implemented as setting the 95-100 percentile as the 95-th percentile and the 0-5 percentile as the 5-th percentile and using the winsorized data to calculate the mean and root mean square error. The winsorized statistics are less sensitive to outliers (Wilcox & Keselman , 2003). The non-winsorized results summarized in the appendix C have similar patterns as the winsorized results reported in the following discussion. The outcome model that we are considering is

$$y_1 = \beta_0 + \beta_1 z_1 + \beta_2 y_2 + \beta_3 y_2^2 + u_1; \tag{25}$$

In the following subsections, we will generate y_2 according to different models.

5.1 Setting where the assumptions of the control function estimator are satisfied

For the setting where the assumptions of control function estimator are satisfied, the model we consider is:

$$\begin{aligned} y_1 &= 1 + z_1 + 10y_2 + 10y_2^2 + u_1; \\ y_2 &= 1 + \frac{1}{8}z_1 + \frac{1}{3}z_2 + \frac{1}{8}z_2^2 + v_2; \end{aligned} \tag{26}$$

where $z_1 \sim N(0,1)$ and $z_2 \sim N(0,1)$ and $\begin{pmatrix} u_1 \\ v_2 \end{pmatrix} \sim N\left[\begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} 1 & 0.5 \\ 0.5 & 1 \end{pmatrix}\right]$. Setting (1) of Table 1 presents the absolute value of ratio of bias of the sample winsorized mean to the true value and the ratio of the sample winsorized root mean square error to the sample winsorized root mean square error of the two stage least squares estimator, where the columns under WMEAN present absolute value of the ratio of the bias and the columns under the WRMSE present the ratio of the root mean square error. Since the ratio of the sample winsorized root mean square error is using the sample winsorized root mean square error of the two stage least squares estimator as the basis, we only report the ratio of the ratio of the sample winsorized root mean square error for the control function estimator and the pretest estimator. ERR represents the empirical rejection rate of the null hypothesis that the extra instrumental variable given by the control function method is valid. The ERR is around 0.05 since the assumptions of CF estimator is satisfied in this model. The usual two stage least squares, control function and pretest estimator all have small bias. The WRMSE of control function estimator is consistently smaller than the WRMSE of the usual two stage least squares estimator. For β_2 and β_3, the WRMSE are more than 7 times smaller than that of the usual two stage least squares estimator. The pretest estimator also gains substantially over the two stage least squares estimator.

5.2 Setting where the assumptions of the control function estimator are moderately violated

We consider two models where the assumptions of the control function estimator are moderately violated,

1. y_2 is involved with a cubic function of z_2

$$\begin{aligned} y_1 &= 1 + z_1 + 10y_2 + 10y_2^2 + u_1; \\ y_2 &= \frac{1}{2} \times \frac{\left(1 + \frac{1}{8}z_1 + \frac{1}{3}z_2 + \frac{1}{8}z_2^2 + z_2^3\right)}{\text{sd}\left(1 + \frac{1}{8}z_1 + \frac{1}{3}z_2 + \frac{1}{8}z_2^2 + z_2^3\right)} + v_2; \end{aligned} \tag{27}$$

where $\text{sd}\left(1 + \frac{1}{8}z_1 + \frac{1}{3}z_2 + \frac{1}{8}z_2^2 + z_2^3\right)$ is the standard deviation of$1+\frac{1}{8}z_1+\frac{1}{3}z_2+\frac{1}{8}z_2^2+z_2^3$ and $z_1 \sim N(0,1)$ and $z_2 \sim N(0,1)$ and $\begin{pmatrix} u_1 \\ v_2 \end{pmatrix} \sim N\left[\begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} 1 & 0.5 \\ 0.5 & 1 \end{pmatrix}\right]$.

2. y_2 is involved with an exponential function of z_2.

$$\begin{aligned} y_1 &= 1 + z_1 + 10y_2 + 10y_2^2 + u_1 \\ y_2 &= \frac{1}{2} \times \frac{\left(1 + \frac{1}{8}z_1 + \frac{1}{3}z_2 + \frac{1}{8}z_2^2 + \exp(z_2)\right)}{\text{sd}\left(1 + \frac{1}{8}z_1 + \frac{1}{3}z_2 + \frac{1}{8}z_2^2 + \exp(z_2)\right)} + v_2; \end{aligned} \tag{28}$$

where $\text{sd}\left(1 + \frac{1}{8}z_1 + \frac{1}{3}z_2 + \frac{1}{8}z_2^2 + \exp(z_2)\right)$ is the standard deviation of$1 + \frac{1}{8}z_1 + \frac{1}{3}z_2 + \frac{1}{8}z_2^2+\exp(z_2)$ and $z_1 \sim N(0,1)$ and $z_2 \sim N(0,1)$ and $\begin{pmatrix} u_1 \\ v_2 \end{pmatrix} \sim N\left[\begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} 1 & 0.5 \\ 0.5 & 1 \end{pmatrix}\right]$.

In these simulation settings, since the terms $1 + \frac{1}{8}z_1 + \frac{1}{3}z_2 + \frac{1}{8}z_2^2 + z_2^3$ or $1 + \frac{1}{8}z_1 + \frac{1}{3}z_2 + \frac{1}{8}z_2^2 + \exp(z_2)$ involved in the y_2 model tend to be much larger than the error v_2,

we standardize these by their standard deviation. The assumptions of the control function estimator are moderately violated in models (27) and (28) since we use a quadratic model of z_2 to fit the endogenous variable y_2, whose conditional mean has a cubic (exponential) term of z_2.

Setting (2) of Table 1 presents the absolute value of ratio of bias of the sample winsorized mean to the true value of the model (27) and the ratio of the sample winsorized root mean square error to the sample winsorized root mean square error of the two stage least squares estimator. The ratio of bias of two stage least squares, control function and pretest estimator to the true value are small. The empirical rejection rate is around 0.10 and the WRMSE of the control function estimator and the pretest estimator are smaller than WRSME of the two stage least squares estimator.

Setting (3) of Table 1 presents the WMEAN and WRMSE results for the exponential model (28). The ratio of the bias of two stage least squares, control function and pretest estimators to the true value are small. The empirical rejection rate is low and the WRMSE of the control function estimator and the pretest estimator are smaller than WRSME of the two stage least squares estimator. For β_3, the WRMSE of the CF estimator and the pretest estimator are around 5% of WRMSE of the usual two stage least squares estimator. Even though the assumption 3 of the control function method is violated for the models (27) and (28), the CF estimator is still approximately unbiased and more efficient than the 2SLS estimator. For these settings, the pretest estimator generally uses the CF estimator and is considerably more efficient than the 2SLS estimator.

5.3 Setting where the assumptions of the control function estimator are drastically violated

We now consider a setting in which the control function assumptions are drastically violated. The model setting is as follows:

$$\begin{aligned} y_2 &= -\gamma_2 + \gamma_1 z_2 + \gamma_2 z_2^2 + v_2 \\ w &= \delta v_2^2 + N(0,1) \\ y_1 &= \beta_2 y_2 + \beta_3 y_2^2 + \beta_4 w + u_1 \end{aligned} \tag{29}$$

where $z_2 \sim N(0,1)$ and $u_1, v_2 \sim N\left(\begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}\right)$ and $\beta_2 = 1, \beta_3 = 0.2, \beta_4 = 1$ and $\gamma_1 = 1, \gamma_2 = 0.2$ and $\delta = 0.5$.

Setting (4) of Table 1 presents the absolute value of ratio of bias of the sample winsorized mean to the true value of the model (29) and the ratio of the sample winsorized root mean square error to the sample winsorized root mean square error of the two stage least squares estimator.

The ratio of bias of the WMEAN of usual two stage least squares and pretest estimators to the true value are close to zero while the ratio of the bias for the control function estimator is far away from zero. The WRMSE of the control function estimator is much larger than that of the usual two stage least squares estimator. The pretest estimator performs well in terms of sample mean and mean square error because the pretest hypothesis testing rejects most of the control function estimators.

	WMEAN			WRMSE	
	2SLS	Control Function	Pretest	Control Function	Pretest
(1)	Satisfied Model (26)(ERR=0.0510)				
β_2	0.001	0.000	0.000	0.139	0.155
β_3	0.000	0.000	0.000	0.070	0.079
(2)	Cubic Model (27)(ERR=0.1073)				
β_2	0.000	0.000	0.000	0.994	0.996
β_3	0.000	0.000	0.000	0.635	0.736

β_3	0.000	0.546	0.000	10.275	1.000

Table 1: The ratio of the bias of the sample winsorized mean (WMEAN) to the true value and the ratio of the Winsorized RMSE (WRMSE) of the control function(Pretest) estimator to WRMSE of the two stage least squares estimator for Satisfied Model (26), Cubic Model (27) with SD = 0.5, Exponential Model (28) with SD = 0.5 and Drastically Violated Model (29). The Empirical Rejection Rate (ERR) stands for the proportion (out of 10,000 simulations) of rejection of the null hypothesis that the extra instrumental variable given by the control function method is valid.

5.4 Sensitivity of joint distribution of errors

In this section, we investigate how sensitive the control function estimator is to different joint distributions of (u_1, v_2); in particular, we consider settings where Assumption 3 is satisfied but Assumption 4 is not satisfied. Assume that we use a quadratic model in z_2 to fit the first stage and the true first stage model is quadratic in z_2,

$$\begin{aligned} y_1 &= 1 + z_1 + 10y_2 + 10y_2^2 + u_1; \\ y_2 &= 1 + \frac{1}{8}z_1 + \frac{1}{3}z_2 + \frac{1}{8}z_2^2 + v_2; \end{aligned} \tag{30}$$

where $z_1 \sim N(0,1)$ and $z_2 \sim N(0,1)$, but u_1 and v_2 are not bivariate normal. We generate u_1 and v_2 in the following three ways

1. Double exponential distribution: $u_1 = \epsilon_1$ and $v_2 = \frac{1}{2}\epsilon_1 + \frac{\sqrt{3}}{2}\epsilon_2$ where ϵ_1 and ϵ_2 are independent double exponential distribution with mean 0 and variance 1.

2. Bivariate log-normal distribution: $u_1 = \exp(\epsilon_1)$ and $v_2 = \exp(\epsilon_2)$ where $\epsilon_1, \epsilon_2 \sim N\left(\begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} 1 & 0.5 \\ 0.5 & 1 \end{pmatrix}\right)$.

3. Bivariate absolutely normal distribution: $u_1 = |\epsilon_1| - E|\epsilon_1|$ and $v_2 = |\epsilon_2| - E|\epsilon_2|$ where $\epsilon_1, \epsilon_2 \sim N\left(\begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} 1 & 0.5 \\ 0.5 & 1 \end{pmatrix}\right)$.

	WMEAN			WRMSE	
	2SLS	Control Function	Pretest	Control Function	Pretest
(1)	Double exponential distribution (ERR=0.0520)				
β_2	0.001	0.000	0.000	0.154	0.174
β_3	0.000	0.000	0.000	0.099	0.112
(2)	Log normal distribution(ERR=0.0509)				
β_2	0.006	0.006	0.006	0.077	0.079
β_3	0.001	0.001	0.001	0.060	0.059
(3)	Absolute normal distribution(ERR=0.1455)				
β_2	0.000	0.017	0.011	0.964	1.063
β_3	0.000	0.004	0.002	0.968	1.065

Table 2: The ratio of the bias of the sample winsorized mean (WMEAN) to the true value and the ratio of the Winsorized RMSE (WRMSE) of the control function(Pretest) estimator to WRMSE of the two stage least squares estimator for the model (30) and different joint distributions of errors. For this model, the assumption 4 of the control function estimator to be consistent is violated.

For these settings, Assumption 3 is satisfied but Assumption 4 is not satisfied. Table 2 presents the ratio of the bias of the sample winsorized mean (WMEAN) to the true value and the ratio of the Winsorized RMSE (WRMSE) of the control function(Pretest) estimator to WRMSE of the two stage least squares estimator for the model (30) and different joint distributions of errors. For the double exponential distribution and the log normal distribution, the ratio of the bias of the usual two stage least squares, the control function and the pretest estimator are small; the WRMSE of the control function and the pretest estimator are much smaller than that of the usual two stage least squares estimator. For the absolute normal distribution, the ratio of the bias of the control function and the pretest estimator are slightly larger than that of the usual two stage least squares; the WRMSE of the control function estimator is slightly smaller than that of the usual two stage least squares estimator and that of the pretest estimator is slightly larger than that of the usual two stage least squares estimator. In summary, the control function estimator is robust to the violations of Assumption 4 considered in this section.

6. Application to a field experiment in Burundi

In this section, we apply the control function method and usual two stage least squares to estimate the effect of exposure to violence on a person's patience (conflict on time preference). The data set consists of 302 observations from a field experiment in Burundi (Voors et al (2012)). Burundi underwent a civil war from 1993-2005, where the intensity of the conflict varied in different parts of the country. Voors et al (2012) sought to access whether the exposure to violence that a person experienced, as measured by the percentage dead in attacks in the area the person lived (y_{i2}) affected a person's patience (y_{i1}), as measured by a person's discount rate for willingness to receive larger amounts of money in the future compared to smaller amounts of money now. A smaller value of the discount rate y_{i1} means

	two stage least squares	control function
β_2	-1.282	2.101
(SD)	(7.033)	(3.479)
β_3	0.2360	0.017
(SD)	(0.451)	(0.217)

Table 3: Estimates and Standard Error of Coefficients before Endogenous Variables

the person is more patient. The exogenous variables $\mathbf{x}_i$ that are available are whether the respondent is literate, the respondent's age, the respondent's sex, the total land holding per capita, land Gini coefficient, distance to market, conflict over land, ethnic homogeneity, socioeconomic homogeneity, population density and per capita total expenditure. As discussed in Voors et al (2012), it is possible that the exposure to violence (y_{i2}) is endogenous because violence may be targeted in a non-random way that is related to patience of the community; for example, violence may be targeted to extract "economic profit", i.e., steal the assets of others, where communities which are more vulnerable to having their assets stolen may also differ in their patience levels from less vulnerable communities. Due to possibility of endogeneity, the OLS estimator of regressing the outcome on the observed covariates maybe a biased estimate of the effect of exposure to violence on time preference. We follow the discussion in the paper Voors et al (2012) and use the following instrumental variables, distance to Bujumbura (the capital of Burundi) and altitude. Fighting was more intense near Bujumbura (the capital of Burundi) and at higher altitudes. The assumption for distance to Bujumbura and altitude to be valid instruments is that they only affect the distribution of violence and are not associated with the patience level of a community. Voors et al (2012) defend this assumption by discussing that most plausible concern with its validity is that distance to the capital and altitude might be associated with distance to market which might be associated with patience, but that in Burundi, since most farmers operate at a substance level, selling goods to nearby market, there are local markets in all communities, reducing the possibility of geography being correlated with preference. See more detailed discussion in page 956 in Voors et al (2012). We are able to express our model as

$$y_{1i} = \beta_0 + \beta_1^T \mathbf{x}_i + \beta_2 y_{2i} + \beta_3 y_{2i}^2 + u,$$

and

$$y_{2i} = \alpha_0 + \alpha_1 z_{i1} + \alpha_2 z_{i2} + \alpha_3 z_{i1}^2 + \alpha_4 z_{i2}^2 + \alpha_5 z_{i1} \times z_{i2} + \alpha_6^\intercal \mathbf{x}_i + v,$$

where z_{i1} represents the distance to Bujumbura and z_{i2} represents the altitude for the i-th subject.

Table 3 presents the control function estimate and two stage least squares estimate of β_2 and β_3. Rather than focus directly on β_2 and β_3, we focus on a more interpretable quantity, the increase of discount rate when percentage dead in attacks increase from y_2 to $y_2 + 1$, which we denote by $\delta(y_2)$,

$$\delta(y_2) = y_1^{y_2+1} - y_1^{y_2} = \beta_2 + \beta_3 (1 + 2y_2).$$

In Figure 3$(a)/(b)$, we plot usual two stage least squares/control function point estimates and corresponding confidence intervals of $\delta(y_2)$ respectively. The middle curve represents

the point estimate of $\delta(y_2)$, and the higher curve and lower curve represent the upper and lower bound of 95% confidence interval of $\delta(y_2)$ respectively. In Figure 3(c), we compare the variance of $\delta(y_2)$ provided by control function and usual two stage least squares by plotting the ratio:

$$\frac{Var.2SLS\left(\delta(y_2)\right)}{Var.CF\left(\delta(y_2)\right)},$$

where $Var.2SLS\left(\delta(y_2)\right)$ represents the variance of $\delta(y_2)$ given by usual two stage least squares and $Var.CF\left(\delta(y_2)\right)$ represents the variance of $\delta(y_2)$ given by control function. Figure 3(c) illustrates that the ratio of variance is always larger than one and shows that the control function estimate is more efficient than the usual two stage least squares estimate. We apply the Hausman test to this real data and the corresponding pvalue is around 0.579 so that the validity of the extra instrumental variable is not rejected and the pretest estimator is equal to the control function estimator.

Figure 3(d) demonstrates the predicted causal relationship between the discount rate and percentage dead in attacks. All the other covariates are set at the sample mean level and we plug in the estimates of the coefficients by the control function method and the two stage least square method. As illustrated, we see that the exposure to violence (measured by percentage dead in attacks) decreases patience (measured by a smaller discount rate).

We present two additional applications of the control function method to estimate the effect of household income on food demand in Appendix D and the effect of smoking during pregnancy on birthweight on Appendix E.

7. Discussion

The model (2) assumes constant treatment effect. The comparison between the CF estimator and the 2SLS estimator presented in this paper can be extended to more general class of models that allows for heterogeneous treatment effects model, as discussed in section 5 of Small (2007). Without loss of generality, we consider the outcome model to be a quadratic model.

$$y_{1,i} = \beta_0 + \beta_{1,i} y_{2,i} + \beta_{2,i} y_{2,i}^2 + \beta_3 z_{1,i} + u_{1,i}, \quad \text{for} \quad i = 1, \cdots, n, \tag{31}$$

and assume that $z_{2,i}$ and $z_{2,i}^2$ are valid instruments for $y_{2,i}$ and $y_{2,i}^2$. We introduce the following notation $\beta_1 = \mathbb{E}\beta_{1,i}$ and $\beta_2 = \mathbb{E}\beta_{2,i}$ and assume that

$$(\beta_{1,i}, \beta_{2,i}) \quad \text{is independent of} \quad y_{2,i}, z_{1,i}, z_{2,i}, u_{1,i}, \tag{32}$$

which is a special case of assumption A.3 in Wooldridge (1997) by setting $\rho_1 = 0$. As discussed in Wooldridge (1997) and Small (2007), the assumption (32) states that the units do not select their treatment levels ($y_{2,i}$ and $y_{2,i}^2$) based on the gains that they would experience from the treatment ($\beta_{1,i}$ and $\beta_{2,i}$). The heterogenous effect model (31) can be expressed as

$$y_{1,i} = \beta_0 + \beta_1 y_{2,i} + \beta_2 y_{2,i}^2 + \beta_3 z_{1,i} + \left(u_{1,i} + (\beta_{1,i} - \beta_1) y_{2,i} + (\beta_{2,i} - \beta_2) y_{2,i}^2\right), \quad \text{for} \quad i = 1, \cdots, n.$$

The new error $\left(u_{1,i} + (\beta_{1,i} - \beta_1) y_{2,i} + (\beta_{2,i} - \beta_2) y_{2,i}^2\right)$ has the following property

$$\mathbb{E}\left(u_{1,i} + (\beta_{1,i} - \beta_1) y_{2,i} + (\beta_{2,i} - \beta_2) y_{2,i}^2\right) z_{1,i} = \mathbb{E}\left(u_{1,i} z_{1,i}\right) + \mathbb{E}\left(\beta_{1,i} - \beta_1\right) y_{2,i} z_{1,i} + \mathbb{E}\left(\beta_{2,i} - \beta_2\right) y_{2,i}^2 z_{1,i} = 0$$

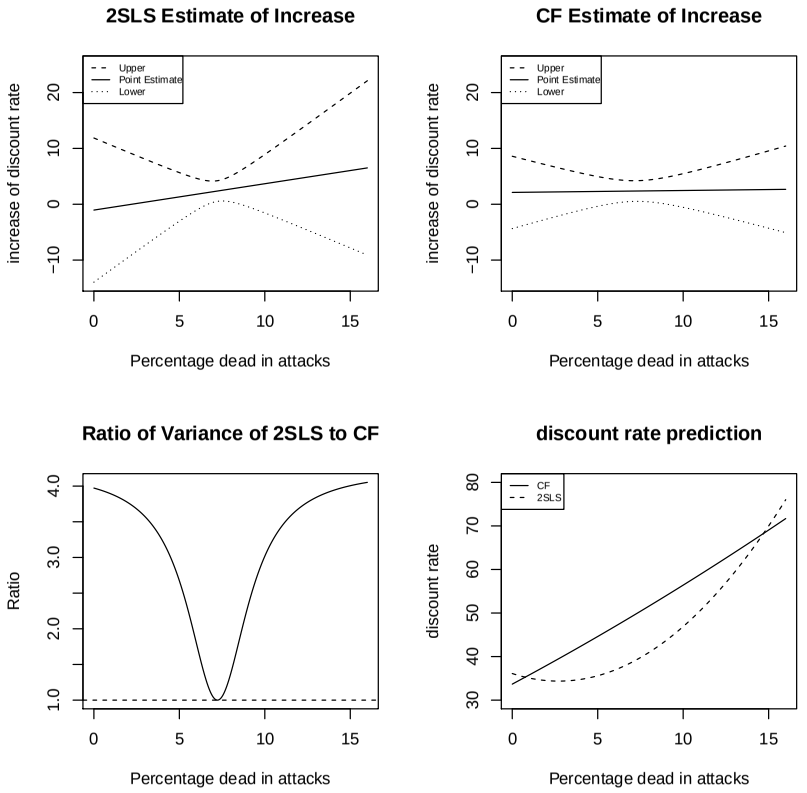

Figure 3: (a) plots the two stage least squares estimate and 95% confidence interval for the increase of discount rate $\delta(y_2)$ with respect to different percentage dead in attacks;(b) plots the control function estimate and 95% confidence interval for the increase of discount rate $\delta(y_2)$ with respect to different percentage dead in attacks;(c) plots the ratio of the variance of two stage least squares to the variance of the control function method with respect to different percentage dead in attacks;(d) plots the discount rate as a function of the percentage dead in attacks with the CF estimate and the 2SLS estimate.

where the first part follows from that $z_{1,i}$ is exogenous and the last two part follows from the assumption (32) . Similarly, we can also show that

$$\mathbb{E}\left(\left(u_{1,i}+\left(\beta_{1,i}-\beta_1\right)y_{2,i}+\left(\beta_{2,i}-\beta_2\right)y_{2,i}^2\right)z_{2,i}\right)=0,$$

and

$$\mathbb{E}\left(\left(u_{1,i}+\left(\beta_{1,i}-\beta_1\right)y_{2,i}+\left(\beta_{2,i}-\beta_2\right)y_{2,i}^2\right)z_{2,i}^2\right)=0.$$

Hence, the instrumental variables are valid for the new error. Our theory for the homogeneous model (2) can be extended to the general (31) under the assumption (32) (it can also be extended under the weaker assumptions than (32) found in Wooldridge (1997)). The pretest estimator provides a consistent estimator and is close to the more efficient estimator between 2SLS and the CF estimator.

We focus on the continuous outcome model in this paper. For a count outcome that follows a log linear model,

$$\log\mathbb{E}\left(y_1|y_2,z\right)=\beta_0+\beta_1y_2+\beta_2z_1+\beta_3u. \tag{33}$$

where

$$y=\alpha_0+\alpha_1z_1+\alpha_2z_2+\delta,$$

and z_1 is the included exogenous variable and z_2 is the instrumental variable and δ is normal variable with zero mean and variance σ^2, Mullahy (1997) shows that the 2SLS estimator is inconsistent while the CF estimator is consistent in this count outcome model. For a binary outcome that follows a logistic regression model, comparison of the CF estimator and the 2SLS estimator for the logistic second stage model can be a further research topic, discussion is found in Cai et al. (2011) and Clarke & Windmeijer (2012).

Imbens & Rubin (1997) formulated the potential outcome model for binary instrumental variable and binary treatment, which can be extended to continuous instrumental variable and treatment as follows: The treatment $y_2=f_c\left(z\right)$ is an increasing function in z given the compliance class c, where $c\in\{1,\cdots,M\}$. We also assume the monotonicity assumption of the compliance class

$$f_{c'}\left(z\right)\leq f_c\left(z\right)\quad\text{for}\quad c'\leq c.$$

The outcome model is

$$y_1|c,z\sim N(f_c(z)+\lambda_c,\sigma^2).$$

As discussed in Imbens & Rubin (1997), the MLE and Bayesian estimator is more efficient than the instrumental variable based method since the instrumental variable method does not take into account the non-negativity of the density function. However, the estimator might be inconsistent if the model is wrong. In this paper, we focus on the semi-parametric model (2), which is robust to the outcome distribution. In the semi-parametric model (2), we show that the CF estimator is equivalent to a 2SLS estimator with an augmented set of instrumental variables. When the extra instrumental variables are valid, we demonstrate by theoretical results and simulation results that the CF estimator is more efficient than the usual 2SLS estimator.

8. Conclusion

This paper compares the control function estimator (Algorithm 2) and the usual two stage least squares estimator (Algorithm 1) for nonlinear causal effect models. Theoretically, we show that the control function estimator is equivalent to a two stage least squares estimator with an augmented set of instrumental variables. When the augmented instrumental variables are valid, the control function method will have a larger set of instrumental variables than the usual two stage least squares estimator and hence the control function estimator will have a smaller variance and root mean square error.

Methodologically, we develop a pretest estimator (Algorithm 3) which tests the validity of the augmented instrumental variables and combines the strength of the control function estimator and the usual two sage least squares estimator. In the simulation study, the pretest estimator provides large gains over two stage least squares in some settings while never being much worse than two stage least squares. Such phenomenon is also observed in the real data analysis.

For practical application, we suggest to use the pretest estimator which means implementing both the two stage least squares estimator and the control function estimator and calculating the Hausman test statistics based on these two estimates. If the Hausman test leads to the rejection of the null, the two stage least squares estimator is more trustworthy; otherwise, we use the control function estimator because it is more efficient and there is no evidence of it being biased.

Appendix A. Consistency of the control function estimator

We now investigate why the control function method works under assumptions 1,2,3 and 4. Define $e = u_1 - \rho v_2$. Since e is the residual of regressing u_1 on v_2, e and v_2 are uncorrelated. By plugging in $u_1 = e + \rho v_2$, we have

$$y_1 = \beta_0 + \beta_1 y_2 + \cdots + \beta_k g_k(y_2) + \beta_{k+1} z_1 + \rho v_2 + e. \tag{34}$$

Since e is uncorrelated with z_1 and v_2, it suffices to show that the new error e is uncorrelated with $g_i(y_2)$. By the law of iterated expectation and the one-to-one correspondence between y_2 and v_2, $E(g_i(y_2)e) = E\left[E(g_i(y_2)e|y_2, z)\right] = E\left[g_i(y_2)E(e|v_2, z)\right]$. By Assumption 3, $E(e|v_2, z) = E(u_1 - \rho v_2|v_2, z) = E(u_1 - \rho v_2|v_2)$. By Assumption 4, $E(u_1 - \rho v_2|v_2) = E(u_1|v_2) - \rho v_2 = 0$. Hence, $E(g_i(y_2)e) = 0$. and the new error e is uncorrelated with $g_i(y_2)$. If we estimate v_2 by its estimate $\hat{v}_2$, the residual of the first stage $y_2 \sim z_1 + z_2 + h_2(z_2) + \cdots + h_k(z_2)$, the consistency of the control function estimate follows if we can verify the regularity conditions in Theorem 1 in Murphy et al (2002), which says that if we obtain the consistent estimates of first stage coefficients, we estimate the second stage coefficients consistently by replacing the residual with its estimate from the first stage. Let Z denote the data matrix where each row is an i.i.d sample of $\{z_1, z_2, h_2(z_2), \cdots, h_k(z_2)\}$, X denote the data matrix where each row is an i.i.d sample of $\{z_1, y_2, g_2(y_2), \cdots, g_k(y_2)\}$ and V_2 denote the data matrix where each row is an i.i.d sample of $\{\hat{v}_2\}$. The regularity conditions for Theorem 1 in Murphy et al (2002) are the following:

(a) $\lim_{n\to\infty} A^T A = Q_0$ where $A = (X, V_2)$ and Q_0 is positive definite matrix.

(b) $v_2 = f(\alpha, Z) = y_2 - (\alpha_0 + \alpha_1 z_1 + \alpha_2 \mathbf{H}(z_2))$ is twice continuously differentiable in α for each Z and $\lim_{n\to\infty} A^T Z = Q_1$.

(c) The first stage estimate $\hat{\alpha}$ is a consistent estimator of α.

We will show that under the following three regularity assumptions, the conditions (a), (b), (c) of Theorem 1 in Murphy et al (2002) are satisfied.

i $\lim_{n\to\infty} A^T A = Q_0$ where $A = (X, V_2)$ and Q_0 is positive definite matrix.

ii $\lim_{n\to\infty} A^T Z = Q_1$.

iii The true model of the first stage is (4).

Assumption i is the same as condition (a). Assumption ii is the second part of condition (b). For the first part of condition (b), since $v_2 = f(\alpha, Z)$ is a linear function of the parameters α, f is twice continuously differentiable. For condition (c), by assuming iii that the true model of the first stage is (4), the first stage regression coefficients $\hat{\alpha}$ of the standard control function estimator (7) are consistent estimates of α.

Appendix B. Proof of the theorems

Lemma 7 *(Adjustment Lemma)*
For the linear model

$$y = \beta_1 x_1 + \beta_2 x_2 + \epsilon,$$

the following two regression give us the same estimate of β_1:

$$y \sim x_1 + x_2,$$

$$y \sim x_{1.2};$$

where $x_{1.2}$ is the residual of the regression $x_1 \sim x_2$.

This lemma is called Adjustment Lemma since we adjust x_1 to x_2 to obtain $x_{1.2}$.
Proof [Proof of Theorem 1] By the adjustment lemma, the coefficients of the regression $y_1 \sim \widetilde{z_1} + \widetilde{y_2} + \widetilde{g_2(y_2)}$ are the same with corresponding coefficients in $y_1 \sim z_1 + y_2 + g_2(y_2) + e_1$ where $\widetilde{x}$ is the residual of the regression $x \sim e_1$. Since z_1 is orthogonal to e_1 by the property of OLS, $\widetilde{z_1} = z_1$. The theorem follows by replacing $\widetilde{z_1}$ with z_1. ■

Proof [Proof of Theorem 2] Let $Z = (1, z_1, z_2, h_2(z_2))$ denote the matrix of observed values of instrumental variables. $y_2^2 = \gamma_c + \gamma e_1 + \widetilde{g_2(y_2)}$ Since e_1 is the residual of the regression

$$y_2 \sim z_1 + z_2 + h_2(z_2),$$

it follows from the property of OLS that $Z^T e_1 = 0_{4\times 1}$. The coefficients given by regression $g_2(y_2) \sim z_1 + z_2 + h_2(z_2)$ are $\left(Z^T Z\right)^{-1} Z^T g_2(y_2)$ and those given by regression $\widetilde{g_2(y_2)} \sim z_1 + z_2 + h_2(z_2)$ are $\left(Z^T Z\right)^{-1} Z^T \widetilde{g_2(y_2)}$. Since

$$\left(Z^T Z\right)^{-1} Z^T g_2(y_2) - \left(Z^T Z\right)^{-1} Z^T \widetilde{g_2(y_2)} = \left(Z^T Z\right)^{-1} Z^T e_1 = 0$$

we come to the conclusion that the regression $g_2(y_2) \sim z_1 + z_2 + h_2(z_2)$ and $\widetilde{g_2(y_2)} \sim z_1 + z_2 + h_2(z_2)$ give the same estimates of coefficients on $1, z_1, z_2, h_2(z_2)$. ■

Proof [Proof of Theorem 3] It is sufficient to show that except for a constant difference,

(1) $\widetilde{y_2}$ is equal to the predicted value of the regression $y_2 \sim z_1 + z_2 + h_2(z_2) + error.iv$.

(2) $\widetilde{g_2(y_2)}$ is equal to the predicted value of the regression $g_2(y_2) \sim z_1 + z_2 + h_2(z_2) + error.iv$.

By the discussion after theorem 2, we have the following decomposition

$$\begin{aligned} g_2(y_2) &= \gamma_c + \gamma e_1 + \widetilde{g_2(y_2)} \\ &= \gamma_c + \gamma e_1 + \gamma_1 z_1 + \gamma_2 z_2 + \gamma_3 h_2(z_2) + error.iv. \end{aligned} \tag{35}$$

where the column vector e_1 is orthogonal to the column vectors $z_2, h_2(z_2)$ and $error.iv$ and $error.iv$ is orthogonal to z_1, z_2 and $h_2(z_2)$ by the property of OLS. By the decomposition (35), we conclude that except for a constant, $\widetilde{g_2(y_2)}$ is equal to the predicted value of the regression $g_2(y_2) \sim z_1 + z_2 + h_2(z_2) + error.iv$. Since $error.iv$ is orthogonal to $z_1, z_2, h_2(z_2)$ and e_1, $error.iv$ is orthogonal to $y_2 = \alpha_0 + \alpha_1 z_1 + \alpha_2 z_2 + \alpha_3 h_2(z_2) + e_1$ and hence the

predicted value of the regression $y_2 \sim z_1 + z_2 + h_2(z_2) + error.iv$ is the same with $\widehat{y_2}$, which is the same with $\widetilde{y_2}$. ■

Proof [Proof of Theorem 4]

It is sufficient to show that except for a constant difference,

(1) $\widetilde{y_2}$ is equal to the predicted value of the regression

$$y_2 \sim z_1 + z_2 + h_2(z_2) + h_3(z_2) + error.iv_1 + error.iv_2.$$

(2) $\widetilde{g_2(y_2)}$ is equal to the predicted value of the regression

$$g_2(y_2) \sim z_1 + z_2 + h_2(z_2) + h_3(z_2) + error.iv_1 + error.iv_2.$$

(3) $\widetilde{g_3(y_2)}$ is equal to the predicted value of the regression

$$g_3(y_2) \sim z_1 + z_2 + h_2(z_2) + h_3(z_2) + error.iv_1 + error.iv_2.$$

We start with a decomposition of $g_3(y_2)$

$$\begin{aligned} g_3(y_2) &= \gamma_c + \gamma e_1 + \widetilde{g_3(y_2)} \\ &= \gamma_c + \gamma e_1 + \gamma_1 z_1 + \gamma_2 z_2 + \gamma_3 h_2(z_2) + \gamma_4 h_3(z_2) + error.iv_2.prime \\ &= \gamma_c + \gamma e_1 + \gamma_1 z_1 + \gamma_2 z_2 + \gamma_3 h_2(z_2) + \gamma_4 h_3(z_2) + \gamma' error.iv_1 + error.iv_2. \end{aligned} \tag{36}$$

Since e_1 is orthogonal to $error.iv_1$, $error.iv_2$ and $z_1, z_2, h_2(z_2), h_3(z_2)$, the predicted value given by the regression $g_3(y_2) \sim z_1 + z_2 + h_2(z_2) + h_3(z_2) + error.iv_1 + error.iv_2$ is the same with $\widetilde{g_3(y_2)}$.

Since $error.iv_2$ is orthogonal to $e_1, z_1, z_2, h_2(z_2), h_3(z_2), error.iv_1$, $error.iv_2$ is orthogonal to $g_2(y_2)$, hence the coefficient of $error.iv_2$ given by the following regression

$$g_2(y_2) \sim z_1 + z_2 + h_2(z_2) + h_3(z_2) + error.iv_1 + error.iv_2 \tag{37}$$

is vanishing, which leads to the predicted value of regression (37) is the same with the predicted value of $g_2(y_2) \sim z_1 + z_2 + h_2(z_2) + h_3(z_2) + error.iv_1$ and by the decomposition (35) and same argument in proof of theorem 3, we obtain (2).

Since $error.iv_1$ and $error.iv_2$ are orthogonal to $e_1, z_1, z_2, h_2(z_2), h_3(z_2)$, then $error.iv_1$ and $error.iv_2$ are orthogonal to y_2 and (1) follows.

■

Appendix C. Further results from the simulation study

All the corresponding non-winsorized results are presented in Tables 4 and 5. The observations are similar to the counter part of winsorized results.

Table 6: Estimates and Standard Error of Coefficients before Endogenous Variables

Appendix D. Application to demand for food

In this section, we apply the control function method and usual two stage least squares to estimate the effect of income on food demand and compare these two methods. The data set is from Bouis & Haddad (1990) and comes from a survey of farm households in the Bukidnon Province of Philippines. Following Bouis & Haddad (1990), we assume that food expenditure is a quadratic function of log income. Here, y_{1i} is the expenditure on food of the i-th household, y_{2i} is the log of income of the i-th household and x_i represents the included exogenous variables of the i-th household, which consist of mother's education, father's education, mother's age, father's age, mother's nutritional knowledge, corn price, rice price , population density of the municipality, number of household members expressed in adult equivalents, and dummy variables for the round of the survey. Then we are able to express our model as $y_{1i} = \beta_0 + \beta_1 x_i + \beta_2 y_{2i} + \beta_3 y_{2i}^2 + u$. Bouis & Haddad (1990) were concerned that regression of y_1 on y_2 (log income) and x would not provide an unbiased estimate of β because of unmeasured confounding variables. In particular, because farm households make production and consumption decisions simultaneously and there are multiple incomplete markets in the study area, the households' production decisions (which affect their log income y_2) are associated with their preferences according to microeconomic theory (Bardhan & Udry (1999), chap. 2). To solve the problem, Bouis & Haddad (1990) proposed cultivated area per capita as an instrumental variable. Bouis and Haddad's reasoning for why cultivated area per capita is an instrumental variable is that "land availability is assumed to be a constraint in the short run, and therefore exogenous to the household decision making process."

Table 6 presents the control function estimate and two stage least squares estimate of β_2 and β_3. Rather than focus directly on β_2 and β_3, we focus on a more interpretable quantity, the income elasticity of food demand at the mean level of food expenditure. This is the percent change in food expenditure caused by a 1% increase in income for households currently spending at the mean food expenditure level, and we denote it by $\eta(y_2)$. The mean food expenditure of households is 31.14 pesos per capita per week and

$$\eta(y_2) = \frac{100}{31.14}\hat{\beta}_2 \log(1.01) + \hat{\beta}_3 \left(2\log(1.01)y_2 + \log(1.01)^2\right).$$

In Figure 4(a), we plot OLS point estimates and corresponding confidence intervals of $\eta(y_2)$ with respect to different levels of log income y_2. The middle curve represents the point estimate of $\eta(y_2)$, and the higher curve and lower curve represent the upper and lower bound of 95% confidence interval of $\eta(y_2)$ respectively. In Figure 4$(b)/(c)$, we plot usual two stage least squares/control function point estimates and corresponding confidence intervals

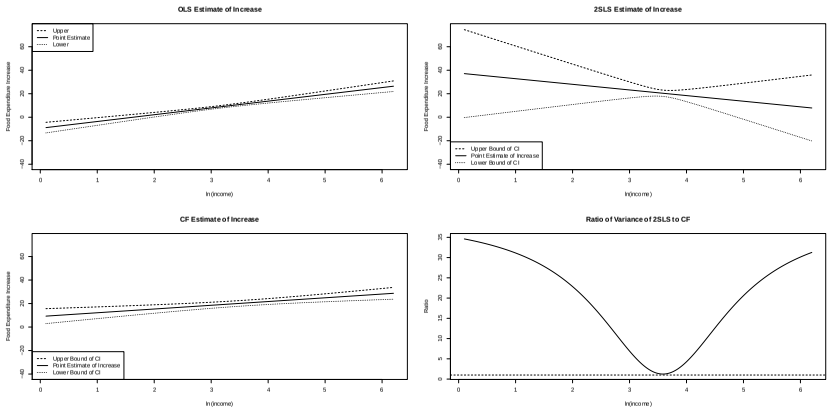

Figure 4: (a) plots the OLS estimate and 95% confidence interval for the income elasticity with respect to different log(income);(b) plots the two stage least squares estimate and 95% confidence interval for the income elasticity with respect to different log(income);(c) plots the control function estimate and 95% confidence interval for the income elasticity with respect to different log(income);(d) plots the ratio of the variance of two stage least squares to the variance of the control function method with respect to different log(income).

of $\eta(y_2)$ respectively. In Figure 4(d), we compare the variance of $\eta(y_2)$ provided by control function and usual two stage least squares by plotting the ratio:

$$\frac{Var.2SLS\left(\eta(y_2)\right)}{Var.CF\left(\eta(y_2)\right)},$$

where $Var.2SLS\left(\eta(y_2)\right)$ represents the variance of $\eta(y_2)$ given by usual two stage least squares and $Var.CF\left(\eta(y_2)\right)$ represents the variance of $\eta(y_2)$ given by control function. Figure 4(b) shows that two stage least squares leads to negative estimate of the non-negative valued Income Elasticity of Food Demand; in contrast, Figure 4(c) shows that the control function estimate of the non-negative valued Income Elasticity of Food Demand is always positive. Figure 4(d) illustrates that the ratio of variance is always larger than one and shows that the control function estimate is more efficient than the usual two stage least squares estimate. We apply the Hausman test to this real data and the corresponding pvalue is around 0.14 so that the validity of the extra instrumental variables is not rejected and the pretest estimator is equal to the control function estimator.

Appendix E. Application to smoking data

In this section, we apply the control function method and usual two stage least squares to estimate the effect of maternal smoking during pregnancy on birth weight. The data set consists of 1388 observations from the Child Health Supplement to the 1998 National Health

	two stage least squares	control function
$\beta_2(\times 10^{-3})$	-12.535	-8.956
$(\mathrm{SD}(\times 10^{-3}))$	(7.463)	(3.040)
$\beta_3(\times 10^{-3})$	0.266	0.121
$(\mathrm{SD}(\times 10^{-3}))$	(0.284)	(0.068)

Table 7: Estimates and Standard Error of Coefficients before Endogenous Variables

Interview Survey. The goal is to estimate the effect of maternal smoking (during pregnancy) on the birth weight. For the i-th observation, the outcome y_{i1} represents the log birth weight, y_{i2} represents the typical number of cigarettes smoked per day during pregnancy and $\mathbf{x}_i$ represents the other exogenous variables: birth order, race and child's sex. As discussed in Wehby et al. (2011), it is possible that mothers who smoke during pregnancy self-select into smoking based on their preferences for health and risk taking and their perceptions of fetal health endowments. These factors, which are typically unobserved in available data samples, can affect the fetal health through other pathways besides smoking. For example, women smoking during pregnancy might adopt other unhealthy behaviors having adverse effects on the fetus (e.g., poorer nutrition or reduced prenatal care). Since some of the confounding variables that are related with both smoking and child health are unobserved, the OLS estimator of regressing the outcome on the observed covariates maybe a biased estimate of the effect of smoking on the birth weight. We follow the discussion in the paper Mullahy (1997) and use the following instrumental variables $\mathbf{z}_i$: maternal schooling, paternal schooling, family income and the per-pack state excise tax on the cigarettes. Then we are able to express our model as

$$y_{1i} = \beta_0 + \beta_1^T \mathbf{x}_i + \beta_2 y_{2i} + \beta_3 y_{2i}^2 + u,$$

and

$$y_{2i} = \alpha^T \mathbf{z}_i + v.$$

Table 7 presents the control function estimate and two stage least squares estimate of β_2 and β_3. Rather than focus directly on β_2 and β_3, we focus on a more interpretable quantity, the increase of log birthweight when the cigarettes increase from y_2 to $y_2 + 1$, which we denote by $\delta(y_2)$,

$$\delta(y_2) = y_1^{y_2+1} - y_1^{y_2} = \beta_2 + \beta_3 (1 + 2y_2).$$

In Figure 5$(a)/(b)$, we plot usual two stage least squares/control function point estimates and corresponding confidence intervals of $\delta(y_2)$ respectively. The middle curve represents the point estimate of $\delta(y_2)$, and the higher curve and lower curve represent the upper and lower bound of 95% confidence interval of $\delta(y_2)$ respectively. In Figure 5(c), we compare the variance of $\delta(y_2)$ provided by control function and usual two stage least squares by plotting the ratio:

$$\frac{Var.2SLS\left(\delta(y_2)\right)}{Var.CF\left(\delta(y_2)\right)},$$

where $Var.2SLS\left(\delta(y_2)\right)$ represents the variance of $\delta(y_2)$ given by usual two stage least squares and $Var.CF\left(\delta(y_2)\right)$ represents the variance of $\delta(y_2)$ given by control function.

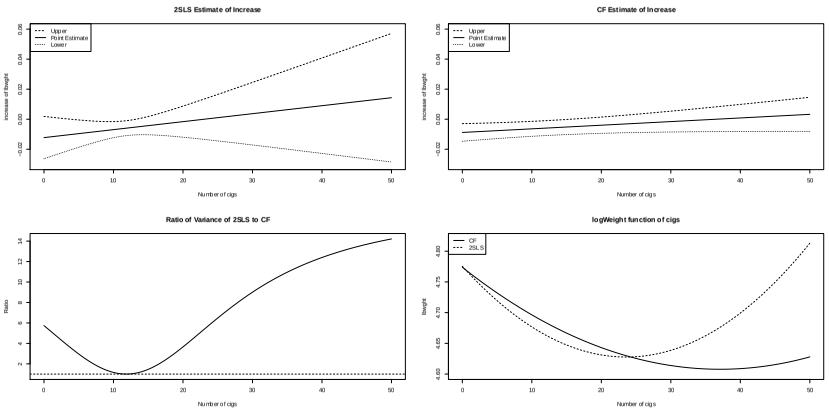

Figure 5: (a) plots the two stage least squares estimate and 95% confidence interval for the increase of lbwght $\delta(y_2)$ with respect to different number of cigarettes;(b) plots the control function estimate and 95% confidence interval for the increase of lbwght $\delta(y_2)$ with respect to different number of cigarettes;(c) plots the ratio of the variance of two stage least squares to the variance of the control function method with respect to different number of cigarettes;(d) plots the lbwght as a function of the number of cigarettes with the CF estimate and the 2SLS estimate.

Figure 5(c) illustrates that the ratio of variance is always larger than one and shows that the control function estimate is more efficient than the usual two stage least squares estimate. We apply the Hausman test to this real data and the corresponding pvalue is around 0.599 so that the validity of the extra instrumental variables is not rejected and the pretest estimator is equal to the control function estimator.

Figure 5(d) demonstrates the predicted causal relationship between the log birthweight and number of cigarettes smoked. All the other covariates are set at the sample mean level and we plug in the estimates of the coefficients by the control function method and the two stage least square method. As illustrated, we see that smoking during pregnancy has a negative effect on birthweight; with the number of cigarettes increasing, the absolute value of the marginal effect is decreasing, that is to say, the effect of additional cigarettes smoked becomes less.

Abstract

We study the Bayesian model averaging approach to learning Bayesian network structures (DAGs) from data. We develop new algorithms including the first algorithm that is able to efficiently sample DAGs of a moderate size (with up to about 25 variables) according to the exact structure posterior. The DAG samples can then be used to construct estimators for the posterior of any feature. We theoretically prove good properties of our estimators and empirically show that our estimators considerably outperform the estimators from the previous state-of-the-art methods.

Keywords: Bayesian model averaging, Bayesian networks, DAG sampling, dynamic programming, order sampling, structure learning

1. Introduction

Bayesian networks are graphical representations of multivariate joint probability distributions and have been widely used in various data-mining tasks for probabilistic inference and causal modeling (Pearl, 2000; Spirtes et al., 2001). The core of a Bayesian network (BN) representation is its Bayesian network structure. A Bayesian network structure is a DAG (directed acyclic graph) whose nodes represent the random variables $X_1, X_2, \cdots, X_n$ in the problem domain and whose edges correspond to the direct probabilistic dependencies. Semantically, a Bayesian network structure G encodes a set of conditional independence assumptions: for each variable (node) X_i, X_i is conditionally independent of its non-descendants given its parents. With the above semantics, a Bayesian network structure provides a compact representation for joint distributions and supports efficient algorithms for answering probabilistic queries. Furthermore, with its semantics, a Bayesian network structure can often provide a deep insight into the problem domain and open the door to the cause-and-effect analysis.

In the last two decades, there have been a large number of research articles focusing on the problem of learning Bayesian network structure(s) from the data. These articles deal with a common real situation where the underlying Bayesian network is typically unknown so that it has to be learned from the observed data. One motivation for the structure learning is to use the learned structure for inference or decision making. For example, we can use the learned model to predict or classify a new instance of data. Another structure-learning motivation, which is more closely related to the semantics of Bayesian network structures, is for discovering the structure of the problem domain. For example, in the context of biological expression data, the discovery of the causal and dependence relation among different genes is often of primary interests. With the semantics of a Bayesian network structure G, the existence of an edge from node X to node Y in G can be interpreted as the fact that variable X directly influences variable Y; the existence of a directed path from node X to node Y can be interpreted as the fact that X eventually influences Y. Furthermore, under certain assumptions (Heckerman et al., 1999; Spirtes et al., 2001), the existence of a directed path from node X to node Y indicates that X causes Y. Thus, with the learned Bayesian network structure, we can answer interesting questions such as whether gene X controls gene Y which in turn controls gene Z by examining whether there is a directed path from node X via node Y to node Z in the learned structure. Just as mentioned by Friedman and Koller (2003), the extraction of these kinds of interesting structural features is often the primary goal in the discovery task.

There are several general approaches to learning BN structures. One approach is to treat learning BN structures as a model-selection problem. This approach defines a scoring criterion that measures how well a BN structure (DAG) fits the data and finds the DAG (or a set of equivalent DAGs) with the optimal score (Silander and Myllymaki, 2006; Jaakkola et al., 2010; Yuan et al., 2011; Malone et al., 2011a,b; Cussens, 2011; Yuan and Malone, 2012; Malone and Yuan, 2013; Cussens and Bartlett, 2013; Yuan and Malone, 2013). (In Bayesian approach, the score of a DAG G is simply the posterior $p(G|D)$ of G given data D.) When the data size is small as compared with the number of variables, however, the posterior $p(G|D)$ often gives significant support to a number of DAGs, and using a single maximum-a-posteriori (MAP) model could lead to unwarranted conclusions (Friedman and Koller, 2003). It is therefore desirable to use the Bayesian model averaging approach by which the posterior probability of any feature of interest is computed by averaging over all the possible DAGs (Heckerman et al., 1999).

Bayesian model averaging is, however, computationally challenging because the number of possible network structures is between $2^{n(n-1)/2}$ and $n!2^{n(n-1)/2}$, super-exponential in the number of variables n. Tractable algorithms have been developed for special cases of averaging over trees (Meila and Jaakkola, 2006) and averaging over DAGs given a node ordering (Dash and Cooper, 2004). Since 2004, dynamic programming (DP) algorithms have been developed for computing exact posterior probabilities of structural features such as edges or subnetworks (Koivisto and Sood, 2004; Koivisto, 2006; Tian and He, 2009). These algorithms have exponential time and space complexity and are capable of handling Bayesian networks of a moderate size with up to around 25 variables (mainly because of their space cost $O(n2^n)$). A big limitation of these algorithms is that they can only compute posteriors of modular features such as an edge but cannot compute non-modular features such as a path ("is there a path from node X to node Y"), a combined path ("is there a path from node X via node Y to node Z" or "is there a path from node X to node Y and no path from node X to node Z"), or a limited-length path ("is there a path of length at most 3 from node X to node Y"). Recently, Parviainen and Koivisto (2011) developed a DP algorithm that can compute the exact posterior probability of a path feature under a certain assumption. (The assump-

tion, called the order-modular assumption, will be discussed in details soon.) This DP algorithm has (even higher) exponential time and space complexity and can only handle a Bayesian network with fewer than 20 variables (mainly because of its space cost $O(3^n)$). Because this DP algorithm can only deal with a path feature, all the other non-modular features (such as a combined path) which would interest various users still cannot be computed by any DP algorithm proposed so far. Note that generally the posterior $p(f|D)$ of a combined feature $f = (f_1, f_2, \ldots, f_J)$ cannot be obtained only from the posterior of each individual feature $p(f_j|D)$ ($j \in \{1, 2, \ldots, J\}$), because the independence among these features does not hold generally. Actually, by comparing $p(f_2|f_1, D)$ with $p(f_2|D)$, a user can know the effect of the feature f_1 upon the feature f_2; but to obtain $p(f_2|f_1, D)$ $(= p(f_1, f_2|D)/p(f_1|D))$, the user typically needs to obtain $p(f_1, f_2|D)$ first. Another limitation of all these DP algorithms is that it is very expensive for them to perform data prediction tasks. They can compute the exact posterior of a new observational data case $p(x|D)$ but the algorithms have to be re-run for each new data case x.

One solution to computing the posterior of an arbitrary non-modular feature is drawing DAG samples $\{G_1, \ldots, G_T\}$ from the posterior $p(G|D)$, which can then be used to approximate the full Bayesian model averaging by estimating the posterior of an arbitrary feature f as $p(f|D)$ $\approx \frac{1}{T}\sum_{i=1}^{T} f(G_i)$, or the posterior predictive distribution as $p(x|D) \approx \frac{1}{T}\sum_{i=1}^{T} p(x|G_i)$. A number of algorithms have been developed for drawing sample DAGs using the bootstrap technique (Friedman et al., 1999) or the Markov chain Monte Carlo (MCMC) techniques (Madigan and York, 1995; Friedman and Koller, 2003; Eaton and Murphy, 2007; Grzegorczyk and Husmeier, 2008; Niinimaki et al., 2011; Niinimaki and Koivisto, 2013). Madigan and York (1995) developed the *Structure MCMC* algorithm that uses the Metropolis-Hastings algorithm in the space of DAGs. Friedman and Koller (2003) developed the *Order MCMC* procedure that operates in the space of orders. The Order MCMC was shown to be able to considerably improve over the Structure MCMC the mixing and convergence of the Markov chain and to outperform the bootstrap approach of Friedman et al. (1999) as well. Eaton and Murphy (2007) developed the *Hybrid MCMC* method (that is, DP+MCMC method) that first runs the DP algorithm of Koivisto (2006) to develop a global proposal distribution and then runs the MCMC phase in the DAG space. Their experiments showed that the Hybrid MCMC converged faster than both the Structure MCMC and the Order MCMC, so that the Hybrid MCMC resulted in more accurate structure-learning performance. An improved MCMC algorithm (often denoted as *REV-MCMC*) traversing in the DAG space with the addition of a new edge-reversal move was developed by Grzegorczyk and Husmeier (2008) and was shown to be superior to the Structure MCMC and nearly as efficient as the Order MCMC in the mixing and convergence. Recently, Niinimaki et al. (2011) proposed the *Partial Order MCMC* method which operates in the space of partial orders. The Partial Order MCMC includes the Order MCMC as its special case (by setting the parameter bucket size b to be 1) and has been shown to be superior to the Order MCMC in terms of the mixing and the structure-learning performance when a more appropriate bucket size $b > 1$ is set. One common drawback of these MCMC algorithms is that there is no guarantee on the quality of the approximation in finite runs. The approach to approximating the full Bayesian model averaging using the K*-best* Bayesian network structures was studied by Tian et al. (2010) and was shown to be competitive with the Hybrid MCMC.

Several of these state-of-the-art algorithms work in the order space, including the exact algorithms (Koivisto and Sood, 2004; Koivisto, 2006; Parviainen and Koivisto, 2011) and the approximate algorithms: the Order MCMC (Friedman and Koller, 2003) and the Partial Order MCMC (Niinimaki et al., 2011). They all assume a special form of the structure prior, termed as the *order-modular* prior (Friedman and Koller, 2003; Koivisto and Sood, 2004), for computational convenience. (Please refer to the beginning of Section 2.1 for the definition of the order-modular prior.) Under the assumption of the order-modular prior, however, the corresponding prior $p(G)$ cannot represent some desirable priors such as a uniform prior over the DAG space [1]; the computed posterior probabilities are biased because a DAG that has a larger number of topological orders will be assigned a larger prior probability. Whether a computed posterior with the bias from the order-modular prior is inferior to its counterpart without such a bias depends on the application scenario and is beyond the scope of this paper. For the detailed discussion about this issue, please see the related papers (Friedman and Koller, 2003; Grzegorczyk and Husmeier, 2008; Parviainen and Koivisto, 2011) [2]. One method that helps the Order MCMC (Friedman and Koller, 2003) to correct this bias was proposed by Ellis and Wong (2008).

In this paper, first we develop a new algorithm that uses the results of the DP algorithm of Koivisto and Sood (2004) to efficiently sample orders according to the *exact* order posterior under the assumption of the order-modular prior. Next, we develop a time-saving strategy for the process of sampling DAGs consistent with given orders. (Such a DAG-sampling process is based on sampling parents for each node as described by Friedman and Koller, 2003 by assuming a bounded node in-degree.) The resulting algorithm (called DDS) is the first algorithm that is able to sample DAGs according to the *exact* DAG posterior with the same order-modular prior assumption. We empirically show that our DDS algorithm is both considerably more accurate and considerably more efficient than the Order MCMC and the Partial Order MCMC when n is moderate so that our DDS algorithm is applicable. Moreover, the estimator based on our DDS algorithm has several desirable properties; for example, unlike the existing MCMC algorithms, the quality of our estimator can be guaranteed by controlling the number of DAGs sampled by our DDS algorithm. The main application of our DDS algorithm is to address the limitation of the exact DP algorithms (Koivisto and Sood, 2004; Koivisto, 2006; Parviainen and Koivisto, 2011) (whose usage is restricted to modular features or path features) in order to estimate the posteriors of various *non-modular* features arbitrarily specified by users. Additionally our DDS algorithm can also be used to efficiently perform data prediction tasks in estimating $p(x|D)$ for a large number of data cases (while the exact DP algorithm has to be re-run for each data case x). Finally, we develop an algorithm (called IW-DDS) to correct the bias (due to the order-modular prior) in the DDS algorithm by extending the idea of Ellis and Wong (2008). We theoretically prove that the estimator based on our IW-DDS has several desirable properties; then we empirically show that our estimator is superior to the estimators based on the Hybrid MCMC method (Eaton and Murphy, 2007) and the K-best algorithm (Tian et al., 2010), two state-of-the-art algorithms that can estimate the posterior of any feature without the order-modular prior assumption. Analogously, our IW-DDS algorithm mainly addresses the limitation of the exact DP algorithm of Tian and He (2009) (whose usage is restricted to modular features) in order to estimate the posteriors of arbitrary *non-modular* features and can additionally be used to efficiently perform data prediction tasks when an application situation prefers to avoid the bias from the order-modular prior.

1. A uniform prior over the DAG space can be represented in another form of the structure prior, termed as the *structure-modular* prior. The definition of the structure-modular prior will be given in Eq. (2) in Section 2.
2. Although a lot of discussions are about the comparison of these two kinds of priors (the order-modular prior and the structure-modular prior), there exist other kinds of priors such as a uniform prior over Markov equivalence classes. Our paper, however, will focus on learning structural features under either the order-modular prior or the structure-modular prior, because these are the two most commonly used priors in applications.

The rest of the paper is organized as follows. In Section 2 we briefly review the Bayesian approach to learning Bayesian networks from data, the related DP algorithms (Koivisto and Sood, 2004; Koivisto, 2006), and the Order MCMC algorithm (Friedman and Koller, 2003). In Section 3 we present our order sampling algorithm, DDS algorithm, and IW-DDS algorithm, and prove good properties of the estimators based on our algorithms. We empirically demonstrate the advantages of our algorithms in Section 4 and conclude the paper in Section 5. Finally, Appendix A provides the proofs of all the conclusions including the propositions, theorems, and corollary referenced in the paper.

2. Bayesian Learning of Bayesian Network Structures

A Bayesian network structure is a DAG G that provides the skeleton for compactly encoding a joint probability distribution over a set $X = \{X_1, \ldots, X_n\}$ of random variables with each node of the DAG representing a variable in X. For convenience we typically work on the index set $V = \{1, \ldots, n\}$ and represent a variable X_i by its index i. We use $X_{Pa_i} \subseteq X$ to represent the parent set of X_i in a DAG G and use $Pa_i \subseteq V$ to represent the corresponding index set. (A pair (i, Pa_i) is often called a family.) Thus, a DAG G can be represented as a vector $(Pa_1, \ldots, Pa_n)$.

Assume that we are given a training data set $D = \{x^1, x^2, \ldots, x^m\}$, where each x^i is a particular instantiation over the set of variables X. We only consider situations where the data are complete, that is, every variable in X is assigned a value. In the Bayesian approach to learning Bayesian networks from the training data D, we compute the posterior probability of a DAG G as

$$p(G|D) = \frac{p(D|G)p(G)}{p(D)} = \frac{p(D|G)p(G)}{\sum_G p(D|G)p(G)}.$$

Assuming global and local parameter independence, and parameter modularity, we can decompose $p(D|G)$ into a product of local marginal likelihoods (often called local scores) as (Cooper and Herskovits, 1992; Heckerman et al., 1995)

$$p(D|G) = \prod_{i=1}^{n} p(X_i|X_{Pa_i} : D) := \prod_{i=1}^{n} score_i(Pa_i : D), \tag{1}$$

where, with appropriate parameter priors, $score_i(Pa_i : D)$ (the local score for a family (i, Pa_i)) has a closed-form solution. In this paper we will assume that these local scores can be computed efficiently from data. The standard assumption for the structure prior $p(G)$ is the *structure-modular* prior (Friedman and Koller, 2003)

$$p(G) = \prod_{i=1}^{n} p_i(Pa_i), \tag{2}$$

where p_i is some nonnegative function over the subsets of $V - \{i\}$.

Combining Eq. (1) and Eq. (2), we have

$$p_{\not\prec}(G, D) = p(D|G)p_{\not\prec}(G) = \prod_{i=1}^{n} score_i(Pa_i : D)p_i(Pa_i). \tag{3}$$

Note that the subscript $\not\prec$ is intentionally added by us to mean that each correspondingly marked probability is the one obtained under the structure-modular prior instead of the order-modular prior. This is different from the probability obtained under the order-modular prior, which will be marked by the subscript $\prec$ for the distinction.

We can compute the posterior probability of any feature of interest by averaging over all the possible DAGs. For example, we are often interested in computing the posteriors of structural features. Let f be a structural feature represented by an indicator function such that $f(G)$ is 1 if the feature is present in G and 0 otherwise. By the full Bayesian model averaging, we have the posterior of f as

$$p(f|D) = \sum_G f(G)p(G|D). \tag{4}$$

Note that $p_{\not\prec}(f|D)$ will be obtained if $p(G|D)$ in Eq. (4) is $p_{\not\prec}(G|D)$; $p_{\prec}(f|D)$ will be obtained if $p(G|D)$ in Eq. (4) is $p_{\prec}(G|D)$. This difference is the key to understanding the bias issue which will be described in details later.

Because directly summing over all the possible DAGs by brute force is generally infeasible for any problem with $n > 6$ using a contemporary computer, one approach to computing the posterior of f is to draw DAG samples $\{G_1, \ldots, G_T\}$ from the posterior $p_{\not\prec}(G|D)$ or $p_{\prec}(G|D)$, which can then be used to estimate the posterior $p_{\not\prec}(f|D)$ or $p_{\prec}(f|D)$ as

$$\hat{p}(f|D) = \frac{1}{T}\sum_{i=1}^{T} f(G_i). \tag{5}$$

2.1 The DP Algorithms

The DP algorithms (Koivisto and Sood, 2004; Koivisto, 2006) work in the order space rather than the DAG space. We define an *order* $\prec$ of variables as a total order (a linear order) on V represented as a vector $(U_1, \ldots, U_n)$, where U_i is the set of predecessors of i in the order $\prec$. To be more clear we may use $U_i^{\prec}$. We say that a DAG $G = (Pa_1, \ldots, Pa_n)$ is consistent with an order $(U_1, \ldots, U_n)$, denoted by $G \subseteq \prec$, if $Pa_i \subseteq U_i$ for each i. If S is a subset of V, we let $\mathcal{L}(S)$ denote the set of linear orders on S. In the following we will largely follow the notation from Koivisto (2006).

The algorithms working in the order space assume the *order-modular* prior defined as follows: if G is consistent with $\prec$, then

$$p(\prec, G) = \prod_{i=1}^{n} q_i(U_i)\rho_i(Pa_i), \tag{6}$$

where each q_i and ρ_i is some function from the subsets of $V - \{i\}$ to the nonnegative real numbers. (If G is not consistent with $\prec$, then $p(\prec, G) = 0$.)

A *modular feature* is defined as

$$f(G) = \prod_{i=1}^{n} f_i(Pa_i),$$

where $f_i(Pa_i)$ is an indicator function returning a $0/1$ value. For example, an edge feature $j \to i$ can be represented by always setting $f_l(Pa_l) = 1$ for each $l \neq i$ and by setting $f_i(Pa_i) = 1$ if and only if $j \in Pa_i$.

With the order-modular prior, we are interested in the posterior $p_{\prec}(f|D) = p_{\prec}(f, D)/p_{\prec}(D)$. Note that $p_{\prec}(f|D)$ can be obtained if the joint probability $p_{\prec}(f, D)$ can be computed, because $p_{\prec}(D) = p_{\prec}(f \equiv 1, D)$ where $f \equiv 1$, meaning that f always equals 1, can be easily achieved by setting each $f_i(Pa_i)$ to be the constant 1. Koivisto and Sood (2004) showed that

$$p(f, \prec, D) = \prod_{i=1}^{n} \alpha_i(U_i^{\prec}), \tag{7}$$

and

$$p_{\prec}(f, D) = \sum_{\prec} \prod_{i=1}^{n} \alpha_i(U_i^{\prec}), \tag{8}$$

where the function α_i is defined for each $i \in V$ and each $S \subseteq V - \{i\}$ as

$$\alpha_i(S) = q_i(S) \sum_{Pa_i \subseteq S} \beta_i(Pa_i),$$

in which the function β_i is defined for each $i \in V$ and each $Pa_i \subseteq V - \{i\}$ as

$$\beta_i(Pa_i) = f_i(Pa_i)\rho_i(Pa_i)score_i(Pa_i : D).$$

Accordingly, the DP algorithm of Koivisto and Sood (2004) consists of the following three steps. The first step computes $\beta_i(Pa_i)$ for each $i \in V$ and each $Pa_i \subseteq V - \{i\}$. The time complexity of this step is $O(n^{k+1}C(m))$ under the assumption of the maximum in-degree k, where n is the number of variables, and $C(m)$ is the cost of computing a single local marginal likelihood $score_i(Pa_i : D)$ for m data instances. The second step computes $\alpha_i(S)$ for each $i \in V$ and each $S \subseteq V - \{i\}$. With the assumed maximum in-degree k, this step takes $O(kn2^n)$ time by using the truncated Möbius transform technique (Koivisto and Sood, 2004), which was extended from the standard fast Möbius transform algorithm (Kennes and Smets, 1991). The third step computes $p_{\prec}(f, D)$ by defining the following function (called forward contribution) for each $S \subseteq V$:

$$L(S) = \sum_{\prec \in \mathcal{L}(S)} \prod_{i \in S} \alpha_i(U_i^{\prec}), \tag{9}$$

where $U_i^{\prec}$ is the set of variables in S ahead of i in the order $\prec \in \mathcal{L}(S)$. It can be shown that for every $S \subseteq V$, $L(S)$ can be computed recursively using the DP technique according to the following equation (Koivisto and Sood, 2004; Koivisto, 2006):

$$L(S) = \sum_{i \in S} \alpha_i(S - \{i\})L(S - \{i\}), \tag{10}$$

starting with $L(\emptyset) = 1$ and ending with $L(V)$. From Eq. (8) and Eq. (9), we have

$$p_{\prec}(f, D) = L(V). \tag{11}$$

The third step takes $O(n2^n)$ time when $L(V)$ is computed using the above DP technique. In summary, the whole DP algorithm of Koivisto and Sood (2004) can compute the posterior of any modular feature (such as an edge feature) in $O(n^{k+1}C(m) + kn2^n)$ time and $O(n2^n)$ space, where its $O(n2^n)$ space cost limits its application to Bayesian networks with up to around 25 variables.

As the extended work of Koivisto and Sood (2004), Koivisto (2006) included the DP algorithm of Koivisto and Sood (2004) as its first three steps and appended two additional steps so that all the $n(n-1)$ edges can be computed in $O(n^{k+1}C(m) + kn2^n)$ time and $O(n2^n)$ space. The foundation of the two additional steps is the introduction of the following function (called backward contribution) for each $T \subseteq V$:

$$R(T) = \sum_{\prec' \in \mathcal{L}(T)} \prod_{i \in T} \alpha_i((V - T) \cup U_i^{\prec'}). \tag{12}$$

Essentially, $R(T)$ represents the contribution of the variables in T when they are the last $|T|$ elements in the unknown linear order on V. Like $L(S)$, $R(T)$ can also be computed recursively using some DP technique. Please refer to the paper of Koivisto (2006) for further details of the two additional steps.

Although the DP algorithms (Koivisto and Sood, 2004; Koivisto, 2006) make significant contributions to the structure learning of Bayesian networks, they have one fundamental limitation: they can only compute the posteriors of modular features. In the next section, we will show how to use the results of the DP algorithm of Koivisto and Sood (2004) to efficiently draw DAG samples, which can then be used to compute the posteriors of arbitrary features.

2.2 Order MCMC

The idea of the Order MCMC is to use the Metropolis-Hastings algorithm to draw order samples $\{\prec_1, \ldots, \prec_{N_o}\}$ that have $p(\prec |D)$ as the invariant distribution, where N_o is the number of sampled orders. For this purpose we need to be able to compute $p(\prec, D)$, which can be obtained from Eq. (7) by setting $f \equiv 1$. Let $\beta_i'(Pa_i)$ denote $\beta_i(Pa_i)$ resulted from setting each $f_i(Pa_i)$ to be the constant 1. Similarly, we define $\alpha_i'(S)$ and $L'(S)$ as the special cases of $\alpha_i(S)$ and $L(S)$ by setting each $f_i(Pa_i)$ to be the constant 1. Then from Eq. (7) and Eq. (11) we have

$$p(\prec, D) = \prod_{i=1}^{n} \alpha_i'(U_i^{\prec}), \tag{13}$$

and

$$p_{\prec}(D) = L'(V). \tag{14}$$

The Order MCMC can estimate the posterior of a modular feature as

$$\hat{p}_{\prec}(f|D) = \frac{1}{N_o} \sum_{i=1}^{N_o} p(f| \prec_i, D). \tag{15}$$

For example, from Propositions 3.1 and 3.2 stated by Friedman and Koller (2003) as well as the definitions of β_i' and α_i', the posterior of a particular choice of parent set $Pa_i \subseteq U_i^{\prec}$ for node i given an order is

$$p((i, Pa_i)| \prec, D) = \frac{\beta_i'(Pa_i)}{\alpha_i'(U_i^{\prec})/q_i(U_i^{\prec})}, \tag{16}$$

and the posterior of the edge feature $j \to i$ given an order is

$$p(j \to i| \prec, D) = 1 - \frac{\alpha'_i(U_i^{\prec} - \{j\})/q_i(U_i^{\prec} - \{j\})}{\alpha'_i(U_i^{\prec})/q_i(U_i^{\prec})}. \quad (17)$$

In order to compute arbitrary non-modular features, we further draw DAG samples after drawing N_o order samples. Given an order, a DAG can be sampled by drawing parents for each node according to Eq. (16). Given DAG samples $\{G_1, \ldots, G_T\}$, we can then estimate any feature posterior $p_{\prec}(f|D)$ using $\hat{p}_{\prec}(f|D)$ shown in Eq. (5).

3. Order Sampling Algorithm and DAG Sampling Algorithms

In this section we present our order sampling algorithm, DDS algorithm, and IW-DDS algorithm. We also prove good properties of the estimators based on our algorithms.

3.1 Order Sampling Algorithm

In this subsection, we show that using the results including $\alpha'_i(S)$ (for each $i \in V$ and each $S \subseteq V - \{i\}$) and $L'(S)$ (for each $S \subseteq V$) computed from the DP algorithm of Koivisto and Sood (2004), we can draw an order sample efficiently by drawing each element in the order one by one. Let an order $\prec$ be represented as $(\sigma_1, \ldots, \sigma_n)$, where σ_i is the ith element in the order.

Proposition 1 *The conditional probability that the kth ($1 \leq k \leq n$) element in the order is σ_k given that the $n-k$ elements after it along the order are $\sigma_{k+1}, \ldots, \sigma_n$ respectively is as follows:*

$$p(\sigma_k|\sigma_{k+1}, \ldots, \sigma_n, D) = \frac{L'(U_{\sigma_k}^{\prec})\alpha'_{\sigma_k}(U_{\sigma_k}^{\prec})}{L'(U_{\sigma_{k+1}}^{\prec})}, \quad (18)$$

where $\sigma_k \in V - \{\sigma_{k+1}, \ldots, \sigma_n\}$, and $U_{\sigma_i}^{\prec} = V - \{\sigma_i, \sigma_{i+1}, \ldots, \sigma_n\}$ so that $U_{\sigma_i}^{\prec}$ denotes the set of predecessors of σ_i in the order $\prec$.
Specifically for $k = n$, we essentially have

$$p(\sigma_n = i|D) = \frac{L'(V - \{i\})\alpha'_i(V - \{i\})}{L'(V)}, \quad (19)$$

where $i \in V$.

Note that all the proofs in this paper are provided in Appendix A.

It is clear that for each $k \in \{1, \ldots, n\}$, $\sum_{i \in U_{\sigma_{k+1}}^{\prec}} p(\sigma_k = i|\sigma_{k+1}, \ldots, \sigma_n, D) = 1$ because of Eq. (10) and $U_{\sigma_k}^{\prec} = U_{\sigma_{k+1}}^{\prec} - \{\sigma_k\}$. Thus, $p(\sigma_k|\sigma_{k+1}, \ldots, \sigma_n, D)$ is a probability mass function (pmf) with k possible σ_k values from $U_{\sigma_{k+1}}^{\prec}$.

Based on Proposition 1, we propose the following order sampling algorithm to sample an order $\prec$:

- Sample σ_n, the last element of the order $\prec$, according to Eq. (19).
- For each k from $n-1$ down to 1: given the sampled $(\sigma_{k+1}, \ldots, \sigma_n)$, sample σ_k, the kth element of the order $\prec$, according to Eq. (18).

Provided that $\alpha'_i(S)$ (for each $i \in V$ and each $S \subseteq V - \{i\}$) and $L'(S)$ (for each $S \subseteq V$) have been computed, sampling an order using the above algorithm takes only $O(n^2)$ time because sampling each element σ_k ($k \in \{1, \ldots, n\}$) in the order takes $O(n)$ time.

The following proposition guarantees the correctness of our order sampling algorithm.

Proposition 2 *An order $\prec$ sampled according to our order sampling algorithm has its pmf equal to the exact posterior $p(\prec|D)$ under the order-modular prior, because*

$$\prod_{k=1}^{n} p(\sigma_k|\sigma_{k+1}, \ldots, \sigma_n, D) = p(\prec|D). \quad (20)$$

The key to our order sampling algorithm is our realization that the results including $\alpha'_i(S)$ and $L'(S)$ computed from the DP algorithm of Koivisto and Sood (2004) are already sufficient to guide the order sampling process. In an abstract point of view, the results computed from the DP algorithm of Koivisto and Sood (2004) are analogous to the answers provided by the #P-oracle stated in Theorem 3.3 of Jerrum et al. (1986). This theorem states that with the aid of a #P-oracle that is always able to provide the exact counting information (the exact number) of accepting configurations from a currently given configuration, a probabilistic Turing machine can serve as a uniform generator so that every accepting configuration will be reached with an equal positive probability. In our situation, instead of providing the exact counting information, the results computed from the DP algorithm of Koivisto and Sood (2004) are able to provide the exact joint probability $p(\sigma_k, \sigma_{k+1}, \ldots, \sigma_n, D)$ for a subsequence $(\sigma_k, \sigma_{k+1}, \ldots, \sigma_n)$ of any order $\prec$ for any $k \in \{1, 2, \ldots, n\}$, which is shown in the proof of Proposition 1 in Appendix A.1. As a result, the order sampling can be efficiently performed based on the definition of the conditional probability distribution.

3.2 DDS Algorithm

After drawing an order sample, we can then easily sample a DAG by drawing parents for each node according to Eq. (16) as described by Friedman and Koller (2003) (assuming a maximum in-degree k). This naturally leads to our algorithm, termed direct DAG sampling (DDS), as follows:

- Step 1: Run the DP algorithm of Koivisto and Sood (2004) with each $f_i(Pa_i)$ set to be the constant 1.
- Step 2 (Order sampling step): Sample N_o orders such that each order $\prec$ is independently sampled according to our order sampling algorithm.
- Step 3 (DAG sampling step): For each sampled order $\prec$, one DAG is independently sampled by drawing a parent set for each node of the DAG according to Eq. (16).

The correctness of our DDS algorithm is guaranteed by the following theorem.

Theorem 3 *The N_o DAGs sampled according to the DDS algorithm are independent and identically distributed (iid) with the pmf equal to the exact posterior $p_{\prec}(G|D)$ under the order-modular prior.*

The time complexity of the DDS algorithm is as follows. Step 1 takes $O(n^{k+1}C(m) + kn2^n)$ time (Koivisto and Sood, 2004), as discussed in Section 2.1. In Step 2, sampling each order takes $O(n^2)$ time. In Step 3, sampling each DAG takes $O(n^{k+1})$ time. Thus, the overall time complexity of our DDS algorithm is $O(n^{k+1}C(m) + kn2^n + n^2N_o + n^{k+1}N_o)$. Because typically we assume $k \geq 1$, the order sampling process (Step 2) does not affect the overall time complexity of the DDS algorithm because of its efficiency.

The time complexity of our DDS algorithm depends on the assumption of the maximum in-degree k. Such an assumption is fairly innocuous, as discussed on page 101 of Friedman and Koller (2003), because DAGs with very large families tend to have low scores. (The maximum-in-degree assumption is also justified in the context of biological expression data on page 270 of Grzegorczyk and Husmeier, 2008.) Accordingly, this assumption has been widely used in the literature (Friedman and Koller, 2003; Koivisto and Sood, 2004; Ellis and Wong, 2008; Grzegorczyk and Husmeier, 2008; Niinimaki et al., 2011; Parviainen and Koivisto, 2011) and the maximum in-degree k has been set to be no greater than 6 in all of their experiments.

Note that the DAG sampling step of the DDS algorithm takes $O(n^{k+1}N_o)$ time. This will dominate the overall running time of the DDS algorithm (even if k is assumed to be 3 or 4), when n is moderate ($n \leq 25$) and the sample size N_o reaches several thousands. Therefore, for the efficiency of our DDS algorithm, we have developed a time-saving strategy for the DAG sampling step, which will be described in details in Section 3.2.1.

Given DAG samples, $\hat{p}_{\prec}(f|D)$, an estimator of the exact posterior of any arbitrary feature f, can be constructed by Eq. (5). Let $C_{n,f}$ denote the time cost of determining the structural feature f in a DAG of n nodes. Then constructing $\hat{p}_{\prec}(f|D)$ takes $O(C_{n,f}N_o)$ time. (For example, $C_{n,f_e} = O(1)$ for an edge feature f_e; $C_{n,f_p} = O(n^2)$ for a path feature f_p.) If we only need order samples, the algorithm consisting of Steps 1 and 2 will be called direct order sampling (DOS). Given order samples, for some modular feature f such as a parent-set feature or an edge feature, $p(f|\ \prec_i, D)$ can be computed by Eq. (16) or (17), and then $p_{\prec}(f|D)$ can be estimated by Eq. (15). (Because computing a parent-set feature or an edge feature by Eq. (16) or (17) takes $O(1)$ time, estimating $p_{\prec}(f|D)$ by Eq. (15) only takes $O(N_o)$ time for these two features.)

As for the space cost of our DDS algorithm, note that Step 1 of our DDS takes $O(n2^n)$ memory space, which limits the application of our DDS to Bayesian networks with up to around 25 variables. Because a total order can be represented as a vector $(U_1, \ldots, U_n)$ and a DAG can be represented as a vector $(Pa_1, \ldots, Pa_n)$, both a total order and a DAG can be represented in $O(n^2)$ space [3]. Therefore, Steps 2 and 3 of our DDS take $O(n^2N_o)$ memory space, and the overall memory requirement of our DDS algorithm is $O(n2^n + n^2N_o)$.

Because of Theorem 3, the estimator $\hat{p}_{\prec}(f|D)$ based on our DDS algorithm has the following desirable properties.

Corollary 4 *For any structural feature f, with respect to the exact posterior $p_{\prec}(f|D)$, the estimator $\hat{p}_{\prec}(f|D)$ based on the N_o DAG samples from the DDS algorithm using Eq. (5) has the following properties:*

(i) $\hat{p}_{\prec}(f|D)$ is an unbiased estimator of $p_{\prec}(f|D)$.

3. When $n \leq 32$, in the vector representation $(Pa_1, \ldots, Pa_n)$ of a DAG, each parent set Pa_i can be represented by a 32-bit integer whose jth bit indicates whether or not node X_j is a parent of node X_i. Thus, a DAG of a moderate size n can be represented by n 32-bit integers. Similarly, when $n \leq 32$, in the vector representation $(U_1, \ldots, U_n)$ of a total order, each U_i can be represented by a 32-bit integer whose jth bit indicates whether or not node X_j is a predecessor of node X_i. Thus, a total order of a moderate size n can also be represented by n 32-bit integers.

(ii) $\hat{p}_{\prec}(f|D)$ converges almost surely to $p_{\prec}(f|D)$.

(iii) If $0 < p_{\prec}(f|D) < 1$, then the random variable

$$\frac{\sqrt{N_o}(\hat{p}_{\prec}(f|D) - p_{\prec}(f|D))}{\sqrt{\hat{p}_{\prec}(f|D)(1 - \hat{p}_{\prec}(f|D))}}$$

has a limiting standard normal distribution.

(iv) For any $\epsilon > 0$ and any $0 < \delta < 1$, if $N_o \geq (\ln(2/\delta))/(2\epsilon^2)$, then $P(|\hat{p}_{\prec}(f|D) - p_{\prec}(f|D)| < \epsilon) \geq 1 - \delta$.

In particular, Corollary 4 (iv), which is essentially from the Hoeffding bound (Hoeffding, 1963; Koller and Friedman, 2009), ensures the probability that the error of the estimator $\hat{p}_{\prec}(f|D)$ from the DDS algorithm is bounded by ϵ to be at least $1-\delta$, as long as the sample size $N_o \geq (\ln(2/\delta))/(2\epsilon^2)$. This property, which the existing MCMC algorithms (Friedman and Koller, 2003; Niinimaki et al., 2011) do not have, can be used to obtain quality guarantee for the estimator from our DDS algorithm.

3.2.1 TIME-SAVING STRATEGY FOR THE DAG SAMPLING STEP OF THE DDS

The running time of the DAG sampling step (Step 3) of the DDS algorithm is $O(n^{k+1}N_o)$, which will dominate the overall running time of the DDS algorithm when n is moderate and the sample size N_o reaches several thousands. Thus, in this sub-subsection we introduce our strategy for effectively reducing the running time of the DAG sampling step so that the efficiency of the overall DDS algorithm can be achieved.

In the DAG sampling step, each sampled order $\prec_i = (\sigma_1, \ldots, \sigma_n)^{\prec_i}$ $(1 \leq i \leq N_o)$ can be represented as $\{(\sigma_1, U_{\sigma_1})^{\prec_i}, \ldots, (\sigma_n, U_{\sigma_n})^{\prec_i}\}$, where U_{σ_j} denotes the set of predecessors of σ_j in the order. For each sampled order $\prec_i$, for each $(\sigma_j, U_{\sigma_j})^{\prec_i}$ $(1 \leq j \leq n)$, we need to sample one Pa_{σ_j} of σ_j (one parent set of σ_j) from a list $\{Pa_{\sigma_j z}\}_z^{\sigma_j}$ including every parent set $Pa_{\sigma_j z} \subseteq U_{\sigma_j}^{\prec_i}$. Let Z_j be the length of such a list. Because $Z_j = \sum_{i=0}^{\min\{k, j-1\}} \binom{j-1}{i} = O(n^k)$, sampling one Pa_{σ_j} for σ_j takes $O(n^k)$ time and sampling one DAG takes $O(n^{k+1})$ time. Note that Z_j is an increasing function of j but in the following we will use the notation Z instead of Z_j for notational convenience when the context is clear. In the following we also will not use the plural for mathematical symbols to avoid notational confusion by ending "s". The reader should assume the correct singular or plural case when reading.

When $N_o > 1$, the overall running time of the DAG sampling step can be reduced as follows. Define $\theta_z^{(\sigma_j, U_{\sigma_j})^{\prec_i}}$ as

$$\begin{aligned}\theta_z^{(\sigma_j, U_{\sigma_j})^{\prec_i}} &= P((\sigma_j, Pa_{\sigma_j z})|\ \prec_i, D) = P((\sigma_j, Pa_{\sigma_j z})|(\sigma_j, U_{\sigma_j})^{\prec_i}, D) \\ &= \beta'_{\sigma_j}(Pa_{\sigma_j z})/[\alpha'_{\sigma_j}(U_{\sigma_j}^{\prec_i})/q_{\sigma_j}(U_{\sigma_j}^{\prec_i})],\end{aligned}$$

for $z \in \{1, \ldots, Z\}$. First, using the common strategy of sampling from a discrete distribution (Koller and Friedman, 2009), for $(\sigma_j, U_{\sigma_j})^{\prec_i}$ we can create $S_I^{(\sigma_j, U_{\sigma_j})^{\prec_i}}$, a sequence of Z probability intervals with the following form:

$$\Big(\big[0, \theta_1^{(\sigma_j,U_{\sigma_j})^{\prec_i}}\big), \big[\theta_1^{(\sigma_j,U_{\sigma_j})^{\prec_i}}, \theta_1^{(\sigma_j,U_{\sigma_j})^{\prec_i}} + \theta_2^{(\sigma_j,U_{\sigma_j})^{\prec_i}}\big), \ldots, \big[\sum_{z=1}^{Z-2} \theta_z^{(\sigma_j,U_{\sigma_j})^{\prec_i}}, \sum_{z=1}^{Z-1} \theta_z^{(\sigma_j,U_{\sigma_j})^{\prec_i}}\big), \big[\sum_{z=1}^{Z-1} \theta_z^{(\sigma_j,U_{\sigma_j})^{\prec_i}}, 1\big)\Big),$$

where the lth interval is $\big[\sum_{z=1}^{l-1} \theta_z^{(\sigma_j,U_{\sigma_j})^{\prec_i}}, \sum_{z=1}^{l} \theta_z^{(\sigma_j,U_{\sigma_j})^{\prec_i}}\big)$. Note that $S_I^{(\sigma_j,U_{\sigma_j})^{\prec_i}}$ can be created in time $O(Z)$ and sampling one Pa_{σ_j} for σ_j from a list $\{Pa_{\sigma_j z}\}_z^{\sigma_j}$ can then be achieved using binary search in time $O(\log Z)$ based on $S_I^{(\sigma_j,U_{\sigma_j})^{\prec_i}}$. Then the following observation is the key reason that the running time of the DAG sampling step can be reduced. For two sampled orders $\prec_i$ and $\prec_{i'}$ ($1 \leq i, i' \leq N_o$), even if $\prec_i \neq \prec_{i'}$, it is possible that $(\sigma_j, U_{\sigma_j})^{\prec_i} = (\sigma_j, U_{\sigma_j})^{\prec_{i'}}$ for some $j \in \{1, \ldots, n\}$. This is because for each j, (σ_j, U_{σ_j}) essentially has a multinomial distribution with N_o trials and a set of $n\binom{n-1}{j-1}$ cell probabilities $\{P((\sigma_j, U_{\sigma_j})|D)\}$. Actually, for any j, the following relation holds for each cell probability:

$$P((\sigma_j, U_{\sigma_j})|D) \propto \alpha'_{\sigma_j}(U_{\sigma_j}) L'(U_{\sigma_j}) R'(V - U_{\sigma_j} - \{\sigma_j\}), \tag{21}$$

where $R'(.)$ is the special case of $R(.)$ by setting $f \equiv 1$ and $R(.)$ is defined in Eq. (12). The proof of Eq. (21) is very similar to the derivation shown by Koivisto (2006) and is provided in Appendix A.5 Note that $(\sigma_j, U_{\sigma_j})^{\prec_i} = (\sigma_j, U_{\sigma_j})^{\prec_{i'}}$ implies $S_I^{(\sigma_j,U_{\sigma_j})^{\prec_i}} = S_I^{(\sigma_j,U_{\sigma_j})^{\prec_{i'}}}$. Thus, by storing the created $S_I^{(\sigma_j,U_{\sigma_j})^{\prec_i}}$ in the memory, once $(\sigma_j, U_{\sigma_j})^{\prec_i} = (\sigma_j, U_{\sigma_j})^{\prec_{i'}}$ for $i' > i$, creating $S_I^{(\sigma_j,U_{\sigma_j})^{\prec_{i'}}}$ can be avoided and sampling one Pa_{σ_j} for σ_j takes only $O(\log Z)$ time.

On one hand, our strategy will definitely save the running time for these j such that $n\binom{n-1}{j-1}$ (the number of all the possible values of (σ_j, U_{σ_j})) is smaller than N_o if every created $S_I^{(\sigma_j,U_{\sigma_j})}$ is stored. This is because the running time of sampling Pa_{σ_j} of σ_j is only $O(\log Z)$ in at least $N_o - n\binom{n-1}{j-1}$ samples out of the overall N_o samples. (In the worst case, $S_I^{(\sigma_j,U_{\sigma_j})}$ will be created for each possible (σ_j, U_{σ_j}).) For example, when $j = n$, the number of all the possible values of (σ_j, U_{σ_j}) is only n, and Z_j (the length of the list $\{Pa_{\sigma_j z}\}_z^{\sigma_j}$) achieves its maximum among all the j, so that sampling one Pa_{σ_n} for σ_n takes $O(\log Z_n)$ time in at least $N_o - n$ samples. Accordingly, when $j = n$, the worst-case running time of sampling the N_o $(\sigma_n, Pa_{\sigma_n})$ families is $O(n(Z_n + \log Z_n) + (N_o - n)\log Z_n) = O(nZ_n + N_o \log Z_n)$.

On the other hand, our strategy usually can also save the running time even for these j such that the number of all the possible values of (σ_j, U_{σ_j}) is larger than N_o. This is because the probability mass usually is not uniformly distributed among the set of all the possible values of (σ_j, U_{σ_j}). Once the majority of the probability mass p_Σ is concentrated on r_j values of (σ_j, U_{σ_j}), where r_j is a number smaller than N_o, the probability that only these r_j values of (σ_j, U_{σ_j}) appear in all the N_o order

samples is $(p_\Sigma)^{N_o}$. Accordingly, with the probability $(p_\Sigma)^{N_o}$, the running time of sampling Pa_{σ_j} for σ_j is $O(\log Z_j)$ in at least $N_o - r_j$ samples. As a result, the expected running time of sampling the N_o $(\sigma_j, Pa_{\sigma_j})$ families is below $O([r_j Z_j + N_o \log Z_j](p_\Sigma)^{N_o} + N_o(Z_j + \log Z_j)(1 - (p_\Sigma)^{N_o}))$; the expected running time of sampling the N_o DAGs is below $O(\sum_{j=1}^{n}\{[r_j Z_j + N_o \log Z_j](p_\Sigma)^{N_o} + N_o(Z_j + \log Z_j)(1 - (p_\Sigma)^{N_o})\})$. Typically, when m is not small, the local score $score_i(Pa_i : D)$ will not be uniform at all. Correspondingly, it is likely that the multinomial probability mass function $P((\sigma_j, U_{\sigma_j})|D)$ will concentrate dominant probability mass on a small number of (σ_j, U_{σ_j}) candidates that these $(\sigma_j, Pa_{\sigma_j})$ having large local scores are consistent with. As a result, our time-saving strategy will usually become more effective when m is not small.

Note that we also include the policy of recycling the created $S_I^{(\sigma_j,U_{\sigma_j})}$ for our strategy because it is possible that all the memory in a computer will be exhausted in order to store all the created $S_I^{(\sigma_j,U_{\sigma_j})}$, especially when n is not small but m is small. (The space complexity of storing all the $S_I^{(\sigma_j,U_{\sigma_j})}$ is $O(\sum_{j=1}^{n} n\binom{n-1}{j-1} Z_j) = O(n^{k+1} 2^{n-1})$.) For this paper, we use a simple recycling method as follows. Some upper limit for the total number of the probability intervals (representing $\big[\sum_{z=1}^{l-1} \theta_z^{(\sigma_j,U_{\sigma_j})^{\prec_i}}, \sum_{z=1}^{l} \theta_z^{(\sigma_j,U_{\sigma_j})^{\prec_i}}\big)$) is pre-specified based on the memory of the computer used. Each time such an upper limit is reached during the DAG sampling step of the DDS, which indicates a large amount of memory has been used to store $S_I^{(\sigma_j,U_{\sigma_j})}$, we recycle the currently stored $S_I^{(\sigma_j,U_{\sigma_j})}$ according to their usage frequencies which serve as the estimates of $P((\sigma_j, U_{\sigma_j})|D)$. The memory for each infrequently used $S_I^{(\sigma_j,U_{\sigma_j})}$ will be reclaimed to ensure that at least a pre-specified number of probability intervals will be recycled from the memory. In addition, in order to have a better use of each created $S_I^{(\sigma_j,U_{\sigma_j})}$ before it possibly gets reclaimed, we sort the N_o sampled orders according to the posterior $p(\prec|D)$ just before executing the DAG sampling step of the DDS. The underlying rationale is that if $p(\prec_i|D)$ is relatively close to $p(\prec_{i'}|D)$, which indicates $p(\prec_i, D)$ is relatively close to $p(\prec_{i'}, D)$ (because $p_\prec(D)$ is a constant), it is likely that $\prec_i$ and $\prec_{i'}$ share some (σ_j, U_{σ_j}) component(s) because of Eq. (13). (The extreme situation is that if $p(\prec_i|D)$ equals $p(\prec_{i'}|D)$, it is very likely that $\prec_i$ equals $\prec_{i'}$ so that $\prec_i$ and $\prec_{i'}$ share every (σ_j, U_{σ_j}).) Thus, $\prec_i$ and $\prec_{i'}$ having similar posteriors tend to be close to each other after the sorting, so that it is likely that the common $S_I^{(\sigma_j,U_{\sigma_j})}$ will be used before the reclamation. Furthermore, as N_o increases, the probability that two orders (out of the N_o sampled orders) share some (σ_j, U_{σ_j}) component(s) increases. Accordingly, after the sorting, the probability of reusing $S_I^{(\sigma_j,U_{\sigma_j})}$ before its reclamation will also increase. As a result, the benefit of our time-saving strategy will typically increase when N_o increases.

The experimental results show that our time-saving strategy for the DAG sampling step of the DDS is very effective. Please see the discussion in Section 4 about $\hat{\mu}(T_{DAG})$ and $\hat{\sigma}(T_{DAG})$, the sample mean and the sample standard deviation of the running time of the DAG sampling step of the DDS, which are reported in Tables 2 and 4.

3.3 IW-DDS Algorithm

In this subsection we present our DAG sampling algorithm under the general structure-modular prior (Eq. 2) by effectively correcting the bias due to the use of the order-modular prior.

As mentioned in Section 1, $p_\prec(f|D)$ has the bias due to the assumption of the order-modular prior. This is essentially because $p_\prec(G|D)$ based on the order-modular prior (Eq. 6) is different from $p_\not\prec(G|D)$ based on the structure-modular prior (Eq. 2).

In fact, with the common setting that $q_i(U_i)$ always equals 1 ($q_i(U_i) \equiv 1$), if $\rho_i(Pa_i)$ in Eq. (6) is set to be always equal to $p_i(Pa_i)$ in Eq. (2) ($\rho_i(Pa_i) \equiv p_i(Pa_i)$), the following relation holds:

$$p_{\prec}(G|D) = \frac{p_{\not\prec}(D)}{p_{\prec}(D)} \cdot \mid \prec_G \mid \cdot p_{\not\prec}(G|D), \tag{22}$$

where $\mid \prec_G \mid$ is the number of orders that G is consistent with. (The proof of Eq. 22 is given in Appendix A.6.) Accordingly,

$$p_{\not\prec}(f|D) = \sum_G f(G) p_{\not\prec}(G|D) = \sum_G f(G) \frac{p_{\prec}(D)}{p_{\not\prec}(D)} \cdot \frac{1}{\mid \prec_G \mid} p_{\prec}(G|D).$$

Note that $p_{\prec}(D)$ can be computed by the DP algorithm of Koivisto and Sood (2004) in $O(n^{k+1}C(m) + kn2^n)$ time, and $p_{\not\prec}(D)$ can be computed by the DP algorithm of Tian and He (2009) in $O(n^{k+1}C(m) + kn2^n + 3^n)$ time. Thus, if $\mid \prec_{G_i} \mid$ is known for each sampled G_i ($i \in \{1, 2, \ldots, N_o\}$), we can use importance sampling to obtain a good estimator

$$\tilde{p}_{\not\prec}(f|D) = \frac{1}{N_o} \sum_{i=1}^{N_o} f(G_i) \frac{p_{\prec}(D)}{p_{\not\prec}(D)} \cdot \frac{1}{\mid \prec_{G_i} \mid}, \tag{23}$$

where each G_i is sampled from our DDS algorithm. Unfortunately, $\mid \prec_{G_i} \mid$ is #P-hard to compute for each G_i (Brightwell and Winkler, 1991); the state-of-the-art DP algorithm proposed by Niinimaki and Koivisto (2013) for computing $\mid \prec_{G_i} \mid$ takes $O(n2^n)$ time. Therefore, in the following we propose an estimator that can be much more efficiently computed than the estimator shown in Eq. (23).

Because $p_{\prec}(f|D)$ has the bias with respect to $p_{\not\prec}(f|D)$, a good estimator $\hat{p}_{\prec}(f|D)$ of $p_{\prec}(f|D)$ typically is not appropriate to be directly used to estimate $p_{\not\prec}(f|D)$. Noticing this problem, Ellis and Wong (2008) proposed to correct this bias for the Order MCMC method as follows: first run the Order MCMC to draw order samples; then for each unique order $\prec$ out of the sampled orders, keep drawing DAGs consistent with $\prec$ (but only keep unique DAGs) until the sum of joint probabilities of these unique DAGs, $\sum_i p(\prec, G_i, D)$, is no less than a pre-specified large proportion (such as 95%) of $p(\prec, D) = \sum_{G \subseteq \prec} p(\prec, G, D)$; finally the resulting union of all the DAG samples is treated as an importance-weighted sample for the structural discovery.

Inspired by the idea of Ellis and Wong (2008), we develop our own bias-correction strategy which is computationally more efficient and can theoretically ensure the resulting estimator to have desirable properties. (Please refer to Section 3.3.1 for detailed discussion.) Our bias-corrected algorithm, termed IW-DDS (importance-weighted DDS), is as follows:

- Step 1 (DDS step): Run the DDS algorithm to draw N_o DAG samples with the setting that $q_i(U_i) \equiv 1$ and $\rho_i(Pa_i) \equiv p_i(Pa_i)$.
- Step 2 (Bias correction step): Make the union set $\mathcal{G}$ of all the sampled DAGs by eliminating the duplicate DAGs.

Given $\mathcal{G}$, $\hat{p}_{\not\prec}(f|D)$, the estimator of the exact posterior of any feature f, can then be constructed as

$$\hat{p}_{\not\prec}(f|D) = \sum_{G \in \mathcal{G}} f(G) \hat{p}_{\not\prec}(G|D), \tag{24}$$

where

$$\hat{p}_{\not\prec}(G|D) = \frac{p_{\not\prec}(G, D)}{\sum_{G \in \mathcal{G}} p_{\not\prec}(G, D)}, \tag{25}$$

and $p_{\not\prec}(G, D)$ is given in Eq. (3).

Because checking the equality of two DAGs takes $O(n^2)$ time [4], with the use of a hash table, both the expected time cost and the space cost of the bias-correction step of the IW-DDS are $O(n^2 N_o)$. Therefore, the expected time cost of our IW-DDS algorithm is $O(n^{k+1}C(m) + kn2^n + n^2 N_o + n^{k+1}N_o)$, and the required memory space of our IW-DDS algorithm is $O(n2^n + n^2 N_o)$.

Note that when each G_i gets sampled, the corresponding joint probability $p_{\not\prec}(G_i, D)$ can be easily computed and stored with G_i. Therefore, just as constructing the estimator from the DDS, constructing the estimator $\hat{p}_{\not\prec}(f|D)$ from the IW-DDS also takes $O(C_{n,f} N_o)$ time, where $C_{n,f}$ denotes the time cost of determining the structural feature f in a DAG of n nodes.

While Ellis and Wong (2008) showed the effectiveness of their method in correcting the bias merely by the experiments, we first theoretically prove that our estimator has desirable properties as follows.

Theorem 5 *For any structural feature f, with respect to the exact posterior $p_{\not\prec}(f|D)$, the estimator $\hat{p}_{\not\prec}(f|D)$ based on the DAG samples from the IW-DDS algorithm using Eq. (24) has the following properties:*

(i) $\hat{p}_{\not\prec}(f|D)$ is an asymptotically unbiased estimator of $p_{\not\prec}(f|D)$.

(ii) $\hat{p}_{\not\prec}(f|D)$ converges almost surely to $p_{\not\prec}(f|D)$.

(iii) The convergence rate of $\hat{p}_{\not\prec}(f|D)$ is $o(a^{N_o})$ for any $0 < a < 1$.

(iv) Define the quantity $\Delta = \sum_{G \in \mathcal{G}} p_{\not\prec}(G|D)$. Then

$$\Delta \cdot \hat{p}_{\not\prec}(f|D) \leq p_{\not\prec}(f|D) \leq \Delta \cdot \hat{p}_{\not\prec}(f|D) + 1 - \Delta. \tag{26}$$

Note that the introduced quantity $\Delta = \sum_{G \in \mathcal{G}} p_{\not\prec}(G, D)/p_{\not\prec}(D)$ and $\Delta \in [0, 1]$ essentially represents the cumulative posterior probability mass of the DAGs in $\mathcal{G}$. Eq. (26) provides a sound interval $[\Delta \cdot \hat{p}_{\not\prec}(f|D), \Delta \cdot \hat{p}_{\not\prec}(f|D) + 1 - \Delta]$ in which $p_{\not\prec}(f|D)$ *must* reside. (The "sound interval" is stronger than the "confidence interval" because there is no probability that $p_{\not\prec}(f|D)$ is outside the sound interval.) The width of the sound interval is $(1 - \Delta)$, where Δ is a nondecreasing function of N_o (because if we increase the original N_o to a larger N_o' and sample additional $N_o' - N_o$ DAGs in the DDS step, the resulting $\mathcal{G}'$ is always a superset of the original $\mathcal{G}$). Thus, in the situations where m (the number of data instances) is not very small, it is possible for Δ to approach 1 by a tractable number N_o of DAG samples so that a desired small-width interval for $p_{\not\prec}(f|D)$ can be obtained. (Please refer to Section 4 for the corresponding experimental results.) Also note that Eq. (26) can be expressed in the following equivalent form:

$$-(1 - \Delta)\hat{p}_{\not\prec}(f|D) \leq p_{\not\prec}(f|D) - \hat{p}_{\not\prec}(f|D) \leq (1 - \Delta)(1 - \hat{p}_{\not\prec}(f|D)), \tag{27}$$

which gives the bound for the estimation error $p_{\not\prec}(f|D) - \hat{p}_{\not\prec}(f|D)$.

4. As described in the footnote in Section 3.2, for the vector representation $(Pa_1, \ldots, Pa_n)$ of a DAG of a size $n \leq 32$, each parent set Pa_i can be represented by a 32-bit integer. Accordingly, for two DAGs of a moderate size n, checking their equality takes at most n comparisons by comparing each integer component in their vector representations.

The competing state-of-the-art algorithms that are also applicable to BNs of a moderate size are the Hybrid MCMC method (Eaton and Murphy, 2007) and the K-best algorithm (Tian et al., 2010). The first competing method, the Hybrid MCMC, includes the DP algorithm of Koivisto (2006) (with time complexity $O(n^{k+1}C(m)+ kn2^n)$ and space complexity $O(n2^n)$) as its first phase and then uses the computed posteriors of all the edges to make the global proposal for its second phase (MCMC phase). When its MCMC phase eventually converges, the Hybrid MCMC will correct the bias coming from the order-prior assumption and provide DAG samples according to the DAG posterior so that the estimator $\hat{p}_{\not\prec}(f|D)$ can be constructed using Eq. (5) for any feature f. The Hybrid MCMC has been empirically shown to converge faster than both the Structure MCMC and the Order MCMC, so that more accurate structure-learning performance can be obtained (Eaton and Murphy, 2007). Note that because the REV-MCMC method (Grzegorczyk and Husmeier, 2008) is shown to be only nearly as efficient as the Order MCMC in the mixing and convergence, the Hybrid MCMC is expected to converge faster than the REV-MCMC method as long as n is moderate so that the Hybrid MCMC is applicable. (But the REV-MCMC method has its own value in learning large BNs since all these methods using some DP technique, including the Hybrid MCMC, the K-best algorithm, and our IW-DDS method, are infeasible for a large n because of the space cost.) One limitation of the Hybrid MCMC is that it cannot obtain the interval for $p_{\not\prec}(f|D)$ as specified by Theorem 5 (iv). Additionally, the convergence rate of the estimator from the Hybrid MCMC is not theoretically provided by its authors.

The second competing method, the K-best algorithm, applies some DP technique to obtain a collection $\mathcal{G}$ of DAGs with the K best scores and then uses these DAGs to construct the estimator $\hat{p}_{\not\prec}(f|D)$ by Eq. (24) and Eq. (25). One advantage of the K-best algorithm is that its estimator also has the property specified by Theorem 5 (iv) so that it can provide the sound interval for $p_{\not\prec}(f|D)$ just as our IW-DDS. However, the K-best algorithm has time complexity $O(n^{k+1}C(m)+ T'(K)n2^{n-1})$ and space complexity $O(Kn2^n)$, where $T'(K)$ is the time spent on the best-first search for K solutions and $T'(K)$ has been shown to be $O(K \log K)$ by Flerova et al. (2012). Thus, the increase in K will dramatically increase the computation cost of the K-best algorithm when n is not small. As a result, to obtain an interval width similar to that from our IW-DDS, much more time and space cost is required for the K-best. In our experiments using an ordinary desktop PC, the computation problem becomes severe for $n \geq 19$ because K can only take some small values (such as no more than 40) before the K-best algorithm exhausts the memory. Accordingly, Δ obtained from the K-best is usually smaller than that from our IW-DDS (so that the interval from the K-best is usually wider) even if K is set to reach the memory limit of a computer. (Please refer to Section 4.2 for detailed discussion.)

3.3.1 COMPARISON BETWEEN OUR BIAS-CORRECTION STRATEGY AND THAT OF ELLIS AND WONG (2008)

Our bias-correction strategy used in the IW-DDS solves the computation problem existing in the idea of Ellis and Wong (2008) and ensures the desirable properties of our estimator $\hat{p}_{\not\prec}(f|D)$ stated in Theorem 5.

Because in the Order MCMC, sampling an order is much more computationally expensive than sampling a DAG given an order, the strategy of Ellis and Wong (2008) emphasizes making the full use of each sampled order $\prec$, that is, keeping drawing DAGs consistent with each sampled $\prec$ until the sum of joint probabilities for the unique sampled DAGs, $\sum_i p(\prec, G_i, D)$, is no less than a large

proportion (such as 95%) of $p(\prec, D)$. Unfortunately, such a strategy has a computational problem when the number of variables n is not small and the number of data instances m is small. Because there are a super-exponential number ($2^{\Theta(kn \log(n))}$) of DAGs (with the maximum in-degree k) consistent with each order (Friedman and Koller, 2003), it is possible that a non-negligible portion of probability mass $p(\prec, D)$ will be distributed almost uniformly to a majority of these consistent DAGs when m is small. Consequently, $N_G^{\prec}$, the required number of DAGs sampled per each sampled order $\prec$, will be extremely large, leading to large computation cost. For sampling $N_G^{\prec}$ DAGs consistent with each sampled order $\prec$, its expected time cost is $O(n^{k+1} + nk \log(n) N_G^{\prec})$ (even if a time-saving strategy as that described in Section 3.2.1 is used) and its memory requirement is $O(n^2 N_G^{\prec})$. If the memory requirement exceeds the memory of the running computer, the hard disk has to be used to temporarily store the sampled DAGs in some way. (We notice that Ellis and Wong, 2008, limited their experiments to the data sets with at most 14 variables.) If we take the data set "Child" (Tsamardinos et al., 2006) with $n = 20$ and $m = 100$ for example, for an order $\prec$ randomly sampled by our order sampling algorithm, our experiment shows that 1×10^7 DAGs (which contain 932,137 unique DAGs) need to be sampled to let the ratio $\sum_i p(\prec, G_i, D) \,/p(\prec, D)$ reach 94.071%; 1.5×10^7 DAGs (which contain 1,204,262 unique DAGs) need to be sampled to let the ratio $\sum_i p(\prec, G_i, D) \,/p(\prec, D)$ reach 94.952%. To solve this problem, based on the efficiency of our order sampling algorithm, our strategy samples only one DAG from each sampled order in the DDS step, so that the large computation cost per each sampled order is avoided for any data set. Meanwhile, unlike the strategy of Ellis and Wong (2008), our strategy does not delete the duplicate order samples. Therefore, if an order $\prec$ gets sampled j (≥ 1) times in the order sampling step, essentially j DAGs will be sampled for such a unique order in the DAG sampling step. Thus, j, the number of occurrences, implicitly serves as an importance indicator for $\prec$ among the orders.

Furthermore, the strategy of Ellis and Wong (2008) cannot guarantee that the sampled DAGs are independent, even if large computation cost is spent in sampling a huge number of DAGs per each sampled order. This is essentially because multiple DAGs sampled from a fixed order according to the strategy of Ellis and Wong (2008) are not independent. For example, given that a DAG G with an edge $X \to Y$ gets sampled from an order $\prec$, which implies that node X precedes node Y in the given order $\prec$, then the conditional probability that any DAG G' with a reverse edge $Y \to X$ gets sampled under the fixed order $\prec$ becomes zero, so that G and G' are not independent. In general, once the number of sampled orders is fixed, even if the number of sampled DAGs per each sampled order keeps increasing, every DAG that is consistent with none of the sampled orders will still have no chance of getting sampled. In contrast, the sampling strategy in our IW-DDS is able to guarantee the property that all the DAGs sampled from the DDS step are independent, which has been stated in Theorem 3. Such a property is a key to ensuring the good properties of our estimator $\hat{p}_{\not\prec}(f|D)$ stated in Theorem 5.

4. Experimental Results

We have implemented our algorithms in a C++ language tool called "BNLearner" and run several experiments to demonstrate its capabilities. (BNLearner is available at `http://www.cs.iastate.edu/~jtian/Software/BNLearner/BNLearner.htm`.) Our tested data sets include ten real data sets from the UCI Machine Learning Repository (Asuncion and Newman, 2007): "Tic-Tac-Toe," (which is also simply called "T-T-T,") "Glass," "Wine," "Housing," "Credit," "Zoo," "Letter," "Tumor," "Vehicle," and "German." Our tested data sets also include three syn-

thetic data sets: the first one is a synthetic data set "Syn15" generated from a gold-standard 15-node Bayesian network built by us; the second one is a synthetic data set "Insur19" generated from a 19-node subnetwork of "Insurance" Bayesian network (Binder et al., 1997); the third one is a synthetic data set "Child" from a 20-node "Child" Bayesian network used by Tsamardinos et al. (2006). All the data sets contain only discrete variables (or are discretized) and have no missing values (or have their missing values filled in). For the four data sets ("Syn15," "Letter," "Insur19," and "Child"), because a large number of data instances are available, we also vary m (the number of instances) to see the corresponding learning performance. (All the data cases are also included in the tool of BNLearner.) All the experiments in this section were run under Linux on one ordinary desktop PC with a 3.0 GHz Intel Pentium processor and 2.0 GB memory if no extra specification is provided. In addition, the maximum in-degree k was assumed to be 5 for all the experiments.

4.1 Experimental Results for the DDS

In this subsection, we compare our DDS algorithm with the Partial Order MCMC method (Niinimaki et al., 2011), the state-of-the-art learning method under the order-modular prior.

The Partial Order MCMC (PO-MCMC) method is implemented in BEANDisco, a C++ language tool provided by Niinimaki et al. (2011). (BEANDisco is available at `http://www.cs.helsinki.fi/u/tzniinim/BEANDisco/`.) The current version of BEANDisco can only estimate the posterior of an edge feature, but as Niinimaki et al. (2011) stated, the PO-MCMC readily enables estimating the posterior of any structural feature by further sampling DAGs consistent with an order.

Because n (the number of the variables) in each investigated data case is moderate, we are able to use REBEL, a C++ language implementation of the DP algorithm of Koivisto (2006), to get the exact posterior of every edge under the assumption of the order-modular prior. (REBEL is available at `http://www.cs.helsinki.fi/u/mkhkoivi/REBEL/`.) Therefore, we can use the criterion of the sum of the absolute differences (SAD) (Eaton and Murphy, 2007) to measure the feature-learning performance for each data case:

$$\text{SAD} = \sum_f |p(f|D) - \hat{p}(f|D)|,$$

where $p(f|D)$ is the exact posterior of the investigated feature f, and $\hat{p}(f|D)$ is the corresponding estimator. In this subsection, SAD is essentially $\sum_{ij} |p_{\prec}(i \to j|D) - \hat{p}_{\prec}(i \to j|D)|$, because the investigated feature is the edge feature $i \to j$ under the order-modular prior. A smaller SAD will indicate a better performance in structure discovery. Note that the criterion SAD is closely related to another criterion MAD (the mean of the absolute differences), because MAD = SAD$/(n(n-1))$. Thus, for each data case the conclusion based on the comparison of SAD values is the same as that based on the comparison of MAD values, because $n(n-1)$ is just a constant for each data case.

For fair comparison, in our algorithms we used the K2 score (Heckerman et al., 1995) and set $q_i(U_i) = 1$ and $\rho_i(Pa_i) = 1/\binom{n-1}{|Pa_i|}$ for each i, U_i, and Pa_i, where $|Pa_i|$ is the size of the set Pa_i, because such a setting is used in both BEANDisco and REBEL.

For the setting of the PO-MCMC, according to the suggestion for the optimal setting from Niinimaki et al. (2011), we set the bucket size b to be 10 for all the data cases except Tic-Tac-Toe. The bucket size b was set to be 9 for the data case Tic-Tac-Toe, because Tic-Tac-Toe has only 10 variables and the setting $b = 10$ will cause the tool BEANDisco to throw a run-time error. We

Table 1: Comparison of the PO-MCMC, the DOS, and the DDS in Terms of SAD

ran the first 10,000 iterations for "burn-in," and then took 200 partial-order samples at intervals of 50 iterations. Thus, there were 20,000 iterations in total. (The time cost of each iteration in the PO-MCMC is $O(n^{k+1} + n^2 2^b n/b)$.) In the PO-MCMC, for each sampled partial order P_i, $p(f|D, P_i)$ is obtained by $p(D, f, P_i)/p(D, P_i) = p(D, f, P_i)/p(D, f \equiv 1, P_i)$, where $p(D, f, P_i) = \sum_{\prec \supseteq P_i} \sum_{G \subseteq \prec} f(G)\, p(\prec, G) p(D|G)$. The notation $\sum_{\prec \supseteq P_i}$ means that all the total orders ($\prec$'s) that are linear extensions of the sampled partial order P_i will be included to obtain $p(D, f, P_i)$. For example, for a data set with $n = 20$, because our bucket size $b = 10$, there are $20!/(10!10!) =$ 184,756 total orders that will be included for each sampled partial order P_i. The inclusion of the information of a large number of total orders consistent with each sampled partial order gives great learning power to the PO-MCMC method; such an inclusion can be efficiently computed by the algorithm of Parviainen and Koivisto (2010) with the assumptions of the order-modular prior and the maximum in-degree k. Finally, for the PO-MCMC, the estimated posterior of each edge is computed using $\hat{p}_{\prec}(f|D) = (1/T) \sum_{i=1}^{T} p(f|D, P_i)$.

Because the to-be-learned feature is the edge feature, we can also use our DOS algorithm for the comparison. For both the DOS algorithm and the DDS algorithm, we set N_o = 20,000, that

Table 2: Comparison of the PO-MCMC, the DOS, and the DDS in Terms of Time (in Seconds)

is, 20,000 (total) orders were sampled. Theoretically, we expect that the learning performance of the DOS should be better than that of the DDS because the additional approximation coming from the DAG sampling step is avoided by the DOS. By listing the performance of the DOS, we mainly intend to examine how much the performance of the DDS decreases because of the additional approximation from sampling one DAG per order. Nevertheless, because the DDS but not the DOS is capable of learning non-modular features, the comparison between the PO-MCMC method and the DDS method is our main task.

Table 1 shows the experimental results in terms of SAD for each data case with n variables and m instances, and Table 2 lists the running-time cost corresponding to Table 1. For each of the three methods, we performed 15 independent runs for each data case. The sample mean and the sample standard deviation of the 15 SAD values of each method, denoted by $\hat{\mu}$(SAD) and $\hat{\sigma}$(SAD), are listed in Table 1. Correspondingly, the sample mean of the total running time T_t of each method, denoted by $\hat{\mu}(T_t)$, is shown in Table 2. (Precisely speaking, the reported total running time T_t of the DDS method includes both the time of running the three steps of the DDS and the relatively tiny $O(N_o)$ time cost of computing $\hat{p}_{\prec}(f|D)$ for each edge f using Eq. 5 at the end. Similarly,

the reported total running time T_t of the DOS method also includes the relatively tiny $O(N_o)$ time cost of computing $\hat{p}_{\prec}(f|D)$ for each edge f using Eq. 17 and Eq. 15 at the end.) In addition, the sample mean and the sample standard deviation of the running time of the three steps of the DDS (including the DP step, the order sampling step, and the DAG sampling step), denoted by $\hat{\mu}(T_{DP})$, $\hat{\sigma}(T_{DP})$, $\hat{\mu}(T_{ord})$, $\hat{\sigma}(T_{ord})$, $\hat{\mu}(T_{DAG})$, and $\hat{\sigma}(T_{DAG})$ respectively, are listed in the last six columns of Table 2. Note that we still show $\hat{\mu}(T_{DP})$, the mean running time of the DP step of the DDS in the 15 independent runs, though the DP step is not a random algorithm at all. The running time of the DP step is not exactly the same in each run because of the randomness from uncontrolled factors such as the internal status of the computer. By showing $\hat{\mu}(T_{DP})$, we can clearly see the percentage of the total running time that the DP step typically takes by comparing $\hat{\mu}(T_{DP})$ and $\hat{\mu}(T_t)$.

Tables 1 and 2 clearly illustrate the performance advantage of our DDS method over the PO-MCMC method. The overall time cost of our DDS based on 20,000 DAG samples is much smaller than the corresponding cost of the PO-MCMC method based on 20,000 MCMC iterations in the partial-order space. Using much shorter time, our DDS method has its $\hat{\mu}$(SAD) much smaller than $\hat{\mu}$(SAD) from the PO-MCMC method for 28 out of all the 33 data cases. The five exceptional cases are Glass, Syn15 with $m = 2{,}000$, Syn15 with $m = 5{,}000$, Insur19 with $m = 2{,}000$, and Insur19 with $m = 5{,}000$. (In both Glass and Insur19 with $m = 2{,}000$, $\hat{\mu}$(SAD) using our DDS method is still smaller than that using the PO-MCMC method, but their difference is not large compared with $\hat{\sigma}$(SAD) from the PO-MCMC method.) Furthermore, because both $\hat{\mu}$(SAD) and $\hat{\sigma}$(SAD) are given in Table 1, by the two-sample t test with unequal variances (Casella and Berger, 2002), we can conclude with strong evidence (at the significance level 5×10^{-3}) that the real mean of SAD using our DDS method is smaller than the real mean of SAD using the PO-MCMC method for each of the 28 data cases. For the exceptional data case Glass, the p-value of the t test is 0.012, so that we can conclude at the significance level 0.05 that the real mean of SAD using our DDS method is smaller than that using the PO-MCMC method. For each of the other four exceptions, by the same t test we cannot reject (with the p-value > 0.2) the null hypothesis that there is no difference in the real means of SAD from the two methods. (Corresponding to Table 1, the comparison is also re-demonstrated using boxplots in the supplementary material for all the 33 data cases.) Thus, the advantage of our DDS algorithm over the PO-MCMC method in learning Bayesian networks of a moderate n can be clearly seen, though the value of the PO-MCMC method still remains for larger n for which our DDS algorithm is infeasible.

In terms of the total running time of the DDS algorithm, Table 2 shows that the running time of the DP step always accounts for the largest portion. The running time of the DAG sampling step is less than 81 seconds to get 20,000 DAG samples for all the 33 cases. Though both the order sampling step and the DAG sampling step involve randomness, the variability of their running time is actually small. This can be seen from the ratio of $\hat{\sigma}(T_{ord})$ to $\hat{\mu}(T_{ord})$ (which is always less than 3.04% for all the 33 cases) and the ratio of $\hat{\sigma}(T_{DAG})$ to $\hat{\mu}(T_{DAG})$ (which is always less than 6.85% for all the 33 cases). The ratio of $\hat{\mu}(T_{DAG})$ to $\hat{\mu}(T_{ord})$ ranges from 0.25 to 75.29 across the 33 cases, which is much smaller than the upper bound of the ratio of $O(n^{k+1}N_o)$ to $O(n^2N_o)$. This indicates that our time-saving strategy introduced in Section 3.2.1 can effectively reduce the running time of the DAG sampling step. In addition, the running time of the DAG sampling step often decreases further when m increases, which can be clearly seen from all the four data sets (Syn15, Letter, Insur19, and Child) with different values of m. Take the data set Letter for example, when m increases from 100 to 1,000, the corresponding $\hat{\mu}(T_{DAG})$ decreases from 6.60 to 0.43

second, a 93.48% of decrease. In summary, the effectiveness of our time-saving strategy introduced in Section 3.2.1 has been clearly shown in Table 2.

In addition, Table 1 clearly shows that the learning performance of the DOS is better than that of the DDS, as expected theoretically. Note that $\hat{\mu}$(SAD) from the DOS is significantly smaller than $\hat{\mu}$(SAD) from the DDS for 28 out of the 33 data cases. The five other cases are Tic-Tac-Toe, Syn15 with $m =$ 5,000, and Insur19 with $m =$ 1,000, 2,000, and 5,000. For each of these 28 data cases, by the two-sample t test with unequal variances (Casella and Berger, 2002), we can conclude (at the significance level 0.05) that the real mean of SAD using the DOS is smaller than that using the DDS. This shows that the additional approximation from the DAG sampling step will usually make the DDS perform worse than the DOS in learning modular features. Nevertheless, the DDS but not the DOS has the ability of learning arbitrary non-modular features, which is the main goal of this paper.

Finally, we present the experimental results for the DDS by varying the sample size. We first choose the data case Letter with $m = 500$ as an example. For the DDS, we tried the sample size $N_o =$ 5,000 $\cdot i$, where $i \in \{1, 2, \ldots, 10\}$. For each i, we independently ran the DDS 15 times to get the sample mean and the sample standard deviation of SAD for the (directed) edge features. For the PO-MCMC, with the bucket size $b = 10$, we ran totally 5,000 $\cdot i$ MCMC iterations in the partial-order space, where $i \in \{1, 2, \ldots, 10\}$. For each i, we discarded the first 2,500 $\cdot i$ MCMC iterations for "burn-in" and set the thinning parameter to be 50, so that $50 \cdot i$ partial orders finally got sampled. Again, for each i, we independently ran the PO-MCMC 15 times to get the sample mean and the sample standard deviation of SAD for the edge features.

Figure 1 shows the SAD performance of the two methods with each i in terms of the edge features, where an error bar represents one sample standard deviation $\hat{\sigma}$(SAD) across 15 runs from a method (the PO-MCMC or the DDS) at each i. For example, Figure 1 shows that when $i = 4$, $\hat{\mu}$(SAD) $= 0.1326$ and $\hat{\sigma}$(SAD) $= 0.0107$ from our DDS algorithm; $\hat{\mu}$(SAD) $= 0.4369$ and $\hat{\sigma}$(SAD) $= 0.1529$ from the PO-MCMC method. This exactly matches the results previously shown in Table 1. Correspondingly, Figure 2 shows $\hat{\mu}(T_t)$ (the sample mean of the total running time) of the PO-MCMC and the DDS with each i, where the running time is in seconds. The advantage of our DDS can be clearly seen from Figures 1 and 2. For each $i \in \{1, 2, \ldots, 10\}$, the real mean of SAD from the DDS is significantly smaller than that from the PO-MCMC with the p-value $< 5 \times 10^{-3}$ returned by the two-sample t test (with unequal variances). Meanwhile, the total running time of the DDS is much shorter than that of the PO-MCMC. For example, $\hat{\mu}(T_t)$ of the DDS increases with respect to i and reaches only 29.55 seconds at $i = 10$. This is shorter than 9% of $\hat{\mu}(T_t)$ of the PO-MCMC at $i = 1$, which is 336.09 seconds. Therefore, the learning performance of the DDS with each sample size is significantly better than that of the PO-MCMC for the data case Letter with $m = 500$.

We also performed the experiment with the same experimental settings for the data cases Tic-Tac-Toe, Wine, Child with $m = 500$, and German. Please refer to the supplementary material for the experimental results. (The supplementary material is available at `http://www.cs.iastate.edu/~jtian/Software/BNLearner/BN_Learning_Sampling_Supplement.pdf`.) The same conclusion about the learning performance can be clearly drawn by examining the figures shown in the supplementary material.

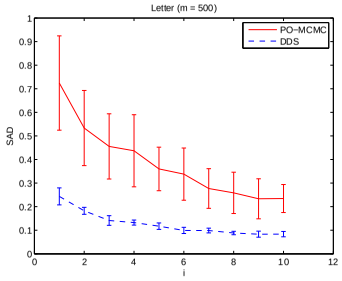

Figure 1: Plot of the SAD Performance of the PO-MCMC and the DDS for Letter ($m = 500$)

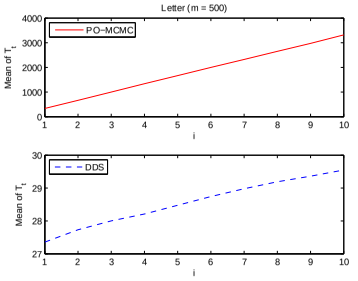

Figure 2: Plot of the Total Running Time of the PO-MCMC and the DDS for Letter ($m = 500$)

4.2 Experimental Results for the IW-DDS

In this subsection, we compare our IW-DDS algorithm with the Hybrid MCMC (that is, DP+MCMC) method (Eaton and Murphy, 2007) and the K-best algorithm (Tian et al., 2010), two state-of-the-art methods that can estimate the posteriors of any features without the order-modular prior assumption. The implementation of the Hybrid MCMC (called BDAGL) and the implementation of the K-best (called KBest) are both made available online by their corresponding authors. (BDAGL is available at `http://www.cs.ubc.ca/~murphyk/Software/BDAGL/`; KBest is available at `http://www.cs.iastate.edu/~jtian/Software/UAI-10/KBest.htm`.)

Because n in each investigated data case is moderate, we are able to use POSTER, a C++ language implementation of the DP algorithm of Tian and He (2009), to get $p_{\not\prec}(i \to j|D)$, the exact posterior of each edge $i \to j$ under the structure-modular prior. (POSTER is available at `http://www.cs.iastate.edu/~jtian/Software/UAI-09/Poster.htm`.) Therefore, we can use the SAD criterion $(\sum_{ij} |p_{\not\prec}(i \to j|D) - \hat{p}_{\not\prec}(i \to j|D)|)$ to measure the performance of these three methods in the structure learning for each data case.

For fair comparison, in our algorithm we used the BDeu score (Heckerman et al., 1995) with equivalent sample size 1 and set $p_i(Pa_i)(\equiv \rho_i(Pa_i)) \equiv 1$, because these settings are also used in POSTER and the implementation of the K-best algorithm.

As for the DP+MCMC, we note that most part of its implementation in BDAGL tool is written in Matlab, whereas both the K-best and the IW-DDS are implemented in C++. In order to make relatively fair comparison in terms of the running time, we used REBEL tool, a C++ implementation of the DP algorithm of Koivisto (2006), to perform the computation in the DP phase of the DP+MCMC; but for fair comparison we changed its scoring criterion into the BDeu score with equivalent sample size 1 and set $q_i(U_i) \equiv 1$ and $\rho_i(Pa_i) \equiv 1$. To perform the computation in the MCMC phase, we used the Matlab implementation of BDAGL [5] and ran it under Windows 7 on

5. The original BDAGL was found to get an out-of-memory error for any data case with more than 19 variables in our experiments. This is because the original BDAGL intends to pre-compute the local scores of all the $n2^{n-1}$ possible families and store them in an array for the later usage in both the DP phase and the MCMC

Table 3: Comparison of the DP+MCMC, the K-best, and the IW-DDS in Terms of SAD

an ordinary laptop with 2.40 GHz Intel Core i5 CPU and 4.0 GB memory. The MCMC used the pure global proposal (with the local proposal choice $\beta = 0$), because such a setting was reported by Eaton and Murphy (2007) to have the best performance for edge discovery when up to about 190,000 MCMC iterations were performed in their experimental results. We ran totally 190,000 MCMC iterations each time and discarded the first 100,000 iterations as the burn-in period. Then we set the thinning parameter to be 3 to get the final 30,000 DAG samples. As a result, the time statistics of the DP phase (the numbers before the + sign in Table 4) but not the MCMC phase (the numbers after the + sign) can be directly compared with those of the other two methods. For each data case, we performed 20 independent MCMC runs based on the DP outcome from REBEL to get the results.

phase. To solve this out-of-memory problem, we have updated the original Matlab code in BDAGL and provided the BDAGL-New package which is also available at `http://www.cs.iastate.edu/~jtian/Software/BNLearner/BNLearner.htm`. The main update is that, with the assumed maximum in-degree, only the local scores of all the families whose sizes are no more than the assumed maximum in-degree are pre-computed and stored in a hash table. With BDAGL-New, the experiments for all the data cases in this paper can be performed without any error.

Table 4: Comparison of the DP+MCMC, the K-best, and the IW-DDS in Terms of Time (in Seconds)

For our IW-DDS, we set $N_o = 30{,}000$. We performed 20 independent runs for each data case to get the results. For the K-best, note that its SAD is fixed because there is no randomness in the computed results. So we only ran it once to get the result. We set K to be 100 for Tic-Tac-Toe, Glass, Wine, Housing, Credit, Zoo, Syn15, and Letter, that is, we got the 100 best DAGs from Tic-Tac-Toe, Glass, Wine, Housing, Credit, Zoo, each of the six cases of Syn15, and each of the six cases of Letter. We set K to be only 80 for Tumor because our experiments showed that for Tumor the K-best program ran out of memory with $K > 80$. Because of the same out-of-memory issue, we set K to be only 40 for Vehicle and Insur19; we set K to be only 20 for Child and 9 for German. The fact that K can only take a value no greater than 40 for $n \geq 19$ in our experiments confirms our claim about the computation problem of the K-best algorithm in terms of its space cost.

Table 3 shows the experimental results in terms of SAD for each data case, and Table 4 shows the running-time cost corresponding to Table 3. The column named DP in Table 3 shows the SAD ($\sum_{ij} |p_{\not\prec}(i \to j|D) - p_{\prec}(i \to j|D)|$), where each edge posterior $p_{\not\prec}(i \to j|D)$ is computed by the exact DP method of Tian and He (2009), and each edge posterior $p_{\prec}(i \to j|D)$ is computed by

the exact DP method of Koivisto (2006). The SAD values reported in this column indicate the bias due to the assumption of the order-modular prior. Next to the DP column, the SAD values of the three methods are listed in Table 3. Because the DP+MCMC method and the IW-DDS method are random, both the sample mean $\hat{\mu}$(SAD) and the sample standard deviation $\hat{\sigma}$(SAD) of the 20 SAD values are shown for these two methods. The outcome of the K-best algorithm is not random, so that only its SAD is shown. Finally Table 3 also shows the cumulative posterior probability mass Δ for both the K-best algorithm and the IW-DDS method. Again, because the IW-DDS method is random, both the sample mean and the sample standard deviation of the 20 Δ values, denoted by $\hat{\mu}(\Delta)$ and $\hat{\sigma}(\Delta)$, are listed for the IW-DDS method in Table 3. As for Table 4, its presentation format is very similar to that of Table 2. Table 4 first shows the sample mean of the total running time T_t (denoted by $\hat{\mu}(T_t)$) of both the DP+MCMC method and the IW-DDS method as well as the total running time T_t of the K-best algorithm. The last six columns of Table 4, similar to the last six columns of Table 2, list the sample mean and the sample standard deviation of the running time of the three steps of the DDS in the IW-DDS algorithm.

Tables 3 and 4 clearly demonstrate the advantage of our method over the other two methods. With much shorter computation time, our method has its $\hat{\mu}$(SAD) less than that from the DP+MCMC for 32 out of the 33 data cases. The only exceptional case is Syn15 with $m = 200$. Furthermore, based on the two-sample t test with unequal variances, we can conclude at the significance level 0.05 that the real mean of SAD using our method is less than that using the DP+MCMC for each of the 31 cases; the two exceptional cases are Syn15 with $m = 100$ and Syn15 with $m = 200$. (For 30 out of these 31 cases, the p-value of the two-sample t test is less than 0.01.) Meanwhile, $\hat{\sigma}$(SAD) using our method is always much smaller than that using the DP+MCMC for each of the 33 cases, which indicates higher stability of the performance of our method. Similarly, with much shorter computation time, our method has its $\hat{\mu}$(SAD) less than the SAD from the K-best for 32 out of the 33 cases. The only exception is Syn15 with m = 5,000. Furthermore, based on the one-sample t test (Casella and Berger, 2002), we can conclude at the significance level 5×10^{-4} that the real mean of SAD using our method is less than the SAD using the K-best for each of these 32 cases. (Corresponding to Table 3, the comparison of the three methods is also re-illustrated using boxplots in the supplementary material for all the 33 data cases.)

There are several other interesting things shown in Tables 3 and 4. In terms of the SAD, for very small m, $\hat{\mu}$(SAD) using the DP+MCMC method is even larger than the SAD from the DP phase (Koivisto, 2006) itself. For example, for the data case Zoo, the SAD from the DP phase is 8.2142, but $\hat{\mu}$(SAD) obtained after the MCMC phase of the DP+MCMC method is 32.4189. Similar situations also occur in Syn15, Letter, Insur19, and Child when $m = 100$. This indicates that for very small m, the MCMC phase of the DP+MCMC method is unable to reduce the bias from the DP method of Koivisto (2006) for all these cases based on 190,000 MCMC iterations. As for the running time, note that $\hat{\mu}(T_{DP})$ of our IW-DDS is always less than the running time of the DP phase of the DP+MCMC method. This is because the DP step of our method uses the DP algorithm of Koivisto and Sood (2004), that is, the first three steps of the DP algorithm of Koivisto (2006); while the DP phase of the DP+MCMC method uses all the five steps of the DP algorithm of Koivisto (2006). In other words, compared with the DP algorithm of Koivisto and Sood (2004), the DP algorithm of Koivisto (2006) includes a larger constant factor hidden in the $O(n^{k+1}C(m) + kn2^n)$ notation though these two DP algorithms have the same time complexity. This difference will make the total running time of our IW-DDS even less than the running time of the DP phase of the DP+MCMC method when the remaining steps of the IW-DDS run faster than the last two steps

of the DP algorithm of Koivisto (2006). For example, for the data case Child with m = 5,000, $\hat{\mu}(T_t)$ of the IW-DDS is 524.63 seconds while the corresponding running time of the DP phase of the DP+MCMC method is 589.99 seconds. Actually, Table 4 shows that there are 21 out of the 33 cases where $\hat{\mu}(T_t)$ of the IW-DDS is less than the running time of the DP phase of the DP+MCMC method. In addition, just as shown in Section 4.1, the effectiveness of our time-saving strategy can also be clearly seen from Table 4. For example, the ratio of $\hat{\mu}(T_{DAG})$ to $\hat{\mu}(T_{ord})$ ranges from 0.07 to 87.29 across the 33 cases, which is much smaller than the upper bound of the ratio of $O(n^{k+1}N_o)$ to $O(n^2N_o)$.

Table 3 also shows the resulting cumulative probability mass Δ from the K-best and our IW-DDS for all the data cases. (Note that Δ is computed by the formula $\Delta = \sum_{G \in \mathcal{G}} p_{\not\perp}(G, D)/p_{\not\perp}(D)$, where $p_{\not\perp}(D)$ is computed using POSTER tool.) In the table, $\hat{\mu}(\Delta)$ from our IW-DDS is greater than Δ from the K-best for 28 out of the 33 data cases. The five exceptional cases are Zoo, Tumor, Syn15 with $m = 100$, Syn15 with m = 5,000, and Letter with $m = 100$. Interestingly, for four out of the five exceptional cases (as well as the other 28 cases), $\hat{\mu}$(SAD) from our IW-DDS is significantly smaller than SAD from the K-best. One possible reason is that the K best DAGs tend to have the same or similar local structures (families (i, Pa_i)'s) that have relatively large local scores, but a large number of DAGs sampled from our IW-DDS include various local structures for each node i. When Δ is far below 1, the inclusion of various local structures seems to be more effective in improving the structure-learning performance.

In addition, Table 3 shows that when m is not very small (such as no smaller than 1,000), Δ from our IW-DDS with N_o = 30,000 can reach a large percentage (such as greater than 90%) in most of our data cases. As a result, we can obtain a sound interval for $p_{\not\perp}(f|D)$ with a small width (such as less than 0.1) for any feature f.

To further demonstrate that our IW-DDS can obtain a large Δ efficiently when m is not very small, we increased N_o from 100,000 to 600,000 with each increment 100,000 to see its performance for the data cases Letter with $m = 500$, Child with $m = 500$, and German. Again, we performed 20 independent runs for each data case to get the results. Figures 3, 5, and 7 show the increase in Δ with respect to the increase in N_o for these three data cases. Correspondingly, Figures 4, 6, and 8 indicate the increase in $\hat{\mu}(T_t)$, $\hat{\mu}(T_{ord})$ and $\hat{\mu}(T_{DAG})$ with respect to the increase in N_o for these three data cases, where the running time is in seconds. These figures clearly show that our IW-DDS can efficiently achieve a large Δ. Take the data case German for example, with the time cost $\hat{\mu}(T_t)$ = 1,493.02 seconds, our IW-DDS can collect N_o = 600,000 DAG samples so that the corresponding mean of Δ can reach 91.74%. Therefore, for any feature f in the data case German, our IW-DDS can provide a sound interval for $p_{\not\perp}(f|D)$ with a width of 0.0826. Note that the K-best can only provide a meaningless sound interval for $p_{\not\perp}(f|D)$ with a huge width of 0.922 because its Δ can only reach 0.078 in the data case German before running out of the memory. Also note that the ratio of $\hat{\mu}(T_{DAG})$ to $\hat{\mu}(T_{ord})$ decreases from 56.45 to 30.95 when N_o increases from 100,000 to 600,000. (The rate of increase of $\hat{\mu}(T_{ord})$ is a constant with respect to N_o, but the rate of increase of $\hat{\mu}(T_{DAG})$ actually decreases as N_o increases.) This confirms our statement in Section 3.2.1 that the benefit from our time-saving strategy will typically increase when N_o increases.

Finally, we present the experimental results for the IW-DDS by varying the sample size. As in Section 4.1, the experiments were performed for the five data cases Tic-Tac-Toe, Wine, Letter with $m = 500$, Child with $m = 500$, and German. For the IW-DDS, we tried the sample size N_o = 5,000 $\cdot i$, where $i \in \{1, 2, \ldots, 10\}$. For each i, we independently ran the IW-DDS 20 times to get the sample mean and the sample standard deviation of SAD for the (directed) edge features. For

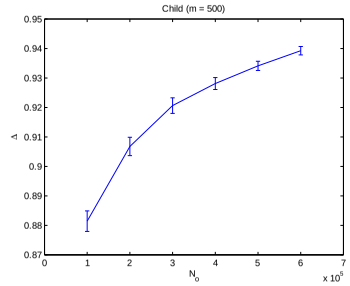

Figure 5: Plot of Δ versus N_o for Child ($m = 500$)

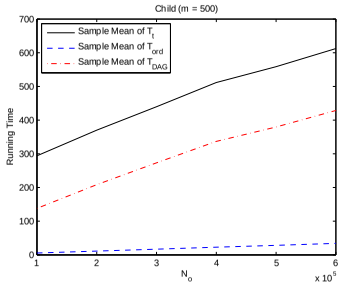

Figure 6: Plot of the Running Time versus N_o for Child ($m = 500$)

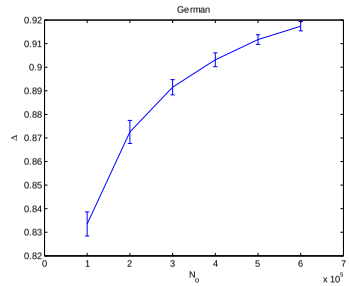

Figure 7: Plot of Δ versus N_o for German

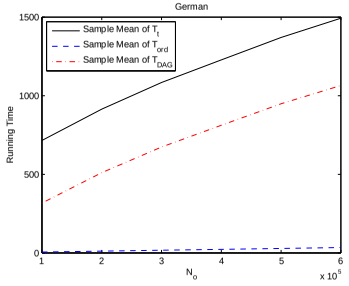

Figure 8: Plot of the Running Time versus N_o for German

the DP+MCMC, we ran totally 50,000 $\cdot i$ MCMC iterations, where $i \in \{1, 2, \ldots, 10\}$. For each i, we discarded the first 25,000 $\cdot i$ MCMC iterations for "burn-in" and set the thinning parameter to be 5, so that 5,000 $\cdot i$ DAGs got sampled. Again, for each i, we independently ran the MCMC 20 times to get the sample mean and the sample standard deviation of SAD for the edge features. As for the K-best, different experimental settings were used for different data cases because of the out-of-memory issue. For the two data cases Tic-Tac-Toe and Wine, we ran the K-best program with $K = 20 \cdot i$, where $i \in \{1, 2, \ldots, 10\}$. (The setting of $K = 20 \cdot i$ guarantees that for these two data cases the running time of the K-best is longer than the running time of the IW-DDS at each i, which will be demonstrated soon.) For the data case Letter with $m = 500$, we only ran the K-best with $K = 162$ because the K-best program will run out of memory when $K > 162$ because of its expensive space cost. The corresponding result of the K-best would be compared with the result of the IW-DDS at $i = 10$ (that is, the IW-DDS with $N_o = 50{,}000$). For the same out-of-memory issue, we only set $K = 20$ for Child with $m = 500$ and set $K = 9$ for German when running the K-best program. Note that because there is no randomness in the outcome of the K-best algorithm, we always ran the K-best program only once to get its fixed SAD for the edge features.

The experimental results of comparing the three methods based on the data case Tic-Tac-Toe are shown in Figures 9 and 10. Figure 9 shows the SAD performance of the three methods with each $i \in \{1, 2, \ldots, 10\}$ in terms of the edge features, where an error bar represents one sample standard deviation $\hat{\sigma}$(SAD) across 20 runs from the DP+MCMC or the IW-DDS at each i. Figure 10 shows $\hat{\mu}(T_t)$ (the sample mean of the total running time) of the DP+MCMC and the IW-DDS as well as T_t (the total running time) of the K-best with each i, where the running time is in seconds. The advantage of our IW-DDS can be clearly seen from Figures 9 and 10. Comparing with the DP+MCMC, for each $i \in \{1, 2, \ldots, 10\}$, the IW-DDS uses shorter running time but has its real mean of SAD significantly smaller than that from the DP+MCMC, with the p-value $< 1 \times 10^{-10}$ from the two-sample t test with unequal variances. Comparing with the K-best, for each $i \in \{1, 2, \ldots, 10\}$, the IW-DDS uses shorter running time but has its real mean of SAD significantly smaller than the SAD from the K-best, with the p-value $< 1 \times 10^{-35}$ from the one-sample t test. Therefore, the learning performance of the IW-DDS is significantly better than that of the other two methods at each i for the data case Tic-Tac-Toe.

The experimental results based on the data case Letter with $m = 500$ are shown in Figures 11 and 12. Just as the description for Figures 9 and 10, Figure 11 shows the SAD performance of the three methods in terms of the edge features, and Figure 12 shows the corresponding time cost of the three methods. The only difference is that in both Figure 11 and Figure 12, the corresponding result of the K-best with $K = 162$ is marked as a star and compared with that of the IW-DDS at $i = 10$. The advantage of our IW-DDS can be clearly seen from Figures 11 and 12. Comparing with the DP+MCMC, for each $i \in \{1, 2, \ldots, 10\}$, the IW-DDS uses much shorter running time but has its real mean of SAD significantly smaller than that from the DP+MCMC, with the p-value < 0.013 from the two-sample t test with unequal variances. ($\hat{\mu}(T_t)$ of the IW-DDS at $i = 10$ is only 33.00 seconds, which is even less than the running time 39.58 seconds of the DP phase of the DP+MCMC method.) Note that $\hat{\sigma}$(SAD) from the DP+MCMC is shown to be very large. The DP+MCMC has its $\hat{\sigma}$(SAD) even larger than its $\hat{\mu}$(SAD) (the sample mean of SAD) when $i \geq 8$, which indicates that the performance of the DP+MCMC is not stable based on the 500,000 MCMC iterations. Comparing with the K-best, the IW-DDS with $N_o = 50{,}000$ uses much shorter running time but has its real mean of SAD significantly smaller than the SAD from the K-best with $K = 162$, because the p-value from the corresponding one-sample t test is less than 1×10^{-35}.

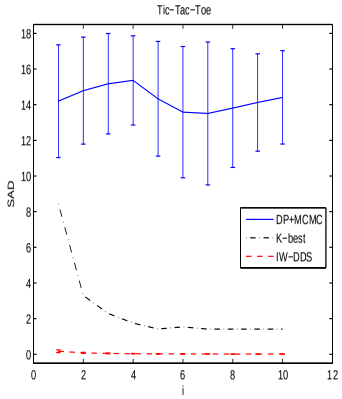

Figure 9: Plot of the SAD Performance of the DP+MCMC, the K-best, and the IW-DDS for Tic-Tac-Toe

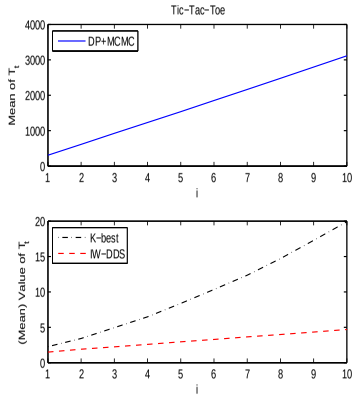

Figure 10: Plot of the Total Running Time of the DP+MCMC, the K-best, and the IW-DDS for Tic-Tac-Toe

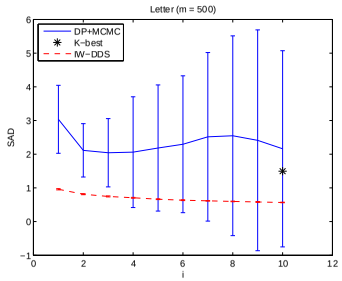

Figure 11: Plot of the SAD Performance of the DP+MCMC, the K-best, and the IW-DDS for Letter ($m = 500$)

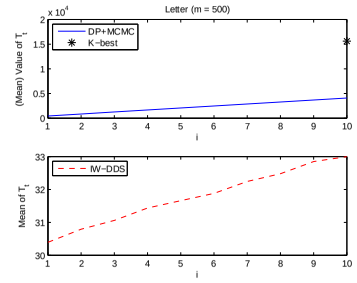

Figure 12: Plot of the Total Running Time of the DP+MCMC, the K-best, and the IW-DDS for Letter ($m = 500$)

Therefore, the learning performance of the IW-DDS is also significantly better than that of the other two methods for the data case Letter with $m = 500$.

The experimental results for the other three data cases Wine, Child with $m = 500$, and German are represented similarly in the supplementary material. The same conclusion about the learning performance can be clearly drawn by examining the figures shown in the supplementary material.

4.3 Learning Performance on Non-modular Features

In Sections 4.1 and 4.2 we did not provide experimental results on the learning performance on non-modular features. We did not do so in Section 4.2 because there is no known method to compute the true/exact posterior probability of any non-modular feature $p_{\not\prec}(f|D)$ except by the brute-force enumeration over all the (super-exponential number of) DAGs so that the quality of the corresponding $\hat{p}_{\not\prec}(f|D)$ learned from any approximate method cannot be precisely measured. We did not do so in Section 4.1 because the current PO-MCMC tool (BEANDisco) only supports the estimation of the posterior of an edge feature so that the comparison of our method and the PO-MCMC can only be made for the edge feature. (Thus, we did not make the comparison for the path feature, which is one particular non-modular feature, though the DP algorithm of Parviainen and Koivisto, 2011 can compute the exact posterior of a path feature $p_{\prec}(f|D)$.) Our idea is that by showing that our algorithms have significantly better performance in computing fundamental structural features (directed edge features), which should be due to the better quality of our DAG samples with respect to the corresponding $p_{\not\prec}(G|D)$ or $p_{\prec}(G|D)$, we expect that our algorithms will also be superior in computing other complicated structural features using the same set of DAG samples.

To verify our expectation, we performed the experiments on the real data set "Iris" (with $n = 5$) from the UCI Machine Learning Repository (Asuncion and Newman, 2007) and the well-studied data set "Coronary" (coronary heart disease) (with $n = 6$) (Edwards, 2000). Because n is small, by enumerating all the DAGs, we were able to compute $p_{\not\prec}(f|D)$, the true posterior probability for any interesting non-modular feature f. For demonstration, we investigated the following five interesting non-modular features. Feature f_1, a directed path feature from node x to node y, denoted by $x \rightsquigarrow y$, represents the situation that variable x eventually influences variable y. Feature f_2, a limited-length directed path feature $x \rightsquigarrow y$ that has its path length no more than 2, represents that variable x can influence variable y via at most one intermediate variable. Feature f_3, a combined path feature $x \rightsquigarrow y \rightsquigarrow z$, can be interpreted as the situation that variable x eventually influences variable y which in turn eventually influences variable z. Feature f_4, a combined path feature $y \leftsquigarrow x \rightsquigarrow z$ with $y \neq z$, means that variable x eventually influences both variable y and variable z. Feature f_5, a combined path feature $y \leftsquigarrow x \not\rightsquigarrow z$ with $x \neq z$, represents that variable x eventually influences variable y but not variable z. Please see Figures 13 to 18 for the example features in the data set Coronary. Then we compared the SAD performance on the (directed) edge feature with the corresponding SAD performance [6] on each feature f_j ($j \in \{1, 2, 3, 4, 5\}$) from the DP+MCMC, the K-best, and the IW-DDS. The experimental results on both data sets show that if the SAD of the IW-DDS is significantly smaller than the SAD of the competing method (the DP+MCMC or the K-best) for the edge feature, then the SAD of the IW-DDS will also be significantly smaller than the SAD of the competing method for each investigated non-modular feature f_j using the same set of DAG samples. Thus, our expectation is supported by the experiments. The detailed experimental results are as follows.

The following is our experimental design for the data set Coronary with $n = 6$ and $m = 1841$. For the IW-DDS, we tried the sample size $N_o = 2{,}500 \cdot i$, where $i \in \{1, 2, \ldots, 20\}$. For each i, we

6. More specifically, SAD = $(\sum_{xy} |p_{\not\prec}(x \rightsquigarrow y|D) - \hat{p}_{\not\prec}(x \rightsquigarrow y|D)|)$ for the path feature $x \rightsquigarrow y$; SAD = $(\sum_{xy} |p_{\not\prec}(x \rightsquigarrow y|D) - \hat{p}_{\not\prec}(x \rightsquigarrow y|D)|)$ for the path feature $x \rightsquigarrow y$ whose length is no more than 2; SAD = $(\sum_{xyz} |p_{\not\prec}(x \rightsquigarrow y \rightsquigarrow z|D) - \hat{p}_{\not\prec}(x \rightsquigarrow y \rightsquigarrow z|D)|)$ for the combined feature $x \rightsquigarrow y \rightsquigarrow z$; SAD = $(\sum_{xyz, y \neq z} |p_{\not\prec}(y \leftsquigarrow x \rightsquigarrow z|D) - \hat{p}_{\not\prec}(y \leftsquigarrow x \rightsquigarrow z|D)|)$ for the combined feature $y \leftsquigarrow x \rightsquigarrow z$ with $y \neq z$; SAD = $(\sum_{xyz, x \neq z} |p_{\not\prec}(y \leftsquigarrow x \not\rightsquigarrow z|D) - \hat{p}_{\not\prec}(y \leftsquigarrow x \not\rightsquigarrow z|D)|)$ for the combined feature $y \leftsquigarrow x \not\rightsquigarrow z$ with $x \neq z$.

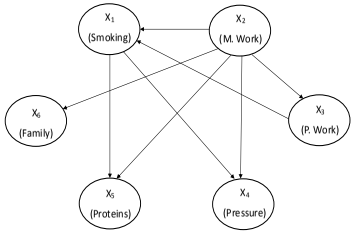

Figure 13: Example Edges in Coronary

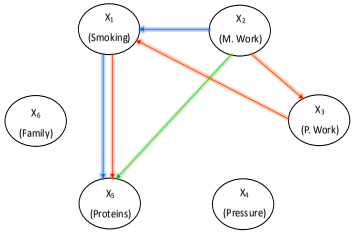

Figure 14: Example f_1 Feature in Coronary

Figure 13 shows every (directed) edge feature e with its true posterior $p_{\not\leftarrow}(e|D) > 0.5$. Figure 14 shows the directed path feature $X_2 \sim\!> X_5$, which has the largest true posterior 0.8348 among all the possible f_1 features. The directed path feature $X_2 \sim\!> X_5$ includes many possible ways going from X_2 to X_5. For clarity, only three possible ways that have every constituent edge with true posterior > 0.5 are shown in Figure 14. These three possible ways are $X_2 \rightarrow X_5$, $X_2 \rightarrow X_1 \rightarrow X_5$, and $X_2 \rightarrow X_3 \rightarrow X_1 \rightarrow X_5$. The figure is best viewed in color.

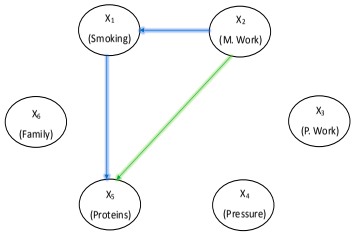

Figure 15: Example f_2 Feature in Coronary

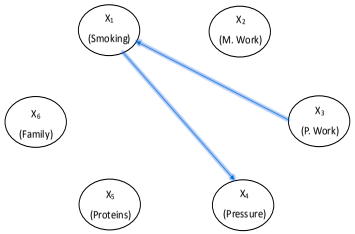

Figure 16: Example f_3 Feature in Coronary

Figure 15 shows the limited-length directed path feature $X_2 \sim\!> X_5$, which has the largest true posterior 0.8348 among all the possible f_2 features. The limited-length directed path feature $X_2 \sim\!> X_5$ includes many possible ways going from X_2 to X_5. For clarity, only two possible ways that have every constituent edge with true posterior > 0.5 are shown in Figure 15. These two possible ways are $X_2 \rightarrow X_5$, and $X_2 \rightarrow X_1 \rightarrow X_5$. Figure 16 shows the combined path feature $X_3 \sim\!> X_1 \sim\!> X_4$, which has the largest true posterior 0.5044 among all the possible f_3 features. The combined path feature $X_3 \sim\!> X_1 \sim\!> X_4$ includes many possible ways going from X_3 via X_1 to X_4. For clarity, only one possible way ($X_3 \rightarrow X_1 \rightarrow X_4$) that has every constituent edge with true posterior > 0.5 is shown in Figure 16.

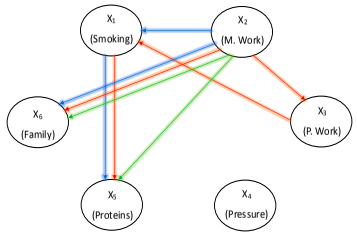

Figure 17: Example f_4 Feature in Coronary

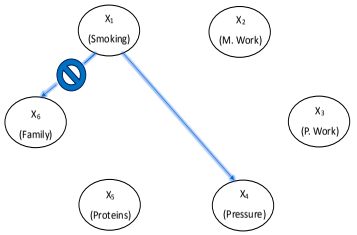

Figure 18: Example f_5 Feature in Coronary

Figure 17 shows the combined path feature $X_5 <\!\sim X_2 \sim\!> X_6$, which has the largest true posterior 0.6020 among all the possible f_4 features. The combined path feature $X_5 <\!\sim X_2 \sim\!> X_6$ includes many possible ways. For clarity, only three possible ways that have every constituent edge with true posterior > 0.5 are shown in Figure 17. These three possible ways are $X_6 \leftarrow X_2 \rightarrow X_5$, $X_6 \leftarrow X_2 \rightarrow X_1 \rightarrow X_5$, and $X_6 \leftarrow X_2 \rightarrow X_3 \rightarrow X_1 \rightarrow X_5$. The figure is best viewed in color. Figure 18 shows the combined path feature $X_4 <\!\sim X_1 \sim\!> X_6$, which has the largest true posterior 0.5139 among all the possible f_5 features. The combined path feature $X_4 <\!\sim X_1 \sim\!> X_6$ excludes any possible way going from X_1 to X_6 but includes many possible ways going from X_1 to X_4. For clarity, only one possible way ($X_1 \rightarrow X_4$) that has every constituent edge with true posterior > 0.5 is shown in Figure 18.

independently ran the IW-DDS 20 times to get the sample mean and the sample standard deviation of SAD for the (directed) edge feature and the five non-modular features (f_1, f_2, f_3, f_4, and f_5). For the DP+MCMC, we ran 25,000 $\cdot i$ MCMC iterations, where $i \in \{1, 2, \ldots, 20\}$. For each i, we discarded the first 12,500 $\cdot i$ MCMC iterations for "burn-in" and set the thinning parameter to be 5, so that 2,500 $\cdot i$ DAGs got sampled. For each i, we independently ran the MCMC 20 times to get the sample mean and the sample standard deviation of SAD for the edge feature, f_1, f_2, f_3, f_4, and f_5. For the K-best, we ran the K-best program with $K = 10 \cdot i$, where $i \in \{1, 2, \ldots, 20\}$. For each i, we ran the K-best just once to get SAD for the edge feature, f_1, f_2, f_3, f_4, and f_5, because there is no randomness in the outcome of the K-best algorithm. [7]

The experimental results for the data set Coronary are demonstrated in Figures 19 to 24. Figure 19 shows the SAD performance of the three methods with each i for the edge feature, where an error bar represents one sample standard deviation across 20 runs for the DP+MCMC or the IW-DDS at each i. Correspondingly, Figures 20 to 24 show the SAD performance of the three methods with each i for the five investigated non-modular features (f_1, f_2, f_3, f_4, and f_5) respectively. From Figure 19 and each of Figures 20 to 24, one can clearly see that if the SAD of the IW-DDS is significantly smaller than the SAD of the competing method (the DP+MCMC or the K-best) for the edge feature, then the SAD of the IW-DDS will also be significantly smaller than the SAD of the competing method for each of the five investigated non-modular features. More

7. The purpose of the experimental setting for the DP+MCMC and the K-best is merely to testify the claimed "if-then" conditional statement: if the SAD performance from the IW-DDS is significantly better than the SAD performance from the competing method for an edge feature, then the SAD performance from the IW-DDS will also be significantly better than that from the competing method for each investigated non-modular feature using the same set of DAG samples.

specifically, comparing with the DP+MCMC, at each $i \in \{1, 2, \dots 20\}$, for the edge feature, the real mean of SAD from the IW-DDS is significantly smaller than that from the DP+MCMC with the p-value < 0.01 from the two-sample t test with unequal variances. Consistently, at each $i \in \{1, 2, \dots 20\}$, for each investigated non-modular feature f_j, the real mean of SAD from the IW-DDS is also significantly smaller than that from the DP+MCMC with the p-value < 0.01 from the same t test. Comparing with the K-best, at each $i \in \{1, 2, \dots 20\}$, for the edge feature, the real mean of SAD from the IW-DDS is significantly smaller than the SAD from the K-best with the p-value $< 1 \times 10^{-20}$ from the one-sample t test. Consistently, at each $i \in \{1, 2, \dots 20\}$, for each investigated non-modular feature f_j, the real mean of SAD from the IW-DDS is also significantly smaller than the SAD from the K-best with the p-value $< 1 \times 10^{-20}$ from the same t test.

We also performed the same kind of experiments for the data set Iris with $n = 5$ and $m = 150$. The results are demonstrated in Figures 25 to 30. Comparing with the DP+MCMC, at each $i \in \{1, 2, \dots 20\}$, just as the comparison result for the edge feature, for each investigated f_j, the real mean of SAD from the IW-DDS is significantly smaller than that from the DP+MCMC with the p-value $< 1 \times 10^{-5}$ from the two-sample t test with unequal variances. Comparing with the K-best, at each $i \in \{1, 2, \dots 20\}$, just as the comparison result for the edge feature, for each investigated f_j, the real mean of SAD from the IW-DDS is also significantly smaller than the SAD from the K-best with the p-value $< 1 \times 10^{-9}$ from the one-sample t test. Thus, a conclusion similar to that from Coronary can be drawn: if the SAD of the IW-DDS is significantly smaller than the SAD of the competing method for the edge feature, then the SAD of the IW-DDS will also be significantly smaller than the SAD of the competing method for each of the five investigated non-modular features.

4.4 Performance Guarantee for the DDS Algorithm

To testify the quality guarantee from Corollary 4 (iv) for the estimator based on the DDS algorithm, we performed experiments based on two data cases (Letter with $m = 100$ and Tic-Tac-Toe), which have relatively large $\hat{\mu}$(SAD) or $\hat{\mu}$(MAD) ($= \hat{\mu}$(SAD) $/(n(n-1))$) from the DDS algorithm shown in Table 1. Based on hypothesis testing, we can conclude with very strong evidence that the performance guarantee for our estimator holds for both data cases. The details of the experiments are as follows.

For the first set of experiments, we choose the data case Letter with $m = 100$, which has the largest $\hat{\mu}$(SAD) ($= 0.2948$) from the DDS among all the 33 data cases shown in Table 1. We first consider the setting of the parameters specified as $\epsilon = 0.02$ and $\delta = 0.05$, which serves as our performance requirement. By setting the DAG sample size $N_o = \lceil (\ln(2/\delta))/(2\epsilon^2) \rceil = 4612$, we intend to show that the estimator $\hat{p}_{\prec}(f|D)$ coming from our DDS has the performance guarantee such that the Hoeffding inequality $P(|\hat{p}_{\prec}(f|D) - p_{\prec}(f|D)| \geq \epsilon) \leq \delta$ holds. Each directed edge feature f is investigated here because the posterior of each edge $p_{\prec}(f|D)$ can be easily obtained by the DP algorithm of Koivisto (2006). For each edge f, we call the event of $|\hat{p}_{\prec}(f|D) - p_{\prec}(f|D)| \geq \epsilon$ as the event of violation (of the pre-specified estimation error bound) in the learning of f. Define the indicator variable W for the event of violation in the learning of f. Thus, W is a Bernoulli random variable with the success probability $p_{vio} = P(|\hat{p}_{\prec}(f|D) - p_{\prec}(f|D)| \geq \epsilon)$. We independently repeat the DDS algorithm (with the same N_o) $R = 400$ times and use the average of W as the estimator $\hat{p}_{vio}$ for each edge. Note that the mean of $\hat{p}_{vio}$ is p_{vio} and the variance of $\hat{p}_{vio}$ is $p_{vio}(1-p_{vio})/R$ because $R\hat{p}_{vio}$ has a binomial distribution with the trial number R and the success probability p_{vio}. Because we expect that p_{vio} will be small so that $p_{vio}(1 - p_{vio})$ will be large as

compared with p_{vio}, we choose large $R = 400$ to make the variance of $\hat{p}_{vio}$ relatively small with respect to the mean of $\hat{p}_{vio}$. Figure 31 shows the histogram of $\hat{p}_{vio}$ for each of all the $n(n-1) = 272$ directed edges. For each of the 272 edges, it can be clearly seen that the corresponding $\hat{p}_{vio}$ is much smaller than $\delta = 0.05$ marked by the vertical bar. For 240 out of the 272 edges, the corresponding $\hat{p}_{vio}$'s are exactly equal to 0. Even for the largest $\hat{p}_{vio} = 0.015$, corresponding to 6 successes among 400 trials, we can use the one-sided hypothesis testing to reject the null hypothesis that $p_{vio} \geq 0.05$ and to conclude that $p_{vio} < 0.05$ with the p-value less than 2×10^{-4}. Therefore, the Hoeffding inequality holds for the learning of each edge in this parameter setting.

Next, we consider another setting of the parameters with $\epsilon = 0.01$ and $\delta = 0.02$, which has a more demanding performance requirement. By setting the DAG sample size $N_o = \lceil (\ln(2/\delta))/(2\epsilon^2) \rceil = 23026$, we want to show that the estimator $\hat{p}_{\prec}(f|D)$ coming from our DDS has the performance guarantee satisfying the Hoeffding inequality. With the same logic, we independently repeat the DDS algorithm (with the same N_o) $R = 1250$ times and use the average of W as the estimator $\hat{p}_{vio}$ for each edge. (Here we choose even larger R because we expect that p_{vio} will be smaller in this parameter setting.) Figure 32 shows the histogram of $\hat{p}_{vio}$ for each of all the 272 directed edges. For each edge, it can be clearly seen that the corresponding $\hat{p}_{vio}$ is much smaller than $\delta = 0.02$. Even for the largest $\hat{p}_{vio} = 0.004$, corresponding to 5 successes among 1250 trials, we can use the one-sided hypothesis testing to reject the null hypothesis that $p_{vio} \geq 0.02$ and to conclude that $p_{vio} < 0.02$ with the p-value less than 2×10^{-6}. Therefore, the Hoeffding inequality also holds in this parameter setting.

For the second set of experiments, we choose the data case Tic-Tac-Toe, which has the largest $\hat{\mu}$(MAD) ($= \hat{\mu}$(SAD) $/(n(n-1)) = 0.1547/90$) from the DDS among all the 33 data cases shown in Table 1. The same kind of experiments are performed for this data case. For the parameter setting with $\epsilon = 0.02$ and $\delta = 0.05$, the corresponding result is shown in Figure 33. For each of the 90 edges, the corresponding $\hat{p}_{vio}$ is clearly much smaller than $\delta = 0.05$. Even for the largest $\hat{p}_{vio} = 0.0125$, corresponding to 5 successes among 400 trials, we can use the one-sided hypothesis testing to conclude that $p_{vio} < 0.05$ with the p-value less than 6×10^{-5}. For the parameter setting with $\epsilon = 0.01$ and $\delta = 0.02$, the corresponding result is shown in Figure 34. For each edge, it can be clearly seen that the corresponding $\hat{p}_{vio}$ is much smaller than $\delta = 0.02$. Even for the largest $\hat{p}_{vio}$ $= 0.0056$, corresponding to 7 successes among 1250 trials, we can use the one-sided hypothesis testing to conclude that $p_{vio} < 0.02$ with the p-value less than 3×10^{-5}. Thus, the Hoeffding inequality also holds in the set of experiments for this data case.

Finally, for the data case Tic-Tac-Toe, we fix $\epsilon = 0.02$ but increase N_o from 2,000 to 10,000 by an increment of 1,000 each time. For each N_o, we plot the Hoeffding bound $2e^{-2N_o\epsilon^2}$ for the probability of violation $p_{vio} = P(|\hat{p}_{\prec}(f|D) - p_{\prec}(f|D)| \geq \epsilon)$ in Figure 35. (Note that the Hoeffding bound decreases at an exponential rate as N_o increases.) Then for each N_o, we also plot both the maximum and the mean of all the $n(n-1)$ $\hat{p}_{vio}$'s in Figure 35. Again $\hat{p}_{vio}$ for each edge is the average of W by independently running the DDS algorithm (with the same N_o) R times. We set $R = \max\{400, \lceil 10/(e^{-2N_o\epsilon^2}) \rceil\}$ and use larger R for larger N_o because we expect that $\hat{p}_{vio}$ will be smaller for larger N_o. From Figure 35, we can clearly see that $\hat{p}^*_{vio}$, the maximum of all the $n(n-1)$ $\hat{p}_{vio}$'s, is always far below the Hoeffding bound for each N_o. Furthermore, for each N_o we can use the one-sided hypothesis testing to reject the null hypothesis that $p_{vio} \geq 2e^{-2N_o\epsilon^2}$ and to conclude that $p_{vio} < 2e^{-2N_o\epsilon^2}$ with the p-value less than 3×10^{-4}. Therefore, the Hoeffding inequality holds for each N_o.

5. Conclusion

We develop new algorithms for efficiently sampling Bayesian network structures (DAGs). The sampled DAGs can then be used to build estimators for the posteriors of any features of interests. Theoretically we show that our estimators have several desirable properties. For example, unlike the existing MCMC algorithms, the estimators based on the DDS algorithm satisfy the Hoeffding bound and therefore enjoy the quality guarantee of the estimation with the given number of samples. Empirically we show that our estimators considerably outperform the previous state-of-the-art estimators with or without assuming the order-modular prior.

Our algorithms are capable of estimating the posteriors of arbitrary (non-modular) features (the DDS under the order-modular prior, and the IW-DDS under the structure-modular prior); while the exact algorithms are available for computing modular features under the order-modular prior with time $O(n^{k+1}C(m)+kn2^n)$ and space $O(n2^n)$ (Koivisto and Sood, 2004; Koivisto, 2006); computing path features under the order-modular prior with time $O(n^{k+1}C(m) + n3^n)$ and space $O(3^n)$ (Parviainen and Koivisto, 2011); and computing modular features under the structure-modular prior with time $O(n^{k+1}C(m) + kn2^n + 3^n)$ and space $O(n2^n)$ (Tian and He, 2009). The bottleneck of our algorithms is their first computation step, the DP algorithm of Koivisto and Sood (2004) whose space cost is $O(n2^n)$. Therefore, the application of our algorithms is limited to the data sets on which the DP algorithm of Koivisto and Sood (2004) is able to run—up to around 25 variables in current desktops, while a parallel implementation of the DP algorithm has been demonstrated on a data set with 33 variables using a cluster including totally 2,048 processors and 8,192 GB memory (Chen et al., 2014).

Appendix A. Proofs of Propositions, Theorems, and Corollary

This appendix provides the proofs of the propositions, theorems, and corollary in the paper.

A.1 Proof of Proposition 1

We first prove a lemma for Proposition 1.

Let an order $\prec$ be represented as $(\sigma_1, \ldots, \sigma_n)$, where σ_i is the ith element in the order.

Lemma 6 *The probability that the last $n-k+1$ elements along the order are $\sigma_k, \sigma_{k+1}, \ldots, \sigma_n$ respectively is given by*

$$p(\sigma_k, \sigma_{k+1}, \ldots, \sigma_n, D) = L'(U_{\sigma_k}^{\prec}) \prod_{i=k}^{n} \alpha'_{\sigma_i}(U_{\sigma_i}^{\prec}),$$

where $U_{\sigma_i}^{\prec} = V - \{\sigma_i, \sigma_{i+1}, \ldots, \sigma_n\}$.

Proof

$$\begin{aligned}
&p(\sigma_k, \sigma_{k+1}, \ldots, \sigma_n, D) \\
&= \sum_{\prec' \in \mathcal{L}(U_{\sigma_k}^{\prec})} p(\prec', \sigma_k, \sigma_{k+1}, \ldots, \sigma_n, D) \\
&= \prod_{i=k}^{n} \alpha'_{\sigma_i}(U_{\sigma_i}^{\prec}) \sum_{\prec' \in \mathcal{L}(U_{\sigma_k}^{\prec})} \prod_{i \in U_{\sigma_k}^{\prec}} \alpha'_i(U_i^{\prec}) \quad \text{(from Eq. 13)} \\
&= L'(U_{\sigma_k}^{\prec}) \prod_{i=k}^{n} \alpha'_{\sigma_i}(U_{\sigma_i}^{\prec}) \quad \text{(from Eq. 9)}.
\end{aligned}$$

■

Proposition 1 can be directly proved by the conclusion of Lemma 6 according to the definition of the conditional probability.

A.2 Proof of Proposition 2

Proof

From Proposition 1 and $L'(U_{\sigma_1}^{\prec} = \emptyset) = 1$, we have

$$\begin{aligned}
&\prod_{k=1}^{n} p(\sigma_k | \sigma_{k+1}, \ldots, \sigma_n, D) \\
&= \frac{\prod_{i=1}^{n} \alpha'_{\sigma_i}(U_{\sigma_i}^{\prec})}{L'(V)} \\
&= \frac{p(\prec, D)}{p_{\prec}(D)} \quad \text{(from Eq. 13 and Eq. 14)} \\
&= p(\prec | D),
\end{aligned}$$

which proves Eq. (20). ■

A.3 Proof of Theorem 3

Proof

First, we show that each DAG G sampled according to our DDS algorithm has its pmf $p_s(G)$ equal to the exact posterior $p_{\prec}(G|D)$ by assuming the order-modular prior.

On one hand, from the following derivation, we can get the exact form for $p_{\prec}(G|D)$:

$$\begin{aligned}
&p_{\prec}(f|D) \\
&= \sum_{\prec} p(\prec | D) p(f | \prec, D) \\
&= \sum_{\prec} p(\prec | D) \sum_{G \subseteq \prec} f(G) p(G | \prec, D) \\
&= \sum_{\prec} \sum_{G \subseteq \prec} f(G) p(\prec, G | D) \\
&= \sum_{G} f(G) \sum_{\prec \text{s.t.} G \subseteq \prec} p(\prec, G | D). \qquad (28)
\end{aligned}$$

Thus, for each possible DAG G_i, by setting $f(G)$ to be the indicator function $I[G = G_i]$ and then relating Eq. (28) with Eq. (4), we know that $p_{\prec}(G_i|D) = \sum_{\prec \text{s.t.} G_i \subseteq \prec} p(\prec, G_i|D)$ for each G_i.

On the other hand, the event that a DAG G gets sampled according to our DDS algorithm occurs if and only if one of the orders that G is consistent with gets sampled in Step 2 of the DDS algorithm and then G gets sampled from the sampled order in Step 3 of the DDS algorithm. Therefore, based on the total probability formula, $p_s(G) = \sum_{\prec \text{s.t.} G \subseteq \prec} p(\prec | D) p(G | \prec, D) = \sum_{\prec \text{s.t.} G \subseteq \prec} p(\prec, G|D)$ $= p_{\prec}(G|D)$.

Second, because N_o orders are sampled independently and each DAG per sampled order is sampled independently, $p_s(G_1, G_2, \ldots, G_{N_o}|D) = \prod_{i=1}^{N_o} [\sum_{\prec \text{s.t.} G \subseteq \prec} p(\prec | D) p(G_i | \prec, D)] = \prod_{i=1}^{N_o}$ $p_{\prec}(G_i|D)$.

Therefore, Theorem 3 is proved.

■

A.4 Proof of Corollary 4

Proof

For each G_i in the DAG set $\{G_1, G_2, \ldots, G_{N_o}\}$ sampled from the DDS algorithm, $f(G_i) \in \{0, 1\}$. Because $G_1, G_2, \ldots, G_{N_o}$ are iid with pmf $p_{\prec}(G|D)$ (by Theorem 3), $f(G_1)$, $f(G_2), \ldots,$ $f(G_{N_o})$ are iid with Bernoulli pmf.

For each G_i, the following is true for $E(f(G_i))$, the expectation of $f(G_i)$:

$$\begin{aligned}
&E(f(G_i)) \\
&= \sum_{G} f(G) p_{\prec}(G|D) \\
&= p_{\prec}(f|D).
\end{aligned}$$

Thus, $f(G_1)$, $f(G_2), \ldots, f(G_{N_o})$ are iid with Bernoulli($p_{\prec}(f|D)$). In other words, $f(G_1)$, $f(G_2), \ldots, f(G_{N_o})$ are independent; and for each G_i, $P(f(G_i) = 1) = p_{\prec}(f|D)$ and $P(f(G_i) = 0) = 1 - p_{\prec}(f|D)$.

(i) Proof that $\hat{p}_\prec(f|D)$ is an unbiased estimator of $p_\prec(f|D)$, that is, $E(\hat{p}_\prec(f|D)) = p_\prec(f|D)$.

$$\begin{aligned}
&E\left(\hat{p}_\prec(f|D)\right)\\
&= E\left(\frac{1}{N_o}\sum_{i=1}^{N_o} f(G_i)\right)\\
&= \frac{1}{N_o}\sum_{i=1}^{N_o} E\left(f(G_i)\right)\\
&= \frac{1}{N_o} N_o p_\prec(f|D)\\
&= p_\prec(f|D).
\end{aligned}$$

(ii) Proof that $\hat{p}_\prec(f|D)$ converges almost surely to $p_\prec(f|D)$.
Because $f(G_1)$, $f(G_2), \ldots, f(G_{N_o})$ are iid with $E(f(G_i)) = p_\prec(f|D) < \infty$ and

$$\hat{p}_\prec(f|D) = \frac{1}{N_o}\sum_{i=1}^{N_o} f(G_i),$$

based on the strong law of large numbers (Theorem 5.5.9 of Casella and Berger, 2002), $\hat{p}_\prec(f|D)$ converges almost surely to $p_\prec(f|D)$ (as $N_o \to \infty$).

Note that, by Theorem 2.5.1 of Athreya and Lahiri (2006), the property that $\hat{p}_\prec(f|D)$ converges almost surely to $p_\prec(f|D)$ implies that $\hat{p}_\prec(f|D)$ converges in probability to $p_\prec(f|D)$, that is, $\hat{p}_\prec(f|D)$ is a consistent estimator of $p_\prec(f|D)$.

(iii) Proof that if $0 < p_\prec(f|D) < 1$, then the random variable

$$\frac{\sqrt{N_o}(\hat{p}_\prec(f|D) - p_\prec(f|D))}{\sqrt{\hat{p}_\prec(f|D)(1-\hat{p}_\prec(f|D))}}$$

has a limiting standard normal distribution, denoted by

$$\frac{\sqrt{N_o}(\hat{p}_\prec(f|D) - p_\prec(f|D))}{\sqrt{\hat{p}_\prec(f|D)(1-\hat{p}_\prec(f|D))}} \longrightarrow^d \mathcal{N}(0,1).$$

Because $f(G_1)$, $f(G_2), \ldots, f(G_{N_o})$ are iid with Bernoulli($p_\prec(f|D)$), for each G_i, the following is true for $\mathrm{Var}(f(G_i))$, the variance of $f(G_i)$:

$$\begin{aligned}
&\mathrm{Var}(f(G_i))\\
&= E(f(G_i))(1 - E(f(G_i)))\\
&= p_\prec(f|D)(1 - p_\prec(f|D))\\
&< \infty.
\end{aligned}$$

Because $0 < p_\prec(f|D) < 1$, $\mathrm{Var}(f(G_i))$ is also strictly greater than 0.
Again, we have already known that $E(f(G_i)) = p_\prec(f|D) < \infty$.
Thus, by the central limit theorem (Theorem 5.5.15 of Casella and Berger, 2002),

$$\frac{\sqrt{N_o}(\hat{p}_\prec(f|D) - E(f(G)))}{\sqrt{\mathrm{Var}(f(G))}} \longrightarrow^d \mathcal{N}(0,1),$$

that is,

$$\frac{\sqrt{N_o}(\hat{p}_\prec(f|D) - p_\prec(f|D))}{\sqrt{p_\prec(f|D)(1-p_\prec(f|D))}} \longrightarrow^d \mathcal{N}(0,1).$$

Because $\hat{p}_\prec(f|D)$ converges in probability to $p_\prec(f|D)$, denoted by $\hat{p}_\prec(f|D) \longrightarrow^p p_\prec(f|D)$, by the continuous mapping theorem (Theorem 5.5.4 of Casella and Berger, 2002),

$$\sqrt{\hat{p}_\prec(f|D)(1-\hat{p}_\prec(f|D))} \longrightarrow^p \sqrt{p_\prec(f|D)(1-p_\prec(f|D))}.$$

Finally, by Slutsky's theorem (Theorem 5.5.17 of Casella and Berger, 2002),

$$\frac{\sqrt{N_o}(\hat{p}_\prec(f|D) - p_\prec(f|D))}{\sqrt{\hat{p}_\prec(f|D)(1-\hat{p}_\prec(f|D))}} \longrightarrow^d \mathcal{N}(0,1).$$

(iv) Proof that for any $\epsilon > 0$, any $0 < \delta < 1$, if $N_o \geq (\ln(2/\delta))/(2\epsilon^2)$, then $P(|\hat{p}_\prec(f|D) - p_\prec(f|D)| < \epsilon) \geq 1 - \delta$.

Because $f(G_1)$, $f(G_2), \ldots, f(G_{N_o})$ are iid with Bernoulli($p_\prec(f|D)$), the Hoeffding bound (Hoeffding, 1963; Koller and Friedman, 2009) holds:

$$P(|\hat{p}_\prec(f|D) - p_\prec(f|D)| \geq \epsilon) \leq 2e^{-2N_o\epsilon^2}.$$

This is equivalent to

$$P(|\hat{p}_\prec(f|D) - p_\prec(f|D)| < \epsilon) \geq 1 - 2e^{-2N_o\epsilon^2} \geq 1 - \delta$$

for $N_o \geq (\ln(2/\delta))/(2\epsilon^2)$.

■

A.5 Proof of Equation (21)

Proof For any $j \in \{1, \ldots, n\}$,

$$\begin{aligned}
&P((\sigma_j, U_{\sigma_j})|D)\\
&\propto P((\sigma_j, U_{\sigma_j}), D)\\
&= \sum_{\substack{(\sigma_1,\ldots,\sigma_{j-1})\\ \in\mathcal{L}(U_{\sigma_j})}} \sum_{\substack{(\sigma_{j+1},\ldots,\sigma_n)\\ \in\mathcal{L}(V-U_{\sigma_j}-\{\sigma_j\})}} P(\sigma_1, \ldots, \sigma_{j-1}, \sigma_j, \sigma_{j+1}, \ldots, \sigma_n, D)\\
&= \sum_{\substack{(\sigma_1,\ldots,\sigma_{j-1})\\ \in\mathcal{L}(U_{\sigma_j})}} \sum_{\substack{(\sigma_{j+1},\ldots,\sigma_n)\\ \in\mathcal{L}(V-U_{\sigma_j}-\{\sigma_j\})}} \prod_{i=1}^{n} \alpha'_{\sigma_i}(U_{\sigma_i})\\
&= \alpha'_{\sigma_j}(U_{\sigma_j}) L'(U_{\sigma_j}) R'(V - U_{\sigma_j} - \{\sigma_j\}).
\end{aligned}$$

■

A.6 Proof of Equation (22)

Proof

$$
\begin{aligned}
& p_{\prec}(G|D) \\
&= \sum_{\prec \text{s.t.} G \subseteq \prec} p(\prec, G|D) \\
&= \frac{1}{p_{\prec}(D)} \sum_{\prec \text{s.t.} G \subseteq \prec} p(\prec, G, D) \\
&= \frac{1}{p_{\prec}(D)} \sum_{\prec \text{s.t.} G \subseteq \prec} p(\prec, G) p(D|G) \\
&= \frac{1}{p_{\prec}(D)} \sum_{\prec \text{s.t.} G \subseteq \prec} \left(\prod_{i=1}^{n} q_i(U_i) \rho_i(Pa_i) \right) p(D|G) \\
&= \frac{1}{p_{\prec}(D)} \sum_{\prec \text{s.t.} G \subseteq \prec} \left(\prod_{i=1}^{n} p_i(Pa_i) \right) p(D|G) \\
&= \frac{1}{p_{\prec}(D)} \sum_{\prec \text{s.t.} G \subseteq \prec} p_{\not\prec}(G) p(D|G) \\
&= \frac{1}{p_{\prec}(D)} \cdot | \prec_G | \cdot p_{\not\prec}(G, D) \\
&= \frac{p_{\not\prec}(D)}{p_{\prec}(D)} \cdot | \prec_G | \cdot p_{\not\prec}(G|D).
\end{aligned}
$$

Because both $p_{\not\prec}(D) > 0$ and $p_{\prec}(D) > 0$, $p_{\prec}(G|D) \propto | \prec_G | \cdot p_{\not\prec}(G|D)$, which also was shown by Ellis and Wong (2008).

■

A.7 Proof of Theorem 5

Proof

Let Ω denote the set of all the DAGs. Define $\mathcal{U}^+ = \{G \in \Omega : p_{\not\prec}(G, D) > 0\}$. $\mathcal{U}^+$ will equal Ω if the user chooses a prior such that $p_{\not\prec}(G) > 0$ for every DAG G (such as a uniform DAG prior $p_{\not\prec}(G) \equiv 1$). If the user, however, has some additional domain knowledge so that he or she sets some prior to exclude some DAGs a priori, $\mathcal{U}^+$ will be a proper subset of Ω. Note that $p_{\not\prec}(f|D) = p_{\not\prec}(f, D)/p_{\not\prec}(D)$, where $p_{\not\prec}(f, D) = \sum_G f(G) p_{\not\prec}(G, D) = \sum_{G \in \mathcal{U}^+} f(G) p_{\not\prec}(G, D)$, and $p_{\not\prec}(D) = p_{\not\prec}(f \equiv 1, D) = \sum_G p_{\not\prec}(G, D) = \sum_{G \in \mathcal{U}^+} p_{\not\prec}(G, D)$.

Let $I[\cdot]$ denote the indicator function. Rewrite $\hat{p}_{\not\prec}(f|D)$ in Eq. (24) as $\hat{p}_{\not\prec}(f, D)/\hat{p}_{\not\prec}(D)$, where $\hat{p}_{\not\prec}(f, D) = \sum_{G \in \mathcal{G}} f(G) p_{\not\prec}(G, D) = \sum_G f(G)\, p_{\not\prec}(G, D) I[G \in \mathcal{G}] = \sum_{G \in \mathcal{U}^+} f(G) p_{\not\prec}(G, D) I[G \in \mathcal{G}]$, and $\hat{p}_{\not\prec}(D) = \hat{p}_{\not\prec}(f \equiv 1, D) = \sum_{G \in \mathcal{G}} p_{\not\prec}(G, D) = \sum_G p_{\not\prec}(G, D) I[G \in \mathcal{G}] = \sum_{G \in \mathcal{U}^+} p_{\not\prec}(G, D) I[G \in \mathcal{G}]$.

Note that by Theorem 3, $P(G \in \mathcal{G}) = 1 - (1 - p_{\prec}(G|D))^{N_o}$, where $p_{\prec}(G|D)$ is the exact posterior of G under the order-modular prior assumption. Also note that by Eq. (22), for any $G \in \Omega$, $p_{\not\prec}(G, D) > 0$ implies $p_{\prec}(G|D) > 0$.

(i) Proof that $\hat{p}_{\not\prec}(f|D)$ is an asymptotically unbiased estimator of $p_{\not\prec}(f|D)$, that is,

$$\lim_{N_o \to \infty} E(\hat{p}_{\not\prec}(f|D)) = p_{\not\prec}(f|D). \tag{29}$$

For notational convenience, let γ denote $\hat{p}_{\not\prec}(f, D)$ and τ denote $\hat{p}_{\not\prec}(D)$. Define $g(\gamma, \tau) = \gamma/\tau$ so that $g(\gamma, \tau)$ is $\hat{p}_{\not\prec}(f|D)$.

Note that

$$
\begin{aligned}
& E(\gamma) \\
&= E(\hat{p}_{\not\prec}(f, D)) \\
&= E\left(\sum_{G \in \mathcal{U}^+} f(G) p_{\not\prec}(G, D) I[G \in \mathcal{G}] \right) \\
&= \sum_{G \in \mathcal{U}^+} E(f(G) p_{\not\prec}(G, D) I[G \in \mathcal{G}]) \\
&= \sum_{G \in \mathcal{U}^+} f(G) p_{\not\prec}(G, D) P(G \in \mathcal{G}) \\
&= \sum_{G \in \mathcal{U}^+} f(G) p_{\not\prec}(G, D)(1 - (1 - p_{\prec}(G|D))^{N_o}).
\end{aligned}
$$

Thus,

$$
\begin{aligned}
& \lim_{N_o \to \infty} E(\gamma) \\
&= \lim_{N_o \to \infty} \left(\sum_{G \in \mathcal{U}^+} f(G) p_{\not\prec}(G, D)(1 - (1 - p_{\prec}(G|D))^{N_o}) \right) \\
&= \sum_{G \in \mathcal{U}^+} f(G) p_{\not\prec}(G, D) \lim_{N_o \to \infty} (1 - (1 - p_{\prec}(G|D))^{N_o}) \\
&= \sum_{G \in \mathcal{U}^+} f(G) p_{\not\prec}(G, D) \\
&= p_{\not\prec}(f, D).
\end{aligned}
$$

Similarly, by setting $f \equiv 1$, we have

$$
\begin{aligned}
& E(\tau) \\
&= E(\hat{p}_{\not\prec}(D)) \\
&= \sum_{G \in \mathcal{U}^+} p_{\not\prec}(G, D)(1 - (1 - p_{\prec}(G|D))^{N_o}),
\end{aligned}
$$

and

$$\lim_{N_o \to \infty} E(\tau) = p_{\not\prec}(D).$$

Next, by Taylor's theorem (with the Lagrange form of the remainder),

$$\begin{aligned} & g(\gamma,\tau) \\ &= g(E(\gamma),E(\tau)) + \left[\frac{\partial g(\gamma,\tau)}{\partial \gamma}\right]_{\gamma=E(\gamma),\tau=E(\tau)} (\gamma^* - E(\gamma)) \\ &\quad + \left[\frac{\partial g(\gamma,\tau)}{\partial \tau}\right]_{\gamma=E(\gamma),\tau=E(\tau)} (\tau^* - E(\tau)), \end{aligned}$$

where $\gamma^* = E(\gamma) + \theta(\gamma - E(\gamma))$, $\tau^* = E(\tau) + \theta(\tau - E(\tau))$, and θ is a random variable such that $0 < \theta < 1$.

Examine the components separately:

$$g(E(\gamma),E(\tau)) = E(\gamma)/E(\tau);$$

$$\begin{aligned} & \left[\frac{\partial g(\gamma,\tau)}{\partial \gamma}\right]_{\gamma=E(\gamma),\tau=E(\tau)} \\ &= \left[\tau^{-1}\right]_{\gamma=E(\gamma),\tau=E(\tau)} \\ &= (E(\tau))^{-1}; \end{aligned}$$

$$\begin{aligned} & \left[\frac{\partial g(\gamma,\tau)}{\partial \tau}\right]_{\gamma=E(\gamma),\tau=E(\tau)} \\ &= \left[-\gamma(\tau)^{-2}\right]_{\gamma=E(\gamma),\tau=E(\tau)} \\ &= -E(\gamma)(E(\tau))^{-2}. \end{aligned}$$

Because neither $E(\gamma)$ nor $E(\tau)$ is random,

$$\begin{aligned} & E\left(g(\gamma,\tau)\right) \\ &= E(\gamma)/E(\tau) + (E(\tau))^{-1}E(\gamma^* - E(\gamma)) - E(\gamma)(E(\tau))^{-2}E(\tau^* - E(\tau)) \\ &= E(\gamma)/E(\tau) + (E(\tau))^{-1}E(\theta(\gamma - E(\gamma))) - E(\gamma)(E(\tau))^{-2}E(\theta(\tau - E(\tau))). \end{aligned}$$

Consider the limit of each component separately:

$$\begin{aligned} & \lim_{N_o\to\infty} (E(\gamma)/E(\tau)) \\ &= \left(\lim_{N_o\to\infty} E(\gamma)\right) / \left(\lim_{N_o\to\infty} E(\tau)\right) \\ &= p_{\not\propto}(f,D)/p_{\not\propto}(D) \\ &= p_{\not\propto}(f|D); \end{aligned}$$

$$\begin{aligned} & \lim_{N_o\to\infty} (E(\tau))^{-1} \\ &= \left(\lim_{N_o\to\infty} E(\tau)\right)^{-1} \\ &= (p_{\not\propto}(D))^{-1}; \end{aligned}$$

$$\begin{aligned} & \lim_{N_o\to\infty} -E(\gamma)(E(\tau))^{-2} \\ &= -\left(\lim_{N_o\to\infty} E(\gamma)\right)\left(\lim_{N_o\to\infty} E(\tau)\right)^{-2} \\ &= -p_{\not\propto}(f,D)(p_{\not\propto}(D))^{-2}. \end{aligned}$$

Note that both $(p_{\not\propto}(D))^{-1}$ and $-p_{\not\propto}(f,D)(p_{\not\propto}(D))^{-2}$ are constant real numbers.
Finally, we intend to prove the following two equalities:

$$\lim_{N_o\to\infty} E(\theta(\gamma - E(\gamma))) = 0, \tag{30}$$

$$\lim_{N_o\to\infty} E(\theta(\tau - E(\tau))) = 0. \tag{31}$$

Once this is done,

$$\begin{aligned} & \lim_{N_o\to\infty} E\left(g(\gamma,\tau)\right) \\ &= \lim_{N_o\to\infty} (E(\gamma)/E(\tau)) + \lim_{N_o\to\infty} (E(\tau))^{-1}\cdot 0 + \lim_{N_o\to\infty} \left(-E(\gamma)(E(\tau))^{-2}\right)\cdot 0 \\ &= p_{\not\propto}(f|D). \end{aligned}$$

The whole proof of Eq. (29) will then be done.
The proof of Eq. (30) is as follows.
Based on the definition of the limit, proving Eq. (30) is equivalent to proving

$$\lim_{N_o\to\infty} |E(\theta(\gamma - E(\gamma)))| = 0. \tag{32}$$

Because

$$\begin{aligned} & |E(\theta(\gamma - E(\gamma)))| \\ &\le E\left(|\theta(\gamma - E(\gamma))|\right) \\ &= E\left(|\theta|\cdot|\gamma - E(\gamma)|\right) \\ &\le E\left(|\gamma - E(\gamma)|\right) \quad \text{(because } 0 < \theta < 1\text{)}, \end{aligned}$$

and $|E(\theta(\gamma - E(\gamma)))| \ge 0$, to prove Eq. (32), it is sufficient to prove

$$\lim_{N_o\to\infty} E\left(|\gamma - E(\gamma)|\right) = 0. \tag{33}$$

Note that

$$
\begin{aligned}
& E\left(|\gamma - E(\gamma)|\right) \\
&= E\left(\left|\sum_{G\in\mathcal{U}^+} f(G)p_{\not\prec}(G,D)I[G\in\mathcal{G}] \ - \sum_{G\in\mathcal{U}^+} f(G)p_{\not\prec}(G,D)P(G\in\mathcal{G})\right|\right) \\
&= E\left(\left|\sum_{G\in\mathcal{U}^+} f(G)p_{\not\prec}(G,D)(I[G\in\mathcal{G}] - P(G\in\mathcal{G}))\right|\right) \\
&\le E\left(\sum_{G\in\mathcal{U}^+} f(G)p_{\not\prec}(G,D)\,|I[G\in\mathcal{G}] - P(G\in\mathcal{G})|\right) \\
&= \sum_{G\in\mathcal{U}^+} f(G)p_{\not\prec}(G,D)E\left(|I[G\in\mathcal{G}] - P(G\in\mathcal{G})|\right) \\
&= \sum_{G\in\mathcal{U}^+} f(G)p_{\not\prec}(G,D)[(1-P(G\in\mathcal{G}))P(G\in\mathcal{G}) \\
&\qquad + (P(G\in\mathcal{G})-0)(1-P(G\in\mathcal{G}))] \\
&= \sum_{G\in\mathcal{U}^+} f(G)p_{\not\prec}(G,D)[2P(G\in\mathcal{G})(1-P(G\in\mathcal{G}))] \\
&= \sum_{G\in\mathcal{U}^+} f(G)p_{\not\prec}(G,D)[2(1-(1-p_{\prec}(G|D))^{N_o}) \times (1-p_{\prec}(G|D))^{N_o}].
\end{aligned}
$$

Because for any $G\in\mathcal{U}^+$, $p_{\prec}(G|D)>0$, we have

$$
\begin{aligned}
& \lim_{N_o\to\infty} \sum_{G\in\mathcal{U}^+} f(G)p_{\not\prec}(G,D)[2(1-(1-p_{\prec}(G|D))^{N_o}) \times (1-p_{\prec}(G|D))^{N_o}] \\
&= \sum_{G\in\mathcal{U}^+} f(G)p_{\not\prec}(G,D) \lim_{N_o\to\infty} [2(1-(1-p_{\prec}(G|D))^{N_o}) \times (1-p_{\prec}(G|D))^{N_o}] \\
&= \sum_{G\in\mathcal{U}^+} f(G)p_{\not\prec}(G,D)\cdot 0 \\
&= 0.
\end{aligned}
$$

Eq. (33) is proved, and the proof of Eq. (30) is done.

Setting $f\equiv 1$ in Eq. (30) leads to Eq. (31).

Thus, the whole proof of Eq. (29) is done.

(ii) Proof that $\hat{p}_{\not\prec}(f|D)$ converges almost surely to $p_{\not\prec}(f|D)$, denoted by $\hat{p}_{\not\prec}(f|D) \longrightarrow^{a.s.} p_{\not\prec}(f|D)$.

Recall that Ω denotes the set of all the DAGs, that is, $\Omega=\{G_1,G_2,\ldots,G_{W^*}\}$, where W^* is $|\Omega|$, the number of all the DAGs. Note that W^* is a finite positive integer though it is super-exponential in the number of variables n.

Let $\mathcal{F}$ be $\mathcal{P}(\Omega)$, the power set of Ω. Thus, $\mathcal{F}$ is a σ-algebra on Ω (Athreya and Lahiri, 2006). Define for any $A\in\mathcal{F}$, $\mu(A)=\sum_{G_j\in A} p_{\prec}(G_j|D)$. It is well-known that μ is a probability measure on $\mathcal{F}$ so that $(\Omega,\mathcal{F},\mu)$ is a probability space (Athreya and Lahiri, 2006).

For each $i\ge 1$, let $\Omega_i=\Omega$, $\mathcal{F}_i=\mathcal{F}$, and $\mu_i=\mu$. Let $\Omega^\infty=\{(G^{(1)},G^{(2)},\ldots): G^{(i)}\in\Omega_i, i\ge 1\}$. Let a cylinder set $\underset{\sim}{A}=A_1\times A_2\times\cdots\times A_k\times\Omega_{k+1}\times\Omega_{k+2}\times\cdots$, where there exists $1\le k<\infty$ such that $A_i\in\mathcal{F}_i$ for $1\le i\le k$ and $A_i=\Omega_i$ for $i>k$. Let $\mathcal{F}^\infty=\sigma<\{\underset{\sim}{A}: \underset{\sim}{A} \text{ is a cylinder set }\}>$, that is, $\mathcal{F}^\infty$ is a σ-algebra generated by the set of all the $\underset{\sim}{A}$'s. $\mathcal{F}^\infty$ is a σ-algebra on Ω^∞ and is called a product σ-algebra.

Define, for each $(A_1,A_2,\ldots,A_k,\Omega_{k+1},\Omega_{k+2},\ldots)\in\mathcal{F}^\infty$, $\mu^\infty(A_1,A_2,\ldots,A_k,\Omega_{k+1},\Omega_{k+2},\ldots)=\mu_1(A_1)\times\mu_2(A_2)\times\cdots\times\mu_k(A_k)$. By Kolmogorov's consistency theorem, $(\Omega^\infty,\mathcal{F}^\infty,\mu^\infty)$ is a probability space (Athreya and Lahiri, 2006).

Let $\Omega^{\infty,0}=\{(G^{(1)},G^{(2)},\ldots)\in\Omega^\infty:$ there exists $G\in\mathcal{U}^+$ such that for any $i\ge 1, G^{(i)}\ne G\}$. Let $\Omega^{\infty,1}=\Omega^\infty-\Omega^{\infty,0}$. Thus, $\Omega^{\infty,1}=\{(G^{(1)},G^{(2)},\ldots)\in\Omega^\infty:$ for any $G\in\mathcal{U}^+,$ there exists $i\ge 1$ such that $G^{(i)}=G\}$.

Define, for each $\omega^\infty\in\Omega^\infty$,

$$
\hat{p}^{N_o}_{\not\prec}(\omega^\infty)=\frac{\sum_{G\in\mathcal{U}^+} f(G)p_{\not\prec}(G,D)I[G\in\mathcal{G}^{N_o}(\omega^\infty)]}{\sum_{G\in\mathcal{U}^+} p_{\not\prec}(G,D)I[G\in\mathcal{G}^{N_o}(\omega^\infty)]},
$$

where $\mathcal{G}^{N_o}(\omega^\infty)$ is the DAG set that includes the first N_o coordinates of ω^∞. By the definition, we know that $\hat{p}^{N_o}_{\not\prec}(\omega^\infty)=\hat{p}_{\not\prec}(f|D)$.

For each $\omega^\infty\in\Omega^{\infty,1}$, for each $G\in\mathcal{U}^+$, let $N(G,\omega^\infty)$ be the smallest integer such that $G^{(N(G,\omega^\infty))}=G$. Let $N(\omega^\infty)=\max_{G\in\mathcal{U}^+} N(G,\omega^\infty)$. Then for each $N_o\ge N(\omega^\infty)$, for each $G\in\mathcal{U}^+$, $I[G\in\mathcal{G}^{N_o}(\omega^\infty)]=1$.

Accordingly, for each $\omega^\infty\in\Omega^{\infty,1}$, there exists $N(\omega^\infty)$ such that for each $N_o\ge N(\omega^\infty)$,

$$
\begin{aligned}
& \hat{p}^{N_o}_{\not\prec}(\omega^\infty) \\
&= \frac{\sum_{G\in\mathcal{U}^+} f(G)p_{\not\prec}(G,D)}{\sum_{G\in\mathcal{U}^+} p_{\not\prec}(G,D)} \\
&= p_{\not\prec}(f|D).
\end{aligned}
$$

This implies that $\lim_{N_o\to\infty}\hat{p}^{N_o}_{\not\prec}(\omega^\infty)=p_{\not\prec}(f|D)$ for each $\omega^\infty\in\Omega^{\infty,1}$.

Finally, we intend to prove the following equality:

$$
\mu^\infty(\Omega^{\infty,1})=1. \tag{34}
$$

Once this is done, the whole proof that $\hat{p}_{\not\prec}(f|D)\longrightarrow^{a.s.} p_{\not\prec}(f|D)$ is done.

Proving Eq. (34) is equivalent to proving

$$
\mu^\infty(\Omega^{\infty,0})=0. \tag{35}
$$

For any $G\in\Omega$, let $\Omega^{\infty,0,G}=\{(G^{(1)},G^{(2)},\ldots)\in\Omega^\infty:$ for any $i\ge 1, G^{(i)}\ne G\}$. Thus, $\Omega^{\infty,0}=\bigcup_{G\in\mathcal{U}^+}\Omega^{\infty,0,G}$. Accordingly, $\mu^\infty(\Omega^{\infty,0})\le\sum_{G\in\mathcal{U}^+}\mu^\infty(\Omega^{\infty,0,G})$.

For each $j\ge 1$, let $\Omega^{\infty,0,G,j}=\{(G^{(1)},G^{(2)},\ldots)\in\Omega^\infty:$ for any $i\in\{1,\ldots,j\}, G^{(i)}\ne G\}$. Note that $\Omega^{\infty,0,G,1}\supseteq\Omega^{\infty,0,G,2}\supseteq\ldots\supseteq\Omega^{\infty,0,G,j-1}\supseteq\Omega^{\infty,0,G,j}$ for each $j\ge 1$. Thus, $\Omega^{\infty,0,G}=\bigcap_{j=1}^\infty\Omega^{\infty,0,G,j}$.

Finally, for any $G \in \mathcal{U}^+$,

$$\begin{aligned}
&\mu^\infty(\Omega^{\infty,0,G}) \\
&= \mu^\infty(\bigcap_{j=1}^{\infty} \Omega^{\infty,0,G,j}) \\
&= \lim_{j\to\infty} \mu^\infty(\Omega^{\infty,0,G,j}) \\
&= \lim_{j\to\infty} \mu_1(\Omega - \{G\}) \times \mu_2(\Omega - \{G\}) \times \cdots \times \mu_j(\Omega - \{G\}) \\
&= \lim_{j\to\infty} [1 - \mu(\{G\})]^j \\
&= \lim_{j\to\infty} [1 - p_\prec(G|D)]^j \\
&= 0.
\end{aligned}$$

Thus, $\sum_{G\in\mathcal{U}^+} \mu^\infty(\Omega^{\infty,0,G}) = 0$, so that Eq. (35) is proved. The whole proof is done.

Note that, by Theorem 2.5.1 of Athreya and Lahiri (2006), the property that $\hat{p}_\prec(f|D)$ converges almost surely to $p_\prec(f|D)$ implies that $\hat{p}_\prec(f|D)$ converges in probability to $p_\prec(f|D)$, that is, $\hat{p}_\prec(f|D)$ is a consistent estimator of $p_\prec(f|D)$.

(iii) Proof that the convergence rate of $\hat{p}_\prec(f|D)$ is $o(a^{N_o})$ for any $0 < a < 1$.

In the proof of (ii), we have shown that for each $\omega^\infty \in \Omega^{\infty,1}$, there exists $N(\omega^\infty)$ such that for each $N_o \geq N(\omega^\infty)$, $\hat{p}^{N_o}_\prec(\omega^\infty) = p_\prec(f|D)$. This means that for any $0 < a < 1$, $(a^{N_o})^{-1}[\hat{p}^{N_o}_\prec(\omega^\infty) - p_\prec(f|D)] = 0$. Thus, $\lim_{N_o\to\infty}(a^{N_o})^{-1}[\hat{p}^{N_o}_\prec(\omega^\infty) - p_\prec(f|D)] = 0$ so that the proof is done.

(iv) Proof that if the quantity $\Delta = \sum_{G\in\mathcal{G}} p_\prec(G|D)$, then $\Delta \cdot \hat{p}_\prec(f|D) \leq p_\prec(f|D) \leq \Delta \cdot \hat{p}_\prec(f|D) + 1 - \Delta$.

The proof is essentially the same as the proof of Proposition 1 of Tian et al. (2010) which proves Eq. (27), an equivalent form of Eq. (26). The direct proof of Eq. (26) is also provided in the supplementary material.

Abstract

Crowdsourcing is a popular paradigm for effectively collecting labels at low cost. The Dawid-Skene estimator has been widely used for inferring the true labels from the noisy labels provided by non-expert crowdsourcing workers. However, since the estimator maximizes a non-convex log-likelihood function, it is hard to theoretically justify its performance. In this paper, we propose a two-stage efficient algorithm for multi-class crowd labeling problems. The first stage uses the spectral method to obtain an initial estimate of parameters. Then the second stage refines the estimation by optimizing the objective function of the Dawid-Skene estimator via the EM algorithm. We show that our algorithm achieves the optimal convergence rate up to a logarithmic factor. We conduct extensive experiments on synthetic and real datasets. Experimental results demonstrate that the proposed algorithm is comparable to the most accurate empirical approach, while outperforming several other recently proposed methods.

Keywords: crowdsourcing, spectral methods, EM, Dawid-Skene model, non-convex optimization, minimax rate

1. Introduction

With the advent of online services such as Amazon Mechanical Turk, crowdsourcing has become an efficient and inexpensive way to collect labels for large-scale data. However, labels collected from the crowd can be of low quality since crowdsourcing workers are often non-experts and sometimes unreliable. As a remedy, most crowdsourcing services resort to labeling redundancy, collecting multiple labels from different workers for each item. Such a strategy raises a fundamental problem in crowdsourcing: how to infer true labels from noisy but redundant worker labels?

For labeling tasks with k different categories, Dawid and Skene (1979) develop a maximum likelihood approach to this problem based on the EM algorithm. They assume that each worker is associated with a $k \times k$ confusion matrix, where the (l, c)-th entry represents the probability that a random chosen item in class l is labeled as class c by the worker. The true labels and worker confusion matrices are jointly estimated by maximizing the likelihood of the observed labels, where the unobserved true labels are treated as latent variables.

Although this EM-based approach has had empirical success (Snow et al., 2008; Raykar et al., 2010; Liu et al., 2012; Zhou et al., 2012; Chen et al., 2013; Zhou et al., 2014), there is as yet no theoretical guarantee for its performance. A recent theoretical study (Gao and Zhou, 2014) shows that the global optimal solutions of the Dawid-Skene estimator can achieve minimax rates of convergence in a simplified scenario, where the labeling task is binary and each worker has a single parameter to represent her labeling accuracy (referred to as the "one-coin" model in what follows). However, since the likelihood function is nonconvex, this guarantee is not operational because the EM algorithm can get trapped in a local optimum. Several alternative approaches have been developed that aim to circumvent the theoretical deficiencies of the EM algorithm, still the context of the one-coin model (Karger et al., 2013, 2014; Ghosh et al., 2011; Dalvi et al., 2013), but, as we survey in Section 2, they either fail to achieve an optimal rate or make restrictive assumptions that can be hard to justify in practice.

We propose a computationally efficient and provably optimal algorithm to simultaneously estimate true labels and worker confusion matrices for multi-class labeling problems. Our approach is a two-stage procedure, in which we first compute an initial estimate of worker confusion matrices using a spectral method, and then in the second stage we turn to the EM algorithm. Under some mild conditions, we show that this two-stage procedure achieves minimax rates of convergence up to a logarithmic factor, even after only one iteration of EM. In particular, given any $\delta \in (0, 1)$, we provide an upper bound on the number of workers and the number of items so that our method can correctly estimate labels for all items with probability at least $1 - \delta$. We also establish a matching lower bound. Further, we provide both upper and lower bounds for estimating the confusion matrix of each worker and show that our algorithm achieves the optimal accuracy.

This work not only provides an optimal algorithm for crowdsourcing but provides new general insight into the method of moments. Empirical studies show that when the spectral method is used as an initialization for the EM algorithm, it outperforms EM with random initialization (Liang, 2013; Chaganty and Liang, 2013). This work provides a concrete way to justify such observations theoretically. It is also known that starting from a root-n consistent estimator obtained by the spectral method, one Newton-Raphson step leads to an asymptotically optimal estimator (Lehmann and Casella, 2003). However, obtaining a root-n consistent estimator and performing a Newton-Raphson step can be demanding computationally. In contrast, our initialization doesn't need to be root-n consistent, thus a small portion of data suffices to initialize. Moreover, performing one iteration of EM is computationally more attractive and numerically more robust than a Newton-Raphson step especially for high-dimensional problems.

The paper is organized as follows. In Section 2, we provide background on crowdsourcing and the method of moments for latent variables models. In Section 3, we describe our crowdsourcing problem. Our provably optimal algorithm is presented in Section 4. Section

5 is devoted to theoretical analysis (with the proofs gathered in the Appendix). In Section 6, we consider the special case of the one-coin model. A simpler algorithm is introduced together with a sharper rate. Numerical results on both synthetic and real datasets are reported in Section 7, followed by our conclusions in Section 8.

2. Related Work

Many methods have been proposed to address the problem of estimating true labels in crowdsourcing (Whitehill et al., 2009; Raykar et al., 2010; Welinder et al., 2010; Ghosh et al., 2011; Liu et al., 2012; Zhou et al., 2012; Dalvi et al., 2013; Karger et al., 2014, 2013; Parisi et al., 2014; Zhou et al., 2014). The methods in Raykar et al. (2010); Ghosh et al. (2011); Karger et al. (2014); Liu et al. (2012); Karger et al. (2013); Dalvi et al. (2013) are based on the generative model proposed by Dawid and Skene (1979). In particular, Ghosh et al. (2011) propose a method based on Singular Value Decomposition (SVD) which addresses binary labeling problems under the one-coin model. The analysis in Ghosh et al. (2011) assumes that the labeling matrix is full, that is, each worker labels all items. To relax this assumption, Dalvi et al. (2013) propose another SVD-based algorithm which explicitly considers the sparsity of the labeling matrix in both algorithm design and theoretical analysis. Karger et al. (2014) propose an iterative algorithm for binary labeling problems under the one-coin model and extended it to multi-class labeling tasks by converting a k-class problem into $k-1$ binary problems (Karger et al., 2013). This line of work assumes that tasks are assigned to workers according to a random regular graph, thus imposes specific constraints on the number of workers and the number of items. In Section 5, we compare our theoretical results with that of existing approaches (Ghosh et al., 2011; Dalvi et al., 2013; Karger et al., 2014, 2013). The methods in Raykar et al. (2010); Liu et al. (2012); Chen et al. (2013) incorporate Bayesian inference into the Dawid-Skene estimator by assuming a prior over confusion matrices. Zhou et al. (2012, 2014) propose a minimax entropy principle for crowdsourcing which leads to an exponential family model parameterized with worker ability and item difficulty. When all items have zero difficulty, the exponential family model reduces to the generative model suggested by Dawid and Skene (1979).

Our method for initializing the EM algorithm in crowdsourcing is inspired by recent work using spectral methods to estimate latent variable models (Anandkumar et al., 2014, 2015, 2012, 2013; Chaganty and Liang, 2013; Zou et al., 2013; Hsu et al., 2012; Jain and Oh, 2014). The basic idea in this line of work is to compute third-order empirical moments from the data and then to estimate parameters by computing a certain orthogonal decomposition of tensor derived from the moments. Given the special symmetric structure of the moments, the tensor factorization can be computed efficiently using the robust tensor power method (Anandkumar et al., 2014). A problem with this approach is that the estimation error can have a poor dependence on the condition number of the second-order moment matrix and thus empirically it sometimes performs worse than EM with multiple random initializations. Our method, by contrast, requires only a rough initialization from the moment of moments; we show that the estimation error does not depend on the condition number (see Theorem 4 (b)).

Recently, Balakrishnan et al. (2016) study the convergence rate of EM algorithm under a good initialization, which belongs to a ball centered at the true parameter. They show that

when the radius of the ball is small enough to satisfy certain gradient stability condition and sample deviation condition, EM has a geometric convergence rate. Although this is an insightful theoretical result, Balakrishnan et al. (2016) fail to provide a practical approach to constructing such an initialization.

Other related work is by Dasgupta and Schulman (2007), who study an EM algorithm for learning mixture of Gaussians under certain initialization. They establish a nearly optimal estimation precision when using a two-round EM algorithm to learn the parameters from a mixture of k well-separated spherical Gaussians in the high-dimensional space. The space dimension d is assumed to be much greater than $\log(k)$. Although the high-level idea is quite similar to ours (i.e., constructing a good initializer and running one or two steps of EM), our work is different from this work in several respects. First, while Dasgupta and Schulman (2007) require the Gaussian means to be well separated, we do not assume the workers' labeling distributions for different true labels to be separated. In fact, for any worker, we allow his/her labeling distributions for two classes to be arbitrarily close or even identical. We only assume that there is a partitioning of the workers into three groups, such that the averaged confusion matrix of each group has full rank. Second, Dasgupta and Schulman (2007) consider the high-dimensional case where the dimension of the parameter space is $d \gg \log(k)$. In crowdsourcing, the labeling distribution lies in a k-dimensional space where k is the number of classes. Typically k is a small integer (below 10). Finally, in terms of analysis technique, Dasgupta and Schulman (2007) heavily rely on Gaussian concentration results. Our work uses a variety of techniques for different theorems. In particular, for Theorem 3, we repeatedly use matrix perturbation and matrix concentration results to establish the sample complexity for the spectral method. For Theorem 4, we create three random events in equation (33) (that holds with high probability), then establish both a prediction error bound and a confusion matrix estimation error bound for the EM algorithm. We use Le Cam's method (Yu, 1997) to establish the minimax lower bound result in Theorem 5.

3. Problem Setting

Throughout this paper, $[a]$ denotes the integer set $\{1, 2, \ldots, a\}$ and $\sigma_b(A)$ denotes the b-th largest singular value of matrix A. Suppose that there are m workers, n items and k classes. The true label y_j of item $j \in [n]$ is assumed to be sampled from a probability distribution $\mathbb{P}[y_j = l] = w_l$ where $\{w_l : l \in [k]\}$ are positive values satisfying $\sum_{l=1}^{k} w_l = 1$. Denote by a vector $z_{ij} \in \mathbb{R}^k$ the label that worker i assigns to item j. When the assigned label is c, we write $z_{ij} = e_c$, where e_c represents the c-th canonical basis vector in $\mathbb{R}^k$ in which the c-th entry is 1 and all other entries are 0. A worker may not label every item. Let π_i indicate the probability that worker i labels a randomly chosen item. If item j is not labeled by worker i, we write $z_{ij} = 0$. Our goal is to estimate the true labels $\{y_j : j \in [n]\}$ from the observed labels $\{z_{ij} : i \in [m], j \in [n]\}$.

For this estimation purpose, we need to make assumptions on the process of generating observed labels. Following the work of Dawid and Skene (1979), we assume that the probability that worker i labels an item in class l as class c is independent of any particular chosen item, that is, it is a constant over $j \in [n]$. Let us denote the constant probability by μ_{ilc}. Let $\mu_{il} = [\mu_{il1}\ \mu_{il2}\ \cdots\ \mu_{ilk}]^T$. The matrix $C_i = [\mu_{i1}\ \mu_{i2}\ \ldots\ \mu_{ik}] \in \mathbb{R}^{k\times k}$ is called the *confusion*

Algorithm 1: Estimating confusion matrices

Input: integer k, observed labels $z_{ij} \in \mathbb{R}^k$ for $i \in [m]$ and $j \in [n]$.

Output: confusion matrix estimates $\widehat{C}_i \in \mathbb{R}^{k\times k}$ for $i \in [m]$.

(1) Partition the workers into three disjoint and non-empty group G_1, G_2 and G_3. Compute the group aggregated labels Z_{gj} by Eq. (1).

(2) For $(a, b, c) \in \{(2, 3, 1), (3, 1, 2), (1, 2, 3)\}$, compute the second and the third order moments $\widehat{M}_2 \in \mathbb{R}^{k\times k}$, $\widehat{M}_3 \in \mathbb{R}^{k\times k\times k}$ by Eq. (2a)-(2d), then compute $\widehat{C}_c^\diamond \in \mathbb{R}^{k\times k}$ and $\widehat{W} \in \mathbb{R}^{k\times k}$ by tensor decomposition:

  (a) Compute whitening matrix $\widehat{Q} \in \mathbb{R}^{k\times k}$ (such that $\widehat{Q}^T \widehat{M}_2 \widehat{Q} = I$) using SVD.

  (b) Compute eigenvalue-eigenvector pairs $\{(\widehat{\alpha}_h, \widehat{v}_h)\}_{h=1}^k$ of the whitened tensor $\widehat{M}_3(\widehat{Q}, \widehat{Q}, \widehat{Q})$ by using the robust tensor power method. Then compute $\widehat{w}_h = \widehat{\alpha}_h^{-2}$ and $\widehat{\mu}_h^\diamond = (\widehat{Q}^T)^{-1}(\widehat{\alpha}_h \widehat{v}_h)$.

  (c) For $l = 1, \ldots, k$, set the l-th column of $\widehat{C}_c^\diamond$ by some $\widehat{\mu}_h^\diamond$ whose l-th coordinate has the greatest component, then set the l-th diagonal entry of $\widehat{W}$ by $\widehat{w}_h$.

(3) Compute $\widehat{C}_i$ by Eq. (5).

matrix of worker i. In the special case of the one-coin model, all the diagonal elements of C_i are equal to a constant while all the off-diagonal elements are equal to another constant such that each column of C_i sums to 1.

4. Our Algorithm

In this section, we present an algorithm to estimate the confusion matrices and true labels. Our algorithm consists of two stages. In the first stage, we compute an initial estimate for the confusion matrices via the method of moments. In the second stage, we perform the standard EM algorithm by taking the result of the Stage 1 as an initialization.

4.1 Stage 1: Estimating confusion matrices

Partitioning the workers into three disjoint and non-empty groups G_1, G_2 and G_3, the outline of this stage is the following: we use the method of moments to estimate the averaged confusion matrices for the three groups, then utilize this intermediate estimate to obtain the confusion matrix of each individual worker. In particular, for $g \in \{1, 2, 3\}$ and $j \in [n]$, we calculate the averaged labeling within each group by

$$Z_{gj} := \frac{1}{|G_g|} \sum_{i\in G_g} z_{ij}. \tag{1}$$

Denoting the aggregated confusion matrix columns by

$$\mu_{gl}^\diamond := \mathbb{E}(Z_{gj}|y_j = l) = \frac{1}{|G_g|} \sum_{i\in G_g} \pi_i \mu_{il},$$

our first step is to estimate $C_g^\diamond := [\mu_{g1}^\diamond, \mu_{g2}^\diamond, \ldots, \mu_{gk}^\diamond]$ and to estimate the distribution of true labels $W := \mathrm{diag}(w_1, w_2, \ldots, w_k)$. The following proposition shows that we can solve for $C_g^\diamond$ and W from the moments of $\{Z_{gj}\}$.

Proposition 1 (Anandkumar et al. (2015)) *Assume that the vectors $\{\mu_{g1}^\diamond, \mu_{g2}^\diamond, \ldots, \mu_{gk}^\diamond\}$ are linearly independent for each $g \in \{1, 2, 3\}$. Let (a, b, c) be a permutation of $\{1, 2, 3\}$. Define*

$$\begin{aligned}
Z'_{aj} &:= \mathbb{E}[Z_{cj} \otimes Z_{bj}] \left(\mathbb{E}[Z_{aj} \otimes Z_{bj}]\right)^{-1} Z_{aj}, \\
Z'_{bj} &:= \mathbb{E}[Z_{cj} \otimes Z_{aj}] \left(\mathbb{E}[Z_{bj} \otimes Z_{aj}]\right)^{-1} Z_{bj}, \\
M_2 &:= \mathbb{E}[Z'_{aj} \otimes Z'_{bj}], \\
M_3 &:= \mathbb{E}[Z'_{aj} \otimes Z'_{bj} \otimes Z_{cj}].
\end{aligned}$$

Then,

$$M_2 = \sum_{l=1}^k w_l \, \mu_{cl}^\diamond \otimes \mu_{cl}^\diamond \quad \textit{and} \quad M_3 = \sum_{l=1}^k w_l \, \mu_{cl}^\diamond \otimes \mu_{cl}^\diamond \otimes \mu_{cl}^\diamond.$$

Since we only have finite samples, the expectations in Proposition 1 must be approximated by empirical moments. In particular, they are computed by averaging over indices $j = 1, 2, \ldots, n$. For each permutation $(a, b, c) \in \{(2, 3, 1), (3, 1, 2), (1, 2, 3)\}$, we compute

$$\widehat{Z}'_{aj} := \Big(\frac{1}{n}\sum_{j=1}^n Z_{cj} \otimes Z_{bj}\Big)\Big(\frac{1}{n}\sum_{j=1}^n Z_{aj} \otimes Z_{bj}\Big)^{-1} Z_{aj}, \tag{2a}$$

$$\widehat{Z}'_{bj} := \Big(\frac{1}{n}\sum_{j=1}^n Z_{cj} \otimes Z_{aj}\Big)\Big(\frac{1}{n}\sum_{j=1}^n Z_{bj} \otimes Z_{aj}\Big)^{-1} Z_{bj}, \tag{2b}$$

$$\widehat{M}_2 := \frac{1}{n}\sum_{j=1}^n \widehat{Z}'_{aj} \otimes \widehat{Z}'_{bj}, \tag{2c}$$

$$\widehat{M}_3 := \frac{1}{n}\sum_{j=1}^n \widehat{Z}'_{aj} \otimes \widehat{Z}'_{bj} \otimes Z_{cj}. \tag{2d}$$

The statement of Proposition 1 suggests that we can recover the columns of $C_c^\diamond$ and the diagonal entries of W by operating on the moments $\widehat{M}_2$ and $\widehat{M}_3$. This is implemented by the tensor factorization method in Algorithm 1. In particular, the tensor factorization algorithm returns a set of vectors $\{(\widehat{\mu}_h^\diamond, \widehat{w}_h) : h = 1, \ldots, k\}$, where each $(\widehat{\mu}_h^\diamond, \widehat{w}_h)$ estimates a particular column of $C_c^\diamond$ (for some $\mu_{cl}^\diamond$) and a particular diagonal entry of W (for some w_l).

It is important to note that the tensor factorization algorithm doesn't provide a one-to-one correspondence between the recovered column and the true columns of $C_c^\diamond$. Thus, $\widehat{\mu}_1^\diamond, \ldots, \widehat{\mu}_k^\diamond$ represents an arbitrary permutation of the true columns.

To discover the index correspondence, we take each $\widehat{\mu}_h^\diamond$ and examine its greatest component. We assume that within each group, the probability of assigning a correct label is always greater than the probability of assigning any specific incorrect label. This assumption will be made precise in the next section. As a consequence, if $\widehat{\mu}_h^\diamond$ corresponds to the l-th column of $C_c^\diamond$, then its l-th coordinate is expected to be greater than other coordinates. Thus, we set the l-th column of $\widehat{C}_c^\diamond$ to some vector $\widehat{\mu}_h^\diamond$ whose l-th coordinate has the greatest component (if there are multiple such vectors, then randomly select one of them; if there is no such vector, then randomly select a $\widehat{\mu}_h^\diamond$). Then, we set the l-th diagonal entry of $\widehat{W}$ to the scalar $\widehat{w}_h$ associated with $\widehat{\mu}_h^\diamond$. Note that by iterating over $(a,b,c) \in \{(2,3,1),(3,1,2),(1,2,3)\}$, we obtain $\widehat{C}_c^\diamond$ for $c = 1,2,3$ respectively. There will be three copies of $\widehat{W}$ estimating the same matrix W—we average them for the best accuracy.

In the second step, we estimate each individual confusion matrix C_i. The following proposition shows that we can recover C_i from the moments of $\{z_{ij}\}$.

Proposition 2 *For any $g \in \{1,2,3\}$ and any $i \in G_g$, let $a \in \{1,2,3\}\backslash\{g\}$ be one of the remaining group index. Then*

$$\pi_i C_i W (C_a^\diamond)^T = \mathbb{E}[z_{ij} Z_{aj}^T].$$

Proof First, notice that

$$\mathbb{E}[z_{ij} Z_{aj}^T] = \mathbb{E}\left[\mathbb{E}[z_{ij} Z_{aj}^T | y_j]\right] = \sum_{l=1}^k w_l \mathbb{E}\left[z_{ij} Z_{aj}^T | y_j = l\right]. \tag{3}$$

Since z_{ij} for $1 \le i \le m$ are conditionally independent given y_j, we can write

$$\mathbb{E}\left[z_{ij} Z_{aj}^T | y_j = l\right] = \mathbb{E}\left[z_{ij} | y_j = l\right] \mathbb{E}\left[Z_{aj}^T | y_j = l\right] = (\pi_i \mu_{il})(\mu_{al}^\diamond)^T. \tag{4}$$

Combining (3) and (4) implies the desired result,

$$\mathbb{E}[z_{ij} Z_{aj}^T] = \pi_i \sum_{l=1}^k w_l \mu_{il} (\mu_{al}^\diamond)^T = \pi_i C_i W (C_a^\diamond)^T.$$

■

Proposition 2 suggests a plug-in estimator for C_i. We compute $\widehat{C}_i$ using the empirical approximation of $\mathbb{E}[z_{ij} Z_{aj}^T]$ and using the matrices $\widehat{C}_a^\diamond$, $\widehat{C}_b^\diamond$, $\widehat{W}$ obtained in the first step. Concretely, we calculate

$$\widehat{C}_i := \text{normalize}\left\{\left(\frac{1}{n}\sum_{j=1}^n z_{ij} Z_{aj}^T\right)\left(\widehat{W}(\widehat{C}_a^\diamond)^T\right)^{-1}\right\}, \tag{5}$$

where the normalization operator rescales the matrix columns, making sure that each column sums to 1. The overall procedure for Stage 1 is summarized in Algorithm 1.

4.2 Stage 2: EM algorithm

The second stage is devoted to refining the initial estimate provided by Stage 1. The joint likelihood of true label y_j and observed labels z_{ij}, as a function of confusion matrices μ_i, can be written as

$$L(\mu; y, z) := \prod_{j=1}^n \prod_{i=1}^m \prod_{c=1}^k (\mu_{iy_jc})^{\mathbb{I}(z_{ij}=e_c)}.$$

By assuming a uniform prior over y, we maximize the marginal log-likelihood function

$$\ell(\mu) := \log\left(\sum_{y\in[k]^n} L(\mu; y, z)\right). \tag{6}$$

We refine the initial estimate of Stage 1 by maximizing the objective function (6), which is implemented by the Expectation Maximization (EM) algorithm. The EM algorithm takes as initialization the values $\{\widehat{\mu}_{ilc}\}$ provided as output by Stage 1, and then executes the following E-step and M-step for at least one round.

E-step Calculate the expected value of the log-likelihood function, with respect to the conditional distribution of y given z under the current estimate of μ:

$$Q(\mu) := \mathbb{E}_{y|z,\widehat{\mu}}\left[\log(L(\mu; y, z))\right] = \sum_{j=1}^n \left\{\sum_{l=1}^k \widehat{q}_{jl} \log\left(\prod_{i=1}^m \prod_{c=1}^k (\mu_{ilc})^{\mathbb{I}(z_{ij}=e_c)}\right)\right\},$$

$$\text{where} \quad \widehat{q}_{jl} \leftarrow \frac{\exp\left(\sum_{i=1}^m \sum_{c=1}^k \mathbb{I}(z_{ij}=e_c)\log(\widehat{\mu}_{ilc})\right)}{\sum_{l'=1}^k \exp\left(\sum_{i=1}^m \sum_{c=1}^k \mathbb{I}(z_{ij}=e_c)\log(\widehat{\mu}_{il'c})\right)} \qquad \text{for } j \in [n],\ l \in [k]. \tag{7}$$

M-step Find the estimate $\widehat{\mu}$ that maximizes the function $Q(\mu)$:

$$\widehat{\mu}_{ilc} \leftarrow \frac{\sum_{j=1}^n \widehat{q}_{jl} \mathbb{I}(z_{ij}=e_c)}{\sum_{c'=1}^k \sum_{j=1}^n \widehat{q}_{jl} \mathbb{I}(z_{ij}=e_{c'})} \qquad \text{for } i \in [m],\ l \in [k],\ c \in [k]. \tag{8}$$

In practice, we alternatively execute the updates (7) and (8), for one iteration or until convergence. Each update increases the objective function $\ell(\mu)$. Since $\ell(\mu)$ is not concave, the EM update doesn't guarantee converging to the global maximum. It may converge to distinct local stationary points for different initializations. Nevertheless, as we prove in the next section, it is guaranteed that the EM algorithm will output statistically optimal estimates of true labels and worker confusion matrices if it is initialized by Algorithm 1.

5. Convergence Analysis

To state our main theoretical results, we first need to introduce some notation and assumptions. Let

$$w_{\min} := \min\{w_l\}_{l=1}^k \quad \text{and} \quad \pi_{\min} := \min\{\pi_i\}_{i=1}^m$$

be the smallest portion of true labels and the most extreme sparsity level of workers. Our first assumption assumes that both $w_{\min}$ and $\pi_{\min}$ are strictly positive, that is, every class and every worker contributes to the dataset.

Our second assumption assumes that the confusion matrices for each of the three groups, namely $C_1^\diamond$, $C_2^\diamond$ and $C_3^\diamond$, are nonsingular. As a consequence, if we define matrices S_{ab} and tensors T_{abc} for any $a, b, c \in \{1, 2, 3\}$ as

$$S_{ab} := \sum_{l=1}^{k} w_l \, \mu_{al}^\diamond \otimes \mu_{bl}^\diamond = C_a^\diamond W (C_b^\diamond)^T \quad \text{and} \quad T_{abc} := \sum_{l=1}^{k} w_l \, \mu_{al}^\diamond \otimes \mu_{bl}^\diamond \otimes \mu_{cl}^\diamond,$$

then there will be a positive scalar σ_L such that $\sigma_k(S_{ab}) \geq \sigma_L > 0$.

Our third assumption assumes that within each group, the average probability of assigning a correct label is always higher than the average probability of assigning any incorrect label. To make this statement rigorous, we define a quantity

$$\kappa := \min_{g \in \{1,2,3\}} \min_{l \in [k]} \min_{c \in [k] \setminus \{l\}} \{\mu_{gll}^\diamond - \mu_{glc}^\diamond\}$$

indicating the smallest gap between diagonal entries and non-diagonal entries in the confusion matrix. The assumption requires that κ is strictly positive. Note that this assumption is group-based, thus doesn't assume the accuracy of any individual worker.

Finally, we introduce a quantity that measures the average ability of workers in identifying distinct labels. For two discrete distributions P and Q, let $\mathbb{D}_{\mathrm{KL}}(P, Q) := \sum_i P(i) \log(P(i)/Q(i))$ represent the KL-divergence between P and Q. Since each column of the confusion matrix represents a discrete distribution, we can define the following quantity:

$$\overline{D} = \min_{l \neq l'} \frac{1}{m} \sum_{i=1}^{m} \pi_i \mathbb{D}_{\mathrm{KL}}(\mu_{il}, \mu_{il'}). \tag{9}$$

The quantity $\overline{D}$ lower bounds the averaged KL-divergence between two columns. If $\overline{D}$ is strictly positive, it means that every pair of labels can be distinguished by at least one subset of workers. As the last assumption, we assume that $\overline{D}$ is strictly positive.

The following two theorems characterize the performance of our algorithm. We split the convergence analysis into two parts. Theorem 3 characterizes the performance of Algorithm 1, providing sufficient conditions for achieving an arbitrarily accurate initialization. We provide the proof of Theorem 3 in Appendix A.

Theorem 3 *For any scalar $\delta > 0$ and any scalar ϵ satisfying $\epsilon \leq \min\left\{\frac{36\kappa k}{\pi_{\min} w_{\min} \sigma_L}, 2\right\}$, if the number of items n satisfies*

$$n = \Omega\left(\frac{k^5 \log((k+m)/\delta)}{\epsilon^2 \pi_{\min}^2 w_{\min}^2 \sigma_L^{13}}\right),$$

then the confusion matrices returned by Algorithm 1 are bounded as

$$\|\widehat{C}_i - C_i\|_\infty \leq \epsilon \qquad \text{for all } i \in [m],$$

with probability at least $1 - \delta$. Here, $\|\cdot\|_\infty$ denotes the element-wise ℓ_∞-norm of a matrix.

Theorem 4 characterizes the error rate in Stage 2. It states that when a sufficiently accurate initialization is taken, the updates (7) and (8) refine the estimates $\widehat{\mu}$ and $\widehat{y}$ to the optimal accuracy. See Appendix B for the proof.

Theorem 4 *Assume that $\mu_{ilc} \geq \rho$ holds for all $(i, l, c) \in [m] \times [k]^2$. For any scalar $\delta > 0$, if confusion matrices $\widehat{C}_i$ are initialized in a way such that*

$$\|\widehat{C}_i - C_i\|_\infty \leq \alpha := \min\left\{\frac{\rho}{2}, \frac{\rho\overline{D}}{16}\right\} \qquad \text{for all } i \in [m] \tag{10}$$

and the number of workers m and the number of items n satisfy

$$m = \Omega\left(\frac{\log(1/\rho)\log(kn/\delta)}{\overline{D}}\right) \quad \text{and} \quad n = \Omega\left(\frac{\log(mk/\delta)}{\pi_{\min} w_{\min} \alpha^2}\right),$$

then, for $\widehat{\mu}$ and $\widehat{q}$ obtained by iterating (7) and (8) (for at least one round), with probability at least $1 - \delta$,

(a) Let $\widehat{y}_j = \arg\max_{l \in [k]} \widehat{q}_{jl}$, then $\widehat{y}_j = y_j$ holds for all $j \in [n]$.

(b) $\|\widehat{\mu}_{il} - \mu_{il}\|_2^2 \leq \frac{48\log(8mk/\delta)}{\pi_i w_l n}$ holds for all $(i, l) \in [m] \times [k]$.

In Theorem 4, the assumption that all confusion matrix entries are lower bounded by $\rho > 0$ is somewhat restrictive. For datasets violating this assumption, we enforce positive confusion matrix entries by adding random noise: Given any observed label z_{ij}, we replace it by a random label in $\{1, ..., k\}$ with probability $k\rho$. In this modified model, every entry of the confusion matrix is lower bounded by ρ, so that Theorem 4 holds. The random noise makes the constant $\overline{D}$ smaller than its original value, but the change is minor for small ρ.

To see the consequence of the convergence analysis, we take error rate ϵ in Theorem 3 equal to the constant α defined in Theorem 4. Then we combine the statements of the two theorems. This shows that if we choose the number of workers m and the number of items n such that

$$m = \widetilde{\Omega}\left(\frac{1}{\overline{D}}\right) \quad \text{and} \quad n = \widetilde{\Omega}\left(\frac{k^5}{\pi_{\min}^2 w_{\min}^2 \sigma_L^{13} \min\{\rho^2, (\rho\overline{D})^2\}}\right); \tag{11}$$

that is, if both m and n are lower bounded by a problem-specific constant and logarithmic terms, then with high probability, the predictor $\widehat{y}$ will be perfectly accurate, and the estimator $\widehat{\mu}$ will be bounded as $\|\widehat{\mu}_{il} - \mu_{il}\|_2^2 \leq \widetilde{\mathcal{O}}(1/(\pi_i w_l n))$. To show the optimality of this convergence rate, we present the following minimax lower bounds. See Appendix C for the proof.

Theorem 5 *There are universal constants $c_1 > 0$ and $c_2 > 0$ such that:*

(a) For any $\{\mu_{ilc}\}$, $\{\pi_i\}$ and any number of items n, if the number of workers $m \le 1/(4\overline{D})$, then

$$\inf_{\widehat{y}} \sup_{v\in[k]^n} \mathbb{E}\Big[\sum_{j=1}^{n} \mathbb{I}(\widehat{y}_j \neq y_j)\Big|\{\mu_{ilc}\},\{\pi_i\}, y = v\Big] \ge c_1 n.$$

(b) For any $\{w_l\}$, $\{\pi_i\}$, any worker-item pair (m,n) and any pair of indices $(i,l) \in [m]\times[k]$, we have

$$\inf_{\widehat{\mu}} \sup_{\mu\in\mathbb{R}^{m\times k\times k}} \mathbb{E}\Big[\|\widehat{\mu}_{il} - \mu_{il}\|_2^2\Big|\{w_l\},\{\pi_i\}\Big] \ge c_2 \min\left\{1, \frac{1}{\pi_i w_l n}\right\}.$$

In part (a) of Theorem 5, we see that the number of workers should be at least $1/\overline{D}$, otherwise any predictor will make many mistakes. This lower bound matches our sufficient condition on the number of workers m (see Eq. (11)). In part (b), we see that the best possible estimate for μ_{il} has $1/(\pi_i w_l n)$ mean-squared error. It verifies the optimality of our estimator $\widehat{\mu}_{il}$. It is also worth noting that the constraint on the number of items n (see Eq. (11)) depends on problem-specific constants, which might be improvable. Nevertheless, the constraint scales logarithmically with m and $1/\delta$, thus is easy to satisfy for reasonably large datasets.

5.1 Discussion of theoretical results

In this section, we present a discussion of the foregoing theoretical results. In particular, we compare Theorem 3 and Theorem 4 to existing theoretical results on crowdsourcing and the EM method.

5.1.1 Sparse sampling regime vs. dense sampling regime

In our theoretical analysis, we make the assumption that the minimum labeling frequency $\pi_{\min}$ is bounded away from zero, i.e., $\pi_{\min} = \Omega(1)$. This corresponds to the *dense sampling regime* where the average number of labels for each item should be $\Theta(m)$. According to Theorem 4, to guarantee perfect label prediction with probability $1-\delta$, we require the average number of samples for each item to be $\Omega\left(\frac{\log(1/\delta)\pi_{\min}}{D}\right)$. Two related works in the dense sampling regime include Ghosh et al. (2011) and Gao and Zhou (2014). Ghosh et al. (2011) studied the one-coin model for binary labeling. To attain a δ prediction error, their algorithm requires m and n to scale with $1/\delta^2$, while our algorithm allows m and n to scale with $\log(1/\delta)$. Gao and Zhou (2014) studied the minimax rate of the prediction error and showed that maximizing likelihood is statistically optimal. However, they didn't provide a polynomial-time algorithm to achieve the minimax rate.

Another sampling regime is the *sparse sampling regime*, where the labeling frequency $\pi_{\min}$ goes to zero as the number of items n goes to infinity. In fact, this is a practical regime for large-scale datasets when workers complete only a vanishing fraction of the total tasks. As can be seen in condition (11), our theoretical result doesn't apply to the very sparse regime when $\pi = o(1/\sqrt{n})$. Several work have been devoted to investigate the sparse sampling regime (Karger et al., 2014, 2013; Dalvi et al., 2013). Under the sparse sampling regime, the high-probability recovery of *all* true labels might be impossible. However, it is still of great interest to establish the upper bound on the prediction error as a function of the average number of labels per item. Karger et al. (2014, 2013) show that if worker labels are organized by a random regular bipartite graph, then the number of labels on each item should scale as $\log(1/\delta)$, where δ is the label prediction error. Their analysis assumes that the limit of number of items goes to infinity, or that the number of workers is many times of the number of items. Dalvi et al. (2013) provide algorithms that improve the theoretical guarantee for the one-coin model. Their algorithms succeed without the regular bipartite graph assumption, and without the requirement that the limit of number of items goes to infinity.

Although our theoretical analysis does not fully cover the sparse sampling regime, the algorithm sill applies to the sparse regime and achieves reasonably good performance (see, e.g., the experiment with TREC data in Section 7.2). Empirically, spectral-initialized EM is rather robust for both dense and sparse sampling regimes.[1]

5.1.2 Lower bound on the number of items

In both Theorem 3 and 4, we require lower bounds on the number of times. It is interesting to see whether these bounds can be improved. One idea is to improve those lower bounds using the technique from Balakrishnan et al. (2016) discussed in Section 2. Nevertheless, as we explain below, such improvement is up to a multiplicative factor $1/\alpha$, which doesn't depend on σ_L, $w_{\min}$ and $\pi_{\min}$. We recall that there are two lower bounds on the number of items n in our theoretical results.

1. The lower bound in the condition of Theorem 3 (denoted by n_{spectral}). It relies on the target error ϵ, the minimum singular value σ_L and the minimum prior probabilities $\pi_{\min}, w_{\min}$.

2. The lower bound in the condition of Theorem 4 (denoted by n_{EM}). It establishes the performance guarantee for EM. This lower bound relies on the initialization accuracy α and the minimum prior probabilities $\pi_{\min}, w_{\min}$.

Theorem 4 shows that it is sufficient to set the target error of Theorem 3 equal to $\epsilon := \alpha$. Thus, the constant n_{spectral} also depends on α. Due to the additional dependence on σ_L, the condition on n_{spectral} is more restrictive than that on n_{EM}.

The result of Balakrishnan et al. (2016) provides conditions (e.g., gradient stability condition and certain sample deviation condition) under which the EM method has geometric convergence rate. Assuming that these conditions are weaker than ours in Theorem 4, then instead of requiring the initialization condition $\|\widehat{C}_i - C_i\|_\infty \le \alpha$ for all $i \in [m]$ as in equation (10), we may have another constant $\alpha' > \alpha$, such that $\|C_i - \widehat{C}_i\|_\infty \le \alpha'$ ensures the linear convergence of EM. (It might be difficult to find the largest α' that makes the conditions of Balakrishnan et al. (2016) hold). The best possible value of α' is 1 since any entry of $\widehat{C}_i$ and C_i is bounded by 1. This means that we can potentially improve n_{spectral} by

1. An anonymous reviewer pointed out that if the system designer has the control over how to assign tasks to the workers, our result can be applied to sparse sampling regime via a grouping technique. In particular, one can partition the items into groups of small size and assign different workers to each groups of items so that the each subgroups of items and workers form a dense sub-matrix.

a factor of $1/\alpha$. Note that α is a constant that doesn't depend on σ_L. Thus, this potential improvement doesn't affect the lower bound's dependence on the condition number of the confusion matrix.

The result of Balakrishnan et al. (2016) provides conditions for EM to work but it doesn't show how to initialize EM to satisfy these conditions. Our paper uses the spectral method to do the initialization. As a consequence, the restriction on n_{spectral} is a premise for the spectral method to work. In order to improve the dependence on the condition number, one has to invent a better initialization scheme, which is out of the scope of this paper.

5.1.3 Discussion of simple majority voting estimator

It is also interesting to compare our algorithm with the majority voting estimator, where the true label is simply estimated by a majority vote among workers. Gao and Zhou (2014) show that if there are many spammers and few experts, the majority voting estimator gives almost a random guess. In contrast, our algorithm requires a sufficiently large $m\overline{D}$ to guarantee good performance. Since $m\overline{D}$ is the aggregated KL-divergence, a small number of experts suffices to ensure it is large enough.

6. One-Coin Model

In this section, we consider a simpler crowdsourcing model that is usually referred to as the "one-coin model." For the one-coin model, the confusion matrix C_i is parameterized by a single parameter p_i. More concretely, its entries are defined as

$$\mu_{ilc} = \begin{cases} p_i & \text{if } l = c, \\ \frac{1-p_i}{k-1} & \text{if } l \neq c. \end{cases} \tag{12}$$

In other words, the worker i uses a single coin flip to decide her assignment. No matter what the true label is, the worker has p_i probability to assign the correct label, and has $1 - p_i$ probability to randomly assign an incorrect label. For the one-coin model, it suffices to estimate p_i for every worker i and estimate y_j for every item j. Because of its simplicity, the one-coin model is easier to estimate and enjoys better convergence properties.

To simplify our presentation, we consider the case where $\pi_i \equiv 1$; noting that with proper normalization, the algorithm can be easily adapted to the case where $\pi_i < 1$. The statement of the algorithm relies on the following notation: For every two workers a and b, let the quantity N_{ab} be defined as

$$N_{ab} := \frac{k-1}{k}\left(\frac{\sum_{j=1}^{n}\mathbb{I}(z_{aj} = z_{bj})}{n} - \frac{1}{k}\right).$$

For every worker i, let workers a_i, b_i be defined as

$$(a_i, b_i) = \arg\max_{(a,b)}\{|N_{ab}| : \ a \neq b \neq i\}.$$

The algorithm contains two separate stages. First, we initialize $\widehat{p}_i$ by an estimator based on the method of moments. In contrast with the algorithm for the general model, the estimator

Algorithm 2: Estimating one-coin model

Input: integer k, observed labels $z_{ij} \in \mathbb{R}^k$ for $i \in [m]$ and $j \in [n]$.
Output: Estimator $\widehat{p}_i$ for $i \in [m]$ and $\widehat{y}_j$ for $j \in [n]$.

(1) Initialize $\widehat{p}_i$ by

$$\widehat{p}_i \leftarrow \frac{1}{k} + \text{sign}(N_{ia_1})\sqrt{\frac{N_{ia_i}N_{ib_i}}{N_{a_ib_i}}} \tag{13}$$

(2) If $\frac{1}{m}\sum_{i=1}^{m}\widehat{p}_i \geq \frac{1}{k}$ does not hold, then set $\widehat{p}_i \leftarrow \frac{2}{k} - \widehat{p}_i$ for all $i \in [m]$.

(3) Iteratively execute the following two steps for at least one round:

$$\widehat{q}_{jl} \propto \exp\Big(\sum_{i=1}^{m}\mathbb{I}(z_{ij} = e_l)\log(\widehat{p}_i) + \mathbb{I}(z_{ij} \neq e_l)\log\Big(\frac{1-\widehat{p}_i}{k-1}\Big)\Big) \qquad \text{for } j \in [n],\ l \in [k], \tag{14}$$

$$\widehat{p}_i \leftarrow \frac{1}{n}\sum_{j=1}^{n}\sum_{l=1}^{k}\widehat{q}_{jl}\mathbb{I}(z_{ij} = e_l) \qquad \text{for } i \in [m], \tag{15}$$

where update (14) normalizes $\widehat{q}_{jl}$, making $\sum_{l=1}^{k}\widehat{q}_{jl} = 1$ hold for all $j \in [n]$.

(4) Output $\{\widehat{p}_i\}$ and $\widehat{y}_j := \arg\max_{l\in[k]}\{\widehat{q}_{jl}\}$.

for the one-coin model doesn't need third-order moments. Instead, it only relies on pairwise statistics N_{ab}. Second, an EM algorithm is employed to iteratively maximize the objective function (6). See Algorithm 2 for a detailed description.

To theoretically characterize the performance of Algorithm 2, we need some additional notation. Let κ_i be the i-th largest element in $\{|p_i - 1/k|\}_{i=1}^{m}$. In addition, let $\overline{\kappa} := \frac{1}{m}\sum_{i=1}^{m}(p_i - 1/k)$ be the average gap between all accuracies and $1/k$. We assume that $\overline{\kappa}$ is strictly positive. We follow the definition of $\overline{D}$ in Eq. (9). The following theorem is proved in Appendix D.

Theorem 6 *Assume that $\rho \leq p_i \leq 1 - \rho$ holds for all $i \in [m]$. For any scalar $\delta > 0$, if the number of workers m and the number of items n satisfy*

$$m = \Omega\left(\frac{\log(1/\rho)\log(kn/\delta)}{\overline{D}}\right) \quad \text{and} \quad n = \Omega\left(\frac{\log(mk/\delta)}{\kappa_3^6\min\{\overline{\kappa}^2, \rho^2, (\rho\overline{D})^2\}}\right), \tag{16}$$

then, for $\widehat{p}$ and $\widehat{y}$ returned by Algorithm 2, with probability at least $1 - \delta$,

(a) $\widehat{y}_j = y_j$ holds for all $j \in [n]$;

(b) $|\widehat{p}_i - p_i| \leq 2\sqrt{\frac{3\log(6m/\delta)}{n}}$ holds for all $i \in [m]$.

	Opt-D&S	MV-D&S	Majority Voting	KOS	Ghosh-SVD	EigenRatio
$\pi = 0.2$	**7.64**	7.65	18.85	8.34	12.35	10.49
$\pi = 0.5$	**0.84**	**0.84**	7.97	1.04	4.52	4.52
$\pi = 1.0$	**0.01**	**0.01**	1.57	0.02	0.15	0.15

Table 1: Prediction error (%) on the synthetic dataset. The parameter π indicates the sparsity of data—it is the probability that the worker labels each task.

It is worth contrasting condition (11) with condition (16), namely the sufficient conditions for the general model and for the one-coin model. It turns out that the one-coin model requires much milder conditions on the number of items. In particular, κ_3 will be close to 1 if among all the workers there are three experts giving high-quality answers. As a consequence, the one-coin model is more robust than the general model. By contrasting the convergence rate of $\widehat{\mu}_{il}$ (by Theorem 4) and $\widehat{p}_i$ (by Theorem 6), the convergence rate of $\widehat{p}_i$ does not depend on $\{w_l\}_{l=1}^k$. This is additional evidence that the one-coin model enjoys a better convergence rate because of its simplicity.

7. Experiments

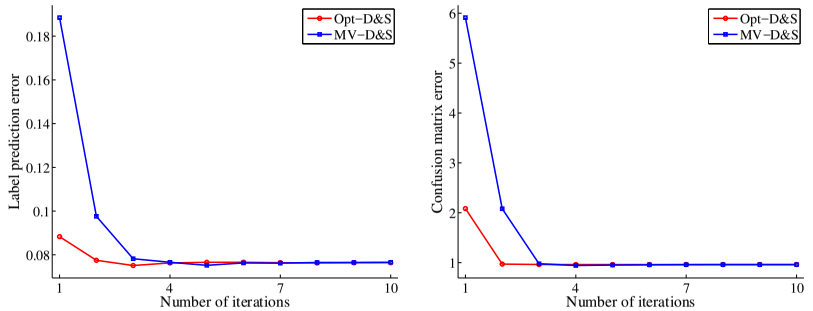
In this section, we report the results of empirical studies comparing the algorithm we propose in Section 4 (referred to as Opt-D&S) with a variety of other methods. We compare to the Dawid & Skene estimator initialized by majority voting (refereed to as MV-D&S), the pure majority voting estimator, the multi-class labeling algorithm proposed by Karger et al. (2013) (referred to as KOS), the SVD-based algorithm proposed by Ghosh et al. (2011) (referred to as Ghost-SVD) and the "Eigenvalues of Ratio" algorithm proposed by Dalvi et al. (2013) (referred to as EigenRatio). The evaluation is made on three synthetic datasets and five real datasets.

7.1 Synthetic data

For synthetic data, we generate $m = 100$ workers and $n = 1000$ binary tasks. The true label of each task is uniformly sampled from $\{1, 2\}$. For each worker, the 2-by-2 confusion matrix is generated as follow: the two diagonal entries are independently and uniformly sampled from the interval $[0.3, 0.9]$, then the non-diagonal entries are determined to make the confusion matrix columns sum to 1. To simulate a sparse dataset, we make each worker label a task with probability π. With the choice $\pi \in \{0.2, 0.5, 1.0\}$, we obtain three different datasets.

We execute every algorithm independently ten times and average the outcomes. For the Opt-D&S algorithm and the MV-D&S estimator, the estimation is outputted after ten EM iterates. For the group partitioning step involved in the Opt-D&S algorithm, the workers are randomly and evenly partitioned into three groups.

The main evaluation metric is the error of predicting the true label of items. The performance of various methods are reported in Table 1. On all sparsity levels, the Opt-D&S algorithm achieves the best accuracy, followed by the MV-D&S estimator. All other



(a) (b)

Figure 1: Comparing the convergence rate of the Opt-D&S algorithm and the MV-D&S estimator on synthetic dataset with $\pi = 0.2$: (a) convergence of the prediction error. (b) convergence of the squared error $\sum_{i=1}^m \|\widehat{C}_i - C_i\|_F^2$ for estimating confusion matrices.

methods are consistently worse. It is not surprising that the Opt-D&S algorithm and the MV-D&S estimator yield similar accuracies, since they optimize the same log-likelihood objective. It is also meaningful to look at the convergence speed of both methods, as they employ distinct initialization strategies. Figure 1 shows that the Opt-D&S algorithm converges faster than the MV-D&S estimator, both in estimating the true labels and in estimating confusion matrices. This can be explained by the general theoretical guarantee associated with Opt-D&S (recall Theorem 3).

The first and the second iteration of the Opt-D&S curve in Figure 1(b) correspond to the confusion matrix estimation error achieved by 1) the spectral method and 2) the spectral method with one iteration of EM, respectively. In Table 2, we provide a more detailed comparison, where the errors are compared with $\pi \in \{0.2, 0.5, 1.0\}$ and at different stages of the iteration. We found that for dense data ($\pi = 1$), the spectral method alone provides a reasonably good estimate on the confusion matrix, but its performance degenerates as the data becomes sparser. For both dense and sparse data, the spectral method with one iteration of EM achieves the nearly optimal error rate, which coincides with our theoretical prediction. In contrast, if the algorithm is initialized by majority voting, then one iteration of EM fails to provide a good estimate. Table 2 shows that its error rate is an order-of-magnitude higher than the spectral method initialized EM. This supports our concern that majority-voting initialization can be far from optimal—a principal motivation for this paper. Nevertheless, both initializations converge to the same error rate after ten iterations. Given the robustness of the EM method, deriving a sufficient and necessary condition under which the majority-voting initialization converges to an optimal solution remains an open problem.

	$\pi = 0.2$	$\pi = 0.5$	$\pi = 1.0$

Table 3: The summary of datasets used in the real data experiment.

7.2 Real data

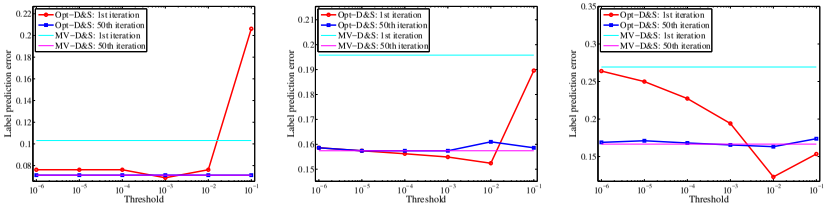
For real data experiments, we compare crowdsourcing algorithms on five datasets: three binary tasks and two multi-class tasks. Binary tasks include labeling bird species (Welinder et al., 2010) (Bird dataset), recognizing textual entailment (Snow et al., 2008) (RTE dataset) and assessing the quality of documents in TREC 2011 crowdsourcing track (Lease and Kazai, 2011) (TREC dataset). Multi-class tasks include labeling the bread of dogs from ImageNet (Deng et al., 2009) (Dog dataset) and judging the relevance of web search results (Zhou et al., 2012) (Web dataset). The statistics for the five datasets are summarized in Table 3. Since the Ghost-SVD algorithm and the EigenRatio algorithm work on binary tasks, they are evaluated on the Bird, RTE and TREC dataset. For the MV-D&S estimator and the Opt-D&S algorithm, we iterate their EM steps until convergence.

Since entries of the confusion matrix are positive, we find it helpful to incorporate this prior knowledge into the initialization stage of the Opt-D&S algorithm. In particular, when estimating the confusion matrix entries by equation (5), we add an extra checking step before the normalization, examining if the matrix components are greater than or equal to a small threshold Δ. For components that are smaller than Δ, they are reset to Δ. The default choice of the thresholding parameter is $\Delta = 10^{-6}$. Later, we will compare the Opt-D&S algorithm with respect to different choices of Δ. It is important to note that this modification doesn't change our theoretical result, since the thresholding step doesn't take effect if the initialization error is bounded by Theorem 3.

Table 4 summarizes the performance of each method. The MV-D&S estimator and the Opt-D&S algorithm consistently outperform the other methods in predicting the true label of items. The KOS algorithm, the Ghost-SVD algorithm and the EigenRatio algorithm yield

	Opt-D&S	MV-D&S	Majority Voting	KOS	Ghosh-SVD	EigenRatio
Bird	**10.09**	11.11	24.07	11.11	27.78	27.78
RTE	**7.12**	**7.12**	10.31	39.75	49.13	9.00
TREC	**29.80**	30.02	34.86	51.96	42.99	43.96
Dog	16.89	**16.66**	19.58	31.72	–	–
Web	15.86	**15.74**	26.93	42.93	–	–

Table 4: Error rate (%) in predicting the true labels on real data.



(a) RTE (b) Dog (c) Web

Figure 2: Comparing the MV-D&S estimator the Opt-D&S algorithm with different thresholding parameter Δ. The predict error is plotted after the 1st EM update and after convergence.

poorer performance, presumably due to the fact that they rely on idealized assumptions that are not met by the real data. In Figure 2, we compare the Opt-D&S algorithm with respect to different thresholding parameters $\Delta \in \{10^{-i}\}_{i=1}^{6}$. We plot results for three datasets (RET, Dog, Web), where the performance of the MV-D&S estimator is equal to or slightly better than that of Opt-D&S. The plot shows that the performance of the Opt-D&S algorithm is stable after convergence. But when only using the spectral method with just one E-step for the label prediction (i.e., the red curve Opt-D&S: 1st iteration in Figure 2), the error rates are more sensitive to the choice of Δ. A proper choice of Δ makes the Opt-D&S algorithm perform better than MV-D&S. The result suggests that a proper spectral initialization with just an E-step is good enough for the purposes of prediction. In practice, the best choice of Δ can be obtained by cross validation.

8. Conclusions

Under the generative model proposed by Dawid and Skene (1979), we propose an optimal algorithm for inferring true labels in the multi-class crowd labeling setting. Our approach utilizes the method of moments to construct an initial estimator for the EM algorithm. We proved that our method achieves the optimal rate with only one iteration of the EM algorithm.

To the best of our knowledge, this work provides the first instance of provable convergence for a latent variable model in which EM is initialized with the method of moments.

One-step EM initialized by the method of moments not only leads to better estimation error in terms of the dependence on the condition number of the second-order moment matrix but it also computationally more attractive than the standard one-step estimator obtained via a Newton-Raphson step. It is interesting to explore whether a properly initialized one-step EM algorithm can achieve the optimal rate for other latent variable models such as latent Dirichlet allocation or other mixed membership models.

Appendix A. Proof of Theorem 3

If $a \neq b$, it is easy to verify that $S_{ab} = C_a^\diamond W (C_b^\diamond)^T = \mathbb{E}[Z_{aj} \otimes Z_{bj}]$. Furthermore, we can upper bound the spectral norm of S_{ab}, namely

$$\|S_{ab}\|_{\text{op}} \leq \sum_{l=1}^{k} w_l \, \|\mu_{al}^\diamond\|_2 \, \|\mu_{bl}^\diamond\|_2 \leq \sum_{l=1}^{k} w_l \, \|\mu_{al}^\diamond\|_1 \, \|\mu_{bl}^\diamond\|_1 \leq 1.$$

For the same reason, it can be shown that $\|T_{abc}\|_{\text{op}} \leq 1$.

Our proof strategy is briefly described as follows: we upper bound the estimation error for computing empirical moments (2a)-(2d) in Lemma 7, and upper bound the estimation error for tensor decomposition in Lemma 8. Then, we combine both lemmas to upper bound the error of formula (5).

Lemma 7 *Given a permutation (a, b, c) of $(1, 2, 3)$, for any scalar $\epsilon \leq \sigma_L/2$, the second and the third moments $\widehat{M}_2$ and $\widehat{M}_3$ computed by equation (2c) and (2d) are bounded as*

$$\max\{\|\widehat{M}_2 - M_2\|_{\text{op}}, \|\widehat{M}_3 - M_3\|_{\text{op}}\} \leq 31\epsilon/\sigma_L^3 \tag{17}$$

with probability at least $1 - \delta$, where $\delta = 6\exp(-(\sqrt{n}\epsilon - 1)^2) + k\exp(-(\sqrt{n/k}\epsilon - 1)^2)$.

Lemma 8 *Suppose that (a, b, c) is permutation of $(1, 2, 3)$. For any scalar $\epsilon \leq \kappa/2$, if the empirical moments $\widehat{M}_2$ and $\widehat{M}_3$ satisfy*

$$\max\{\|\widehat{M}_2 - M_2\|_{\text{op}}, \|\widehat{M}_3 - M_3\|_{\text{op}}\} \leq \epsilon H \tag{18}$$

$$\text{for} \quad H := \min\left\{\frac{1}{2}, \frac{2\sigma_L^{3/2}}{15k(24\sigma_L^{-1} + 2\sqrt{2})}, \frac{\sigma_L^{3/2}}{4\sqrt{3/2}\sigma_L^{1/2} + 8k(24/\sigma_L + 2\sqrt{2})}\right\}$$

then the estimates $\widehat{C}_c^\diamond$ and $\widehat{W}$ are bounded as

$$\|\widehat{C}_c^\diamond - C_c^\diamond\|_{\text{op}} \leq \sqrt{k}\epsilon \qquad \text{and} \qquad \|\widehat{W} - W\|_{\text{op}} \leq \epsilon.$$

with probability at least $1 - \delta$, where δ is defined in Lemma 7.

Combining Lemma 7, Lemma 8, if we choose a scalar ϵ_1 satisfying

$$\epsilon_1 \leq \min\{\kappa/2, \pi_{\min} w_{\min} \sigma_L/(36k)\}, \tag{19}$$

then the estimates $\widehat{C}_g^\diamond$ (for $g = 1, 2, 3$) and $\widehat{W}$ satisfy

$$\|\widehat{C}_g^\diamond - C_g^\diamond\|_{\text{op}} \leq \sqrt{k}\epsilon_1 \qquad \text{and} \qquad \|\widehat{W} - W\|_{\text{op}} \leq \epsilon_1. \tag{20}$$

with probability at least $1 - 6\delta$, where

$$\delta = (6 + k)\exp\Big(-(\sqrt{n/k}\epsilon_1 H \sigma_L^3/31 - 1)^2\Big).$$

To be more precise, we obtain the bound (20) by plugging $\epsilon := \epsilon_1 H\sigma_L^3/31$ into Lemma 7, then plugging $\epsilon := \epsilon_1$ into Lemma 8. The high probability statement is obtained by applying a union bound.

Assuming inequality (20), for any $a \in \{1,2,3\}$, since $\|C_a^\diamond\|_{\text{op}} \le \sqrt{k}$, $\|\widehat{C}_a^\diamond - C_a^\diamond\|_{\text{op}} \le \sqrt{k}\epsilon_1$ and $\|W\|_{\text{op}} \le 1$, $\left\|\widehat{W} - W\right\|_{\text{op}} \le \epsilon_1$, Lemma 18 (the preconditions are satisfied by inequality (19)) implies that

$$\left\|\widehat{W}\widehat{C}_a^\diamond - WC_a^\diamond\right\|_{\text{op}} \le 4\sqrt{k}\epsilon_1,$$

Since condition (19) implies

$$\|\widehat{W}\widehat{C}_a^\diamond - WC_a^\diamond\|_{\text{op}} \le 4\sqrt{k}\epsilon_1 \le \sqrt{w_{\min}\sigma_L}/2 \le \sigma_k(WC_a^\diamond)/2$$

Lemma 17 yields that

$$\left\|\left(\widehat{W}\widehat{C}_a^\diamond\right)^{-1} - (WC_a^\diamond)^{-1}\right\|_{\text{op}} \le \frac{8\sqrt{k}\epsilon_1}{w_{\min}\sigma_L}.$$

By Lemma 19, for any $i \in [m]$, the concentration bound

$$\left\|\frac{1}{n}\sum_{j=1}^n z_{ij}Z_{aj}^T - \mathbb{E}[z_{ij}Z_{aj}^T]\right\|_{\text{op}} \le \epsilon_1$$

holds with probability at least $1 - m\exp(-(\sqrt{n}\epsilon_1 - 1)^2)$. Combining the above two inequalities with Proposition 2, then applying Lemma 18 with preconditions

$$\left\|(WC_a^\diamond)^{-1}\right\|_{\text{op}} \le \frac{1}{w_{\min}\sigma_L} \quad \text{and} \quad \left\|\mathbb{E}\left[z_{ij}Z_{aj}^T\right]\right\|_{\text{op}} \le 1,$$

we have

$$\Bigg\| \underbrace{\left(\frac{1}{n}\sum_{j=1}^n z_{ij}Z_{aj}^T\right)\left(\widehat{W}\widehat{C}_a^\diamond\right)^{-1}}_{\widehat{G}} - \pi_i C_i \Bigg\|_{\text{op}} \le \frac{18\sqrt{k}\epsilon_1}{w_{\min}\sigma_L}. \tag{21}$$

Let $\widehat{G} \in \mathbb{R}^{k\times k}$ be the first term on the left hand side of inequality (21). Each column of $\widehat{G}$, denoted by $\widehat{G}_l$, is an estimate of $\pi_i\mu_{il}$. The ℓ_2-norm estimation error is bounded by $\frac{18\sqrt{k}\epsilon_1}{w_{\min}\sigma_L}$. Hence, we have

$$\|\widehat{G}_l - \pi_i\mu_{il}\|_1 \le \sqrt{k}\|\widehat{G}_l - \pi_i\mu_{il}\|_2 \le \sqrt{k}\|\widehat{G} - \pi_i C_i\|_{\text{op}} \le \frac{18k\epsilon_1}{w_{\min}\sigma_L}, \tag{22}$$

and consequently, using the fact that $\sum_{c=1}^k \mu_{ilc} = 1$, we have

$$\begin{aligned}\left\|\text{normalize}(\widehat{G}_l) - \mu_{il}\right\|_2 &= \left\|\frac{\widehat{G}_l}{\pi_i + \sum_{c=1}^k\left(\widehat{G}_{lc} - \pi_i\mu_{ilc}\right)} - \mu_{il}\right\|_2 \\ &\le \frac{\|\widehat{G}_l - \pi_i\mu_{il}\|_2 + \|\widehat{G}_l - \pi_i\mu_{il}\|_1\|\mu_{il}\|_2}{\pi_i - \|\widehat{G}_l - \pi_i\mu_{il}\|_1} \\ &\le \frac{72k\epsilon_1}{\pi_{\min}w_{\min}\sigma_L}\end{aligned} \tag{23}$$

where the last step combines inequalities (21), (22) with the bound $\frac{18k\epsilon_1}{w_{\min}\sigma_L} \le \pi_i/2$ from condition (19), and uses the fact that $\|\mu_{il}\|_2 \le 1$.

Note that inequality (23) holds with probability at least

$$1 - (36+6k)\exp\Big(-(\sqrt{n/k}\epsilon_1 H\sigma_L^3/31 - 1)^2\Big) - m\exp(-(\sqrt{n}\epsilon_1 - 1)^2).$$

It can be verified that $H \ge \frac{\sigma_L^{5/2}}{230k}$. Thus, the above expression is lower bounded by

$$1 - (36+6k+m)\exp\Big(-\Big(\frac{\sqrt{n}\epsilon_1\sigma_L^{11/2}}{31\times 230\cdot k^{3/2}} - 1\Big)^2\Big),$$

If we represent this probability in the form of $1-\delta$, then

$$\epsilon_1 = \frac{31\times 230\cdot k^{3/2}}{\sqrt{n}\sigma_L^{11/2}}\left(1 + \sqrt{\log((36+6k+m)/\delta)}\right). \tag{24}$$

Combining condition (19) and inequality (23), we find that to make $\|\widehat{C} - C\|_\infty$ bounded by ϵ, it is sufficient to choose ϵ_1 such that

$$\epsilon_1 \le \min\left\{\frac{\epsilon\pi_{\min}w_{\min}\sigma_L}{72k}, \frac{\kappa}{2}, \frac{\pi_{\min}w_{\min}\sigma_L}{36k}\right\}$$

This condition can be further simplified to

$$\epsilon_1 \le \frac{\epsilon\pi_{\min}w_{\min}\sigma_L}{72k} \tag{25}$$

for small ϵ, that is $\epsilon \le \min\left\{\frac{36\kappa k}{\pi_{\min}w_{\min}\sigma_L}, 2\right\}$. According to equation (24), the condition (25) will be satisfied if

$$\sqrt{n} \ge \frac{72\times 31\times 230\cdot k^{5/2}}{\epsilon\pi_{\min}w_{\min}\sigma_L^{13/2}}\left(1 + \sqrt{\log((36+6k+m)/\delta)}\right).$$

Squaring both sides of the inequality completes the proof.

A.1 Proof of Lemma 7

Throughout the proof, we assume that the following concentration bound holds: for any distinct indices $(a', b') \in \{1, 2, 3\}$, we have

$$\left\| \frac{1}{n} \sum_{j=1}^{n} Z_{a'j} \otimes Z_{b'j} - \mathbb{E}[Z_{a'j} \otimes Z_{b'j}] \right\|_{\text{op}} \leq \epsilon. \tag{26}$$

By Lemma 19 and the union bound, this event happens with probability at least $1 - 6\exp(-(\sqrt{n}\epsilon - 1)^2)$. By the assumption that $\epsilon \leq \sigma_L/2 \leq \sigma_k(S_{ab})/2$ and Lemma 17, we have

$$\left\| \frac{1}{n} \sum_{j=1}^{n} Z_{cj} \otimes Z_{bj} - \mathbb{E}[Z_{cj} \otimes Z_{bj}] \right\|_{\text{op}} \leq \epsilon \quad \text{and}$$

$$\left\| \left(\frac{1}{n} \sum_{j=1}^{n} Z_{aj} \otimes Z_{bj} \right)^{-1} - (\mathbb{E}[Z_{aj} \otimes Z_{bj}])^{-1} \right\|_{\text{op}} \leq \frac{2\epsilon}{\sigma_k^2(S_{ab})}$$

Under the preconditions

$$\|\mathbb{E}[Z_{cj} \otimes Z_{bj}]\|_{\text{op}} \leq 1 \quad \text{and} \quad \left\|(\mathbb{E}[Z_{aj} \otimes Z_{bj}])^{-1}\right\|_{\text{op}} \leq \frac{1}{\sigma_k(S_{ab})},$$

Lemma 18 implies that

$$\begin{aligned} &\left\| \left(\frac{1}{n} \sum_{j=1}^{n} Z_{cj} \otimes Z_{bj} \right) \left(\frac{1}{n} \sum_{j=1}^{n} Z_{aj} \otimes Z_{bj} \right)^{-1} - \mathbb{E}[Z_{cj} \otimes Z_{bj}](\mathbb{E}[Z_{aj} \otimes Z_{bj}])^{-1} \right\|_{\text{op}} \\ &\quad \leq 2 \left(\frac{\epsilon}{\sigma_k(S_{ab})} + \frac{2\epsilon}{\sigma_k^2(S_{ab})} \right) \leq 6\epsilon/\sigma_L^2 \end{aligned} \tag{27}$$

and for the same reason, we have

$$\left\| \left(\frac{1}{n} \sum_{j=1}^{n} Z_{cj} \otimes Z_{aj} \right) \left(\frac{1}{n} \sum_{j=1}^{n} Z_{bj} \otimes Z_{aj} \right)^{-1} - \mathbb{E}[Z_{cj} \otimes Z_{aj}](\mathbb{E}[Z_{bj} \otimes Z_{aj}])^{-1} \right\|_{\text{op}} \leq 6\epsilon/\sigma_L^2 \tag{28}$$

Now, let matrices F_2 and F_3 be defined as

$$F_2 := \mathbb{E}[Z_{cj} \otimes Z_{bj}](\mathbb{E}[Z_{aj} \otimes Z_{bj}])^{-1},$$
$$F_3 := \mathbb{E}[Z_{cj} \otimes Z_{aj}](\mathbb{E}[Z_{bj} \otimes Z_{aj}])^{-1},$$

and let the matrix on the left hand side of inequalities (27) and (28) be denoted by Δ_2 and Δ_3, we have

$$\begin{aligned} \left\| \widehat{Z}'_{aj} \otimes \widehat{Z}'_{bj} - F_2 \left(Z_{aj} \otimes Z_{bj} \right) F_3^T \right\|_{\text{op}} &= \left\| \left(F_2 + \Delta_2 \right) \left(Z_{aj} \otimes Z_{bj} \right) \left(F_3 + \Delta_3 \right)^T - F_2 \left(Z_{aj} \otimes Z_{bj} \right) F_3^T \right\|_{\text{op}} \\ &\leq \|Z_{aj} \otimes Z_{bj}\|_{\text{op}} \left(\|\Delta_2\|_{\text{op}} \|F_3 + \Delta_2\|_{\text{op}} + \|F_2\|_{\text{op}} \|\Delta_3\|_{\text{op}} \right) \leq 30\epsilon \|Z_{aj} \otimes Z_{bj}\|_{\text{op}} / \sigma_L^3. \end{aligned}$$

where the last steps uses inequality (27), (28) and the fact that $\max\{\|F_2\|_{\text{op}}, \|F_3\|_{\text{op}}\} \leq 1/\sigma_L$ and

$$\|F_3 + \Delta_2\|_{\text{op}} \leq \|F_3\|_{\text{op}} + \|\Delta_2\|_{\text{op}} \leq 1/\sigma_L + 6\epsilon/\sigma_L^2 \leq 4/\sigma_L.$$

To upper bound the norm $\|Z_{aj} \otimes Z_{bj}\|_{\text{op}}$, notice that

$$\|Z_{aj} \otimes Z_{bj}\|_{\text{op}} \leq \|Z_{aj}\|_2 \|Z_{bj}\|_2 \leq \|Z_{aj}\|_1 \|Z_{bj}\|_1 \leq 1.$$

Consequently, we have

$$\left\| \widehat{Z}'_{aj} \otimes \widehat{Z}'_{bj} - F_2 \left(Z_{aj} \otimes Z_{bj} \right) F_3^T \right\|_{\text{op}} \leq 30\epsilon/\sigma_L^3. \tag{29}$$

For the rest of the proof, we use inequality (29) to bound $\widehat{M}_2$ and $\widehat{M}_3$. For the second moment, we have

$$\begin{aligned} \left\| \widehat{M}_2 - M_2 \right\|_{\text{op}} &\leq \frac{1}{n} \sum_{j=1}^{n} \left\| \widehat{Z}'_{aj} \otimes \widehat{Z}'_{bj} - F_2 \left(Z_{aj} \otimes Z_{bj} \right) F_3^T \right\|_{\text{op}} + \left\| F_2 \left(\frac{1}{n} \sum_{j=1}^{n} Z_{aj} \otimes Z_{bj} \right) F_3^T - M_2 \right\|_{\text{op}} \\ &\leq 30\epsilon/\sigma_L^3 + \left\| F_2 \left(\frac{1}{n} \sum_{j=1}^{n} Z_{aj} \otimes Z_{bj} - \mathbb{E}[Z_{aj} \otimes Z_{bj}] \right) F_3^T \right\|_{\text{op}} \\ &\leq 30\epsilon/\sigma_L^3 + \epsilon/\sigma_L^2 \leq 31\epsilon/\sigma_L^3. \end{aligned}$$

For the third moment, we have

$$\begin{aligned} \widehat{M}_3 - M_3 = &\frac{1}{n} \sum_{j=1}^{n} \left(\widehat{Z}'_{aj} \otimes \widehat{Z}'_{bj} - F_2 \left(Z_{aj} \otimes Z_{bj} \right) F_3^T \right) \otimes Z_{cj} \\ &+ \left(\frac{1}{n} \sum_{j=1}^{n} F_2 \left(Z_{aj} \otimes Z_{bj} \right) F_3^T \otimes Z_{cj} - \mathbb{E}\left[F_2 \left(Z_{aj} \otimes Z_{bj} \right) F_3^T \otimes Z_{cj} \right] \right). \end{aligned} \tag{30}$$

We examine the right hand side of equation (30). The first term is bounded as

$$\begin{aligned} \left\| \left(\widehat{Z}'_{aj} \otimes \widehat{Z}'_{bj} - F_2 \left(Z_{aj} \otimes Z_{bj} \right) F_3^T \right) \otimes Z_{cj} \right\|_{\text{op}} &\leq \left\| \widehat{Z}'_{aj} \otimes \widehat{Z}'_{bj} - F_2 \left(Z_{aj} \otimes Z_{bj} \right) F_3^T \right\|_{\text{op}} \|Z_{cj}\|_2 \\ &\leq 30\epsilon/\sigma_L^3. \end{aligned} \tag{31}$$

For the second term, since $\|F_2 Z_{aj}\|_2 \leq 1/\sigma_L$, $\|F_3 Z_{bj}\|_2 \leq 1/\sigma_L$ and $\|Z_{cj}\|_2 \leq 1$, Lemma 19 implies that

$$\left\| \frac{1}{n} \sum_{j=1}^{n} F_2 \left(Z_{aj} \otimes Z_{bj} \right) F_3^T \otimes Z_{cj} - \mathbb{E}\left[F_2 \left(Z_{aj} \otimes Z_{bj} \right) F_3^T \otimes Z_{cj} \right] \right\|_{\text{op}} \leq \epsilon/\sigma_L^2 \tag{32}$$

with probability at least $1 - k\exp(-(\sqrt{n/k}\epsilon - 1)^2)$. Combining inequalities (31) and (32), we have

$$\left\| \widehat{M}_3 - M_3 \right\|_{\text{op}} \leq 30\epsilon/\sigma_L^3 + \epsilon/\sigma_L^2 \leq 31\epsilon/\sigma_L^3.$$

Applying a union bound to all high-probability events completes the proof.

A.2 Proof of Lemma 8

Chaganty and Liang (2013) (Lemma 4) prove that when condition (18) holds, the tensor decomposition method of Algorithm 1 outputs $\{\widehat{\mu}_h^\diamond, \widehat{w}_h\}_{h=1}^k$, such that with probability at least $1-\delta$, a permutation π satisfies

$$\|\widehat{\mu}_h^\diamond - \mu_{c\pi(h)}^\diamond\|_2 \le \epsilon \qquad \text{and} \qquad \left\|\widehat{w}_h - w_{\pi(h)}\right\|_\infty \le \epsilon.$$

Note that the constant H in Lemma 8 is obtained by plugging upper bounds $\|M_2\|_{\text{op}} \le 1$ and $\|M_3\|_{\text{op}} \le 1$ into Lemma 4 of Chaganty and Liang (2013).

The $\pi(h)$-th component of $\mu_{c\pi(h)}^\diamond$ is greater than other components of $\mu_{c\pi(h)}^\diamond$, by a margin of κ. Assuming $\epsilon \le \kappa/2$, the greatest component of $\widehat{\mu}_h^\diamond$ is its $\pi(h)$-th component. Thus, Algorithm 1 is able to correctly estimate the $\pi(h)$-th column of $\widehat{C}_c^\diamond$ by the vector $\widehat{\mu}_h^\diamond$. Consequently, for every column of $\widehat{C}_c^\diamond$, the ℓ_2-norm error is bounded by ϵ. Thus, the spectral-norm error of $\widehat{C}_c^\diamond$ is bounded by $\sqrt{k}\epsilon$. Since W is a diagonal matrix and $\left\|\widehat{w}_h - w_{\pi(h)}\right\|_\infty \le \epsilon$, we have $\|\widehat{W} - W\|_{\text{op}} \le \epsilon$.

Appendix B. Proof of Theorem 4

We define three random events that will be shown holding with high probability:

$$\mathcal{E}_1: \ \sum_{i=1}^m \sum_{c=1}^k \mathbb{I}(z_{ij}=e_c)\log(\mu_{iy_jc}/\mu_{ilc}) \ge m\overline{D}/2 \qquad \text{for all } j\in[n] \text{ and } l\in[k]\backslash\{y_j\}.$$

$$\mathcal{E}_2: \ \left|\sum_{j=1}^n \mathbb{I}(y_j=l)\mathbb{I}(z_{ij}=e_c) - nw_l\pi_i\mu_{ilc}\right| \le nt_{ilc} \qquad \text{for all } (i,l,c)\in[m]\times[k]^2.$$

$$\mathcal{E}_3: \ \left|\sum_{j=1}^n \mathbb{I}(y_j=l)\mathbb{I}(z_{ij}\ne 0) - nw_l\pi_i\right| \le \frac{nt_{ilc}}{\mu_{ilc}} \qquad \text{for all } (i,l,c)\in[m]\times[k]^2. \tag{33}$$

where $t_{ilc} > 0$ are scalars to be specified later. We define $t_{\min}$ to be the smallest element among $\{t_{ilc}\}$. Assuming that $\mathcal{E}_1 \cap \mathcal{E}_2$ holds, the following lemma shows that performing updates (7) and (8) attains the desired level of accuracy. See Section B.1 for the proof.

Lemma 9 *Assume that $\mathcal{E}_1\cap\mathcal{E}_2$ holds. Also assume that $\mu_{ilc} \ge \rho$ for all $(i,l,c)\in[m]\times[k]^2$. If $\widehat{C}$ is initialized such that inequality (10) holds, and scalars t_{ilc} satisfy*

$$2\exp\Big(-m\overline{D}/4 + \log(k)\Big) \le t_{ilc} \le \pi_{\min}w_{\min}\min\left\{\frac{\rho}{8}, \frac{\rho\overline{D}}{64}\right\}. \tag{34}$$

Then by alternating updates (7) and (8) for at least one round, the estimates $\widehat{C}$ and $\widehat{q}$ are bounded as

$$|\widehat{\mu}_{ilc} - \mu_{ilc}| \le 4t_{ilc}/(\pi_i w_l). \qquad \text{for all } i\in[m],\ l\in[k],\ c\in[k].$$

$$\max_{l\in[k]}\{|\widehat{q}_{jl} - \mathbb{I}(y_j=l)|\} \le \exp\big(-m\overline{D}/4 + \log(k)\big) \qquad \text{for all } j\in[n].$$

Next, we characterize the probability that events $\mathcal{E}_1$, $\mathcal{E}_2$ and $\mathcal{E}_3$ hold. For measuring $\mathbb{P}[\mathcal{E}_1]$, we define auxiliary variable $s_i := \sum_{c=1}^k \mathbb{I}(z_{ij}=e_c)\log(\mu_{iy_jc}/\mu_{ilc})$. It is straightforward to see that $s_1, s_2, \ldots, s_m$ are mutually independent on any value of y_j, and each s_i belongs to the interval $[0, \log(1/\rho)]$. it is easy to verify that

$$\mathbb{E}\left[\sum_{i=1}^m s_i \Big| y_i\right] = \sum_{i=1}^m \pi_i \mathbb{D}_{\text{KL}}\left(\mu_{iy_j}, \mu_{il}\right).$$

We denote the right hand side of the above equation by D. The following lemma shows that the second moment of s_i is bounded by the KL-divergence between labels.

Lemma 10 *Conditioning on any value of y_j, we have*

$$\mathbb{E}[s_i^2|y_i] \le \frac{2\log(1/\rho)}{1-\rho}\pi_i\mathbb{D}_{\text{KL}}\left(\mu_{iy_j}, \mu_{il}\right).$$

According to Lemma 10, the aggregated second moment of s_i is bounded by

$$\mathbb{E}\left[\sum_{i=1}^m s_i^2 \Big| y_i\right] \le \frac{2\log(1/\rho)}{1-\rho}\sum_{i=1}^m \pi_i\mathbb{D}_{\text{KL}}\left(\mu_{iy_jc}, \mu_{ilc}\right) = \frac{2\log(1/\rho)}{1-\rho}D$$

Thus, applying the Bernstein inequality, we have

$$\mathbb{P}\Big[\sum_{i=1} s_i \ge D/2 | y_i\Big] \ge 1 - \exp\left(-\frac{\frac{1}{2}(D/2)^2}{\frac{2\log(1/\rho)}{1-\rho}D + \frac{1}{3}(2\log(1/\rho))(D/2)}\right),$$

Since $\rho \le 1/2$ and $D \ge m\overline{D}$, combining the above inequality with the union bound, we have

$$\mathbb{P}[\mathcal{E}_1] \ge 1 - kn\exp\left(-\frac{m\overline{D}}{33\log(1/\rho)}\right). \tag{35}$$

For measuring $\mathbb{P}[\mathcal{E}_2]$, we observe that $\sum_{j=1}^n \mathbb{I}(y_j=l)\mathbb{I}(z_{ij}=e_c)$ is the sum of n i.i.d. Bernoulli random variables with mean $p := \pi_i w_l \mu_{ilc}$. Since $t_{ilc} \le \pi_{\min}w_{\min}\rho/8 \le p$, applying the Chernoff bound implies

$$\mathbb{P}\left[\left|\sum_{j=1}^n \mathbb{I}(y_j=l)\mathbb{I}(z_{ij}=e_c) - np\right| \ge nt_{ilc}\right] \le 2\exp(-nt_{ilc}^2/(3p)) = 2\exp\left(-\frac{nt_{ilc}^2}{3\pi_i w_l\mu_{ilc}}\right),$$

For measuring $\mathbb{P}[\mathcal{E}_3]$, note that $\sum_{j=1}^n \mathbb{I}(y_j=l)\mathbb{I}(z_{ij}\ne e_c)$ is the sum of n i.i.d. Bernoulli random variables with mean $q := \pi_i w_l$. Since $\frac{t_{ilc}}{\mu_{ilc}} \le \frac{\pi_{\min}w_{\min}\rho/8}{\rho} \le q$, using a Chernoff bound yields

$$\mathbb{P}\left[\left|\sum_{j=1}^n \mathbb{I}(y_j=l)\mathbb{I}(z_{ij}\ne 0) - nq\right| \ge n\frac{t_{ilc}}{\mu_{ilc}}\right] \le 2\exp(-\frac{nt_{ilc}^2}{3q\mu_{ilc}^2}) \le 2\exp\left(-\frac{nt_{ilc}^2}{3\pi_i w_l\mu_{ilc}}\right),$$

Summarizing the probability bounds on $\mathcal{E}_1$, $\mathcal{E}_2$ and $\mathcal{E}_3$, we conclude that $\mathcal{E}_1\cap\mathcal{E}_2\cap\mathcal{E}_3$ holds with probability at least

$$1 - kn\exp\left(-\frac{m\overline{D}}{33\log(1/\rho)}\right) - \sum_{i=1}^m\sum_{l=1}^k 4\exp\left(-\frac{nt_{ilc}^2}{3\pi_i w_l\mu_{ilc}}\right). \tag{36}$$

Proof of Part (a) According to Lemma 9, for $\widehat{y}_j = y_j$ being true, it sufficient to have $\exp(-m\overline{D}/4 + \log(k)) < 1/2$, or equivalently

$$m > 4\log(2k)/\overline{D}. \tag{37}$$

To ensure that this bound holds with probability at least $1-\delta$, expression (36) needs to be lower bounded by δ. It is achieved if we have

$$m \geq \frac{33\log(1/\rho)\log(2kn/\delta)}{\overline{D}} \quad \text{and} \quad n \geq \frac{3\pi_i w_l \mu_{ilc}\log(8mk/\delta)}{t_{ilc}^2} \tag{38}$$

If we choose

$$t_{ilc} := \sqrt{\frac{3\pi_i w_l \mu_{ilc}\log(8mk/\delta)}{n}}. \tag{39}$$

then the second part of condition (38) is guaranteed. To ensure that t_{ilc} satisfies condition (34). We need to have

$$\sqrt{\frac{3\pi_i w_l \mu_{ilc}\log(8mk/\delta)}{n}} \geq 2\exp\Big(-m\overline{D}/4 + \log(k)\Big) \quad \text{and}$$
$$\sqrt{\frac{3\pi_i w_l \mu_{ilc}\log(8mk/\delta)}{n}} \leq \pi_{\min} w_{\min}\alpha/4.$$

The above two conditions require that m and n satisfy

$$m \geq \frac{4\log(2k\sqrt{n/(3\pi_{\min}w_{\min}\rho\log(8mk/\delta))})}{\overline{D}} \tag{40}$$
$$n \geq \frac{48\log(8mk/\delta)}{\pi_{\min}w_{\min}\alpha^2} \tag{41}$$

The four conditions (37), (38), (40) and (41) are simultaneously satisfied if we have

$$m \geq \frac{33\log(1/\rho)\log(2kn/\delta)}{\overline{D}} \quad \text{and}$$
$$n \geq \frac{48\log(8mk/\delta)}{\pi_{\min}w_{\min}\alpha^2}.$$

Under this setup, $\widehat{y}_j = y_j$ holds for all $j \in [n]$ with probability at least $1-\delta$.

Proof of Part (b) If t_{ilc} is set by equation (39), combining Lemma 9 with this assignment, we have

$$(\widehat{\mu}_{ilc} - \mu_{ilc})^2 \leq \frac{48\mu_{ilc}\log(8mk/\delta)}{\pi_i w_l n}$$

with probability at least $1-\delta$. Summing both sides of the inequality over $c = 1, 2, \ldots, k$ completes the proof.

B.1 Proof of Lemma 9

To prove Lemma 9, we study the consequences of update (7) and update (8). We prove two important lemmas, which show that both updates provide good estimates if they are properly initialized.

Lemma 11 *Assume that event $\mathcal{E}_1$ holds. If μ and its estimate $\widehat{\mu}$ satisfy*

$$\mu_{ilc} \geq \rho \quad \text{and} \quad |\widehat{\mu}_{ilc} - \mu_{ilc}| \leq \delta_1 \qquad \text{for all } i \in [m],\ l \in [k],\ c \in [k], \tag{42}$$

and $\widehat{q}$ is updated by formula (7), then $\widehat{q}$ is bounded as:

$$\max_{l\in[k]}\{|\widehat{q}_{jl} - \mathbb{I}(y_j = l)|\} \leq \exp\left(-m\left(\frac{\overline{D}}{2} - \frac{2\delta_1}{\rho - \delta_1}\right) + \log(k)\right) \qquad \text{for all } j \in [n]. \tag{43}$$

Proof

For an arbitrary index $l \neq y_j$, we consider the quantity

$$A_l := \sum_{i=1}^{m}\sum_{c=1}^{k}\mathbb{I}(z_{ij} = e_c)\log(\widehat{\mu}_{iy_jc}/\widehat{\mu}_{ilc})$$

By the assumption that $\mathcal{E}_1$ and inequality (42) holds, we obtain that

$$A_l = \sum_{i=1}^{m}\sum_{c=1}^{k}\mathbb{I}(z_{ij} = e_c)\log(\mu_{iy_jc}/\mu_{ilc}) + \sum_{i=1}^{m}\sum_{c=1}^{k}\mathbb{I}(z_{ij} = e_c)\left[\log\left(\frac{\widehat{\mu}_{iy_jc}}{\mu_{iy_jc}}\right) - \log\left(\frac{\widehat{\mu}_{ilc}}{\mu_{ilc}}\right)\right]$$
$$\geq \left(\sum_{i=1}^{m}\frac{\pi_i\mathbb{D}_{\mathrm{KL}}\left(\mu_{iy_j}, \mu_{il}\right)}{2}\right) - 2m\log\left(\frac{\rho}{\rho - \delta_1}\right) \geq m\left(\frac{\overline{D}}{2} - \frac{2\delta_1}{\rho - \delta_1}\right). \tag{44}$$

Thus, for every index $l \neq y_j$, combining formula (7) and inequality (44) implies that

$$\widehat{q}_{jl} \leq \frac{1}{\exp(A_l)} \leq \exp\left(-m\left(\frac{\overline{D}}{2} - \frac{2\delta_1}{\rho - \delta_1}\right)\right).$$

Consequently, we have

$$\widehat{q}_{jy_j} \geq 1 - \sum_{l\neq y_j}\widehat{q}_{jl} \geq 1 - k\exp\left(-m\left(\frac{\overline{D}}{2} - \frac{2\delta_1}{\rho - \delta_1}\right)\right).$$

Combining the above two inequalities completes the proof. ■

Lemma 12 *Assume that event $\mathcal{E}_2$ holds. If $\widehat{q}$ satisfies*

$$\max_{l\in[k]}\{|\widehat{q}_{jl} - \mathbb{I}(y_j = l)|\} \leq \delta_2 \qquad \text{for all } j \in [n], \tag{45}$$

and $\widehat{\mu}$ is updated by formula (8), then $\widehat{\mu}$ is bounded as:

$$|\widehat{\mu}_{ilc} - \mu_{ilc}| \leq \frac{2nt_{ilc} + 2n\delta_2}{(7/8)n\pi_i w_l - n\delta_2}. \qquad \text{for all } i \in [m],\ l \in [k],\ c \in [k]. \tag{46}$$

Proof By formula (8), we can write $\widehat{\mu}_{ilc} = A/B$, where

$$A := \sum_{j=1}^{n} \widehat{q}_{jl}\mathbb{I}(z_{ij} = e_c) \quad \text{and} \quad B := \sum_{c'=1}^{k}\sum_{j=1}^{n} \widehat{q}_{jl}\mathbb{I}(z_{ij} = e_{c'}) = \sum_{j=1}^{n} \widehat{q}_{jl}\mathbb{I}(z_{ij} \neq 0).$$

Combining this definition with the assumption that event $\mathcal{E}_2$ and inequality (45) hold, we find that

$$\begin{aligned}|A - n\pi_i w_l \mu_{ilc}| &\leq \left|\sum_{j=1}^{n} \mathbb{I}(q_{jl} = y_j)\mathbb{I}(z_{ij} = e_c) - n\pi_i w_l \mu_{ilc}\right| + \left|\sum_{j=1}^{n} \widehat{q}_{jl}\mathbb{I}(z_{ij} = e_c) - \sum_{j=1}^{n} \mathbb{I}(q_{jl} = y_j)\mathbb{I}(z_{ij} = e_c)\right| \\ &\leq nt_{ilc} + n\delta_2.\end{aligned}$$

Similarly, using the assumption that event $\mathcal{E}_3$ and inequality (45) hold, we have

$$\begin{aligned}|B - n\pi_i w_l| &\leq \left|\sum_{j=1}^{n} \mathbb{I}(q_{jl} = y_j)\mathbb{I}(z_{ij} \neq 0) - n\pi_i w_l\right| + \left|\sum_{j=1}^{n} \widehat{q}_{jl}\mathbb{I}(z_{ij} \neq 0) - \sum_{j=1}^{n} \mathbb{I}(q_{jl} = y_j)\mathbb{I}(z_{ij} \neq 0)\right| \\ &\leq \frac{nt_{ilc}}{\mu_{ilc}} + n\delta_2.\end{aligned}$$

Combining the bound for A and B, we obtain that

$$\begin{aligned}|\widehat{\mu}_{ilc} - \mu_{ilc}| &= \left|\frac{n\pi_i w_l \mu_{ilc} + (A - n\pi_i w_l \mu_{ilc})}{n\pi_i w_l + (B - n\pi_i w_l)} - \mu_{ilc}\right| = \left|\frac{(A - n\pi_i w_l \mu_{ilc}) - \mu_{ilc}(B - n\pi_i w_l)}{n\pi_i w_l + (B - n\pi_i w_l)}\right| \\ &\leq \frac{2nt_{ilc} + 2n\delta_2}{n\pi_i w_l - n(t_{ilc}/\mu_{ilc}) - n\delta_2}.\end{aligned}$$

Condition (34) implies

$$\frac{t_{ilc}}{\mu_{ilc}} \leq \frac{t_{ilc}}{\rho} \leq \frac{\pi_{\min} w_{\min}\rho}{8\rho} = \frac{\pi_{\min} w_{\min}}{8},$$

lower bounding the denominator. Plugging in this bound completes the proof. ■

To proceed with the proof, we assign specific values to δ_1 and δ_2. Let

$$\delta_1 := \min\left\{\frac{\rho}{2}, \frac{\rho\overline{D}}{16}\right\} \quad \text{and} \quad \delta_2 := t_{\min}/2. \tag{47}$$

We claim that at any step in the update, the preconditions (42) and (45) always hold.

We prove the claim by induction. Before the iteration begins, $\widehat{\mu}$ is initialized such that the accuracy bound (10) holds. Thus, condition (42) is satisfied at the beginning. We assume by induction that condition (42) is satisfied at time $1, 2, \ldots, \tau - 1$ and condition (45) is satisfied at time $2, 3, \ldots, \tau - 1$. At time τ, either update (7) or update (8) is performed. If update (7) is performed, then by the inductive hypothesis, condition (42) holds before the update. Thus, Lemma 11 implies that

$$\max_{l\in[k]}\{|\widehat{q}_{jl} - \mathbb{I}(y_j = l)|\} \leq \exp\left(-m\left(\frac{\overline{D}}{2} - \frac{2\delta_1}{\rho - \delta_1}\right) + \log(k)\right).$$

The assignment (47) implies $\frac{\overline{D}}{2} - \frac{2\delta_1}{\rho - \delta_1} \geq \frac{\overline{D}}{4}$, which yields that

$$\max_{l\in[k]}\{|\widehat{q}_{jl} - \mathbb{I}(y_j = l)|\} \leq \exp(-m\overline{D}/4 + \log(k)) \leq t_{\min}/2 = \delta_2,$$

where the last inequality follows from condition (34). It suggests that condition (45) holds after the update.

On the other hand, we assume that update (8) is performed at time τ. Since update (8) follows update (7), we have $\tau \geq 2$. By the inductive hypothesis, condition (45) holds before the update, so Lemma 12 implies

$$|\widehat{\mu}_{ilc} - \mu_{ilc}| \leq \frac{2nt_{ilc} + 2n\delta_2}{(7/8)n\pi_i w_l - n\delta_2} = \frac{2nt_{ilc} + nt_{\min}}{(7/8)n\pi_i w_l - nt_{\min}/2} \leq \frac{3nt_{ilc}}{(7/8)n\pi_i w_l - nt_{\min}/2},$$

where the last step follows since $t_{\min} \leq t_{ilc}$. Noticing $\rho \leq 1$, condition (34) implies that $t_{\min} \leq \pi_{\min} w_{\min}/8$. Thus, the right hand side of the above inequality is bounded by $4t_{ilc}/(\pi_i w_l)$. Using condition (34) again, we find

$$\frac{4t_{ilc}}{\pi_i w_l} \leq \frac{4t_{ilc}}{\pi_{\min} w_{\min}} \leq \min\left\{\frac{\rho}{2}, \frac{\rho\overline{D}}{16}\right\} = \delta_1,$$

which verifies that condition (42) holds after the update. This completes the induction.

Since preconditions (42) and (45) hold for any time $\tau \geq 2$, Lemma 11 and Lemma 12 implies that the concentration bounds (43) and (46) always hold. These two concentration bounds establish the lemma's conclusion.

B.2 Proof of Lemma 10

By the definition of s_i, we have

$$\mathbb{E}[s_i^2] = \pi_i \sum_{c=1}^{k} \mu_{iy_jc}(\log(\mu_{iy_jc}/\mu_{ilc}))^2 = \pi_i \sum_{c=1}^{k} \mu_{iy_jc}(\log(\mu_{ilc}/\mu_{iy_jc}))^2$$

We claim that for any $x \geq \rho$ and $\rho < 1$, the following inequality holds:

$$\log^2(x) \leq \frac{2\log(1/\rho)}{1 - \rho}(x - 1 - \log(x)). \tag{48}$$

We defer the proof of inequality (48), focusing on its consequence. Let $x := \mu_{ilc}/\mu_{iy_jc}$, then inequality (48) yields that

$$\mathbb{E}[s_i^2] \leq \frac{2\log(1/\rho)}{1 - \rho}\pi_i\left(\sum_{c=1}^{k} \mu_{ilc} - \mu_{iy_jc} - \mu_{iy_jc}\log(\mu_{ilc}/\mu_{iy_jc})\right) = \frac{2\log(1/\rho)}{1 - \rho}\pi_i \mathbb{D}_{\mathrm{KL}}\left(\mu_{iy_j}, \mu_{il}\right).$$

It remains to prove the claim (48). Let $f(x) := \log^2(x) - \frac{2\log(1/\rho)}{1-\rho}(x - 1 - \log(x))$. It suffices to show that $f(x) \leq 0$ for $x \geq \rho$. First, we have $f(1) = 0$ and

$$f'(x) = \frac{2(\log(x) - \frac{\log(1/\rho)}{1-\rho}(x - 1))}{x}.$$

For any $x > 1$, we have

$$\log(x) < x - 1 \leq \frac{\log(1/\rho)}{1-\rho}(x-1)$$

where the last inequality holds since $\log(1/\rho) \geq 1 - \rho$. Hence, we have $f'(x) < 0$ and consequently $f(x) < 0$ for $x > 1$.

For any $\rho \leq x < 1$, notice that $\log(x) - \frac{\log(1/\rho)}{1-\rho}(x-1)$ is a concave function of x, and equals zero at two points $x = 1$ and $x = \rho$. Thus, $f'(x) \geq 0$ at any point $x \in [\rho, 1)$, which implies $f(x) \leq 0$.

Appendix C. Proof of Theorem 5

In this section we prove Theorem 5. The proof separates into two parts.

C.1 Proof of Part (a)

Throughout the proof, probabilities are implicitly conditioning on $\{\pi_i\}$ and $\{\mu_{ilc}\}$. We assume that (l, l') are the pair of labels such that

$$\overline{D} = \frac{1}{m}\sum_{i=1}^{m} \pi_i \mathbb{D}_{\mathrm{KL}}\left(\mu_{il}, \mu_{il'}\right).$$

Let $\mathbb{Q}$ be a uniform distribution over the set $\{l, l'\}^n$. For any predictor $\widehat{y}$, we have

$$\begin{aligned}\max_{v\in[k]^n} \mathbb{E}\Big[\sum_{j=1}^{n} \mathbb{I}(\widehat{y}_j \neq y_j)\Big| y = v\Big] &\geq \sum_{v\in\{l,l'\}^n} \mathbb{Q}(v)\, \mathbb{E}\Big[\sum_{j=1}^{n} \mathbb{I}(\widehat{y}_j \neq y_j)\Big| y = v\Big] \\ &= \sum_{j=1}^{n}\sum_{v\in\{l,l'\}^n} \mathbb{Q}(v)\, \mathbb{E}\Big[\mathbb{I}(\widehat{y}_j \neq y_j)\Big| y = v\Big]. \end{aligned} \tag{49}$$

Thus, it is sufficient to lower bound the right hand side of inequality (49).

For the rest of the proof, we lower bound the quantity $\sum_{y\in\{l,l'\}^n} \mathbb{Q}(v)\, \mathbb{E}[\mathbb{I}(\widehat{y}_j \neq y_j)|y]$ for every item j. Let $Z := \{z_{ij} : i \in [m],\ j \in [n]\}$ be the set of all observations. We define two probability measures $\mathbb{P}_0$ and $\mathbb{P}_1$, such that $\mathbb{P}_0$ is the measure of Z conditioning on $y_j = l$, while $\mathbb{P}_1$ is the measure of Z conditioning on $y_j = l'$. By applying Le Cam's method (Yu, 1997) and Pinsker's inequality, we have

$$\begin{aligned}\sum_{v\in\{l,l'\}^n} \mathbb{Q}(v)\, \mathbb{E}\Big[\mathbb{I}(\widehat{y}_j \neq y_j)\Big| y = v\Big] &= \mathbb{Q}(y_j = l)\mathbb{P}_0(\widehat{y}_j \neq l) + \mathbb{Q}(y_j = l')\mathbb{P}_1(\widehat{y}_j \neq l') \\ &\geq \frac{1}{2} - \frac{1}{2}\|\mathbb{P}_0 - \mathbb{P}_1\|_{\mathrm{TV}} \\ &\geq \frac{1}{2} - \frac{1}{4}\sqrt{\mathbb{D}_{\mathrm{KL}}\left(\mathbb{P}_0, \mathbb{P}_1\right)}. \end{aligned} \tag{50}$$

The remaining arguments upper bound the KL-divergence between $\mathbb{P}_0$ and $\mathbb{P}_1$. Conditioning on y_j, the set of random variables $Z_j := \{z_{ij} : i \in [m]\}$ are independent of $Z\backslash Z_j$ for both

$\mathbb{P}_0$ and $\mathbb{P}_1$. Letting the distribution of X with respect to probability measure $\mathbb{P}$ be denoted by $\mathbb{P}(X)$, we have

$$\mathbb{D}_{\mathrm{KL}}\left(\mathbb{P}_0, \mathbb{P}_1\right) = \mathbb{D}_{\mathrm{KL}}\left(\mathbb{P}_0(Z_j), \mathbb{P}_1(Z_j)\right) + \mathbb{D}_{\mathrm{KL}}\left(\mathbb{P}_0(Z\backslash Z_j), \mathbb{P}_1(Z\backslash Z_j)\right) = \mathbb{D}_{\mathrm{KL}}\left(\mathbb{P}_0(Z_j), \mathbb{P}_1(Z_j)\right), \tag{51}$$

where the last step follows since $\mathbb{P}_0(Z\backslash Z_j) = \mathbb{P}_1(Z\backslash Z_j)$. Next, we observe that $z_{1j}, z_{2j}, \ldots, z_{mj}$ are mutually independent given y_j, which implies

$$\begin{aligned}\mathbb{D}_{\mathrm{KL}}\left(\mathbb{P}_0(Z_j), \mathbb{P}_1(Z_j)\right) &= \sum_{i=1}^{m} \mathbb{D}_{\mathrm{KL}}\left(\mathbb{P}_0(z_{ij}), \mathbb{P}_1(z_{ij})\right) \\ &= \sum_{i=1}^{m}\left[(1-\pi_i)\log\left(\frac{1-\pi_i}{1-\pi_i}\right) + \sum_{c=1}^{k}\pi_i\mu_{ilc}\log\left(\frac{\pi_i\mu_{ilc}}{\pi_i\mu_{il'c}}\right)\right] \\ &= \sum_{i=1}^{m}\sum_{c=1}^{k}\pi_i\mathbb{D}_{\mathrm{KL}}\left(\mu_{ilc}, \mu_{il'c}\right) = m\overline{D}. \end{aligned} \tag{52}$$

Combining inequality (50) with equations (51) and (52), we have

$$\sum_{v\in\{l,l'\}^n} \mathbb{Q}(v)\, \mathbb{E}\Big[\mathbb{I}(\widehat{y}_j \neq y_j)\Big| y = v\Big] \geq \frac{1}{2} - \frac{1}{4}\sqrt{m\overline{D}}.$$

Thus, if $m \leq 1/(4\overline{D})$, then the above inequality is lower bounded by $3/8$. Plugging this lower bound into inequality (49) completes the proof.

C.2 Proof of Part (b)

Throughout the proof, probabilities are implicitly conditioning on $\{\pi_i\}$ and $\{w_l\}$. We define two vectors

$$u_0 := \left(\frac{1}{2}, \frac{1}{2}, 0, \ldots, 0\right)^T \in \mathbb{R}^k \qquad \text{and} \qquad u_1 := \left(\frac{1}{2}+\delta, \frac{1}{2}-\delta, 0, \ldots, 0\right)^T \in \mathbb{R}^k,$$

where $\delta \leq 1/4$ is a scalar to be specified. Consider a m-by-k random matrix V whose entries are uniformly sampled from $\{0, 1\}$. We define a random tensor $u_V \in \mathbb{R}^{m\times k\times k}$, such that $(u_V)_{il} := u_{V_{il}}$ for all $(i, l) \in [m] \times [k]$. Givan an estimator $\widehat{\mu}$ and a pair of indices $(\bar{i}, \bar{l})$, we have

$$\sup_{\mu\in\mathbb{R}^{m\times k\times k}} \mathbb{E}\Big[\|\widehat{\mu}_{\bar{i}\bar{l}} - \mu_{\bar{i}\bar{l}}\|_2^2\Big] \geq \sum_{v\in[k]^n} \mathbb{P}(y = v)\left(\sum_V \mathbb{P}(V)\, \mathbb{E}\Big[\|\widehat{\mu}_{\bar{i}\bar{l}} - \mu_{\bar{i}\bar{l}}\|_2^2\Big|\mu = u_V, y = v\Big]\right). \tag{53}$$

For the rest of the proof, we lower bound the term $\sum_V \mathbb{P}(V)\, \mathbb{E}[\|\widehat{\mu}_{\bar{i}\bar{l}} - \mu_{\bar{i}\bar{l}}\|_2^2|\mu = u_V, y = v]$ for every $v \in [k]^n$. Let $\widehat{V}$ be an estimator defined as

$$\widehat{V} = \begin{cases} 0 & \text{if } \|\widehat{\mu}_{\bar{i}\bar{l}} - u_0\|_2 \leq \|\widehat{\mu}_{\bar{i}\bar{l}} - u_1\|_2. \\ 1 & \text{otherwise.} \end{cases}$$

If $\mu = u_V$, then $\widehat{V} \neq V_{\bar{i}\bar{l}} \Rightarrow \|\widehat{\mu}_{\bar{i}\bar{l}} - \mu_{\bar{i}\bar{l}}\|_2 \geq \frac{\sqrt{2}}{2}\delta$. Consequently, we have

$$\sum_V \mathbb{P}(V)\, \mathbb{E}[\|\widehat{\mu}_{\bar{i}\bar{l}} - \mu_{\bar{i}\bar{l}}\|_2^2 | \mu = u_V, y = v] \geq \frac{\delta^2}{2} \mathrm{P}[\widehat{V} \neq V_{\bar{i}\bar{l}} | y = v]. \tag{54}$$

Let $Z := \{z_{ij} : i \in [m],\ j \in [n]\}$ be the set of all observations. We define two probability measures $\mathbb{P}_0$ and $\mathbb{P}_1$, such that $\mathbb{P}_0$ is the measure of Z conditioning on $y = v$ and $\mu_{\bar{i}\bar{l}} = u_0$, and $\mathbb{P}_1$ is the measure of Z conditioning on $y = v$ and $\mu_{\bar{i}\bar{l}} = u_1$. For any other pair of indices $(i, l) \neq (\bar{i}, \bar{l})$, $\mu_{il} = u_{V_{il}}$ for both $\mathbb{P}_0$ and $\mathbb{P}_1$. By this definition, the distribution of Z conditioning on $y = v$ and $\mu = u_V$ is a mixture of distributions $\mathbb{Q} := \frac{1}{2}\mathbb{P}_0 + \frac{1}{2}\mathbb{P}_1$. By applying Le Cam's method (Yu, 1997) and Pinsker's inequality, we have

$$\begin{aligned} \mathrm{P}[\widehat{V} \neq V_{\bar{i}\bar{l}} | y = v] &\geq \frac{1}{2} - \frac{1}{2}\|\mathbb{P}_0 - \mathbb{P}_1\|_{\mathrm{TV}} \\ &\geq \frac{1}{2} - \frac{1}{4}\sqrt{\mathbb{D}_{\mathrm{KL}}\left(\mathbb{P}_0, \mathbb{P}_1\right)}. \end{aligned} \tag{55}$$

Conditioning on $y = v$, the set of random variables $Z_i := \{z_{ij} : j \in [n]\}$ are mutually independent for both $\mathbb{P}_0$ and $\mathbb{P}_1$. Letting the distribution of X with respect to probability measure $\mathbb{P}$ be denoted by $\mathbb{P}(X)$, we have

$$\mathbb{D}_{\mathrm{KL}}\left(\mathbb{P}_0, \mathbb{P}_1\right) = \sum_{i=1}^m \mathbb{D}_{\mathrm{KL}}\left(\mathbb{P}_0(Z_i), \mathbb{P}_1(Z_i)\right) = \mathbb{D}_{\mathrm{KL}}\left(\mathbb{P}_0(Z_{\bar{i}}), \mathbb{P}_1(Z_{\bar{i}})\right), \tag{56}$$

where the last step follows since $\mathbb{P}_0(Z_i) = \mathbb{P}_1(Z_i)$ for all $i \neq \bar{i}$. Next, we let $J := \{j : v_j = \bar{l}\}$ and define a set of random variables $Z_{iJ} := \{z_{ij} : j \in J\}$. It is straightforward to see that Z_{iJ} is independent of $Z_i \backslash Z_{iJ}$ for both $\mathbb{P}_0$ and $\mathbb{P}_1$. Hence, we have

$$\begin{aligned} \mathbb{D}_{\mathrm{KL}}\left(\mathbb{P}_0(Z_{\bar{i}}), \mathbb{P}_1(Z_{\bar{i}})\right) &= \mathbb{D}_{\mathrm{KL}}\left(\mathbb{P}_0(Z_{\bar{i}J}), \mathbb{P}_1(Z_{\bar{i}J})\right) + \mathbb{D}_{\mathrm{KL}}\left(\mathbb{P}_0(Z_{\bar{i}} \backslash Z_{\bar{i}J}), \mathbb{P}_1(Z_{\bar{i}} \backslash Z_{\bar{i}J})\right) \\ &= \mathbb{D}_{\mathrm{KL}}\left(\mathbb{P}_0(Z_{\bar{i}J}), \mathbb{P}_1(Z_{\bar{i}J})\right), \end{aligned} \tag{57}$$

where the last step follows since $\mathbb{P}_0(Z_{\bar{i}} \backslash Z_{\bar{i}J}) = \mathbb{P}_1(Z_{\bar{i}} \backslash Z_{\bar{i}J})$. Finally, since $\mu_{\bar{i}\bar{l}}$ is explicitly given in both $\mathbb{P}_0$ and $\mathbb{P}_1$, the random variables contained in $Z_{\bar{i}J}$ are mutually independent. Consequently, we have

$$\begin{aligned} \mathbb{D}_{\mathrm{KL}}\left(\mathbb{P}_0(Z_{\bar{i}J}), \mathbb{P}_1(Z_{\bar{i}J})\right) &= \sum_{j \in J} \mathbb{D}_{\mathrm{KL}}\left(\mathbb{P}_0(z_{\bar{i}j}), \mathbb{P}_1(z_{\bar{i}j})\right) = |J|\ \pi_{\bar{i}}\, \frac{1}{2} \log\left(\frac{1}{1 - 4\delta^2}\right) \\ &\leq \frac{5}{2}|J|\ \pi_{\bar{i}}\delta^2. \end{aligned} \tag{58}$$

Here, we have used the fact that $\log(1/(1 - 4x^2)) \leq 5x^2$ holds for any $x \in [0, 1/4]$.

Combining the lower bound (55) with upper bounds (56), (57) and (58), we find

$$\mathbb{P}[\widehat{V}_{il} \neq V_{il} | y = v] \geq \frac{3}{8}\mathbb{I}\left(\frac{5}{2}|J|\ \pi_{\bar{i}}\delta^2 \leq \frac{1}{4}\right).$$

Plugging the above lower bound into inequalities (53) and (54) implies that

$$\sup_{\mu \in \mathbb{R}^{m \times k \times k}} \mathbb{E}\left[\|\widehat{\mu}_{\bar{i}\bar{l}} - \mu_{\bar{i}\bar{l}}\|_2^2\right] \geq \frac{3\delta^2}{16}\mathbb{P}\left[|\{j : y_j = \bar{l}\}| \leq \frac{1}{10\pi_{\bar{i}}\delta^2}\right].$$

Note than $|\{j : y_j = \bar{l}\}| \sim \mathrm{Binomial}(n, w_{\bar{l}})$. Thus, if we set

$$\delta^2 := \min\left\{\frac{1}{16}, \frac{1}{10\pi_{\bar{i}}w_{\bar{l}}n}\right\},$$

then $\frac{1}{10\pi_{\bar{i}}\delta^2}$ is greater than or equal to the median of $|\{j : y_j = \bar{l}\}|$, and consequently,

$$\sup_{\mu \in \mathbb{R}^{m \times k \times k}} \mathbb{E}\left[\|\widehat{\mu}_{\bar{i}\bar{l}} - \mu_{\bar{i}\bar{l}}\|_2^2\right] \geq \min\left\{\frac{3}{512}, \frac{3}{320\pi_{\bar{i}}w_{\bar{l}}n}\right\},$$

which establishes the theorem.

Appendix D. Proof of Theorem 6

Our proof strategy is briefly described as follow: We first upper bound the error of Step (1)-(2) in Algorithm 2. This upper bound is presented as lemma 13. Then, we analyze the performance of Step (3), taking the guarantee obtained from the previous two steps.

Lemma 13 *Assume that $\kappa_3 > 0$. Let $\widehat{p}_i$ be initialized by Step (1)-(2). For any scalar $0 < t < \frac{\overline{\kappa}\kappa_3^3}{18}$, the upper bound*

$$\max_{i \in [m]}\{|\widehat{p}_i - p_i|\} \leq \frac{18t}{\kappa_3^3} \tag{59}$$

holds with probability at least $1 - m^2\exp(-nt^2/2)$.

The rest of the proof upper bounds the error of Step (3). The proof follows very similar steps as in the proof of Theorem 4. We first define two events that will be shown holding with high probability.

$$\mathcal{E}_1: \ \sum_{i=1}^m \sum_{c=1}^k \mathbb{I}(z_{ij} = e_c)\log(\mu_{iy_jc}/\mu_{ilc}) \geq m\overline{D}/2 \qquad \text{for all } j \in [n] \text{ and } l \in [k] \backslash \{y_j\}.$$

$$\mathcal{E}_2: \ \left|\sum_{j=1}^n \mathbb{I}(z_{ij} = e_{y_j}) - np_i\right| \leq nt_i \qquad \text{for all } i \in [m].$$

Lemma 14 *Assume that $\mathcal{E}_1 \cap \mathcal{E}_2$ holds. Also assume that $\rho \leq p_i \leq 1 - \rho$ for all $i \in [m]$. If $\widehat{p}$ is initialized such that*

$$|\widehat{p}_i - p_i| \leq \alpha := \min\left\{\frac{\overline{\kappa}}{2}, \frac{\rho}{2}, \frac{\rho\overline{D}}{16}\right\} \qquad \textit{for all } i \in [m] \tag{60}$$

and scalars t_i satisfy

$$\exp\Big(-m\overline{D}/4+\log(k)\Big)\le t_i\le \min\left\{\frac{\rho}{4},\frac{\rho\overline{D}}{32}\right\} \tag{61}$$

Then the estimates $\widehat{p}$ and $\widehat{q}$ obtained by alternating updates (14) and (15) satisfy:

$$|\widehat{p}_i-p_i|\le 2t_i. \qquad \text{for all } i\in[m].$$
$$\max_{l\in[k]}\{|\widehat{q}_{jl}-\mathbb{I}(y_j=l)|\}\le \exp\big(-m\overline{D}/4+\log(k)\big) \qquad \text{for all } j\in[n].$$

As in the proof of Theorem 4, we can lower bound the probability of the event $\mathcal{E}_1\cap\mathcal{E}_2$ by applying Bernstein's inequality and the Chernoff bound. In particular, the following bound holds:

$$\mathbb{P}[\mathcal{E}_1\cap\mathcal{E}_2]\ge 1-kn\exp\left(-\frac{m\overline{D}}{33\log(1/\rho)}\right)-\sum_{i=1}^{m}2\exp\left(-\frac{nt_i^2}{3p_i}\right). \tag{62}$$

The proof of inequality (62) precisely follows the proof of Theorem 4.

Proof of upper bounds (a) and (b) in Theorem 6 To apply Lemma 14, we need to ensure that condition (60) holds. If we assign $t:=\alpha\kappa_3^3/18$ in Lemma 13, then condition (60) holds with probability at least $1-m^2\exp(-n\alpha^2\kappa_3^6/648)$. To ensure that this event holds with probability at least $1-\delta/3$, we need to have

$$n\ge\frac{648\log(3m^2/\delta)}{\alpha^2\kappa_3^6}. \tag{63}$$

By Lemma 14, for $\widehat{y}_j=y_j$ being true, it suffices to have

$$m>4\log(2k)/\overline{D} \tag{64}$$

To ensure that $\mathcal{E}_1\cap\mathcal{E}_2$ holds with probability at least $1-2\delta/3$, expression (62) needs to be lower bounded by $1-2\delta/3$. It is achieved by

$$m\ge\frac{33\log(1/\rho)\log(3kn/\delta)}{\overline{D}}\quad\text{and}\quad n\ge\frac{3p_i\log(6m/\delta)}{t_i^2} \tag{65}$$

If we choose

$$t_i:=\sqrt{\frac{3\log(6m/\delta)}{n}}. \tag{66}$$

then the second part of condition (65) is guaranteed. To ensure that t_{ilc} satisfies condition (61). We need to have

$$\sqrt{\frac{3\log(6m/\delta)}{n}}\ge\exp\Big(-m\overline{D}/4+\log(k)\Big)\quad\text{and}$$
$$\sqrt{\frac{3\log(6m/\delta)}{n}}\le\alpha/2.$$

The above two conditions requires that m and n satisfy

$$m\ge\frac{4\log(k\sqrt{n/(3\log(6m/\delta))})}{\overline{D}} \tag{67}$$
$$n\ge\frac{12\log(6m/\delta)}{\alpha^2}. \tag{68}$$

The five conditions (63), (64), (65), (67) and (68) are simultaneously satisfied if we have

$$m\ge\frac{33\log(1/\rho)\log(3kn/\delta)}{\overline{D}}\quad\text{and}$$
$$n\ge\frac{648\log(3m^2/\delta)}{\alpha^2\kappa_3^6}.$$

Under this setup, $\widehat{y}_j=y_j$ holds for all $j\in[n]$ with probability at least $1-\delta$. Combining equation (66) with Lemma 14, the bound

$$|\widehat{p}_i-p_i|\le 2\sqrt{\frac{3\log(6m/\delta)}{n}}$$

holds with probability at least $1-\delta$.

D.1 Proof of Lemma 13

We claim that after initializing $\widehat{p}$ via formula (13), it satisfies

$$\min\left\{\max_{i\in[m]}\{|\widehat{p}_i-p_i|\},\max_{i\in[m]}\{|\widehat{p}_i-(2/k-p_i)|\}\right\}\le\frac{18t}{\kappa_3^3} \tag{69}$$

with probability at least $1-m^2\exp(-nt^2/2)$. Assuming inequality (69), it is straightforward to see that this bound is preserved by the algorithm's step (2). In addition, step (2) ensures that $\frac{1}{m}\sum_{i=1}^m\widehat{p}_i\ge\frac{1}{k}$, which implies

$$\begin{aligned}\max_{i\in[m]}\{|\widehat{p}_i-(2/k-p_i)|\}&\ge\left|\frac{1}{m}\sum_{i=1}^m\widehat{p}_i-\left(\frac{2}{k}-\frac{1}{m}\sum_{i=1}^m p_i\right)\right|\\&\ge\frac{1}{k}-\left(\frac{1}{k}-\overline{\kappa}\right)=\overline{\kappa}>\frac{18t}{\kappa_3^3}.\end{aligned} \tag{70}$$

Combining inequalities (69) and (70) establishes the lemma.

We turn to prove claim (69). For any worker a and worker b, it is obvious that $\mathbb{I}(z_{aj}=z_{bj})$ are independent random variables for $j=1,2,\ldots,n$. Since

$$\mathbb{E}[\mathbb{I}(z_{aj}=z_{bj})]=p_ap_b+(k-1)\,\frac{1-p_a}{k-1}\,\frac{1-p_b}{k-1}=\frac{k}{k-1}\,(p_a-1/k)(p_b-1/k)+\frac{1}{k}$$

and $\frac{k-1}{k}(\mathbb{I}(z_{aj}=z_{bj})-\frac{1}{k})$ belongs to the interval $[-1,1]$, applying Hoeffding's inequality implies that

$$\mathbb{P}(|N_{ab}-(p_a-1/k)(p_b-1/k)|\le t)\ge 1-\exp(-nt^2/2)\quad\text{for any } t>0.$$

By applying the union bound, the inequality

$$|N_{ab} - (p_a - 1/k)(p_b - 1/k)| \le t \tag{71}$$

holds for all $(a, b) \in [m]^2$ with probability at least $1 - m^2 \exp(-nt^2/2)$. For the rest of the proof, we assume that this high-probability event holds.

Given an arbitrary index i, we take indices (a_i, b_i) such that

$$(a_i, b_i) = \arg\max_{(a,b)} \{|N_{ab}| : a \neq b \neq i\}. \tag{72}$$

We consider another two indices (a^*, b^*) such that $|p_{a^*} - 1/k|$ and $|p_{b^*} - 1/k|$ are the two greatest elements in $\{|p_a - 1/k| : a \in [m]\backslash\{i\}\}$. Let $\beta_i := p_i - 1/k$ be a shorthand notation, then inequality (71) and equation (72) yields that

$$|\beta_{a_i}\beta_{b_i}| \ge |N_{a_ib_i}| - t \ge |N_{a^*b^*}| - t \ge |\beta_{a^*}\beta_{b^*}| - 2t \ge |\beta_{a^*}\beta_{b^*}|/2, \tag{73}$$

where the last step follows since $2t \le \kappa_3^2/2 \le |\beta_{a^*}\beta_{b^*}|/2$. Note that $|\beta_{b_i}| \le |\beta_{a^*}|$ (since $|\beta_{a^*}|$ is the largest entry by its definition), inequality (73) implies that $|\beta_{a_i}| \ge \frac{|\beta_{b^*}\beta_{a^*}|}{2|\beta_{b_i}|} \ge \frac{|\beta_{b^*}|}{2} \ge \kappa_3/2$. By the same argument, we obtain $|\beta_{b_i}| \ge |\beta_{b^*}|/2 \ge \kappa_3/2$. To upper bound the estimation error, we write $|N_{ia_i}|$, $|N_{ib_i}|$, $|N_{a_ib_i}|$ in the form of

$$\begin{aligned} |N_{ia_i}| &= |\beta_i\beta_{a_i}| + \delta_1 \\ |N_{ib_i}| &= |\beta_i\beta_{b_i}| + \delta_2 \\ |N_{a_ib_i}| &= |\beta_{a_i}\beta_{b_i}| + \delta_3, \end{aligned}$$

where $|\delta_1|, |\delta_2|, |\delta_3| \le t$. Firstly, notice that $N_{ia_i}, N_{ib_i} \in [-1, 1]$, thus,

$$\left|\sqrt{\frac{|N_{ia_i}N_{ib_i}|}{|N_{a_ib_i}|}} - \sqrt{\frac{|N_{ia_i}N_{ib_i}|}{|\beta_{a_i}\beta_{b_i}|}}\right| \le \left|\frac{1}{\sqrt{|N_{a_ib_i}|}} - \frac{1}{\sqrt{|\beta_{a_i}\beta_{b_i}|}}\right| \le \frac{t}{2(|\beta_{a_i}\beta_{b_i}| - t)^{3/2}} \le \frac{t}{(\kappa_3^2/4)^{3/2}}, \tag{74}$$

where the last step relies on the inequality $|\beta_{a_i}\beta_{b_i}| - t \ge \kappa_3^2/4$ obtained by inequality (73). Secondly, we upper bound the difference between $\sqrt{|N_{ia_i}N_{ib_i}|}$ and $\sqrt{|\beta_i^2\beta_{a_i}\beta_{b_i}|}$. If $|\beta_i| \le t$, using the fact that $|\beta_{a_i}|, |\beta_{b_i}| \le 1$, we have

$$\left|\sqrt{|N_{ia_i}N_{ib_i}|} - \sqrt{|\beta_i^2\beta_{a_i}\beta_{b_i}|}\right| \le \sqrt{|N_{ia_i}N_{ib_i}|} + \sqrt{|\beta_i^2\beta_{a_i}\beta_{b_i}|} \le \sqrt{4t^2} + \sqrt{t^2} \le 3t.$$

If $|\beta_i| > t$, using the fact that $|\beta_{a_i}|, |\beta_{b_i}| \in [\kappa_3/2, 1]$ and $|\beta_{a_i}\beta_{b_i}| \ge \kappa_3^2/2$, we have

$$\begin{aligned} \left|\sqrt{|N_{ia_i}N_{ib_i}|} - \sqrt{|\beta_i^2\beta_{a_i}\beta_{b_i}|}\right| &\le \frac{|\beta_i\beta_{b_i}\delta_1| + |\beta_i\beta_{a_i}\delta_2| + |\delta_1\delta_2|}{\sqrt{|\beta_i^2\beta_{a_i}\beta_{b_i}|}} \\ &\le \frac{|\delta_1|}{\sqrt{|\beta_{a_i}/\beta_{b_i}|}} + \frac{|\delta_2|}{\sqrt{|\beta_{b_i}/\beta_{a_i}|}} + \frac{|\delta_1\delta_2|}{t\sqrt{|\beta_{a_i}\beta_{b_i}|}} \\ &\le 3\sqrt{2}t/\kappa_3. \end{aligned}$$

Combining the above two upper bounds implies

$$\left|\sqrt{\frac{|N_{ia_i}N_{ib_i}|}{|\beta_{a_i}\beta_{b_i}|}} - \sqrt{\frac{|\beta_i^2\beta_{a_i}\beta_{b_i}|}{|\beta_{a_i}\beta_{b_i}|}}\right| = \frac{\left|\sqrt{|N_{ia_i}N_{ib_i}|} - \sqrt{|\beta_i^2\beta_{a_i}\beta_{b_i}|}\right|}{\sqrt{|\beta_{a_i}\beta_{b_i}|}} \le \frac{6t}{\kappa_3^2}. \tag{75}$$

Combining inequalities (74) and (75), we obtain

$$\left|\sqrt{\frac{|N_{ia_i}N_{ib_i}|}{|N_{a_ib_i}|}} - |\beta_i|\right| \le \frac{14t}{\kappa_3^3}. \tag{76}$$

Finally, we turn to analyzing the sign of N_{ia_1}. According to inequality (71), we have

$$N_{ia_1} = \beta_i\beta_{a_1} + \delta_4,$$

where $|\delta_4| \le t$. Following the same argument for β_{a_i} and β_{b_i}, it was shown that $|\beta_{a_1}| \ge \kappa_3/2$. We combine inequality (76) with a case study of $\mathrm{sign}(N_{ia_1})$ to complete the proof. Let

$$\widehat{p}_i := \frac{1}{k} + \mathrm{sign}(N_{ia_1})\sqrt{\frac{|N_{ia_i}N_{ib_i}|}{|N_{a_ib_i}|}}.$$

If $\mathrm{sign}(N_{ia_1}) \neq \mathrm{sign}(\beta_i\beta_{a_1})$, then $|\beta_i\beta_{a_1}| \le |\delta_4| \le t$. Thus, $|\beta_i| \le t/|\beta_{a_i}| \le 2t/\kappa_3$, and consequently,

$$\begin{aligned} \max\{|\widehat{p}_i - p_i|, |\widehat{p}_i - (2/k - p_i)|\} &\le \left|\sqrt{\frac{|N_{ia_i}N_{ib_i}|}{|N_{a_ib_i}|}} + |p_i - 1/k|\right| \\ &\le \left|\sqrt{\frac{|N_{ia_i}N_{ib_i}|}{|N_{a_ib_i}|}} - |p_i - 1/k|\right| + 2|p_i - 1/k| \le \frac{18t}{\kappa_3^3} \end{aligned} \tag{77}$$

Otherwise, we have $\mathrm{sign}(N_{ia_1}) = \mathrm{sign}(\beta_i\beta_{a_1})$ and consequently $\mathrm{sign}(\beta_i) = \mathrm{sign}(N_{ia_1})\mathrm{sign}(\beta_{a_1})$. If $\mathrm{sign}(\beta_{a_1}) = 1$, then $\mathrm{sign}(\beta_i) = \mathrm{sign}(N_{ia_1})$, which yields that

$$|\widehat{p}_i - p_i| = \left|\mathrm{sign}(N_{ia_1})\sqrt{\frac{|N_{ia_i}N_{ib_i}|}{|N_{a_ib_i}|}} - \mathrm{sign}(\beta_i)|\beta_i|\right| \le \frac{14t}{\kappa_3^3}. \tag{78}$$

If $\mathrm{sign}(\beta_{a_1}) = -1$, then $\mathrm{sign}(\beta_i) = -\mathrm{sign}(N_{ia_1})$, which yields that

$$|\widehat{p}_i - (2/k - p_i)| = \left|\mathrm{sign}(N_{ia_1})\sqrt{\frac{|N_{ia_i}N_{ib_i}|}{|N_{a_ib_i}|}} + \mathrm{sign}(\beta_i)|\beta_i|\right| \le \frac{14t}{\kappa_3^3}. \tag{79}$$

Combining inequalities (77), (78) and (79), we find that

$$\min\left\{\max_{i\in[m]}\{|\widehat{p}_i - p_i|\}, \max_{i\in[m]}\{|\widehat{p}_i - (2/k - p_i)|\}\right\} \le \frac{18t}{\kappa_3^3}.$$

which establishes claim (69).

D.2 Proof of Lemma 14

The proof follows the argument in the proof of Lemma 9. We present two lemmas upper bounding the error of update (14) and update (15), assuming proper initialization.

Lemma 15 *Assume that event $\mathcal{E}_1$ holds. If p and its estimate $\widehat{p}$ satisfies*

$$\rho \le p_i \le 1-\rho \quad \text{and} \quad |\widehat{p}_i - p_i| \le \delta_1 \qquad \text{for all } i \in [m], \tag{80}$$

and $\widehat{q}$ is updated by formula (14), then $\widehat{q}$ is bounded as:

$$\max_{l\in[k]}\{|\widehat{q}_{jl} - \mathbb{I}(y_j = l)|\} \le \exp\left(-m\left(\frac{\overline{D}}{2} - \frac{2\delta_1}{\rho - \delta_1}\right) + \log(k)\right) \qquad \text{for all } j \in [n]. \tag{81}$$

Proof Following the proof of Lemma 11, the lemma is established since both $|\log(\widehat{p}_i/p_i)|$ and $|\log((1-\widehat{p}_i)/(1-p_i))|$ are bounded by $\log(\rho/(\rho-\delta_1))$. ■

Lemma 16 *Assume that event $\mathcal{E}_2$ holds. If $\widehat{q}$ satisfies*

$$\max_{l\in[k]}\{|\widehat{q}_{jl} - \mathbb{I}(y_j = l)|\} \le \delta_2 \qquad \text{for all } j \in [n], \tag{82}$$

and $\widehat{p}$ is updated by formula (15), then $\widehat{p}$ is bounded as:

$$|\widehat{p}_i - p_i| \le t_i + \delta_2. \qquad \text{for all } i \in [m]. \tag{83}$$

Proof By formula (15), we have

$$\widehat{p}_i - p_i = \frac{1}{n}\left(\sum_{j=1}^{n}\mathbb{I}(z_{ij} = e_{y_i}) - np_i\right) + \frac{1}{n}\sum_{j=1}^{n}\sum_{l=1}^{k}(\widehat{q}_{il} - \mathbb{I}(y_j = l))\mathbb{I}(z_{ij} = e_l).$$

Combining inequality (82) with the inequality implied by event $\mathcal{E}_2$ completes the proof. ■

Following the steps in the proof of Lemma 9, we assign specific values to δ_1 and δ_2. Let

$$\delta_1 := \min\left\{\frac{\rho}{2}, \frac{\rho\overline{D}}{16}\right\} \quad \text{and} \quad \delta_2 := \min_{i\in[m]}\{t_i\}.$$

By the same inductive argument for proving Lemma 9, we can show that the upper bounds (81) and (83) always hold after the first iteration. Plugging the assignments of δ_1 and δ_2 into upper bounds (81) and (83) completes the proof.

Appendix E. Basic Lemmas

In this section, we prove some standard lemmas that we use for proving technical results.

Lemma 17 (Matrix Inversion) *Let $A, E \in \mathbb{R}^{k\times k}$ be given, where A is invertible and E satisfies that $\|E\|_{\text{op}} \le \sigma_k(A)/2$. Then*

$$\|(A+E)^{-1} - A^{-1}\|_{\text{op}} \le \frac{2\|E\|_{\text{op}}}{\sigma_k^2(A)}.$$

Proof A little bit of algebra reveals that

$$(A+E)^{-1} - A^{-1} = (A+E)^{-1}EA^{-1}.$$

Thus, we have

$$\|(A+E)^{-1} - A^{-1}\|_{\text{op}} \le \frac{\|E\|_{\text{op}}}{\sigma_k(A)\sigma_k(A+E)}.$$

We can lower bound the eigenvalues of $A+E$ by $\sigma_k(A)$ and $\|E\|_{\text{op}}$. More concretely, since

$$\|(A+E)\theta\|_2 \ge \|A\theta\|_2 - \|E\theta\|_2 \ge \sigma_k(A) - \|E\|_{\text{op}}$$

holds for any $\|\theta\|_2 = 1$, we have $\sigma_k(A+E) \ge \sigma_k(A) - \|E\|_{\text{op}}$. By the assumption that $\|E\|_{\text{op}} \le \sigma_k(A)/2$, we have $\sigma_k(A+E) \ge \sigma_k(A)/2$. Then the desired bound follows. ■

Lemma 18 (Matrix Multiplication) *Let $A_i, E_i \in \mathbb{R}^{k\times k}$ be given for $i = 1, \ldots, n$, where the matrix A_i and the perturbation matrix E_i satisfy $\|A_i\|_{\text{op}} \le K_i$, $\|E_i\|_{\text{op}} \le K_i$. Then*

$$\left\|\prod_{i=1}^{n}(A_i + E_i) - \prod_{i=1}^{n}A_i\right\|_{\text{op}} \le 2^{n-1}\left(\sum_{i=1}^{n}\frac{\|E_i\|_{\text{op}}}{K_i}\right)\prod_{i=1}^{n}K_i.$$

Proof By the triangle inequality, we have

$$\begin{aligned}
\left\|\prod_{i=1}^{n}(A_i + E_i) - \prod_{i=1}^{n}A_i\right\|_{\text{op}} &= \left\|\sum_{i=1}^{n}\left(\prod_{j=1}^{i-1}A_j\right)\left(\prod_{k=i+1}^{n}(A_k + E_k)\right)E_i\right\|_{\text{op}} \\
&\le \sum_{i=1}^{n}\|E_i\|_{\text{op}}\left(\prod_{j=1}^{i-1}\|A_j\|_{\text{op}}\right)\left(\prod_{k=i+1}^{n}\|A_k + E_k\|_{\text{op}}\right) \\
&\le \sum_{i=1}^{n}2^{n-i}\frac{\|E_i\|_{\text{op}}}{K_i}\prod_{i=1}^{n}K_i \\
&= 2^{n-1}\left(\sum_{i=1}^{n}\frac{\|E_i\|_{\text{op}}}{K_i}\right)\prod_{i=1}^{n}K_i
\end{aligned}$$

which completes the proof. ■

Lemma 19 (Matrix and Tensor Concentration) *Let $\{X_j\}_{j=1}^n$, $\{Y_j\}_{j=1}^n$ and $\{Z_j\}_{j=1}^n$ be i.i.d. samples from some distribution over $\mathbb{R}^k$ with bounded support ($\|X\|_2 \le 1$, $\|Y\|_2 \le 1$ and $\|Z\|_2 \le 1$ with probability 1). Then with probability at least $1-\delta$,*

$$\left\| \frac{1}{n}\sum_{j=1}^n X_j \otimes Y_j - \mathbb{E}[X_1 \otimes Y_1] \right\|_F \le \frac{1+\sqrt{\log(1/\delta)}}{\sqrt{n}}. \tag{84}$$

$$\left\| \frac{1}{n}\sum_{j=1}^n X_j \otimes Y_j \otimes Z_j - \mathbb{E}[X_1 \otimes Y_1 \otimes Z_1] \right\|_F \le \frac{1+\sqrt{\log(k/\delta)}}{\sqrt{n/k}}. \tag{85}$$

Proof Inequality (84) is proved in Lemma D.1 of Anandkumar et al. (2015). To prove inequality (85), we note that for any tensor $T \in \mathbb{R}^{k\times k\times k}$, we can define k-by-k matrices $T_1, \ldots, T_k$ such that $(T_i)_{jk} := T_{ijk}$. As a result, we have $\|T\|_F^2 = \sum_{i=1}^k \|T_i\|_F^2$. If we set T to be the tensor on the left hand side of inequality (85), then

$$T_i = \frac{1}{n}\sum_{j=1}^n (Z_j^{(i)}\ X_j) \otimes Y_j - \mathbb{E}[(Z_j^{(i)}\ X_1) \otimes Y_1]$$

By applying the result of inequality (84), we find that with probability at least $1-k\delta'$, we have

$$\left\| \frac{1}{n}\sum_{j=1}^n X_j \otimes Y_j \otimes Z_j - \mathbb{E}[X_1 \otimes Y_1 \otimes Z_1] \right\|_F^2 \le k\left(\frac{1+\sqrt{\log(1/\delta')}}{\sqrt{n}}\right)^2.$$

Setting $\delta' = \delta/k$ completes the proof. ■

Abstract

The future predictive performance of a Bayesian model can be estimated using Bayesian cross-validation. In this article, we consider Gaussian latent variable models where the integration over the latent values is approximated using the Laplace method or expectation propagation (EP). We study the properties of several Bayesian leave-one-out (LOO) cross-validation approximations that in most cases can be computed with a small additional cost after forming the posterior approximation given the full data. Our main objective is to assess the *accuracy of the approximative LOO cross-validation estimators*. That is, for each method (Laplace and EP) we compare the approximate fast computation with the exact brute force LOO computation. Secondarily, we evaluate the accuracy of the Laplace and EP approximations themselves against a ground truth established through extensive Markov chain Monte Carlo simulation. Our empirical results show that the approach based upon a Gaussian approximation to the LOO marginal distribution (the so-called cavity distribution) gives the most accurate and reliable results among the fast methods.

Keywords: predictive performance, leave-one-out cross-validation, Gaussian latent variable model, Laplace approximation, expectation propagation

1. Introduction

Bayesian cross-validation can be used to assess predictive performance. Vehtari and Ojanen (2012) provide an extensive review of theory and methods in Bayesian predictive performance assessment including decision theoretical assumptions made in Bayesian cross-validation. Gelman et al. (2014) provide further details on theoretical properties of leave-one-out cross-validation and information criteria, and Vehtari et al. (2016) provide practical fast computation in the case of Monte Carlo posterior inference. In this article, we present the properties of several Bayesian leave-one-out (LOO) cross-validation approximations for *Gaussian latent variable models* (GLVM) with factorizing likelihoods. Integration over the latent variables is performed with either the Laplace method or expectation propagation (EP). We show that for these methods leave-one-out cross-validation can be computed accurately with zero or a negligible additional cost after forming the full data posterior approximation.

Global (Gaussian) and factorizing variational approximations for latent variable inference are not considered in this paper. They have the same order computational complexity as Laplace and EP but with a larger pre-factor on the dominating $\mathcal{O}(n^3)$ term, where n is the number of observations (Nickisch and Rasmussen, 2008). EP may be expected to be the most accurate method (e.g. Nickisch and Rasmussen, 2008; Vanhatalo and Vehtari, 2010; Jylänki et al., 2011; Riihimäki et al., 2013) and Laplace to have the smallest computational overhead. So EP and Laplace may be considered the methods of choice for accuracy and speed, respectively. We expect that our overall results and conclusions for Laplace and EP carry over to Gaussian variational. For non-GLVM models such as generalized linear and deep generative models, the (factorized) Gaussian variational approximations scale to large data sets (Challis and Barber, 2013; Ranganath et al., 2014; Kingma and Welling, 2014; Rezende et al., 2014). It is of interest to derive approximate LOO estimators for these models, but that is outside the scope of this paper.

We consider a prediction problem with an explanatory variable x and an outcome variable y. The same notation is used interchangeably for scalar and vector-valued quantities. The observed data are denoted by $D = \{(x_i, y_i)\}_{i=1}^n$ and future observations by $(\tilde{x}, \tilde{y})$. We focus on GLVMs, where the observation model $p(y_i|f_i, \phi)$ depends on a local latent value f_i and possibly on some global parameters ϕ, such as the scale of the measurement error process. Latent values $f = (f_1, \ldots, f_n)$ have a joint Gaussian prior $p(f|x, \theta)$ which depends on covariates x and hyperparameters θ (e.g., covariance function parameters for a Gaussian process). The posterior of the latent f is then

$$p(f|D, \theta, \phi) \propto p(f|x, \theta) \prod_{i=1}^{n} p(y_i|f_i, \phi). \tag{1}$$

As a specific example we use Gaussian process (GP) models (reviewed, e.g., by Rasmussen and Williams, 2006), but the methods are applicable also for other GLVMs which have the same factorizing form (e.g. Gaussian Markov random field models used in the R-INLA software (Lindgren and Rue, 2015)). Some of the presented methods are applicable more generally, requiring only a factorizing likelihood with terms $p(y_i|f_i, \phi)$ and a method to integrate over the marginal posteriors $p(f_i|D, \theta, \phi)$. The results presented in this paper can be generalized to the cases where a likelihood term depends upon more than one latent variable (e.g. Tolvanen et al., 2014) or the latent value prior is non-Gaussian (e.g. Seeger, 2008; Hernández-Lobato et al., 2008; Hernáandez-Lobato et al., 2010). For clarity we restrict our treatment to the case of one likelihood term with one latent value.

We are interested in assessing the predictive performance of our models to report this to application experts or to perform model selection. For simplicity, in this paper we use only the logarithmic score, but the methods can be also be used with application specific utilities such as classification error. Logarithmic score is the standard scoring rule in Bayesian cross-validation (see Geisser and Eddy (1979)) and it has desirable properties for scientific inference (Bernardo and Smith, 1994; Gneiting and Raftery, 2007).

The predictive distribution for a future observation $\tilde{y}$ given future covariate values $\tilde{x}$ is

$$p(\tilde{y}|\tilde{x}, D) = \int p(\tilde{y}|\tilde{f}, \phi)p(\tilde{f}|\tilde{x}, D, \theta)p(\phi, \theta|D)d\tilde{f}d\phi d\theta. \quad (2)$$

The expected predictive performance using the log score and unknown true distribution of the future observation $p_t(\tilde{x}, \tilde{y})$ is

$$\int p_t(\tilde{x}, \tilde{y}) \log p(\tilde{y}|\tilde{x}, D)d\tilde{x}d\tilde{y}. \quad (3)$$

This expectation can be approximated by re-using the observations and computing the leave-one-out Bayesian cross-validation estimate

$$\text{LOO} = \frac{1}{n}\sum_{i=1}^{n} \log p(y_i|x_i, D_{-i}), \quad (4)$$

where D_{-i} is all other observations except (x_i, y_i). Here we consider only cases with random $\tilde{x}$ from the same distribution as x. See Vehtari and Ojanen (2012) for discussion of fixed, shifted, deterministic, or constrained $\tilde{x}$.

In addition to estimating the expected log predictive density, it may be interesting to look at a single value, $\log p(y_i|x_i, D_{-i})$. These terms, also called conditional predictive ordinates (CPO_i), may reveal observations which are highly influential or not well explained by the model (see, e.g., Gelfand, 1996). The probability integral transform (PIT) values $F(y_i|x_i, D_{-i})$, where F is the predictive CDF, can be used to assess the calibration of the predictions (see, e.g., Gneiting et al., 2007).

The straightforward brute force implementation of leave-one-out cross-validation requires recomputing the posterior distribution n times. Often leave-one-out cross-validation is replaced with k-fold cross-validation requiring only k recomputations of the posterior, with k usually 10 or less. Although k-fold-CV is robust and would often be computationally feasible, there are several fast approximations for computing LOO with a negligible additional computational cost after forming the posterior with the full data.

Several studies have shown that the Laplace method and EP perform well (compared to the gold standard Markov chain Monte Carlo inference) for GLVMs with many log-concave likelihoods (e.g. Rue et al., 2009; Vanhatalo et al., 2010; Martins et al., 2013; Riihimäki and Vehtari, 2014). EP has also been shown to be close to Markov chain Monte Carlo inference for classification models (log-concave likelihood, but potentially highly skewed posterior) and non-log-concave likelihoods (e.g. Nickisch and Rasmussen, 2008; Vanhatalo and Vehtari, 2010; Jylänki et al., 2011; Cseke and Heskes, 2011; Riihimäki et al., 2013; Vanhatalo et al., 2013; Tolvanen et al., 2014). In this paper we also consider the accuracy of approximative LOO with standard Markov chain Monte Carlo inference for LOO as our benchmark.

In practical data analysis work, it is useful to start with fast approximations and step by step check whether a computationally more expensive approach can improve the predictive accuracy. We propose the following three step approach:

1. Find the MAP estimate $(\hat{\phi}, \hat{\theta})$ using the Laplace method to approximately integrate over the latent values f.

2. Using $(\hat{\phi}, \hat{\theta})$ obtained in the previous step, use EP to integrate over the latent values and check whether the predictive performance improves substantially compared to using the Laplace method (we may also re-estimate $\hat{\phi}$ and $\hat{\theta}$).

3. Integrate over ϕ and θ and check whether integration over the parameters improves predictive performance.

Details of the computations involved are given in Sections 2 and 3. Based on these steps we can continue with the model that has the best predictive performance or the one that makes predictions fastest, or both. Often we also need to re-estimate models when data are updated or additional covariates become available, and then again a fast and accurate posterior approximation is useful. To follow the above approach, we need accurate predictive performance estimates for the Laplace method and EP.

The main contributions of this paper are:

- A unified presentation and thorough empirical comparison of methods for approximate LOO for Gaussian latent variable models with both log-concave and non-log-concave likelihoods and MAP and hierarchical approaches for handling hyperparameter inference (Section 3).

- The main conclusion from the empirical investigation (Section 4) is the observed superior accuracy/complexity tradeoff of Gaussian latent cavity distribution based LOO estimators. Although there are more accurate non-Gaussian approximations of the marginal posteriors, their use does not translate into substantial improvements in terms of LOO cross-validation accuracy and also introduces considerable instability. Using the widely applicable information criterion (WAIC) in the computation does not provide any benefits.

- The Laplace Gaussian cavity distribution (LA-LOO) (Section 3.5), although mentioned by Cseke and Heskes (2011), has not been used previously for LOO estimation. LOO consistency of LA-LOO using linear response theory is proved (Appendix A).

- Truncated weights quadrature integration (Section 3.7) inspired by truncated importance sampling is a novel way to stabilize the quadrature used in some LOO computations.

2. Gaussian Latent Variable Models

In this section, we briefly review the notation and methods for Gaussian latent variable models used in the rest of the article. We focus on Gaussian processes (see, e.g., Rasmussen and Williams, 2006), but most of the discussion also holds for other factorizing GLVMs. We consider models with a Gaussian prior $p(f|x, \theta)$ on latent values $f = (f_1, \ldots, f_n)$ and factorizing likelihood

$$p(f|D, \theta, \phi) = \frac{1}{Z}\prod_{i=1}^{n} p(y_i|f_i, \phi)p(f|X, \theta), \quad (5)$$

where Z is a normalization factor and equal to the marginal likelihood $p(y|X,\theta,\phi) = \int \prod_{i=1}^{n} p(y_i|f_i,\phi)p(f|X,\theta)df$. For example, in the Gaussian process framework the multivariate Gaussian prior on latent values is $p(f|x,\theta) = \mathrm{N}(f|\mu_0, K)$, where μ_0 is the prior mean and K is a covariance matrix constructed by a covariance function $K_{i,j} = k(x_i, x_j; \theta)$, which characterizes the correlation between two points. In this paper, we assume that the prior mean μ_0 is zero, but the results generalize to nonzero prior means as well.

2.1 Gaussian Observation Model

With a Gaussian observation model,

$$p(y_i|f_i,\sigma^2) = \mathrm{N}(y_i|f_i,\sigma^2), \tag{6}$$

where $\phi = \sigma^2$ is the noise variance, the conditional posterior of the latent variables is a multivariate Gaussian

$$\begin{aligned} &p(f|D,\theta,\phi) = \mathrm{N}(f|\mu,\Sigma),\\ &\quad\text{where}\quad \mu = K(K+\sigma^2 I)^{-1}y\\ &\quad\text{and}\quad \Sigma = (K^{-1}+\sigma^{-2}I)^{-1} = K - K(K+\sigma^2 I)^{-1}K. \end{aligned} \tag{7}$$

The marginal posterior is simply $p(f_i|D,\theta,\sigma^2) = \mathrm{N}(\mu_i, \Sigma_{ii})$ and the marginal likelihood $p(y|X,\theta,\sigma^2)$ can be computed analytically using properties of the multivariate Gaussian (see, e.g., Rasmussen and Williams, 2006).

2.2 Non-Gaussian Observation Model

In the case of a non-Gaussian likelihood, the conditional posterior $p(f|D,\theta,\phi)$ needs to be approximated. In this paper, we focus on expectation propagation (EP) and the Laplace method (LA), which form a multivariate Gaussian approximation of the joint latent posterior

$$q(f|D,\theta,\phi) = \frac{1}{Z}p(f|X,\theta)\prod_{i=1}^{n}\tilde{t}_i(f_i), \tag{8}$$

where the $\tilde{t}_i$ are (unnormalized) Gaussian approximations of the likelihood contributions. We use q to denote approximative joint and marginal distributions in general, or the specific approximation used in each case can be inferred from the context.

2.3 Expectation Propagation

Expectation propagation (Opper and Winther, 2000; Minka, 2001) approximates independent non-Gaussian likelihood terms by unnormalized Gaussian form site approximations (aka pseudo-observations),

$$p(y_i|f_i) \simeq \tilde{t}_i(f_i|\tilde{Z}_i,\tilde{\mu}_i,\tilde{\Sigma}_i) = \tilde{Z}_i\,\mathrm{N}(f_i|\tilde{\mu}_i,\tilde{\Sigma}_i), \tag{9}$$

where $\tilde{Z}_i = \int p(y_i|f_i)\,\mathrm{N}(f_i|\tilde{\mu}_i,\tilde{\Sigma}_i)df_i$, and $\tilde{\mu}_i$ and $\tilde{\Sigma}_i$ are the parameters of the site approximations, or *site parameters*. The joint latent posterior approximation is then

$$\begin{aligned} p(f|D,\phi,\theta) &= \frac{1}{Z}p(f|X,\theta)\prod_i p(y_i|f_i,\phi)\\ &\approx \frac{1}{Z_{\mathrm{EP}}}p(f|X,\theta)\prod_i \tilde{t}_i(f_i) = q(f|D,\phi,\theta), \end{aligned} \tag{10}$$

where Z is the normalization constant or the marginal likelihood, Z_{EP} is the EP approximation to the marginal likelihood and $q(f|D)$ is a multivariate Gaussian posterior approximation.

EP updates the site approximations by iteratively improving accuracy of the marginals. To update the ith site approximation, it is first removed from the marginal approximation to form a cavity distribution,

$$q_{-i}(f_i) \propto q(f_i|D)/\tilde{t}_i(f_i), \tag{11}$$

where the marginal $q(f_i|D)$ is obtained analytically using properties of the multivariate Gaussian.

The cavity distribution is combined with the original likelihood term to form a more accurate marginal distribution called the tilted distribution:

$$q_{-i}(f_i)p(y_i|f_i,\phi). \tag{12}$$

Minimization of Kullback-Leibler divergence from the tilted distribution to the marginal approximation corresponds to matching the moments of the distributions. Hence for Gaussian approximation, the zeroth, first and second moments of this tilted distribution are computed, for example, using one-dimensional numerical integration. The site parameters are updated so that moments of the marginal approximation $q(f_i|D)$ match the moments of the tilted distribution $q_{-i}(f_i)p(y_i|f_i,\phi)$. The new $q(f)$ can be computed after a single site approximation has been updated (sequential EP) or after all the site approximations have been updated (parallel EP).

2.4 Laplace Approximation

The Laplace approximation is constructed from the second-order Taylor expansion of $\log p(f|y,\theta,\phi)$ around the mode $\hat{f}$, which gives a Gaussian approximation to the conditional posterior,

$$q(f|D,\theta,\phi) = \mathrm{N}(f|\hat{f},\hat{\Sigma}) \approx p(f|D,\theta,\phi), \tag{13}$$

where $\hat{\Sigma} = (K^{-1}+\tilde{\Sigma}^{-1})^{-1}$ is the inverse of the Hessian at the mode with $\tilde{\Sigma}$ being a diagonal matrix with elements (e.g., Rasmussen and Williams, 2006; Gelman et al., 2013),

$$\tilde{\Sigma}_i = -\frac{1}{\nabla_i\nabla_i \log p(y_i|f_i,\phi)|_{f_i=\hat{f}_i}}. \tag{14}$$

From this joint Gaussian approximation we can analytically compute an approximation of the marginal posterior $p(f_i|D,\theta,\phi)$ and the marginal likelihood $p(y|x,\theta,\phi)$. The Laplace approximation can also be written as

$$q(f|D,\theta,\phi) = \frac{1}{Z} p(f|X,\theta) \prod_{i=1}^{n} \tilde{t}_i(f_i), \tag{15}$$

where $\tilde{t}_i(f_i)$ are Gaussian terms $\mathrm{N}(f_i|\tilde{\mu}_i, \tilde{\Sigma}_i)$ with

$$\tilde{\mu}_i = \hat{f} + \tilde{\Sigma}_i \nabla_i \log p(y_i|f_i,\phi)|_{f_i=\hat{f}_i}. \tag{16}$$

2.5 Marginal Posterior Approximations

Many leave-one-out approximation methods require explicit computation of full posterior marginal approximations. We thus review alternative Gaussian and non-Gaussian approximations of the marginal posteriors $p(f_i|D,\theta,\phi)$ following the article by Cseke and Heskes (2011). The exact joint posterior can be written as (dropping θ, ϕ and D for brevity)

$$p(f) \propto q(f) \prod_i \epsilon_i(f_i) \quad \text{with} \quad \epsilon_i(f_i) = p(y_i|f_i,\phi)/\tilde{t}_i(f_i), \tag{17}$$

where $\epsilon_i(f_i)$ is the ratio of the exact likelihood and the site term approximating the likelihood. By integrating over the other latent variables, the marginal posterior can be written as

$$p(f_i) \propto q(f_i)\epsilon_i(f_i) \underbrace{\int q(f_{-i}|f_i) \prod_{j\neq i} \epsilon_j(f_j) df_{-i}}_{c_i(f_i)}, \tag{18}$$

where f_{-i} represents all other latent variables except f_i. Local methods use $\epsilon_i(f_i)$ which depends locally only on f_i. Global methods additionally use an approximation of $c_i(f_i)$ which depends globally on all latent variables. Next we briefly review different marginal posterior approximations of this exact marginal (see Table 1 for a summary).

2.5.1 Gaussian Approximations

The simplest approximation is to use the Gaussian marginals $q(f_i)$, which are easily obtained from the joint Gaussian obtained by the Laplace approximation or expectation propagation; we call these LA-G and EP-G. By denoting the mean and variance of the pseudo observations (defined by the site terms) by $\tilde{\mu}_i$ and $\tilde{\sigma}_i^2$ respectively, the joint approximation has the same form as in the Gaussian case:

$$\begin{aligned} &q(f|D,\theta,\phi) = \mathrm{N}(\mu,\Sigma) \\ &\quad \text{with} \quad \mu = \Sigma\tilde{\Sigma}^{-1}\tilde{\mu}, \quad \text{and} \quad \Sigma = (K^{-1} + \tilde{\Sigma}^{-1})^{-1}, \end{aligned} \tag{19}$$

where $\tilde{\Sigma}$ is diagonal matrix with $\tilde{\Sigma}_{ii} = \tilde{\sigma}^2$. Then the marginal is simply $q(f_i) = \mathrm{N}(\mu_i, \Sigma_{ii})$.

Method	Improvement	Explanation
LA-G	-	Gaussian marginal $q(f_i)$ from the joint distribution
LA-L	local	tilted distribution $q(f_i)\tilde{t}_i(f_i)^{-1}p(y_i\|f_i,\phi)$
LA-TK	global	$q(f_i)\tilde{t}_i(f_i)^{-1}p(y_i\|f_i,\phi)c_i(f_i)$, where $c_i(f_i)$ is approximated using the Laplace approximation
LA-CM/CM2/FACT	global	$q(f_i)\tilde{t}_i(f_i)^{-1}p(y_i\|f_i,\phi)c_i(f_i)$, where $c_i(f_i)$ is approximated using the Laplace approximation with simplifications
EP-G	-	Gaussian marginal $q(f_i)$ from the joint distribution
EP-L	local	tilted distribution $q_{-i}(f_i)p(y_i\|f_i,\phi)$, where $q_{-i}(f_i)$ is obtained as a part of EP method
EP-FULL	global	$q_{-i}(f_i)p(y_i\|f_i,\phi)c_i(f_i)$, where $c_i(f_i)$ is approximated using EP
EP-1STEP/FACT	global	$q_{-i}(f_i)p(y_i\|f_i,\phi)c_i(f_i)$, where $c_i(f_i)$ is approximated using EP with simplifications

Table 1: Summary of the methods for computing approximate marginal posteriors. In global methods $c_i(f_i) = \int q(f_{-i}|f_i)\prod_{j\neq i}\epsilon_j(f_j)df_{-i}$ is a multivariate integral and $\epsilon_j(f_j) = p(y_j|f_j,\phi)/\tilde{t}_j(f_j)$.

2.5.2 Non-Gaussian Approximations Using a Local Correction

The simplest improvement to Gaussian marginals is to include the local term $\epsilon_i(f_i)$, and assume that the global term $c_i(f_i) \approx 1$. For EP the result is the tilted distribution $q(f_i)\epsilon_i(f_i) = q_{-i}(f_i)p(y_i|f_i,\phi)$ which is obtained as a part of the EP algorithm (Opper and Winther, 2000). As only the local terms are used to compute the improvement, Cseke and Heskes (2011) refer to it as the local improvement and denote the locally improved EP marginal as EP-L.

For the Laplace approximation, Cseke and Heskes (2011) propose a similar local improvement LA-L which can be written as $q(f_i)\tilde{t}_i(f_i)^{-1}p(y_i|f_i,\phi)$, where the site approximation $\tilde{t}_i(f_i)$ is based on the second order approximation of $\log p(y_i|f_i,\phi)$ (see Section 2.4). In Section 3.5, we propose an alternative way to compute the equivalent marginal improvement using a tilted distribution $q_{-i}(f_i)p(y_i|f_i,\phi)$, where the cavity distribution $q_{-i}(f_i)$ is based on a leave-one-out formula derived using linear response theory (Appendix A). The local methods EP-L and LA-L can improve the marginal posterior approximation only at the observed x, and the marginal posterior at new $\tilde{x}$ is the usual Gaussian predictive distribution.

2.5.3 Non-Gaussian Approximations Using a Global Correction

Global approximations also take into account the global term $c_i(f_i)$ by approximating the multidimensional integral in Equation (18), again using Laplace or EP. To obtain an approximation for the marginal distribution, the integral $c_i(f_i)$ has to be evaluated with several f_i values and the computations can be time consuming unless some simplifications are

used. Global methods can be used to obtain an improved non-Gaussian posterior marginal approximation also at the not yet observed $\tilde{x}$.

Using the Laplace approximation to evaluate $c_i(f_i)$ corresponds to an approach proposed by Tierney and Kadane (1986), and so we label the marginal improvement as LA-TK. Rue et al. (2009) proposed an approach that can be seen as a compromise between the computationally intensive LA-TK and the local approximation LA-L. Instead of finding the mode for each f_i, they evaluate the Taylor expansion around the conditional mean obtained from the joint approximation $q(f)$. The method is referred to as LA-CM. Cseke and Heskes (2011) propose the improvement LA-CM2 which adds a correction to take into account that the Taylor expansion is not done at the mode. To further reduce the computational effort, Rue et al. (2009) propose additional approximations with performance somewhere between LA-CM and LA-L. Rue et al. (2009) also discuss computationally efficient schemes for selecting values of f_i and interpolation or parametric model fitting to estimate the marginal density for other values of f_i. Cseke and Heskes (2011) propose similar approaches for EP, with EP-FULL corresponding to LA-TK, and EP-1STEP corresponding to LA-CM/LA-CM2. Cseke and Heskes (2011) also propose EP-FACT and LA-FACT which use factorized approximation to speed up the computation of the normalization terms.

The local improvements EP-L and LA-L are obtained practically for free and all global approximations are significantly slower. See Appendix B for the computational complexities of the global approximations. Based on the results by Cseke and Heskes (2011), EP-L is inferior to global approximations, but the difference is often small, and LA-L is often worse than the global approximations. Also based on the results by Cseke and Heskes (2011) and our own experiments, we chose to use LA-CM2 and EP-FACT as the global corrections in the experiments.

2.6 Integration Over the Parameters

To marginalize out the parameters θ and ϕ from the previously mentioned conditional posteriors, we can use the exact or approximated marginal likelihood $p(y|x,\theta,\phi)$ to form the marginal posterior for the parameters

$$p(\theta,\phi|D) \propto p(y|X,\theta,\phi)p(\theta,\phi), \tag{20}$$

and use numerical integration to integrate over θ and ϕ. Commonly used methods include various Monte Carlo algorithms (see list of references in Vanhatalo et al., 2013) as well as deterministic procedures, such as the central composite design (CCD) method by Rue et al. (2009). Using stochastic or deterministic samples, the marginal posterior can be approximated as

$$p(f|\mathcal{D}) \approx \sum_{s=1}^{S} p(f|\mathcal{D},\phi^s,\theta^s)w^s, \tag{21}$$

where w^s is a weight for the sample (ϕ^s,θ^s).

If the marginal posterior distribution $p(\theta,\phi|D)$ is narrow, which can happen if n is large and the dimensionality of (θ,ϕ) is small, then the effect of the integration over the parameters may be negligible and we can use Type II MAP, that is, choose $(\hat{\phi},\hat{\theta}) = \arg\max_{\phi,\theta} p(\phi,\theta|D)$.

Table 2: Summary of the leave-one-out (LOO) cross-validation approximations reviewed.

3. Leave-One-Out Cross-Validation Approximations

We start by reviewing the generic exact LOO equations, which are then used to provide a unifying view of the different approximations in the subsequent sections. We first review some special cases and then more generic approximations. The LOO approximations and their abbreviations are listed in Table 2. The computational complexities of the LOO approximations have been collected in Appendix B.

3.1 LOO from the Full Posterior

Consider the case where we have not yet seen the ith observation. Then using Bayes' rule we can add information from the ith observation:

$$p(f_i|D) = \frac{p(y_i|f_i)p(f_i|x_i,D_{-i})}{p(y_i|x_i,D_{-i})}, \tag{22}$$

again dropping ϕ and θ for brevity. Correspondingly we can remove the effect of the ith observation from the full posterior:

$$p(f_i|x_i,D_{-i}) = \frac{p(f_i|D)p(y_i|x_i,D_{-i})}{p(y_i|f_i)} \tag{23}$$

If we now integrate both sides over f_i and rearrange the terms we get

$$p(y_i|x_i,D_{-i}) = 1/\int \frac{p(f_i|D)}{p(y_i|f_i)} df_i. \tag{24}$$

In theory this gives the exact LOO result, but in practice we usually need to approximate $p(f_i|D)$ and the integral over f_i. In the following sections we first discuss the hierarchical approach, then the analytic, Monte Carlo, quadrature, WAIC, and Taylor series approaches for computing the conditional version of Equation (24). We then consider how the different marginal posterior approximations affect the result.

In some cases, we can compute $p(f_i|x_i,D_{-i})$ exactly or approximate it efficiently and then we can compute the LOO predictive density for y_i,

$$p(y_i|x_i,D_{-i}) = \int p(y_i|f_i)p(f_i|x_i,D_{-i})df_i. \tag{25}$$

Or, if we are interested in the predictive distribution for a new observation $\tilde{y}_i$, we can compute

$$p(\tilde{y}_i|x_i, D_{-i}) = \int p(\tilde{y}_i|f_i)p(f_i|x_i, D_{-i})df_i, \tag{26}$$

which is evaluated with different values of $\tilde{y}_i$ as it is not fixed like y_i.

3.2 Hierarchical Approximations

Instead of approximating the leave-one-out predictive density $p(y_i|x_i, D_{-i})$ directly, for hierarchical models such as GLVMs it is often easier to first compute the leave-one-out predictive density conditional on the parameters $p(y_i|x_i, D_{-i}, \theta, \phi)$, then compute the leave-one-out posteriors for the parameters $p(\theta, \phi|D_{-i})$ and combine the results

$$p(y_i|x_i, D_{-i}) = \int p(y_i|x_i, D_{-i}, \theta, \phi)p(\theta, \phi|D_{-i})d\theta d\phi. \tag{27}$$

Sometimes the leave-one-out posterior of the hyperparameters is close to the full posterior, that is, $p(\theta, \phi|D_{-i}) \approx p(\theta, \phi|D)$. The joint leave-one-out posterior can be then approximated as

$$p(f_i|x_i, D_{-i}) \approx \int p(f_i|x_i, D_{-i}, \theta, \phi)p(\theta, \phi|D)d\theta d\phi \tag{28}$$

(see, e.g., Marshall and Spiegelhalter, 2003). This approximation is a reasonable alternative if removing (x_i, y_i) has only a small impact on $p(\theta, \phi|D)$ but a larger impact on $p(f_i|D, \phi, \theta)$. Furthermore, if the posterior $p(\theta, \phi|D)$ is narrow, a Type II MAP point estimate of the parameters $\hat{\phi}, \hat{\theta}$ may produce similar predictions as integrating over the parameters,

$$p(f_i|x_i, D_{-i}) \approx p(f_i|x_i, D_{-i}, \hat{\theta}, \hat{\phi}). \tag{29}$$

3.3 LOO with Gaussian Likelihood

If both $p(y_i|f_i, \phi)$ and $p(f|\theta)$ are Gaussian, then we can compute $p(f_i|x_i, D_{-i})$ analytically. Starting from the marginal posterior we can remove the contribution of the ith factor in the likelihood:

$$\begin{aligned} p(f_i|x_i, D_{-i}, \theta, \phi) &\propto \frac{p(f_i|D, \theta)}{p(y_i|f_i, \phi)} \\ &= \mathrm{N}(f_i|\mu_{-i}, v_{-i}), \end{aligned} \tag{30}$$

where

$$\begin{aligned} \mu_{-i} &= v_{-i}(\Sigma_{ii}^{-1}\mu_i - \sigma^{-2}y_i) \\ v_{-i} &= \left(\Sigma_{ii}^{-1} - \sigma^{-2}\right)^{-1}. \end{aligned} \tag{31}$$

These equations correspond to the cavity distribution equations in EP.

Sundararajan and Keerthi (2001) derived the leave-one-out predictive distribution $p(y_i|x_i, D_{-i})$ directly from the joint posterior using prediction equations and properties of

partitioned matrices. This gives a numerically alternative but mathematically equivalent way to compute the leave-one-out posterior mean and variance:

$$\begin{aligned} \mu_{-i} &= y_i - \bar{c}_{ii}^{-1}g_i \\ v_{-i} &= \bar{c}_{ii}^{-1} - \sigma^2, \end{aligned} \tag{32}$$

where

$$\begin{aligned} g_i &= \left[(K + \sigma^2 I)^{-1}y\right]_i \\ \bar{c}_{ii} &= \left[(K + \sigma^2 I)^{-1}\right]_{ii}. \end{aligned} \tag{33}$$

Sundararajan and Keerthi (2001) also provided the equation for the LOO log predictive density

$$\log p(y_i|x_i, D_{-i}, \theta, \phi) = -\frac{1}{2}\log(2\pi) - \frac{1}{2}\log \bar{c}_{ii} - \frac{1}{2}\frac{g_i^2}{\bar{c}_{ii}}. \tag{34}$$

Instead of integrating over the parameters, Sundararajan and Keerthi (2001) used the result (and its gradient) to find a point estimate for the parameters maximizing the LOO log predictive density.

3.4 LOO with Expectation Propagation

In EP, the leave-one-out marginal posterior of the latent variable is computed explicitly as a part of the algorithm. The cavity distribution (11) is formed from the marginal posterior approximation by removing the site approximation (pseudo observation) using (31) and can be used to approximate the LOO posterior

$$p(f_i|x_i, D_{-i}, \theta, \phi) \approx q_{-i}(f_i). \tag{35}$$

The approximation for the LOO predictive density

$$p(y_i|x_i, D_{-i}, \theta, \phi) \approx \int p(y_i|f_i)q_{-i}(f_i)df_i \tag{36}$$

is the same as the zeroth moment of the tilted distribution. Hence we obtain an approximation for $p(f_i|x_i, D_{-i}, \theta, \phi)$ and $p(y_i|x_i, D_{-i}, \theta, \phi)$ as a free by-product of the EP algorithm. We denote this approach as EP-LOO. For certain likelihoods (36) can be computed analytically, but otherwise quadrature methods with a controllable error tolerance are usually used.

The EP algorithm uses all observations when converging to its fixed point and thus the cavity distribution $q_{-i}(f_i)$ technically depends on the observation y_i. Opper and Winther (2000) showed using linear response theory that the cavity distribution is up to first order leave-one-out consistent. Opper and Winther (2000) also showed experimentally in one case that the cavity distribution approximation is accurate. Cseke and Heskes (2011) did not consider LOO, but compared visually the tilted distribution marginal approximation EP-L to many global marginal posterior improvements. Based on these results, EP-L has some error on the shape of the marginal approximation if there is a strong prior correlation, but even then the zeroth moment — the LOO predictive density — is accurate. Our experiments provide much more evidence of the excellent accuracy of the EP-LOO approximation.

3.5 LOO with Laplace Approximation

Using linear response theory, which was used by Opper and Winther (2000) to prove LOO consistency of EP, we also prove the LOO consistency of Laplace approximation (derivation in Appendix A). Hence, we obtain a good approximation for $p(f_i|x_i, D_{-i}, \theta, \phi)$ also as a free by-product of the Laplace method. Linear response theory can be used to derive two alternative ways to compute the cavity distribution $q_{-i}(f_i)$.

The Laplace approximation can be written in terms of the Gaussian prior times the product of (unnormalized) Gaussian form site approximations. Cseke and Heskes (2011) define the LA-L marginal approximation as $q(f_i)\tilde{t}_i(f_i)^{-1}p(y_i|f_i, \phi)$, from which the cavity distribution, that is the leave-one-out distribution, follows as $q_{-i}(f_i) = q(f_i)\tilde{t}_i(f_i)^{-1}$. It can be computed using (31). We refer to this approach as LA-LOO. The LOO predictive density can be obtained by numerical integration

$$p(y_i|x_i, D_{-i}, \theta, \phi) \approx \int q_{-i}(f_i)p(y_i|f_i, \phi)df_i. \tag{37}$$

An alternative way to compute the Laplace LOO derived using linear response theory is

$$p(f_i|x_i, D_{-i}, \theta, \phi) \approx \mathrm{N}(f_i|\hat{f}_i - v_{-i}\hat{g}_i, v_{-i}), \tag{38}$$

where $\hat{f}$ is the posterior mode, $\hat{g}_i = \nabla_i \log p(y_i|f_i)|_{f_i=\hat{f}_i}$ is the derivative of the log likelihood at the mode, and

$$v_{-i} = \left(\frac{1}{\Sigma_{ii}} - \frac{1}{\tilde{\Sigma}_i}\right)^{-1}. \tag{39}$$

If we consider having pseudo observations with means $\hat{f}_i$ and variances $1/\hat{h}_i$, then these resemble the exact LOO equations for a Gaussian likelihood given in Section 3.3.

3.6 Importance Sampling and Weighting

A generic approach not restricted to GLVMs is based on obtaining Monte Carlo samples $(f_i^s, \phi^s, \theta^s)$ from the full posterior $p(f_i, \phi, \theta|D)$ and approximating (24) as

$$p(y_i|x_i, D_{-i}) \approx \frac{1}{\frac{1}{S}\sum_{s=1}^{S}\frac{1}{p(y_i|f_i^s,\phi^s)}}, \tag{40}$$

where θ^s drops out since y_i is independent of θ^s given f_i^s and ϕ^s. This approach was first proposed by Gelfand et al. (1992) (see also, Gelfand, 1996) and it corresponds to importance sampling (IS) where the full posterior is used as the proposal distribution. We refer to this approach as IS-LOO.

A more general importance sampling form is

$$p(\tilde{y}_i|x_i, D_{-i}) \approx \frac{\sum_{s=1}^{S} p(\tilde{y}_i|f_i^s, \phi^s)w_i^s}{\sum_{s=1}^{S} w_i^s}, \tag{41}$$

where w_i^s are importance weights and

$$w_i^s = \frac{p(f_i^s|x_i, D_{-i})}{p(f_i^s|D)} \propto \frac{1}{p(y_i|f_i^s, \phi^s)}. \tag{42}$$

This form shows the importance weights explicitly and allows the computation of other leave-one-out quantities like the LOO predictive distribution. If the predictive density $p(\tilde{y}_i|f_i^s, \phi^s)$ is evaluated with the observed value $\tilde{y}_i = y_i$, Equation (41) reduces to (40).

The approximation (40) has the form of the harmonic mean, which is notoriously unstable (see, e.g., Newton & Raftery 1994). However the leave-one-out version is not as unstable as the harmonic mean estimator of the marginal likelihood, which uses the harmonic mean of $\prod_{i=1}^{n} p(y_i|f_i^s, \phi^s)$ and corresponds to using the joint posterior as the importance sampling proposal distribution for the joint prior.

3.6.1 Integrated Importance Sampling

For the Gaussian observation model, Vehtari (2001) and Vehtari and Lampinen (2002) used exact computation for $p(y_i|x_i, D_{-i}, \theta, \phi)$ and importance sampling only for $p(\theta, \phi|D_{-i})$. The integrated importance weights are then

$$w_i^s \propto \frac{1}{p(y_i|x_i, D_{-i}, \theta^s, \phi^s)}, \tag{43}$$

and the LOO predictive density is

$$p(y_i|x_i, D_{-i}) \approx \frac{1}{\sum_{s=1}^{S}\frac{1}{p(y_i|x_i,D_{-i},\theta^s,\phi^s)}}. \tag{44}$$

The same marginalization approach can be used in the case of non-Gaussian observation models. Held et al. (2010) used the Laplace approximation, marginal improvements, and numerical integration to obtain an approximation for $p(y_i|x_i, D_{-i}, \theta^s, \phi^s)$ (see more in Section 3.7). Vanhatalo et al. (2013) use EP and the Laplace method for the marginalisation in the GPstuff toolbox. Li et al. (2014) considered generic latent variable models using Monte Carlo inference, and propose to marginalise f_i by obtaining additional Monte Carlo samples from the posterior $p(f_i|x_i, D_{-i}, \theta, \phi)$. Li et al. (2014) also proposed the name integrated IS and provided useful results illustrating the benefits of the marginalization. As we are focusing on EP and Laplace approximations for the latent inference, in our experiments we use IS only for hyperparameters.

3.6.2 The Variance of Importance Weights

The variance of the estimate (40) depends on the variance of the importance weights. The full posterior marginal $p(f_i^s|D)$ is likely to be narrower and have thinner tails than the leave-one-out distribution $p(f_i^s|x_i, D_{-i})$. This may cause the importance weights to have high or infinite variance (Peruggia, 1997; Epifani et al., 2008) as rare samples from the low density region in the tails of $p(f_i^s|D)$ may have very large weights.

If the variance of the importance weights is finite, the central limit theorem holds (Epifani et al., 2008), and the corresponding estimates converge quickly. If the variance of the raw importance ratios is infinite but the mean exists, the generalized central limit theorem for stable distributions holds, and the convergence of the estimate is slower (Vehtari and Gelman, 2015).

If the variance of the weights is finite, then an effective sample size estimate can be estimated as

$$S_{\text{eff}} = 1/\sum_{s=1}^{S}(\tilde{w}^s)^2, \tag{45}$$

where $\tilde{w}^s$ are normalized weights (with a sum equal to one) (Kong et al., 1994). This estimate is noisy if the variance is large, but with smaller variances it provides an easily interpretable estimate of the efficiency of the importance sampling.

3.6.3 Pareto Smoothed Importance Sampling

Vehtari et al. (2016) propose to use Pareto smoothed importance sampling (PSIS) by Vehtari and Gelman (2015) for diagnostics and to regularize the importance weights in IS-LOO. Pareto smoothed importance sampling uses the empirical Bayes estimate of Zhang and Stephens (2009) to fit a generalized Pareto distribution to the tail. By examining the estimated shape parameter $\hat{k}$ of the Pareto distribution, we are able to obtain sample based estimates of the existence of the moments (Koopman et al., 2009). When the tail of the weight distribution is long, a direct use of importance sampling is sensitive to one or few largest values. To stabilize the estimates, Vehtari et al. (2016) propose to replace the M largest weights by the expected values of the order statistics of the fitted generalized Pareto distribution. Vehtari et al. (2016) also apply optional truncation for very large weights following truncated importance sampling by Ionides (2008) to guarantee finite and reduced variance of the estimate in all cases. Even if the raw importance weights do not have finite variance, the PSIS-LOO estimate still has a finite variance, although at the cost of additional bias. Vehtari et al. (2016) demonstrate that this bias is likely to be small when the estimated Pareto shape parameter $\hat{k} < 0.7$.

3.6.4 Importance Weighting of Deterministic Points

Importance weighting can also be used with deterministic evaluation points (ϕ^s, θ^s) obtained from, for example, grid or CCD by re-weighting the weights w^s in (21); see Held et al. (2010) and Vanhatalo et al. (2013). As the deterministic points are usually used in the low dimensional case and the evaluation points are not far in the tails, the variance of the observed weights is usually smaller than with Monte Carlo. If the full posterior $p(\theta, \phi|D)$ is a poor fit to each LOO posterior $p(\theta, \phi|D_{-i})$, then the problem remains that the tails are not well approximated and LOO is biased towards the hierarchical approximation (28) that uses the full posterior of the parameters $p(\theta, \phi|D)$.

In the ideal case, the CCD evaluation points except the modal point would have equal weights. The CCD approach adjusts these weights based on the actual density and importance weighting will further adjust them, making it possible that a small number of evaluation points have large weights. Although the CCD evaluation points have been chosen deterministically, we can diagnose the reliability of CCD by investigating the distribution of the weights. If there is a small number of CCD points, we examine the effective sample size, and in cases where the number of points exceed 280 (which happens when there are more than 11 parameters), we also estimate the Pareto shape parameter $\hat{k}$.

3.7 Quadrature LOO

Held et al. (2010) proposed to use numerical integration to approximate

$$p(y_i|x_i, D_{-i}, \theta, \phi) \approx 1/\int \frac{q(f_i|D, \theta, \phi)}{p(y_i|f_i, \phi)} df_i. \tag{46}$$

We call this quadrature LOO (Q-LOO), as one-dimensional numerical integration methods are usually called quadrature. Given exact $p(f_i|D, \theta, \phi)$ and accurate quadrature, this would provide an accurate result (e.g., if the true posterior is Gaussian, quadrature should give a result similar to the analytic solution apart from numerical inaccuracies). However, some error will be introduced when the latent posterior is approximated with $q(f_i|D, \theta, \phi)$. The numerical integration of the ratio expression may also be numerically unstable if the tail of the likelihood term $p(y_i|f_i, \phi)$ decays faster than the tail of the approximation $q(f_i|D, \theta, \phi)$. For example, the probit likelihood, which has a tail that goes as $\exp(-f^2/2)/f$, will be numerically unstable if $q(f_i|D, \theta, \phi)$ is Gaussian with a variance below one.

Held et al. (2010) tested the Gaussian marginal approximation (LA-G) and two non-Gaussian improved marginal approximations (LA-CM and simplified LA-CM, see Section 2.5). All had problems with the tails, although less so with the more accurate approximations. Held et al. proposed to rerun the failed LOO cases with actual removal of the data. As Held et al. had 13 to 56 failures in their experiments, the proposed approach would make LOO relatively expensive. In our experiments with Gaussian marginal approximations LA-G/EP-G, we also had several severe failures with some data sets. However with the non-Gaussian approximations LA-CM2/EP-FACT, we did not observe severe failures (see Section 4).

If we use marginal approximations EP-L or LA-L based on the tilted distribution $q_{-i}(f_i)p(y_i|f_i, \phi)$ (see Table 1), we can see that the tail problem vanishes. Inserting the normalized tilted distribution from (46), the equation reduces to

$$p(y_i|x_i, D_{-i}, \theta, \phi) \approx \int q_{-i}(f_i)p(y_i|f_i, \phi)df_i, \tag{47}$$

which is the EP-LOO or LA-LOO predictive density estimate depending on which approximation is used.

3.7.1 Alternative Form for Quadrature LOO

We also present an alternative form of (46), which gives additional insight about the numerical stability when the global marginal improvements are used. As discussed in Section 2.5, we can write the marginal approximation with a global improvement as

$$\frac{Z_q}{Z_p} q(f_i)\tilde{t}(f_i)^{-1} p(y_i|f_i, \phi)c_i(f_i), \tag{48}$$

where $c_i(f_i)$ is a global correction term (see Eq. (18)). Replacing $q(f_i)\tilde{t}(f_i)^{-1}$ with the cavity distribution from EP-L or LA-L gives

$$\frac{Z_q}{Z_p} q_{-i}(f_i)p(y_i|f_i, \phi)c_i(f_i), \tag{49}$$

which we can insert into (46) to obtain

$$p(y_i|x_i, D_{-i}, \theta, \phi) \approx \frac{\int p(y_i|f_i, \phi) q_{-i}(f_i) c_i(f_i) df_i}{\int q_{-i}(f_i) c_i(f_i) df_i}. \tag{50}$$

Here $q_{-i}(f_i)c_i(f_i)$ is a global corrected leave-one-out posterior, and we can see that the stability will depend on $c_i(f_i)$. The correction term $c_i(f_i)$ may have increasing tails, which is usually not a problem in $q_{-i}(f_i)p(y_i|f_i, \phi)c_i(f_i)$, but may be a problem in $q_{-i}(f_i)c_i(f_i)$. In addition, the evaluation of $c_i(f_i)$ at a small number of points and using interpolation for the quadrature (as proposed by Rue et al., 2009) is sometimes unstable, which may increase the instability of $\int q_{-i}(f_i)c_i(f_i)df_i$. Depending on the details of the computation, (46) and (50) can produce the same result up to numerical accuracy, if the relevant terms cancel out numerically in Equation (46). This happens in our implementation with global marginal posterior improvements, and thus in Section 4 we do not report the results separately for (46) and (50).

Held et al. (2010) and Vanhatalo et al. (2013) use quadrature LOO in a hierarchical approximation, where the parameter level is handled using importance weighting (Section 3.6). Our experiments also use this approach. Alternatively, we could approximate by integrating over the parameters in the marginal and likelihood separately and approximate LOO as

$$p(y_i|x_i, D_{-i}) \approx 1/\int \frac{q(f_i|D)}{p(y_i|f_i, D)} df_i. \tag{51}$$

If the integration over θ and ϕ is made using Monte Carlo or deterministic sampling (e.g. CCD), then this is equivalent to using quadrature for conditional terms and importance weighting of the parameter samples.

3.7.2 Truncated Weights Quadrature

As the quadrature approach may also be applied beyond simple GLVMs, we propose an approach for stabilizing the general form. Inspired by truncated importance sampling by Ionides (2008), we propose a modification of the quadrature approach, which makes it more robust to approximation errors in tails:

$$p(y_i|x_i, D_{-i}, \theta, \phi) \approx \frac{\int p(y_i|f_i, \phi)\ p(f_i|D, \theta, \phi)\tilde{w}(f_i) df_i}{\int p(f_i|D, \theta, \phi)\tilde{w}(f_i) df_i}, \tag{52}$$

where

$$\tilde{w}(f_i) = \frac{1}{\max(p(y_i|f_i, \phi), c)}, \tag{53}$$

and c is a small positive constant. When $c = 0$, we get the original equation. When c is larger than the maximum value of $p(y_i|f_i, \phi)$, we get the posterior predictive density $p(y_i|D)$.

With larger values of $p(y_i|f_i, \phi)$ and c we avoid the possibility that the ratio explodes. In easy cases, where the numerator gets close to zero before c is used, we get a negligible bias. In difficult cases, we have a bias towards the full posterior predictive density.

In truncated importance sampling, the truncation level is based on the average raw weight size and the number of samples (see details in Ionides, 2008). Following this idea we choose

$$c^{-1} = c_0^{-1} \int_a^b \frac{p(f_i|D, \theta, \phi)}{p(y_i|f_i, \phi)} df_i.$$

By limiting the integral to interval (a, b), we avoid tail problems while capturing information about the average level of the weights. Based on experiments not reported here, we choose $c_0 = 10^{-4}$ and the interval (a, b) to extend 6 standard deviations from the mode of the marginal posterior in each direction. A case-specific c_0 could further improve results, but a fixed c_0 already shows the usefulness of the truncation. We refer to truncated weights quadrature LOO by TQ-LOO. In the experiments we show that TQ-LOO can provide more stable results than Q-LOO.

3.8 Widely Applicable Information Criterion

Watanabe (2010a,b) showed that the widely applicable information criterion (WAIC) is asymptotically equivalent to Bayesian LOO. Watanabe (2010a,b) provided two forms for WAIC, which we refer to as WAIC_G and WAIC_V following Vehtari and Ojanen (2012). WAIC was originally defined on the scale of mean negative log density, but for better cohesion within this paper we use the scale of mean log density. In the following discussion we drop the dependence on ϕ and θ and return to this point towards the end of the section. Both WAIC forms consist of the mean training log predictive density $\frac{1}{n}\sum_{i=1}^n \log p(y_i|D)$ and a second term to correct for its optimistic bias. These correction terms may be interpreted as the complexity of the model or the effective number of parameters in the model, but the interpretation does not always seem to be clear.

The correction term in WAIC_G is based on the difference between the training utility and Gibbs utility ($\frac{1}{n}\sum_{i=1}^n \int \log p(y_i|f_i)p(f_i|D)df_i$) giving

$$\text{WAIC}_G = \frac{1}{n}\sum_{i=1}^n \log p(y_i|D) - 2\sum_{i=1}^n \left[\log E_{f_i|D}[p(y_i|f_i)] - E_{f_i|D}[\log p(y_i|f_i)] \right], \tag{54}$$

where the Gibbs utility differs from the mean training log predictive density by the changed order of the logarithm and the expectation over the posterior.

The correction term in WAIC_V is based on the functional variance which describes the fluctuation of the posterior distribution:

$$\text{WAIC}_V = \frac{1}{n}\sum_{i=1}^n \log p(y_i|D) - \frac{1}{n}\sum_{i=1}^n \text{Var}_{f_i|D}[\log p(y_i|f_i)]. \tag{55}$$

Both of these criteria are easy to compute using Monte Carlo samples from the joint posterior $p(f|D)$, or marginal posterior approximation of $p(f_i|D)$ and quadrature integration.

Watanabe (2010b) used a Taylor series expansion to prove the asymptotic equivalence to Bayesian LOO with error term $O_p(n^{-2})$. To examine this relation we write the LOO log predictive density using condensed notation for (24)

$$-\frac{1}{n}\sum_{i=1}^n \log E_{f_i|D}[p(y_i|f_i)^{-1}]. \tag{56}$$

By defining a generating function of functional cumulants,

$$F(\alpha) = \frac{1}{n}\sum_{i=1}^{n} \log E_{f_i|D}[p(y_i|f_i)^\alpha], \tag{57}$$

and applying a Taylor expansion of $F(\alpha)$ around 0 with $\alpha = -1$, we obtain an expansion of the leave-one-out predictive density:

$$\text{LOO} = F'(0) - \frac{1}{2}F''(0) + \frac{1}{6}F^{(3)}(0) - \sum_{i=4}^{\infty} \frac{(-1)^i F^{(i)}(0)}{i!}. \tag{58}$$

From the definition of $F(\alpha)$ we get

$$\begin{aligned} F(0) &= 0 \\ F(1) &= \frac{1}{n}\sum_{i=1}^{n} \log E_{f_i|D}[p(y_i|f_i)] \\ F'(0) &= \frac{1}{n}\sum_{i=1}^{n} E_{f_i|D}[\log p(y_i|f_i)] \\ F''(0) &= \frac{1}{n}\sum_{i=1}^{n} \text{Var}_{f_i|D}[\log p(y_i|f_i)]. \end{aligned} \tag{59}$$

Furthermore, the expansion for the mean training log predictive density is

$$F(1) = F'(0) + \frac{1}{2}F''(0) + \frac{1}{6}F^{(3)}(0) + \sum_{i=4}^{\infty} \frac{F^{(i)}(0)}{i!}, \tag{60}$$

the expansion for WAIC_G is

$$\begin{aligned} \text{WAIC}_G(n) &= F(1) - 2[F(1) - F'(0)] = -F(1) + 2F'(0) \\ &= F'(0) - \frac{1}{2}F''(0) - \frac{1}{6}F^{(3)}(0) - \sum_{i=4}^{\infty} \frac{F^{(i)}(0)}{i!}, \end{aligned} \tag{61}$$

and the expansion for WAIC_V is

$$\begin{aligned} \text{WAIC}_V(n) &= F(1) - F''(0) \\ &= F'(0) - \frac{1}{2}F''(0) + \frac{1}{6}F^{(3)}(0) + \sum_{i=4}^{\infty} \frac{F^{(i)}(0)}{i!}. \end{aligned} \tag{62}$$

The first two terms of the expansion of WAIC_G and the first three terms of the expansion of WAIC_V match with the expansion of LOO. Based on the expansion we may assume that WAIC_V is the more accurate approximation for LOO.

Watanabe (2010b) shows that the error of WAIC_V is $O_p(n^{-2})$ and argues that asymptotically further terms have negligible contribution. However, the error can be significant in the case of finite n and weak prior information, as shown by Gelman et al. (2014), and for

hierarchical models, as demonstrated by Vehtari et al. (2016). For example, with Gaussian processes, if x_i is far from all other x_j, then f_i has a low correlation with any other f_j and the effective number of observations affecting the posterior of f_i is close to 1. In such cases, the higher order terms of the expansion are significant. The higher order terms of WAIC_V match the higher order terms of the mean training log predictive density and thus WAIC_V will be biased towards that. This is also evident from our experiments (see Section 4). It is not as clear what happens with WAIC_G, but experimentally the behavior is similar but with higher variance than with WAIC_V. The performance of both WAICs clearly also depend on the accuracy of the marginal approximation $q(f_i|D)$.

Instead of WAIC, we could directly compute a desired number of terms from the series expansion of LOO. In theory, we could approximate the exact result with a desired accuracy if enough higher order functional cumulants exist. This does not always work (e.g., if the posterior is Cauchy and the observation model is Gaussian), but it is true with a Gaussian prior on latent variables and a log-concave likelihood (An, 1998). In practice, the accuracy is limited by the computational precision of the higher cumulants, which is limited by the number of Monte Carlo samples or by the distributional approximation $q(f_i|D)$. If the cumulants are computed using $q(f_i|D)$ and quadrature, then the approximation based on Taylor series expansion converges eventually to Q-LOO (within numerical accuracy).

In the above equations we had dropped dependency on ϕ and θ. Like in other LOO-CV approximations, the parameter level can be handled using importance weighting. Alternatively we can handle the parameter level in full WAIC style by computing the cumulants of the marginal posteriors, where ϕ and θ have been integrated out, and using these cumulants to compute WAIC.

WAIC is related to the deviance information criterion (DIC). We do not review DIC here and instead refer to Gelman et al. (2014) for the reasons we prefer WAIC to DIC. Indeed, in our experiments not reported here, DIC had larger error than WAIC.

4. Results

Using several real data sets we present results illustrating the properties of the reviewed LOO-CV approximations. Table 3 lists the basic properties of four classification data sets (Ripley, Australian, Ionosphere, Sonar), one survival data set with censoring (Leukemia), and one data set for a Student's t regression (Boston). All data sets are available from the internet. Several classification data sets were selected as the posterior is likely to be skewed and there are often differences in performance between Laplace approximation and expectation propagation. The classification data sets have different numbers of covariates so we can investigate to what degree this affects the accuracy of the LOO-CV approximations. The leukemia survival data set was selected as we often analyze survival data with censoring. The Boston data set for a regression with a Student's t observation model was selected to illustrate the performance in the case of a non-log-concave likelihood, which may produce multimodal latent posterior. Similar results were obtained with other data sets not reported here.

For all data sets we fit Gaussian processes with constant, linear, and squared exponential covariance functions. When using the squared exponential covariance function, we use a separate length scale for each covariate except with the Ionosphere and Sonar data sets,

Data set	n	d	$\#(\phi, \theta)$	observation model
Ripley	250	2	5	probit
Australian	690	14	17	probit
Ionosphere	351	33	4	probit
Sonar	208	60	4	probit
Leukemia	1043	4	7	log-logistic with censoring
Boston	506	13	17	Student's t

Table 3: Summary of data sets and models in our examples.

where we use one common length scale. For the classification data sets we use a Bernoulli observation model with probit link. For the Leukemia data set we use a log-logistic model with censoring (as in Gelman et al., 2013, p. 511). For the Boston data set we use a Student's t observation model with $\nu = 4$ degrees of freedom. A fixed ν was chosen as the Laplace approximation (Vanhatalo et al., 2009) had occasional problems when integrating over an unknown ν. Robust-EP by Jylänki et al. (2011) works well also with ν unknown. All the experiments were done using GPstuff toolbox[1] (Vanhatalo et al., 2013). The Laplace method is implemented as described in Vanhatalo et al. (2010). The Laplace-EM method for Student's t model is implemented as described in Vanhatalo et al. (2009). Parallel EP for other data sets than Boston and parallel robust-EP for Student's t models are implemented as described in Jylänki et al. (2011). CCD is implemented as described in Vanhatalo et al. (2010). Markov chain Monte Carlo (MCMC) sampling is based on elliptical slice sampling for latent values (Murray et al., 2010) and surrogate slice sampling (Murray and Adams, 2010) for jointly sampling latent values and hyperparameters. The practical speed comparisons of the posterior and LOO approximation methods are shown in Appendix C.

Although in the review we described the estimation of the expected performance $\mathrm{LOO} = \frac{1}{n}\sum_{i=1}^{n} \log p(y_i|x_i, D_{-i})$, below we report $n \times \mathrm{LOO}$. For these data sets this puts the approximation errors for all sets on the same scale. This scale has two other interpretations. First, the difference between the sum training log predictive density and $n \times \mathrm{LOO}$ can be interpreted sometimes as the effective number of parameters measuring the model complexity (Vehtari and Ojanen, 2012; Gelman et al., 2014). Second, the significance of the difference between two models can be approximately calibrated if $n \times \mathrm{LOO}$ is interpreted as a pseudo log Bayes factor and if a similar calibration scale is used as for the Bayes factor (Vehtari and Ojanen, 2012). As a rule of thumb, based upon asymptotic theory and experience we would like the approximation error for nLOO to be smaller than 1. See the additional discussion of using Bayesian cross-validation in model selection in Vehtari and Lampinen (2002) and Vehtari and Ojanen (2012). We let $\mathrm{LOO}_i \equiv \log p(y_i|x_i, D_{-i})$ and $\widehat{\mathrm{LOO}}_i$ be the corresponding approximate quantity. In the tables we report a bias and deviation of individual terms as

$$\mathrm{Bias} = \sum_{i=1}^{n} (\widehat{\mathrm{LOO}}_i - \mathrm{LOO}_i) \tag{63}$$

$$\mathrm{Std}^2 = \sum_{i=1}^{n} (\widehat{\mathrm{LOO}}_i - \mathrm{LOO}_i - \mathrm{Bias})^2. \tag{64}$$

1. GPstuff is available at http://research.cs.aalto.fi/pml/software/gpstuff/

The acronyms used in the following are MCMC=Markov chain Monte Carlo, CCD=central composite design, MAP=Type II maximum a posteriori, PSIS=Pareto smoothed importance sampling, and those listed in Tables 1 and 2.

4.1 Exact LOO Comparison to MCMC

The ground truth exact LOO results were obtained by brute force computation of each $p(y_i|x_i, D_{-i})$ separately by leaving out the ith observation. We do that for each method: Laplace, EP and MCMC. MCMC serves as the golden standard for the posterior inference to which we compare Laplace and EP. We show results separately for estimating the predictive performance with and without a global correction (CM2/FACT). As discussed in Section 2.5, only the global corrections produce non-Gaussian predictive distributions for the latent variable $\tilde{f}$ at a new point $\tilde{x}$. Our main interest is in approximating $p(y_i|x_i, D_{-i})$, but we also show exact LOO results for the conditional $p(y_i|x_i, D_{-i}, \phi, \theta)$ with fixed parameters θ, ϕ, which were obtained by optimizing the marginal posterior $p(\theta, \phi|D)$ (type II MAP). In this case, LOO-CV is unbiased only conditionally as it does not take into account the effect of the fitting of the parameters θ, ϕ. However, it is useful to first evaluate the accuracy of approximations for $p(y_i|x_i, D_{-i}, \theta, \phi)$, as these can be used with integrated importance sampling (see Section 3.6) for hierarchical computation of $p(y_i|x_i, D_{-i})$.

The first part of Table 4 shows the exact LOO results with hyperparameters fixed to Laplace Type II MAP. LA has similar performance to MCMC for all data sets except Ionosphere and Sonar, for which LA is significantly inferior. LA-CM2 is able to improve the predictive performance for the Sonar data set to be similar with MCMC, and for the Ionosphere, the performance is even better than for MCMC.

The second part of Table 4 shows the exact LOO results with hyperparameters fixed to EP Type II MAP. EP has similar performance to MCMC for all data sets and EP-FACT is not able improve the performance. The small differences between MCMC results conditional on either LA-MAP or EP-MAP fixed hyperparameters are due to differences in the marginal likelihood approximations of LA and EP leading to different MAP estimates. However, this difference between LA-MAP and EP-MAP results is less interesting than differences with full integration.

The third part of Table 4 shows the exact LOO results with hyperparameters integrated with MCMC or CCD. LA+CCD is as good as MCMC for the Ripley, Australian and Leukemia data sets. LA-CM2+CCD improves the predictive performance for Ionosphere and Sonar. The performance of LA-CM2+CCD for Sonar is even better than MCMC and EP(-FACT)+CCD. LA-CM2+CCD failed to produce an answer in about 9% of leave-one-out rounds (the LA-CM2 method failing with some hyperparameter values) and thus no result is shown. EP is as good as MCMC for all data sets other than Boston and EP+FACT is not able to improve the performance at all.

Overall, when integrating over the hyperparameters, the difference between the predictive performance of LA and EP is small except for the Ionosphere and Sonar data sets. LA(-CM2)+CCD and EP(-FACT)+CCD have significantly worse predictive performance than MCMC for the Student's t regression with the Boston data. Since LA(-CM2) and EP(-FACT) performed as well as MCMC with fixed hyperparameters, the worse performance of CCD is due to error in the approximation of the marginal likelihood (see Jylänki et al., 2011) and

Table 4: Exact LOO (with brute force computation) using MCMC, Laplace (LA), Laplace with CM2 marginal corrections (LA-CM2), EP or EP with FACT marginal corrections (EP-FACT) for the latent values f, and fixed hyperparameters ϕ, θ (type II MAP) or integration over the hyperparameters with MCMC or CCD. The values in the parentheses are standard deviations of the pairwise differences from the corresponding MCMC result. Bolded values are not significantly different from the best accuracy in the corresponding category. NA indicates failed computation.

full MCMC is able to find better hyperparameters during the joint sampling of the latent values and hyperparameters.

4.2 Approximate LOO Comparison to Exact LOO – Fixed Hyperparameters

As discussed in Section 3.2, we compute LOO densities $p(y_i|x_i, D_{-i})$ hierarchically by first computing the conditional LOO densities $p(y_i|x_i, D_{-i}, \theta, \phi)$. As the accuracy of the full LOO densities depends crucially on the conditional LOO densities, we first analyze the LOO approximations conditional on fixed hyperparameters. The ground truth in this section are the LA, LA-CM2, EP, and EP-FACT results shown in Table 4.

Table 5 shows results when *the ground truth is exact LOO with fixed parameters and Laplace approximation without a global correction* (LA in Table 4). LA-LOO gives the best accuracy for all data sets by a significant margin. Quadrature LOO with Gaussian approximation of the latent marginals (Q-LOO-LA-G) produces bad results for the classification data sets and sometimes completely fails. The posterior marginals in the case of the Leukemia model are so close to Gaussian that Q-LOO-LA-G also provides a useful result. Truncated quadrature (TQ-LA-LOO-G) is more stable, but it cannot fix the whole problem. Using more accurate marginal approximation improves WAICs. WAIC_V with the LA-L marginal approximation gives useful results for the two simplest data sets.

Table 6 shows results when *the ground truth is exact LOO with fixed parameters and expectation propagation without a global correction* (EP in Table 4). EP-LOO gives the best accuracy for all data sets by a significant margin. Other results are similar to the Laplace case, that is, all methods except EP-LOO fail badly for several data sets. Only the Ripley

and Leukemia data sets are easy enough for most of the methods to produce useful accuracy.

Table 7 shows results when *the ground truth is exact LOO with fixed parameters and Laplace approximation with LA-CM2 global correction* (LA-CM2 in Table 4). Quadrature LOO with LA-CM2 approximation of the latent marginals (Q-LOO-LA-CM2) has the best accuracy for all data sets except for Boston, but the accuracy is satisfactory only for the Ripley and Leukemia data sets. Here LA-LOO has a negative bias as the global correction LA-CM2 can improve the marginal approximation and therefore also the expected performance estimated with exact LOO. The results for truncated quadrature (TQ-LOO-LA-CM2) are not reported in the table as with adaptive truncation it produced the same results as quadrature LOO (Q-LOO-LA-CM2). WAIC_V performs better than WAIC_G, but worse than Q-LOO-LA-CM2.

Table 8 shows results when *the ground truth is exact LOO with fixed parameters and expectation propagation with EP-FACT global correction* (EP-FACT in Table 4). EP-LOO provides significantly better accuracy for the Sonar and Leukemia data sets than the other methods. EP-LOO also gives the best accuracy for the other data sets, but not significantly better than quadrature with EP-FACT approximation of the latent marginals (Q-LOO-EP-FACT). In addition, for the Ripley data set all methods except WAIC_G provide good

results. The EP-LOO using the EP-L tilted distribution approximation is already good and the global correction does not change the result much. Small errors in the quadrature integration cumulate and Q-LOO-EP-FACT produces slightly worse results than EP-LOO.

4.3 LOO and WAIC with Varying Model Flexibility

Above we saw that the methods other than LA-LOO and EP-LOO had more difficulties with most of the data sets and especially with data sets with a large number of covariates. Figures 1–4 illustrate how the flexibility of the Gaussian process models affects the performance of the approximations. We took the models with MAP parameter values and re-ran the models and LOO tests, varying the length scales for all data sets except Boston (see later). With a smaller length scale, the GPs are more flexible and more non-linear. With a larger length scale GPs approach the linear model. We measure the flexibility by the difference between the mean training log predictive density and LOO, which can be interpreted as the degree to which the model has fit to the data or the relative effective number of parameters (p_{eff}/n). When the length scale gets smaller, there will be more such f_is that have a low correlation with any other f_j. In this case the full marginal posterior and LOO marginal posterior are likely to be more different and most LOO approximations become less accurate. This phenomenon will also occur more easily in the case of many covariates, because more data points will tend to be located at the corners of the data. Figures 1–4 show that LA-LOO and EP-LOO work well with different flexibilities. All the other methods have difficulties when the model flexibility increases and the marginal distribution and the cavity distribution are more different. If we look at the accuracy for each i, the methods other than LA-LOO and EP-LOO start to fail when the estimated $p_{\text{eff},i}$ is larger than 10%–20%. As a quick overall

rule of thumb, methods other than LA-LOO and EP-LOO start to fail when the relative effective number of parameters (p_{eff}/n) is larger than 2%–5%.

Figures 1–4 also show for Boston data how the degrees of freedom ν in the Student's t observation model affects the accuracy. When ν increases, the observation model is closer to Gaussian and the latent posterior is more likely to be unimodal. Although the latent posterior is easier to approximate with a Gaussian when ν is large, the posterior is less robust to influential observations ("outliers") and the error made by the methods other than LA-LOO and EP-LOO increases.

4.4 Approximate LOO Comparison to Exact LOO – Hierarchical Model

Next we examine the accuracy of hierarchical LOO approximation of $p(y_i|x_i, D_{-i})$ (see Section 3.2), where the conditional LOO densities $p(y_i|x_i, D_{-i}, \theta, \phi)$ are approximated with LA-LOO or EP-LOO, which we found performed best for conditional densities (see previous section).

Table 9 shows the results when *the ground truth is exact LOO with CCD used to integrate over the parameter posterior and the Laplace method is used to integrate over the latent values* (LA+CCD in Table 4). The Laplace approximation combined with type II MAP parameter estimates or CCD integration but no importance weighting has an error size related to the number of hyperparameters (θ, ϕ). The unweighted CCD or MAP gives a small error only if the number of parameters (θ, ϕ) is small. Importance weighting of CCD works well for all data sets except Australian and Boston. These data sets have more parameters (17) than the others (4-8), making the inference more difficult. The minimum relative effective sample sizes (Ripley=60%, Australian=16%, Ionosphere=59%, Sonar=70%, Leukemia=36%, Boston=0.3%) correctly indicate that importance weighting for Australian and Boston data sets is unreliable.

Table 10 shows the corresponding results when *the ground truth is exact LOO with CCD used to integrate over the parameter posterior and expectation propagation used to integrate over the latent values* (EP+CCD in Table 4). EP with the unweighted CCD or MAP gives a small error only if the number of parameters (θ, ϕ) is small. Importance weighting of CCD works well for all data sets except Australian and Boston. Again the minimum relative effective sample sizes (Ripley=60%, Australian=12%, Ionosphere=36%, Sonar=65%, Leukemia=35%, Boston=9%) correctly indicate that importance weighting for Australian and Boston is unreliable.

As CCD integration provided good results for exact LOO (Table 4), the larger errors of CCD+IS for the Australian and Boston data is not due to CCD itself failing, but importance weighting failing. As an additional check we sampled the hyperparameters with MCMC (6000 samples with slice sampling) and computed Pareto smoothed importance sampling estimates (MCMC+PSIS) shown also in Tables 9 and 10. Due to larger number of samples, the errors are slightly reduced, but still for the Australian and Boston data sets the errors are larger. The PSIS diagnostics (maximum of Pareto shape parameters $\hat{k}$ for Laplace: Ripley=0.4, Australian=1.2, Ionosphere=0.4, Sonar=0.4, Leukemia=0.2, Boston=1.3; for EP: Ripley=0.3, Australian=1.6, Ionosphere=0.3, Sonar=0.3, Leukemia=0.2, Boston=0.7) correctly indicate the problematic cases ($\hat{k} > 0.7$).

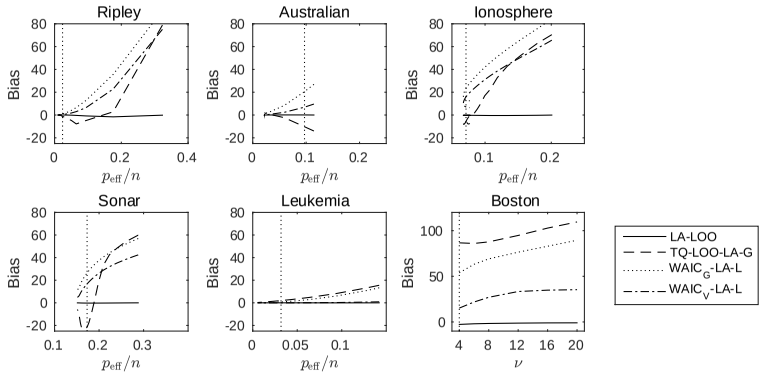

Figure 1: Bias when the ground truth is exact LOO with Laplace (LA in Table4) and varying flexibility of the model, or degrees of freedom in the Student's t model for the Boston data. Model flexibility was varied by rescaling the length scale(s) in the GP model. Model flexibility is measured by the relative effective number of parameters p_{eff}/n. The flexibility of the MAP model is shown with a vertical dashed line. For the Student's t model the vertical dashed line is at $\nu = 4$.

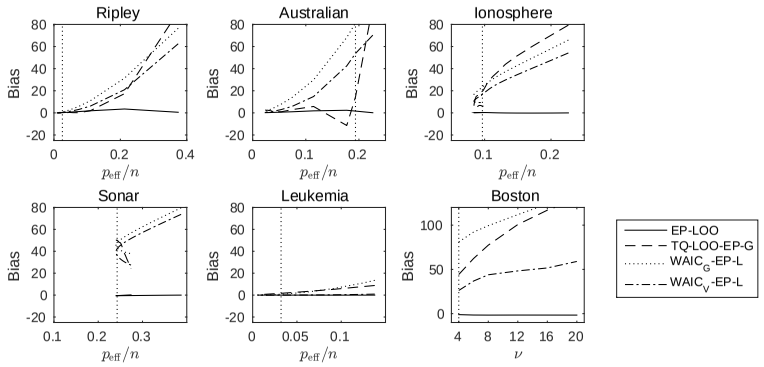

Figure 2: Bias when the ground truth is exact LOO with EP (EP in Table4) and varying flexibility of the model, or degrees of freedom in the Student's t model for the Boston data. Model flexibility was varied by rescaling the length scale(s) in the GP model. Model flexibility is measured by the relative effective number of parameters p_{eff}/n. The flexibility of the MAP model is shown with a vertical dashed line. For the Student's t the vertical dashed line is at $\nu = 4$.

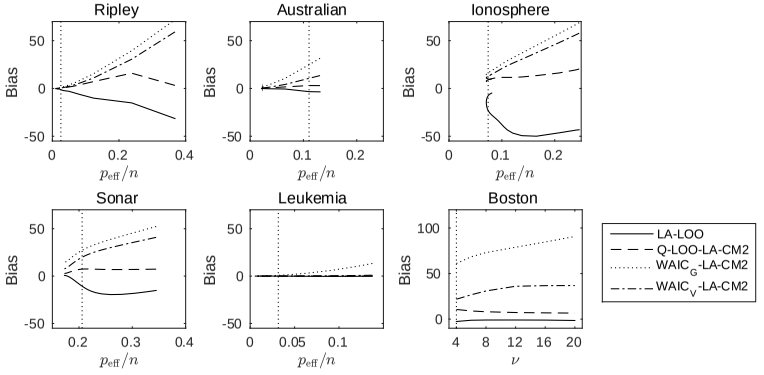

Figure 3: Bias when the ground truth is exact LOO with Laplace-CM2 (LA-CM2 in Table4) and varying flexibility of the model, or degrees of freedom in the Student's t model for the Boston data. Model flexibility was varied by rescaling the length scale(s) in the GP model. Model flexibility is measured by the relative effective number of parameters p_{eff}/n. The flexibility of the MAP model is shown with a vertical dashed line. For the Student's t the vertical dashed line is at $\nu = 4$.

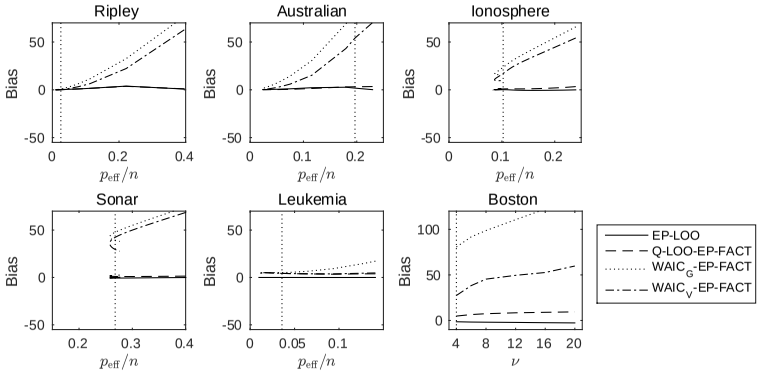

Figure 4: Bias when the ground truth is exact LOO with EP-FACT (EP-FACT in Table4) and varying flexibility of the model, or degrees of freedom in the Student's t model for the Boston data. Model flexibility was varied by rescaling the length scale(s) in the GP model. Model flexibility is measured by the relative effective number of parameters p_{eff}/n. The flexibility of the MAP model is shown with a vertical dashed line. For the Student's t the vertical dashed line is at $\nu = 4$.

If the minimum relative effective sample size or PSIS diagnostics warn about potential problems, depending on the application it may be necessary to run, for example, k-fold cross-validation.

5. Discussion

We have shown that LA-LOO and EP-LOO provide fast and accurate conditional LOO results when the predictions at new points are made using the Gaussian latent value distribution. If the predictions at new points are made using non-Gaussian distributions obtained from the global correction, then quadrature LOO gives useful results, but it would be faster and more accurate to just use EP without the global correction. Both Laplace-LOO and EP-LOO can be combined with importance sampling or importance weighted CCD to get fast and accurate full Bayesian leave-one-out cross-validation results.

If other methods than LA-LOO or EP-LOO are used, we propose the following rule of thumb for diagnostics: The methods other than LA-LOO and EP-LOO start to fail when the relative effective number of parameters (p_{eff}/n) is larger than 2%–5%.

Here we have considered fully factorizing likelihoods, but the methods can be extended for use with likelihoods with grouped factorization, such as in multi-class classification, multi-output regression, and some hierarchical models with lowest level grouping. We assume that the accuracy using Laplace-LOO and EP-LOO would also be good in these cases.

In this paper, we have concentrated on how well exact LOO can be estimated with fast approximations. LOO is useful for estimating the predictive performance of of a model or in model comparison, but it should not be used to select a single model among a large number of models due to a selection induced bias as demonstrated by Piironen and Vehtari (2016).

A. Linear Response Laplace Leave-One-Out

Using linear response theory, used by Opper and Winther (2000) to prove LOO consistency of EP, we here derive approximative Laplace leave-one-out equations.

The idea is to express the posterior mode solution for the LOO problem in terms of the solution for the full problem. The computationally cheap solution can be obtained by making the assumption that the difference between these two solutions is small such that their difference may be treated as a second order Taylor expansion. We will give two different derivations of the result stated in Section 3.5; One is based on a second order expansion of the log likelihood and the second on a classical linear response argument.

In the expansion approach we make the approximation that when example i is removed we can treat the change in the mode for the remaining variables to second order. The log prior is already quadratic so it is only the non-linearity in the log likelihood terms $j \neq i$ that we expand to second order:

$$\log p(y_j|f_j,\phi) \approx \log p(y_j|\hat{f}_j,\phi) + (f_j - \hat{f}_j)\nabla_j \log p(y_j|f_j,\phi)|_{f_j=\hat{f}_j} - \frac{(f_j-\hat{f}_j)^2}{2\tilde{\Sigma}_j} , \qquad (65)$$

where $\tilde{\Sigma}_j$ is defined in Equation (14). We collect the first and second order contributions of the expansion to give the Gaussian type leave i out factors for the likelihood terms $j \neq i$. We recognize that *these approximate factors coincide with those introduced in the full Laplace approximation* in Equation (8). We can now write the approximate leave one out posterior as

$$q(f|D_{-i},\theta,\phi) \propto \prod_{j\neq i} \tilde{t}_j(f_j) p(f|X,\theta) \qquad (66)$$

and the marginal as

$$\begin{aligned} p(f_i|D_{-i},\theta,\phi) \approx q_{-i}(f_i) &\propto \frac{1}{\tilde{t}_i(f_i)} \int \prod_j \tilde{t}_j(f_j) p(f|X,\theta) df_{-i} \\ &\propto \frac{1}{\tilde{t}_i(f_i)} \int \mathrm{N}(f|\hat{f},\hat{\Sigma}) df_{-i} = \frac{\mathrm{N}(f_i|\hat{f}_i,\hat{\Sigma}_{ii})}{\tilde{t}_i(f_i)} . \end{aligned} \qquad (67)$$

This result shows that in a self-consistent second order approximation, where we take into account both the explicit removal of likelihood term i and the implicit effect on the remaining variables, the leave one out posterior is obtained simply by dividing by the Gaussian factor for i. Finally we complete the square and obtain the result in Equation (38).

Next we show how the same result can be obtained by a linear response argument. The equation for the mode is

$$K^{-1}\hat{f} = \hat{g} , \qquad (68)$$

where $\hat{g} = \nabla \log p(y|\hat{f}, \phi)$ is the vector of derivatives of the terms in the log likelihood (depending non-linearly on $\hat{f}$). Because this defines an equation for the mode, we only need to make a variation to first order in this case to recover the result we obtained above. When we remove likelihood term i the change in the mode can be written as

$$K^{-1}\delta\hat{f} = \delta\hat{g} \tag{69}$$

with the change in $\hat{g}$ to first order

$$\delta\hat{g} \approx -\tilde{\Sigma}^{-1}\delta\hat{f} + e_i\tilde{\Sigma}_i^{-1}\delta\hat{f}_i - e_i\hat{g}_i, \tag{70}$$

where we have used $\frac{\partial\hat{g}_i}{\partial\hat{f}_i} = -\hat{h}_i = -\tilde{\Sigma}_i^{-1}$ and e_i is a unit vector in the ith direction. The first two terms on the right hand side are the indirect change of the equation due to the removal of term i and the last is the direct contribution. We can now solve the linearized equation with respect to $\delta\hat{f}$ using the definition of the Laplace covariance $\Sigma = (K^{-1} + \tilde{\Sigma}^{-1})^{-1}$

$$\delta\hat{f} = \Sigma e_i(\tilde{\Sigma}_i^{-1}\delta\hat{f}_i - \hat{g}_i). \tag{71}$$

Specializing to $\delta\hat{f}_i$ we get

$$\delta\hat{f}_i = \Sigma_{ii}(\tilde{\Sigma}_i^{-1}\delta\hat{f}_i - \hat{g}_i) \tag{72}$$

which can be solved with respect to $\delta\hat{f}_i$ to give $\delta\hat{f}_i = -v_{-i}\hat{g}_i$. This is in agreement with the change in the mode equation (38) we found above. The variance term can be derived with a related linear response argument (Opper and Winther, 2000).

B. Computational Complexities

We summarize here the computational complexities of different methods in the paper. We first summarize the computational complexities of the Laplace method, expectation propagation, and marginal approximations used to obtain the full data posterior and its marginals. Then we summarize the additional computational complexities of the LOO methods. The related practical speed comparison results are shown in Appendix C.

The computational complexity for both the Laplace method and EP for GLVMs is dominated by matrix computations related to the covariance or precision matrix. We denote this basic cost as c_{basic}. For GLVMs with a full rank dense covariance matrix (such as Gaussian processes used in Section 4), c_{basic} scales with n^3. For reduced rank approximations in Gaussian processes such as FITC (Quiñonero-Candela and Rasmussen, 2005), c_{basic} scales with m^2n, where $m \ll n$ is the reduced rank (affecting the flexibility of GP). For sparse precision (in Gaussian Markov random field models (see, e.g., Rue et al., 2009)) or covariance matrices (in compact support covariance function GPs (see, e.g., Vanhatalo and Vehtari, 2008)), c_{basic} scales with n^2_{nonzeros}, where $n < n_{\text{nonzeros}} < n^2/2$ is the number of non-zeros in the precision, covariance, or Cholesky matrix (see more detailed analysis of sparse GLVMs in Cseke and Heskes, 2011).

For fixed ϕ and θ, the computation of the conditional posterior and marginal likelihoods scales for the Laplace method with $n^{\text{Newton}}_{\text{steps}} \times c_{\text{basic}}$ and for EP with $n^{\text{EP}}_{\text{steps}} \times (c_{\text{basic}} + n \times n_{\text{quad}})$, where n_{quad} is the number of potential quadrature evaluations to compute moments (for a probit classification model the moments can be computed in closed form).

Method	Additional computational complexity
EP-LOO	0
LA-LOO	$n \times n_{\text{quad}}$
(T)Q-LOO-LA/EP-G	$n \times n_{\text{quad}}$
WAIC$_{G/V}$-LA/EP-G/L	$n \times n_{\text{quad}}$
(T)Q-LOO-EP-FACT	$n^2 \times n_{\text{quad},1} \times n_{\text{quad},2}$
WAIC$_{G/V}$-EP-FACT	$n^2 \times n_{\text{quad},1} \times n_{\text{quad},2}$
(T)Q-LOO-LA-CM2	$n \times c_{\text{basic}} \times n_{\text{quad}}$
WAIC$_{G/V}$-LA-CM2	$n \times c_{\text{basic}} \times n_{\text{quad}}$
Exact brute force LOO EP	$n \times (n^{\text{EP}}_{\text{steps}} \times (c_{\text{basic}} + n \times n_{\text{quad}}))$
Exact brute force LOO Laplace	$n \times (n^{\text{Newton}}_{\text{steps}} \times c_{\text{basic}} + n_{\text{quad}})$

Table 11: Additional computational complexity of LOO methods for fixed θ and ϕ after obtaining the full posterior approximation with the Laplace method or EP.

After the last step of the Newton or EP algorithm, the additional computational complexities for different LOO methods are shown in Table 11. EP-LOO has zero additional complexity as the LOO log predictive density is computed as part of the algorithm. LA-LOO and methods using Gaussian marginals require n quadrature integrals to obtain log predictive densities and thus have negligible additional complexity. EP-FACT and LA-CM2 based methods have significantly larger additional complexity. The additional complexity of EP-FACT based methods scale with $n^2 \times n_{\text{quad},1} \times n_{\text{quad},2}$, where $n_{\text{quad},1}$ and $n_{\text{quad},2}$ refer to two different quadratures in the method. The additional complexity of LA-CM based methods scale with $n \times c_{\text{basic}} \times n_{\text{quad}} > n^3 \times n_{\text{quad}}$, which can be more than the complexity for the conditional posterior.

The computational complexity for the Type II MAP solution is the computational complexity of forming the conditional posterior given θ and ϕ times the number of marginal posterior evaluations in optimisation. The additional computation to obtain LOO after Type II MAP is the computation of LOO with fixed θ and ϕ.

The computational complexity for integration over the marginal posterior of θ and ϕ is the computational complexity of forming the conditional posterior given θ and ϕ times the number of marginal posterior evaluations in the (deterministic or stochastic) algorithm forming the posterior approximation. The additional computation for LOO requires the computation of LOO with fixed θ and ϕ for each point in the final marginal posterior approximation and computation of importance weights which has a negligible additional cost.

C. Practical Speed Comparison

To further give some idea of the practical speed differences between the different algorithm implementations we show examples of computation times for computing the marginal likelihood and LOO given fixed θ and ϕ. The speed comparisons were run with a laptop (Intel Core i5-4300U CPU @ 1.90GHz x 4 + 8GB memory). As one of the reviewers was interested in comparison to global Gaussian variational method, we have included it in this speed comparison, verifying the previous results that it is much slower than EP (Nickisch and

				GPstuff		GPML

Ripley	250	2	probit	0.02	0.04	0.06	0.71	155
Australian	690	14	probit	0.13	0.40	0.26	10	704
Ionosphere	351	33	probit	0.05	0.13	0.08	1.7	516
Sonar	208	60	probit	0.03	0.04	0.06	0.47	233
Leukemia	1043	4	log-logistic w. cens.	0.18	3.5	NA[3]	NA[3]	NA[3]
Boston	506	13	Student's t	1.1[4]	1.1	NA[5]	NA[6]	39[7]

Table 12: Time (in seconds) to compute the posterior and marginal likelihood with fixed hyperparameters. [1]GPstuff uses parallel EP (van Gerven et al., 2009) except for Student's t parallel robust-EP (Jylänki et al., 2011) is used. [2]GPML uses random order sequential EP (Rasmussen and Williams, 2006). [3]GPML does not have log-logistic model with censoring. [4]For Student's t Laplace-EM method (Vanhatalo et al., 2009) was used. [5]The GPML's Laplace inference algorithm did run without errors, but the results were really bad (difference in LOO-LPD 1.4e4). [6]GPML does not support EP for non-log-concave likelihoods. [7]For Student's t the performance of global Gaussian variational (KL) method was much worse than the performance of Laplace-EM and EP (difference in LOO-LPD 147)

Rasmussen, 2008). As GPstuff does not have the global Gaussian variational approximation, we use the KL method in GPML toolbox (Rasmussen and Nickisch, 2010) to compute that. To take into account potential general speed differences between GPstuff and GPML we also timed GPML Laplace and EP methods. Computations were timed several times so that caching of the previous computations were not used.

Table 12 shows the time to compute the latent posterior and marginal likelihood with fixed hyperparameters. In optimization (or gradient based MCMC), the computation of gradients would have additional computational cost. When hyperparameters are integrated out, the approximative computation time is these multiplied by the number of unique parameter values evaluated when obtaining the marginal posterior samples (there are additional overheads and potential speed-ups). For probit, where the moments required in EP can be computed analytically, GPstuff-EP is about 1.5–5 times slower than GPstuff-LA. For log-logistic with censoring GPstuff-EP is about 18 times slower due to slow quadrature based moment computations (which could be made faster). For the Student's t model GPstuff-LA and GPstuff-EP have similar performance, as the robust Laplace-EM method by Vanhatalo et al. (2009) is slower than basic Laplace approximation. GPstuff-LA and GPML-LA have quite similar speed, GPstuff being slightly faster. GPstuff-EP is 10-25 times faster than GPML-EP, which is probably due to using parallel updates and better vectorization allowed by parallel updates. GPstuff has robust-EP implementation which also works for non-log-concave likelihoods such as Student's t. Although KL has the same $O(n^3)$ computational scaling as EP, its computational overhead makes GPML-KL 70-500 times slower than GPML-EP.

Table 13 shows time to compute the LOO for fixed parameters after the full posterior has been computed (see Table 12). When hyperparameters are integrated out, the approximative computation time is these multiplied by the number of parameter samples approximating

Table 13: Time (in seconds) to compute LOO for fixed parameters after the full posterior has been computed. Here Q-LOO computations also include the time to compute the marginal corrections (LA-CM2 and EP-FACT).

the marginal posterior. There is no added computational cost of going from EP to EP-LOO and the time is spent retrieving the stored result. The computational cost of LA-LOO is computing cavity distributions and one quadrature. Here Q-LOO computations also include the time to compute the marginal corrections (LA-CM2 and EP-FACT), which make them much slower.

Abstract

In many fields one encounters the challenge of identifying out of a pool of possible designs those that simultaneously optimize multiple objectives. In many applications an exhaustive search for the Pareto-optimal set is infeasible. To address this challenge, we propose the ϵ-*Pareto Active Learning* (ϵ-PAL) algorithm which adaptively samples the design space to predict a set of Pareto-optimal solutions that cover the true Pareto front of the design space with some granularity regulated by a parameter ϵ. Key features of ϵ-PAL include (1) modeling the objectives as draws from a Gaussian process distribution to capture structure and accommodate noisy evaluation; (2) a method to carefully choose the next design to evaluate to maximize progress; and (3) the ability to control prediction accuracy and sampling cost. We provide theoretical bounds on ϵ-PAL's sampling cost required to achieve a desired accuracy. Further, we perform an experimental evaluation on three real-world data sets that demonstrate ϵ-PAL's effectiveness; in comparison to the state-of-the-art active learning algorithm PAL, ϵ-PAL reduces the amount of computations and the number of samples from the design space required to meet the user's desired level of accuracy. In addition, we show that ϵ-PAL improves significantly over a state-of-the-art multi-objective optimization method, saving in most cases 30% to 70% evaluations to achieve the same accuracy.

Keywords: multi-objective optimization, active learning, pareto optimality, Bayesian optimization, design space exploration

1. Introduction

A fundamental challenge in many problems in engineering and other domains is to find the right balance amongst several objectives. As a concrete example, in hardware design, one often has to choose between different candidate designs that trade multiple objectives

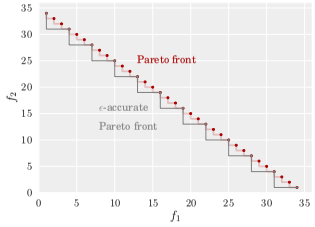

Figure 1: Assume that two objective functions are to be maximized simultaneously. This figure shows an example of the true Pareto front of a design space contrasted with an ϵ-accurate Pareto front, with $\epsilon = (3, 3)$.

such as energy consumption, throughput, or chip area. Usually there is not a single design that excels in all objectives, and therefore one may be interested in identifying all (Pareto-)optimal designs. Furthermore, often in these domains, evaluating the objective functions is expensive and noisy. In hardware design, for example, synthesis of only one design can take hours or even days. The fundamental problem addressed in this paper is how to predict a Pareto-optimal set at low cost, i.e., by evaluating as few designs as possible.

In this paper we propose a solution for finite design spaces that we call the ϵ-*Pareto Active Learning* (ϵ-PAL) algorithm. The parameter ϵ allows users to control the accuracy of the prediction produced by the algorithm. This accuracy is defined in terms of the density or granularity of the estimated Pareto front that is returned. Decreasing granularity means the algorithm can discard more points along its execution. Fewer Pareto points are returned, but spread to offer a wide range of trade-offs in the objective space.

More specifically, the granularity is controlled by a vector ϵ, containing one value per objective, which is given in the same units as the corresponding objective function. It specifies that for the user a difference of ϵ in the objective space is negligible. Accordingly, an ϵ-accurate Pareto front might have fewer points than the true Pareto front. Fig. 1 visualizes this idea for two objective functions that are to be maximized simultaneously. The true Pareto-front is shown in red, and an ϵ-accurate Pareto front, which contains fewer points, is shown in grey. While the true Pareto front of a design space is unique, there can be many ϵ-accurate Pareto fronts; finding one of them efficiently is our goal.

ϵ-PAL has several key features. In the spirit of Bayesian optimization, it captures domain knowledge about the regularity of the design space by using Gaussian process (GP) models to predict objective values for designs that have not been evaluated yet. Further, it uses the predictive uncertainty associated with these nonparametric models in order to guide the iterative sampling. Specifically, ϵ-PAL's sampling strategy aims to maximize progress on designs that are likely to be Pareto-optimal. ϵ-PAL iteratively discards points that are either redundant or suboptimal, and it terminates when no more points can be removed in order to guarantee that, with high probability, the remaining points define an ϵ-accurate Pareto set of the given design space.

A main contribution of this paper is the theoretical performance analysis of ϵ-PAL, that provides bounds on the sampling cost required to achieve a desired accuracy. These bounds depend on the parameter ϵ and on the characteristics of the covariance function used for the GP models. Finally, we carry out an extensive empirical evaluation, where we demonstrate ϵ-PAL's effectiveness on several real-world multi-objective optimization problems. Two cases are from different applications in the domain of hardware design, in which it is very expensive to run low level synthesis to obtain the exact cost and performance of a single design (Zuluaga et al., 2012b; Almer et al., 2011). The third application is from software optimization, where different compilation settings are evaluated for performance and memory footprint size (Siegmund et al., 2012).

We compare the performance of ϵ-PAL against PAL, a predecessor of ϵ-PAL proposed by Zuluaga et al. (2013), and with another state-of-the-art multi-objective optimization method called ParEGO, proposed by Knowles (2006). Across all data sets and almost all desired accuracies, ϵ-PAL outperforms ParEGO, requiring in most cases 30% to 70% less function evaluations. In comparison to PAL, our experiments show that ϵ-PAL reduces the runtime by one to two orders of magnitude, while also reducing the number of evaluations and offering more flexibility in the desired error.

1.1 Main Contributions

Our main contributions are summarized as follows.

- We propose ϵ-PAL, an active learning approach towards identifying a set of optimal solutions in a given multi-objective optimization problem in which function evaluations are expensive. This includes sampling strategy and stopping criteria. ϵ-PAL allows users to specify the desired level of granularity through the parameter ϵ, and guarantees that with high probability an ϵ-accurate Pareto front is returned.
- We theoretically analyze ϵ-PAL when the design space is a finite set, and the objective functions satisfy regularity assumptions as specified via a positive definite kernel. We provide bounds on the number of iterations required by the algorithm to achieve a desired target accuracy.
- In comparison to the state-of-the-art algorithm PAL, ϵ-PAL reduces the asymptotic complexity of the number of computations performed in each iteration, making it more suitable for larger design spaces.
- We perform an extensive experimental evaluation to demonstrate ϵ-PAL's effectiveness and superiority over PAL and ParEGO on three real-world multi-objective optimization problems.

1.2 Organization

In Section 2, we introduce background concepts such as multi-objective optimization, Pareto optimality, ϵ-accurate Pareto optimality, and Gaussian processes. In addition, we formally define the problem tackled in this paper. Section 3 presents the proposed algorithm ϵ-PAL, explains the stages that take place during its execution, and analyzes run time. In

Section 4, we present the theoretical analysis of the algorithm and provide upper bounds for the number of samples needed before ϵ-PAL terminates, when the target functions have bounded RKHS norm. Section 5 discusses some implementation issues that might arise in practice when using our algorithm. Section 6 reviews related work in the areas of multi-objective optimization, Bayesian optimization and evolutionary algorithms. Section 7 shows the effectiveness of ϵ-PAL in comparison with state-of-the-art alternative algorithms, using three data sets obtained from real applications. In the Appendix, we prove our main Theorem, which is stated in Section 4.

2. Background and Problem Statement

In this section, we review multi-objective optimization and Pareto optimality, and introduce the terminology and notation used in the rest of the paper. At the end of the section, we formally define the problem addresses by ϵ-PAL.

2.1 Multi-Objective Optimization

We consider a multi-objective optimization problem over a finite set E (called the *design space*). This means that we wish to simultaneously optimize m objective functions $f_1, \ldots, f_m : E \to \mathbb{R}$. In our analysis, we assume that $f_1(\boldsymbol{x}), \ldots, f_m(\boldsymbol{x})$ are to be maximized, however our results straightforwardly generalize to a minimization or a combined minimization/maximization problem. We use the notation $\boldsymbol{f}(\boldsymbol{x}) = (f_1(\boldsymbol{x}), \ldots, f_m(\boldsymbol{x}))$ to refer to the vector of all objectives evaluated on the input $\boldsymbol{x}$. The *objective space* is the image $\boldsymbol{f}(E) \subset \mathbb{R}^m$.[1]

2.2 Pareto Optimality

The goal in multi-objective optimization is to identify[2] the *Pareto set* of E. Formally, we consider the canonical partial order in $\mathbb{R}^m$: $\boldsymbol{y} \succeq \boldsymbol{y}'$ iff $y_i \geq y'_i$, $1 \leq i \leq m$, and define the induced relation on E: $\boldsymbol{x} \succeq \boldsymbol{x}'$ iff $\boldsymbol{f}(\boldsymbol{x}) \succeq \boldsymbol{f}(\boldsymbol{x}')$. We say that $\boldsymbol{x}$ dominates $\boldsymbol{x}'$ in this case. Note that $\succeq$ on E is not a partial order, but only a preorder, since it lacks antisymmetry (i.e., two different designs can have the same objectives).

Definition 1 (Pareto set) *The Pareto set $\Pi(\boldsymbol{f}(E)))$ in the objective space $\boldsymbol{f}(E) \subset \mathbb{R}^m$ is, as usual, the set of maximal points. Further, we call any set $\Pi(E) \subseteq E$ a Pareto set of E if it satisfies*

$$\boldsymbol{f}(\Pi(E)) = \Pi(\boldsymbol{f}(E))).$$

In words, $\Pi(E)$ is any set of designs that yields all optimal objectives. It is not unique since $\succeq$ on E is not antisymmetric.

1. Scalars and functions that return scalars are written unbolded; tuples and vectors are boldfaced.
2. Note that one may also approach multi-objective optimization via scalarization, see, e.g., Roijers et al. (2013). In our approach, we focus on retrieving an approximate Pareto-frontier, so that we do not have to commit to a particular family of scalarization functions.

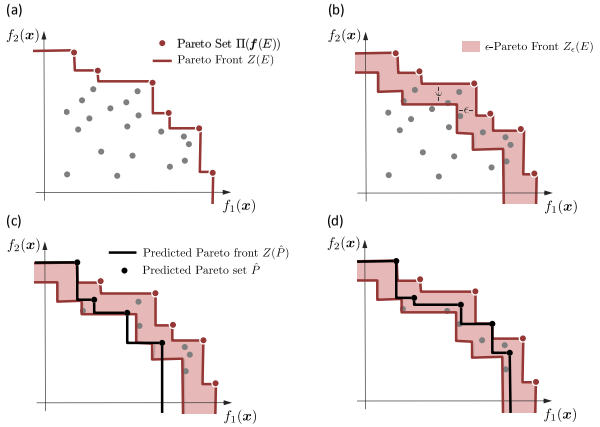

Figure 2: (a) Example of Pareto set and Pareto front for $m = 2$. (b) Example of an $\boldsymbol{\epsilon}$-Pareto front for $m = 2$. (c) Example of a predicted Pareto set that is not ϵ-accurate. (d) Example of a predicted Pareto set that is ϵ-accurate.

Definition 2 (Pareto front) *We define the Pareto front $Z(E)$ as the set of points in $\mathbb{R}^m$ that constitutes the surface of the space dominated by the Pareto set $\Pi(\boldsymbol{f}(E))$. Formally,*

$$Z(E) = \partial\{\boldsymbol{y} \in \mathbb{R}^m : \text{ there is an } \boldsymbol{x} \in E \text{ with } \boldsymbol{f}(\boldsymbol{x}) \succeq \boldsymbol{y})\}. \tag{1}$$

Hereby, the operator ∂ applied to a set Y denotes the boundary of Y.

Fig. 2(a) visualizes the concepts of Pareto set and Pareto front for $m = 2$.

2.3 $\boldsymbol{\epsilon}$-Pareto Optimality

We now relax the relation $\succeq$ in $\mathbb{R}^m$ and E for the purpose of our algorithm by adding a small tolerance. Consider a vector $\boldsymbol{\epsilon} = (\epsilon_1, \ldots, \epsilon_d)$, with $\epsilon_i \geq 0$, $1 \leq i \leq m$. We say that a point $\boldsymbol{y} \in \mathbb{R}^m$ $\boldsymbol{\epsilon}$-dominates $\boldsymbol{y}'$, written as $\boldsymbol{y} \succeq_\epsilon \boldsymbol{y}'$, if $\boldsymbol{y} + \boldsymbol{\epsilon} \succeq \boldsymbol{y}'$. As before, we pull the relation to E: $\boldsymbol{x} \succeq_\epsilon \boldsymbol{x}'$ iff $\boldsymbol{f}(\boldsymbol{x}) \succeq_\epsilon \boldsymbol{f}(\boldsymbol{x}')$. Note that this relation is neither a partial order nor a preorder: antiysmmetry and transitivity do not hold.

We use this relation next to define an appropriate notion of $\boldsymbol{\epsilon}$-accurate Pareto set. To do so we first need two auxiliary definitions.

Definition 3 ($\boldsymbol{\epsilon}$-Pareto front) *We define the $\boldsymbol{\epsilon}$-Pareto front $Z_\epsilon(E)$ of E as the set of points between $Z(E)$ and $Z(E) - \boldsymbol{\epsilon}$, including the boundaries. Formally,*

$$Z_\epsilon(E) = \{\boldsymbol{y} \in \mathbb{R}^m : \boldsymbol{y}' \succeq \boldsymbol{y} \text{ for some } \boldsymbol{y}' \in Z(E) \text{ and } \boldsymbol{y} \succeq_\epsilon \boldsymbol{y}'' \text{ for some } \boldsymbol{y}'' \in Z(E)\}$$

Fig. 2(b) shows the $\boldsymbol{\epsilon}$-Pareto front associated with Fig. 2(a).

Definition 4 ($\boldsymbol{\epsilon}$-Pareto front covering) *We say that a nonempty set $C \subseteq Z_\epsilon(E)$ covers $Z_\epsilon(E)$, if for every point $\boldsymbol{y} \in Z_\epsilon(E)$ there is at least one point $\boldsymbol{y}' \in C$ s.t. $\boldsymbol{y}' \succeq_\epsilon \boldsymbol{y}$.*

In words, Definition 4 requires that the Pareto front spanned by $\Pi(C)$ is contained in $Z_\epsilon(E)$.

Definition 5 ($\boldsymbol{\epsilon}$-Accurate Pareto set) *We call a set of points $\Pi_\epsilon(E) \subseteq E$ an $\boldsymbol{\epsilon}$-accurate Pareto set of E, if $\boldsymbol{f}(\Pi_\epsilon(E))$ covers $Z_\epsilon(E)$.*

In words, for an $\boldsymbol{\epsilon}$-accurate Pareto set, the associated front is contained in the $\boldsymbol{\epsilon}$-Pareto front $Z_\epsilon(E)$ and it contains no suboptimal designs. As examples, the set with objectives $\hat{P}$ in Fig. 2(c) does not satisfy this property, but in Fig. 2(d) it does. Note that the $\boldsymbol{\epsilon}$-accurate Pareto set may have fewer points than the actual Pareto set.

An $\boldsymbol{\epsilon}$-accurate Pareto set $\Pi_\epsilon(E)$ is a natural approximate substitute of the original set E. Having access to it, one can rest assured that for any point on the Pareto front $Z(E)$ associated with E, there is some element $\boldsymbol{x} \in \Pi_\epsilon(E)$ which is at most ϵ worse according to all of the objectives. The high level goal of our algorithm $\boldsymbol{\epsilon}$-PAL is to find, with few evaluations $\boldsymbol{f}(\boldsymbol{x})$, a small $\boldsymbol{\epsilon}$-accurate Pareto set of E.

2.4 Gaussian Processes (GP)

$\boldsymbol{\epsilon}$-PAL models $\boldsymbol{f}$ as a draw from an m-variate Gaussian process (GP) distribution. A GP distribution over a real function $f(\boldsymbol{x})$ is fully specified by its mean function $\mu(\boldsymbol{x})$ and its covariance function $k(\boldsymbol{x}, \boldsymbol{x}')$ (Rasmussen and Williams, 2006). The *kernel* or covariance function k captures regularity in the form of the correlation of the marginal distributions $f(\boldsymbol{x})$ and $f(\boldsymbol{x}')$.

In our multi-objective setting, we model each objective function $f_i(\boldsymbol{x})$ as a draw from an independent[3] GP distribution.

On every iteration t in our algorithm we choose a design $\boldsymbol{x}_t$ to evaluate, which yields a noisy sample[4] $y_{t,i} = f_i(\boldsymbol{x}_t) + \nu_{t,i}$; after T iterations we have a vector $\boldsymbol{y}_{T,i} = (y_{1,i}, \ldots, y_{T,i})$. Assuming $\nu_{t,i} \sim N(0, \sigma^2)$ (i.i.d. Gaussian noise), the posterior distribution of f_i is a Gaussian process with mean $\mu_{T,i}(\boldsymbol{x})$, covariance $k_{T,i}(\boldsymbol{x}, \boldsymbol{x}')$, and variance $\sigma^2_{T,i}(\boldsymbol{x})$:

$$\mu_{T,i}(\boldsymbol{x}) = \boldsymbol{k}_{T,i}(\boldsymbol{x})^T (\boldsymbol{K}_{T,i} + \sigma^2 \boldsymbol{I})^{-1} \boldsymbol{y}_{T,i}, \tag{2}$$

$$k_{T,i}(\boldsymbol{x}, \boldsymbol{x}') = k_i(\boldsymbol{x}, \boldsymbol{x}') - \boldsymbol{k}_{T,i}(\boldsymbol{x})^T (\boldsymbol{K}_{T,i} + \sigma^2 \boldsymbol{I})^{-1} \boldsymbol{k}_{T,i}(\boldsymbol{x}'), \tag{3}$$

$$\sigma^2_{T,i}(\boldsymbol{x}) = k_{T,i}(\boldsymbol{x}, \boldsymbol{x}), \tag{4}$$

where $\boldsymbol{x}, \boldsymbol{x}' \in E$, $\boldsymbol{k}_{T,i}(\boldsymbol{x}) = (k_i(\boldsymbol{x}, \boldsymbol{x}_t))_{1 \leq t \leq T}$ and $\boldsymbol{K}_{T,i} = (k_i(\boldsymbol{x}_j, \boldsymbol{x}_\ell))_{1 \leq j, \ell \leq T}$. Note that this posterior distribution captures our uncertainty about $\boldsymbol{f}(\boldsymbol{x})$ for all points $\boldsymbol{x} \in E$.

2.5 Reproducing Kernel Hilbert Spaces (RKHS)

Using Gaussian processes to model the target functions f_i assumes that we know the prior from which they have been generated. This is rarely the case in practice. Therefore, for

3. Note that dependence amongst the outputs could be captured as well; e.g., Bonilla et al. (2008).
4. We use the term "sampling" to refer to evaluating a design via a noisy measurement.

our theoretical analysis we take a more agnostic approach in which we assume that f_i are arbitrary functions from the RKHS associated with kernel k.

The RKHS $\mathcal{H}_k(E)$ is a Hilbert space consisting of functions f on the domain E, endowed with an inner product $\langle \cdot, \cdot \rangle_k$ that satisfies the following properties with respect to a positive definite function k:

- For every $\boldsymbol{x} \in E$, $k(\boldsymbol{x}, \boldsymbol{x}')$ as a function of $\boldsymbol{x}'$ belongs to $\mathcal{H}_k(E)$.
- The reproducing property holds for k, i.e., $\langle f, k(\boldsymbol{x}, \cdot) \rangle_k = f(\boldsymbol{x})$.

The smoothness of the functions $f \in \mathcal{H}_k(E)$ with respect to k is encoded by the norm $||f||_k = \sqrt{\langle f, f \rangle_k}$. Functions with low norm are usually relatively smooth. In our case, as E is a finite set, any f is guaranteed to have bounded norm, i.e., $||f||_k < \infty$, as long as the kernel is universal (such as the Gaussian kernel).

2.6 Problem Statement

Let E be a finite set with a positive definite kernel. We wish to simultaneously optimize m objective functions $f_1, \ldots, f_m : E \to \mathbb{R}$, considering that evaluating $\boldsymbol{f}(\boldsymbol{x})$ for any $\boldsymbol{x} \in E$ is expensive. We wish to identify an $\boldsymbol{\epsilon}$-accurate Pareto set $\Pi_\epsilon(E) \subseteq E$ while minimizing the number of evaluations $\boldsymbol{f}(\boldsymbol{x})$.

In the following, we develop an active learning algorithm that iteratively and adaptively selects a sequence of designs $\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots$ to be evaluated, and that uses these evaluations along with the model's predictive uncertainty to predict an $\boldsymbol{\epsilon}$-accurate Pareto set of E. This iterative algorithm terminates when, with high probability, an $\boldsymbol{\epsilon}$-accurate Pareto set of E has been found, and therefore no more evaluations are needed. In addition, we theoretically analyze our algorithm and provide a bound on the number of evaluations required by the algorithm to generate an $\boldsymbol{\epsilon}$-accurate prediction.

3. $\boldsymbol{\epsilon}$-PAL Algorithm

In this section we describe our algorithm: $\boldsymbol{\epsilon}$-*Pareto Active Learning* ($\boldsymbol{\epsilon}$-PAL).

3.1 Overview

Our approach to predicting an $\boldsymbol{\epsilon}$-accurate Pareto set of E trains GP models on a small subset of E. The models predict the objective functions f_i, $1 \leq i \leq m$, allowing us to make statistical inferences about the Pareto-optimality of every point in E. The true value of $\boldsymbol{f}(\boldsymbol{x})$ is approximated by the models as $\hat{\boldsymbol{f}}(\boldsymbol{x}) = \boldsymbol{\mu}(\boldsymbol{x}) = (\mu_i(\boldsymbol{x}))_{1 \leqslant i \leqslant m}$. Additionally $\boldsymbol{\sigma}(\boldsymbol{x}) = (\sigma_i(\boldsymbol{x}))_{1 \leqslant i \leqslant m}$ is interpreted as the uncertainty of this prediction. We capture this uncertainty through the hyper-rectangle[5]

$$Q_{\boldsymbol{\mu},\boldsymbol{\sigma},\beta}(\boldsymbol{x}) = \{\boldsymbol{y} : \boldsymbol{\mu}(\boldsymbol{x}) - \beta^{1/2}\boldsymbol{\sigma}(\boldsymbol{x}) \preceq \boldsymbol{y} \preceq \boldsymbol{\mu}(\boldsymbol{x}) + \beta^{1/2}\boldsymbol{\sigma}(\boldsymbol{x})\}, \tag{5}$$

where β is a scaling parameter to be chosen later.

The goal of the algorithm is to return a set $\hat{P} \subseteq E$ such that, with high probability, $\hat{P}$ is an $\boldsymbol{\epsilon}$-accurate Pareto set of E. $\hat{P}$ may contain points that are not sampled yet, but

5. conservatively bounding the ellipsoid with radii σ_i.

probabilistically, it is guaranteed to cover $Z_\epsilon(E)$, i.e., with high probability, all points in E are $\boldsymbol{\epsilon}$-dominated by a point in $\hat{P}$.

$\boldsymbol{\epsilon}$-PAL iterates over four stages: modeling, discarding, $\boldsymbol{\epsilon}$-Pareto front covering, and sampling. It stops when all remaining points have been either sampled, discarded or determined to belong to $Z_\epsilon(E)$ with high probability. The following sections explain each of these stages, and Alg. 1 presents the corresponding pseudocode.

The algorithm maintains two working sets, indexed by the iteration number t, starting at 0:

- U_t: undecided points, $U_0 = E$,
- P_t: points predicted to be members of an $\boldsymbol{\epsilon}$-accurate Pareto set of E, $P_0 = \emptyset$.

On the first iteration ($t = 0$), all points in E are copied to a set U_0. Subsequently, on any iteration t, a point to be sampled is chosen from U_t or P_t. Points in U_t that with high probability are $\boldsymbol{\epsilon}$-dominated by another point are discarded, i.e., removed from U_t, and points that are determined to belong to $Z_\epsilon(E)$ are moved from U_t to set P_t. The algorithm terminates at some iteration T when U_T is empty. Then $\hat{P} = P_T$ is returned. $\boldsymbol{\epsilon}$-PAL guarantees that with high probability $\hat{P}$ is an $\boldsymbol{\epsilon}$-accurate Pareto set of E.

3.2 Modeling

$\boldsymbol{\epsilon}$-PAL uses Gaussian process inference to predict the mean vector $\boldsymbol{\mu}_t(\boldsymbol{x})$ and the standard deviation vector $\boldsymbol{\sigma}_t(\boldsymbol{x})$ of any point $\boldsymbol{x} \in E$ that has not been discarded yet. This prediction is generated based on the noisy samples obtained. Each point $\boldsymbol{x} \in P_t \cup U_t$ is then assigned its *uncertainty region*, which is the hyperrectangle

$$R_t(\boldsymbol{x}) = R_{t-1}(\boldsymbol{x}) \cap Q_{\boldsymbol{\mu}_t,\boldsymbol{\sigma}_t,\beta_{t+1}}(\boldsymbol{x}), \tag{6}$$

where β_{t+1} is a positive value that defines how large this region is in proportion to $\boldsymbol{\sigma}_t$. In Section 4 we will suggest a value for this parameter. The iterative intersection ensures that all uncertainty regions are non-increasing with t. Intuitively, for a point $\boldsymbol{x} \in E$ that has not been evaluated yet, we can say that with high probability $\boldsymbol{f}(\boldsymbol{x}) \in R_t(\boldsymbol{x})$.

Within $R_t(\boldsymbol{x})$, the pessimistic and optimistic outcomes are $\min(R_t(\boldsymbol{x}))$ and $\max(R_t(\boldsymbol{x}))$, respectively, both taken in the partial order $\preceq$ and unique. Fig. 3(a) shows this with an example. Notice that points that have been evaluated also have an uncertainty region, since we only have access to noisy samples on those points.

3.3 Discarding

The goal of this stage is to discard points in U_t that with high probability are $\boldsymbol{\epsilon}$-dominated by another point in E, while making sure that at least one of such dominating points ends up in P_T.

Under uncertainty, a point $\boldsymbol{x}$ is $\boldsymbol{\epsilon}$-dominated by another point $\boldsymbol{x}'$, with high probability, if the pessimistic outcome of $\boldsymbol{x}'$ ($\min(R_t(\boldsymbol{x}'))$) $\boldsymbol{\epsilon}$-dominates the optimistic outcome of $\boldsymbol{x}$ ($\max(R_t(\boldsymbol{x}))$):

$$\max(R_t(\boldsymbol{x})) \preceq_\epsilon \min(R_t(\boldsymbol{x}')).$$

In this case, $\boldsymbol{x}$ can be discarded, i.e., removed from U_t.

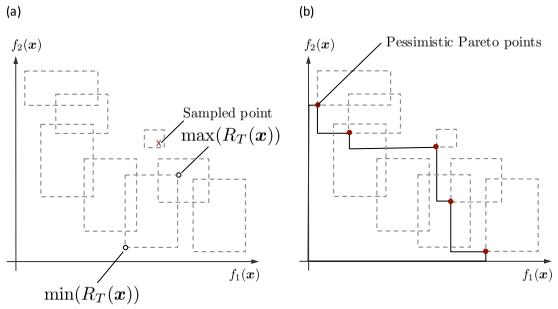

Figure 3: (a) Example of $\min(R_t(\boldsymbol{x}))$ and $\max(R_t(\boldsymbol{x}))$ for $m = 2$. (b) Example of a set of pessimistic Pareto points for $m = 2$.

If this relationship does not hold, either the uncertainty regions are still too large to draw any conclusions, or $\boldsymbol{x}$ and $\boldsymbol{x}'$ are not comparable.

To check if a point is $\boldsymbol{\epsilon}$-dominated by another one in E, $\boldsymbol{\epsilon}$-PAL compares its relationship with all *pessimistic Pareto points*.

Definition 6 (Pessimistic Pareto set) *For a subset $D \subseteq E$, we define $p_{pess}(D)$, or the* pessimistic Pareto set *of D, as the set of points $\boldsymbol{x} \in D$ for which there is no other point $\boldsymbol{x}' \in D$ such that*

$$\min(R_t(\boldsymbol{x})) \preceq \min(R_t(\boldsymbol{x}')).$$

Fig. 3(b) illustrates this situation.

We discard any point $\boldsymbol{x} \in U_t \setminus p_{\text{pess}}(P_t \cup U_t)$ if $\boldsymbol{x} \preceq_\epsilon \boldsymbol{x}'$ for some $\boldsymbol{x}' \in p_{\text{pess}}(P_t \cup U_t)$. This ensures that no element in $p_{\text{pess}}(S_t \cup P_t \cup U_t)$ is discarded and therefore, for every point that is discarded there will always be a point in the working sets that $\boldsymbol{\epsilon}$-dominates it.

A point in $p_{\text{pess}}(P_t \cup U_t)$ is only discarded if it is $\boldsymbol{\epsilon}$-dominated by any point in P_t, since all points in P_t are already guaranteed to belong to the returned set $\hat{P}$. Points in P_t are never discarded.

3.4 $\boldsymbol{\epsilon}$-Pareto Front Covering

The goal of $\boldsymbol{\epsilon}$-PAL is to empty U_t as fast as possible, i.e., with the least amount of points sampled and with the least amount of points in P_t needed to cover the $\boldsymbol{\epsilon}$-Pareto front of E. As previously stated, a point is moved to P_t if it can be determined that with high probability it belongs to $Z_\epsilon(E)$.

Therefore, care must be taken not to sample when all points in U_t can be either discarded or moved to P_t. If there is at least one point in U_t that cannot be discarded or moved to P_t, we proceed with sampling.

Definition 7 ($\boldsymbol{x}$ belongs to $\boldsymbol{Z_\epsilon(E)}$ with high probability) *We can determine that with high probability $\boldsymbol{x} \in E$ belongs to $Z_\epsilon(E)$ if there is no other point $\boldsymbol{x}' \in P_t \cup U_t$ such that*

$$\max(R_t(\boldsymbol{x}')) \succeq_\epsilon \min(R_t(\boldsymbol{x})).$$

In this stage we attempt to update the set P_t, to make progress in covering the $\boldsymbol{\epsilon}$-Pareto front of E, until we find a point in U_t that cannot be moved to P_t. After a point is moved to P_t, we check what points in U_t are $\boldsymbol{\epsilon}$-dominated by it, and therefore can be discarded. Details on this procedure can be found in Alg. 1.

3.5 Sampling

As long as $U_t \neq \emptyset$, on each iteration, a new point $\boldsymbol{x}_t$ is selected for sampling with the following selection rule. Each point $\boldsymbol{x} \in U_t \cup P_t$ is assigned a value

$$w_t(\boldsymbol{x}) = \max_{\boldsymbol{y}, \boldsymbol{y}' \in R_t(\boldsymbol{x})} ||\boldsymbol{y} - \boldsymbol{y}'||_2,$$

which is the diameter of its uncertainty region $R_t(\boldsymbol{x})$. Amongst these points, the one with the largest $w_t(\boldsymbol{x})$ (i.e., most uncertain) is chosen as the next sample $\boldsymbol{x}_t$ to be evaluated. We refer to $w_t(\boldsymbol{x}_t)$ as $\overline{w}_t$. Note that our approach does not simply pick the most uncertain point over the whole space E, but only over the set $U_t \cup P_t$, i.e., the points that (in a statistically plausible manner) might be useful in constructing an $\boldsymbol{\epsilon}$-accurate Pareto set. This is similar to exploration–exploitation tradeoffs commonly encountered in Bayesian optimization.

3.6 Stopping Criteria

The iterations terminate at $t = T$ when $U_T = \emptyset$, i.e., all points have been either moved to P_T or have been discarded. The predicted set $\hat{P} = P_T$ is guaranteed to be an $\boldsymbol{\epsilon}$-accurate Pareto set of E. Termination occurs at the latest when $\overline{w}_t \leq \epsilon$. In this case, dominated points can be discarded in one pass.

3.7 Analysis of Execution Time

In this section, we review the most time consuming subroutines of $\boldsymbol{\epsilon}$-PAL and analyze their computational cost, which depends on the number of points in the working sets: $n_t = |U_t| + |P_t|$. While $n_0 = |E|$ in the first iteration, discarded points are removed from the working sets and thus the number of computations is reduced as t increases. As it is not possible to make conclusions in how n_t decreases with t, we assume the upper bound $n = |E|$. In practice, the number of computations is much lower for most iterations of the algorithm. On the other hand, we assume that the number m of objective functions is a small constant.

In the modeling stage, $\boldsymbol{\epsilon}$-PAL updates Gaussian process models and evaluates the prediction μ and the uncertainty σ for every point. Let s be the number of points that have been sampled, the complexity of this step is $O(s^3 + ns^2)$ (Rasmussen and Williams, 2006). Note that typically $s \ll n$.

In the discarding stage, $\boldsymbol{\epsilon}$-PAL first finds the Pareto pessimistic points of a set. The problem of efficiently determining the Pareto points (or maxima) of a set of vectors is

Algorithm 1 The $\boldsymbol{\epsilon}$-PAL algorithm

Input: design space E ($|E| = n$); GP prior $\mu_{0,i}, \sigma_0, k_i$ for all $1 \leq i \leq n$; $\boldsymbol{\epsilon}$; β_t for $t \in \mathbb{N}$
Output: predicted Pareto set $\hat{P}$

$P_0 = \emptyset$ {predicted set}, $U_0 = E$ {undecided set}
$R_0(\boldsymbol{x}) = \mathbb{R}^n$ for all $\boldsymbol{x} \in E$, $t = 1$

addressed by Kung et al. (1975). For $m = 2$, their algorithm starts by ordering the list of vectors in the first dimension f_1. Then, the list is traversed in ascending order while discarding the vectors for which the second dimension f_2 is smaller than the greatest value

of f_2 seen so far. This procedure exhibits computational complexity of $O(n \log n)$ for $m = 2$. The same computational complexity is achieved by a similar implementation for $m = 3$. For $m > 3$, Kung et al. (1975) presents a divide and conquer algorithm with worst case asymptotic complexity of $O(n(\log n)^{m-2}) + O(n \log n)$.

In the discarding stage, $\boldsymbol{\epsilon}$-PAL also discards points in a set U that are $\boldsymbol{\epsilon}$-dominated by a set p_{pess}. This means that, if done naively, every point $\max(\boldsymbol{x})$ with $\boldsymbol{x} \in U$ must be compared with every $\min(\boldsymbol{x}') + \boldsymbol{\epsilon}$ with $\boldsymbol{x}' \in p_{\text{pess}}$. However, this can be done by adapting the above mentioned implementations to compute the Pareto points of a set of vectors to substantially reduce the runtime of the algorithm. Alg. 2 shows the pseudocode for this adaptation. A joined set U' is created from points $\max(\boldsymbol{x})$ with $\boldsymbol{x} \in U$ and $\min(\boldsymbol{x}') + \boldsymbol{\epsilon}$ with $\boldsymbol{x}' \in p_{\text{pess}}$. This joint list is ordered with respect to the first dimension f_1. Then, the list is traversed in ascending order, but the maximum value of f_2 is only updated by a point that belongs to p_{pess}, and only points that belong to U can be discarded. For $m \geq 3$ the adaptation of the algorithm by Kung et al. (1975) is analogous.

In the $\boldsymbol{\epsilon}$-Pareto front covering stage, $\boldsymbol{\epsilon}$-PAL checks if a point $\boldsymbol{x}$ can be guaranteed to belong to $Z_\epsilon(E)$ according to Definition 7. This is done by comparing $\boldsymbol{x}$ with the rest of the points $\boldsymbol{x}'$ in the working sets, until a case in which $\min(R_t(\boldsymbol{x}')) + \boldsymbol{\epsilon} \preceq \max(R_t(\boldsymbol{x}))$ is found. The number of computations for this step is $O(n)$; in practice, however, it is much smaller than n for most iterations. This operation might be done several times per iteration, until no more points in U_t can be moved to P_t or $U_t = \emptyset$. The number of times is assumed to be much smaller than n.

The computational complexity of an iteration is therefore dependent on m and s. For $m = 2$ and $m = 3$ it is $O(ns^2 + s^3 + n \log n)$, and for $m > 3$ it is $O(n(\log n)^{m-2}) + O(ns^2 + s^3 + n \log n)$.

4. Correctness and Sample Complexity

So far we have left the parameter β_t undefined. In this section, we will choose a β_t that guarantees the correctness of the algorithm, and the number of iterations required to meet our bounds.

Of key importance in the convergence analysis is the effect of the regularity imposed by the kernel function k. In our analysis, this effect is quantified by the *maximum information gain* associated with the GP prior. Formally, we consider the information gain

$$I(\boldsymbol{y}_1 \dots \boldsymbol{y}_T; \boldsymbol{f}) = H(\boldsymbol{f}) - H(\boldsymbol{f} \mid \boldsymbol{y}_1 \dots \boldsymbol{y}_T),$$

i.e, the reduction of uncertainty on $\boldsymbol{f}$ caused by (noisy) observations of $\boldsymbol{f}$ on the T first sampled points. The crucial quantity governing the convergence rate is

$$\gamma_T = \max_{\boldsymbol{y}_1 \cdots \boldsymbol{y}_T} I(\boldsymbol{y}_1 \dots \boldsymbol{y}_T; \boldsymbol{f}),$$

i.e., the maximal reduction of uncertainty achievable by sampling T points. Intuitively, if the kernel k imposes strong regularity (smoothness) on $\boldsymbol{f}$, few samples suffice to gather much information about $\boldsymbol{f}$, and as a consequence γ_T grows sub-linearly (exhibits a strong diminishing returns effect). In contrast, if k imposes little regularity (e.g., is close to diagonal), γ_T grows almost linearly with T. Srinivas et al. (2010, 2012) established γ_T as

key quantity in bounding the regret in single-objective GP optimization. Here, we show that this quantity more broadly governs convergence in the much more general problem of predicting the Pareto-optimal set in multi-criterion optimization.

We obtain bounds on the number of iterations required when assuming that the target functions f_i, $0 \leq i \leq m$, lie in the RKHS $\mathcal{H}_k(E)$ corresponding to kernel $k(\boldsymbol{x}, \boldsymbol{x}')$, and that the noise ν_t is an arbitrary martingale difference sequence which has zero mean and is uniformly bounded by σ. Furthermore, in order to obtain the bounds, it is necessary to specify an upper bound[6] B on all $||f_i||_k$.

The following theorem constitutes our main theoretical result.

Theorem 1 *Assume that the true functions f_i lie in the RKHS $\mathcal{H}_k(E)$ corresponding to kernel $k(\boldsymbol{x}, \boldsymbol{x}')$, and that the noise ν_t has zero mean conditioned on the history and is bounded by σ almost surely. Let $\delta \in (0,1)$ and $||f_i||_k^2 \leq B$. Running $\boldsymbol{\epsilon}$-PAL with $\beta_t = 2B^2 + 300\gamma_t \log^3(m|E|t/\delta)$, prior $GP(0, k(\boldsymbol{x}, \boldsymbol{x}'))$ and noise $N(0, \sigma^2)$, the following holds with probability $1-\delta$.*

An $\boldsymbol{\epsilon}$-accurate Pareto set can be obtained after at most T iterations, where T is the smallest number satisfying

$$\sqrt{\frac{C_1 \beta_T \gamma_T}{T}} \geq \epsilon. \tag{7}$$

Here, $C_1 = 8/\log(1+\sigma^{-2})$, $\epsilon = ||\boldsymbol{\epsilon}||_\infty$, and γ_T depends on the type of kernel used.

This means that, with high probability, $\overline{w}_t$ is bounded by $O^*((B\sqrt{\gamma_T}+\gamma_T)/\sqrt{T})$. Note that in practice one might want to, in addition to *identifying* an $\boldsymbol{\epsilon}$-accurate Pareto front, seek to be sufficiently confident such that for all predicted Pareto points (i.e., points $\mathbf{x}$ in P_T in Algorithm 1) it holds that $w_T(\mathbf{x}) \leq \epsilon$. This requirement can be added to the stopping condition in Line 26 of Algorithm 1, and the same sample complexity of Theorem 1 holds.

4.1 Proof Outline

The above theorem implies that by specifying δ and a target accuracy $\boldsymbol{\epsilon}$, $\boldsymbol{\epsilon}$-PAL automatically stops when the target error is achieved with confidence $1-\delta$. Additionally, the theorem bounds the number of iterations T required to obtain this result.

Our strategy for the proof consists of four parts. First, Lemma 1 shows that $|f_i(\boldsymbol{x}) - \mu_{t-1,i}(x)| \leq \beta_t^{1/2}\sigma_{t-1,i}(\boldsymbol{x})$ for $1 \leq i \leq m$, $t \geq 1$, and for all $\boldsymbol{x} \in E$. Then, we analyze how $\overline{w}_t$ decreases with t. Subsequently, we relate $\boldsymbol{\epsilon}$ and $\overline{w}_t$ to ensure the termination of the algorithm. The last two parts are analyzed in Section 4.2. Finally, Lemma 8 supports the accuracy of the $\boldsymbol{\epsilon}$-PAL, given that the proper β_t value is used on every iteration t.

4.2 Reduction in Uncertainty

The first step of the proof is to show that with probability at least $1-\delta$, $\boldsymbol{f}(\boldsymbol{x})$ lies for all $\boldsymbol{x} \in E$ within the uncertainty region (see (5) and (6)):

$$R_t(\boldsymbol{x}) = Q_{\boldsymbol{\mu}_0, \boldsymbol{\sigma}_0, \beta_1}(\boldsymbol{x}) \cap \cdots \cap Q_{\boldsymbol{\mu}_t, \boldsymbol{\sigma}_t, \beta_{t+1}}(\boldsymbol{x}),$$

6. While in practice this might not be possible, a standard guess-and-doubling approach can be applied.

which is achieved by choosing $\beta_t = 2B^2 + 300\gamma_t \log^3(m|E|t/\delta)$.

Srinivas et al. (2010) showed that information gain can be expressed in terms of the predicted variances. Similarly, we show how the cumulative $\sum_{k=1}^{t} \overline{w}_k$ can also be expressed in terms of maximum information gain γ_t. Since the sampling rules used by $\boldsymbol{\epsilon}$-PAL guarantee that $\overline{w}_t$ decreases with t, we get the following bound for $\overline{w}_t$. With probability $\geq 1-\delta$,

$$\overline{w}_t \leq \sqrt{\frac{C_1 \beta_t \gamma_t}{t}} \text{ for all } t \geq 1, \tag{8}$$

where $C_1 = 8/\log(1+\sigma^{-2})$ and β_t is as before.

The proof is supported by Lemmas 1 to 5 found in the appendix of this paper. Key challenges and differences in comparison to Srinivas et al. (2010) include (1) dealing with multiple objectives; (2) the use of a different sampling criterion; and (3) incorporating the monotonic classification scheme.

We also show that, with probability $1-\delta$, the algorithm terminates with no further sampling at iteration T if

$$\overline{w}_T \leq \epsilon, \tag{9}$$

where $\epsilon = ||\boldsymbol{\epsilon}||_\infty = \max(\epsilon_i)_{1 \leq i \leq m}$. This is proved in Lemma 7.

4.3 Explicit Bounds for the Squared Exponential Kernel

Theorem 1 holds for general covariance functions $k(\boldsymbol{x}, \boldsymbol{x}')$. Srinivas et al. (2010) derived bounds for γ_T depending on the choice of kernel. These can be used to specialize Theorem 1.

We illustrate this using the squared exponential kernel as example, i.e., $k(\boldsymbol{x}, \boldsymbol{x}') = \exp\left(l^{-2}\|\boldsymbol{x} - \boldsymbol{x}'\|_2^2\right)$ for some $l > 0$.

Let $E \subset \mathbb{R}^d$ be compact and convex, $d \in \mathbb{N}$. According to Srinivas et al. (2010), for $m = 1$, there exists a constant K such that

$$\gamma_t \leq K \log^{d+1} t \text{ for all } t > 1.$$

For $m > 1$, since we assume i.i.d. GPs, we thus get

$$\gamma_t \leq Km \log^{d+1} t$$

and hence the following corollary to Theorem 1.

Corollary 1 *Let k_i be the squared exponential kernel used by $\boldsymbol{\epsilon}$-PAL, and assume f_i lies in the RKHS with its norm bounded by $||f_i||_k^2 \leq B$, for all $1 \leq i \leq m$. When choosing $\delta \in (0,1)$, a target accuracy specified by $\boldsymbol{\epsilon}$, the following holds with probability $1-\delta$. $\boldsymbol{\epsilon}$-PAL terminates after at most T iterations, where T is the smallest number satisfying*

$$\frac{\sqrt{16B^2K^2m\log^{d+1}T + 2400K^2m^2\log^{2(d+1)}T\log^3(m|E|T/\delta)}}{\sqrt{T\log(1+\sigma^{-2})}} \geq \epsilon.$$

These results suggests that, under both scenarios, ϵ increases as T decreases in the following manner: Asymptotically, for any $\rho > 0$, as well as fixed m, n and d, we have $T = O(\frac{1}{\epsilon^{2+\rho}})$.

5. Discussion and Implementation Details

We now discuss some of the limitations, choices made, and other aspects that arose when implementing and using our $\boldsymbol{\epsilon}$-PAL algorithm.

5.1 Sampling Strategy

After clearly non-competitive designs are removed in the discarding phase, our sampling strategy (Section 3.5) chooses the one with the highest uncertainty. Other choices would be possible, e.g, chosing the one that maximizes the expected gain in hypervolume. Our choice aims at reducing time to termination, which is achieved by reducing uncertainty in the model as fast as possible.

5.2 Parameterization

For practical usage, two parameters, namely $\boldsymbol{\epsilon}$ and δ, need to be specified. These parameters relate to the desired level of accuracy of the prediction. Our theoretical bounds are likely to be loose in practice; thus, it may be useful to choose more "aggressive" values than recommended by the theory. The choice of δ impacts the value of β_t and therefore the convergence rate of the algorithm, since the latter scales the uncertainty regions $R_t(\boldsymbol{x})$. Since the analysis is conservative, scaling down β_t, possibly to be constant, is a viable option.

In contrast, the choice of $\boldsymbol{\epsilon}$ should pose no problem. One only may consider scaling the objective functions so that all ϵ_i components of $\boldsymbol{\epsilon}$ have comparable values.

5.3 Kernel Hyper-Parameters

So far, we have assumed that the kernel function is given. Usually, its parameters need to be chosen. Therefore, prior to running $\boldsymbol{\epsilon}$-PAL, it may be practical to randomly sample a small fraction of the design space and to optimize the parameters (e.g., by maximizing the marginal likelihood). One may also consider maintaining uncertainty in the hyper-parameters by placing and updating priors on them. These can then be marginalized to obtain suitable hyper-rectangles to capture the uncertainty about the designs. This extension poses new challenges in computational efficiency (i.e., using approximate Bayesian inference), and we defer it to future work.

5.4 Scalability

The computational complexity of our algorithm depends on our ability to perform efficient inference in Gaussian processes. In general, this complexity grows cubically with the number of samples (function evaluations), which can pose a challenge in large design spaces. This is a general issue in Bayesian optimization, and not specific to our approach. Fortunately, there are many techniques available for scaling up Gaussian process inference that our approach can immediately benefit from (see, e.g., Rasmussen and Williams (2006)).

5.5 Continuous vs. discrete domains

In our approach, we have focused on finite, discrete domains E, which often naturally arise in design-space exploration problems as those considered in our experiments. For Lipschitz-continuous objectives (which are commonly assumed in Bayesian optimization), it is be possible to handle continuous compact domains E via standard covering arguments. Given the allowed tolerances $\boldsymbol{\epsilon}$ and Lipschitz constants, one can construct a discretization $\hat{E}$ such that for any point $\boldsymbol{x} \in E$ in the domain, there is one in the discretization $\boldsymbol{x}' \in \hat{E}$ such that $\boldsymbol{f}(\boldsymbol{x}') \succeq_\epsilon \boldsymbol{f}(\boldsymbol{x})$. It can be seen that any $\boldsymbol{\epsilon}$-accurate Pareto set of $\hat{E}$ is a $2\boldsymbol{\epsilon}$-accurate Pareto set of E. This discretization-based approach becomes impractical with higher dimensions. Developing a variant of our approach that does not require an explicit discretization is an interesting direction for future work.

5.6 Current Implementation

For our experimental evaluation, we implemented a prototype that is restricted to $m = 2$ objectives. The code is available at Zuluaga et al. (2015).

6. Related Work

We now discuss different lines of related work.

6.1 Evolutionary Algorithms

One class of approaches uses evolutionary algorithms to approximate the Pareto frontier via a population of evaluated designs that is iteratively evolved (Künzli et al., 2005; Coello et al., 2006; Zitzler et al., 2002). Most of these approaches do not use models for the objectives, and consequently cannot make predictions about unevaluated designs. As a consequence, a large number of evaluations are typically needed for convergence with reasonable accuracy. To overcome this challenge, model-based (or "response surface") approaches approximate the objectives by models, which are fast to evaluate. A concrete example is the algorithm presented by Emmerich et al. (2006), which uses Gaussian random fields metamodels to predict the objective functions. These models are used to screen each generation of the population and to extract promising individuals. On the other hand, Laumanns and Ocenasek (2002) and Buche et al. (2005) investigate the use of Gaussian models to maintain and improve the diversity of the population during the offspring-generation phase.

We will compare against ParEGO (Knowles, 2006) (explained in Section 6.6 below), which improves on the above work by combining the evolutionary approach with optimization to reduce the number of evaluations needed.

6.2 Scalarization to the Single-Objective Setting

An alternative approach to multi-objective optimization problems is the reduction to a single-objective problem (for which a wealth of methods are available). This is commonly done via scalarization, for example by considering convex combinations of the objective functions (Boyd and Vandenberghe, 2004). Some evolutionary algorithms use this approach to tackle multiple objectives. For example, the approach presented by Zhang and Li (2007)

optimizes simultaneously several single-objective subproblems that are created using different scalarization criteria. The diversity amongst the subproblems will lead to diversity in the approximated Pareto front.

A number of global optimization algorithms are also conditioned to the multi-objective setting by using scalarization. As a concrete example, Zhang et al. (2010) and Knowles (2006) extend the single-objective efficient global optimization (EGO) approach of Jones et al. (1998) by decomposing the optimization problem into several single-objective subproblems. A GP model is built for every subproblem, and sample candidates are selected based on their expected improvement.

A major disadvantage of the scalarization approach is that without further assumptions (e.g., convexity) on the objectives, not all Pareto-optimal solutions can be recovered (Boyd and Vandenberghe, 2004). Therefore, we avoid scalarization in our approach.

6.3 Heuristics-based Methods

Instead of weighted combinations, numerous domain-specific heuristics have been proposed that aim at identifying Pareto-optimal solutions. These approaches typically combine search algorithms to suit the nature of the problem (Deng et al., 2008; Palermo et al., 2009; Zuluaga et al., 2012a) and defy theoretical analysis to provide bounds on the sampling cost. With this work we aim at creating a method that generalizes across a large range of applications and target scenarios and that is analyzable, i.e., comes with theoretical guarantees.

6.4 Single-Objective Bayesian Optimization and Active Learning

In the single-objective setting, there has been much work on active learning, in particular for classification (see, e.g., Settles (2010) for an overview). For optimization, model-based approaches are used to address settings where the objective is noisy and expensive to evaluate. In particular in Bayesian optimization (see the survey by Brochu et al. (2010)), the objective is modeled as a draw from a stochastic process (often a Gaussian process), as originally proposed by Mockus et al. (1978). The advantage of this approach is the flexibility in encoding prior assumptions (e.g., via choice of the kernel and likelihood functions), as well as the ability to guide sampling: several different (usually greedy) heuristic criteria have been proposed to pick the next sample based on the predictive uncertainty of the Bayesian model. A common example is the EGO approach of Jones et al. (1998), which uses the expected improvement. In recent years, there have been considerable theoretical advances in Bayesian optimization. Several analyses focus on the case of deterministic (i.e., noise-free) observations. Vazquez and Bect (2010) prove that under some conditions the EGO approach produces a dense sequence of samples in the domain, i.e., asymptotically getting arbitrarily close to the optimum. Bull (2011) go further in providing convergence rates for this setting. Srinivas et al. (2010) analyzed the GP-UCB criterion (Cox and John, 1997), and proved global convergence guarantees and rates for Bayesian optimization allowing noisy observations. We build on their results to establish guarantees about our ϵ-PAL algorithm in the multi-objective setting. de Freitas et al. (2012) improve the results of Srinivas et al. (2010) using a UCB-like algorithm under deterministic observations to obtain exponential regret bounds.

6.5 Multi-Objective Bayesian Optimization and Active Learning

The algorithm PAL by Zuluaga et al. (2013), is an earlier version of ϵ-PAL. It also requires a parameter ϵ that allows the user to set different levels of prediction accuracy. PAL attempts to classify points as Pareto optimal or not Pareto-optimal until all points have been classified; it uses ϵ to ease this classification. However, it fails to generate an ϵ-accurate Pareto set. It only uses ϵ to stop the algorithm in different stages of training, and as a result, less accuracy is achieved when the value of ϵ is increased.

There are two main advantages of ϵ-PAL over PAL. The more effective use of ϵ is one of them. This not only allows it to generate an ϵ-accurate Pareto set, but it also reduces the runtime of the algorithm, as it attempts to remove redundancy and discards points more efficiently along the execution of the algorithm. In addition, the convergence bounds are also defined in terms of ϵ, which is intuitive. In contrast, PAL uses the hypervolume error, a concept that is more difficult to reason about.

The other advantage is the asymptotic improvement in the number of computations required per iteration, which is independent to the improvements just mentioned above. As analyzed in Section 3.7, for problems with two or three objective functions, ϵ-PAL requires $O(n \log n)$ computations on every iteration, whereas PAL requires $O(n^2 \log n)$. For problems with more than two objective functions, ϵ-PAL requires $O(n(\log n)^{m-2}) + O(n \log n)$ computations on every iteration, whereas PAL requires $O(n^2(\log n)^{m-2}) + O(n \log n)$. Here, n is the number of elements in the design space. This is very important since it allows ϵ-PAL to handle larger design spaces.

There have been recent approaches that simplify to some extent the PAL algorithm. Campigotto et al. (2014) proposes an active learning algorithm that also uses Gaussian process modeling to predict the objective function. It iteratively samples the most uncertain point in the design space until a threshold in information gain is reached. On the other hand, Steponavice et al. (2014) propose an algorithm that probabilistically classifies points as Pareto-optimal or not. This probability is used to provide flexibility on the accuracy of the prediction. This algorithm does not use Gaussian process modeling with the goal of improving runtime. Neither of these two approaches provides an approximation to the Pareto front with some granularity as ϵ-PAL does. Also, they do not provide any theoretical support on the convergence of the algorithm.

Multi-objective Bayesian optimization is also related to several other variants of Bayesian optimization studied in the literature. For example, there has been work on contextual (Krause and Ong, 2011), multi-task (Swersky et al., 2013) and collaborative (Bardenet et al., 2013) Bayesian optimization. These approaches can be viewed as carrying out Bayesian optimization for multiple related objectives, exploiting dependencies between them in order to share statistical strength. While also considering multiple objectives, the goal is to find separate optimizers for each of them, rather than identifying a Pareto frontier. Lastly Multi-objective Bayesian optimization is also related to Bayesian optimization under unknown constraints (Gelbart et al., 2014), since one way to obtain Pareto-optimal solutions is to optimize one objective under constraints on the others. The approach of (Gelbart et al., 2014) however only aims to identify a (single) optimal feasible solution as opposed to an entire Pareto frontier.

6.6 Multi-Objective Global Optimization and Evolutionary Algorithms

Global optimization algorithms have been paired with evolutionary algorithms to find the solution that maximizes an acquisition function, for example expected improvement. The best amongst these appears to be ParEGO (Knowles, 2006), which also uses GP models of the objective functions. On every iteration, the problem is scalarized using a different weight vector, and the solution that maximizes the expected improvement, based on the current single-objective function, is chosen for evaluation. An evolutionary algorithm performs the search using the GP models to asses the expected improvement of each solution. A similar approach, presented by Zhang et al. (2010), generates several populations per iteration to take advantage of a parallel implementation. As a result, several points are sampled on every iteration. We will compare our approach against ParEGO, as it also generates serialized function evaluations; this method might be preferred when the objective functions are expensive to evaluate.

7. Experiments

In this section we evaluate $\boldsymbol{\epsilon}$-PAL on three real world data sets obtained from different applications in computer science and engineering. We assess the prediction error versus the number of evaluations required to obtain it, for different settings of the accuracy parameter $\boldsymbol{\epsilon}$. Further, we compare with PAL (Zuluaga et al. (2013)) and ParEGO (Knowles, 2006), a state-of-the-art multi-objective optimization method based on evolutionary algorithms, using an implementation provided by the authors and adapted to run with our data sets. ParEGO also uses GP modeling to aid convergence.

Before presenting the results we introduce the data sets, and explain the experimental setup.

7.1 Data Sets

The first data set, called SNW, is taken from Zuluaga et al. (2012b). The design space consists of 206 different hardware implementations of a sorting network for 256 inputs. Each design is characterized by $d = 3$ parameters. The objectives are area and throughput when synthesized for a field-programmable gate array (FPGA) platform. This synthesis is very costly and can take up to many hours for large designs.

The second data set, called NoC, is taken from Almer et al. (2011). The design space consists of 259 different implementations of a tree-based network-on-chip, targeting application-specific circuits (ASICs) and multi-processor system-on-chip designs. Each design is defined by $d = 4$ parameters. The objectives are energy and runtime for the synthesized designs run on the Coremark benchmark workload. Again, the evaluation of each design is very costly.

The third data set, called SW-LLVM, is taken from Siegmund et al. (2012). The design space consists of 1023 different compiler settings for the LLVM compiler framework. Each setting is specified by $d = 11$ binary flags. The objectives are performance and memory footprint for a given suite of software programs when compiled with these settings. Note that the Pareto-optimal set consists of two points only.

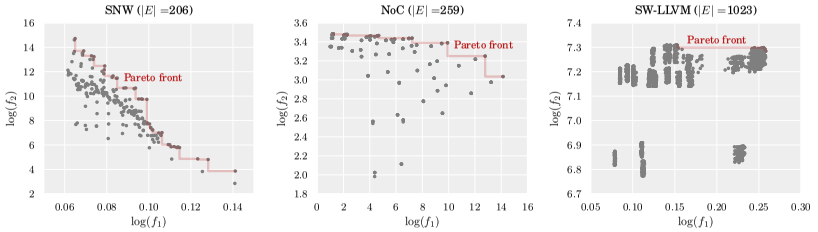

Figure 4: Objective space of the input sets use in our experiments.

Data set	d	m	$\lvert E\rvert$
SNW	3	2	206
NoC	4	2	259
SW-LLVM	11	2	1023

Table 1: Data sets used in our experiments.

The main characteristics of the data sets are summarized in Table 1; note that in all cases $m = 2$. To obtain the ground truth, we completely evaluated all data sets to determine P in each case. This was very costly, most notably, it took 20 days for NoC alone. The evaluations are plotted in log scale in Fig. 4; the Pareto fronts are emphasized. All the data is normalized such that all objectives are to be maximized.

7.2 Experimental Setup

Our implementation of $\boldsymbol{\epsilon}$-PAL uses the Gaussian Process Regression and Classification Toolbox for Matlab (Rasmussen and Nickisch, 2013). In our experiments we used the squared exponential covariance function with automatic relevance determination. The standard deviation of the noise ν is fixed to 0.1. We use

$$\beta_t^{1/2} = \frac{1}{3}\sqrt{2\log(m|E|\pi^2 t^2/(6\delta))},$$

which is the value suggested in Zuluaga et al. (2013) scaled by 1/3. This factor is empirical and used because the theoretical analysis is too conservative. In Srinivas et al. (2010) 1/5 is used.

All of the experiments were repeated 200 times and the median of the outcomes is shown in the plots. Additionally, several values of $\boldsymbol{\epsilon} = (\epsilon_i)_{1\leq i\leq 2}$ were evaluated, where ϵ_i is proportional to the range $r_i = \max_{\boldsymbol{x}\in E}\{f_i(\boldsymbol{x})\} - \min_{\boldsymbol{x}\in E}\{f_i(\boldsymbol{x})\}$. We start with $\epsilon_i = 0.01\times r_i$ and increase it up to $\epsilon_i = 0.3\times r_i$. When we say $\epsilon = 1\%$, we mean that ϵ_i is 1% of the range r_i.

Prior to running $\boldsymbol{\epsilon}$-PAL, a subset of the design space was evaluated in order to initialize the training set and optimize the kernel parameters used by the model. For SNW and NoC,

15 points were chosen uniformly at random. For LLVM-SW, as the dimensionality of the design space is much larger, 30 points were taken.

All of the experiments were run on a machine equipped with two 6-Core Intel Xeon X5680 (3.06GHz) and 144GB (1333MHz) of memory.

7.3 Prediction Error

After running $\boldsymbol{\epsilon}$-PAL with any of the data sets, a prediction $\hat{P} \subset E$ of the true Pareto set is returned. Some of the points in $\hat{P}$ are then already evaluated, i.e., $\boldsymbol{f}$ is already known; for the others the exact value of $\boldsymbol{f}$ was not necessary to generate the prediction. For such points, the objective functions are evaluated after running $\boldsymbol{\epsilon}$-PAL to determine their values and thus all of $\boldsymbol{f}(\hat{P})$. We compare the prediction $\hat{P}$ with the true Pareto set P, where $\boldsymbol{f}(P)$ is obtained through exhaustive evaluation. The comparison uses a percentage prediction error $e(P, \hat{P})$ based on the concept of $\boldsymbol{\epsilon}$-dominance. It is the average maximum distance found between a point in $\boldsymbol{f}(P)$ and the closest point in $\boldsymbol{f}(\hat{P})$.

When considering two objective functions, i.e., $m = 2$, $\boldsymbol{f}(\boldsymbol{x}) = (f_1(\boldsymbol{x}), f_2(\boldsymbol{x}))$. In this case, the prediction error is calculated as

$$e(P, \hat{P}) = \text{avg}_{x \in P} \text{min}_{x' \in \hat{P}} \text{max}_{1 \leq i \leq 2} \frac{(f_i(\boldsymbol{x}) - f_i(\boldsymbol{x}')) \cdot 100}{r_i}.$$

The distance is expressed as a percentage of the range r_i, in order to compare the results between the two dimensions and amongst the different data sets.

7.4 Quality of Pareto Front Prediction

The first row of Fig. 5 shows the $\boldsymbol{\epsilon}$-accurate Pareto front $Z(\hat{P})$ obtained with $\boldsymbol{\epsilon}$-PAL for three different configurations of $\boldsymbol{\epsilon}$, using the first data set. The red shaded line is the true Pareto front found by exhaustive evaluation. The gray points are the ones that have been either sampled during the execution of $\boldsymbol{\epsilon}$-PAL or selected to be part of the $\boldsymbol{\epsilon}$-Pareto front. We can see that, as intended, with larger values of $\boldsymbol{\epsilon}$, a less accurate Pareto front is obtained, but also fewer points are evaluated. The rest of the points are discarded by $\boldsymbol{\epsilon}$-PAL during its execution.

The second row of Fig. 5 shows equivalent plots obtained with PAL. PAL attempts to classify points as Pareto optimal or not Pareto-optimal until all points have been classified; it uses $\boldsymbol{\epsilon}$ to ease this classification. Therefore, as $\boldsymbol{\epsilon}$ increases, more points are selected as Pareto optimal. The gray points in the plots correspond to solutions that are either evaluated during the execution of PAL or classified as Pareto optimal. It is clear that PAL does not generate an $\boldsymbol{\epsilon}$-accurate Pareto set, but simply uses a parameter $\boldsymbol{\epsilon}$ to make the algorithm terminate at different stages. The prediction can be as precise as the models for f_i generated with the samples gathered by the termination of the algorithm. For small values of $\boldsymbol{\epsilon}$, the resulting Pareto front is close to the true Pareto front because more samples have been taken and a more accurate classification can be made. On the other hand, for large values of $\boldsymbol{\epsilon}$, this happens because most points are classified as Pareto optimal, even though they are far from the true Pareto front. In all cases, the returned Pareto front attempts to be as close as possible to the true Pareto front.

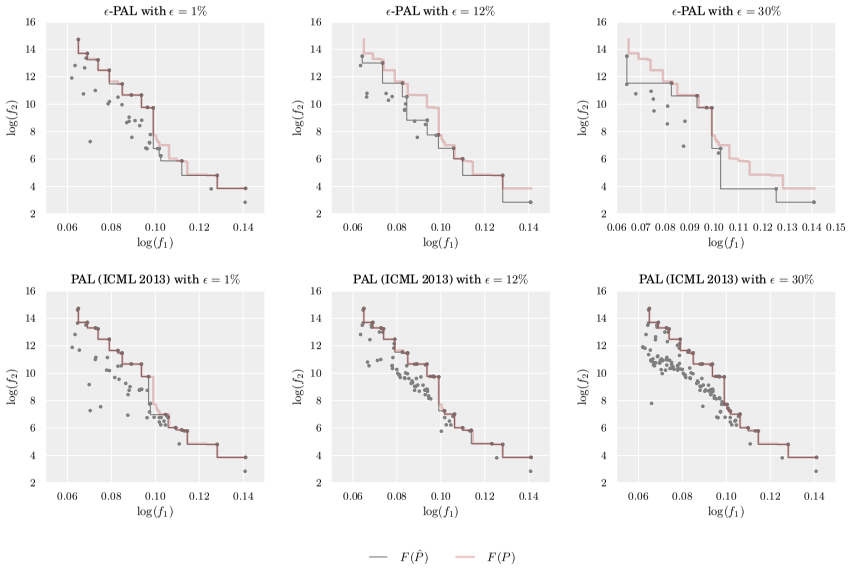

Figure 5: The first row shows the $\boldsymbol{\epsilon}$-accurate Pareto fronts (black line) of the SNW design space obtained with $\boldsymbol{\epsilon}$-PAL for $\epsilon \in \{1\%, 12\%, 30\%\}$. The second row shows equivalent plots for PAL in which the prediction $\hat{P}$ is composed of the sampled points and the points classified as Pareto optimal at the termination of the algorithm. The red shaded line in each plots is the true Pareto front of the design space.

Fig. 6 shows a set of experiments in which we do both, exploring the effect of choosing $\boldsymbol{\epsilon}$ and comparing against PAL and ParEGO (Knowles, 2006). Every plot in Fig. 6 corresponds to one data set in Table 1. In each case, the x-axis shows the number of evaluations (sampling cost) of $\boldsymbol{f}$. For $\boldsymbol{\epsilon}$-PAL and PAL this is T (the total number of iterations) plus the evaluations of designs in $\hat{P}$ that have not been evaluated yet while running the algorithm. On the y-axis, we show the average percentage error $e(P, \hat{P})$ as defined above. We measure the error at each iteration, and plot $(t, e(P, \hat{P}))$. As expected, the error in all cases decreases with increasing numbers of evaluations.

$\boldsymbol{\epsilon}$-PAL provides a wide range of accuracy-cost trade-offs as an effect of choosing different $\boldsymbol{\epsilon}$ configurations. When $\epsilon = 30\%$, only a few iterations are made by the algorithm, returning an error of less than 7% with less than 30 function evaluations in all cases. On the other hand, for $\epsilon = 1\%$, $\boldsymbol{\epsilon}$-PAL yields an error of less than 0.7% with less than 50 function evaluations in all cases.

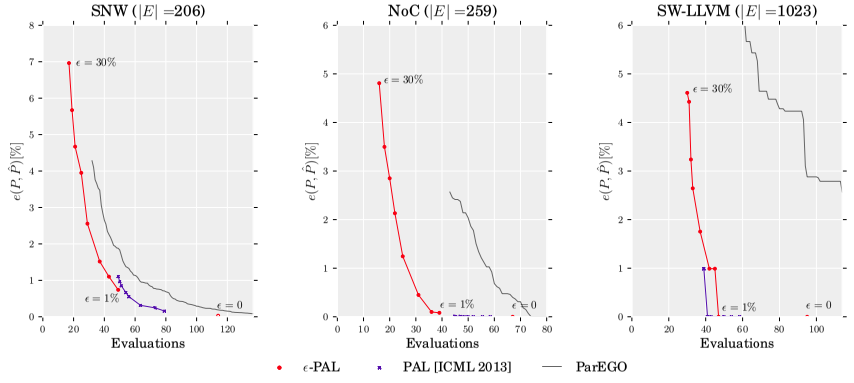

Figure 6: Prediction error $e(P, \hat{P})$ vs. number of evaluations. For $\boldsymbol{\epsilon}$-PAL and PAL the values $\epsilon \in \{30\%, 20\%, 16\%, 12\%, 8\%, 4\%, 2\%, 1\%\}$ are used. The corresponding points are consecutive in the lines for $\boldsymbol{\epsilon}$-PAL and PAL.

The measured error $e(P, \hat{P})$ is comparable with ϵ as they both measure how far the predicted Pareto front is from the true Pareto front. ϵ measures the desired accuracy, and $e(P, \hat{P})$ measures what is obtained. We can then say that $\boldsymbol{\epsilon}$-PAL meets the expectations on the prediction for all $\boldsymbol{\epsilon}$ configurations and in all cases.

The plots in Fig. 6 also show a point in which $\boldsymbol{\epsilon}$-PAL achieves an error of 0. This is obtained with $\epsilon = 0$, $\delta = 0.05$ and β_t having the exact value suggested by Theorem 1. Under these configurations, $\boldsymbol{\epsilon}$-PAL yields a perfect prediction with less than 115 evaluations in all cases.

PAL (purple line) generates a more constrained set of trade-offs using the same $\boldsymbol{\epsilon}$ configurations that were used for $\boldsymbol{\epsilon}$-PAL. The actual $\hat{P}$ reported in (Zuluaga et al., 2013) corresponds to the Pareto-optimal points amongst all pairs $(\mu_1(\boldsymbol{x}), \mu_2(\boldsymbol{x}))$ for $\boldsymbol{x} \in E$. On the other hand, ParEGO (gray line) does not provide a methodology to stop the algorithm in different stages of accuracy and cost. We then plot a continuous line that shows the error obtained by the set S_t of sampled points on every iteration of the algorithm t, i.e., we plot points $(|S_t|, e(P, S_t))$. ParEGO uses a heuristic to find the number of samples of the starting population depending on the characteristics of the design space. Hence the line always starts with a certain minimum number of evaluations.

We observe that $\boldsymbol{\epsilon}$-PAL and PAL in all cases significantly improve over ParEGO. In particular, the gains on SW-LLVM were considerable. Overall, the number of evaluations was reduced by 1/3 to 2/3 in all cases when comparing against ParEGO. $\boldsymbol{\epsilon}$-PAL overall compares favorably to PAL except for SW-LLVM, where PAL wins for a small range in the error/performance tradeoff space.

As explained above, $\boldsymbol{\epsilon}$-PAL returns an $\boldsymbol{\epsilon}$-accurate Pareto set and PAL returns a more dense Pareto set, therefore, the prediction error in PAL is always fairly small and in most of the cases it requires more function evaluations. In the case of SW-LLVM, there are some trade-offs obtained with $\boldsymbol{\epsilon}$-PAL that yield slightly higher errors than those obtained with PAL. This is because $\boldsymbol{\epsilon}$-PAL eliminates solutions along its execution and as the corresponding design space has only one Pareto point, when this is removed, the error obtained increases considerably. However the error is within the expected range, i.e., below that indicated by $\boldsymbol{\epsilon}$. Additionally, if the design space is not too large, after the termination of the algorithm, all points that were discarded can be again predicted by the model to find a more accurate Pareto set similar to what PAL returns.

In conclusion, $\boldsymbol{\epsilon}$-PAL in most cases produces better trade-offs than PAL and ParEGO. In comparison to PAL, it uses more effectively the fact that the users, by setting $\boldsymbol{\epsilon}$, are expressing their desire to generate only $\boldsymbol{\epsilon}$-accurate Pareto fronts in exchange for a smaller number of function evaluations. This means that it can offer a wider range of trade-offs between accuracy and number of evaluations. Moreover, the resulting Pareto fronts contain a variety of trade-offs between the underlying multi-objective design space, that are spread evenly along the range of possibilities.

7.5 Execution Time

A drawback of PAL is the high number of computations required per iteration, which constrains it to small design spaces. As explained in Section 6, $\boldsymbol{\epsilon}$-PAL reduces the number of computations per iteration by a factor of n while achieving better results than PAL. In this section, we compare the runtime of executing PAL and $\boldsymbol{\epsilon}$-PAL with our three data sets. Another advantage of $\boldsymbol{\epsilon}$-PAL that helps improving its computational efficiency is that it uses $\boldsymbol{\epsilon}$ to discard more points from the design space as its value increases. In PAL on the other hand, as $\boldsymbol{\epsilon}$ increases, the number of points classified as Pareto optimal increases, and thus those points require computations on every iteration until the algorithm terminates.

The first plot in Fig. 7 shows runtime speedups, obtained with the three data sets and all the values of $\boldsymbol{\epsilon}$ considered before. We measured for each value of $\boldsymbol{\epsilon}$ the runtime for $\boldsymbol{\epsilon}$-PAL and PAL and divide them to obtain the speedups. Here we assume that the cost of evaluating $\boldsymbol{f}$ is 0. The plot shows that, as expected, the speedups improve as n increases. Therefore, LLVM-SW, which has the largest design space of all data sets, obtains the largest speedups, from 45× with $\epsilon = 1\%$ up to 420× with $\epsilon = 30\%$. Better speedups are obtained with larger values of $\boldsymbol{\epsilon}$ since more points can be discarded during the first iterations.

The second plot in Fig. 7 shows equivalent results but this time assuming that evaluating $\boldsymbol{f}$ takes 30 minutes. In this case, the speedups are smaller, going up to almost 3× for $\epsilon = 30\%$. This is because the data sets are relatively small and thus the gains in runtime are offset by the high cost of evaluating $\boldsymbol{f}$. In other words, the speedups that we observed here are speedups on function evaluations and are related to the improvements that can be visualized in Fig. 6. These improvements come from the fact that $\boldsymbol{\epsilon}$-PAL requires less function evaluations than PAL to achieve an error equivalent to the requested $\boldsymbol{\epsilon}$. As a result, the denser the true Pareto front of the design space, the better the speedups obtained by using $\boldsymbol{\epsilon}$-PAL. For this reason, LLVM-SW does not generate important speedups on function evaluations, since the true Pareto front is composed of only one point. The best speedups

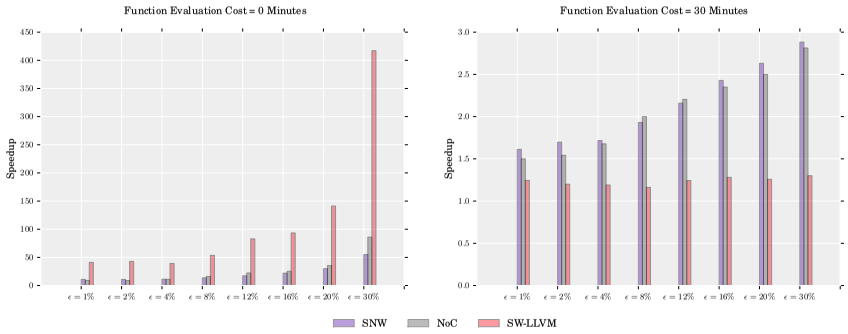

Figure 7: Speedups obtained by using ϵ-PAL against using PAL. The plot of the left shows the speedups on the runtime of ϵ-PAL, assuming that function evaluations are free. The plot on the right shows speedups assuming that one function evaluation takes 30 minutes.

are obtained with SNW, followed by NoC, tha same order as the densities of their true Pareto curves.

8. Conclusions

In this paper, we proposed a novel algorithm for efficiently localizing an ϵ-accurate Pareto-frontier in multi-objective optimization. In the spirit of Bayesian optimization, it uses Gaussian processes to exploit prior information about the objective functions' regularity to predict the objective functions, to guide the sampling process, and to make inferences about the optimality of designs without directly evaluating them. We presented an extensive theoretical analysis including bounds for the number of samples required to achieve the desired target accuracy.

The algorithm described in this paper presents major improvements from its predecessor PAL. First, it returns an ϵ-accurate Pareto front instead of a dense approximation of the true Pareto front. It is often the case that a small difference in the objective function, conveyed to the algorithm with the parameter ϵ, does not affect the quality of a design significantly. Thus, it is preferable to reduce the number of evaluations made and to obtain a set of close-to-optimal solutions well distributed in the objective space.

A second improvement over PAL is that ϵ-PAL reduces the asymptotic runtime, which facilitates the exploration of larger design spaces, in which perhaps the function evaluation is less expensive.

Finally, we demonstrated the effectiveness of our approach on three case studies obtained from real engineering applications. Our results show that we offer better cost-performance trade-offs in comparison to ParEGO and PAL. Across all data sets and almost all desired accuracies, ϵ-PAL outperforms ParEGO, requiring in most cases 30% to 70% less function

evaluations. Moreover, we showed that our parameterization strategy provides a wide range of cost-performance trade-offs. In comparison to PAL, our experiments show that ϵ-PAL reduces the amount of computations by up to 420×, and the number of samples from the design space required to meet the user's desired level of accuracy by up to 2.9×.

Acknowledgments. We would like to thank the authors of (Almer et al., 2011) and (Siegmund et al., 2012) for providing the data for our experiments. This research was supported in part by SNSF grants 200021_137971, 200021_137528, DARPA MSEE FA8650-11-1-7156 and ERC StG 307036.

Appendix A. Theoretical Analysis and Asymptotic Bounds

This section provides the proofs of Theorem 1, which follows from Lemmas 1 to 8.

Lemma 1 *Assume that the target functions f_i, $0 \leq i \leq m$, are bounded on their RKHS norm $||f_i||_k$. Given $\delta \in (0,1)$ and $\beta_t = 2||f_i||_k^2 + 300\gamma_t \log^3(m|E|t/\delta)$, the following holds with probability $\geq 1-\delta$:*

$$\begin{aligned} |f_i(\boldsymbol{x}) - \mu_{t-1,i}(x)| &\leq \beta_t^{1/2}\sigma_{t-1,i}(\boldsymbol{x}) \\ \text{for all } 1 \leq i \leq m,\ \boldsymbol{x} \in E,\ &\text{for all } t \geq 1. \end{aligned} \tag{10}$$

In other words, with probability $\geq 1-\delta$:

$$\boldsymbol{f}(\boldsymbol{x}) \in R_t(\boldsymbol{x}) \text{ for all } \boldsymbol{x} \in E, \text{ for all } t \geq 1$$

Proof According to Theorem 6 in (Srinivas et al., 2012), the following inequality holds:

$$Pr\left\{|f_i(\boldsymbol{x}) - \mu_{t-1,i}(\boldsymbol{x})| > \beta_t^{1/2}\sigma_{t-1,i}(\boldsymbol{x})\right\} \leq \delta',$$

with $\beta_t = 2||f_i||_k^2 + 300\gamma_t \log^3(t/\delta')$. Applying the union bound for $i, t \in \mathbb{N}$, we obtain that the following holds with probability $\geq 1 - m|E|\delta'$:

$$\begin{aligned} |f_i(\boldsymbol{x}) - \mu_{t-1,i}(\boldsymbol{x})| &\leq \beta_t^{1/2}\sigma_{t-1,i}(\boldsymbol{x}) \\ \text{for all } 1 \leq i \leq m,\ &\text{for all } \boldsymbol{x} \in E, \end{aligned} \tag{11}$$

with $\beta_t = 2||f_i||_k^2 + 300\gamma_t \log^3(t/\delta')$. The lemma holds by choosing $\delta = m|E|\delta'$. ■

Lemma 2 *If $m = 1$ and $\boldsymbol{f}_T = (\boldsymbol{f}(\boldsymbol{x}_t))_{1 \leq t \leq T}$, then*

$$I(\boldsymbol{y}_T; \boldsymbol{f}_T) = \frac{1}{2}\sum_{t=1}^{T} \log(1 + \sigma^{-2}\sigma_{t-1}^2(\boldsymbol{x}_t)).$$

This is directly taken from Lemma 5.3 in (Srinivas et al., 2010). Hereby $I(\boldsymbol{y}_T; \boldsymbol{f}_T) = H(\boldsymbol{f}_T) - H(\boldsymbol{f}_T \mid (\boldsymbol{x}_1, \boldsymbol{y}_1), \ldots, (\boldsymbol{x}_T, \boldsymbol{y}_T))$ is the mutual information between the function values $\boldsymbol{f}_T$ and the noisy observations $\boldsymbol{y}_T = \boldsymbol{f}_T + \nu_T$ where where $\nu_T \sim N(\boldsymbol{0}, \sigma^2\boldsymbol{I})$. This relation holds no matter in what sequence the samples $\boldsymbol{x}_t$ are picked by $\boldsymbol{\epsilon}$-PAL, and no matter what values $\boldsymbol{y}_t$ are being observed. Latter statement is true since for Gaussian processes the posterior variance over $\boldsymbol{f}$ only depends on where it is evaluated, i.e., $\boldsymbol{x}_T$, not on the actual values $\boldsymbol{y}_T$ observed (Srinivas et al., 2010).

Lemma 3 *Given $\delta \in (0,1)$ and $\beta_t = 2\log(m|E|\pi_t/\delta)$, the following holds:*

$$\sum_{t=1}^{T} \overline{w}_t^2 \leq \beta_T C_1 I(\boldsymbol{y}_T; \boldsymbol{f}_T) \leq C_1 \beta_T \gamma_T \text{ for all } T \geq 1,$$

where $C_1 = 8/\log(1+\sigma^{-2})$.

Proof One of the rectangles of which $R_t(\boldsymbol{x}_t)$ is the intersection has a diagonal length of $2\beta_t^{1/2}\|\boldsymbol{\sigma}_{t-1}(\boldsymbol{x}_t)\|_2$: as a consequence,

$$\overline{w}_t^2 \leq 4\beta_t \|\boldsymbol{\sigma}_{t-1}(\boldsymbol{x}_t)\|_2^2.$$

As β_t is increasing, we have that

$$\begin{aligned} \overline{w}_t^2 &\leq 4\beta_T\sigma^2 \sum_{i=1}^{m} \sigma^{-2}\sigma_{t-1,i}^2(\boldsymbol{x}_t) \\ &\leq 4\beta_T\sigma^2 C_2 \sum_{i=1}^{m} \log(1 + \sigma^{-2}\sigma_{t-1,i}^2(\boldsymbol{x}_t)) \end{aligned}$$

with $C_2 = \sigma^{-2}/\log(1+\sigma^{-2}) \geq 1$, since $s^2 \leq C_2 \log(1+s^2)$ for $0 \leq s \leq \sigma^{-2}$, and $\sigma^{-2}\sigma_{t-1,i}^2(\boldsymbol{x}_t) \leq \sigma^{-2}k_i(\boldsymbol{x}_t, \boldsymbol{x}_t) \leq \sigma^{-2}$.

Using $C_1 = 8\sigma^2 C_2$ and Lemma 2 we have that

$$\begin{aligned} \sum_{t=1}^{T} \overline{w}_t^2 &\leq \beta_T C_1 \sum_{i=1}^{m} I(\boldsymbol{y}_T; f_{T,i}) \\ &\leq \beta_T C_1 I(\boldsymbol{y}_T; \boldsymbol{f}_T) \end{aligned}$$

■

Lemma 4 *Given $\delta \in (0,1)$ and $\beta_t = 2\log(m|E|\pi_t/\delta)$, the following holds with probability $\geq 1-\delta$:*

$$\sum_{t=1}^{T} \overline{w}_t \leq \sqrt{C_1 T \beta_T \gamma_T} \text{ for all } T \geq 1$$

Proof This follows from Lemma 3, since $(\sum_t^T \overline{w}_t)^2 \leq T\sum_{t=1}^T \overline{w}_t^2$ by the Cauchy-Schwarz inequality. ■

Lemma 5 *Running $\boldsymbol{\epsilon}$-PAL with a monotonic classification, it holds that $\overline{w}_t$ decreases with t.*

Proof As a direct consequence of the sample selection rule, $w_{t-1}(\boldsymbol{x}_t) \leq \overline{w}_{t-1}$. On the other hand, $w_t(\boldsymbol{x}) \leq w_{t-1}(\boldsymbol{x})$ and thus, $\overline{w}_t \leq w_{t-1}(\boldsymbol{x}_t)$. The lemma follows. ■

Lemma 6 *Running $\boldsymbol{\epsilon}$-PAL with $\delta \in (0,1)$ and $\beta_t = 2\log(m|E|\pi_t/\delta)$, the following holds:*

$$Pr\left\{\overline{w}_T \leq \sqrt{\frac{C_1\beta_T\gamma_T}{T}} \text{ for all } T \geq 1\right\} \geq 1-\delta, \tag{12}$$

where $C_1 = 8/\log(1+\sigma^{-2})$ and $\pi_t = \pi^2 t^2/6$.

Proof This is derived from Lemmas 4 and 5, since $\sum_{t=1}^{T} \overline{w}_t/T \geq \overline{w}_T$. ■

Lemma 7 *If when running ϵ-PAL, $\overline{w}_t \leq ||\boldsymbol{\epsilon}||_\infty$ holds at iteration t, then the algorithm terminates without further sampling.*

Proof Since $\overline{w}_t$ is un upper bound of $||\max(R_t(\boldsymbol{x})) - \min(R_t(\boldsymbol{x}))||_2$, it is enough to show that the statement is true if $\boldsymbol{w} = \max(R_t(\boldsymbol{x}_i)) - \min(R_t(\boldsymbol{x}_i)) = (\overline{w}_t^{(1)}, \ldots, \overline{w}_t^{(m)})$ for all $\boldsymbol{x}_i \in U_t \cup P_t$. Therefore, $\overline{w}_t \leq ||\boldsymbol{\epsilon}||_\infty$ implies $\boldsymbol{w} \preceq \boldsymbol{\epsilon}$.

We show that if $\boldsymbol{w} \preceq \boldsymbol{\epsilon}$, in the same iteration of $\boldsymbol{\epsilon}$-PAL all points in U_t will be either moved to P_t or discarded.

If a point $\boldsymbol{x}$ does not belong to $Z_\epsilon(E)$, then there is a point $\boldsymbol{x}'$ such that

$$\max(R_t(\boldsymbol{x}')) \succeq \min(R_t(\boldsymbol{x})) + \boldsymbol{\epsilon}.$$

Using $\max(R_t(\boldsymbol{x}')) = \min(R_t(\boldsymbol{x}')) + \boldsymbol{w}$, we can rewrite

$$\min(R_t(\boldsymbol{x})) + \boldsymbol{\epsilon} \preceq \min(R_t(\boldsymbol{x}')) + \boldsymbol{w}.$$

Since $\boldsymbol{w} \preceq \boldsymbol{\epsilon}$, this is equivalent to

$$\min(R_t(\boldsymbol{x})) + \boldsymbol{w} \preceq \min(R_t(\boldsymbol{x}')) + \boldsymbol{\epsilon}.$$

It follows that

$$\max(R_t(\boldsymbol{x})) \preceq \min(R_t(\boldsymbol{x}')) + \boldsymbol{\epsilon},$$

which is the condition that ensures that $\boldsymbol{x} \preceq_\epsilon \boldsymbol{x}'$. This means that there is a point $\boldsymbol{x}' \in U_t \cup P_t$ that dominates $\boldsymbol{x}$, and therefore $\boldsymbol{x}$ will be discarded. ■

Lemma 8 *If ϵ-PAL is run until its termination with some $\boldsymbol{\epsilon}$ and confidence parameter δ, then with probability at least $1-\delta$ it holds that $\Pi(\hat{P})$ is an $\boldsymbol{\epsilon}$-accurate Pareto set of E.*

Proof According to Definition 5, an $\boldsymbol{\epsilon}$-accurate Pareto set of E requires every point of E to have an $\boldsymbol{\epsilon}$-dominator in $\hat{P}$. In the discarding stage of $\boldsymbol{\epsilon}$-PAL, points in U_t are discarded if they are $\boldsymbol{\epsilon}$-dominated by a pessimistic Pareto point. If a point is $\boldsymbol{\epsilon}$-dominated in E, it is $\boldsymbol{\epsilon}$-dominated by a point in the pessimistic Pareto set of E. Therefore, the discarding stage of $\boldsymbol{\epsilon}$-PAL ensures that there will be always be a point in the remaining sets that $\boldsymbol{\epsilon}$-dominates the points that are discarded. Pessimistic Pareto points are only discarded if they are $\boldsymbol{\epsilon}$-dominated by any point in P_t. Hence, all discarding decisions are "safe", in the sense that for every discarded point, there is always at least one $\boldsymbol{\epsilon}$-dominating point remaining. They are also "complete", i.e., only points that belong to $Z_\epsilon(E)$ are moved to P_t. Hence, at termination, since U_t is empty, all remaining points P_t form an $\boldsymbol{\epsilon}$-accurate Pareto set of E. ■

Abstract

We introduce a family of adaptive estimators on graphs, based on penalizing the ℓ_1 norm of discrete graph differences. This generalizes the idea of trend filtering (Kim et al., 2009; Tibshirani, 2014), used for univariate nonparametric regression, to graphs. Analogous to the univariate case, graph trend filtering exhibits a level of local adaptivity unmatched by the usual ℓ_2-based graph smoothers. It is also defined by a convex minimization problem that is readily solved (e.g., by fast ADMM or Newton algorithms). We demonstrate the merits of graph trend filtering through both examples and theory.

Keywords: *trend filtering, graph smoothing, total variation denoising, fused lasso, local adaptivity*

1. Introduction

Nonparametric regression has a rich history in statistics, carrying well over 50 years of associated literature. The goal of this paper is to port a successful idea in univariate nonparametric regression, trend filtering (Steidl et al., 2006; Kim et al., 2009; Tibshirani, 2014; Wang et al., 2014), to the setting of estimation on graphs. The proposed estimator, graph trend filtering, shares three key properties of trend filtering in the univariate setting.

1. **Local adaptivity:** graph trend filtering can adapt to inhomogeneity in the level of smoothness of an observed signal across nodes. This stands in contrast to the usual ℓ_2-based methods, e.g., Laplacian regularization (Smola and Kondor, 2003), which enforce smoothness globally with a much heavier hand, and tends to yield estimates that are either smooth or else wiggly throughout.
2. **Computational efficiency:** graph trend filtering is defined by a regularized least squares problem, in which the penalty term is nonsmooth, but convex and structured enough to permit efficient large-scale computation.
3. **Analysis regularization:** the graph trend filtering problem directly penalizes (possibly higher order) differences in the fitted signal across nodes. Therefore graph trend filtering falls into what is called the *analysis* framework for defining estimators. Alternatively, in the *synthesis* framework, we would first construct a suitable basis over the graph, and then regress the observed signal over this basis; e.g., Shuman et al. (2013) survey a number of such approaches using wavelets; likewise, kernel methods regularize in terms of the eigenfunctions of the graph Laplacian (Kondor and Lafferty, 2002). An advantage of analysis regularization is that it easily yields complex extensions of the basic estimator by mixing penalties.

As a motivating example, consider a denoising problem on 402 census tracts of Allegheny County, PA, arranged into a graph with 402 vertices and 2382 edges obtained by connecting spatially adjacent tracts. To illustrate the adaptive property of graph trend filtering we generated an artificial signal with inhomogeneous smoothness across the nodes, and two sharp peaks near the center of the graph, as can be seen in the top left panel of Figure 1. (The signal was formed using a mixture of five Gaussians, in the underlying spatial coordinates.) We drew noisy observations around this signal, shown in the top right panel of the figure, and we fit graph trend filtering, graph Laplacian smoothing, and wavelet smoothing to these observations. Graph trend filtering is to be defined in Section 2 (here we used $k = 2$, quadratic order); the latter two, recall, are defined by the optimization problems

$$\min_{\beta \in \mathbb{R}^n} \|y - \beta\|_2^2 + \lambda \beta^\top L \beta \quad \text{(Laplacian smoothing)},$$
$$\min_{\theta \in \mathbb{R}^n} \frac{1}{2}\|y - W\theta\|_2^2 + \lambda \|\theta\|_1 \quad \text{(wavelet smoothing)},$$

where $y \in \mathbb{R}^n$ the vector of observations measured over the $n = 402$ nodes in the graph, $L \in \mathbb{R}^{n \times n}$ is the graph Laplacian matrix, and $W \in \mathbb{R}^{n \times n}$ is a wavelet basis built over the graph. The wavelet smoothing problem displayed above is really an oversimplified representation of the class of wavelets methods, since it only encapsulates estimators that employ an orthogonal wavelet basis W (and soft-threshold the wavelet coefficients). For the present experiment, we constructed W according to the spanning tree wavelet design of Sharpnack et al. (2013a); we found this construction performed best among the graph wavelet designs we considered for the data at hand. For completeness, the results from alternative wavelet designs are given in the Appendix.

Graph trend filtering, Laplacian smoothing, and wavelet smoothing each have their own regularization parameters λ, and these parameters are not generally on the same scale. Therefore, in our comparisons we use effective degrees of freedom (df) as a common measure for the complexities of the fitted models. The top right panel of Figure 1 shows the graph trend filtering estimate with 68 df. We see that it adaptively fits the sharp peaks in the center of the graph, and smooths out the surrounding regions appropriately. The graph Laplacian estimate with 68 df (bottom left), substantially oversmooths the high peaks in the center, while at 132 df (bottom middle), it begins to detect the high peaks in the center, but undersmooths neighboring regions. Wavelet smoothing performs quite poorly across all df values—it appears to be most affected by the level of noise in the observations.

As a more quantitative assessment, Figure 2 shows the mean squared errors between the estimates and the true underlying signal. The differences in performance here are analogous to the univariate case, when comparing trend filtering to smoothing splines (Tibshirani, 2014). At smaller df values, Laplacian smoothing, due to its global considerations, fails to adapt to local differences across nodes. Trend filtering performs much better at low df values, and yet it matches Laplacian smoothing when both are sufficiently complex, i.e., in the overfitting regime. This demonstrates that the local flexibility of trend filtering estimates is a key attribute.

Here is an outline for the rest of this article. Section 2 defines graph trend filtering and gives underlying motivation and intuition. Section 3 covers basic properties and extensions of the graph

trend filtering estimator. Section 4 examines computational approaches, and Section 5 looks at a number of both real and simulated data examples. Section 6 presents asymptotic error bounds for graph trend filtering. Section 7 concludes with a discussion. As for notation, we write X_A to extract the rows of a matrix $X \in \mathbb{R}^{m \times n}$ that correspond to a subset $A \subseteq \{1, \dots m\}$, and X_{-A} to extract the complementary rows. We use a similar convention for vectors: x_A and x_{-A} denote the components of a vector $x \in \mathbb{R}^m$ that correspond to the set A and its complement, respectively. We write $\mathrm{row}(X)$ and $\mathrm{null}(X)$ for the row and null spaces of X, respectively, and $X^\dagger$ for the pseudoinverse of X, with $X^\dagger = (X^\top X)^\dagger X^\top$ when X is rectangular.

2. Trend Filtering on Graphs

In this section, we motivate and formally define graph trend filtering.

2.1 Review: Univariate Trend Filtering

We begin by reviewing trend filtering in the univariate setting, where discrete difference operators play a central role. Suppose that we observe $y = (y_1, \dots y_n) \in \mathbb{R}^n$ across input locations $x = (x_1, \dots x_n) \in \mathbb{R}^n$; for simplicity, suppose that the inputs are evenly spaced, say, $x = (1, \dots n)$. Given an integer $k \geq 0$, the kth order trend filtering estimate $\hat{\beta} = (\hat{\beta}_1, \dots \hat{\beta}_n)$ is defined as

$$\hat{\beta} = \underset{\beta \in \mathbb{R}^n}{\operatorname{argmin}} \ \frac{1}{2}\|y - \beta\|_2^2 + \lambda \|D^{(k+1)}\beta\|_1, \tag{1}$$

where $\lambda \geq 0$ is a tuning parameter, and $D^{(k+1)}$ is the discrete difference operator of order $k+1$. When $k = 0$, problem (1) employs the first difference operator,

$$D^{(1)} = \begin{bmatrix} -1 & 1 & 0 & \dots & 0 \\ 0 & -1 & 1 & \dots & 0 \\ \vdots & & \ddots & \ddots & \\ 0 & 0 & \dots & -1 & 1 \end{bmatrix}. \tag{2}$$

Therefore $\|D^{(1)}\beta\|_1 = \sum_{i=1}^{n-1} |\beta_{i+1} - \beta_i|$, and the 0th order trend filtering estimate in (1) reduces to the 1-dimensional fused lasso estimator (Tibshirani et al., 2005), also called 1-dimensional total variation denoising (Rudin et al., 1992). For $k \geq 1$ the operator $D^{(k+1)}$ is defined recursively by

$$D^{(k+1)} = D^{(1)} D^{(k)}, \tag{3}$$

with $D^{(1)}$ above denoting the $(n-k-1) \times (n-k)$ version of the first difference operator in (2). In words, $D^{(k+1)}$ is given by taking first differences of kth differences. The interpretation is hence that problem (1) penalizes the changes in the kth discrete differences of the fitted trend. The estimated components $\hat{\beta}_1, \dots \hat{\beta}_n$ exhibit the form of a kth order piecewise polynomial function, evaluated over the input locations $x_1, \dots x_n$. This can be formally verified (Tibshirani, 2014; Wang et al., 2014) by examining a continuous-time analog of (1).

2.2 Trend Filtering over Graphs

Let $G = (V, E)$ be an graph, with vertices $V = \{1, \dots n\}$ and undirected edges $E = \{e_1, \dots e_m\}$, and suppose that we observe $y = (y_1, \dots y_n) \in \mathbb{R}^n$ over the nodes. Following the univariate

definition in (1), we define the kth order *graph trend filtering* (GTF) estimate $\hat{\beta} = (\hat{\beta}_1, \dots \hat{\beta}_n)$ by

$$\hat{\beta} = \underset{\beta \in \mathbb{R}^n}{\operatorname{argmin}} \frac{1}{2}\|y - \beta\|_2^2 + \lambda \|\Delta^{(k+1)}\beta\|_1. \tag{4}$$

In broad terms, this problem (like univariate trend filtering) is a type of generalized lasso problem (Tibshirani and Taylor, 2011), in which the penalty matrix $\Delta^{(k+1)}$ is a suitably defined *graph difference operator*, of order $k+1$. In fact, the novelty in our proposal lies entirely within the definition of this operator.

When $k = 0$, we define first order graph difference operator $\Delta^{(1)}$ in such a way it yields the graph-equivalent of a penalty on local differences:

$$\|\Delta^{(1)}\beta\|_1 = \sum_{(i,j) \in E} |\beta_i - \beta_j|.$$

so that the penalty term in (4) sums the absolute differences across connected nodes in G. To achieve this, we let $\Delta^{(1)} \in \{-1, 0, 1\}^{m \times n}$ be the oriented incidence matrix of the graph G, containing one row for each edge in the graph; specifically, if $e_\ell = (i, j)$, then $\Delta^{(1)}$ has ℓth row

$$\Delta^{(1)}_\ell = (0, \dots \underset{\uparrow}{-1}_i, \dots \underset{\uparrow}{1}_j, \dots 0), \tag{5}$$

where the orientations of signs are arbitrary. Like trend filtering in the 1d setting, the 0th order graph trend filtering estimate coincides with the fused lasso (total variation regularized) estimate over G (Hoefling, 2010; Tibshirani and Taylor, 2011; Sharpnack et al., 2012).

For $k \geq 1$, we use a recursion to define the higher order graph difference operators, in a manner similar to the univariate case. The recursion alternates in multiplying by the first difference operator $\Delta^{(1)}$ and its transpose (taking into account that this matrix not square):

$$\Delta^{(k+1)} = \begin{cases} (\Delta^{(1)})^\top \Delta^{(k)} = L^{\frac{k+1}{2}} & \text{for odd } k \\ \Delta^{(1)} \Delta^{(k)} = D L^{\frac{k}{2}} & \text{for even } k. \end{cases} \tag{6}$$

Above, we abbreviated the oriented incidence matrix $\Delta^{(1)}$ by D of G, and exploited the fact that $L = D^\top D$ is one representation for the graph Laplacian matrix. Note that $\Delta^{(k+1)} \in \mathbb{R}^{n \times n}$ for odd k, and $\Delta^{(k+1)} \in \mathbb{R}^{m \times n}$ for even k.

An important point is that our defined graph difference operators (5), (6) reduce to the univariate ones (2), (3) in the case of a chain graph (in which $V = \{1, \dots n\}$ and $E = \{(i, i+1) : i = 1, \dots n-1\}$), modulo boundary terms. That is, when k is even, if one removes the first $k/2$ rows and last $k/2$ rows of $\Delta^{(k+1)}$ for the chain graph, then one recovers $D^{(k+1)}$; when k is odd, if one removes the first and last $(k+1)/2$ rows of $\Delta^{(k+1)}$ for the chain graph, then one recovers $D^{(k+1)}$. Further intuition for our graph difference operators is given next.

2.3 Piecewise Polynomials over Graphs

We give some insight for our definition of graph difference operators (5), (6), based on the idea of piecewise polynomials over graphs. In the univariate case, as described in Section 2.1, sparsity of β under the difference operator $D^{(k+1)}$ implies a specific kth order piecewise polynomial structure for

the components of β (Tibshirani, 2014; Wang et al., 2014). Since the components of β correspond to (real-valued) input locations $x = (x_1, \dots x_n)$, the interpretation of a piecewise polynomial here is unambiguous. But for a graph, one might ask: does sparsity of $\Delta^{(k+1)}\beta$ mean that the components of β are piecewise polynomial? And what does the latter even mean, as the components of β are defined over the nodes? To address these questions, we intuitively *define* a piecewise polynomial over a graph, and show that it implies sparsity under our constructed graph difference operators.

- **Piecewise constant ($k = 0$):** we say that a signal β is piecewise constant over a graph G if many of the differences $\beta_i - \beta_j$ are zero across edges $(i, j) \in E$ in G. Note that this is exactly the property associated with sparsity of $\Delta^{(1)}\beta$, since $\Delta^{(1)} = D$, the oriented incidence matrix of G.

- **Piecewise linear ($k = 1$):** we say that a signal β has a piecewise linear structure over G if β satisfies

  $$\beta_i - \frac{1}{n_i} \sum_{(i,j) \in E} \beta_j = 0,$$

  for many nodes $i \in V$, where n_i is the number of nodes adjacent to i. In words, we are requiring that the signal components can be linearly interpolated from its neighboring values at many nodes in the graph. This is quite a natural notion of (piecewise) linearity: requiring that β_i be equal to the average of its neighboring values would enforce linearity at β_i under an appropriate embedding of the points in Euclidean space. Again, this is precisely the same as requiring $\Delta^{(2)}\beta$ to be sparse, since $\Delta^{(2)} = L$, the graph Laplacian.

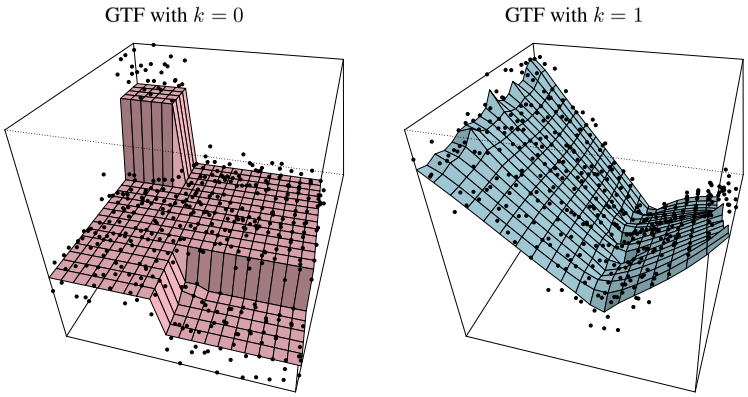
- **Piecewise polynomial ($k \geq 2$):** We say that β has a piecewise quadratic structure over G if the first differences $\alpha_i - \alpha_j$ of the second differences $\alpha = \Delta^{(2)}\beta$ are mostly zero, over edges $(i, j) \in E$. Likewise, β has a piecewise cubic structure over G if the second differences $\alpha_i - \frac{1}{n_i}\sum_{(i,j) \in E} \alpha_j$ of the second differences $\alpha = \Delta^{(2)}\beta$ are mostly zero, over nodes $i \in V$. This argument extends, alternating between leading first and second differences for even and odd k. Sparsity of $\Delta^{(k+1)}\beta$ in either case exactly corresponds to many of these differences being zero, by construction.

In Figure 3, we illustrate the graph trend filtering estimator on a 2d grid graph of dimension 20×20, i.e., a grid graph with 400 nodes and 740 edges. For each of the cases $k = 0, 1, 2$, we generated synthetic measurements over the grid, and computed a GTF estimate of the corresponding order. We chose the 2d grid setting so that the piecewise polynomial nature of GTF estimates could be visualized. Below each plot, the utilized graph trend filtering penalty is displayed in more explicit detail.

2.4 ℓ_1 versus ℓ_2 Regularization

It is instructive to compare the graph trend filtering estimator, as defined in (4), (5), (6) to Laplacian smoothing (Smola and Kondor, 2003). Standard Laplacian smoothing uses the same least squares loss as in (4), but replaces the penalty term with $\beta^\top L \beta$. A natural generalization would be to allow for a power of the Laplacian matrix L, and define kth order graph Laplacian smoothing according to

$$\hat{\beta} = \underset{\beta \in \mathbb{R}^n}{\operatorname{argmin}} \|y - \beta\|_2^2 + \lambda \beta^\top L^{k+1} \beta. \tag{7}$$



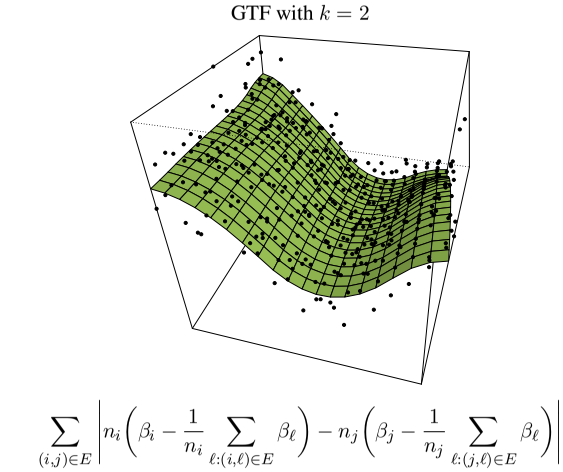


Figure 3: Graph trend filtering estimates of orders $k = 0, 1, 2$ on a 2d grid. The utilized ℓ_1 graph difference penalties are shown in elementwise detail below each plot (first, second, and third order graph differences).

The above penalty term can be written as $\|L^{(k+1)/2}\beta\|_2^2$ for odd k, and $\|DL^{k/2}\beta\|_2^2$ for even k; i.e., this penalty is exactly $\|\Delta^{(k+1)}\beta\|_2^2$ for the graph difference operator $\Delta^{(k+1)}$ defined previously.

As we can see, the critical difference between graph Laplacian smoothing (7) and graph trend filtering (4) lies in the choice of penalty norm: ℓ_2 in the former, and ℓ_1 in the latter. The effect of the ℓ_1 penalty is that the GTF program can set many (higher order) graph differences to zero exactly, and leave others at large nonzero values; i.e., the GTF estimate can simultaneously be smooth in some parts of the graph and wiggly in others. On the other hand, due to the (squared) ℓ_2 penalty, the graph Laplacian smoother cannot set any graph differences to zero exactly, and roughly speaking, must choose between making all graph differences small or large. The relevant analogy here is the comparison between the lasso and ridge regression, or univariate trend filtering and smoothing splines (Tibshirani, 2014), and the suggestion is that GTF can adapt to the proper local degree of smoothness, while Laplacian smoothing cannot. This is strongly supported by the examples given throughout this paper.

2.5 Related Work

Some authors from the signal processing community, e.g., Bredies et al. (2010); Setzer et al. (2011), have studied total generalized variation (TGV), a higher order variant of total variation regularization. Moreover, several discrete versions of these operators have been proposed. They are often similar to the construction that we have. However, the focus of these works is mostly on how well a discrete functional approximates its continuous counterpart. This is quite different from our concern, as a signal on a graph (say a social network) may not have any meaningful continuous-space embedding at all. In addition, we are not aware of any study on the statistical properties of these regularizers. In fact, our theoretical analysis in Section 6 may be extended to these methods too.

3. Properties and Extensions

We first study the structure of graph trend filtering estimates, then discuss interpretations and extensions.

3.1 Basic Structure and Degrees of Freedom

We describe the basic structure of graph trend filtering estimates and present an unbiased estimate for their degrees of freedom. Let the tuning parameter λ be arbitrary but fixed. By virtue of the ℓ_1 penalty in (4), the solution $\hat{\beta}$ satisfies $\text{supp}(\Delta^{(k+1)}\hat{\beta}) = A$ for some active set A (typically A is smaller when λ is larger). Trivially, we can reexpress this as $\Delta^{(k+1)}_{-A}\hat{\beta} = 0$, or $\hat{\beta} \in \text{null}(\Delta^{(k+1)}_{-A})$. Therefore, the basic structure of GTF estimates is revealed by analyzing the null space of the sub-operator $\Delta^{(k+1)}_{-A}$.

Lemma 1 *Assume without a loss of generality that G is connected (otherwise the results apply to each connected component of G). Let D, L be the oriented incidence matrix and Laplacian matrix of G. For even k, let $A \subseteq \{1, \dots m\}$, and let G_{-A} denote the subgraph induced by removing the edges indexed by A (i.e., removing edges e_ℓ, $\ell \in A$). Let $C_1, \dots C_s$ be the connected components of G_{-A}. Then*

$$\text{null}(\Delta^{(k+1)}_{-A}) = \text{span}\{\mathbb{1}\} + (L^\dagger)^{\frac{k}{2}}\text{span}\{\mathbb{1}_{C_1}, \dots \mathbb{1}_{C_s}\},$$

where $\mathbb{1} = (1, \dots 1) \in \mathbb{R}^n$*, and* $\mathbb{1}_{C_1}, \dots \mathbb{1}_{C_s} \in \mathbb{R}^n$ *are the indicator vectors over connected components. For odd* k*, let* $A \subseteq \{1, \dots n\}$*. Then*

$$\mathrm{null}(\Delta_{-A}^{(k+1)}) = \mathrm{span}\{\mathbb{1}\} + \{(L^\dagger)^{\frac{k+1}{2}} v : v_{-A} = 0\}.$$

The proof of Lemma 1 appears in the Appendix. The lemma is useful for a few reasons. First, as motivated above, it describes the coarse structure of GTF solutions. When $k = 0$, we can see (as $(L^\dagger)^{0/2} = I$) that $\hat{\beta}$ will indeed be piecewise constant over groups of nodes $C_1, \dots C_s$ of G. For $k = 2, 4, \dots$, this structure is smoothed by multiplying such piecewise constant levels by $(L^\dagger)^{k/2}$. Meanwhile, for $k = 1, 3 \dots$, the structure of the GTF estimate is based on assigning nonzero values to a subset A of nodes, and then smoothing through multiplication by $(L^\dagger)^{(k+1)/2}$. Both of these smoothing operations, which depend on $L^\dagger$, have interesting interpretations in terms of to the electrical network perspective for graphs. This is developed in the next subsection.

A second use of Lemma 1 is that it leads to a simple expression for the degrees of freedom, i.e., the effective number of parameters, of the GTF estimate $\hat{\beta}$. From results on generalized lasso problems (Tibshirani and Taylor, 2011, 2012), we have $\mathrm{df}(\hat{\beta}) = \mathbb{E}[\mathrm{nullity}(\Delta_{-A}^{(k+1)})]$, with A denoting the support of $\Delta^{(k+1)}\hat{\beta}$, and $\mathrm{nullity}(X)$ the dimension of the null space of a matrix X. Applying Lemma 1 then gives the following.

Lemma 2 *Assume that* G *is connected. Let* $\hat{\beta}$ *denote the GTF estimate at a fixed but arbitrary value of* λ*. Under the normal error model* $y \sim \mathcal{N}(\beta_0, \sigma^2 I)$*, the GTF estimate* $\hat{\beta}$ *has degrees of freedom given by*

$$\mathrm{df}(\hat{\beta}) = \begin{cases} \mathbb{E}\left[\max\{|A|, 1\}\right] & \textit{odd } k, \\ \mathbb{E}\left[\textit{number of connected components of } G_{-A}\right] & \textit{even } k. \end{cases}$$

Here $A = \mathrm{supp}(\Delta^{(k+1)}\hat{\beta})$ *denotes the active set of* $\hat{\beta}$*.*

As a result of Lemma 2, we can form simple unbiased estimate for $\mathrm{df}(\hat{\beta})$; for k odd, this is $\max\{|A|, 1\}$, and for k even, this is the number of connected components of G_{-A}, where A is the support of $\Delta^{(k+1)}\hat{\beta}$. When reporting degrees of freedom for graph trend filtering (as in the example in the introduction), we use these unbiased estimates.

3.2 Electrical Network Interpretation

Lemma 1 reveals a mathematical structure for GTF estimates $\hat{\beta}$, which satisfy $\hat{\beta} \in \mathrm{null}(\Delta_{-A}^{(k+1)})$ for some set A. It is interesting to interpret the results using the electrical network perspective for graphs (Vishnoi, 2012). In this perspective, we imagine replacing each edge in the graph with a resistor of value 1. If $u \in \mathbb{R}^n$ describes how much current is going in at each node in the graph, then $v = Lu$ describes the induced voltage at each node. Provided that $\mathbb{1}^\top c = 0$, which means that the total accumulation of current in the network is 0, we can solve for the current values from the voltage values: $u = L^\dagger v$.

The odd case in Lemma 1 asserts that

$$\mathrm{null}(\Delta_{-A}^{(k+1)}) = \mathrm{span}\{\mathbb{1}\} + \{(L^\dagger)^{\frac{k+1}{2}} v : v_{-A} = 0\}.$$

For $k = 1$, this says that GTF estimates are formed by assigning a sparse number of nodes in the graph a nonzero voltage v, then solving for the induced current $L^\dagger v$ (and shifting this entire current

vector by a constant amount). For $k = 3$, we assign a sparse number of nodes a nonzero voltage, solve for the induced current, and then *repeat this*: we relabel the induced current as input voltages to the nodes, and compute the new induced current. This process is again iterated for $k = 5, 7, \dots$.

The even case in Lemma 1 asserts that

$$\mathrm{null}(\Delta_{-A}^{(k+1)}) = \mathrm{span}\{\mathbb{1}\} + (L^\dagger)^{\frac{k}{2}} \mathrm{span}\{\mathbb{1}_{C_1}, \dots \mathbb{1}_{C_s}\}.$$

For $k = 2$, this result says that GTF estimates are given by choosing a partition $C_1, \dots C_s$ of the nodes, and assigning a constant input voltage to each element of the partition. We then solve for the induced current (and potentially shift this by an overall constant amount). The process is iterated for $k = 4, 6, \dots$ by relabeling the induced current as input voltage.

The comparison between the structure of estimates for $k = 2$ and $k = 3$ is informative: in a sense, the above tells us that 2nd order GTF estimates will be *smoother* than 3rd order estimates, as a sparse input voltage vector need not induce a current that is piecewise constant over nodes in the graph. For example, an input voltage vector that has only a few nodes with very large nonzero values will induce a current that is peaked around these nodes, but not piecewise constant.

3.3 Extensions

Several extensions of the proposed graph trend filtering model are possible. Trend filtering over a weighted graph, for example, could be performed by using a properly weighted version of the edge incidence matrix in (5), and carrying forward the same recursion in (6) for the higher order difference operators. As another example, the Gaussian regression loss in (4) could be changed to another suitable likelihood-derived losses in order to accommodate a different data type for y, say, logistic regression loss for binary data, or Poisson regression loss for count data.

In Section 5.2, we explore a modest extension of GTF, where we add a strongly convex prior term to the criterion in (4) to assist in performing graph-based imputation from partially observed data over the nodes. In Section 5.3, we investigate a modification of the proposed regularization scheme, where we add a pure ℓ_1 penalty on β in (4), hence forming a sparse variant of GTF. Other potentially interesting penalty extensions include: mixing graph difference penalties of various orders, and tying together several denoising tasks with a group penalty. Extensions such as these are easily built, recall, as a result of the analysis framework used by the GTF program, wherein the estimate defined through direct regularization via an analyzing operator, the ℓ_1-based graph difference penalty $\|\Delta^{(k+1)}\beta\|_1$.

4. Computation

Graph trend filtering is defined by a convex optimization problem (4). In principle this means that, at least for small or moderately sized problems, its solutions can be reliably computed using a variety of standard algorithms. In order to handle larger scale problems, we describe two specialized algorithms that improve on generic procedures by taking advantage of the structure of $\Delta^{(k+1)}$.

4.1 A Fast ADMM Algorithm

We reparametrize (4) by introducing auxiliary variables, so that we can apply ADMM. For even k, we use a special transformation that is critical for fast computation (following Ramdas and Tibshirani (2015) in univariate trend filtering); for odd k, this is not possible. The reparametrizations for

even and odd k are

$$\min_{\beta, z \in \mathbb{R}^n} \frac{1}{2}\|y-\beta\|_2^2 + \lambda\|Dz\|_1 \;\text{ s.t. }\; z = L^{\frac{k}{2}} x,$$
$$\min_{\beta, z \in \mathbb{R}^n} \frac{1}{2}\|y-\beta\|_2^2 + \lambda\|z\|_1 \;\text{ s.t. }\; z = L^{\frac{k+1}{2}} x,$$

respectively. Recall that D is the oriented incidence matrix and L is the graph Laplacian. The augmented Lagrangian is

$$\frac{1}{2}\|y-\beta\|_2^2 + \lambda\|Sz\|_1 + \frac{\rho}{2}\|z - L^q\beta + u\|_2^2 - \frac{\rho}{2}\|u\|_2^2,$$

where $S = D$ or $S = I$ depending on whether k is even or odd, and likewise $q = k/2$ or $q = (k+1)/2$. ADMM then proceeds by iteratively minimizing the augmented Lagrangian over β, minimizing over z, and performing a dual update over u. The β and z updates are of the form, for some b,

$$\beta \leftarrow (I + \rho L^{2q})^{-1} b, \tag{8}$$
$$z \leftarrow \operatorname*{argmin}_{x \in \mathbb{R}^n} \frac{1}{2}\|b-x\|_2^2 + \frac{\lambda}{\rho}\|Sx\|_1, \tag{9}$$

The linear system in (8) is well-conditioned, sparse, and can be solved efficiently using the preconditioned conjugate gradient method. This involves only multiplication with Laplacian matrices. For a small enough choices of $\rho > 0$ (the augmented Lagrangian parameter), the system in (8) is diagonally dominant, special Laplacian/SDD solvers can be applied, which run in almost linear time (Spielman and Teng, 2004; Koutis et al., 2011; Kelner et al., 2013).

For $S = I$, the update in (9) is simply given by soft-thresholding, and for $S = D$, it is given by graph TV denoising, i.e., given by solving a graph fused lasso problem. Note that this subproblem has the exact structure of the graph trend filtering problem (4) with $k = 0$. A direct approach for graph TV denoising is available based on parametric max-flow (Chambolle and Darbon, 2009), and this algorithm is empirically much faster than its worst-case complexity (Boykov and Kolmogorov, 2004). In the special case that the underlying graph is a grid, a promising alternative method employs proximal stacking techniques (Barbero and Sra, 2014).

4.2 A Fast Newton Method

As an alternative to ADMM, a projected Newton-type method (Bertsekas, 1982; Barbero and Sra, 2011) can be used to solve (4) via its dual problem:

$$\hat{v} = \operatorname*{argmin}_{v \in \mathbb{R}^r} \|y - (\Delta^{(k+1)})^\top v\|_2^2 \;\text{ s.t. }\; \|v\|_\infty \le \lambda.$$

The solution of (4) is then given by $\hat{\beta} = y - (\Delta^{(k+1)})^\top \hat{v}$. (For univariate trend filtering, Kim et al. (2009) adopt a similar strategy, but instead use an interior point method.) The projected Newton method performs updates using a reduced Hessian, so abbreviating $\Delta = \Delta^{(k+1)}$, each iteration boils down to

$$v \leftarrow a + (\Delta_I^\top)^\dagger b, \tag{10}$$

for some a, b and set of indices I. The linear system in (10) is always sparse, but conditioning becomes an issue as k grows (note that the same problem does not occur in (8) because of the addition of the identity matrix I). We have found empirically that a preconditioned conjugate gradient method works quite well for (10) for $k = 1$, but struggles for larger k.

4.3 Computation Summary

In our experience, the following algorithms work well for the various order k of graph trend filtering. We remark that orders $k = 0, 1, 2$ are of most practical interest (and solutions of polynomial order $k \ge 3$ are less likely to be sought in practice).[1]

Order	Algorithm
$k = 0$	Parametric max-flow
$k = 1$	Projected Newton method
$k = 2, 4, \ldots$	ADMM with parametric max-flow
$k = 3, 5, \ldots$	ADMM with soft-thresholding

Figure 4 compares performances of the described algorithms on a moderately large simulated example, using a 2d grid graph. We see that when $k = 1$, the projected Newton method converges faster than ADMM (superlinear versus at best linear convergence). When $k = 2$, the story is reversed, as the projected Newton iterations quickly become stagnant, and the ADMM enjoys better convergence.

5. Examples

In this section, we present a variety of examples of running graph trend filtering on real graphs.

5.1 Trend Filtering over the Facebook Graph

In the Introduction, we examined the denoising power of graph trend filtering in a spatial setting. Here we examine the behavior of graph trend filtering on a nonplanar graph: the Facebook graph from the Stanford Network Analysis Project (`http://snap.stanford.edu`). This is composed of 4039 nodes representing Facebook users, and 88,234 edges representing friendships, collected from real survey participants; the graph has one connected component, but the observed degree sequence is very mixed, ranging from 1 to 1045 (refer to McAuley and Leskovec (2012) for more details).

We generated synthetic measurements over the Facebook nodes (users) based on three different ground truth models, so that we can precisely evaluate and compare the estimation accuracy of GTF, Laplacian smoothing, and wavelet smoothing. For the latter, we again used the spanning tree wavelet design of Sharpnack et al. (2013a), because it performed among the best of wavelets designs in all data settings considered here. Results from other wavelet designs are presented in

1. Loosely speaking, each order $k = 0, 1, 2$ provides solutions that exhibit a different class of structure: $k = 0$ gives piecewise constant solutions, $k = 1$ gives piecewise linear, and $k = 2$ gives piecewise smooth. All orders $k \ge 3$ continue to give piecewise smooth fits, with less and less transparent differences (the practical differences between piecewise quadratic versus piecewise linear fits is greater than piecewise cubic versus piecewise quadratic, etc.). Since the conditioning of the graph trend filtering operator $\Delta^{(k+1)}$ worsens as k increases, which makes computation more difficult, it makes most practical sense to simply choose $k = 2$ whenever a piecewise smooth fit is desired.

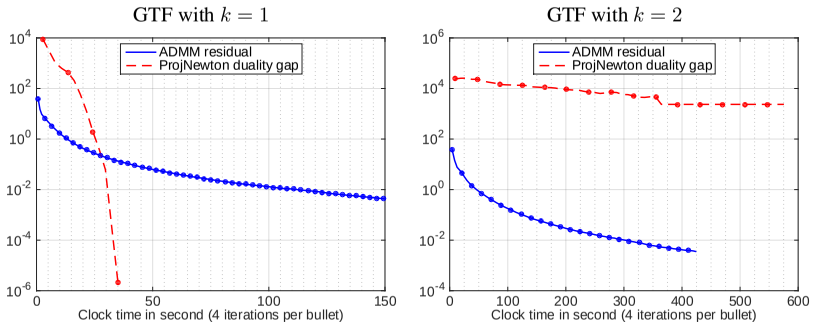

Figure 4: Convergence plots for projected Newton method and ADMM for solving GTF with $k = 1$ and $k = 2$. The algorithms are all run on a 2d grid graph (an 512×512 image) with 262,144 nodes and 523,264 edges. For projected Newton, we plot the duality gap across iterations; for ADMM, we plot the average of the primal and dual residuals (which also serves as a valid suboptimality bound in the ADMM framework).

the Appendix. The three ground truth models represent very different scenarios for the underlying signal x, each one favorable to different estimation methods. These are:

1. **Dense Poisson equation:** we solved the Poisson equation $Lx = b$ for x, where b is arbitrary and dense (its entries were i.i.d. normal draws).
2. **Sparse Poisson equation:** we solved the Poisson equation $Lx = b$ for x, where b is sparse and has 30 nonzero entries (again i.i.d. normal draws).
3. **Inhomogeneous random walk:** we ran a set of decaying random walks at different starter nodes in the graph, and recorded in x the total number of visits at each node. Specifically, we chose 10 nodes as starter nodes, and assigned each starter node a decay probability uniformly at random between 0 and 1 (this is the probability that the walk terminates at each step instead of travelling to a neighboring node). At each starter node, we also sent out a varying number of random walks, chosen uniformly between 0 and 1000.

In each case, the synthetic measurements were formed by adding noise to x. We note that model 1 is designed to be favorable for Laplace smoothing; model 2 is designed to be favorable for GTF; and in the inhomogeneity in model 3 is designed to be challenging for Laplacian smoothing, and favorable for the more adaptive GTF and wavelet methods.

Figure 5 shows the performance of the three estimation methods, over a wide range of noise levels in the synthetic measurements; performance here is measured by the best achieved mean squared error, allowing each method to be tuned optimally at each noise level. The summary: GTF estimates are (expectedly) superior when the Laplacian-based sparsity pattern is in effect (model 2), but are nonetheless highly competitive in both other settings—the dense case, in which Laplacian smoothing thrives, and the inhomogeneous random walk case, in which wavelets thrive.

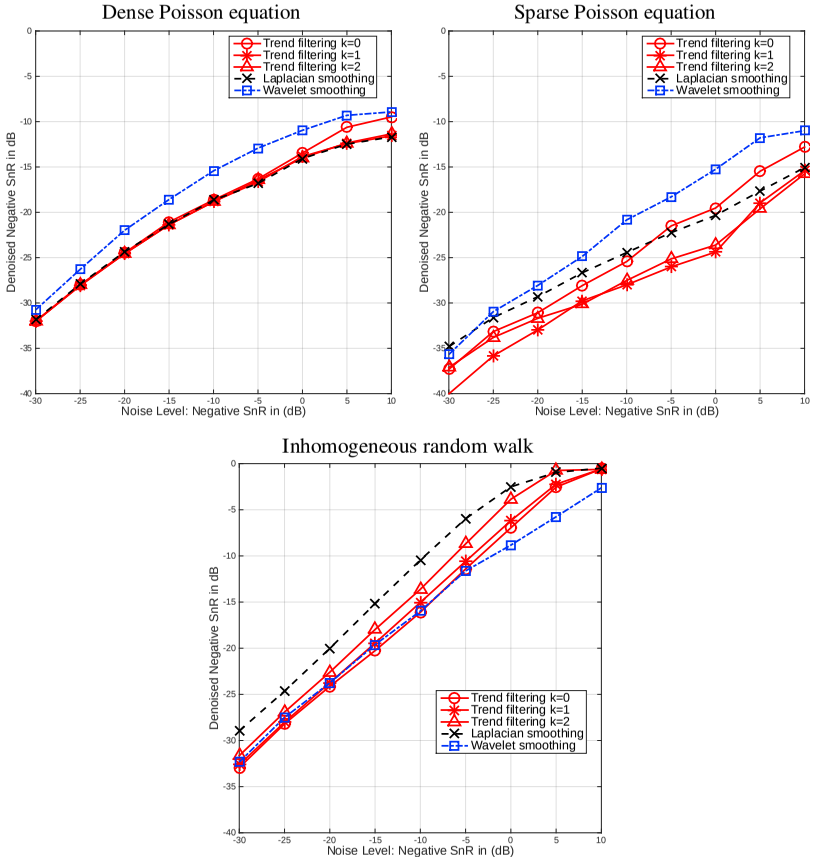

Figure 5: Performance of GTF and others for three generative models on the Facebook graph. The x-axis shows the negative SnR: $10 \log_{10}(n\sigma^2/\|x\|_2^2)$, where $n = 4039$, x is the underlying signal, and σ^2 is the noise variance. Hence the noise level is increasing from left to right. The y-axis shows the denoised negative SnR: $10 \log_{10}(\text{MSE}/\|x\|_2^2)$, where MSE denotes mean squared error, so the achieved MSE is increasing from bottom to top.

5.2 Graph-Based Transductive Learning over UCI Data

Graph trend filtering can used for graph-based transductive learning, as motivated by the work of Talukdar and Crammer (2009); Talukdar and Pereira (2010), who rely on Laplacian regularization. Consider a semi-supervised learning setting, where we are given only a small number of seed labels over nodes of a graph, and the goal is to impute the labels on the remaining nodes. Write $O \subseteq \{1, \dots n\}$ for the set of observed nodes, and assume that each observed label falls into $\{1, \dots K\}$. Then we can define the modified absorption problem under graph trend filtering regularization (MAD-GTF) by

$$\hat{B} = \underset{B \in \mathbb{R}^{n \times K}}{\operatorname{argmin}} \sum_{j=1}^{K} \sum_{i \in O} (Y_{ij} - B_{ij})^2 + \lambda \sum_{j=1}^{K} \|\Delta^{(k+1)} B_j\|_1 + \epsilon \sum_{j=1}^{K} \|R_j - B_j\|_2^2. \tag{11}$$

The matrix $Y \in \mathbb{R}^{n \times K}$ is an indicator matrix: each observed row $i \in O$ is described by $Y_{ij} = 1$ if class j is observed and $Y_{ij} = 0$ otherwise. The matrix $B \in \mathbb{R}^{n \times K}$ contains fitted probabilities, with B_{ij} giving the probability that node i is of class j. We write B_j for its jth column, and hence the middle term in the above criterion encourages each set of class probabilities to behave smoothly over the graph. The last term in the above criterion ties the fitted probabilities to some given prior weights $R \in \mathbb{R}^{n \times K}$. In principle ϵ could act as a second tuning parameter, but for simplicity we take ϵ to be small and fixed, with any $\epsilon > 0$ guaranteeing that the criterion in (11) is strictly convex, and thus has a unique solution $\hat{B}$. The entries of $\hat{B}$ need not be probabilites in any strict sense, but we can still interpret them as relative probabilities, and imputation can be performed by assigning each unobserved node $i \notin O$ a class label j such that $\hat{B}_{ij}$ is largest.

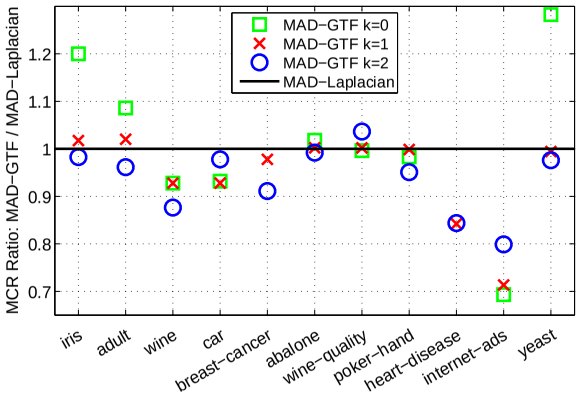

Figure 6: Ratio of the misclassification rate of MAD-GTF to MAD-Laplacian, for graph-based imputation, on the 11 most popular UCI classification data sets.

Our specification of MAD-GTF only deviates from the MAD proposal of Talukdar and Crammer (2009) in that these authors used the Laplacian regularization term $\sum_{j=1}^{K} B_j^\top L B_j$, in place of ℓ_1-based graph difference regularizer in (11). If the underlying class probabilities are thought

Table 1: Misclassification rates of MAD-Laplacian and MAD-GTF for imputation in the UCI data sets. We also compute p-values over the 10 repetitions for each data set (10 draws of nodes to serve as seed labels) via paired t-tests. Cases where MAD-GTF achieves significantly better misclassification rate, at the 0.1 level, are highlighted in green; cases where MAD-GTF achieves a significantly worse miclassification rate, at the 0.1 level, are highlighted in red.

to have heterogeneous smoothness over the graph, then replacing the Laplacian regularizer with the GTF-designed one might lead to better performance. As a broad comparison of the two methods, we ran them on the 11 most popular classification data sets from the UCI Machine Learning repository (`http://archive.ics.uci.edu/ml/`).[2] For each data set, we constructed a 5-nearest-neighbor graph based on the Euclidean distance between provided features, and randomly selected 5 seeds per class to serve as the observed class labels. Then we set $\epsilon = 0.01$, used prior weights $R_{ij} = 1/K$ for all i and j, and chose the tuning parameter λ over a wide grid of values to represent the best achievable performance by each method, on each experiment. Figure 6 and Table 1 summarize the misclassification rates from imputation using MAD-Laplacian and MAD-GTF, averaged over 10 repetitions of the randomly selected seed labels. We see that MAD-GTF with $k = 0$ (basically a graph partition akin to MRF-based graph cut, using an Ising model) does not seem to work as well as the smoother alternatives. Importantly, MAD-GTF with $k = 1$ and $k = 2$ both perform at least as well, and sometimes better, than MAD-Laplacian on each one of the UCI data sets. Recall that these data sets were selected entirely based on their popularity, and not at all on the belief that they might represent favorable scenarios for GTF (i.e., not on the prospect that they might exhibit some heterogeneity in the distribution of class labels over their respective graphs). Therefore, the fact that MAD-GTF nonetheless performs competitively in such a broad range of experiments is convincing evidence for the utility of the GTF regularizer.

5.3 Event Detection with NYC Taxi Trips Data

We illustrate a sparse variant of our proposed regularizers, given by adding a pure ℓ_1 penalty to the coefficients in (4), as in

$$\hat{\beta} = \underset{\beta \in \mathbb{R}^n}{\operatorname{argmin}} \frac{1}{2} \|y - \beta\|_2^2 + \lambda_1 \|\Delta^{(k+1)} \beta\|_1 + \lambda_2 \|\beta\|_1. \tag{12}$$

We call this *sparse graph trend filtering*, now with two tuning parameters $\lambda_1, \lambda_2 \geq 0$. Under the proper tuning, the sparse GTF estimate will be zero at many nodes in the graph, and will otherwise

2. We used all data sets here, except the "forest-fires" data set, which is a regression problem. Also, we zero-filled the missing data in "internet-ads" data set and used a random one third of the data in the "poker" data set.

deviate smoothly from zero. This can be useful in situations where the observed signal represents a difference between two smooth processes that are mostly similar, but exhibit (perhaps significant) differences over a few regions of the graph. Here we apply it to the problem of detecting events based on abnormalities in the number of taxi trips at different locations of New York city. This data set was kindly provided by authors of Doraiswamy et al. (2014), who obtained the data from NYC Taxi & Limosine Commission.[3] Specifically, we consider the graph to be the road network of Manhattan, which contains 3874 nodes (junctions) and 7070 edges (sections of roads that connect two junctions). For measurements over the nodes, we used the number of taxi pickups and dropoffs over a particular time period of interest: 12:00–2:00 pm on June 26, 2011, corresponding to the Gay Pride parade. As pickups and dropoffs do not generically occur at road junctions, we used interpolation to form counts over the graph nodes. A baseline seasonal average was calculated by considering data from the same time block 12:00–2:00 pm on the same day of the week across the nearest eight weeks. Thus the measurements y were then taken to be the difference between the counts observed during the Gay Pride parade and the seasonal averages.

Note that the nonzero node estimates from sparse GTF applied to y, after proper tuning, mark events of interest, because they convey substantial differences between the observed and expected taxi counts. According to descriptions in the news, we know that the Gay Pride parade was a giant march down at noon from 36th St. and Fifth Ave. all the way to Christopher St. in Greenwich Village, and traffic was blocked over the entire route for two hours (meaning no pickups and dropoffs could occur). We therefore hand-labeled this route as a crude "ground truth" for the event of interest, illustrated in the left panel of Figure 7.

In the bottom two panels of Figure 7, we compare sparse GTF with $k = 0$ (i.e., the sparse graph fused lasso) and a sparse variant of Laplacian smoothing, obtained by replacing the first regularization term in (12) by $\beta^\top L\beta$. For a qualitative visual comparison, the smoothing parameter λ_1 was chosen so that both methods have 200 degrees of freedom (without any sparsity imposed). The sparsity parameter was then set as $\lambda_2 = 0.2$. Similar to what we have seen already, GTF is able to better localize its estimates around strong inhomogenous spikes in the measurements, and is able to better capture the event of interest. The result of sparse Laplacian smoothing is far from localized around the ground truth event, and displays many nonzero node estimates throughout distant regions of the graph. If we were to decrease its flexibility (increase the smoothing parameter λ_1 in its problem formulation), then the sparse Laplacian output would display more smoothness over the graph, but the node estimates around the ground truth region would also be grossly shrunken.

6. Estimation Error Bounds

In this section, we assume that $y \sim \mathcal{N}(\beta_0, \sigma^2 I)$, and study asymptotic error rates for graph trend filtering. (The assumption of a normal error model could be relaxed, but is used for simplicity). Our analysis actually focuses more broadly on the generalized lasso problem

$$\hat{\beta} = \underset{\beta \in \mathbb{R}^n}{\operatorname{argmin}} \ \frac{1}{2}\|y - \beta\|_2^2 + \lambda\|\Delta\beta\|_1, \tag{13}$$

3. These authors also considered event detection, but their topological definition of an "event" is very different from what we considered here, and hence our results not directly comparable.

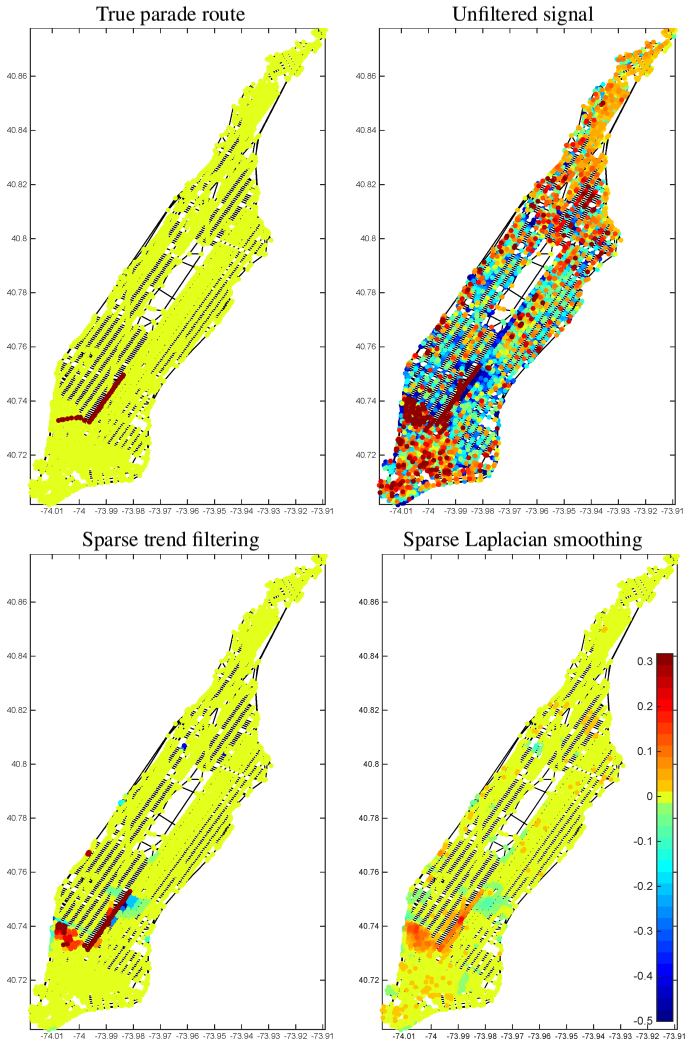

Figure 7: Comparison of sparse GTF and sparse Laplacian smoothing. We can see qualitatively that sparse GTF delivers better event detection with fewer false positives (zoomed-in, the sparse Laplacian plot shows a scattering of many non-zero colors).

where $\Delta \in \mathbb{R}^{r \times n}$ is an arbitrary linear operator, and r denotes its number of rows. Throughout, we specialize the derived results to the graph difference operator $\Delta = \Delta^{(k+1)}$, to obtain concrete statements about GTF over particular graphs. All proofs are deferred to the Appendix.

6.1 Basic Error Bounds

Using similar arguments to the basic inequality for the lasso (Buhlmann and van de Geer, 2011), we have the following preliminary bound.

Theorem 3 *Let M denote the maximum ℓ_2 norm of the columns of $\Delta^\dagger$. Then for a tuning parameter value $\lambda = \Theta(M\sqrt{\log r})$, the generalized lasso estimate $\hat{\beta}$ in (13) has average squared error*

$$\frac{\|\hat{\beta} - \beta_0\|_2^2}{n} = O_{\mathbb{P}}\left(\frac{\mathrm{nullity}(\Delta)}{n} + \frac{M\sqrt{\log r}}{n} \cdot \|\Delta\beta_0\|_1\right).$$

Recall that $\mathrm{nullity}(\Delta)$ denotes the dimension of the null space of Δ. For the GTF operator $\Delta^{(k+1)}$ of any order k, note that $\mathrm{nullity}(\Delta^{(k+1)})$ is the number of connected components in the underlying graph.

When both $\|\Delta\beta_0\|_1 = O(1)$ and $\mathrm{nullity}(\Delta) = O(1)$, Theorem 3 says that the estimate $\hat{\beta}$ converges in average squared error at the rate $M\sqrt{\log r}/n$, in probability. This theorem is quite general, as it applies to any linear operator Δ, and one might therefore think that it cannot yield fast rates. Still, as we show next, it does imply consistency for graph trend filtering in certain cases.

Corollary 4 *Consider the trend filtering estimator $\hat{\beta}$ of order k, and the choice of the tuning parameter λ as in Theorem 3. Then:*

1. *for univariate trend filtering (i.e., essentially GTF on a chain graph),*

$$\frac{\|\hat{\beta} - \beta_0\|_2^2}{n} = O_{\mathbb{P}}\left(\sqrt{\frac{\log n}{n}} \cdot n^k \|D^{(k+1)}\beta_0\|_1\right);$$

2. *for GTF on an Erdos-Renyi random graph, with edge probability p, and expected degree $d = np \geq 1$,*

$$\frac{\|\hat{\beta} - \beta_0\|_2^2}{n} = O_{\mathbb{P}}\left(\frac{\sqrt{\log(nd)}}{nd^{\frac{k+1}{2}}} \cdot \|\Delta^{(k+1)}\beta_0\|_1\right);$$

3. *for GTF on a Ramanujan d-regular graph, and $d \geq 1$,*

$$\frac{\|\hat{\beta} - \beta_0\|_2^2}{n} = O_{\mathbb{P}}\left(\frac{\sqrt{\log(nd)}}{nd^{\frac{k+1}{2}}} \cdot \|\Delta^{(k+1)}\beta_0\|_1\right).$$

Cases 2 and 3 of Corollary 4 stem from the simple inequality $M \leq \|\Delta^\dagger\|_2$, the largest singular value of $\Delta^\dagger$. When $\Delta = \Delta^{(k+1)}$, the GTF operator of order $k+1$, we have

$$\|(\Delta^{(k+1)})^\dagger\|_2 \leq 1/\lambda_{\min}(L)^{(k+1)/2},$$

where $\lambda_{\min}(L)$ is the smallest nonzero eigenvalue of the Laplacian L (also known as the Fiedler eigenvalue (Fiedler, 1973)). In general, $\lambda_{\min}(L)$ can be very small, leading to loose error bounds,

but for the particular graphs in question, it is well-controlled. When $\|\Delta^{(k+1)}\beta_0\|_1$ is bounded, cases 2 and 3 of the corollary show that the average squared error of GTF converges at the rate $\sqrt{\log(nd)}/(nd^{(k+1)/2})$. As k increases, this rate is stronger, but so is the assumption that $\|\Delta^{(k+1)}\beta_0\|_1$ is bounded.

Case 1 in Corollary 4 covers univariate trend filtering (which, recall, is basically the same as GTF over a chain graph; the only differences between the two are boundary terms in the construction of the difference operators). The result in case 1 is based on direct calculation of M, using specific facts that are known about the univariate difference operators. It is natural in the univariate setting to assume that $n^k\|D^{(k+1)}\beta_0\|_1$ is bounded (this is the scaling that would link β_0 to the evaluations of a piecewise polynomial function f_0 over $[0,1]$, with $\mathrm{TV}(f_0^{(k)})$ bounded). Under such an assumption, the above corollary yields a convergence rate of $\sqrt{\log n/n}$ for univariate trend filtering, which is not tight. A more refined analysis shows the univariate trend filtering estimator to converge at the minimax optimal rate $n^{-(2k+2)/(2k+3)}$, proved in Tibshirani (2014) by using a connection between univariate trend filtering and locally adaptive regression splines, and relying on sharp entropy-based rates for locally adaptive regression splines from Mammen and van de Geer (1997). We note that in a pure graph-centric setting, the latter strategy is not generally applicable, as the notion of a spline function does not obviously extend to the nodes of an arbitrary graph structure.

In the next subsections, we develop more advanced strategies for deriving fast GTF error rates, based on incoherence, and entropy. These can provide substantial improvements over the basic error bound established in this subsection, but are only applicable to certain graph models. Fortunately, this includes common graphs of interest, such as regular grids. To verify the sharpness of these alternative strategies, we will show that they can be used to recover optimal rates of convergence for trend filtering in the 1d setting.

6.2 Strong Error Bounds Based on Incoherence

A key step in the proof of Theorem 3 argues, roughly speaking, that

$$\epsilon^\top \Delta^\dagger \Delta x \leq \|(\Delta^\dagger)^\top \epsilon\|_\infty \|\Delta x\|_1 = O_{\mathbb{P}}(M\sqrt{\log r}\|\Delta x\|_1), \tag{14}$$

where $\epsilon \sim \mathcal{N}(0, \sigma^2 I)$. The second bound holds by a standard result on maxima of Gaussians (recall that M is largest ℓ_2 norm of the columns of $\Delta^\dagger$). The first bound above uses Holder's inequality; note that this applies to any ϵ, Δ, i.e., it does not use any information about the distribution of ϵ, or the properties of Δ. The next lemma reveals a potential advantage that can be gained from replacing the bound (14), stemming from Holder's inequality, with a "linearized" bound.

Lemma 5 *Denote $\epsilon \sim \mathcal{N}(0, \sigma^2 I)$, and assume that*

$$\max_{x \in \mathcal{S}_\Delta(1)} \frac{\epsilon^\top x - A}{\|x\|_2} = O_{\mathbb{P}}(B), \tag{15}$$

where $\mathcal{S}_\Delta(1) = \{x \in \mathrm{row}(\Delta) : \|\Delta x\|_1 \leq 1\}$. With $\lambda = \Theta(A)$, the generalized lasso estimate $\hat{\beta}$ satisfies

$$\frac{\|\hat{\beta} - \beta_0\|_2^2}{n} = O_{\mathbb{P}}\left(\frac{\mathrm{nullity}(\Delta)}{n} + \frac{B^2}{n} + \frac{A}{n} \cdot \|\Delta\beta_0\|_1\right).$$

The inequality in (15) is referred to as a "linearized" bound because it implies that for $x \in \mathcal{S}_\Delta(1)$,

$$\epsilon^\top x = O_{\mathbb{P}}(A + B\|x\|_2),$$

and the right-hand side is a linear function of $\|x\|_2$. Indeed, for $A = M\sqrt{2\log r}$ and $B = 0$, this encompasses the bound in (14) as a special case, and the result of Lemma 5 reduces to that of Theorem 3. But the result in Lemma 5 can be much stronger, if A, B can be adjusted so that A is smaller than $M\sqrt{2\log r}$, and B is also small. Such an arrangement is possible for certain operators Δ; e.g., it is possible under an incoherence-type assumption on Δ.

Theorem 6 *Let $q = \mathrm{rank}(\Delta)$, and let $\xi_1 \leq \ldots \leq \xi_q$ denote the singular values of Δ, in increasing order. Also let $u_1, \ldots u_q$ be the corresponding left singular vectors. Assume that these vectors are incoherent:*

$$\|u_i\|_\infty \leq \mu/\sqrt{n}, \quad i = 1, \ldots q,$$

for some constant $\mu \geq 1$. For $i_0 \in \{1, \ldots q\}$, let

$$\lambda = \Theta\left(\mu\sqrt{\frac{\log r}{n}\sum_{i=i_0+1}^{q}\frac{1}{\xi_i^2}}\right).$$

Then the generalized lasso estimate $\hat{\beta}$ has average squared error

$$\frac{\|\hat{\beta} - \beta_0\|_2^2}{n} = O_{\mathbb{P}}\left(\frac{\mathrm{nullity}(\Delta)}{n} + \frac{i_0}{n} + \frac{\mu}{n}\sqrt{\frac{\log r}{n}\sum_{i=i_0+1}^{q}\frac{1}{\xi_i^2}} \cdot \|\Delta\beta_0\|_1\right).$$

Theorem 6 is proved by leveraging the linearized bound (15), which holds under the incoherence condition on the singular vectors of Δ. Compared to the basic result in Theorem 3, the result in Theorem 6 is clearly stronger as it allows us to replace M—which can grow like the reciprocal of the minimum nonzero singular value of Δ—with something akin to the average reciprocal of larger singular values. But it does, of course, also make stronger assumptions (incoherence). It is interesting to note that the functional in the theorem, $\sum_{i=i_0+1}^{q}\xi_i^{-2}$, was also determined to play a leading role in error bounds for a graph Fourier based scan statistic in the hypothesis testing framework (Sharpnack et al., 2013b).

Applying the above theorem to the GTF estimator requires knowledge of the singular vectors of $\Delta = \Delta^{(k+1)}$, the $(k+1)$st order graph difference operator. The validity of an incoherence assumption on these singular vectors depend on the graph G in question. When k is odd, these singular vectors are eigenvectors of the Laplacian L; when k is even, they are left singular vectors of the edge incidence matrix D. Loosely speaking, these vectors will be incoherent when neighborhoods of different vertices look roughly the same. Most social networks will have this property for the bulk of their vertices (i.e., with the exception of a small number of high degree vertices). Grid graphs also have this property. First, we consider trend filtering over a 1d grid, i.e., a chain (which, recall, is essentially equivalent to univariate trend filtering).

Corollary 7 *Consider the GTF estimator $\hat{\beta}$ of order k, over a chain graph, i.e., a 1d grid graph. Letting*

$$\lambda = \Theta\left(n^{\frac{2k+1}{2k+3}}(\log n)^{\frac{1}{2k+3}}\|\Delta^{(k+1)}\beta_0\|_1^{-\frac{2k+1}{2k+3}}\right),$$

the estimator $\hat{\beta}$ (here, essentially, the univariate trend filtering estimator) satisfies

$$\frac{\|\hat{\beta} - \beta_0\|_2^2}{n} = O_{\mathbb{P}}\left(n^{-\frac{2k+2}{2k+3}}(\log n)^{\frac{1}{2k+3}} \cdot \left(n^k\|\Delta^{(k+1)}\beta_0\|_1\right)^{\frac{2}{2k+3}}\right).$$

We note that the above corollary essentially recovers the optimal rate of convergence for the univariate trend filtering estimator, for all orders k. (To be precise, it studies GTF on a chain graph instead, but this is basically the same problem.) When $n^k\|\Delta^{(k+1)}\beta_0\|_1$ is assumed to be bounded, a natural assumption in the univariate setting, the corollary shows the estimator to converge at the rate $n^{-(2k+2)/(2k+3)}(\log n)^{1/(2k+3)}$. Ignoring the log factor, this matches the minimax optimal rate as established in Tibshirani (2014); Wang et al. (2014). Importantly, the proof of Corollary 7, unlike that used in previous works, is free from any dependence on univariate spline functions; it is completely graph-theoretic, and only uses on the incoherence properties of the 1d grid graph. The strength of this approach is its wider applicability, which we demonstrate by moving up to 2d grids.

Corollary 8 *Consider the GTF estimator $\hat{\beta}$ of order k, over a 2d grid graph, of size $\sqrt{n} \times \sqrt{n}$. Letting*

$$\lambda = \Theta\left(n^{\frac{2k+1}{2k+5}}(\log n)^{\frac{1}{2k+5}}\|\Delta^{(k+1)}\beta_0\|_1^{-\frac{2k+1}{2k+5}}\right),$$

the estimator $\hat{\beta}$ satisfies

$$\frac{\|\hat{\beta} - \beta_0\|_2^2}{n} = O_{\mathbb{P}}\left(n^{-\frac{2k+4}{2k+5}}(\log n)^{\frac{1}{2k+5}} \cdot \left(n^{\frac{k}{2}}\|\Delta^{(k+1)}\beta_0\|_1\right)^{\frac{4}{2k+5}}\right).$$

The 2d result in Corollary 8 is written in a form that mimics the 1d result in Corollary 7, as we claim that the analog of boundedness of $n^k\|\Delta^{(k+1)}\beta_0\|_1$ in 1d is boundedness of $n^{k/2}\|\Delta^{(k+1)}\beta_0\|_1$ in 2d.[4] Thus, under the appropriate boundedness condition, the 2d rate shows improvement over the 1d rate, which makes sense, since regularization here is being enforced in a richer manner. It is worthwhile highlighting the result for $k = 0$ in particular: this says that, when the sum of absolute discrete differences $\|\Delta^{(1)}\beta_0\|_1$ is bounded over a 2d grid, the 2d fused lasso (i.e., 2d total variation denoising) has error rate $n^{-4/5}$. This is faster than the $n^{-2/3}$ rate for the 1d fused lasso, when the sum of absolute differences $\|D^{(1)}\beta_0\|_1$ is bounded. Rates for higher dimensional grid graphs (for all k) follow from analogous arguments, but we omit the details.

6.3 Strong Error Bounds Based on Entropy

A different "fractional" bound on the Gaussian contrast $\epsilon^\top x$, over $x \in \mathcal{S}_\Delta(1)$, provides an alternate route to deriving sharper rates. This style of bound is inspired by the seminal work of van de Geer (1990).

Lemma 9 *Denote $\epsilon \sim \mathcal{N}(0, \sigma^2 I)$, and assume that for a constant $w < 2$,*

$$\max_{x \in \mathcal{S}_\Delta(1)} \frac{\epsilon^\top x}{\|x\|_2^{1-w/2}} = O_{\mathbb{P}}(K), \tag{16}$$

where recall $\mathcal{S}_\Delta(1) = \{x \in \mathrm{row}(\Delta) : \|\Delta x\|_1 \leq 1\}$. Then with

$$\lambda = \Theta\left(K^{\frac{2}{1+w/2}} \cdot \|\Delta\beta_0\|_1^{-\frac{1-w/2}{1+w/2}}\right),$$

4. This is because $1/\sqrt{n}$ is the distance between adjacent 2d grid points, when viewed as a 2d lattice over $[0,1]^2$.

the generalized lasso estimate $\hat{\beta}$ satisfies

$$\frac{\|\hat{\beta} - \beta_0\|_2^2}{n} = O_{\mathbb{P}}\left(\frac{\text{nullity}(\Delta)}{n} + \frac{K^{\frac{2}{1+w/2}}}{n} \cdot \|\Delta\beta_0\|_1^{\frac{w}{1+w/2}}\right).$$

The main motivation for bounds of the form (16) is that they follow from entropy bounds on the set $\mathcal{S}_\Delta(1)$. Recall that for a set S, the covering number $N(\delta, S, \|\cdot\|)$ is the fewest number of balls of radius δ that cover S, with respect to the norm $\|\cdot\|$. The log covering or entropy number is $\log N(\delta, S, \|\cdot\|)$. In the next result, we make the connection between between entropy and fractional bounds precise; this follows closely from Lemma 3.5 of van de Geer (1990).

Theorem 10 *Suppose that there exist a constant $w < 2$ such that for n large enough,*

$$\log N(\delta, \mathcal{S}_\Delta(1), \|\cdot\|_2) \leq E\Big(\frac{\sqrt{n}}{\delta}\Big)^w, \tag{17}$$

for $\delta > 0$, where E can depend on n. Then the fractional bound in (16) *holds with $K = \sqrt{E}n^{w/4}$, and as a result, for*

$$\lambda = \Theta\left(E^{\frac{1}{1+w/2}} n^{\frac{w/2}{1+w/2}} \|\Delta\beta_0\|_1^{-\frac{1-w/2}{1+w/2}}\right),$$

the generalized lasso estimate $\hat{\beta}$ has average squared error

$$\frac{\|\hat{\beta} - \beta_0\|_2^2}{n} = O_{\mathbb{P}}\left(\frac{\text{nullity}(\Delta)}{n} + E^{\frac{1}{1+w/2}} n^{-\frac{1}{1+w/2}} \cdot \|\Delta\beta_0\|_1^{\frac{w}{1+w/2}}\right).$$

To make use of the result in Theorem 10, we must obtain an entropy bound as in (17), on the set $\mathcal{S}_\Delta(1)$. The literature on entropy numbers is rich, and there are various methods for computing entropy bounds, any of which can be used for these purposes as long as the bounds fit the form of (17), as required by the theorem. For bounding the entropy of a set like $\mathcal{S}_\Delta(1)$, two common techniques are to use a characterization of the spectral decay of $\Delta^\dagger$, or an analysis of the correlations between columns of $\Delta^\dagger$. For a nice review of such strategies and their applications, we refer the reader to Section 6 of van de Geer and Lederer (2013) and Section 14.12 of Buhlmann and van de Geer (2011). We do not pursue either of these two strategies in the current paper. We instead consider a third, somewhat more transparent strategy, based on a covering number bound of the columns of $\Delta^\dagger$.

Lemma 11 *Let $g_1, \ldots g_r$ denote the "atoms" associated with the operator Δ, i.e., the columns of $\Delta^\dagger$, and let $\mathcal{G} = \{\pm g_i : i = 1, \ldots r\}$ denote the symmetrized set of atoms. Suppose that there exists constants ζ, C_0 with the following property: for each $j = 1, \ldots 2r$, there is an arrangement of j balls having radius at most*

$$C_0 \sqrt{n} j^{-1/\zeta},$$

with respect to the norm $\|\cdot\|_2$, that covers $\mathcal{G}$. Then the entropy bound in (17) *is met with $w = 2\zeta/(2+\zeta)$ and $E = O(1)$. Therefore, the generalized lasso estimate $\hat{\beta}$, with*

$$\lambda = \Theta\left(n^{\frac{\zeta}{2+2\zeta}} \|\Delta\beta_0\|_1^{-\frac{1}{1+\zeta}}\right),$$

satisfies

$$\frac{\|\hat{\beta} - \beta_0\|_2^2}{n} = O_{\mathbb{P}}\left(\frac{\text{nullity}(\Delta)}{n} + n^{-\frac{2+\zeta}{2+2\zeta}} \cdot \|\Delta\beta_0\|_1^{\frac{\zeta}{1+\zeta}}\right).$$

The entropy-based results in this subsection (Lemma 9, Theorem 10, and Lemma 11) may appear more complex than those involving incoherence in the previous subsection (Lemma 5 and Theorem 6). Indeed, the same can be said of their proofs, which can be found in the Appendix. But after all this entropy machinery has all been established, it can actually be remarkably easy to use, say, Lemma 11 to produce sharp results. We conclude by giving an example.

Corollary 12 *Consider the 1d fused lasso, i.e., the GTF estimator with $k = 0$ over a chain graph. In this case, we have $\Delta = D^{(1)}$, the univariate difference operator, and the symmetrized set $\mathcal{G}$ of atoms can be covered by j balls with radius at most $\sqrt{2n/j}$, for $j = 1, \ldots 2(n-1)$. Hence, with $\lambda = \Theta(n^{1/3}\|D^{(1)}\beta_0\|_1^{-1/3})$, the 1d fused lasso estimate $\hat{\beta}$ satisfies*

$$\frac{\|\hat{\beta} - \beta_0\|_2^2}{n} = O_{\mathbb{P}}\left(n^{-2/3} \cdot \|D^{(1)}\beta_0\|_1^{2/3}\right).$$

This corollary rederives the optimal convergence rate of $n^{-2/3}$ for the univariate fused lasso, assuming boundedness of $\|D^{(1)}\beta_0\|_1$, as has been already shown in Mammen and van de Geer (1997); Tibshirani (2014). Like Corollary 7 (but unlike previous works), its proof does not rely on any special facts about 1d functions of bounded variation. It only uses a covering number bound on the columns of the operator $(D^{(1)})^+$, a strategy that, in principle, extends to many other settings (graphs). It is worth emphasizing just how simple this covering number construction is, compared to the incoherence-based arguments that lead to the same result; we invite the curious reader to compare the proofs of Corollaries 7 and 12.

7. Discussion

In this work, we proposed graph trend filtering as a useful alternative to Laplacian and wavelet smoothers on graphs. This is analogous to the usefulness of univariate trend filtering in nonparametric regression, as an alternative to smoothing splines and wavelets (Tibshirani, 2014). We have documented empirical evidence for the superior local adaptivity of the ℓ_1-based GTF over the ℓ_2-based graph Laplacian smoother, and the superior robustness of GTF over wavelet smoothing in high-noise scenarios. Our theoretical analysis provides a basis for a deeper understanding of the estimation properties of GTF. More precise theoretical characterizations involving entropy will be the topic of future work, as will comparisons between the error rates achieved by GTF and other common estimators, such as Laplacian smoothing. These extensions, and many others, are well within reach.

ACKNOWLEDGMENTS

The authors would like to thank Harish Doraiswamy, Nivan Ferreira, Theodoros Damoulas and Claudio Silva for sharing the pre-processed NYC taxi data, Jeff Irion and Naoki Saito for their help with the implementation of the graph wavelet algorithms, as well as the associate editor and anonymous reviewers for the valuable feedback.

Appendix A. Additional Analysis from Alternative Wavelet Designs

We provide detailed comparisons to a few recently proposed wavelet approaches for graph smoothing.

A.1 Allegheny County Example

In addition to considering the wavelet design of Sharpnack et al. (2013a) for the Allegheny County example, we also considered designs of Coiman and Maggioni (2006)—a classic method that builds diffusion wavelets on a graph, and Irion (2015)—a more recent graph wavelet construction. In contrast to Sharpnack et al. (2013a), which produces a single signal-independent orthogonal basis for a graph, both Coiman and Maggioni (2006); Irion (2015) build wavelet packets from a given graph structure. A wavelet packet is an overcomplete basis indexed by a hierarchical data structure that can be used to generate an exponential number of orthogonal bases. This construction is computationally expensive as it typically involves computing eigendecompositions of large matrices. Once the wavelet packet has been constructed, for each input signal that one observes over the graph in question, one runs a "best basis" algorithm to choose a particular orthogonal basis from the wavelet packet by optimizing a particular cost function of the eventual wavelet coefficients. This is based on a message-passing-like dynamic programming algorithm, and can be quite efficient. Lastly, the denoising procedure is defined as usual (e.g., as in Donoho and Johnstone (1995)), namely, one performs the basis transformation, soft-thresholds (or hard-thresholds) the coefficients, and then reconstructs the denoised signal.

In our experiments, we used the wavelet implementations released by the authors of Coiman and Maggioni (2006); Irion (2015) with their default settings. In particular, the former implementation of Coiman and Maggioni (2006) builds wavelets from a diffusion operator constructed from the adjacency matrix of a graph, and the cost function for the best basis is defined by the ℓ_1 norm of the wavelet coefficients. The latter implementation of Irion (2015) uses a more exhaustive search, building wavelet packets through a hierarchical partitioning and eigentransform of three different Laplacian matrices and a fourth generalized Haar-Walsh transform (GHWT), then choosing the best basis from all four collections by optimizing a meta cost function of the ℓ_p norm of wavelet coefficients over $p \in \{0.1, 0.2, \dots 2\}$. This is the "cumulative relative error" defined in equation (7.5) of Irion (2015).

In the left panel of Figure 8, we plot the mean squared errors for these new wavelet methods over the same 10 simulations from the Allegheny County example in Figure 2 of Section A.1. The middle and right panels of the figure show the denoised signals from the new methods fit to the data in Figure 1, at their optimal degrees of freedom (df) values (in terms of the achieved MSE). We can see that the spanning tree wavelet design of Sharpnack et al. (2013a) is the best performer among the three candidate wavelet designs. In a rough sense, the construction of Irion (2015) seems to perform similarly to that of Sharpnack et al. (2013a), in that the MSE is best for larger df values (corresponding to more nonzero wavelet coefficients, i.e., complex fitted models), whereas the construction of Coiman and Maggioni (2006) performs best for smaller df values (fewer nonzero wavelet coefficients, i.e., simpler fitted models).

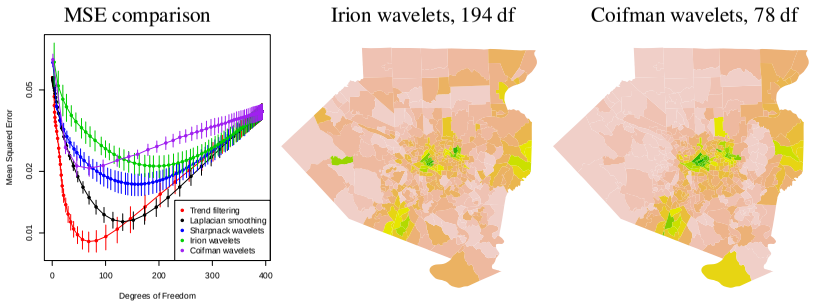

Figure 8: Additional wavelet analysis of the Allegheny County example.

A.2 Facebook Graph Example

Again, we consider the designs of Coiman and Maggioni (2006); Irion (2015) for the Facebook graph example of Section 5.1. Due to practical reasons, we had to change some of the default settings in the implementations provided by the authors of these wavelet methods; in the wavelet implementation of Coiman and Maggioni (2006), we took the power of the diffusion operator to be 1 instead of 4 (since the latter choice threw an error in the provided code); and in the wavelet implementation of Irion (2015), we used another "best basis" algorithm that only searches within the basis collection from the GHWT eigendecomposition, as the original algorithm was too slow due to the larger scale considered in this example. (In most examples in Irion (2015), the chosen bases come from the GHWT eigendecomposition.) We view these changes as minor, because when the same changes were applied to the methods of Coiman and Maggioni (2006); Irion (2015) on the smaller Allegheny County example, there are no obvious differences in the results.

Figure 9 shows the results for the two new wavelet methods on the Facebook graph simulation, using the same setup as in Figure 5. Once again, we find that the spanning tree wavelets of Sharpnack et al. (2013a) perform better or on par with the other two wavelet methods across essentially all scenarios.

Appendix B. Proofs of Theoretical Results

Here we present proofs of our theoretical results presented in Sections 3 and 6.

B.1 Proof of Lemma 1

For even k, we have $\Delta^{(k+1)} = DL^{k/2}$, so if A denotes a subset of edges, then $\Delta_{-A}^{(k+1)} = D_{-A}L^{k/2}$. Recall that for a connected graph, $\mathrm{null}(L) = \mathrm{span}\{\mathbb{1}\}$, and the same is true for any power of L. This means that we can write

$$\mathrm{null}(\Delta^{(k+1)}) = \mathrm{span}\{\mathbb{1}\} + \mathrm{span}\{\mathbb{1}\}^{\perp} \cap \{u : DL^{\frac{k}{2}}u = 0\}.$$

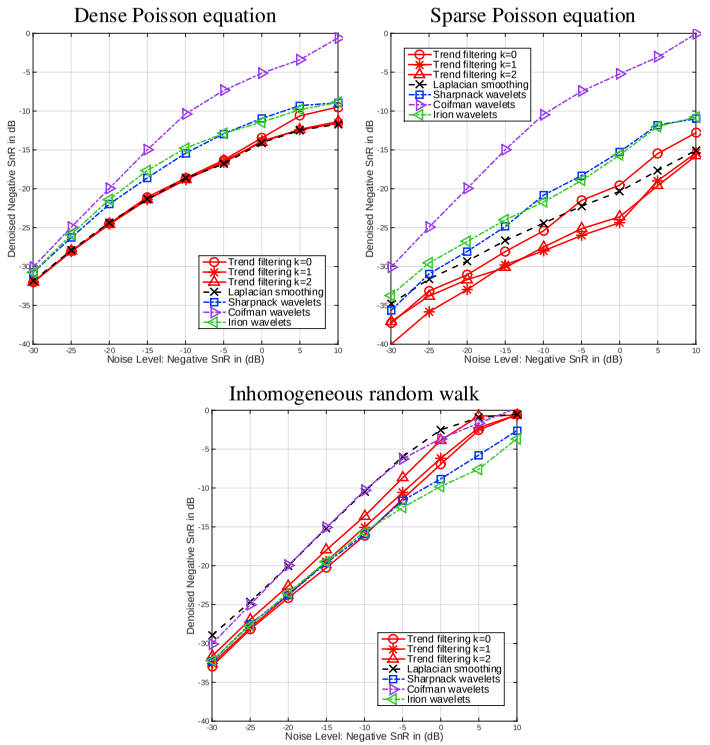

Figure 9: Additional wavelet analysis of the Facebook graph example.

Note that if $\mathbb{1}^\top u = 0$, then $v = L^{\frac{k}{2}} u \iff u = (L^\dagger)^{\frac{k}{2}} u$. Moreover, if G_{-A} has connected components $C_1, \ldots C_s$, then $\mathrm{null}(D_{-A}) = \mathrm{span}\{\mathbb{1}_{C_1}, \ldots \mathbb{1}_{C_s}\}$. Putting these statements together proves the result for even k. For k odd, the arguments are similar.

B.2 Proof of Theorem 3

By assumption we can write

$$y = \beta_0 + \epsilon, \quad \epsilon \sim \mathcal{N}(0, \sigma^2 I).$$

Denote $R = \mathrm{row}(\Delta)$, the row space of Δ, and $R^\perp = \mathrm{null}(\Delta)$, the null space of Δ. Also let P_R be the projection onto R, and $P_{R^\perp}$ the projection onto $R^\perp$. Consider

$$\hat{\beta} = \operatorname*{argmin}_{\beta \in \mathbb{R}^n} \frac{1}{2}\|y - \beta\|_2^2 + \lambda \|\Delta \beta\|_1,$$
$$\tilde{\beta} = \operatorname*{argmin}_{\beta \in \mathbb{R}^n} \frac{1}{2}\|P_R y - \beta\|_2^2 + \lambda \|\Delta \beta\|_1.$$

The first quantity $\hat{\beta} \in \mathbb{R}^n$ is the estimate of interest, the second one $\tilde{\beta} \in R$ is easier to analyze. Note that

$$\hat{\beta} = P_{R^\perp} y + \tilde{\beta},$$

and write $\|x\|_R = \|P_R x\|_2$, $\|x\|_{R^\perp} = \|P_{R^\perp} x\|_2$. Then

$$\|\hat{\beta} - \beta_0\|_2^2 = \|\epsilon\|_{R^\perp}^2 + \|\tilde{\beta} - \beta_0\|_R^2.$$

The first term is on the order $\dim(R^\perp) = \mathrm{nullity}(\Delta)$, and it suffices to bound the second term. Now we establish a basic inequality for $\tilde{\beta}$. By optimality of $\tilde{\beta}$, we have

$$\frac{1}{2}\|y - \tilde{\beta}\|_R^2 + \lambda \|\Delta \tilde{\beta}\|_1 \leq \frac{1}{2}\|y - \beta_0\|_R^2 + \lambda \|\Delta \beta_0\|_1,$$

and after rearranging terms,

$$\|\tilde{\beta} - \beta_0\|_R^2 \leq 2\epsilon^\top P_R(\tilde{\beta} - \beta_0) + 2\lambda \|\Delta \beta_0\|_1 - 2\lambda \|\Delta \tilde{\beta}\|_1. \tag{18}$$

This is our basic inequality. In the first term above, we use $P_R = \Delta^\dagger \Delta$, and apply Holder's inequality:

$$\epsilon^\top \Delta^\dagger \Delta(\tilde{\beta} - \beta_0) \leq \|(\Delta^\dagger)^\top \epsilon\|_\infty \|\Delta(\tilde{\beta} - \beta_0)\|_1. \tag{19}$$

If $\lambda \geq \|(\Delta^\dagger)^\top \epsilon\|_\infty$, then from (18), (19), and the triangle inequality, we see that

$$\|\tilde{\beta} - \beta_0\|_R^2 \leq 4\lambda \|\Delta \beta_0\|_1.$$

Well, $\|(\Delta^\dagger)^\top \epsilon\|_\infty = O_{\mathbb{P}}(M\sqrt{\log r})$ by a standard result on the maximum of Gaussians (derived using the union bound, and Mills' bound on the Gaussian tail), where recall M is the maximum ℓ_2 norm of the columns of $\Delta^\dagger$. Thus with $\lambda = \Theta(M\sqrt{\log r})$, we have from the above that

$$\|\tilde{\beta} - \beta_0\|_R^2 = O_{\mathbb{P}}\big(M\sqrt{\log r}\|\Delta \beta_0\|_1\big),$$

as desired.

B.3 Proof of Corollary 4

Case 1. When $\hat{\beta}$ is the univariate trend filtering estimator of order k, we are considering a penalty matrix $\Delta = D^{(k+1)}$, the univariate difference operator of order $k+1$. Note that $D^{(k+1)} \in \mathbb{R}^{(n-k-1)\times n}$, and its null space has constant dimension $k+1$. We show in Lemma 13 of Appendix B.4 that $(D^{(k+1)})^\dagger = P_R H_2^{(k)}/k!$, where $R = \mathrm{row}(D^{(k+1)})$, and $H_2^{(k)} \in \mathbb{R}^{n\times(n-k-1)}$ contains the last $n-k-1$ columns of the order k falling factorial basis matrix (Wang et al., 2014), evaluated

over the input points $x_1 = 1, \dots x_n = n$. The largest column norm of $P_R H_2^{(k)}/k!$ is on the order of $n^{k+1/2}$, which proves the result.

Cases 2 and 3. When G is the Ramanujan d-regular graph, the number of edges in the graph is $O(nd)$. The operator $\Delta = \Delta^{(k+1)}$ has number of rows $r = n$ when k is odd and $r = O(nd)$ when k is even; overall this is $O(nd)$. The dimension of the null space of Δ is constant (it is in fact 1, since the graph is connected). When G is the Erdos-Renyi random graph, the same bounds apply to the number of rows and the dimension of the null space, except that the bounds become probabilistic ones.

Now we apply the crude inequality, with e_i, $i = 1, \dots r$ denoting the standard basis vectors,

$$M = \max_{i=1,\dots r} \Delta^\dagger e_i \leq \max_{\|x\|_2 \leq 1} \Delta^\dagger x = \|\Delta^\dagger\|_2,$$

the right-hand side being the maximum singular value of $\Delta^\dagger$. As $\Delta = \Delta^{(k+1)}$, the graph difference operator of order $k+1$, we claim that

$$\|\Delta^\dagger\|_2 \leq 1/\lambda_{\min}(L)^{\frac{k+1}{2}}, \tag{20}$$

where $\lambda_{\min}(L)$ denotes the smallest nonzero eigenvalue of the graph Laplacian L. To see this, note first that $\|\Delta^\dagger\|_2 = 1/\sigma_{\min}(\Delta)$, where the denominator is the smallest nonzero singular value of Δ. Now for odd k, we have $\Delta^{(k+1)} = L^{(k+1)/2}$, and the claim follows as

$$\sigma_{\min}(L^{\frac{k+1}{2}}) = \min_{x \in R: \|x\|_2 \leq 1} \|L^{\frac{k+1}{2}} x\|_2 \geq \big(\sigma_{\min}(L)\big)^{\frac{k+1}{2}},$$

and $\sigma_{\min}(L) = \lambda_{\min}(L)$, since L is symmetric. Above, R denotes the row space of L (the space orthogonal to the vector $\mathbb{1}$ of all 1s). For even k, we have $\Delta^{(k+1)} = DL^{k/2}$, and again

$$\sigma_{\min}(DL^{\frac{k}{2}}) = \min_{x \in R: \|x\|_2 \leq 1} \|DL^{\frac{k+1}{2}} x\|_2 \geq \sigma_{\min}(D)\big(\sigma_{\min}(L)\big)^{\frac{k}{2}},$$

where $\sigma_{\min}(D) = \sqrt{\lambda_{\min}(L)}$, since $D^\top D = L$. This verifies the claim.

Having established (20), it suffices to lower bound $\lambda_{\min}(L)$ for the two graphs in question. Indeed, for both graphs, we have the lower bound

$$\lambda_{\min}(L) = \Omega(d - \sqrt{d}).$$

e.g., see Lubotzky et al. (1988); Marcus et al. (2014) for the Ramanujan graph and Feige and Ofek (2005); Chung and Radcliffe (2011) for the Erdos-Renyi graph. This completes the proof.

B.4 Calculation of $(D^{(k+1)})^\dagger$

Lemma 13 *The $(k+1)$st order discrete difference operator has pseudoinverse*

$$(D^{(k+1)})^\dagger = P_R H_2^{(k)}/k!,$$

where we denote $R = \mathrm{row}(D^{(k+1)})$, and $H_2^{(k)} \in \mathbb{R}^{n \times (n-k-1)}$ the last $n-k-1$ columns of the kth order falling factorial basis matrix.

Proof We abbreviate $D = D^{(k+1)}$, and consider the linear system

$$DD^\top x = Db \tag{21}$$

in x, where $b \in \mathbb{R}^n$ is arbitrary. We seek an expression for $x = (DD^\top)^{-1} D^\top = (D^\dagger)^\top b$, and this will tell us the form of $D^\dagger$. Define

$$\tilde{D} = \begin{bmatrix} C \\ D \end{bmatrix} \in \mathbb{R}^{n \times n},$$

where $C \in \mathbb{R}^{(k+1) \times n}$ is the matrix that collects the first row of each lower order difference operator, defined in Lemma 2 of Wang et al. (2014). From this same lemma, we know that

$$\tilde{D}^{-1} = H/k!,$$

where $H = H^{(k)}$ is falling factorial basis matrix of order k, evaluated over $x_1, \dots x_n$. With this in mind, consider the expanded linear system

$$\begin{bmatrix} CC^\top & CD^\top \\ DC^\top & DD^\top \end{bmatrix} \begin{bmatrix} w \\ x \end{bmatrix} = \begin{bmatrix} a \\ Db \end{bmatrix}. \tag{22}$$

The second equation reads

$$DC^\top w + DD^\top x = Db,$$

and so if we can choose a in (22) so that at the solution we have $w = 0$, then x is the solution in (21). The first equation in (22) reads

$$CC^\top w + CD^\top x = a,$$

i.e.,

$$w = (CC^\top)^{-1}(a - CD^\top x).$$

That is, we want to choose

$$a = CD^\top x = CD^\top (DD^\top)^{-1} Db = CP_R b,$$

where P_R is the projection onto row space of D. Thus we can reexpress (22) as

$$\tilde{D}\tilde{D}^\top \begin{bmatrix} w \\ x \end{bmatrix} = \begin{bmatrix} CP_R b \\ Db \end{bmatrix} = \tilde{D} P_R b$$

and, using $\tilde{D}^{-1} = H/k!$,

$$\begin{bmatrix} w \\ x \end{bmatrix} = H^\top P_R b/k!.$$

Finally, writing H_2 for the last $n-k-1$ columns of H, we have $x = H_2^\top P_R b/k!$, as desired. ■

Remark. The above proof did not rely on the input points $x_1, \dots x_n$; indeed, the result holds true for any sequence of inputs used to define the discrete difference matrix and falling factorial basis matrix.

B.5 Proof of Lemma 5

We follow the proof of Theorem 3, up until the application of Holder's inequality in (19). In place of this step, we use the linearized bound in (15), which we claim implies that

$$\epsilon^\top P_R(\tilde{\beta} - \beta_0) \leq \tilde{B}\|\tilde{\beta} - \beta_0\|_R + A\|\Delta(\tilde{\beta} - \beta_0)\|_1,$$

where $\tilde{B} = O_{\mathbb{P}}(B)$. This simply follows from applying (15) to $x = P_R(\tilde{\beta} - \beta_0)/\|\Delta(\tilde{\beta} - \beta_0)\|_1$, which is easily seen to be an element of $\mathcal{S}_\Delta(1)$. Hence we can take take $\lambda = \Theta(A)$, and argue as in the proof of Theorem 3 to arrive at

$$\|\tilde{\beta} - \beta_0\|_R^2 \leq \tilde{B}\|\tilde{\beta} - \beta_0\|_R + \tilde{A}\|\Delta\beta_0\|_1,$$

where $\tilde{A} = O_{\mathbb{P}}(A)$. Note that the above is a quadratic inequality of the form $ax^2 - bx - c \leq 0$ with $x = \|\tilde{\beta} - \beta_0\|_R$. As $a > 0$, the larger of its two roots serves as a bound for x, i.e., $x \leq (b + \sqrt{b^2 + 4ac})/(2a) \leq b/a + \sqrt{c/a}$, or $x^2 \leq 2b^2/a^2 + 2c/a$, which means that

$$\|\tilde{\beta} - \beta_0\|_R^2 \leq 2\tilde{B}^2 + 2\tilde{A}\|\Delta\beta_0\|_1 = O_{\mathbb{P}}\big(B^2 + A\|\Delta\beta_0\|_1\big),$$

completing the proof.

B.6 Proof of Theorem 6

For an index $i_0 \in \{1, \dots q\}$, let

$$C = \mu\sqrt{\frac{2\log 2r}{n}\sum_{i=i_0+1}^{q}\frac{1}{\xi_i^2}}.$$

We will show that

$$\max_{x \in \mathcal{S}_\Delta(1)} \frac{\epsilon^\top x - 1.001\sigma C}{\|x\|_2} = O_{\mathbb{P}}(\sqrt{i_0}).$$

Invoking Lemma 5 with $A = 1.001\sigma C$ and $b = \sqrt{i_0}$ would then give the result.

Henceforth we denote $[i] = \{1, \dots i\}$. Recall that $q = \mathrm{rank}(\Delta)$. Let the singular value decomposition of Δ be

$$\Delta = U\Sigma V^\top,$$

where $U \in \mathbb{R}^{r \times q}$, $V \in \mathbb{R}^{n \times q}$ are orthogonal, and $\Sigma \in \mathbb{R}^{q \times q}$ has diagonal elements $(\Sigma)_{ii} = \xi_i > 0$ for $i \in [q]$. First, let us establish that

$$\Delta^\dagger = V\Sigma^{-1}U^\top.$$

Consider an arbitrary point $x = P_R z \in \mathcal{S}_\Delta(1)$. Denote the projection $P_{[i_0]} = V_{[i_0]}V_{[i_0]}^\top$ where $V_{[i_0]}$ contains the first i_0 right singular vectors. We can decompose

$$\epsilon^\top P_R z = \epsilon^\top P_{[i_0]} P_R z + \epsilon^\top (I - P_{[i_0]}) P_R z.$$

The first term can be bounded by

$$\epsilon^\top P_{[i_0]} P_R z \leq \|P_{[i_0]}\epsilon\|_2 \|z\|_R = O_{\mathbb{P}}(\sqrt{i_0}\|z\|_R),$$

using the fact that $\|P_{[i_0]}\epsilon\|_2^2 \overset{d}{=} \sum_{i=1}^{i_0}\epsilon_i^2$. We can bound the second term by

$$\epsilon^\top (I - P_{[i_0]}) P_R z = \epsilon^\top (I - P_{[i_0]})\Delta^\dagger \Delta z \leq \|(\Delta^\dagger)^\top (I - P_{[i_0]})\epsilon\|_\infty,$$

using $P_R = \Delta^\dagger\Delta$, Holder's inequality, and the fact that $\|\Delta z\|_1 \leq 1$. Define $g_j = (I - P_{[i_0]})\Delta^\dagger e_j$ for $j \in [r]$ with e_j the jth canonical basis vector. So,

$$\|g_j\|_2^2 = \|[\,0 \;\; V_{[n]\setminus[i_0]}\,] \cdot \Sigma^{-1}U^\top e_j\|_2^2 \leq \frac{\mu^2}{n}\sum_{i=i_0+1}^{q}\frac{1}{\xi_i^2},$$

by rotational invariance of $\|\cdot\|_2$ and the incoherence assumption on the columns of U. By a standard result on maxima of Gaussians,

$$\|(\Delta^\dagger)^\top (I - P_{[i_0]})\epsilon\|_\infty = \max_{j \in [r]} |g_j^\top \epsilon| \leq 1.001\sigma\sqrt{2\log(2r)\frac{\mu^2}{n}\sum_{i=i_0+1}^{q}\frac{1}{\xi_i^2}} = 1.001\sigma C,$$

with probability approaching 1. Putting these two terms together completes the proof, as we have shown that

$$\frac{\epsilon^\top P_R z - 1.001\sigma C}{\|z\|_R} = O_{\mathbb{P}}(\sqrt{i_0}),$$

with the probability bound on the right-hand side not depending on z.

B.7 Proof of Corollary 7

We focus on the k odd and k even cases separately.

Case for k odd. When k is odd, we have $\Delta = \Delta^{(k+1)} = L^{(k+1)/2}$, where L the graph Laplacian of a chain graph (i.e., 1d grid graph), to be perfectly explicit,

$$L = \begin{bmatrix} 1 & -1 & 0 & \dots & 0 & 0 \\ -1 & 2 & -1 & \dots & 0 & 0 \\ 0 & -1 & 2 & \dots & 0 & 0 \\ \vdots & & \ddots & \ddots & \ddots & \\ 0 & 0 & \dots & -1 & 2 & -1 \\ 0 & 0 & \dots & 0 & -1 & 1 \end{bmatrix}.$$

In numerical methods for differential equations, this matrix L is called the finite difference operator for the 1d Laplace equation with Neumann boundary conditions (e.g., Conte and de Boor, 1980; Godunov and Ryabenkii, 1987), and is known to have eigenvalues and eigenvectors

$$\xi_i = 4\sin^2\Big(\frac{\pi(i-1)}{2n}\Big), \quad \text{for } i = 1, \dots n,$$

$$u_{ij} = \begin{cases} \frac{1}{\sqrt{n}} & \text{if } i = 1 \\ \sqrt{\frac{2}{n}}\cos\Big(\frac{\pi(i-1)(j-1/2)}{n}\Big) & \text{otherwise} \end{cases}, \quad \text{for } i, j = 1, \dots n.$$

Therefore, the eigenvectors of L are incoherent with constant $\mu = \sqrt{2}$. This of course implies the same of $L^{(k+1)/2}$, which shares the eigenvectors of L. Meanwhile, the eigenvalues of $L^{(k+1)/2}$ are just given by raising those of L to the power of $(k+1)/2$, and for $i_0 \in \{1, \dots n\}$, we compute the partial sum of their squared reciprocals, as in

$$\frac{1}{n} \sum_{i=i_0+1}^{n} \frac{1}{\xi_i^{k+1}} = \frac{1}{n} \sum_{i=i_0+1}^{n} \frac{1}{4^{k+1} \sin^{2k+2}(\pi(i-1)/(2n))} \leq \int_{(i_0-1)/n}^{(n-2)/n} \frac{1}{4^{k+1} \sin^{2k+2}(\pi x/2)} dx,$$

where we have used the fact that the right-endpoint Riemann sum, for a monotone nonincreasing function, is an underestimate of its integral. Continuing on, the above integral can be bounded by

$$\frac{1}{4^{k+1} \sin^{2k}(\pi i_0/(2n))} \int_{(i_0-1)/n}^{1} \frac{1}{\sin^2(\pi x/2)} dx = \frac{2 \cot(\pi i_0/(2n))}{4^{k+1} \pi \sin^{2k}(\pi i_0/(2n))} \leq \frac{1}{4^{k+1}\pi} \left(\frac{2n}{\pi i_0}\right)^{2k+1},$$

the last step using a Taylor expansion around 0. Hence to choose a tight a bound as possible in Theorem 6, we seek to balance i_0 with $\sqrt{(n/i_0)^{2k+1} \log n} \cdot \|\Delta^{(k+1)} \beta_0\|_1$. This is accomplished by choosing

$$i_0 = n^{\frac{2k+1}{2k+3}} (\log n)^{\frac{1}{2k+3}} \|\Delta^{(k+1)} \beta_0\|_1^{\frac{2}{2k+3}},$$

and applying Theorem 6 gives the result for k odd.

Case for k even. When k is even, we instead have $\Delta = \Delta^{(k+1)} = DL^{k/2}$, where D is the edge incidence matrix of a 1d chain, and $L = D^\top D$. It is clear that the left singular vectors of $DL^{k/2}$ are simply the left singular vectors of D, or equivalently, the eigenvectors of $DD^\top$. To be explicit,

$$DD^\top = \begin{bmatrix} 2 & -1 & 0 & \dots & 0 & 0 \\ -1 & 2 & -1 & \dots & 0 & 0 \\ 0 & -1 & 2 & \dots & 0 & 0 \\ \vdots & & \ddots & \ddots & \ddots & \\ 0 & 0 & \dots & -1 & 2 & -1 \\ 0 & 0 & \dots & 0 & -1 & 2 \end{bmatrix},$$

which is called the finite difference operator associated with the 1d Laplace equation under Dirichlet boundary conditions in numerical methods (e.g., Conte and de Boor, 1980; Godunov and Ryabenkii, 1987), and is known to have eigenvectors

$$u_{ij} = \sqrt{\frac{2}{n}} \sin\left(\frac{\pi i j}{n}\right), \quad \text{for } i, j = 1, \dots n-1.$$

It is evident that these vectors are incoherent, with constant $\mu = \sqrt{2}$. Furthermore, the singular values of $DL^{k/2}$ are exactly the eigenvalues of L raised to the power of $(k+1)/2$, and the remainder of the proof goes through as in the k odd case.

B.8 Proof of Corollary 8

Again we treat the k odd and even cases separately.

Case for k odd. As k is odd, the GTF operator is $\Delta = \Delta^{(k+1)} = L^{(k+1)/2}$, where the L is the Laplacian matrix of a 2d grid graph. Writing $L_{1\text{d}} \in \mathbb{R}^{\ell \times \ell}$ for the Laplacian matrix over a 1d grid of size $\ell = \sqrt{n}$ (and $I \in \mathbb{R}^{\ell \times \ell}$ for the identity matrix), we note that

$$L = I \otimes L_{1\text{d}} + L_{1\text{d}} \otimes I,$$

i.e., the 2d grid Laplacian L is the Kronecker sum of the 1d grid Laplacian $L_{1\text{d}}$, so its eigenvectors are given by all pairwise Kronecker products of eigenvectors of $L_{1\text{d}}$, of the form $u_i \otimes u_j$. Moreover, it is not hard to see that each $u_i \otimes u_j$ has unit norm (since u_i, u_j do) and $\|u_i \otimes u_j\|_\infty \leq 2/\sqrt{n}$. This allows us to conclude that the eigenvectors of L obey the incoherence property with $\mu = 2$.

The eigenvalues of L are given by all pairwise sums of eigenvalues in the 1d case. Indexing by 2d grid coordinates, we may write these as

$$\xi_{j_1, j_2} = 4 \sin^2\left(\frac{\pi(j_1 - 1)}{2\ell}\right) + 4 \sin^2\left(\frac{\pi(j_2 - 1)}{2\ell}\right), \quad \text{for } j_1, j_2 = 1, \dots \ell.$$

Eigenvalues of $L^{(k+1)/2}$ are just given by raising the above to the power of $(k+1)/2$, and for $j_0 \in \{1, \dots \ell\}$, we let $i_0 = j_0^2$, and compute the sum

$$\frac{1}{n} \sum_{\max\{j_1 j_2\} > j_0} \frac{1}{\xi_{j_1, j_2}^{k+1}} \leq \frac{2}{n} \sum_{j_1 = j_0+1}^{\ell} \sum_{j_2=1}^{\ell} \frac{1}{\xi_{j_1, j_2}^{k+1}} \leq \frac{2}{\ell} \sum_{j_1 = j_0+1}^{\ell} \frac{1}{4^{k+1} \sin^{2k+2}(\pi(j_1 - 1)/(2\ell))}.$$

Just as we argued in the 1d case (for k odd), the above is bounded by

$$\frac{2}{4^{k+1}\pi} \left(\frac{2\ell}{\pi j_0}\right)^{2k+1},$$

and thus we seek to balance $i_0 = j_0^2$ with $\sqrt{(\ell/j_0)^{2k+1} \log n} \cdot \|\Delta^{(k+1)} \beta_0\|_1$. This yields

$$j_0 = \ell^{\frac{2k+1}{2k+5}} (\log n)^{\frac{1}{2k+5}} \|\Delta^{(k+1)} \beta_0\|_1^{\frac{2}{2k+5}},$$

i.e.,

$$i_0 = n^{\frac{2k+1}{2k+5}} (\log n)^{\frac{2}{2k+5}} \|\Delta^{(k+1)} \beta_0\|_1^{\frac{4}{2k+5}},$$

and applying Theorem 6 gives the result for k odd.

Case for k even. For k even, we have the GTF operator being $\Delta = \Delta^{(k+1)} = DL^{k/2}$, where D is the edge incidence matrix of a 2d grid, and $L = D^\top D$. It will be helpful to write

$$D = \begin{bmatrix} I \otimes D_{1\text{d}} \\ D_{1\text{d}} \otimes I \end{bmatrix},$$

where $D_{1\text{d}} \in \mathbb{R}^{(\ell-1) \times \ell}$ is the difference operator for a 1d grid of size $\ell = \sqrt{n}$ (and $I \in \mathbb{R}^{\ell \times \ell}$ is the identity matrix). It suffices to check the incoherence of the left singular vectors of $DL^{k/2}$, since the eigenvalues of $DL^{k/2}$ are those of L raised to the power of $(k+1)/2$, and so the rest of the proof then follows precisely as in the case when k is odd. The left singular vectors of $DL^{k/2}$ are the same as the left singular vectors of D, which are the eigenvectors of $DD^\top$. Observe that

$$DD^\top = \begin{bmatrix} I \otimes D_{1\text{d}} D_{1\text{d}}^\top & D_{1\text{d}}^\top \otimes D_{1\text{d}} \\ D_{1\text{d}} \otimes D_{1\text{d}}^\top & D_{1\text{d}} D_{1\text{d}}^\top \otimes I \end{bmatrix}.$$

Let u_i, $i = 1, \dots \ell - 1$ be the eigenvectors of $D_{1\mathrm{d}} D_{1\mathrm{d}}^\top$, corresponding to eigenvalues λ_i, $i = 1, \dots \ell - 1$. Define $v_i = D_{1\mathrm{d}}^\top u_i / \sqrt{\lambda_i}$, $i = 1, \dots \ell - 1$, and $e = \mathbb{1}/\sqrt{\ell}$, where $\mathbb{1} = (1, \dots 1) \in \mathbb{R}^\ell$ is the vector of all 1s. A straightforward calculation verifies that

$$
\begin{aligned}
DD^\top \begin{bmatrix} v_i \otimes u_i \\ u_i \otimes v_i \end{bmatrix} &= 2\lambda_i \begin{bmatrix} v_i \otimes u_i \\ u_i \otimes v_i \end{bmatrix}, \quad \text{for } i = 1, \dots \ell - 1, \\
DD^\top \begin{bmatrix} e \otimes u_i \\ 0 \end{bmatrix} &= \lambda_i \begin{bmatrix} e \otimes u_i \\ 0 \end{bmatrix}, \quad \text{for } i = 1, \dots \ell - 1, \\
DD^\top \begin{bmatrix} 0 \\ u_i \otimes e \end{bmatrix} &= \lambda_i \begin{bmatrix} 0 \\ u_i \otimes e \end{bmatrix}, \quad \text{for } i = 1, \dots \ell - 1.
\end{aligned}
$$

Hence we have derived $3(\ell - 1)$ eigenvectors of $DD^\top$. Note that the vectors v_i, $i = 1, \dots \ell - 1$ are actually the eigenvectors of $L_{1\mathrm{d}} = D_{1\mathrm{d}}^\top D_{1\mathrm{d}}$ (corresponding to the $\ell - 1$ nonzero eigenvalues), and from our work in the 1d case, recall, both v_i, $i = 1, \dots \ell - 1$ (studied for k odd) and u_i, $i = 1, \dots \ell - 1$ (studied for k even) are unit vectors satisfying the incoherence property with $\mu = \sqrt{2}$. This means that the above eigenvectors are all unit norm, and are also incoherent, with constant $\mu = 2$.

There are $(\ell - 1)(\ell - 2)$ more eigenvectors of $DD^\top$, as the rank of $DD^\top$ is $n - 1 = \ell^2 - 1$. A somewhat longer but still straightforward calculation verifies that

$$
\begin{aligned}
DD^\top \begin{bmatrix} v_i \otimes u_j + v_j \otimes u_i \\ \sqrt{\frac{\lambda_i}{\lambda_j}} u_i \otimes v_j + \sqrt{\frac{\lambda_j}{\lambda_i}} u_j \otimes v_i \end{bmatrix} &= (\lambda_i + \lambda_j) \begin{bmatrix} v_i \otimes u_j + v_j \otimes u_i \\ \sqrt{\frac{\lambda_i}{\lambda_j}} u_i \otimes v_j + \sqrt{\frac{\lambda_j}{\lambda_i}} u_j \otimes v_i \end{bmatrix}, \text{ for } i < j, \\
DD^\top \begin{bmatrix} \sqrt{\frac{\lambda_j}{\lambda_i}} v_i \otimes u_j + \sqrt{\frac{\lambda_i}{\lambda_j}} v_j \otimes u_i \\ u_i \otimes v_j + u_j \otimes v_i \end{bmatrix} &= (\lambda_i + \lambda_j) \begin{bmatrix} \sqrt{\frac{\lambda_j}{\lambda_i}} v_i \otimes u_j + \sqrt{\frac{\lambda_i}{\lambda_j}} v_j \otimes u_i \\ u_i \otimes v_j + u_j \otimes v_i \end{bmatrix}, \text{ for } i < j.
\end{aligned}
$$

Modulo the appropriate normalization, we have derived the remaining $(\ell - 1)(\ell - 2)$ eigenvectors of $DD^\top$. It remains to check their incoherence, once we have normalized them (to have unit norm). As the eigenvectors in the first and second expressions above are simply (block) rearrangements of each other, it does not matter which form we study; consider, say, those in the second expression, and fix $i < j$. The entrywise absolute maximum of the eigenvector in question is at most $\sqrt{\lambda_j/\lambda_i}(4/\sqrt{n})$. Thus it suffices show that the normalization constant for this eigenvector is on the order of $\sqrt{\lambda_j/\lambda_i}$. Observe that

$$
\left\| \begin{bmatrix} \sqrt{\frac{\lambda_j}{\lambda_i}} v_i \otimes u_j + \sqrt{\frac{\lambda_i}{\lambda_j}} v_j \otimes u_i \\ u_i \otimes v_j + u_j \otimes v_i \end{bmatrix} \right\|_2^2 = \left\| \begin{bmatrix} \sqrt{\frac{\lambda_j}{\lambda_i}} v_i \otimes u_j \\ u_i \otimes v_j \end{bmatrix} \right\|_2^2 + \left\| \begin{bmatrix} \sqrt{\frac{\lambda_i}{\lambda_j}} v_j \otimes u_i \\ u_j \otimes v_i \end{bmatrix} \right\|_2^2.
$$

Here the cross-term is $(v_i^\top \otimes u_j^\top)(v_j \otimes u_i) = (v_i^\top v_j)(u_i^\top u_j) = 0$, as $v_i^\top v_j = 0$ and $u_i^\top u_j = 0$. This means that the normalization constant lies within $[\sqrt{\lambda_j/\lambda_i + 2}, \sqrt{2\lambda_j/\lambda_i + 2}]$. In particular, the lower bound shows that the incoherence property holds with $\mu = 4$. This completes the proof.

B.9 Proof of Lemma 9

As before, we follow the proof of Theorem 3 up until the application of Holder's inequality in (19), but we use the fractional bound in (16) instead. We claim that this implies

$$
\epsilon^\top P_R(\tilde{\beta} - \beta_0) \leq \tilde{K} \|\tilde{\beta} - \beta_0\|_R^{1-w/2} (\|\Delta\tilde{\beta}\|_1 + \|\Delta\beta_0\|_1)^{w/2},
$$

where $\tilde{K} = O_{\mathbb{P}}(K)$. This is verified by noting that $x = P_R(\tilde{\beta} - \beta_0)/(\|\Delta\tilde{\beta}\|_1 + \|\Delta\beta_0\|_1) \in \mathcal{S}_\Delta(1)$, applying (16) to x, and then rearranging. Therefore, as in the proof of Theorem 3, we have

$$
\|\tilde{\beta} - \beta_0\|_R^2 \leq 2\tilde{K} \|\tilde{\beta} - \beta_0\|_R^{1-w/2} (\|\Delta\tilde{\beta}\|_1 + \|\Delta\beta_0\|_1)^{w/2} + 2\lambda(\|\Delta\beta_0\|_1 - \|\Delta\tilde{\beta}\|_1), \tag{23}
$$

We now set

$$
\lambda = \Theta\left(K^{\frac{2}{1+w/2}} \|\Delta\beta_0\|_1^{-\frac{1-w/2}{1+w/2}} \right),
$$

and in the spirit of van de Geer (1990); Mammen and van de Geer (1997), we proceed to argue in cases.

Case 1. Suppose that $\frac{1}{2}\|\Delta\tilde{\beta}\|_1 \geq \|\Delta\beta_0\|_1$. Then we see that (23) implies

$$
0 \leq \|\tilde{\beta} - \beta_0\|_R^2 \leq \tilde{K} \|\tilde{\beta} - \beta_0\|_R^{1-w/2} \left(\frac{3}{2}\right)^{w/2} \|\Delta\tilde{\beta}\|_1^{w/2} - \lambda\|\Delta\tilde{\beta}\|_1, \tag{24}
$$

so that

$$
\lambda\|\Delta\tilde{\beta}\|_1 \leq \tilde{K} \|\tilde{\beta} - \beta_0\|_R^{1-w/2} \|\Delta\tilde{\beta}\|_1^{w/2},
$$

where for simplicity have absorbed a constant factor $2(3/2)^{w/2}$ into $\tilde{K}$ (since this does not change the fact that $\tilde{K} = O_{\mathbb{P}}(K)$), and thus

$$
\|\Delta\tilde{\beta}\|_1 \leq \left(\frac{\tilde{K}}{\lambda}\right)^{\frac{1}{1-w/2}} \|\tilde{\beta} - \beta_0\|_R.
$$

Plugging this back into (24) gives

$$
\|\tilde{\beta} - \beta_0\|_R^2 \leq \tilde{K} \|\tilde{\beta} - \beta_0\|_R^{1-w/2} \left(\frac{\tilde{K}}{\lambda}\right)^{\frac{w/2}{1-w/2}} \|\tilde{\beta} - \beta_0\|_R^{w/2},
$$

or

$$
\|\tilde{\beta} - \beta_0\|_R \leq \tilde{K}^{\frac{1}{1+w/2}} \left(\frac{1}{\lambda}\right)^{\frac{w/2}{1-w/2}} = O_{\mathbb{P}}\left(K^{\frac{1}{1+w/2}} \|\Delta\beta_0\|_1^{\frac{w/2}{1+w/2}} \right),
$$

as desired.

Case 2. Suppose that $\frac{1}{2}\|\Delta\tilde{\beta}\|_1 \leq \|\Delta\beta_0\|_1$. Then from (23),

$$
\|\tilde{\beta} - \beta_0\|_R^2 \leq \underbrace{2\lambda\|\Delta\beta_0\|_1}_{a} + \underbrace{2\tilde{K} \|\tilde{\beta} - \beta_0\|_R^{1-w/2} 3^{w/2} \|\Delta\beta_0\|_1^{w/2}}_{b},
$$

and hence either $\|\tilde{\beta} - \beta_0\|_R^2 \leq 2a$, or $\|\tilde{\beta} - \beta_0\|_R^2 \leq 2b$, and $a \leq b$. The first subcase is straightforward and leads to

$$
\|\tilde{\beta} - \beta_0\|_R \leq 2\sqrt{\lambda\|\Delta\beta_0\|_1} = O_{\mathbb{P}}\left(K^{\frac{1}{1+w/2}} \|\Delta\beta_0\|_1^{\frac{w/2}{1+w/2}} \right),
$$

as desired. In the second subcase, we have by assumption

$$
\|\tilde{\beta} - \beta_0\|_R^2 \leq 2\tilde{K} \|\tilde{\beta} - \beta_0\|_R^{1-w/2} \|\Delta\beta_0\|_1^{w/2}, \tag{25}
$$

$$
2\lambda\|\Delta\beta_0\|_1 \leq \tilde{K} \|\tilde{\beta} - \beta_0\|_R^{1-w/2} \|\Delta\beta_0\|_1^{w/2}, \tag{26}
$$

where again we have absorbed a constant factor $2(3^{w/2})$ into $\tilde{K}$. Working from (26), we derive

$$\|\Delta\beta_0\|_1 \leq \Big(\frac{\tilde{K}}{2\lambda}\Big)^{\frac{1}{1-w/2}} \|\tilde{\beta} - \beta_0\|_R,$$

and plugging this back into (25), we see

$$\|\tilde{\beta} - \beta_0\|_R^2 \leq 2\tilde{K}\|\tilde{\beta} - \beta_0\|_R^{1-w/2} \Big(\frac{\tilde{K}}{2\lambda}\Big)^{\frac{w/2}{1-w/2}} \|\tilde{\beta} - \beta_0\|_R^{w/2},$$

and finally

$$\|\tilde{\beta} - \beta_0\|_R \leq 2\tilde{K}^{\frac{1}{1+w/2}} \Big(\frac{1}{\lambda}\Big)^{\frac{w/2}{1-w/2}} = O_{\mathbb{P}}\left(K^{\frac{1}{1+w/2}} \|\Delta\beta_0\|_1^{\frac{w/2}{1+w/2}}\right).$$

This completes the second case, and the proof.

B.10 Proof of Theorem 10

The proof follows closely from Lemma 3.5 of van de Geer (1990). However, this author uses a different problem scaling than ours, so some care must be taken in applying the lemma. First we abbreviate $\mathcal{S} = \mathcal{S}_\Delta(1)$, and define $\tilde{\mathcal{S}} = \mathcal{S} \cdot \sqrt{n}/M$, where recall M is the maximum column norm of $\Delta^\dagger$. Now it is not hard to check that

$$\mathcal{S} = \{x \in \mathrm{row}(\Delta) : \|\Delta x\|_1 \leq 1\} = \Delta^\dagger\{\alpha \in \mathrm{col}(\Delta) : \|\alpha\|_1 \leq 1\},$$

so that $\max_{x\in\mathcal{S}} \|x\|_2 \leq M$, and $\max_{x\in\tilde{\mathcal{S}}} \|x\|_2 \leq \sqrt{n}$. This is important because Lemma 3.5 of van de Geer (1990) concerns a form of "local" entropy that allows for deviations on the order of $\sqrt{n}$ in the norm $\|\cdot\|_2$, or equivalently, constant order in the scaled metric $\|\cdot\|_n = \|\cdot\|_2/\sqrt{n}$. Hence, the entropy bound in (17) translates into

$$\log N(\delta, \tilde{\mathcal{S}}, \|\cdot\|_2) \leq E\Big(\frac{\sqrt{n}}{M}\Big)^w \Big(\frac{\sqrt{n}}{\delta}\Big)^w,$$

that is,

$$\log N(\delta, \tilde{\mathcal{S}}, \|\cdot\|_n) \leq E\Big(\frac{\sqrt{n}}{M}\Big)^w \delta^{-w}.$$

Now we apply Lemma 3.5 of van de Geer (1990): in the scaled metric used by this author,

$$\max_{x\in\tilde{\mathcal{S}}} \frac{\epsilon^\top x}{\sqrt{n}\|x\|_n^{1-w/2}} = O_{\mathbb{P}}\left(\sqrt{E}\Big(\frac{\sqrt{n}}{M}\Big)^{w/2}\right),$$

that is,

$$\max_{x\in\tilde{\mathcal{S}}} \frac{\epsilon^\top x}{\|x\|_2^{1-w/2}} = O_{\mathbb{P}}\left(\sqrt{E}(\sqrt{n})^{w/2}\Big(\frac{\sqrt{n}}{M}\Big)^{w/2}\right),$$

and finally,

$$\max_{x\in\mathcal{S}} \frac{\epsilon^\top x}{\|x\|_2^{1-w/2}} = O_{\mathbb{P}}\left(\sqrt{E}(\sqrt{n})^{w/2}\right),$$

as desired.

B.11 Proof of Corollary 11

For each $j = 1, \dots 2r$, if $\mathcal{G}$ is covered by j balls having radius at most $C_0\sqrt{n}j^{-1/\zeta}$, with respect to the norm $\|\cdot\|_2$, then it is covered by j balls having radius at most $C_0 j^{-1/\zeta}$, with respect to the scaled norm $\|\cdot\|_n = \|\cdot\|_2/\sqrt{n}$. By Theorem 1 of Carl (1997), this implies that for each $j = 1, 2, 3, \dots$, the convex hull $\mathrm{conv}(\mathcal{G})$ is covered by 2^j balls having radius at most $C_0' j^{-(1/2+1/\zeta)}$, with respect to $\|\cdot\|_n$, for another constant C_0'. Converting this back to an entropy bound in our original metric, and noting that $\mathrm{conv}(\mathcal{G}) = \mathcal{S}_\Delta(1)$, we have

$$\log(\delta, \mathcal{S}_\Delta(1), \|\cdot\|_2) \leq C_0''\Big(\frac{\sqrt{n}}{\delta}\Big)^{\frac{1}{1/2+1/\zeta}},$$

for a constant C_0'', as needed. This proves the lemma.

B.12 Proof of Corollary 12

According to Lemma 13, we know that $(D^{(1)})^\dagger = P_{\mathbb{1}}^\perp H$, where H is an $n \times (n-1)$ lower triangular matrix with $H_{ij} = 1$ if $i > j$ and 0 otherwise, and $P_{\mathbb{1}}^\perp$ is the projection map orthogonal to the all 1s vector. Thus $g_i = P_{\mathbb{1}}^\perp h_i$, $i = 1, \dots n-1$, with $h_1, \dots h_{n-1}$ denoting the columns of H. It is immediately apparent that

$$\|g_i - g_\ell\|_2 \leq \|h_i - h_\ell\|_2 \leq \sqrt{i-\ell},$$

for all $i > \ell$. Now, given $2j$ balls at our disposal, consider centering the first j balls at

$$g_d, g_{2d}, \dots g_{jd},$$

where $d = \lfloor n/j \rfloor$. Also let these balls have radius $\sqrt{n/j}$. By construction, then, we see that

$$\|g_1 - g_d\|_2 \leq \sqrt{n/j},\ \|g_d - g_{2d}\|_2 \leq \sqrt{n/j},\ \dots \|g_{jd} - g_{n-1}\|_2 \leq \sqrt{n/j},$$

which means that we have covered $g_1, \dots g_{n-1}$ with j balls of radius $\sqrt{n/j}$.

We can cover $-g_1, \dots, -g_{n-1}$ with the remaining j balls analogously. Therefore, we have shown that $2j$ balls require a radius of $\sqrt{n/j}$, or in other words, j balls require a radius of $\sqrt{2n/j}$.

Abstract

Parallel processing frameworks (Dean and Ghemawat, 2004) accelerate jobs by breaking them into tasks that execute in parallel. However, slow running or *straggler* tasks can run up to 8 times slower than the median task on a production cluster (Ananthanarayanan et al., 2013), leading to delayed job completion and inefficient use of resources. Existing straggler mitigation techniques wait to detect stragglers and then relaunch them, delaying straggler detection and wasting resources. We built Wrangler (Yadwadkar et al., 2014), a system that predicts when stragglers are going to occur and makes scheduling decisions to avoid such situations. To capture node and workload variability, Wrangler built separate models for every node and workload, requiring the time-consuming collection of substantial training data. In this paper, we propose multi-task learning formulations that share information between the various models, allowing us to use less training data and bring training time down from 4 hours to 40 minutes. Unlike naive multi-task learning formulations, our formulations capture the shared structure in our data, improving generalization performance on limited data. Finally, we extend these formulations using group sparsity inducing norms to automatically discover the similarities between tasks and improve interpretability.

1. Introduction

Distributed processing frameworks, such as (Dean and Ghemawat, 2004; Isard et al., 2007; Li, 2009), split a data intensive computation job into multiple smaller tasks, which are then executed in parallel on commodity clusters to achieve faster job completion. A natural consequence of such a parallel execution model is that the slow-running tasks, commonly called *stragglers*, potentially delay overall job completion. In a recent study, Ananthanarayanan et al. (2013) show that straggler tasks are on an average 6 to 8 times slower than the median task of the corresponding job, despite existing mitigation techniques. Suri and Vassilvitskii (2011) describe the intensity of straggler problem as the "curse of the last reducer", causing the last 1% of the computation to take much longer to finish execution. Mitigating stragglers thus remains an important problem. In this paper, our focus is on machine learning approaches for predicting and avoiding these stragglers.

Existing approaches to straggler mitigation, whether reactive or proactive, fall short in multiple ways. Commonly used reactive approaches such as speculative execution (Dean and Ghemawat, 2004), act after the tasks have already slowed down. Proactive approaches that launch redundant copies of a task in a hope that at least one of them will finish in a timely manner (Ananthanarayanan et al., 2013), waste resources. It is hard to, *a priori*, identify which factors, and configurations lead to stragglers, motivating a data driven machine learning approach to straggler prediction. Bortnikov et al. (2012) explored predictive models for predicting slowdown for tasks. But they learn a single model for a cluster of nodes, ignoring the variability caused due to the heterogeneity across nodes and across jobs from different workloads. Moreover, they built models but did not show if these models could indeed improve job completion times, which is what matters ultimately. Gupta et al. (2013) explored learning based job scheduling by matching node capabilities to job requirements. However, their approach is not designed to deal with stragglers effectively because it does not model the time-varying state of the nodes (for instance, how busy they are). Moreover, the effectiveness of these methods in reducing job-completion times in real world clusters hasn't been shown. To this end, we built Wrangler (Yadwadkar et al., 2014), a system that builds predictive models of straggler behavior and incorporates this model in the scheduler, improving the 99^{th} percentile job completion time by up to 61% as compared to speculative execution for real world production level workloads[1] from Facebook and Cloudera's customers.

Proactive model based approaches including Wrangler, have previously treated each workload and even compute node as a separate straggler estimation task with independent models. The decision to model each workload and node independently is motivated by the observation that the resource contention patterns that cause stragglers can vary from node to node and workload to workload. For a detailed analysis about causes of stragglers across nodes and workloads, see Section 4.2.2. of Wrangler, Yadwadkar et al. (2014). To address such heterogeneity in the nodes and changing workload patterns, training separate models for each workload being run on each node, is considered necessary. However, such independent models pose two critical challenges: (1) each new node and workload requires new training data which can take hours to collect, delaying the application of model based scheduling, and (2) clusters with many nodes may only have limited data for a given workload on each node leading to lower quality models.

These shortcomings can be addressed if each classifier is able to leverage information gleaned at other nodes and from other workloads. For instance, when there is not enough

1. Clusters are used for different purposes, and statistics such as the kinds of jobs submitted, their resource requirements and the frequency at which they are submitted vary depending upon the usage. We call one such distribution of jobs a workload. Section 3.2 explains the notion of workloads in further detail.

data at a node for a workload, we can gain from the data collected at that node while it was executing other workloads, or from other nodes running the same workload. Such information sharing falls in the ambit of multi-task learning (MTL), where the learner is embedded in an environment of related tasks, and the learner's aim is to leverage similarities between the tasks to improve performance of all tasks.

In this paper, we propose an MTL formulation for learning predictors that are more accurate and generalize better than existing straggler predicting models. Basic MTL formulations often assume only limited correlation structure between learning tasks. However, our application has an additional overlapping group structure: models built on the same node for different workloads can be grouped together, as can be the models corresponding to the same workload running on different nodes. We propose a new formulation that leverages this overlapping group structure, and show that doing so significantly reduces the number of parameters and improves generalization to tasks with very little data.

In applications such as ours, high accuracy is not the only objective: we also want to be able to gain some insight into what is causing these stragglers. Such insight can aid in debugging root causes of stragglers and system performance degradation. Automatically learned classifiers can be opaque and hard to interpret. To this end, we propose group sparsity inducing mixed-norm regularization on top of our basic MTL formulation to automatically reveal the group structure that exists in the data, and hopefully provide insights into how straggler behavior is related across nodes and workloads. We also explore sparsity-inducing formulations based on feature selection that attempt to reveal the characteristics of straggler behavior.

For our experimental evaluation, we use a collection of real-world workloads from Facebook and Cloudera's customers. We evaluate not only the prediction accuracy but also the improvement in job completion times, which is the metric that directly impacts the end user. We show that our formulation to predict stragglers allows us to reduce job completion times by up to 59% over the previous state-of-the-art learning base system, Wrangler (Yadwadkar et al. (2014)). This large reduction arises from a 7 point increase in prediction accuracy. Further, we can get equal or better accuracy than Wrangler (Yadwadkar et al. (2014)) using a sixth of the training data, thus bringing the training time down from 4 hours to about 40 minutes. We also provide empirical evidence that compared to naive MTL formulations, our formulation indeed generalizes to new tasks, i.e, it is significantly better at predicting straggler behavior for nodes for which we have not collected enough data.

Finally, while our initial motivation and experimental validation focus on the straggler avoidance problem, our learning formulations are general and can be applied to other systems that train node or workload dependent classifiers (Gupta et al., 2013; Delimitrou and Kozyrakis, 2014). For instance, ThroughputScheduler (Gupta et al., 2013) uses such classifiers to allot resources to tasks, and can benefit from such multitask reasoning. We leave these extensions to future work.

To summarize, our key contributions are:

1. An MTL formulation of the straggler estimation problem that allows us to use less data and reduce parameters, improving generalization (Section 4.1).

2. A mixed-norm group sparsity inducing formulation, that automatically detects group structure (Section 4.3) facilitating interpretability.

3. An efficient optimization technique based on a reduction to the standard SVM (Cortes and Vapnik (1995)) formulation (Section 4.2).

4. A comprehensive evaluation as part of a complete system for predicting and avoiding stragglers in real world production cluster traces (Section 5). We show that, compared to existing approaches, our formulations

   (a) avoid stragglers better with 7% improved prediction accuracy, improving job completion times significantly with up to 57.8% improvement in the 99^{th} percentile, and reducing net resource usage by up to 40%, and

   (b) can work even with a sixth of the training data and thus a much shorter training period, reducing the training data collection time significantly from 4 hours to 40 minutes.

In what follows, we first give some background on stragglers in Section 2. We then describe Wrangler and discuss its shortcomings in Section 3. In Section 4, we describe our multi-task learning formulations. In Section 5, we empirically evaluate our formulations on real world production level traces from Facebook and Cloudera's customers. We end with a discussion of related work.

2. Background and Motivation

The growing popularity of Internet-based applications, in addition to reduced costs of storage media, has resulted in generation of data at an unprecedented scale. Analytics on such huge datasets has become a driving factor for business. Parallel processing on commodity clusters has emerged as the de-facto way of dealing with the scale and complexity of such data-intensive applications. Dean and Ghemawat (2004) originally proposed the MapReduce framework at Google to process enormous amounts of data. MapReduce is highly scalable to large clusters of inexpensive commodity computers. Hadoop (White, 2009), an open source implementation of MapReduce, has been widely adopted by industry over the last decade.

A data intensive application is submitted to a cluster of commodity computers as a MapReduce *job*. To accelerate completion, MapReduce divides a job into multiple *tasks*. A cluster scheduler assigns these to machines (nodes), where they are executed in parallel. A job finishes when all its tasks have finished execution. A key benefit of such frameworks is that they automatically handle failures (which are more likely to occur on a cluster of commodity computers) without needing extra efforts from the programmer. Two basic modes of failures are the failure of a node and the failure of a task. If a node crashes, MapReduce re-runs all the tasks it was executing on a different node. If a task fails, MapReduce automatically re-launches it.

However, a tricky situation arises when a node is available, but is performing poorly. This causes the tasks scheduled on that node to execute slower than other tasks of the same job scheduled on other nodes in the cluster. Since a job finishes execution only when all its

tasks have finished execution, such slow-running tasks, called *stragglers*, extend the job's completion time. This, in turn, leads to increased user costs.

Stragglers abound in the real world. According to Ananthanarayanan et al. (2013), if stragglers did not exist in real-world production clusters, the average job completion times would have been improved by 47%, 29% and 36% in the Facebook, Bing and Yahoo traces respectively. We observed that 22-28% of the total tasks are stragglers in a replay[2] of Facebook and Cloudera's customers' Hadoop production cluster traces. Thus, stragglers are a major hurdle in achieving faster job completions.

It is challenging to deal with stragglers (Dean and Ghemawat, 2004; Zaharia et al., 2008; Ananthanarayanan et al., 2010). Dean and Ghemawat (2004) mentioned that stragglers could arise due to various reasons, such as competition for resources, problematic hardware, and mis-configurations. Ananthanarayanan et al. (2010) report that consistently slow nodes are rarely the reason behind stragglers; the majority are caused by transient node behavior. The reason is simple: cluster schedulers assign multiple tasks, belonging to the same or different jobs, to be executed simultaneously on a node. Depending on the node's characteristics and current load, as well as the characteristics of the workloads, these jobs may result in counterproductive resource contention patterns. Moreover, this gives rise to dynamically changing task execution environments, causing large variations in task execution times. We cannot simply look at the initial configuration of the node and decide if it will cause stragglers. We must track the continuously changing state of the node (its memory usage, cpu usage etc.) and use that to predict straggler behavior.

Above and beyond this temporal variability is the variability across nodes and workloads. If the scheduler assigns memory hungry tasks on a memory-constrained node, stragglers could occur due to contention for memory. While for another node that has slower disk, straggler behavior will primarily depend on how many I/O-intensive tasks are being run. To predict straggler behavior, we need to consider both the current state of each node and tailor the decision to the node type (its resource capabilities) and particular kind of tasks being executed (their resource requirements). In our experiments, we find that models that do not take this into account do about 6-7% worse than models that do (see Table 5 in Section 5.3).

Due to these difficulties in understanding the causes behind stragglers, and the challenges involved in predicting stragglers, initial attempts at mitigating stragglers have been *reactive* (Dean and Ghemawat, 2004; Zaharia et al., 2008; Ananthanarayanan et al., 2010). Dean and Ghemawat (2004) suggested *speculative execution* as a mitigation mechanism for stragglers. This is a reactive scheme that is dominantly used on production clusters including those at Facebook and Microsoft Bing (Ananthanarayanan et al., 2014). It operates in two steps: (1) wait-and-speculate if a task is executing slower than other tasks of the same job, and (2) replicate or spawn multiple redundant copies of such tasks hoping a copy will reach completion before the original. As soon as one of the copies or the original task finishes execution, the rest are killed.

The benefits of Speculative execution, in terms of improved job completion times at the cost of resources consumed, are unclear. Due to the wait-and-speculate step, this scheme is inefficient in time, leading to a delay before speculation begins. Also, due to the second

2. Please see Chen et al. (2012) for details on the faithful replay of production level traces.

Trace	% of speculatively executed tasks that were killed
Facebook 2009 (FB2009)	77.9%
Facebook 2010 (FB2010)	88.6%
Cloudera's Customer b (CC_b)	74.4%
Cloudera's Customer e (CC_e)	48.8%

Table 1: Majority of the speculatively executed tasks eventually get killed since the original task finishes execution before them.

step that replicates tasks, such mechanisms lead to increased resource consumption without necessarily gaining performance benefits. Moreover, we observed that the original task, that was marked as a straggler in the wait-and-speculate step, often finishes execution before any of the redundant copies launched in the second step. Thus, a significant number of such redundant copies end up getting killed, resulting in wastage of resources and perhaps additional unnecessary contention. Table 1 shows that about 48% to 88% of the speculatively executed copies were killed in our replay of Facebook and Cloudera's customers' production cluster traces. LATE (Zaharia et al., 2008) improves over speculative execution using a notion of progress scores, but still results in resource wastage due to replication.

Since reactive mechanisms fall short of efficiently mitigating stragglers, some proactive approaches have been proposed. Dolly (Ananthanarayanan et al., 2013) is a cloning mechanism that avoids the wait-and-speculate phase of speculative execution and immediately launches redundant copies of tasks belonging to small jobs. However, being replication-based, it also incurs resource overhead.

Machine learning has shown promise in dealing with the challenges of estimating task completion times and predicting stragglers in parallel processing environments (Bortnikov et al., 2012; Gupta et al., 2013). We built Wrangler (Yadwadkar et al., 2014) (see Section 3), a system that learns to predict nodes that might create stragglers and uses these predictions as hints to the scheduler so as to avoid creating stragglers by rejecting bad placement decisions. Thus, being proactive, Wrangler is time efficient. Also, by smarter scheduling, we avoid replication of straggler tasks. Thus, Wrangler is also efficient in terms of reducing the resources consumed. Wrangler was the first complete system that demonstrated the utility of learning methods in reducing job-completion times in real world clusters.

In the following sections, we review Wrangler, describe its architecture, discuss its limitations and avenues for improvements. Then in Section 4, we present our multi-task learning based approach that improves upon Wrangler by resolving its limitations.

3. Wrangler

Wrangler is a system that predicts stragglers based on cluster resource usage counters and uses these predictions to inform scheduling decisions. Wrangler achieves this by adding two main components to the scheduling system of data intensive computational frameworks: (i) model-builder, and (ii) predictive scheduler. Figure 1 summarizes Wrangler's architecture. The model-builder learns to predict stragglers using cluster resource usage counters. We explain this component in more detail in the following Sections 3.1, 3.2, and 3.3. Then, every time a task is scheduled to run on a particular node, Wrangler makes a prediction

using these models, for whether the task will become a straggler. It then uses this prediction to modify the scheduling decisions if straggler behavior is predicted. Section 3.4 provides a brief explanation of the predictive scheduler.

3.1 Features and labels

To predict whether scheduling a task at a particular node will lead to straggler behavior, Wrangler uses the resource usage counters at the node. Dean and Ghemawat (2004) mentioned that stragglers could arise due to various reasons such as competition for CPU, memory, local disk, network bandwidth. Zaharia et al. (2008) further suggest that stragglers could be caused due to faulty hardware and misconfiguration. Ananthanarayanan et al. (2010) report that the dynamically changing resource contention patterns on an underlying node could give rise to stragglers. Based on these findings, we collected the performance counters for CPU, memory, disk, network, and other operating system level counters describing the degree of concurrency before launching a task on a node. The counters we collected span multiple broad categories as follows:

1. *CPU utilization:* CPU idle time, system and user time and speed of the CPU, etc.
2. *Network utilization:* Number of bytes sent and received, statistics of remote read and write, statistics of RPCs, etc.
3. *Disk utilization:* The local read and write statistics from the datanodes, amount of free space, etc.
4. *Memory utilization:* Amount of virtual, physical memory available, amount of buffer space, cache space, shared memory space available, etc.
5. *System-level features:* Number of threads in different states (waiting, running, terminated, blocked, etc.), memory statistics at the system level.

In total, we collect 107 distinct features characterizing the state of the machine. See Section 5.1 for details of our dataset.

Features: Multiple tasks from jobs of each workload may be run on each node. Therefore to simplify notation, we index the execution of a particular task by i and define $S_{n,l}$ as the set of tasks corresponding to workload l executed on node n. *Before* executing task $i \in S_{n,l}$ corresponding to workload l on node n we collect the resource usage counters described above on node n to form the feature vector $x_i \in \mathbb{R}^{107}$. For each feature described above we subtract the minimum across the entire dataset and rescale so that it lies between 0 and 1 for the entire dataset.

Labels: After running task i we measure the normalized task duration $nd(i)$ which is the ratio of task execution time to the amount of work done (bytes read/written) by task i. From the normalized duration, we determine whether a task has *straggled* using the following definition:

Definition 1 *A task i of a job J is called a straggler if*

$$nd(i) > \beta \times \underset{\forall j \in J}{\text{median}}\{nd(j)\} \tag{1}$$

where $nd(i)$ is the normalized duration of task i computed as the ratio of task execution time to the amount of work done (bytes read/written) by task i.

In this paper, as in Wrangler, we set β to 1.3. Given the definition of a straggler, for task i we define $y_i \in \{0, 1\}$ as a binary label indicating whether the corresponding task i ended up being a straggler relative to other tasks in the same job.

3.2 Prediction Task

While the resource usage counters do track the time-varying state of the node, they do not model the variability across nodes, or the properties of the particular task we are executing. To deal with the variability of nodes, Wrangler builds a separate predictor for each node.

Modeling the variability across tasks is harder since it would require understanding the code that the task is executing. Instead, Wrangler uses the notion of "workloads", which we define next. Companies such as Facebook, Google, use compute clusters for various computational purposes. The specific pattern of execution of jobs on these clusters is called a *workload*. These workloads are specified using various statistics, such as submission times of multiple jobs, number of their constituent tasks along with their input data sizes, shuffle sizes, and output sizes. Wrangler assumes that all tasks in a particular workload have similar properties in terms of resource requirements etc., and it captures the variability across workloads by building separate predictors for each workload. Thus Wrangler builds separate predictors for each node and for every workload.

Putting it all together, we can state the binary classification problem for predicting straggler tasks more formally as follows. A datapoint in our setting corresponds to a task i of job J from a particular workload l that is executed on a node n in our cluster. Before running task i we collect the features x_i which characterize the state of node n. After running task i we then measure the normalized duration and determine whether the task straggled with respect to other tasks of job J (see Definition 1). Our goal is to learn a function:

$$f_{n,l} : x \longrightarrow y,$$

for each node n and workload l that maps the current characteristics $x \in \mathbb{R}^d$ of that node (e.g., current CPU utilization) to the binary variable $y \in \{0, 1\}$ indicating whether that task will straggle (i.e., run longer than β times the median runtime).

3.3 Training

For any workload l, Wrangler first collects data and ground truth labels for training and validation. In particular, for every task i launched on node n, Wrangler records both the resource usage counters x_i and the label y_i which indicates if the task straggles or not. Since there is a separate predictor for each node and workload, Wrangler produces separate datasets for each node and workload. Let $S_{n,l}$ be the set of tasks of jobs corresponding to workload l, executed on node n. Thus, we record the dataset for node n, workload l as:

$$D_{n,l} = \{(x_i, y_i) : i \in S_{n,l}\}.$$

Then Wrangler divides each dataset into a training set and test set temporally, i.e, the first few jobs constitute the train set and the rest form the validation. The predictors are

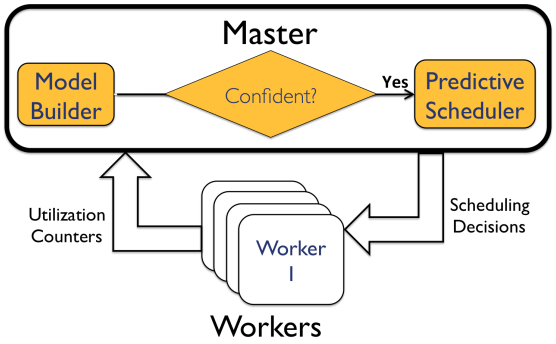

Figure 1: Architecture of *Wrangler*.

then trained on these datasets. Stragglers, by definition are fewer than the non-straggler tasks. Therefore for training, Wrangler statistically oversampled the class of stragglers to avoid the skew in the strengths of the two classes. This gets the two classes represented equally.

After this initial training phase, the classifiers are frozen, and the trained classifiers are incorporated into the job scheduler as described above. They are then tested on the next $T_{test} = 10$ hours by measuring the impact of these classifiers on job completion times. Further details about the train and test splits are in Section 5.

3.4 Model-aware scheduling

Job scheduling in Hadoop is handled by a master, which controls the workers. The master assigns tasks to the worker nodes. The assignments depend upon the number of available slots as well as data-locality. Wrangler modifies this scheduler to incorporate its predictions. Before launching a task i of a job coming from a workload l, on a node n, the scheduler collects the node's resource usage counters x_i and runs the classifier $f_{n,l}$. If the classifier predicts that the task will be a straggler with high enough "confidence" (Wrangler uses SVMs with scaling by Platt (1999) to produce a confidence), the scheduler does not assign the task to that node. It is later assigned to a node that is not predicted to create a straggler. See Yadwadkar et al. (2014) for details on the algorithm and implementation.

3.5 Shortcomings of Wrangler and avenues for improvements

Due to the heterogeneity of nodes in a cluster, the model builder trains a separate classifier for each node. Note that to build a training set per node, every node should have executed sufficient number of tasks. Wrangler takes a few hours (approximately 2-4 hours, depending on the workload) for this process. Additionally, because each workload might be different, these models are retrained for every new workload. Thus, for every new workload that is executed on the cluster, there is a 2-4 hour model building period. In typical large

production clusters with tens of thousands of nodes, it might be a long time before a node collects enough data to train a classifier. (In Table 5 we show that the prediction accuracy of Wrangler rapidly degrades as the amount of training data is reduced). In some cases, workloads may only be run a few times in total, limiting the ability of systems like Wrangler to make meaningful predictions.

Alternatively, large clusters with locality aware scheduling can lead to poor sample coverage. Recall that, in our case, each task of a workload executed on a node amounts to a training data point. The placement of input data on nodes in a cluster is managed by the underlying distributed file system (Ghemawat et al., 2003). To achieve locality for faster reading of input data, sophisticated locality-aware schedulers (Zaharia et al., 2008, 2010) try to assign tasks to nodes already having the appropriate data. Based on the popularity of the data, number of tasks assigned to a node could vary. Hence, we may not get uniform number of training data points, i.e., tasks executed, across all the nodes in a cluster. There could be other reasons behind skewed assignment of tasks to nodes (Kwon et al., 2012): even when every map task has the same amount of data, a task may take longer depending on the code path it takes based on the data it processes. Hence, the node slots will be busy due to such long running tasks. This could lead to some nodes executing fewer tasks than others.

These observations suggest that our modeling framework needs to be robust to limited and potentially skewed data. Thus, there is a need for straggler prediction models (1) that can be trained using minimum available data, and (2) that generalize to unseen nodes or workloads. In the following section, we describe our multi-task learning based approach with these goals for avoiding stragglers. We evaluate it using real world production level traces from Facebook and Cloudera's customers, and compare the gains with Wrangler.

4. Multi-task learning for straggler avoidance

As described in the previous section, Wrangler builds separate models for each workload and for every node. Thus, every {node, workload} tuple is a separate learning problem. However, learning problems corresponding to different workloads executed on the same node clearly have something in common, as do learning tasks corresponding to different nodes executing the same workload. We want to use this shared structure between the learning problems to reduce data collection time.

Concretely, a task executing on a node will be a straggler because of a combination of factors. Some of these factors involve the properties of the node where the task is executing (for instance, the node may be memory-constrained) and some others involve particular requirements that the tasks might have in terms of resources (for instance, the task may require a lot of memory). These are workload-related factors. When collecting data for a new workload executing on a given node, one must be able to use information about the workload collected while it executed on other nodes, and information collected about the node collected while it executed other workloads.

We turn to multi-task learning to leverage this shared structure. In the terminology of multi-task learning, each {node, workload} pair forms a separate learning-task[3] and these learning problems have a shared structure between them. However, unlike typical MTL formulations, our learning-tasks are not simply correlated with each other; they share a specific structure, clustering along node- or workload-dependent axes. In what follows, we first describe a general MTL formulation that can capture such learning-task grouping. We then detail how we apply this formulation to our application of straggler avoidance.

4.1 Partitioning tasks into groups

Suppose there are T learning tasks, with the training set for the t-th learning-task denoted by $D_t = \{(\mathbf{x}_{it}, y_{it}) : i = 1, \ldots, k_t\}$, with $\mathbf{x}_{it} \in \mathbb{R}^d$. We begin with the formulation proposed by Evgeniou and Pontil (2004). Evgeniou, et al. proposed a basic hierarchical regression formulation with the linear model, $\mathbf{w}_t$, for learning-task t as:

$$\mathbf{w}_t = \mathbf{w}_0 + \mathbf{v}_t \tag{2}$$

The intuition here is that $\mathbf{w}_0$ captures properties common to all learning-tasks, while $\mathbf{v}_t$ captures how the individual learning-tasks deviate from $\mathbf{w}_0$.

We then frame learning in the context of empirical loss minimization. Given the variability in node behavior and the need for robust predictions we adopt the hinge-loss and apply l_2 regularization to both the base w_0 and learning-task specific weights v_t:

$$\min_{\mathbf{w}_0, \mathbf{v}_t, b} \lambda_0 \|\mathbf{w}_0\|^2 + \frac{\lambda_1}{T} \sum_{t=1}^{T} \|\mathbf{v}_t\|^2 + \sum_{t=1}^{T} \sum_{i=1}^{k_t} L_{Hinge}\left(y_{it}, (\mathbf{w}_0 + \mathbf{v}_t)^T \mathbf{x}_{it} + b\right) \tag{3}$$

where $L_{Hinge}(y_{it}, s_{it}) = \max(0, 1 - y_{it} s_{it})$ is the hinge loss.

In the above formulation, all learning-tasks are treated equivalently. However, as discussed above, in our application some learning-tasks naturally cluster together. Suppose that the learning-tasks cluster into G non-overlapping *groups*, with the t-th learning-task belonging to the $g(t)$-th group. Note that while we derive our formulations for non-overlapping groups, which is true in our application, the modification for overlapping groups is trivial. Using the same intuition as Equation 2, we can write the classifier $\mathbf{w}_t$ as:

$$\mathbf{w}_t = \mathbf{w}_0 + \mathbf{v}_t + \mathbf{w}_{g(t)} \tag{4}$$

In general, there may be more than one way of dividing our learning-tasks into groups. In our application, one may split learning-tasks into groups based on workload or based on nodes. We call one particular way of dividing learning-tasks into groups a *partition*. The p-th partition has G_p groups, and the learning-task t belongs to the $g_p(t)$ group under this partition. Now, we also have a separate set of weight vectors for each partition p, and the weight vector of the g-th group of the p-th partition is denoted by $\mathbf{w}_{p,g}$. Then, we can write the classifier $\mathbf{w}_t$ as:

$$\mathbf{w}_t = \mathbf{w}_0 + \mathbf{v}_t + \sum_{p=1}^{P} \mathbf{w}_{p,g_p(t)} \tag{5}$$

3. The machine learning notion of a "task" as a learning problem differs from the cloud computing notion of a "task" as a part of a job that is run in parallel. The intended meaning should be clear from the context.

Finally, note that $\mathbf{w}_0$ and $\mathbf{v}_t$ can also be seen as weight vectors corresponding to trivial partitions: $\mathbf{w}_0$ corresponds to the partition where all learning-tasks belong to a single group, and $\mathbf{v}_t$ corresponds to the partition where each learning-task is its own group. Thus, we can include $\mathbf{w}_0$ and $\mathbf{v}_t$ in our partitions and write Equation 5 as:

$$\mathbf{w}_t = \sum_{p=1}^{P} \mathbf{w}_{p,g_p(t)} \tag{6}$$

Intuitively, at test time, we get the classifier for the t-th learning-task by summing weight vectors corresponding to each group to which t belongs.
As in Equation 3, the learning problem involves minimizing the sum of l_2 regularizers on each of the weight vectors and the hinge loss:

$$\min_{\mathbf{w}_{p,g}, b} \sum_{p=1}^{P} \sum_{g=1}^{G_p} \lambda_{p,g} \|\mathbf{w}_{p,g}\|^2 + \sum_{t=1}^{T} \sum_{i=1}^{k_t} L_{Hinge}\left(y_{it}, \left(\sum_{p=1}^{P} \mathbf{w}_{p,g_p(t)}\right)^T \mathbf{x}_{it} + b\right) \tag{7}$$

Here, the regularizer coefficient $\lambda_{p,g} = \frac{\lambda_p \#(p,g)}{T}$, where $\#(p,g)$ denotes the number of learning-tasks assigned to the g-th group of the p-th partitioning. The scaling factor $\frac{\lambda_p \#(p,g)}{T}$ interpolates smoothly between λ_0, when all learning-tasks belong to a single group, and $\frac{\lambda_1}{T}$, when each learning-task is its own group. Lowering λ_p for a particular partition will reduce the penalty on the weights of the p-th partition and thus cause the model to rely more on the p-th partitioning. For the base partition $p = 0$, setting $\lambda_p = 0$ would thus favor as much parameter sharing as feasible.

4.2 Reduction to a standard SVM

One advantage of the formulation we use is that it can be reduced to a standard SVM (Cortes and Vapnik, 1995), allowing the usage of off-the-shelf SVM solvers. Below, we show how this reduction can be achieved. Given λ, for every group g of every partition p, define:

$$\tilde{\mathbf{w}}_{p,g} = \sqrt{\frac{\lambda_{p,g}}{\lambda}} \mathbf{w}_{p,g} \tag{8}$$

Now concatenate these vectors into one large weight vector $\tilde{\mathbf{w}}$:

$$\tilde{\mathbf{w}} = [\tilde{\mathbf{w}}_{1,1}^T, \ldots, \tilde{\mathbf{w}}_{p,g}^T, \ldots, \tilde{\mathbf{w}}_{P,G_P}^T]^T \tag{9}$$

Then, it can be seen that $\lambda \|\tilde{\mathbf{w}}\|^2 = \sum_{p=1}^{P} \sum_{g=1}^{G_p} \lambda_{p,g} \|\mathbf{w}_{p,g}\|^2$. Thus, with this change of variables, the regularizer in our optimization problem resembles a standard SVM. Next, we transform the data points $\mathbf{x}_{it}$ into $\phi(\mathbf{x}_{it})$ such that we can replace the scoring function with $\tilde{\mathbf{w}}^T \phi(\mathbf{x}_{it})$. This transformation is as follows. Again, define:

$$\phi_{p,g}(\mathbf{x}_{it}) = \delta_{g_p(t),g} \sqrt{\frac{\lambda}{\lambda_{p,g}}} \mathbf{x}_{it} \tag{10}$$

Here, $\delta_{g_p(t),g}$ is a kronecker delta, which is 1 if $g_p(t) = g$ (i.e. , if the learning-task t belongs to group g in the p-th partitioning) and 0 otherwise. Our feature transformation is then the concatenation of all these vectors:

$$\phi(\mathbf{x}) = [\phi_{1,1}(\mathbf{x})^T, \ldots, \phi_{p,g}(\mathbf{x})^T, \ldots, \phi_{P,G_P}(\mathbf{x})^T]^T \tag{11}$$

It is easy to see that:

$$\tilde{\mathbf{w}}^T \phi(\mathbf{x}_{it}) = \left(\sum_{p=1}^{P} \mathbf{w}_{p,g_p(t)} \right)^T \mathbf{x}_{it} \tag{12}$$

Intuitively, $\tilde{\mathbf{w}}$ concatenates all our parameters with their appropriate scalings into one long weight vector, with one block for every group of every partitioning. $\phi(\mathbf{x}_{it})$ transforms a data point into an equally long feature vector, by placing scaled copies of $\mathbf{x}_{it}$ in the appropriate blocks and zeros everywhere else.

With these transformations, we can now write our learning problem as :

$$\min_{\tilde{\mathbf{w}},b} \lambda \|\tilde{\mathbf{w}}\|^2 + \sum_{t=1}^{T} \sum_{i=1}^{k_t} L_{Hinge}(y_{it}, \tilde{\mathbf{w}}^T \phi(\mathbf{x}_{it}) + b) \tag{13}$$

which corresponds to a standard SVM. In practice, we use this transformation and change of variables, both at train time and at test time.

4.3 Automatically selecting groups or partitions

In many real world applications including our own, good classification accuracy is not an end in itself. Model interpretability is of critical importance. A large powerful classifier working on tons of features may do a very good job of classification, but will not provide any insight to an engineer trying to identify the root causes of a problem. It will also be difficult to debug such a classifier if and when it fails. In the absence of sufficient training data, large models may also overfit. Thus, interpretability and simplicity of the model are important goals. In the context of the formulation above, this means that we want to keep only a minimal set of groups/partitions while maintaining high classification accuracy.

We can use mixed l_1 and l_2 norms to induce a sparse selection of groups or partitions (Bach et al., 2011). Briefly, suppose we are given a long weight vector $\mathbf{w}$ divided into M blocks, with the m-th block denoted by $\mathbf{w}_m$. Then the squared mixed l_1 and l_2 norm is:

$$\Omega(\mathbf{w}) = \left(\sum_{m=1}^{M} \|\mathbf{w}_m\|_2 \right)^2 \tag{14}$$

This can be considered as an l_1 norm on a vector with elements $\|\mathbf{w}_m\|_2$. When $\Omega(\cdot)$ is used as a regularizer, the l_1 norm will force some elements of this vector to be set to 0, which in turn would force the corresponding *block* of weights $\mathbf{w}_m$ to be set to 0. It thus encourages entire blocks of the weight vector to be set to 0, a sparsity pattern that is often called "group sparsity".

In our context, our weight vector $\tilde{\mathbf{w}}$ is made up of $\tilde{\mathbf{w}}_{p,g}$. We consider two alternatives:

1. We can put all the weight vectors corresponding to a single partition in the same block. Then, the regularizer becomes:

$$\Omega_{ps}(\tilde{\mathbf{w}}) = \left(\sum_{p=1}^{P} \|\tilde{\mathbf{w}}_p\|_2 \right)^2 \tag{15}$$

   where $\tilde{\mathbf{w}}_p = [\tilde{\mathbf{w}}_{p,1}^T, \ldots, \tilde{\mathbf{w}}_{p,G_p}^T]^T$ concatenates all weight vectors corresponding to the p-th partition. This regularizer will thus tend to kill entire partitions. In other words, it will uncover notions of grouping, or learning-task similarity, that are the most important.

2. We can put the weight vector of each group of each partition in separate blocks. Then the regularizer becomes:

$$\Omega_{gs}(\tilde{\mathbf{w}}) = \left(\sum_{p=1}^{P} \sum_{g=1}^{G} \|\tilde{\mathbf{w}}_{p,g}\|_2 \right)^2 \tag{16}$$

   This regularizer will tend to select a small set of groups which are needed to get a good performance.

4.4 Automatically selecting features

Mixed norms can also be used to select a sparse set of feature blocks that are most useful for classification. This is again useful for interpretability. In our application, features are resource counters at a node. Some of these features are related to memory, others to cpu usage, etc. If our model is able to predict straggler behavior solely on the basis of memory usage counters, for instance, then it might indicate that the cluster or the workload is memory constrained.

In our multi-task setting, such feature selection can also interact with the different groups and partitions of learning-tasks. Suppose each feature vector $\mathbf{x}$ is made up of blocks corresponding to different kinds of features, denoted by $\mathbf{x}^{(1)}, \mathbf{x}^{(2)}, \ldots \mathbf{x}^{(B)}$. We can similarly divide each weight vector $\tilde{\mathbf{w}}_{p,g}$ into blocks denoted by $\tilde{\mathbf{w}}_{p,g}^{(1)}$, $\tilde{\mathbf{w}}_{p,g}^{(2)}$ and so on. Then we have two alternatives.

1. One can concatenate corresponding feature blocks from all the weight vectors to get $\tilde{\mathbf{w}}^{(1)}, \ldots, \tilde{\mathbf{w}}^{(B)}$. Then a mixed l_1 and l_2 regularizer using these weight blocks can be written as:

$$\Omega_{fs1}(\tilde{\mathbf{w}}) = \left(\sum_{b=1}^{B} \|\tilde{\mathbf{w}}^{(b)}\|_2 \right)^2 \tag{17}$$

   Such a regularizer will encourage the model to select a sparse set of feature blocks on which to base its decision, setting *all* weights corresponding to all the other feature blocks to 0.

2. An alternative would be to let each group vector choose its own sparse set of feature blocks. This can be achieved with the following regularizer:

$$\Omega_{fs2}(\tilde{\mathbf{w}}) = \left(\sum_{p,g} \sum_{b=1}^{B} \|\tilde{\mathbf{w}}_{p,g}^{(b)}\|_2 \right)^2 \tag{18}$$

4.5 Kernelizing the formulation

We have till now described our formulation in primal space. However, kernelizing this formulation is simple. First, note that if we use a simple squared l_2 regularizer, then our formulation is equivalent to a standard SVM in a transformed feature space. This transformed feature space corresponds to a new kernel:

$$\begin{aligned} K_{new}(\mathbf{x}_{it}, \mathbf{x}_{ju}) &= \langle \phi(\mathbf{x}_{it}), \phi(\mathbf{x}_{ju}) \rangle \\ &= \sum_{p,g} \langle \phi_{p,g}(\mathbf{x}_{it}), \phi_{p,g}(\mathbf{x}_{ju}) \rangle \\ &= \sum_{p,g} \delta_{g_p(t),g} \delta_{g_p(u),g} \frac{\lambda}{\lambda_{p,g}} K(\mathbf{x}_{it}, \mathbf{x}_{jt}) \end{aligned} \tag{19}$$

Thus, the transformed kernel corresponds to the linear combination of a set of kernels, one for each group. Each group kernel is zero unless both data points belong to the group, in which case it equals a scaled version of the kernel in the original feature space.

When using the mixed-norm regularizers, the derivation is a bit more involved. We first note that (Aflalo et al., 2011):

$$\left(\sum_{m=1}^{M} \|\mathbf{w}_m\|_2 \right)^2 = \min_{0 \le \eta \le 1, \|\eta\|_1 \le 1} \sum_{m=1}^{M} \frac{\|\mathbf{w}_m\|_2^2}{\eta_m} \tag{20}$$

Using this transformation leads to the following primal objective:

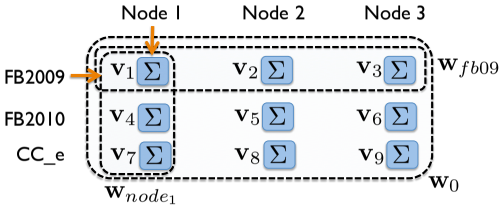
$$\min_{\mathbf{w}, b, 0 \le \eta \le 1, \|\eta\|_1 \le 1} \sum_{m=1}^{M} \frac{\|\mathbf{w}_m\|_2^2}{\eta_m} + \sum_{i,t} L(x_{it}, y_{it}, \mathbf{w}) \tag{21}$$

where $L(x_{it}, y_{it}, \mathbf{w})$ is the hinge loss. This corresponds to a 1-norm multiple kernel learning formulation (Kloft et al., 2011) where each block of feature weights corresponds to a separate kernel. We refer the reader to Kloft et al. (2011) for a description of the dual of this formulation.

We note that these kernelized versions are very similar to the ones derived in (Widmer et al., 2010; Blanchard et al., 2011). However, the group and partition structure and the application domain are unique to ours.

4.6 Application to straggler avoidance

We apply this formulation to straggler avoidance as follows. Suppose there are N nodes and L workloads. Then there are $N \times L$ learning-tasks, and Wrangler trains as many models, one for each {node, workload} tuple. For our proposal, we consider four different partitions:



$$\mathbf{w}_1 = \mathbf{w}_0 + \mathbf{w}_{node_1} + \mathbf{w}_{fb09} + \mathbf{v}_1$$

Figure 2: In our context of straggler avoidance, the learning-tasks naturally cluster into various groups in multiple partitions. When a particular learning- task, for example, node 1 and workload FB2009 ($\mathbf{v}_1$), has limited training data available, we learn its weight vector, $\mathbf{w}_1$, by adding the weight vectors of groups it belongs to from different partitions.

1. A single group consisting of all nodes and workloads. This gives us the single weight vector $\mathbf{w}_0$.

2. One group for each node, consisting of all L learning-tasks belonging to that node. This gives us one weight vector for each node $\mathbf{w}_n, n = 1, \ldots, N$, that captures the heterogeneity of nodes.

3. One group for each workload, consisting of all N learning-tasks belonging to that workload. This gives us one weight vector for each workload $\mathbf{w}_l, l = 1, \ldots, L$, that captures peculiarities of particular workloads.

4. Each {node, workload} tuple as its own group. Since there are $N \times L$ such pairs, we get $N \times L$ weight vectors, which we denote as $\mathbf{v}_t$, following the notation considered in Evgeniou and Pontil (2004).

Thus, if we use all four partitions, the weight vector $\mathbf{w}_t$ for a given workload l_t and a given node n_t is:

$$\mathbf{w}_t = \mathbf{w}_0 + \mathbf{w}_{n_t} + \mathbf{w}_{l_t} + \mathbf{v}_t \tag{22}$$

Figure 2 shows an example. The learning problem for the FB2009[4] workload running on node 1 belongs to one group from each of the four partitions mentioned above: (1) the global partition, denoted by the weight vector, $\mathbf{w}_0$, (2) the group corresponding to node 1 from the node-wise partition, denoted by the weight vector $\mathbf{w}_{node_1}$, (3) the group corresponding to the FB2009 workload from the workload-wise partition, denoted by the weight vector $\mathbf{w}_{fb09}$, and (4) the group containing just this individual learning problem, denoted by the weight vector $\mathbf{v}_1$. Thus, we can learn the weight vector $\mathbf{w}_1$ as:

$$\mathbf{w}_1 = \mathbf{w}_0 + \mathbf{w}_{node_1} + \mathbf{w}_{fb09} + \mathbf{v}_1 \tag{23}$$

The corresponding training problem is then:

4. See Section 5.1 for details about the workloads we use.

$$\min_{\mathbf{w},b} \lambda_0\|\mathbf{w}_0\|^2 + \frac{\nu}{N}\sum_{n=1}^{N}\|\mathbf{w}_n\|^2 + \frac{\omega}{L}\sum_{l=1}^{L}\|\mathbf{w}_l\|^2 + \frac{\tau}{T}\sum_{t=1}^{T}\|\mathbf{v}_t\|^2 + \sum_{t=1}^{T}\sum_{i=1}^{k_t} L_{Hinge}\left(y_{it}, (\mathbf{w}_0 + \mathbf{w}_{n_t} + \mathbf{w}_{l_t} + \mathbf{v}_t)^T\mathbf{x}_{it} + b\right) \quad (24)$$

where λ_0, ν, ω, τ are hyperparameters. We ran an initial grid search on a validation set to fix these hyperparameters and found that prediction accuracy was not very sensitive to these settings: several settings gave very close to optimal results. We used $\lambda_0 = \nu = \omega = \tau = 1$, which was one of the highest performing settings, for all our experiments. Appendix A provides the details of this grid search experiment along with the sensitivity of these hyperparameters to a set of values. As described in Section 4.2, we work in a transformed space in which the above problem reduces to a standard SVM. In this space the weight vector is

$$\tilde{\mathbf{w}} = [\tilde{\mathbf{w}}_0^T, \tilde{\mathbf{w}}_{n_1}^T, \ldots, \tilde{\mathbf{w}}_{n_N}^T, \tilde{\mathbf{w}}_{l_1}^T, \ldots, \tilde{\mathbf{w}}_{l_L}^T, \tilde{\mathbf{v}}_{t_1}^T, \ldots, \tilde{\mathbf{v}}_{t_T}^T]^T \quad (25)$$

This decomposition will change depending on which partitions we use.

As described in the previous section, we can also use mixed l_1 and l_2 norms to automatically select groups or partitions. To select partitions, we combine all the node-related weight vectors $\tilde{\mathbf{w}}_{n_1}, \ldots, \tilde{\mathbf{w}}_{n_N}$ into one long vector $\tilde{\mathbf{w}}_N$, all workload vectors $\tilde{\mathbf{w}}_{l_1}, \ldots, \tilde{\mathbf{w}}_{l_L}$ into $\tilde{\mathbf{w}}_L$ and all $\tilde{\mathbf{v}}_1, \ldots, \tilde{\mathbf{v}}_T$ into $\tilde{\mathbf{v}}_T$. We then solve the following optimization:

$$\min_{\tilde{\mathbf{w}},b} \left(\|\tilde{\mathbf{w}}_0\|_2 + \|\tilde{\mathbf{w}}_N\|_2 + \|\tilde{\mathbf{w}}_L\|_2 + \|\tilde{\mathbf{v}}_T\|_2\right)^2 + C\sum_{i,t} L_{Hinge}\left(y_{it}, \tilde{\mathbf{w}}^T\phi(\mathbf{x}_{it}) + b\right) \quad (26)$$

This model will learn which notion of grouping is most important. For instance if $\tilde{\mathbf{w}}_L$ is set to 0, then we might conclude that straggler behaviour doesn't depend that much on the particular workload being executed.

To select individual groups, we solve the optimization problem:

$$\min_{\tilde{\mathbf{w}},b,\xi\geq 0} \left(\|\tilde{\mathbf{w}}_0\|_2 + \sum_{n=1}^{N}\|\tilde{\mathbf{w}}_n\|_2 + \sum_{l=1}^{L}\|\tilde{\mathbf{w}}_l\|_2 + \sum_{t=1}^{T}\|\tilde{\mathbf{v}}_t\|_2\right)^2 + C\sum_{i,t} L_{Hinge}\left(y_{it}, \tilde{\mathbf{w}}^T\phi(\mathbf{x}_{it}) + b\right) \quad (27)$$

This formulation can set some individual node or workload models to 0. This would mean that straggler behavior on some nodes or workloads can be predicted by generic models, but others require more node-specific or workload-specific reasoning.

We can also use mixed norms for feature selection. The features in our feature vector correspond to resource usage counters, and we divide them into 5 categories, as explained

in Section 3.1: counters based on cpu, those based on network, those based on disk, those based on memory, and other system-level counters. Then each $\tilde{\mathbf{w}}_n$, $\tilde{\mathbf{w}}_l$ and $\tilde{\mathbf{v}}_t$ gets similarly split up. As described before, we can either let each model choose its own set of features using this regularizer:

$$\begin{aligned}\Omega(\tilde{\mathbf{w}}) \quad &= (\|\tilde{\mathbf{w}}_0^{mem}\|_2 + \|\tilde{\mathbf{w}}_0^{disk}\|_2 + \|\tilde{\mathbf{w}}_0^{cpu}\|_2 + \|\tilde{\mathbf{w}}_0^{network}\|_2 + \|\tilde{\mathbf{w}}_0^{system}\|_2 + \\ &+ \textstyle\sum_{n=1}^{N}[\|\tilde{\mathbf{w}}_n^{mem}\|_2 + \|\tilde{\mathbf{w}}_n^{disk}\|_2 + \|\tilde{\mathbf{w}}_n^{cpu}\|_2 + \|\tilde{\mathbf{w}}_n^{network}\|_2 + \|\tilde{\mathbf{w}}_n^{system}\|_2] \\ &+ \textstyle\sum_{l=1}^{L}[\|\tilde{\mathbf{w}}_l^{mem}\|_2 + \|\tilde{\mathbf{w}}_l^{disk}\|_2 + \|\tilde{\mathbf{w}}_l^{cpu}\|_2 + \|\tilde{\mathbf{w}}_l^{network}\|_2 + \|\tilde{\mathbf{w}}_l^{system}\|_2] \\ &+ \textstyle\sum_{t=1}^{T}[\|\tilde{\mathbf{v}}_t^{mem}\|_2 + \|\tilde{\mathbf{v}}_t^{disk}\|_2 + \|\tilde{\mathbf{v}}_t^{cpu}\|_2 + \|\tilde{\mathbf{v}}_t^{network}\|_2 + \|\tilde{\mathbf{v}}_t^{system}\|_2])^2 \quad (28)\end{aligned}$$

or choose a single set of features globally using this regularizer:

$$\Omega(\tilde{\mathbf{w}}) = \left(\|\tilde{\mathbf{w}}^{mem}\|_2 + \|\tilde{\mathbf{w}}^{cpu}\|_2 + \|\tilde{\mathbf{w}}^{disk}\|_2 + \|\tilde{\mathbf{w}}^{network}\|_2 + \|\tilde{\mathbf{w}}^{system}\|_2\right)^2 \quad (29)$$

where $\tilde{\mathbf{w}}^{mem}$ concatenates all memory related weights from all models,

$$\tilde{\mathbf{w}}^{mem} = [\tilde{\mathbf{w}}_0^{memT}, \tilde{\mathbf{w}}_{n_1}^{memT}, \ldots, \tilde{\mathbf{w}}_{n_N}^{memT}, \tilde{\mathbf{w}}_{l_1}^{memT}, \ldots, \tilde{\mathbf{w}}_{l_L}^{memT}]^T \quad (30)$$

$\tilde{\mathbf{w}}^{cpu}$, $\tilde{\mathbf{w}}^{disk}$ etc. are defined similarly.

4.7 Exploring the relationships between the weight vectors

Before getting into the experiments, we can get some insights on what our formulation will learn by looking at the KKT conditions. Equation 24 can equivalently be written as:

$$\begin{aligned}\min_{\mathbf{w},b,\xi} \lambda_0\|\mathbf{w}_0\|^2 + \frac{\nu}{N}\sum_{n=1}^{N}\|\mathbf{w}_n\|^2 + \frac{\omega}{L}\sum_{l=1}^{L}\|\mathbf{w}_l\|^2 \\ + \frac{\tau}{T}\sum_{t=1}^{T}\|\mathbf{v}_t\|^2 + \sum_{t=1}^{T}\sum_{i=1}^{k_t}\xi_{it} \quad (31) \\ \text{s.t. } y_{it}\left((\mathbf{w}_0 + \mathbf{w}_{n_t} + \mathbf{w}_{l_t} + \mathbf{v}_t)^T\mathbf{x}_{it} + b\right) \geq 1 - \xi_{it} \ \ \forall i,t \\ \xi_{it} \geq 0 \ \ \forall i,t\end{aligned}$$

The Lagrangian of the formulation in Equation 31 is:

$$\begin{aligned}\mathcal{L}(\mathbf{w}, b, \boldsymbol{\alpha}, \boldsymbol{\gamma}) = \lambda_0\|\mathbf{w}_0\|^2 + \frac{\nu}{N}\sum_{n=1}^{N}\|\mathbf{w}_n\|^2 + \frac{\omega}{L}\sum_{l=1}^{L}\|\mathbf{w}_l\|^2 \\ + \frac{\tau}{T}\sum_{t=1}^{T}\|\mathbf{v}_t\|^2 + \sum_{t=1}^{T}\sum_{i=1}^{k_t}\xi_{it} - \sum_{t=1}^{T}\sum_{i=1}^{k_t}\gamma_{it}\xi_{it} \quad (32) \\ + \sum_{t=1}^{T}\sum_{i=1}^{k_t}\alpha_{it}\left(1 - \xi_{it} - y_{it}\left(\mathbf{w}_t^T\mathbf{x}_{it} + b\right)\right)\end{aligned}$$

Taking derivatives w.r.t the primal variables and setting to 0 gives us relationships between $\mathbf{w}_0, \mathbf{v}_t, \mathbf{w}_n$ and $\mathbf{w}_l$:

$$\lambda_0 \mathbf{w}_0^* = \frac{\tau}{T} \sum_t \mathbf{v}_t^* \tag{33}$$

$$\nu \mathbf{w}_n^* = \frac{\tau}{T/N} \sum_{t:n_t=n} \mathbf{v}_t^* \tag{34}$$

$$\omega \mathbf{w}_l^* = \frac{\tau}{T/L} \sum_{t:l_t=l} \mathbf{v}_t^* \tag{35}$$

$$\lambda_0 \mathbf{w}_0^* = \frac{\nu}{N} \sum_n \mathbf{w}_n^* \tag{36}$$

$$\lambda_0 \mathbf{w}_0^* = \frac{\omega}{L} \sum_l \mathbf{w}_l^* \tag{37}$$

Evgeniou and Pontil (2004) also obtain Equation 33 in their formulation, but the other relationships are specific to ours. These relationships imply that these variables shouldn't be considered independent. $\mathbf{w}_n$, $\mathbf{w}_l$ and $\mathbf{w}_0$ are scaled means of the $\mathbf{v}_t$'s of the group they capture.

4.8 Generalizing to unseen nodes and workloads

Consider what happens when we remove the partition corresponding to individual {node, workload} tuples, i.e., $\mathbf{v}_t$, from our formulations. We now do not have any parameters specific to a node-workload combination, but can still capture both node- and workload-dependent properties of the learning problem. Such formulations are thus similar to factorized models where the node and workload dependent factors are grouped into separate blocks. We end up with only $(N + L)d$ parameters, whereas a formulation like that of (Evgeniou and Pontil, 2004; Evgeniou et al., 2005; Jacob et al., 2009) will still have NLd parameters (here d is the input dimensionality). Thus, we can *reduce* the number of parameters while still capturing the essential properties of the learning problems.

In addition, since we no longer have a separate weight vector for each {node, workload} tuple, we can generalize to node-workload pairs that are completely unseen at train time: the classifier for such an unseen combination t will simply be $\mathbf{w}_0 + \mathbf{w}_{n_t} + \mathbf{w}_{l_t}$. We thus explicitly use knowledge gleaned from prior workloads run on this node (through $\mathbf{w}_{n_t}$) and other nodes running this workload (through $\mathbf{w}_{l_t}$). This is especially useful in our application where there may be a large number of nodes and workloads. In such cases, collecting data for each node-workload pair will be time consuming, and generalizing to unseen combinations will be a significant advantage.

In most of our experiments, therefore, we remove the partition corresponding to individual {node, workload} tuples. We explicitly evaluate how well we generalize by doing so in Section 5.4.

5. Empirical Evaluation

In this section, we describe our dataset, provide variants to our proposed formulation and then evaluate them using the following metrics: first, classification accuracy when there is

Trace	#Machines	Length	Date	#Jobs
FB2009	600	6 month	2009	1129193
FB2010	3000	1.5 months	2010	1169184
CC_b	300	9 days	2011	22974
CC_e	100	9 days	2011	10790
Total	≈ 4000	≈ 8.5 months	-	2332141

Table 2: Dataset. *FB*: Facebook, *CC*: Cloudera Customer.

sufficient data and also when sufficient data is not available, and second, improvement in overall job completion times, and third, reduction in resources consumed.

5.1 Datasets

The set of real-world workloads considered in this paper are collected from the production compute clusters at Facebook and Cloudera's customers, which we denote as $FB2009$, $FB2010$, CC_b and CC_e. Table 2 provides details about these workloads in terms of the number of machines in the actual clusters, the length and date of data capture, total number of jobs in those workloads. Chen, et al., explain the data in further details in (Chen et al., 2012). Together, the dataset consists of traces from over about 4000 machines captured over almost eight months. For faithfully replaying these real-world production traces on our 20 node EC2 cluster, we used a statistical workload replay tool, SWIM (Chen et al., 2011) that synthesizes a workload with representative job submission rates and patterns, shuffle/input data size and output/shuffle data ratios (see Chen et al. (2011) for details of replay methodology). SWIM scales the workload to the number of nodes in the experimental cluster.

For each workload, we need data with ground-truth labels for training and validating our models. We collect this data by running tasks from the workload as described above and recording the resource usage counters x_i at a node at the time a task i is launched, and the ground truth label y_i by checking if it ends up becoming a straggler. Then we divide this dataset temporally into a training set and a validation set. In other words, the first few tasks that were executed form the train set and the rest of the tasks form the validation set. In the experiments below, we vary the percentage of data that is used for training, and compute the prediction accuracy on the validation set. We train our final model using two-thirds of this dataset and proceed to evaluate it on our ultimate metric, i.e., job completion times.

To measure job completion times, we then incorporate the trained models into the job scheduler (as in Wrangler). We then run the replay for the workload again, but with a fresh set of tasks. These fresh set of tasks form our test set, and this test set is only used to measure job completion times. Table 3 shows the sizes of the datasets.

Each data point is represented by a 107 dimensional feature vector comprising the node's resource usage counters at the time of launching a task on it. We optimize all our formulations using Liblinear (Fan et al., 2008) for the l_2 regularized variants and using the algorithm proposed by Aflalo et al. (2011) (modified to work in the primal) for the mixed norm variants.

Workload	No of tasks (Training+Validation)	No of tasks Test
$FB2009$	4885	13632
$FB2010$	3843	38158
CC_b	5991	30203
CC_e	39014	94550

Table 3: Number of tasks we use for each workload in the train+val and test sets.

Below, we describe (1) how we use different MTL formulations and prediction accuracy achieved by these formulations, (2) how we learn a classifier for previously unseen node and/or workload and the prediction accuracy it achieves, (3) the improvement in overall job completion times achieved by our formulation and Wrangler over speculative execution, and (4) reduction in resources consumed using our formulation compared to Wrangler.

5.2 Variants of proposed formulation

We consider several variants of the general formulation described in Section 4. Using a simple squared l_2 regularizer, we first consider $\mathbf{w}_0$, $\mathbf{w}_n$ and $\mathbf{w}_l$, individually:

- f_0: In this formulation, we consider only the global partition in which all learning problems belong to a single group. This corresponds to removing $\mathbf{v}_t$, $\mathbf{w}_n$ and $\mathbf{w}_l$. This formulation thus learns a single global weight vector, $\mathbf{w}_0$, for all the nodes and all the workloads.

- f_n: Here we consider only the partition based on nodes. This corresponds to only learning a $\mathbf{w}_n$, that is, one model for each node. This model learns to predict stragglers based on a node's resource usage counters across different workloads, but it cannot capture any properties that are specific to a particular workload.

- f_l: Here we consider only the partition based on workloads. This means we only learn $\mathbf{w}_l$, i.e., a workload dependent model across nodes executing a particular workload. This model learns to predict stragglers based on the resource usage pattern caused due to a workload across nodes, but ignores the characteristics of a specific node.

The above three formulations either discard the node information, the workload information, or both. We now consider multi-task variants that capture both, node and workload properties:

- $f_{0,t}$: This is the formulation proposed by Evgeniou and Pontil (2004), and corresponds to using the global partition where all learning-tasks belong to one group, and the partition where each learning-task is its own group. This learns $\mathbf{w}_0$ and $\mathbf{v}_t$. Note that this formulation still has to learn on the order of NLd different parameters, and has to collect enough data to learn a separate weight vector for each {node, workload} combination.

- $f_{0,t,l}$: This formulation extends the formulation in $f_{0,t}$ by additionally adding the partition based on workloads. It learns $\mathbf{w}_0, \mathbf{w}_l$ and $\mathbf{v}_t$.

- $f_{0,n,l}$: We remove the partition corresponding to individual {node, workload} tuples, removing $\mathbf{v}_t$ entirely and only learning $\mathbf{w}_0$, $\mathbf{w}_l$ and $\mathbf{w}_n$. As described in Section 4.8, this formulation reduces the total number of parameters to $(N + L)d$ and can also generalize to unseen {node, workload} tuples.

For all these formulations, the hyperparameters λ_0, ν, ω and τ were set to 1 wherever applicable. We found this setting to be close to optimal in our initial cross-validation experiments (see Appendix A).

In addition to these, we also consider sparsity-inducing formulations for automatically selecting partitions or groups or blocks of features, as explained in Sections 4.3, 4.4, and 4.6.

- f_{ps} : We use the global, node-based and workload-based formulations thus removing $\mathbf{v}_t$ entirely as in $f_{0,n,l}$ and use mixed l_1 and l_2 norms to automatically select the useful partitions from among these. This model will learn the notion of grouping that is most important. To select partitions, we combine all the node-related weight vectors $\tilde{\mathbf{w}}_{n_1}, \ldots, \tilde{\mathbf{w}}_{n_N}$ into one long vector $\tilde{\mathbf{w}}_N$ and all workload vectors into $\tilde{\mathbf{w}}_L$ as shown below:

$$\tilde{\mathbf{w}} = [\tilde{\mathbf{w}}_0^T, \underbrace{\tilde{\mathbf{w}}_{n_1}^T, \ldots, \tilde{\mathbf{w}}_{n_N}^T}_{\tilde{\mathbf{w}}_N^T}, \underbrace{\tilde{\mathbf{w}}_{l_1}^T, \ldots, \tilde{\mathbf{w}}_{l_L}^T}_{\tilde{\mathbf{w}}_L^T}]^T \tag{38}$$

  Thus our weight vector $\tilde{\mathbf{w}}$ is split up into blocks corresponding to node, workload and global models.

- f_{gs} : This is the formulation where we use mixed l_1 and l_2 norms to automatically select groups within a partition. Again, we only consider the global, node-based and workload-based formulations. This formulation can set individual node or workload models to zero, unlike f_{ps}, that can set a complete partition, i.e. in our case, a combined model of all the nodes or all the workloads to zero. This would mean that predicting straggler behavior on some nodes or workloads does not need reasoning that is specific to those nodes or workloads; instead a generic model would work.

Finally, we also try the following two mixed norms formulations for feature selection. As before, both these formulations remove the partition corresponding to individual {node, workload} tuples, i.e., remove $\mathbf{v}_t$.

- f_{fs1} : As explained in Equation 28, we divide our features into five categories corresponding to cpu, memory, disk, network and other system-level counters. Then each weight vector gets similarly split up into these categories. This formulation learns which categories of features are more important for some nodes or workloads than others.

- f_{fs2} : This formulation, as given in Equation 29, selects a category of features across all the weight vectors of nodes and workloads. This formulation can learn if stragglers in a cluster are caused due to contention for a specific resource.

5.3 Prediction accuracy

In this section, we evaluate the formulations described in the previous section for their straggler prediction accuracy. In the following subsection 5.3.1, we evaluate formulations that use l_2 regularizers, viz., f_0, f_n, f_l, $f_{0,n,l}$, $f_{0,t}$, and $f_{0,t,l}$. Then, in Section 5.3.2, we evaluate the mixed norm formulations (a) that automatically selects partitions, f_{ps}, (b) that automatically selects groups, f_{gs}, and then the formulations (c) f_{fs1}, and (d) f_{fs2} that can automatically select features. We list our formulations with a brief description in Table 4.

5.3.1 Formulations with l_2 regularizers

We aim at learning to predict stragglers using as small amount of data as feasible, as this means shorter data capture time. Note that stragglers are fewer than non-stragglers, so we oversample from the stragglers' class to represent the two classes equally in both, the training and validation sets[5]. Table 5 shows the percentage accuracy of predicting stragglers with varying amount of training data. We observe that:

- With very small amounts of data, all MTL variants outperform Wrangler. In fact, all of f_0 to $f_{0,t,l}$ need only one sixth of the training data to achieve the same or better accuracy.
- It is important to capture both node- and workload-dependent aspects of the problem: $f_{0,n,l}$, $f_{0,t}$ and $f_{0,t,l}$ consistently outperform f_0, f_n and f_l.
- $f_{0,t}$ and $f_{0,t,l}$ perform up to 7 percentage points better than Wrangler with the same amount of training data, with $f_{0,n,l}$ not far behind.

For a better visualization, Figure 3 shows the comparison of prediction accuracy of these formulations, in terms of percentage true positives and percentage false positives when 50% of total data is available.

Next, we evaluate and discuss the sparsity-inducing formulations, f_{ps} (Equation 26), f_{gs} (Equation 27), f_{fs1} (Equation 28), and f_{fs2} (Equation 29).

5.3.2 Formulations with mixed l_1 and l_2 norms

Automatically selecting partitions or groups: In this Section, we evaluate f_{ps} and f_{gs}. Table 6 shows the prediction accuracy of these formulations compared to f_0, f_n, f_l and $f_{0,n,l}$. f_{ps} and f_{gs} show comparable prediction accuracy to $f_{0,n,l}$. We also found interesting sparsity patterns in the learnt weight vectors.

- f_{ps} : Recall that f_{ps} attempts to set the weights of entire partitions to 0. In our case we have a global partition, a node-based partition and a workload-based partition. We observed that only $\tilde{\mathbf{w}}_0$ is zero in the resulting weight vector learned. This means that given node-specific and workload-specific factors, the global factors that are common across all the nodes and workloads do not contribute to the prediction. In other words, similar accuracy could be achieved without using $\tilde{\mathbf{w}}_0$. However, both node- and workload-dependent weights are necessary.

5. An alternative to statistical oversampling would be to use class-sensitive miss-classification penalties.

Formulation	Description
f_0	uses a single, global weight vector
f_n	uses only node-specific weights
f_l	uses only workload-specific weights
$f_{0,n,l}$	uses global, node- and workload-specific weights
$f_{0,t}$	uses global weights and weights specific to {node, workload} tuples
$f_{0,t,l}$	uses global and workload-specific weights and weights specific to {node, workload} tuples
f_{ps}	selects partitions automatically
f_{gs}	selects groups automatically
f_{fs1}	selects feature-blocks automatically for individual groups
f_{fs2}	selects feature-blocks automatically across all the groups

Table 4: Brief description of all our formulations.

%Training Data	Wrangler Yadwadkar et al. (2014)	f_0	f_n	f_l	$f_{0,n,l}$	$f_{0,t}$	$f_{0,t,l}$
1	Insufficient data	66.9	63.5	66.5	65.5	63.7	66.2
2	Insufficient Data	67.1	63.3	67.7	67.5	64.3	67.7
5	Insufficient Data	67.5	68.1	69.1	69.8	69.6	69.1
10	63.9	67.8	70.9	69.4	72.3	73.1	72.9
20	67.2	68.0	72.6	70.1	72.9	74.7	74.8
30	68.5	68.5	73.2	70.3	74.1	75.9	75.8
40	69.7	68.2	73.9	70.5	74.3	76.4	76.4
50	70.1	68.5	74.1	70.4	75.3	77.1	77.2

Table 5: Prediction accuracies (in %) of various MTL formulations for straggler prediction with varying amount of training data. See Section 5.3.1 for details.

- f_{gs} : In f_{gs}, we encourage individual nodes-specific or individual workloads-specific weight vectors separately to be set to zero. We observed that some of the nodes' weight vectors and some of the workload-specific weight vectors were zero, indicating that in some cases we do not need node or workload specific reasoning. (One can use the learnt sparsity pattern and attempt to correlate it with some node and workload characteristics; however we have not explored this in this paper.)

We also note that our mixed-norm formulations automatically learn a grouping that achieves comparable accuracy with lesser total number of groups, and thus fewer parameters.

Automatically selecting features: In this section, we evaluate the remaining formulations f_{fs1} and f_{fs2}. These two formulations group sets of features based on resources. We divide the features in five different categories viz., features measuring (1) CPU utilization, (2) memory utilization, (3) network usage, (5) disk utilization, (6) other system level performance counters. We evaluate their straggler prediction accuracy and then discuss their interpretability in terms of understanding the causes behind stragglers.

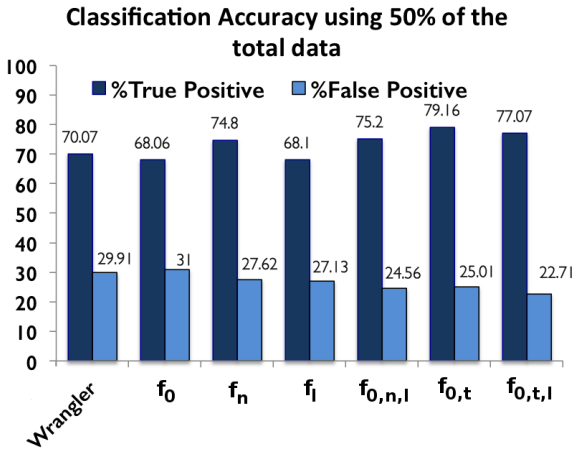


Figure 3: Classification accuracy of various MTL formulations as compared to Wrangler using 50% of the total data. This plot shows the percentage of true positives and the percentage of false positives in each of the cases. These quantities are computed as: % True Positive = (fraction of stragglers predicted correctly as stragglers) $\times$ 100, and % False Positive = (fraction of non-stragglers predicted incorrectly to be stragglers) $\times$ 100.

Formulation	Straggler Prediction Accuracy
f_0	68.5
f_n	74.1
f_l	70.4
$f_{0,n,l}$	75.3
f_{ps}	74.4
f_{gs}	73.8

Table 6: Straggler prediction accuracies (in %) using the four mixed-norm formulations f_{ps} and f_{gs} compared with formulations that use l_2 regularizers. Note that f_{ps} and f_{gs} perform with comparable accuracy with $f_{0,n,l}$, however, use lesser number of groups and parameters, resulting in simpler models.

Table 7 shows the percentage prediction accuracies of these formulations on our test set. Note that these formulations show comparable prediction accuracy. Next, we discuss the impact of f_{fs1} and f_{fs2} on understanding the straggler behavior.

- f_{fs1}: Because this formulation divides each group weight vector further into blocks based on the kind of features, it can potentially provide fine-grained insight into what kinds of features are most important for each group weight vector. Indeed, we found that some node models assign zero weight to features from the network category, while others assign a zero weight to the disk category. However, no global patterns emerge.

Formulation	Straggler Prediction Accuracy (in %)
f_{fs1}	74.9
f_{fs2}	74.9

Table 7: Straggler prediction accuracies (in %) using f_{fs1} and f_{fs2} that encourage sparsity across bocks of features.

Table 8: Straggler Prediction accuracies (in %) of $f_{0,n,l}$ and $f_{0,t}$ on test data from an unseen node-workload pair. See Section 5.4 for details.

This reinforces our belief that the causes of stragglers vary quite a bit from node to node or workload to workload.

- f_{fs2}: This formulation considers these feature categories across the various nodes and workloads and provides a way of knowing if there are certain dominating factors causing stragglers in a cluster. However, we observed that none of the feature categories had zero weights in the weight vector learned for our dataset. Again, this means that there is no single, easily discoverable reason for straggler behavior, and provides evidence to the claim made by Ananthanarayanan et al. (2013, 2014) that the causes behind stragglers are hard to figure out.

5.4 Prediction accuracy for a {node, workload} tuple with insufficient data

One of our goals in this work is to reduce the amount of training data required to get a straggler prediction model up and running. When a new workload begins to execute on a node, we want to learn a model as quickly as possible. Recall that (Section 5.3) with enough training data available we found that $f_{0,n,l}$, $f_{0,t}$ and $f_{0,t,l}$ seem to perform similarly, with $f_{0,n,l}$ performing slightly worse. However, as mentioned in Section 4.8, formulation $f_{0,n,l}$ has fewer parameters and, because it has no weight vector specific to a particular {node, workload} tuple, can generalize to new {node, workload} tuples unseen at train time. This is in contrast to $f_{0,t}$ which has to fall back on $\mathbf{w}_0$ in such a situation, and thus may not generalize as well. In this section, we see if this is indeed true.

We trained classifiers based on $f_{0,n,l}$ and $f_{0,t}$ leaving out 95% of the data of one node-workload pair every time. We then test the models on the left-out data. Table 8 shows the percentage classification accuracy from 20 such runs. We note the following:

- For 13 out of 20 classification experiments, $f_{0,n,l}$ performs better than $f_{0,t}$. For 10 out of these 13 cases, the difference in performance is more than 5 percentage points.
- For workloads $FB2009$ and CC_b, we see $f_{0,n,l}$ performs better consistently.

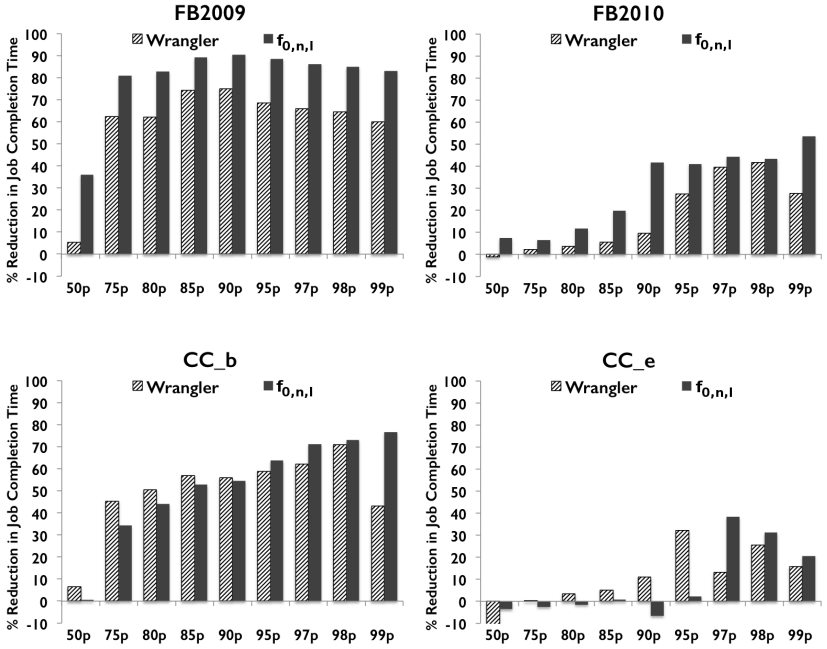

Figure 4: Improvement in the overall job completion times achieved by $f_{0,n,l}$ and Wrangler over speculative execution.

- $f_{0,n,l}$ sometimes performs worse, but in only 3 of these cases is it significantly worse (worse by more than 5 percentage points). All 3 of these instances are in case of the CC_e workload. In general, for this workload, we also notice a huge variance in the numbers obtained across multiple nodes. See Yadwadkar et al. (2014), for a discussion of some of the issues in this workload.

This shows that $f_{0,n,l}$ works better in real-world settings where one cannot expect enough data for all node-workload pairs. Therefore, we evaluate $f_{0,n,l}$ in our next experiment (Section 5.5) to see if it improves job completion times.

5.5 Improvement in overall job completion time

We now evaluate our formulation, $f_{0,n,l}$, using the second metric, improvement in the overall job completion times over speculative execution. We compare these improvements to that achieved by Wrangler (Figure 4). Improvement at the 99^{th} percentile is a strong indicator of the effectiveness of straggler mitigation techniques. We see that $f_{0,n,l}$ significantly

Workload	% Reduction in total task-seconds (MTL with $f_{0,n,l}$)	(Wrangler)
FB-2009	73.33	55.09
FB-2010	8.9	24.77
CC_b	64.12	40.15
CC_e	13.04	8.24

Table 9: Resource utilization with $f_{0,n,l}$ and with *Wrangler* over speculative execution, in terms of total task execution times (in seconds) across all the jobs. $f_{0,n,l}$ reduces resources consumed over Wrangler for $FB2009$, CC_b and CC_e.

improves over Wrangler, reflecting the improvements in prediction accuracy. At the 99^{th} percentile, we improve Wrangler's job completion times by $57.8\%, 35.8\%, 58.9\%$ and 5.7% for $FB2009, FB2010, CC\_b$ and CC_e respectively. Note that Wrangler is already a strong baseline. Hence, the improvement in job completion times on top of the improvement achieved by Wrangler is significant.

5.6 Reduction in resources consumed

When a job is launched on a cluster, it will be broken into small tasks and these tasks will be run in a distributed fashion. Thus, to calculate the resources used, we can sum the resources used by all the tasks. As in Yadwadkar et al. (2014), we use the time taken by each task as a measure of the resources used by the task. Note that, because these tasks will likely be executing in parallel, the total time taken by the tasks will be much larger than the time taken for the whole job to finish, which is what job completion time measures (shown in Figure 4). Ideally, straggler prediction will prevent tasks from becoming stragglers. Fewer stragglers means fewer tasks that need to be replicated by straggler mitigation mechanisms (like speculative execution) and thus lower resource consumption. Thus, improved straggler prediction should also reduce the total task-seconds i.e., resources consumed.

Table 9 compares the percentage reduction in resources consumed in terms of total task-seconds achieved by $f_{0,n,l}$ and Wrangler over speculative execution. We see that the improved predictions of $f_{0,n,l}$ reduce resource consumption significantly more than Wrangler for 3 out of 4 workloads, thus supporting our intuitions. In particular, for $FB2009$ and CC_b, $f_{0,n,l}$ reduces Wrangler's resource consumption by about 40%, while for CC_e the reduction is about 5%.

6. Related Work on Multi-task Learning

The idea that multiple learning problems might be related and can gain from each other dates back to Thrun (1996) and Caruana (1993). They pointed out that humans do not learn a new task from scratch but instead reuse knowledge gleaned from other learning tasks. This notion was formalized by, among others, Baxter (2000) and Ando and Zhang (2005), who quantified this gain. Much of this early work relied on neural networks as a means of learning these shared representations. However, contemporary work has also focused on SVMs and kernel machines.

Our work is an extension of the work of Evgeniou and Pontil (2004), who proposed an additive model for MTL that decomposes classifiers into a shared component and a task-

specific component. In later work, Evgeniou et al. (2005) propose an MTL framework that uses a general quadratic form as a regularizer. They show that if the tasks can be grouped into clusters, they can use a regularizer that encourages all the weight vectors of the group to be closer to each other. Jacob et al. (2009) extend this formulation when the group structure is not known a priori. Xue et al. (2007) infer the group structure using a Bayesian approach. The approach of Widmer et al. (2010) is similar to ours and groups tasks into "meta-tasks", and tries to automatically figure out the meta-tasks required to get good performance. The formulation we propose is also designed to handle group structure, but allows us to dispense with task-specific classifiers entirely, reducing the number of parameters drastically. This allows us to handle tasks that have very little training data by transferring parameters learnt on other tasks. Our formulation shares this property with that of Blanchard et al. (2011), and indeed our basic formulation can be written down in the kernel-based framework they describe for learning to generalize onto a completely unseen task. Other ways of controlling parameters include learning a distance metric (Parameswaran and Weinberger, 2010), and using low rank regularizers (Pong et al., 2010).

Our setting is an example of multilinear multitask learning where each learning problem is indexed by two indices: the node and the workload. Previous work on this subfield of multitask learning has typically used low-rank regularizers on the weight matrix represented as tensors (Romera-Paredes et al., 2013; Wimalawarne et al., 2014). It is also possible to define a similarity between tasks based on how many indices they share (Signoretto et al., 2014). Our formulation captures some of the same intuitions, but has the added advantage of simplicity and ease of implementation.

Using mixed norms for inducing sparsity has a rich history. Donoho (2006) showed that minimizing the l_1 norm recovers sparse solutions when solving linear systems. When used as a regularizer, the l_1 norm learns sparse models, where most weights are 0. The most well known of such sparse formulations is the lasso (Tibshirani, 1996), which uses the l_1 norm to select features in regression. Yuan and Lin (2006) extend the lasso to group lasso, where they use a mixed l_1 and l_2 norm to select a sparse set of *groups* of features. Bach (2008) study the theoretical properties of group lasso. Since these initial papers, mixed norms have found use in a variety of applications. For instance , Quattoni et al. (2008) use a mixed l_∞ and l_1 norm for feature selection. Such mixed norms also show up in the literature on kernel learning, where they are used to select a sparse set of kernels (Varma and Ray, 2007; Kloft et al., 2011) or a sparse set of groups of kernels (Aflalo et al., 2011). Bach et al. (2011) provides an accessible review of mixed norms and their optimization, and we direct the interested reader to that article for more details.

7. Conclusion

Through this work, we have shown the utility of multitask learning in solving the real-world problem of avoiding stragglers in distributed data processing. We have presented a novel MTL formulation that captures the structure of our learning-tasks and reduces job completion times by up to 59% over prior work (Yadwadkar et al., 2014). This reduction comes from a 7 percentage point increase in prediction accuracy. Our formulation can achieve better accuracy with only a sixth of the training data and can generalize better than other MTL approaches for learning-tasks with little or no data. We have also presented extensions

to our formulation using group sparsity inducing mixed norms that automatically discover the structure of our learning tasks and make the final model more interpretable. Finally, we note that, although we use straggler avoidance as the motivation, our formulation is more generally applicable, especially for other prediction problems in distributed computing frameworks, such as resource allocation (Gupta et al., 2013; Delimitrou and Kozyrakis, 2014).

Appendix A. Cross-validating hyperparameter settings

Our formulation reduces the number of hyperparameters to just one per partitioning, which makes it much easier to cross-validate to set their values. In particular, our formulation in the context of straggler avoidance, Equation (24), has four hyperparameters: λ_0, ν, ω, τ. To tune these parameters we used a simple grid search with cross-validation (results are shown in Tables 10, 11, 12, and 13). In general we found that the model formulation is relatively robust to the choice of hyperparameters so long as they are within the correct order of magnitude.

Abstract

Despite tremendous progress in computer vision, there has not been an attempt to apply machine learning on very large-scale medical image databases. We present an interleaved text/image deep learning system to extract and mine the semantic interactions of radiology images and reports from a national research hospital's Picture Archiving and Communication System. With natural language processing, we mine a collection of ∼216K representative two-dimensional images selected by clinicians for diagnostic reference and match the images with their descriptions in an automated manner. We then employ a weakly supervised approach using all of our available data to build models for generating approximate interpretations of patient images. Finally, we demonstrate a more strictly supervised approach to detect the presence and absence of a number of frequent disease types, providing more specific interpretations of patient scans. A relatively small amount of data is used for this part, due to the challenge in gathering quality labels from large raw text data. Our work shows the feasibility of large-scale learning and prediction in electronic patient records available in most modern clinical institutions. It also demonstrates the trade-offs to consider in designing machine learning systems for analyzing large medical data.

Keywords: Deep learning, Convolutional Neural Networks, Topic Models, Natural Language Processing, Medical Imaging

1. Introduction

The ImageNet Large Scale Visual Recognition Challenge by Deng et al. (2009) provides more than one million labeled images of 1,000 object categories. The accessibility of a huge amount of well-annotated image data in computer vision rekindled deep convolutional neural networks (CNNs) as the premier learning tool to solve the visual object class recognition tasks, as shown by Krizhevsky et al. (2012); Simonyan and Zisserman (2015); Szegedy et al. (2015). Deep CNNs can perform significantly better than traditional shallow learning methods but usually require much more training data as was shown by Krizhevsky et al. (2012);

Russakovsky et al. (2015). In the medical domain, however, there are no similar large-scale labeled image data sets available. On the other hand, large collections of radiology images and reports are stored in many modern hospitals' Picture Archiving and Communication Systems (PACS). The invaluable semantic diagnostic knowledge inhabiting the mapping between hundreds of thousands of clinician-created high-quality text reports and linked image volumes remains largely unexplored. One of our primary goals is to extract and associate radiology images with clinically semantic labels via interleaved text/image data mining and deep learning on a large-scale PACS database (∼780K imaging examinations). To the best of our knowledge, this is the first reported work performing automated mining and prediction on a hospital PACS database at a very large scale.

The Radiology reports are text documents describing patient history, symptoms, image observations and impressions written by board-certified radiologists. However, the reports do not contain specific image labels to be trained by a machine learning algorithm. Building the ImageNet database (Deng et al., 2009) was mainly a manual process: harvesting images returned from Google image search engine according to the WordNet (Miller, 1995) ontology hierarchy and pruning falsely tagged images using crowd-sourcing such as Amazon Mechanical Turk (AMT). This does not meet our data collection and labeling needs due to the demanding difficulties of medical annotation tasks and the need for data privacy. Thus, we first propose to mine categorical semantic labels using a non-parametric topic modeling method—latent Dirichlet Allocation (LDA) by Blei et al. (2003)—to provide a semantic interpretation of a patient image in three levels. While this provides a first-level interpretation of a patient image, labeling based on categorization can be nonspecific. To alleviate the issue of non-specificity, we further mine specific disease words in the reports mentioning the images. Feed-forward CNNs were then used to train and predict the presence/absence of the specific disease categories.

Our work has been inspired by the works of Deng et al. (2009); Russakovsky et al. (2015) building very large-scale image databases and the works establishing semantic connections of texts and images by Kulkarni et al. (2013). Please note that there has not yet been much comparable development on large-scale medical imaging interpretation. Kulkarni et al. (2013) have spearheaded the efforts of learning the semantic connections between image contents and the sentences describing them, such as image captions. Detecting objects of interest, attributes and prepositions and applying contextual regularization with a conditional random field (CRF) is a feasible approach as shown by Kulkarni et al. (2013), and many useful tools for image annotation using it are available in computer vision.

In this work, both deep feed-forward CNNs of Krizhevsky et al. (2012); Simonyan and Zisserman (2015) and word-embedding networks of Mikolov et al. (2013a,b) are used to model image and text. Also, the CNN parameters pre-trained on ImageNet are used to initialize CNNs for medical image analysis. We show the benefit of this transfer learning and domain adaptation in Section 4.2. The fact that deep learning requires no hand-crafted image features is very desirable since significant adaptation would be needed to apply conventional image features, (for example, HOG, SIFT) to medical images. The large-scale data sets of extracted representative images (referred to as "key images" in this paper) and their categorization, vector labels, and describing sentences can be harnessed to alleviate deep learning's "data-hungry" challenge in the medical domain.

1.1 Related Work

The ImageCLEF medical image annotation tasks of 2005-2007 by Deselaers and Ney (2008) have 9,000 training and 1,000 test images, converted to 32×32 pixel thumbnails with 57 labels. Local image descriptors and intensity histograms are used as a bag-of-features approach for this scene-recognition-like problem. However, the data set is limited to radiographs (for example, chest and bone x-rays), and it is difficult to detect any disease from 32×32 size images. Unsupervised LDA-based matching from lung disease words (for example, fibrosis, emphysema) to two-dimensional image blocks from axial CT chest scans is studied by Carrivick et al. (2005) where data were collected from a relatively small number (24) of patients. The works of Barnard et al. (2003); Blei and Jordan (2003) using generative models of combining words and images under a very limited word/image vocabulary has also motivated this study.

Socher et al. (2013); Frome et al. (2013) first map words into vector space using recurrent neural networks and then project images into the label-associated word-vector embeddings by minimizing the L_2 (Socher et al., 2013) or hinge rank losses (Frome et al., 2013) between the visual and label manifolds. The language model is trained on the texts of Wikipedia and tested on label-associated images from the CIFAR (Krizhevsky and Hinton, 2009; Socher et al., 2013) and ImageNet data sets (Deng et al., 2009; Frome et al., 2013). Image-to-language correspondence was learned from the ImageNet data set and reasonably high quality image description data sets (Pascal1K (Rashtchian et al., 2010), Flickr8K (Hodosh et al., 2013), Flickr30K (Young et al., 2014), MS-COCO Lin et al. (2014)) by Karpathy et al. (2014); Vinyals et al. (2015); Donahue et al. (2015); Xu et al. (2015); Mao et al. (2015), where such caption data sets are not available in the medical domain.

The tasks of mining and labeling images from a data set of blog posts with user photos and related texts and retrieving them with query words were demonstrated in Kim et al. (2015b,a, 2014). Similarly, a noisy image-text data set consisting of product photos (such as bags, clothing and shoes) and their associated text description (Berg et al., 2010) was used to demonstrate image retrieval with text queries and image description generation. Nonetheless, they all require pre-trained models either from the large ImageNet data set or a large text data set (for example, word representations trained on Wikipedia or Reuters news data sets (Turian et al., 2010)). Still there exists no such large data set of images and texts in the medical domain.

Graphical models have been employed to predict image attributes by Lampert et al. (2014); Scheirer et al. (2012), or to describe images by Kulkarni et al. (2013) using manually annotated data sets. Automatic label mining on large, unlabeled data sets is presented by Ordonez et al. (2011); Jaderberg et al. (2014), however, the variety of the label-space is limited to image text annotations. In this work, we demonstrate the automatic generation of descriptive attributes of patient images as well as the detection of frequent disease types with associated confidences. A large data set of patient images and radiologist text reports from a hospital is used for the demonstration, and we highlight the key issues to consider when analyzing large-scale medical data with minimal annotation.

total number of		# words in documents		# image modalities

Table 1: Some statistics of the data set. "Others" include computed radiography, and ultrasound.

2. Data

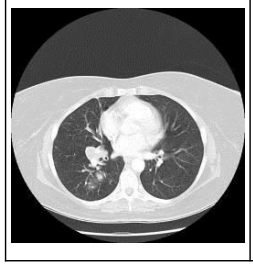
To gain the most comprehensive interpretation of diagnostic semantics, we use all available radiology reports of around 780,000 imaging examinations, stored in the PACS of National Institutes of Health Clinical Center since the year 2000. Around 216,000 two-dimensional representative image slices referred by doctors are studied here, instead of using all three-dimensional image volumes. Within three-dimensional patient scans, most of the imaging information represented are normal anatomy, therefore they are often not the focus of the radiology reports. The two-dimensional "key images" referenced by radiologists manually during radiology report writing provide a visual reference to pathologies or other notable findings (Figure 1). Therefore, the two-dimensional key images are more correlated with the diagnostic semantics in the reports than the whole three-dimensional scans, but not all reports have referenced key images (215,786 images from about 61,845 unique patients). Table 1 provides some statistics of the extracted database, and Table 2 shows examples of the most frequently occurring words in the radiology reports collected. Leveraging our deep learning models exploited in this paper will make it possible to automatically select key images from three-dimensional patient scans to avoid mis-referencing.

Finding and extracting key images from radiology reports is done by natural language processing (NLP), that is, finding a sentence mentioning a referenced image. For example, "*There may be mild fat stranding of the right parapharyngeal soft tissues (series 1001, image 32)*" is listed in Figure 1. The NLP steps are sentence tokenization, word/number matching and stemming, and rule-based information extraction (for example, translating "image 1013-78" to "images 1013-1078"). A total of ∼187K images are retrieved and matched this way, whereas the rest of ∼28K key images were extracted according to their reference accession numbers in PACS. The image-text matching is accurate as we use exact annotations from the sentences in reports in retrieving the images, however, it is possible we missed some image-text pairs due to limitations in our NLP pipelines. We do not evaluate the recall-rate of our method in this study, but it can be considered as a future work. The software package of Bird et al. (2009) is used for the basic NLP pipelines.

3. Document Topic Learning with Latent Dirichlet Allocation

It is difficult to annotate the ∼216K images and the sentences referring to them. Unlike the images of ImageNet (Deng et al., 2009; Russakovsky et al., 2015) which often have a dominant object appearing in the center, our key images are mostly CT and MRI slices showing

0001 REPORT : REASON FOR EXAM (Entered by ordering clinician into CRIS): hx of head and neck cancer. needs scan CT of the nasopharynx.
HISTORY: Head and neck cancer.
TECHNIQUE: Contiguous 2.5 mm axial images of the nasopharynx were performed without IV contrast. COMPARISON: xx/xx/xxxx.
FINDINGS: No soft tissue masses are seen within the soft tissues of the neck. The parotid and submandibular glands are predominantly fatty-replaced. Soft tissues of the Naso, oropharynx are unremarkable. There may be mild fat stranding of the right parapharyngeal soft tissues (series 1001, image 32). No abnormal masses are seen at that site. No bulky lymphadenopathy is seen. There is a fusiform aneurysm of the basilar artery as previously described. It appears to the mildly increased in size and currently measures 2.0 cm in transverse dimensions and previously measured 1.8 cm. It measured 1.5 cm in transverse dimensions on xx/xx/xxxx. Atherosclerotic calcifications are also seen within the carotid arteries bilaterally. There is near-complete opacification of the maxillary sinuses bilaterally. This has increased predominantly within the left maxillary sinus and mildly within the right maxillary sinus. The ethmoidal air cells are clear. Sphenoidal and frontal sinuses are clear. Degenerative changes of the cervical spine are noted.
IMPRESSIONS: 1. No soft tissue masses however, mild right parapharyngeal fat stranding is seen it may be postoperative or post radiation in nature. 2. Basilar artery aneurysm that has gradually increased in size when compared to prior examinations. 3. Atherosclerotic disease of the coronary arteries bilaterally..



0001 Report: CHEST, ABDOMEN, PELVIS CT: Multidetector helical (5 mm, quad) images following, and abdomen images prior to vascular contrast infusion (45 s delay, 2 cc/s, 130 cc Isovue) obtained without apparent complication. History: renal cell pt on Medarex protocol here for end of course evaluation.
CHEST: Multiple right, and at least one left lung masses minimally-moderately increasing since xx/xx/xxxx, compatible with metastases despite moderate decrease in at least one right mid-lung mass (e.g. series 4 image 30). Minimal pretracheal and subcarinal adenopathy increasing. Spine osteophytes. Enlargement thyroid on right side, and thyroid heterogeneity unchanged, possibly due to goiter. No evidence of pleural or pericardial effusion, axilla or left hilum adenopathy.
ABDOMEN, PELVIS: Few right and left liver foci, left periaortic and left adrenal fossa, and right sacrum mass and lytic lesion (series 3 image 88-95) increasing minimally, compatible with metastases. Scattered lumbar vertebra and bilateral ilium foci (e.g. series 3 image 55, 60, 80, 84-7, 96) foci possibly due to bone metastases. Uterine fundus focus (series 3 image 95) increasing in density since xx/xx/xxxx, possibly due to fibroid, metastasis. No evidence of splenomegaly, hydronephrosis, gallbladder calcification, or bulky mesenteric adenopathy.

Figure 1: Two examples of radiology reports and the referenced "key images" (providing a visual reference to pathologies or other notable findings).

Table 2: Examples of the most frequently occurring words in the radiology report documents.

several organs usually with pathologies. There is a high amount of intrinsic ambiguity in defining and assigning a semantic label set to images, even for experienced clinicians. We therefore propose to mine image categorization labels using the non-parametric topic-modeling algorithm of Blei et al. (2003) on the ∼780K radiology text reports in PACS. Our

hypothesis is that the large collection of radiology reports statistically defines the categories meaningful for topic-mining and visual correspondence learning for these topics.

Latent Dirichlet Allocation (LDA) was originally proposed by Blei et al. (2003) to find latent topics for a collection of text documents such as newspaper articles. There are some other popular methods for document topic modeling, such as Probabilistic Latent Semantic Analysis (pLSA) by Hofmann (1999) and Non-negative Matrix Factorization (NMF) by Lee and Seung (1999). In a study done by Stevens et al. (2012) LDA showed the most favorable results overall in human evaluations of the generated topics compared to other popular methods. Furthermore, pLSA can be regarded as a special case of LDA (Girolami and Kabán, 2003) and NMF as a semi-equivalent model of pLSA (Gaussier and Goutte, 2005; Ding et al., 2006).

LDA offers a hierarchy of extracted topics and the number of topics can be chosen by evaluating each model's *perplexity score* (Equation 1), which is a common way to measure how well a probabilistic model generalizes by evaluating the log-likelihood of the model on a held-out validation set. For an unseen document set D_{val}, the perplexity score is defined as in Equation 1, where M is the number of documents in the validation set, $\mathbf{w}_d$ the words in the unseen document d, N_d the number of words in document d, with $\mathbf{\Phi}$ the topic matrix, and α the hyper-parameter for topic distribution of the documents.

$$perplexity(D_{val}) = \exp\left\{-\frac{\sum_{d=1}^{M}\log p(\mathbf{w}_d|\mathbf{\Phi},\alpha)}{\sum_{d=1}^{M}N_d}\right\} \quad (1)$$

A lower perplexity score generally implies a better fit of the model for a given document set (Blei et al., 2003).

Based on the perplexity score evaluated on 80% of the total documents used for training and 20% used for validation, the number of topics chosen is 80 for the document-level model using perplexity scores for model selection (Figure 2). Although the document distribution in the topic space is approximately balanced, the distribution of image counts for the topics is more unbalanced (Figure 3). Specifically, topic #77 (non-primary metastasis spreading across a variety of body parts) contains nearly half of the ∼216K key images. To address this data bias, sub-topics are obtained for each of the first document-level topics, resulting in 800 topics, where the number of the sub-topics is also chosen based on the average perplexity scores evaluated on each document-level topic. Lastly, to compare the method of using the whole report with using only the sentence directly describing the key images for latent topic mining, sentence-level LDA topics are obtained based on three sentences only: the sentence mentioning the key-image (Figure 1) and its adjacent sentences as proximal context. The perplexity scores keep decreasing with an increasing number of topics; we choose the topic count to be 1000 as the rate of the perplexity score decrease is very small beyond that point (Figure 2).

We observe that LDA-generated image categorization labels are valid, demonstrating good semantic coherence among clinician observers. Some examples of document-level topics with their corresponding images and topic key words are shown in Figure 4. All reports and sentences referring to the images have associated topics, and images are sampled from the sentences belonging to the multi-level topics. The lists of key words and sampled images per topic label are subjected to a board-certified radiologist's review and validation.

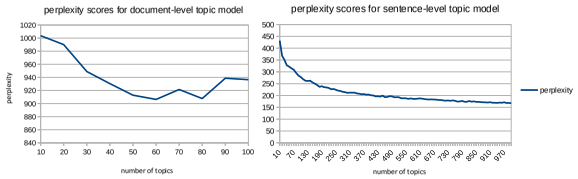

Figure 2: Perplexity scores for document-/sentence- level topic models. Number of topics with low perplexity score is selected as the optimal (80 for document-level, 1000 for sentence-level).

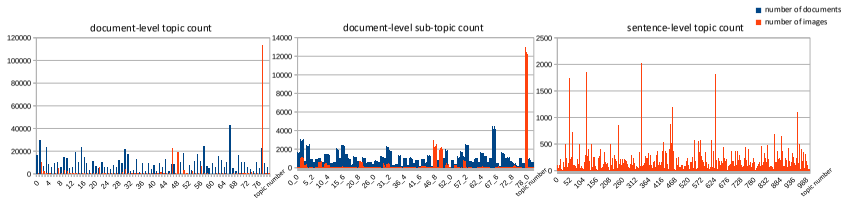

Figure 3: Distribution of documents and images for document-level topic, document-level sub-topic, and sentence-level topic. Sixth sub-topic (second-level topic) of (first-level) document topic 41 is noted as 40_5.

There are 73 low-level concepts, for example, pathology examination of certain body regions and organs: topic #47 - sinus diseases; #2 - lesions of solid abdominal organs, primarily kidney; #10 - pulmonary diseases; #13 - brain MRI; #19 - renal diseases on mixed imaging modalities; #36 - brain tumors. There are 7 mid- to high-level concepts, such as: topic #77 - non-primary metastasis spreading across a variety of body parts; topic #79 - cases with high diagnosis uncertainty or equivocation; #72 - indeterminate lesions; #74 - instrumentation artifacts limiting interpretation. Low-level topic images tend to be visually more coherent than the higher-level topic images.

High-level topics may be analogous to the high-level visual concepts in natural images as was studied by Kiapour et al. (2014); Ordonez and Berg (2014). About half of the key images are associated with topic #77, implying that the clinicians' image referencing behavior patterns heavily focuses on metastatic patients. Sub-topics of document-level topic #77 are sub-categories of metastatic disease, for example: #77-0 - abdominal mass; #77-2 - bulky tumor; #77-4 - multifocal metastatic disease; #77-9 - liver tumor. Meanwhile, some of the sub-topics of document-level #77 do not seem very focused. Many of the sentence-level topics have valid semantics too, for example, 'renal imaging', 'musculoskeletal imaging',

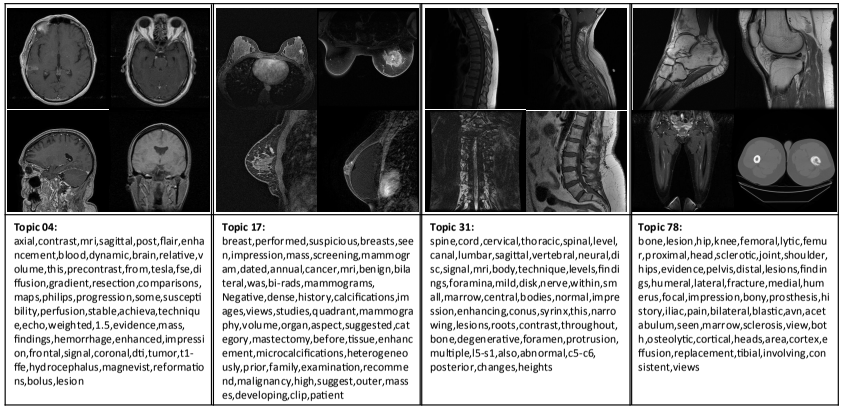

Figure 4: Examples of LDA generated document-level topics with corresponding images and key words. Topic #4 is MRI of brain tumor; topic #17: breast imaging; topic #31: degenerative spine disc disease; and topic #78: bone metastases. These are verified by a radiologist.

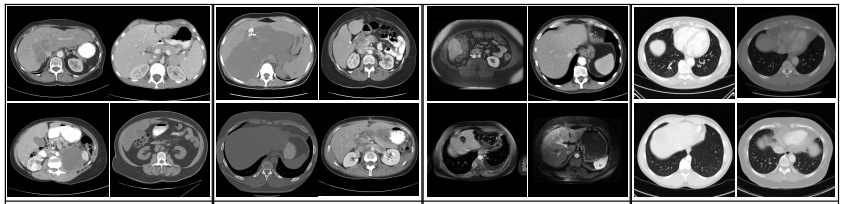
'chest port catheter', 'chest imaging with disease or pathology', and 'degenerative disease in bone'.

We also obtained LDA topics on the reports having associated images only, resulting in 20 topics according to perplexity score. However, these did not add any more meaningful semantics in addition to the already obtained topics in three levels, so that we do not include the topics. For more details and the image-topic associations, refer to Figures 4, 5, and the supplementary material. Even though LDA labels are computed with text information only, we next investigate the plausibility of mapping images to the topic labels of different levels via deep CNN models.

4. Image to Document Topic Mapping with Deep Convolutional Neural Networks

For each level of topics discussed in Section 3, we train deep CNNs to map the images into document categories using the Caffe framework of Jia et al. (2014). We split our whole key image data set as follows: 85% used as the training data set, 5% as the validation, and 10% as the test data set. If a topic has too few images to be divided into training/validation/test for deep CNN learning, then that topic is neglected for the CNN training. These cases are normally the topics of rare imaging protocols, for example: topic #5 - Abdominal ultrasound; topic #28& #49 - DEXA scans of different usages. In total, 60 topics were used for the document-level topic mapping, 385 for the document-level sub-topic mapping,



Topic 77-0:	Topic 77-2:	Topic 77-5:	Topic 77-9:
kidney,images,abdomen,e.g,prior,mass,pancreas,following,cysts,adrenal,liver,foci,renal,contrast,approximate,including,focus,cyst,bilateral,masses,size,enhancing,for,also,given,possibly,mid,2.5,vascular,without,due,nephrectomy,please,1.5,from,few,multiphase,subcentimeter,least,comparison,patient,dual-phase,length,apparent,complication,obtained,upper,study,lower,vhl	bulky,pelvis,bone,gross,since,liver,abdomen,calcification,vascular,study,lung,mass,isovue,dfov,without,contrast,administration,impression,metastasis,chest,for,images,mesenteric,axilla,following,hilum,cc/s,helical,multidetector,ascites,enteric,reason,apparent,complication,pleural,splenomegaly,pericardial,hydronephrosis,delay,effusion,mediastinum,obtained,300,spine,gallbladder,report,130,retroperitoneal,spleen,e.g	images,axial,t1-weighted,without,prior,liver,following,t2-weighted,tesla,fat-suppressed,multiple,sequences,e.g,characteristic,obtained,1.5,foci,fat,abdomen,for,prolonged,coronal,including,relaxation,hydronephrosis,mri,magnevist,splenomegaly,complication,apparent,vascular,pleural,impression,report,effusion,contrast,reason,study,mass,administration,since,focus,multiphase,definite,echo,defect,gross,filling,ascites,into	lung,chest,pleural,images,bilateral,minimal,effusion,lower,obtained,pericardial,multidetector,helical,axilla,study,report,mass,infiltrate,for,scarring,since,bulky,and/or,clinical,splenomegaly,dfov,cavity,e.g,impression,decreasing,infiltrates,focal,mediastinum,disease,atelectasis,hydronephrosis,small,reason,upper,untoward,history,probable,appearing,calcification,lobe,8-channel,supine,scattered,prone,bone,intervals

and 717 for the sentence-level mapping. Systematic diagrams showing how each level of semantic topics are learned, assigned to images, and trained to map from images to topics are shown in Figure 6.

4.1 Implementation

All our CNN network settings are similar or the same as the ImageNet Challenge "AlexNet" (Krizhevsky et al., 2012), and "VGG-16 & 19" (Simonyan and Zisserman, 2015) models. For "AlexNet" we use the Caffe reference network of Jia et al. (2014), which is a slight modification to the "AlexNet" by Krizhevsky et al. (2012). The AlexNet model by Krizhevsky et al. (2012) has about 60 million parameters (650,000 neurons) and consists of five convolutional layers (1st, 2nd and 5th followed by max-pooling layers), and three fully-connected (FC) layers with a final classification layer. The VGG variations of CNN models by Simonyan and Zisserman (2015) are significantly deeper by having 16-19 convolutional layers and 133-144 million parameters. The top-1 error rates on ImageNet data set of these models are AlexNet: 15.3% (Krizhevsky et al., 2012); VGG-16: 7.4%; and VGG-19: 7.3% (Simonyan and Zisserman, 2015), respectively.

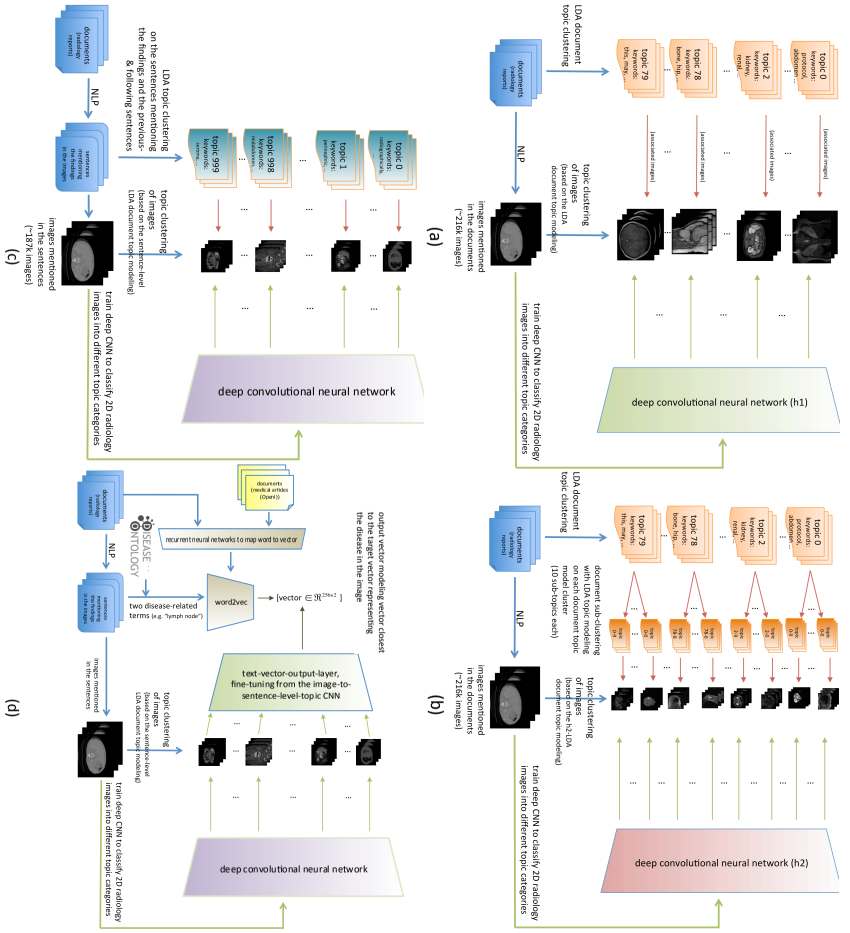

Figure 6: Systematic diagrams for training CNNs to learn to classify images into (a) document-level topics (b) document-level sub-topics, (c) sentence-level topics. A systematic diagram for image-to-word model (in Section 5.3) is shown in (d).

For the image to topic mapping, we change the numbers of output nodes in the last softmax classification layer, that is, 60, 385 and 717 for the document-level, document-level

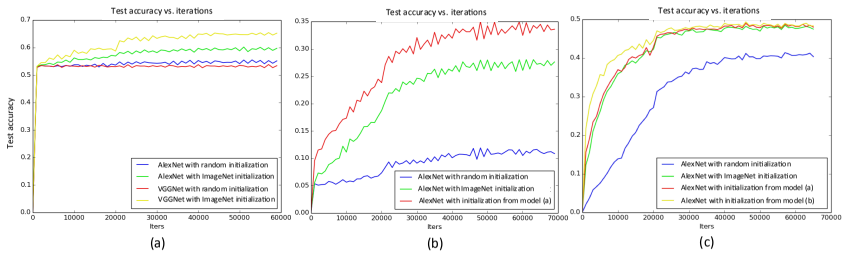

Figure 7: Traces of classification accuracies during training, showing the benefits of using ImageNet data set as pre-training for this task with medical images and improvements of fine-tuning from CNN neural networks of similar tasks (for example, from document-level (h1) CNN model to document-level sub-topic (h2) CNN model). (a) Image-to-document-level-topic (h1) classification, (b) image-to-document-level-sub-topic (h2) classification, and (c) image-to-sentence-level-topic (h3) classification.

sub-topics, and sentence-level respectively. The networks for first-level semantic labels are fine-tuned from the pre-trained ImageNet models, where the networks for the lower-level semantic labels are fine-tuned from the models of the higher-level semantic labels.

4.2 Transfer Learning and Domain Adaptation

We find that transfer learning from the ImageNet pre-trained CNN parameters on natural images to our medical image modalities (mostly CT, MRI) significantly helps the image classification performance. Additionally, transfer learning from a CNN trained for a more related task (for example, from CNN trained on the image-to-document-level-topic models to train CNN for the image-to-document-level-sub-topic model) is found to be more effective than from a CNN trained for a less related task (for example, from CNN trained on ImageNet to train CNN for image-to-document-level-sub-topic model). Examples of classification accuracy traces during training using CNNs from random initialization, transfer learning from CNN trained on ImageNet and transfer learning from higher level image-to-topic model to lower level image-to-topic models are shown in Figure 7. Similar findings that deep CNN features can be generalized across different image modalities have been reported by Gupta et al. (2014, 2013) but are empirically verified with only much smaller data sets than ours. Our key image data set is about one-fifth the size of ImageNet (Russakovsky et al., 2015) and is the largest annotated medical image data set to date.

From Figure 7 we can see that: (1) CNN testing accuracy quickly increases from $\sim$0% to 50+% in roughly 1600 iterations due to the unbalanced data distribution among classes in document-level; (2) A more complex, deeper CNN model (VGG-Net) performs better than the model which already is a good benchmark (AlexNet), but only when starting from a good initialization (that is, pre-training via ImageNet models); (3) Fine-tuning from a more closely related task CNN model is even better than fine-tuning from less related task model (alexnet_tp80_h2_start_tp80h1 > alexnet_tp80_h2_start_imagenet).

With these findings, we train our CNN models with transfer-learning by default for the remaining parts of our study. All the CNN layers except the newly modified ones are initialized with the weights of a previously trained related model and trained with a new task with a low learning rate of 0.001. The modified layers with a new number of classes are initialized randomly, and their learning rates are set with a higher learning rate of 0.01. All the key images are re-sampled to a spatial resolution of 256×256 pixels. Then we follow the approach of Simonyan and Zisserman (2015) to crop the input images from 256×256 to 227×227 for training.

4.3 Classification Results and Discussion

We would expect that the level of difficulties for learning and classifying the images into the LDA-induced topics will be different for each semantic level. Low-level semantic classes can have key images of axial/sagittal/coronal slices with position variations and across MRI/CT modalities. Mid- to high-level concepts all demonstrate much larger within-class variations in their visual appearance since they are diseases occurring within different organs and are only coherent at high-level semantics. Table 3 provides the top-1 and top-5 testing in classification accuracies for each level of topic models using AlexNet (Krizhevsky et al., 2012), and VGG-16&19 Simonyan and Zisserman (2015) based deep CNN models.

All top-5 accuracy scores are significantly higher than top-1 values, for example, increasing from 0.658 to 0.946 using VGG-19, or 0.607 to 0.929 via AlexNet in document-level. This indicates that the classification errors or fusions are not uniformly distributed among other false classes. Latent "blocky subspace of classes" may exist in our discovered label space, where several topic classes form a tightly correlated subgroup. The confusion matrices in Figure 8 verify this finding.

It is shown that the deeper models (VGG-16&19) perform consistently better than the shallower 8-layer model (AlexNet) in classification accuracy, especially for document-level sub-topics. While the images of some topic categories and some body parts are easily distinguishable as shown in Figure 4, the visual differences in abdominal parts are rather subtle as in Figure 5. Distinguishing the subtleties and high-level concept categories in the images could benefit from a more complex model so that the model can handle these subtleties.

It is also noticeable that VGG-16&19 models require significantly more computational resource and time to train than the shallower model. Table 4 shows the memory consumption and time required to train the CNN models for the image-to-sentence-level-topic model with up to 70,000 iterations using the NVidia Tesla K40 GPU. However, comparing VGG-16 and VGG-19, three additional convolutional layers seem to have contributed to raise the top-5 accuracies by a small amount ($\sim$2%), which is coherent with the results reported by Simonyan and Zisserman (2015) for object recognition task on the ImageNet data set.

Compared with the ImageNet 2014 results, top-1 error rates are moderately higher (34% versus 30%) and top-5 test errors ($6\% - 8\%$) are comparable. In summary, our quantitative results are very encouraging, but there also exist some uncertainties in annotations because labels stem from an unsupervised learning algorithm. Multi-level semantic concepts

	AlexNet 8-layers		VGG 16-layers		VGG 19-layers	
	top-1	top-5	top-1	top-5	top-1	top-5
document-level	0.61	0.93	0.66	0.93	0.66	0.95
document-level-h2	0.33	0.56	0.54	0.70	0.54	0.70
sentence-level	0.48	0.56	0.50	0.56	0.50	0.58

Table 3: Top-1, top-5 test classification accuracies for image to document-level topics, document-level sub-topics (document-level-h2) and sentence-level topics, using AlexNet (Krizhevsky et al., 2012), and VGG-16&19 (Simonyan and Zisserman, 2015) deep CNN models.

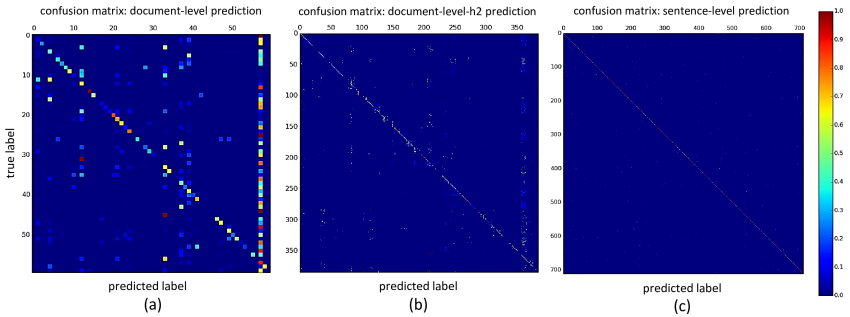

Figure 8: Confusion matrices of (a) document-level topic, (b) document-level sub-topic (document-level-h2), and (c) sentence- level classification Simonyan and Zisserman (2015) ((b) and (c) can be viewed best in electronic version of this document).

show good image learnability by deep CNN models which shed light on the feasibility of automatically parsing very large-scale radiology image databases.

5. Generating Image-to-Text Description

The image-to-topic mapping in Section 4 is a promising first step towards large-scale automated medical image interpretation. However, generating image descriptions as in Lampert et al. (2014); Scheirer et al. (2012); Kulkarni et al. (2013) will be more readily interpretable and descriptive.In addition, key words in the topics can help to understand the content of a given image with more semantic meaning. We therefore propose to generate relevant key-word text descriptions similarly to Kulkarni et al. (2013), using deep language/image CNN models.

	AlexNet 8-layers	VGG 16-layers	VGG 19-layers
time	4 hours 35 mins	3 days 2 hours	4 days 40 mins
memory	~1.4 GBytes	~10 GBytes	~11 GBytes

Table 4: Training times for the CNN models used to reach 70,000 iterations, and their memory consumption, using Caffe framework (Jia et al., 2014) on NVidia Tesla K40 GPU.

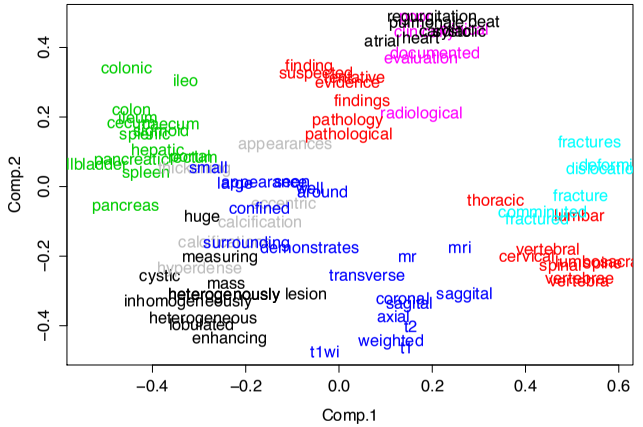

Figure 9: Example words embedded in the vector space using word-to-vector modeling (https://code.google.com/p/word2vec/) visualized on a two-dimensional space, showing (clinical) words with similar meanings are located nearby in the vector space (colors are used to highlight these in visualization).

5.1 Word-to-Vector Modeling and Removing Word-Level Ambiguity

In radiology reports, there exist many recurring word morphisms in text identification, for example, [mr, mri, t1-/t2-weighted] (natural language expressions for imaging modalities of magnetic resonance imaging (MRI)), [cyst, cystic, cysts], [tumor, tumour, tumors, metastasis, metastatic], etc. We train the word-to-vector embedding model of Mikolov et al. (2013c,b,a) to address this word-level labeling space ambiguity while also transforming the words to vectors. A total of 1.2 billion words from our radiology reports as well as from biomedical research articles obtained from OpenI (ope: `http://openi.nlm.nih.gov`) are used. Words with similar meaning are mapped or projected to closer locations in the vector space than dissimilar ones. An example visualization of the word vectors on a two-dimensional space using principal component analysis is shown in Figure 9.

Figure 10: Word-to-vector models trained on a collection of biomedical research articles (from OpenI ope) and radiology reports, and radiology reports only. Search words (with quotes) and their closest words in vector-space cosine similarity (higher the better) are listed in a descending order.

A skip-gram model of Mikolov et al. (2013a,b) is employed with the mapping vector dimension of $\mathbb{R}^{256\times1}$ per word, trained using the *hierarchical softmax* cost function, the sliding-window size of 10 and frequent words sub-sampled in the frequency of 0.01. It is found that combining an additional, more diverse set of related documents such as OpenI biomedical research articles, is helpful for the model to learn a better vector representation while keeping all the hyper-parameters the same. Similar findings on unsupervised feature learning models, that robust features can be learned from a slightly noisy and diverse set of input, were reported by Vincent et al. (2010, 2008); Shin et al. (2013). Some examples of query words and their corresponding closest words with respect to cosine similarity for the word-to-vector models (Mikolov et al., 2013c), which are trained on radiology reports only (total of ∼1 billion words) and with additional OpenI articles (total of 1.2 billion words), are shown in Figure 10.

#words/sentence	mean	median	std	max	min
reports-wide	11.70	9	8.97	1014	1
image references	23.22	19	16.99	221	4
image references, no stopwords no digits	13.46	11	9.94	143	2
image references, disease terms only	5.17	4	2.52	25	1

Table 5: Some statistics about number of words per sentence—across the radiology reports (reports-wide), across the sentences identifying the key images and its two adjacent ones (image references) and these not counting stop-words and digits as well as counting disease related words only.

5.2 Image-to-Description Relation Mining and Matching

The sentence referring to a key image and its adjacent sentences may contain a variety of words, but we are mostly interested in the disease-related terms which are highly correlated to diagnostic semantics. To obtain only the disease-related terms, we exploit the human disease terms and their synonyms from the Disease-Ontology (DO; Schriml et al. (2012)), a collection of 8,707 unique disease-related terms. While the sentences referring to an image and their adjacent sentences have 50.08 words on average, the number of disease-related terms in the three consecutive sentences is 5.17 on average with a standard deviation of 2.5. Therefore, we chose to use bi-grams for the image descriptions, to achieve a good trade-off between the medium level complexity without neglecting too many text-image pairs. Some statistics about the number of words in the documents are shown in Table 5.

Bi-gram disease terms are extracted so that we can train a deep CNN model in Section 5.3 to predict the vector-/word- level image representation of $\mathbb{R}^{256\times2}$. If multiple bi-grams can be extracted per image from the sentence referring the image and the two adjacent ones, the image is trained as many times as the number of different bi-grams with different target vectors ($\mathbb{R}^{256\times2}$). If a disease term cannot form a bi-gram, then the term is ignored, where the process is illustrated in Figure 11. This is a challenging *weakly annotated learning* problem using referring sentences for labels. The bi-grams of DO disease-related terms in the vector representation of $\mathbb{R}^{256\times2}$ are somewhat analogous to the work of Kulkarni et al. (2013) detecting multiple objects of interest and describing their spatial configurations in the image caption. A deep regression CNN model is employed here, to map an image to a continuous output word-vector space from an image. The resulting bi-gram vector can be matched against a reference disease-related vocabulary in the word-vector space using cosine similarity.

5.3 Image-to-Words Deep CNN Regression

To learn the image-to-text representation, we map the images to the vectors of word sequences describing the image. This can be formulated as a regression CNN, replacing the

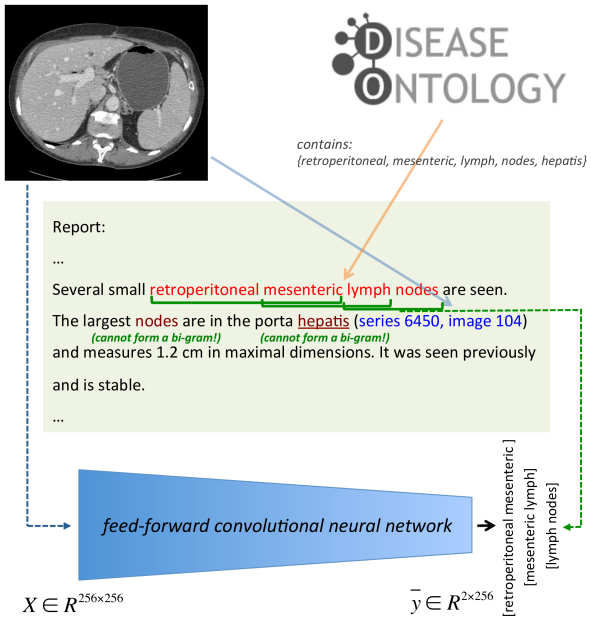

Figure 11: Illustration of how word sequences are learned for an image. Bi-grams are selected from the image's reference sentences containing disease-related terms from the disease ontology (DO; Schriml et al. (2012)). Each bi-gram is converted to a vector of $\mathbf{Z} \in \mathbb{R}^{256\times2}$ to learn from an image. Image input vectors as $\{\mathbf{X} \in \mathbb{R}^{256\times256}\}$ are learned through a CNN by minimizing the cross-entropy loss between the target vector and output vector. The words "nodes" and "hepatis" in the second line are DO terms but are ignored since they can not form a bi-gram. The DO logo is reproduced with permission from `http://disease-ontology.org`.

softmax cost in Section 4 with the cross-entropy cost function for the last output layer of VGG-19 CNN model (Simonyan and Zisserman, 2015):

$$E = -\frac{1}{n}\sum_{n=1}^{N}[g(\mathbf{z})_n \hat{g}(\bar{\mathbf{z}}_n) + (1 - g(\mathbf{z}_n))\log(1 - g(\hat{\mathbf{z}}_n))], \tag{2}$$

where $\mathbf{z}_n$ or $\hat{\mathbf{z}}_n$ is any uni-element of the target word vectors $\mathbf{Z}_n$ or optimized output vectors $\hat{\mathbf{Z}}_n$, $g(x)$ is the sigmoid function ($g(x) = 1/(1 + e^{-x})$), and n is the number of samples in the database.

We adopt the CNN model of Simonyan and Zisserman (2015) for the image-to-text representation since it works consistently better than the other relatively simpler model of Krizhevsky et al. (2012) in our image-to-topic mapping tasks. We fine-tune the parameters of the CNNs for predicting the topic-level labels in Section 4 with the modified cost function, to model the image-to-text representation instead of classifying images into categories. The newly modified output layer has 512 nodes for bi-grams as 256 nodes for each word in a bi-gram.

5.4 Key-Word Generation from Images and Discussion

For any key image in testing, first, we predict its topics at three levels (document-level, document-level sub-topics, sentence-level) using the three deep CNN models of Simonyan and Zisserman (2015) in Section 4. Based on each word's probability of appearing in the LDA document topic, the fifty key-words with highest probability are mapped into the word-to-vector space of multivariate variables in $\mathbb{R}^{256\times1}$ (Section 5.1). Then, the image is mapped to a $\mathbb{R}^{256\times2}$ output vector using the bi-gram CNN model in Section 5.3. Lastly, we match each of the 50 topic key-word vectors of $\mathbb{R}^{256\times1}$ against the first and second half of the $\mathbb{R}^{256\times2}$ output vector using cosine similarity. The closest key-words at three levels of topics (with the highest cosine similarity against either of the bi-gram words) are kept per image.

The rate of predicted disease-related words matching the actual words in the report sentences of test set (recall-at-K, K=1 (R@1 score)) is 0.56. Two examples of key-word generation are shown in Figure 12, with three key-words from three categorization levels per image. We only report R@1 score on disease-related words compared to the previous works of Karpathy et al. (2014); Frome et al. (2013), where they report from R@1 up to R@20 on the entire image caption words (for example, R@1=0.16 on Flickr30K data set by Karpathy et al. (2014)). As we use NLP to parse and extract image-describing sentences from the radiology reports, our ground-truth image-to-text associations are much noisier than the caption data set used by Frome et al. (2013); Karpathy et al. (2014). Also for that reason, our generated image-to-text associations are not as exact as the generated descriptions by Frome et al. (2013); Karpathy et al. (2014).

5.4.1 Discussion

Generating key-words for images by CNN regression shows good feasibility for automated interpretation of patient images. The generated key-words describe what to expect from the given image, although sometimes unrelated words can be generated too. Finding and understanding the relations between the generated words will be the next step to explore, for example via more thorough text mining using sophisticated NLP parsing as by Li et al. (2011) and combining them with the specific frequent disease prediction in the next section.

6. Predicting Presence or Absence of Frequent Disease Types

While the key-words generation in Section 5 can aid the interpretation of a patient scan, the generated key-words, for example, "spine", "lung", are not very specific to a disease in an image. Nonetheless, one of the ultimate goals for large-scale radiology image/text analysis

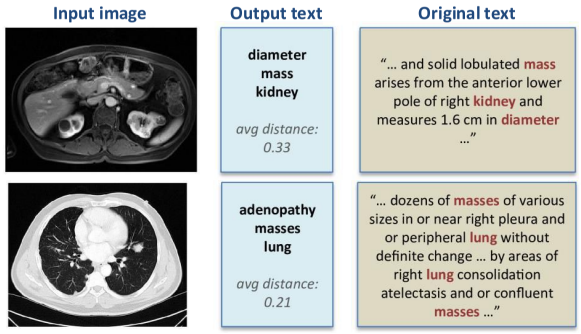

Figure 12: Examples of text key-word generation results, and average cosine distances between the generated words from the disease-related words in the original texts. The word "diameter" appears in the original radiology report of the first image, but not much can be derived by the word only. The rate of predicted disease-related words matching the actual words in the report sentences (recall-at-K, K=1 (R@1 score)) on test set is 0.56.

would be to automatically diagnose disease from a patient scan. In order to achieve the goal of automated disease detection, we add an additional pipeline of mining disease words rather than disease-related words using radiology semantics and predicting these in an image using CNNs with softmax cost-function.

6.1 Mining Presence/Absence of Frequent Disease Terms

The disease names in Disease Ontology (DO) contain not only disease terms but also non-disease terms describing a disease. Some examples of disease names in DO containing non-disease terms are "occlusion of gallbladder" (DOID: 9714), "acute diarrhea" (DOID: 0050140), "strawberry gallbladder" (DOID: 10254), and "exocrine pancreatic insufficiency" (DOID: 13316). Nonetheless, it is rare that "occlusion of gallbladder" or "exocrine pancreatic insufficiency" is described in radiology reports exactly that way, making it difficult to mine specific disease terms with presence or absence.

The Unified Medical Language System (UMLS) of Lindberg et al. (1993); Humphreys et al. (1998) integrates and distributes key terminology, classification and coding standards, and associated resources to promote the creation of more effective and inter-operable biomedical information systems and services, including electronic health records. It is a compendium of many controlled vocabularies in the biomedical sciences, created in 1986 and maintained by the National Library of Medicine.

The Metathesaurus (Schuyler et al., 1993) forms the base of the UMLS and comprises over 1 million biomedical concepts and 5 million concept names, where all of them are

collected from over 100 incorporated controlled vocabularies and classification systems. The Metathesaurus is organized by concept, where each concept has specific attributes defining its meaning and is linked to the corresponding concept names. The Metathesaurus has 133 semantic types that provide a consistent categorization of all concepts represented in it. Among the 133 semantic types we chose to focus on "T033: finding" and "T047: disease or syndrome", as they seemed most relevant to be disease specific. Examples of some other semantic types we do not focus on this study are: "T017: anatomical structure", "T074: medical device", and "T184: sign or symptom".

RadLex (Langlotz, 2006) is a unified language to organize and retrieve radiology imaging reports and medical records. While the Metathesaurus has a vast resource of biomedical concepts, we also use RadLex to confine our disease-term-mining more specifically to radiology related terms. The mined words are one-word terms appearing in the "T033: finding" and "T047: disease or syndrome" of the UMLS Metathesaurus appearing also in RadLex (RadLex is not a subset of Metathesaurus).

We are not only interested in disease terms associated with an image, but also whether the disease mentioned is present or absent. After detecting semantic terms of "T033: finding" and "T047: disease or syndrome", we use the assertion/negation detection algorithm of Chapman et al. (2001, 2013) to detect presence and absence of disease terms. The algorithm of Chapman et al. (2001, 2013) locates trigger terms which can indicate a clinical condition as negated or possible and determines which text falls within the scope of the trigger terms. The number of occurrences "T033: finding" and "T047: disease or syndrome" detected as assertion or negations in radiology reports are shown in Figure 13.

While the assertion/negation detection of "T047: disease or syndrome" seemed specific enough, the detection of "T033: finding" was not. For example, it seemed difficult to derive any specific disease information from 43,219 occurrences of possible "unchanged" and 422 occurrences of negated "unchanged". Some other similar examples are: 10,236 occurrences of possible "finding" and 1,129 occurrences of negated "finding"; 3,781 occurrences of possible "t2" (an MRI image modality) and 661 occurrences of negated "t2". We therefore decided to focus on "T047: disease or syndrome" terms only, and further ignored the terms which occurred less than 10 times in the radiology reports. The total number of "T047: disease or syndrome" terms for detecting their presence are 59, and the total number of the terms for detecting their absence are 18.

6.2 Predicting Disease in Images using CNN

Similarly to the object detection task in the ImageNet challenge, we match and detect disease terms found in the sentences of radiology reports referring to an image using a CNN and softmax cost function.

In addition to assigning disease terms to images, we also assign negated disease terms as the absence of the diseases in the images. The total number of labels is 77 (59 present, 18 absent). If more than one disease term is mentioned for an image, we simply assign the terms multiple times for an image. Some statistics on the number of assertion/negation occurrences per image are shown in Table 6.

As we found in Section 4.2 that transfer learning from the most related model is helpful, we fine-tune the image-to-topic CNN model for the disease prediction model. For this task,

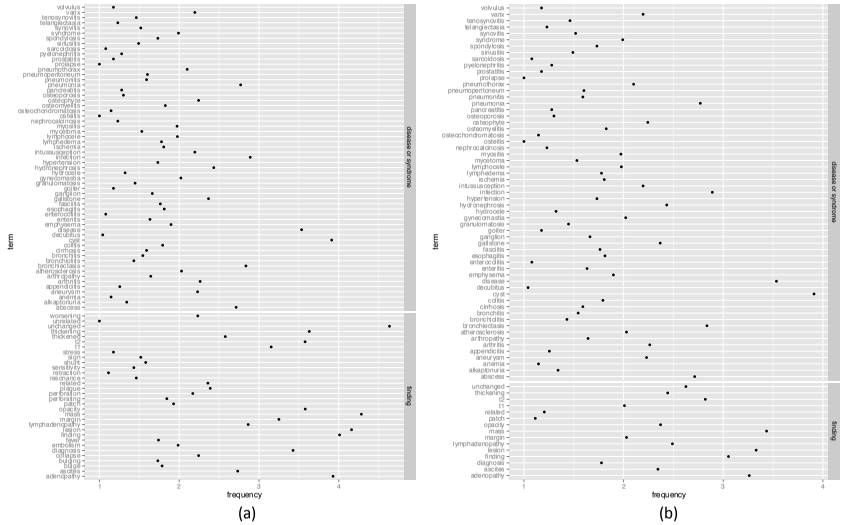

Figure 13: Number of occurrences (frequencies) of semantic terms "T033: finding" and "T047: disease or syndrome" in UMLS Metathesaurus and also appearing in RadLex, detected as (a) assertion and (b) negation in the radiology reports. Frequencies are shown in $\log_{10}$ scale.

# images		per image mean/std		# assertions per image		# negations per image	
total matching	18291	# assertions mean	1.05	1/image	16133	1/image	1581
total not matching	197495	# negations mean	1.05	2/image	613	2/image	84
with assertions	16827	# assertions std	0.23	3/image	81	3/image	0
with negations	1665	# negations std	0.22	4/image	0	4/image	0

Table 6: Some statistics of images-to-disease presence/absence label matching.

we fine-tune from the image to sentence-level-topic (h3) model in Section 4, as the image-to-sentence-level-topic seems to be most closely related to the image-to-disease-specific-terms model. Similarly to Section 4, 85% of image-label pairs are used for training, 5% for validation, and 10% for testing.

6.3 Prediction Result and Discussion

With the CNN trained to model image to disease presence/absence prediction, the top-1 test accuracy achieved is 0.71, and top-5 accuracy is 0.88. We combine this with the

previous image-to-topic mapping and key-word generation (Section 5.4) to generate the final output for comprehensive image interpretation. Some examples of test cases where top-1 probability output matches the originally assigned disease labels are shown in Figure 14. It is noticeable that specific disease words are detected with high probability when there is one disease word per image, but with relatively lower top-1 probability for one disease word and other words within the top-5 probabilities (Figure 14 (b)—" ... infection abscess").

We also observe that automatic label assignment to images can sometimes be challenging. In Figure 14 (d) "cyst" is assigned as the correct label based on the original statement "... possibly due to cyst ...", but it would be unclear whether cyst will be present in the image (and the cyst is not visibly apparent). It applies similarly to Figure 14 (e) where the presence of "osteophyte" is not clear from the referring sentence but is assigned as the correct label (and osteophyte is not visibly apparent on the image). In Figure 14 (f) "no cyst" is labeled and predicted correctly, but it is not obvious what to derive from this prediction that indicates an absence of a disease versus a presence.

Some examples of test cases where top-1 probability does not match the originally assigned labels are shown in Figure 15. Four ((a),(c),(e),(f)) of the six examples, however, contain the originally assigned label in the top-5 probability predictions, which is coherent with the relatively high (88%) top-5 prediction accuracy.

Here again, Figure 15 (a) is automatically labeled as "cyst", but the cyst is not clearly visible on the image where the original statement "... too small to definitely characterize cyst ..." supports this. The example of Figure 15 (b) shows a failed case of assertion/negation algorithm, where "cyst" is detected as negated based on the statement "... small cyst". Nonetheless, true label ("cyst") is detected as its top-1 probability. For Figure 15 (c) "cyst" is predicted where the true label assigned was "abscess"; however cyst and abscess are sometimes visibly similar. Similarly to Figure 14 (d), it is unclear whether we should expect to find emphysema in the image from the statement such as " ... possibly due to emphysema" (and emphysema is not visibly present). Therefore, it would be challenging to correctly interpret such statement for label assignment. Figure 15 (e) shows a disease which can be bronchiectasis, but it is also unclear from the image. However, bronchiectasis is predicted with the second highest probability. Bronchiectasis is visible in Figure 15 (f), and it was predicted with second highest probability too.

6.3.1 Discussion

Automated mining of disease-specific terms with semantics enables us to predict disease more specifically with promising results. However, compared to image-to-topic modeling in Section 4 where image labeling was based on topic modeling and loose coupling of image-to-keyword pairs, by matching the images to more specific disease words we lose about 90% of the images for the analysis due to nonspecific original statements. The proportion of the cases where radiologists indicate a disease as strongly positive or negative is often much less than the cases where they describe a finding rather vaguely. Mining and assigning the semantic label "T033: finding" will yield more images for specific disease-label pairs. However, it is probably less specific to model an image with a generic term as "mass" (which is a more vague indication of a specific disease such as "cyst" or "tumor") and detecting

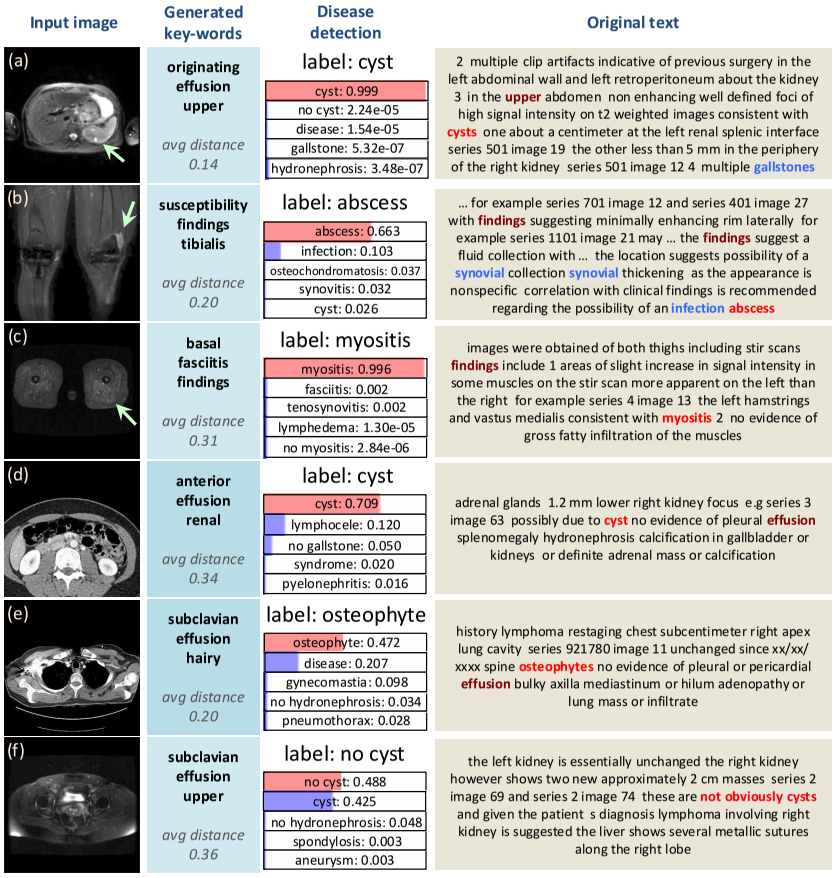

Figure 14: Some examples of final outputs for automated image interpretation, where top-1 probability matches the originally assigned label. Generated key-words appearing in the original text in radiology reports mentioning the image are shown in bold brown, specific disease words assigned as label mentioned in the reports are shown in bold red, and disease words predicted with top-5 probability in the reports are shown in bold blue. The probability assigned to the originally assigned label is shown with a red bar, and the other top-5 probabilities are shown with blue bars. Disease region identified in an image is pointed by arrow.

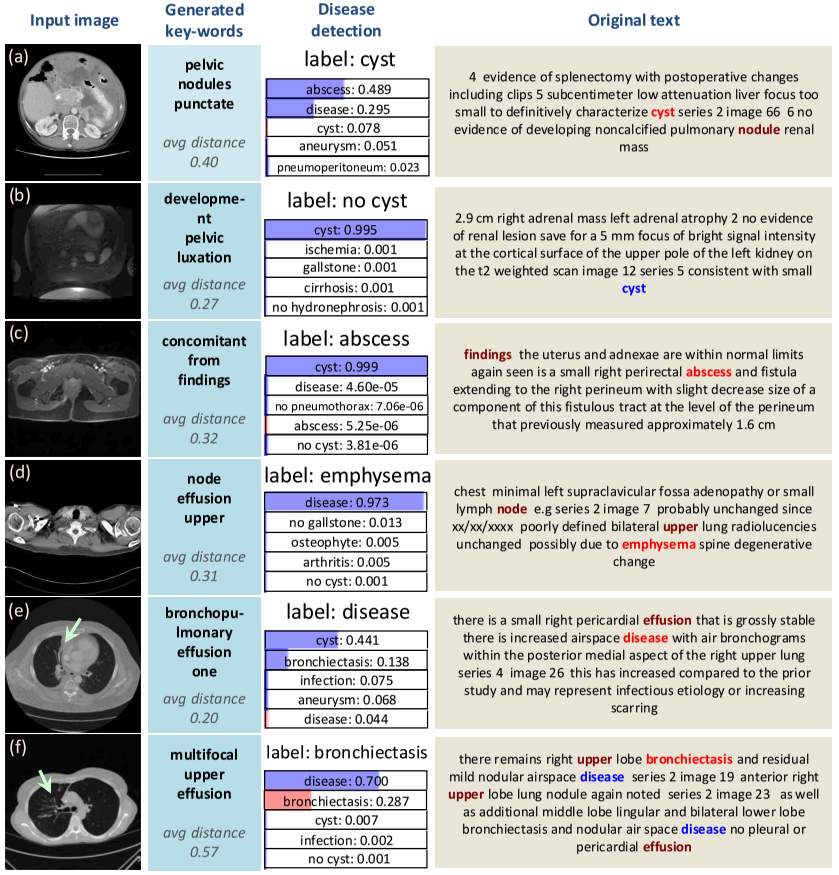

Figure 15: Some examples of final outputs for automated image interpretation where top-1 probability does not match the originally assigned label. One of the top-5 probabilities match the originally assigned labels in the examples of images (a), (c), (d), and (f). None of the top-5 probabilities match the originally assigned labels in the examples of image (b) and (d). However, label assignment of second row example is incorrect, as a failed case of assertion/negation detection algorithm used. Nonetheless, the CNN predicted "true" label correctly ("cyst").

it than modeling and detecting an image with a more specific term as "cyst" (similarly to "finding" or "unchanged").

It is a compromise between whether to go for big data and loose labels or to go for smaller data and more accurate labels. The key-word generation from the rather loose labeling scheme enables us to use most of the available 216K images. While the generated key-words can help understand the contents of the image, sometimes they are not specific and can also be irrelevant. More specific mining and assignment of specific disease labels to images could provide more accurate and precise disease prediction; however, only about 10% of the total images are made available by this scheme. Another alternative is to obtain annotation by radiologists to be even more specific, but the amount of data available will be even smaller due to the time and cost limitations.

Consequently, utilizing bigger data will enable us to make a more generalizable model, but labeling will become more challenging as the amount of data gets bigger and becomes more heterogeneous. The compromise between the amount of data and the quality of labels seems to be a recurring dilemma in the majority of automated mining in big data applications. More advanced NLP techniques and comprehensive analysis of hospital discharge summaries, progress notes, and patient histories might address the need to obtain more specific information relating to an image even when the original image descriptions are not very specific.

7. Conclusion

It has been unclear how to extend the significant success in image classification using deep convolutional neural networks from computer vision to medical imaging. What are the clinically relevant image labels to be defined, how to annotate the huge amount of medical images required by deep learning models, and to what extent and scale the deep CNN architecture is generalizable to medical image analysis are open questions.

In this paper, we present an interleaved text/image deep mining system to extract the semantic interactions of radiology reports and diagnostic key images at a very large, unprecedented scale in the medical domain. Images are classified into hierarchies of topics according to their associated documents, and a neural language model is learned to assign disease terms to predict the image interpretation. However, by generating the "attributes" of patient images, the generated descriptions are not disease-specific, whereas one of the primary goals for medical image analysis is to automatically diagnose diseases. In order to address this issue, we mine and match frequent disease types using disease ontology and semantics, and demonstrate prediction of the presence/absence of disease with probability outputs. Yet, only about 10% of the entire data set could be used for this study due to the challenge of more precisely matching the disease words with semantics. This raises interesting questions regarding the trade-offs in designing a machine learning system analyzing large medical data.

To the best of our knowledge, this is the first study performing a large-scale image/text analysis on a hospital picture archiving and communication system database. Our database is the largest one ever reported and is highly representative of the huge collection of radiology diagnostic semantics over the last decade. Exploring effective deep learning models on this database opens new ways to parse and understand large-scale radiology image data sets.

We hope that this study will inspire and encourage other institutions in mining other large unannotated clinical databases, to achieve the goal of establishing a central training resource and performance benchmark for large-scale medical image research, similar to the ImageNet of Deng et al. (2009) for computer vision.

Abstract

Domain-invariant representations are key to addressing the domain shift problem where the training and test examples follow different distributions. Existing techniques that have attempted to match the distributions of the source and target domains typically compare these distributions in the original feature space. This space, however, may not be directly suitable for such a comparison, since some of the features may have been distorted by the domain shift, or may be domain specific. In this paper, we introduce a Distribution-Matching Embedding approach: An unsupervised domain adaptation method that overcomes this issue by mapping the data to a latent space where the distance between the empirical distributions of the source and target examples is minimized. In other words, we seek to extract the information that is invariant across the source and target data. In particular, we study two different distances to compare the source and target distributions: the Maximum Mean Discrepancy and the Hellinger distance. Furthermore, we show that our approach allows us to learn either a linear embedding, or a nonlinear one. We demonstrate the benefits of our approach on the tasks of visual object recognition, text categorization, and WiFi localization.

Keywords: Domain Adaptation, Maximum Mean Discrepancy, Hellinger Distance, Distribution Matching, Domain Invariant Representations

1. Introduction

As evidenced by the recent surge of interest in domain adaptation (Saenko et al., 2010; Jain and Learned-Miller, 2011; Gong et al., 2012; Gopalan et al., 2011), domain shift is a fundamental problem for visual recognition. This problem typically occurs when the training and test images are acquired with different cameras, or in very different conditions (e.g., commercial website versus home environment, images taken under different illuminations). As a consequence, the training (source) and test (target) samples follow different distributions. As demonstrated in, e.g., (Saenko et al., 2010; Gopalan et al., 2011; Gong et al., 2012, 2013), failing to model this distribution shift in the hope that the image features will be robust enough often yields poor recognition accuracy. While labeling sufficiently many images from the target domain to train a discriminative classifier specific to this domain could alleviate this problem, it typically is prohibitively time-consuming and impractical in realistic scenarios. Domain adaptation therefore seeks to prevent this by explicitly modeling the domain shift.

Existing domain adaptation methods can be divided into two categories: Semi-supervised approaches that assume that a small number of labeled examples from the target domain are available during training, and unsupervised approaches that do not require any labels from the target domain. In the former category, modifications of existing classifiers have been proposed to exploit the availability of labeled and unlabeled data from the target domain (Daumé III and Marcu, 2006; Duan et al., 2009b; Bergamo and Torresani, 2010; Tommasi and Caputo, 2013). Co-regularization and adaptive regularization of similar classifiers was also introduced to utilize unlabeled target data during training (Daumé III et al., 2010; Rückert and Kloft, 2011). Multi-Model knowledge transfer was proposed to select and weigh prior knowledge coming from different categories (Jie et al., 2011; Tommasi et al., 2014, 2010). For visual recognition, metric learning (Saenko et al., 2010) and transformation learning (Kulis et al., 2011) were shown to be effective at making use of the labeled target examples. Furthermore, semi-supervised methods have also been employed to tackle the case where multiple source domains are available (Duan et al., 2009a; Hoffman et al., 2012). While semi-supervised methods are often effective, in many applications, labeled target examples are not available and cannot easily be acquired.

By contrast, unsupervised domain adaptation approaches rely on purely unsupervised target data (Xing et al., 2007; Bruzzone and Marconcini, 2010; Chen et al., 2011; Kuzborskij and Orabona, 2013). In particular, two types of methods have proven quite successful at the task of visual object recognition: Subspace-based approaches and sample re-weighting techniques. Subspace-based approaches (Blitzer et al., 2011; Gong et al., 2012; Gopalan et al., 2011) typically model each domain with a subspace, and attempt to relate the source and target representations via intermediate subspaces. While these methods have proven effective in practice, they suffer from the fact that they do not explicitly try to match the probability distributions of the source and target data. Therefore, they may easily yield sub-optimal representations for classification. By contrast, sample selection, or re-weighting, approaches (Huang et al., 2006; Gretton et al., 2009; Gong et al., 2013) explicitly attempt to match the source and target distributions by finding the most appropriate source examples for the target data. However, these methods fail to account for the fact that the image features themselves may have been distorted by the domain shift, and that some of these features may be specific to one domain and thus irrelevant for classification in the other one.

In light of the above discussion, we propose to tackle the problem of domain shift by discovering the information that is invariant across the source and target domains. To this end, we introduce a Distribution-Matching Embedding (DME) approach, which aims to learn a latent space where the source and target distributions are similar. Learning such a projection allows us to account for the potential distortions induced by the domain shift, as well as for the presence of domain-specific image features. Furthermore, since the distributions of the source and target data in the latent space are similar, we expect a classifier trained on the source samples to perform well on the target domain.

More specifically, here, we study two different distances to compare the source and target distributions in the latent space. First, we make use of the Maximum Mean Discrepancy (MMD) (Gretton et al., 2012a), which compares the means of two empirical distributions in a reproducing kernel Hilbert space. While the MMD is endowed with nice properties (Gretton et al., 2012a), it does not truly consider the geometry of the space of probability distributions. From information geometry,

This research was performed while M. Salzmann was affiliated with the Australian National University and NICTA.

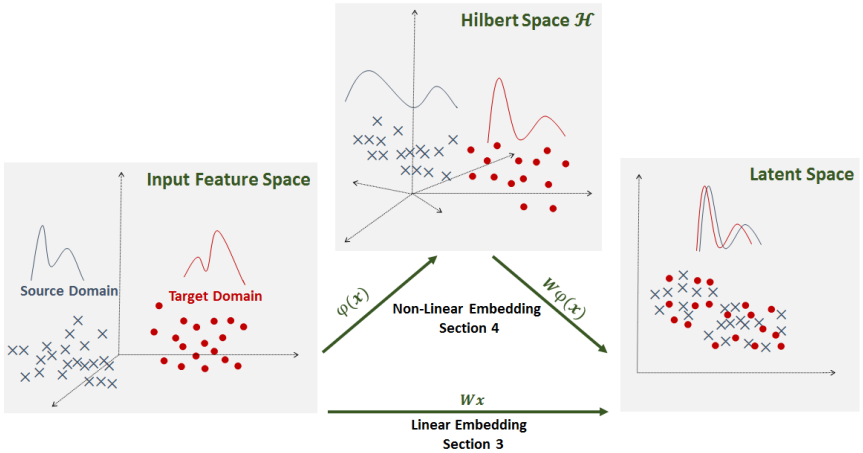

Figure 1: **Illustration of our approach.** Our goal is to learn a latent space, via either a linear mapping or a nonlinear one, such that the source and target distributions in this latent space are as similar as possible.

we know that probability distributions lie on a Riemannian manifold named the statistical manifold. In computer vision, it has been consistently demonstrated that exploiting the Riemannian metric of the manifold to compare manifold-values entities, such as covariance descriptors (Tuzel et al., 2008), linear subspaces (Harandi et al., 2013), or rotation matrices (Hartley et al., 2013), was beneficial for the task at hand. Therefore, we follow a similar intuition here and make use of the Riemannian metric on the statistical manifold as a second distance measure to compare the source and target distributions. Since the true Riemmannian metric, i.e., the Fisher-Rao metric, is difficult to use with general, non-parametric distributions, such as those obtained by kernel density estimation, we propose to rely on the Hellinger distance, which we show to be closely related to the Fisher-Rao Riemannian metric.

Given these two distances, we first introduce algorithms to learn a linear mapping to a low-dimensional latent space where the source and target distributions are similar. By exploiting the Riesz representer theorem (Schölkopf and Smola, 2002), we then show that, for both distances, our approach also allows us to learn a nonlinear embedding to a distribution-matching latent space. In the linear and the nonlinear scenarios, learning our Distribution-Matching Embeddings can then be formulated as an optimization problem on a Grassmann manifold. This lets us utilize Grassmannian geometry to effectively obtain our latent representations. Fig. 1 illustrates our approach, both for linear and nonlinear mappings. In essence, our approach consists of two main components: (i) a mapping to a latent space, which in the nonlinear case is achieved via a mapping to a high-dimensional Hilbert space; and (ii) a distance to compare the source and target distributions in the latent space. While, here, we rely on either the MMD or the Hellinger distance, our approach is general and could potentially be extended to other distance measures.

In short, we introduce the idea of finding a distribution-matching representation of the source and target data, and propose several effective algorithms to learn such a representation. We demonstrate the benefits of our approach on the tasks of visual object recognition, text categorization and Wifi localization using standard domain adaptation data sets. This article is an extended version of our ICCV 2013 (Baktashmotlagh et al., 2013) and CVPR 2014 (Baktashmotlagh et al., 2014) papers. Compared to the conference papers, it contains additional details about the linear formulations, as well as new results. Furthermore, it introduces the nonlinear formulations of our previous methods.

2. Preliminaries

In this section, we provide the background theory and groundwork for the techniques described in the following sections. In particular, we discuss the idea of Maximum Mean Discrepancy and review the derivation of the Hellinger distance on statistical manifolds, as well as study its relationship with the Fisher-Rao Riemannian metric. We then introduce some notions of Grassmannian geometry, as well as discuss the conjugate gradient (CG) algorithm that will be used in our optimization process.

2.1 Maximum Mean Discrepancy (MMD)

In this work, we are interested in measuring the distance between two probability distributions s and t. Rather than restricting these distributions to take a specific parametric form, we opt for a non-parametric approach to compare s and t. Non-parametric representations are very well-suited to visual data, which typically exhibits complex probability distributions in high-dimensional spaces.

To this end, here, we employ the Maximum Mean Discrepancy (Gretton et al., 2012a). The MMD is an effective non-parametric criterion that compares the distributions of two sets of data by mapping the data to RKHS. Given two distributions s and t, the MMD between s and t is defined as

$$D'(\mathfrak{F}, s, t) = \sup_{f \in \mathfrak{F}} \left(E_{\boldsymbol{x}^s \sim s}[f(\boldsymbol{x}^s)] - E_{\boldsymbol{x}^t \sim t}[f(\boldsymbol{x}^t)] \right) \ ,$$

where $E_{\boldsymbol{x} \sim s}[\cdot]$ is the expectation under distribution s. By defining $\mathfrak{F}$ as the set of functions in the unit ball in a universal RKHS $\mathcal{H}$, it was shown that $D'(\mathfrak{F}, s, t) = 0$ if and only if $s = t$ (Gretton et al., 2012a).

Let $\boldsymbol{X_s} = \{\boldsymbol{x}_1^s, \cdots, \boldsymbol{x}_n^s\}$ and $\boldsymbol{X_t} = \{\boldsymbol{x}_1^t, \cdots, \boldsymbol{x}_m^t\}$ be two sets of observations drawn i.i.d. from s and t, respectively. An empirical estimate of the MMD can be computed as

$$\begin{aligned} \hat{D}_M(\tilde{\boldsymbol{X}}_s, \tilde{\boldsymbol{X}}_t) &= \left\| \frac{1}{n} \sum_{i=1}^{n} \phi(\boldsymbol{x}_i^s) - \frac{1}{m} \sum_{j=1}^{m} \phi(\boldsymbol{x}_j^t) \right\|_{\mathcal{H}} \\ &= \left(\sum_{i,j=1}^{n} \frac{k(\boldsymbol{x}_i^s, \boldsymbol{x}_j^s)}{n^2} + \sum_{i,j=1}^{m} \frac{k(\boldsymbol{x}_i^t, \boldsymbol{x}_j^t)}{m^2} - 2 \sum_{i,j=1}^{n,m} \frac{k(\boldsymbol{x}_i^s, \boldsymbol{x}_j^t)}{nm} \right)^{\frac{1}{2}} , \end{aligned}$$

where $\phi(\cdot)$ is the mapping to the RKHS $\mathcal{H}$, and $k(\cdot, \cdot) = \langle \phi(\cdot), \phi(\cdot) \rangle$ is the universal kernel associated with this mapping. In short, the MMD between the distributions of two sets of observations is equivalent to the distance between the sample means in a high-dimensional feature space.

2.2 Hellinger Distance on Statistical Manifolds

In this section, we review some concepts of Riemannian geometry on statistical manifolds. In particular, we focus on the derivation of the Hellinger distance, which will be used in our algorithms.

Statistical manifolds are Riemannian manifolds whose elements are probability distributions. Loosely speaking, given a non-empty set $\mathcal{X}$ and a family of probability density functions $p(\boldsymbol{x}|\boldsymbol{\theta})$ parametrized by $\boldsymbol{\theta}$ on $\mathcal{X}$, the space $\mathcal{M} = \{p(\boldsymbol{x}|\boldsymbol{\theta})|\boldsymbol{\theta} \in \mathbb{R}^d\}$ forms a Riemannian manifold. The Fisher-Rao Riemannian metric on $\mathcal{M}$ is a function of $\boldsymbol{\theta}$ and induces geodesics, i.e., curves with minimum length on $\mathcal{M}$.

While the Fisher-Rao metric can be computed for specific parametric distributions, such as a Gaussian or a Gaussian mixture (Peter and Rangarajan, 2006), for other parametric forms, it does not even have a closed form solution. More importantly, in general, the parametrization of the PDFs of the data at hand is unknown, and choosing a specific distribution may not reflect the reality. Unfortunately, the Fisher-Rao metric is ill-suited to handle non-parametric distributions, which are of interest for our purpose. Therefore, several studies have opted for approximations of the Fisher-Rao metric. For instance, (Srivastava et al., 2007) proposed to map distributions to the hyper-sphere and use geodesics on this different type of manifold. By contrast, here, we make use of another class of approximations relying on f-divergences, which can be expressed as

$$D_f(s\|t) = \int f(\frac{s(\boldsymbol{x})}{t(\boldsymbol{x})})t(\boldsymbol{x})d\boldsymbol{x} \ .$$

The (squared) Hellinger distance is a special case of f-divergences, obtained by taking $f(y) = (\sqrt{y}-1)^2$. The (squared) Hellinger distance can thus be written as

$$D_H^2(s\|t) = \int \left(\sqrt{s(\boldsymbol{x})} - \sqrt{t(\boldsymbol{x})}\right)^2 d\boldsymbol{x} \ , \tag{1}$$

which is symmetric, satisfies the triangle inequality and is bounded from above by 2.

More importantly, in the following theorem, we show an interesting relationship between the Hellinger distance and the Fisher-Rao Riemannian metric.

Theorem 1 *The length of any curve γ is the same under the Fisher-Rao metric D_{FR} and the Hellinger distance D_H up to a scale of 2.*

Proof We start with the definition of intrinsic metric and curve length. Without any assumption on differentiability, let (M, d) be a metric space. A curve in M is a continuous function $\gamma : [0, 1] \to M$ and joins the starting point $\gamma(0) = p$ to the end point $\gamma(1) = q$. Our proof then relies on two theorems from (Hartley et al., 2013) stated below. To state and exploit these two theorems, we first need the following two definitions coming from (Hartley et al., 2013):

Definition 2 *The length of a curve γ is the supremum of $\ell(\gamma; \alpha_i)$ over all possible partitions α_i such that $0 = \alpha_0 < \alpha_1 < ... < \alpha_n = 1$, where $\ell(\gamma; \alpha_i) = \sum_i d(\gamma(\alpha_i), \gamma(\alpha_{i-1}))$.*

Definition 3 *The intrinsic metric $\hat{\delta}(x, y)$ between two points x and y on a metric space M is defined as the infimum of the lengths of all paths from x to y.*

Theorem 4 *(Hartley et al., 2013) If the intrinsic metrics induced by two metrics d_1 and d_2 are identical to scale ξ, then the length of any given curve is the same under both metrics up to ξ.*

Proof We refer the reader to (Hartley et al., 2013) for the proof of this theorem. ■

Theorem 5 *(Hartley et al., 2013) If $d_1(s, t)$ and $d_2(s, t)$ are two metrics defined on a space M such that*

$$\lim_{d_1(s,t)\to 0} \frac{d_2(s,t)}{d_1(s,t)} = 1 \tag{2}$$

uniformly (with respect to s and t), then their intrinsic metrics are identical.

Proof We refer the reader to (Hartley et al., 2013) for the proof of this theorem. ■

In (Kass and Vos, 2011), it was shown that $\lim_{s\to t} D_H(s\|t) = 0.5 D_{FR}(s\|t)$. The asymptotic behavior of the Hellinger distance and the Fisher-Rao metric can be expressed as $D_H(s, t) = 0.5 * D_{FR}(s, t) + O(D_{FR}(s, t)^3)$ as $s \to t$. This guarantees uniform convergence since the higher order terms are bounded and vanish rapidly independently of the path between s and t. It therefore directly follows from Theorems 5 and 4 that the length of a curve under D_H and D_{FR} is the same up to a scale of 2, which concludes the proof. ■

2.2.1 EMPIRICAL ESTIMATE OF THE HELLINGER DISTANCE

In a practical scenario, our goal is to compute the Hellinger distance between the distributions s and t when discrete observations are provided. In other words, we are interested in estimating Eq. 1 given n samples $\{\boldsymbol{x}_i^s\}$ drawn from s and m samples $\{\boldsymbol{x}_i^t\}$ drawn from t.

To have a symmetric and bounded estimate of the Hellinger distance with respect to a single density, we begin by defining $T(x) = \frac{s(x)}{s(x)+t(x)}$. The Hellinger distance can then be defined in terms of $T(x)$ as

$$\begin{aligned} D_H = & \int (\sqrt{s(x)} - \sqrt{t(x)})^2 dx \\ = & \int \left(\sqrt{\frac{s(x)}{s(x)+t(x)}} - \sqrt{\frac{t(x)}{s(x)+t(x)}}\right)^2 (s(x)+t(x))\, dx \\ = & \int (\sqrt{T(x)} - \sqrt{1-T(x)})^2 s(x) dx + \int (\sqrt{T(x)} - \sqrt{1-T(x)})^2 t(x) dx \ . \end{aligned} \tag{3}$$

Since the two terms in Eq. 3 are expectations, and following the strong law of large numbers, given our two sets of samples $\{\boldsymbol{x}_i^s\}$ and $\{\boldsymbol{x}_i^t\}$, an empirical estimate of the Hellinger distance can be obtained as (Carter, 2009)

$$\hat{D}_H^2 = \frac{1}{n}\sum_{i=1}^{n} \left(\sqrt{\hat{T}(\boldsymbol{x}_i^s)} - \sqrt{1-\hat{T}(\boldsymbol{x}_i^s)}\right)^2 + \frac{1}{m}\sum_{i=1}^{m} \left(\sqrt{\hat{T}(\boldsymbol{x}_i^t)} - \sqrt{1-\hat{T}(\boldsymbol{x}_i^t)}\right)^2 \ , \tag{4}$$

where $\hat{T}(\boldsymbol{x}) = \hat{s}(\boldsymbol{x})/\big(\hat{s}(\boldsymbol{x}) + \hat{t}(\boldsymbol{x})\big)$, with $\hat{s}(\boldsymbol{x})$ and $\hat{t}(\boldsymbol{x})$ the empirical estimates of $s(\boldsymbol{x})$ and $t(\boldsymbol{x})$, respectively. Importantly, this numerical approximation respects some of the properties of the true Hellinger distance (Carter, 2009). In particular, it is symmetric and bounded from above by 2.

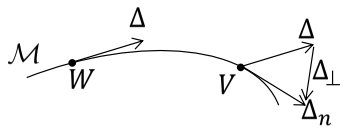

Figure 2: Parallel transport of a tangent vector Δ from a point $\boldsymbol{W}$ to point $\boldsymbol{V}$ on the manifold.

2.3 Grassmann Manifolds

The Grassmann manifold $\mathcal{G}(d, D)$ consists of the set of all linear d-dimensional subspaces of $\mathbb{R}^D$. In particular, for $\boldsymbol{W} \in \mathcal{G}(d, D)$, this lets us handle constraints of the form $\boldsymbol{W}^T\boldsymbol{W} = \boldsymbol{I}$. As will be shown in Section 3, our mappings to latent space involve nonlinear optimization on the Grassmann manifold. Below, we therefore review some useful notions of differential geometry.

In differential geometry, the shortest path between two points on a manifold is a curve called a *geodesic*. The *tangent space* at a point on a manifold is a vector space that consists of the tangent vectors of all possible curves passing through this point. *Parallel transport* is the action of transferring a tangent vector between two points on a manifold. As illustrated in Fig. 2, unlike in flat spaces, this cannot be achieved by simple translation, but requires subtracting a normal component at the end point (Edelman et al., 1998).

On a Grassmann manifold, the above-mentioned operations have efficient numerical forms and can thus be used to perform optimization on the manifold. In particular, we make use of a conjugate gradient (CG) algorithm on the Grassmann manifold (Edelman et al., 1998). CG techniques are popular nonlinear optimization methods with fast convergence rates. These methods iteratively optimize the objective function in linearly independent directions called conjugate directions (Ruszczynski, 2006). CG on a Grassmann manifold can be summarized by the following steps:

(i) Compute the gradient $\nabla f_{\boldsymbol{W}}$ of the objective function f on the manifold at the current estimate $\boldsymbol{W}$ as

$$\nabla f_{\boldsymbol{W}} = \partial f_{\boldsymbol{W}} - \boldsymbol{W}\boldsymbol{W}^T\partial f_{\boldsymbol{W}} \ , \tag{5}$$

with $\partial f_{\boldsymbol{W}}$ the matrix of usual partial derivatives.

(ii) Determine the search direction $\boldsymbol{H}$ by parallel transporting the previous search direction and combining it with $\nabla f_{\boldsymbol{W}}$.

(iii) Perform a line search along the geodesic at $\boldsymbol{W}$ in the direction $\boldsymbol{H}$.

These steps are repeated until convergence to a local minimum, or until a maximum number of iterations is reached.

Note that, while we rely on a conjugate gradient method, other optimization strategies have been studied on Grassmann manifolds, such as (i) Stochastic-gradient flow, where a stochastic component is added to the gradient to construct a stochastic gradient process such that the solution converges to a global optimum in the limit; (ii) Acceptance-rejection methods, where the stochastic gradient part provides candidates to update the estimate, that are accepted/rejected according to a probability density function (Metropolis-Hastings type acceptance-rejection step); and (iii) Simulated annealing, where instead of sampling from a probability distribution, an annealing procedure is applied to find the optimal points of the function f (Srivastava and Liu, 2005). A complete study of these Grassmannian optimization strategies goes beyond the scope of this paper.

3. Distribution-Matching Embedding (DME)

In this section, we introduce our approach to unsupervised domain adaptation, which relies on mapping the data to a low-dimensional latent space such that the distance between the source and target distributions is minimized. Intuitively, with such a latent representation, a classifier trained on the source domain should perform equally well on the target domain. In particular, here, we make use of a linear mapping of the form

$$\boldsymbol{y} = \boldsymbol{W}^T\boldsymbol{x} \ , \tag{6}$$

where $\boldsymbol{x} \in \mathbb{R}^D$ is the original data (e.g., image features), $\boldsymbol{y} \in \mathbb{R}^d$ is the resulting low-dimensional representation, and $\boldsymbol{W} \in \mathbb{R}^{D\times d}$ is the parameter matrix that we seek to learn. Furthermore, we enforce orthogonality constraints on $\boldsymbol{W}$, such that

$$\boldsymbol{W}^T\boldsymbol{W} = \boldsymbol{I} \ . \tag{7}$$

These constraints typically avoid degeneracies, such as having all samples collapsing to the origin, and have proven effective in many dimensionality reduction methods, such as Principal Component Analysis (PCA) and Canonical Correlation Analysis (CCA).

In the remainder of this section, we denote by $s(\boldsymbol{x})$ and $t(\boldsymbol{x})$ the probability density functions of the source samples $\boldsymbol{X_s} = [\boldsymbol{x}_1^s, \cdots, \boldsymbol{x}_n^s]$ and target samples $\boldsymbol{X_t} = [\boldsymbol{x}_1^t, \cdots, \boldsymbol{x}_m^t]$, respectively, where each $\boldsymbol{x}_i^* \in \mathbb{R}^D$. We first derive our MMD-based algorithm (DME-MMD), and then discuss our formulation based on the Hellinger distance (DME-H).

3.1 DME with the MMD (DME-MMD)

To derive our first approach to learning a distribution-matching representation, we make use of the MMD to measure the distance between the source and target distributions. Following the derivations provided in Section 2, and by making use of the linear mapping defined in Eq. 6, the MMD in the latent space can be expressed as

$$\hat{D}_M(\boldsymbol{W}^T\boldsymbol{X_s}, \boldsymbol{W}^T\boldsymbol{X_t}) = \left\| \frac{1}{n}\sum_{i=1}^{n}\phi(\boldsymbol{W}^T\boldsymbol{x}_i^s) - \frac{1}{m}\sum_{j=1}^{m}\phi(\boldsymbol{W}^T\boldsymbol{x}_j^t) \right\|_{\mathcal{H}} , \tag{8}$$

with $\phi(\cdot)$ the mapping from $\mathbb{R}^D$ to the high-dimensional RKHS $\mathcal{H}$. Note that, here, $\boldsymbol{W}$ appears inside $\phi(\cdot)$ in order to measure the MMD of the projected samples.

Using the MMD, in conjunction with the constraints described in Eq. 7, learning $\boldsymbol{W}$ can be expressed as the optimization problem

$$\begin{aligned} \boldsymbol{W}^* \quad &= \quad \underset{\boldsymbol{W}}{\operatorname{argmin}} \ D^2(\boldsymbol{W}^T\boldsymbol{X_s}, \boldsymbol{W}^T\boldsymbol{X_t}) \\ &\text{s.t.} \quad \boldsymbol{W}^T\boldsymbol{W} = \boldsymbol{I} \ . \end{aligned} \tag{9}$$

As shown in Section 2, the MMD can be expressed in terms of a kernel function $k(\cdot, \cdot)$. Here, we first propose to exploit the Gaussian kernel function, which is known to be universal (Steinwart,

2002). This lets us rewrite our objective function as

$$\begin{aligned}\hat{D}^2_M(\boldsymbol{W}^T\boldsymbol{X_s},\boldsymbol{W}^T\boldsymbol{X_t}) = &\frac{1}{n^2}\sum_{i,j=1}^{n}\exp\left(-\frac{(\boldsymbol{x}_i^s-\boldsymbol{x}_j^s)^T\boldsymbol{W}\boldsymbol{W}^T(\boldsymbol{x}_i^s-\boldsymbol{x}_j^s)}{\sigma}\right)\\ &+\frac{1}{m^2}\sum_{i,j=1}^{m}\exp\left(-\frac{(\boldsymbol{x}_i^t-\boldsymbol{x}_j^t)^T\boldsymbol{W}\boldsymbol{W}^T(\boldsymbol{x}_i^t-\boldsymbol{x}_j^t)}{\sigma}\right)\\ &-\frac{2}{mn}\sum_{i,j=1}^{n,m}\exp\left(-\frac{(\boldsymbol{x}_i^s-\boldsymbol{x}_j^t)^T\boldsymbol{W}\boldsymbol{W}^T(\boldsymbol{x}_i^s-\boldsymbol{x}_j^t)}{\sigma}\right)\ ,\end{aligned} \tag{10}$$

where, in practice, we take σ to be the median squared distance between all the source examples.

Since the Gaussian kernel satisfies the universality condition of the MMD, it is a natural choice for our approach. However, it was shown that, in practice, choices of non-universal kernels may be more appropriate to measure the MMD (Borgwardt et al., 2006). In particular, the more general class of characteristic kernels can also be employed. This class incorporates all strictly positive definite kernels, such as the well-known polynomial kernel. Therefore, here, we also consider the polynomial kernel of degree two. The fact that this kernel yields a distribution distance that only compares the first and second moment of the two distributions (Gretton et al., 2012a) will be shown to have little impact on our experimental results, thus showing the robustness of our approach to the choice of kernel.

Replacing the Gaussian kernel with this polynomial kernel in our objective function yields

$$\begin{aligned}\hat{D}^2_M(\boldsymbol{W}^T\boldsymbol{X_s},\boldsymbol{W}^T\boldsymbol{X_t}) = &\frac{1}{n^2}\sum_{i=1}^{n}\sum_{j=1}^{n}(1+\boldsymbol{x}_i^{sT}\boldsymbol{W}\boldsymbol{W}^T\boldsymbol{x}_j^s)^2\\ &+\frac{1}{m^2}\sum_{i=1}^{m}\sum_{j=1}^{m}(1+\boldsymbol{x}_i^{tT}\boldsymbol{W}\boldsymbol{W}^T\boldsymbol{x}_j^t)^2\\ &-\frac{2}{mn}\sum_{i=1}^{n}\sum_{j=1}^{m}(1+\boldsymbol{x}_i^{sT}\boldsymbol{W}\boldsymbol{W}^T\boldsymbol{x}_j^t)^2.\end{aligned} \tag{11}$$

The two variants of the MMD introduced in Eqs. 10 and 11 can be computed efficiently in matrix form as

$$\hat{D}^2_M(\boldsymbol{W}^T\boldsymbol{X_s},\boldsymbol{W}^T\boldsymbol{X_t}) = Tr(\boldsymbol{K_W}\boldsymbol{L})\ , \tag{12}$$

where

$$\begin{aligned}\boldsymbol{K_W} &= \begin{bmatrix}\boldsymbol{K}_{s,s} & \boldsymbol{K}_{s,t}\\ \boldsymbol{K}_{t,s} & \boldsymbol{K}_{t,t}\end{bmatrix}\in\mathbb{R}^{(n+m)\times(n+m)}\ ,\ \text{and}\\ L_{ij} &= \begin{cases}1/n^2 & i,j\in\mathcal{S}\\ 1/m^2 & i,j\in\mathcal{T}\\ -1/(nm) & \text{otherwise}\end{cases}\ ,\end{aligned}$$

with $\mathcal{S}$ and $\mathcal{T}$ the sets of source and target indices, respectively. Each element in $\boldsymbol{K_W}$ is computed using the kernel function (either Gaussian, or polynomial), and thus depends on $\boldsymbol{W}$. Note that,

with both kernels, $\boldsymbol{K_W}$ can be computed efficiently in matrix form (i.e., without looping over its elements). This yields the optimization problem

$$\begin{aligned}\boldsymbol{W}^* &= \underset{\boldsymbol{W}}{\text{argmin}}\ Tr(\boldsymbol{K_W}\boldsymbol{L})\\ &\text{s.t. } \boldsymbol{W}^T\boldsymbol{W}=\boldsymbol{I}\ ,\end{aligned} \tag{13}$$

which is a nonlinear constrained problem. Due to the constraints, this problem can be solved either on the Stiefel manifold, or on the Grassmann manifold. The main difference between these two manifolds lies in the fact that, on the Grassmannian, two subspaces that are identical up to a d-dimensional rotation are identified as the same point on the manifold. In other words, a point on the Grassmann manifold is an equivalence class. It can easily be verified that, with our two kernels, a rotation of $\boldsymbol{W}$ would yield exactly the same objective function value. Therefore, our problem can be solved on the Grassmann manifold. The details of the optimization scheme and the resulting algorithm will be discussed in Section 3.3.

3.2 DME with the Hellinger Distance (DME-H)

While the MMD has nice properties (Gretton et al., 2012a), it does not truly consider the geometry of the space of probability distributions. Furthermore, according to (Gretton et al., 2012b), non-optimal choices of kernel and kernel parameters can lead to poor estimates of the distance between two distributions. This therefore motivates the use of the Hellinger distance instead of the MMD, since, as shown in Section 2.2, the Hellinger distance is related to the geodesic distance on the statistical manifold.

Given the linear mapping in Eq. 6 and the definition of the empirical estimate of the Hellinger distance in Eq. 4, we can express the (squared) distance between the source and target distributions as

$$\begin{aligned}\hat{D}^2_H(\boldsymbol{W}^T\boldsymbol{X_s},\boldsymbol{W}^T\boldsymbol{X_t}) &= \frac{1}{n}\sum_{i=1}^{n}\left(\sqrt{\hat{T}(\boldsymbol{W}^T\boldsymbol{x}_i^s)}-\sqrt{1-\hat{T}(\boldsymbol{W}^T\boldsymbol{x}_i^s)}\right)^2\\ &+ \frac{1}{m}\sum_{i=1}^{m}\left(\sqrt{\hat{T}(\boldsymbol{W}^T\boldsymbol{x}_i^t)}-\sqrt{1-\hat{T}(\boldsymbol{W}^T\boldsymbol{x}_i^t)}\right)^2\ .\end{aligned} \tag{14}$$

This distance depends on the function $\hat{T}(\boldsymbol{W}^T\boldsymbol{x})$, which, as mentioned in Section 2.2.1, is derived from the empirical estimates of the source and target distributions, $\hat{s}(\boldsymbol{W}^T\boldsymbol{x})$ and $\hat{t}(\boldsymbol{W}^T\boldsymbol{x})$, respectively.

In this work, we make use of kernel density estimation (KDE) with a Gaussian kernel to model these distributions. This lets us write

$$\hat{s}(\boldsymbol{W}^T\boldsymbol{x}) = \frac{1}{n}\sum_{j=1}^{n}\frac{1}{\sqrt{|2\pi\boldsymbol{H}_s|}}\exp\left(-\frac{(\boldsymbol{x}-\boldsymbol{x}_j^s)^T\boldsymbol{W}\boldsymbol{H}_s^{-1}\boldsymbol{W}^T(\boldsymbol{x}-\boldsymbol{x}_j^s)}{2}\right), \tag{15}$$

where $\boldsymbol{H}_s$ is a diagonal matrix. In practice, we take $\boldsymbol{H}_s=\sigma_s\boldsymbol{I}$, where σ_s is computed using the maximal smoothing principle (Terrell, 1990) and kept constant. A similar estimate $\hat{t}(\boldsymbol{W}^T\boldsymbol{x})$ can be obtained from the m projected target samples $\{\boldsymbol{W}^T\boldsymbol{x}_j^t\}$. As such, we can write $\hat{T}(\boldsymbol{W}^T\boldsymbol{x})$ as:

$$\hat{T}(\boldsymbol{W}^T\boldsymbol{x}) = \frac{\frac{1}{n}\sum_{j=1}^{n}k(\boldsymbol{W}^T\boldsymbol{x},\boldsymbol{W}^T\boldsymbol{x}_j^s)}{\frac{1}{n}\sum_{j=1}^{n}k(\boldsymbol{W}^T\boldsymbol{x},\boldsymbol{W}^T\boldsymbol{x}_j^s)+\frac{1}{m}\sum_{j=1}^{m}k(\boldsymbol{W}^T\boldsymbol{x},\boldsymbol{W}^T\boldsymbol{x}_j^t)}\ , \tag{16}$$

where $k(\cdot,\cdot)$ is the Gaussian kernel function.

Finding a mapping that minimizes the Hellinger distance between the source and target distributions can then be expressed as

$$\begin{aligned} \boldsymbol{W}^* &= \min_{\boldsymbol{W}} \hat{D}_H^2(\boldsymbol{W}^T\boldsymbol{X_s}, \boldsymbol{W}^T\boldsymbol{X_t}) \\ \text{s.t.} \quad & \boldsymbol{W}^T\boldsymbol{W} = \boldsymbol{I}\ . \end{aligned} \tag{17}$$

As with the MMD, this is a nonlinear, constrained optimization problem, which, because of the form of the constraints, can be modeled as an optimization problem on either the Stiefel manifold or the Grassmannian. As before, it can easily be verified that the objective function will be unaffected by a rotation of $\boldsymbol{W}$. Therefore, this corresponds to a problem on the Grassmann manifold.

3.3 Learning the Mapping

As mentioned in the previous two sections, both DME-MMD and DME-H correspond to optimization problems on the Grassmann manifold. Optimization on Grassmann manifolds has proven effective at avoiding bad local minima (Absil et al., 2008). More precisely, manifold optimization methods often have better convergence behavior than iterative projection methods, which can be crucial with a nonlinear objective function (Absil et al., 2008).

By expressing $\boldsymbol{W}$ as a point on a Grassmann manifold, we can rewrite our constrained optimization problems as unconstrained problems on the manifold $\mathcal{G}(d,D)$. More specifically, we can generally express Problems (13) and (17) as

$$\boldsymbol{W^*} = \operatorname*{argmin}_{\boldsymbol{W}\in\mathcal{G}(d,D)} f(\boldsymbol{W})\ , \tag{18}$$

where $f(\boldsymbol{W})$ represents either the MMD-based objective function, or the Hellinger-based one.

While the optimization problem above has become unconstrained, it remains nonlinear. To effectively address this, we make use of a conjugate gradient method on the manifold. Recall from Section 2.3 that CG on a Grassmann manifold involves **(i)** computing the gradient on the manifold $\nabla f_{\boldsymbol{W}}$, **(ii)** estimating the search direction $\boldsymbol{H}$, and **(iii)** performing a line search along a geodesic. Our general approach to learning $\boldsymbol{W}$ can then be summarized by Algorithm 1, where we denote by $\tau(\Delta, \boldsymbol{W}, \boldsymbol{V})$ the parallel transport of tangent vector Δ from $\boldsymbol{W}$ to $\boldsymbol{V}$. In practice, we initialize $\boldsymbol{W}$ to the truncated identity matrix. We observed that learning $\boldsymbol{W}$ typically converges in only a few iterations.

Note that Eq. 5 shows that the gradient on the manifold depends on the partial derivatives of the objective function w.r.t. $\boldsymbol{W}$, i.e., $\partial f/\partial \boldsymbol{W}$. These derivatives depend on the specific form of the objective function, and are thus different for DME-MMD and DME-H.

For DME-MMD, the general form of $\partial f/\partial \boldsymbol{W}$ can be expressed as

$$\frac{\partial f}{\partial \boldsymbol{W}} = \sum_{i,j=1}^{n} \frac{\boldsymbol{G}_{ss}(i,j)}{n^2} + \sum_{i,j=1}^{m} \frac{\boldsymbol{G}_{tt}(i,j)}{m^2} - 2\sum_{i,j=1}^{n,m} \frac{\boldsymbol{G}_{st}(i,j)}{mn}\ ,$$

where $\boldsymbol{G}_{ss}(\cdot,\cdot)$, $\boldsymbol{G}_{tt}(\cdot,\cdot)$ and $\boldsymbol{G}_{st}(\cdot,\cdot)$ are matrices of size $D\times d$. With the definition of the MMD in Eq. 10 based on the Gaussian kernel $k_G(\cdot,\cdot)$, the matrix, e.g., $\boldsymbol{G}_{ss}(i,j)$ has the form

$$\boldsymbol{G}_{ss}(i,j) = -\frac{2}{\sigma} k_G(\boldsymbol{x}_s^i, \boldsymbol{x}_s^j)(\boldsymbol{x}_s^i - \boldsymbol{x}_s^j)(\boldsymbol{x}_s^i - \boldsymbol{x}_s^j)^T\boldsymbol{W}\ ,$$

Algorithm 1 : Learning on a Grassmann Manifold

Input:
$\boldsymbol{X_s}$: the source examples
$\boldsymbol{X_t}$: the target examples
d: the dimensionality of the subspace

Output:
$\boldsymbol{W}^* \in \mathbb{R}^{D\times d}$, such that $\boldsymbol{W}^{*T}\boldsymbol{W}^* = \boldsymbol{I}$

$\boldsymbol{W}_{prev} \leftarrow \boldsymbol{I}_{D\times d}$ (i.e., truncated identity matrix)
$\boldsymbol{W}_{cur} \leftarrow \boldsymbol{W}_{prev}$
$\boldsymbol{H}_{prev} \leftarrow \boldsymbol{0}$
repeat
  $\boldsymbol{D}_{cur} \leftarrow \nabla f_{\boldsymbol{W}_i}$
  $\boldsymbol{H}_{cur} \leftarrow -\boldsymbol{D}_{cur} + \eta\tau(\boldsymbol{H}_{prev}, \boldsymbol{W}_{prev}, \boldsymbol{W}_{cur})$
  Line search to find $\boldsymbol{W}^*$ that minimizes $f(\boldsymbol{W})$ along the geodesic at $\boldsymbol{W}_{cur}$ in the direction $\boldsymbol{H}_{cur}$
  $\boldsymbol{H}_{prev} \leftarrow \boldsymbol{H}_{cur}$
  $\boldsymbol{W}_{prev} \leftarrow \boldsymbol{W}_{cur}$
  $\boldsymbol{W}_{cur} \leftarrow \boldsymbol{W}^*$
until convergence

and similarly for $\boldsymbol{G}_{tt}(\cdot,\cdot)$ and $\boldsymbol{G}_{st}(\cdot,\cdot)$. With the MMD of Eq. 11 based on the degree 2 polynomial kernel $k_P(\cdot,\cdot)$, $\boldsymbol{G}_{ss}(i,j)$ becomes

$$\boldsymbol{G}_{ss}(i,j) = 2k_P(\boldsymbol{x}_s^i, \boldsymbol{x}_s^j)(\boldsymbol{x}_s^i\boldsymbol{x}_s^{jT} + \boldsymbol{x}_s^j\boldsymbol{x}_s^{iT})\boldsymbol{W}\ ,$$

and similarly for $\boldsymbol{G}_{tt}(\cdot,\cdot)$ and $\boldsymbol{G}_{st}(\cdot,\cdot)$. Similarly to the objective function itself, these derivatives can be efficiently computed in matrix form.

For DME-H, the derivatives can be written as

$$\begin{aligned} \frac{\partial f}{\partial \boldsymbol{W}} &= \tfrac{1}{n}\textstyle\sum_i^n \left\{ \sqrt{\frac{2T\left(\boldsymbol{W}^T\boldsymbol{x}_i^s\right)-1}{T\left(\boldsymbol{W}^T\boldsymbol{x}_i^s\right)\left(1-T\left(\boldsymbol{W}^T\boldsymbol{x}_i^s\right)\right)}}\frac{\partial T\left(\boldsymbol{W}^T\boldsymbol{x}_i^s\right)}{\partial \boldsymbol{W}} \right\} \\ &\quad + \tfrac{1}{m}\textstyle\sum_i^m \left\{ \sqrt{\frac{2T\left(\boldsymbol{W}^T\boldsymbol{x}_i^t\right)-1}{T\left(\boldsymbol{W}^T\boldsymbol{x}_i^t\right)\left(1-T\left(\boldsymbol{W}^T\boldsymbol{x}_i^t\right)\right)}}\frac{\partial T\left(\boldsymbol{W}^T\boldsymbol{x}_i^t\right)}{\partial \boldsymbol{W}} \right\}, \end{aligned} \tag{19}$$

where

$$\begin{aligned} \frac{\partial T(\boldsymbol{W}^T\boldsymbol{x})}{\partial \boldsymbol{W}} &= \frac{\partial}{\partial \boldsymbol{W}}\frac{s(\boldsymbol{W}^T\boldsymbol{x})}{s(\boldsymbol{W}^T\boldsymbol{x}) + t(\boldsymbol{W}^T\boldsymbol{x})} \\ &= \frac{1}{\left(s(\boldsymbol{W}^T\boldsymbol{x}) + t(\boldsymbol{W}^T\boldsymbol{x})\right)^2}\left(t(\boldsymbol{W}^T\boldsymbol{x})\frac{\partial s(\boldsymbol{W}^T\boldsymbol{x})}{\partial \boldsymbol{W}} - s(\boldsymbol{W}^T\boldsymbol{x})\frac{\partial t(\boldsymbol{W}^T\boldsymbol{x})}{\partial \boldsymbol{W}}\right). \end{aligned} \tag{20}$$

This lets us learn a linear mapping to a low-dimensional subspace that minimizes either the MMD or the Hellinger distance between the source and target data in a completely unsupervised

manner. A classifier can then be learned from the labeled source samples projected to this latent space, and directly applied to the projected target samples.

4. Nonlinear DME (NL-DME)

The Distribution-Matching Embedding methods introduced in the previous section make use of a linear mapping. As such, they have limited power to represent complex transformations between the source and target domains. To overcome this limitation, we introduce a nonlinear version of DME, which, as is often the case with nonlinear embedding techniques, boils down to applying a linear method after mapping the data to a high-dimensional Reproducing Kernel Hilbert Space.

More specifically, let $\varphi : \mathbb{R}^D \rightarrow \tilde{\mathcal{H}}$ be the function mapping an input vector $\boldsymbol{x}$ to a high-dimensional RKHS. Our goal is to learn an embedding of the form

$$\boldsymbol{y} = \boldsymbol{W}^T\varphi(\boldsymbol{x}) \; . \tag{21}$$

Since, in theory, $\tilde{\mathcal{H}}$ can be infinite-dimensional, learning the matrix $\boldsymbol{W}$ directly is not practical. Therefore, here, we make use of the Riesz representer theorem (Schölkopf and Smola, 2002; Canu and Smola, 2006) to express $\boldsymbol{W}$ as a linear combination of the examples in $\tilde{\mathcal{H}}$. In other words, we write

$$\boldsymbol{W} = \varphi(\boldsymbol{X_{s+t}})\boldsymbol{\alpha} \; , \tag{22}$$

where $\varphi(\boldsymbol{X_{s+t}})$ is the matrix containing all samples (i.e., source and target) mapped to $\tilde{\mathcal{H}}$, and $\boldsymbol{\alpha} \in \mathbb{R}^{(n+m)\times d}$ corresponds to the new parameters of the mapping.

4.1 NL-DME with the MMD (NL-DME-MMD)

Given the definition of the mapping above, we can write the Gaussian-kernel-based MMD as

$$\begin{aligned}
\hat{D}^2_M(\boldsymbol{W}^T\varphi(\boldsymbol{X_s}), \boldsymbol{W}^T\varphi(\boldsymbol{X_t})) &= \left\| \frac{1}{n}\sum_{i=1}^{n}\phi(\boldsymbol{\alpha}^T\varphi(\boldsymbol{X_{s+t}})^T\varphi(\boldsymbol{x}_i^s)) - \frac{1}{m}\sum_{j=1}^{m}\phi(\boldsymbol{\alpha}^T\varphi(\boldsymbol{X_{s+t}})^T\varphi(\boldsymbol{x}_j^t)) \right\|^2_{\mathcal{H}} \\
&= \frac{1}{n^2}\sum_{i,j=1}^{n}\exp\left(-\frac{(\tilde{k}(\boldsymbol{X_{s+t}},\boldsymbol{x}_i^s) - \tilde{k}(\boldsymbol{X_{s+t}},\boldsymbol{x}_j^s))^T\boldsymbol{\alpha}\boldsymbol{\alpha}^T(\tilde{k}(\boldsymbol{X_{s+t}},\boldsymbol{x}_i^s) - \tilde{k}(\boldsymbol{X_{s+t}},\boldsymbol{x}_j^s))}{\sigma}\right) \\
&+ \frac{1}{m^2}\sum_{i,j=1}^{m}\exp\left(-\frac{(\tilde{k}(\boldsymbol{X_{s+t}},\boldsymbol{x}_i^t) - \tilde{k}(\boldsymbol{X_{s+t}},\boldsymbol{x}_j^t))^T\boldsymbol{\alpha}\boldsymbol{\alpha}^T(\tilde{k}(\boldsymbol{X_{s+t}},\boldsymbol{x}_i^t) - \tilde{k}(\boldsymbol{X_{s+t}},\boldsymbol{x}_j^t))}{\sigma}\right) \\
&- \frac{2}{mn}\sum_{i,j=1}^{n,m}\exp\left(-\frac{(\tilde{k}(\boldsymbol{X_{s+t}},\boldsymbol{x}_i^s) - \tilde{k}(\boldsymbol{X_{s+t}},\boldsymbol{x}_j^t))^T\boldsymbol{\alpha}\boldsymbol{\alpha}^T(\tilde{k}(\boldsymbol{X_{s+t}},\boldsymbol{x}_i^s) - \tilde{k}(\boldsymbol{X_{s+t}},\boldsymbol{x}_j^t))}{\sigma}\right) \; ,
\end{aligned} \tag{23}$$

where $\tilde{k}(\cdot,\cdot)$ is the kernel function corresponding to the mapping to $\tilde{\mathcal{H}}$. Note that the MMD then only depends on kernel values and not on the high-dimensional representation $\varphi(\boldsymbol{x})$. It can easily be verified that this remains true when expressing the MMD with the degree 2 polynomial kernel, as in Eq. 11.

Learning a nonlinear distribution-matching embedding with the MMD can then be expressed as the optimization problem

$$\begin{aligned}
\boldsymbol{\alpha}^* &= \underset{\boldsymbol{\alpha}}{\text{argmin}} \; \hat{D}^2_M(\boldsymbol{\alpha}^T\varphi(\boldsymbol{X_{s+t}})^T\varphi(\boldsymbol{X_s}), \boldsymbol{\alpha}^T\varphi(\boldsymbol{X_{s+t}})^T\varphi(\boldsymbol{X_t})) \\
&\text{s.t.} \quad \boldsymbol{\alpha}^T\boldsymbol{K}\boldsymbol{\alpha} = \boldsymbol{I} \; ,
\end{aligned} \tag{24}$$

As in the linear case, the objective function can be computed efficiently in matrix form, thus yielding the optimization problem

$$\begin{aligned}
\boldsymbol{\beta}^* &= \underset{\boldsymbol{\beta}}{\text{argmin}} \; Tr\left(\boldsymbol{K'}_{\boldsymbol{\beta}}\boldsymbol{L}\right) \\
&\text{s.t.} \; \boldsymbol{\beta}^T\boldsymbol{\beta} = \boldsymbol{I} \; ,
\end{aligned} \tag{25}$$

where $\boldsymbol{L}$ is defined as in (12), $\boldsymbol{K'}_{\boldsymbol{\beta}}$ can be written as

$$\boldsymbol{K'}_{\boldsymbol{\beta}} = \begin{bmatrix} \boldsymbol{K}(\tilde{\boldsymbol{K}}_{s,s+t}, \tilde{\boldsymbol{K}}_{s,s+t}) & \boldsymbol{K}(\tilde{\boldsymbol{K}}_{s,s+t}, \tilde{\boldsymbol{K}}_{t,s+t}) \\ \boldsymbol{K}(\tilde{\boldsymbol{K}}_{t,s+t}, \tilde{\boldsymbol{K}}_{s,s+t}) & \boldsymbol{K}(\tilde{\boldsymbol{K}}_{t,s+t}, \tilde{\boldsymbol{K}}_{t,s+t}) \end{bmatrix} \; ,$$

and we defined a new variable $\boldsymbol{\beta} = \boldsymbol{K}^{1/2}\boldsymbol{\alpha}$. This new variable $\boldsymbol{\beta}$ can be represented as a point on a Grassmann manifold. Therefore, it allows us to make use of the same conjugate gradient method on the manifold as before. The original variable $\boldsymbol{\alpha}$ can then be obtained as $\boldsymbol{\alpha} = \boldsymbol{K}^{-1/2}\boldsymbol{\beta}$.

4.2 NL-DME with the Hellinger Distance (NL-DME-H)

Similarly, from the definition of our nonlinear mapping, the Hellinger distance can be written as

$$\begin{aligned}
\hat{D}^2_H(\boldsymbol{W}^T\varphi(\boldsymbol{X_s}), \boldsymbol{W}^T\varphi(\boldsymbol{X_t})) &= \\
&\frac{1}{n}\sum_{i=1}^{n}\left(\sqrt{\hat{T}(\boldsymbol{\alpha}^T\varphi(\boldsymbol{X_{s+t}})^T\varphi(x_i^s))} - \sqrt{1-\hat{T}(\boldsymbol{\alpha}^T\varphi(\boldsymbol{X_{s+t}})^T\varphi(x_i^s))}\right)^2 \\
&+ \frac{1}{m}\sum_{i=1}^{m}\left(\sqrt{\hat{T}(\boldsymbol{\alpha}^T\varphi(\boldsymbol{X_{s+t}})^T\varphi(x_i^t))} - \sqrt{1-\hat{T}(\boldsymbol{\alpha}^T\varphi(\boldsymbol{X_{s+t}})^T\varphi(x_i^t))}\right)^2 \; .
\end{aligned} \tag{26}$$

Using KDE, the distribution of the source data in the latent space can then be expressed as

$$\hat{s}(\boldsymbol{W}^T\varphi(\boldsymbol{x})) = \frac{1}{n}\sum_{j=1}^{n}\frac{1}{\sqrt{|2\pi\boldsymbol{H}|}}\exp\left(-\frac{(\tilde{k}(\boldsymbol{X_{s+t}},\boldsymbol{x}) - \tilde{k}(\boldsymbol{X_{s+t}},\boldsymbol{x}_j^s))^T\boldsymbol{\alpha}\boldsymbol{H}^{-1}\boldsymbol{\alpha}^T(\tilde{k}(\boldsymbol{X_{s+t}},x) - \tilde{k}(\boldsymbol{X_{s+t}},\boldsymbol{x}_j^s))}{2}\right) \; , \tag{27}$$

and similarly for the target distribution. Note that, here again, this only depends on kernel values.

This lets us write NL-DME-H as the optimization problem

$$\begin{aligned}
\boldsymbol{\alpha}^* &= \min_{\boldsymbol{\alpha}} \; \hat{D}^2_H(\boldsymbol{\alpha}^T\varphi(\boldsymbol{X_{s+t}})^T\varphi(\boldsymbol{X_s}), \boldsymbol{\alpha}^T\varphi(\boldsymbol{X_{s+t}})^T\varphi(\boldsymbol{X_t})) \\
&\text{s.t.} \quad \boldsymbol{\alpha}^T\boldsymbol{K}\boldsymbol{\alpha} = \boldsymbol{I} \; .
\end{aligned} \tag{28}$$

As with the MMD, this problem can be re-written in terms of a new variable $\boldsymbol{\beta} = \boldsymbol{K}^{1/2}\boldsymbol{\alpha}$, and solved using a conjugate gradient method on the Grassmann manifold.

5. Related Work

We now discuss the domain adaptation methods that are most related to our approach. In particular, we focus on sample selection, or re-weighting, techniques and subspace-based methods.

Similarly to our approach, sample selection methods focus on comparing the distributions of the source and target data. In particular, in (Huang et al., 2006; Gretton et al., 2009), the source examples are re-weighted so as to minimize the MMD between the source and target distributions. More recently, an approach to selecting landmarks among the source examples based on the MMD was introduced (Gong et al., 2013). This sample selection approach was shown to be very effective, especially for the task of visual object recognition, to the point that it outperforms state-of-the-art semi-supervised approaches. Despite their success, it is important to note that sample re-weighting and selection methods compare the source and target distributions directly in the original feature space. More precisely, these techniques place a weight outside the mapping to Hilbert space $\phi(\cdot)$ performed in the MMD. Unfortunately, the original feature space may not be well-suited to compare the distributions, since the features may have been distorted by the domain shift, and since some of the features may only be relevant to one specific domain. By contrast, in this work, we compare the source and target distributions in a low-dimensional latent space where these effects are removed, or reduced.

Several techniques have also proposed to rely on subspaces to address the problem of domain adaptation. A popular approach in this class of methods differs significantly from our work in that, instead of learning a projection of the data, it seeks to directly represent the data with multiple subspaces (Blitzer et al., 2011; Gopalan et al., 2011; Gong et al., 2012). In particular, in (Blitzer et al., 2011), coupled subspaces are learned using Canonical Correlation Analysis (CCA). Rather than limiting the representation to one source and one target subspaces, several techniques exploit intermediate subspaces, which link the source data to the target data. This idea was originally introduced in (Gopalan et al., 2011), where the subspaces were modeled as points on a Grassmann manifold, and intermediate subspaces were obtained by sampling points along the geodesic between the source and target subspaces. This method was extended in (Gong et al., 2012), which showed that all intermediate subspaces could be taken into account by integrating along the geodesic. While this formulation nicely characterizes the change between the source and target data, it is not clear why all the subspaces along this path should yield meaningful representations. More importantly, these subspace-based methods do not explicitly exploit the statistical properties of the data.

By contrast, and similarly to our goal, a few methods have proposed to learn linear transformations of the data by considering the distributions of the different domains (Pan et al., 2011; Muandet et al., 2013). In particular, Transfer Component Analysis (TCA) (Pan et al., 2011) makes use of an MMD-based criterion to learn a subspace. However, in TCA, the linear transformation is applied outside the mapping to Hilbert space $\phi(\cdot)$ performed by the MMD. In other words, the distance between the sample means is measured in a lower-dimensional space rather than in RKHS, which somewhat contradicts the intuition behind the use of kernels. Domain-Invariant Component Analysis (DICA) (Muandet et al., 2013) is closely related to TCA in the sense that it is a kernel-based optimization algorithm that learns an invariant transformation of the data by minimizing the dissimilarity across domains. Moreover, it preserves the functional relationship between input and output variables based on the assumption that the functional relationship is stable or varies smoothly across domains.

Importantly, while the above-mentioned approaches have indeed also followed the idea of comparing distributions, they are all confined to using the MMD. In our experiments, we will show that in many cases the Hellinger distance yields better performance. Furthermore, to the best of our knowledge, no existing method has proposed to learn a nonlinear transformation of the data to account for the domain shift. As evidenced by our results, this again can yield to significant gains in accuracy.

6. Experiments

We evaluated our approach on the tasks of visual object recognition, cross-domain text categorization, and cross-domain WiFi localization, and compare its performance against the state-of-the art methods in each task.

In all our experiments, we used the subspace disagreement measure of (Gong et al., 2012) to automatically determine the dimensionality of the projection matrix $\boldsymbol{W}$. This method can be summarized as follows: We extracted PCA subspaces for the source data, the target data, and their combination. Intuitively, the similarity of the source and target domains should be directly proportional to the distance between these three subspaces on the Grassmann manifold. Therefore, the dimensionality d is taken as the one minimizing the sum of the minimum correlation distances (Hamm and Lee, 2008) between the source and combination subspaces and the target and combination subspaces, respectively. The same dimensionality was used for all dimensionality-reduction-based methods, which makes the comparison fair, since the dimensionality was not tuned for our approach either.

For recognition, we employed either a kernel SVM classifier with a degree 2 polynomial kernel, or a linear SVM classifier. These classifiers were trained on the projected source samples. The same types of classifiers were trained for all the baselines that do not inherently include a classifier (i.e., all the baselines except SVMA and DAM). The only parameter of such classifiers is the regularizer weight C. For each method, we tested with $C \in \{10^{-5}, 10^{-3}, 10^{-2}, 10^{-1}, 10^{0}, 10^{1}, 10^{2}\}$, and report the best result. Note that the parameters for SVMA, DAM and KMM were chosen using the code provided by the authors of these methods.

As mentioned earlier, the two hyperparameters of our approach were set as follows: The bandwidth of the Gaussian RBF kernel used in MMD was taken as the median distance computed over all pairwise data points; the value σ_s, such that $\boldsymbol{H}_s = \sigma_s \boldsymbol{I}$ in Eq. 15, was computed using the maximal smoothing principle (Terrell, 1990) .

6.1 Visual Object Recognition

We first evaluated our approach on the task of visual object recognition using the benchmark domain adaptation data set introduced in (Saenko et al., 2010). This data set contains images from four different domains: Amazon, DSLR, Webcam, and Caltech. The Amazon domain consists of images acquired in a highly-controlled environment with studio lighting conditions. These images capture the large intra-class variations of 31 classes, but typically show the objects only from one canonical viewpoint. The DSLR domain consists of high resolution images of 31 categories that were taken with a digital SLR camera in a home environment under natural lighting. The Webcam images were acquired in a similar environment as the DSLR ones, but have much lower resolution and contain significant noise, as well as color and white balance artifacts. The last domain, Caltech (Griffin et al., 2007), consists of images of 256 object classes downloaded from Google images. Following (Gong

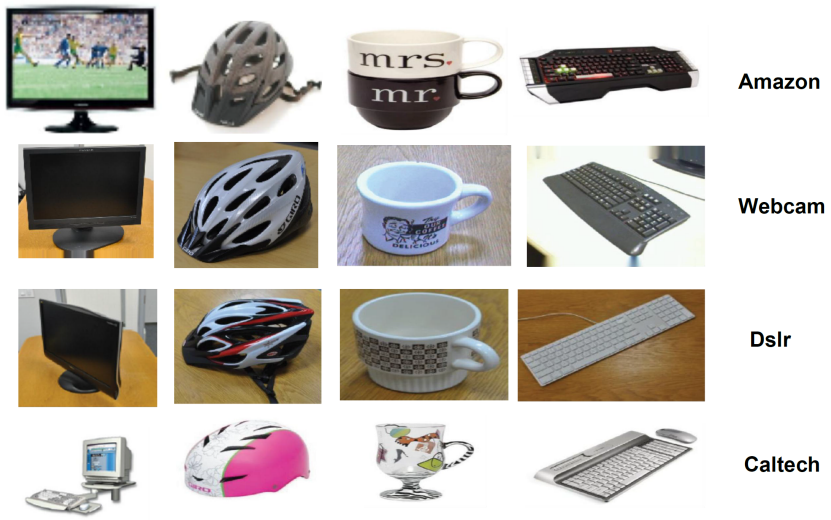

Figure 3: Sample images from the object categories ***monitor***, ***helmet***, ***mug*** and ***keyboard*** *in the four domains* ***Amazon***, ***Webcam***, ***DSLR***, *and* ***Caltech***.

et al., 2012), we used the 10 object classes common to all four data sets. This yields 2533 images in total, with 8 to 151 images per category and per domain. Fig. 3 depicts sample images from the four domains.

For our evaluation, we used two different types of image features. First, we employed the features provided by (Gong et al., 2012), which were obtained using the protocol described in (Saenko et al., 2010). More specifically, all images were converted to grayscale and resized to have the same width. Local scale-invariant interest points were detected by the SURF detector (Bay et al., 2006), and a 64-dimensional rotation invariant SURF descriptor was extracted from the image patch around each interest point. A codebook of size 800 was then generated from a subset of the Amazon data set using k-means clustering on the SURF descriptors. The final feature vector for each image is the normalized histogram of visual words obtained from this codebook. As a second feature type, we used the deep learning features of (Donahue et al., 2014) which have shown promising results for object recognition. Specifically, as visual features, we used the outputs derived from the activation of the 6th, 7th, and 8th layers of a deep convolutional network (CNN) with weights trained on the ImageNet data set (Deng et al., 2009), leading to 4096-dimensional $DeCAF_6$ and $DeCAF_7$ features, as well as 1000-dimensional $DeCAF_8$ features (Tommasi and Tuytelaars, 2014).

We used the conventional evaluation protocol introduced in (Saenko et al., 2010), which consists of splitting the data into multiple partitions. For each source/target pair, we report the average recognition accuracy and standard deviation over the 20 partitions provided with GFK[1]. With this protocol, we evaluated all possible combinations of source and target domains. For all the methods based on dimensionality reduction, we used the dimensionalities provided in the GFK code (i.e.,

Table 2: Recognition accuracies on the remaining 6 pairs of source/target domains using the evaluation protocol of (Saenko et al., 2010) and using SURF features with Kernel SVM. C**: Caltech,** A**: Amazon,** W**: Webcam,** D**: DSLR**. As shown by the average accuracy over all pairs in the last columns, our approach clearly outperforms the baselines, with best performance for NL-DME-H.

W-D: 10, D-A: 20, W-A: 10, C-W: 20, C-D: 10, C-A: 20. Note that the dimensionality for X-Y is the same as for Y-X).

For the kernel SVM classifier, we report the results of our algorithms and several baselines on all source and target pairs in Tables 1 and 2 for the SURF features, in Tables 3 and 4 for the DeCAF6 features, in Tables 5 and 6 for the DeCAF7 features, and in Tables 7 and 8 for the DeCAF8 features. Similar results using a linear SVM classifier are provided in Tables 9 to 16. In the last column of every other table, we report the average accuracy over all the source-target pairs. Note that, with SURF features, all our algorithms clearly outperform the baselines, with the best average accuracy

Table 4: Recognition accuracies on the remaining 6 pairs of source/target domains using the evaluation protocol of (Saenko et al., 2010) and using Decaf6 features with Kernel SVM. C**: Caltech,** A**: Amazon,** W**: Webcam,** D**: DSLR**. As shown by the average accuracy over all pairs in the last columns, NL-DME-H still yields the best accuracy.

achieved by NL-DME-H. To the best of our knowledge, this represents the state-of-the-art result on this data. With deep learning features, our algorithms yield accuracies that are on par with the state-of-the-art results. Note that, among our algorithms, the best results are achieved using Decaf7 features with NL-DME-H. In Fig. 4, we illustrate the behavior of our algorithms on the *mug* class. As shown in the bottom-right panel, even humans would have a hard time to correctly label some of the misclassified examples.

We then further compare the results of our approach and the previous baselines with two recent deep learning DA methods, Deep Domain Confusion (DDC) (Tzeng et al., 2014) and Reverse Gradient (RG) (Ganin and Lempitsky, 2015). Table 17 was computed from the Office-Caltech data set with 10 classes, as in the previous experiments. In this setting, only the results of DDC for 6 pairs

were available. Note that our approach yields slightly better accuracies than DDC. In Table 18, we compare our results with both deep learning baselines using the 31 classes of the original Office data set, and for the 3 pairs that were reported in (Ganin and Lempitsky, 2015). Note that, here, while our approach is among the top performer non-deep-learning methods, the two works that jointly learn the features and perform domain adaptation tend to perform better. This suggests an interesting avenue for future research by incorporating our Hellinger-based metric within a deep learning framework.

6.2 Cross-domain Text Categorization

As a second type of experiment, we made use of the 20 Newsgroups data set, which has become popular in the machine learning community to evaluate methods tackling problems such as text classification and text clustering. The 20 Newsgroups data set is a collection of 18,774 newsgroup documents organized in a hierarchical structure of six main categories and 20 subcategories, each corresponding to a different topic. Some of the newsgroups (from the same category) are very closely related to each other (e.g., comp.sys.ibm.pc.hardware / comp.sys.mac.hardware), while others are highly unrelated (e.g., misc.forsale / soc.religion.christian), making this data set well-suited to evaluate cross-domain learning algorithms.

For this experiment, we used the protocol of (Duan et al., 2012): The four largest main categories (comp, rec, sci, and talk) were chosen for evaluation. Specifically, for each main category, the largest

Table 10: Recognition accuracies on the remaining 6 pairs of source/target domains using the evaluation protocol of (Saenko et al., 2010) and using SURF features with Linear SVM. C**: Caltech,** A**: Amazon,** W**: Webcam,** D**: DSLR**. As shown by the average accuracy over all pairs in the last columns, our approach outperforms the baselines, with best performance for NL-DME-H.

subcategory was selected as the target domain. We considered the largest category "comp" as the positive class and one of the three other categories as the negative class for each setting. Table 19 provides detailed information about the three settings. We used word-frequency features to represent each document. To construct the training set, we used 1000 randomly selected samples (evenly distributed positive and negative samples) from the source domain, and repeated this procedure 5 times. For each such partition, our mappings were then learned using this training data and the unlabeled samples from the target domain.

In Table 20, we report the mean recognition accuracies of our algorithms and of state-of-the-art baselines. For all the baselines, we employed a kernel SVM classifier with a degree 2 polynomial kernel, we tested with the regularizer weight $C \in \{10^{-5}, 10^{-3}, 10^{-2}, 10^{-1}, 10^{0}, 10^{1}, 10^{2}\}$, and report the best result. For all the baselines based on dimensionality reduction, we set the dimen-

different access points. The different domains represent two different time periods during which the collected RSS values may have different distributions. The data set contains 621 labeled examples collected during time period A (i.e., the source) and 3128 unlabeled examples collected during time period B (i.e., the target). We followed the transductive setting of Pan et al. (2011), which uses all the samples from the source and 400 random samples from the target.

In this case, we report the mean Average Error Distance (AED) over 10 random selections of target samples. The AED is computed as $AED = \frac{\sum_i l(\boldsymbol{x}_i) - y_i}{N}$, where $\boldsymbol{x}_i$ is a vector of RSS values, $l(\boldsymbol{x}_i)$ is the predicted location and y_i the corresponding ground-truth location. Note that, here, all results were obtained with a nearest-neighbor classifier to follow the procedure of (Pan et al., 2011). Fig. 5 depicts the accuracy as a function of the dimensionality of the learned subspace for several

subspace-based methods. As before, NL-DME-H yields the best average accuracy of all methods. Note that all our algorithms are quite robust to the choice of subspace dimension.

7. Conclusion and Future Work

In this paper, we have introduced an approach to unsupervised domain adaptation that focuses on extracting a domain-invariant representation of the source and target data. To this end, we have proposed to match the source and target distributions in a low-dimensional latent space, rather than in the original feature space. In particular, we have studied two different metrics to compare the distributions and have introduced linear and nonlinear techniques to map the data to latent spaces. Our experiments have evidenced the importance of exploiting distribution invariance for domain adaptation by revealing that our algorithms yield state-of-the-art results on several problems, with best

performance achieved by NL-DME-H. A current limitation of our approach is the non-convexity of the optimization problems. Although, in practice, optimization on the Grassmann manifold has proven well-behaved, we intend to study if the use of other characteristic kernels in conjunction with different optimization strategies, such as the convex-concave procedure, could yield theoretical convergence guarantees within our formalism. Finally, we also plan to study the performance of other metrics, such as the KL-divergence and the Bhattacharyya distance, to compare the source and target distributions.

Abstract

Real-world machine learning applications may have requirements beyond accuracy, such as fast evaluation times and interpretability. In particular, guaranteed monotonicity of the learned function with respect to some of the inputs can be critical for user confidence. We propose meeting these goals for low-dimensional machine learning problems by learning flexible, monotonic functions using calibrated interpolated look-up tables. We extend the structural risk minimization framework of lattice regression to monotonic functions by adding linear inequality constraints. In addition, we propose jointly learning interpretable calibrations of each feature to normalize continuous features and handle categorical or missing data, at the cost of making the objective non-convex. We address large-scale learning through parallelization, mini-batching, and random sampling of additive regularizer terms. Case studies on real-world problems with up to sixteen features and up to hundreds of millions of training samples demonstrate the proposed monotonic functions can achieve state-of-the-art accuracy in practice while providing greater transparency to users.

Keywords: interpretability, interpolation, look-up tables, monotonicity

1. Introduction

Many challenging issues arise when making machine learning useful in practice. Evaluation of the trained model may need to be fast. Features may be categorical, missing, or poorly calibrated. A blackbox model may be unacceptable: users may require guarantees that the function will behave sensibly for all samples, and prefer functions that are easier to understand and debug. In this paper we address these practical issues, without trading-off for accuracy.

We have found that a key interpretability issue in practice is whether the learned model can be guaranteed to be *monotonic* with respect to some features. For example, suppose the goal is to estimate the value of a used car, and one of the features is the number of km it has been driven. If all the other feature values are held fixed, we expect the value of the used car to never increase as the number of km driven increases. But a model learned from a small set of noisy samples may not, in fact, respect this prior knowledge.

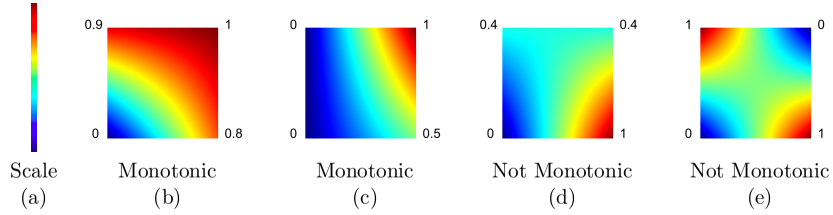

Figure 1: Example 2×2 interpolated look-up table functions over a unit square, with color scale shown in (a). Each function is defined by a 2×2 lattice with four parameters, which are the values of the function in the four corners (shown). The function is linearly interpolated from its parameters (see Figure 2 for a pictorial description of linear interpolation). The function in (b) is strictly monotonically increasing in both features, which can be verified by checking that each upper parameter is larger than the parameter below it, and that each parameter on the right is larger than the parameter to its left. The function in (c) is strictly monotonically increasing in the first feature, and monotonically increasing in the second feature (but not strictly so since the parameters on the left are both zero). The function in (d) is monotonically increasing in the first feature (one verifies this by noting that $1 \geq 0$ and $0.4 \geq 0.4$), but non-monotonic in the second feature: on the left side the function increases from $0 \rightarrow 0.4$, but on the right side the function decreases from $1 \rightarrow 0.4$. The function in (e) is a saddle function interpolating an exclusive-OR, and is non-monotonic in both features.

In this paper, we propose learning monotonic, efficient, and flexible functions by constraining and calibrating interpolated look-up tables in a structural risk minimization framework. Learning monotonic functions is difficult, and previously published work has only been illustrated on small problems (see Table 1). Our experimental results demonstrate learning flexible, guaranteed monotonic functions on more features and data than prior work, and that these functions achieve state-of-the-art performance on real-world problems.

The parameters of an interpolated look-up table are simply values of the function, regularly spaced in the input space, and these values are interpolated to compute $f(x)$ for any x. See Figures 1 and 2 for examples of 2×2 and 2×3 look-up tables and the functions produced by interpolating them. Each parameter has a clear meaning: it is the value of the function for a particular input, for a set of inputs on a regular grid. These parameters can be individually read and checked to understand the learned function's behavior.

Interpolating look-up tables is a classic strategy for representing low-dimensional functions. For example, backs of old textbooks have pages of look-up tables for one-dimensional functions like $sin(x)$, and interpolating look-up tables is standardized by the ICC Profile for the three and four dimensional nonlinear transformations needed to color manage printers (Sharma and Bala, 2002). In this paper we interpolate look-up tables defined over much

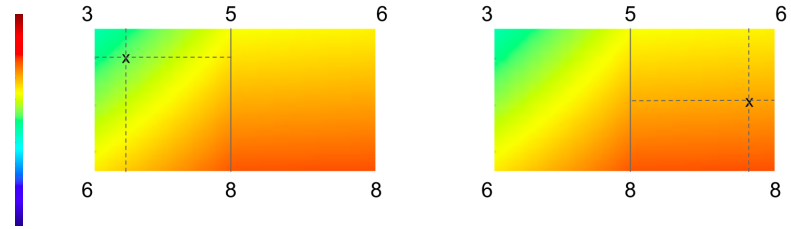

Figure 2: Figure illustrates a 3×2 lattice function and multilinear interpolation, with color scale given by (a) and parameters as shown. The lattice function shown is continuous everywhere, and differentiable everywhere except at the boundary between lattice cells, which is the vertical edge joining the middle parameters 5 and 8. As shown in (b), to evaluate $f(x)$, any x that falls in the left cell of the lattice is linearly interpolated from the parameters at the vertices of the left cell, here 6, 3, 5 and 8. Linear interpolation is linear not in x but in the lattice parameters, that is $f(x)$ is a weighted combination of the parameter values 6, 3, 5, and 8. The weights on the parameters are the areas of the four boxes formed by the dotted lines drawn orthogonally through x, with each parameter weighted by the area of the box farthest from it, so that as x moves closer to a parameter the weight on that parameter gets bigger. Because the dotted lines partition a unit square cell, the sum of these linear interpolation weights is always one. As shown in (c), samples like the marked x that fall in the right cell of the lattice are interpolated from that cell's parameters: 8, 5, 6 and 8.

larger feature spaces. Using an efficient linear interpolation method we refer to as *simplex interpolation*, the interpolation of a D-dimensional look-up table can be computed in $O(D \log D)$ time. For example, we found that interpolating a look-up table defined over $D = 20$ features takes only 2 microseconds on a standard CPU. The number of parameters in the look-up table scales as 2^D, which limits the size of D, but still enables us to learn higher-dimensional flexible monotonic functions than ever before.

Estimating the parameters of an interpolated look-up table using structural risk minimization was proposed by Garcia and Gupta (2009) and called *lattice regression*. Lattice regression can be viewed as a kernel method that uses the explicit nonlinear feature transformation formed by mapping an input $x \in [0, 1]^D$ to a vector of linear interpolation weights $\phi(x) \in \Delta^{2^D}$ over the 2^D vertices of the look-up table cell that contains x, where Δ denotes the standard simplex. Then the function is linear in these transformed features: $f(x) = \theta^T \phi(x)$. We will refer to the look-up table parameters θ as the *lattice*, and to the interpolated look-up table $f(x)$ as the *lattice function*. Earlier work in lattice regression focused on learning highly nonlinear functions over 2 to 4 features with fine-grained lattices, such as a $17 \times 17 \times 17$ lattice for modeling a color printer or super-resolution of spherical

images (Garcia et al., 2010, 2012). In this paper, we apply lattice regression to more generic machine learning problems with $D = 5$ to 16 features, and show that 2^D lattices work well for many real-world classification and ranking problems, especially when paired with jointly trained one-dimensional pre-processing functions.

We begin with a survey of related work in machine learning of interpretable and monotonic functions. Then we review lattice regression in Section 3. The main contribution is learning monotonic lattices in Section 4. We discuss efficient linear interpolation in Section 5. We propose an interpretable torsion lattice regularizer in Section 6. We propose jointly learning one-dimensional calibration functions in Section 7, and consider two strategies for supervised handling of missing data for lattice regression in Section 8. In Section 9, we consider strategies for speeding up training and handling large-scale problems and large-scale constraint-handling. A series of case studies in Section 10 experimentally explore the paper's proposals, and demonstrate that monotonic lattice regression achieves similar accuracy as a random forest, and that monotonicity is a common issue that arises in many different applications. The paper ends with conclusions and open questions in Section 11.

2. Related Work

We give a brief overview of related work in interpretable machine learning, then survey related work in learning monotonic functions.

2.1 Related Work in Interpretable Machine Learning

Two key themes of the prior work on interpretable machine learning are *(i)* interpretable function classes, and *(ii)* preferring simpler functions within a function class.

2.1.1 Interpretable Function Classes

The function classes of decision trees and rules are generally regarded as relatively interpretable. Naïve Bayes classifiers can be interpreted in terms of weights of evidence (Good, 1965; Spiegelhalter and Knill-Jones, 1984). Similarly, linear models form an interpretable function class in that the parameters dictate the relative importance of each feature. Linear approaches can be generalized to sum nonlinear components, as in generalized additive models (Hastie and Tibshirani, 1990) and some kernel methods, while still retaining some of their interpretable aspects.

The function class of interpolated look-up tables is interpretable in that the function's parameters are the look-up table values, and so are semantically meaningful: they are simply examples of the function's output, regularly spaced in the domain. Given two look-up tables with the same structure and the same features, one can analyze how their functions differ by analyzing how the look-up table parameters differ. Analyzing which parameters change by how much can help answer questions like "If I add training examples and re-train, what changes about the model?"

2.1.2 Prefer Simpler Functions

Another body of work focuses on choosing simpler functions within a function class, optimizing an objective of the form: minimize empirical error and maximize simplicity, where

simplicity is usually defined as some manifestation of Occam's Razor or variant of Kolmogorov complexity. For example, Ishibuchi and Nojima (2007) minimize the number of fuzzy rules in a rule set, Osei-Bryson (2007) prunes a decision tree for interpretability, Rätsch et al. (2006) finds a sparse convex combination of kernels for a multi-kernel support vector machine, and Nock (2002) prefers smaller committees of ensemble classifiers. Similarly, Garcia et al. (2009) measure the interpretability of rule-based classifiers in terms of the number of rules and number of features used. More generally, this category of interpretability includes model selection criteria like the Bayesian information criterion and Akaike information criterion (Hastie et al., 2001), sparsity regularizers like sparse linear regression models, and feature selection methods. Other approaches to simplicity may include simplified structure in graphical models or neural nets, such as the structured neural nets of Strannegaard (2012).

While sparsity-based approaches to interpretability can provide regularization that reduces over-fitting and hence increases accuracy, it has also been noted that such strategies may create a trade-off between interpretability and accuracy (Casillas et al., 2002; Nock, 2002; Yu and Xiao, 2012; Shukla and Tripathi, 2012). We hypothesize this occurs when the assumed simpler structure is a poor model of the true function.

Monotonicity is another way to choose a semantically simpler function to increase interpretability (and regularize). Our case studies in Section 10 illustrate that when applied to problems where monotonicity is warranted true, we do not see a trade-off with accuracy.

2.2 Related Work in Monotonic Functions

A function $f(x)$ is monotonically increasing with respect to feature d if $f(x_i) \geq f(x_j)$ for any two feature vectors $x_i, x_j \in \mathbb{R}^D$ where $x_i[d] \geq x_j[d]$ and $x_i[m] = x_j[m]$ for $m \neq d$.

A number of approaches have been proposed for enforcing and encouraging monotonicity in machine learning. The computational complexity of these algorthims tends to be high, and most methods scale poorly in the number of features D and samples n, as summarized in Table 1.

We detail the related work in the following sections organized by the type of machine learning, but these methods could instead be organized by strategy, which mostly falls into one of four categories:

1. Constrain a more flexible function class to be monotonic, such as linear functions with positive coefficients, or a sigmoidal neural network with positive weights.
2. Post-process by pruning or reducing monotonicity violations after training.
3. Penalize monotonicity violations by pairs of samples or sample derivatives when training.
4. Re-label samples to be monotonic before training.

2.2.1 Monotonic Linear and Polynomial Functions

Linear functions can be easily constrained to be monotonic in certain inputs by requiring the corresponding slope coefficients to be non-negative, but linear functions are not sufficiently flexible for many problems. Polynomial functions (equivalently, linear functions with pre-defined crosses of features) can also be easily forced to be monotonic by requiring all coefficients to be positive. However, this is only a sufficient and not necessary condition: there are monotonic polynomials whose coefficients are not all positive. For example, consider the simple case of second degree multilinear polynomials defined over the unit square $f : [0, 1]^2 \to \mathbb{R}$ such that:

$$f(x) = a_0 + a_1 x[0] + a_2 x[1] + a_3 x[0]x[1]. \tag{1}$$

Restricting the function to a bounded domain the domain $x \in [0, 1]^2$ and forcing the derivative to be positive over that domain, one sees that the complete set of monotonic functions of the form (1) on the unit square is described by four linear inequalities:

$$\begin{array}{ll} a_1 > 0 & a_2 > 0 \\ a_1 + a_3 > 0 & a_2 + a_3 > 0. \end{array}$$

The general problem of checking whether a particular choice of polynomial coefficients produces a monotonic function requires checking whether the polynomial's derivative (also a polynomial) is positive everywhere, which is equivalent to checking if the derivative has any real roots, which can be computationally challenging (see, for example, Sturm's theorem for details).

Functions of the form (1) can be equivalently expressed as a 2×2 lattice interpolated with multilinear interpolation, but as we will show in Section 4, with this alternate parameterization it is easier to check and enforce the complete set of monotonic functions.

2.2.2 Monotonic Splines

In this paper we extend lattice regression, which is a spline method with fixed knots on a regular grid and a linear kernel (Garcia et al., 2012), to be monotonic. There have been a number of proposals to learn monotonic one-dimensional splines. For example, building on Ramsay (1998), Shively et al. (2009) parameterize the set of all smooth and strictly monotonic one-dimensional functions using an integrated exponential form $f(x) = a + \int_0^x e^{b+u(t)}dt$, and showed better performance than the monotone functions estimators of Neelon and Dunson (2004) and Holmes and Heard (2003) for smooth functions. In other related spline work, Villalobos and Wahba (1987) considered smoothing splines with linear inequality constraints, but did not address monotonicity.

2.2.3 Monotonic Decision Trees and Forests:

Stumps and forests of stumps are easily constrained to be monotonic. However, for deeper or broader trees, all pairs of leaves must be checked to verify monotonicity (Potharst and Feelders, 2002b). Non-monotonic trees can be pruned to be monotonic using various strategies that iteratively reduce the non-monotonic branches (Ben-David, 1992; Potharst and Feelders, 2002b). Monontonicity can also be encouraged during tree construction by penalizing the splitting criterion to reduce the number of non-monotonic leaves a split would create (Ben-David, 1995). Potharst and Feelders (2002a) achieved completely flexible monotonic trees using a strategy akin to bogosort (Gruber et al., 2007): train many trees on different random subsets of the training samples, then select one that is monotonic.

	Method	Monotonicity Strategy	Guaranteed Monotonic?	Max D	Max n
Archer and Wang (1993)	neural net	constrain function	yes	2	50

Neumann et al. (2013)	neural net	sample derivatives	no	3	625

Table 1: Some related work in learning monotonic functions. Many of these methods *guarantee* a monotonic solution, but some only *encourage* monotonicity. The last two columns gives the largest number of features D and the largest number of samples n used in any of the experiments in that paper (generally not the same experiment).

2.2.4 Monotonic Support Vector Machines

With a linear kernel, it may be easy to check and enforce monotonicity of support vector machines, but for nonlinear kernels it will be more challenging. Lauer and Bloch (2008) encouraged support vector machines to be more monotonic by constraining the derivative of the function at the training samples. Riihimäki and Vehtari (2010) used the same strategy to encourage more monotonic Gaussian processes.

2.2.5 Monotonic Neural Networks

In perhaps the earliest work on monotonic neural networks, Archer and Wang (1993) adaptively down-weighted samples during training whose gradient updates would violate monotonicity, to produce a positive weighted neural net. Other researchers explicitly proposed constraining the weights to be positive in a single hidden-layer neural network with the sigmoid or other monotonic nonlinear transformation (Wang, 1994; Kay and Ungar, 2000; Dugas et al., 2000, 2009; Minin et al., 2010). Dugas et al. (2009) showed with simulations of four features and 400 training samples that both bias and variance were reduced by enforcing monotonicity. However, Daniels and Velikova (2010) showed this approach requires D hidden layers to arbitrarily approximate any D-dimensional monotonic function. In addition to a general proof, they provide a simple and realistic example of a two-dimensional monotonic function that cannot be fit with one hidden layer and positive weights.

Abu-Mostafa (1993) and Sill and Abu-Mostafa (1997) proposed regularizing a function to be more monotonic by penalizing squared deviations in monotonicity for virtual pairs of input samples that are added for this purpose. Unfortunately, it generally does not guarantee monotonicity everywhere, only with respect to those virtual input pairs. (And in fact, to guarantee monotonicity for the sampled pairs, an exact penalty function would be needed with a sufficiently large regularization parameter to ensure the regularization was equivalent to a constraint).

Lauer and Bloch (2008), Riihimäki and Vehtari (2010), and Neumann et al. (2013) encouraged *extreme learning machines* to be more monotonic by constraining the derivative of the function to be positive for a set of sampled points.

Qu and Hu (2011) did a small-scale comparison of encouraging monotonicity by constraining input pairs to be monotonic, versus encouraging monotonic neural nets by constraining the function's derivatives at a subset of samples (analogous to Lauer and Bloch (2008)), versus using a sigmoidal function with positive weights. They concluded the positive-weight sigmoidal function is best.

Sill (1998) proposed a guaranteed monotonic neural network with two hidden layers by requiring the first linear layer's weights to be positive, using hidden nodes that take the maximum of groups of first layer variables, and a second hidden layer that takes the minimum of the maxima. The resulting surface is piecewise linear, and as such can represent any continuous differentiable function arbitrarily well. The resulting objective function is not strictly convex, but the authors propose training such monotonic networks using gradient descent where samples are associated with one active hyperplane at each iteration. Daniels and Velikova (2010) generalized this approach to handle the "partially monotonic" case that the function is only monotonic with respect to some features.

2.2.6 Isotonic Regression and Monotonic Nearest Neighbors

Isotonic regression re-labels the input samples with values that are monotonic and close to the original labels. These monotonically re-labeled samples can then be used, for example, to define a monotonic piecewise constant or piecewise linear surface. This is an old approach; see Barlow et al. (1972) for an early survey. Isotonic regression can be solved in $O(n)$ time if monotonicity implies a total ordering of the n samples. But for usual multi-dimensional machine learning problems, monotonicity implies only a partial order, and solving the n-parameter quadratic program is generally $O(n^4)$, and $O(n^3)$ for two-dimensional samples (Spouge et al., 2003). Also problematic for large n is the $O(n)$ evaluation time for new samples.

Mukarjee and Stern (1994) proposed a suboptimal monotonic kernel regression that is computationally easier to train than isotonic regression. It computes a standard kernel estimate, then locally upper and lower bounds it to enforce monotonicity.

The *isotonic separation* method of Chandrasekaran et al. (2005) is like the work of Abu-Mostafa (1993) in that it penalizes violations of monotonicity by pairs of training samples. Like isotonic regression, the output is a re-labeling of the original samples, the solution is at least $O(n^3)$ in the general case, and evaluation time is $O(n)$.

Ben-David et al. (1989); Ben-David (1992) constructed a monotonic rule-based classifier by sequentially adding training examples (each of which defines a rule) that do not violate monotonicity restrictions.

Duivesteijn and Feelders (2008) proposed re-labeling samples before applying nearest neighbors based on a monotonicity violation graph with the training examples at the vertices. Coupled with a proposed modified version of k-NN, they can enforce monotonic outputs. Similar pre-processing of samples can be used to encourage any subsequently trained classifier to be more monotonic (Feelders, 2010).

Similarly, Kotlowski and Slowinski (2009) try to solve the isotonic regression problem to re-label the dataset to be monotonic, then fit a monotonic ensemble of rules to the re-labeled data, requiring zero training error. They showed overall better performance than the ordinal learning model of Ben-David et al. (1989) and isotonic separation (Chandrasekaran et al., 2005).

3. Review of Lattice Regression

Before proposing *monotonic* lattice regression, we review lattice regression (Garcia and Gupta, 2009; Garcia et al., 2012). Key notation is listed in Table 2.

Let $M_d \in \mathbb{N}$ be a hyperparameter specifying the number of vertices in the look-up table (that is, lattice) for the dth feature. Then the lattice is a regular grid of $M \triangleq M_1 \times M_2 \times \ldots M_D$ parameters placed at natural numbers so that the lattice spans the hyper-rectangle $\mathcal{M} \triangleq [0, M_1 - 1] \times [0, M_2 - 1] \times \ldots [0, M_D - 1]$. See Figure 1 for examples of 2×2 lattices, and Figure 2 for an example 3×2 lattice. For machine learning problems we find $M_d = 2$ for all d to often work well in practice, as detailed in the case studies in Section 10. For image processing applications with only two to four features, much larger values of M_d were needed (Garcia et al., 2012).

D	number of features
n	number of samples
$M_d \in \mathbb{N}$	number of vertices in the lattice along the dth feature
$M \in \mathbb{N}$	total number of vertices in the lattice: $M = \prod_d M_d$
$\mathcal{M}$	hyper-rectangular span of the lattice: $[0, M_1 - 1] \times \ldots \times [0, M_D - 1]$
x_i	ith training sample with D components. Domain depends on section.
$y_i \in \mathbb{R}$	ith training sample label
$x[d]$	dth component of feature vector x
$\phi(x) \in [0,1]^M$	linear interpolation weights for x
$\theta \in \mathbb{R}^M$	lattice values (parameters)
$v_j \in \{0,1\}^D$	jth vertex of a 2^D lattice

Table 2: Key Notation

The feature values are assumed to be bounded and linearly scaled to fit the lattice, so that the dth feature vector value $x[d]$ lies in $[0, M_d - 1]$. (We propose learning non-linear scalings of features jointly with the lattice parameters in Section 7.)

Lattice regression is a kernel method that maps $x \in \mathcal{M}$ to a transformed feature vector $\phi(x) \in [0,1]^M$. The values of $\phi(x)$ are the interpolation weights for x for the 2^D indices corresponding to the 2^D vertices of the hypercube surrounding x; for all other indices, $\phi(x) = 0$.

The function $f(x)$ is linear in $\phi(x)$ such that $f(x) = \theta^T \phi(x)$. That is, the function parameters θ each correspond to a vertex in the lattice, and $f(x)$ linearly interpolates the θ for the lattice cell containing x.

Before reviewing the lattice regression objective for learning the parameters θ, we review standard multilinear interpolation to define $\phi(x)$.

3.1 Multilinear Interpolation

Multilinear interpolation is the multi-dimensional generalization of the familiar bilinear interpolation that is commonly used to up-sample images. See Figure 2 for a pictorial explanation.

For notational simplicity, we assume a 2^D lattice such that $x \in [0,1]^D$. For multi-cell lattices, the same math and logic is applied to the lattice cell containing the x. Denote the kth component of $\phi(x)$ as $\phi_k(x)$. Let $v_k \in \{0,1\}^D$ be the kth vertex of the unit hypercube. The multilinear interpolation weight on the vertex v_k is

$$\phi_k(x) = \prod_{d=0}^{D-1} x[d]^{v_k[d]} (1 - x[d])^{1 - v_k[d]}. \tag{2}$$

Note the exponents in (2) are v_k and $1 - v_k[d]$, which either equal 0 and 1, or equal 1 and 0, so these exponents act like selectors that multiply in either $x[d]$ or $1 - x[d]$ for each

dimension d. Equivalently, one can write

$$\phi_k(x) = \prod_{i=0}^{D-1} \left((1 - \texttt{bit}[i,k]) \, (1 - x[i]) + \texttt{bit}[i,k] x[i] \right), \tag{3}$$

where $\texttt{bit}[i,k] \in \{0,1\}$ denotes the ith bit of vertex v_k, and can be computed $\texttt{bit}[i,k] = (k \gg i) \,\&1$ using bitwise arithmetic.

The resulting $f(x) = \theta^T \phi(x)$ is a multilinear polynomial over each lattice cell. For example, a 2×2 lattice interpolated with multilinear interpolation gives:

$$f(x) = \theta[0](1-x[0])(1-x[1]) + \theta[1]x[0](1-x[1]) + \theta[2](1-x[0])x[1] + \theta[3]x[0]x[1]. \tag{4}$$

Expanding (4), one sees it is a different parameterization of the multilinear function given in (1), where the parameter vectors are related by a linear matrix transform: $a = T\theta$ for $T \in \mathbb{R}^{4\times 4}$. But the θ parameterization has the advantage that each parameter is the function value for a feature vector at the vertex of the lattice (see Figure 1), and as we show in Section 4, makes it easier to learn the complete set of monotonic functions.

The linear interpolation is applied per lattice cell. At lattice cell boundaries the resulting function is continuous, but not differentiable. The overall function is piecewise polynomial, and hence a spline, and can be equivalently formulated using a linear basis function. Higher-order basis functions like the popular cubic spline will lead to smoother and potentially slightly more accurate functions (Garcia et al., 2012). However, higher-order basis functions destroy the interpretable localized effect of the parameters, and increase the computational complexity.

The multilinear interpolation weights are just one type of linear interpolation. In general, linear interpolation weights are defined as solutions to the system of $D+1$ equations:

$$\sum_{k=0}^{2^D} \phi_k(x) v_k = x \text{ and } \sum_{k=0}^{2^D} \phi_k(x) = 1. \tag{5}$$

This system of equations is under-determined and has many solutions for an x in the convex hull of a lattice cell. The multilinear interpolation weights given in (2) are the maximum entropy solution to (5) (Gupta et al., 2006), and thus have good noise averaging and smoothness properties compared to other solutions. We discuss a more efficient linear interpolation in Sec. 5.2.

3.2 The Lattice Regression Objective

Consider the standard supervised machine learning set-up of a training set of randomly sampled pairs $\{(x_i, y_i)\}$ pairs, where $x_i \in \mathcal{M}$ and $y_i \in \mathbb{R}$, for $i = 1, \ldots, n$. Historically, people created look-up tables by first fitting a function $h(x)$ to the $\{x_i, y_i\}$ using a regression algorithm such as a neural net or local linear regression, and then evaluating $h(x)$ on a regular grid to produce the look-up table values (Sharma and Bala, 2002). However, even if they fit the function to minimize empirical risk on the training samples, they did not minimize the *actual* empirical risk because these approaches did not take into account that the trained look-up table would be interpolated at run-time, and this interpolation changes the error on the training samples.

Garcia and Gupta (2009) proposed directly optimizing the look-up table parameters θ to minimize the actual empirical error between the training labels and the interpolated look-up table:

$$\arg\min_{\theta \in \mathbb{R}^M} \sum_{i=1}^{n} \ell(y_i, \theta^T \phi(x_i)) + R(\theta), \tag{6}$$

where ℓ is a loss function such as squared error, $\phi(x_i) \in [0,1]^M$ is the vector of linear interpolation weights over the lattice for training sample x_i (detailed in Section 3.1 and Sec. 5.2), $f(x_i) = \theta^T \phi(x_i)$ is the linear interpolation of x_i from the look-up table parameters θ, and $R(\theta)$ is a regularizer on the lattice parameters. In general, we assume the loss ℓ and regularizer R are convex functions of θ so that solving (6) is a convex optimization. Prior work focused on squared error loss, and used graph regularizers $R(\theta)$ of the form $\theta^T K \theta$ for some PSD matrix K, in which case (6) has a closed-form solution which can be computed with sparse matrix inversions (Garcia and Gupta, 2009; Garcia et al., 2010, 2012).

4. Monotonic Lattices

In this section we propose constraining lattice regression to learn monotonic functions.

4.1 Monotonicity Constraints For a Lattice

In general, simply checking whether a nonlinear function is monotonic can be quite difficult (see the related work in Section 2.2). But for a linearly interpolated look-up table, checking for monotonicity is relatively easy: if the lattice values increase in a given direction, then the function increases in that direction. See Figure 1 for examples. Specifically, one must check that $\theta_s > \theta_r$ for each pair of adjacent look-up table parameters θ_r and θ_s. If all features are specified to be monotonic for a 2^D lattice, this results in $D2^{D-1}$ pairwise linear inequality constraints to check.

These same pairwise linear inequality constraints can be imposed when learning the parameters θ to ensure a monotonic function is learned. The following result establishes these constraints are sufficient and necessary for a 2^D lattice to be monotonically increasing in the dth feature (the result extends trivially to larger lattices):

Lemma 1 (Monotonicity Constraints) *Let $f(x) = \theta^T \phi(x)$ for $x \in [0,1]^D$ and $\phi(x)$ given in (2). The partial derivative $\partial f(x)/\partial x[d] > 0$ for fixed d and any x iff $\theta_{k'} > \theta_k$ for all k, k' such that $v_k[d] = 0$, $v_{k'}[d] = 1$ and $v_k[m] = v_{k'}[m]$ for all $m \neq d$.*

Proof First we show the constraints are necessary to ensure monotonicity. Consider the function values $f(v_k)$ and $f(v_{k'})$ for some adjacent pair of vertices $v_k, v_{k'}$ that differ only in the dth feature. For $f(v_k)$ and $f(v_{k'})$, all of the interpolation weight falls on θ_k or $\theta_{k'}$ respectively, such that $f(v_k) = \theta_k$ and $f(v_{k'}) = \theta_{k'}$. So $\theta_{k'} > \theta_k$ is necessary for $\partial f(x)/\partial x[d] > 0$ everywhere.

Next we show the constraints are sufficient to ensure monotonicity. Pair the terms in the interpolation $f(x) = \theta^T \phi(x)$ corresponding to adjacent parameters $\theta_k, \theta_{k'}$ so that for

each k, k' it holds that $v_k[d] = 0, v_{k'}[d] = 1, v_k[m] = v_{k'}[m]$ for $m \neq d$:

$$\begin{aligned} f(x) &= \sum_{k,k'} \theta_k \phi_k(x) + \theta_{k'} \phi_{k'}(x), \text{ then expand } \phi_k(x) \text{ and } \phi_{k'}(x) \text{ using (2) :} \\ &= \sum_{k,k'} \alpha_k \left(\theta_k x[d]^{v_k[d]} (1 - x[d])^{(1-v_k[d])} + \theta_{k'} x[d]^{v_{k'}[d]} (1 - x[d])^{(1-v_{k'}[d])} \right), \\ &\quad \text{where } \alpha_k \text{ is the product of the } m \neq d \text{ terms in (2) that are the same for } k \text{ and } k', \\ &= \sum_{k,k'} \alpha_k \left(\theta_k (1 - x[d]) + \theta_{k'} x[d] \right) \text{ by the definition of } v_k \text{ and } v_{k'}. \end{aligned} \tag{7}$$

The partial derivative of (7) is $\frac{\partial f(x)}{\partial x[d]} = \sum_{k,k'} \alpha_k (\theta_{k'} - \theta_k)$. Because each $\alpha_k \in [0, 1]$, it is sufficient that $\theta_{k'} > \theta_k$ for each k, k' pair to guarantee this partial is positive for all x. ■

4.2 Monotonic Lattice Regression Objective

We relax strict monotonicity to monotonicity by allowing equality in the adjacent parameter constraints (for an example, see the second function from the left in Figure 1). Then the set of pairwise constraints can be expressed as $A\theta \leq 0$ for the appropriate sparse matrix A with one 1 and -1 per row of A, and one row per constraint. Each feature can independently be left unconstrained, or constrained to be either monotonically increasing or decreasing by the specification of A.

Thus the proposed monotonic lattice regression objective is convex with linear inequality constraints:

$$\arg\min_{\theta} \sum_{i=1}^{n} \ell(y_i, \theta^T \phi(x_i)) + R(\theta), \text{ s.t. } A\theta \leq b. \tag{8}$$

Additional linear constraints can be included in $A\theta \leq b$ to also constrain the fitted function in other practical ways, such as $f(x) \in [0, 1]$ or $f(x) \geq 0$.

The approach extends to the standard learning to rank from pairs problem (Liu, 2011), where the training data is pairs of samples x_i^+ and x_i^- and the goal is to learn a function such that $f(x_i^+) \geq f(x_i^-)$ for as many pairs as possible. For this case, the monotonic lattice regression objective is:

$$\arg\min_{\theta} \sum_{i=1}^{n} \ell(1, \theta^T \phi(x_i^+) - \theta^T \phi(x_i^-)) + R(\theta), \text{ s.t. } A\theta \leq b. \tag{9}$$

The loss functions in (6), (8) and (9) all have the same form, for example, squared loss $\ell(y, z) = (y - z)^2$, hinge loss $\ell(y, z) = \max(0, 1 - yz)$, or logistic loss $\ell(y, z) = \log(1 + \exp(y - z))$.

5. Faster Linear Interpolation

Interpolating a look-up table has long been considered an efficient way to specify and evaluate a low-dimensional non-linear function (Sharma and Bala, 2002; Garcia et al., 2012).

But computing linear interpolation weights with (3) requires $O(D)$ operations for each of the 2^D interpolation weights, for a total cost of $O(D2^D)$ to evaluate a sample. In Section 5.1, we show the multilinear interpolation weights of (3) can be computed in $O(2^D)$ operations. Then, in Section 5.2, we review and analyze a different linear interpolation that we refer to as *simplex* interpolation that takes only $O(D \log D)$ operations.

5.1 Fast Multilinear Interpolation

Much of the computation in (3) can be shared between the different weights. In Algorithm 1 we give a dynamic programming solution that loops D times, where the dth loop takes 2^d time, so in total there are $\sum_{d=0}^{D-1} 2^d = O(2^D)$ operations.

Algorithm 1 Computes the multilinear interpolation weights and corresponding vertex indices for a unit lattice cell $[0, 1]^D$ and an $x \in [0, 1]^D$. Let the lattice parameters be indexed such that $s_d = 2^d$ is the difference in the indices of the parameters corresponding to any two vertices that are adjacent in the dth dimension, for example, for the 2×2 lattice, order the vertices [0 0], [1 0], [0 1], [1 1] and index the corresponding lattice parameters in that order.

```
CalculateMultilinearInterpolationWeightsAndParameterIndices(x)
1  Initialize indices[] = [0], weights[] = [1]
2  For d = 0 to D − 1:
3      For k = 0 to 2^d − 1:
4          Append s_d + indices[k] to indices
5          Append x[d] × weights[k] to weights
6          Update weights[k] = (1 − (x[d])) × weights[k]
7  Return indices and weights
```

The following lemma establishes the correctness of Algorithm 1.

Lemma 2 (Fast Multilinear Interpolation) *Under its assumptions, Algorithm 1 returns the indices of the 2^D parameters corresponding to the vertices of the lattice cell containing x:*

$$\texttt{indices}[k] = \sum_{d=0}^{D-1} \left(\lfloor x[d] \rfloor + \texttt{bit}_i(k) \right) s_d, \text{ for } k = 1, 2, \ldots, 2^D \tag{10}$$

and the corresponding 2^D multilinear interpolation weights given by (3).

Proof At the end of the D'th iteration over the dimension in Algorithm 1:

$$\begin{aligned} \texttt{size}\,(\texttt{indices}) = \texttt{size}\,(\texttt{weights}) &= 2^{D'+1} \\ \texttt{indices}[k] &= \sum_{d=0}^{D'} \left(\lfloor x[d] \rfloor + \texttt{bit}_d(k) \right) s_d \\ \texttt{weights}[k] &= \prod_{d=0}^{D'} \left((1 - \texttt{bit}_d(k)) \left(1 - (x[d] - \lfloor x_d \rfloor)\right) + \texttt{bit}_d(k)(x[d] - \lfloor x_d \rfloor) \right). \end{aligned}$$

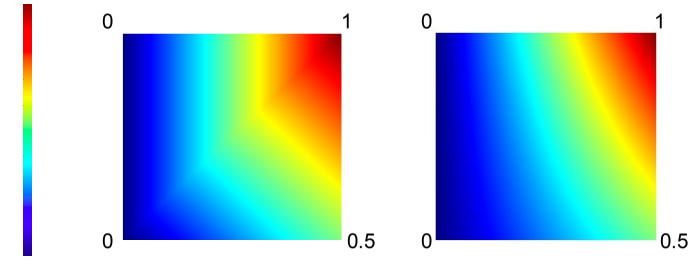

Figure 3: Illustration of two different linear interpolations of the same 2×2 look-up table with parameters $0, 0, 0.5$ and 1. The simplex interpolation splits the unit square into two simplices (the upper and lower triangle) and interpolates within each. The function is continuous because the points along the diagonal are interpolated from only the two corner vertices, and the interpolated function is linear over each simplex. Both interpolations produce monotonic functions over both features.

The above holds for the $D' = 1$ case by the initialization and inspection of the loop. It is straightforward to verify that if the above hold for D', then they also hold for $D' + 1$. Then by induction it holds for $D' = D - 1$, as claimed. ■

5.2 Simplex Linear Interpolation

For speed, we propose using a more efficient linear interpolation for lattice regression that linearly interpolates each x from only $D+1$ of the 2^D surrounding vertices. Many different linear interpolation strategies have been proposed to interpolate look-up tables using only a subset of the 2^D vertices (for a review, see Kang (1997)). However, most such strategies suffer from being too computationally expensive to determine the subset of vertices needed to interpolate a given x. The wonder of *simplex interpolation* is that it takes only $O(D \log D)$ operations to determine the $D+1$ vertices needed to interpolate any given x, and then only $O(D)$ operations to interpolate the identified $D+1$ vertices. An illustrative comparison of simplex and multilinear interpolation is given in Figure 3 for the same lattice parameters.

Simplex interpolation was proposed in the color management literature by Kasson et al. (1993), and independently later by Rovatti et al. (1998). Simplex interpolation is also known as the *Lovasz extension* in submodular optimization, where it is used to extend a function defined on the vertices of a unit hypercube to be defined on its interior (Bach, 2013).

After reviewing how simplex interpolation works, we show in Section 5.2.3 that it requires the same constraints for monotonicity as multilinear interpolation, and then we discuss how its rotational dependence impacts its use for machine learning in Section 5.2.4. We give example runtime comparisons in Section 10.7.

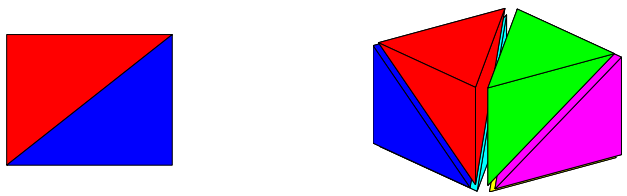

Figure 4: Simplex interpolation decomposes the D-dimensional unit hypercube into $D!$ simplices. **Left:** For the unit square, there are two simplices, one is defined by the three vertices [0 0], [0 1], and [1 1], and the other is defined by the three vertices [0 0], [1 0], and [1 1]. **Right:** For the unit cube there are $3! = 6$ simplices, each defined by four vertices. The first has vertices: [0 0 0], [0 0 1], [0 1 1] , [1 1 1]. The second has vertices: [0 0 0], [0 0 1], [1 0 1], [1 1 1]. And so on. All six simplices have vertices [0 0 0] and [1 1 1], and thus share the diagonal between those two vertices.

5.2.1 Partitioning of the Unit Hypercube Into Simplices

Simplex interpolation implicitly partitions the hypercube into the set of D! congruent simplices that satisfy the following: each simplex includes the all 0's vertex, one vertex is all zeros but has a single 1, one vertex is all zeros but has two 1's, and so on, ending with one vertex that is all 1's, for a total of $D+1$ vertices in each simplex. Figure 4 shows the partitioning for the $D = 2$ and $D = 3$ unit hypercubes.

This decomposition can also be described by the hyperplanes $x_k = x_r$ for $1 \le k \le r \le D$ (Schimdt and Simon, 2007). Knop (1973) discussed this decomposition as a special case of Eulerian partitioning of the hypercube, and Mead (1979) showed this is the smallest possible equivolume decomposition of the unit hypercube.

5.2.2 Simplex Interpolation

Given $x \in [0,1]^D$, the $D+1$ vertices that specify the simplex that contains x can be computed in $O(D \log D)$ operations by sorting the D values of the feature vector x, and then the dth simplex vertex has ones in the first d sorted components of x. For example, if x =[.8 .2 .3], the $D+1$ vertices of its simplex are [0 0 0], [1 0 0], [1 0 1], [1 1 1].

Let V be the $D+1$ by D matrix whose dth row is the dth vertex of the simplex containing x. Then the simplex interpolation weights $\psi(x)$ must satisfy the linear interpolation equations given in (5) such that $\begin{bmatrix} V^T \\ \mathbf{1}^T \end{bmatrix} \psi(x) = \begin{bmatrix} x \\ 1 \end{bmatrix}$. Thus $\psi(x) = \begin{bmatrix} V^T \\ \mathbf{1}^T \end{bmatrix}^{-1} \begin{bmatrix} x \\ 1 \end{bmatrix}$, where because of the highly structured nature of the simplex decomposition the required inverse always exists, and has a simple form such that $\psi(x)$ is the vector of differences of sequential sorted components of x. For example, for a $2 \times 2 \times 2$ lattice, and an x such that $x[0] > x[1] > x[2]$, the simplex interpolation weights $\psi(x) = [1 - x[0], x[0] - x[1], x[1] - x[2], x[2]]$ on the vertices

$[0,0,0],[1,0,0],[1,1,0],[1,1,1]$, respectively. The general formula is detailed in Algorithm 2; for more mathematical details see Rovatti et al. (1998).

Algorithm 2 Computes the simplex interpolation weights and corresponding vertex indices for a unit lattice cell $[0,1]^D$ and an $x \in [0,1]^D$. Let the lattice parameters be indexed such that $s_d = 2^d$ is the difference in the indices of the parameters corresponding to any two vertices that are adjacent in the dth dimension, for example, for the 2×2 lattice, order the vertices [0 0], [1 0], [0 1], [1 1] and index the corresponding lattice parameters in that order.

`CalculateSimplexInterpolationWeightsAndParameterIndices`(x)
1. Compute the sorted order π of the components of x such that $x[\pi[k]]$ is the kth largest value of x,
2. that is, $x[\pi[1]]$ is the largest value of x, etc.
3. Initialize `index` $= 0$, $z = 1$, `indices`$[] = []$, `weights`$[] = []$
4. For $d = 0$ to $D-1$:
5. Append `index` to `indices`
6. Append $z - x[\pi[d]]$ to `weights`
7. Update `index` $=$ `index` $+ s_{\pi[d]}$
8. Update $z = x[\pi[d]]$
9. Append `index` to `indices`
10. Append z to `weights`
11. Return `indices` and `weights`

5.2.3 Simplex Interpolation and Monotonicity

We show that the same linear inequality constraints that guarantee monotonicity for multilinear interpolation also guarantee monotonicity with simplex interpolation:

Lemma 3 (Monotonic Constraints with Simplex Interpolation) *Let $f(x) = \theta^T \phi(x)$ for $\phi(x)$ given in Algorithm 2. The partial derivative $\partial f(x)/\partial x[d] > 0$ iff $\theta_{k'} > \theta_k$ for all k, k' such that $v_k[d] = 0$, $v_{k'}[d] = 1$, and $v_k[m] = v_{k'}[m]$ for all $m \neq d$.*

Proof Simplex interpolation linearly interpolates from $D+1$ vertices at a time, and thus the resulting function is linear over each simplex. Thus to prove that the function is monotonic everywhere, we need only to show that each locally linear function is monotonically increasing in dimension d, and that the function is continuous everywhere. Each simplex only has one pair of vertices v_k and $v_{k'}$ that differ in dimension d such that $v_k[d] = 0$, $v_{k'}[d] = 1$, and $v_k[m] = v_{k'}[m]$ for all $m \neq d$. In addition, we can verify that for the linear function over this simplex, $\partial f(x)/\partial x[d] = \theta_{k'} - \theta_k$, where θ_k and $\theta_{k'}$ are the parameters corresponding to these vertices. Therefore if $\theta_{k'} > \theta_k$, then the linear function over that simplex must be increasing with respect to d. Conversely, if it does not hold that $\theta_{k'} > \theta_k$, then the linear function over that simplex must have non-positive slope with respect to d. Further, $f(x)$ is continuous for all x, because any x on a boundary between simplices only has nonzero interpolation weight on the vertices defining that boundary. In conclusion, the function is piecewise monotonic and continuous, and thus monotonic everywhere. ■

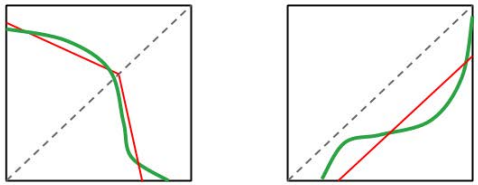

Figure 5: Illustrates rotational dependence of simplex interpolation for a 2×2 lattice and its impact on a binary classification problem. Green thick line denotes the true decision boundary of a binary classification problem. Red thin lines denote the piecewise linear decision boundary fit by lattice regression using simplex interpolation. Dotted gray line separates the two simplices; the function is locally linear over each simplex. **Left:** The true decision boundary (green) crosses the two simplices. The simplex decision boundary (red) has two linear pieces and can fit the green boundary well. **Right:** The same green boundary has been rotated ninety degrees, and now lies entirely in one simplex. The simplex decision boundary (in red) is linear within each simplex, and hence has less flexibility to fit the true green decision boundary.

5.2.4 Using Simplex Interpolation for Machine Learning

Simplex interpolation produces a locally linear continuous function made-up of $D!$ hyperplanes oriented around the main diagonal axis of the unit hypercube. Compared to multilinear interpolation, simplex interpolation is not as smooth (though continuous), and it is rotationally-dependent.

For low-dimensional regression problems using a look-up table with many cells, performance of the two interpolation methods has been found to be similar, particularly if one is using a fine-grained lattice with many cells. For example, in a comparison by Sun and Zhou (2012) for the three-dimensional regression problem of color managing an LCD monitor, multilinear interpolation of a $9 \times 9 \times 9$ look-up table (also called trilinear interpolation in the special case of three-dimensions) produced around 1% worse average error than simplex interpolation, but the maximum error with multilinear interpolation was only 60% of the maximum simplex interpolation error. Another study by Kang (1995) using simulations concluded that the interpolation errors of these methods was "about the same."

However, when using a coarser lattice like 2^D, as we have found useful in practice for machine learning, the rotational dependence of simplex interpolation can cause problems because the flexibility of the interpolated function $f(x)$ differs in different parts of the feature space. Figure 5 illustrates this for a binary classifier on two features.

To address the rotational dependence, we recommend using prior knowledge to define the features positively or negatively in a way that aligns the simplices' shared diagonal axis along the assumed slope of $f(x)$. If there are monotonicity constraints, this is done by specifying each feature so that it is monotonically increasing, rather than monotonically

decreasing. For binary classification, features should be specified so that the feature vector for the most prototypical example of the negative class is the all-zeros feature vector, and the feature vector for the most prototypical example of a positive class is the all-ones feature vector. This should put the decision boundary as orthogonal to the shared diagonal axis as possible, providing the interpolated function the most flexibility to model that decision boundary. In addition, for low-dimensional problems, using a finer-grained lattice will produce more flexibility overall, so that the flexibility within each lattice cell is less of an issue.

Following these guidelines, we surprisingly and consistently find that simplex interpolation of 2^D lattices is roughly as accurate as multilinear interpolation, and much faster for $D \geq 8$. This is demonstrated in the case studies of Section 10 (runtime comparisons given in Section 10.7).

6. Regularizing the Lattice Regression To Be More Linear

We propose a new regularizer that takes advantage of the lattice structure and encourages the fitted function to be more linear by penalizing differences in parallel edges:

$$R_{\text{torsion}}(\theta) = \sum_{d=1}^{D} \sum_{\substack{\tilde{d}=1 \\ \tilde{d}\neq d}}^{D} \sum_{\substack{r,s,t,u \text{ such that} \\ v_r \text{ and } v_s \text{ adjacent in dimension } d, \\ v_t \text{ and } v_u \text{ adjacent in dimension } d, \\ v_r \text{ and } v_t \text{ adjacent in dimension } \tilde{d}}} ((\theta_r - \theta_s) - (\theta_t - \theta_u))^2. \qquad (11)$$

This regularizer penalizes how much the lattice function twists from side-to-side, and hence we refer to this as the *torsion* regularizer. The larger the weight on the torsion regularizer in the objective function, the more linear the lattice function will be over each 2^D lattice cell.

Figure 6 illustrates the torsion regularizer and compares it to previously proposed lattice regularizers, the standard graph Laplacian (Garcia and Gupta, 2009) and graph Hessian (Garcia et al., 2012). As shown in the figure, for multi-cell lattices, the torsion and graph Hessian regularizers make the function more linear in different ways, and may both be needed to closely approximate a linear function. Like the graph Laplacian and graph Hessian regularizers, the proposed torsion regularizer is convex but not strictly convex, and can be expressed in quadratic form as $\theta^T K \theta$, where K is a positive semidefinite matrix.

7. Jointly Learning Feature Calibrations

One can learn arbitrary bounded functions with a sufficiently fine-grained lattice, but increasing the number of lattice vertices M_d for the dth feature multiplicatively grows the total number of parameters $M = \prod_d M_d$. However, we find in practice that if the features are first each transformed appropriately, then many problems require only a 2^D lattice to capture the feature interactions. For example, a feature that measures distance might be better specified as log of the distance. Instead of relying on a user to determine how to best transform each feature, we automate this feature pre-processing by augmenting our function class with D one-dimensional transformations $c_d(x[d])$ that we learn jointly with the lattice, as shown in Figure 7.

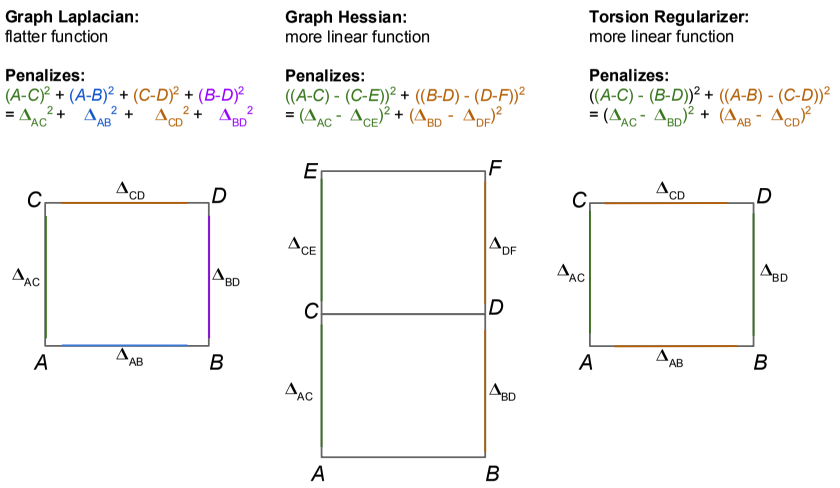

Figure 6: Comparison of lattice regularizers. The lattice parameters are denoted by A, B, C, D, E, and F. The deltas indicate the differences between adjacent parameters along each edge, and thus each delta is the slope of the function along its edge. Each color corresponds to a different additive term in a regularizer. The graph Laplacian regularizer *(left)* minimizes the sum of the squared slopes, producing a flatter function. The graph Hessian regularizer *(middle)* minimizes the change in slope in each direction of a multi-cell lattice, keeping the function from bending too much between lattice cells. The proposed torsion regularizer *(right)* minimizes the change in slope between sides of the lattice, for each direction, minimizing the twisting of the function.

7.1 Calibrating Continuous Features

We calibrate each continuous feature with a one-dimensional monotonic piecewise linear function, as illustrated in Figure 8. Our approach is similar to the work of Howard and Jebara (2007), which jointly learns monotonic piecewise linear one-dimensional transformations and a linear function.

This joint estimation makes the objective non-convex, discussed further in Section 9.3. To simplify estimating the parameters, we treat the number of changepoints C_d for the dth feature as a hyperparameter, and fix the C_d changepoint locations (also called knots) at equally-spaced quantiles of the feature values. The changepoint values are then optimized jointly with the lattice parameters, detailed in Section 9.3.

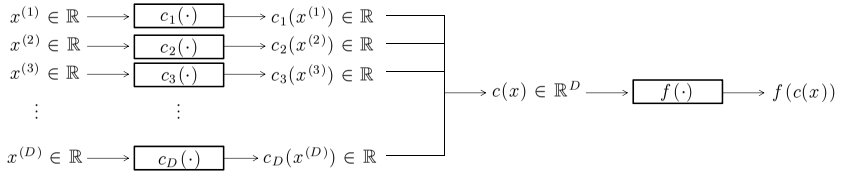

Figure 7: Block diagram showing one-dimensional calibration functions $\{c_d(\cdot)\}$ to pre-process each feature before the lattice $f(\cdot)$ fuses the features together nonlinearly.

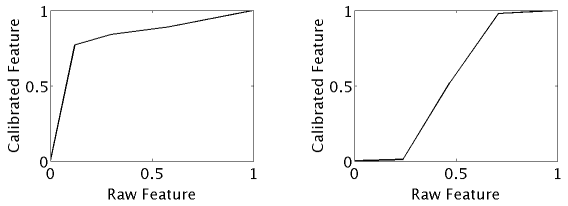

Distance Calibration Address Similarity Calibration

Figure 8: Learned one-dimensional piecewise linear calibration functions for a distance and address-similarity feature for the business-matching case study in Section 10.2. **Left:** The raw distance is measured in meters, and its calibration has a log-like effect. **Right:** The raw address feature is calibrated with a sigmoid-like transformation.

7.2 Calibrating Categorical Features

If the dth feature is categorical, we propose using a calibration function $c_d(\cdot)$ to map each category to a real value in $[0, M_d - 1]$. That is, let the set of possible categories for the dth feature be denoted $\mathcal{G}_d$, then $c_d : \mathcal{G}_d \to [0, M_d - 1]$, adding $|\mathcal{G}_d|$ additional parameters to the model. Figure 9 shows an example lattice with a categorical country feature that has been calibrated to lie on $[0, 2]$. If prior knowledge is given about the ordering of the original discrete values or categories, then partial or full pairwise constraints can be added on the mapped values to respect the known ordering information. These can be expressed as additional sparse linear constraints on pairs of parameters.

8. Calibrating Missing Data and Using Missing Data Vertices

We propose two supervised approaches to handle missing values in the training or test set.

First, one can do a supervised imputation of missing data values by calibrating a missing data value for each feature. This is the same approach proposed for calibrating categorical

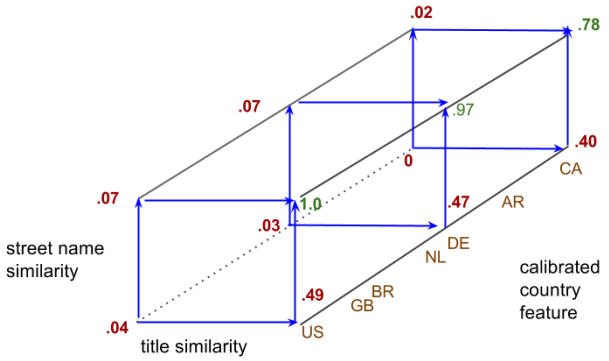

Figure 9: A $2 \times 2 \times 3$ lattice illustrating calibrating a categorical feature. In this example, each sample is a pair of business listings, and the problem is to classify whether the two listings are about the same business, based on the similarity of their street names, titles, and the country. A score $f(x)$ is interpolated from the parameters corresponding to the vertices of the $2 \times 2 \times 2$ lattice cell in which x lies, then thresholded at 0.5. The red parameter values are below the matching threshold of 0.50, and the green parameters are above the matching threshold. The blue arrows denote that the lattice was constrained to be monotonically increasing in the street name similarity and the title similarity. In this toy example, we only show the calibrated values for a few countries: US maps to 0, Great Britain maps to .3, Brazil to .4, Netherlands to .9, Germany to 1, Argentina to 1.5, and Canada to 2. One can interpret this lattice as modeling three classifiers, sliced along the country vertices: a classifier for country = 0, one for country = 1, and one for country = 2. Samples from Argentina (AR) are interpolated equally from the parameters where country = 1 and country = 2. Samples from Great Britain, and Netherlands are interpolated from the two classifiers specified at country = 0 and 1, with Netherlands putting the most weight on the classifier where country = 1. The lattice parameters can be interpreted as showing that both the street name and title features are stronger positive evidence in the US than in Canada.

values in Section 7.2: learn the numeric value in $[0, M_d - 1]$ to impute if the dth feature is missing that minimizes the structural risk minimization obejctive. In this approach, missing data is handled by a calibration function $c_d(\cdot)$, and like the other calibration function parameters. Other researchers have also considered joint training of classifiers and imputations for missing data, for example van Esbroeck et al. (2014) and Liao et al. (2007).

Second, a more flexible option is to give missing data its own *missing data vertices* in the lattice, as shown in Figure 10. This is similar to a decision tree handling a missing data value by splitting a node on whether that feature is missing. For example, the non-

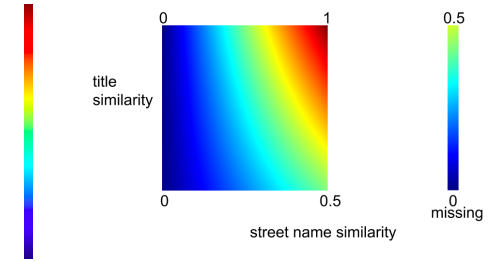

Figure 10: Illustration of handling missing data by assigning missing data to its own slice of vertices in the lattice. In this example, one feature is a title similarity and is always given, and the other feature is a street name similarity that can be missing. The lattice has $3 \times 2 = 6$ parameters, with the parameter values shown. For example, given a feature vector x with title similarity 0.5 and missing street name similarity, the two parameters corresponding to the missing street name slice of the lattice would be interpolated with equal weights, producing the output $f(x) = 0.25$.

missing feature values can be scaled to $[0, M_d - 2]$, and if the data is missing is it mapped to $M_d - 1$. This increases the number of parameters but gives the model the flexibility to handle missing data differently than non-missing data. For example, missing the street number in a business description may correlate with lower quality information for all the features.

To regularize the lattice parameters corresponding to missing data vertices, we apply the graph regularizers detailed in Section 6. These could be use to tie any of the parameters to the missing data parameters. In our experiments, for the purposes of graph regularization, we treat the missing data vertices as though they were adjacent to the minimum and maximum vertices of that feature in the lattice.

With either of these two proposed strategies, linear inequalities can be added on the appropriate parameters (the calibrator parameters in the first proposal, or the missing data vertex parameters in the second proposal) to ensure that the function value for missing data is bounded by the minimum and maximum function values, that is, that missing $x[d]$ never produces a smaller $f(x)$ than $x[d] = 0$, nor a larger $f(x)$ than $x[d] = M_d$.

9. Large-Scale Training

For convex loss functions $\ell(\theta)$ and convex regularizers $R(\theta)$, any solver for convex problems with linear inequality constraints can be used to optimize the lattice parameters θ in (8). However, for large n and for even relatively small D, training the proposed calibrated monotonic lattices is challenging due to the number of linear inequality constraints, the number

of terms in the graph-regularizers, and the non-convexity created by using calibration functions.

In this section we discuss various standard and new strategies we found useful in practice: our use of stochastic gradient descent (SGD), stochastic handling of the regularizers, parallelizing-and-averaging for distributed training, handling the large number of constraints in the context of SGD, and finally some details on how we optimize the non-convex problem of training the calibrator functions and the lattice parameters. Throughout this section, we assume the standard setting of (8); the generalization to the pairwise ranking problem of (9) is straightforward.

9.1 SGD and Reducing Variance of the Subgradients

To scale to a large number of samples n, we used SGD for all our experiments. For each SGD iteration t, a labeled training sample (x_i, y_i) is sampled uniformly from the set of training sample pairs. One finds the corresponding subgradient of (8), and takes a tiny step in its negative gradient direction. (The resulting parameters may then violate the constraints, which we discuss in Section 9.4.)

A straightforward SGD implementation for (8) would use the subgradient:

$$\Delta = \nabla_\theta \ell\left(\theta^T \phi\left(x_i\right), y_i\right) + \nabla_\theta R\left(\theta\right), \tag{12}$$

where the ∇_θ operator finds an arbitrary subgradient of its argument w.r.t. θ. Ideally, these subgradients should be cheap-to-compute, so each iteration is fast. The computational cost is dominated by computing the regularizer, if using any of the graph regularizers discussed in Section 6.

Because the training example (x_i, y_i) in (12) is randomly sampled, the above subgradient is a realization of a stochastic subgradient whose expectation is equal to the true gradient. The number of iterations needed for the SGD to converge depends on the squared Euclidean norms of the stochastic subgradients (Nemirovski et al., 2009), with larger norms resulting in slower convergence. The expected squared norm of the stochastic subgradient can be decomposed into the sum of two terms: the squared expected subgradient magnitude, and the variance. We can do little about the expected magnitude, but we can improve the trade-off between the computational cost of each subgradient and the variance of the stochastic subgradients. In the next two sub-sections, we describe two such strategies.

9.1.1 Mini-Batching

We reduce the variance of the stochastic subgradient's loss term by mini-batching over multiple random samples (Dekel et al., 2012). Let $\mathcal{S}_\ell$ denote a set of k_ℓ training indices sampled uniformly with replacement from $1, \ldots, n$, then the mini-batched subgradient is:

$$\Delta = \frac{1}{k_\ell} \sum_{i \in \mathcal{S}_\ell} \nabla_\theta \ell\left(\theta^T \phi\left(x_i\right), y_i\right) + \nabla_\theta R\left(\theta\right). \tag{13}$$

This simultaneously reduces the variance and increases the computational cost of the loss term by a factor of k_ℓ. For sufficiently small k_ℓ, this is a net win because differentiating the regularizer is the dominant computational term.

9.1.2 Stochastic Subgradients for Regularizers

We propose to reduce the computational cost of each SGD iteration by randomly sampling the additive terms of the regularizer, for regularizers that can be expressed as a sum of terms: $R(\theta) = \sum_{j=1}^{m} r_j(\theta)$. For example, for a 2^D lattice, each calculation of the graph Laplacian regularizer subgradient sums over $m = D2^{D-1}$ terms, and the graph torsion regularizer subgradient sums over $m = D(D-1)2^{D-3}$ terms.

Let $\mathcal{S}_R$ denote a set of k_R indices sampled uniformly with replacement from $1, l \ldots, m$, then define the subgradient:

$$\Delta = \frac{1}{k_\ell} \sum_{i \in \mathcal{S}_\ell} \nabla_\theta \ell\left(\theta^T \phi\left(X_i\right), Y_i\right) + \frac{m}{k_R} \sum_{j \in \mathcal{S}_R} \nabla_\theta r_j\left(\theta\right). \tag{14}$$

While this makes the subgradient's regularizer term stochastic, and hence increases the subgradient variance, we find that good choices of k_ℓ and k_R in (14) can produce a useful tradeoff between the computational cost of computing each subgradient and the number of SGD iterations needed for acceptable converge. For example, in one real-world application using torsion regularization, the choice of $k_R = 1024$ and $k_\ell = 1$ led to a 150× speed-up in training and produced statistically indistinguishable accuracy on a held-out test set.

9.2 Parallelizing and Averaging

For a large number of training samples n, one can split the n training samples into K sets, then independently and in-parallel train a lattice on each of the K sets. Once trained, the vector lattice parameters for the K lattices can simply be averaged. This parallelize-and-average approach was investigated for large-scale training of linear models by Mann et al. (2009). Their results showed similar accuracies to distributed gradient descent, but 1000× less network traffic and reduced wall-clock time for large datasets. In our implementation of the parallelize-and-average approach we do multiple syncs: averaging the lattices, then sending out the averaged lattice to parallelized workers to keep improving with further training. We illustrate the performance and speed-up of this simple parallelize-and-average for learning monotonic lattices in Section 10.6 and Section 10.7. A more complicated implementation of this strategy would use the alternating direction method of multipliers with a consensus constraint (Boyd et al., 2010), but that requires an additional regularization towards a local copy of the most recent consensus parameters.

Note that if calibration functions are used, they must be held fixed during the parallelization of the lattice training, as it does not make mathematical sense to average differently calibrated lattices.

9.3 Jointly Optimizing Lattice and Calibration Functions

To learn a *calibrated* monotonic lattice, we jointly optimize the calibration functions and the lattice parameters. Let x denote a feature vector with D components, each of which is either a continuous or categorical value (discrete features can be modeled either as continuous features or categorical as the user sees fit). Let $c_d(x[d]; \alpha^{(d)})$ be a calibration function that acts on the dth component of x and has parameters $\alpha^{(d)}$.

If the dth feature is continuous, we assume it has a bounded domain such that $x[d] \in [l_d, u_d]$ for finite $l_d, u_d \in \mathbb{R}$. Then the dth calibration function $c_d(x[d]; \alpha^{(d)})$ is a monotonic

piecewise linear transform with fixed knots at l_d, u_d, and the $C_d - 2$ equally-spaced quantiles of dth feature over the training set. Let the first and last knots of the piecewise linear function map to the lattice bounds 0 and $M_d - 1$ respectively (as shown in Figure 8), that is, if $C_d = 2$ then $c_d(x[d]; \alpha^{(d)})$ simply linearly scales the raw range $[l_d, u_d]$ to the lattice domain $[0, M_d - 1]$ and there are no parameters $\alpha^{(d)}$. For $C_d > 2$, the parameters $\alpha^{(d)} \in [0, M_d - 1]^{C_d - 2}$ are the $C_d - 2$ output values of the piecewise linear function for the middle $C_d - 2$ knots.

If the dth feature is categorical with finite category set $\mathcal{G}_d$ such that $x[d] \in \mathcal{G}_d$, then the dth calibration function maps the categories to the lattice span such that $c_d(x[d]; \alpha^{(d)}) : \mathcal{G}_d \rightarrow [0, M_d - 1]$ and the parameters are the $|\mathcal{G}_d|$ categorical mappings such that $c_d(x[d]; \alpha^{(d)}) = \alpha^{(d)}[k]$ if $x[d]$ belongs to category k and $\alpha^{(d)} \in [0, M_d - 1]^{|\mathcal{G}_d|}$.

Let $c(x; \alpha)$ denote the vector function with dth component function $c_d(x[d]; \alpha^{(d)})$, and note $c(x; \alpha)$ maps a feature vector x to the domain $\mathcal{M}$ of the lattice function. Use e_d to denote the standard unit basis vector that is one for the dth component and zero elsewhere with length D, then one can write:

$$c(x; \alpha) = \sum_{d=1}^{D} e_d c_d(e_d^T x; \alpha^{(d)}), \tag{15}$$

Then the proposed calibrated monotonic lattice regression objective expands the monotonic lattice regression objective (8) to:

$$\arg\min_{\theta, \alpha} \sum_{i=1}^{n} \ell(y_i, \theta^T \phi(c(x_i, \alpha)) + R(\theta) \text{ s.t. } A\theta \leq b \text{ and } \tilde{A}\alpha \leq \tilde{b},$$

where each row of A specifies a monotonicity constraint for a pair of adjacent lattice parameters (as before), and each row of $\tilde{A}$ similarly specifies a monotonicity constraint for a pair of adjacent calibration parameters for one of the piecewise linear calibration functions.

This turns the convex optimization problem (8) into a non-convex problem that is marginally convex in the lattice parameters θ for fixed α, but not necessarily convex with respect to α even if θ is fixed. Despite the non-convexity of the objective, in our experiments we found sensible and effective solutions by using projected SGD, updating θ and α with the appropriate stochastic subgradient for each x_i. Calculate the subgradient w.r.t. θ holding α constant, essentially the same as before. Calculate the subgradient w.r.t α by holding θ constant and using the chain rule:

$$\frac{\partial \theta^T \phi(c(x_i, \alpha))}{\partial \alpha^{(d)}} = \frac{\partial \theta^T \phi(c(x_i, \alpha))}{\partial c(x_i, \alpha)} \frac{\partial c(x_i, \alpha)}{\partial \alpha^{(d)}}. \tag{16}$$

If the dth feature is categorical, the partial derivative is 1 for the calibration mapping parameter corresponding to the category of $x_i[d]$ and zero otherwise:

$$\frac{\partial c(x_i, \alpha)}{\partial \alpha^{(d)}[k]} = 1 \text{ if } x_i[d] \text{ is the } k\text{th category and 0 otherwise.} \tag{17}$$

If the dth feature is continuous, then the parameters $\alpha^{(j)}[d]$ are the values of the calibration function at the knots of the piecewise linear function. If $x_i[d]$ lies between the kth

and $(k+1)$th knots at (fixed) positions β_k and β_{k+1}, then

$$\frac{\partial c(x_i, \alpha)}{\partial \alpha^{(d)}[k]} = \frac{(\beta_{k+1} - x_i[d])}{(\beta_{k+1} - \beta_k)}$$
$$\frac{\partial c(x_i, \alpha)}{\partial \alpha^{(d)}[k+1]} = \frac{(x_i[d] - \beta_k)}{(\beta_{k+1} - \beta_k)},$$

and the partial derviative is zero for all other components of $\alpha^{(d)}$. After taking an SGD step that updates $\alpha^{(d)}[k]$ and $\alpha^{(d)}[k+1]$, the $\alpha^{(d)}$ may violate the monotonicity constraints that ensure a monotonic calibration function, which can be fixed with a projection onto the constraints (see Section 9.4 for details).

A standard strategy with nonconvex gradient descent is to try multiple random initializations of the parameters. We did not explore this avenue; instead we simply try to initialize sensibly. Each lattice parameter is initialized to be the sum of its monotonically increasing components (multiply by -1 for any monotonically decreasing components) so that the lattice initialization respects the monotonicity constraints and is a linear function. The piecewise linear calibration functions are initialized to scale linearly to $[0, M_d - 1]$. The categorical calibration parameters are ordered by their mean label, then spaced uniformly on $[0, M_d - 1]$ in that order.

9.4 Large-Scale Projection Handling

Standard projected stochastic gradient descent projects the parameters onto the constraints after each stochastic gradient update. Given the extremely large number of linear inequality constraints needed to enforce monotonicity for even small D, we found a full projection each iteration impractical and un-necessary. We avoid the full projection at each iterate by using one of two strategies.

9.4.1 Suboptimal Projections

We found that modifying the SGD update to approximate the projection worked well. Specifically, for each new stochastic subgradient $\eta\Delta$, we create a set of active constraints initialized to $\emptyset$, and, starting from the last parameter values, move along the portion of $\eta\Delta$ that is orthogonal to the current active set until we encounter a constraint, add this constraint to the active set, and then continue until the update $\eta\Delta$ is exhausted or it is not possible to move orthogonal to the current active set. At all times, the parameters satisfy the constraints. It can be particularly fast because it is possible to exploit the sparsity of the monotonicity constraints (each of which depends on only two parameters) and the sparsity of Δ (when using simplex interpolation) to optimize the implementation.

But, this strategy is sub-optimal because we do not remove any constraints from the active set during each iteration, and thus parameters can "get stuck" at a corner of the feasible set, as illustrated in Figure 11. In practice, we found such problems resolve themselves because the stochasticity of the subsequent stochastic gradients eventually jiggles the parameters free. Experimentally, we found this suboptimal strategy to be very effective and to produce statistically similar objective function values and test accuracies more optimal approaches. All of the experimental results reported in this paper used this strategy. See Section 10.7 for example runtimes.

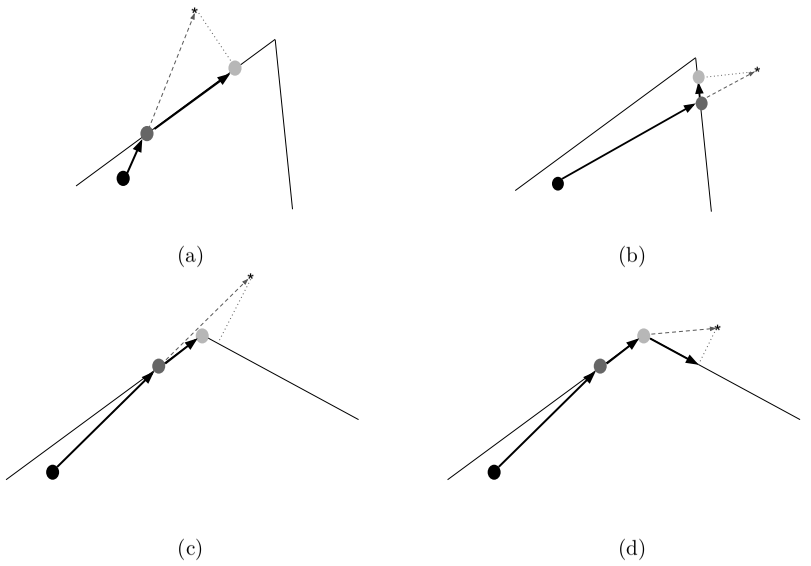

Figure 11: Four examples of the suboptimal projection stochastic gradient descent step described in Section 9.4. In each case, the constraints are marked by thin solid lines, the black dot represents the parameters at the end of the last SGD iteration, and the new full stochastic gradient descent update is marked by the dashed line, ending in a star. The optimal projection of the star onto the constraints is marked by the dotted line. The stochastic gradient is followed until it hits a constraint, and then the component of the remaining gradient orthogonal to the active constraint is applied. The update ends at the light gray dot. In cases (a) and (b), the resulting light dot is the optimal projection of the star onto the constraints. But in case (c), first one constraint is hit, and then another constraint is hit, and the update gets stuck at the corner of the feasible set without being able to apply all of the stochastic gradient. The resulting light gray dot is *not* the projection of the star onto the constraints, hence the projection for this iteration is suboptimal. However, it is likely that a future stochastic gradient will jiggle the optimization loose, as pictured in (d), producing an update that is again an optimal projection of the latest stochastic gradient.

9.4.2 Stochastic Constraints with LightTouch

An optimal approach we compared with for handling large-scale constraints is called *LightTouch* (Cotter et al., 2015). At each iteration, LightTouch does not project onto any constraints, but rather moves the constraints into the objective, and applies a random sub-

set of constraints each iteration as stochastic gradient updates to the parameters, where the distribution over the constraints is learned as the optimization proceeds to focus on constraints that are more likely to be active. This replaces the per-iteration projections with cheap gradient updates. Intermediate solutions may not satisfy all the constraints, but one full projection is performed at the very end to ensure final satisfaction of the constraints. Experimentally, we found LightTouch generally converged faster (see Cotter et al. (2015) for its theoretical convergence rate), while producing similar experimental results to the above approximate projected SGD. LightTouch does require a more complicated implementation to effectively learn the distribution over the constraints.

9.4.3 Adapting Stepsizes with Adagrad

One can generally improve the speed of SGD with adagrad (Duchi et al., 2011), even for nonconvex problems (Gupta et al., 2014). Adagrad decays the step-size adaptively for each parameter, so that parameters updated more often or with larger magnitude gradients have a smaller step size. We found adagrad did speed up convergence slightly, but required a complicated implementation to correctly handle the constraints because the projections must be with respect to the adagrad norm rather than the Euclidean norm. We experimented with approximating the adagrad norm projection with the Euclidean projection, but found this approximation resulted in poor convergence. The experimental results did not make use of adagrad.

10. Case Studies

We present a series of experimental case studies on real world problems to demonstrate different aspects of the proposed methods, followed by some example runtimes for interpolation and training in Section 10.7, and some observations about the practical value of imposing monotonicity in Section 10.8.

Previous datasets used to evaluate monotonic algorithms have been small, both in the number of samples and the number of dimensions, as detailed in Table 1. In order to produce statistically significant experimental results, and to better demonstrate the practical need for monotonicity constraints, we use real-world case studies with relatively large datasets, and for which the application engineers have confirmed that they expect or want the learned function to be monotonic with respect to some subset of features. The datasets used are detailed in Table 3, and include datasets with eight thousand to 400 million samples, and nine to sixteen features, most of which are constrained to be monotonic.

The case studies demonstrate that for problems where the monotonicity assumption is warranted, the proposed calibrated monotonic lattice regression produces similar accuracy to random forests. Random forests is an unconstrained method that consistently provides competitive results on benchmark datasets, compared to many other types of machine learning methods (Fernandez-Delgado et al., 2014)).

Because any bounded function can be expressed using a sufficiently fine-grained interpolation look-up table, we expect that with appropriate use of regularizers, monotonic lattice regression will perform similarly to other guaranteed monotonic methods that use a flexible function class and are appropriately regularized, such as monotonic neural nets (see 2.2.5). However, of guaranteed monotonic methods, the only monotonic strategy that has

Dataset	# Training Samples	# Test Samples	# Features	# Lattice Parameters
Business Matching	8,000	4,000	9	1728
Ad–Query Matching	235,996	58,224	5	32
Rendering Classifier	20,000	2,500	16	65,536
Fusing Pipelines	1.6 million	390k	12	24,576
Video Ranking	400 million	25 million	12	531,441

Table 3: Summary of datasets used in the case studies.

been demonstrated to scale to the number of training samples and the number of features treated in our case studies is linear regression with non-negative coefficients (see Table 1).

10.1 General Experimental Details

We used ten-fold cross-validation on each training set to choose hyperparameters, including: whether to use graph Laplacian regularization or torsion regularization, how much regularization (in powers of ten), whether to calibrate missing data or use a missing data vertex, the number of change-points if feature calibration was used from the choices: $\{2, 3, 5, 10, 20, 50\}$, and the number of vertices for each feature was started at 2 and increased by 1 as long as cross-validation accuracy increased. The step size was tuned using ten-fold cross-validation and choices were powers of 10; it was usually chosen to be one of $\{.01, .1, 1\}$. If calibration functions were used, a hyperparameter was used to scale the step size for the calibration function gradients compared to the lattice function gradients; this calibration step size scale was also chosen using ten-fold cross-validation and powers of 10, and was usually chosen to be one of $\{.01, .1, 1, 10\}$. Multilinear interpolation was used unless it is noted that simplex interpolation was used. The loss function was squared error, unless noted that logistic loss was used.

Comparisons were made to random forests (Breiman, 2001), and to linear models, with either the logistic loss (logistic regression) or squared error loss (linear regression), and a ridge regularizer on the linear coefficients, with any categorical or missing features converted to Boolean features. All comparisons were trained on the same training set, hyperparameters were tuned using cross-validation, and tested on the same test set. Statistical significance was measured using a binomial statistical significance test with a p-value of .05 on the test samples rated differently by two models.

10.2 Case Study: Business Entity Resolution

In this case study, we compare the relative impact of several of our proposed extensions to lattice regression. The business entity resolution problem is to determine if two business descriptions refer to the same real-world business. This problem is also treated by Dalvi et al. (2014), where they focus on defining a good title similarity. Here, we consider only the problem of fusing different similarities (such as a title similarity and phone similarity) into one score that predicts whether a pair of businesses are the same business. The learned function is required to be monotonically increasing in seven attribute similarities, such as

the similarity between the two business titles and the similarity between the street names. There are two other features with no monotonicity constraints, such as the geographic region, which takes on one of 14 categorical values. Each sample is derived from a pair of business descriptions, and a label provided by an expert human rater indicating whether that pair of business descriptions describe the same real-world business. We measure accuracy in terms of whether a predicted label matches the ground truth label, but in actual usage, the learned function is also used to rank multiple matches that pass the decision threshold, and thus a strictly monotonic function is preferred to a piecewise constant function. The training and test sets, detailed in Table 3, were randomly split from the complete labeled set. Most of the samples were drawn using active sampling, so most of the samples are difficult to classify correctly.

Table 4 reports results. The linear model performed poorly, because there are many important high-order interactions between the features. For example, the pair of businesses might describe two pizza places at the same location, one of which recently closed, and the other recently opened. In this case, location-based features will be strongly positive, but the classifier must be sensitive to low title similarity to determine the businesses are different. On the other hand, high title similarity is not sufficient to classify the pair as the same, for example, two Starbucks cafes across the street from each other in downtown London.

The lattice regression model was first optimized using cross-validation, and then we made the series of minor changes (with all else held constant) listed in Table 4 to illustrate the impact of these changes on accuracy. First, removing the monotonicity constraints resulted in a statistically significant drop in accuracy of half a percent. Thus it appears the monotonicity constraints are successfully regularizing given the small amount of training data and the known high Bayes error in some parts of the feature space. Lattice regression without the monotonicity constraints performed similarly to random forests (and not statistically significantly better), as expected due to the similar modeling abilities of the methods.

The cross-validated lattice was $3 \times 3 \times 3 \times 2^6$, where the first three features used a missing data vertex (so the non-missing data is interpolated from a 2^9 lattice). Calibrating the missing values for those three features instead of using missing data vertices statistically significantly dropped the accuracy from 81.9% to 80.7%. (However, if one subsamples the training set down to 3000 samples, then the less flexible option of calibrating the missing values works better than using missing data vertices.)

The cross-validated calibration used five changepoints for two of the four continuous features, and no calibration for the two other continuous features. Figure 8 shows the calibrations learned in the optimized lattice regression. Removing the continuous signal calibration resulted in a statistically significant drop in accuracy.

Another important proposal of this paper is calibrating categorical features to real-valued features. For this problem, this is applied to a feature specifying which of 14 possible geographical categories the businesses are in. Removing this geographic feature statistically significantly reduced the accuracy by half a percent.

The amount of torsion regularization was cross-validated to be 10^{-4}. Changing to graph Laplacian and re-optimizing the amount of regularization decreased accuracy slightly, but not statistically significantly so. This is consistent with what we often find: torsion is

	Test Set Accuracy	Monotonic Guarantee?
Linear Model	66.6%	yes
Random Forest	81.2%	no
Lattice Regression, Optimized	81.9%	yes
... Remove Monotonicity Constraints	81.4%	no
... Calibrate All Missing Data	80.7%	yes
... Remove Calibration	81.1%	yes
... Remove the Geographic Feature	81.4%	yes
... Change to Graph Laplacian	81.7%	yes
... Change to Simplex Interpolation	81.6%	yes

Table 4: Comparison on a business entity resolution problem.

often slightly better, but often not statistically significantly so, than the graph Laplacian regularizer.

Changing the multilinear interpolation to simplex interpolation (see Section 5.2) dropped the accuracy slightly, but not statistically significantly. For some problems we even see simplex interpolation provide slightly better results, but generally the accuracy difference between simplex and multilinear interpolation is negligible.

10.3 Case Study: Scoring Ad–Query Pairs

In this case study, we demonstrate the potential of the calibration functions. The goal is to score how well an ad matches a web search query, based on five different features that each measure a different notion of a good match. The score is required to be monotonic with respect to all five features. The labels are binary, so this is trained and tested as a classification problem. The train and test sets were independently and identically distributed, and are detailed in Table 3.

Results are shown in Table 5. The cross-validated lattice size was $2 \times 2 \times 2 \times 2 \times 2$, and the calibration functions each used 5 changepoints. Removing the calibration functions and re-cross-validating the lattice size resulted in a larger lattice sized $4 \times 4 \times 4 \times 4 \times 4$, and slightly worse (but not statistically significantly worse) accuracy. In total, the uncalibrated lattice model used 1024 parameters, whereas the calibrated lattice model used only 57 parameters. We hypothesize that the smaller calibrated lattice will be more robust to feature noise and drift in the test sample distribution than the larger uncalibrated lattice model. In general, we find that the one-dimensional calibration functions are a very efficient way to capture the flexibility needed, and that in conjunction with good one-dimensional calibrations, only coarse-grained (e.g. 2^D) lattices are needed.

Both with and without calibration functions, the lattice regression models were statistically significantly better than the linear model. The random forest performed well, but was not statistically significantly better than the lattice regression.

A boosted stumps model was also trained for this problem. See Fig. 12 for a comparison of two-dimensional slices of the boosted stumps and lattice functions. The boosted stumps' test set accuracy was relatively low at 75.4%. In practice, the goal of this problem is to have

	Test Set Accuracy	Monotonic Guarantee?
Linear Model	77.2%	yes
Random Forests	78.8%	no
Lattice Regression	78.7%	yes
... Remove Continuous Signal Calibration	78.4%	yes

Table 5: Comparison on an ad-query scoring problem.

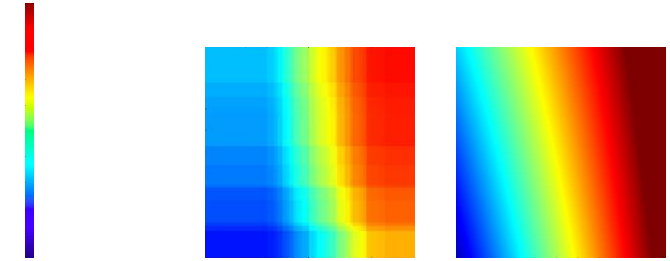

Figure 12: Slices of the learned ad-query matching functions for boosted stumps and a $2 \times 2 \times 2 \times 2 \times 2$ lattice regression, plotted as a function of two of the five features, with median values chosen for the other three features. The boosted stumps required hundreds of stumps to approximate the function, and the resulting function is piecewise constant, creating frequent ties when ranking a large number of ads for a given query, despite a priori knowledge that the output should be strictly monotonic in each of the features.

a score useful for ranking candidates as well as determining if they are a sufficiently good match. Even with many trees, this model produces many ties due its piecewise-constant surface. In addition, the live experiments with the boosted stumps showed that the output was problematically sensitive to feature noise, which would cause samples near the boundary of two piecewise constant surfaces to experience fluctuating scores.

10.4 Case Study: Rendering Classifier

This case study demonstrates training a flexible function (using a lattice) that is monotonic with respect to fifteen features. The goal is to score whether a particular display element should be rendered on a webpage. The score is required to be monotonic in fifteen of the features, and there is a sixteenth Boolean feature that is not constrained. The training and test sets (detailed in Table 3) consisted almost entirely of samples known to be difficult to correctly classify (hence the rather low accuracies).

We used a fixed 2^{16} lattice size, a fixed 5 changepoints per feature for the six continuous signals (the other ten signals were Boolean), and no graph regularization, so no hyperpa-

	Test Set Accuracy	Monotonic Guarantee?
Linear Model	54.6%	yes
Random Forest	61.3%	no
Lattice Regression	63.0%	yes

Table 6: Comparison on a rendering classifier.

rameters were optimized for this case study. Simplex interpolation was used for speed. A single training loop through the 20,000 training samples took around five minutes on a Xeon-type Intel desktop using a single-threaded C++ implementation with sparse vectors, with the training time dominated by the constraint handling. Training in total took around five hours.

Results in Table 6 show substantial gains over the linear model, while still producing a monotonic, smooth function. The lattice regression was also statistically significantly better than random forests, we hypothesize due to the regularization provided by the monotonicity constraints which is important in this case due to the difficulty of the problem on the given examples and the relatively small number of training samples.

10.5 Case Study: Fusing Pipelines

While this paper focuses on learning monotonic functions, we believe it is also the first paper to propose applying lattice regression to classification problems, rather than only regression problems. With that in mind, we include this case study demonstrating that lattice regression *without constraints* also performs similarly to random forests on a real-world large-scale multi-class problem.

The goal in this case study is to fuse the predictions from two pipelines, each of which makes a prediction about the likelihood of seven user categories based on a different set of high-dimensional features. Because each pipeline's probability estimates sum to one, only the first six probability estimates from each pipeline are needed as features to the fusion, for a total of twelve features. The training and test set were split by time, with the older 1.6 million samples used for training, and the newest 390,000 samples used as a test set.

The lattice was trained with a multi-class logistic loss, and used simplex interpolation for speed. The cross-validated model was a 2^{12} lattice for six of the output classes (with the probability of the seventh class being subtracted from one) and no calibration functions, resulting in a total of $2^{12} \times 6 = 24,576$ parameters.

The results are reported in Table 7. Even though Pipeline 2 alone is 6.5% more accurate than Pipeline 1 alone, the test set accuracy can be increased by fusing the estimates from both pipelines, with a small improvement in accuracy by lattice regression over the random forest classifier, logistic regression, or simply averaging the two pipeline estimates.

10.6 Case Study: Video Ranking and Large-Scale Learning

This case study demonstrates large-scale training of a large monotonic lattice and learning from ranked pairs. The goal is to learn a function to rank videos a user might like to watch,

	Test Set Accuracy Gain on top of Pipeline 1 Accuracy
Pipeline 2 Only	6.5%
Average the Two Pipeline Estimates	7.4%
Fuse with Linear Model	8.5%
Fuse with Random Forest	9.3%
Fuse with Lattice Regression	9.7%

Table 7: Comparison on fusing user category prediction pipelines.

based on the video they have just watched. Experiments were performed on anonymized data from YouTube.

Each feature vector x_i is a vector of features about a pair of videos, $x_i = h(v_j, v_k)$, where v_j is the watched video, v_k is a candidate video to watch next, and h is a function that takes a pair of videos and outputs a twelve-dimensional feature vector x_i. For example, a feature might be the number of times that video v_j and video v_k were watched in the same session.

Each of the twelve features was specified to be positively correlated with users viewing preference, and thus we constrained the model to be monotonically increasing with respect to each. Of course, human preference is complicated and these monotonicity constraints cannot fully model human judgement. For example, knowing that a video that has been watched many times is generally a very good indicator that it is good to suggest, and yet a very popular video at some point will flare out and become less popular.

Monotonicity constraints can also be useful to enforce secondary objectives. For example, all other features equal, one might prefer to serve fresher videos. While users in the long-run want to see fresh videos, they may preferentially click on familiar videos, thus click data may not capture this desire. This secondary goal can be enforced by constraining the learned function to be monotonic in a feature that measures video freshness. This achieves a multi-objective function without overly-complicating or distorting the training label definition.

There are billions of videos in YouTube, and thus many many pairs of watched-and-candidate videos to score and re-score as the underlying feature values change over time. Thus it is important the learned ranking functions to be cheap to evaluate, and so we use simplex interpolation for its evaluation speed; see Section 10.7 for comparison of evaluation speeds.

We trained to minimize the ranked pairs objective from (9), such that the learned function f is trained for the goal of minimizing pairwise ranking errors,

$$f(h(v_j, v_k^+)) > f(h(v_j, v_k^-)),$$

for each training event consisting of a watched video v_j, and a pair of candidate videos v_k^+ and v_k^- where there is information that a user who has just watched video v_j prefers to watch v_k^+ next over v_k^-.

10.6.1 Which Pairs of Candidate Videos?

A key question is which sample pairs of candidate videos v_k^+ and v_k^- should be used as the preferred and unpreferred videos for a given watched video v_j. We used anonymized click data from YouTube's current video-suggestion system. For each watched video v_j, if a user clicked a suggested video in the second position or below, then we took the clicked video as the preferred video v_k^+, and the video suggested right above the clicked video as the unpreferred video v_j^-. We call this choice of v_k^+ and v_k^- a *bottom-clicked pair*. This choice is consistent with the findings of Joachims et al. (2005), whose eye-tracking experiments on webpage search results showed that users on average look at least at one result above the clicked result, and that these pairs of preferred/unpreferred samples correlated strongly with explicit relevance judgements. Also, using bottom-clicked pairs removes the *trust bias* that users know they are being presented with a ranked list and prefer samples that are ranked-higher (Joachims et al., 2005). In a set of preliminary experiments, we also tried training using either a randomly sampled video as v_k^-, or the video just after the clicked video, and then tested on bottom-clicked pairs. Those results showed test accuracy on bottom-clicked pairs was up to 1% more accurate if the training set only included the bottom-clicked pairs, even though that meant fewer training pairs.

An additional goal (and one that is common in commercial large-scale machine learning systems for various practical reasons) is for the learned ranking function to be as similar to the current ranking function as possible. That is, we wish to minimize changes to the current scoring if they do not improve accuracy; such accuracy-neutral changes are referred to as *churn*. To reduce churn, we added in additional pairs that reflect the decisions of the current ranking function. Each of these pairs also takes the clicked video as the preferred v_k^+, but sets the unpreferred video v_k^- to be the video that the current system ranked ten candidates lower than the clicked video. The dataset is a 50-50 mix of these churn-reducing pairs and bottom-clicked pairs.

10.6.2 More Experimental Details

The dataset was randomly split into mutually exclusive training, test, and validation sets of size 400 million, 25 million, and 25 million pairs, respectively. To ensure privacy, the dataset only contained the feature vector, and no information identifying the video or user. The disadvantage of that is the train, test and validation sets are likely to have some samples from the same videos and same users. However, in total the datasets capture millions of unique users and unique watched videos.

We used a fixed 3^{12} lattice, for a total of 531,441 parameters. The pre-processing functions were fixed in this case, so no calibration functions were learned. We compared training on increasingly-larger randomly-sampled subsets of the 400 million training set (see Figure 13 for training set sizes). We compared training on a single worker to the parallelize-and-average strategy explained in Section 9.2. Parallel results were parallelized over 100 workers. The stepsize was chosen independently for each training set based on accuracy on the validation set.

We report results with and without monotonicity constraints. For the unconstrained results, each training (single or parallel) touched each sample in the training set once. For the monotonic results (single or parallelized), each sample was touched ten times, and

minibatching was used with a minibatch size of 32 stochastic gradients. Logistic loss was used.

10.6.3 Results

Figure 13 compares test set accuracy for single and parallelized training for different amounts of training data, with and without monotonicity constraints. For each dataset, the single and parallel training saw the same total number of training samples and were allowed the same total number of stochastic gradient updates.

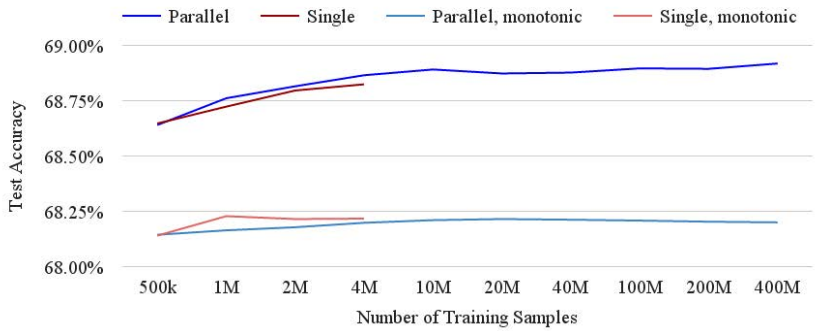

Figure 13: Comparison of training with a single worker versus 100 workers in parallel, as a function of training set size.

On the click data test set, not using monotonicity constraints (the dark lines) is about .5% better at pairwise accuracy than if we constrain the function to be monotonic. However, in live experiments that required ranking all videos (not only ones that had been top-ranked in the past, and hence included in the click data sets), models trained with monotonicity constraints showed better performance on the actual measures of user-engagement (as opposed to the training metric of pairwise accuracy). This discrepancy appears to be due to the biased sampling of the click data, as the click-data has a biased distribution over the feature space compared to the distribution of all videos which must get ranked in practice. The biased distribution of the click data appears to cause parameters in sparser regions of the feature space to be non-monotonic in an effort to increase the flexibility (and accuracy) of the function in the denser regions, thus increasing the accuracy on the click data. Enforcing monotonicity helps address this sampling bias problem by not allowing the training to ignore the accuracy in sparser regions that are important in practice to accurately rank all videos.

Even though there are 500k parameters to train, the click-data accuracy is already very good with only 500k training samples, and test accuracy increases only slightly when trained on 400 million samples compared to 10 million samples. This is largely because the click-

data samples are densely clustered in the feature space, and with simplex interpolation, only a small fraction of the 500k parameters control the function over the dense part of the feature space.

The darker lines of Figure 13 show the parallelization versus single-machine results *without* monotonicity constraints. Unconstrained, the parallelized runs appear to perform slightly better to the single-machine training given the same number of training samples (and the same total number of gradient updates). We hypothesize this slight improvement is due to some noise-averaging across the 100 parallelized trained lattices. The lighter lines of Figure 13 show the parallelization versus single-machine results *with* monotonicity constraints. Trained on 500k pairs, the parallelized training and single-machine monotonic training produce the same test accuracy. However, as the training set size increases, the parallelized training takes more data to achieve the same accuracy as the single-machine training. We believe this is because averaging the 100 monotonic lattices is a convex combination of lattices likely on the edge of the monotonicity constraint set, producing an average lattice in the interior of the constraint set, that is, the averaged lattice is over-constrained.

10.7 Run Times

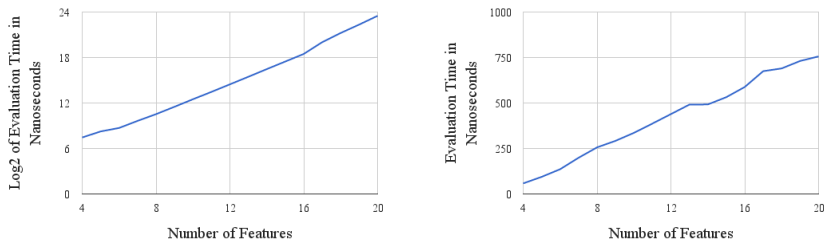
We give some timing examples for the different interpolations and for training.

Figure 14 shows average evaluation times for multilinear and simplex interpolation of one sample from a 2^D lattice for $D = 4$ to $D = 20$ using a single-threaded 3.5GHz Intel Ivy Bridge processor. Note the multilinear evaluation times are reported on a log-scale, and on a log scale the evaluation time increases roughly linearly in D, matching the theoretical $O(2^D)$ complexity given in Section 5.1. The simplex evaluation times scale roughly linearly with D, consistent with the theoretical $O(D \log D)$ complexity. For $D = 6$ features, simplex interpolation is already three times faster than multilinear. With $D = 20$ features, the simplex interpolation is still only 750 nanoseconds, but the multilinear interpolation is about $15,000$ times slower, at around 12 milliseconds.

Training times are difficult to report in an accurate or meaningful way due to the high-variance of running on a large, shared, distributed cluster. Here is one example: with every feature constrained to be monotonic, a single worker training one loop of a 2^{12} lattice on 4 million samples usually takes around 15 minutes, whereas with 100 parallelized workers one loop through 400 million samples (4 million samples for each worker) usually takes around 20 minutes. Large step-sizes can take much longer than smaller stepsizes, because larger updates tend to violate more monotonicity constraints and thus require more expensive projections. Minibatching is particularly effective at speeding up training because the averaged batch of stochastic gradients reduces the number of monotonicity violations and the need for projections. Without monotonicity constraints, training is generally $10\times$ to $1000\times$ faster, depending on how non-monotonic the data is.

10.8 Interpretability in Practice

It is difficult to quantify interpretability, but we summarize our observations from working with around 50 different users on around a dozen different real-world machine learning problems where there are a relatively small number of semantically meaningful features.



(a) Multilinear Interpolation

(b) Simplex Interpolation

Figure 14: Average evaluation time to interpolate a sample from a 2^D lattice. Figure (a) shows the multilinear interpolation time on a $\log_2$ scale in nanoseconds. Figure (b) shows the much faster simplex interpolation time in nanoseconds. Simplex interpolation is $10\times$ faster than multilinear for $D = 9$ features, about $100\times$ faster for $D = 13$ features, and over $1,000\times$ faster for $D = 17$ features.

First, we do find that being able to summarize a model as being a positive or negative function with respect to each input feature does help users feel that they understand and can predict the model's behavior better than a comparable unconstrained model. In particular, while aggregate measures like accuracy, precision, or recall over a test set provide summary statistics over that particular test set, we find that users in some cases do worry about the *unknown unknowns* of using a machine learning model, and that adding monotonicity constraints gives these users more confidence that the model can be trusted not to behave unreasonably for any examples. And this confidence is well-founded: as discussed in the video ranking case study in Section 10.6, monotonicity constraints do in practice guard against potentially strange behavior of highly nonlinear functions in rarer parts of the feature space.

We have also found that monotonicity constraints make debugging highly nonlinear models easier. We find that one particularly useful debugging tool is sensitivity plots like the one shown in Figure 15, which show how $f(x)$ relates to each feature value of x, for a particular sample x. Monotonicity constraints make these sensitivity plots monotonic, which we find makes it easier to identify problems with signals and training data.

Apart from the issue of monotonicity, we expected that using one-dimensional calibration functions and interpolated look-up tables would produce parameters that were interpretable. These expectations were half-right. We do find it helpful and common for users to check and analyze the signals' calibration functions, and that the calibrations provide useful information to users about what the model has learned, and helps identify unexpected behavior or problems with features. But, we do not find that users examine the *lattice* parameters directly very often, and that the readability of the lattice parameters becomes generally less useful as D increases. Users are more likely to utilize other analytics, such as how correlated the output is with each calibrated feature. While this information does not

control for between-feature correlations (so a feature might be highly correlated with the output but not needed if it correlates with another feature), users can conclude the model behaves a lot like highly-correlated features, and this aids model understanding. Low correlation between a calibrated feature and the output either indicates an unimportant feature, or, if the feature is known to be important (because dropping it hurts accuracy), that it plays an important role interacting or conditioning other features.

To understand feature interactions, again we find that rather than analyze the lattice parameters explicitly, users generally prefer to analyze two-dimensional visualizations of the model over pairs of features (averaged or sliced over the other features), or to examine examples to check their hypotheses about expected higher-order interactions.

Another common problem is to understand how two similar models are different (for example, one might have been trained with more training data, or one might use an additional feature). For this purpose, we find it is again rare that users want to directly analyze differences in model parameters except for very tiny models, preferring instead to look at examples that are scored differently by the two models, and analyzing these example samples in their raw form (for example, looking at the videos that have been promoted or demoted by a new model, in conjunction with the features used by the model).

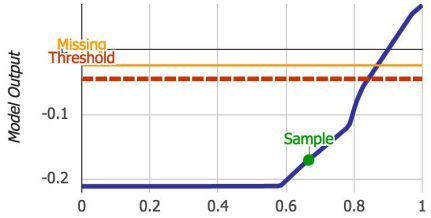


Figure 15: Illustration of a sensitivity plot for a calibrated monotonic lattice with respect to one of the D features. The blue line shows how the output $f(x)$ (y-axis) of a calibrated monotonic lattice changes if only this one feature value of x (x-axis) is changed, but all other components of x are kept fixed. The green dot marks the current input and output. The yellow line shows the model output if the first feature is missing. The red dotted line shows the binary classification threshold. This plot is piecewise linear because the calibrator function is piecewise linear and the simplex interpolation is also piecewise linear, and monotonically increasing because the function was constrained to be monotonic with respect to this feature. In this example, one sees that to change the classification decision without changing any other features, this feature would have to be increased from its current value of 0.67 to at least 0.84 at which point it would cross the red line marking the decision threshold.

11. Discussion and Some Open Questions

We have proposed using constrained interpolated look-up tables to effectively learn flexible, monotonic functions for low-dimensional machine learning problems of classification, ranking, and regression. We addressed a number of practical issues, including interpretability, evaluation speed, automated pre-processing of features, missing data, and categorical features. Experimental results show state-of-the-art performance on the largest training sets and largest number of features published for monotonic methods.

Practical experience has shown us that being able to check and ensure monotonicity helps users trust the model, and leads to models that generalize better. For us, the monotonicity constraints have come from engineers who believe the output should be monotonic in the feature. In the absence of clear prior information about monotonicity, it may be tempting to use the direction of a linear fit to specify a monotonic direction and then use monotonicity as a regularizer. Magdon-Ismail and Sill (2008) point out that using the linear regression coefficients for this purpose can be misleading if features are correlated and not jointly Gaussian.

For classifiers, requiring the entire function to be monotonic is a stronger requirement than needed to simply guarantee that the decision boundary (and hence classifier) is monotonic. It is an open question how to enforce only the thresholded function to be monotonic, and whether that would be more useful in practice.

One surprise was that for practical machine learning problems like those of Section 10, we found a simple 2^D lattice is often sufficient to capture the interactions of D features, especially if we jointly optimized D one-dimensional feature calibration functions. When we began this work, we expected to have to use much more fine-grained lattices with many vertices in each feature, or perhaps irregular lattices to achieve state-of-the-art accuracy. In fact, calibration functions help approximately linearize each feature with respect to the label, making a 2^D lattice sufficiently flexible for most of the real-world problems we have encountered.

For some cases, a 2^D lattice is too flexible. We reduced lattice flexibility with new regularizers: monotonicity, and the torsion regularizer that encourages a more linear model. While good for interpretability and accuracy, these regularization strategies do not reduce the model size.

For a large number of features D, the exponential model size of a 2^D lattice is a memory issue. On a single machine, training and evaluating with a few million parameters is viable, but this still limits this approach to not much more than $D = 20$ features. An open question is how such large models could be sparsified, and if useful sparsification approaches could also provide additional useful regularization.

A second surprise was that simplex interpolation provides similar accuracy to multilinear interpolation. The rotational dependence of simplex interpolation seemed at first troubling, but the proposed approach of aligning the shared axis of the simplices with the main increasing axis of the function appears to solve this problem in practice. The geometry of the simplices at first seemed odd in that it produces a locally linear surface over elongated simplices. However, this partitioning turns out to work well because it provides a very flexible piecewise linear decision boundary. Lastly, we found that the theoretical

$O(D \log D)$ computational complexity does result in practice in orders of magnitude faster interpolation than multilinear interpolation as D increases.

A common practical issue in machine learning is handling categorical data. We proposed to learn a mapping from mutually exclusive categories to feature values, jointly with the other model parameters. We found categorical-mapping to be interpretable, flexible, and accurate. The proposed categorical mapping can be viewed as learning a one-dimensional embedding of the categories. Though we generally only needed two vertices in the lattice for continuous features, for categorical features we often find it helpful to use more vertices (a finer-grained lattice) for more flexibility. Some preliminary experiments learning two-dimensional embeddings of categories (that is, mapping one category to $[0, 1]^2$) showed promise, but we found this required more careful initialization and handling of the increased non-convexity.

Learning the monotonic lattice is a convex problem, but composing the lattice and the one-dimensional calibration functions creates a non-convex objective. We used only one initialization of the lattice and calibrators for all our experiments, but tuned the stepsize of the stochastic gradient descent separately for the set of lattice parameters and the set of calibration parameters. In some cases we saw a substantial sensitivity of the accuracy to the initial SGD stepsizes. We hypothesize that this is caused by some interplay of the relative stepsizes and the relative size of the local optima.

We employed a number of strategies to speed up training. One of the biggest speed-ups comes from randomly sampling the additive terms of the graph regularizers, analogous to the random sampling of the additive terms of the empirical loss that SGD uses. We showed that a parallelize-and-average strategy works for training the lattices. The largest computational bottleneck remains the projections onto the monotonicity constraints. Mini-batching the samples reduces the number of projections and provides speed-ups, but a faster approach to optimization given possibly hundreds of thousands of constraints would be valuable.

Lastly, this work leaves open a number of theoretical questions for the function class of interpolated look-up tables, for example how monotonicity constraints theoretically affect convergence speed.

Abstract

The JMLR study *Do we need hundreds of classifiers to solve real world classification problems?* benchmarks 179 classifiers in 17 families on 121 data sets from the UCI repository and claims that "the random forest is clearly the best family of classifier". In this response, we show that the study's results are biased by the lack of a held-out test set and the exclusion of trials with errors. Further, the study's own statistical tests indicate that random forests do not have significantly higher percent accuracy than support vector machines and neural networks, calling into question the conclusion that random forests are the best classifiers.

Keywords: classification, benchmarking, random forests, support vector machines, neural networks

1. Errors in Results

The authors state that they used the following training procedure for 102 of the 121 benchmarked data sets, which were not already divided into training and test sets:

> "One training and one test set are generated randomly (each with 50% of the available patterns) [...]. This couple of sets is used only for parameter tuning (in those classifiers which have tunable parameters), selecting the parameter values which provide the best accuracy on the test set. [...] Then, using the selected values for the tunable parameters, a 4-fold cross validation is developed using the whole available data. [...] The test results is the average over the 4 test sets."

This procedure is incorrect because **it does not use a held-out test set**. Since half the test examples are also used as a validation set for hyperparameter tuning, selecting hyperparameters which maximize accuracy on the validation set will by definition inflate performance on half the test examples. This error has likely inflated the reported performance of at least some of the benchmarked classifiers with tunable hyperparameters (based on the descriptions in the original paper, these include `rrlda_R`, `sda_t`, `PenalizedLDA_t`, `sparseLDA_R`, `fda_t`, `mda_t`, `pda_t`, `rda_R`, `hdda_R`, `rbf_m`, `rbf_t`, `rbfDDA_t`, `mlp_m`, `mlp_C`, `mlp_t`, `avNNet_t`, `mlpWeightDecay_t`, `nnet_t`, `pcaNNet_t`, `pnn_m`, `elm_m`, `elm_kernel_m`, `lvq_R`, `lvq_t`, `dkp_C`, `svm_C`, `svmlight_C`, `LibSVM_w`, `svmRadial_t`, `svmRadialCost_t`, `svmLinear_t`, `svmPoly_t`, `lssvmRadial_t`, `rpart_t`, `rpart2_t`, `ctree_t`, `ctree2_t`, `JRip_t`, `C5.0_t`, `MultiBoostAB_LibSVM_w`, `Bagging_LibSVM_w`, `rf_t`, `RRF_t`, `cforest_t`, `parRF_t`, `RRFglobal_t`, `MultiScheme_w`, `knn_R`, `knn_t`, `IBk_w`, `pls_t`, `spls_R`, `multinom_t`, `CVParameterSelection_w`, `gaussprRadial_t` and possibly others). The authors justify the procedure by stating that:

> "We must emphasize that, since parameter tuning and testing use different data sets, the final result can not be biased by parameter optimization, because the set of parameter values selected in the tuning stage is not necessarily the best on the test set."

While hyperparameter tuning and testing do technically use different sets of examples, since one is a subset of the other, the two sets must be disjoint to avoid bias.

Further, the authors did not follow the stated procedure: the test evaluation does not use cross-validation since the 4 test sets[1] are not independent. For instance, trains, the smallest benchmark with 10 examples, has two examples in each test set, with the following indices: $\{2,9\}$, $\{4,9\}$, $\{4,9\}$, and $\{4,7\}$. This means that examples 4 and 9 are given three times the weight of examples 2 and 7 when calculating the test accuracy, and the other six examples are ignored. This negates the purpose of cross-validation, which is to give equal importance to every example.

The results are also biased by the exclusion of trials with errors. If a classifier is unable to run a particular benchmark, that benchmark is excluded when calculating the classifier's mean percent accuracy—but it is not excluded for classifiers that ran it successfully. Effectively, each classifier is evaluated on a slightly different set of benchmarks, so the mean percent accuracies are not directly comparable. We re-evaluated the mean percent accuracy of the top 8 classifiers on only the benchmarks successfully run by all 8, and found that a neural network, `elm_kernel_matlab`, was competitive with random forests (Table 1), even having the highest mean accuracy (albeit by a very small, insignificant, margin). Still, this neural network also had the highest number of failures (which did not count toward mean accuracy).

2. Flawed Conclusions

The conclusion that "The random forest is clearly the best family of classifiers" is flawed. The paper gives three arguments for why random forests are the best family: "The eight random forest classifiers are included among the 25 best classifiers having all of them low ranks", "The family RF has the lowest minimum rank (32.9) and mean (46.7), and also a narrow interval (up to 60.5), which means that all the RF classifiers work very well", and "3 out of [the] 5" best classifiers are random forests.

The problem with the first two arguments is that the notion of a "best family" is not well defined, and is sensitive to the choice of classifiers included in each family. For instance,

1. Partitions are available at http://persoal.citius.usc.es/manuel.fernandez.delgado/papers/jmlr/data.tar.gz.

Rank	Classifier	Mean % accuracy		# failed
		Original	Corrected	
1	elm_kernel_matlab	81.96	81.84	7
2	rf_caret	82.30	81.78	1
3	rforest_R	81.93	81.58	1
4	parRF_caret	81.96	81.32	0
5	svm_C	81.81	81.30	2
6	svmRadialCost_caret	81.43	81.17	6
7	svmPoly_caret	81.19	81.06	6
8	svmRadial_caret	81.04	80.82	6

Table 1: Mean percent accuracy of the top 8 classifiers reported in Fernández-Delgado et al. ("Original") and when re-evaluated on only the benchmarks successfully run by all 8 ("Corrected"). The number of benchmarks which failed to run for each classifier is also shown. A neural network, elm_kernel_m, has the highest mean percent accuracy, followed by three random forest models and then four support vector machine models.

the worst-performing neural network is the direct parallel perceptron (Fernandez-Delgado et al. (2011)), developed by the authors of the original paper and designed to favour extreme computational efficiency over accuracy. Similarly, the worst rule-based classifier, ZeroR_w, is a baseline that always predicts the majority class. Mean accuracy conflates these classifiers with others in the same family that are designed to favour accuracy. Also, larger families will tend to have greater variance, with a lower minimum rank and a higher maximum rank.

The argument that "3 out of [the] 5" best classifiers are random forests is also questionable. The three best random forest classifiers are actually a single classifier (randomForest in R) with different wrappers (parRF_t is parallelized; parRF_t and rf_t use caret) and settings for mtry, the number of features in each tree (parRF_t uses a grid search of 2 to 8 in steps of 2; rf_t searches from 2 to 29 in steps of 3, and rforest_R sets mtry = $\sqrt{\#features}$), so it would be more correct (but still not fully correct) to say that one out of the three best classifiers is a random forest and two are support vector machines.

Most importantly, the results do not show that the best random forests perform any better than the best support vector machines and neural networks. The authors conducted paired t-tests showing that the differences in accuracy between the top-ranked random forest parRF_t and the other top eight models, including support vector machines, neural networks and other random forests, are not statistically significant (left panel of Fig. 4 in Fernández-Delgado et al.). This calls into question the conclusion that random forests are the best classifiers.

The use of a paired t-test is itself incorrect, since the test assumes that the difference between the two distributions under comparison is normally distributed, yet none of the differences between parRF_t and the other top 10 classifiers are normally distributed according to a χ^2 goodness-of-fit test for normality (Table 2). Also, before calculating the p values in Fig. 4, missing values were imputed by setting accuracies for benchmarks with errors to 82%, the mean accuracy of parRF_t across all benchmarks. This biases the results because 82% is an average over many benchmarks, some of which are so simple that every classifier achieves

Classifier	Normality p

avNNet_caret	6e-10
C5.0_caret	1e-21

Table 2: p values that the differences between parRF_t and each of the other top 10 classifiers, across all benchmarks where both classifiers ran without errors, are not normally distributed. All p values are significant, indicating that none of the differences are normally distributed.

Classifier	Paired t-test p, errors set to 82% (Fig. 4 in original paper)	Paired t-test p, excluding errors	Wilcoxon signed-rank p, excluding errors
elm_kernel_matlab	1	0.5	0.4
rf_caret	0.4	0.3	1
rforest_R	1	0.9	0.1
svm_C	0.8	1	0.8
svmRadialCost_caret	0.5	0.6	0.6
svmPoly_caret	0.3	0.4	0.4
svmRadial_caret	0.1	0.2	0.1
avNNet_caret	0.03	0.03	0.02
C5.0_caret	0.001	0.001	0.0001

Table 3: Using a Wilcoxon signed-rank test instead of a paired t-test, and removing missing values rather than incorrectly imputing them, results in the same conclusions about the significance of the differences between parRF_t and each of the other top 10 classifiers.

100% accuracy and others of which are so difficult that most classifiers achieves below 30% accuracy, so it is unreasonable to assume that a classifier would achieve 82% accuracy on every failed benchmark. A hypothetical classifier that failed to run every benchmark would be considered as good as parRF_t according to this imputation method! However, using the Wilcoxon signed-rank test, which does not make the same assumption of normality, and removing benchmarks where either classifier gave an error rather than imputing to 82%, results in the same conclusions about significance (Table 3).

To support the conclusion that parRF_t is better than the second-ranked classifier svm_C, even though the paired t-test showed them to be statistically indistinguishable, Fernández-Delgado et al. states that:

> "Although `parRF_t` is better than `svm_C` in 56 of 121 data sets, worse than `svm_C` in 55 sets, and equal in 10 sets, [...] `svm_C` is never much better than `parRF_t`: when `svm_C` outperforms `parRF_t`, the difference is small, but when `parRF_t` outperforms `svm_C`, the difference is higher [...]. In fact, calculating for each data set the difference between the accuracies of `parRF_t` and `svm_C`, the sum of positive differences (parRF is better) is 193.8, while the negative ones (`svm_C` better) sum [to] 139.8."

`parRF_t` and `svm_C` are only equal for 8 benchmarks, not 10: the two benchmarks where `svm_C` gave an error are erroneously counted towards this total. Also, the quoted figures are for `rf_t`, not `parRF_t`: the true figures, based on the online results, are 220.4 and 219.6. The above statement does not imply that the difference between `parRF_t` and `svm_C` is significant, since it is equivalent to saying that the difference in mean percent accuracy between the two classifiers, across the 119 benchmarks where both ran without errors, is $\frac{220.4-219.6}{119 \text{ benchmarks}} \approx 0.007$, a difference that the paired t-test already showed to be insignificant ($p = 0.834$ in Fig. 4 of the original paper, or $p = 0.8$ using a Wilcoxon signed-rank test). (Note that 0.007 does not exactly equal $82.0 - 81.8$, the difference between the reported mean percent accuracies of `parRF_t` and `svm_C`, because these accuracies are biased by the exclusion of trials with errors as discussed in Section 1.) Notably, the difference between `rf_t` and `svm_C` (193.8 vs 139.8), while larger, is also insignificant (Wilcoxon signed-rank $p = 0.8$).

3. Availability of Code

Code to reproduce the three tables and calculate the sum of positive and negative accuracy differences between pairs of classifiers is available as a supplement to this paper.

Abstract

We consider stationary hidden Markov models with finite state space and nonparametric modeling of the emission distributions. It has remained unknown until very recently that such models are identifiable. In this paper, we propose a new penalized least-squares estimator for the emission distributions which is statistically optimal and practically tractable. We prove a non asymptotic oracle inequality for our nonparametric estimator of the emission distributions. A consequence is that this new estimator is rate minimax adaptive up to a logarithmic term. Our methodology is based on projections of the emission distributions onto nested subspaces of increasing complexity. The popular spectral estimators are unable to achieve the optimal rate but may be used as initial points in our procedure. Simulations are given that show the improvement obtained when applying the least-squares minimization consecutively to the spectral estimation.

Keywords: nonparametric estimation, hidden Markov models, minimax adaptive estimation, oracle inequality, penalized least-squares.

1. Introduction

1.1 Context and Motivations

Finite state space hidden Markov models (HMMs for short) are widely used to model data evolving in time and coming from heterogeneous populations. They seem to be reliable tools to model practical situations in a variety of applications such as economics, genomics, signal processing and image analysis, ecology, environment, speech recognition, to name but a few. From a statistical view point, finite state space HMMs are stochastic processes $(X_j, Y_j)_{j\geq 1}$ where $(X_j)_{j\geq 1}$ is a Markov chain with finite state space and conditionally on $(X_j)_{j\geq 1}$ the Y_j's are independent with a distribution depending only on X_j. The observations are $Y_{1:N} = (Y_1, \ldots, Y_N)$ and the associated states $X_{1:N} = (X_1, \ldots, X_N)$ are unobserved. The parameters of the model are the initial distribution, the transition matrix of the hidden chain, and the emission distributions of the observations, that is the probability distributions of the Y_j's conditionally to $X_j = x$ for all possible x's. In this paper we shall consider stationary ergodic HMMs so that the initial distribution is the stationary distribution of the (ergodic) hidden Markov chain.

Until very recently, asymptotic performances of estimators were proved only in the parametric setting (that is, with finitely many unknown parameters). Though, nonparametric methods for HMMs have been considered in applied papers, but with no theoretical guarantees, see for instance Couvreur and Couvreur (2000) for voice activity detection, Lambert et al. (2003) for climate state identification, Lefèvre (2003) for automatic speech recognition, Shang and Chan (2009) for facial expression recognition, Volant et al. (2014) for methylation comparison of proteins, Yau et al. (2011) for copy number variants identification in DNA analysis.

The preliminary obstacle to obtain theoretical results on general finite state space nonparametric HMMs was to understand when such models are indeed identifiable. Marginal distributions of finitely many observations are finite mixtures of products of the emission distributions. It is clear that identifiability can not be obtained based on the marginal distribution of only one observation. It is needed, and it is enough, to consider the marginal distribution of at least three consecutive observations to get identifiability, see Gassiat et al. (2016), following Allman et al. (2009) and Hsu et al. (2012).

1.2 Contribution

The aim of our paper is to propose a new approach to estimate nonparametric HMMs with a statistically optimal and practically tractable method. We obtain this way nonparametric estimators of the emission distributions that achieve the minimax rate of estimation in an adaptive setting.

Our perspective is based on estimating the projections of the emission laws onto nested subspaces of increasing complexity. Our analysis encompasses any family of nested subspaces of Hilbert spaces and works with a large variety of models. In this framework one could think to use the spectral estimators as proposed by Hsu et al. (2012); Anandkumar et al. (2012) in the parametric framework, by extending them to the nonparametric framework. But a careful analysis of the tradeoff between sampling size and approximation complexity shows that they do not lead to rate optimal estimators of the emission densities, see De Castro et al. (2015) for a formal statement and proof. This can be easily understood. Indeed, the spectral estimators of the emission densities are computed as functions of the empirical estimator of the marginal distribution of three consecutive observations on $\mathcal{Y}^3$ (where $\mathcal{Y}$ is the observation space), for which, roughly speaking, when $\mathcal{Y}$ is a subset of $\mathbb{R}$, the optimal rate is $N^{-s/(2s+3)}$, N being the number of observations and s the smoothness of the emission densities. Thus the rate obtained this way for the emission densities is also $N^{-s/(2s+3)}$. But since those emission densities describe one dimensional random variables on $\mathcal{Y}$, one could hope to be able to obtain the sharper rate $N^{-s/(2s+1)}$. This is the rate we obtain, up to a $\log N$ term, with our new method. Let us explain how it works.

Using the HMM modeling, and using sieves for the emission densities on $\mathcal{Y}$, we propose a penalized least squares estimator in the model selection framework. We prove an oracle inequality for the L_2-risk of the estimator of the density of (Y_1, Y_2, Y_3), see Theorem 4. Since the complexity of the model is that given by the sieves for the emission densities, this leads, up to a $\log N$ term, to the adaptive minimax rate computed as for the density of only

one observation Y_1 though we estimate the density of (Y_1, Y_2, Y_3). Roughly speaking, when the observations are one dimensional, that is when $\mathcal{Y}$ is a subset of $\mathbb{R}$, the obtained rate for the density of (Y_1, Y_2, Y_3) is of order $N^{-s/(2s+1)}$ up to a $\log N$ term, N being the number of observations and s the smoothness of the emission densities.

The key point is then to be able to go back to the emission densities. This is the cornerstone of our main result. We prove in Theorem 6 that, under the assumption **[HD]** defined in Section 4.2, the quadratic risk for the density of (Y_1, Y_2, Y_3) is lower bounded by some positive constant multiplied by the quadratic risk for the emission densities. This technical assumption is generically satisfied in the sense that it holds for all possible emission densities for which the L_2-norms and Hilbert dot products do not lie on a particular algebraic surface with coefficients depending on the transition matrix of the hidden chain. Moreover, we prove that, when the number of hidden states equals two, this assumption is always verified when the two emission densities are distinct, see Lemma 5.

Our methodology requires that we have a preliminary estimator of the transition matrix. To get such an estimator, it is possible to use spectral methods. Thus our approach is the following. First, get a preliminary estimator of the initial distribution and the transition matrix of the hidden chain. Second, apply penalized least squares estimation on the density of three consecutive observations, using HMM modeling, model selection on the emission densities, and initial distribution and stationary matrix of the hidden chain set at the estimated value. This gives emission density estimators which have minimax adaptive rate, as our main result states, see Theorem 7. A simplified version of this theorem can be given as follows.

Theorem 1 *Assume $(Y_j)_{j\geq 1}$ is a hidden Markov model on $\mathbb{R}$, with latent Markov chain $(X_j)_{j\geq 1}$ with K possible values and true transition matrix $\mathbf{Q}^\star$. Denote $f_k^\star$ the density of Y_n given $X_n = k$, for $k = 1, \dots, K$. Assume the true transition matrix $\mathbf{Q}^\star$ is full rank and the true emission densities $f_k^\star$, $k = 1, \dots, K$ are linearly independent, with smoothness s. Assume that* **[HD]** *holds true. Then, up to label switching, for N the number of observations large enough, the estimators $\hat{\mathbf{Q}}$, $\hat{f}_k$, $k = 1, \dots, K$ built in Section 3 and 5 satisfy*

$$\mathbb{E}\left[\|\mathbf{Q}^\star - \hat{\mathbf{Q}}\|^2\right] = O\Big(\frac{\log N}{N}\Big) \quad \text{and} \quad \mathbb{E}\left[\|f_k^\star - \hat{f}_k\|_2^2\right] = O\Big(\big[\frac{\log N}{N}\big]^{\frac{s}{2s+1}}\Big),\ k = 1, \dots, K.$$

Moreover, since the family of sieves we consider is that given by finite dimensional spaces described by an orthonormal basis, we are able to use the spectral estimators of the coefficients of the densities as initial points in the least squares minimization. This is important since, in the HMM framework, least squares minimization does not have an explicit solution and may lead to several local minima. However, since the spectral estimates are proved to be consistent, we may be confident that their use as initial point is enough. Simulations indeed confirm this point.

To conclude we claim that our results support a powerful new approach to estimate, for the first time, nonparametric HMMs with a statistically optimal and practically tractable method.

1.3 Related Works

The papers Allman et al. (2009), Hsu et al. (2012) and Anandkumar et al. (2012) paved the way to obtain identifiability under reasonable assumptions. In Anandkumar et al. (2012)

the authors point out a structural link between multivariate mixtures with conditionally independent observations and finite state space HMMs. In Hsu et al. (2012) the authors propose a spectral method to estimate all parameters for finite state space HMMs (with finitely many observations), under the assumption that the transition matrix of the hidden chain is non singular, and that the (finitely valued) emission distributions are linearly independent. Extension to emission distributions on any space, under the linear independence assumptions (and keeping the assumption of non singularity of the transition matrix), allowed to prove the general identifiability result for finite state space HMMs, see Gassiat et al. (2016), where also model selection likelihood methods and nonparametric kernel methods are proposed to get nonparametric estimators. Let us notice also Vernet (2015) that proves theoretical consistency of the posterior in nonparametric Bayesian methods for finite state space HMMs with adequate assumptions. Later, Alexandrovich et al. (2016) obtained identifiability when the emission distributions are all distinct (not necessarily linearly independent) and still when the transition matrix of the hidden chain is full rank. In the nonparametric multivariate mixture model, Song et al. (2014) prove that any linear functional of the emission distributions may be estimated with parametric rate of convergence in the context of reproducing kernel Hilbert spaces. The latter uses spectral methods, not the same but similar to the ones proposed in Hsu et al. (2012) and Anandkumar et al. (2012).

Recent papers that contain theoretical results on different kinds of nonparametric HMMs are Gassiat and Rousseau (2016), where the emitted distributions are translated versions of each other, and Dumont and Le Corff (2017) in which the authors consider regression models with hidden regressor variables that can be Markovian on a continuous state space. Parallel to our work, the article Bonhomme et al. (2016) introduces a non-adaptive spectral method to estimate hidden parameters in latent-structure models.

1.4 Outline of the paper

In Section 2, we set the notations, the model we tudy, and the assumptions we consider. We then state an identifiability lemma (see Lemma 3) that will be useful for our estimation method. In Sections 3 and 4 we give our main results. We explain the penalized least-squares estimation method in Section 3, and we prove in Section 4 that, when the transition matrix is irreducible and aperiodic, when the emission distributions are linearly independent and the penalty is adequately chosen, then, under a technical assumption, the penalized least squares estimator is asymptotically minimax adaptive up to a $\log N$ term, see Theorem 7 and Corollary 10. For this, we first prove an oracle inequality for the estimation of the density of (Y_1, Y_2, Y_3), see Theorem 4, then we prove the key result relating the risk of the density of (Y_1, Y_2, Y_3) to that of the emission densities, see Theorem 6. The latter holds under a technical assumption which we prove to be always verified in case $K = 2$, see Lemma 5. Finally, we need the performances of the spectral estimator of the transition matrix and of the stationary distribution which are given in Section 5, see Theorem 11, proved in De Castro et al. (2015). We finally present simulations in Section 6 to illustrate our theoretical results. Those simulations show in particular the improvement obtained when applying the least-squares minimization consecutively to the spectral estimation. Detailed proofs are given in Section 8.

2. Notations and Assumptions

2.1 Nonparametric Hidden Markov Model

Let K, D be positive integers and let $\mathcal{L}^D$ be the Lebesgue measure on $\mathbb{R}^D$. Denote by $\mathcal{X}$ the set $\{1,\dots,K\}$ of hidden states, $\mathcal{Y} \subset \mathbb{R}^D$ the observation space, and Δ_K the space of probability measures on $\mathcal{X}$ identified to the $(K-1)$-dimensional simplex. Let $(X_n)_{n\geq 1}$ be a Markov chain on $\mathcal{X}$ with $K \times K$ transition matrix $\mathbf{Q}^\star$ and initial distribution $\pi^\star \in \Delta_K$. Let $(Y_n)_{n\geq 1}$ be a sequence of observed random variables on $\mathcal{Y}$. Assume that, conditional on $(X_n)_{n\geq 1}$, the observations $(Y_n)_{n\geq 1}$ are independent and, for all $n \in \mathbb{N}$, the distribution of Y_n depends only on X_n. Denote by $\mu_k^\star$ the conditional law of Y_n conditional on $\{X_n = k\}$, and assume that $\mu_k^\star$ has density $f_k^\star$ with respect to the measure $\mathcal{L}^D$ on $\mathcal{Y}$:

$$\forall k \in \mathcal{X}\,, \quad \mathrm{d}\mu_k^\star = f_k^\star \mathrm{d}\mathcal{L}^D\,.$$

Denote by $\mathfrak{F}^\star := \{f_1^\star,\dots,f_K^\star\}$ the set of emission densities with respect to the Lebesgue measure. Then, for any integer n, the distribution of $(Y_1,\dots,Y_n)$ has density with respect to $(\mathcal{L}^D)^{\otimes n}$

$$\sum_{k_1,\dots,k_n=1}^{K} \pi^\star(k_1)\mathbf{Q}^\star(k_1,k_2)\dots\mathbf{Q}^\star(k_{n-1},k_n) f_{k_1}^\star(y_1)\dots f_{k_n}^\star(y_n).$$

We shall denote $g^\star$ the density of (Y_1,Y_2,Y_3).

In this paper we shall address two observations schemes. We shall consider N i.i.d. samples $(Y_1^{(s)},Y_2^{(s)},Y_3^{(s)})_{s=1}^N$ of three consecutive observations **(Scenario A)** or consecutive observations of the same chain **(Scenario B)**:

$$\forall s \in \{1,\dots,N\}, \quad (Y_1^{(s)},Y_2^{(s)},Y_3^{(s)}) := (Y_s,Y_{s+1},Y_{s+2})\,.$$

2.2 Projections of the population joint laws

Denote by $(\mathbf{L}^2(\mathcal{Y},\mathcal{L}^D),\|\cdot\|_2)$ the Hilbert space of square integrable functions on $\mathcal{Y}$ with respect to the Lebesgue measure $\mathcal{L}^D$ equipped with the usual inner product $\langle\cdot,\cdot\rangle$ on $\mathbf{L}^2(\mathcal{Y},\mathcal{L}^D)$. Assume $\mathfrak{F}^\star \subset \mathbf{L}^2(\mathcal{Y},\mathcal{L}^D)$.

Let $(M_r)_{r\geq 1}$ be an increasing sequence of integers, and let $(\mathfrak{P}_{M_r})_{r\geq 1}$ be a sequence of nested subspaces with dimension M_r such that their union is dense in $\mathbf{L}^2(\mathcal{Y},\mathcal{L}^D)$. Let $\Phi_{M_r} := \{\varphi_1,\dots,\varphi_{M_r}\}$ be an orthonormal basis of $\mathfrak{P}_{M_r}$. Recall that for all $f \in \mathbf{L}^2(\mathcal{Y},\mathcal{L}^D)$,

$$\lim_{r\to\infty} \sum_{m=1}^{M_r} \langle f,\varphi_m\rangle\varphi_m = f\,, \tag{1}$$

in $\mathbf{L}^2(\mathcal{Y},\mathcal{L}^D)$. Note that changing M_r may change all functions φ_m, $1 \leq m \leq M_r$ in the basis Φ_{M_r}, which we shall not indicate in the notation for sake of readability. Also, we drop the dependence on r and write M instead of M_r. Define the projection of the emission laws onto $\mathfrak{P}_M$ by

$$\forall k \in \mathcal{X}, \quad f_{M,k}^\star := \sum_{m=1}^{M} \langle f_k^\star,\varphi_m\rangle\varphi_m\,.$$

We shall write $\mathbf{f}_M^\star := (f_{M,1}^\star,\dots,f_{M,K}^\star)$ and $\mathbf{f}^\star := (f_1^\star,\dots,f_K^\star)$ throughout this paper.

Remark 2 *One can consider the following standard examples:*

(Spline) *The space of piecewise polynomials of degree bounded by d_r based on the regular partition with p_r^D regular pieces on $\mathcal{Y} = [0,1]^D$. It holds that $M_r = (d_r+1)^D p_r^D$.*

(Trig.) *The space of real trigonometric polynomials on $\mathcal{Y} = [0,1]^D$ with degree less than r. It holds that $M_r = (2r+1)^D$.*

(Wav.) *A wavelet basis Φ_{M_r} of scale r on $\mathcal{Y} = [0,1]^D$, see Meyer (1992). In this case, it holds that $M_r = 2^{(r+1)D}$.*

2.3 Assumptions

We shall use the following assumptions on the hidden chain.

[H1] *The transition matrix $\mathbf{Q}^\star$ has full rank,*

[H2] *The Markov chain $(X_n)_{n\geq 1}$ is irreducible and aperiodic,*

[H3] *The initial distribution $\pi^\star = (\pi_1^\star,\dots,\pi_K^\star)$ is the stationary distribution.*

Notice that under **[H1]**, **[H2]** and **[H3]**, one has for all $k \in \mathcal{X}$, $\pi_k^\star \geq \pi_{\min}^\star > 0$. We shall use the following assumption on the emission densities.

[H4] *The family of emission densities $\mathfrak{F}^\star := \{f_1^\star,\dots,f_K^\star\}$ is linearly independent.*

Those assumptions appear in spectral methods, see for instance Hsu et al. (2012); Anandkumar et al. (2012), and in identifiability issues, see for instance Allman et al. (2009); Gassiat et al. (2016).

2.4 Identifiability Lemma

For any $\mathbf{f} = (f_1,\dots,f_K) \in (\mathbf{L}^2(\mathcal{Y},\mathcal{L}^D))^K$ and any transition matrix $\mathbf{Q}$, denote by $g^{\mathbf{Q},\mathbf{f}} : \mathcal{Y}^3 \to \mathbb{R}$ the function given by

$$g^{\mathbf{Q},\mathbf{f}}(y_1,y_2,y_3) = \sum_{k_1,k_2,k_3=1}^{K} \pi(k_1)\mathbf{Q}(k_1,k_2)\mathbf{Q}(k_2,k_3) f_{k_1}(y_1) f_{k_2}(y_2) f_{k_3}(y_3), \tag{2}$$

where π is the stationary distribution of $\mathbf{Q}$. When $\mathbf{Q} = \mathbf{Q}^\star$ and $\mathbf{f} = \mathbf{f}^\star$, we get $g^{\mathbf{Q}^\star,\mathbf{f}^\star} = g^\star$. When $f_1,\dots,f_K$ are probability densities on $\mathcal{Y}$, $g^{\mathbf{Q},\mathbf{f}}$ is the probability distribution of three consecutive observations of a stationary HMM. We now state a lemma that gathers all what we need about identifiability.

For any transition matrix $\mathbf{Q}$, let $T_{\mathbf{Q}}$ be the set of permutations τ such that for all i and j, $\mathbf{Q}(\tau(i),\tau(j)) = \mathbf{Q}(i,j)$. The permutations in $T_{\mathbf{Q}}$ describe how the states of the Markov chain may be permuted without changing the distribution of the whole chain: for any τ in $T_{\mathbf{Q}}$, $(\tau(X_n))_{n\geq 1}$ has the same distribution as $(X_n)_{n\geq 1}$. Since the hidden chain is not observed, if the emission distributions are permuted using τ, we get the same HMM. In other words, if $\mathbf{f}^\tau = (f_{\tau(1)},\dots,f_{\tau(K)})$, then $g^{\mathbf{Q},\mathbf{f}^\tau} = g^{\mathbf{Q},\mathbf{f}}$. Since identifiability up to permutation of the hidden states is obtained from the marginal distribution of three consecutive observations, we get the following lemma whose detailed proof is given in Section 8.1.

Lemma 3 *Assume that* $\mathbf{Q}$ *is a transition matrix for which* [**H1**] *and* [**H2**] *hold. Assume that* [**H4**] *holds. Then for any* $\mathbf{h} \in (\mathbf{L}^2(\mathcal{Y}, \mathcal{L}^D))^K$,

$$g^{\mathbf{Q},\mathbf{f}^\star+\mathbf{h}} = g^{\mathbf{Q},\mathbf{f}^\star} \iff \exists \tau \in T_{\mathbf{Q}} \text{ such that } h_j = f^\star_{\tau(j)} - f^\star_j,\ j = 1,\dots,K.$$

In particular, if $T_{\mathbf{Q}}$ *reduces to the identity permutation,* $g^{\mathbf{Q},\mathbf{f}^\star+\mathbf{h}} = g^{\mathbf{Q},\mathbf{f}^\star} \iff \mathbf{h} = (0,\dots,0)$.

3. The Penalized Least-Squares Estimator

In this section we shall estimate the emission densities using the so-called penalized least squares method. Here, the least squares adjustment is made on the density $g^\star$ of (Y_1, Y_2, Y_3). Starting from the operator $\Gamma : \ t \mapsto \|t - g^\star\|_2^2 - \|g^\star\|_2^2 = \|t\|_2^2 - 2\int t g^\star$ which is minimal for the target $g^\star$, we introduce the corresponding empirical contrast γ_N. Namely, for any $t \in \mathbf{L}^2(\mathcal{Y}^3, \mathcal{L}^{D^{\otimes 3}})$, set

$$\gamma_N(t) = \|t\|_2^2 - \frac{2}{N}\sum_{s=1}^N t(Z_s),$$

with $Z_s := (Y_1^{(s)}, Y_2^{(s)}, Y_3^{(s)})$ (**Scenario A**) or $Z_s := (Y_s, Y_{s+1}, Y_{s+2})$ (**Scenario B**). As N tends to infinity, $\gamma_N(t) - \gamma_N(g^\star)$ converges almost surely to $\|t - g^\star\|_2^2$, thus the name least squares contrast function. A natural estimator is then a function t such that $\gamma_N(t)$ is minimal over a judicious approximation space which is a set of functions of form $g^{\mathbf{Q},\mathbf{f}}$, $\mathbf{Q}$ a transition matrix and $\mathbf{f} \in \mathcal{F}^K$, for $\mathcal{F}$ a subset of $\mathbf{L}^2(\mathcal{Y}, \mathcal{L}^D)$. We thus define a whole collection of estimates $\hat{g}_M$, each M indexing an approximation subspace (also called model). Considering (2) we shall introduce a collection of model of functions by projection of possible $\mathbf{f}$'s on the subspaces $(\mathfrak{P}_M)_M$. Thus, for any irreducible transition matrix $\mathbf{Q}$ with stationary distribution π, we define $\mathcal{S}(\mathbf{Q}, M)$ as the set of functions $g^{\mathbf{Q},\mathbf{f}}$ such that $\mathbf{f} \in \mathcal{F}^K$ and, for each $k = 1,\dots,K$, there exists $(a_{m,k})_{1\le m\le M} \in \mathbb{R}^M$ such that

$$f_k = \sum_{m=1}^M a_{m,k}\varphi_m.$$

We now assume that we have in hand an estimator $\hat{\mathbf{Q}}$ of $\mathbf{Q}^\star$. For instance, one can use a spectral estimator, we recall such a construction in Section 5. Then, $(\mathcal{S}(\hat{\mathbf{Q}}, M))_M$ is the collection of models we use for the least squares minimization. For any M, define $\hat{g}_M$ as a minimizer of $\gamma_N(t)$ for $t \in \mathcal{S}(\hat{\mathbf{Q}}, M)$. Then $\hat{g}_M$ can be written as $\hat{g}_M = g^{\hat{\mathbf{Q}},\hat{\mathbf{f}}_M}$ with $\hat{\mathbf{f}}_M \in \mathcal{F}^K$ and $\hat{f}_{M,k} = \sum_{m=1}^M \hat{a}_{m,k}\varphi_m$ $(k = 1,\dots,K)$ for some $(\hat{a}_{m,k})_{1\le m\le M} \in \mathbb{R}^M$, $k = 1,\dots,K$. It then remains to select the best model, that is to choose M which minimizes $\|\hat{g}_M - g^\star\|_2^2 - \|g^\star\|_2^2$. This quantity is close to $\gamma_N(\hat{g}_M)$, but we need to take into account the deviations of the process $\Gamma - \gamma_N$. Then we rather minimize $\gamma_N(\hat{g}_M) + \mathrm{pen}(N, M)$ where $\mathrm{pen}(N, M)$ is a penalty term to be specified. Our final estimator will be a penalized least squares estimator. For this purpose we choose a penalty function $\mathrm{pen}(N, M)$ and we let

$$\hat{M} = \arg\min_{M=1,\dots,N} \{\gamma_N(\hat{g}_M) + \mathrm{pen}(N, M)\}.$$

Notice that, with N observations, we consider N subspaces as candidates for model selection. Then the estimator of $g^\star$ is $\hat{g} = \hat{g}_{\hat{M}}$, and the estimator of $\mathbf{f}^\star$ is $\hat{\mathbf{f}} := \hat{\mathbf{f}}_{\hat{M}}$ so that $\hat{g} = g^{\hat{\mathbf{Q}},\hat{\mathbf{f}}}$.

The least squares estimator does not have an explicit form such as in usual nonparametric estimation, so that one has to use numerical minimization algorithms. As initial point of the minimization algorithm, we shall use the spectral estimator, see Section 6 for more details. Since the spectral estimator is consistent, see De Castro et al. (2015), the algorithm does not suffer from initialization problems.

4. Adaptive Estimation of the Emission Distributions

4.1 Oracle Inequality for the Estimation of $g^\star$

We now fix a subset $\mathcal{F}$ of $\mathbf{L}^2(\mathcal{Y}, \mathcal{L}^D)$, and we shall use the following assumption:

[**HF**] $\mathcal{F}$ *is a closed subset of* $\mathbf{L}^2(\mathcal{Y}, \mathcal{L}^D)$ *such that: for any* $f \in \mathcal{F}$, $\int f d\mathcal{L}^D = 1$, $\|f\|_2 \le C_{\mathcal{F},2}$ *and* $\|f\|_\infty \le C_{\mathcal{F},\infty}$ *for some fixed positive* $C_{\mathcal{F},2}$ *and* $C_{\mathcal{F},\infty}$.

Our first main result is an oracle inequality for the estimation of $g^\star$ which is stated below and proved in Section 8.2. We denote by $\mathfrak{S}_K$ the set of permutations of $\{1,\dots,K\}$. When a is a vector, $\|a\|_2$ denotes its Euclidian norm, and when A is a matrix, $\|A\|_F$ denotes its Frobenius norm.

Theorem 4 *Assume* [**H1**]-[**H4**] *and* [**HF**]. *Assume also* $\mathbf{f}^\star \in \mathcal{F}^K$, *and for all* M, $\mathbf{f}^\star_M \in \mathcal{F}^K$. *Then, there exists positive constants* N_0, $\rho^\star$ *and* $A_1^\star$ (*depending on* $C_{\mathcal{F},2}$ *and* $C_{\mathcal{F},\infty}$ (**Scenario B**) *or on* $\mathbf{Q}^\star$, $C_{\mathcal{F},2}$ *and* $C_{\mathcal{F},\infty}$ (**Scenario A**)) *such that, if*

$$\mathrm{pen}(N, M) \ge \rho^\star \frac{M \log N}{N}$$

then for all $x > 0$, *for all* $N \ge N_0$, *one has with probability* $1 - (e-1)^{-1}e^{-x}$, *for any permutation* $\tau \in \mathfrak{S}_K$,

$$\begin{aligned}\|\hat{g} - g^\star\|_2^2 \ \le\ & 6 \inf_M \left\{\|g^\star - g^{\mathbf{Q}^\star,\mathbf{f}^\star_M}\|_2^2 + \mathrm{pen}(N, M)\right\} + A_1^\star \frac{x}{N} \\ & + 18 C_{\mathcal{F},2}^6 (2\|\mathbf{Q}^\star - \mathbb{P}_\tau \hat{\mathbf{Q}}_N \mathbb{P}_\tau^\top\|_F^2 + \|\pi^\star - \mathbb{P}_\tau \hat{\pi}\|_2^2).\end{aligned}$$

Here, $\mathbb{P}_\tau$ *is the permutation matrix associated to* τ.

The important fact in this oracle inequality is that the minimal possible penalty is of order M/N (up to logarithmic terms) and not M^3/N as is usually the case when estimating a joint density of three random variables, so that we get a minimax rate adaptive estimator of the joint density $g^\star$.

4.2 Main Result

The problem is now to deduce from Theorem 4 a result on $\|f_k^\star - \hat{f}_k\|_2^2$, $k = 1,\dots,K$. This is the cornerstone of our work: we prove that, under a technical assumption on the parameters of the unknown HMM, a direct lower bound links $\|\hat{g} - g^\star\|_2^2$ to $\sum_{k=1}^K \|f_1^\star - \hat{f}_k\|_2^2$, up to some positive constant. Let us now describe the assumption and comment on its genericity.

For any $\mathbf{f} \in \mathcal{F}^K$, define $G(\mathbf{f})$ the $K \times K$ matrix with coefficients $G(\mathbf{f})_{i,j} = \langle f_i, f_j\rangle$, $i, j = 1,\dots,K$. Notice that under the assumption [**H4**], $G(\mathbf{f}^\star)$ is positive definite. Let $\mathbf{Q}$

be a transition matrix verifying **[H1]**-**[H2]** and let A_Q be the diagonal matrix having the stationary distribution π of $\mathbf{Q}$ on the diagonal. We shall now define a quadratic form with coefficients depending on $\mathbf{Q}$ and $G(\mathbf{f})$. If U is a $K \times K$ matrix such that $U\mathbf{1}_K = 0$,

$$\begin{aligned}\mathcal{D} := \sum_{i,j=1}^{K} \Big\{ & (\mathbf{Q}^T A_Q U G(\mathbf{f}) U^T A_Q \mathbf{Q})_{i,j} (G(\mathbf{f}))_{i,j} (\mathbf{Q} G(\mathbf{f}) \mathbf{Q}^T)_{i,j} \\ & + (\mathbf{Q}^T A_Q G(\mathbf{f}) A_Q \mathbf{Q})_{i,j} (UG(\mathbf{f})U^T)_{i,j} (\mathbf{Q} G(\mathbf{f}) \mathbf{Q}^T)_{i,j} \\ & + (\mathbf{Q}^T A_Q G(\mathbf{f}) A_Q \mathbf{Q})_{i,j} (G(\mathbf{f}))_{i,j} (\mathbf{Q} U G(\mathbf{f}) U^T \mathbf{Q}^T)_{i,j} \Big\} \\ +2 \sum_{i,j} \Big\{ & (\mathbf{Q}^T A_Q U G(\mathbf{f}) A_Q \mathbf{Q})_{i,j} (UG(\mathbf{f}))_{j,i} (\mathbf{Q} G(\mathbf{f}) \mathbf{Q}^T)_{i,j} \\ & + (\mathbf{Q}^T A_Q U G(\mathbf{f}) A_Q \mathbf{Q})_{i,j} (\mathbf{Q} U G(\mathbf{f}) \mathbf{Q}^T)_{j,i} (G(\mathbf{f}))_{i,j} \\ & + (UG(\mathbf{f}))_{i,j} (\mathbf{Q} U G(\mathbf{f}) \mathbf{Q}^T)_{j,i} (\mathbf{Q}^T A_Q G(\mathbf{f}) A_Q \mathbf{Q})_{i,j} \Big\}\end{aligned}$$

defines a semidefinite positive quadratic form $\mathcal{D}$ in the coefficients $U_{i,j}$, $i = 1, \dots, K$, $j = 1, \dots, K-1$. The determinant of this quadratic form is a polynomial in the coefficients of the matrices $\mathbf{Q}$, A_Q and $G(\mathbf{f})$. Since the coefficients of A_Q are rational functions of the coefficients of the matrix $\mathbf{Q}$, this determinant is also a rational function of the coefficients of the matrices $\mathbf{Q}$ and $G(\mathbf{f})$. Define $H(\mathbf{Q}, G(\mathbf{f}))$ the numerator of the determinant. Then $H(\mathbf{Q}, G(\mathbf{f}))$ is a polynomial in the coefficients of the matrices $\mathbf{Q}$ and $G(\mathbf{f})$. Our assumption will be:

$$\textbf{[HD]} \quad H(\mathbf{Q}^\star, G(\mathbf{f}^\star)) \neq 0.$$

Since H is a polynomial function of $Q^\star_{i,j}$, $i = 1, \dots, K$, $j = 1, \dots, K-1$, and $\langle f_i^\star, f_j^\star \rangle$, $i, j = 1, \dots, K$, the assumption **[HD]** is generically satisfied. We have been able to prove that **[HD]** always holds in the case $K = 2$. We were only able to prove this result by direct computation, it is given in Section 8.4.

Lemma 5 *Assume $K = 2$. Then for all $\mathbf{Q}^\star$ and $\mathbf{f}^\star$ such that* **[H1]**-**[H4]** *hold, one has $H(\mathbf{Q}^\star, G(\mathbf{f}^\star)) > 0$.*

Notice now that, when **[HD]** and **[H1]**-**[H3]** hold, it is possible to define a compact neighborhood $\mathcal{V}$ of $\mathbf{Q}^\star$ such that, for all $\mathbf{Q} \in \mathcal{V}$, $H(\mathbf{Q}, G(\mathbf{f}^\star)) \neq 0$, **[H1]**-**[H3]** hold for $\mathbf{Q}$ and $T_{\mathbf{Q}} \subset T_{\mathbf{Q}^\star}$.

For any $\mathbf{h} \in \left(\mathbf{L}^2(\mathcal{Y}, \mathcal{L}^D)\right)^K$, define $\|\mathbf{h}\|^2_{\mathbf{Q}} := \min_{\tau \in T_{\mathbf{Q}}} \{\sum_{k=1}^K \|h_k + f_k^\star - f^\star_{\tau(k)}\|_2^2\}$. Denote $\|\mathbf{h}\|_2^2 := \{\sum_{k=1}^K \|h_k\|_2^2\}$. We may now state the theorem which is the cornerstone of our main result.

Theorem 6 *Assume* **[H1]**-**[H4]** *and* **[HD]**. *Let $\mathcal{K}$ be a closed bounded subset of $\left(\mathbf{L}^2(\mathcal{Y}, \mathcal{L}^D)\right)^K$ such that if $\mathbf{h} \in \mathcal{K}$, then $\int h_i d\mathcal{L}^D = 0$, $i = 1, \dots, K$. Let $\mathcal{V}$ be a compact neighborhood of $\mathbf{Q}^\star$ such that, for all $\mathbf{Q} \in \mathcal{V}$, $H(\mathbf{Q}, G(\mathbf{f}^\star)) \neq 0$,* **[H1]**-**[H3]** *holds for $\mathbf{Q}$ and $T_{\mathbf{Q}} \subset T_{\mathbf{Q}^\star}$. Then there exists a positive constant $c(\mathcal{K}, \mathcal{V}, \mathfrak{F}^\star)$ such that*

$$\forall \mathbf{h} \in \mathcal{K}, \ \forall \mathbf{Q} \in \mathcal{V}, \quad \|g^{\mathbf{Q}, \mathbf{f}^\star + \mathbf{h}} - g^{\mathbf{Q}, \mathbf{f}^\star}\|_2 \geq c(\mathcal{K}, \mathcal{V}, \mathfrak{F}^\star) \|\mathbf{h}\|_{\mathbf{Q}^\star}.$$

This theorem is proved in Section 8.3.

We are now ready to prove our main result on the penalized least squares estimator of the emission densities. The following theorem gives an oracle inequality for the estimators of the emission distributions provided the penalty is adequately chosen. It is proved in Section 8.5.

Theorem 7 (Adaptive estimation) *Assume* **[H1]**-**[H4]**, **[HF]** *and* **[HD]**. *Assume also that for all M, $\mathbf{f}^\star_M \in \mathcal{F}^K$. Let $\mathcal{V}$ be a compact neighborhood of $\mathbf{Q}^\star$ such that, for all $\mathbf{Q} \in \mathcal{V}$, $H(\mathbf{Q}, G(\mathbf{f}^\star)) \neq 0$ and* **[H1]**-**[H3]** *holds for $\mathbf{Q}$. Then, there exists a positive constant $A^\star$ (depending on $\mathcal{V}$, $\mathbf{f}^\star$, $C_{\mathcal{F},2}$ and $C_{\mathcal{F},\infty}$) and positive constants N_0 and $\rho^\star$ (depending on $C_{\mathcal{F},2}$ and $C_{\mathcal{F},\infty}$ (**Scenario A**) or on $\mathbf{Q}^\star$, $C_{\mathcal{F},2}$ and $C_{\mathcal{F},\infty}$ (**Scenario B**)) such that, if*

$$\mathrm{pen}(N, M) \geq \rho^\star \frac{M \log N}{N}$$

then for all $x > 0$, for all $N \geq N_0$, for any permutation $\tau_N \in \mathfrak{S}_K$, with probability larger than $1 - (e-1)^{-1} e^{-x} - \mathbb{P}\left(\mathbb{P}_{\tau_N} \hat{\mathbf{Q}} \mathbb{P}^T_{\tau_N} \notin \mathcal{V}\right)$, there exists $\tau \in T_{\mathbf{Q}^\star}$ such that

$$\begin{aligned}\sum_{k=1}^K \|f^\star_{\tau(k)} - \hat{f}_{\tau_N(k)}\|_2^2 \leq A^\star \Big[\inf_M \Big\{ \sum_{k=1}^K \|f_k^\star - f^\star_{M,k}\|_2^2 + \mathrm{pen}(N, M) \Big\} \\ + \|\mathbf{Q}^\star - \mathbb{P}_{\tau_N} \hat{\mathbf{Q}} \mathbb{P}^\top_{\tau_N}\|_F^2 + \|\pi^\star - \mathbb{P}_{\tau_N} \hat{\pi}\|_2^2 + \frac{x}{N} \Big].\end{aligned}$$

Remark 8 *As usual in HMM or mixture model, it is only possible to estimate the model up to label switching of the hidden states, this is the meaning of the permutation τ_N.*

Remark 9 *An important consequence of the theorem is that a right choice of the penalty leads to a rate minimax adaptive estimator up to a $\log N$ term, see Corollary 10 below. For this purpose, one has to choose an estimator $\hat{\mathbf{Q}}$ of $\mathbf{Q}^\star$ which is, up to label switching, consistent with controlled rate. One possible choice is a spectral estimator.*

To apply Theorem 7 one has to choose an estimator $\hat{\mathbf{Q}}$ with controlled behavior, to be able to evaluate the probability of the event $\{\mathbb{P}_{\tau_N} \hat{\mathbf{Q}} \mathbb{P}_{\tau_N} \in \mathcal{V}\}$ and the rate of convergence of $\mathbb{P}_{\tau_N} \hat{\mathbf{Q}} \mathbb{P}_{\tau_N}$ and $\mathbb{P}_{\tau_N} \hat{\pi}$. One possibility is to use the spectral estimator described in Section 5. To get the following result (proved in Section 8.6), we propose to use the spectral estimator with, for each N, the dimension M_N chosen such that $\eta_3(\Phi_{M_N}) = O\big((\log N)^{1/4}\big)$, see Section 5 for a definition of η_3.

Corollary 10 *With this choice of $\hat{\mathbf{Q}}$, under the assumptions of Theorem 7 , there exists a sequence of permutations $\tau_N \in \mathfrak{S}_K$ such that as N tends to infinity,*

$$\mathbb{E}\left[\sum_{k=1}^K \|f_k^\star - \hat{f}_{\tau_N(k)}\|_2^2\right] = O\left(\inf_{M'} \left\{ \sum_{k=1}^K \|f_k^\star - f^\star_{M',k}\|_2^2 + \mathrm{pen}(N, M') \right\} + \frac{\log N}{N}\right).$$

Thus, choosing $\mathrm{pen}(N, M) = \rho M \log N / N$ for a large ρ leads to the minimax asymptotic rate of convergence up to a power of $\log N$. Indeed, standard results in approximation theory (see DeVore and Lorentz (1993) for instance) show that one can upper bound the approximation error $\|f_k^\star - f^\star_{M,k}\|_2$ by $\mathcal{O}(M^{-\frac{s}{D}})$ where $s > 0$ denotes a regularity parameter.

Then the trade-off is obtained for $M^{\frac{1}{D}} \sim (N/\log N)^{\frac{1}{2s+D}}$, which leads to the quasi-optimal rate $(N/\log N)^{-\frac{s}{2s+D}}$ for the nonparametric estimation when the minimal smoothness of the emission densities is s. Notice that the algorithm automatically selects the best M leading to this rate.

To implement the estimator, it remains to choose a value for ρ in the penalty. The calibration of this parameter is a classical issue and could be the subject of a full paper. In practice one can use the slope heuristic as in Baudry et al. (2012).

5. Nonparametric Spectral Method

This section is devoted to a short description of the nonparametric spectral method for sake of completeness: we describe the algorithm, and give the results we need to support the use of spectral estimators to initialize our algorithm. A detailed study of the nonparametric spectral method is given in De Castro et al. (2015).

The following procedure (see Algorithm 1) describes a tractable approach to estimate the transition matrix in a way that can be used for the penalized least squares estimator of the emission densities, and also for the estimation of the projections of the emission densities that may be used to initialize the least squares algorithm. The procedure is based on recent developments in parametric estimation of HMMs. For each fixed M, we estimate the projection of the emission distributions on the basis Φ_M using the spectral method proposed in Anandkumar et al. (2012). As the authors of the latter paper explain, this allows further to estimate the transition matrix (we use a modified version of their estimator), and we set the estimator of the stationary distribution as the stationary distribution of the estimator of the transition matrix. The computation of those estimators is particularly simple: it is based on one SVD, some matrix inversions and one diagonalization. One can prove, with overwhelming probability, all matrix inversions and the diagonalization can be done rightfully, see De Castro et al. (2015). In the following, when A is a $(p \times q)$ matrix with $p \geq q$, $A^\top$ denotes the transpose matrix of A, $A(k,l)$ its (k,l)th entry, $A(.,l)$ its lth column and $A(k,.)$ its kth line. When v is a vector of size p, we denote by $\mathfrak{Diag}[v]$ the diagonal matrix with diagonal entries v_i and, by abuse of notation, $\mathfrak{Diag}[v] = \mathfrak{Diag}[v^\top]$.

We now state a result which allows to derive the asymptotic properties of the spectral estimators. Let us define:

$$\eta_3^2(\Phi_M) := \sup_{y,y' \in \mathcal{Y}^3} \sum_{a,b,c=1}^{M} (\varphi_a(y_1)\varphi_b(y_2)\varphi_c(y_3) - \varphi_a(y_1')\varphi_b(y_2')\varphi_c(y_3'))^2.$$

Note that in the examples **(Spline)**, **(Trig.)** and **(Wav.)** we have

$$\eta_3(\Phi_M) \leq C_\eta M^{\frac{3}{2}}$$

where $C_\eta > 0$ is a constant. The following theorem is proved in De Castro et al. (2015). Its statement concerns **(Scenario B)** (same chain sampling) and the interested reader may consult De Castro et al. (2015) for its statement under **(Scenario A)**.

Algorithm 1: Nonparametric spectral estimation of HMMs

Data: An observed chain $(Y_1, \ldots, Y_N)$ and a number of hidden states K.
Result: Spectral estimators $\hat{\pi}$, $\hat{\mathbf{Q}}$ and $(\hat{f}_{M,k})_{k \in \mathcal{X}}$.

[Step 1] Consider the following empirical estimators: For any a, b, c in $\{1, \ldots, M\}$,
$\hat{\mathbf{L}}_M(a) := \frac{1}{N}\sum_{s=1}^N \varphi_a(Y_1^{(s)})$, $\hat{\mathbf{M}}_M(a,b,c) := \frac{1}{N}\sum_{s=1}^N \varphi_a(Y_1^{(s)})\varphi_b(Y_2^{(s)})\varphi_c(Y_3^{(s)})$,
$\hat{\mathbf{N}}_M(a,b) := \frac{1}{N}\sum_{s=1}^N \varphi_a(Y_1^{(s)})\varphi_b(Y_2^{(s)})$, $\hat{\mathbf{P}}_M(a,c) := \frac{1}{N}\sum_{s=1}^N \varphi_a(Y_1^{(s)})\varphi_c(Y_3^{(s)})$.

[Step 2] Let $\hat{\mathbf{U}}$ be the $M \times K$ matrix of orthonormal right singular vectors of $\hat{\mathbf{P}}_M$ corresponding to its top K singular values.

[Step 3] Form the matrices for all $b \in \{1, \ldots, M\}$,
$\hat{\mathbf{B}}(b) := (\hat{\mathbf{U}}^\top \hat{\mathbf{P}}_M \hat{\mathbf{U}})^{-1} \hat{\mathbf{U}}^\top \hat{\mathbf{M}}_M(.,b,.)\hat{\mathbf{U}}$.

[Step 4] Set Θ a $(K \times K)$ random unitary matrix uniformly drawn and form the matrices for all $k \in \{1, \ldots, K\}$, $\hat{\mathbf{C}}(k) := \sum_{b=1}^M (\hat{\mathbf{U}}\Theta)(b,k)\hat{\mathbf{B}}(b)$.

[Step 5] Compute $\hat{\mathbf{R}}$ a $(K \times K)$ unit Euclidean norm columns matrix that diagonalizes the matrix $\hat{\mathbf{C}}(1)$: $\hat{\mathbf{R}}^{-1}\hat{\mathbf{C}}(1)\hat{\mathbf{R}} = \mathfrak{Diag}[(\hat{\Lambda}(1,1), \ldots, \hat{\Lambda}(1,K))]$.

[Step 6] Set for all $k, k' \in \mathcal{X}$, $\hat{\Lambda}(k,k') := (\hat{\mathbf{R}}^{-1}\hat{\mathbf{C}}(k)\hat{\mathbf{R}})(k',k')$ and $\hat{\mathbf{O}}_M := \hat{\mathbf{U}}\Theta\hat{\Lambda}$.

[Step 7] Consider the emission laws estimator $\tilde{\mathbf{f}} := (\tilde{f}_{M,k})_{k \in \mathcal{X}}$ defined by for all $k \in \mathcal{X}$, $\tilde{f}_{M,k} := \sum_{m=1}^M \hat{\mathbf{O}}_M(m,k)\varphi_m$.

[Step 8] Set $\tilde{\pi} := \left(\hat{\mathbf{U}}^\top \hat{\mathbf{O}}_M\right)^{-1} \hat{\mathbf{U}}^\top \hat{\mathbf{L}}_M$.

[Step 9] Consider the transition matrix estimator:

$$\hat{\mathbf{Q}} := \Pi_{\mathrm{TM}}\Big((\hat{\mathbf{U}}^\top \hat{\mathbf{O}}_M \mathfrak{Diag}[\tilde{\pi}])^{-1} \hat{\mathbf{U}}^\top \hat{\mathbf{N}}_M \hat{\mathbf{U}} (\hat{\mathbf{O}}_M^\top \hat{\mathbf{U}})^{-1} \Big),$$

where Π_{TM} denotes the projection onto the convex set of transition matrices, and define $\hat{\pi}$ as the stationary distribution of $\hat{\mathbf{Q}}$.

Theorem 11 (Spectral estimators) *Assume that* **[H1]**-**[H4]** *hold. Then, there exist positive constant numbers $M_{\mathfrak{F}^\star}$, $x(\mathbf{Q}^\star)$, $\mathcal{C}(\mathbf{Q}^\star, \mathfrak{F}^\star)$ and $\mathbf{N}(\mathbf{Q}^\star, \mathfrak{F}^\star)$ such that the following holds. For any $x \geq x(\mathbf{Q}^\star)$, for any $\delta \in (0,1)$, for any $M \geq M_{\mathfrak{F}^\star}$, there exists a permutation $\tau_M \in \mathfrak{S}_K$ such that the spectral method estimators $\hat{f}_{M,k}$, $\hat{\pi}$ and $\hat{\mathbf{Q}}$ satisfy: For any $N \geq \mathbf{N}(\mathbf{Q}^\star, \mathfrak{F}^\star)\eta_3(\Phi_M)^2 x(-\log\delta)/\delta^2$, with probability greater than $1 - 2\delta - 4e^{-x}$,*

$$\|f_{M,k}^\star - \hat{f}_{M,\tau_M(k)}\|_2 \leq \mathcal{C}(\mathbf{Q}^\star, \mathfrak{F}^\star)\frac{\sqrt{-\log\delta}}{\delta}\frac{\eta_3(\Phi_M)}{\sqrt{N}}\sqrt{x}\,,$$

$$\|\pi^\star - \mathbb{P}_{\tau_M}\hat{\pi}\|_2 \leq \mathcal{C}(\mathbf{Q}^\star, \mathfrak{F}^\star)\frac{\sqrt{-\log\delta}}{\delta}\frac{\eta_3(\Phi_M)}{\sqrt{N}}\sqrt{x}\,,$$

$$\|\mathbf{Q}^\star - \mathbb{P}_{\tau_M}\hat{\mathbf{Q}}\mathbb{P}_{\tau_M}^\top\| \leq \mathcal{C}(\mathbf{Q}^\star, \mathfrak{F}^\star)\frac{\sqrt{-\log\delta}}{\delta}\frac{\eta_3(\Phi_M)}{\sqrt{N}}\sqrt{x}\,.$$

6. Numerical experiments

6.1 General description

In this section we present the numerical performances of our method. We recall that the experimenter knows nothing about the underlying hidden Markov model but the number of hidden states K. In this set of experiments, we consider the regular histogram basis or the trigonometric basis for estimating emission laws given by beta laws from a single chain observation of length $N = 50{,}000$.

Our procedure is based on the computation of the empirical least squares estimators $\hat{g}_M$ defined as minimizers of the empirical contrast γ_N on the space $\mathcal{S}(\hat{\mathbf{Q}}, M)$ where $\hat{\mathbf{Q}}$ is an estimator of the transition matrix (for instance the spectral estimation of the transition matrix). Since the function γ_N is non-convex, we use a second order approach estimating a positive definite matrix (using a covariance matrix) within an iterative procedure called CMAES for Covariance Matrix Adaptation Evolution Strategy, see Hansen (2006). Using this latter algorithm, we search for the minimum of γ_N with starting point the spectral estimation of the emission laws.

Then, we estimate the size of the model thanks to

$$\hat{M}(\rho) \in \arg \min_{M=1,\dots,M_{\max}} \left\{ \gamma_N(\hat{g}_M) + \rho \frac{M \log N}{N} \right\} , \tag{3}$$

where the penalty term ρ has to be tuned and the maximum size of the model $M_{\max}$ can be set by the experimenter in a data-driven procedure.

Indeed, we shall apply the slope heuristic to adjust the penalty term and to choose $M_{\max}$. As presented in Baudry et al. (2012), the minimum contrast function $M \mapsto \gamma_N(\hat{g}_M)$ should have a linear behavior for large values of M. The experimenter has to consider $M_{\max}$ large enough in order to observe this linear stabilization, as depicted in Figure 2. The slope of the linear interpolation is then $(\hat{\rho}/2) \log N/N$ (recall that the sample size N is fixed here) where $\hat{\rho}$ is the slope heuristic choice on how ρ should be tuned. Another procedure (theoretically equivalent) consists in plotting the function $\rho \mapsto \hat{M}(\rho)$ which is a non-increasing piecewise constant function. The estimated $\hat{\rho}$ is such that the largest drop (called "dimension jump") of this function occurs at point $\hat{\rho}/2$. We illustrate this procedure in Figure 3 where one can clearly point the jump and deduce the size $\hat{M}$.

To summarize, our procedure reads as follows.

1. For all $M \leq M_{\max}$, compute the spectral estimations $(\hat{\mathbf{Q}}, \hat{\pi})$ of the transition matrix and its stationary distribution and the spectral estimation $\tilde{\mathbf{f}}$ of the emission laws. This is straightforward using the procedure described by **[Step1-9]** in Section 5.

2. For all $M \leq M_{\max}$, compute a minimum $\hat{g}_M$ of the empirical contrast function γ_N using "Covariance Matrix Adaptation Evolution Strategy", see Hansen (2006). Use the estimation $\tilde{\mathbf{f}}$ of the spectral method as a starting point of CMAES.

3. Tune the penalty term using the slope heuristic procedure and select $\hat{M}$.

4. Return the emission laws of the solution of point (2) for $M = \hat{M}$.

Note that the size M of the projection space for the spectral estimator has been set as the one chosen by the slope heuristic for the empirical least squares estimators.

All the codes of the numerical experiments are available at `https://mycore.core-cloud.net/public.php?service=files&t=44459ccb178a3240cfb8712f27a28d75`. We shall indicate that the slope heuristic has been done using CAPUSHE, the Matlab graphical user interface presented in Baudry et al. (2012).

6.2 Complexity

A crucial step of our method lies in computing the empirical least squares estimators $\hat{g}_M$. One may struggle to compute $\hat{g}_M$ since the function γ_N is non-convex. It follows that an acceptable procedure must start from a good approximation of $\hat{g}_M$. This is done by the spectral method. Observe that the key leitmotiv throughout this paper is a two steps estimation procedure that starts by the spectral estimator. This latter has rate of convergence of the order of $N^{-s/(2s+3)}$ and seems to be a good candidate to initialize an iterative scheme that will converge towards $\hat{g}_M$. It follows that the main consuming operations in our algorithm are the following steps.

- The computation of the tensor $\hat{\mathbf{M}}_M$ of the empirical law of three consecutive observations where we use three loops of size M and one loop of size N so the complexity is $\mathcal{O}(NM^3)$,
- The singular value decomposition of $\hat{\mathbf{P}}_M$ in the spectral method (complexity: $\mathcal{O}(M^3)$),
- The computation of the minimum of the empirical contrast function: cost of one evaluation of the empirical contrast function $\mathcal{O}(K^3M^3) = \mathcal{O}(M^3)$ times the number $f(M, K)$ of evaluations while minimizing the empirical contrast. Recall that we start from the spectral estimator solution to get the minimum so a constant number of evaluation is enough in practice, say `stopeval` $=1e4$ using CMAES.

We have to compute the minimal contrast value for all models of size $M = 1, \dots, M_{\max}$ where $M_{\max}$ has to be chosen so that one can apply the slope heuristic. We deduce that the overall complexity of our algorithm is $\mathcal{O}((f(M_{\max}, K)K^3 \vee N)M_{\max}^4)$ where $f(M_{\max}, K)$ is the number of evaluations of γ_N while minimizing the empirical contrast. Since we use the spectral estimator as a starting point of the minimization of the empirical contrast, we believe that $f(M_{\max}, K)$ can be considered as constant, say $1e4$. Note that the upper bound $M_{\max}$ has to be large enough in order to observe a linear stabilization of $M \mapsto \hat{g}_M$, see Baudry et al. (2012) for instance. Moreover, recall that the trade-off between the approximation bias and the penalty term (accounting for the standard error of the empirical law) is obtained for $M \sim (N/\log N)^{\frac{D}{2s+D}}$ where $s > 0$ denotes the minimal smoothness parameter of the emission laws. In order to properly apply the slope heuristic, it is enough to consider models with this order of magnitude, so that $M_{\max} = \mathcal{O}((N/\log N)^{\frac{D}{2s+D}})$. It follows that the overall complexity of our procedure can be expressed in terms of the minimal smoothness parameter s of the emission laws as

$$\text{Complexity} = \mathcal{O}(N^{1+\frac{4D}{2s+D}}) ,$$

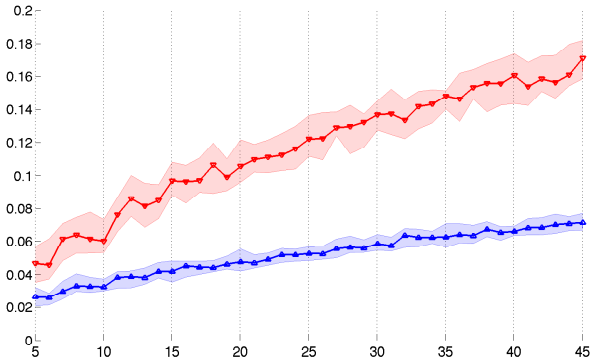

Figure 1: Variance comparison of the spectral and empirical least squares estimators. The upper curve (in red) present the performance (median value of the variance over 40 iterations) of the spectral method while the lower curve (in blue) the performance of the empirical least squares estimator. For each curve, we have plotted a shaded box plot representing the first and third quartiles.

as soon as $K = \mathcal{O}(N^{1/3})$ which is a reasonable assumption. Nevertheless, this theoretical bound is unknown for the practitioner since it involves the unknown minimal smoothness parameter $s > 0$. For chains of length $\mathcal{O}(1e5)$, we have witnessed that one can afford a maximal model size $M_{\max} \leq 50$ and this allows to consider problems where typical sizes of M ranges between 1 and 50. All numerical experiments of this paper fall in this frame.

6.3 Comparison of the Variances

The quadratic loss can be expressed as a variance term and a bias term as follows

$$\forall 1 \leq k \leq K,\ \forall M \geq 0, \quad \|f_k^\star - \hat{f}_k\|_2^2 = \|\hat{f}_k - f_{M,k}^\star\|_2^2 + \|f_k^\star - f_{M,k}^\star\|_2^2$$

where $f_{M,k}^\star$ is the orthogonal projection of $f_k^\star$ on $\mathfrak{P}_M$ and $\hat{f}_k$ is any estimator such that $\hat{f}_k$ belongs to $\mathfrak{P}_M$. Note that the bias term $\|f_k^\star - f_{M,k}^\star\|_2$ does not depend on the estimator $\hat{f}_k$. Hence, the variance term

$$\text{Variance}_M(\hat{f}) := \min_{\tau \in \mathfrak{S}_K} \max_{1 \leq k \leq K} \|\hat{f}_k - f_{M,\tau(k)}^\star\|_2^2 ,$$

accounts for the performances of the estimator $\hat{f}_k$.

As depicted in Figure 1, we have compared, for each M, the variance terms obtained by the spectral method and the empirical least squares method over 40 iterations on chains of length $N = 5e4$. We have considered $K = 2$ hidden states whose emission variables are distributed with respect to beta laws of parameters $(2, 5)$ and $(4, 2)$. This numerical experiment consolidates the idea that the least squares method significantly improves upon

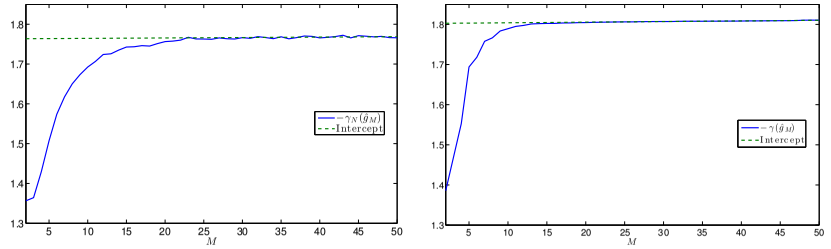

Figure 2: Slope heuristic to choose M: the experimenter may observe a linear stabilization of the empirical contrast γ_N for estimating beta emission laws of parameters $(2, 5)$ and $(4, 2)$. We have $K = 2$ hidden states and $N = 5e4$ samples along a single chain. On the left panel we have used the trigonometric basis as approximation space, the stabilization occurs on the points $M = 30$ to $M = 50$ and the interpolation of the slope leads to $\hat{M} = 23$. On the right panel we have considered the trigonometric basis, the stabilization occurs on the points $M = 20$ to $M = 50$ and it leads to $\hat{M} = 21$.

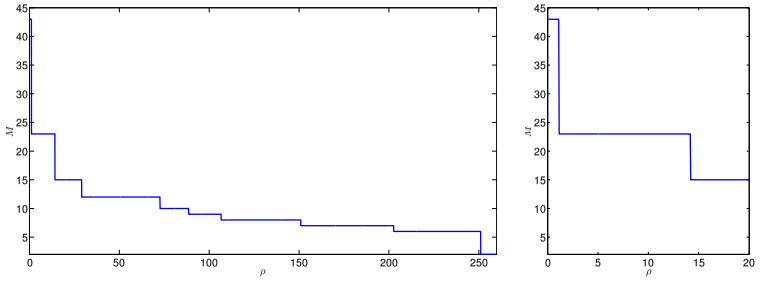

Figure 3: Slope heuristic to choose M: the experimenter observes the largest drop of the function $\rho \mapsto \hat{M}(\rho)$ at 1.1 so that $\hat{\rho} = 2.2$ and $\hat{M} = 23$. We have $K = 2$ hidden states and a single chain of length $N = 5e4$. We have used the histogram basis as approximation space.

the spectral method. Indeed, even for small values of M, one may see in Figure 1 that the variance term is divided by a constant factor.

6.4 Histogram Basis and Trigonometric Basis as Approximation Spaces

An illustrative example of our method can be given using the histogram basis (regular basis with M bins) or the trigonometric basis. In the following experiments, we have $K = 2$

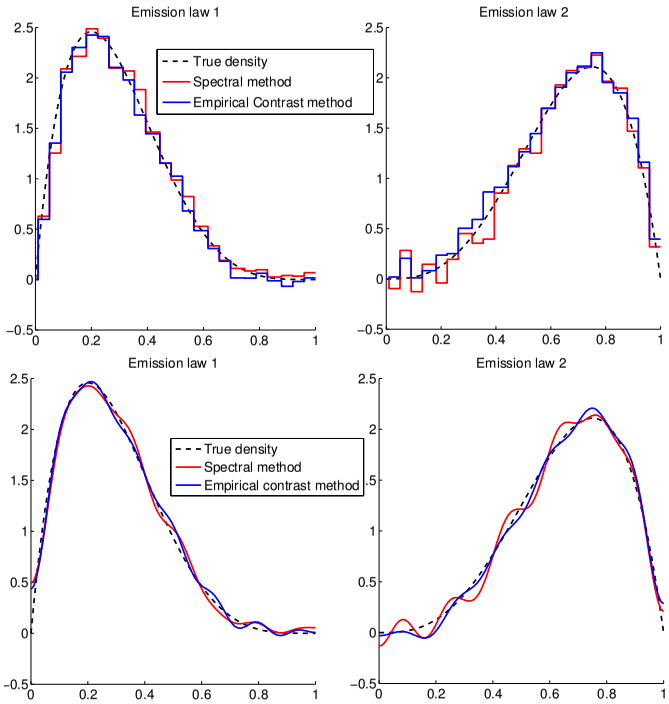

Figure 4: Estimators of the emissions densities (beta laws of parameters $(2,5)$ and $(4,2)$) from the observation of a single chain of length $N = 5e4$. On the top panels, we have used the histogram basis ($\hat{M} = 23$). On the bottom panels, we have considered the trigonometric basis ($\hat{M} = 21$).

hidden states and emission laws given by beta laws of parameters $(2,5)$ and $(4,2)$. Recall we observe a single chain of length $N = 5e4$.

We begin with the computation of the minimum contrast function $M \mapsto \gamma(\hat{g}_M)$, as depicted in Figure 2. Observe that the slope of this function unquestionably stabilizes at a critical value refer to as $\hat{\rho}/2$ in both the histogram and the trigonometric case. This leads to an adaptive choice of $\hat{M} = 23$ for the histogram basis and $\hat{M} = 21$ for the trigonometric basis, see Figures 2 and 3.

Furthermore, one can see on Figure 4 that our method also qualitatively improves upon the spectral method in both the histogram and the trigonometric case.

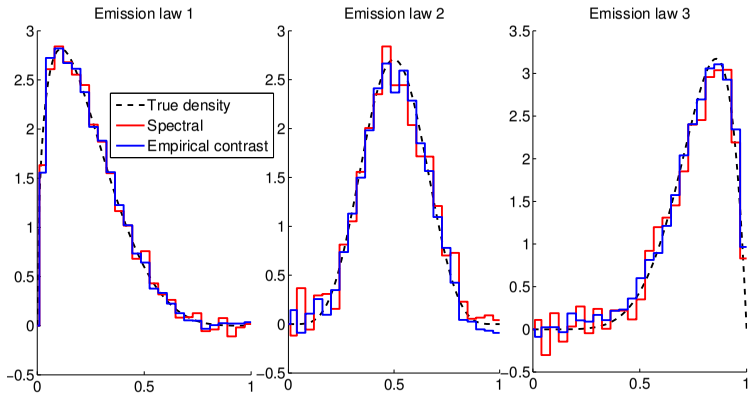

Figure 5: Estimation of three densities given by beta laws of parameters $(1.5,5)$, $(6,6)$ and $(7,2)$ from a single chain of length $N = 5e4$. We have used the histogram basis and we have found $\hat{M} = 25$ using the slope heuristic.

6.5 Three States

Our method can be performed for $K > 2$ as illustrated in Figure 5. In this example $K = 3$, the sample size is $N = 5e4$ and the emission laws are three beta distributions with parameters $(1.5,5)$, $(6,6)$ and $(7,2)$. Note that the number of hidden states K does not really impact on the complexity of the algorithm as we have seen in Section 6.2.

In this example, we were able to observe a linear stabilization of the minimum contrast function. The slope heuristic procedure led to an adaptive choice $\hat{M} = 25$.

7. Discussion

We have proposed a penalized least squares method to estimate the emission densities of the hidden chain when the transition matrix of the hidden chain is full rank and the emission probability distributions are linearly independent. The algorithm may be initialized using spectral estimators. The obtained estimators are adaptive rate optimal up to a log factor, where adaptivity is upon the family of emission densities. The results hold under an assumption on the parameter that holds generically. We have proved that this assumption is always verified when there are two hidden states. We did not find a general argument to prove that the assumption always holds when $K > 2$, and a natural question is to ask if, when the number of hidden states is $K > 2$, this assumption is also always verified.
It is proved in Alexandrovich et al. (2016) that identifiability holds as soon as $f_1^\star, \ldots, f_K^\star$ are distinct densities. The identifiability is obtained in that case using the marginal distribution of dimension $2K+1$, that is the marginal distribution of $Y_1, \ldots, Y_{2K+1}$. Thus, to get consistent estimators, one needs to use the joint distribution of $2K+1$ consecutive observations.

Though linear independence is generically satisfied, one may wonder what happens when emission densities are not far to be linearly dependent. Simulations in Lehéricy (2015) show that estimation becomes harder. In those practical situations where estimation becomes difficult, it is observed that the Gram matrix of $f_1^\star, \dots, f_K^\star$ has an eigenvalue close to 0. On the theoretical side, the proof of Theorem 6 uses the linear independence of the emission densities by using that Gram matrices are positive. An interesting problem would be to investigate if it is possible to estimate the emission densities with the classical adaptive rate for density estimation when the emission densities are linearly dependent (though all distinct). It is possible using model selection to get the classical rate for the estimation of the density of $2K+1$ consecutive observations, but it does not seem obvious to see whether this rate can be transferred to the estimators of the emission densities. This is the subject of further work, see Lehéricy (2016).
Another question arising from our work is whether it is possible to adapt to different smoothnesses of the emission densities.

8. Proofs

8.1 Proof of lemma 3

In Hsu et al. (2012) it is proved that when **[H1]**, **[H2]**, **[H3]** hold and when the rank of the matrix $\mathbf{O}_M := (\langle \varphi_m, f_k^\star \rangle_{1\le m\le M, 1\le k\le K}$ is K, the knowledge of the tensor $\mathbf{M}_M$ given by $\mathbf{M}_M(a,b,c) = \mathbb{E}(\varphi_a(Y_1)\varphi_b(Y_2)\varphi_c(Y_3))$ for all a,b,c in $\{1,\dots,M\}$ allows to recover $\mathbf{O}_M$ and $\mathbf{Q}$ up to relabelling of the hidden states. Thus, when **[H1]**, **[H2]**, **[H3]** and **[H4]** hold, the knowledge of $g^{\mathbf{Q},\mathbf{f}^\star}$ is equivalent to the knowledge of the sequence $(\mathbf{M}_M)_M$, which allows to recover $\mathbf{Q}$ and the sequence $(\mathbf{O}_M)_M$, up to relabelling of the hidden states, which allows to recover $\mathbf{f}^\star = (f_1^\star, \dots, f_K^\star)$ up to relabelling of the hidden states, thanks to (1). See also Gassiat et al. (2016).

8.2 Proof of Theorem 4

Throughout the proof N is fixed, and we write γ (instead of γ_N) for the contrast function.

8.2.1 Beginning of the proof: algebraic manipulations

Let us fix some M and some permutation τ. Using the definitions of $\hat{g}_M$ and $\hat{M}$, we can write

$$\gamma(\hat{g}_{\hat{M}}) + \mathrm{pen}(N,\hat{M}) \le \gamma(\hat{g}_M) + \mathrm{pen}(N,M) \le \gamma(g^{\hat{\mathbf{Q}},\mathbf{f}^\star_{M,\tau^{-1}}}) + \mathrm{pen}(N,M)\,,$$

where $\mathbf{f}^\star_{M,\tau^{-1}} = (f^\star_{M,\tau^{-1}(1)}, \dots, f^\star_{M,\tau^{-1}(K)})$ (here we use that $\mathbf{f}^\star_{M,\tau^{-1}} \in \mathcal{F}^K$). But we can compute for all functions t_1, t_2,

$$\gamma(t_1) - \gamma(t_2) = \|t_1 - g^\star\|_2^2 - \|t_2 - g^\star\|_2^2 - 2\nu(t_1 - t_2)\,,$$

where ν is the centered empirical process

$$\nu(t) = \frac{1}{N}\sum_{s=1}^N t(Y_1^{(s)}, Y_2^{(s)}, Y_3^{(s)}) - \int t g^\star\,.$$

This gives

$$\|\hat{g}_{\hat{M}} - g^\star\|_2^2 \le \|g^{\hat{\mathbf{Q}},\mathbf{f}^\star_{M,\tau^{-1}}} - g^\star\|_2^2 + 2\nu(\hat{g}_{\hat{M}} - g^{\hat{\mathbf{Q}},\mathbf{f}^\star_{M,\tau^{-1}}}) + \mathrm{pen}(N,M) - \mathrm{pen}(N,\hat{M}) \qquad (4)$$

Now, we denote by $B_M = \|g^{\mathbf{Q}^\star,\mathbf{f}^\star_M} - g^\star\|_2^2$ a bias term and we notice that $g^{\hat{\mathbf{Q}},\mathbf{f}^\star_{M,\tau^{-1}}} = g^{\mathbb{P}_\tau\hat{\mathbf{Q}}\mathbb{P}_\tau^\top,\mathbf{f}^\star_M}$. Then

$$\begin{aligned}\|g^{\hat{\mathbf{Q}},\mathbf{f}^\star_{M,\tau^{-1}}} - g^\star\|_2^2 &\le 2\|g^{\hat{\mathbf{Q}},\mathbf{f}^\star_{M,\tau^{-1}}} - g^{\mathbf{Q}^\star,\mathbf{f}^\star_M}\|_2^2 + 2\|g^{\mathbf{Q}^\star,\mathbf{f}^\star_M} - g^\star\|_2^2 \\ &\le 2\|g^{\mathbb{P}_\tau\hat{\mathbf{Q}}\mathbb{P}_\tau^\top,\mathbf{f}^\star_M} - g^{\mathbf{Q}^\star,\mathbf{f}^\star_M}\|_2^2 + 2B_M\,.\end{aligned}$$

But, using Schwarz inequality, $\|g^{\mathbf{Q}_1,\mathbf{f}^\star_M} - g^{\mathbf{Q}_2,\mathbf{f}^\star_M}\|_2^2$ can be bounded by

$$\begin{aligned}&\sum_{m_1,m_2,m_3=1}^M \Big| \sum_{k_1,k_2,k_3=1}^K (\pi_1(k_1)\mathbf{Q}_1(k_1,k_2)\mathbf{Q}_1(k_2,k_3) - \pi_2(k_1)\mathbf{Q}_2(k_1,k_2)\mathbf{Q}_2(k_2,k_3)) \\ &\qquad \langle f^\star_{k_1}, \varphi_{m_1}\rangle\langle f^\star_{k_2}, \varphi_{m_2}\rangle\langle f^\star_{k_3}, \varphi_{m_3}\rangle\Big|^2 \\ &\le \left(\sum_{k_1,k_2,k_3=1}^K (\pi_1(k_1)\mathbf{Q}_1(k_1,k_2)\mathbf{Q}_1(k_2,k_3) - \pi_2(k_1)\mathbf{Q}_2(k_1,k_2)\mathbf{Q}_2(k_2,k_3))^2\right) \\ &\quad \sum_{m_1,m_2,m_3=1}^M \sum_{k_1,k_2,k_3=1}^K \Big|\langle f^\star_{k_1}, \varphi_{m_1}\rangle\langle f^\star_{k_2}, \varphi_{m_2}\rangle\langle f^\star_{k_3}, \varphi_{m_3}\rangle\Big|^2 \\ &\le 3K^3 C^6_{\mathcal{F},2}\left(\|\pi_1 - \pi_2\|_2^2 + 2\|\mathbf{Q}_1 - \mathbf{Q}_2\|_F^2\right) \qquad (5)\end{aligned}$$

so that

$$\|g^{\hat{\mathbf{Q}},\mathbf{f}^\star_{M,\tau^{-1}}} - g^\star\|_2^2 \le 6K^3 C^6_{\mathcal{F},2}\left(\|\mathbb{P}_\tau\hat{\pi} - \pi^\star\|_2^2 + 2\|\mathbb{P}_\tau\hat{\mathbf{Q}}\mathbb{P}_\tau^\top - \mathbf{Q}^\star\|_F^2\right) + 2B_M\,.$$

Next we set $S_M = \cup_{\mathbf{Q}}\mathcal{S}(\mathbf{Q},M)$ and

$$Z_M = \sup_{t\in S_M}\left[\frac{|\nu(t-g^\star)|}{\|t-g^\star\|_2^2 + x_M^2}\right]$$

for x_M to be determined later. Then

$$\begin{aligned}\nu(\hat{g}_{\hat{M}} - g^{\hat{\mathbf{Q}},\mathbf{f}^\star_{M,\tau^{-1}}}) &= \nu(\hat{g}_{\hat{M}} - g^\star) + \nu(g^\star - g^{\hat{\mathbf{Q}},\mathbf{f}^\star_{M,\tau^{-1}}}) \\ &\le Z_{\hat{M}}(\|\hat{g}_{\hat{M}} - g^\star\|_2^2 + x_{\hat{M}}^2) + Z_M(\|g^{\hat{\mathbf{Q}},\mathbf{f}^\star_{M,\tau^{-1}}} - g^\star\|_2^2 + x_M^2).\end{aligned}$$

Denoting by $R_{\hat{M}} = \|\hat{g}_{\hat{M}} - g^\star\|_2^2$ the squared risk, (4) becomes

$$\begin{aligned} R_{\hat{M}} &\leq 6K^3C_{\mathcal{F},2}^6\left(\|\mathbb{P}_\tau\hat{\pi} - \pi^\star\|_2^2 + 2\|\mathbb{P}_\tau\hat{\mathbf{Q}}\mathbb{P}_\tau^\top - \mathbf{Q}^\star\|_F^2\right) + 2B_M + 2Z_{\hat{M}}(R_{\hat{M}} + x_{\hat{M}}^2) \\ &\quad + 2Z_M\left(6K^3C_{\mathcal{F},2}^6\left(\|\mathbb{P}_\tau\hat{\pi} - \pi^\star\|_2^2 + 2\|\mathbb{P}_\tau\hat{\mathbf{Q}}\mathbb{P}_\tau^\top - \mathbf{Q}^\star\|_F^2\right) + 2B_M + x_M^2\right) \\ &\quad + 2\mathrm{pen}(N,M) - \mathrm{pen}(N,\hat{M}) - \mathrm{pen}(N,M)\,, \\ R_{\hat{M}}(1 - 2Z_{\hat{M}}) &\leq (2 + 4Z_M)B_M + 2\mathrm{pen}(N,M) \\ &\quad + (1 + 2Z_M)6K^3C_{\mathcal{F},2}^6\left(\|\mathbb{P}_\tau\hat{\pi} - \pi^\star\|_2^2 + 2\|\mathbb{P}_\tau\hat{\mathbf{Q}}\mathbb{P}_\tau^\top - \mathbf{Q}^\star\|_F^2\right) \\ &\quad + 2\sup_{M'}(2Z_{M'}x_{M'}^2 - \mathrm{pen}(N,M'))\,. \end{aligned}$$

To conclude it is then sufficient to establish that, with probability larger than $1 - (e-1)^{-1}e^{-x}$, it holds

$$\sup_{M'} Z_{M'} \leq \frac{1}{4} \quad \text{and} \quad \sup_{M'}(2Z_{M'}x_{M'}^2 - \mathrm{pen}(N,M')) \leq A\frac{x}{N}\,,$$

with A a constant depending only on $\mathbf{Q}^\star$ and $\mathbf{f}^\star$ and not on N, M, x. Thus we will have, for any M, with probability larger than $1 - (e-1)^{-1}e^{-x}$,

$$\begin{aligned} \frac{1}{2}R_{\hat{M}} &\leq 3B_M + 2\mathrm{pen}(N,M) + 2A\frac{x}{N} \\ &\quad + 9C_{\mathcal{F},2}^6\left(\|\mathbb{P}_\tau\hat{\pi} - \pi^\star\|_2^2 + 2\|\mathbb{P}_\tau\hat{\mathbf{Q}}\mathbb{P}_\tau^\top - \mathbf{Q}^\star\|_F^2\right) \end{aligned}$$

which is the announced result.

The heart of the proof is then the study of Z_M. We introduce u_M a projection of $g^\star$ on S_M and we split Z_M into two terms: $Z_M \leq 4Z_{M,1} + Z_{M,2}$ with

$$\begin{cases} Z_{M,1} = \sup_{t\in S_M}\left[\dfrac{|\nu(t-u_M)|}{\|t-u_M\|_2^2 + 4x_M^2}\right] \\ Z_{M,2} = \dfrac{|\nu(u_M - g^\star)|}{\|u_M - g^\star\|_2^2 + x_M^2} \end{cases}$$

Indeed u_M verifies: for all $t \in S_M$,

$$\|u_M - g^\star\|_2 \leq \|t - g^\star\|_2 \quad \text{and} \quad \|u_M - t\|_2 \leq 2\|t - g^\star\|_2\,.$$

8.2.2 Deviation inequality for $Z_{M,2}$

Bernstein's inequality (24) for HMMs (see Appendix A) gives, with probability larger than $1 - e^{-z}$:

$$|\nu(u_M - g^\star)| \leq 2\sqrt{2c^\star\|u_M - g^\star\|_2^2\|g^\star\|_\infty\frac{z}{N}} + 2\sqrt{2}c^\star\|u_M - g^\star\|_\infty\frac{z}{N}\,.$$

Then, using $a^2 + b^2 \geq 2ab$, with probability larger than $1 - e^{-z}$:

$$\frac{|\nu(u_M - g^\star)|}{\|u_M - g^\star\|_2^2 + x_M^2} \leq 2\sqrt{2c^\star\|g^\star\|_\infty}\frac{1}{2x_M}\sqrt{\frac{z}{N}} + 2\sqrt{2}c^\star\frac{\|u_M\|_\infty + \|g^\star\|_\infty}{x_M^2}\frac{z}{N}\,.$$

But any function t in S_M can be written

$$t = \sum_{k_1,k_2,k_3=1}^K \pi(k_1)\mathbf{Q}(k_1,k_2)\mathbf{Q}(k_2,k_3)f_{k_1}\otimes f_{k_2}\otimes f_{k_3}\,,$$

with $f_k \in \mathcal{F}$ for $k = 1,\dots,K$, so that $\sup_{t\in S_M}\|t\|_\infty \leq C_{\mathcal{F},\infty}^3$. Then, with probability larger than $1 - e^{-z_M - z}$

$$Z_{M,2} \leq \sqrt{2c^\star\|g^\star\|_\infty}\sqrt{\frac{z_M + z}{x_M^2 N}} + 4\sqrt{2}c^\star C_{\mathcal{F},\infty}^3\frac{z_M + z}{x_M^2 N}\,. \tag{6}$$

8.2.3 Deviation inequality for $Z_{M,1}$

We shall first study the term $\sup_{t\in B_\sigma}|\nu(t-u_M)|$ where

$$B_\sigma = \{t \in S_M, \|t - u_M\|_2 \leq \sigma\}.$$

Remark that, for all $t \in \mathcal{S}(\mathbf{Q}, M)$,

$$\|t\|_2^2 \leq \sum_{k_1,k_2,k_3=1}^K \pi^2(k_1)\mathbf{Q}^2(k_1,k_2)\mathbf{Q}^2(k_2,k_3)\sum_{k_1,k_2,k_3=1}^K C_{\mathcal{F},2}^2C_{\mathcal{F},2}^2C_{\mathcal{F},2}^2 \leq K^3C_{\mathcal{F},2}^6.$$

Then, if $t \in B_\sigma$, $\|t - u_M\|_2 \leq \sigma \wedge 2K^{3/2}C_{\mathcal{F},2}^3$. Notice also that for all $t \in S_M$, $\|t - u_M\|_\infty \leq 2C_{\mathcal{F},\infty}^3$. Now Proposition 13 in Appendix A (applied to a countable dense set in B_σ) gives that for any measurable set A such that $\mathbb{P}(A) > 0$,

$$\mathbb{E}^A(\sup_{t\in B_\sigma}|\nu(t-u_M)|) \leq C^\star\left[\frac{E}{N} + \sigma\sqrt{\frac{1}{N}\log\left(\frac{1}{\mathbb{P}(A)}\right)} + \frac{2C_{\mathcal{F},\infty}^3}{N}\log\left(\frac{1}{\mathbb{P}(A)}\right)\right],$$

and

$$E = \sqrt{N}\int_0^\sigma\sqrt{H(u)\wedge N}du + (2C_{\mathcal{F},\infty}^3 + 2K^{3/2}C_{\mathcal{F},2}^3)H(\sigma)\,.$$

Here, for any integrable random variable Z, $E^A[Z]$ denotes $E[Z\mathbb{1}_A]/\mathbb{P}(A)$.

We shall compute E later and find σ_M and φ such that

$$\forall\sigma \geq \sigma_M \qquad E \leq (1 + 2C_{\mathcal{F},\infty}^3 + 2K^{3/2}C_{\mathcal{F},2}^3)\varphi(\sigma)\sqrt{N}. \tag{7}$$

(see Section 8.2.4). We then use Lemma 4.23 in Massart (2007) to write (for $x_M \geq \sigma_M$)

$$\mathbb{E}^A\left(\sup_{t\in S_M}\left[\frac{|\nu(t-u_M)|}{\|t-u_M\|_2^2 + 4x_M^2}\right]\right) \leq \frac{C^\star}{x_M^2}\left[C\frac{\varphi(2x_M)}{\sqrt{N}} + 2x_M\sqrt{\frac{1}{N}\log\left(\frac{1}{\mathbb{P}(A)}\right)} + \frac{2C_{\mathcal{F},\infty}^3}{N}\log\left(\frac{1}{\mathbb{P}(A)}\right)\right]$$

Finally, Lemma 2.4 in Massart (2007) ensures that, with probability $1 - e^{-z_M - z}$:

$$Z_{M,1} = \sup_{t\in S_M}\left[\frac{|\nu(t-u_M)|}{\|t-u_M\|_2^2 + 4x_M^2}\right] \leq C^\star\left[C\frac{\varphi(2x_M)}{x_M^2\sqrt{N}} + 2\sqrt{\frac{z_M + z}{x_M^2 N}} + 2C_{\mathcal{F},\infty}^3\frac{z_M + z}{x_M^2 N}\right]. \tag{8}$$

8.2.4 Computation of the entropy and function φ

The definition of H given in Proposition 13 shows that $H(\delta)$ is bounded by the classical bracketing entropy for $\mathbf{L}^2$ distance at point $\delta/C^3_{\mathcal{F},\infty}$ (where $C^3_{\mathcal{F},\infty}$ bounds the sup norm of $g^\star$): $H(\delta) \leq H(\delta/C^3_{\mathcal{F},\infty}, S_M, \mathbf{L}^2)$. We denote by $N(u, S, \mathbf{L}^2) = e^{H(u,S,\mathbf{L}^2)}$ the minimal number of brackets of radius u to cover S. Recall that when t_1 and t_2 are real valued functions, the bracket $[t_1, t_2]$ is the set of real valued functions t such that $t_1(\cdot) \leq t(\cdot) \leq t_2(\cdot)$, and the radius of the bracket is $\|t_2 - t_1\|_2$. Now, observe that $S_M = \cup_{\mathbf{Q}} \mathcal{S}(\mathbf{Q}, M)$ is a set of mixtures of parametric functions. Denoting $\mathbf{k} = (k_1, k_2, k_3)$, S_M is included in

$$\left\{ \sum_{\mathbf{k}\in\{1,\dots,K\}^3} \mu(\mathbf{k}) f_{k_1} \otimes f_{k_2} \otimes f_{k_3},\ \mu \geq 0,\ \sum_{\mathbf{k}\in\{1,\dots,K\}^3} \mu(\mathbf{k}) = 1, \right.$$
$$\left. f_{k_i} \in \mathcal{F} \cap \mathrm{Span}(\varphi_1, \dots, \varphi_M),\ i = 1, 2, 3 \right\} .$$

Set

$$\mathcal{A} = \{ f_1 \otimes f_2 \otimes f_3, f_i \in \mathcal{F} \cap \mathrm{Span}(\varphi_1, \dots, \varphi_M),\ i = 1, 2, 3 \}.$$

Then following the proof in Appendix A of Bontemps and Toussile (2013), we can prove

$$N(\varepsilon, S_M, \mathbf{L}^2) \leq \left(\frac{C_1}{\varepsilon}\right)^{K^3-1} \left[N\left(\frac{\varepsilon}{3}, \mathcal{A}, \mathbf{L}^2\right) \right]^{K^3} . \tag{9}$$

where C_1 depends on K and $C_{\mathcal{F},2}$. Denote $\mathcal{B} = \mathcal{F} \cap \mathrm{Span}(\varphi_1, \dots, \varphi_M)$. Let $a = (a_m)_{1\leq m\leq M} \in \mathbb{R}^M$ and $b = (b_m)_{1\leq m\leq M} \in \mathbb{R}^M$ such that $a_m < b_m$, $m = 1, \dots, M$. For each $m = 1, \dots, M$ and $y \in \mathcal{Y}$, let

$$u_m(y) = \begin{cases} a_m & \text{if } \varphi_m(y) \geq 0 \\ b_m & \text{otherwise} \end{cases}$$
$$v_m(y) = a_m + b_m - u_m(y).$$

Then, if $(c_m)_{1\leq m\leq M} \in \mathbb{R}^M$ is such that for all $m = 1, \dots, M$, $a_m \leq c_m \leq b_m$, then

$$U^1_{a,b}(y) := \sum_{m=1}^M u_m(y)\varphi_m(y) \leq \sum_{m=1}^M c_m\varphi_m(y) \leq \sum_{m=1}^M v_m(y)\varphi_m(y) = U^2_{a,b}(y).$$

Moreover,

$$\|U^2_{a,b} - U^1_{a,b}\|_2^2 = \| \sum_{m=1}^M |b_m - a_m|.|\varphi_m| \|_2^2$$
$$\leq M\|b - a\|_2^2$$

using Cauchy-Schwarz inequality. Thus, one may cover $\mathcal{B}$ with brackets of form $[U^1_{a,b}, U^2_{a,b}]$. Also, for $i = 1, 2$,

$$\|U^i_{a,b}\|_2^2 \leq \| \sum_{m_i=1}^M |b_m + a_m|.|\varphi_m| \|_2^2$$
$$\leq 2M(\|a\|_2^2 + \|b\|_2^2).$$

If now for some a^i, b^i in $\mathbb{R}^M$, $f_i \in [U^1_{a^i,b^i}, U^2_{a^i,b^i}]$, $i = 1, 2, 3$, then

$$f_1 \otimes f_2 \otimes f_3 \in [V, W]$$

with

$$V = \min\{ U^{i_1}_{a^1,b^1} U^{i_2}_{a^2,b^2} U^{i_3}_{a^3,b^3},\ i_1, i_2, i_3 \in \{1, 2\} \}$$

and

$$W = \max\{ U^{i_1}_{a^1,b^1} U^{i_2}_{a^2,b^2} U^{i_3}_{a^3,b^3},\ i_1, i_2, i_3 \in \{1, 2\} \},$$

pointwise. Moreover, one can see that

$$\begin{aligned} |W - V| &\leq \left|U^2_{a^1,b^1} - U^1_{a^1,b^1}\right| \max_{j_1,j_2\in\{1,2\}} \left|U^{j_1}_{a^2,b^2}\right| . \left|U^{j_2}_{a^3,b^3}\right| \\ &\quad + \left|U^2_{a^2,b^2} - U^1_{a^2,b^2}\right| \max_{j_1,j_2\in\{1,2\}} \left|U^{j_1}_{a^1,b^1}\right| . \left|U^{j_2}_{a^3,b^3}\right| \\ &\quad + \left|U^2_{a^3,b^3} - U^1_{a^3,b^3}\right| \max_{j_1,j_2\in\{1,2\}} \left|U^{j_1}_{a^1,b^1}\right| . \left|U^{j_2}_{a^2,b^2}\right| \\ &\leq \sum_{i=1}^3 \left|U^2_{a^i,b^i} - U^1_{a^i,b^i}\right| \prod_{j\neq i} \left(\left|U^1_{a^j,b^j}\right| + \left|U^2_{a^j,b^j}\right| \right) \end{aligned}$$

so that

$$\begin{aligned} \|W - V\|_2^2 &\leq 12 \sum_{i=1}^3 \left\|U^2_{a^i,b^i} - U^1_{a^i,b^i}\right\|_2^2 \prod_{j\neq i} \left(\left\|U^1_{a^j,b^j}\right\|_2^2 + \left\|U^2_{a^j,b^j}\right\|_2^2 \right) \\ &\leq 48M^3 \sum_{i=1}^3 \|b^i - a^i\|_2^2 \prod_{j\neq i} \left(\|a^j\|_2^2 + \|b^j\|_2^2 \right) \\ &\leq 192M^3 C^4_{\mathcal{F},2} \sum_{i=1}^3 \|b^i - a^i\|_2^2. \end{aligned}$$

Thus one may cover $\mathcal{A}$ by covering the ball of radius $C_{\mathcal{F},2}$ in $\mathbb{R}^M$ with hypercubes $[a, b]$, for which $\|a\|_2$, $\|b\|_2$ are less than $C_{\mathcal{F},2}$. To get a bracket with radius u, it is enough that $\|b^i - a^i\|_2^2 \leq u^2/(576M^3C^4_{\mathcal{F},2})$, $i = 1, 2, 3$. We finally obtain that

$$N\left(u, \mathcal{A}, \mathbf{L}^2\right) \leq \left(\frac{48\sqrt{3}M^{3/2}C^3_{\mathcal{F},2}}{u} \right)^{3M} . \tag{10}$$

We deduce from (9) and (10) that

$$N(u, S_M, \mathbf{L}^2) \leq \left(\frac{C_1}{u}\right)^{K^3-1} \left(\frac{48\sqrt{3}M^{3/2}C^3_{\mathcal{F},2}}{u} \right)^{3MK^3} ,$$

and then

$$H(u, S_M, \mathbf{L}^2) \leq (K^3 - 1) \log(\frac{C_1}{u}) + 3MK^3 \log\left(\frac{C_2 M^{3/2}}{u} \right) ,$$

with C_2 depending on K and $C_{\mathcal{F},2}$. To conclude we use that $\int_0^\sigma \sqrt{\log\left(\frac{1}{x}\right)}dx \leq \sigma(\sqrt{\pi} + \sqrt{\log\left(\frac{1}{\sigma}\right)})$, see Baudry et al. (2012). Finally we can write for $\sigma \leq M^{3/2}$:

$$\int_0^\sigma \sqrt{H(u)}du \leq C_3\sqrt{M}\sigma\left(1+\sqrt{\log\left(\frac{M^{3/2}}{\sigma}\right)}\right),$$

where C_3 depends on K, $C_{\mathcal{F},2}$ and $C_{\mathcal{F},\infty}$. Set

$$\varphi(x) = C_3\sqrt{M}x\left(1+\sqrt{\log\left(\frac{M^{3/2}}{x}\right)}\right)$$

The function φ is increasing on $]0, M^{3/2}]$, and $\varphi(x)/x$ is decreasing. Moreover $\varphi(\sigma) \geq \int_0^\sigma \sqrt{H(u)}du$ and $\varphi^2(\sigma) \geq \sigma^2 H(\sigma)$.

8.2.5 End of the proof, choice of parameters

As soon as $N \geq C_3^2/M^2 := N_0$, we may define σ_M as the solution of equation $\varphi(x) = \sqrt{N}x^2$. Then, for all $\sigma \geq \sigma_M$,

$$H(\sigma) \leq \frac{\varphi(\sigma)^2}{\sigma^2} \leq \frac{\varphi(\sigma)}{\sigma}\sigma\sqrt{N}.$$

This yields, for all $\sigma \geq \sigma_M$,

$$E \leq (1 + 2C_{\mathcal{F},\infty}^3 + 2K^{3/2}C_{\mathcal{F},2}^3)\varphi(\sigma)\sqrt{N},$$

which was required in (7).

Moreover $\frac{\varphi(2x_M)}{x_M\sqrt{N}} \leq 2\sigma_M$ as soon as $x_M \geq \sigma_M$. Combining (8) and (6), we obtain, with probability $1 - e^{-z_M - z}$:

$$Z_M \leq C^{\star\star}\left[\frac{\sigma_M}{x_M} + \sqrt{\frac{z_M+z}{x_M^2 N}} + \frac{z_M+z}{x_M^2 N}\right],$$

where $C^{\star\star}$ depends on K, $C_{\mathcal{F},2}$, $C_{\mathcal{F},\infty}$, $\mathbf{Q}^\star$. Now let us choose $x_M = \theta^{-1}\sqrt{\sigma_M^2 + \frac{z_M+z}{N}}$ with θ such that $2\theta + \theta^2 \leq (C^{\star\star})^{-1}/4$. This choice entails: $x_M \geq \theta^{-1}\sigma_M$ and $x_M^2 \geq \theta^{-2}\frac{z_M+z}{N}$. Then with probability $1 - e^{-z_M - z}$:

$$Z_M \leq C^{\star\star}(\theta + \theta + \theta^2).$$

We now choose $z_M = M$ which implies $\sum_{M\geq 1} e^{-z_M} = (e-1)^{-1}$. Then, with probability $1 - (e-1)^{-1}e^{-z}$,

$$\forall M \qquad Z_M \leq C^{\star\star}(2\theta + \theta^2) \leq \frac{1}{4},$$

and for all M,

$$\begin{aligned} Z_M x_M^2 &\leq C^{\star\star}\left[\sigma_M x_M + x_M\sqrt{\frac{z_M+z}{N}} + \frac{z_M+z}{N}\right] \\ &\leq C^{\star\star}\theta^{-1}\left(\sigma_M + \sqrt{\frac{z_M+z}{N}}\right)^2 + C^{\star\star}\frac{z_M+z}{N}. \end{aligned}$$

Then, with probability $1 - (e-1)^{-1}e^{-z}$, for all M,

$$Z_M x_M^2 - C^{\star\star}\left(2\theta^{-1}\sigma_M^2 + (2\theta^{-1}+1)\frac{M}{N}\right) \leq C^{\star\star}(2\theta^{-1}+1)\frac{z}{N}.$$

Then the result is proved as soon as

$$\mathrm{pen}(N,M) \geq 2C^{\star\star}\left(2\theta^{-1}\sigma_M^2 + (2\theta^{-1}+1)\frac{M}{N}\right). \tag{11}$$

It remains to get an upper bound for σ_M. Recall that σ_M is defined as the solution of equation $C_3\sqrt{M}x(1+\sqrt{\log\left(\frac{M^3}{x}\right)}) = \sqrt{N}x^2$. Then we obtain that for some C_4

$$\sigma_M \leq C_4\sqrt{\frac{M}{N}}(1+\sqrt{\log(N)}),$$

and (11) holds as soon as

$$\mathrm{pen}(N,M) \geq \rho^\star\frac{M\log(N)}{N}$$

for some constant $\rho^\star$ depending on $C_{\mathcal{F},2}$ and $C_{\mathcal{F},\infty}$ (**Scenario A**) or on $\mathbf{Q}^\star$, $C_{\mathcal{F},2}$ and $C_{\mathcal{F},\infty}$ (**Scenario B**).

8.3 Proof of Theorem 6

For any $\mathbf{h} \in \mathcal{K}^K$ and $\mathbf{Q} \in \mathcal{V}$, denote $N(\mathbf{Q},\mathbf{h}) = \|g^{\mathbf{Q},\mathbf{f}^\star+\mathbf{h}} - g^{\mathbf{Q},\mathbf{f}^\star}\|_2^2$. What we want to prove is that

$$c := c(\mathcal{K},\mathcal{V},\mathfrak{F}^\star)^2 := \inf_{\mathbf{Q}\in\mathcal{V},\mathbf{h}\in\mathcal{K}^K,\|\mathbf{h}\|_2\neq 0}\frac{N(\mathbf{Q},\mathbf{h})}{\|\mathbf{h}\|_{\mathbf{Q}}^2} > 0.$$

One can compute:

$$\begin{aligned} N(\mathbf{Q},\mathbf{h}) = &\sum_{k_1,k_2,k_3,k_1',k_2',k_3'=1}^{K}\pi(k_1)\mathbf{Q}(k_1,k_2)\mathbf{Q}(k_2,k_3)\pi(k_1')\mathbf{Q}(k_1',k_2')\mathbf{Q}(k_2',k_3') \\ &\left(\prod_{i=1}^3\langle f_{k_i}^\star + h_{k_i}, f_{k_i'}^\star + h_{k_i'}\rangle + \prod_{i=1}^3\langle f_{k_i}^\star, f_{k_i'}^\star\rangle - \prod_{i=1}^3\langle f_{k_i}^\star + h_{k_i}, f_{k_i'}^\star\rangle - \prod_{i=1}^3\langle f_{k_i}^\star, f_{k_i'}^\star + h_{k_i'}\rangle\right). \end{aligned}$$

Let $\mathbf{u} = (u_1,\ldots,u_K)$ be such that u_i, $i = 1,\ldots,K$, is the orthogonal projection of h_i on the subspace of $\mathbf{L}^2(\mathcal{Y},\mathcal{L}^D)$ spanned by $f_1^\star\ldots,f_K^\star$. Then

$$N(\mathbf{Q},\mathbf{h}) = N(\mathbf{Q},\mathbf{u}) + M(\mathbf{Q},\mathbf{u},\mathbf{h}-\mathbf{u}) \tag{12}$$

where, for any $\mathbf{a} = (a_1, \ldots, a_K) \in \mathbf{L}^2(\mathcal{Y}, \mathcal{L}^D)^K$,

$$M(\mathbf{Q}, \mathbf{u}, \mathbf{a}) = \sum_{k_1,k_2,k_3,k_1',k_2',k_3'=1}^{K} \pi(k_1)\mathbf{Q}(k_1,k_2)\mathbf{Q}(k_2,k_3)\pi(k_1')\mathbf{Q}(k_1',k_2')\mathbf{Q}(k_2',k_3')$$
$$\left(\prod_{i=1}^{3}\langle a_{k_i}, a_{k_i'}\rangle + \sum_{i=1}^{3}\langle a_{k_i}, a_{k_i'}\rangle \prod_{j\neq i}\langle f^\star_{k_j} + u_{k_j}, f^\star_{k_j'} + u_{k_j'}\rangle + \sum_{i=1}^{3}\langle f^\star_{k_i} + u_{k_i}, f^\star_{k_i'} + u_{k_i'}\rangle \prod_{j\neq i}\langle a_{k_j}, a_{k_j'}\rangle\right).$$

Let $A = \mathfrak{Diag}[\pi]$ with π the stationary distribution of $\mathbf{Q}$. Then $M(\mathbf{Q}, \mathbf{u}, \mathbf{a})$ may be rewritten as:

$$\begin{aligned}
M(\mathbf{Q}, \mathbf{u}, \mathbf{a}) \quad = \sum_{i,j=1}^{K} \quad & \langle (\mathbf{Q}^T A\mathbf{a})_i, (\mathbf{Q}^T A\mathbf{a})_j\rangle\langle a_i, a_j\rangle\langle (\mathbf{Q}\mathbf{a})_i, (\mathbf{Q}\mathbf{a})_j\rangle \\
& + \langle (\mathbf{Q}^T A\mathbf{a})_i, (\mathbf{Q}^T A\mathbf{a})_j\rangle\langle (\mathbf{f}^\star + \mathbf{u}_i), (\mathbf{f}^\star + \mathbf{u})_j\rangle\langle (\mathbf{Q}(\mathbf{f}^\star + \mathbf{u}))_i, (\mathbf{Q}(\mathbf{f}^\star + \mathbf{u}))_j\rangle \\
& + \langle (\mathbf{Q}^T A(\mathbf{f}^\star + \mathbf{u}))_i, (\mathbf{Q}^T A(\mathbf{f}^\star + \mathbf{u}))_j\rangle\langle a_i, a_j\rangle\langle (\mathbf{Q}(\mathbf{f}^\star + \mathbf{u}))_i, (\mathbf{Q}(\mathbf{f}^\star + \mathbf{u}))_j\rangle \\
& + \langle (\mathbf{Q}^T A(\mathbf{f}^\star + \mathbf{u}))_i, (\mathbf{Q}^T A(\mathbf{f}^\star + \mathbf{u}))_j\rangle\langle (\mathbf{f}^\star + \mathbf{u})_i, (\mathbf{f}^\star + \mathbf{u})_j\rangle\langle (\mathbf{Q}\mathbf{a})_i, (\mathbf{Q}\mathbf{a})_j\rangle \\
& + \langle (\mathbf{Q}^T A(\mathbf{f}^\star + \mathbf{u}))_i, (\mathbf{Q}^T A(\mathbf{f}^\star + \mathbf{u}))_j\rangle\langle a_i, a_j\rangle\langle (\mathbf{Q}\mathbf{a})_i, (\mathbf{Q}\mathbf{a})_j\rangle \\
& + \langle (\mathbf{Q}^T A\mathbf{a})_i, (\mathbf{Q}^T A\mathbf{a})_j\rangle\langle (\mathbf{f}^\star + \mathbf{u})_i, (\mathbf{f}^\star + \mathbf{u})_j\rangle\langle (\mathbf{Q}\mathbf{a})_i, (\mathbf{Q}\mathbf{a})_j\rangle \\
& + \langle (\mathbf{Q}^T A\mathbf{a})_i, (\mathbf{Q}^T A\mathbf{a})_j\rangle\langle a_i, a_j\rangle\langle (\mathbf{Q}(\mathbf{f}^\star + \mathbf{u}))_i, (\mathbf{Q}(\mathbf{f}^\star + \mathbf{u}))_j\rangle.
\end{aligned}$$

All terms in this sum are non negative. Let us prove it for the first one, the argument for the others is similar. Define V the $K \times K$ matrix given by

$$V_{i,j} = \langle (\mathbf{Q}^T A\mathbf{a})_i, (\mathbf{Q}^T A\mathbf{a})_j\rangle\langle (\mathbf{Q}\mathbf{a})_i, (\mathbf{Q}\mathbf{a})_j\rangle, \quad i,j = 1, \ldots, K.$$

V is the Hadamard product of two Gram matrices which are non negative, thus V is itself non negative by the Schur product Theorem, see Schur (1911), and

$$\sum_{i,j=1}^{K} V_{i,j}\langle a_i, a_j\rangle = \int \mathbf{a}(y)^T V \mathbf{a}(y) dy \geq 0.$$

Thus we have that $M(\mathbf{Q}, \mathbf{u}, \mathbf{a})$ is lower bounded by one term of the sum so that

$$M(\mathbf{Q}, \mathbf{u}, \mathbf{a}) \geq \sum_{i,j=1}^{K} \langle (\mathbf{Q}^T A(\mathbf{f}^\star + \mathbf{u}))_i, (\mathbf{Q}^T A(\mathbf{f}^\star + \mathbf{u}))_j\rangle\langle a_i, a_j\rangle\langle (\mathbf{Q}(\mathbf{f}^\star + \mathbf{u}))_i, (\mathbf{Q}(\mathbf{f}^\star + \mathbf{u}))_j\rangle.$$

The minimal eigenvalue of the Hadamard product of two non negative matrices is lower bounded by the product of the minimal eigenvalues of each matrix, and we get

$$M(\mathbf{Q}, \mathbf{u}, \mathbf{a}) \geq \left(\min_{i=1,\ldots,K} \lambda_i(\mathbf{Q}^T A(\mathbf{f}^\star + \mathbf{u}))\right)\left(\min_{i=1,\ldots,K} \lambda_i(\mathbf{Q}(\mathbf{f}^\star + \mathbf{u}))\right)\|\mathbf{a}\|_2^2 \qquad (13)$$

where $\|\mathbf{a}\|_2^2 = \sum_{k=1}^{k} \|a_k\|_2^2$, and where, if $\mathbf{h} \in \mathbf{L}^2(\mathcal{Y}, \mathcal{L}^D)^K$, $\lambda_1(\mathbf{h})$, $\ldots$, $\lambda_K(\mathbf{h})$ are the (non negative) eigenvalues of the Gram matrix of $h_1, \ldots, h_K$.

Let now $(\mathbf{Q}_n, \mathbf{h}_n)_n$ be a sequence in $\mathcal{V} \times \mathcal{K}$ such that $c = \lim_n \frac{N(\mathbf{Q}_n, \mathbf{h}_n)}{\|\mathbf{h}_n\|^2_{\mathbf{Q}^\star}}$. Let $\mathbf{u}_n$ be the vector of the orthogonal projections of the coordinate functions of $\mathbf{h}_n$ on the subspace of $\mathbf{L}^2(\mathcal{Y}, \mathcal{L}^D)$ spanned by $f_1^\star \ldots, f_K^\star$. Notice that

$$\|\mathbf{h}_n\|^2_{\mathbf{Q}^\star} = \|\mathbf{u}_n\|^2_{\mathbf{Q}^\star} + \|\mathbf{h}_n - \mathbf{u}_n\|_2^2.$$

Let $C_{\mathcal{K},2}$ be the upper bound of the norm of elements of $\mathcal{K}$. We have, for any $n \geq 1$,

$$\|\mathbf{h}_n\|^2_{\mathbf{Q}^\star} \leq K(C_{\mathcal{K},2} + 2C_{\mathcal{F},2})^2$$

so that for any $n \geq 1$,

$$\|\mathbf{u}_n\|^2_{\mathbf{Q}^\star} \leq K(C_{\mathcal{K},2} + 2C_{\mathcal{F},2})^2.$$

Since $(\mathbf{Q}_n, \mathbf{u}_n)_n$ is a bounded sequence in a finite dimensional space it has a limit point $(\mathbf{Q}, \mathbf{u})$. Now, using (12) and the non negativity of $M(\mathbf{Q}_n, \mathbf{u}_n, \mathbf{h}_n - \mathbf{u}_n)$, we get on the converging subsequence

$$c \geq \lim_{n\to+\infty} \frac{N(\mathbf{Q}_n, \mathbf{u}_n)}{K(C_{\mathcal{K},2} + 2C_{\mathcal{F},2})^2} = \frac{N(\mathbf{Q}, \mathbf{u})}{K(C_{\mathcal{K},2} + 2C_{\mathcal{F},2})^2}.$$

Since $\mathbf{Q} \in \mathcal{V}$, $T_{\mathbf{Q}} \subset T_{\mathbf{Q}^\star}$ so that $\|\mathbf{u}\|_{\mathbf{Q}} \geq \|\mathbf{u}\|_{\mathbf{Q}^\star}$. Thus if $\|\mathbf{u}\|_{\mathbf{Q}^\star} \neq 0$, $\|\mathbf{u}\|_{\mathbf{Q}} \neq 0$, and using Lemma 3, $N(\mathbf{Q}, \mathbf{u}) \neq 0$ so that $c > 0$ in this case.

Consider now the situation where $\|\mathbf{u}\|_{\mathbf{Q}^\star} = 0$. Since $\lim_{n\to+\infty} \|\mathbf{u}_n\|_{\mathbf{Q}^\star} = 0$, there exists n_1 and $\tau \in T_{\mathbf{Q}^\star}$ such that for all $n \geq n_1$, one has $\|\mathbf{u}_n\|^2_{\mathbf{Q}^\star} = \sum_{k=1}^{K} \|u_{n,k} + f_k^\star - f_{\tau(k)}^\star\|_2^2$, and it is possible to exchange the states in the transition matrix using τ so that we just have to consider the situation where $\|\mathbf{u}_n\|^2_{\mathbf{Q}^\star} = \|\mathbf{u}_n\|_2^2$ for large enough n.
Eigenvalues of Gram matrices of functions are continuous in the functions so that using (12) and (13) we get

$$c \geq \lim_{n\to+\infty} \frac{N(\mathbf{Q}_n, \mathbf{u}_n)}{\|\mathbf{u}_n\|_2^2 + \|\mathbf{h}_n - \mathbf{u}_n\|_2^2} + \left(\min_{i=1,\ldots,K} \lambda_i(\mathbf{Q}^T A\mathbf{f}^\star)\right)\left(\min_{i=1,\ldots,K} \lambda_i(\mathbf{Q}\mathbf{f}^\star)\right) \liminf_{n\to+\infty} \frac{\|\mathbf{h}_n - \mathbf{u}_n\|_2^2}{\|\mathbf{u}_n\|_2^2 + \|\mathbf{h}_n - \mathbf{u}_n\|_2^2}.$$

Under assumptions **[H1]** and **[H4]**, $\mathbf{Q}^T A\mathbf{f}^\star$ is a vector of linearly independent functions and $\mathbf{Q}\mathbf{f}^\star$ also, so that

$$\left(\min_{i=1,\ldots,K} \lambda_i(\mathbf{Q}^T A\mathbf{f}^\star)\right)\left(\min_{i=1,\ldots,K} \lambda_i(\mathbf{Q}\mathbf{f}^\star)\right) > 0.$$

Thus, if $\liminf_{n\to+\infty} \frac{\|\mathbf{h}_n - \mathbf{u}_n\|_2^2}{\|\mathbf{u}_n\|_2^2 + \|\mathbf{h}_n - \mathbf{u}_n\|_2^2} > 0$ we obtain $c > 0$.
If now it holds that $\liminf_{n\to+\infty} \frac{\|\mathbf{h}_n - \mathbf{u}_n\|_2^2}{\|\mathbf{u}_n\|_2^2 + \|\mathbf{h}_n - \mathbf{u}_n\|_2^2} = 0$. On a subsequence it holds that $\|\mathbf{h}_n - \mathbf{u}_n\|_2 = o(\|\mathbf{u}_n\|_2)$ and we have

$$c \geq \lim_{n\to+\infty} \frac{N(\mathbf{Q}_n, \mathbf{u}_n)}{\|\mathbf{u}_n\|_2^2} \frac{\|\mathbf{u}_n\|_2^2}{\|\mathbf{u}_n\|_2^2 + \|\mathbf{h}_n - \mathbf{u}_n\|_2^2} = \lim_{n\to+\infty} \frac{N(\mathbf{Q}_n, \mathbf{u}_n)}{\|\mathbf{u}_n\|_2^2} \qquad (14)$$

with $(\mathbf{u}_n)_n$ a sequence of vectors of functions in the finite dimensional space spanned by $f_1^\star, \ldots, f_K^\star$. Writing

$$\frac{(\mathbf{u}_n)_i(y)}{\|\mathbf{u}_n\|_2} = \frac{\|\mathbf{h}_n\|_2}{\|\mathbf{u}_n\|_2}\frac{(\mathbf{u}_n)_i(y)}{\|\mathbf{h}_n\|_2} = \frac{\|\mathbf{h}_n\|_2}{\|\mathbf{u}_n\|_2}\Big[\frac{(\mathbf{h}_n-\mathbf{u}_n)_i+(\mathbf{u}_n)_i(y)}{\|\mathbf{h}_n\|_2} - \frac{(\mathbf{h}_n-\mathbf{u}_n)_i}{\|\mathbf{h}_n\|_2}\Big],$$

it follows that for $i = 1, \ldots, K$,

$$\lim_{n\to+\infty}\int \frac{(\mathbf{u}_n)_i(y)}{\|\mathbf{u}_n\|_2}dy = 0 \tag{15}$$

since for all n and all $i = 1, \ldots, K$, $\int \frac{(\mathbf{h}_n-\mathbf{u}_n)_i+(\mathbf{u}_n)_i(y)}{\|\mathbf{h}_n\|_2}dy = 0$, and it holds that $\frac{\|\mathbf{h}_n\|_2}{\|\mathbf{u}_n\|_2} \to 1$ and $\|\mathbf{h}_n - \mathbf{u}_n\|_2/\|\mathbf{u}_n\|_2 = o(1)$.
Let us return to general considerations on the function $N(\cdot,\cdot)$. As it may be seen from its formula, $N(\tilde{\mathbf{Q}}, \tilde{\mathbf{h}})$ is polynomial in the variables $\tilde{\mathbf{Q}}_{i,j}$, $\langle f_i^\star, f_j^\star\rangle$, $\langle \tilde{h}_i, f_j^\star\rangle$, $\langle \tilde{h}_i, \tilde{h}_j\rangle$, $i, j = 1, \ldots, K$. Let $D(\tilde{\mathbf{Q}}, \tilde{\mathbf{h}})$ denote the part of $N(\tilde{\mathbf{Q}}, \tilde{\mathbf{h}})$ which is homogeneous of degree 2 with respect to the variable $\tilde{\mathbf{h}}$, that is

$$\begin{aligned} D(\tilde{\mathbf{Q}}, \tilde{\mathbf{h}}) \;=\; & \sum_{k_1,k_2,k_3,k_1',k_2',k_3'=1}^{K} \tilde{\pi}(k_1)\tilde{\mathbf{Q}}(k_1,k_2)\tilde{\mathbf{Q}}(k_2,k_3)\tilde{\pi}(k_1')\tilde{\mathbf{Q}}(k_1',k_2')\tilde{\mathbf{Q}}(k_2',k_3') \\ & \Big(\sum_{i=1}^{3}\langle \tilde{h}_{k_i}, \tilde{h}_{k_i'}\rangle \prod_{j\neq i}\langle f_{k_j}^\star, f_{k_j'}^\star\rangle + 2\sum_{i=1}^{3}\langle f_{k_i}^\star, f_{k_i'}^\star\rangle \prod_{j\neq j'\neq i}\langle f_{k_j}^\star, \tilde{h}_{k_j'}\rangle\langle \tilde{h}_{k_{j'}}, f_{k_{j'}'}^\star\rangle\Big). \end{aligned} \tag{16}$$

One gets

$$N(\tilde{\mathbf{Q}}, \tilde{\mathbf{h}}) = D(\tilde{\mathbf{Q}}, \tilde{\mathbf{h}}) + O\left(\|\tilde{\mathbf{h}}\|_2^3\right)$$

where the $O(\cdot)$ depends only on $\mathbf{f}^\star$. Let us first notice that $D(\cdot,\cdot)$ is always non negative. Indeed, since for all $\tilde{\mathbf{Q}} \in \mathcal{V}$ and all $\tilde{\mathbf{h}} \in (\mathbf{L}^2(\mathcal{Y}, \mathcal{L}^D))^K$ one has $N(\tilde{\mathbf{Q}}, \tilde{\mathbf{h}}) \geq 0$, it holds

$$\forall \tilde{\mathbf{Q}} \in \mathcal{V},\ \forall \tilde{\mathbf{h}} \in (\mathbf{L}^2(\mathcal{Y}, \mathcal{L}^D))^K,\ \frac{D(\tilde{\mathbf{Q}}, \tilde{\mathbf{h}})}{\|\tilde{\mathbf{h}}\|_2^2} + O(\|\tilde{\mathbf{h}}\|_2) \geq 0,$$

so that, since for all $\lambda \in \mathbb{R}$, $D(\tilde{\mathbf{Q}}, \lambda\tilde{\mathbf{h}}) = \lambda^2 D(\tilde{\mathbf{Q}}, \tilde{\mathbf{h}})$,

$$\forall \tilde{\mathbf{Q}} \in \mathcal{V},\ \forall \tilde{\mathbf{h}} \in (\mathbf{L}^2(\mathcal{Y}, \mathcal{L}^D))^K,\ D(\tilde{\mathbf{Q}}, \tilde{\mathbf{h}}) \geq 0. \tag{17}$$

Then we obtain from (14)

$$c \geq \liminf_{n\to+\infty} D(\mathbf{Q}_n, \frac{\mathbf{u_n}}{\|\mathbf{u_n}\|_2}).$$

Let $\mathbf{b} = (b_1, \ldots, b_K)$ be a limit point of the sequence $(\frac{\mathbf{u_n}}{\|\mathbf{u_n}\|_2})_n$. We then have

$$c \geq D(\mathbf{Q}, \mathbf{b}).$$

Now, using (15) we get that

$$\int b_k d\mathcal{L}^D = 0,\ k = 1, \ldots, K.$$

Thus there exists a $K \times K$ matrix U such that $\mathbf{b}^T = U(\mathbf{f}^\star)^T$ and $U\mathbf{1}_k = 0$, and equation (16) leads to

$$\begin{aligned} & D(\mathbf{Q}, \mathbf{b}) = \\ & \sum_{i,j}\Big\{\left(\mathbf{Q}^T AUG^\star U^T A\mathbf{Q}\right)_{i,j}(G^\star)_{i,j}\left(\mathbf{Q}G^\star\mathbf{Q}^T\right)_{i,j} + \left(\mathbf{Q}^T AG^\star A\mathbf{Q}\right)_{i,j}\left(UG^\star U^T\right)_{i,j}\left(\mathbf{Q}G^\star\mathbf{Q}^T\right)_{i,j} \\ & + \left(\mathbf{Q}^T AG^\star A\mathbf{Q}\right)_{i,j}(G^\star)_{i,j}\left(\mathbf{Q}UG^\star U^T\mathbf{Q}^T\right)_{i,j}\Big\} + 2\sum_{i,j}\Big\{\left(\mathbf{Q}^T AUG^\star A\mathbf{Q}\right)_{i,j}(UG^\star)_{j,i}\left(\mathbf{Q}G^\star\mathbf{Q}^T\right)_{i,j} \\ & + \left(\mathbf{Q}^T AUG^\star A\mathbf{Q}\right)_{i,j}\left(\mathbf{Q}UG^\star\mathbf{Q}^T\right)_{j,i}(G^\star)_{i,j} + (UG^\star)_{i,j}\left(\mathbf{Q}UG^\star\mathbf{Q}^T\right)_{j,i}\left(\mathbf{Q}^T AG^\star A\mathbf{Q}\right)_{i,j}\Big\}. \end{aligned}$$

with $G^\star$ the $K \times K$ Gram matrix such that $(G^\star)_{i,j} = \langle f_i^\star, f_j^\star\rangle$, $i = 1, \ldots, K$.
This is the quadratic form $\mathcal{D}$ in $U_{i,j}$, $i = 1, \ldots, K$, $j = 1, \ldots, K-1$ defined in Section 4.2. This quadratic form is non negative, and as soon as it is positive, we get that $c > 0$. But the quadratic form $\mathcal{D}$ is positive as soon as its determinant is non zero, that is if and only if $H(\mathbf{Q}, G(\mathbf{f}^\star)) \neq 0$.

8.4 Proof of Lemma 5

Here we specialize to the situation where $K = 2$. In such a case, $\mathbf{f}^\star = (f_1^\star, f_2^\star)$, and

$$\mathbf{Q}^\star = \begin{pmatrix} 1-p^\star & p^\star \\ q^\star & 1-q^\star \end{pmatrix}$$

for some $p^\star, q^\star$ in $[0,1]$ for which $0 < p^\star < 1,\ 0 < q^\star < 1,\ p^\star \neq 1-q^\star$. Now

$$U = \begin{pmatrix} \alpha & -\alpha \\ \beta & -\beta \end{pmatrix}$$

for some real numbers α and β, and brute force computation gives $D(\mathbf{Q}, \mathbf{b}) = D_{1,1}\alpha^2 + 2D_{1,2}\alpha\beta + D_{2,2}\beta^2$ with, denoting $p = \mathbf{Q}(1,2)$ and $q = \mathbf{Q}(2,1)$:

$$\begin{aligned} \frac{(p+q)^2 D_{1,1}}{q^2} =& 2(1-p)^2\|f_1^\star - f_2^\star\|^2\|f_1^\star\|^2\|(1-p)f_1^\star + pf_2^\star\|^2 + \|(1-p)f_1^\star + pf_2^\star\|^4\|f_1^\star - f_2^\star\|^2 \\ & + 4p(1-p)\left(\langle (1-p)f_1^\star + pf_2^\star, qf_1^\star + (1-q)f_2^\star\rangle\right)\langle f_1^\star, f_2^\star\rangle\|f_1^\star - f_2^\star\|^2 \\ & + 2p^2\|f_1^\star - f_2^\star\|^2\|f_2^\star\|^2\|qf_1^\star + (1-q)f_2^\star\|^2 \\ & + 2(1-p)^2\left(\langle (1-p)f_1^\star + pf_2^\star, f_1^\star - f_2^\star\rangle\right)^2\|f_1^\star\|^2 \\ & + 2p^2\left(\langle qf_1^\star + (1-q)f_2^\star, f_1^\star - f_2^\star\rangle\right)^2\|f_2^\star\|^2 \\ & + 4p(1-p)\langle qf_1^\star + (1-q)f_2^\star, f_1^\star - f_2^\star\rangle\langle (1-p)f_1^\star + pf_2^\star, f_1^\star - f_2^\star\rangle\langle f_1^\star, f_2^\star\rangle \\ & + 4(1-p)\langle (1-p)f_1^\star + pf_2^\star, f_1^\star - f_2^\star\rangle\langle f_1^\star, f_1^\star - f_2^\star\rangle\|(1-p)f_1^\star + pf_2^\star\|^2 \\ & + 4p\langle (1-p)f_1^\star + pf_2^\star, f_1^\star - f_2^\star\rangle\langle f_2^\star, f_1^\star - f_2^\star\rangle\langle (1-p)f_1^\star + pf_2^\star, qf_1^\star + (1-q)f_2^\star\rangle, \end{aligned}$$

$$
\begin{aligned}
\frac{(p+q)^2 D_{2,2}}{p^2} =& 2q^2\|f_1^\star - f_2^\star\|^2\|f_1^\star\|^2\|(1-p)f_1^\star + pf_2^\star\|^2 + \|qf_1^\star + (1-q)f_2^\star\|^4\|f_1^\star - f_2^\star\|^2 \\
&+ 4(1-q)q\left(\langle (1-p)f_1^\star + pf_2^\star, qf_1^\star + (1-q)f_2^\star\rangle\right)\langle f_1^\star, f_2^\star\rangle\|f_1^\star - f_2^\star\|^2 \\
&+ 2(1-q)^2\|f_1^\star - f_2^\star\|^2\|f_2^\star\|^2\|qf_1^\star + (1-q)f_2^\star\|^2 \\
&+ 2q^2\left(\langle (1-p)f_1^\star + pf_2^\star, f_1^\star - f_2^\star\rangle\right)^2\|f_1^\star\|^2 \\
&+ 2(1-q)^2\left(\langle qf_1^\star + (1-q)f_2^\star, f_1^\star - f_2^\star\rangle\right)^2\|f_2\|^2 \\
&+ 4q(1-q)\langle qf_1^\star + (1-q)f_2^\star, f_1^\star - f_2^\star\rangle\langle (1-p)f_1^\star + pf_2^\star, f_1^\star - f_2^\star\rangle\langle f_1^\star, f_2^\star\rangle \\
&+ 4q\langle qf_1^\star + (1-q)f_2^\star, f_1^\star - f_2^\star\rangle\langle f_1^\star, f_1^\star - f_2^\star\rangle\langle (1-p)f_1^\star + pf_2^\star, qf_1^\star + (1-q)f_2^\star\rangle \\
&+ 4(1-q)\langle qf_1^\star + (1-q)f_2^\star, f_1^\star - f_2^\star\rangle\langle f_2^\star, f_1^\star - f_2^\star\rangle\|qf_1^\star + (1-q)f_2^\star\|^2,
\end{aligned}
$$

and:

$$
\begin{aligned}
\frac{(p+q)^2 D_{1,2}}{pq} =& 2(1-p)q\|f_1^\star - f_2^\star\|^2\|f_1^\star\|^2\|(1-p)f_1^\star + pf_2^\star\|^2 \\
&+ 2[pq + (1-p)(1-q)]\left(\langle (1-p)f_1^\star + pf_2^\star, qf_1^\star + (1-q)f_2^\star\rangle\right)\langle f_1^\star, f_2^\star\rangle\|f_1^\star - f_2^\star\|^2 \\
&+ \left(\langle (1-p)f_1^\star + pf_2^\star, qf_1^\star + (1-q)f_2^\star\rangle\right)^2\|f_1^\star - f_2^\star\|^2 \\
&+ 2p(1-q)\|f_1^\star - f_2^\star\|^2\|f_2^\star\|^2\|qf_1^\star + (1-q)f_2^\star\|^2 \\
&+ 2q(1-p)\left(\langle (1-p)f_1^\star + pf_2^\star, f_1^\star - f_2^\star\rangle\right)^2\|f_1^\star\|^2 \\
&+ 2p(1-q)\left(\langle qf_1^\star + (1-q)f_2^\star, f_1^\star - f_2^\star\rangle\right)^2\|f_2^\star\|^2 \\
&+ 2pq\langle qf_1^\star + (1-q)f_2^\star, f_1^\star - f_2^\star\rangle\langle (1-p)f_1^\star + pf_2^\star, f_1 - f_2^\star\rangle\langle f_1^\star, f_2^\star\rangle \\
&+ 2(1-p)(1-q)\langle qf_1^\star + (1-q)f_2^\star, f_1 - f_2^\star\rangle\langle (1-p)f_1^\star + pf_2^\star, f_1^\star - f_2^\star\rangle\langle f_1^\star, f_2^\star\rangle \\
&+ q\langle (1-p)f_1^\star + pf_2^\star, f_1^\star - f_2^\star\rangle\langle f_1^\star, f_1^\star - f_2^\star\rangle\|(1-p)f_1^\star + pf_2^\star\|^2 \\
&+ 2(1-p)\langle qf_1^\star + (1-q)f_2^\star, f_1^\star - f_2^\star\rangle\langle f_1^\star, f_1^\star - f_2^\star\rangle\langle (1-p)f_1^\star + pf_2^\star, qf_1^\star + (1-q)f_2^\star\rangle \\
&+ 2(1-q)\langle (1-p)f_1^\star + pf_2^\star, f_1^\star - f_2^\star\rangle\langle f_2^\star, f_1^\star - f_2^\star\rangle\langle (1-p)f_1^\star + pf_2^\star, qf_1^\star + (1-q)f_2^\star\rangle \\
&+ 2p\langle qf_1^\star + (1-q)f_2^\star, f_1^\star - f_2^\star\rangle\langle f_2^\star, f_1^\star - f_2^\star\rangle\|qf_1^\star + (1-q)f_2^\star\|^2.
\end{aligned}
$$

We have:

$$H(\mathbf{Q}, G(\mathbf{f}^\star)) = D_{1,1}D_{2,2} - D_{1,2}^2.$$

We shall now write $H(\mathbf{Q}, G(\mathbf{f}^\star))$ using

$$n_1 = \|f_1^\star\|_2,\ n_2 = \|f_2^\star\|_2,\ a = \frac{\langle f_1^\star, f_2^\star\rangle}{\|f_1^\star\|_2\|f_2^\star\|_2},$$

for which the range is $[1,\infty[^2\times[0,1[$. Doing so, we obtain a polynomial P_1 in the variables n_1, n_2, a, p and q.
First observe that, by symmetry,

$$P_1(n_1, n_2, a, p, q) = P_1(n_2, n_1, a, q, p),$$

so that it is sufficient to prove that the polynomial P_1 is positive on the domain

$$1 \le n_2 \le n_1, \tag{18}$$

and $0 \le a < 1$ and $0 < p \ne q < 1$.
Furthermore, consider the change of variable

$$q = 1 - p + d$$

then we have a polynomial P_2 in the variables n_1, n_2, a, p and d which factorizes with

$$\frac{p^2(1-a^2)d^2n_1^2n_2^2(1+d-p)^2}{(1+d)^4}.$$

Dividing by this factor, one gets a polynomial P_3 which is homogeneous of degree 8 in n_1 and n_2, so that one may set $n_1 = 1$ and keep $b = n_2 \in]0,1]$ (observe that we have used (18) to reduce the problem to the domain $n_2/n_1 \le 1$) and obtain a polynomial P_4 in the variables b, a, p and d. It remains to prove that P_4 is positive on $\mathcal{D}_4 = \{b \in]0,1], a \in [0,1[, p \in]0,1[, d \in]p-1, 0[\cup]0, p[\}$.
Consider now the following change of variables

$$b = \frac{1}{1+x^2}, \quad a = \frac{y^2}{1+y^2}, \quad p = \frac{z^2}{1+z^2}, \quad \text{and} \quad d = \frac{(tz)^2 - 1}{(1+t^2)(1+z^2)},$$

mapping $(x,y,z,t) \in \mathbb{R}^4$ onto $(b,a,p,d) \in \mathcal{D}_5 = \{b \in]0,1], a \in [0,1[, p \in [0,1[, d \in]p-1, p[\}$ which contains $\mathcal{D}_4$. This change of variables maps P_4 onto a rational fraction with positive denominator, namely

$$(1+t^2)^4(1+y^2)^4(1+z^2)^4(1+x^2)^8$$

So it remains to prove that its numerator P_5, which is polynomial, is positive on $\mathbb{R}^4$. An expression of P_5 can be found in Appendix B. Observe that P_5 is polynomial in x^2, y^2, z^2 and t^2 and there are only three monomials with negative coefficients. These monomials can be expressed as sum of squares using others monomials, namely:

- $-18x^{12}t^2 + 27x^{12} + 1979x^{12}t^4 = 18x^{12} + 9(x^6 - x^6t^2)^2 + 1970x^{12}t^4$,
- $-108x^{10}t^2 + 1970x^{12}t^4 + 495x^8 = 439x^8 + 56(x^4 - x^6t^2)^2 + 1914x^{12}t^4 + 4t^2x^{10}$,
- and $-114x^8t^2 + 972x^4 + 1914x^{12}t^4 = 915x^4 + 57(x^2 - x^6t^2)^2 + 1857x^{12}t^4$.

Thus P_5 is equal to 144 more a sum of squares, hence it is positive. This proves that $H(\mathbf{Q}, G(\mathbf{f}^\star))$ is always positive.

8.5 Proof of Theorem 7

Let $\mathcal{K} = \{\mathbf{h} = \mathbf{f} - \mathbf{f}^\star, \mathbf{f} \in \mathcal{F}^K\}$. Using Theorem 4 we get that for all $x > 0$, for all $N \ge N_0$, with probability $1 - (e-1)^{-1}e^{-x}$, one has for any permutation τ_N,

$$
\begin{aligned}
\|\hat{g} - g^\star\|_2^2 \le\ & 6\inf_M\left\{\|g^\star - g^{\mathbf{Q}^\star, \mathbf{f}_M^\star}\|_2^2 + \mathrm{pen}(N,M)\right\} + A_1^\star\frac{x}{N} \\
& + 18C_{\mathcal{F},2}^6\left(\|\mathbf{Q}^\star - \mathbb{P}_{\tau_N}\hat{\mathbf{Q}}_N\mathbb{P}_{\tau_N}^\top\|_F^2 + \|\pi^\star - \mathbb{P}_{\tau_N}\hat{\pi}\|_2^2\right).
\end{aligned} \tag{19}
$$

Notice that writing

$$\hat{g}\,(y_1,y_2,y_3) = \sum_{k_1,k_2,k_3=1}^{K} (\mathbb{P}_{\tau_N}\hat{\pi})(k_1)(\mathbb{P}_{\tau_N}\hat{\mathbf{Q}}\mathbb{P}_{\tau_N}^\top)(k_1,k_2)(\mathbb{P}_{\tau_N}\hat{\mathbf{Q}}\mathbb{P}_{\tau_N}^\top)(k_2,k_3) \times \hat{f}_{\tau_N(k_1)}(y_1)\hat{f}_{\tau_N(k_2)}(y_2)\hat{f}_{\tau_N(k_3)}(y_3)\,,$$

and applying Theorem 6 we get that, on the event $\mathbb{P}_{\tau_N}\hat{\mathbf{Q}}\mathbb{P}_{\tau_N}^\top \in \mathcal{V}$, there exists $\tau \in T_{\mathbf{Q}^\star}$ such that

$$\sum_{k=1}^{K} \|f^\star_{\tau(k)} - \hat{f}_{\tau_N(k)}\|_2^2 \leq \frac{1}{c(\mathcal{K},\mathcal{V},\mathfrak{F}^\star)^2}\|\hat{g} - g^{\mathbb{P}_{\tau_N}\hat{\mathbf{Q}}\mathbb{P}_{\tau_N}^\top,\mathbf{f}^\star}\|_2^2. \tag{20}$$

Now by the triangular inequality

$$\|\hat{g} - g^{\mathbb{P}_{\tau_N}\hat{\mathbf{Q}}\mathbb{P}_{\tau_N}^\top,\mathbf{f}^\star}\|_2 \leq \|\hat{g} - g^\star\|_2 + \|g^{\mathbf{Q}^\star,\mathbf{f}^\star} - g^{\mathbb{P}_{\tau_N}\hat{\mathbf{Q}}\mathbb{P}_{\tau_N}^\top,\mathbf{f}^\star}\|_2. \tag{21}$$

Similarly to (5), we have

$$\|g^{\mathbf{Q}^\star,\mathbf{f}^\star} - g^{\mathbb{P}_{\tau_N}\hat{\mathbf{Q}}\mathbb{P}_{\tau_N}^\top,\mathbf{f}^\star}\|_2^2 \leq 3K^3C_{\mathcal{F},2}^6\left[\|\pi^\star - \mathbb{P}_{\tau_N}\hat{\pi}\|_2^2 + 2\|\mathbf{Q}^\star - \mathbb{P}_{\tau_N}\hat{\mathbf{Q}}\mathbb{P}_{\tau_N}^\top\|_F^2\right]. \tag{22}$$

In the same way,

$$\left(g^\star - g^{\mathbf{Q}^\star,\mathbf{f}^\star_M}\right)(y_1,y_2,y_3) = \sum_{k_1,k_2,k_3=1}^{K} \pi^\star(k_1)\mathbf{Q}^\star(k_1,k_2)\mathbf{Q}^\star(k_2,k_3)\left(f^\star_{k_1}(y_1)f^\star_{k_2}(y_2)f^\star_{k_3}(y_3) - f^\star_{M,k_1}(y_1)f^\star_{M,k_2}(y_2)f^\star_{M,k_3}(y_3)\right)$$

so that

$$\|g^\star - g^{\mathbf{Q}^\star,\mathbf{f}^\star_M}\|_2^2 \leq 3K^3C_{\mathcal{F},2}^4 \max\{\|f^\star_k - f^\star_{M,k}\|_2^2,\ k=1,\dots,K\}.$$

Thus collecting (19), (20), (21), (22) and with an appropriate choice of $A^\star$ we get Theorem 7.

8.6 Proof of Corollary 10

We shall apply Theorem 11 where, for each N, we define δ_N such that $(-\log\delta_N)/\delta_N^2 := (\log N)^{1/2}$. Notice first that δ_N goes to 0 and that M_N tends to infinity as N tends to infinity, so that for large enough N, $M_N \geq M_{\mathfrak{F}^\star}$. By denoting τ_N the τ_{M_N} given by Theorem 11 we get that for all $x \geq x(\mathbf{Q}^\star)$, for all $N \geq \mathbf{N}(\mathbf{Q}^\star,\mathfrak{F}^\star)x\log N$, with probability $1-[4+(e-1)^{-1}]e^{-x} - 2\delta_N$,

$$\|\pi^\star - \mathbb{P}_{\tau_N}\hat{\pi}\|_2 \leq \mathcal{C}(\mathbf{Q}^\star,\mathfrak{F}^\star)\sqrt{\frac{\log N}{N}}\sqrt{x}$$

and

$$\|\mathbf{Q}^\star - \mathbb{P}_{\tau_N}\hat{\mathbf{Q}}\mathbb{P}_{\tau_N}^\top\| \leq \mathcal{C}(\mathbf{Q}^\star,\mathfrak{F}^\star)\sqrt{\frac{\log N}{N}}\sqrt{x}\,.$$

We first obtain that

$$\limsup_{N\to+\infty}\mathbb{E}\left[\frac{N}{\log N}\|\mathbf{Q}^\star - \mathbb{P}_{\tau_N}\hat{\mathbf{Q}}\mathbb{P}_{\tau_N}^T\|^2\right] \leq \mathcal{C}(\mathbf{Q}^\star,\mathfrak{F}^\star)^2\int_0^{+\infty}\limsup_{N\to+\infty}\mathbb{P}\left(\frac{\sqrt{N}}{\mathcal{C}(\mathbf{Q}^\star,\mathfrak{F}^\star)\sqrt{\log N}}\|\mathbf{Q}^\star - \mathbb{P}_{\tau_N}\hat{\mathbf{Q}}\mathbb{P}_{\tau_N}^T\| \geq \sqrt{x}\right)dx \leq \mathcal{C}(\mathbf{Q}^\star,\mathfrak{F}^\star)^2x(\mathbf{Q}^\star) + \mathcal{C}(\mathbf{Q}^\star,\mathfrak{F}^\star)^2\int_{x(\mathbf{Q}^\star)}^{+\infty}[4+(e-1)^{-1}]e^{-x}dx < +\infty$$

so that

$$\mathbb{E}\left[\|\mathbf{Q}^\star - \mathbb{P}_{\tau_N}\hat{\mathbf{Q}}\mathbb{P}_{\tau_N}^T\|^2\right] = O\left(\frac{\log N}{N}\right).$$

Similarly, one has $\mathbb{E}\left[\|\pi^\star - \mathbb{P}_{\tau_N}\hat{\pi}\|^2\right] = O\left(\frac{\log N}{N}\right)$. We also obtain, by taking $x = N/(\log N)^{1/4}$, that

$$\limsup_{N\to+\infty}\mathbb{P}\left(\mathbb{P}_{\tau_N}\hat{\mathbf{Q}}\mathbb{P}_{\tau_N}^T \notin \mathcal{V}\right) = 0,$$

so that, using Theorem 7, we get for some $\tau \in T_{\mathbf{Q}^\star}$,

$$\limsup_{N\to+\infty}\mathbb{P}\left(\frac{N}{A^\star}\left[\sum_{k=1}^{K}\|f^\star_k - \hat{f}_{\tau^{-1}\circ\tau_N(k)}\|_2^2 - \inf_M\left\{\sum_{k=1}^{K}\|f^\star_k - f^\star_{M,k}\|_2^2 + \mathrm{pen}(N,M)\right\} - \|\mathbf{Q}^\star - \mathbb{P}_{\tau_N}\hat{\mathbf{Q}}\mathbb{P}_{\tau_N}^\top\|_F^2 - \|\pi^\star - \mathbb{P}_{\tau_N}\hat{\pi}\|_2^2 + \frac{x}{N}\right] \geq x\right) \leq (e-1)^{-1}e^{-x}.$$

Thus, by integration and the previous results, Corollary 10 follows.

Acknowledgments

We would like to thank N. Curien and D. Henrion for their help in the computation of P_5. We are deeply grateful to V. Magron for pointing us that P_5 can be explicitly expressed as a Sum-Of-Squares. Thanks are due to Luc Lehericy for a careful reading of the manuscript. We are grateful to anonymous referees for their careful reading of this work.

Appendix A. Concentration Inequalities

We first recall results that hold both for **(Scenario A)** (where we consider N i.i.d. samples $(Y_1^{(s)}, Y_2^{(s)}, Y_3^{(s)})_{s=1}^N$ of three consecutive observations) and for **(Scenario B)** (where we consider consecutive observations of the same chain).

The following proposition is the classical Bernstein's inequality for **(Scenario A)** and is proved in Paulin (2015), Theorem 2.4, for **(Scenario B)**.

Proposition 12 *Let t be a real valued and measurable bounded function on $\mathcal{Y}^3$. Let $V = \mathbb{E}[t^2(Z_1)]$. There exists a positive constant $c^\star$ depending only on $\mathbf{Q}^\star$ such that for all $0 \leq \lambda \leq 1/(2\sqrt{2}c^\star\|t\|_\infty)$:*

$$\log \mathbb{E}\exp\left[\lambda \sum_{s=1}^N (t(Z_s) - \mathbb{E}t(Z_s))\right] \leq \frac{2Nc^\star V\lambda^2}{1 - 2\sqrt{2}c^\star\|t\|_\infty\lambda} \tag{23}$$

so that for all $x \geq 0$,

$$\mathbb{P}\left(\sum_{s=1}^N (t(Z_s) - \mathbb{E}t(Z_s)) \geq 2\sqrt{2Nc^\star Vx} + 2\sqrt{2}c^\star\|t\|_\infty x\right) \leq e^{-x}. \tag{24}$$

We now state a deviation inequality, which comes from Massart (2007) Theorem 6.8 and Corollary 6.9 for **(Scenario A)**. For **(Scenario B)** the proof of the following proposition follows *mutatis mutandis* from the proof of Theorem 6.8 (and then Corollary 6.9) in Massart (2007) the early first step being equation (23). Recall that when t_1 and t_2 are real valued functions, the bracket $[t_1, t_2]$ is the set of real valued functions t such that $t_1(\cdot) \leq t(\cdot) \leq t_2(\cdot)$. For any measurable set A such that $\mathbb{P}(A) > 0$, and any integrable random variable Z, denote $E^A[Z] = E[Z\mathbb{1}_A]/\mathbb{P}(A)$.

Proposition 13 *Let $\mathcal{T}$ be some countable class of real valued and measurable functions on $\mathcal{Y}^3$. Assume that there exists some positive numbers σ and b such that for all $t \in \mathcal{T}$, $\|t\|_\infty \leq b$ and $\mathbb{E}[t^2(Z_1)] \leq \sigma^2$.*
Assume furthermore that for any positive number δ, there exists some finite set B_δ of brackets covering $\mathcal{F}$ such that for any bracket $[t_1, t_2] \in B_\delta$, $\|t_1 - t_2\|_\infty \leq b$ and $\mathbb{E}[(t_1 - t_2)^2(Z_1)] \leq \delta^2$. Let $e^{H(\delta)}$ denote the minimal cardinality of such a covering. Then, there exists a positive constant $C^\star$ depending only on $\mathbf{Q}^\star$ such that: for any measurable set A,

$$\mathbb{E}^A\left(\sup_{t\in\mathcal{T}} \sum_{s=1}^N (t(Z_s) - \mathbb{E}t(Z_s))\right) \leq C^\star\left[E + \sigma\sqrt{N\log\left(\frac{1}{\mathbb{P}(A)}\right)} + b\log\left(\frac{1}{\mathbb{P}(A)}\right)\right]$$

and for all positive number x

$$\mathbb{P}\left(\sup_{t\in\mathcal{T}} \sum_{s=1}^N (t(Z_s) - \mathbb{E}t(Z_s)) \geq C^\star[E + \sigma\sqrt{Nx} + bx]\right) \leq \exp(-x),$$

where

$$E = \sqrt{N}\int_0^\sigma \sqrt{H(u) \wedge N}du + (b + \sigma)H(\sigma).$$

Appendix B. Expression of Polynomial P_5

Computer assisted computations (available at `https://mycore.core-cloud.net/public.php?service=files&t=db7b8c1a2bcbcca157dcda5ecab84374`) give that:

Abstract

Focal cortical dysplasia (FCD) is the most common cause of pediatric epilepsy and the third most common cause in adults with treatment-resistant epilepsy. Surgical resection of the lesion is the most effective treatment to stop seizures. Technical advances in MRI have revolutionized the diagnosis of FCD, leading to high success rates for resective surgery. However, 45% of histologically confirmed FCD patients have normal MRIs (*MRI-negative*). Without a visible lesion, the success rate of surgery drops from 66% to 29%. In this work, we cast the problem of detecting potential FCD lesions using MRI scans of MRI-negative patients in an image segmentation framework based on hierarchical conditional random fields (HCRF). We use surface based morphometry to model the cortical surface as a two-dimensional surface which is then segmented at multiple scales to extract superpixels of different sizes. Each superpixel is assigned an outlier score by comparing it to a control population. The lesion is detected by fusing the outlier probabilities across multiple scales using a tree-structured HCRF. The proposed method achieves a higher detection rate, with superior recall and precision on a sample of twenty MRI-negative FCD patients as compared to a baseline across four morphological features and their combinations.

Keywords: Conditional Random Fields, LOF, Focal Cortical Dysplasia, Epilepsy

1. Introduction

Epilepsy is a common neurological disorder, affecting approximately 1% of the world's population (Hauser and Hesdorffer, 1990). It is characterized by profound abnormal neural activity during seizures and inter-ictal periods. Uncontrolled epilepsy can have harmful effects on the brain and has increased risk of injuries and sudden death (Bernasconi et al., 2011). About one third of epilepsy patients suffer from treatment-resistant epilepsy (TRE); their seizures cannot be managed by medicine (Kwan and Brodie, 2000). Cortical malformations, particularly focal cortical dysplasia (FCD) is recognized as the most common source of pediatric epilepsy and the third most common source in adults with TRE (Kuzniecky and Barkovich, 2001; Lerner et al., 2009).

Early detection and subsequent surgical removal of the FCD lesion is the most effective treatment to stop seizures and is often the last hope for TRE patients. A growing number of studies demonstrate that surgery is highly effective for FCD patients (Benbadis et al., 2003). However, the surgical procedure remains underutilized. One of the main reasons for this is that about 45% of histologically-verified FCD patients have normal MRIs (Wang et al., 2013). The chance of success for the surgical resection based on a visually detected lesion (*MRI-positive*) is 66%, which drops to 29% when the MRI is read as normal (*MRI-negative*) (Bell et al., 2009). Therefore patients who lack an MRI-visible lesion are less likely to be referred to specialized epilepsy centers by neurologists (Benbadis et al., 2003) likely because epilepsy specialists are reluctant to operate without a well-defined lesion (Tllez-Zenteno et al., 2005).

In this paper, we present an automated method for detecting FCD lesions using surface-based morphometry (SBM) (Dale et al., 1999) to extract the cortical surface from the T1-weighted structural MRI scans. The key advantage of using SBM is that the cortical surfaces of different individuals can be registered to an average surface allowing for point-wise comparisons between different individuals. The proposed method first applies a multiscale segmentation of the cortical surface and then combines the results via a hierarchical conditional random field (HCRF) (Reynolds and Murphy, 2007). Because we do not have accurately labeled training data, we cast the problem as a semi-supervised outlier detection task and thus we extend the HRCF framework proposed in (Reynolds and Murphy, 2007) to perform semi-supervised outlier detection. The resulting outlier regions (lesions), sorted by their probability and surface area, are shown to a team of radiologists and neurosurgeons who can combine the MRI lesion-detection results with other information such as the pattern of seizure onset and the patient's intracranial EEG (iEEG) data to determine the final candidate resection zone.

HCRFs have been effectively applied in computer vision for semantic image labeling (Plath et al., 2009), figure-ground segmentation (Reynolds and Murphy, 2007) and object detection (Awasthi et al., 2007). To train the HCRF, previous applications required either

that each pixel in the image have a label or that a bounding box around the object(s) of interest is provided. Consequently, the accuracy of the labels directly impacts the final performance of the HCRF. In this paper, we propose an extension of the HCRF-based image segmentation and object detection framework for problems in which pixel-level labels are not available. For our task, we are given the MRIs of patients and of normal controls, but information about which pixels form a lesion in the patient MRIs is either missing or highly noisy (Ahmed et al., 2015). Thus, we have a global label for each image indicating either that the image contains no lesions (healthy control) or that it contains one or more lesions (FCD patient). In Section 2 we explain in more detail why we cannot use the lesions/resection zones of previously treated patients as labels during training.

In a preliminary version of this work (Ahmed et al., 2014), we applied the proposed HCRF framework to both MRI-positive and MRI-negative patients using only cortical thickness as the feature of interest. Our preliminary findings showed that HCRF was able to achieve a higher detection rate with significantly higher precision and recall as compared to a recently reported semi-supervised approach (Thesen et al., 2011) and a human expert.[1] The current work extends that body of work by evaluating the proposed method on three new morphological features. In addition we investigate different mechanisms of combining the detections produced by the different features to achieve higher detection rates. In our experiments we observed that it is not straightforward to combine the detections of individual features, because some of the features are noisier than others i.e., have a higher false positive rate than others. We show that this issue can be overcome by either using feature selection or changing the cluster ranking criterion. We provide extensive results on a larger set of patients[2] as compared to our previous work, showing that feature selection can be used to achieve a high detection rate by appropriately tuning the ranking criterion.

The remainder of this paper is organized as follows. In Section 2 we briefly introduce SBM, the different morphological features that can be extracted within the SBM framework, and describe the current state of the art in lesion detection using SBM and its shortcomings. In Section 3 we detail how we pose the lesion detection task within the object detection/segmentation framework, where the saliency of the target object is defined based on its "outlier-ness". We present different methods for combining the results of using four different morphological features in our proposed lesion detection framework. Section 4, provides the details of our ranking and evaluation methodology and it also provides an empirical comparison of our approach and a baseline approach across different morphological features and their combinations.

This work makes a significant contribution toward the detection of FCD lesions. Our empirical evaluation demonstrates that the proposed method was able to detect abnormal regions within the resection zones in a higher number of MRI-negative patients as compared to a baseline approach across four morphological features and their combinations. Not only was our method able to achieve a higher detection rate, it did so while achieving significantly higher precision and recall. Indeed, our 75% detection rate on the MRI-Negative patients

1. We omit the results of the blind comparison to a human expert in this paper. Interested readers can refer to (Ahmed et al., 2014).
2. The current sample has twenty patients, fourteen of which are retained from the previous study. In Section 4 we exlain that the twenty patients comprise the *entire* set of MRI-Negative patients successfully treated via surgical resection over a three year period at NYU's Comprehensive Epilepsy Center.

in our evauation dataset (compared to a human expert detection rate of 0%), suggests that this method can be used as an effective tool in the pre-surgical evaluation of TRE patients who are likely to undergo surgical resection; our method has started to be incorporated in the weekly meetings of radiologists and neurosurgeons to help identify the seizure onset zones in MRI-Negative patients. Thus, this work has the potential to increase the number of patients who are referred to resective surgery, and ultimately who are seizure free after surgery.

Our contribution to machine learning in addition to making progress on a challenging and important application is a new method for using HCRFs for binary object detection/segmentation for which only image captions are available. The proposed method can be generalized for other data modalities such as time series data, where it can be used for time series segmentation. A caveat to this contribution is that the individual data (images/time series) must be able to be accurately aligned such that a one-to-one correspondence can be made between them.

2. Surface Based Morphometry

Surface based morphometry (SBM) provides the means to characterize and analyze the human brain by explicitly modeling the cortex using a suitable geometric model (Dale et al., 1999). The cortical surface represents the outer layer of the brain modeled as a folded two-dimensional surface in three-dimensional space. T1-weighted structural MRI scans are used to extract the cortical surface by delineating the boundary between the gray and white matter (Dale et al., 1999). This process is referred to as surface reconstruction, and involves a number of reconstruction and segmentation steps aimed at locating the gray/white matter boundary up to submillimeter accuracy (Fischl et al., 1999a). The reconstructed surface is represented as a triangulated mesh and at each vertex different morphological features are estimated to characterize the cortex. It should be noted that the spatial resolution of the reconstructed surface is different from that of the MRI volume.

This section introduces surface based morphometry. We first describe the different features that can be used to characterize the cortex that have been used for detecting FCD lesions. We also provide the related work where machine learning methods have been used in conjunction with SBM to detect FCD lesions.

2.1 Morphological Features

In this work, we use four morphological features to characterize the cortex:

1. *Cortical thickness:* represents the thickness of the cortex which is defined as the distance between the gray/white matter boundary and the outermost surface of the gray matter (pial surface). It is calculated at each vertex using an average of two measurements (Fischl and Dale, 2000): (a) the shortest distance from the white matter surface to the pial surface; and (b) the shortest distance from the pial surface at each point to the white matter surface.

2. *Gray/white-matter contrast (GWC):* represents the degree of blurring at the gray/white-matter boundary. GWC is estimated by calculating the non-normalized T1 image intensity contrast at 0.5mm above and below the gray/white boundary with trilinear

interpolation of the images. The range of GWC values lies in $[-1, 0]$, with values near zero indicating a higher degree of blurring of the gray/white boundary.

3. *Sulcal depth:* characterizes the folded structure of the cortex. It is estimated by calculating the dot product of the movement vectors with the surface normal (Fischl et al., 1999a), and results in the calculation of the depth/height of each point above the average surface. The values of sulcal depth lie in the range $[-2, 2]$ with lower values indicating a location in the sulcus whereas higher values indicate a location on the gyral crown.

4. *Curvature:* Curvature is measured as $\frac{1}{r}$, where r is the radius of an inscribed circle and mean curvature represents the average of two principal curvatures with a unit of 1/mm (Pienaar et al., 2008). Mean curvature quantifies the sharpness of cortical folding at the gyral crown or within the sulcus, and can be used to assess the folding of small secondary and tertiary folds in the cortical surface.

Thesen et al. (2011) nominate cortical thickness along with GWC as the two most informative features for detecting FCD lesions in MRI-positive patients, using a vertex-based detection scheme. Similarly, Hong et al. (2014) identify GWC, cortical thickness and sulcal depth as being more sensitive to detecting FCD lesions in MRI-negative patients. However, they also note that most of the false positives detected using their proposed approach were largely caused by sulcal depth. The technical details of both these works are provided in the next subsection. In this study we use the four features described above, and also analyze different mechanisms to combine their detections in order to achieve higher sensitivity.

After surface reconstruction, different morphological transforms can be applied to register the cortical surface to a standard surface also known as a group-atlas. Registration is achieved by aligning specific sulcal and gyral patterns across the *reconstructed* cortical surfaces allowing for a more precise comparison of individual cortical structures across subjects (Fischl et al., 1999b). SBM has been used successfully for analyzing and detecting neurological abnormalities in various neurological disorders such as Schizophrenia (Rimol et al., 2012), Autism (Nordahl et al., 2007), and Epilepsy (Thesen et al., 2011; Hong et al., 2014).

2.2 Current Methods for Detecting FCD using Surface Based Morphometry

In this section we first define the related work with regards to automated techniques of FCD lesion detection. We then discuss the critical limitations of existing approaches. Most of the techniques reported thus far in literature deal either with MRI-positive patients (Besson et al., 2008; Thesen et al., 2011) or patients who were initially deemed MRI-negative during their preliminary radiological screening, but later their lesions were found to visible on MRI (Hong et al., 2014). As opposed to these studies, we evaluate our proposed methods on a sample of *pure* MRI-negative patients whose lesions are not visible on their MRI.

SBM has been used in conjunction with supervised machine learning techniques to identify lesions in FCD patients. Besson et al. (2008) use texture, GWC and a number of morphological features including cortical thickness to represent each vertex on the reconstructed cortical surface of MRI-positive patients. They then train a neural network to classify each

vertex as being normal or lesional. Hong et al. (2014) developed a two-stage Fisher linear discriminant analysis (LDA) (Bishop, 2006) classifier to detect FCD lesions in patients who were radiologically classified as MRI-negative. Initially they train a vertex-level classifier that classifies each vertex on the reconstructed cortical surface as being lesional or non-lesional for both controls and patients. These detections are further refined using a second LDA classifier that is trained to distinguish between actual FCD lesions (detections made inside the manually traced resection zones of patients) and spurious lesional detections made on controls. The lesions for all the patients included in the study were ultimately found to be visible and were manually traced by an expert using texture-based maps. Thesen et al. (2011) use a semi-supervised uni-variate z-score based thresholding approach on registered SBM data of MRI-positive patients to classify each vertex as being lesional or normal, using cortical thickness, GWC, curvature, sulcal depth and Jacobian-distortion, individually. They nominate cortical thickness along with GWC as being the most informative features for FCD lesion detection in MRI-positive patients.

These studies classify individual vertices of the cortical surface as lesional or normal, using labeled training data from MRI-positive patients and controls. There are four crucial issues that these studies fail to address:

(1) The goal of resective surgery is to remove the entire lesion. If any part of the lesion is left behind, the outcome will not be successful. This introduces label noise, because the expert-marked lesion can contain normal vertices; the margin around the lesion is marked in a "generous" manner so as to increase the chances of capturing the entire lesion. In our previous work (Ahmed et al., 2015) we used a stratified logistic regression classifier to detect lesions in MRI-negative patients. By manually reducing the resection masks for MRI-negative patients to correct for label noise we were able to achieve a detection rate of 58%, as opposed to 12% when the original resection masks were used as the ground truth.

(2) These studies assume that individual vertices are i.i.d., completely ignoring the spatial correlation that exists between neighboring vertices. It has been shown in other domains such as object detection and segmentation in natural images, that modeling spatial correlations leads to superior performance (Reynolds and Murphy, 2007; Plath et al., 2009).

(3) Vertex-based classification methods typically employ a post-processing method to reduce the false positive rate. In this strategy a portion of the vertices labeled lesional by the classifier are re-labeled as normal. This can be done by training a second-level classifier to classify the detected clusters as lesional or non-lesional (Besson et al., 2008; Hong et al., 2014). Similarly, different heuristics can also be used such as the surface area of the detected clusters (Thesen et al., 2011). Discarding any detected region based on its size or surface area can result in discarding the actual lesion or part of the lesion, because FCD can be located in any part of the cortex, is highly variable in size, and may occur in multiple lobes (Blumcke et al., 2011).

(4) Results are evaluated on MRI-positive patients, but the real challenge is to find lesions in MRI-negative patients.

Our proposed method is designed to explicitly address these issues. First, we model lesion detection as an outlier detection problem. The assumption is that a lesional region is an outlier in feature space when compared to the same region across a control population. This view eliminates the use of noisy class labels. Second, instead of classifying individual vertices we classify segmented patches of the cortex. The patches are obtained

using unsupervised segmentation of the flattened cortex that isolates regions of homogeneous feature values. As the size of the FCD lesions has a wide range, using a single scale to isolate the lesion may not be effective. To minimize the chances of missing the lesion, we employ a multiscale strategy where the segmentation is carried out at different scales of varying granularity. The interplay between the patches obtained in this scale hierarchy is modeled as a tree structured HCRF, rooted at the most crude scale and having leaves at the finest scale. We fully exploit the spatial dependencies in the data by classifying image patches rather than by individual vertices, and furthermore larger spatial interactions are accomodated by explicitly modeling the dependencies using HCRF between image patches at different scales. Third, we define a ranking criterion which takes into account both the size and probability of a cortical region (cluster) that is labeled as being lesional. This ranking approach eliminates the need to post process the results, and provides a natural way of presenting the results to a radiologist to function as a focus of attention mechanism. Finally, we evaluate our approach on MRI-negative patients whose resections contained the primary FCD lesion, confirmed by a histological exam on the resected tissue. Since the proposed method is semi-supervised we use the z-score based approach (Thesen et al., 2011) as the baseline from which to contrast the performance of the HCRF method. Furthermore, the patients and healthy controls used in this work were treated and scanned at the NYU Comprehensive Epilepsy Center, where the z-score based method is currently part of the pre-surgical evaluation protocol of epilepsy patients. The next section describes the details of the HCRF construction and inference.

3. Hierarchical Conditional Random Fields

Hierarchical Conditional Random Fields (HCRFs) provide a suitable framework for supervised image segmentation (Reynolds and Murphy, 2007), object detection and semantic image labeling (Plath et al., 2009). In the original HCRF framework proposed for figure-ground segmentation (Reynolds and Murphy, 2007), an image is first segmented into a number of patches at different scales. Each patch is then classified as being part of the background or foreground, using a suitable binary classifier based on image features such as texture, scale-invariant feature transform (SIFT) (Lowe, 1999), etc. Exploiting the fact that the labels assigned to overlapping patches between different scales should agree, an HCRF (a tree-structured conditional random field) is constructed to model these inter-scale interactions. The image is thus modeled as a forest, where the root node for each tree corresponds to a patch obtained at the coarsest scale, while the leaves reside at the finest scale. The joint probability of all the patch labels is estimated by running inference on the HCRFs. The image is segmented by thresholding the final probabilities at the leaves. Plath et al. (2009) extend this framework to work with more than two classes. Mutliclass image labeling using HCRFs is also done in (Awasthi et al., 2007), where instead of obtaining image patches using segmentation, the authors impose a grid structure on the image at different scales and model the HCRF as a quad-tree structure. These multiscale methods are highly sensitive to the accuracy of pixel-level labels. For example in (Reynolds and Murphy, 2007) the bounding boxes around the region of interest (ROI) in training images were manually refined to eliminate extraneous pixels and this resulted in a significant increase in accuracy. In this section we first provide an overview of the different steps involved in the

construction and inference of an HCRF for lesion detection. Subsequent sections provide the necessary technical and processing details involved at each step.

3.1 Adapting HCRFs for Lesion Detection

For FCD lesion detection, we have training data from MRI-negative patients who have undergone surgical resection and are seizure-free. The resected coritcal region, can be used to obtain vertex-level labels which can be used to train a classifier. However, as explained previously these labels tend to be highly noisy and using them to train a classifier will result in noisy predictions (Ahmed et al., 2015). To ameliorate this problem we extend the HCRF framework proposed in (Reynolds and Murphy, 2007) to perform outlier detection on registered image data. In contrast to the approaches mentioned previously, we cannot utilize vertex-level labels. Our proposed method works in a semi-supervised manner, where only global labels are available i.e., whether the cortical surface belongs to a healthy control or a patient. Thus, we define an FCD lesion as a region of the brain which is considered an outlier when compared to the same region across a population of normal controls.

The construction of the HCRF for FCD lesion detection involves the following steps (Ahmed et al., 2014):

1. Segment the cortex at multiple scales, to obtain image patches of varying sizes.
2. Assign an outlier score to each image patch by comparing it to the same cortical region across the control population. This one-to-one comparison is made possible by registering all the control's and patient's cortical surface to the same average surface.
3. Construct multiple HCRFs, one for each image patch obtained at the coarsest scale.
4. Run inference on the HCRFs to calculate the posterior probability at each node. The final lesion is detected by thresholding the posterior at the leaves.

We start by describing our approach to segmentation.

3.2 Segmentation

The functional organization of the cortex is two-dimensional, e.g., the functional mapping of the primary visual areas (Van Essen et al., 1998). Therefore, as an initial simplification we have chosen to work with the flattened cortex because it will simplify the segmentation procedure and will allow us to use already well-established image segmentation techniques. Using SBM, the cortex is modeled as a two-dimensional surface, which on average contains approximately 0.15 million vertices. Even though it is possible to flatten the entire cortex, it's segmentation and subsqeuent inference on the resulting HCRFs would require significant computational resources. Thus, to reduce the processing overload we have chosen to subdivide the lesion detection task into smaller regions of the cortical surface as defined by a standard neuroanatomical atlas, which outlines cortical regions based on their morpho-functional properties (Fischl et al., 2002). These regions are also known as *parcellations*. Instead of segmenting the entire cortical surface at once, we isolate these parcellations one at a time and flatten them individually to obtain a standard two-dimensional image, which we then segment at multiple scales. Any morphological feature (e.g., cortical thickness,

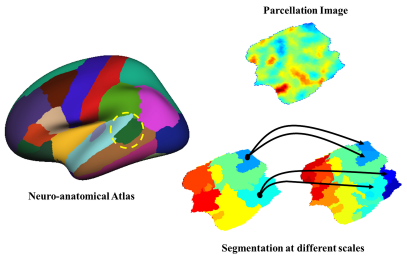

Figure 1: Constructing an HCRF using a standard neuroanatomical atlas (*left*), and a parcellation image (*top-right*). Any morphological feature can be used to represent the image (the image is created using cortical thickness). At the bottom we have image patches obtained at two different scales using Quickshift. Each image patch on the coarser scale (*bottom-left*) becomes a root having children at the adjacent finer scale (*bottom-right*).

curvature, etc.), can be used to represent the intensity values in the resulting image. Figure 1 illustrates the overall HCRF construction process for a parcellation.

We use quick shift (Vedaldi and Soatto, 2008b) for unsupervised segmentation. One of the main advantages of using quick shift is that the number and size of segments need not be specified. Additionally, quick shift does not penalize for boundary regions, and produces a diverse set of segments having different shapes and sizes. It should be noted that any segmentation method can be used, as long as it has the ability to segment the image at different scales.

The standard quick shift algorithm is a fast mode seeking algorithm similar to mean shift (Comaniciu and Meer, 2002). It performs a hierarchical segmentation of the image, where the sub-trees represent image segments. It has two parameters namely the size of the Gaussian kernel (σ) used by a Parzen window density estimator, and the maximum distance (Δ) between two pixels permitted while remaining part of the same segment. We vary the scale parameter σ to change the average size of segments, and set Δ to be a multiple of σ (Vedaldi and Fulkerson, 2008a). Thus, higher values of σ produce larger segments. By using different combinations of these parameters, we construct the scale-hierarchy which is the basic building block of the HCRF, as explained next.

3.3 Multiscale HCRFs

Once the multiscale segmentation is complete for a particular subject, we obtain a set of patches at different scales. Let I_p^k be the p^{th} patch obtained at the k^{th} scale. We can collect the corresponding patches from all controls and then estimate a label $y \in \{0,1\}$ for I_p^k, where $y = 1$ indicates that I_p^k is an outlier. This label cannot be considered independent from the labels of other patches that overlap with I_p^k at other scales.

We model the joint prediction of these mutually dependent labels of all the patches using a tree structured HCRF. Let I_p^{k+1} be an image patch at level $k+1$, it has a parent I_q^k at the immediately coarser level k, such that I_q^k has maximal overlap with I_p^{k+1} (Reynolds and Murphy, 2007). We find the index q as follows:

$$q := \arg\max_q \frac{|I_p^{k+1} \cap I_q^k|}{|I_q^k|} \tag{1}$$

Each patch at the coarsest scale is the root of a tree having leaves at the finest scale. Therefore, the parcellation image is represented by a forest, where each tree is modeled as an HCRF, as shown in Figure 1.

CRFs model the joint conditional probability distribution of all the patch labels $y = (y_1, \ldots, y_n)$ in the tree based on the values of the input morphological feature (x). Generally, this can be written as:

$$p(y|x,\theta) = \frac{1}{Z(x,\theta)} \prod_i \phi(y_i|x,\theta) \prod_{i,\pi(i)} \psi(y_i, y_{\pi(i)}) \tag{2}$$

where, $\pi(.)$ represents the parent patch, and $Z(x,\theta)$ is the normalization constant also called the partition function. $\phi(.)$ is called the node potential and represents the local evidence for the label y_i based on the observed data x. The edge potentials that model the coupling between adjacent labels are represented by $\psi(.)$. As the graph is a tree we can efficiently calculate $Z(x,\theta)$ and the posterior probabilities of the patch labels at all scales using standard belief propagation (Pearl, 1988).

When labeled training data is available the node and edge potentials are parameterized, and the parameters are learned jointly (see (Sutton and McCallum, 2010) for details). For our application, because the labels are noisy and we have chosen to work in an unsupervised manner, we set the node and edge potentials separately, which we describe next. Similar strategies for parameter estimation in HCRFs have been used for figure-ground segmentation (Reynolds and Murphy, 2007) and for object detection (Plath et al., 2009) in natural images.

3.3.1 Node Potentials

The node potential is modeled to reflect our belief about the abnormality of an individual image patch. Most of the available outlier detection mechanisms produce outlier scores that are poorly calibrated i.e., the range of the outlier score is dependant on the dataset (Schubert et al., 2012). This makes it difficult to compare the outlier scores between datasets produced by the same method. Popular outlier detection methods such as local outlier factor (LOF) (Breunig et al., 2000) and local correlation integral (LOCI) (Papadimitriou et al., 2003) suffer from the same problem. In our case we would like to work with an outlier detection method that produces standardized scores that carry the same semantics at each scale and can be compared between different scales. This is an important design choice because running inference on non-standardized scores, which are not comparable between different scales, will produce meaningless results. To overcome this, we have chosen to work with local outlier probabilities (LoOP) (Kriegel et al., 2009), a standardized version of LOF that

produces standardized scores within the range $[0, 1]$ which can be treated as the probability that a data point is an outlier.

LoOP assumes that each data instance x has a context set $S \subseteq D$, and the set of distances between x and $s \in S$ has a Gaussian distribution (Kriegel et al., 2009). The standard deviation of these distances $\sigma(x, S)$ combined with a significance factor λ produces the *probabilistic set distance of x to S* (Kriegel et al., 2009) defined as:

$$pdist(\lambda, x, S) := \lambda \cdot \sigma(x, S) \tag{3}$$

where S is determined using a k-nearest neighbor query. The parameter λ defines the sensitivity of the final probability estimates. It denotes that any instance that deviates more than λ times the standard deviation would be considered an outlier. Its values are analogous to the empirical confidence levels defined for the standard normal distribution (Kriegel et al., 2009). The probabilistic local outlier factor for x can then be calculated in a manner similar to LOF:

$$PLOF_{\lambda,S}(x) := \frac{pdist(\lambda, x, S)}{E_{s \in S}[pdist(\lambda, s, S(s))]} - 1 \tag{4}$$

PLOF values of greater than zero indicate that the given instance may be an outlier. In order to convert a PLOF value into a probability estimate it can be assumed that they are distributed around 0 with a standard deviation calculated as $\sqrt{E[(PLOF)^2]}$. The final probability can then be calculated as:

$$LoOP_S(x) := \max\left\{0, \mathrm{erf}\left(\frac{PLOF_{\lambda,S}(x)}{\lambda\sqrt{2E[(PLOF)^2]}}\right)\right\} \tag{5}$$

where, erf(.) is the Gauss error function (Andrews, 1992).

3.3.2 Edge Potentials

Each edge in the HCRF represents the dependency between the "parent" image patch at scale t and the "child" patch at scale $t + 1$. We set the edge potential to reflect the visual similarity between the two patches, using the chi-squared distance between the histograms of scale invariant feature transform (SIFT) features (Lowe, 1999) of the parent and child patches. Thus, the labels of image patches that bear close visual similarity to each other in the scale hierarchy are more strongly coupled than those with lower similarity. This heuristic is similar to one chosen by Reynolds and Murphy (2007).

To estimate the histograms of the SIFT features for each image, we initially learn a codebook of m codewords using the control data. For each control image in the subset we flatten and isolate the parcellation, and then calculate a SIFT feature vector at each pixel. These vectors are then clustered into m clusters using *k-means* clustering. Each feature has its own range of values and defines separate morphological properties of the cortex (see Section 2.1), we learn a separate codebook for each parcellation/feature combination. The edge potential between two adjacent nodes in the tree is then calculated as (Reynolds and Murphy, 2007; Plath et al., 2009):

$$\psi(y_i, y_j) = \begin{bmatrix} e^{\gamma.\eta_{ij}} & e^{-\gamma.\eta_{ij}} \\ e^{-\gamma.\eta_{ij}} & e^{\gamma.\eta_{ij}} \end{bmatrix} \tag{6}$$

where, γ is a free parameter that represents the strength of coupling between adjacent levels in the CRF and $\eta_{ij} = e^{-\chi^2(x_i, x_j)}$. x_l represents the normalized histogram of SIFT features for the l^{th} patch in the HCRF, and $\chi^2(.,.)$ is the chi-squared distance between two normalized histograms each having n bins and defined as:

$$\chi^2(P, Q) = \frac{1}{2} \cdot \sum_{i=1}^{n} \frac{(P_i - Q_i)^2}{(P_i + Q_i)} \tag{7}$$

where, P and Q are normalized histograms.

3.4 Lesion Detection

For each subject, we calculate the posterior probabilities at each node of the HCRF for every parcellation by running belief propagation (Pearl, 1988). The final detection is obtained by thresholding the posterior beliefs at the leaves of each HCRF (Reynolds and Murphy, 2007; Plath et al., 2009). Different strategies for thresholding can be used, such as defining a single threshold across all subjects, or calculating a threshold for each subject individually. In this work we calculate an adaptive threshold for each patient separately. This decision is based on the observations that 1) FCD lesions can manifest differently for different individuals, and 2) the morphological features vary with different demographic factors such as gender and age. For example cortical thickness is correlated with the age of the patient (Salat et al., 2004). To this end, we sort the posterior probabilities and define the threshold as the lowest probability among the top K probability estimates. In practice the value of K can be left as a free parameter that the user can vary to see the different regions which are deemed lesional with varying levels of confidence. Thus, the radiologist has a knob to turn which shows more/fewer possible candidate lesions. This is a desirable feature, because the detection scheme presented here is designed to be a part of the comprehensive pre-surgical evaluation protocol that includes MRI, Positron Emission Tomography (PET), scalp EEG and iEEG. The final resection target is determined by combining evidence from all evaluations. Therefore, the ability to generate multiple cortical maps delineating possible lesions at different confidence levels provides a richer set of evidence which in turn increases the probability of capturing the actual lesion.

4. Empirical Evaluation

Our data consists of MRI-negative patients who have undergone resective surgery and for whom their resected tissue was histologically verified to contain FCD. Each patient who undergoes surgery is assigned an "Engel" class. An Engel class of 1 represents complete seizure freedom while an Engel class of 4 represents no improvement. We selected only patients with an Engel class outcome of 1 for our experiments in order to verify that the region resected was indeed the primary lesion and that no additional epileptogenic lesions were present in other parts of the brain. This resulted in a dataset with twenty MRI-negative patients, whose information is provided in Table-1. This may appear to be a small dataset, but few patients proceed to surgery when no visible lesion is found on their MRI, and of those that do, less than a third experience complete seizure freedom (Bell et al., 2009). These twenty patients represent *all* MRI-negative patients who underwent surgery

at New York University comprehensive epilepsy treatment center during the past three years, and were classified post-surgically as Engel class 1. Developing automated lesion mechanisms for MRI-negative patients is an active area of research and our sample size is consistent with the existing work in the domain (Besson et al. (2008); Thesen et al. (2011); Hong et al. (2014)). However, in contrast to our evaluation, most of these studies evaluate their proposed detection schemes on MRI-positive patients i.e., patients whose lesion was visible on the MRI during the initial evaluation or was found visually at a later stage. It is important to note that our sample consists of "pure" MRI-Negative patients, and therefore our results target that patient population where there is an actual need of an automated lesion detection scheme and where such a scheme can have a positive impact impact on the outcome of resective surgery.

4.1 Imaging

Imaging for both the subjects and the controls was performed on a Siemens Allegra 3T scanner. Image acquisitions included a conventional 3-plane localizer and a T1-weighted volume pulse sequence (TE=3.25 ms, TR =2530 ms, TI =1100 ms, flip angle =7 deg field of view (FOV) = 256 mm, matrix = 256×256, vertex size =$1 \times 1 \times 1.3$ mm, scan time: 8:07 min). Acquisition parameters were optimized for increased gray/white matter image

contrast. The T1-weighted image was re-oriented into a common space, roughly similar to alignment based on the AC-PC line. Images were corrected for nonlinear warping caused by no-uniform fields created by the gradient coils. In this study we have a total of 115 controls, 55 males (33.7 ± 12.5 years) and 60 females (32.0 ± 11.5 years). It should be noted that all the patients were scanned on the same scanner, and the data used here is based on these research scans, which is different from their original clinical scans, as most of them were referred from external epilepsy centers.

Resection Tracing: For all patients, the post-operative T1-weighted image (with the resection area removed) was rigid-body coregistered to the (intact) pre-operative T1-weighted image. The brain resection area was manually traced on the post-surgical MRI scan by a trained technician blinded to patient diagnosis and reviewed by a board-certified neurologist. The manual masks in the MRI volume were subsequently projected onto the cortical surface by assigning each MRI voxel to the nearest surface vertex. Because the surface has sub-voxel resolution, a morphological closing operation was used to fill in any unlabeled vertices.

4.2 Data Pre-processing and Parameter Selection

After the surface has been reconstructed using the freesurfer software[3] we used the Desikan-Killiany atlas (Desikan et al., 2006) to isolate the different parcellations. It should be noted that any suitable neuroanatomical atlas can be used to subdivide the cortical surface. Each parcellation is flattened to obtain a standard 2-d image, where the intensity of each pixel can be represented by any one of the four morphological features.

The values of the different parameters such as the segmentation scales, number of nearest neighbors in calculating the outlier probabilities, etc., depend on various factors, such as the size of the control population, the distribution of ages across the control cohort and the gender of the subject. We therefore present these parameters as actual free parameters that can be varied over a pre-set range of values to get different detection results. Whether an image patch is an outlier depends on the set of controls used to learn the "normal" model. Most morphological features vary with different demographic factors such as age, gender, handedness, etc. Ideally, we could choose a customized set of controls for each patient, but currently we do not have enough controls to customize for age and other factors, but we do select controls based on the patient's gender.

To select the parameters for the various aspects of our method, we used a validation set consisting of two MRI-positive and two MRI-negative patients, which are distinct from the patients used to evaluate our method. We used all 115 controls to learn a separate codebook of SIFT features for every parcellation/feature combination. Dense SIFT features were calculated at each pixel. We tested vocabulary sizes of 50, 100 and 500 and selected a vocabulary size of 50 as it resulted in higher recall and precision on the validation set. This codebook was used subsequently to estimate the histograms of SIFT features at each pixel location for all patient parcellation images in the test set.

Each parcellation image was segmented at three different scales using quick shift. We used $\sigma = \{2, 3, 4\}$ and Δ was set to 5σ. These values were chosen such that the smallest lesion in our validation set is over-segmented i.e., there are multiple segments that contain

3. Available at http://surfer.nmr.mgh.harvard.edu/

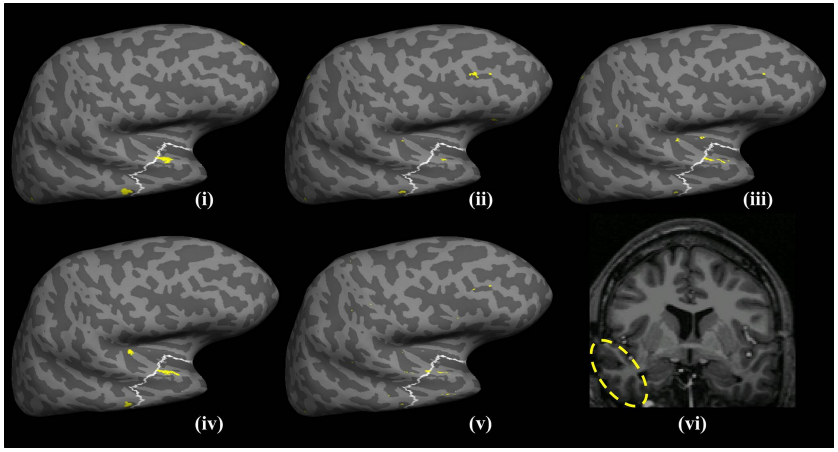

Figure 2: Detection results for NY67 using cortical thickness shown on an inflated model of the lateral cortical surface. The resected region is delineated as the white circled region and the detection results are shown as filled yellow regions. It can be seen that the lesion is detected at individual scales (i) and (iii) prior to combining the outlier probabilities using HCRF. However, at the second scale (ii) a large cluster is detected outside the resection. When these findings are combined using the HCRF as shown in (iv) the largest detected cluser is within the resection zone while the false detection in (ii) is suppressed. (v) shows the detection made by the the z-score based approach. The results are shown for the most stringent (first) threshold without any post-processing. (vi) shows the lesion highlighted on a T1 MRI slice.

the lesional area. This increases the probability that a patch can be entirely formed from lesional vertices, rather than having patches that partially overlap with the lesion, which would be harder to detect as outliers. Based on these settings, the validation set resulted an average of 4255 ± 107 HCRF models per patient, with 19292 ± 373 leaves at the finest scale using cortical thickness. Although the size of the validation set seems small as far as the number of patients are concerned, we conjecture that the resulting number of HCRF models and number of instances are adequate for setting the model parameters.

Finally, before performing outlier detection, we apply a standard dimension reduction technique on each patch using principal component analysis (PCA). Note that the PCA is done using only the control data. We retained the top m principal components that accounted for 95% of the variance in data. Based on results for the validation set (carried out independently for each feature), the parameters for outlier detection were set to $k = 10$ in LoOP and γ (c.f. equation (6)) was set to 50.

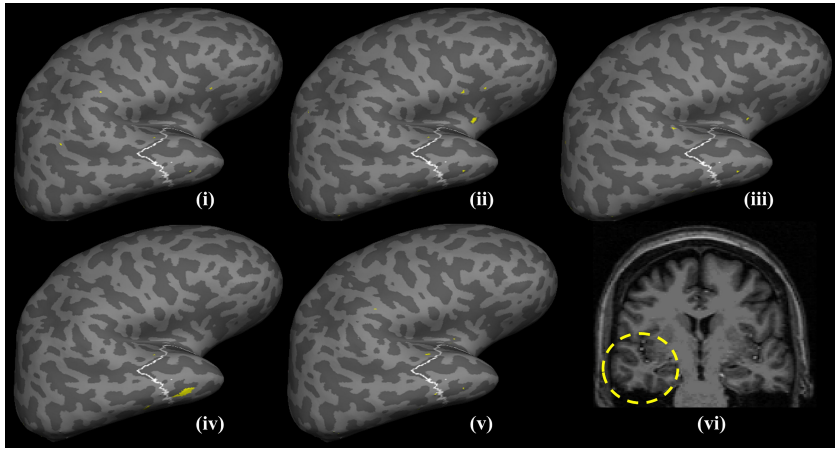

Figure 3: Detection results for NY294 based on curvature. The white outlined area represents the region that was resected, while the filled yellow patches represent the detected clusters at the first detection threshold for both the HCRF and the z-score based method. The detected clusters at the individual scales are shown in (i)-(iii). It can be seen that very small (almost negligible) clusters are detected that overlap with the resected region. However, after running belief propagation (iv) a large cluster is detected within the resection zone while the outliers are eliminated. (v) shows the results for z-score based method while (vi) shows the lesion highlighted on a T1 MRI slice.

4.3 Evaluation Methodology

The final detection for each subject is determined by thresholding the posterior probabilities at the leaves of the CRF, which represent the segments obtained at the finest scale. We determine the detection thresholds by dividing the last percentile of the final outlier probabilities into ten equal parts. The first threshold corresponds to the lowest probability in the highest 0.1% scores and so on. For the results presented in this section we determine five such thresholds to get five different possible detections. Because, this is an adaptive mechanism, it has a possible drawback that it always detects something even when the probabilities are very small. Thus we set 1×10^{-4} as the minimum probability, such that no threshold is calculated below this value. This limiting value was selected based on the observation that any threshold calculated below this value resulted in more than 80% of the cortex being labeled as lesional for the patients in the validation set.

We have chosen to evaluate and contrast the performance of the detection techniques in an information retrieval framework. We first calculate the clusters by thresholding the posterior probability at a given threshold. All the detected clusters are then ranked based

on the following score function:

$$score(c\,;\alpha) = \alpha s(c) + (1-\alpha)o(c) \;\; ; \;\; 0 \leq \alpha \leq 1 \tag{8}$$

where c is a cluster detected at a pre-defined threshold, $s(.) \in [0,1]$ is the relative surface area of the cluster calculated as the ratio between the surface area of c and the total surface area labeled as lesional. $o(.) \in [0,1]$ is a scoring function that represents the degree of "outlier-ness" of the cluster. For the HCRF, we model $o(.)$ as the average of the outlier probabilities calculated at each vertex that is part of the cluster. α is a tradeoff parameter such that $\alpha = 1$ defines a ranking that is based solely on cluster-size, while $\alpha = 0$ ranks the clusters based only on their average probability of being lesional. Intermediate values of α define a ranking in which a smaller cluster detected at a stringent threshold is ranked higher than a larger cluster detected at a more lenient threshold and vice versa. In the ideal case clusters having a higher rank should be within the lesion/resection zone of the patient.

We compare the results of our proposed technique against a recently reported univariate technique (Thesen et al., 2011) to detect FCD lesions using SBM. In this baseline approach all control and subject surfaces are registered to the average surface. After registration, it calculates the z-scores at each vertex for the subjects, which are then thresholded to obtain the detection results. We calculate the z-score based on gender matched controls instead of using all the controls. To facilitate comparison we calculate multiple thresholds in the exact same manner as outlined above for HCRF, and rank the clusters at each threshold based on Equation 8. We omit the last step of the baseline method, which post processes the detections to eliminate "small" clusters (Thesen et al., 2011). We have chosen this technique as the baseline method because, i) it is a semi-supervised approach and does not require accurate vertex-level labels, and ii) it has been part of the pre-surgical evaluation at the NYU comprehensive epilepsy treatment center where the patients included in our evaluation were treated. We use the following measures to evaluate our proposed method.

4.3.1 Detection Rate

Detection rate is defined as the number of patients for whom one or more detected clusters overlap with the resected area. Usually a post-processing step is applied to the raw detections before estimating the detection rate. Hong et al. (2014) train a classifier to distinguish between clusters detected in the resection/lesional area and the extra-lesional clusters using the training data, this classifier is then applied to the clusters detected on the test subject before estimating the detection rate. Similarly, in Thesen et al. (2011) all clusters below a pre-set size threshold are discarded, and a successful detection results if one or more of the remaining cluster overlap with the lesional area. Discarding any detected cluster based on its size increases the risk of discarding subtle lesions. Instead of discarding detected clusters, we use cluster ranking to estimate the detection rate. To this end, we calculate five thresholds based on the outlier probabilities for the HRCF method, and similarly for the z-score method. After ranking the detected clusters based on (Equation 8), at each threshold we consider a subject to be correctly detected if a cluster amongst the top n (where n is relatively small as compared to the total number of detected clusters) completely or partially overlaps with the lesion/resection. This produces more conservative estimates of the detection rate as compared to approaches that do not use cluster ranking.

4.3.2 Precision and Recall

In order to compare the quality of detections, we calculated the precision and recall for both HCRF and the z-score based method. To this end, we consider all detected clusters at each threshold. We define recall as the ratio of the total surface area of all the clusters that overlap with the resection zone to the surface area of the resection zone. Similarly, we define precision as the ratio of the surface areas of clusters overlapping with the resection zone to the sum of the surface area of all the detected clusters.

Accurately calculating the false postive rate for the proposed detection scheme is challenging for several reasons. A patient can have abnormalities outside the lesion/resection zone which may not be epileptogenic. For example, abnormal cortical thinning remote from the epileptogenic onset region has been observed in focal epilepsy (McDonald et al., 2008; Lin et al., 2007) and attributed to the destructive impact of chronic seizures on brain structure rather than from malformations during cortical development. This might result in elevated extra-lesional false positives when detecting structural malformations characterized by abnormal cortical thickness. In our previous work (Ahmed et al. (2014)) we compared our detections on MRI-positive patients with an expert neuroradiologist. In 50% of the cases, the expert identified abnormal regions that coincided with detections outside the resection that were classified as false positives by our evaluation methodology that used the resection zone as the ground truth. This problem becomes more challenging for MRI-negative patients whose structural abnormalities are not visible on their MRI. In order to circumvent the presence of false negatives in our labeled data that would result in elevated estimates of the false positive rate, we use precision to evaluate the efficacy of our proposed scheme. Furthermore, based on the existence of structural abnormalities outside the resection zone (*false negatives*) the precision estimates provided here should be treated as lower bounds.

4.4 Results

In our experiments we first evaluate the HCRF framework independently for each of the four morphological features: cortical thickness, gray/white-matter contrast, curvature and sulcal depth. In the next set of experiments we analyze different mechanisms of combining the detections from individual features. Recall, that the ranking function (Equation 8) has a direct impact on the detection rate and by setting the tradeoff parameter we can assign more weight to either cluster size or the average cluster outlier probability. To facilitate comparison between the proposed method and the baseline we initially set the tradeoff parameter α to 1, so that all clusters are ranked based only on their surface area.

Figure 4(a) shows the comparison of the detection rates for MRI-negative patients when cortical thickness is used to represent the cortex. HCRF performs better than the z-score baseline across all the five thresholds, for the top five detections. HCRF detects the lesion in 14 (70%) patients, while the baseline detects only 11 (55%) subjects when considering the top ten largest clusters. HCRF is also able to achieve higher recall and precision as shown in Figures 4(b)-4(c). The difference between the recall values of the proposed method (1.1140 ± 0.5654) and the baseline (0.8035 ± 0.4745) was significant at $t(9) = 7.9927,\ p < 0.001$. Similarly, the differences in precision for HCRF (10.4710 ± 1.0248) and the baseline (9.0608 ± 0.5577) were found to be significant at $t(9) = 6.1161,\ p < 0.001$ using a paired

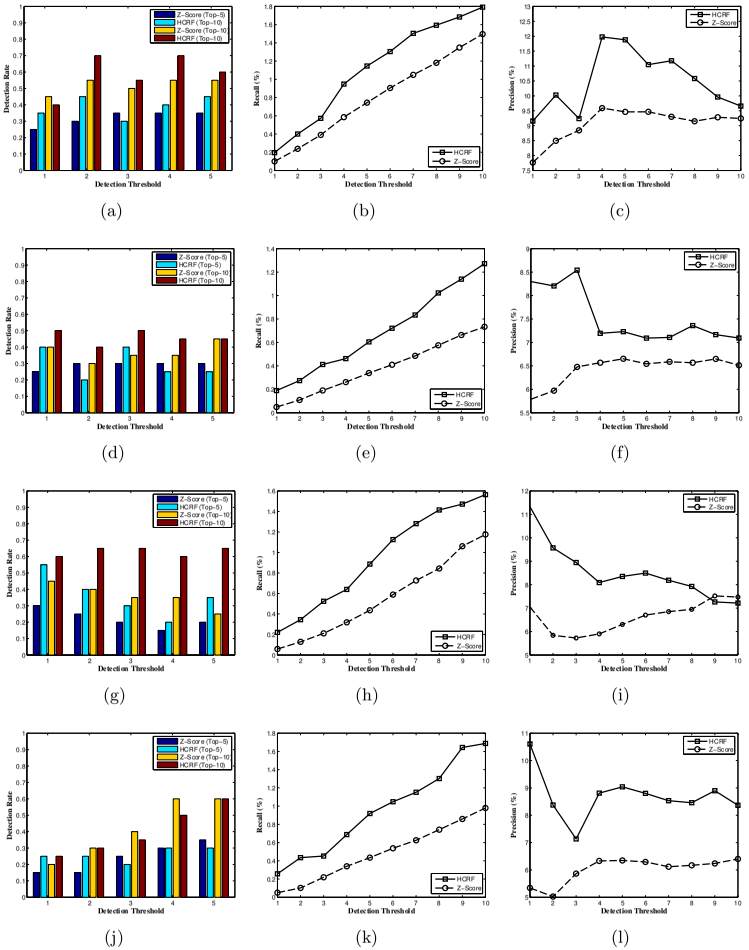

Figure 4: Comparison of detection rates, precision and recall between then HCRF based approach and the baseline method using thickness (a)-(c), GWC (d)-(f), curvature (g)-(i) and sulcal depth (j)-(l). Here, $\alpha = 1$ so that larger clusters are ranked higher (refer to Equation 8).

t-test. Figure-2 provides an example of the detected clusters using HCRF and the baseline for a patient.

Using GWC, HCRF is able to detect abnormal clusters within the resection zones of ten (50%) patients as opposed to the baseline that detects only nine (45%), as shown in Figure 4(d). Figure 4(e) shows the recall for HCRF method (0.6931 ± 0.3702) that is significantly higher ($t(9) = 7.1317,\ p < 0.001$) than the recall of the baseline method (0.3815 ± 0.2334). Figure 4(f) compares the precision of the HCRF and baseline using GWC. The differences in the precision values for HCRF (7.5286 ± 0.5769) and the baseline (6.4313 ± 0.2987) were found to be significant at $t(9) = 4.2350, p = 0.0022$ using a paired t-test. Although, using GWC HCRF is able to outperform the baseline, the resulting detection rate is worse than HCRF with cortical thickness.

Figure 4(g) shows the comparison of the detection rates using curvature to represent the cortex. HCRF dominates the z-score baseline across all the five thresholds, for both top five and top ten detections. HCRF detects abnormal clusters within the resection zones of 13 (65%) patients, while the baseline detects only 9 (45%) subjects when the top ten largest clusters are considered. Figures 4(h)-4(i) show that HCRF is able to achieve higher recall and precision, respectively. The difference between the recall values of the proposed method (0.9473 ± 0.4927) and the baseline (0.5549 ± 0.3903) was significant at $t(9) = 8.825,\ p < 0.001$. Similarly, the differences in precision for HCRF (8.5373 ± 1.2063) and the baseline (6.6313 ± 0.6597) were found to be significant at $t(9) = 3.9135,\ p < 0.0035$ using a paired t-test. Figure 3 shows the resulting detections from both the HCRF and the baseline when curvature is used to characterize the cortex for an MRI-negative patient.

When sulcal depth is used to represent the cortex, both the HCRF and the baseline method achieve the same detection rate. Both approaches are able to detect abnormal clusters that overlap with the resections of 12 (60%) patients (Figure 4(j)). However, as Figures 4(k)-4(l) show, HCRF is able to achieve higher recall and precision values. The difference between the recall values for HCRF (0.9585 ± 0.5013) and the baseline (0.4891 ± 0.3165) was significant at $t(9) = 7.7730,\ p < 0.001$. Similarly, the differences in precision for HCRF (8.7008 ± 0.8541) and the baseline (6.0124 ± 0.4679) were found to be significant at $t(9) = 8.0983,\ p < 0.001$ using a paired t-test.

Using individual features, HCRF is able to achieve a maximum detection rate of 70% while the baseline has a maximum detection rate of 60%, when top ten largest clusters are considered. For the baseline sulcal depth and cortical thickness achieve higher detection rates as compared to GWC and curvature. Cortical thickness outperforms all other features based on its average precision and recall. For the HCRF method sulcal-depth and curvature achieve identical performance with GWC ranking the lowest.

An important consideration is the degree of consensus between the individual features with respect to the detected patients. If there is some degree of disagreement between the features, then combining their detection can potentially increase the overall detection rate. Considering top ten largest clusters, two patients were not detected by any of the four features. Both cortical thickness and curvature detect a combined total of 16 patients, differing on one patient each. On the other hand all except a single patient detected by GWC and sulcal depth were also detected by either thickness or curvature. Based on these results if we combine the output probabilities of all four features, and then use the same thresholding and ranking technique we should be able to achieve a detection rate that is higher than the detection rate of the individual features. We investigate the combination of all four features in the next section.

4.5 Combining Features

In this section we explore the question of whether the HCRF based method will achieve a higher detection rate if the detections of the individual features are combined. As a first strategy, we can simply aggregate the posterior probabilities as obtained by the application of HCRF to each individual feature. Because every feature defines its own segmentation of a given parcellation image, it is not possible to directly aggregate the probabilities obtained at the leaves of the HCRF. To solve this issue we map the posterior probabilities obtained at the leaves of the HCRF, back to the cortical surface for each feature and then define a combination rule at every vertex. We use two basic aggregation rules, in the first we average the probabilities across the four features, and in the second each vertex is assigned a probability that is calculated as the maximum of the four individual probabilities. Similarly, for comparison to the baseline method we use the same techniques to calculate a single z-score estimate at each vertex for the baseline.

Aggregation based on averaging is similar to majority vote rule. In this strategy, vertices for whom most of the features have a high probability of being abnormal will be considered abnormal in the final detection. This has the effect of lowering estimation errors leading to a lower false positive rate by smoothing the outlier probabilities at each vertex. The second strategy that uses the maximum across the probabilities would label a vertex as lesional even if one of the features assigns it a higher outlier probability. This would lead to a higher detection rate along with a high number of false positives.

4.5.1 Performance Comparison to Baseline

Figure 5 shows the results of applying the two aggregation strategies in conjunction with the HCRF and baseline methods. In particular, Figure-5(a) shows the detection rates when the probabilities are averaged across features. It can be seen that the baseline performs better than the HCRF at the early thresholds, however the HCRF is able to produce better results as the threshold becomes more lenient. Considering the top ten largest clusters, HCRF is able to achieve a detection rate of 60% which is slightly higher than the baseline that achieves a detection rate of 55%. The recall and precision for the HCRF method are significantly higher than the baseline as shown in Figures 5(b)-5(c). Using a paired t-test, the difference in the recall values of the HCRF (1.0206 ± 0.5797) and the baseline (0.7046 ± 0.4410) was significant at $t(9) = 7.1317,\ p < 0.001$, and the difference in the precision values of the HCRF (9.2946 ± 0.9708) and the baseline (8.1422 ± 0.5595) was significant at $t(9) = 4.2350, p = 0.0022$.

When the posterior probability at each vertex is calculated as the maximum across the four features, HCRF achieves higher detection rates as shown in Figure 5(d). HCRF detects abnormal clusters within the resection zones of 13 (65%) patients, while the baseline detects only 10 (50%) subjects when top ten largest clusters are considered. HCRF achieves higher recall ($t(9) = 8.825,\ p < 0.001$) and precision ($t(9) = 3.9135,\ p < 0.0035$), as shown in Figures 5(e)-5(f), respectively.

4.5.2 Performance Comparison to Individual Features

A comparison of the detection rate of both aggregation strategies with the detection rates of the individual features is shown in Figure 5(g). We can see that both perform worse than

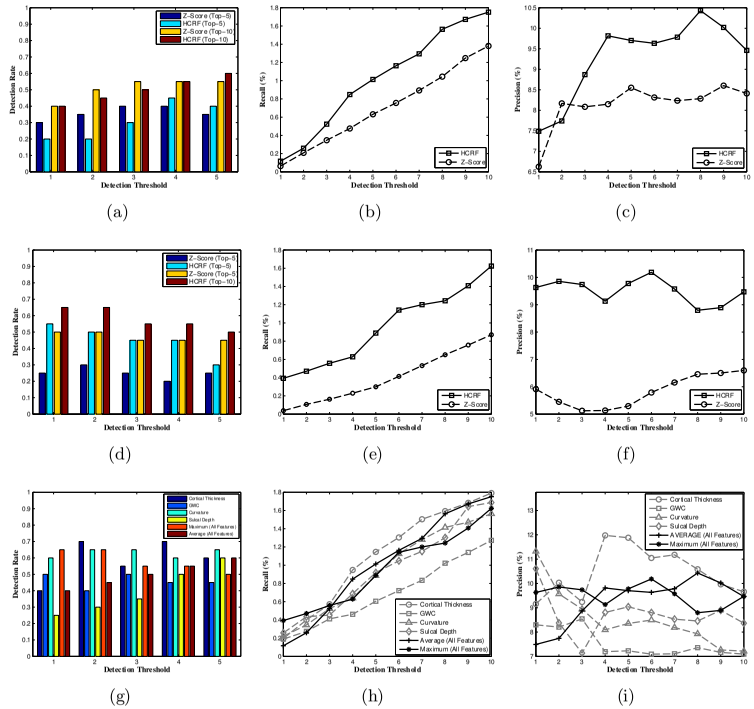

Figure 5: Comparison of detection rates, precision and recall between then HCRF based approach and the z-score based baseline method when the detection scores are averaged across features (a)-(c), and when the final output score is computed as the maximum across features (d)-(f). (g) contrasts the detection rate of both aggregation strategies with that of the individual features when the top ten largest clusters are considered and (h)-(i) provide the same comparison for recall and precision. Note that $\alpha = 1$ such that larger clusters are ranked higher (refer to Equation 8).

cortical thickness, and achieve a maximum detection rate of 65% when the top ten largest clusters are considered. The same detection rate is also achieved by curvature. Similarly, based on recall and precision values we can see that both the combination strategies fail to outperform any of the individual features with the exception of GWC.

Both the averaging and maximum strategies achieved lower recall and precision than cortical thickness (Figures 5(h) and 5(i), respectively). In addition to cortical thickness, the maximum strategy achieved lower average recall than both curvature and sulcal-depth. On

the other hand, for the averaging technique the differences in recall and precision were not significant when compared to curvature and sulcal depth. For the sake of brevity we omit the results of the paired t-tests that were used to establish these pairwise comparisons.

One reason for the failure of the combined strategies is that each feature has its own idiosyncrasies, which when not accounted for will introduce noise in the ranking/detection process. As an example, consider sulcal depth and curvature. Both features when used within the HCRF framework, achieve similar precision and recall but different detection rates. This shows that although, sulcal depth detects clusters within the resection zones of patients, it detects larger clusters outside the resection zone. If the detections of sulcal depth and curvature are combined then the noisy clusters detected by sulcal depth will cause a drop in the overall detection rate. There are two possible solutions: 1) select only informative features and discard the ones that are noisy, and 2) tune the tradeoff parameter (α) in the ranking function (Equation 8) such that the ranks of smaller clusters that are highly abnormal remain resilient to the presence of larger noisy clusters. It should be noted that changing the ranking function will have no effect on the overall precision and recall, because cluster ranks only influence the detection rate.

To explore option 1, feature selection, we selected cortical thickness and curvature because of their higher detection rates, precision and recall. We employ the same aggregation strategies as before, namely averaging and maximum. In Figure 6 we observe that when using only thickness and curvature, both the averaging and maximum strategies produce higher detection rates, precision and recall than the baseline (Figures 6(a)-6(f)).

More interestingly, when compared to individual features, the combination of curvature and cortical thickness is able to achieve significantly higher precision and recall, with the exception of cortical thickness (the average precision and recall is higher but the differences are not statistically significant), as shown in Figures 6(h)-6(i), respectively. However, as Figure 6(g) shows the detection rate although higher than when all four features are aggregated does not exceed that achieved by thickness alone. However these results confirm that when clusters are ranked based only on their size, both GWC and sulcal depth produce noisy detections, that can lower overall detection rate. Our finding that sulcal depth produces noisy or large extra-lesional clusters is also corroborated by Hong et al. (2014).

Next, we explore the effects of tuning the size/probability tradeoff parameter α, on the detection rate of both individual and combined strategies.

4.5.3 Ranking Criterion and the Detection Rate

Thus far we have fixed the ranking criterion to be the size of the detected cluster. However, as defined in Equation 8, we can tune the tradeoff parameter such that the cluster ranking criterion pays attention to both the size and the average outlier probability of the cluster. To ascertain how α influences the performance of HCRF framework, we varied α over its entire range of values and determined the detection rate for individual features, the combination of all features, and the combination of the top two features.

For a given input feature (or a combination of features) we divided the range of $\alpha \in [0, 1]$ uniformly into twenty 21 points. At each resulting value of α we re-estimated the ranking of the clusters. The detection rate corresponding to each value of α was determined by taking the maximum number of patients detected using the top ten ranked clusters, across

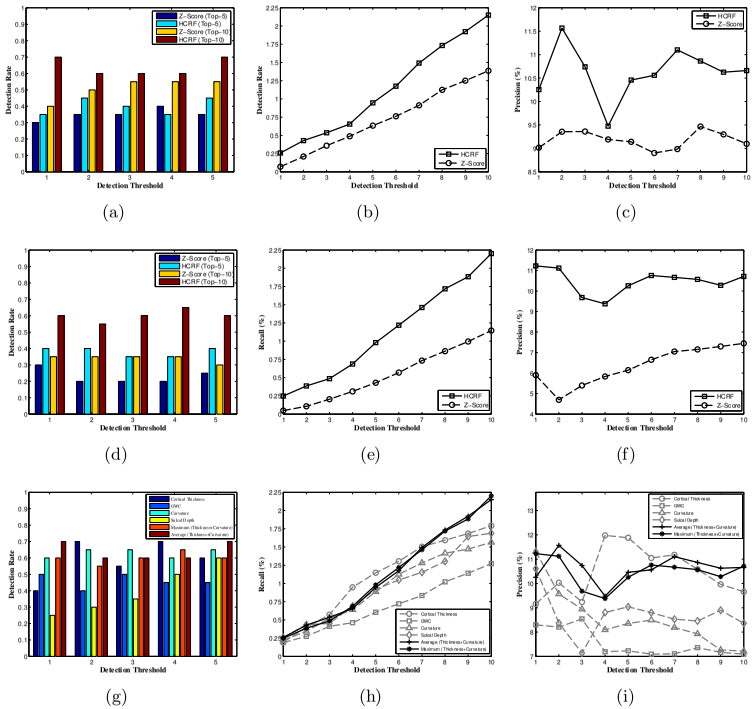

Figure 6: Comparison of detection rates, precision and recall between then HCRF based approach and the z-score based baseline method when the detection scores are averaged across thickness and curvature (a)-(c), and when the final output score is computed as the maximum between the two features (d)-(f). (g) contrasts the detection rate of both averaging and maximum with that of the individual features when the top ten largest clusters are considered and (h)-(i) compare the recall and precision. Note that, $\alpha = 1$ so that larger clusters are ranked higher (refer to Equation 8).

the first five thresholds. Figure 7(a) shows the detection rates of each individual feature for different values of α. Both cortical thickness and sulcal depth achieve their maximum detection rates when $\alpha = 1$, while curvature does so for intermediate values of $\alpha = 50,\ 75$. On the other hand the detection rate of GWC drops as α increases. Thus, every feature has its own idiosyncratic dependency on α which should be taken into account when combining the outputs from multiple features, especially because the goal is to improve the overall detection rate.

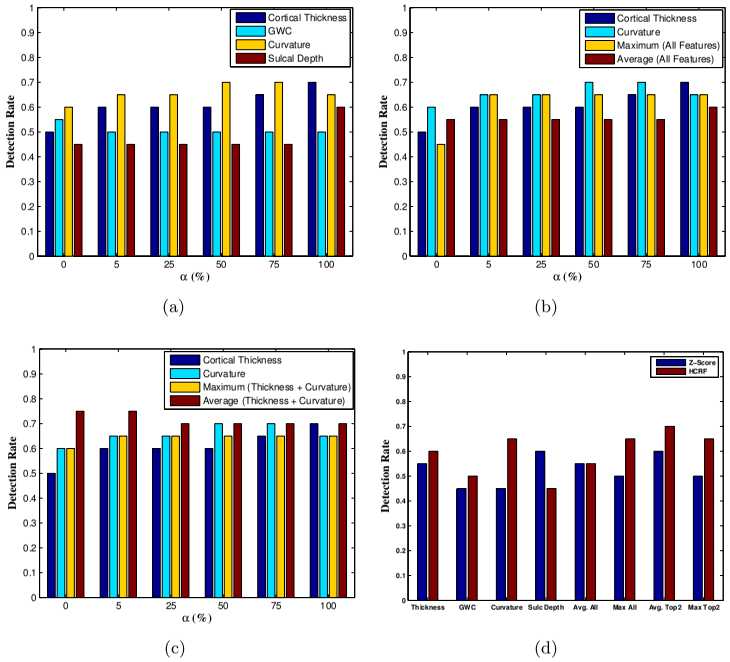

Figure 7: Effect of α on the detection rates of (a) individual features, (b) combination of all four morphological features and (c) combination of the top two ranked features. In (b) and (c) we have omitted the detection rates of sulcal depth and GWC to improve the clarity of the plot. (d) compares the overall median detection rate of HCRF with the baseline method using different input features and their combinations across the entire range of α.

Figures 7(b)-7(c) compare the influence of alpha on the detection rates of the two combination strategies (averaging and maximum) when all the features are used and when only cortical thickness and curvature are used, respectively. It can be observed that the highest detection rate, 75%, results from using an averaging technique to combine the posterior probabilities of cortical thickness and curvature (Figure 7(c)).

In order to contrast the performance of the HCRF based method based on different input settings across the entire range of α, we used a a two-sided Wilcoxon signed-rank test (Japkowicz and Shah, 2011). Figure 7(d) compares the median detection rate of HCRF and the z-score based method for different input features (and their combinations). For each individual feature HCRF achieves a higher detection rate as compared to the baseline, except

in the case of sulcal-depth, where the baseline is able to outperform HCRF. Similarly, when we combine cortical thickness and curvature to define the final detection, HCRF dominates the baseline, achieving the highest detection rate 75% using an averaging technique to combine the posterior probabilities of the two input features. However, when the same averaging technique is used to combine the results of all four features, both HCRF and the baseline perform comparably (albeit worse than using only two features) and the difference in their performance across the different values of α is not statistically significant.

5. Discussion

Any method of automated detection of FCD lesions is meant to augment the standard comprehensive clinical evaluation protocol for epilepsy surgery candidates. This standard protocol typically involves a neurological exam, scalp electroencephalography (EEG), neuropsychological exam, positron emission tomography (PET), and magnetic resonance imaging (MRI). Due to the common occurrence of widespread network abnormalities in focal epilepsy, each of these methods has a high rate of false positives. Thus, convergence of evidence from multiple sources is critical to determining the region(s) with the highest likelihood of hosting the seizure onset zone. In this work, we addressed this challenging task of detecting FCD lesions in a semi-supervised image segmentation framework. To this end, we developed a novel semi-supervised image segmentation method based on hierarchical conditional random fields (HCRF). We evaluated the proposed method on four morphological features, and also investigated different mechanisms of combining the outcomes of these input features.

In an empirical evaluation that involved 20 histologically verified MRI-negative patients, who had undergone resective surgery and were subsequently seizure-free, our proposed method was able to achieve higher detection rates using four morphological features as compared to a baseline method. Furthermore, when the detections based on these features were combined, HCRF was still able to detect abnormal clusters within the resection zone of a higher number of patients as compared to the selected baseline. Not only did the proposed method have a high detection rate, it also achieved significantly higher precision and recall across all features and their combinations.

Furthermore, in this work we establish that each of the four morphological features, namely cortical thickness, GWC, curvature and sulcal depth exhibit different behavior for different settings of the cluster ranking criterion and some of them produce noisier detections as compared to others. These two observations show that any method that aims at combining the detections from different features should consider feature specific properties such as the false positive rate and adjust the ranking criterion to achieve a high detection rate.

Because, identifying the abnormal region in cryptogenic epilepsy is a multifaceted procedure that is based on a confluence of evidence from multiple sources; the high detection rate of our proposed method will have a deeper impact in the application domain by enhancing the sensitivity of the patient evaluation methodology. Indeed, our 75% detection rate on the MRI-Negative patients in our evauation dataset (compared to a human expert detection rate of 0%), suggests that this method can be used as an effective tool in the presurgical evaluation of TRE patients who are likely to undergo surgical resection. Currently,

HCRF results have started being incorporated into the weekly meeting of radiologists and neurosurgeons to help identify the seizure onset zones for MRI-negative patients who may be candidates for resective surgery at the New York Universityś Comprehensive Epilepsy Center.

As part of the pre-surgical protocol, all patients undergo an intra-cranial EEG (iEEG) exam in which invasive subdural electrodes are placed directly on the cortex to record electrical activity. As a future research direction, we plan to use the results of the iEEG exam to augment the resection zones such that they provide "soft" labels that can be used to jointly learn the parameters of the node and edge potentials in the HCRF. Another avenue of future research is to further expand the feature set to include other features such as diffusivity, connectivity, etc.

Acknowledgments

We thank the reviewers for their helpful comments. We would also like to thank John Brumm, Omar Khan, Hugh Wang and Christine Chao for help with data processing. This research was funded by the Epilepsy Foundation and FACES - Finding A Cure for Epilepsy and Seizures.

Abstract

As data sets of related studies become more easily accessible, combining data sets of similar studies is often undertaken in practice to achieve a larger sample size and higher power. A major challenge arising from data integration pertains to data heterogeneity in terms of study population, study design, or study coordination. Ignoring such heterogeneity in data analysis may result in biased estimation and misleading inference. Traditional techniques of remedy to data heterogeneity include the use of interactions and random effects, which are inferior to achieving desirable statistical power or providing a meaningful interpretation, especially when a large number of smaller data sets are combined. In this paper, we propose a regularized fusion method that allows us to identify and merge inter-study homogeneous parameter clusters in regression analysis, without the use of hypothesis testing approach. Using the fused lasso, we establish a computationally efficient procedure to deal with large-scale integrated data. Incorporating the estimated parameter ordering in the fused lasso facilitates computing speed with no loss of statistical power. We conduct extensive simulation studies and provide an application example to demonstrate the performance of the new method with a comparison to the conventional methods.

Keywords: Fused lasso, Data integration, Extended BIC, Generalized Linear Models

1. Introduction

Combining data sets collected from multiple studies is undertaken routinely in practice to achieve a larger sample size and higher statistical power. Such information integration is commonly seen in biomedical research, for example, the study of genetics or rare diseases where data repositories are available. The motivation of this paper arises from the consideration of data heterogeneity during data integration. Although data integration has different meanings, in here, we consider the concatenation of data sets of similar studies over different subjects, where the number of integrated data sets can be very large.

Inter-study heterogeneity can result from the differences in study environment, population, design and protocols (Leek and Storey, 2007; Sutton and Higgins, 2008; Liu et al., 2015). Data heterogeneity is likely attributed to population parameter heterogeneity, where the association of interest can differ across different study populations from which data sets are collected. Examples include multi-center clinical trials when participant data from different sites are combined (Shekelle et al., 2003) and genetics studies when genomic data

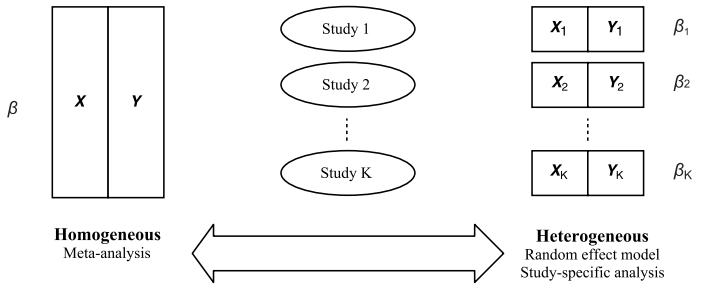

Figure 1: Homogeneous assumption (left) versus heterogeneous assumption (right).

from multiple similar studies are combined (Lohmueller et al., 2003; Sullivan et al., 2000). Discrepancies in treatment effect or trait-gene association may arise due to the differences in facilities, practices and patient characteristics across studies, albeit the adjustment of confounding (Leek and Storey, 2007). The parameter heterogeneity introduced in data integration compromises the power of the larger sample size and may even lead to biased results and misleading scientific conclusions. Thus, counterintuitively, the model obtained from the combined studies may not serve as a proper prediction model for each individual study in the case of heterogeneous study populations.

Traditional treatments of parameter heterogeneity are not optimal. Meta-analysis methods such as combining summary statistics (Glass, 1976), estimating functions (Hansen, 1982; Qin and Lawless, 1994) or p-values functions (Xie et al., 2012) are built upon the assumption of complete parameter homogeneity, as shown in the left panel of Figure 1. This assumption is hardly valid in practice. When individual participant data from multiple data sets are available, a retreat to the classical meta-analysis methods is necessary, because in this case assessing the assumption of inter-study homogeneity becomes possible. The two most common approaches to handling parameter heterogeneity include (i) specifying study-specific effects by including interaction terms between study indicator and covariates (e.g., Lin et al. (1998)), and (ii) utilizing random covariate effects by allowing variations across studies as random variables (e.g., DerSimonian and Kacker (2007)). Both approaches essentially assume fully heterogeneous covariate effects, namely, each study having its own set of regression coefficients, as shown in the right panel of Figure 1.

When study-specific effects are of interest, the interaction-based formulation may lead to over-parameterization, which impairs statistical power. The most straightforward way to reduce the number of parameters is to identify clusters of homogeneous parameters through exhaustive tests for the differences between every pair of study-specific coefficients. However, when the number of data sets is large, the use of hypothesis testing to determine parameter clusters becomes untrackable in addition to the multiple-testing problem. One may draw different or even conflicting conclusions due to different orders of hypotheses performed.

In reality, covariate effects from multiple studies are likely to form groups, a scenario falling in between the complete heterogeneity and the complete homogeneity. This leads

to the following two essential yet related analytic tasks: (i) to assess the inter-study heterogeneity, so to determine an appropriate form of parsimonious parameterization in model specification; and (ii) to identify and merge groups of homogeneous parameters for better statistical power for parameter estimation and inference based on a more parsimonious model. Along the idea of lasso shrinkage estimator (Tibshirani, 1996), fused lasso methods (Tibshirani et al., 2005; Friedman et al., 2007; Yang et al., 2012) have been introduced to achieve covariate grouping, where covariate adjacencies are naturally defined by a metric of time, location or network structure. In our problem of data integration, there does not exist a natural metric to define the ordering of regression coefficients from different studies. Shen and Huang (2010) proposed the grouping pursuit via penalization of all pairwise coefficient differences in a single study, where covariate orderings are not considered. To reduce the computational burden in the all-pairs based regularization, Wang et al. (2016) and Ke et al. (2015) used the initial coefficient estimates to establish certain ordering and then to define parameter adjacencies. However, most of these studies have been entirely focusing on a single cohort of subjects from a single study. For example, Shin et al. (2016) proposed to fuse regression coefficients of different loss functions obtained from a single study, such as coefficients from different quantile regression models. Limited publication of fusion learning and grouping pursuit has been available in the literature, except Wang et al. (2016), to assess the differences and similarities among regression coefficients across multiple studies in the scenario of data integration.

In this paper, we propose an agglomerative clustering method for regression coefficients in the context of data integration, named as the *Fused Lasso Approach in Regression Coefficients Clustering (FLARCC)*. FLARCC is proposed to identify heterogeneity patterns of regression coefficients across studies (or data sets) and to provide estimates of all regression coefficients simultaneously. It is interesting to draw a connection between our method and Pan et al. (2013) where they consider a classic clustering problem of individual responses by pairwise coefficient fusion via penalized regression. Their method aims at clustering subjects, while our method focuses on clustering regression coefficients across multiple data sets, and these two methods coincide only in a special case where each study is composed of only one subject. FLARCC achieves clustering of study-specific effects by penalizing the ℓ_1-norm differences of adjacent coefficients, with adjacency defined by the estimated ranks. Our method extends the bCARDS method in Ke et al. (2015) from one study to multiple studies as well as from the linear model to the generalized linear models, and focuses on simultaneous clustering of regression coefficients of individual covariates from multiple studies in data integration. An R package `metafuse` is created as part of our methodology development to perform the proposed integrated data analysis which can be downloaded from the Comprehensive R Archive Network (web link `https://cran.r-project.org/web/packages/metafuse`).

In the proposed method, tuning parameter is used to determine the clustering pattern of coefficients across data sets. Specifically, let λ be the tuning parameter of regularization. If $\lambda = 0$ (i.e., no penalty), FLARCC becomes a method under the setting of complete heterogeneity, so that study-specific regression coefficients for each covariate are assumed different across data sets. If λ is large enough that all differences of regression coefficients are shrunk to zero, FLARCC reduces to a homogeneous model in that a common regression coefficient for each covariate is assumed for all studies. In light of the hierarchical clustering

scheme, these two extreme cases above correspond to the start and end of an agglomerative clustering, respectively; however, the reality is believed to reside in between. Analogous to dendrograms in the hierarchical clustering, we propose a new tree-type graphic display, named as *fusogram*, which presents tree-based coefficient clusters according to solution paths obtained from FLARCC. The selection of optimal λ pertains to pruning of clustering trees, which can be based on certain model selection criterion. We use the extended Bayesian information criterion (EBIC) proposed by Chen and Chen (2008) as our model selection criterion and show that EBIC exhibits better performance than BIC when the number of studies (or data sets) is large. In addition, we propose a scaling strategy to "harmonize" solution paths by covariate-wise adaptive weights to allow flexible tuning, which further improves the clustering performance.

The rest of this paper is organized as follows. Section 2 describes FLARCC in detail under the generalized linear models (GLM) framework. Section 3 presents the theoretical properties of the proposed method (with technical proofs presented in the Appendix). Section 4 discusses the interpretation and selection of the tuning parameter. In Section 5, we use simulation studies to evaluate the performance of our method. A real data analysis is given in Section 6 with interpretation of coefficient estimates and illustration of *fusograms*. Discussion and concluding remarks are in Section 7.

2. Method of Parameter Fusion

In this section, we present the method and algorithm of FLARCC.

2.1 Notations and Method

We start by introducing necessary notations. Throughout this paper, i, j and k are used to index subject, covariate and study, respectively. For instance, $X_{j,k}^{(i)}$ denotes the measurement of the jth covariate from the ith individual from study k, and $Y_k^{(i)}$ is the measurement of a response variable from the ith individual from study k. The total number of studies is denoted as K and the number of covariates involved is p. The sample size for study k is n_k, $k = 1, \ldots, K$, and the combined sample size is $N = \sum_{k=1}^{K} n_k$. The collection of all coefficients (covariates-wise) is denoted as $\boldsymbol{\beta} = (\boldsymbol{\beta}_{1,\bullet}^\top, \boldsymbol{\beta}_{2,\bullet}^\top, \ldots, \boldsymbol{\beta}_{p,\bullet}^\top)^\top$ with $\boldsymbol{\beta}_{j,\bullet} = (\beta_{j,1}, \ldots, \beta_{j,K})^\top$ for $j = 1, \ldots, p$. An indicator vector $\boldsymbol{c} = (c_1, \ldots, c_p)^\top$ is used to flag heterogeneous covariates, namely if the jth covariate is treated as heterogeneous (i.e., all different coefficients across K studies) then $c_j = 1$ and as homogeneous (a common coefficient across K studies) otherwise. Thus $c_j = 0$ for some $j \in \{1, \ldots, p\}$ implies that coefficient vector $\boldsymbol{\beta}_{j,\bullet}$ reduces to a common scalar parameter β_j for all K studies.

For illustration, let us consider a simple scenario of $\boldsymbol{c} = (1, 1, 0, \ldots, 0)^\top$, in which the first two covariates are set as heterogeneous and the remaining $p-2$ covariates are set as homogeneous. The resulting coefficient vector is $\boldsymbol{\beta} = (\boldsymbol{\beta}_{1,\bullet}^\top, \boldsymbol{\beta}_{2,\bullet}^\top, \beta_3, \ldots, \beta_p)^\top$. Then the corresponding design matrix $\boldsymbol{X}$ can be written as

$$\boldsymbol{X} = \begin{pmatrix} \boldsymbol{X}_{1,1} & & & \boldsymbol{X}_{2,1} & & & \boldsymbol{X}_{3,1} & \cdots & \boldsymbol{X}_{p,1} \\ & \ddots & & & \ddots & & \vdots & \ddots & \vdots \\ & & \boldsymbol{X}_{1,K} & & & \boldsymbol{X}_{2,K} & \boldsymbol{X}_{3,K} & \cdots & \boldsymbol{X}_{p,K} \end{pmatrix}_{N \times (2K+p-2)}$$

where $\boldsymbol{X}_{j,k} = (X_{j,k}^{(1)}, \ldots, X_{j,k}^{(n)})^\top$, $j = 1, \ldots, p$, $k = 1, \ldots, K$. The specification of $\boldsymbol{c}$ is can be dependent on the study interest. For example, in a multi-center clinical trial where we believe that the differences between the services provided across centers are non-negligible, but the study participants are similar, we can specify the clinic-related variables (e.g., treatment and cost) to be heterogeneous and the patient-related variables (e.g., age and gender) to be homogeneous. In addition, the specification of $\boldsymbol{c}$ can be dependent on preliminary marginal analysis of the homogeneousness of each variable, such as tests for random effects. When the homogeneousness of a covariate is unclear, we suggest specifying it as heterogeneous rather than homogeneous.

Under the assumption that both within-study and between-study samples are independent, for any $\boldsymbol{c} = (c_1, \ldots, c_p)^\top$ with $c_j \in \{0, 1\}$, $j = 1, \ldots, p$, the initial estimate of $\boldsymbol{\beta}$, which gives the starting level of clustering (i.e., $\lambda = 0$), can be consistently estimated by the maximum likelihood estimator

$$\hat{\boldsymbol{\beta}} = \underset{\boldsymbol{\beta} \in \mathbb{R}^{(K \times p)}}{\operatorname{argmax}} \frac{1}{K} \sum_{k=1}^{K} \frac{1}{n_k} \log L_k(\boldsymbol{\beta}), \tag{1}$$

where $L_k(\boldsymbol{\beta}) = \prod_{i=1}^{n_k} L_k^{(i)}(\boldsymbol{\beta})$, $k = 1, \ldots, K$ are the study-specific likelihoods from the given GLMs. For the purpose of parameter grouping and fusion, we propose the regularized maximum likelihood estimation for $\boldsymbol{\beta}$ by minimizing the following objective function:

$$\min_{\boldsymbol{\beta} \in \mathbb{R}^{(K \times p)}} \left(-\frac{1}{K} \sum_{k=1}^{K} \frac{1}{n_k} \log L_k(\boldsymbol{\beta}) + P(\boldsymbol{\beta}) \right), \tag{2}$$

where $P(\boldsymbol{\beta})$ is a penalty function of certain form. Here we adopt weighting $\frac{1}{n_k}$ to balance the contribution from each study so to avoid the dominance of large studies. Other types of weighting schemes may be considered to serve for different purposes, such as the inverse of estimated variances of initial estimates, which helps to achieve better estimation precision.

To achieve parameter fusion, Shen and Huang (2010) proposed the grouping pursuit algorithm, which specifies the sum of ℓ_1-norm differences of all study-specific coefficient pairs among individual heterogeneous coefficient vectors $\boldsymbol{\beta}_{j,\cdot}$, where $c_j = 1$, as the penalty:

$$P_\lambda(\boldsymbol{\beta}) = \lambda \sum_{j=1}^{p} c_j \sum_{k=1}^{K-1} \sum_{k'>k}^{K} |\beta_{j,k} - \beta_{j,k'}|,$$

with $\lambda \geq 0$. In this penalty, there are $\binom{K}{2}$ terms of pairwise differences for each heterogeneous covariate and the total number of terms increases by an order of $O(K^2)$, given p fixed. This penalty contains many redundant constraints and imposes great computational challenges as pointed out in Shen and Huang (2010) and Ke et al. (2015).

Following arguments in Wang et al. (2016) and Ke et al. (2015), we develop the method of FLARCC by a simplified penalty function that uses the information on the ordering of coefficients. For the jth covariate, let $\boldsymbol{U}_j = (U_{j,1}, \ldots, U_{j,K})^\top$ be the ranking with no ties of $\boldsymbol{\beta}_{j,\cdot} = (\beta_{j,1}, \ldots, \beta_{j,K})^\top$, from the smallest to the largest. Specifically, $U_{j,k} = \sum_{k'=1}^{K} \mathbf{1}\{\beta_{j,k'} \leq \beta_{j,k}\}$ if there are no ties in $\boldsymbol{\beta}_{j,\cdot}$; otherwise, the ties in $\boldsymbol{U}_j$ are resolved by the first-occurrence-wins

rule according to k to ensure rank uniqueness. Then, the fusion penalty in FLARCC with parameter orderings $\boldsymbol{U}_j$, $j = 1, \ldots, p$, takes the form:

$$P_\lambda(\boldsymbol{\beta}) = \lambda \sum_{j=1}^{p} c_j \nu_j \sum_{k=1}^{K-1} \sum_{k'>k}^{K} \mu_{j,k,k'} \mathbf{1}\{|U_{j,k} - U_{j,k'}| = 1\} |\beta_{j,k} - \beta_{j,k'}|, \tag{3}$$

where the constraints occur effectively only on adjacent ordered pairs. Clearly, the penalty in (3) only involves $K - 1$ terms for each case of $c_j = 1$, which is of an order $O(K)$, given p fixed. The ν_j's and $\mu_{j,k,k'}$'s in (3) are weights. Following Zou (2006), we choose adaptive weights $\hat{\mu}_{j,k,k'} = 1/|\hat{\beta}_{j,k} - \hat{\beta}_{j,k'}|^r$, $r > 0$, so that parameters with smaller difference will be penalized more than those with larger differences. Similarly, for a group of parameters $\boldsymbol{\beta}_{j,\cdot} = (\beta_{j,1}, \ldots, \beta_{j,K})^\top$, ν_j is an adaptive weight to characterize the degree of heterogeneousness of $\boldsymbol{\beta}_{j,\cdot}$. Specifically, in this paper we let $\hat{\nu}_j = 1/|\hat{\beta}_{j,(K)} - \hat{\beta}_{j,(1)}|^s$, the inverse of the range of the estimates, with $s \geq 0$; when a covariate is homogeneous, the differences of study-specific coefficients will be penalized more than those that are heterogeneous. In this way, we can "harmonize" solution paths so to greatly improve the performance by a single tuning parameter. We compare $s = 0$ and $s = 1$ in the simulation experiments and show in Section 5 that the introduction of such group-wise weights ν_j, $j = 1, \ldots, p$, gives rise to improvement on the performance of identifying homogeneous covariates when K and p are large.

A sparse version of FLARCC can also be achieved by including the traditional lasso penalty in (3) for covariate selection. In order to minimize the interference between fusion and sparsity penalties, we only encourage sparsity for the coefficient closest to zero in each $\boldsymbol{\beta}_{j,\cdot} = (\beta_{j,1}, \ldots, \beta_{j,K})^\top$, for $j = 1, \ldots, p$. Similar to the definition of $\boldsymbol{U}_j$, let $\boldsymbol{V}_j = (V_{j,1}, \ldots, V_{j,K})^\top$ be the ranking with no ties, from the smallest to the largest, of the absolute values of $\boldsymbol{\beta}_{j,\cdot}$, i.e., $(|\beta_{j,1}|, \ldots, |\beta_{j,K}|)^\top$. First we calculate $\boldsymbol{V}_j$ by $V_{j,k} = \sum_{k'=1}^{K} \mathbf{1}\{|\beta_{j,k'}| \leq |\beta_{j,k}|\}$, then we resolve the ties in $\boldsymbol{V}_j$ by the first-occurrence-wins rule according to k. Thus we can extend (3) to achieve variable selection by the following penalty function:

$$\begin{aligned} P_{\lambda,\alpha}(\boldsymbol{\beta}) = \lambda \sum_{j=1}^{p} c_j \nu_j \sum_{k=1}^{K-1} \sum_{k'>k}^{K} \mu_{j,k,k'} \mathbf{1}\{|U_{j,k} - U_{j,k'}| = 1\} |\beta_{j,k} - \beta_{j,k'}| \\ + \alpha\lambda \sum_{j=1}^{p} \sum_{k=1}^{K} \mu_{j,k} \mathbf{1}\{V_{j,k} = 1\} |\beta_{j,k}|, \end{aligned} \tag{4}$$

where $\alpha \geq 0$ is another tuning parameter that controls the relative ratio between fusion and sparsity penalties, and $\hat{\mu}_{j,k} = 1/|\hat{\beta}_{j,k}|^r$. The sparsity penalty, although only enforced on the smallest coefficient in absolute value of $\boldsymbol{\beta}_{j,\cdot}$, is capable of shrinking a group of coefficients to zero when combined with the fusion penalty.

In practice, the weights (ν_j, $\mu_{j,k,k'}$ and $\mu_{j,k}$) and the parameter orderings ($\boldsymbol{U}_j$ and $\boldsymbol{V}_j$) are unknown, for $j = 1, \ldots, p$. We replace them with their estimates based on root-n consistent estimates $\hat{\boldsymbol{\beta}} = (\hat{\boldsymbol{\beta}}_{1,\cdot}^\top, \ldots, \hat{\boldsymbol{\beta}}_{p,\cdot}^\top)^\top$, such as those from (1). In the simulation experiments and the real data application of this paper, we set $r = 1$ in $\hat{\mu}_{j,k,k'}$ and $\hat{\mu}_{j,k}$.

2.2 Algorithm

Optimization problem (2) with $P(\boldsymbol{\beta}) = P_{\lambda,\alpha}(\boldsymbol{\beta})$ given in (4) can be carried out by a lasso regression through suitable reparameterization. Let the ordered coefficients of $\boldsymbol{\beta}_{j,\bullet}$ in an ascending order based on ranking $\boldsymbol{U}_j$ be $(\beta_{j,(1)}, \ldots, \beta_{j,(K)})^\top$, $j = 1, \ldots, p$. For the jth covariate, consider a set of transformed parameters $\boldsymbol{\theta}_{j,\bullet} = (\theta_{j,1}, \ldots, \theta_{j,K})^\top$ defined by

$$\begin{aligned} \theta_{j,1} &= \beta_{j,k}, && \text{for } k \text{ s.t. } V_{j,k} = 1; \\ \theta_{j,k} &= \beta_{j,(k)} - \beta_{j,(k-1)}, && \text{for } k = 2, \ldots, K. \end{aligned}$$

Then the $P_{\lambda,\alpha}(\boldsymbol{\beta})$ in (4) can be rewritten as

$$P_{\lambda,\alpha}(\boldsymbol{\theta}) = \lambda \sum_{j=1}^{p} \sum_{k=1}^{K} \omega_{j,k} |\theta_{j,k}|, \tag{5}$$

where

$$\hat{\omega}_{j,k} = \begin{cases} \alpha \frac{1}{|\hat{\theta}_{j,1}|^r}, & \text{if } k = 1 \\ c_j \frac{1}{|\sum_{k'=2}^{K} \hat{\theta}_{j,k'}|^s} \frac{1}{|\hat{\theta}_{j,k}|^r}, & \text{if } k = 2, \ldots, K, \end{cases} \tag{6}$$

for $j = 1, \ldots, p$. Since no ties are allowed in the parameter ordering of FLARCC, one-to-one transformation exists between $\boldsymbol{\beta} = (\boldsymbol{\beta}_{1,\bullet}^\top, \boldsymbol{\beta}_{2,\bullet}^\top, \ldots, \boldsymbol{\beta}_{p,\bullet}^\top)^\top$ and $\boldsymbol{\theta} = (\boldsymbol{\theta}_{1,\bullet}^\top, \boldsymbol{\theta}_{2,\bullet}^\top, \ldots, \boldsymbol{\theta}_{p,\bullet}^\top)^\top$ by suitable sorting matrix $\boldsymbol{S}$ and reparameterization matrix $\boldsymbol{R}$; that is, $\boldsymbol{\theta} = \boldsymbol{RS\beta}$ and $\boldsymbol{\beta} = (\boldsymbol{RS})^{-1}\boldsymbol{\theta}$ with both $\boldsymbol{S}$ and $\boldsymbol{R}$ being full-rank square matrices. Thus, a solution to the fused lasso problem can be obtained equivalently by solving a routine lasso problem with respect to coefficient vector $\boldsymbol{\theta}$ and a transformed design matrix $\boldsymbol{X}(\boldsymbol{RS})^{-1}$. As aforementioned, the estimated parameter ordering is used to construct $\boldsymbol{S}$. It is obvious that the constraint in (5) is convex, thus FLARCC does not suffer from multiple local minimal issue. The optimization is done using R package `glmnet` (version 2.0-2) (Friedman et al., 2010), which accommodates GLMs with Gaussian, binomial and Poisson distributions.

3. Large-sample Properties

First we present the oracle property of our method when the parameter ordering is known, then we prove that the same large-sample properties are preserved when consistently estimated parameter ordering is used. Here we assume K is fixed. Theorems will be stated under the setting of all coefficients being heterogeneous, i.e., $\boldsymbol{c} = (1, \ldots, 1)^\top$. The large-sample theories for other specification of $\boldsymbol{c}$ can be established as a special case.

Denote the true parameter values as $\boldsymbol{\beta}^*$ and $\boldsymbol{\theta}^*$. Let the collection of true parameter orderings of all covariates and their absolute values be $\boldsymbol{W} = \{\boldsymbol{U}_j, \boldsymbol{V}_j\}_{j=1}^p$, and the estimated orderings based on the root-n consistent estimator $\hat{\boldsymbol{\beta}}$ from (1) as $\hat{\boldsymbol{W}} = \{\hat{\boldsymbol{U}}_j, \hat{\boldsymbol{V}}_j\}_{j=1}^p$. Denote the FLARCC estimator of $\boldsymbol{\theta}^*$ as $\hat{\boldsymbol{\theta}}^{\boldsymbol{W}}$ when $\boldsymbol{W}$ is known, and $\hat{\boldsymbol{\theta}}^{\hat{\boldsymbol{W}}}$ when the estimated parameter ordering $\hat{\boldsymbol{W}}$ is used. Let $\mathcal{A} = \bigcup_{j=1}^p \{\mathcal{A}_j\}$ be the index set of nonzero values in $\boldsymbol{\theta}^*$, where $\mathcal{A}_j = \{(j,k) : \theta_{j,k}^* \neq 0\}$, and $\mathcal{A}^c$ be the complement of $\mathcal{A}$. Thus, $\boldsymbol{\theta}^*$ can be partitioned into two subsets, the true-zero set $\boldsymbol{\theta}_{\mathcal{A}^c}^*$ and the nonzero set $\boldsymbol{\theta}_{\mathcal{A}}^*$. Similarly, let $\hat{\mathcal{A}}^{\boldsymbol{W}}$ and $\hat{\mathcal{A}}^{\hat{\boldsymbol{W}}}$ be the index sets of nonzero elements in $\hat{\boldsymbol{\theta}}^{\boldsymbol{W}}$ and $\hat{\boldsymbol{\theta}}^{\hat{\boldsymbol{W}}}$, respectively. Let $n = \min_{1 \le k \le K} n_k$, $N = \sum_{k=1}^K n_k$, and $\lambda_N = N\lambda$.

Theorem 1 *Suppose that tuning parameter λ_N satisfies $\lambda_N/\sqrt{N} \to 0$ and $\lambda_N N^{(r-1)/2} \to \infty$. Then under some mild regularity conditions (see Appendix A), the FLARCC estimator $\hat{\boldsymbol{\theta}}^{\boldsymbol{W}}$ based on the true parameter ordering $\boldsymbol{W}$ satisfies*

(i) (Selection Consistency) $\lim_n P(\hat{\mathcal{A}}^{\boldsymbol{W}} = \mathcal{A}) = 1$;

(ii) (Asymptotic Normality) $\sqrt{N}(\hat{\boldsymbol{\theta}}_{\mathcal{A}}^{\boldsymbol{W}} - \boldsymbol{\theta}_{\mathcal{A}}^*) \xrightarrow{d} \mathcal{N}(0, \boldsymbol{I}_{11}^{-1})$ *as $n \to \infty$, where $\boldsymbol{I}_{11}$ is the submatrix of Fisher information matrix $\boldsymbol{I}$ corresponding to set $\mathcal{A}$.*

Theorem 1 states that when the coefficient orderings $\boldsymbol{W}$ of $\boldsymbol{\beta}$ is known, under mild regularity conditions, the FLARCC estimator $\hat{\boldsymbol{\theta}}^{\boldsymbol{W}}$ enjoys selection consistency and asymptotic normality. The proof of Theorem 1 follows Zou (2006) and is given in Appendix A. Now we present Theorem 3, which states that the same properties of Theorem 1 hold for $\hat{\boldsymbol{\theta}}^{\hat{\boldsymbol{W}}}$, the FLARCC estimator of $\boldsymbol{\theta}^*$ based on the estimated parameter ordering $\hat{\boldsymbol{W}}$. In effect, Theorem 3 is a consequence of the following lemma.

Lemma 2 *If $\hat{\boldsymbol{\beta}}$ is a root-n consistent estimator of $\boldsymbol{\beta}$, then* $\lim_n P(\hat{\boldsymbol{U}}_j = \boldsymbol{U}_j) = 1$ *and* $\lim_n P(\hat{\boldsymbol{V}}_j = \boldsymbol{V}_j) = 1$ *for $j = 1, \ldots, p$.*

The proof of Lemma 2 is given in Appendix A. Lemma 2 implies that the parameter ordering can be consistently estimated. Using Lemma 2, we are able to extend the properties of $\hat{\boldsymbol{\theta}}^{\boldsymbol{W}}$ in Theorem 1 to the proposed FLARCC estimator $\hat{\boldsymbol{\theta}}^{\hat{\boldsymbol{W}}}$.

Theorem 3 *Suppose that $\lambda_N/\sqrt{N} \to 0$ and $\lambda_N N^{(r-1)/2} \to \infty$. Let the estimated parameter ordering $\hat{\boldsymbol{W}}$ be the ranks from a root-n initial consistent estimator $\hat{\boldsymbol{\beta}}$. Under the same regularity conditions of Theorem 1, the FLARCC estimator $\hat{\boldsymbol{\theta}}^{\hat{\boldsymbol{W}}}$ satisfies*

(i) (Selection Consistency) $\lim_n P(\hat{\mathcal{A}}^{\hat{\boldsymbol{W}}} = \mathcal{A}) = 1$;

(ii) (Asymptotic Normality) $\sqrt{N}(\hat{\boldsymbol{\theta}}_{\mathcal{A}}^{\hat{\boldsymbol{W}}} - \boldsymbol{\theta}_{\mathcal{A}}^*) \xrightarrow{d} \mathcal{N}(0, \boldsymbol{I}_{11}^{-1})$ *as $n \to \infty$, where $\boldsymbol{I}_{11}$ is the submatrix of Fisher information matrix $\boldsymbol{I}$ corresponding to set $\mathcal{A}$.*

The proof of Theorem 3 is given in Appendix A. The asymptotic normality for $\hat{\boldsymbol{\beta}}$ can also be derived by a simple linear transformation.

4. Tuning Parameter

In this section, we provide interpretation of the tuning parameter λ and discuss the selection criteria used for selecting λ.

4.1 Interpretation of ν_j's

Intuitively speaking, the study-specific coefficients of a homogeneous covariate tend to be fused at a small λ value, say λ_1, but the fusion of a heterogeneous covariate requires another λ value, λ_2, assuming $\lambda_2 > \lambda_1$. The region to draw correct clustering conclusion is $[\lambda_1, \lambda_2]$, that is, any λ within this region will produce the correct clustering result. However, when the number of covariates p is large, the region that λ can take value from to ensure the correct clustering of all p coefficient vectors simultaneously becomes narrower and may even

be empty. For example, when $\lambda_2 < \lambda_1$ in the above case, no single λ is able to correctly cluster both sets of parameters. The introduction of ν_j's in (4) creates larger separation between homogeneous and heterogeneous groups, so that the range for λ to identify the correct clustering pattern for all covariates is better established than the case with $s = 0$, namely no use of weighting ν_j's. When the number of covariates p is large, ν_j plays a more important role in harmonizing solution paths across covariates, and the performance will be greatly improved by simultaneous tuning via a single λ.

4.2 Model Selection

In the current literature, the tuning parameter λ may be selected by multiple model selection criteria, such as Bayesian information criterion (BIC) (Schwarz, 1978) and generalized cross-validation (GCV) (Golub et al., 1979). In this paper, we consider the widely used BIC and its modification, extended BIC, i.e., EBIC (Chen and Chen, 2008; Gao and Song, 2010), which has showed the benefit of achieving sparse solutions.

Following the derivation of BIC for weighted likelihoods in Lumley and Scott (2015), the conventional BIC for FLARCC is defined as follows:

$$BIC_\lambda = -2\sum_{k=1}^{K} \frac{\bar{n}}{n_k} \log L_k(\hat{\boldsymbol{\beta}}(\lambda)) + \mathrm{df}(\hat{\boldsymbol{\beta}}(\lambda)) \log(N), \tag{7}$$

where $\bar{n} = N/K$ is the average sample size per study, $L_k(\boldsymbol{\beta})$ is the study-specific likelihood, $\hat{\boldsymbol{\beta}}(\lambda)$ is the estimation of $\boldsymbol{\beta}$ at tuning parameter value λ, and $\mathrm{df}(\hat{\boldsymbol{\beta}}(\lambda)) = \sum_{j=1}^{p} \mathrm{df}(\hat{\boldsymbol{\beta}}_{j,\bullet}(\lambda))$ is the total number of distinct parameters in $\hat{\boldsymbol{\beta}}(\lambda)$. The study-specific log-likelihoods for three most common models are listed below:

$$\text{Normal: } \log L_k(\hat{\boldsymbol{\beta}}(\lambda)) \propto -\frac{n_k}{2} \log \left\{ \sum_{i=1}^{n_k} \left(Y_k^{(i)} - \boldsymbol{X}_k^{(i)\top} \hat{\boldsymbol{\beta}}(\lambda) \right)^2 / n_k \right\};$$

$$\text{Logistic: } \log L_k(\hat{\boldsymbol{\beta}}(\lambda)) \propto \sum_{i=1}^{n_k} \left\{ Y_k^{(i)} \boldsymbol{X}_k^{(i)\top} \hat{\boldsymbol{\beta}}(\lambda) - \log \left(1 + e^{\boldsymbol{X}_k^{(i)\top} \hat{\boldsymbol{\beta}}(\lambda)} \right) \right\};$$

$$\text{Poisson: } \log L_k(\hat{\boldsymbol{\beta}}(\lambda)) \propto \sum_{i=1}^{n_k} \left\{ Y_k^{(i)} \boldsymbol{X}_k^{(i)\top} \hat{\boldsymbol{\beta}}(\lambda) - e^{\boldsymbol{X}_k^{(i)\top} \hat{\boldsymbol{\beta}}(\lambda)} \right\}.$$

To improve the BIC by further controlling model size and encouraging sparer models, we adapt the EBIC for FLARCC, which takes the following form:

$$EBIC_\lambda = -2\sum_{k=1}^{K} \frac{\bar{n}}{n_k} \log L_k(\hat{\boldsymbol{\beta}}(\lambda)) + \mathrm{df}(\hat{\boldsymbol{\beta}}(\lambda)) \log(N) + 2\gamma \log \sum_{j=1}^{p} \binom{K}{\mathrm{df}(\hat{\boldsymbol{\beta}}_{j,\bullet}(\lambda))}, \tag{8}$$

where $\gamma \in [0, 1]$ is a tuning parameter that is typically fixed at 1 as done in our numerical experiments. Note that EBIC reduces to BIC when $\gamma = 0$. The last term in (8) encourages a sparser solution in comparison to the conventional BIC. Simulation studies in Section 5 provide numerical evidence to elucidate the difference between BIC and EBIC in terms of their performance on achieving sparsity.

In a view of hierarchical clustering, the solution path of each covariate can be thought of as a hierarchical clustering tree. For the jth covariate, $\lambda = 0$ corresponds to the bottom of the clustering tree; and $\lambda = \lambda_{Fuse,j}$, the smallest λ value to achieve complete parameter fusion, corresponds to the top of the clustering tree. The completely heterogeneous model corresponds to the position on the solution path at $\lambda = 0$ and the completely homogeneous model corresponds to the model at $\lambda = \lambda_{Fuse} := \max_{1 \le j \le p} \lambda_{Fuse,j}$.

5. Simulation Studies

This section presents results from two simulation experiments. The first simulation compares the performance of FLARCC under different GLM regression models. The second simulation is a more complicated scenario with large K and more non-important covariates, where covariate selection is also of interest.

5.1 Simulation Experiment 1

The first simulation study aims to assess the performance of our method for different GLM regression models. For this, we consider combining data sets from $K = 10$ different studies with, for simplicity, equal sample size $n_1 = \cdots = n_{10} = 100$. Data are simulated from the following mean regression model:

$$h\{E(Y_k^{(i)})\} = \beta_{1,k} X_{1,k}^{(i)} + \beta_{2,k} X_{2,k}^{(i)} + \beta_{3,k} X_{3,k}^{(i)},\ i = 1, \ldots, 100,\ k = 1, \ldots, 10,$$

where the true coefficient vectors have the following clustering structures:

$$\begin{aligned}
\boldsymbol{\beta}_{1,\bullet} &= (\underbrace{0, \ldots, 0}_{10})^\top; \\
\boldsymbol{\beta}_{2,\bullet} &= (\underbrace{0, \ldots, 0}_{5}, \underbrace{1, \ldots, 1}_{5})^\top; \\
\boldsymbol{\beta}_{3,\bullet} &= (\underbrace{-1, \ldots, -1}_{3}, \underbrace{0, \ldots, 0}_{4}, \underbrace{1, \ldots, 1}_{3})^\top.
\end{aligned}$$

The true values in $\boldsymbol{\beta}_2$ and $\boldsymbol{\beta}_3$ are heterogeneous, while the true values in $\boldsymbol{\beta}_1$ are homogeneous across studies. The three covariates are correlated with exchangeable correlation of 0.3 and marginally distributed according to the standard normal distributions, $\mathcal{N}(0, 1)$. Three types of GLM regression models are considered: linear model for continuous normal outcomes (with errors simulated from $\mathcal{N}(0, 1)$), logistic model for binary outcomes and Poisson model for count outcomes.

To evaluate the performance of FLARCC to correctly detect patterns of all covariates, we assume all covariates are heterogeneous across studies with no prior knowledge on clustering structure of any covariate. Intercept is fitted and assumed to be homogeneous. No sparsity penalty is applied on the covariates (i.e., $\alpha = 0$) in this simulation experiment. Coefficients of all three covariates are fused simultaneously, and the optimal tuning parameter λ_{opt} is selected by EBIC. We report sensitivity and specificity as metrics of the performance of FLARCC to identify similar and distinct coefficient pairs. Sensitivity measures the proportion of equal coefficient pairs that are correctly identified. Similarly, specificity measures

Table 1: Results of simulation experiment 1 for FLARCC when scaling weight parameter $s = 0$ and $s = 1$ with λ selected by EBIC, for the linear, logistic and Poisson models. Tuning parameters are reported in log scale, i.e., $\tilde{\lambda} = \log_{10}(\lambda+1)$. Results are summarized from 1,000 replications.

the proportion of unequal coefficients pairs that are correctly identified; however, specificity is not defined for homogeneous covariates which have no unequal coefficient pairs. In addition, we calculate the mean squared error (MSE) for each $\hat{\boldsymbol{\beta}}_{j,\bullet}$ across all K studies, defined as $\text{MSE}_j = \sum_{k=1}^{K}(\hat{\beta}_{j,k} - \beta_{j,k})^2/K, j = 1, \ldots, p$, and compare with the MSE of each estimate based on homogeneous model ($\lambda = \lambda_{Fuse}$) and heterogeneous model ($\lambda = 0$).

Table 1 shows the results of simulation experiment 1 from 1,000 simulation replicates. The MSE of all estimated covariates based on FLARCC ($\lambda = \lambda_{opt}$) are consistently and significantly smaller than those based on the homogeneous ($\lambda = \lambda_{Fuse}$) and heterogeneous ($\lambda = 0$) models, regardless of the model type. FLARCC performs very well in the linear and Poisson regressions in terms of identifying the correct clustering, with the sensitivity and specificity both above 95% for all covariates (specificity is not reported for $\boldsymbol{\beta}_1$ since there is no unequal pair within $\boldsymbol{\beta}_{1,\bullet}$). Sensitivity and specificity of FLARCC drop in the logistic regression, especially as the level of heterogeneity increases. One reason for the reduced performance of FLARCC in the logistic regression is that the estimated variances of

regression coefficients in the logistic model are larger than in the linear and Poisson models, given the same coefficient setting. Therefore, the estimated parameter ordering for which our method is based on may be less accurate. For the logistic regression, increasing sample sizes is one of the possible ways to improve the performance. The performance difference between scaling weight parameter $s = 0$ and $s = 1$ in (4) is small in this case because of the relatively small number of covariates $p = 3$. Additionally, since K is small in this case, the optimal λ selected by BIC and EBIC are very close, thus we only display results based on EBIC. As p and K become larger, FLARCC will increasingly benefit from the additional weights ν_j (i.e., $s = 1$) and EBIC, as will be shown in Section 5.2. A sensitivity analysis to investigate how the initial ordering affect the performance of FLARCC is conducted, with results shown in Appendix B. We show that when the initial parameter ordering is slightly distorted, our method still achieves satisfactory performance.

5.2 Simulation Experiment 2

The second simulation study aims to evaluate the performance of FLARCC in a more challenging setting. More specifically, we consider data sets from $K = 100$ studies, each with a sample size 100, totaling 10,000 subject-level observations. Comparing to the previous setting, we increase the number of covariates and reduce the gaps between heterogeneous coefficients. For each study, we simulate data from the following linear regression model:

$$E(Y_k^{(i)}) = \sum_{j=1}^{8} \beta_{j,k} X_{j,k}^{(i)}, \ i = 1, \ldots, 100, \ k = 1, \ldots, 100.$$

The signals are set sparse; only the first four covariates with coefficient vectors, $\boldsymbol{\beta}_1$ to $\boldsymbol{\beta}_4$, are influential to Y with the true clustered effect patterns given as follows:

$$\begin{aligned}
\boldsymbol{\beta}_{1,\bullet} &= (\underbrace{0, \ldots, 0}_{50}, \underbrace{0.5, \ldots, 0.5}_{50})^\top, \\
\boldsymbol{\beta}_{2,\bullet} &= (\underbrace{-0.5, \ldots, -0.5}_{30}, \underbrace{0, \ldots, 0}_{40}, \underbrace{0.5, \ldots, 0.5}_{30})^\top, \\
\boldsymbol{\beta}_{3,\bullet} &= (\underbrace{-0.5, \ldots, -0.5}_{25}, \underbrace{0, \ldots, 0}_{25}, \underbrace{0.5, \ldots, 0.5}_{25}, \underbrace{1, \ldots, 1}_{25})^\top, \\
\boldsymbol{\beta}_{4,\bullet} &= (\underbrace{-1, \ldots, -1}_{20}, \underbrace{-0.5, \ldots, -0.5}_{20}, \underbrace{0, \ldots, 0}_{20}, \underbrace{0.5, \ldots, 0.5}_{20}, \underbrace{1, \ldots, 1}_{20})^\top,
\end{aligned}$$

whereas $\boldsymbol{\beta}_5$ to $\boldsymbol{\beta}_8$ are all zero, i.e., $\boldsymbol{\beta}_{j,\bullet} = (0, \ldots, 0)^\top$, for $j = 5, 6, 7, 8$. All covariates are equally correlated with an exchangeable correlation of 0.3 and marginally distributed according to $\mathcal{N}(0, 1)$. We set $\boldsymbol{\beta}_1$ to $\boldsymbol{\beta}_8$ as being heterogeneous from the start and fuse all of them simultaneously. We apply the additional sparsity penalty to all covariates by setting $\alpha = 1$. The intercept is assumed to be homogeneous in the analysis.

Since K is large, we also present results from individual covariate K-means clustering. This is a two-step method where we first estimate regression coefficients within each study, and then separately for each covariate, we perform the K-means clustering on the estimated study-specific coefficients of each covariate. The number of clusters is selected by the generalized cross-validation criterion $\sum_{k=1}^{K}(\hat{\beta}_k - \hat{\beta}_{c(k)})^2/(K - \text{GDF})^2$, with $\hat{\beta}_{c(k)}$ being the

Method ($\tilde{\lambda}_{opt}$)	$\boldsymbol{\beta}$	$\hat{\boldsymbol{\beta}}$ size	$\tilde{\lambda}_{Fuse,j}$	Sensitivity	Specificity	Sparsity	MSE when $\lambda =$ λ_{opt}	λ_{Fuse}	0

Table 2: Result of simulation experiment 2 under the linear model. Scaling weight parameter is set at $s = 0$ and $s = 1$. Tuning parameters are reported in log scale, i.e., $\tilde{\lambda} = \log_{10}(\lambda+1)$. Sparsity denotes the proportion of zero in estimation. Results are summarized from 1,000 replications.

cluster center of $\hat{\beta}_k$ and GDF is the generalized degrees of freedom estimated according to Ye (1998), where purturbations are generated independently from $\mathcal{N}(0, 0.01)$. The cluster centroids are then used as the estimates of the group-level parameters.

Table 2 summarizes the simulation results for linear model where the errors are generated independently from $\mathcal{N}(0, 1)$. Similar to simulation 1, FLARCC gives the smallest MSE for heterogeneous covariates, $\boldsymbol{\beta}_1$ to $\boldsymbol{\beta}_4$, among all three models, and has comparable MSE as the homogeneous model for homogeneous covariates, $\boldsymbol{\beta}_5$ to $\boldsymbol{\beta}_8$. More interestingly, when K is large, BIC does not provide satisfactory model selection, erring on the lack of parsimony, while EBIC encourages stronger fusion and improves the ability to detect equal coefficient pairs in all eight covariates, regardless of their levels of heterogeneity. In addition, EBIC improves the sparsity detection among both the important and nonimportant covariates. It is interesting to note that the choice between BIC and EBIC does not alter solution paths, but only model selection. FLARCC with scaling weight parameter $s = 1$ has the best clustering performance among all compared methods. The difference between the choices of $s = 0$ and $s = 1$ is substantial in simulation 2, in contrast to the results from simulation 1. This indicates that the covariate-specific weights for heterogeneity $\{\nu_j\}_{j=1}^p$ are very effective to improve the performance of the proposed fusion learning, especially when K and p are large. Sensitivity and specificity of the two-step K-means clustering method are higher than those of FLARCC with $s = 0$, but lower than those of FLARCC with $s = 1$. The two-step K-means has larger MSE than FLARCC because it does not consider the correlation between covariates. More importantly, the K-means clustering is a model-free method, so the results obtained from this method cannot be plugged in back to the model for prediction. As suggested from the empirical results of both simulation experiments, EBIC tends to provide better model selection for FLARCC than the conventional BIC.

6. Application: Clustering of Cohort Effects

In this data analysis example, we like to demonstrate the use of our method to derive clusters of cohort effects. Here we consider the Panel Study of Income Dynamics (PSID), which is a household survey study following thousands of families across different states in the US. PSID collects information of employment, income, health, and so on. In this data analysis, we focus on the association of household income with body mass index (BMI) on school-aged children between age of 11 and 19, adjusted for age, gender and birth weight. Data of 1880 children were gathered from four census regions (1-Northeast, 2-Midwest, 3-South and 4-West), as defined by U.S. Census Bureau (2015). All variables are standardized before model fitting. We are interested in investigating if regional heterogeneity exists and if the effects of interest differ across regions with region-dependent patterns.

Table 3 shows the results of coefficient estimates obtained from three different models: (A) homogeneous model ($\lambda = \lambda_{Fuse}$), coefficients estimated by combining data sets from four regions, (B) heterogeneous model ($\lambda = 0$), coefficients estimated separately by region-specific data, and (C) FLARCC ($\lambda = \lambda_{EBIC}$). Model A suggests that age and birth weight are positively associated with BMI for the subjects, but income was negatively associated with BMI. The estimates from Model B suggest that heterogeneous coefficient patterns exist among these associations since conclusions differ between regions. Model C appears more sensible when regression coefficients are heterogeneous across these regions. Since K and p are small in this data application, we apply FLARCC with $s = 0$ on the PSID data, assuming effects of income, age, gender and birth weight are heterogeneous across regions, and set sparsity parameter $\alpha = 1$ for variable selection.

Region	n	Intercept $\boldsymbol{\beta}_0$	Age $\boldsymbol{\beta}_1$	Sex $\boldsymbol{\beta}_2$	Birth Wt. $\boldsymbol{\beta}_3$	Income $\boldsymbol{\beta}_4$
(A) Homogeneous model – combine all regions						
All regions	1880	0.000	0.206	0.016	0.063	-0.096
(B) Heterogeneous model – region specific estimates						
1-Northeast	239	-0.133	0.228	-0.079	-0.003	0.004
2-Midwest	493	-0.054	0.229	0.017	0.124	-0.132
3-South	805	0.128	0.158	0.095	0.068	-0.071
4-West	343	-0.155	0.236	-0.083	0.057	-0.074
(C) Fused model using FLARCC						
1-Northeast	239	-0.093	0.201	-0.036	0.000	0.000
2-Midwest	493	-0.093	0.201	0.000	0.021	-0.047
3-South	805	0.075	0.201	0.000	0.021	-0.047
4-West	343	-0.093	0.201	-0.036	0.021	-0.047

Table 3: Coefficient estimates of the homogeneous model ($\lambda = \lambda_{Fuse}$), the heterogeneous model ($\lambda = 0$) and the fused model using FLARCC with λ selected by EBIC, respectively.

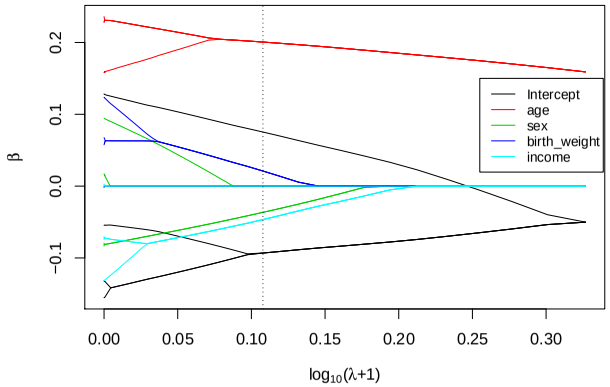

Figure 2: FLARCC solution paths of all covariates over the transformed tuning parameter $\tilde{\lambda} = \log_{10}(\lambda+1)$, with $s = 0$. The vertical dotted line denotes the optimal tuning parameter value $\tilde{\lambda}_{EBIC}$.

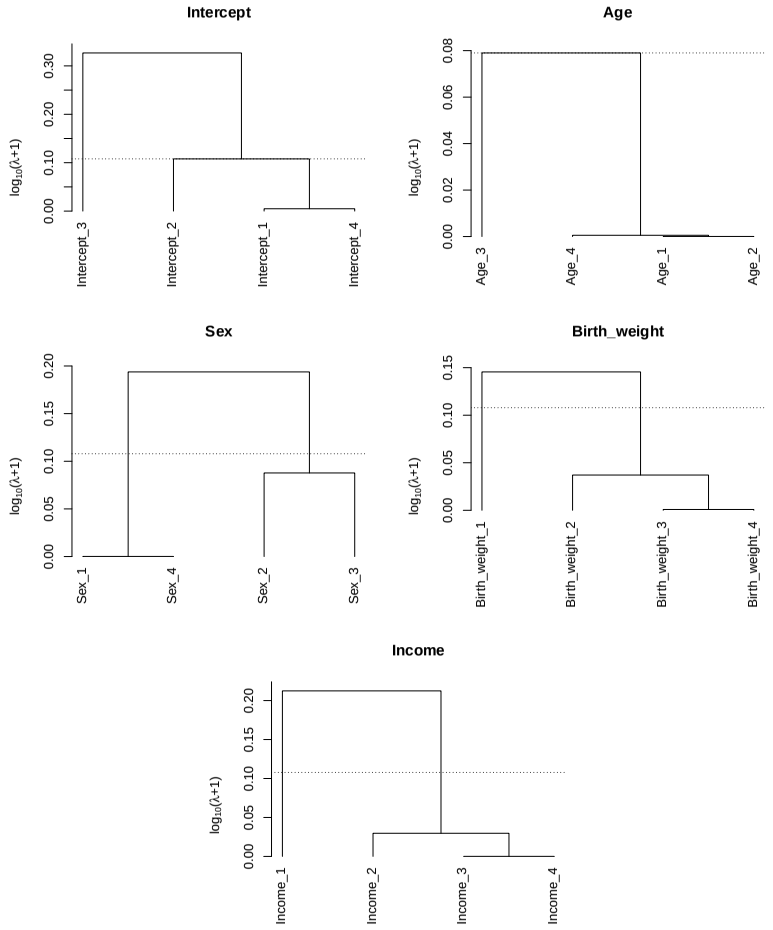

Figure 3: *Fusograms* of all covariates based on FLARCC solution paths. The horizontal dotted lines denote the optimal regression coefficient clustering determined by EBIC.

Based on the results from FLARCC, the estimated mean of standardized BMI in the South is 0.168 higher (or 0.97 higher in original scale of BMI) than that of the other three regions, which share the same mean. The effects of age are consistent across four regions. The effects of gender are classified into two clusters. The mean of standardized BMI of females is 0.036 lower (or 0.42 lower in original scale) than that of males in the Northeast and the West, but males and females have the same mean BMI in the Midwest and the South. Standardized BMI increases by 0.021 for every standard deviation increase of birth weight (or BMI increases by 0.19 for every unit increase of birth weight) in all regions except the Northeast. Similarly, standardized BMI decreases by 0.047 for every standard deviation increase of log income (or BMI decreases by 0.27 for every unit increase of income) in all regions except the Northeast where BMI is not affected by income. The leave-one-out mean squared prediction errors for model A, B and C are 0.953, 0.945 and 0.950, respectively. The differences between the prediction errors are small because of the relatively small effect sizes of the heterogeneous covariates identified by FLARCC, i.e., sex, birth weight and income. The most significant covariate, age, is homogeneous thus it does not differentiate the prediction power among the three models. Solution paths and *fusograms* of all covariates are shown in Figure 2 and Figure 3, respectively, for illustration. In summary, FLARCC ensures parsimony where necessary to maximize the prediction power of the final model; and it provides more informative interpretation and better visualization than the other two traditional models.

7. Concluding Remarks

The proposed method brings a new perspective to model fitting when combining multiple data sets from different sources is of primary interest. As data volumes and data sources grow fast, more and more opportunities and demands emerge in practice to borrow strengths of combined data sets. In such case, traditional methods are challenged by the complex data structures and do not provide desirable treatments and meaningful interpretations to data heterogeneity, especially when the number of data sets is very large. FLARCC allows the flexibility to explore the heterogeneity pattern of parameters among large number of data sets by tuning the shrinkage parameter.

When K and p are small, weights $\{\nu_j\}_{j=1}^p$ do not contribute to much difference in terms of clustering and estimation. However, since only one tuning parameter is used to regularize the fusion of all covariates, when both K and p are large, we suggest letting $s > 0$ to allow covariate-specific weights adapting to the heterogeneousness of coefficients from individual covariates to achieve better results. In addition, the estimation consistency of rank estimator is a critical component needed to determine adjacent pairs. The current consistency is established under the case of K being fixed, and the validity of its property is unknown when K increases along the total sample size.

FLARCC can be applied to various scientific problems, such as the detection of outlying studies by singling out outlying coefficients; it can also be applied to the clustering of patient trajectories by viewing the time series data of patients as individual studies. Essentially, all study that are interested in the group-specific effects may be analyzed from the perspective of parameter fusion using the proposed method.

Acknowledgments

Appendix A. Theorem Proofs

Proof of Theorem 1: The proof of Theorem 1 closely follows arguments given in Zou (2006). Without loss of generality, we assume $n_1 = \cdots = n_K = n$ and $N = Kn$. As K is fixed, $n \to \infty$ implies $N \to \infty$ in the same order. We assume the following regularity conditions:

(i) The Fisher information matrix is finite and positive definite,

$$\boldsymbol{I}(\boldsymbol{\theta}^*) = E\left[\phi''\left(\boldsymbol{X}^\top\boldsymbol{\theta}^*\right)\boldsymbol{X}\boldsymbol{X}^\top\right].$$

Here, $\boldsymbol{\theta}^*_{(Kp\times 1)}$ is the true parameters, $\boldsymbol{X}_{(N\times Kp)}$ is the design matrix corresponding to $\boldsymbol{\theta}$ and ϕ is the link function (i.e., $\phi' = h^{-1}$) defined in the following optimization problem

$$\hat{\boldsymbol{\theta}}^{\boldsymbol{W}} = \underset{\boldsymbol{\theta}}{\operatorname{argmin}}\left\{-\frac{1}{K}\sum_{k=1}^{K}\frac{1}{n_k}\sum_{i=1}^{n_k}\left(Y_k^{(i)}\boldsymbol{X}_k^{(i)\top}\boldsymbol{\theta}(\lambda) - \phi\left(\boldsymbol{X}_k^{(i)\top}\boldsymbol{\theta}(\lambda)\right)\right) + P_{\lambda,\alpha}(\boldsymbol{\theta})\right\}$$

with $P_{\lambda,\alpha}(\boldsymbol{\theta})$ as defined in (4), and $\hat{\boldsymbol{\theta}}^{\boldsymbol{W}}$ is the estimator with true ordering $\boldsymbol{W}$ given.

(ii) There is a sufficiently large open set $\mathcal{O}$ that contains $\boldsymbol{\theta}^*$ such that $\forall\boldsymbol{\theta}\in\mathcal{O}$,

$$|\phi'''(\boldsymbol{X}^\top\boldsymbol{\theta})| \le M(\boldsymbol{X}^\top) < \infty, \text{ and}$$
$$E\left[M(\boldsymbol{X})|x_j x_k x_l|\right] < \infty$$

for a suitable function M and all $1 \le j,k,l \le Kp$.

First we prove asymptotic normality. For $\forall s \ge 0$ and $r > 0$, let $\boldsymbol{\theta} = \boldsymbol{\theta}^* + \boldsymbol{u}/\sqrt{N}$. Define

$$\Gamma_N(\boldsymbol{u}) = -\sum_{k=1}^{K}\sum_{i=1}^{n}\left(Y_k^{(i)}\boldsymbol{X}_k^{(i)\top}\left(\boldsymbol{\theta}^* + \frac{\boldsymbol{u}}{\sqrt{N}}\right) - \phi\left(\boldsymbol{X}_k^{(i)\top}\left(\boldsymbol{\theta}^* + \frac{\boldsymbol{u}}{\sqrt{N}}\right)\right)\right)$$
$$+\lambda_N\sum_{j=1}^{p}\sum_{k=1}^{K}\hat{\omega}_{j,k}\left|\theta^*_{j,k} + \frac{u_{j,k}}{\sqrt{N}}\right|$$

where $\hat{\omega}_{j,k}$ is specified in (6). Let $\hat{\boldsymbol{u}}^{(N)} = \arg\min_{\boldsymbol{u}}\Gamma_N(\boldsymbol{u})$; then $\hat{\boldsymbol{u}}^{(N)} = \sqrt{N}(\hat{\boldsymbol{\theta}}^{\boldsymbol{W}} - \boldsymbol{\theta}^*)$. By Taylor expansion, we have $\Gamma_N(\boldsymbol{u}) - \Gamma_N(\boldsymbol{0}) = H^{(N)}(\boldsymbol{u})$, where

$$H^{(N)}(\boldsymbol{u}) \equiv A_1^{(N)} + A_2^{(N)} + A_3^{(N)} + A_4^{(N)},$$

with

$$A_1^{(N)} = -\sum_{k=1}^{K}\sum_{i=1}^{n}\left[Y_k^{(i)} - \phi'(\boldsymbol{X}_k^{(i)\top}\boldsymbol{\theta}^*)\right]\frac{\boldsymbol{X}_k^{(i)\top}\boldsymbol{u}}{\sqrt{N}},$$
$$A_2^{(N)} = \sum_{k=1}^{K}\sum_{i=1}^{n}\frac{1}{2}\phi''(\boldsymbol{X}_k^{(i)\top}\boldsymbol{\theta}^*)\boldsymbol{u}^\top\frac{\boldsymbol{X}_k^{(i)}\boldsymbol{X}_k^{(i)\top}}{\sqrt{N}}\boldsymbol{u},$$
$$A_3^{(N)} = \frac{\lambda_N}{\sqrt{N}}\sum_{j=1}^{p}\sum_{k=1}^{K}\hat{\omega}_{j,k}\sqrt{N}\left(\left|\theta_{j,k}^* + \frac{u_{j,k}}{\sqrt{N}}\right| - \left|\theta_{j,k}^*\right|\right),$$
$$\text{and } A_4^{(N)} = N^{-3/2}\sum_{k=1}^{K}\sum_{i=1}^{n}\frac{1}{6}\phi'''\left(\boldsymbol{X}_k^{(i)\top}\tilde{\boldsymbol{\theta}}_*\right)\left(\boldsymbol{X}_k^{(i)\top}\boldsymbol{u}\right)^3,$$

where $\tilde{\boldsymbol{\theta}}_*$ is between $\boldsymbol{\theta}^*$ and $\boldsymbol{\theta}^* + \boldsymbol{u}/\sqrt{N}$. The asymptotic limits of $A_1^{(N)}$, $A_2^{(N)}$ and $A_4^{(N)}$ is exactly the same as those in the proof of Theorem 4 in Zou (2006). It suffice to show that $A_3^{(N)}$ has the same asymptotic limit. If $\theta_{j,k}^* \neq 0$, $\hat{\omega}_{j,1} \to_p \alpha|\theta_{j,1}^*|^{-r}$, $\hat{\omega}_{j,k} \to_p |\sum_{k'=2}^{K}\theta_{j,k'}^*|^{-s}|\theta_{j,k}^*|^{-r}$ for $k = 2,\ldots,K$, and $\sqrt{N}\left(\left|\theta_{j,k}^* + \frac{u_{j,k}}{\sqrt{N}}\right| - \left|\theta_{j,k}^*\right|\right) \to u_{j,k}\operatorname{sgn}(\theta_{j,k}^*)$. Thus by Slutsky's theorem, $A_3^{(N)} \to 0$. If $\theta_{j,k}^* = 0$, for $k = 1$, since $\sqrt{N}\hat{\theta}_{j,1} = O_p(1)$, $\frac{\lambda_N}{\sqrt{N}}N^{r-2}\alpha(|\sqrt{N}\hat{\theta}_{j,1}|)^{-r} \to \infty$; for $k = 2,\ldots,K$, if $\sum_{k'=2}^{K}\theta_{j,k'}^* = 0$ (i.e., homogeneous), $\sqrt{N}\sum_{k'=2}^{K}\hat{\theta}_{j,k'} = O_p(1)$, thus $\frac{\lambda_N}{\sqrt{N}}N^{\frac{s+r}{2}}(|\sqrt{N}\sum_{k'=2}^{K}\hat{\theta}_{j,k'}|)^{-s}(|\sqrt{N}\hat{\theta}_{j,k}|)^{-r} \to \infty$; similarly, if $\sum_{k'=2}^{K}\theta_{j,k'}^* \neq 0$ (i.e., heterogeneous), $\sum_{k'=2}^{K}\hat{\theta}_{j,k'} \to_p \sum_{k'=2}^{K}\theta_{j,k'}^*$, $\frac{\lambda_N}{\sqrt{N}}\hat{\omega}_{j,k} \to \infty$ still holds. And since $\sqrt{N}\left(\left|\theta_{j,k}^* + \frac{u_{j,k}}{\sqrt{N}}\right| - \left|\theta_{j,k}^*\right|\right) \to |u_{j,k}|$, we have the following result summary:

$$\frac{\lambda_N}{\sqrt{N}}\hat{\omega}_{j,k}\sqrt{N}\left(\left|\theta_{j,k}^* + \frac{u_{j,k}}{\sqrt{N}}\right| - \left|\theta_{j,k}^*\right|\right) \to_p \begin{cases} 0 & \text{if } \theta_{j,k}^* \neq 0 \\ 0 & \text{if } \theta_{j,k}^* = 0 \text{ and } u_{j,k} = 0 \\ \infty & \text{if } \theta_{j,k}^* = 0 \text{ and } u_{j,k} \neq 0. \end{cases}$$

Following same arguments in Zou (2006)'s proof of Theorem 4, we have $\hat{\boldsymbol{u}}_{\mathcal{A}}^{(N)} \to_d \mathcal{N}(0, \boldsymbol{I}_{11}^{-1})$ and $\hat{\boldsymbol{u}}_{\mathcal{A}^c}^{(N)} \to_d \boldsymbol{0}$. The proof of the consistency part is similar and thus omitted. ■

Proof of Lemma 2: The estimated ordering $\hat{\boldsymbol{U}}_j$ of $\boldsymbol{\beta}_{j,\bullet}^*$ is only determined by the differences between distinct parameter groups within $\boldsymbol{\beta}_{j,\bullet}^*$. First note that for any $0 < \epsilon < 1$, if two parameters $\beta_{j,k}^*$ and $\beta_{j,k'}^*$ are in the same parameter group (i.e., $\beta_{j,k}^* = \beta_{j,k'}^*$), assigning arbitrary ordering between them will not affect the estimated ordering of the parameters between groups, because the ordering within the same parameter group is exchangeable. On the other hand, when two parameters $\beta_{j,k}^*$ and $\beta_{j,k'}^*$ are from different parameter groups,

without loss of generality, let $\beta_{j,k}^* > \beta_{j,k'}^*$, the probability of estimating a wrong ordering

$$\begin{aligned} P\left(\mathbf{1}\{\hat{\beta}_{j,k'} \geq \hat{\beta}_{j,k}\} > \epsilon\right) &= P\left(\hat{\beta}_{j,k'} \geq \hat{\beta}_{j,k}\right) \\ &= P\left(\hat{\beta}_{j,k'} - \hat{\beta}_{j,k} + \beta_{j,k}^* - \beta_{j,k'}^* \geq \beta_{j,k}^* - \beta_{j,k'}^*\right) \\ &\leq P\left(|\hat{\beta}_{j,k'} - \beta_{j,k'}^*| + |\hat{\beta}_{j,k} - \beta_{j,k}^*| > 0\right) \\ &= 1 - P\left(\hat{\beta}_{j,k'} = \beta_{j,k'}^*\right)P\left(\hat{\beta}_{j,k} = \beta_{j,k}^*\right) \to 0 \end{aligned}$$

as $n \to \infty$ since $\hat{\beta}_{j,k'}$ and $\hat{\beta}_{j,k}$ are independent and consistent estimators. Similarly, the consistency of the estimated ordering $\hat{\boldsymbol{V}}_j$ of the absolute values in vector $\boldsymbol{\beta}_{j,\bullet}^*$ can be derived by taking the square of the absolute values and following the same argument as for $\hat{\boldsymbol{U}}_j$. ■

Proof of Theorem 3: Here we assume the same regularity condition as in Theorem 1. To complete this proof, we first define the event $\mathcal{W}$ when the orderings of all p covariates are correctly assigned as

$$\mathcal{W} = \bigcap_{j=1}^{p}\left(\{\hat{\boldsymbol{U}}_j = \boldsymbol{U}_j\} \cap \{\hat{\boldsymbol{V}}_j = \boldsymbol{V}_j\}\right).$$

Let $\hat{\boldsymbol{\theta}}^{\hat{\boldsymbol{W}}}$ be $\hat{\boldsymbol{\theta}}_{\mathcal{W}}$ when $\mathcal{W}$ occurs; otherwise, denote it as $\hat{\boldsymbol{\theta}}_{\mathcal{W}^c}$. Then, the estimator can be rewritten as

$$\hat{\boldsymbol{\theta}}^{\hat{\boldsymbol{W}}} = \hat{\boldsymbol{\theta}}_{\mathcal{W}}\mathbf{1}\{\mathcal{W}\} + \hat{\boldsymbol{\theta}}_{\mathcal{W}^c}\mathbf{1}\{\mathcal{W}^c\}$$

and therefore

$$\sqrt{N}\left(\hat{\boldsymbol{\theta}}^{\hat{\boldsymbol{W}}} - \boldsymbol{\theta}^*\right) = \sqrt{N}\left(\hat{\boldsymbol{\theta}}_{\mathcal{W}} - \boldsymbol{\theta}^*\right)\mathbf{1}\{\mathcal{W}\} + \sqrt{N}\left(\hat{\boldsymbol{\theta}}_{\mathcal{W}^c} - \boldsymbol{\theta}^*\right)\mathbf{1}\{\mathcal{W}^c\}. \tag{9}$$

By Theorem 1, we have $\sqrt{N}\left(\hat{\boldsymbol{\theta}}_{\mathcal{W}} - \boldsymbol{\theta}^*\right) = O(1)$ and $\sqrt{N}\left(\hat{\boldsymbol{\theta}}_{\mathcal{W}^c} - \boldsymbol{\theta}^*\right) = O(1)$ as $n \to \infty$. By Lemma 2, we have $P(\mathcal{W}) \to 1$ and $P(\mathcal{W}^c) \to 0$ as $n \to \infty$. Therefore, by Slutsky's Theorem, (9) converge to the same distribution as $\sqrt{N}\left(\hat{\boldsymbol{\theta}}_{\mathcal{W}} - \boldsymbol{\theta}^*\right)$. Similarly, by results from Theorem 1 and Lemma 2, we have selection consistency

$$P(\hat{\mathcal{A}}^{\hat{\boldsymbol{W}}} = \mathcal{A}) = P(\hat{\mathcal{A}}^{\hat{\boldsymbol{W}}} = \mathcal{A}|\mathcal{W})P(\mathcal{W}) + P(\hat{\mathcal{A}}^{\hat{\boldsymbol{W}}} = \mathcal{A}|\mathcal{W}^c)P(\mathcal{W}^c) \to 1$$

as $n \to \infty$. This completes the proof of the Theorem 3. ■

Appendix B. Performance with Distorted Parameter Ordering

Under the same setting as simulation experiment 1 in Section 5.1 with $\alpha = 0$ and $s = 0$, we conduct a sensitivity analysis to evaluate the performance of FLARCC when parameter ordering is incorrectly specified. Specifically, we report results of sensitivity, specificity and MSE for the linear regression model when the coefficient ordering is determined from the initial estimate with distortion through an added disturbance ϵ, $\hat{\boldsymbol{\beta}} + \epsilon$, where $\hat{\boldsymbol{\beta}}$ from (1) and $\epsilon \sim \mathcal{N}(0, v^2)$. As v^2 increases, the percent of order switching in initial estimates increases. Sensitivity, specificity and MSE in relation to the percentage of wrongly ordered

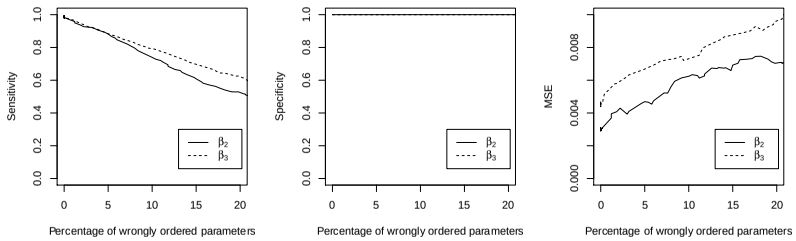

Figure 4: Clustering sensitivity and mean squared error of two heterogeneous slope parameters $\boldsymbol{\beta}_2$ and $\boldsymbol{\beta}_3$ based on FLARCC with λ selected by EBIC, as the percent of distorted ordering increases. Results are summarized from 100 replications.

parameters are displayed in Figure 4 for the two heterogeneous effects $\boldsymbol{\beta}_2$ and $\boldsymbol{\beta}_3$, and the homogeneous parameter $\boldsymbol{\beta}_1$ is not included in the comparison because of no effect from the distortion on its performance. As the percentage of wrongly ordered parameters increases, as expected, sensitivity becomes lower and MSE becomes larger. However, specificity remains unaffected. When the distortion of ordering is mild ($\leq 10\%$), the performance of FLARCC appears satisfactory in this simulation setting.

Abstract

The Layer-wise Relevance Propagation (LRP) algorithm explains a classifier's prediction specific to a given data point by attributing *relevance scores* to important components of the input by using the topology of the learned model itself. With the LRP Toolbox we provide platform-agnostic implementations for explaining the predictions of pre-trained state of the art Caffe networks and stand-alone implementations for fully connected Neural Network models. The implementations for Matlab and python shall serve as a playing field to familiarize oneself with the LRP algorithm and are implemented with readability and transparency in mind. Models and data can be imported and exported using raw text formats, Matlab's `.mat` files and the `.npy` format for numpy or plain text.

Keywords: layer-wise relevance propagation, explaining classifiers, deep learning, artificial neural networks, computer vision

1. Introduction

Classification of images has become a key ingredient in many computer vision applications, with nonlinear methods such as Deep Neural Networks (DNNs) being the gold standard in the fields of vision (Krizhevsky et al., 2012; Ciresan et al., 2012b; Szegedy et al., 2014; Ciresan et al., 2012a), natural language processing (Collobert et al., 2011; Socher et al., 2013), speech recognition (Yu and Deng, 2014) or physics (Montavon et al., 2013); see also (Montavon et al., 2012). Although performing incredibly well, they lack transparency. In the sciences, however, understanding a learning machine in order to gain scientific insight on the problem analysed is often as important as record prediction performance. This is also one of the reasons for the popularity of linear modeling as interpretation is straight forward. In this sense DNNs so far held a disadvantage in practice over simpler but interpretable models. Especially DNNs act as black boxes due to their multilayer nonlinear structure. However, interest in gaining insight into the decision process of nonlinear methods has peaked recently. Several works have been using sensitivity maps (Baehrens et al., 2010; Rasmussen et al., 2012) for visualization of classifier predictions which were based on using partial derivatives at the prediction point $\boldsymbol{x}$.

For DNNs promising approaches for opening the black box are deconvolution networks (Zeiler and Fergus, 2014) highlighting activated input patterns for object detected during the forward pass of a convolutional neural network, saliency maps (Simonyan et al., 2013) visualizing local sensitivities at the input point and LRP (Bach et al., 2015) producing explanatory input patterns that indicate evidence for or against a prediction target of choice in given data. The latter – for which this toolbox is provided and (Samek et al., 2015) have measured and verified meaningfulnes of the computed heatmaps – takes a pre-trained model and an evaluation data point and explains the classifier's decision, e.g. LRP decomposes the decision function such that for each input dimension d a *relevance score* $R_d^{(1)}$ is computed, which indicates that the state of x_d speaks for the presence of the prediction target if $R_d^{(1)} > 0$ and against it if $R_d^{(1)} < 0$. By allowing both signs for $R_d^{(1)}$ also class background information can be modelled in a natural manner.

To this end, the model output $f(\boldsymbol{x})$ is backwards-propagated through the model to the input layer as *relevance* R, by taking into account the model's reaction to the input $\boldsymbol{x}$ in all its intermediate representations at all computational layers l. Due to the relevance conservation principle as a constraint to LRP (Bach et al., 2015), no relevance is lost or gained in between layers of computation, e.g.

$$\sum_i R_i^{(l)} = \sum_j R_j^{(l+1)} \text{ and thus } \sum_d R_d^{(1)} = f(\boldsymbol{x}).$$

Note that to this end, the propagated relevances are always normalized. The relevance values $R_d^{(1)}$ can then be visualized as a heatmap, providing valuable insight to the classifier's decision process. For a theoretical view on LRP we refer the reader to Montavon et al. (2015)

2. Capabilities of the LRP Toolbox for Artificial Neural Networks

The LRP Toolbox provides platform-independant stand-alone implementations of the LRP algorithm for python and Matlab, as well as adapted `.cpp` modules to support LRP for the Caffe deep learning framework (Jia et al., 2014) and operates on pre-trained neural network models. The functionality of the framework and a demo thereof is accessible via command line or an IDE of choice for Matlab, python and Caffe (C++). The Caffe version is based on the caffe-master branched on 3rd October 2015. The latest official release is available from `http://www.heatmapping.org`.

We provide three implementations due to the different strengths and advantages of the three implementations. Caffe is an established toolbox for neural networks, written in C++, and has the big advantage that it comes with many pretrained neural networks in the Caffe Model Zoo. The Caffe version works out of the box with the BVLC reference, the

GoogLeNet model and the VGG CNN models from Chatfield et al. (2014). On the other hand, many scientists are unfamiliar with programming C++ interfaces, thus creating a barrier for experimentation when one is interested in modifying and trying out different LRP implementations. Note that LRP is a principle which permits multiple solutions. The python and Matlab implementations allow an easier access and for easy modification of LRP rules, in particular because python and Matlab are popular among machine learners and are taught in many undergrad university curricula. Furthermore the python and Matlab implementations require less external libraries which is practical in restricted setups where the user does not have full control over the installed packages. These trade-offs lead us to the choice of implementing LRP in three ways.

2.1 Platforms and Requirements

The python and Matlab implementations are available for systems running Linux, Windows and OSX due to the platform agnostic nature of python and Matlab. Caffe runs on Linux and OSX, however Caffe ports for Windows became available very recently on github (e.g. `https://github.com/happynear/caffe-windows`). Known and successfully tested minimum package requirements are available in the toolbox manual.

2.2 User Interface

The example implementations of the LRP pipeline can be executed and modified with the provided files `matlab/lrp_demo.m` and `python/lrp_demo.py` by navigating to the respective folders and executing the scripts using the chosen language's interpreter, e.g. for unix-based systems

```
cd <toolbox_location>/matlab
matlab -nodesktop -r lrp_demo
```

or

```
cd <toolbox_location>/python
python lrp_demo.py
```

The C++-based Caffe implementation of LRP uses a configuration file with its settings being explained in the manual. It takes as further input a text file which contains in each line the path to one image and an integer denoting the class for which the heatmap is to be computed. The third input is a path prefix.

```
cd <toolbox_location>/caffe-master-lrp/demonstrator
./lrp_demo ./config_sequential.txt ./testfilelist.txt ./
```

will then compute heatmaps for the images listed in `./testfilelist.txt`.

2.3 Documentation and Examples

The user manual guides through the installation and use of the toolbox. It also explains the LRP algorithm in detail and instructs on how to compute and interpret the results.

2.4 Developer Access, Licensing and Availability

The source code is provided under FreeBSD (2-Clause) License and is available in a separate archive for each released version. The latest official release of the toolbox code is available from `http://heatmapping.org`. More recent and work-in-progress versions can be found at `https://github.com/sebastian-lapuschkin/lrp_toolbox`.

3. Conclusion

The presented LRP package provides a simple and easy to use implementation that allows a user to explore LRP in Matlab and python or run more involved applications within the Caffe framework. We would like to emphasize that the user can readily take an existing network to apply the LRP procedure. In other words also DNNs from past projects could be retrospectively explained by LRP. Furthermore note that the usage of LRP is not limited to DNNs, in fact, as shown in (Bach et al., 2015) also kernel methods and other learning machines, e.g. using Bag of Words representations can yield heatmaps through LRP. Future work will use the LRP framework and software package in the sciences and for general applications that require explanation.

Equivalence of Graphical Lasso and Thresholding for Sparse Graphs

Somayeh Sojoudi, SOJOUDI@BERKELEY.EDU
Department of Electrical Engineering and Computer Sciences
University of California, Berkeley

Editor: Michael Mahoney

Abstract

This paper is concerned with the problem of finding a sparse graph capturing the conditional dependence between the entries of a Gaussian random vector, where the only available information is a sample correlation matrix. A popular approach to address this problem is the graphical lasso technique, which employs a sparsity-promoting regularization term. This paper derives a simple condition under which the computationally-expensive graphical lasso behaves the same as the simple heuristic method of thresholding. This condition depends only on the solution of graphical lasso and makes no direct use of the sample correlation matrix or the regularization coefficient. It is proved that this condition is always satisfied if the solution of graphical lasso is close to its first-order Taylor approximation or equivalently the regularization term is relatively large. This condition is tested on several random problems, and it is shown that graphical lasso and the thresholding method lead to highly similar results in the case where a sparse graph is sought. We also conduct two case studies on brain connectivity networks of twenty subjects based on fMRI data and the topology identification of electrical circuits to support the findings of this work on the similarity of graphical lasso and thresholding.

Keywords: Graphical Lasso, Graphical Models, Sparse Graphs, Brain Connectivity Networks, Electrical Circuits

1. Introduction

In recent years, there has been a growing interest in developing techniques for estimating sparse undirected graphical models (Banerjee et al., 2008; Bruckstein et al., 2009; Chandrasekaran et al., 2010; Goldstein and Osher, 2009; Jalali et al., 2011; Schmidt et al., 2007). Finding sparse solutions have become essential to many applications, including signal processing, pattern recognition, and data mining. Many applications use L_1-regularized models such as the Lasso (Tibshirani, 1996). L_1 regularization aims to find sparse solutions, which is especially useful for high-dimensional problems with a large number of features (Bühlmann and Van De Geer, 2011; Fan and Lv, 2010; Meinshausen and Yu, 2009; Richtárik and Takáč, 2012; Wright et al., 2009; Zhang and Huang, 2008). Although Lasso-type algorithms are shown to be effective in recovering sparse solutions, they are computationally expensive for large-scale problems. In this work, we derive a simple condition under which the computationally-expensive graphical lasso behaves the same as the simple heuristic method of thresholding.

Consider a random vector $\mathbf{x} = (x_1, x_2, ..., x_n)$ with a multivariate normal distribution. Let $\Sigma_* \in \mathbb{S}^n_+$ denote the correlation matrix associated with the vector $\mathbf{x}$. The inverse of the correlation matrix can be used to determine the conditional independence between the random variables $x_1, x_2, ..., x_n$. In particular, if the $(i,j)^{\text{th}}$ entry of Σ_*^{-1} is zero, then x_i and x_j are conditionally independent. The graph $\mathcal{G}(\Sigma_*^{-1})$ (i.e., the sparsity graph of Σ_*^{-1}) represents a graphical model capturing the conditional independence between the elements of $\mathbf{x}$. Assume that $\mathcal{G}(\Sigma_*^{-1})$ is a sparse graph. Finding this graph is nontrivial in practice because the exact correlation matrix Σ_* is rarely known. More precisely, $\mathcal{G}(\Sigma_*^{-1})$ should be constructed from a given sample correlation matrix as opposed to Σ_*. Let Σ denote an arbitrary $n \times n$ positive semidefinite matrix, which is provided as an estimate of Σ_*. In this paper, we do not impose any assumption on the error $\|\Sigma - \Sigma_*\|$. Consider the convex optimization problem

$$\underset{S \in \mathbb{S}^n_+}{\text{minimize}} \quad -\log\det(S) + \text{trace}(\Sigma S) \tag{1}$$

where $\mathbb{S}^n_+$ denotes the set of $n \times n$ positive semidefinite matrices. It is easy to verify that the optimal solution of the above problem is $S^{\text{opt}} = \Sigma^{-1}$. Hence, S^{opt} aims to estimate Σ_*^{-1}. On the other hand, although the inverse of Σ_* is assumed to be a sparse graph, a small perturbation of Σ_* would make its inverse a dense graph. This implies that the sparsity graph of S^{opt}, denoted as $\mathcal{G}(S^{\text{opt}})$, may not resemble the graphical model $\mathcal{G}(\Sigma_*^{-1})$ in general. Hence, the optimization problem (1) needs to be modified to indirectly enforce some sparsity on its solution. To this end, consider the problem

$$\underset{S \in \mathbb{S}^n_+}{\text{minimize}} \quad -\log\det(S) + \text{trace}(\Sigma S) + \lambda\|S\|_1 \tag{2}$$

where $\lambda \in \mathbb{R}_+$ is a regularization parameter and $\|S\|_1$ is defined as $\sum_{i=1}^n \sum_{j=1}^n |S_{ij}|$. This problem is referred to as *graphical lasso* (Banerjee et al., 2008; Friedman et al., 2008; Yuan and Lin, 2007). Intuitively, the penalty term $\lambda\|S\|_1$ with a large λ aims to decrease the off-diagonal entries of S in magnitude and enforce most of them to be zero. Henceforth, the notation S^{opt} is used to denote a solution of the graphical lasso instead of the unregularized optimization problem (1). There is a large body of literature suggesting that $\mathcal{G}(S^{\text{opt}})$ is a good estimate of the graphical model $\mathcal{G}(\Sigma_*^{-1})$ for a suitable choice of λ (Banerjee et al., 2008; Danaher et al., 2014; Friedman et al., 2008; Krämer et al., 2009; Liu et al., 2010; Witten et al., 2011; Yuan and Lin, 2007). Note that although graphical lasso is motivated by multivariate normal random variables, its application is beyond this class of random variables and it applies to all problems for which a *sparse* inverse correlation matrix is sought.

Suppose that it is known *a priori* that the true graph $\mathcal{G}(\Sigma_*^{-1})$ has k edges, for some given number k. Assume that the nonzero entries of the upper triangular part of Σ (excluding its diagonal) have different magnitudes (this assumption is satisfied both generically and under an infinitesimal perturbation of the nonzero entries of Σ). Two heuristic methods for finding an approximation of $\mathcal{G}(\Sigma_*^{-1})$ are as follows:

- *Graphical Lasso:* We solve the optimization problem (2) repeatedly for different values of λ until a solution S^{opt} with exactly $2k$ nonzero off-diagonal entries are found. Note

that λ can be updated in the optimization problem using the bisection technique (Theorem 3 in Fattahi and Lavaei (2016) guarantees the existence of an appropriate interval for λ under generic conditions).

- *Thresholding:* Without solving any optimization problem, we simply identify those $2k$ entries of Σ that have the largest magnitudes among all off-diagonal entries of Σ. We then replace the remaining $n^2 - n - 2k$ off-diagonal entries of Σ with zero and denote the resulting matrix as Σ_k. Note that Σ and Σ_k have the same diagonal. Finally, we consider the sparsity graph of Σ_k, namely $\mathcal{G}(\Sigma_k)$, as an estimate of $\mathcal{G}\big(\Sigma_*^{-1}\big)$.

The connection between graphical lasso and the thresholding technique is not well understood and there are only a few studies on this subject. The work Mazumder and Hastie (2012) has recently shown that if the sample covariance matrix is thresholded at λ and its corresponding graph is decomposed into connected components, then the vertex-partition induced by these components is equal to the one induced by the connected components of the estimated graph obtained from graphical lasso for the same λ. The paper Guillot and Rajaratnam (2011) obtains graph conditions that are required for preserving the positive definiteness of the sample correlation matrix after thresholding.

This paper is focused on the investigation of the connection between graphical lasso and thresholding. First, we derive a condition under which the heuristic thresholding method performs very similarly to the computationally-heavy graphical lasso. We then argue that this condition is satisfied as long as λ is large enough. Moreover, we demonstrate in numerical examples that graphical lasso and thresholding lead to the same approximate graph for $\mathcal{G}\big(\Sigma_*^{-1}\big)$. Note that although the condition provided here depends on the solution of graphical lasso, it can be systematically expressed in terms of the sample correlation matrix Σ for certain types of graphs (see the technical report Sojoudi (2016) for the derivation of such conditions for acyclic graphs).

Recently, there has been a significant interest in studying the human brain functional connectivity networks using functional MRI (fMRI) data. Functional connectivity is measured as the temporal coherence or correlation between the activities of disjoint brain areas, where the direct statistical dependence between every two brain regions in the functional network can be obtained using partial correlation. In most fMRI studies, computing partial correlations is a daunting challenge due to the limitation on the number samples available from fMRI scans. Graphical lasso has become popular in the literature for the identification of the direct correlations between the activities of different parts of the brain using a small number of samples (Huang et al., 2010). In this work, we apply graphical lasso and thresholding to the resting-state fMRI data collected from twenty subjects and observe a high degree of similarity between the outcomes of these two techniques for each individual subject. Note that the matrix Σ is not invertible for the fMRI study conducted here. More precisely, this work makes no assumption on the invertibility of the sample correlation matrix Σ (although the true correlation matrix Σ_* needs to be invertible).

In Sojoudi and Doyle (2014), we have developed a new method for generating synthetic data based on sparse electrical circuit models, where certain nodes of each circuit are connected to one another through resistors and capacitors that are subject to thermal noise (to create stochasticity). The main property of this model is that the connectivity of the circuit model can be obtained from the sparsity pattern of the inverse covariance matrix associated with the nodal voltages. In other words, the sparsity pattern of the inverse covariance matrix has the same structure as the adjacency matrix of the circuit network. In this work, we use the above circuit model to verify the high similarity between graphical lasso and the thresholding technique for electrical networks.

This paper is organized as follows. The main results are presented in Section 2. Simulations on random systems are provided in Section 3. Two case studies on fMRI data and electrical circuits are conducted in Sections 4 and 5, respectively. Some concluding remarks are drawn in Section 6.

1.1 Notations and Definitions

Notations: $\mathbb{R}$, $\mathbb{S}^n$, and $\mathbb{S}^n_+$ denote the sets of real numbers, $n \times n$ (real) symmetric matrices, and $n \times n$ positive semidefinite matrices, respectively. $\text{trace}\{M\}$ and $\log\det\{M\}$ denote the trace and the logarithm of the determinant of a matrix M. The (i,j) entry of M is shown as M_{ij}. The notations $|x|$ and $\|M\|_1$ represent the absolute value of a scalar x and the sum of absolute values of a matrix M, respectively. The symbol $\text{sign}(\cdot)$ denotes the sign function (note that $\text{sign}(0) = 0$). The standard basis vectors in $\mathbb{R}^n$ are shown as $e_1, e_2, ..., e_n$. The optimal value of a matrix variable M is denoted as M^{opt}.

Definition 1 *Given a symmetric matrix $S \in \mathbb{S}^n$, the support (sparsity) graph of S is defined as a graph with the vertex set $\mathcal{V} := \{1, 2, ..., n\}$ and the edge set $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$ such that $(i,j) \in \mathcal{V}$ if and only if $S_{ij} \neq 0$, for every two different vertices $i, j \in \mathcal{V}$. The support graph of S captures the sparsity of the matrix S and is denoted as $\mathcal{G}(S)$.*

Definition 2 *Given two graphs $\mathcal{G}$ and $\mathcal{G}'$ with the same vertex set, define $\mathcal{G} - \mathcal{G}'$ as a graph obtained from $\mathcal{G}$ by removing the common edges of $\mathcal{G}$ and $\mathcal{G}'$.*

2. Main Results

In this section, we study the connection between thresholding and graphical lasso. To simplify the presentation, we assume that the nonzero entries of the upper triangular part of Σ (excluding its diagonal) have different magnitudes. Assume also that the number of such nonzero entries is greater than or equal to k (in order to guarantee that the thresholding method is able to obtain a graph with k edges). For notational convenience, we denote the $(i,j)^{\text{th}}$ entry of the matrix $(S^{\text{opt}})^{-1}$ as $(S^{\text{opt}})^{-1}_{ij}$ throughout this work.

2.1 Optimality Conditions

Consider the convex optimization problem (2) together with an optimal solution S^{opt}. First, we aim to obtain necessary and sufficient optimality conditions for graphical lasso.

Lemma 3 *S^{opt} is an optimal solution of graphical lasso if and only if the conditions*

$$(S^{opt})^{-1}_{ij} = \Sigma_{ij} + \lambda \qquad \text{if} \quad i = j \tag{3a}$$
$$(S^{opt})^{-1}_{ij} = \Sigma_{ij} + \lambda \times \text{sign}(S^{opt}_{ij}) \qquad \text{if} \quad S^{opt}_{ij} \neq 0 \tag{3b}$$
$$(S^{opt})^{-1}_{ij} \leq \Sigma_{ij} + \lambda \qquad \text{if} \quad S^{opt}_{ij} = 0 \tag{3c}$$
$$(S^{opt})^{-1}_{ij} \geq \Sigma_{ij} - \lambda \qquad \text{if} \quad S^{opt}_{ij} = 0 \tag{3d}$$

are satisfied for all indices $i, j \in \{1, ..., n\}$.

Proof Due to the convexity of graphical lasso, a locally optimal solution of this problem is a global solution and, therefore, a local perturbation analysis can be used to prove the lemma. To this end, notice that $-\log(0) = +\infty$, $\text{trace}(\Sigma S) \geq 0$, and $\|S\|_1$ is finite only when all entries of S are finite. It follows from these properties that S^{opt} has bounded entries and a nonzero determinant, i.e., $S^{\text{opt}} \succ 0$ (note that a zero determinant for S^{opt} makes the objective function of graphical lasso equal to $+\infty$). This means that $S^{\text{opt}}(\varepsilon; i, j)$ defined as $S^{\text{opt}} + \varepsilon(e_i e_j^T + e_j e_i^T)$ is a feasible solution of the optimization problem (2) for small values of ε (note that the matrix $e_i e_j^T + e_j e_i^T$ is sign indefinite). On the other hand, for every $i, j \in \{1, ..., n\}$, one can write:

$$\begin{aligned} &\big[-\log\det(S^{\text{opt}}) + \text{trace}(\Sigma S^{\text{opt}}) + \lambda\|S^{\text{opt}}\|_1\big] \\ &- \big[-\log\det(S^{\text{opt}}(\varepsilon; i, j)) + \text{trace}(\Sigma S^{\text{opt}}(\varepsilon; i, j)) + \lambda\|S^{\text{opt}}(\varepsilon; i, j)\|_1\big] \\ &\qquad = 2\left((S^{\text{opt}})^{-1}_{ij} - \Sigma_{ij}\right)\varepsilon + 2\left(|S^{\text{opt}}_{ij}| - |S^{\text{opt}}_{ij} + \varepsilon|\right)\lambda + \tau\varepsilon^2 + O(\varepsilon^3) \end{aligned} \tag{4}$$

where τ is a positive number due to the strict convexity of the objective of the optimization problem (2). The above equation is derived based on the Taylor series expansion of $\log\det(\cdot)$ and the fact that the derivative of $\log\det(S)$ with respect to S is equal to S^{-1}. Now, recall that S^{opt} is an optimal solution of (2), whereas $S^{\text{opt}} + \varepsilon(e_i e_j^T + e_j e_i^T)$ is only a feasible solution. Hence, the left side of the equality (4) must always be non-positive for all sufficiently small values of ε. A simple analysis of this equation leads to the conditions provided in (3). ■

Lemma 3 offers a set of necessary and sufficient conditions for the matrix S^{opt} to be an optimal solution of graphical lasso. These optimality conditions can be summarized as:

- The diagonal of $(S^{\text{opt}})^{-1}$ is obtained from that of Σ after a shift by the number λ.
- Each off-diagonal element (i, j) of the matrix $(S^{\text{opt}})^{-1}$ is in the interval $[\Sigma_{ij} - \lambda, \Sigma_{ij} + \lambda]$, and is located at one of the endpoints of this interval if (i, j) is an edge of the graphical model $\mathcal{G}(S^{\text{opt}})$.

2.2 First Condition for Equivalence

In this part, we derive a condition under which graphical lasso and thresholding result in the same estimate graphical model for the random vector $\mathbf{x}$.

Definition 4 *A symmetric matrix $\hat{S}$ is said to be equivalent to S^{opt} if $\hat{S}$ can be obtained from S^{opt} through two operations: (i) permutation of its off-diagonal entries, and (ii) flipping the sign of some of its off-diagonal entries. We use the notation $\hat{S} \sim S^{opt}$ to show this equivalence.*

Theorem 5 *Let k denote the number of edges of the graph $\mathcal{G}(S^{opt})$. Consider the optimization problems*

$$\underset{S \in \mathbb{S}^n}{\text{minimize}} \quad \text{trace}(\Sigma S) + \lambda\|S\|_1 \quad \text{subject to} \quad \text{S} \sim \text{S}^{opt} \tag{5}$$

and

$$\underset{S \in \mathbb{S}^n_+}{\text{minimize}} \quad -\log\det(S) + \text{trace}(\Sigma S) + \lambda\|S\|_1 \quad \text{subject to} \quad \text{S} \sim \text{S}^{opt} \tag{6}$$

If these two problems possess the same solution, then S^{opt} and Σ_k will have the same support graph.

Proof Let $\hat{S}^{\text{opt}}$ denote an optimal solution of the optimization problem (5). Our first goal is to show that $\mathcal{G}(\hat{S}^{\text{opt}}) = \mathcal{G}(\Sigma_k)$. To this end, notice that every feasible solution S of (5) satisfies the equality $\|S\|_1 = \|S^{\text{opt}}\|_1$ due to Definition 4. This implies that the additive term $\lambda\|S\|_1$ can be eliminated from the objective function of the optimization problem (5). On the other hand, the first part of the objective function can be expressed as $\text{trace}(\Sigma S) = \sum_{i,j=1}^{n} (\Sigma_{ij} S_{ij})$. By investigating this sum, it is straightforward to show that the optimization problem (5) has a unique solution $\hat{S}^{\text{opt}}$ that can be obtained as follows:

- First, we focus on the upper triangular part of Σ (excluding the diagonal) and identify those k entries with the largest absolute values, which are denoted as $\Sigma_{i_1 j_1}, \Sigma_{i_2 j_2}, ...,$ $\Sigma_{i_k j_k}$ such that
$$|\Sigma_{i_1 j_1}| > |\Sigma_{i_2 j_2}| > ... > |\Sigma_{i_k j_k}| \tag{7}$$
(note that the nonzero entries of the upper triangular part of Σ have different magnitudes, by assumption).
- Second, we repeat the above procedure on the matrix S^{opt} and identify those k entries with the greatest absolute values, which are denoted as $(p_1, q_1), ..., (p_k, q_k)$ such that
$$|S^{\text{opt}}_{p_1 q_1}| \geq |S^{\text{opt}}_{p_2 q_2}| \geq ... \geq |S^{\text{opt}}_{p_k q_k}| \tag{8}$$
- For every $l \in \{1, ..., k\}$, the $(i_l, j_l)^{\text{th}}$ entry of $\hat{S}^{\text{opt}}$ is equal to -sign$(\Sigma_{i_l j_l})|S^{\text{opt}}_{p_l q_l}|$.

Now, it is easy to verify that

$$\mathcal{G}(\hat{S}^{\text{opt}}) = \mathcal{G}(\Sigma_k) \tag{9}$$

On the other hand, since the objective of the optimization problem (2) is strictly convex, $\mathcal{S}^{\text{opt}}$ is a unique solution of this problem. Hence, due to the fact the feasible set of the problem (6) is contained in that of (2), the optimization problem (6) has the unique solution $\mathcal{S}^{\text{opt}}$. Therefore, the two solutions $\hat{S}^{\text{opt}}$ and $\mathcal{S}^{\text{opt}}$ of the problem (6) are identical. Now, the proof follows from the relation (9). ■

As verified by the author, the condition given in Theorem 5 is satisfied for many numerical examples, leading to the equivalence of thresholding and graphical lasso. The main intuition behind the satisfaction of the above condition is as follows:

- Consider a small number k (or a large number λ) for which the matrix S^{opt} is highly sparse.
- Due to Lemma 3, the diagonal entries of S^{opt} would be relatively much larger than the nonzero off-diagonal entries of S^{opt}.
- Hence, the permutation of the (small) off-diagonal entries of the positive semidefinite S^{opt} would not make the matrix sign indefinite and also has a negligible effect on the $\log\det$ of the matrix.
- Under such circumstances, the condition derived in Theorem 5 would be satisfied (note that (5) is obtained from (6) by dropping the sign-definite condition and the $\log\det$ term).

To strengthen the above argument, an easy-to-check condition will be provided next to guarantee the equivalence of thresholding and graphical lasso.

2.3 Second Condition for Equivalence

Consider the solution S^{opt}. The objective of this part is to derive a condition of equivalence that depends only on the entries of S^{opt}, without using λ or Σ explicitly. Recall that this equivalence does not requite that the matrices S^{opt} and Σ_k be identical (which is unlikely to occur in practice), and is only concerned with the sparsity patterns of these matrices.

Theorem 6 *Let k denote the number of edges of the graph $\mathcal{G}(S^{opt})$. Assume that the inequalities*

$$\text{sign}\left(S^{opt}_{ij}\right) \times \text{sign}\left((S^{opt})^{-1}_{ij}\right) \leq 0 \tag{10a}$$

$$|(S^{opt})^{-1}_{ij}| \geq |(S^{opt})^{-1}_{pq}| \tag{10b}$$

hold for every two pairs (i,j) and (p,q) satisfying

$$(i,j) \in \mathcal{G}(S^{opt}) \tag{11a}$$

$$(p,q) \in \mathcal{G}((S^{opt})^{-1}) - \mathcal{G}(S^{opt}) \tag{11b}$$

Then, graphical lasso and thresholding produce the same graph, i.e., $\mathcal{G}(S^{opt}) = \mathcal{G}(\Sigma_k)$.

Proof Consider two arbitrary pairs (i,j) and (p,q) satisfying (11). It follows from (10) and Lemma 3 that

$$|\Sigma_{ij}| \geq \lambda \tag{12}$$

and that

$$|\Sigma_{ij}| - \lambda \geq |(S^{\text{opt}})^{-1}_{pq}| \tag{13}$$

Similar to the proof of Theorem 5, let the entries of the upper triangular part of Σ_k be ordered as

$$|\Sigma_{i_1 j_1}| > ... > |\Sigma_{i_k j_k}| > |\Sigma_{i_{k+1} j_{k+1}}| \geq \cdots \geq |\Sigma_{i_m j_m}| \tag{14}$$

where $m = \frac{n^2-n}{2}$. To prove the theorem by contradiction, assume that $\mathcal{G}(S^{\text{opt}}) \neq \mathcal{G}(\Sigma_k)$. Recall that $\mathcal{G}(\Sigma_k)$ is a graph with n vertices and the edges $(i_1,j_1),(i_2,j_2),...,(i_k,j_k)$. Since $\mathcal{G}(S^{\text{opt}})$ has exactly k edges, the above assumption implies that there exist two numbers s and r such that

$$s \in \{1,...,k\} \qquad \text{and} \qquad (i_s,j_s) \notin \mathcal{G}(S^{\text{opt}}) \tag{15a}$$

$$r \in \{s+1,...,m\} \qquad \text{and} \qquad (i_r,j_r) \in \mathcal{G}(S^{\text{opt}}) \tag{15b}$$

Therefore, it follows from (13) that

$$|(S^{\text{opt}})^{-1}_{i_s j_s}| \leq |\Sigma_{i_r j_r}| - \lambda < |\Sigma_{i_s j_s}| - \lambda \tag{16}$$

However, the inequality

$$|(S^{\text{opt}})^{-1}_{i_s j_s}| < |\Sigma_{i_s j_s}| - \lambda \tag{17}$$

is in contradiction with the relation

$$(S^{\text{opt}})^{-1}_{i_s j_s} \in [\Sigma_{i_s j_s} - \lambda, \Sigma_{i_2 j_s} + \lambda] \tag{18}$$

that is given in (3). This completes the proof. ■

Theorem 6 states that graphical lasso and thresholding are equivalent if two conditions are satisfied:

- *Condition 1:* The sign of every nonzero off-diagonal entry of S^{opt} is different from that of its corresponding entry in the inverse of S^{opt}.
- *Condition 2:* If a zero off-diagonal entry of S^{opt} takes a nonzero value in the inverse of S^{opt}, then its magnitude is not larger than the magnitude of any off-diagonal element of $(S^{\text{opt}})^{-1}$ corresponding to a nonzero entry of S^{opt}.

Note that the above conditions only depend on S^{opt} and are not directly related to Σ. To better understand these conditions, we decompose S^{opt} as

$$S^{\text{opt}} = D^{\text{opt}} + O^{\text{opt}} \tag{19}$$

where D^{opt} is a diagonal matrix and O^{opt} has a zero diagonal. If the norm of $(D^{\text{opt}})^{-1}O^{\text{opt}}$ is less than 1, one can write

$$(S^{\text{opt}})^{-1} = \left(\sum_{t=0}^{\infty}\left(-(D^{\text{opt}})^{-1}O^{\text{opt}}\right)^t\right)(D^{\text{opt}})^{-1} \tag{20}$$

In general, we have

$$(S^{\text{opt}})^{-1} = (D^{\text{opt}})^{-1} - (D^{\text{opt}})^{-1}O^{\text{opt}}(D^{\text{opt}})^{-1} + h.o.t. \tag{21}$$

where $h.o.t$ stands for *higher order terms* in the Taylor series expansion if the norm of $(D^{\rm opt})^{-1}O^{\rm opt}$ is less than 1, and otherwise is equal to $(S^{\rm opt})^{-1}O^{\rm opt}(D^{\rm opt})^{-1}O^{\rm opt}(D^{\rm opt})^{-1}$ (as a general formula). We refer to

$$E^{\rm opt} := (D^{\rm opt})^{-1} - (D^{\rm opt})^{-1}O^{\rm opt}(D^{\rm opt})^{-1} \tag{22}$$

as the first-order approximation of $(S^{\rm opt})^{-1}$. Note that if λ is relatively large, it is expected that $O^{\rm opt}$ will be small compared to $D^{\rm opt}$, which will lead to small higher order terms.

Theorem 7 *The condition* (10) *given in Theorem 6 to guarantee the equivalence of graphical lasso and thresholding is satisfied if $(S^{opt})^{-1}$ is replaced by its first-order approximation E^{opt} in the condition.*

Proof Equation (22) yields that

$$E^{\rm opt}_{ij} = \begin{cases} (D^{\rm opt})^{-1}_{ii} & \text{if} \quad i=j \\ -(D^{\rm opt})^{-1}_{ii}O^{\rm opt}_{ij}(D^{\rm opt})^{-1}_{jj} & \text{if} \quad (i,j)\in\mathcal{G}(S^{\rm opt}) \\ 0 & \text{otherwise} \end{cases} \tag{23}$$

for every $i,j\in\{1,...,n\}$. Note that $D^{\rm opt}>0$ due to the positive definiteness of $S^{\rm opt}$. Hence, given a pair $(i,j)\in\mathcal{G}(S^{\rm opt})$, one can write:

$$\text{sign}\left(S^{\rm opt}_{ij}\right)\text{sign}\left(E^{\rm opt}_{ij}\right) = -\text{sign}\left(O^{\rm opt}_{ij}\right)^2(D^{\rm opt})^{-1}_{ii}(D^{\rm opt})^{-1}_{jj} \leq 0 \tag{24}$$

Moreover, given arbitrary pairs (i,j) and (p,q) satisfying (11), it follows from (23) that $E^{\rm opt}_{pq}=0$. Therefore,

$$|E^{\rm opt}_{ij}| \geq |E^{\rm opt}_{pq}| \tag{25}$$

The proof is completed by combining (24) and (25). ■

Before further simplifying the conditions of Theorem 6 based on Theorem 7, it is desirable to offer a more general condition measuring the "similarity" of graphical lasso and thresholding (as opposed to their "equivalence").

Definition 8 *Define $\mathbb{I}_k$ as the set of indices (locations) of those k entries of the upper triangular part of $(\mathcal{S}^{opt})^{-1}$ that have the largest magnitudes.*

Note that if multiple entries of $(\mathcal{S}^{\rm opt})^{-1}$ have the same value, then $\mathbb{I}_k$ may not be uniquely defined. In that case, $\mathbb{I}_k$ can be considered as any of the sets satisfying the properties given in Definition 8.

Theorem 9 *Let k denote the number of edges of the graph $\mathcal{G}(S^{opt})$, and h be the number of indices (i,j)'s in the set $\mathbb{I}_k$ for which the relation*

$$\text{sign}\left(S^{opt}_{ij}\right)\times\text{sign}\left((S^{opt})^{-1}_{ij}\right) < 0 \tag{26}$$

holds. Then, the graphs $\mathcal{G}(\Sigma_k)$ and $\mathcal{G}(\mathcal{S}^{opt})$ have at least h edges in common. In particular, graphical lasso and thresholding are equivalent if $h=k$.

Proof The proof of Theorem 6 can be adopted to prove this theorem. The details are omitted for brevity. ■

Theorem 9 states that the graph $\mathcal{G}(\mathcal{S}^{\rm opt})$ (obtained using graphical lasso) and the graph $\mathcal{G}(\Sigma_k)$ (obtained using thresholding) share at least h edges. Hence, this theorem provides a simple mechanism to check the similarity between graphical lasso and thresholding through a simple test on $\mathcal{S}^{\rm opt}$. This mechanism will be further studied below.

Definition 10 *Given a matrix $H\in\mathbb{S}^n$ and a positive integer $t\in\{1,2,...,k\}$, define $f(H,t)$ as the magnitude of the t^{th} largest entry (in magnitude) of the upper triangular part of H (excluding its diagonal). For example, $f(H,1)$ is equal to the absolute value of an off-diagonal entry of H with the largest magnitude.*

We define $\Delta E^{\rm opt}$ as the difference between the matrix $(S^{\rm opt})^{-1}$ and its first-order approximation $E^{\rm opt}$.

Theorem 11 *Given a positive integer $t\in\{1,2,...,k\}$, the graphs $G(\Sigma_k)$ and $G(S^{opt})$ have at least t edges in common if*

$$2\ f(\Delta E^{opt},1) < f(E^{opt},t) \tag{27}$$

In particular, graphical lasso and thresholding lead to the same approximate graph if the above inequality is satisfied for $t=k$.

Proof The proof follows from Theorems 7 and 9. The main idea will be sketched for $t=k$ below. Consider arbitrary pairs (i,j) and (p,q) satisfying (11). It follows from (27) that

$$|E^{\rm opt}_{ij}| \geq f(E^{\rm opt},k) \geq 2f(\Delta E^{\rm opt},1) \geq\ 2|\Delta E^{\rm opt}_{ij}| \tag{28}$$

Similarly,

$$|E^{\rm opt}_{ij}| \geq f(E^{\rm opt},k) \geq 2f(\Delta E^{\rm opt},1) \geq\ 2|\Delta E^{\rm opt}_{pq}| \tag{29}$$

On the other hand, $(S^{\rm opt})^{-1}_{ij} = E^{\rm opt}_{ij} + \Delta E^{\rm opt}_{ij}$ and $\text{sign}(S^{\rm opt}_{ij}) = \text{sign}(O^{\rm opt}_{ij}) = -\text{sign}(E^{\rm opt}_{ij})$. The above relations together with (23) imply the condition (10). This completes the proof. ■

Roughly speaking, $f(\Delta E^{\rm opt},1)$ is small for a relatively large number λ, and $f(E^{\rm opt},t)$ would stay away from zero due to Lemma 3. Theorem 11 explains that the relationship between $E^{\rm opt}$ and $\Delta E^{\rm opt}$ determines the degree of similarity between graphical lasso and thresholding. Note that Theorem 11 is more conservative than Theorem 9, but its condition is more insightful.

Note that the definition of graphical lasso in (2) is based on the regularization term $\lambda\|S\|_1$. Consider a second version of graphical lasso where only the off-diagonal entries of S are penalized in the regularization term. This is realized by replacing the term $\|S\|_1$ with $2\sum_{i=1}^n\sum_{j=i+1}^n|S_{ij}|$. The optimality conditions given in Lemma 3 for graphical lasso are valid for the second version of graphical lasso after dropping λ from the right side of (3a). As a result, the original and second version of graphical lasso are very similar, and the only

$$\Sigma = \begin{bmatrix} 1 & 0.5448 & 0.4980 & 0.2045 & -0.2818 & -0.1452 \\ 0.5448 & 1 & -0.1327 & -0.0604 & -0.6860 & -0.0457 \\ 0.4980 & -0.1327 & 1 & 0.1283 & -0.1859 & -0.5174 \\ 0.2045 & -0.0604 & 0.1283 & 1 & 0.4019 & 0.6238 \\ -0.2818 & -0.6860 & -0.1859 & 0.4019 & 1 & 0.5139 \\ -0.1452 & -0.0457 & -0.5174 & 0.6238 & 0.5139 & 1 \end{bmatrix} \tag{30}$$

$$\mathcal{S}^{\text{opt}} = \begin{bmatrix} 0.6934 & -0.0453 & -0.0229 & 0 & 0 & 0 \\ -0.0453 & 0.7114 & 0 & 0 & 0.1153 & 0 \\ -0.0229 & 0 & 0.6919 & 0 & 0 & 0.0321 \\ 0 & 0 & 0 & 0.6997 & 0 & -0.0839 \\ 0 & 0.1153 & 0 & 0 & 0.7098 & -0.0305 \\ 0 & 0 & 0.0321 & -0.0839 & -0.0305 & 0.7025 \end{bmatrix} \tag{31}$$

$$(\mathcal{S}^{\text{opt}})^{-1} = \begin{bmatrix} 1.4500 & 0.0949 & 0.0480 & -0.0003 & -0.0155 & -0.0029 \\ 0.0949 & 1.4500 & 0.0036 & -0.0013 & -0.2360 & -0.0106 \\ 0.0480 & 0.0036 & 1.4500 & -0.0081 & -0.0035 & -0.0674 \\ -0.0003 & -0.0013 & -0.0081 & 1.4500 & 0.0077 & 0.1738 \\ -0.0155 & -0.2360 & -0.0035 & 0.0077 & 1.4500 & 0.0640 \\ -0.0029 & -0.0106 & -0.0674 & 0.1738 & 0.0640 & 1.4500 \end{bmatrix} \tag{32}$$

difference is in the diagonal of $(S^{\text{opt}})^{-1}$. It is easy to verify that the theorems developed in this work are all valid for the second version of graphical lasso as well. However, note that in order to obtain a graph with k edges, the value of the regularization term λ may not be the same for the original and the second version of graphical lasso.

3. Numerical Examples

Example 1: Consider Σ as the randomly generated matrix given in (30). The solution $\mathcal{S}^{\text{opt}}$ of graphical lasso with $\lambda = 0.45$ is provided in (31) (this value of λ guarantees that $\mathcal{G}(\mathcal{S}^{\text{opt}})$ will have n edges). It can be deduced from this solution that the graph $\mathcal{G}(\mathcal{S}^{\text{opt}})$ consists of the vertex set $\mathcal{V} := \{1, 2, ..., 6\}$ and the edge set $\mathcal{E} := \{(1,2), (1,3), (2,5), (3,6), (4,6), (5,6)\}$. On the other hand, it follows from a simple inspection of the matrix Σ that $\mathcal{E}$ coincides with the index set of the 6 largest absolute values of the upper triangular part of Σ. Hence, graphical lasso and thresholding are equivalent in this example, meaning that $\mathcal{G}(\mathcal{S}^{\text{opt}}) = \mathcal{G}(\Sigma_6)$.

It is desirable to find out whether the simple conditions proposed in Theorem 9 can be used to detect this equivalence. Recall that these conditions are expressed in terms of the matrix $\mathcal{S}^{\text{opt}}$, without using λ and Σ explicitly. To check these conditions, the matrix $(\mathcal{S}^{\text{opt}})^{-1}$ can be obtained as the one given in (32). Since the upper triangular part of $\mathcal{S}^{\text{opt}}$ has 6 nonzero entries, the index set $\mathbb{I}_6$ needs to be found. After the identification of the

$$\Sigma = \begin{bmatrix} 1 & 0.9342 & 0.8156 & 0.8609 & 0.6994 & 0.8457 \\ 0.9342 & 1 & 0.7110 & 0.7736 & 0.7283 & 0.8532 \\ 0.8156 & 0.7110 & 1 & 0.8593 & 0.8905 & 0.7958 \\ 0.8609 & 0.7736 & 0.8593 & 1 & 0.7876 & 0.7793 \\ 0.6994 & 0.7283 & 0.8905 & 0.7876 & 1 & 0.7040 \\ 0.8457 & 0.8532 & 0.7958 & 0.7793 & 0.7040 & 1 \end{bmatrix} \tag{35}$$

$$\Sigma_5 = \begin{bmatrix} 1 & 0.9342 & 0 & 0.8609 & 0 & 0 \\ 0.9342 & 1 & 0 & 0 & 0 & 0.8532 \\ 0 & 0 & 1 & 0.8593 & 0.8905 & 0 \\ 0.8609 & 0 & 0.8593 & 1 & 0 & 0 \\ 0 & 0 & 0.8905 & 0 & 1 & 0 \\ 0 & 0.8532 & 0 & 0 & 0 & 1 \end{bmatrix} \tag{36}$$

$$\mathcal{S}^{\text{opt}} = \begin{bmatrix} 0.5417 & -0.0247 & 0 & -0.0032 & 0 & 0 \\ -0.0247 & 0.5417 & 0 & 0 & 0 & -0.0009 \\ 0 & 0 & 0.5408 & -0.0027 & -0.0118 & 0 \\ -0.0032 & 0 & -0.0027 & 0.5406 & 0 & 0 \\ 0 & 0 & -0.0118 & 0 & 0.5408 & 0 \\ 0 & -0.0009 & 0 & 0 & 0 & 0.5405 \end{bmatrix} \tag{37}$$

$$(\mathcal{S}^{\text{opt}})^{-1} = \begin{bmatrix} 1.8500 & 0.0842 & 0.0001 & 0.0109 & 0.0000 & 0.0002 \\ 0.0842 & 1.8500 & 0.0000 & 0.0005 & 0.0000 & 0.0032 \\ 0.0001 & 0.0000 & 1.8500 & 0.0093 & 0.0405 & 0.0000 \\ 0.0109 & 0.0005 & 0.0093 & 1.8500 & 0.0002 & 0.0000 \\ 0.0000 & 0.0000 & 0.0405 & 0.0002 & 1.8500 & 0.0000 \\ 0.0002 & 0.0032 & 0.0000 & 0.0000 & 0.0000 & 1.8500 \end{bmatrix} \tag{38}$$

largest absolute values of the matrix $(\mathcal{S}^{\text{opt}})^{-1}$, it turns out that

$$\mathbb{I}_6 = \{(1,2), (1,3), (2,5), (3,6), (4,6), (5,6)\} \tag{33}$$

In addition, the relation

$$\text{sign}\left(S^{\text{opt}}_{ij}\right) \times \text{sign}\left((S^{\text{opt}})^{-1}_{ij}\right) < 0, \quad \forall (i,j) \in \mathbb{I}_6 \tag{34}$$

holds. Therefore, it follows from Theorem 9 that graphical lasso and thresholding lead to the same result.

Example 2: Consider the randomly generated matrix in (35). Thresholding this matrix at the level of $k = 5$ yields the solution given in (36). On the other hand, solving the graphical

lasso for $\lambda = 0.85$ leads to the solution $\mathcal{S}^{\text{opt}}$ provided in (37), with the inverse given in (38) (this value of λ guarantees that $\mathcal{G}(\mathcal{S}^{\text{opt}})$ will have $n-1$ edges). By analyzing the matrix $\mathcal{S}^{\text{opt}}$ and its inverse, it can be verified that the conditions provided in Theorem 9 are satisfied. Hence, thresholding and graphical lasso are equivalent. An interesting observation is that the matrix Σ has two close entries 0.8457 and 0.8532 such that only one of them is removed through thresholding, but graphical lasso recognizes this fact and selects the entry with a slightly higher value. In other words, even in the case where the matrix Σ have entries with similar values (which makes it hard to decide what entries should be included in the graphical model), graphical lasso may still behave the same as thresholding.

Example 3: We construct a matrix NN^T, where the entries of $N \in \mathbb{R}^{30\times 30}$ are chosen at random according to some probably distribution. Define Σ as a matrix obtained from NN^T through a normalization to make its diagonal entries all equal to 1. We order the entries of Σ according to (14) and consider λ as $\frac{|\Sigma_{i_{30}j_{30}}|+|\Sigma_{i_{29}j_{29}}|}{2}$ (i.e., the average of the 29^{th} and 30^{th} largest absolute values of the upper triangular part of Σ). Two experiments will be concluded below.

Experiment I: By choosing every entry of the matrix N from a normal probability distribution, we generated 100 random matrices Σ's. In Figure 1(a), the number of edges of $\mathcal{G}(\mathcal{S}^{\text{opt}})$ is shown for each of the 100 trials (the trials are reordered to make the curve increasing). In Figure 1(b), the number of edges of the difference graph $\mathcal{G}(\mathcal{S}^{\text{opt}}) - \mathcal{G}(\Sigma_k)$ is depicted, where k is considered as the number of edges of $\mathcal{G}(\mathcal{S}^{\text{opt}})$. It can be seen that graphical lasso and thresholding are equivalent in more than 75 trials and are different by at most 2 edges in the remaining trials (note that the orderings of the trials for Figures 1(a) and 1(b) are different to ensure that each curve changes smoothly). This supports the claim of the paper that graphical lasso and thresholding would behave highly similarly. As opposed to computing the graph $\mathcal{G}(\mathcal{S}^{\text{opt}}) - \mathcal{G}(\Sigma_k)$ directly, Theorem 9 offers a simple insightful condition to find a subset of the common edges of $\mathcal{G}(\mathcal{S}^{\text{opt}})$ and $\mathcal{G}(\Sigma_k)$. This simple condition is tested on the 100 trials and the results are summarized in Figure 1(c). This figure shows the percentage of the common edges of $\mathcal{G}(\mathcal{S}^{\text{opt}})$ and $\mathcal{G}(\Sigma_k)$ that are detected by Theorem 9. It can be observed that the condition provided in the paper is able to detect a similarity degree on the order of 80% for more than 90% of the trials.

Experiment II: This study is the same as the previous experiment with the only difference that every entry of the matrix N was chosen from the interval $[0, 1]$ with a uniform probability distribution. The results are shown in Figures 1(d), (e) and (f). It can be seen that graphical lasso and thresholding are similar with the probability of at least 95%.

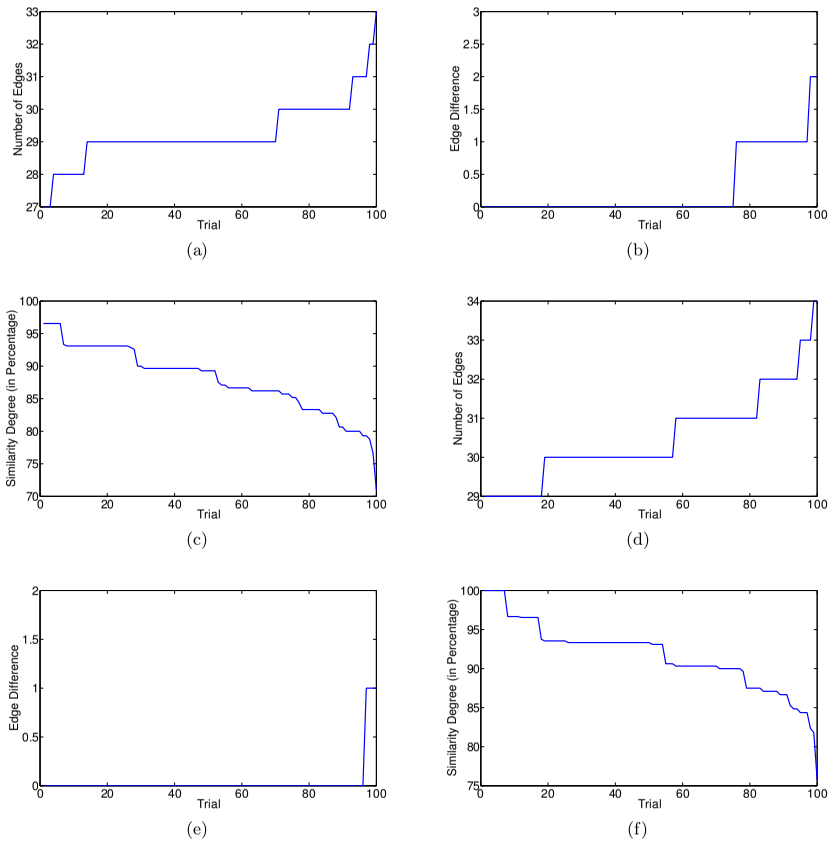

Figure 1: Figures (a), (b) and (c) show the number of edges of $\mathcal{G}(\mathcal{S}^{\text{opt}})$, the number of edges of $\mathcal{G}(\mathcal{S}^{\text{opt}}) - \mathcal{G}(\Sigma_k)$, and the similarity degree of thresholding and graphical lasso detected via Theorem 9 for Experiment I. Figures (d), (e) and (f) show the number of edges of $\mathcal{G}(\mathcal{S}^{\text{opt}})$, the number of edges of $\mathcal{G}(\mathcal{S}^{\text{opt}}) - \mathcal{G}(\Sigma_k)$, and the similarity degree of thresholding and graphical lasso detected via Theorem 9 for Experiment II.

4. Case Study on Brain Networks

Brain functional connectivity is defined as the statistical dependencies between the activities of disjoint brain regions. A brain functional network can be represented by a set of nodes and edges, where each node corresponds to a brain region and each edge shows the presence of correlated activities (namely, a nonzero partial correlation) between two disjoint regions. We apply graphical lasso and thresholding techniques to the fMRI data collected from twenty subjects to obtain their associated brain functional networks. These fMRI data sets are borrowed form Vértes et al. (2012). Each data set includes 134 samples of the low frequency oscillations, taken at 140 cortical brain regions in the right hemisphere. The goal is to find the brain functional connectivity network of each subject that specifies the

direct interactions (or conditional dependence/independence) between the activities of these cortical regions.

Using the aforementioned time series data, a 140×140 sample correlation matrix can be computed for each subject. Note that the number of samples is smaller than the number of variables and, therefore, the sample correlation matrix is not invertible. As a result, it is not possible to take the inverse of the sample correlation matrix for estimating a partial correlation matrix. The brain network being sought has $n = 140$ nodes (brain regions). In an effort to find a subgraph of this network as closely as possible to a spanning tree, we choose the regularization parameter λ in the graphical lasso algorithm and the level of thresholding in such a way that they both lead to graphs with $n - 1 = 139$ edges. As illustrated in Figure 2, the similarity degree between the outcomes of these two techniques is above 90% for all twenty subjects. The outcomes of graphical lasso and thresholding obtained for 4 of these subjects are given in Figure 3 for illustration. Note that these graphs are not spanning trees as indented, which imply that graphical lasso and thresholding are able to obtain graphs with $n - 1$ edges but they inevitably have cycles.

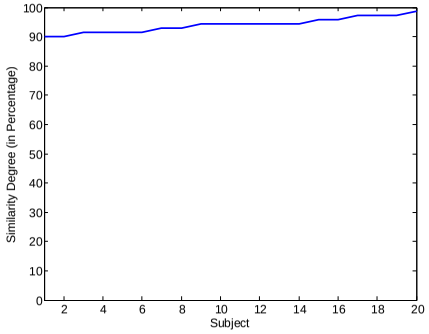

Figure 2: The similarity degree of thresholding and graphical lasso for obtaining brain networks of 20 subjects.

5. Case Study on Electrical Circuits

Consider an arbitrary resistor-capacitor (RC) circuit with n nodes, where certain nodes are connected to each other or the ground via resistor-capacitor elements. Figure 4(a) illustrates an RC circuit. The connectivity of each circuit can be represented by a graph, as demonstrated in Figure 4(b). Assume that the physical structure of the circuit is unknown and only the nodal voltages are available for measurement. It is desirable to find the structural connectivity of the circuit from the measured signals. Given a time instance t, let $V(t)$ denote the vector of the voltages for nodes $1, ..., n$ at time t. Assume that the circuit elements are subject to white thermal noise, namely Johnson-Nyquist noise, and that the conductance and capacitance in each resistor-capacitor element are identical. Let

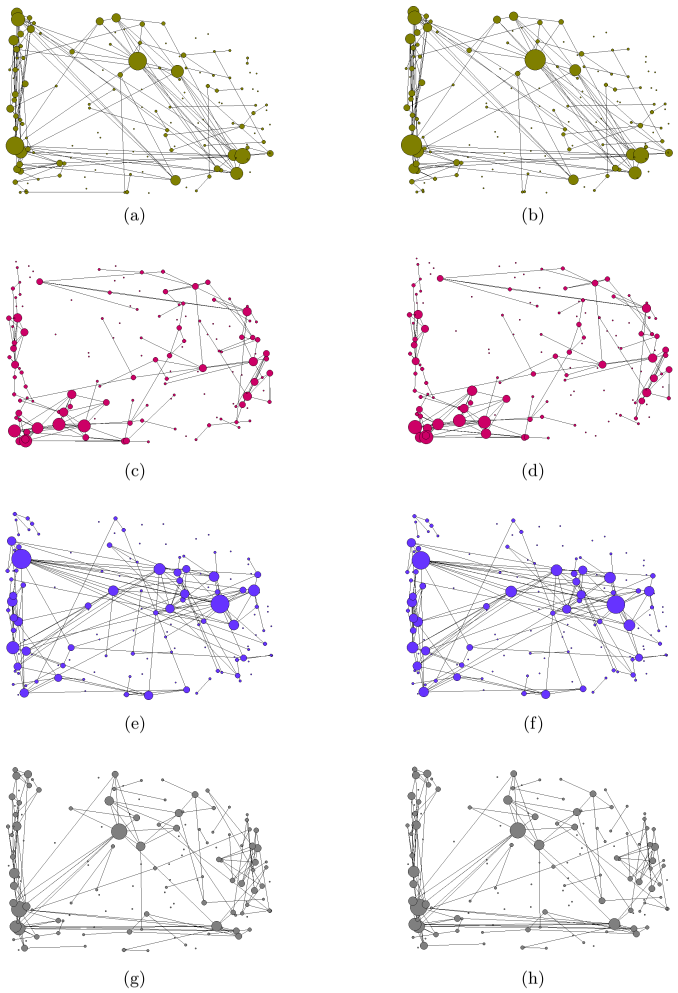

Figure 3: Figures (a) and (b) show the brain networks of one subject obtained from graphical lasso and thresholding, respectively. Similarly, figures (c)-(d), (e)-(f) and (g)-(h) show the networks obtained from graphical lasso and thresholding for three other subjects. The size of each node in these networks reflects its degree.

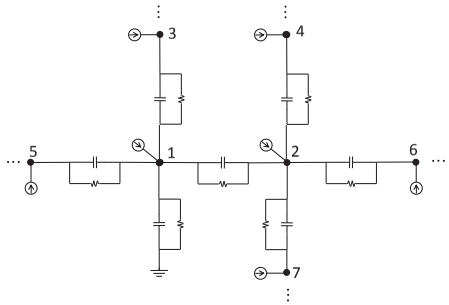
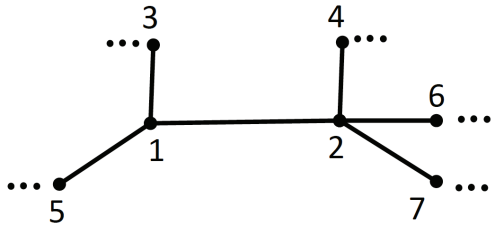
Σ_* denote the "steady-state" covariance of the voltage measurements. It can be shown that $\Sigma_* = C^{-1}$, where C is the $n \times n$ capacitance matrix of the circuit (Sojoudi and Doyle, 2014). Note that the sparsity pattern of C is consistent with the topology of the circuit. Therefore, the inverse covariance matrix Σ_*^{-1} and the partial correlation matrix both have the same sparsity structure as the circuit. In other words, the partial correlation matrix unveils the physical connectivity of the circuit. Assuming that the circuit under study has a sparse structure, it can be concluded that

- Σ_* is generically a dense matrix, due to being the inverse of the sparse matrix C.
- Σ_*^{-1} is sparse and its sparsity pattern conforms with the circuit topology.



(a)



(b)

Figure 4: a) An RC network with node 1 connected to the ground via a resistor and a capacitor, b) a graph representation of the RC network connectivity.

The above physical model illustrates the fact that the topology of a system may have been encoded in the partial correlation matrix. To recover the circuit topology from the voltage vector $V(t)$, one can sample the vector $V(t)$ at different times $t_1, t_2, ..., t_r$ and construct a sample covariance matrix as

$$\Sigma = \frac{1}{r} \sum_{i=1}^{r} V_i(t_i) V_i(t_i)^T \tag{39}$$

where r denotes the number of samples. Note that Σ converges to the population covariance Σ_* as $r \to \infty$. When r is finite, two possible scenarios arise: i) Σ is invertible but the inverse matrix needs to be thresholded to some level due to the error $\Sigma_* - \Sigma$, ii) Σ is not invertible and therefore alternative methods are needed to estimate the inverse matrix.

The above circuit model can be used to study the relationship between the thresholding and graphical lasso techniques. As an example, consider a mesh circuit with $n = 100$ nodes that are connected to one another through 180 links. The graphical model of this grid circuit is depicted in Figure 5(a). With no loss of generality, assume that $C_{ij} = -1$ for all $(i, j) \in \mathcal{E}$. Furthermore, suppose that nodes 2, 9, 22, 61 and 70 of the circuit are connected to the ground through parallel RC circuits with values equal to 0.1. For $r = 99$ and 10 different trials, we have calculated the sample covariance matrices and applied the thresholding technique and graphical lasso to these matrices in order to recover networks with 180 edges. Note that since the number of samples is less than the number of variables, the sample partial correlations cannot be obtained through matrix inversion. The degree of similarity between graphical lasso and thresholding for these 10 trials are given in Figure 5(b). Figures 5(c) and 5(d) show the networks obtained from thresholding and graphical lasso for one of the trials. False positives are marked in red and false negatives are colored in blue. These two graphs have 178 edges in common (out of 180 edges), which indicates a high degree of similarity between the outcomes of the two techniques under study (to observe some of the few differences, one can inspect the existence of the edges $(64, 75)$ and $(55, 56)$ in these two graphs). We have repeated the above experiment on many circuit models beyond mesh networks and observed a very similar result.

6. Conclusions

The objective of this paper is to study the problem of finding a sparse conditional dependence graph associated with a multivariate random vector, where the only available information is a sample correlation matrix. A commonly used technique for this problem is a convex program, named graphical lasso, where the objective function of this optimization problem has a sparsity-promoting penalty term. In this work, a simple condition is derived under which the graph obtained from graphical lasso coincides with the one obtained by simply thresholding the sample correlation matrix. This condition depends only on the solution of graphical lasso, and makes no use of the regularization coefficient or the sample correlation matrix. The focus of the paper is on the case where the regularization term is high enough to search for a sparse graph. A theoretical result is developed to support that graphical lasso and thresholding behave similarly in this regime, and this statement is verified in several random simulations as well as two case studies on brain connectivity networks and electrical circuits.

A Network That Learns Strassen Multiplication

Editor: Nando de Freitas

Abstract

We study neural networks whose only non-linear components are multipliers, to test a new training rule in a context where the precise representation of data is paramount. These networks are challenged to discover the rules of matrix multiplication, given many examples. By limiting the number of multipliers, the network is forced to discover the Strassen multiplication rules. This is the mathematical equivalent of finding low rank decompositions of the $n \times n$ matrix multiplication tensor, M_n. We train these networks with the conservative learning rule, which makes minimal changes to the weights so as to give the correct output for each input at the time the input-output pair is received. Conservative learning needs a few thousand examples to find the rank 7 decomposition of M_2, and 10^5 for the rank 23 decomposition of M_3 (the lowest known). High precision is critical, especially for M_3, to discriminate between true decompositions and "border approximations".

Keywords: sum-product networks, Strassen multiplication, tensor decomposition

1. Introduction

Questions related to the Strassen algorithm (1969) for matrix multiplication provide an opportunity for testing neural networks in the interesting setting where the representation of knowledge is both exact and poorly understood (an open mathematical problem). In this short contribution we define Strassen multiplication (SM) for non-experts, construct a neural network that has the capacity to implement SM, and introduce a simple protocol for training the network called conservative learning. We also present numerical experiments that are unique in the degree of precision required to establish results.

2. What is Strassen Multiplication?

In 1969 Volker Strassen published a paper that showed, among other things, that a pair of 2×2 matrices could be multiplied with just seven scalar multiplications, one less than the eight required in the standard algorithm. Strassen's trick becomes practical on very large matrices where it can be applied recursively on blocks. Finding the fewest number of scalar multiplications for general $n \times n$ matrices is the subject of intensive research.

A glance at the network that implements Strassen multiplication (SM) in Figure 1 quickly establishes two things that make this application of machine learning unique:

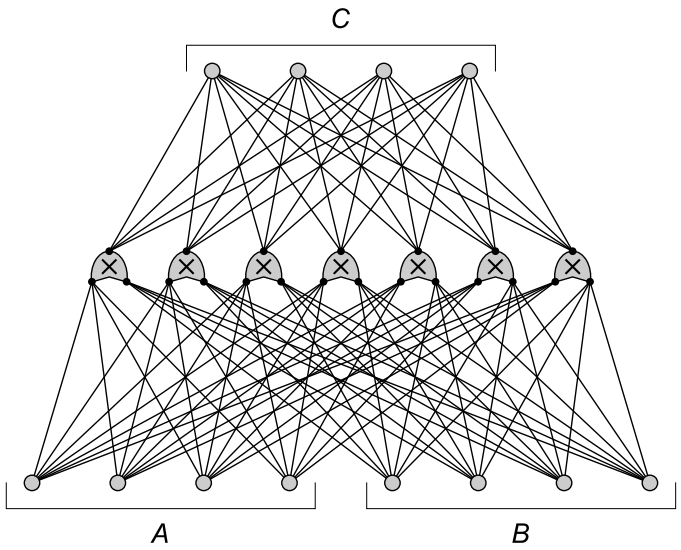

Figure 1: A network for multiplying 2×2 matrices that uses only seven multipliers. Multiplication by a constant ("weight") occurs at each of the lines connecting input and output registers (for the matrices A, B and C) to the multipliers in the middle layer of the network.

- The architecture of the network and the operations performed by its components are *a perfect match to the mathematical problem*, as opposed to being just a well motivated platform for general machine learning applications.
- The design of the network is deliberately naive and lives up to the standard that the machine should have the capacity *to learn something that we don't already know*. Our network, in fact, does not even know how numbers are arranged to form a matrix!

Figure 1 is an engineer's representation of SM. The elements of the 2×2 matrices A and B are read in from two registers of numbers $a(i)$ and $b(i)$, $i = 1, \ldots, 4$ on the left and right. Those from A are 'pooled' into the left inputs of the seven multipliers in the middle layer of the network, those from B into the right inputs. Pooling is the most general linear-homogeneous operation. Denoting the inputs to the multipliers $a^*(j)$ and $b^*(j)$, $j = 1, \ldots, 7$, the pooling equations are

$$a^*(j) = \sum_{i=1}^{4} W_a(j,i)a(i) \qquad b^*(j) = \sum_{i=1}^{4} W_b(j,i)b(i). \tag{1}$$

The 7×4 sets of real numbers W_a and W_b are called *weights*, though they are not required to be non-negative. Multiplication by a weight is not counted as one of the multiplies in SM. Unlike the multiplications performed by the seven multipliers, weight multiplication is a linear operation in the inputs to the network. The challenge of SM is to find a set of weights that work for all conceivable matrices we wish to multiply. We will see that this set is not unique, and there exist transformations from one set to another that works just as well. In the most practical set found by Strassen (1969), all the nonzero weights are just ± 1, so the weight-multiplications are really just additions and subtractions.

The output end of the network works in the same way as the input end: the outputs of the seven multipliers are pooled into the four output registers of the C matrix, $c(i)$, $i = 1, \ldots, 4$, again in the most general way with a set of weights:

$$c(i) = \sum_{j=1}^{7} W_c(i,j)\, a^*(j) b^*(j). \tag{2}$$

Strassen's discovery can now be expressed in purely engineering terms. That is, there exists a fixed set of weights W_a, W_b and W_c such that the four numbers in the product of any pair of matrices can be computed with the 7-multiplier network of Figure 1 (*i.e.* the 8-multiplier network implicit in the standard algorithm is sub-optimal).

3. Mathematical Digression: Tensor Rank

Combining (1) and (2) we obtain a curious statement about matrix multiplication, now for $n \times n$ matrices:

$$c(i) = \sum_{k=1}^{n^2} \sum_{l=1}^{n^2} M_n(i,k,l)\, a(k) b(l)$$

$$M_n(i,k,l) = \sum_{j=1}^{r} W_c(i,j)\, W_a(j,k)\, W_b(j,l).$$

The universal three-index set of numbers M_n is a tensor of order three, the $(n \times n)$-*matrix multiplication tensor*. We see that M_n can be written as a sum of r products of three 1-tensors, the atoms of all tensors. The minimum r in the decomposition into products of 1-tensors is called the rank of the tensor. Unlike the problem of determining the rank of a matrix (a 2-tensor), determining the ranks of higher order tensors such as M_n is computationally difficult (Håstad, 1990). While we know $\mathrm{rank}\,(M_2) = 7$ (Winograd, 1971), already for the next case we currently only have bounds (Bläser, 2003; Laderman, 1976): $19 \leq \mathrm{rank}\,(M_3) \leq 23$.

A general transformation of the weights that gives another correct network (decomposition of M_n) can be inferred from the fact that the transformed matrices

$$\tilde{A} = UAV^{-1} \qquad \tilde{B} = VBW^{-1} \qquad \tilde{C} = UCW^{-1}, \tag{3}$$

for arbitrary invertible (U, V, W), satisfy the matrix product property whenever A, B and C do ($\tilde{A}\tilde{B} = \tilde{C}$). But feeding $\tilde{A}$ and $\tilde{B}$ into the network, and seeing the correct output $\tilde{C}$, is

equivalent to feeding in A and B and seeing C in the output after the three sets of weights have been appropriately transformed by the linear relations (3).

When we test our network for "matrix multiplication fidelity" we would like to do better than spot check its accuracy on sample instances. To assess how well it will perform on *any* instance of matrix multiplication we compute ϵ, where

$$\epsilon^2 = \frac{1}{(n^2)^3} \sum_{i\,k\,l} \left(M_n(i,k,l) - \sum_{j=1}^{r} W_c(i,j)\, W_a(j,k)\, W_b(j,l) \right)^2 \tag{4}$$

is the mean-square error in how our weights are decomposing the true M_n.

4. Conservative Learning

The amazing thing about the network in Figure 1 is not that, given the special Strassen weights, it manages to produce the product $C = AB$ with only seven multiplies. What is truly remarkable is the fact that the network can learn a correct set of weights just by being shown enough examples of correctly multiplied matrices.

A huge industry has grown up around the problem of training networks. Most methods start with some initial weights and adjust these to minimize the discrepancy between the correct output and the actual output of the network. There are many schemes for minimization, though most are local and based on gradients of some measure of discrepancy ("loss") with respect to the weights. We will use a somewhat different approach for the Strassen network called conservative learning.

Conservative learning is not the oxymoron it would seem, but a combination of two very reasonable principles:

- When presented with a training item for which the network gives the wrong output, change the weights so that at least this item produces the correct output.
- Make the smallest possible change to the weights when learning each new item.

By making the smallest possible change, when obsessing over the most recent item, we stand a better chance of not corrupting the accumulated knowledge derived from all previous items. To add mathematical support to this statement we analyze a very simple network.

Consider a network that implements a linear transformation from a set of inputs $x \in \mathbb{R}^m$ to a set of outputs $y \in \mathbb{R}^n$. We use matrix notation in what follows. The transformation to be learned corresponds to a matrix of weights $W^\star$, and training samples are pairs (x, y) where $y = W^\star x$. Suppose W is the current matrix and $(x, W^\star x)$ a new training item. As our network is linear, we choose to train only with normalized inputs, $x^T x = 1$. We wish to find the smallest change Δ such that

$$(W + \Delta)x = W^\star x, \tag{5}$$

where small is defined by the Frobenius norm $\|\Delta\| = \mathrm{Tr}\,\Delta\Delta^T$. We may decompose Δ as a sum of terms

$$\Delta = \Delta_\parallel x^T + \Delta_\perp,$$

where the first defines its action on the subspace generated by x, and the second gives its action on the orthogonal complement. Since $\Delta_\perp x = 0$, from (5) we infer

$$\Delta_\parallel = (W^\star - W)x.$$

Moreover,

$$\begin{aligned} \operatorname{Tr}\Delta\Delta^T &= \operatorname{Tr}(\Delta_\parallel x^T + \Delta_\perp)(x\Delta_\parallel^T + \Delta_\perp^T) \\ &= \operatorname{Tr}\Delta_\parallel\Delta_\parallel^T + \operatorname{Tr}\Delta_\perp\Delta_\perp^T, \end{aligned}$$

shows that minimizing the norm of Δ requires $\Delta_\perp = 0$, since the second term is a sum of squares. The conservative learning rule is therefore:

$$W \to W' = W + (W^\star - W)xx^T.$$

The current weights are incremented by a rank 1 matrix comprising the transposed input vector x^T as one factor and the output discrepancy $(W^\star - W)x$ as the other. After the change, the weights W' are correct on the item $(x, W^\star x)$.

To better understand how we are doing relative to the corpus of all possible items, we make note of the following relationship between old and new weights:

$$\begin{aligned} W' - W^\star &= (W - W^\star)(1 - xx^T) \\ &= P_x^\perp(W - W^\star). \end{aligned} \tag{6}$$

The operator $P_x^\perp$ projects rows to the orthogonal complement of x. From (6) we infer the norm inequality

$$\|W' - W^\star\| \le \|W - W^\star\|,$$

where we get equality only in the rare case that x is orthogonal to all the rows of $W - W^\star$. This inequality proves that conservatism is sound: by minimally accommodating each new item there is monotone improvement in our approximation of the transformation $(W^\star)$ itself.

Conservative learning has the nice feature that there are no parameters that have to be tuned, such as the step size in gradient descent. This continues to be true when the principle is applied to general networks. However, multiple layers and nonlinear components make the problem of finding the exact weight modifications intractable. Fortunately, there is a systematic procedure for keeping track of the order of smallness of the changes in the general network so that an approximate learning rule can be written down. The update procedure for the weights in the multilayer setting has similarities with the back-propagation rules in gradient-based learning, but there are also some differences. Not surprisingly, proving convergence is also out of reach. Our experiments with the Strassen network show spectacular convergence, even without imposing a small parameter to keep changes in check.

A derivation of the conservative learning rules for the Strassen network is given in the Appendix. This network has most of the features that need to be addressed in general networks and therefore serves as a good vehicle for explaining the method.

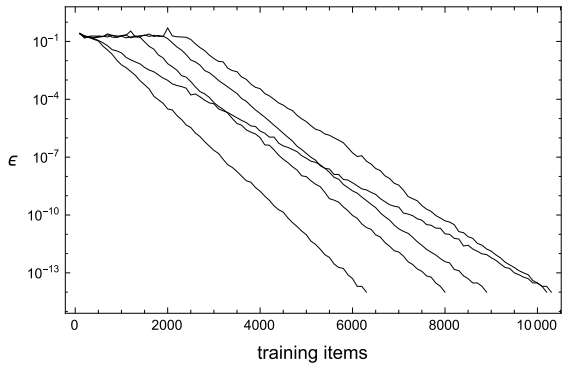

Figure 2: Root-mean-square error ϵ in the rank 7 decomposition of the 2×2 matrix multiplication tensor by the network in Figure 1. Shown are results for five runs of the network, each starting with random weights and trained on streams of random instances of correctly multiplied matrices.

5. Conservative Learning with the Strassen Network

There are two sources of randomness when training a network: the distribution of the initial weights and the distribution of the training items. We did not explore this dimension in our experiments with the Strassen network. The weights were initialized with independent uniform samples from a symmetric interval about the origin. Clearly the scale of this interval is not arbitrary, since the tensor M_n being decomposed has a definite scale. A scale for the weights is also implied by the error objective (4). Conservative learning proved not to be very sensitive to the scale of the initial weights, with only extreme limits (small and large scales) showing performance degradation. For simplicity we therefore chose to always initialize with samples drawn from $[-1, 1]$.

Adding an interesting bias to the distribution of training matrices is also something we did not try. Our input matrices were simply constructed from uniform samples of $[-1, 1]$ in each element of A and B. After rescaling to conform with our normalization convention $\operatorname{Tr} A^T A = \operatorname{Tr} B^T B = 1$, these together with $C = AB$ were handed to the network for training.

It astonished us how quickly the network discovers Strassen's trick for 2×2 matrices, when the weights are updated by the conservative learning rules. Figure 2 shows the decomposition error ϵ converging linearly, after an initial training set of only a few thousand. The five runs shown have slightly different convergence rates, a variability that can only be attributed to the initial weights and the early training items (before the onset of linear convergence). We did not compare with other learning rules, all of which, unlike conservative

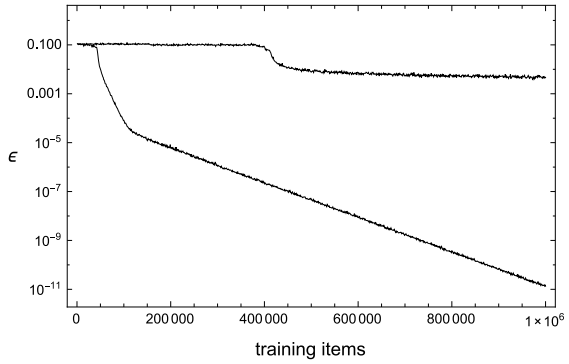

Figure 3: Root-mean-square error ϵ, in rank 23 decompositions of the 3×3 matrix multiplication tensor, on two runs. The absence of convincing linear convergence in one of the runs is accompanied (Figure 4) by a slow growth in the maximum weight magnitude.

learning, come with parameters and batch protocols that we were not prepared to manage with competence.

When we remove one multiplier from the middle layer of the network in Figure 1, that is, attempt to find a rank 6 decomposition of M_2, the error ϵ fluctuates indefinitely. This of course is what we expect, since there is a proof that M_2 has rank 7 (Winograd, 1971). For 3×3 matrices the network exhibits a new kind of behavior. Since it is known that rank $(M_3) \leq 23$ (Laderman, 1976), convergent behavior is possible in principle when we have 23 multipliers. We find that this indeed happens in about 64% of all runs, an example of which is the lower plot in Figure 3. In the remaining runs ϵ decays much more slowly; an example of this behavior is the higher plot in Figure 3.

The phenomenon of there being two qualitatively different asymptotic states of the network, when decomposing M_3, is consistent with the *border rank* property. This property, peculiar to tensors of order three and higher, refers to the topological closure properties of the space of tensor decompositions. When this space is not closed, the abstract closure defines tensor decompositions on the "border" of the space that have lower rank. In more concrete terms, it gives rise to approximate decompositions of lower rank, where the approximation as measured by ϵ can be arbitrarily good when the weights are allowed to diverge without limit.

We see evidence of "border" behavior when we compare the evolution of the maximum weight magnitude, $\max(|W_a|, |W_b|, |W_c|)$, for the two runs in Figure 3. These are plotted in Figure 4. In contrast to the linearly convergent run, where the maximum weight saturates, the run with slow convergence has a corresponding slow growth in the maximum weight. An interpretation of our results, consistent with what is known about tensor decompositions of

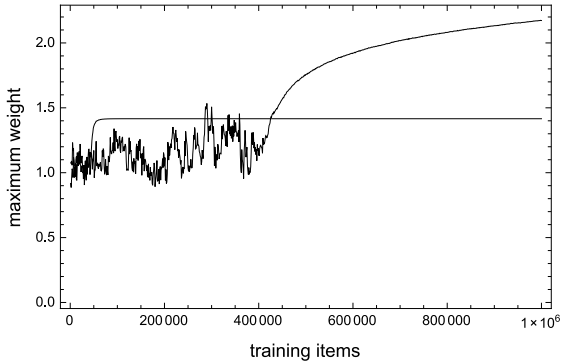

Figure 4: The maximum weight magnitudes, $\max(|W_a|, |W_b|, |W_c|)$, for the two training runs shown in Figure 3.

M_3, is that the weights in the slowly converging runs are rank 23 border approximations to true rank 24 or higher decompositions. Running the network with 22 multipliers we only observe the slow convergence/growing weight behavior. While this does not prove the true rank is 23, it is consistent with M_3 having rank 22 border approximations (Schönhage, 1981). That slow convergence was never observed in our experiments with M_2 is in agreement with the known fact (Landsberg, 2006) that this tensor does not have lower rank border approximations.

Conservative learning with the Strassen network for 3×3 matrices is summarized in Figure 5. This gives the distribution of the final decomposition error ϵ for 10^3 runs, each limited to 10^8 training items and terminated when the error dropped below 10^{-14}. Runs with linear convergence, such as the one in Figure 3, typically required far fewer than 10^8 training items. The large peak at the low end of the distribution in Figure 5, about 64% of all runs, therefore gives the probability that the network finds a true rank 23 decomposition. As explained above, we believe the network is slowly converging to border approximations in the other runs.

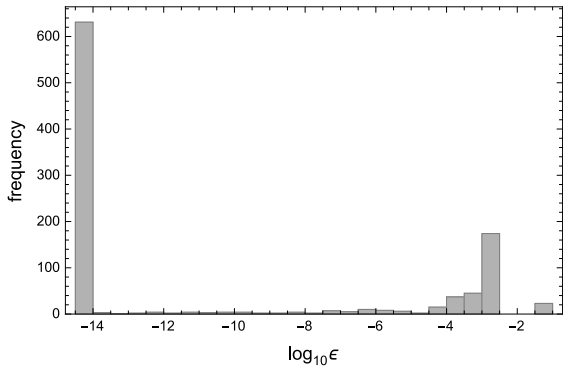

Figure 5: Distribution of the final decomposition error of M_3 in 10^3 runs, each with 10^8 training items. Runs were terminated when ϵ dropped below 10^{-14}.

6. Some History and Concluding Remarks

Not surprisingly, given the naturalness of the principle, a number of prior applications of conservative learning came to light after submission of the manuscript. Our definition is practically indistinguishable from the "minimal disturbance principle" that Bernard Widrow and coworkers (1988) applied to multi-layer networks with two-valued (sign) activation functions. The following is a direct quote from their paper:

> The idea is to adapt the network to properly respond to the newest input pattern while minimally disturbing the responses already trained in for the previous input patterns. Unless this principle is practiced, it is difficult for the network to simultaneously store all of the required pattern responses.

Due to the discontinuous activation functions in their network, the implementation of conservative learning (the minimal disturbance principle) posed a greater challenge than the non-linearity in the Strassen network. Combinations of flips of signs (activations) had to be exhaustively tested, for each training item, to discover the minimal modification of the weights. We were able to avoid a combinatorial explosion in the Strassen network because differentiability gave a set of equations for the minimum whose linearization could be solved for a unique, approximate solution.

While nearly forgotten by the neural network community, minimal disturbance has stood as a major design principle for adaptive filters (Widrow and Hoff, 1960), where it is known as the least mean squares (LMS) algorithm. With the development of efficient optimization algorithms such as ADMM for implementation, the application of the principle to neural networks should now be feasible, and offers an interesting training alternative to stochastic gradient descent.

Acknowledgments

Appendix A. Conservative Learning Rules for the Strassen Network

The starting point for deriving the conservative learning rules for the Strassen network (Fig. 1) is the Lagrangian function

$$\mathcal{L} = \frac{1}{2}\,\mathrm{Tr}\,(\Delta_a^T\Delta_a) + \frac{1}{2}\,\mathrm{Tr}\,(\Delta_b^T\Delta_b) + \frac{1}{2}\,\mathrm{Tr}\,(\Delta_c^T\Delta_c) + \alpha^T\,(a^* - (W_a+\Delta_a)a) + \beta^T\,(b^* - (W_b+\Delta_b)b) + \gamma^T\,(c - (W_c+\Delta_c)a^*\circ b^*)\,.$$

To streamline the derivation we use matrix notation. The new training item is the triplet of vectors (a, b, c) corresponding to the unrolled matrices $(A, B, C = AB)$. We should think of (a, b) as inputs to the network and c as the output. Prior to this item the network has weight matrices W_a and W_b that map the inputs to the pairs of inputs of the multipliers in the middle layer, (a^*, b^*). The outputs of the multipliers is the vector $c^* = a^* \circ b^*$, where $\circ$ denotes componentwise multiplication. If the network weights are correct even for the new item, then mapping c^* with the weight matrix W_c should match the output vector c. In general, the three weight matrices have to be changed by $(\Delta_a, \Delta_b, \Delta_c)$ for this to be true, and the first three terms of $\mathcal{L}$ are the Frobenius norm objective on these changes to keep them small. The last three terms are constraints imposed via three vectors of Lagrange multipliers, (α, β, γ). These insure that with the changed weights the inputs/outputs of the network match the inputs/outputs of the multipliers in the middle layer.

Given the current weights (W_a, W_b, W_c) and the new training item (a, b, c), our task is then to find a stationary point of Lagrangian $\mathcal{L}$ for the variables $(\Delta_a, \Delta_b, \Delta_c)$, (a^*, b^*), and (α, β, γ). In the derivation below we assume that the inputs are normalized as $a^T a = b^T b = 1$.

Stationarity with respect to Δ_a and Δ_b imply

$$\Delta_a = \alpha\, a^T \qquad \Delta_b = \beta\, b^T. \tag{7}$$

Comparing with the update rule for the linear network in Section 4 prompts us to interpret α and β as discrepancies associated with the multiplier inputs. Multiplying (7) on the right respectively by a and b we also have

$$\Delta_a\, a = \alpha \qquad \Delta_b\, b = \beta. \tag{8}$$

These equations and ones to follow are consistent with the Lagrange multipliers vanishing proportionately with the changes in the weights.

Before we impose stationarity with respect to the other variables, we define a set of approximate vectors associated with implementing the network using the current (unchanged)

weights. This mode of evaluating the nodes (vectors) in the network is called a forward pass.

$$\tilde{a}^* = W_a\, a \qquad \tilde{b}^* = W_b\, b. \tag{9}$$

$$\tilde{c} = W_c\, \tilde{a}^* \circ \tilde{b}^*. \tag{10}$$

Imposing stationarity with respect to (α, β) and comparing the resulting equations with (9) and (8), we obtain

$$a^* = (W_a + \Delta_a)a \qquad b^* = (W_b + \Delta_b)b,$$

$$a^* - \tilde{a}^* = \Delta_a\, a = \alpha \qquad b^* - \tilde{b}^* = \Delta_b\, b = \beta.$$

This shows that the discrepancies represented by α and β are the differences between their true values (after the conservative-learning update) and their forward-pass values.

Learning in some sense starts at the output layer, where the $\tilde{c}$ of the forward pass is compared with the output c of the training item. To obtain the conservative learning rule for this we start by imposing stationarity of $\mathcal{L}$ with respect to Δ_c:

$$\Delta_c = \gamma\, (a^* \circ b^*)^T. \tag{11}$$

We now make the first of a series of approximations. Extending to the output layer the property of the middle layer, that the pairs (Δ_a, α) and (Δ_b, β) have the same order of smallness, we expect (Δ_c, γ) also to vanish proportionately. A good approximation of (11) is then to replace a^* and b^* by their forward pass values (the error being higher order),

$$\Delta_c \approx \gamma\, (\tilde{a}^* \circ \tilde{b}^*)^T = \gamma\, \tilde{c}^{*T}, \tag{12}$$

where we have expressed the result in terms of the forward pass value of the multiplier outputs, $\tilde{c}^*$. Now imposing stationarity of $\mathcal{L}$ with respect to γ,

$$c = (W_c + \Delta_c)\, a^* \circ b^*,$$

and comparing with (10) we obtain

$$\begin{aligned} c - \tilde{c} &\approx \Delta_c\, \tilde{c}^* + W_c \left((a^* - \tilde{a}^*) \circ \tilde{b}^* + \tilde{a}^* \circ (b^* - \tilde{b}^*) \right) \\ &\approx \gamma\, \tilde{c}^{*T} \tilde{c}^* + W_c\, (\alpha \circ \tilde{b}^* + \tilde{a}^* \circ \beta), \end{aligned} \tag{13}$$

where we have neglected second order terms and used (7) and (12).

By imposing stationarity with respect to the two remaining sets of variables (a^*, b^*) we will obtain equations that relate (α, β) to γ, enabling us to cast the equation for the output discrepancy (13) just in terms of the unknown γ:

$$\alpha = b^* \circ (W_c^T + \Delta_c^T)\gamma \qquad \beta = a^* \circ (W_c^T + \Delta_c^T)\gamma,$$

$$\alpha \approx b^* \circ (W_c^T \gamma) \qquad \beta \approx a^* \circ (W_c^T \gamma). \tag{14}$$

In (14) we again discarded second order terms. Substituting α and β from (14) into (13) we arrive at the equation that begins the process of updating the weights:

$$c - \tilde{c} \approx (\tilde{c}^{*T} \tilde{c}^*)\, \gamma + W_c\, (\tilde{a}^* \circ \tilde{a}^* + \tilde{b}^* \circ \tilde{b}^*)\, W_c^T\, \gamma. \tag{15}$$

Equation (15) relates the discrepancy, between the true (training) c and the $\tilde{c}$ of the forward pass, to the Lagrange multipliers γ. Were we to neglect the off-diagonal terms in this linear matrix equation and determine γ by

$$\gamma \leftarrow \frac{1}{\tilde{c}^{*T} \tilde{c}^*} (c - \tilde{c}), \tag{16}$$

then the process of learning item (a, b, c) would be completely analogous to the usual "back-propagation" scheme. After forward-propagating the inputs (a, b) with W_a, W_b and W_c to determine the discrepancy $c - \tilde{c}$, the γ given by (16) is back-propagated (14) by W_c^T to get α and β. The three Lagrange multipliers then determine the weight changes by (7) and (12).

Lacking an argument for discarding the off-diagonal terms in (15), we need to look for methods to solve this more complex linear equation. The off-diagonal terms correspond to one-level of back-propagation followed by forward-propagation. An iterative solution of the linear equation would thus involve multiple backward-forward propagations between just the final two layers of the network. This is not as intimidating as it might seem for two reasons. First, when using the conjugate gradient (CG) method, the number of backward-forward iterations is bounded by the number of components of the vector γ. Second, given a reasonable initial solution-estimate, CG usually requires only few iterations in practice.

Since our derivation of the conservative learning rules has been based on the premise that the discrepancies $(a^* - \tilde{a}^*, b^* - \tilde{b}^*, c - \tilde{c})$ are small, we are keeping with this premise when we take as our initial CG solution-estimate $\gamma = 0$. As a better motivated alternative to (16) we apply the fewest (non-trivial) number of CG iterations — a single one — to this solution-estimate. At this single-iteration level of CG the approximate solution has a simple interpretation. Let

$$G = (\tilde{c}^{*T} \tilde{c}^*) + W_c\, (\tilde{a}^* \circ \tilde{a}^* + \tilde{b}^* \circ \tilde{b}^*)\, W_c^T \tag{17}$$

be the symmetric positive definite matrix in our linear equation

$$\delta = c - \tilde{c} = G\gamma.$$

The single-iteration CG solution has the form $\gamma_1 = \lambda\delta$, where λ is a scalar multiplier and determined by projecting the equation on δ:

$$\delta^T(\delta - G(\lambda\delta)) = 0.$$

The conservative learning alternative to (16) is therefore

$$\gamma \leftarrow \gamma_1 = \frac{(c - \tilde{c})^T (c - \tilde{c})}{(c - \tilde{c})^T G (c - \tilde{c})} (c - \tilde{c}). \tag{18}$$

Not surprisingly this reduces to (16) when the off-diagonal terms in G are dropped.

We conclude this Appendix with a short summary of the conservative learning rules for updating the network weights when given a new training item (a, b, c).

1. Forward propagate (a, b) using (9) and (10) to get $(\tilde{a}^*, \tilde{b}^*, \tilde{c}^* = \tilde{a}^* \circ \tilde{b}^*)$ and $\tilde{c}$.
2. From the output discrepancy $c - \tilde{c}$ compute γ using (18). Computing the scalar multiple of $c - \tilde{c}$ in this expression requires a single backward-forward propagation by the matrix G in (17).
3. The update Δ_c of W_c is the rank 1 matrix (12) constructed from γ and $\tilde{c}^*$.
4. Backward propagate γ by (14) to obtain α and β.
5. The updates (Δ_a, Δ_b) of (W_a, W_b) are given by the rank 1 matrices (7) constructed from (α, β) and (a, b).

Abstract

We reconsider randomized algorithms for the low-rank approximation of symmetric positive semi-definite (SPSD) matrices such as Laplacian and kernel matrices that arise in data analysis and machine learning applications. Our main results consist of an empirical evaluation of the performance quality and running time of sampling and projection methods on a diverse suite of SPSD matrices. Our results highlight complementary aspects of sampling versus projection methods; they characterize the effects of common data preprocessing steps on the performance of these algorithms; and they point to important differences between uniform sampling and nonuniform sampling methods based on leverage scores. In addition, our empirical results illustrate that existing theory is so weak that it does not provide even a qualitative guide to practice. Thus, we complement our empirical results with a suite of worst-case theoretical bounds for both random sampling and random projection methods. These bounds are qualitatively superior to existing bounds—*e.g.*, improved additive-error bounds for spectral and Frobenius norm error and relative-error bounds for trace norm error—and they point to future directions to make these algorithms useful in even larger-scale machine learning applications.

Keywords: Nyström approximation, low-rank approximation, kernel methods, randomized algorithms, numerical linear algebra

1. Introduction

We reconsider randomized algorithms for the low-rank approximation of symmetric positive semi-definite (SPSD) matrices such as Laplacian and kernel matrices that arise in data analysis and machine learning applications. Our goal is to obtain an improved understanding, both empirically and theoretically, of the complementary strengths of sampling versus projection methods on realistic data. Our main results consist of an empirical evaluation of the performance quality and running time of sampling and projection methods on a diverse suite of dense and sparse SPSD matrices drawn both from machine learning as well as more general data analysis applications. These results are not intended to be comprehensive but instead to be illustrative of how randomized algorithms for the low-rank approximation of SPSD matrices behave in a broad range of realistic machine learning and data analysis applications.

Our empirical results point to several directions that are not explained well by existing theory. (For example, that the results are much better than existing worst-case theory would suggest, and that sampling with respect to the statistical leverage scores leads to results that are complementary to those achieved by projection-based methods.) Thus, we complement our empirical results with a suite of worst-case theoretical bounds for both random sampling and random projection methods. These bounds are qualitatively superior to existing bounds—*e.g.*, improved additive-error bounds for spectral and Frobenius norm error and relative-error bounds for trace norm error. By considering random sampling and random projection algorithms on an equal footing, we identify within our analysis deterministic structural properties of the input data and sampling/projection methods that are responsible for high-quality low-rank approximation.

In more detail, our main contributions are fourfold.

- First, we provide an empirical illustration of the complementary strengths and weaknesses of data-independent random projection methods and data-dependent random sampling methods when applied to SPSD matrices. We do so for a diverse class of SPSD matrices drawn from machine learning and data analysis applications, and we consider reconstruction error with respect to the spectral, Frobenius, and trace norms. Depending on the parameter settings, the matrix norm of interest, the data set under consideration, etc., one or the other method might be preferable. In addition, we illustrate how these empirical properties can often be understood in terms of the structural nonuniformities of the input data that are of independent interest.
- Second, we consider the running time of high-quality sampling and projection algorithms. For random sampling algorithms, the computational bottleneck is typically the exact or approximate computation of the importance sampling distribution with respect to which one samples; and for random projection methods, the computational bottleneck is often the implementation of the random projection. By exploiting and extending recent work on "fast" random projections and related recent work on "fast" approximation of the statistical leverage scores, we illustrate that high-quality leverage-based random sampling and high-quality random projection algorithms have comparable running times. Although both are slower than simple (and in general much lower-quality) uniform sampling, both can be implemented more quickly than a naïve computation of an orthogonal basis for the top part of the spectrum.
- Third, our main technical contribution is a set of deterministic structural results that hold for any "sketching matrix" applied to an SPSD matrix. We call these "deterministic structural results" since there is no randomness involved in their statement or analysis and since they depend on structural properties of the input data matrix and the way the sketching matrix interacts with the input data. In particular, they highlight the importance of the statistical leverage scores, which have proven important in other applications of random sampling and random projection algorithms.
- Fourth, our main algorithmic contribution is to show that when the low-rank sketching matrix represents certain random projection or random sampling operations, then we obtain worst-case quality-of-approximation bounds that hold with high probability. These bounds are qualitatively better than existing bounds and they illustrate

how high-quality random sampling algorithms and high-quality random projection algorithms can be treated from a unified perspective.

A novel aspect of our work is that we adopt a unified approach to these low-rank approximation questions—unified in the sense that we consider both sampling and projection algorithms on an equal footing, and that we illustrate how the structural nonuniformities responsible for high-quality low-rank approximation in worst-case analysis also have important empirical consequences in a diverse class of SPSD matrices. By identifying deterministic structural conditions responsible for high-quality low-rank approximation of SPSD matrices, we highlight complementary aspects of sampling and projection methods; and by illustrating the empirical consequences of structural nonuniformities, we provide theory that is a much closer guide to practice than has been provided by prior work. We note also that our deterministic structural results could be used to check, in an *a posteriori* manner, the quality of a sketching method for which one cannot establish an *a priori* bound.

Our analysis is timely for several reasons. First, in spite of the empirical successes of Nyström-based and other randomized low-rank methods, existing theory for the Nyström method is quite modest. For example, existing worst-case bounds such as those of Drineas and Mahoney (2005) are very weak, especially compared with existing bounds for least-squares regression and general low-rank matrix approximation problems (Drineas et al., 2008, 2010; Mahoney, 2011).[1] Moreover, many other worst-case bounds make very strong assumptions about the coherence properties of the input data (Kumar et al., 2012; Gittens, 2012). Second, there have been conflicting views in the literature about the usefulness of uniform sampling versus nonuniform sampling based on the empirical statistical leverage scores of the data in realistic data analysis and machine learning applications. For example, some work has concluded that the statistical leverage scores of realistic data matrices are fairly uniform, meaning that the coherence is small and thus uniform sampling is appropriate (Williams and Seeger, 2001; Kumar et al., 2012); while other work has demonstrated that leverage scores are often very nonuniform in ways that render uniform sampling inappropriate and that can be essential to highlight properties of downstream interest (Paschou et al., 2007; Mahoney and Drineas, 2009). Third, in recent years several high-quality numerical implementations of randomized matrix algorithms for least-squares and low-rank approximation problems have been developed (Avron et al., 2010; Meng et al., 2014; Woolfe et al., 2008; Rokhlin et al., 2009; Martinsson et al., 2011). These have been developed from a "scientific computing" perspective, where condition numbers, spectral norms, etc. are of greater interest (Mahoney, 2012), and where relatively strong homogeneity assumptions can be made about the input data. In many "data analytics" applications, the questions one asks are very different, and the input data are much less well-structured. Thus, we expect that some of our results will help guide the development of algorithms and implementations that are more appropriate for large-scale analytics applications.

In the next section, Section 2, we start by presenting some notation, preliminaries, and related prior work. Then, in Section 3 we present our main empirical results; and in Section 4 we present our main theoretical results. We conclude in Section 5 with a brief discussion of our results in a broader context.

1. This statement may at first surprise the reader, since an SPSD matrix is an example of a general matrix, and one might suppose that the existing theory for general matrices could be applied to SPSD matrices. While this is true, these existing methods for general matrices do not in general respect the symmetry or positive semi-definiteness of the input.

2. Notation, Preliminaries, and Related Prior Work

In this section, we introduce the notation used throughout the paper, and we address several preliminary considerations, including reviewing related prior work.

2.1 Notation

Let $\mathbf{A} \in \mathbb{R}^{n\times n}$ be an arbitrary SPSD matrix with eigenvalue decomposition $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{U}^T$, where we partition $\mathbf{U}$ and $\mathbf{\Sigma}$ as

$$\mathbf{U} = \begin{pmatrix}\mathbf{U}_1 & \mathbf{U}_2\end{pmatrix} \text{ and } \mathbf{\Sigma} = \begin{pmatrix}\mathbf{\Sigma}_1 & \\ & \mathbf{\Sigma}_2\end{pmatrix}. \tag{1}$$

Here, $\mathbf{U}_1$ has k columns and spans the top k-dimensional eigenspace of $\mathbf{A}$, and $\mathbf{\Sigma}_1 \in \mathbb{R}^{k\times k}$ is full-rank.[2] We denote the eigenvalues of $\mathbf{A}$ with $\lambda_1(\mathbf{A}) \geq \ldots \geq \lambda_n(\mathbf{A})$.

Given $\mathbf{A}$ and a rank parameter k, the *statistical leverage scores of* $\mathbf{A}$ *relative to the best rank-k approximation to* $\mathbf{A}$ equal the squared Euclidean norms of the rows of the $n \times k$ matrix $\mathbf{U}_1$:

$$\ell_j = \|(\mathbf{U}_1)_j\|^2. \tag{2}$$

The leverage scores provide a more refined notion of the structural nonuniformities of $\mathbf{A}$ than does the notion of *coherence*, $\mu = \frac{n}{k}\max_{i\in\{1,\ldots,n\}} \ell_i$, which equals (up to scale) the largest leverage score; and they have been used historically in regression diagnostics to identify particularly influential or outlying data points. Less obviously, the statistical leverage scores play a crucial role in recent work on randomized matrix algorithms: they define the key structural nonuniformity that must be dealt with in order to obtain high-quality low-rank and least-squares approximation of general matrices via random sampling and random projection methods (Mahoney, 2011). Although Equation (2) defines them with respect to a particular basis, the statistical leverage scores equal the diagonal elements of the projection matrix onto the span of that basis, and thus they can be computed from any basis spanning the same space. Moreover, they can be approximated more quickly than the time required to compute that basis with a truncated SVD or a QR decomposition (Drineas et al., 2012).

We denote by $\mathbf{S}$ an arbitrary $n \times \ell$ "sketching" matrix that, when post-multiplying a matrix $\mathbf{A}$, maps points from $\mathbb{R}^n$ to $\mathbb{R}^\ell$. We are most interested in the case where $\mathbf{S}$ is a random matrix that represents a random sampling process or a random projection process, but we do not impose this as a restriction unless explicitly stated. We let

$$\mathbf{\Omega}_1 = \mathbf{U}_1^T\mathbf{S} \quad \text{and } \mathbf{\Omega}_2 = \mathbf{U}_2^T\mathbf{S} \tag{3}$$

denote the projection of $\mathbf{S}$ onto the top and bottom eigenspaces of $\mathbf{A}$, respectively.

2. Variants of our results hold trivially if the rank of $\mathbf{A}$ is k or less, so we focus on this more general case here.

Recall that, by keeping just the top k singular vectors, the matrix $\mathbf{A}_k := \mathbf{U}_1\mathbf{\Sigma}_1\mathbf{U}_1^T$ is the best rank-k approximation to $\mathbf{A}$, when measured with respect to any unitarily-invariant matrix norm, *e.g.*, the spectral, Frobenius, or trace norm. For a vector $\mathbf{x} \in \mathbb{R}^n$, let $\|\mathbf{x}\|_\xi$, for $\xi = 1, 2, \infty$, denote the 1-norm, the Euclidean norm, and the ∞-norm, respectively, and let $\mathrm{Diag}(\mathbf{A})$ denote the vector consisting of the diagonal entries of the matrix $\mathbf{A}$. Then, $\|\mathbf{A}\|_2 = \|\mathrm{Diag}(\mathbf{\Sigma})\|_\infty$ denotes the *spectral norm* of $\mathbf{A}$; $\|\mathbf{A}\|_\mathrm{F} = \|\mathrm{Diag}(\mathbf{\Sigma})\|_2$ denotes the *Frobenius norm* of $\mathbf{A}$; and $\|\mathbf{A}\|_\star = \|\mathrm{Diag}(\mathbf{\Sigma})\|_1$ denotes the *trace norm* (or nuclear norm) of $\mathbf{A}$. Clearly,

$$\|\mathbf{A}\|_2 \leq \|\mathbf{A}\|_\mathrm{F} \leq \|\mathbf{A}\|_\star \leq \sqrt{n}\,\|\mathbf{A}\|_\mathrm{F} \leq n\,\|\mathbf{A}\|_2\,.$$

We quantify the quality of our algorithms by the "additional error" (above and beyond that incurred by the best rank-k approximation to $\mathbf{A}$). In the theory of algorithms, bounds of the form provided by (16) below are known as *additive-error bounds*, the reason being that the additional error is an additive factor of the form ϵ times a size scale that is larger than the "base error" incurred by the best rank-k approximation. In this case, the goal is to minimize the "size scale" of the additional error. Bounds of this form are very different and in general weaker than when the additional error enters as a multiplicative factor, such as when the error bounds are of the form $\|\mathbf{A} - \tilde{\mathbf{A}}\| \leq f(n, k, \eta)\|\mathbf{A} - \mathbf{A}_k\|$, where $f(\cdot)$ is some function and η represents other parameters of the problem. These latter bounds are of greatest interest when $f = 1 + \epsilon$, for an error parameter ϵ, as in (18) and (19) below. These *relative-error bounds*, in which the size scale of the additional error equals that of the base error, provide a *much* stronger notion of approximation than additive-error bounds.

2.2 Preliminaries

In many machine learning and data analysis applications, one is interested in symmetric positive semi-definite (SPSD) matrices, *e.g.*, kernel matrices and Laplacian matrices. One common column-sampling-based approach to low-rank approximation of SPSD matrices is the so-called Nyström method (Williams and Seeger, 2001; Drineas and Mahoney, 2005; Kumar et al., 2012). The Nyström method—both randomized and deterministic variants—has proven useful in applications where the kernel matrices are reasonably well-approximated by low-rank matrices; and it has been applied to Gaussian process regression, spectral clustering and image segmentation, manifold learning, and a range of other common machine learning tasks (Williams and Seeger, 2001; Williams et al., 2002; Fowlkes et al., 2004; Talwalkar et al., 2008; Zhang and Kwok, 2010; Kumar et al., 2012). The simplest Nyström-based procedure selects columns from the original data set uniformly at random and then uses those columns to construct a low-rank SPSD approximation. Although this procedure can be effective in practice for certain input matrices, two extensions (both of which are more expensive) can substantially improve the performance, *e.g.*, lead to lower reconstruction error for a fixed number of column samples, both in theory and in practice. The first extension is to sample columns with a judiciously-chosen nonuniform importance sampling distribution; and the second extension is to randomly mix (or combine linearly) columns before sampling them. For the random sampling algorithms, an important question is what importance sampling distribution should be used to construct the sample; while for the random projection algorithms, an important question is how to implement the random projections. In either case, appropriate consideration should be paid to questions such as

whether the data are sparse or dense, how the eigenvalue spectrum decays, the nonuniformity properties of eigenvectors, *e.g.*, as quantified by the statistical leverage scores, whether one is interested in reconstructing the matrix or performing a downstream machine learning task, and so on.

The following sketching model subsumes both of these classes of methods.

- *SPSD Sketching Model.* Let $\mathbf{A}$ be an $n \times n$ positive semi-definite matrix, and let $\mathbf{S}$ be a matrix of size $n \times \ell$, where $\ell \ll n$. Take

$$\mathbf{C} = \mathbf{AS} \quad \text{and } \mathbf{W} = \mathbf{S}^T\mathbf{AS}.$$

  Then $\mathbf{CW}^\dagger\mathbf{C}^T$ is a low-rank approximation to $\mathbf{A}$ with rank at most ℓ.

We should note that the SPSD Sketching Model, formulated in this way, is *not* guaranteed to be numerically stable: if $\mathbf{W}$ is ill-conditioned, then instabilities may arise in forming the product $\mathbf{CW}^\dagger\mathbf{C}^T$. For simplicity in our presentation, we do not describe the generalizations of our results that could be obtained for the various algorithmic tweaks that have been considered to address this potential issue (Drineas et al., 2008; Mahoney and Drineas, 2009; Chiu and Demanet, 2013).

The choice of distribution for the sketching matrix $\mathbf{S}$ leads to different classes of low-rank approximations. For example, if $\mathbf{S}$ represents the process of column sampling, either uniformly or according to a nonuniform importance sampling distribution, then we refer to the resulting approximation as a Nyström extension; if $\mathbf{S}$ consists of random linear combinations of most or all of the columns of $\mathbf{A}$, then we refer to the resulting approximation as a projection-based SPSD approximation. In this paper, we focus on Nyström extensions and projection-based SPSD approximations that fit the above SPSD Sketching Model. In particular, we do not consider adaptive schemes, which iteratively select columns to progressively decrease the approximation error. While these methods often perform well in practice (Belabbas and Wolfe, 2009b,a; Farahat et al., 2011; Kumar et al., 2012), rigorous analyses of them are hard to come by—interested readers are referred to the discussion in (Farahat et al., 2011; Kumar et al., 2012).

2.3 The Power Method

One can obtain the optimal rank-k approximation to $\mathbf{A}$ by forming an SPSD sketch where the sketching matrix $\mathbf{S}$ is an orthonormal basis for the range of $\mathbf{A}_k$, because with such a choice,

$$\mathbf{CW}^\dagger\mathbf{C}^T = \mathbf{AS}(\mathbf{S}^T\mathbf{AS})^\dagger\mathbf{S}^T\mathbf{A} = \mathbf{A}(\mathbf{SS}^T\mathbf{ASS}^T)^\dagger\mathbf{A} = \mathbf{A}(\mathbf{P}_{\mathbf{A}_k}\mathbf{AP}_{\mathbf{A}_k})^\dagger\mathbf{A} = \mathbf{AA}_k^\dagger\mathbf{A} = \mathbf{A}_k.$$

Of course, one cannot quickly obtain such a basis; this motivates considering sketching matrices $\mathbf{S}_q$ obtained using the power method: that is, taking $\mathbf{S}_q = \mathbf{A}^q\mathbf{S}_0$ where q is a positive integer and $\mathbf{S}_0 \in \mathbb{R}^{n\times\ell}$ with $l \geq k$. As $q \to \infty$, assuming $\mathbf{U}_1^T\mathbf{S}_0$ has full row-rank, the matrices $\mathbf{S}_q$ increasingly capture the dominant k-dimensional eigenspaces of $\mathbf{A}$ (see Golub and Van Loan, 1996, Chapter 8), so one can reasonably expect that the sketching matrix $\mathbf{S}_q$ produces SPSD sketches of $\mathbf{A}$ with lower additional error.

SPSD sketches produced using q iterations of the power method have lower error than sketches produced without using the power method, but are roughly q times more costly to

produce. Thus, the power method is most applicable when $\mathbf{A}$ is such that one can compute the product $\mathbf{A}^q\mathbf{S}_0$ fast. We consider the empirical performance of sketches produced using the power method in Section 3, and we consider the theoretical performance in Section 4.

2.4 Related Prior Work

Motivated by large-scale data analysis and machine learning applications, recent theoretical and empirical work has focused on "sketching" methods such as random sampling and random projection algorithms. A large part of the recent body of this work on randomized matrix algorithms has been summarized in the recent monograph by Mahoney (2011) and the recent review article by Halko et al. (2011). Here, we note that, on the empirical side, both random projection methods (*e.g.*, Bingham and Mannila, 2001; Fradkin and Madigan, 2003; Venkatasubramanian and Wang, 2011; Banerjee et al., 2012) and random sampling methods (*e.g.*, Paschou et al., 2007; Mahoney and Drineas, 2009) have been used in applications for clustering and classification of general data matrices; and that some of this work has highlighted the importance of the statistical leverage scores that we use in this paper (Paschou et al., 2007; Mahoney and Drineas, 2009; Mahoney, 2011; Yip et al., 2014). In parallel, so-called Nyström-based methods have also been used in machine learning applications. Originally used by Williams and Seeger to solve regression and classification problems involving Gaussian processes when the SPSD matrix $\mathbf{A}$ is well-approximated by a low-rank matrix (Williams and Seeger, 2001; Williams et al., 2002), the Nyström extension has been used in a large body of subsequent work. For example, applications of the Nyström method to large-scale machine learning problems include the work of Talwalkar et al. (2008); Kumar et al. (2009a,c); Mackey et al. (2011b) and Zhang et al. (2008); Li et al. (2010); Zhang and Kwok (2010), and applications in statistics and signal processing include the work of Parker et al. (2005); Belabbas and Wolfe (2007a,b); Spendley and Wolfe (2008); Belabbas and Wolfe (2008, 2009b,a).

Much of this work has focused on new proposals for selecting columns (*e.g.*, Zhang et al., 2008; Zhang and Kwok, 2009; Liu et al., 2010; Arcolano and Wolfe, 2010; Li et al., 2010) and/or coupling the method with downstream applications (*e.g.*, Bach and Jordan, 2005; Cortes et al., 2010; Jin et al., 2013; Homrighausen and McDonald, 2011; Machart et al., 2011; Bach, 2013). The most detailed results are provided by Kumar et al. (2012) as well as the conference papers on which it is based (Kumar et al., 2009a,b,c). Interestingly, they observe that uniform sampling performs quite well, suggesting that in the data they considered the leverage scores are quite uniform, which also motivated the related works of Talwalkar and Rostamizadeh (2010); Mohri and Talwalkar (2011). This is in contrast with applications in genetics (Paschou et al., 2007), term-document analysis (Mahoney and Drineas, 2009), and astronomy (Yip et al., 2014), where the statistical leverage scores were seen to be very nonuniform in ways of interest to the downstream scientist; we return to this issue in Section 3.

On the theoretical side, much of the work has followed that of Drineas and Mahoney (2005), who provided the first rigorous bounds for the Nyström extension of a general SPSD matrix. They show that when $\Omega(k\epsilon^{-4}\ln\delta^{-1})$ columns are sampled with an importance sampling distribution that is proportional to the square of the diagonal entries of $\mathbf{A}$, then

$$\|\mathbf{A}-\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\|_\xi \leq \|\mathbf{A}-\mathbf{A}_k\|_\xi + \epsilon\sum_{k=1}^n(\mathbf{A})_{ii}^2 \tag{4}$$

holds with probability $1-\delta$, where $\xi = 2, F$ represents the Frobenius or spectral norm. (Actually, they prove a stronger result of the form given in Equation (4), except with $\mathbf{W}^\dagger$ replaced with $\mathbf{W}_k^\dagger$, where $\mathbf{W}_k$ represents the best rank-k approximation to $\mathbf{W}$ (Drineas and Mahoney, 2005).) Subsequently, Kumar, Mohri, and Talwalkar show that if $\mu k\ln(k/\delta))$ columns are sampled uniformly at random with replacement from an $\mathbf{A}$ that has *exactly* rank k, then one achieves exact recovery, *i.e.*, $\mathbf{A}=\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T$, with high probability (Kumar et al., 2009a). Gittens (2012) extends this to the case where $\mathbf{A}$ is only approximately low-rank. In particular, he shows that if $\ell=\Omega(\mu k\ln k)$ columns are sampled uniformly at random (either with or without replacement), then

$$\left\|\mathbf{A}-\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\right\|_2 \leq \|\mathbf{A}-\mathbf{A}_k\|_2\left(1+\frac{2n}{\ell}\right) \tag{5}$$

with probability exceeding $1-\delta$ and

$$\left\|\mathbf{A}-\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\right\|_2 \leq \|\mathbf{A}-\mathbf{A}_k\|_2 + \frac{2}{\delta}\cdot\|\mathbf{A}-\mathbf{A}_k\|_\star \tag{6}$$

with probability exceeding $1-2\delta$.

We have described these prior theoretical bounds in detail to emphasize how strong, relative to the prior work, our new bounds are. For example, Equation (4) provides an additive-error approximation with a very large scale; the bounds of Kumar, Mohri, and Talwalkar require a sampling complexity that depends on the coherence of the input matrix (Kumar et al., 2009a), which means that unless the coherence is very low one needs to sample essentially all the rows and columns in order to reconstruct the matrix; Equation (5) provides a bound where the additive scale depends on n; and Equation (6) provides a spectral norm bound where the scale of the additional error is the (much larger) trace norm. Table 1 compares the bounds on the approximation errors of SPSD sketches derived in this work to those available in the literature. We note further that Wang and Zhang recently established lower-bounds on the worst-case relative spectral and trace norm errors of uniform Nyström extensions (Wang and Zhang, 2013). Our Lemma 8 provides matching upper bounds, showing the optimality of these estimates.

A related stream of research concerns projection-based low-rank approximations of general (*i.e.*, non-SPSD) matrices (Halko et al., 2011; Mahoney, 2011). Such approximations are formed by first constructing an approximate basis for the top left invariant subspace of $\mathbf{A}$, and then restricting $\mathbf{A}$ to this space. Algorithmically, one constructs $\mathbf{Y}=\mathbf{A}\mathbf{S}$, where $\mathbf{S}$ is a sketching matrix, then takes $\mathbf{Q}$ to be a basis obtained from the QR decomposition of $\mathbf{Y}$, and then forms the low-rank approximation $\mathbf{Q}\mathbf{Q}^T\mathbf{A}$. The survey paper Halko et al. (2011) proposes two schemes for the approximation of SPSD matrices that fit within this paradigm: $\mathbf{Q}(\mathbf{Q}^T\mathbf{A}\mathbf{Q})\mathbf{Q}^T$ and $(\mathbf{A}\mathbf{Q})(\mathbf{Q}^T\mathbf{A}\mathbf{Q})^\dagger(\mathbf{Q}^T\mathbf{A})$. The first scheme—for which Halko et al. (2011) provides quite sharp error bounds when $\mathbf{S}$ is a matrix of i.i.d. standard Gaussian random variables—has the salutary property of being numerically stable. In Wang and Zhang (2013), the authors show that using the first scheme with an adaptively sampled $\mathbf{S}$ results in approximations with expected Frobenius error within a factor of $1+\epsilon$ of the optimal rank-k approximation error when $\mathrm{O}(k/\epsilon^2)$ columns are sampled.

Halko et al. (2011) does not provide any theoretical guarantees for the second scheme, but observes that this latter scheme produces noticeably more accurate approximations in

Table 1: Comparison of our bounds on the approximation errors of several types of SPSD sketches with those provided in prior works. Only the asymptotically largest terms (as $\epsilon\to 0$) are displayed and constants are omitted, for simplicity. Here, $\epsilon\in(0,1)$, opt_ξ is the smallest ξ-norm error possible when approximating $\mathbf{A}$ with a rank-k matrix ($k\geq\ln n$), $r=\mathrm{rank}(\mathbf{A})$, ℓ is the number of column samples sufficient for the stated bounds to hold, k is a target rank, and μ_s is the coherence of $\mathbf{A}$ relative to the best rank-s approximation to $\mathbf{A}$. The parameter $\beta\in(0,1]$ allows for the possibility of sampling using β-approximate leverage scores (see Section 4.2.1) rather than the exact leverage scores. With the exception of (Drineas and Mahoney, 2005), which samples columns with probability proportional to their Euclidean norms, and our novel leverage-based Nyström bound, these bounds are for sampling columns or linear combinations of columns uniformly at random. All bounds hold with constant probability.

practice. In Section 3, we show this second scheme is an instantiation of the power method (as described in Section 2.3) with $q=1$. Accordingly, the deterministic and stochastic error bounds provided in Section 4 provide theoretical guarantees for this SPSD sketch.

Table 2: The min/mean/max ratios of the errors of several non-rank-restricted SPSD sketches to the optimal rank-k approximation error for several of the matrices considered in Table 4. Here k is the target rank and ℓ is the number of column samples used to form the SPSD sketches. The min/mean/max ratios were computed using 30 trials for each combination of ℓ and sketching method.

Table 3: Comparison of the empirically observed approximation errors to the guarantees provided in this and other works, for several data sets. Each approximation was formed using $\ell = 6k \ln k$ samples. To evaluate the error guarantees, $\delta = 1/2$ was taken and all constants present in the statements of the bounds were replaced with ones. The observed errors were taken to be the average errors over 30 runs of the approximation algorithms. The data sets, described in Section 3.1, are representative of several classes of matrices prevalent in machine learning applications.

2.5 An Overview of Our Bounds

Our bounds in Table 1 (established as Lemmas 5–8 in Section 4.2) exhibit a common structure: for the spectral and Frobenius norms, we see that the additional error is on a larger scale than the optimal error, and the trace norm bounds all guarantee relative error approximations. This follows from the fact, as detailed in Section 4.1, that low-rank approximations that conform to the SPSD sketching model can be understood as forming column-sample/projection-based approximations to the *square root* of $\mathbf{A}$, and thus squaring this approximation yields the resulting approximation to $\mathbf{A}$. The squaring process unavoidably results in potentially large additional errors in the case of the spectral and Frobenius norms— whether or not the additional errors are large in practice depends upon the properties of the matrix and the form of stochasticity used in the sampling process. For instance, from our bounds it is clear that Gaussian-based SPSD sketches are expected to have lower additional error in the spectral norm than any of the other sketches considered.

From Table 1, we also see, in the case of uniform Nyström extensions, a necessary dependence on the coherence of the input matrix since columns are sampled uniformly at random. However, we also see that the scales of the additional error of the Frobenius and trace norm bounds are substantially improved over those in prior results. The large additional error in the spectral norm error bound is necessary in the worse case (Gittens, 2012). Lemmas 5, 6 and 7 in Section 4.2—which respectively address leverage-based, Fourier-based, and Gaussian-based SPSD sketches—show that spectral norm additive-error bounds with additional error on a substantially smaller scale can be obtained if one first mixes the columns before sampling from $\mathbf{A}$ or one samples from a judicious nonuniform distribution over the columns.

Table 2 compares the minimum, mean, and maximum approximation errors of several SPSD sketches of four matrices (described in Section 3.1) to the optimal rank-k approximation errors. We consider three regimes for ℓ, the number of column samples used to construct the sketch: $\ell = \mathrm{O}(k)$, $\ell = \mathrm{O}(k \ln k)$, and $\ell = \mathrm{O}(k \ln n)$. These matrices exhibit a diverse range of properties: *e.g.*, Enron is sparse and has a slowly decaying spectrum, while Protein is dense and has a rapidly decaying spectrum. Yet we notice that the sketches perform quite well on each of these matrices. In particular, when $\ell = \mathrm{O}(k \ln n)$, the average errors of the sketches are within $1 + \epsilon$ of the optimal rank-k approximation errors, where $\epsilon \in [0, 1]$. Also note that the leverage-based sketches consistently have lower average errors (in all of the three norms considered) than all other sketches. Likewise, the uniform Nyström extensions usually have larger average errors than the other sketches. These two sketches represent opposite extremes: uniform Nyström extensions (constructed using uniform column sampling) are constructed using no knowledge about the matrix, while leverage-based sketches use an importance sampling distribution derived from the SVD of the matrix to determine which columns to use in the construction of the sketch.

Table 3 illustrates the gap between the theoretical results currently available in the literature and what is observed in practice: it depicts the ratio between the error bounds in Table 1 and the average errors observed over 30 runs of the SPSD approximation algorithms (the error bound from (Talwalkar and Rostamizadeh, 2010) is not considered in the table, as it does not apply at the number of samples ℓ used in the experiments). Several trends can be identified; among them, we note that the bounds provided in this paper for Gaussian-based

sketches come quite close to capturing the errors seen in practice, and the Frobenius and trace norm error guarantees of the leverage-based and Fourier-based sketches tend to more closely reflect the empirical behavior than the error guarantees provided in prior work for Nyström sketches. Overall, the trace norm error bounds are quite accurate. On the other hand, prior bounds are sometimes more informative in the case of the spectral norm (with the notable exception of the Gaussian sketches). Several important points can be gleaned from these observations. First, the accuracy of the Gaussian error bounds suggests that the main theoretical contribution of this work, the deterministic structural results given as Theorems 2 through 4, captures the underlying behavior of the SPSD sketching process. This supports our belief that this work provides a foundation for truly informative error bounds. Given that this is the case, it is clear that the analysis of the stochastic elements of the SPSD sketching process is much sharper in the Gaussian case than in the leverage-score, Fourier, and uniform Nyström cases. We expect that, at least in the case of leverage and Fourier-based sketches, the stochastic analysis can and will be sharpened to produce error guarantees almost as informative as the ones we have provided for Gaussian-based sketches.

3. Empirical Aspects of SPSD Low-rank Approximation

In this section, we present our main empirical results, which consist of evaluating sampling and projection algorithms applied to a diverse set of SPSD matrices. The bulk of our empirical evaluation considers two random projection procedures and two random sampling procedures for the sketching matrix $\mathbf{S}$: for random projections, we consider using SRFTs (Subsampled Randomized Fourier Transforms) as well as uniformly sampling from Gaussian mixtures of the columns; and for random sampling, we consider sampling columns uniformly at random as well as sampling columns according to a nonuniform importance sampling distribution that depends on the empirical statistical leverage scores. In the latter case of leverage score-based sampling, we also consider the use of both the (naïve and expensive) exact algorithm as well as a (recently-developed fast) approximation algorithm. Section 3.1 starts with a brief description of the data sets we consider; Section 3.2 describes the details of our SPSD sketching algorithms; Section 3.3 summarizes our experimental results to help guide in the selection of sketching methods; in Section 3.4, we present our main results on reconstruction quality for the random sampling and random projection methods; and, in Section 3.5, we discuss running time issues, and we present our main results for running time and reconstruction quality for both exact and approximate versions of leverage-based sampling.

We emphasize that we don't intend these results to be "comprehensive" but instead to be "illustrative" case-studies—that are representative of a much wider range of applications than have been considered previously. In particular, we would like to illustrate the tradeoffs between these methods in different realistic applications in order, *e.g.*, to provide directions for future work. In addition to clarifying some of these issues, our empirical evaluation also illustrates ways in which existing theory is insufficient to explain the success of sampling and projection methods. This motivates our improvements to existing theory that we describe in Section 4.

All of our computations were conducted using 64-bit MATLAB R2012a under Ubuntu on a 2.6–GHz quad-core Intel i7 machine with 6Gb of RAM. To allow for accurate timing

comparisons, all computations were carried out in a single thread. When applied to an $n \times n$ SPSD matrix $\mathbf{A}$, our implementation of the SRFT requires $\mathrm{O}(n^2 \ln n)$ operations, as it applies MATLAB's `fft` to the entire matrix $\mathbf{A}$ and *then* it samples ℓ columns from the resulting matrix. A more rigorous implementation of the SRFT algorithm could reduce this running time to $\mathrm{O}(n^2 \ln \ell)$, but due to the complexities involved in optimizing pruned FFT codes, we did not pursue this avenue.

3.1 Data Sets

Table 4 provides summary statistics for the data sets used in our empirical evaluation. We consider four classes of matrices commonly encountered in machine learning and data analysis applications: normalized Laplacians of very sparse graphs drawn from "informatics graph" applications; dense matrices corresponding to Linear Kernels from machine learning applications; dense matrices constructed from a Gaussian Radial Basis Function Kernel (RBFK); and sparse RBFK matrices constructed using Gaussian radial basis functions, truncated to be nonzero only for nearest neighbors. This collection of data sets represents a wide range of data sets with very different (sparsity, spectral, leverage score, etc.) properties that have been of interest recently not only in machine learning but in data analysis more generally.

To understand better the Laplacian data, recall that, given an undirected graph with weighted adjacency matrix $\mathbf{W}$, its normalized graph Laplacian is

$$\mathbf{A} = \mathbf{I} - \mathbf{D}^{-1/2}\mathbf{W}\mathbf{D}^{-1/2},$$

where $\mathbf{D}$ is the diagonal matrix of weighted degrees of the nodes of the graph, *i.e.*, $D_{ii} = \sum_{j \neq i} W_{ij}$.

The remaining data sets are kernel matrices associated with data drawn from a variety of application areas. Recall that, given given points $\mathbf{x}_1, \ldots, \mathbf{x}_n \in \mathbb{R}^d$ and a function $\kappa : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}$, the $n \times n$ matrix with elements

$$A_{ij} = \kappa(\mathbf{x}_i, \mathbf{x}_j)$$

is called the kernel matrix of κ with respect to $\mathbf{x}_1, \ldots, \mathbf{x}_n$. Appropriate choices of κ ensure that $\mathbf{A}$ is positive semidefinite. When this is the case, the entries A_{ij} can be interpreted as measuring, in a sense determined by the choice of κ, the similarity of points i and j. Specifically, if $\mathbf{A}$ is SPSD, then κ determines a so-called *feature map* $\Phi_\kappa : \mathbb{R}^d \to \mathbb{R}^n$ such that

$$A_{ij} = \langle \Phi_\kappa(\mathbf{x}_i), \Phi_\kappa(\mathbf{x}_j) \rangle$$

measures the similarity (correlation) of $\mathbf{x}_i$ and $\mathbf{x}_j$ in feature space (Schölkopf and Smola, 2001).

When κ is the usual Euclidean inner-product, so that

$$A_{ij} = \langle \mathbf{x}_i, \mathbf{x}_k \rangle,$$

$\mathbf{A}$ is called a Linear Kernel matrix. Gaussian RBFK matrices, defined by

$$A^\sigma_{ij} = \exp\left(\frac{-\|\mathbf{x}_i - \mathbf{x}_j\|_2^2}{\sigma^2}\right),$$

Table 4: The data sets used in our empirical evaluation (Leskovec et al., 2007; Klimt and Yang, 2004; Guyon et al., 2005; Gustafson et al., 2006; Nielsen et al., 2002; Corke, 1996; Asuncion and Newman, 2012). Here, n is the number of data points, d is the number of features in the input space before kernelization, and %nnz is the percentage of nonzero entries in the matrix. For Laplacian "kernels," n is the number of nodes in the graph (and thus there is no d since the graph is "given" rather than "constructed"). The %nnz for the Sparse RBF Kernels depends on the σ parameter; see Table 5.

correspond to the similarity measure $\kappa(\mathbf{x},\mathbf{y}) = \exp(-\|\mathbf{x}-\mathbf{y}\|_2^2/\sigma^2)$. Here σ, a nonnegative number, defines the scale of the kernel. Informally, σ defines the "size scale" over which pairs of points $\mathbf{x}_i$ and $\mathbf{x}_j$ "see" each other. Typically σ is determined by a global cross-validation criterion, as $\mathbf{A}^\sigma$ is generated for some specific machine learning task; and, thus, one may have no *a priori* knowledge of the behavior of the spectrum or leverage scores of $\mathbf{A}^\sigma$ as σ is varied. Accordingly, we consider Gaussian RBFK matrices with different values of σ.

Finally, given the same data points, $\mathbf{x}_1,\ldots,\mathbf{x}_n$, one can construct sparse Gaussian RBFK matrices

$$A_{ij}^{(\sigma,\nu,C)} = \left[\left(1-\frac{\|\mathbf{x}_i-\mathbf{x}_j\|_2}{C}\right)^\nu\right]^+ \cdot \exp\left(\frac{-\|\mathbf{x}_i-\mathbf{x}_j\|_2^2}{\sigma^2}\right),$$

where $[x]^+ = \max\{0,x\}$. When ν is larger than $(d+1)/2$, this kernel matrix is positive semidefinite (Genton, 2002). Increasing ν shrinks the magnitudes of the off-diagonal entries of the matrix toward zero. As the cutoff point C decreases the matrix becomes more sparse; in particular, $C \to 0$ ensures that $\mathbf{A}^{(\sigma,\nu,C)} \to \mathbf{I}$. On the other hand, $C \to \infty$ ensures that

Name	%nnz	$\lceil \frac{\|\mathbf{A}\|_F^2}{\|\mathbf{A}\|_2^2} \rceil$	k	$\frac{\lambda_{k+1}}{\lambda_k}$	$100\frac{\|\mathbf{A}-\mathbf{A}_k\|_F}{\|\mathbf{A}\|_F}$	$100\frac{\|\mathbf{A}-\mathbf{A}_k\|_\star}{\|\mathbf{A}\|_\star}$	kth-largest leverage score scaled by n/k

Table 5: Summary statistics for the data sets from Table 4 that we used in our empirical evaluation.

$\mathbf{A}^{(\sigma,\nu,C)}$ approaches the (dense) Gaussian RBFK matrix $\mathbf{A}^\sigma$. For simplicity, in our empirical evaluations, we fix $\nu = \lceil (d+1)/2 \rceil$ and $C = 3\sigma$, and we vary σ.

To illustrate the diverse range of properties exhibited by these four classes of data sets, consider Table 5. Several observations are particularly relevant to our discussion below.

- All of the Laplacian Kernels drawn from informatics graph applications are extremely sparse in terms of number of nonzeros, and they all tend to have very slow spectral decay, as illustrated both by the quantity $\lceil \|\mathbf{A}\|_F^2 / \|\mathbf{A}\|_2^2 \rceil$ (this is the *stable rank*, which is a numerically stable (under)estimate of the rank of $\mathbf{A}$) as well as by the relatively small fraction of the Frobenius norm that is captured by the best rank-k approximation to $\mathbf{A}$.

- Both the Linear Kernels and the Dense RBF Kernels are much denser and are much more well-approximated by moderately to very low-rank matrices. In addition, both the Linear Kernels and the Dense RBF Kernels have statistical leverage scores that are much more uniform—there are several ways to illustrate this, none of them perfect. Here, we illustrate this by considering the k^{th} largest leverage score, scaled by the factor n/k (if $\mathbf{A}$ were exactly rank k, this would be the coherence of $\mathbf{A}$). For the Linear Kernels and the Dense RBF Kernels, this quantity is typically one to two orders of magnitude smaller than for the Laplacian Kernels.

- For the Dense RBF Kernels, we consider two values of the σ parameter, again chosen (somewhat) arbitrarily. For both AbaloneD and WineD, we see that decreasing σ from 1 to 0.15, *i.e.*, letting data points "see" fewer nearby points, has two important effects: first, it results in matrices that are much *less* well-approximated by low-rank matrices; and second, it results in matrices that have *much* more heterogeneous leverage scores.

- For the Sparse RBF Kernels, there are a range of sparsities, ranging from above the sparsity of the sparsest Linear Kernel, but all are denser than the Laplacian Kernels. Changing the σ parameter has the same effect (although it is even more pronounced) for Sparse RBF Kernels as it has for Dense RBF Kernels. In addition, "sparsifying" a Dense RBF Kernel also has the effect of making the matrix less well approximated by a low-rank matrix and of making the leverage scores more nonuniform.

As we see below, when we consider the RBF Kernels as the width parameter and sparsity are varied, we observe a range of intermediate cases between the extremes of the ("nice") Linear Kernels and the (very "non-nice") Laplacian Kernels.

3.2 SPSD Sketching Algorithms

The sketching matrix $\mathbf{S}$ may be selected in a variety of ways. For sampling-based sketches, the sketching matrix $\mathbf{S}$ contains exactly one nonzero in each column, corresponding to a single sample from the columns of $\mathbf{A}$. For projection-based sketches, $\mathbf{S}$ is dense, and mixes the columns of $\mathbf{A}$ before sampling from the resulting matrix.

In more detail, we consider two types of sampling-based SPSD sketches (*i.e.* Nyström extensions): those constructed by sampling columns uniformly at random with replacement, and those constructed by sampling columns from a distribution based upon the leverage scores of the matrix filtered through the optimal rank-k approximation of the matrix. In the case of column sampling, the sketching matrix $\mathbf{S}$ is simply the first ℓ columns of a matrix that was chosen uniformly at random from the set of all permutation matrices.

In the case of leverage-based sampling, $\mathbf{S}$ has a more complicated distribution. Recall that the leverage scores relative to the best rank-k approximation to $\mathbf{A}$ are the squared Euclidean norms of the rows of the $n \times k$ matrix $\mathbf{U}_1$:

$$\ell_j = \|(\mathbf{U}_1)_j\|^2.$$

It follows from the orthonormality of $\mathbf{U}_1$ that $\sum_j (\ell_j/k) = 1$, and the leverage scores can thus be interpreted as a probability distribution over the columns of $\mathbf{A}$. To construct a sketching matrix corresponding to sampling from this distribution, we first select the columns to be used by sampling with replacement from this distribution. Then, $\mathbf{S}$ is constructed as $\mathbf{S} = \mathbf{RD}$ where $\mathbf{R} \in \mathbb{R}^{n\times\ell}$ is a column selection matrix that samples columns of $\mathbf{A}$ from the given distribution—*i.e.*, $\mathbf{R}_{ij} = 1$ iff the ith column of $\mathbf{A}$ is the jth column selected—and $\mathbf{D}$ is a diagonal rescaling matrix satisfying $\mathbf{D}_{jj} = \frac{1}{\sqrt{\ell p_i}}$ iff $\mathbf{R}_{ij} = 1$. Here, $p_i = \ell_i/k$ is the probability of choosing the ith column of $\mathbf{A}$. It is often expensive to compute the leverage scores exactly; in Section 3.5, we consider the performance of sketches based on several leverage score approximation algorithms.

The two projection-based sketches we consider use Gaussians and the real Fourier transform. In the former case, $\mathbf{S}$ is a matrix of i.i.d. $\mathcal{N}(0,1)$ random variables. In the latter case,

$\mathbf{S}$ is a *subsampled randomized Fourier transform* (SRFT) matrix; that is, $\mathbf{S} = \sqrt{\frac{n}{\ell}}\mathbf{DFR}$, where $\mathbf{D}$ is a diagonal matrix of Rademacher random variables, $\mathbf{F}$ is the real Fourier transform matrix, and $\mathbf{R}$ restricts to ℓ columns.

For conciseness, we do not present results for sampling-based sketches where rows are selected with probability proportional to their row norms. This form of sampling can be similar to leverage-score sampling for sparse graphs with highly connected vertices (Mahoney and Drineas, 2009), and in cases where the matrix has been preprocessed to have uniform row lengths, reduces to uniform sampling.

In the figures, we refer to sketches constructed by selecting columns uniformly at random with the label 'unif', leverage score-based sketches with 'lev', Gaussian sketches with 'gaussian', and Fourier sketches with 'srft'.

3.3 Guidelines for Selecting Sketching Schemes

In the remainder of this section of the paper, we provide empirical evaluations of the sampling and projection-based sketching schemes just described, with an eye towards identifying the aspects of the datasets that affect the relative performance of the sketching schemes. However our experiments also provide some practical guidelines for selecting a particular sketching scheme.

- Despite the theoretical result that the worst-case spectral error in using Nyström sketches obtained via uniform column-samples can be much worse than that of using projection or leverage-based sketches, on the corpus of data sets we considered, such sketches perform within a small multiple of the error of more computationally expensive leverage-based and projection-based sketches. For data sets with more nonuniform leverage score properties, random projections and leverage-based sampling will do better (Ma et al., 2014).

- In the case where parsimony of the sketch is of primary concern, *i.e.* where the primary concern is to maintain $\ell \approx k$, leverage sketches are an attractive option. In particular, when an RBF kernel with small bandwidth is used, or the data set is sparse, leverage-based sketches often provide higher accuracy than projection or uniform-sampling based sketches.

- The norm in which the error is measured should be taked into consideration when selecting the sketching algorithm. In particular, sketches which use power iterations are most useful when the error is measured in the spectral norm, and in this case, projection-based sketches (in particular, *prolonged* sketches– see Section 3.6) noticeably outperform uniform sampling-based sketches.

3.4 Reconstruction Accuracy of Sampling and Projection Algorithms

Here, we describe the performances of the SPSD sketches described in Section 3.2—column sampling uniformly at random without replacement, column sampling according to the nonuniform leverage score probabilities, and sampling using Gaussian and SRFT mixtures of the columns—in terms of reconstruction accuracy for the data sets described in Section 3.1. We describe general observations we have made about each class of matrices in

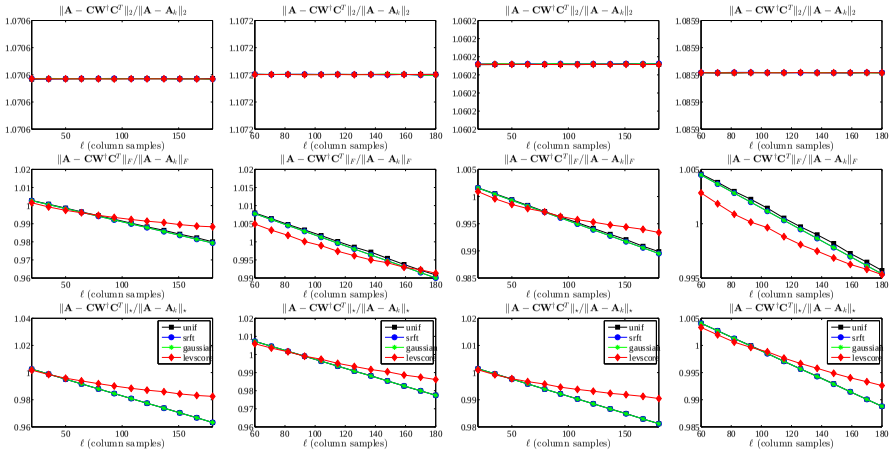
turn, and then we summarize our observations. We consider only the use of exact leverage scores here, and we postpone until Section 3.5 a discussion of running time issues and similar reconstruction results when approximate leverage scores are used for the importance sampling distribution. The relative errors

$$\left\|\mathbf{A}-\mathbf{C}\mathbf{W}^{\dagger}\mathbf{C}^{T}\right\|_{\xi} / \left\|\mathbf{A}-\mathbf{A}_{k}\right\|_{\xi} \tag{7}$$

are plotted, with each point in the figures of this section representing the average errors observed over 30 trials.

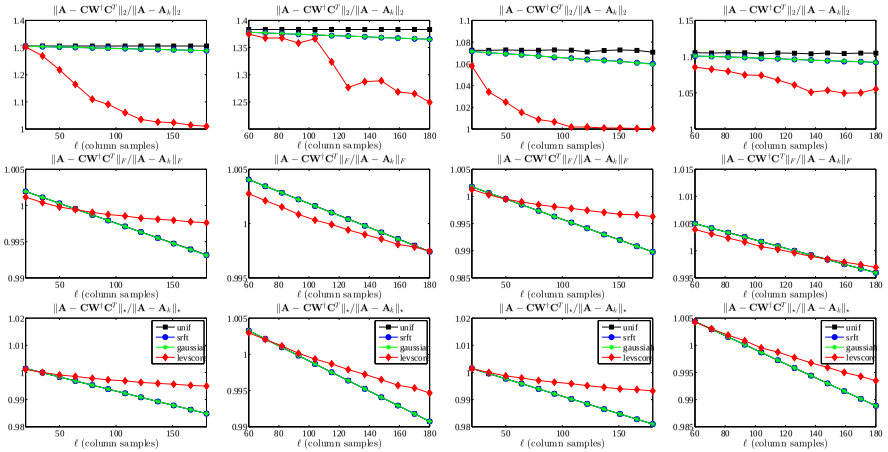
3.4.1 Graph Laplacians

Figure 1 and Figure 2 show the reconstruction error results for sampling and projection methods applied to several normalized graph Laplacians. The former shows GR and HEP, each for two values of the rank parameter, and the latter shows Enron and Gnutella, again each for two values of the rank parameter. Both figures show the spectral, Frobenius, and trace norm approximation errors, as a function of the number of column samples ℓ, relative to the error of the optimal rank-k approximation of $\mathbf{A}$.



(a) GR, $k = 20$ (b) GR, $k = 60$ (c) HEP, $k = 20$ (d) HEP, $k = 60$

Figure 1: The spectral, Frobenius, and trace norm errors (top to bottom, respectively, in each subfigure) of several SPSD sketches, as a function of the number of column samples ℓ, for the GR and HEP Laplacian data sets, with two choices of the rank parameter k.



(a) Enron, $k = 20$ (b) Enron, $k = 60$ (c) Gnutella, $k = 20$ (d) Gnutella, $k = 60$

Figure 2: The spectral, Frobenius, and trace norm errors (top to bottom, respectively, in each subfigure) of several SPSD sketches, as a function of the number of column samples ℓ, for the Enron and Gnutella Laplacian data sets, with two choices of the rank parameter k.

These and subsequent figures contain a lot of information, some of which is peculiar to the given data sets and some of which is more general. In light of subsequent discussion, several observations are worth making about the results presented in these two figures.

- All of the SPSD sketches provide quite accurate approximations—relative to the best possible approximation factor for that norm, and relative to bounds provided by existing theory, as reviewed in Section 2.4—even with only k column samples (or in the case of the Gaussian and SRFT mixtures, with only k linear combinations of columns). Upon examination, this is partly due to the extreme sparsity and extremely slow spectral decay of these data sets which means, as shown in Table 4, that only a small fraction of the (spectral or Frobenius or trace) mass is captured by the optimal rank 20 or 60 approximation. Thus, although an SPSD sketch constructed from 20 or 60 vectors also only captures a small portion of the mass of the matrix, the relative error is small, since the scale of the residual error is large.

- The scale of the Y axes is different between different figures and subfigures. This is to highlight properties within a given plot, but it can hide several things. In particular, note that the scale for the spectral norm is generally larger than for the Frobenius norm, which is generally larger than for the trace norm, consistent with the size of those norms; and that the scale is larger for higher-rank approximations, *e.g.* compare

GR $k = 20$ with GR $k = 60$. This is also consistent with the larger amount of mass captured by higher-rank approximations.

- For $\ell > k$, the errors tend to decrease (or at least not increase, as for GR and HEP the spectral norm error is flat as a function of ℓ), which is intuitive.

- The X axes ranges from k to $9k$ for the $k = 20$ plots and from k to $3k$ for the $k = 60$ plots. As a practical matter, choosing ℓ between k and (say) $2k$ or $3k$ is probably of greatest interest. In this regime, there is an interesting tradeoff: for moderately large values of ℓ in this regime, the error for leverage-based sampling is moderately better than for uniform sampling or random projections, while if one chooses ℓ to be much larger then the improvements from leverage-based sampling saturate and the uniform sampling and random projection methods are better. This is most obvious in the Frobenius norm plots, although it is also seen in the trace norm plots, and it suggests that some combination of leverage-based sampling and uniform sampling might be best.

- The behavior of the approximations with respect to the spectral norm is quite different from the behavior in the Frobenius and trace norms. In the latter, as the number of samples ℓ increases, the errors tend to decrease; while for the former, the errors tend to be much flatter as a function of increasing ℓ for at least the Gaussian, SRFT, and uniformly sampled sketches.

All in all, there seems to be quite complicated behavior for low-rank sketches for these Laplacian data sets. Several of these observations can also be made for subsequent figures; but in some other cases the (very sparse and not very low rank) structural properties of the data are primarily responsible.

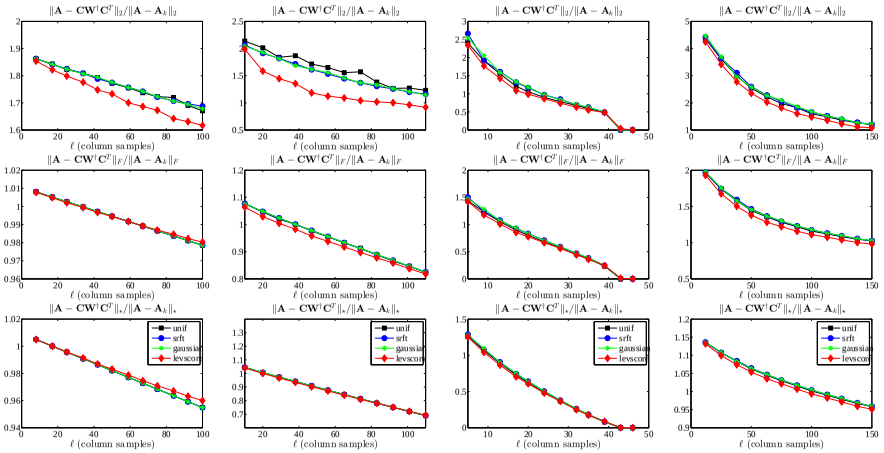
3.4.2 Linear Kernels

Figure 3 shows the reconstruction error results for sampling and projection methods applied to several Linear Kernels. The data sets (Dexter, Protein, SNPs, and Gisette) are all quite low-rank and have fairly uniform leverage scores. Several observations are worth making about the results presented in this figure.

- All of the methods perform quite similarly: all have errors that decrease smoothly with increasing ℓ, and in this case there is little advantage to using methods other than uniform sampling (since they perform similarly and are more expensive). Also, since the ranks are so low and the leverage scores are so uniform, the leverage score sketch is no longer significantly distinguished by its tendency to saturate quickly.

- The scale of the Y axes is much larger than for the Laplacian data sets, mostly since the matrices are much more well-approximated by low-rank matrices, although the scale decreases as one goes from spectral to Frobenius to trace reconstruction error, as before.

These linear kernels (and also to some extent the dense RBF kernels below that have larger σ parameter) are examples of relatively "nice" machine learning data sets that are similar



(a) Dexter, $k = 8$ (b) Protein, $k = 10$ (c) SNPs, $k = 5$ (d) Gisette, $k = 12$

Figure 3: The spectral, Frobenius, and trace norm errors (top to bottom, respectively, in each subfigure) of several SPSD sketches, as a function of the number of column samples ℓ, for the Linear Kernel data sets.

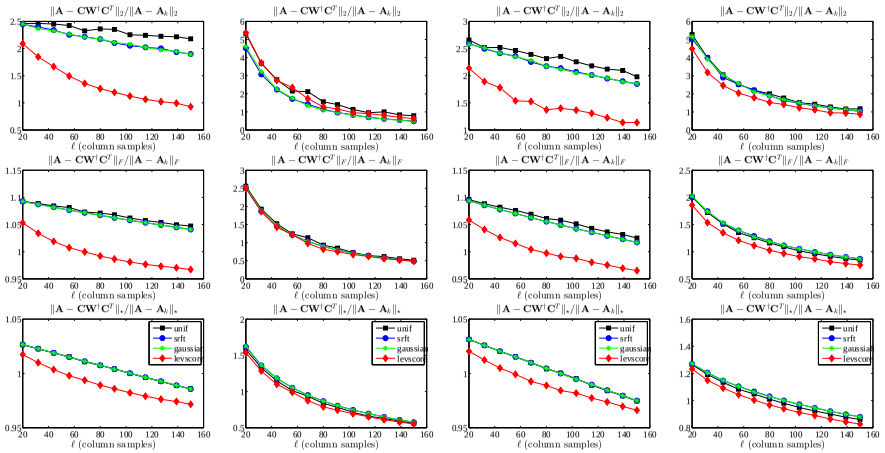
to matrices where uniform sampling has been shown to perform well previously (Talwalkar et al., 2008; Kumar et al., 2009a,c, 2012); for these matrices our empirical results agree with these prior works.

3.4.3 Dense and Sparse RBF Kernels

Figure 4 and Figure 5 present the reconstruction error results for sampling and projection methods applied to several dense RBF and sparse RBF kernels. Several observations are worth making about the results presented in these figures.

- All of the methods have errors that decrease with increasing ℓ, but for larger values of σ and for denser data, the decrease is somewhat more regular, and the four methods tend to perform similarly. For larger values of σ and sparser data, leverage score sampling is somewhat better. This parallels what we observed with the Linear Kernels, except that here the leverage score sampling is somewhat better for all values of ℓ.

- For smaller values of σ, leverage score sampling tends to be much better than uniform sampling and projection-based methods. For sparse data, however, this effect saturates; and we again observe (especially when σ is smaller in AbaloneS and WineS) the tradeoff we observed previously with the Laplacian data—leverage score sampling is better when ℓ is moderately larger than k, while uniform sampling and random projections are better when ℓ is much larger than k.



(a) AbaloneD, $\sigma = .15, k = 20$ (b) AbaloneD, $\sigma = 1, k = 20$ (c) WineD, $\sigma = 1, k = 20$ (d) WineD, $\sigma = 2.1, k = 20$

Figure 4: The spectral, Frobenius, and trace norm errors (top to bottom, respectively, in each subfigure) of several SPSD sketches, as a function of the number of column samples ℓ, for several dense RBF data sets.

Recall from Table 5 that for smaller values of σ and for sparser kernels, the SPSD matrices are less well-approximated by low-rank matrices, and they have more heterogeneous leverage scores. Thus, they are more similar to the Laplacian data than the Linear Kernel data; this suggests (as we have observed) that leverage score sampling should perform relatively better than uniform column sampling and projection-based schemes when in these two cases.

3.4.4 Summary of Comparison of Sampling and Projection Algorithms

Before proceeding, there are several summary observations that we can make about sampling versus projection methods for the data sets we have considered.

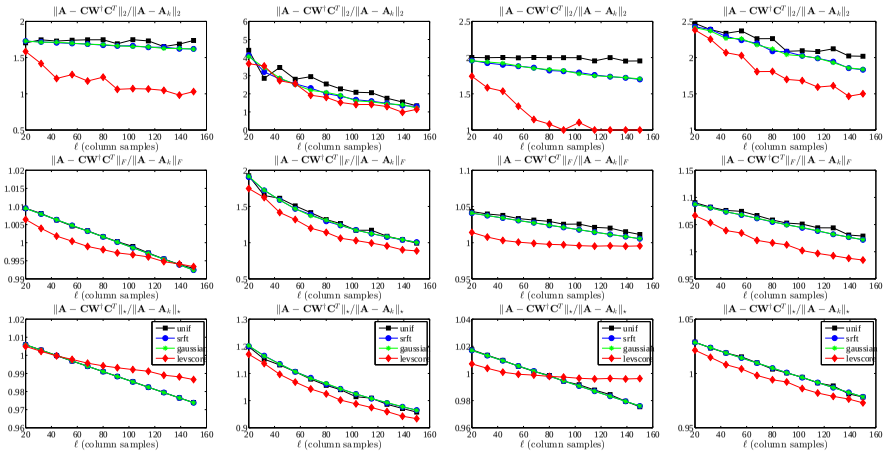
- Linear Kernels and to a lesser extent Dense RBF Kernels with larger σ parameter have relatively low rank and relatively uniform leverage scores, and in these cases uniform sampling does quite well. These data sets correspond most closely with those that have been studied previously in the machine learning literature, and for these data sets our results are in agreement with that prior work.

- Sparsifying RBF Kernels and/or choosing a smaller σ parameter tends to make these kernels less well-approximated by low-rank matrices and to have more heterogeneous leverage scores. In general, these two properties need not be directly related—the spectrum is a property of eigenvalues, while the leverage scores are determined by the eigenvectors—but for the data we examined they are related, in that matrices with more slowly decaying spectra also often have more heterogeneous leverage scores.

- For Dense RBF Kernels with smaller σ and Sparse RBF Kernels, leverage score sampling tends to do much better than other methods. Interestingly, the Sparse RBF Kernels have many properties of very sparse Laplacian Kernels corresponding to relatively-unstructured informatics graphs, an observation which should be of interest for researchers who construct sparse graphs from data using, *e.g.*, "locally linear" methods, to try to reconstruct hypothesized low-dimensional manifolds.

- Reconstruction quality under leverage score sampling saturates, as a function of choosing more samples ℓ. As a consequence, there can be a tradeoff between leverage score sampling or other methods being better, depending on the values of ℓ that are chosen.

In general, *all* of the sampling and projection methods we considered perform *much* better on the SPSD matrices we considered than previous worst-case bounds (*e.g.*, (Drineas and Mahoney, 2005; Kumar et al., 2012; Gittens, 2012)) would suggest. Specifically, even the worst results correspond to single-digit approximation factors in relative scale. This observation is intriguing, because the motivation of leverage score sampling (recall that in this context random projections should be viewed as performing uniform random sampling in a



(a) AbaloneS, $\sigma = .15, k = 20$ (b) AbaloneS, $\sigma = 1, k = 20$ (c) WineS, $\sigma = 1, k = 20$ (d) WineS, $\sigma = 2.1, k = 20$

Figure 5: The spectral, Frobenius, and trace norm errors (top to bottom, respectively, in each subfigure) of several SPSD sketches, as a function of the number of column samples ℓ, for several sparse RBF data sets.

randomly-rotated basis where the leverage scores have been approximately uniformized (Mahoney, 2011)) is very much tied to the Frobenius norm, and so there is no *a priori* reason to expect its good performance to extend to the spectral or trace norms. Motivated by this, we revisit the question of proving improved worst-case theoretical bounds in Section 4.

Before describing these improved theoretical results, however, we address in Section 3.5 running time questions. After all, a naïve implementation of sampling with exact leverage scores is slower than other methods (and much slower than uniform sampling). As shown below, by using the recently-developed approximation algorithm of Drineas et al. (2012), not only does this approximation algorithm run in time comparable with random projections (for certain parameter settings), it also leads to approximations that soften the strong bias that the exact leverage scores provide toward the best rank-k approximation to the matrix, thereby leading to improved reconstruction results in many cases.

3.5 Reconstruction Accuracy of Leverage Score Approximation Algorithms

A naïve view might assume that computing probabilities that permit leverage-based sampling requires an $O(n^3)$ computation of the full SVD, or at least the full computation of a partial SVD, and thus that it would be much more expensive than recently-developed random projection methods. Indeed, an "exact" computation of the leverage scores with a truncated SVD takes roughly $\mathrm{O}(n^2k)$ time. Recent work, however, has shown that relative-error approximations to all the statistical leverage scores can be computed more quickly than this exact algorithm (Drineas et al., 2012). Here, we implement and evaluate a version of this algorithm. We evaluate it both in terms of running time and in terms of reconstruction quality on the diverse suite of real data matrices we considered above. This is the first work to provide an empirical evaluation of an implementation of the leverage score approximation algorithms of Drineas et al. (2012), illustrating empirically the tradeoffs between cost and efficiency in a practical setting.

3.5.1 Description of the Fast Approximation Algorithm of Drineas et al. (2012)

Algorithm 1 (which originally appeared as Algorithm 1 in Drineas et al. (2012)) takes as input an arbitrary $n \times d$ matrix $\mathbf{A}$, where $n \gg d$, and it returns as output a $1 \pm \epsilon$ approximation to *all* of the statistical leverage scores of the input matrix. The original algorithm of Drineas et al. (2012) uses a subsampled Hadamard transform and requires r_1 to be somewhat larger than what we state in Algorithm 1. That an SRFT with a smaller value of r_1 can be used instead is a consequence of the fact that (Drineas et al., 2012, Lemma 3) is also satisfied by an SRFT matrix with the given r_1; this is established in (Tropp, 2011; Boutsidis and Gittens, 2013).

The running time of this algorithm, given in the caption of the algorithm, is roughly $O(nd \ln d)$ when $d = \Omega(\ln n)$. Thus Algorithm 1 generates relative-error approximations to the leverage scores of a tall and skinny matrix $\mathbf{A}$ in time $o(nd^2)$, rather than the $\Omega(nd^2)$ time that would be required to compute a QR decomposition or a thin SVD of the $n \times d$ matrix $\mathbf{A}$. The basic idea behind Algorithm 1 is as follows. If we had a QR decomposition of $\mathbf{A}$, then we could postmultiply $\mathbf{A}$ by the inverse of the "R" matrix to obtain an orthogonal matrix spanning the column space of $\mathbf{A}$; and from this $n \times d$ orthogonal matrix, we could read off

Input: $\mathbf{A} \in \mathbb{R}^{n \times d}$ (with SVD $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^T$), error parameter $\epsilon \in (0, 1/2]$.

Output: $\tilde{\ell}_i, i = 1, \ldots, n$, approximations to the leverage scores of $\mathbf{A}$.

1. Let $\mathbf{\Pi}_1 \in \mathbb{R}^{r_1 \times n}$ be an SRFT with
$$r_1 = \Omega(\epsilon^{-2}(\sqrt{d} + \sqrt{\ln n})^2 \ln d)$$
2. Compute $\mathbf{\Pi}_1\mathbf{A} \in \mathbb{R}^{r_1 \times d}$ and its QR factorization $\mathbf{\Pi}_1\mathbf{A} = \mathbf{QR}$.
3. Let $\mathbf{\Pi}_2 \in \mathbb{R}^{d \times r_2}$ be a matrix of i.i.d. standard Gaussian random variables, where
$$r_2 = \Omega\left(\epsilon^{-2} \ln n\right).$$
4. Construct the product $\mathbf{\Omega} = \mathbf{A}\mathbf{R}^{-1}\mathbf{\Pi}_2$.
5. For $i = 1, \ldots, n$ compute $\tilde{\ell}_i = \left\|\Omega_{(i)}\right\|_2^2$.

Algorithm 1: Algorithm (Drineas et al., 2012, Algorithm 1) for approximating the leverage scores ℓ_i of an $n \times d$ matrix $\mathbf{A}$, where $n \gg d$, to within a multiplicative factor of $1 \pm \epsilon$. The running time of the algorithm is $\mathrm{O}(nd \ln(\sqrt{d} + \sqrt{\ln n}) + nd\epsilon^{-2} \ln n + d^2\epsilon^{-2}(\sqrt{d} + \sqrt{\ln n})^2 \ln d)$.

the leverage scores from the Euclidean norms of the rows. Of course, computing the QR decomposition would require $O(nd^2)$ time. To get around this, Algorithm 1 premultiplies $\mathbf{A}$ by a structured random projection $\mathbf{\Pi}_1$, computes a QR decomposition of $\mathbf{\Pi}_1\mathbf{A}$, and postmultiplies $\mathbf{A}$ by $\mathbf{R}^{-1}$, *i.e.*, the inverse of the "R" matrix from the QR decomposition of $\mathbf{\Pi}_1\mathbf{A}$. Since $\mathbf{\Pi}_1$ is an SRFT, premultiplying by it takes roughly $O(nd \ln d)$ time. In addition, note that $\mathbf{\Pi}_1\mathbf{A}$ needs to be post multiplied by a second random projection in order to compute all of the leverage scores in the allotted time; see (Drineas et al., 2012) for details. This algorithm is simpler than the algorithm in which we are primarily interested that is applicable to square SPSD matrices, but we start with it since it illustrates the basic ideas of how our main algorithm works and since our main algorithm calls it as a subroutine. We note, however, that this algorithm is directly useful for approximating the leverage scores of Linear Kernel matrices $\mathbf{A} = \mathbf{X}\mathbf{X}^T$, when $\mathbf{X}$ is a tall and skinny matrix.

Consider, next, Algorithm 2 (which originally appeared as Algorithm 4 in (Drineas et al., 2012)), which takes as input an *arbitrary* $n \times d$ matrix $\mathbf{A}$ and a rank parameter k, and returns as output a $1 \pm \epsilon$ approximation to *all* of the statistical leverage scores (relative to the best rank-k approximation) of the input. An important technical point is that the problem of computing the leverage scores of a matrix relative to a low-dimensional space is ill-posed, essentially because the spectral gap between the k^{th} and the $(k+1)^{st}$ eigenvalues can be small, and thus Algorithm 2 actually computes approximations to the leverage scores of a matrix that is near to $\mathbf{A}$ in the spectral norm (or the Frobenius norm if $q = 0$). See (Drineas et al., 2012) for details. Basically, this algorithm uses Gaussian sampling to find

Input: $\mathbf{A} \in \mathbb{R}^{n\times d}$, a rank parameter k, and an error parameter $\epsilon \in (0, 1/2]$.

Output: $\hat{\ell}_i, i = 1, \ldots, n$, approximations to the leverage scores of $\mathbf{A}$ filtered through its dominant dimension-k subspace.

1. Construct $\mathbf{\Pi} \in \mathbb{R}^{d\times 2k}$ with i.i.d. standard Gaussian entries.
2. Compute $\mathbf{B} = \left(\mathbf{A}\mathbf{A}^T\right)^q \mathbf{A}\mathbf{\Pi} \in \mathbb{R}^{n\times 2k}$ with
$$q \geq \left\lceil \frac{\ln\left(1 + \sqrt{\frac{k}{k-1}} + \mathrm{e}\sqrt{\frac{2}{k}}\sqrt{\min\{n,d\} - k}\right)}{2\ln\left(1+\epsilon/10\right) - 1/2} \right\rceil .$$
3. Approximate the leverage scores of $\mathbf{B}$ by calling Algorithm 1 with inputs $\mathbf{B}$ and ϵ; let $\hat{\ell}_i$ for $i = 1, \ldots, n$ be the outputs of Algorithm 1.

Algorithm 2: Algorithm (Drineas et al., 2012, Algorithm 4) for approximating the leverage scores (relative to the best rank-k approximation to $\mathbf{A}$) of a general $n \times d$ matrix $\mathbf{A}$ with those of a matrix that is close by in the spectral norm (or the Frobenius norm if $q = 0$). This algorithm runs in time $\mathrm{O}(ndkq) + T_1$, where T_1 is the running time of Algorithm 1.

a matrix close to $\mathbf{A}$ in the Frobenius norm or spectral norm, and then it approximates the leverage scores of this matrix by using Algorithm 1 on the smaller, very rectangular matrix $\mathbf{B}$. When $\mathbf{A}$ is square, as in our applications, Algorithm 2 is typically more costly than direct computation of the leverage scores, at least for dense matrices (but it does have the advantage that the number of iterations is bounded, independent of properties of the matrix, which is not true for typical iterative methods to compute low-rank approximations).

Of greater practical interest is Algorithm 3, which is a modification of Algorithm 2 in which the Gaussian random projection is replaced with an SRFT. That is, Algorithm 3 uses an SRFT projection to find a matrix close by to $\mathbf{A}$ in the Frobenius norm or spectral norm (depending on the value of q), and then it exactly computes the leverage scores of this matrix. This improves the running time to $\mathrm{O}(n^2\ln(\sqrt{k}+\sqrt{\ln n}) + n^2(\sqrt{k}+\sqrt{\ln n})^2\ln(k)q + n(\sqrt{k}+\sqrt{\ln n})^4\ln^2(k))$, which is $o(n^2k)$ when $q = 0$. Thus an important point for Algorithm 3 (as well as for Algorithm 2) is the parameter q which describes the number of iterations. For $q = 0$ iterations, we get an inexpensive Frobenius norm approximation; while for higher q, we get better spectral norm approximations that are more expensive.[3] This flexibility is of interest, as one may want to approximate the actual leverage scores accurately or one may simply want to find crude approximations useful for obtaining SPSD sketches with low reconstruction error.

3. Observe that since $\mathbf{A}$ is rectangular in Algorithms 2 and 3, we approximate the leverage scores of $\mathbf{A}$ with those of $\mathbf{B} = (\mathbf{A}\mathbf{A}^T)^q\mathbf{A}\mathbf{\Pi}$; in particular the case $q = 0$ corresponds to taking $\mathbf{B} = \mathbf{A}\mathbf{\Pi}$. By way of contrast, when we use the power method to construct sketches of an SPSD matrix, we take $\mathbf{C} = \mathbf{A}^q\mathbf{S}$, so the case $q = 1$ corresponds to $\mathbf{C} = \mathbf{A}\mathbf{S}$.

Input: $\mathbf{A} \in \mathbb{R}^{n\times d}$, a rank parameter k, and an iteration parameter q.

Output: $\hat{\ell}_i, i \in= 1, \ldots, n$, approximations to the leverage scores of $\mathbf{A}$ filtered through its dominant dimension-k subspace.

1. Construct an SRHT matrix $\mathbf{\Pi} \in \mathbb{R}^{d\times r}$, where
$$r \geq \left\lceil 36\epsilon^{-2}[\sqrt{k} + \sqrt{8\ln(kd)}]^2\ln(k) \right\rceil .$$
2. Compute $\mathbf{B} = \left(\mathbf{A}\mathbf{A}^T\right)^q \mathbf{A}\mathbf{\Pi} \in \mathbb{R}^{n\times r}$, where $q \geq 0$ is an integer.
3. Return the exact leverage scores of $\mathbf{B}$.

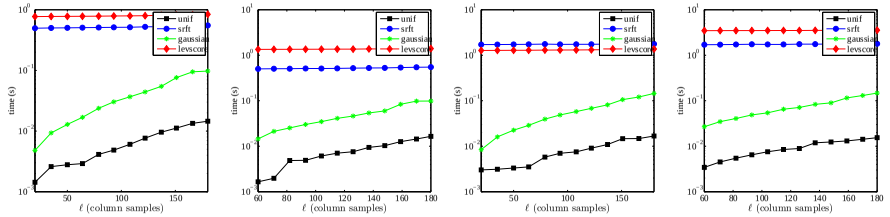
Algorithm 3: Algorithm for approximating the leverage scores (relative to the best rank-k approximation to $\mathbf{A}$) of a general $n \times d$ matrix $\mathbf{A}$ with those of a matrix that is close by in the spectral norm. This is a modified version of Algorithm 2, in which the random projection is implemented with an SRFT rather than a Gaussian random matrix, and where the number of "iterations" q is prespecified. This algorithm runs in time $\mathrm{O}(nd\ln r + ndrq + nr^2)$ since $\mathbf{A}\mathbf{\Pi}$ can be computed in time $\mathrm{O}(nd\ln r)$.

Finally, note that although choosing the number of iterations q as we did in Algorithm 2 is convenient for worst-case analysis, as a practical implementational matter it is easier either to choose q based on spectral gap information revealed during the running of the algorithm or to prespecify q to be a small integer, *e.g.*, 2 or 3, before the algorithm runs. Both of these have an interpretation of accelerating the rate of decay of the spectrum with a power iteration, but they behave somewhat differently due to the different stopping conditions. Below, we consider both variants.

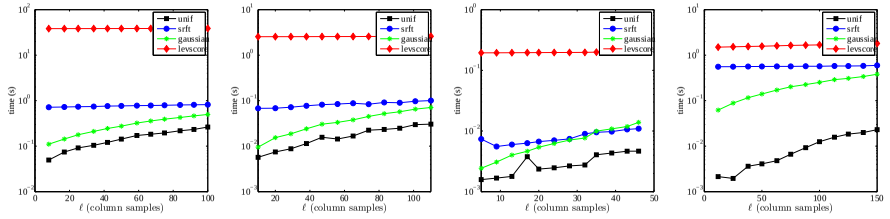
3.5.2 Running Time Comparisons

Here, we describe the performances of the various random sampling and random projection low-rank sketches considered in Section 3.4 in terms of their running time, where the method that involves using the leverage scores to construct the importance sampling distribution is implemented both by computing the leverage scores "exactly" by calling a truncated SVD, as a black box, as well as computing them approximately by using one of several versions of Algorithm 3. Our running time results are presented in Figure 6 and Figure 7.

We start with the results described in Figure 6, which shows the running times, as a function of ℓ, for the low-rank approximations described in Section 3.4: *i.e.*, for column sampling uniformly at random without replacement; for column sampling according to the exact nonuniform leverage score probabilities; and for sketching using Gaussian and SRFT mixtures of the columns. Several observations are worth making about the results presented in this figure.



(a) GR, $k = 20$ (b) GR, $k = 60$ (c) HEP, $k = 20$ (d) HEP, $k = 60$



(e) Dexter, $k = 8$ (f) Protein, $k = 10$ (g) SNPs, $k = 5$ (h) Gisette, $k = 12$

Figure 7: The times required to compute approximate leverage score-based SPSD sketches, as a function of the number of column samples ℓ for several data sets.

- Uniform sampling is always less expensive and typically much less expensive than the other methods, while (with one minor exception) sampling according to the *exact* leverage scores is always the most expensive method.

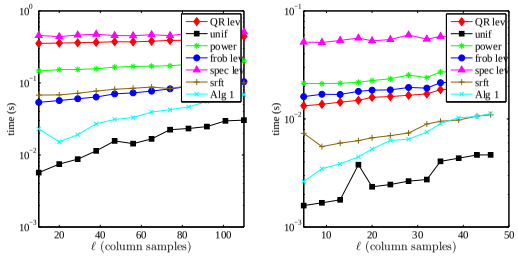
- For most matrices, using the SRFT is nearly as expensive as exact leverage score sampling. This is most true for the very sparse graph Laplacian Kernels, largely since the SRFT does not respect sparsity. The main exception to this is for the dense and relatively well-behaved Linear Kernels, where especially for large values of ℓ the SRFT is quite fast and usually not too much more expensive than uniform sampling.

- The "fast Fourier" methods underlying the SRFT can take advantage of the structure of the Linear Kernels to yield algorithms that are similar to Gaussian projections and much better than exact leverage score computation. Note that the reason that SRFT is worse than Gaussians here is that the matrices we are considering are *not* extremely large, and we are not considering very large values of the rank parameter. Extending in both those directions leads to Gaussian projections being slower than SRFT, as the trends in the figures clearly indicate.

- Gaussian projections are not too much slower than uniform sampling for the extremely sparse Laplacian Kernels—this is due to the sparsity of the Laplacian Kernels, since Gaussian projections can take advantage of fast matrix-vector multiplies, while the SRFT-based scheme cannot—but this advantage is lost for the (denser) Sparse RBF Kernels, to the extent that there is little running time improvement relative to the Dense RBF Kernels. In addition, Gaussian projections are relatively slower, when compared to the SRFT and uniform sampling, for the Dense RBF Kernels than for the Linear Kernels, although both of those data sets are maximally dense.

We next turn to the results described in Figure 7, which shows the running times, as a function of ℓ, for several variants of approximate leverage-based sampling. For ease of comparison, the timings for uniform sampling ("unif") and exact leverage score sampling ("levscore") are depicted in Figure 7 using the same shading as used in Figure 6. In addition to these two baselines, Figure 7 shows running time results for the following three variants of approximate leverage score sampling: "frob levscore" (which is Algorithm 3 with $q = 0$ and $r = 2k$); "spec levscore" (Algorithm 3 with $q = 4$ and $r = 2k$); and "power". The "power" scheme is a version of Algorithm 3 where $r = k$ and q is determined by monitoring the convergence of the leverage scores of $\mathbf{A}^{2q+1}\mathbf{\Pi}$ and terminating when the change in the leverage scores between iterations, as measured in the infinity norm, is smaller than 10^{-2}. This is simply a version of subspace iteration with a convergence criterion appropriate for the task at hand. Since "frob levscore" requires one application of an SRFT, its timing results are depicted using the same shade as the SRFT timing results in Figure 6. (There are no other correspondences between the shadings in the two figures.) Several observations are worth making about the results presented in this figure.

- These approximate leverage score-based algorithms can be orders of magnitude faster than exact leverage score computation; but, especially for "spec levscore" when q is not prespecified to be 2 or 3, they can even be somewhat slower. Exactly which is



(a) Protein, $k = 10$ (b) SNPs, $k = 5$

Figure 8: The running time of SPSD sketches computed using Algorithm 1 compared with that of other approximate leverage score-based SPSD sketches, as a function of the number of column samples ℓ for two Linear Kernel datasets. The parameters in Algorithm 1 were taken to be $r_1 = \epsilon^{-2}\ln(d\delta^{-1})(\sqrt{d} + \sqrt{\ln(n\delta^{-1})})^2$ and $r_2 = \epsilon^{-2}(\ln n + \ln \delta^{-1})$ with $\epsilon = 1$ and $\delta = 1/10$.

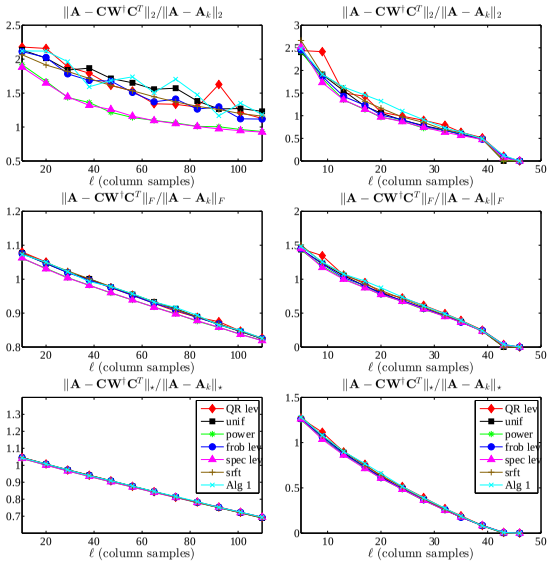
the case depends upon the properties of the matrix and the parameters used in the approximation algorithm, including especially the number of power iterations.

- The "frob levscore" approximation method has running time comparable to the running time of the SRFT, which is expected, given that the computation of the SRFT is the theoretical bottleneck for the running time of the "frob levscore" algorithm. In particular, for larger values of ℓ for Linear Kernels, "frob levscore" is not much slower than uniform sampling.

- The "spec levscore" and "power" approximations with $q > 0$ are more expensive than the $q = 0$ "frob lev" approximation, which is a result of the relatively-expensive matrix-matrix multiplication. For the Linear Kernels, both are much better than the exact leverage score computation, and for most other data at least "power" is somewhat less expensive than the exact leverage score computation. For example, this is particularly true for the Laplacian Kernels.

Recall that the cost associated with these SPSD sketches is two-fold: first, the cost to construct the sample—by sampling columns uniformly at random, by computing a nonuniform importance sampling distribution, or by performing a random projection to uniformize the leverage scores; and second, the cost to construct the low-rank approximation from the sample. For uniform sampling, the latter step dominates the cost, while for more sophisticated methods the former step typically dominates the cost. The approximate leverage score sampling methods are still sufficiently expensive that the cost of computing the sampling probabilities still dominates the cost to construct the low-rank approximation.

Finally, Algorithm 1 can be used to approximate quickly the leverage scores of matrices of the form $\mathbf{A} = \mathbf{X}\mathbf{X}^T$, when $\mathbf{X} \in \mathbb{R}^{n\times d}$ is a rectangular matrix of sufficent aspect ratio, and



(a) Protein, $k = 10$ (b) SNPs, $k = 5$

Figure 9: The spectral, Frobenius, and trace norm errors (top to bottom, respectively, in each subfigure) of SPSD sketches computed using Algorithm 1 compared with those of other approximate leverage score-based sketching schemes, as a function of the number of column samples ℓ, for two Linear Kernel data sets. The parameters in Algorithm 1 were taken to be $r_1 = \epsilon^{-2}\ln(d\delta^{-1})(\sqrt{d}+\sqrt{\ln(n\delta^{-1})})^2$ and $r_2 = \epsilon^{-2}(\ln n + \ln\delta^{-1})$ with $\epsilon = 1$ and $\delta = 1/10$.

in such cases it is faster than Algorithm 3. Specifically, for the first dimensional reduction step in Algorithm 1 to be beneficial (*i.e.*, to ensure $r_1 < n$), the condition $n = \Omega(d\ln d)$ is necessary; for the second dimensional reduction step to be beneficial (*i.e.*, to ensure $r_2 < d$), the condition $d = \Omega(\ln n)$ must be satisfied. Figure 8 summarizes our main results for the run time of Algorithm 1 applied to rectangular matrices with $n \gg d$. Among other things, Figure 8 illustrates, using the Linear Kernel datasets Protein and SNPs (which satisfy these constraints), two points.

- Most importantly, the running time of Algorithm 1 on these rectangular matrices is faster than performing a QR decomposition on $\mathbf{A}$ and is comparable to applying a SRFT to $\mathbf{A}$. This is expected, since the running time bottleneck for Algorithm 1 is the application of the SRFT.
- In addition, the running time of Algorithm 1 is significantly faster than the other approximate leverage score algorithms. This too is expected, since these other algorithms are applied to $\mathbf{A}$ and ignore the rectangular structure of $\mathbf{X}$.

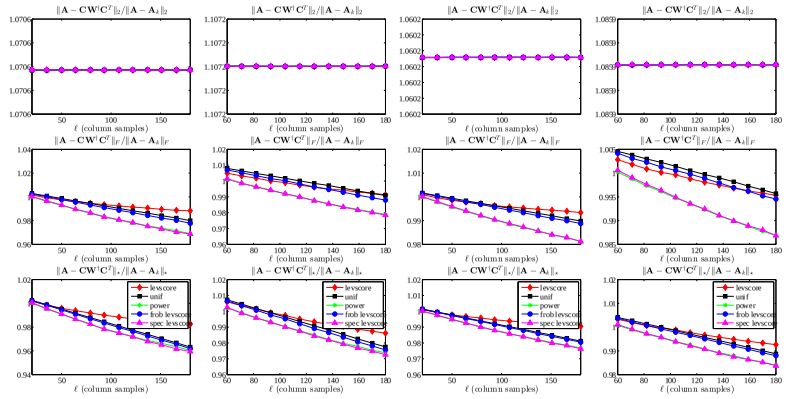
Figure 9 shows that these improved running time gains for Algorithm 1 can come at the cost of a slight loss in the reconstruction accuracy (relative to the exact computation of the leverage scores) of the low-rank approximations; the accuracy of the other approximate leverage score algorithms is discussed in the following subsection.

3.5.3 Reconstruction Accuracy Results

Here, we describe the performances of the various low-rank approximations that use approximate leverage scores in terms of reconstruction accuracy for the data sets described in Section 3.1. The results are presented in Figure 10 through Figure 14. The setup for these results parallels that for the low-rank approximation results described in Section 3.4, and these figures parallel Figure 1 through Figure 5. To provide a baseline for the comparison, we also plot the previous reconstruction errors for sampling with the exact leverage scores as well as the uniform column sampling sketch. Several observations are worth making about the results presented in these figures.

For Laplacian Kernels, "frob levscore" is only slightly better than uniform sampling, while "power" and "spec levscore" are substantially better than uniform sampling; all of those methods also lead to even *better* reconstruction results than using the exact leverage scores (suggesting that some form of implicit regularization is taking place): the reconstruction quality is higher for a given ℓ and, also, using approximate leverage scores does not lead to the saturation effect observed when using the exact leverage scores. For the Linear Kernels, all the methods perform similarly. For both the dense and the sparse RBF data sets, the approximate leverage score algorithms tend to parallel the exact leverage score algorithm, and they are not substantially better. In particular, both "power" and "spec levscore" tend to saturate when the exact method saturates, but in those cases "frob levscore" tends not to saturate.

Note that the difference between different approximate leverage score algorithms often corresponds to a difference in the spectral gaps of the corresponding matrices. From Table 5, if we fix k and use the approximate leverage scores filtered through rank k to form a Nyström approximation to $\mathbf{A}$, the accuracy of that approximation has a strong dependence on the



(a) GR, $k = 20$ (b) GR, $k = 60$ (c) HEP, $k = 20$ (d) HEP, $k = 60$

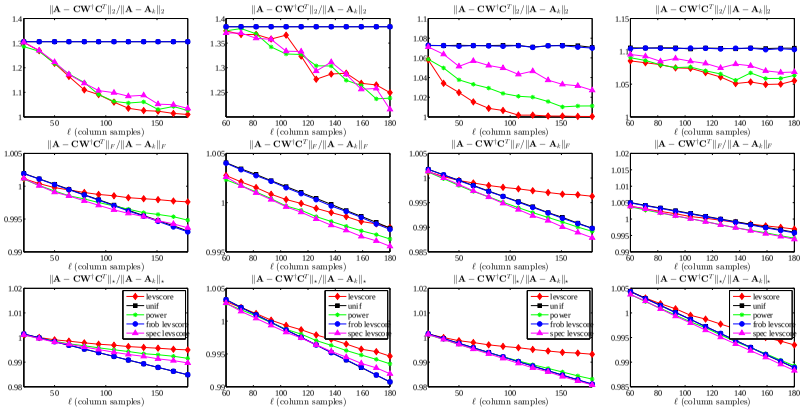
Figure 10: The spectral, Frobenius, and trace norm errors (top to bottom, respectively, in each subfigure) of several approximate leverage score-based SPSD sketches, as a function of the number of column samples ℓ, for the GR and HEP Laplacian data sets, with two choices of the rank parameter k.

spectral gap of $\mathbf{A}$ at rank k, as measured by $\frac{\lambda_k}{\lambda_{k+1}}$. In general, the larger the spectral gap, the more accurate the approximation. This phenomena can also be understood in terms of the convergence of the approximate leverage scores: the approximation algorithms (Algorithm 2 and Algorithm 3) are essentially truncated versions of the subspace iteration method for computing the top k eigenvectors of $\mathbf{A}$. It is a classical result that the spectral gap determines the rate of convergence of the subspace iteration process to the desired eigenvectors: the larger it is, the fewer iterations of the process are required to get accurate approximations of the top eigenvectors. It follows immediately that the larger the spectral gap, the more accurate the approximate leverage scores generated by these approximation algorithms are. Our empirical results illustrate the complexities and subtle consequences of these properties in realistic machine learning applications of even modestly-large size.

3.5.4 Summary of Leverage Score Approximation Algorithms

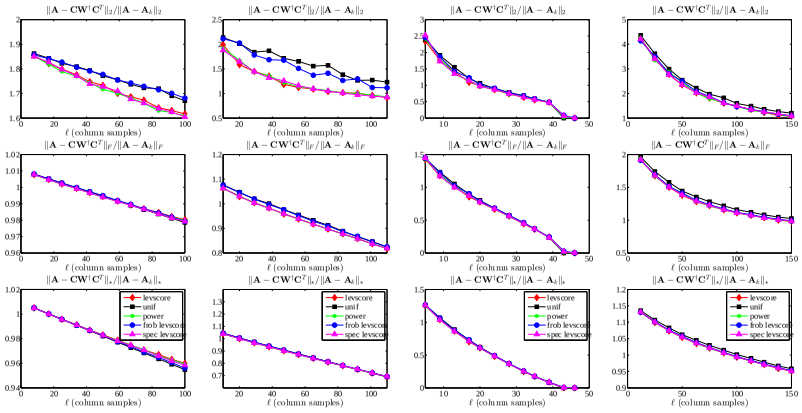
Before proceeding, there are several summary observations that we can make about the running time and reconstruction quality of approximate leverage score sampling algorithms for the data sets we have considered.

- The running time of computing the exact leverage scores is generally much worse than that of uniform sampling and both SRFT-based and Gaussian-based random projection methods.



(a) Enron, $k = 20$ (b) Enron, $k = 60$ (c) Gnutella, $k = 20$ (d) Gnutella, $k = 60$

Figure 11: The spectral, Frobenius, and trace norm errors (top to bottom, respectively, in each subfigure) of several approximate leverage score-based SPSD sketches, as a function of the number of column samples ℓ, for the Enron and Gnutella Laplacian data sets, with two choices of the rank parameter k.



(a) Dexter, $k = 8$ (b) Protein, $k = 10$ (c) SNPs, $k = 5$ (d) Gisette, $k = 12$

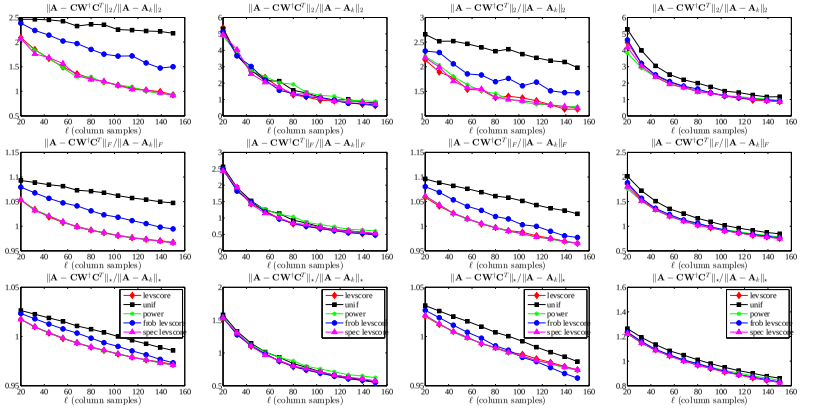
Figure 12: The spectral, Frobenius, and trace norm errors (top to bottom, respectively, in each subfigure) of several approximate leverage score-based SPSD sketches, as a function of the number of column samples ℓ, for the Linear Kernel data sets.

- The running time of computing approximations to the leverage scores can, with appropriate choice of parameters, be much faster than the exact computation of the leverage scores; and, especially for "frob levscore," can be comparable to the running time of the random projection (SRFT or Gaussian) used in the leverage score approximation algorithm. For the methods that involve $q > 0$ iterations to compute stronger approximations to the leverage scores, the running time can vary considerably depending on details of the stopping condition.

- The leverage scores computed by the "frob levscore" procedure are typically very different than the "exact" leverage scores, but they are leverage scores for a low-rank space that is near the best rank-k approximation to the matrix. This is often sufficient for good low-rank approximation.

- The approximate leverage scores computed from "power" and "spec levscore" approach those of the exact leverage scores, as q is increased; and they obtain reconstruction accuracy that is no worse, and in many cases is better, than that obtained by the exact leverage scores. This suggests that, by not fitting exactly to the empirical statistical leverage scores, we are observing a form of implicit regularization.

- The running time of Algorithm 1, when applied to "tall" matrices for which $n \gg d$, is faster than the running time of performing a QR decomposition of the matrix $\mathbf{A}$; and it is comparable to the running time of applying a random projection to $\mathbf{A}$ (which is the computational bottleneck of applying Algorithm 1). Thus, in particular, one could



(a) AbaloneD, $\sigma = .15, k = 20$ (b) AbaloneD, $\sigma = 1, k = 20$ (c) WineD, $\sigma = 1, k = 20$ (d) WineD, $\sigma = 2.1, k = 20$

(a) AbaloneS, $\sigma = .15, k = 20$ (b) AbaloneS, $\sigma = 1, k = 20$ (c) WineS, $\sigma = 1, k = 20$ (d) WineS, $\sigma = 2.1, k = 20$

Figure 14: The spectral, Frobenius, and trace norm errors (top to bottom, respectively, in each subfigure) of several approximate leverage score-based SPSD sketches, as a function of the number of column samples ℓ, for several sparse RBF data sets.

use this algorithm to compute approximations to the leverage scores to obtain a sketch that provides a relative-error approximation to a least-squares problem involving $\mathbf{A}$ (Drineas et al., 2008, 2010; Mahoney, 2011); or one could use the sketch thereby obtained as a preconditioner to an iterative method to solve the least-squares problem, in a manner analogous to how Blendenpik or LSRN do so with a random projection (Avron et al., 2010; Meng et al., 2014).

Previous work has showed that one can implement random projection algorithms to provide low-rank approximations with error comparable to that of the SVD in less time than state-of-the art Krylov solvers and other "exact" numerical methods (Halko et al., 2011; Mahoney, 2011). Our empirical results show that these random projection algorithms can be used in two complementary ways to approximate SPSD matrices of interest in machine learning: first, they can be used directly to compute a projection-based low-rank approximation; and second, they can be used to compute approximations to the leverage scores, which can be used to compute a sampling-based low-rank approximation. With the right choice of parameters, the two complementary approaches have roughly comparable running times, and neither one dominates the other in terms of reconstruction accuracy.

3.6 Projection-based Sketches

Finally, for completeness, we consider the performance of the two projection-based SPSD sketches proposed by Halko et al. (2011), and we show how they perform when compared with the sketches we have considered. Recall that the idea of these sketches is to construct low-rank approximations by forming an approximate basis $\mathbf{Q}$ for the top eigenspace of $\mathbf{A}$ and then restricting $\mathbf{A}$ to that eigenspace. In more detail, given a sketching matrix $\mathbf{S}$, form the matrix $\mathbf{Y} = \mathbf{AS}$ and take the QR decomposition of $\mathbf{Y}$ to obtain $\mathbf{Q}$, a matrix with orthonormal columns. The first sketch, which we eponymously refer to as the *pinched* sketch, is simply $\mathbf{A}$ pinched to the space spanned by $\mathbf{Q}$:

$$\mathbf{Q}(\mathbf{Q}^T\mathbf{AQ})\mathbf{Q}^T. \tag{8}$$

The second sketch, which we refer to as the *prolonged* sketch, is

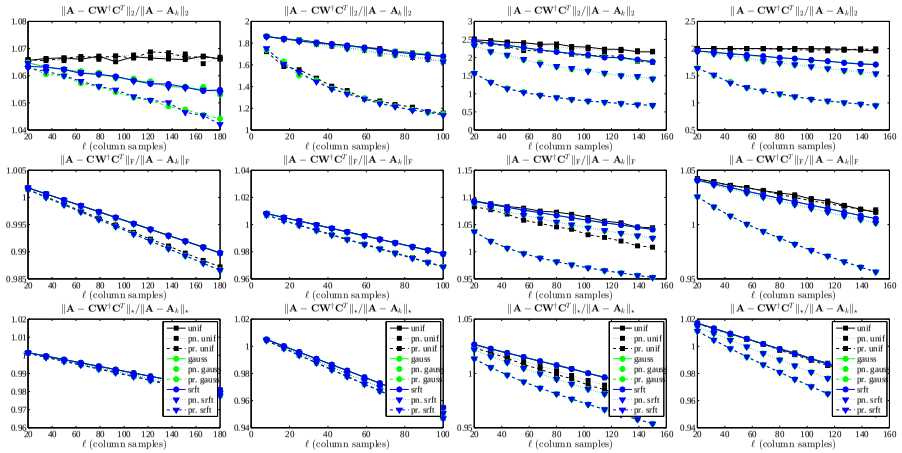
$$\mathbf{AQ}(\mathbf{Q}^T\mathbf{AQ})^\dagger\mathbf{Q}^T\mathbf{A}. \tag{9}$$

It is clear that the prolonged sketch can be constructed using our SPSD Sketching Model by taking $\mathbf{Q}$ as the sketching matrix. In fact, a stronger statement can be made. As stated in Lemma 1 below, it is the case, for any sketching matrix $\mathbf{X}$, that when $\mathbf{C} = \mathbf{AX}$ and $\mathbf{W} = \mathbf{X}^T\mathbf{AX}$,

$$\mathbf{CW}^\dagger\mathbf{C}^T = \mathbf{A}^{1/2}\mathbf{P}_{\mathbf{A}^{1/2}\mathbf{X}}\mathbf{A}^{1/2}.$$

By considering the sketching matrix $\mathbf{X} = \mathbf{A}^1\mathbf{S}$, we see that in fact the prolonged sketch is exactly the sketch obtained by applying the power method with $q = 1$:

$$\begin{aligned}\mathbf{AQ}(\mathbf{Q}^T\mathbf{AQ})^\dagger\mathbf{Q}^T\mathbf{A} &= \mathbf{A}^{1/2}\mathbf{P}_{\mathbf{A}^{1/2}\mathbf{Q}}\mathbf{A}^{1/2} \\ &= \mathbf{A}^{1/2}\mathbf{P}_{\mathbf{A}^{1/2}(\mathbf{AS})}\mathbf{A}^{1/2} \\ &= \mathbf{A}^2\mathbf{S}(\mathbf{S}^T\mathbf{A}^3\mathbf{S})^\dagger\mathbf{S}^T\mathbf{A}^2 \\ &= \mathbf{AX}(\mathbf{X}^T\mathbf{AX})^\dagger\mathbf{X}^T\mathbf{A}.\end{aligned}$$



(a) Gnutella, $k = 20$ (b) Dexter, $k = 8$ (c) AbaloneD, $\sigma = .15, k = 20$ (d) WineS, $\sigma = 1, k = 20$

Figure 15: The spectral, Frobenius, and trace norm errors (top to bottom, respectively, in each subfigure) of several SPSD sketches, including the pinched and prolonged sketches, as a function of the number of column samples ℓ, for several datasets. Pinched and prolonged sketches, respectively indicated by "pn." and "pr.", are defined in Equations (8) and (9).

It follows that the bounds we provide in Section 4 on the performance of sketches obtained using the power method pertain also to prolonged sketches.

In Figure 15, we compare the empirical performances of several of the SPSD sketches considered earlier with their pinched and prolonged variants. Specifically, we plot the errors of pinched and prolonged sketches for several choices of sketching matrices—corresponding to uniform column sampling, gaussian column mixtures, and SRFT-based column mixtures—along with the errors of non-pinched, non-prolonged sketches constructed using the same choices of $\mathbf{S}$. In the interest of brevity, we provide results only for several of the datasets listed in Table 4.

Some trends are clear from Figure 15.

- In the spectral norm, the prolonged sketches are considerably more accurate than the pinched and standard sketches for all the datasets considered. Without exception, the prolonged Gaussian and SRFT column-mixture sketches are the most accurate in the spectral norm, of all the sketches considered. Only in the case of the Dexter Linear Kernel is the prolonged uniformly column-sampled sketch nearly as accurate in the spectral norm as the prolonged Gaussian and SRFT sketches. To a lesser extent, the prolonged sketches are also more accurate in the Frobenius and trace norms than the other sketches considered. The increased Frobenius and trace norm accuracy is particularly notable for the two RBF Kernel datasets; again, the prolonged Gaussian and SRFT sketches are considerably more accurate than the prolonged uniformly column-sampled sketches.

- After the prolonged sketches, the pinched Gaussian and SRFT column-mixture sketches exhibit the least spectral, Frobenius, and trace norm errors. Again, however, we see that the pinched uniformly column-sampled sketches are considerably less accurate than the pinched Gaussian and SRFT column-mixture sketches. Particularly in the spectral and Frobenius norms, the pinched uniformly column-sampled sketches are not any more accurate than the basic uniformly column-sampled sketches.

From these considerations, it seems evident that the benefits of pinched and prolonged sketches are most prominent when the spectral norm is the error metric, or when the dataset is an RBF Kernel. In particular, pinched and prolonged sketches are not significantly more accurate (than the sketches considered in the previous subsections) in the Frobenius and trace norms for any of the datasets considered.

It is also evident from Figure 15 that the pinched sketches often have a much slighter increase in accuracy over the basic sketches than do the prolonged sketches. To understand why the pinched sketches are less accurate than the prolonged sketches, observe that the pinched sketches satisfy

$$\begin{aligned}\mathbf{Q}(\mathbf{Q}^T\mathbf{A}\mathbf{Q})\mathbf{Q}^T &= \mathbf{P}_{\mathbf{AS}}\mathbf{A}\mathbf{P}_{\mathbf{AS}} \\ &= (\mathbf{P}_{\mathbf{AS}}\mathbf{A}^{1/2})(\mathbf{A}^{1/2}\mathbf{P}_{\mathbf{AS}}),\end{aligned}$$

while, as noted above, the prolonged sketches can be written in the form

$$\mathbf{A}\mathbf{Q}(\mathbf{Q}^T\mathbf{A}\mathbf{Q})^{\dagger}\mathbf{Q}^T\mathbf{A} = (\mathbf{A}^{1/2}\mathbf{P}_{\mathbf{A}^{3/2}\mathbf{S}})(\mathbf{P}_{\mathbf{A}^{3/2}\mathbf{S}}\mathbf{A}^{1/2}).$$

Thus, pinched and prolonged sketches approximate the square root of $\mathbf{A}$ by projecting, respectively, onto the ranges of $\mathbf{AS}$ and $\mathbf{A}^{3/2}\mathbf{S}$. The spectral decay present in $\mathbf{A}$ is increased when $\mathbf{A}$ is raised to a power larger than one; consequently, the range of $\mathbf{A}^{3/2}\mathbf{S}$ is more biased towards the top k-dimensional invariant subspace of $\mathbf{A}$ than is the range of $\mathbf{AS}$. It follows that the approximate square root used to construct the prolonged sketches more accurately captures the top k-dimensional subspace of $\mathbf{A}$ than does that used to construct the pinched sketches.

4. Theoretical Aspects of SPSD Low-rank Approximation

In this section, we present our main theoretical results, which consist of a suite of bounds on the quality of low-rank approximation under several different sketching methods. As mentioned above, these were motivated by our empirical observation that *all* of the sampling and projection methods we considered perform *much* better on the SPSD matrices we considered than previous worst-case bounds (*e.g.*, Drineas and Mahoney, 2005; Kumar et al., 2012; Gittens, 2012) would suggest. We start in Section 4.1 with deterministic structural conditions for the spectral, Frobenius, and trace norms. In Section 4.2, we use these results to provide our bounds for several random sampling and random projection procedures.

4.1 Deterministic Error Bounds for Low-rank SPSD Approximation

In this section, we present three theorems that provide error bounds for the spectral, Frobenius, and trace norm approximation errors under the SPSD Sketching Model of Section 2.2. These bounds hold for *any*, *e.g.*, deterministic or randomized, sketching matrix $\mathbf{S}$. Thus, *e.g.*, one could use them to check, in an *a posteriori* manner, the quality of a sketching method for which one cannot establish an *a priori* bound. Rather than doing this, we use these results (in Section 4.2 below) to derive *a priori* bounds for when the sketching operation consists of common random sampling and random projection algorithms. We note that the bounds can be interpreted geometrically in terms of the angles between the subspace spanned by the sampling matrix $\mathbf{S}$ and the dominant eigenspaces of $\mathbf{A}$; we refer the interested reader to the technical report (Gittens and Mahoney, 2013) for details.

Our results are based on the fact that approximations which satisfy our SPSD Sketching Model can be written in terms of a projection onto a subspace of the range of the square root of the matrix being approximated. The following fact appears in the proof of (Gittens, 2012, Proposition 1).

Lemma 1 *Let $\mathbf{A}$ be an SPSD matrix and $\mathbf{S}$ be a conformal sketching matrix. Then when $\mathbf{C} = \mathbf{AS}$ and $\mathbf{W} = \mathbf{S}^T\mathbf{AS}$, the corresponding low-rank SPSD approximation satisfies*

$$\mathbf{CW}^\dagger\mathbf{C}^T = \mathbf{A}^{1/2}\mathbf{P}_{\mathbf{A}^{1/2}\mathbf{S}}\mathbf{A}^{1/2}.$$

4.1.1 Spectral Norm Bounds

We start with a bound on the spectral norm of the residual error. Although this result is trivial to prove given prior work, it highlights several properties that we use in the analysis of our subsequent results.

Theorem 2 *Let $\mathbf{A}$ be an $n \times n$ SPSD matrix with eigenvalue decomposition partitioned as in Equation (1), $\mathbf{S}$ be a sketching matrix of size $n \times \ell$, q be a positive integer, and $\mathbf{\Omega}_1$ and $\mathbf{\Omega}_2$ be as defined in Equation (3). Then when $\mathbf{C} = \mathbf{A}^q\mathbf{S}$ and $\mathbf{W} = \mathbf{S}^T\mathbf{A}^{2q-1}\mathbf{S}$, the corresponding low-rank SPSD approximation satisfies*

$$\left\|\mathbf{A} - \mathbf{CW}^\dagger\mathbf{C}^T\right\|_2 \leq \|\mathbf{\Sigma}_2\|_2 + \left\|\mathbf{\Sigma}_2^{q-1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_2^{2/(2q-1)},$$

assuming $\mathbf{\Omega}_1$ has full row rank.

Proof Apply Lemma 1 with the sampling matrix $\mathbf{S}' = \mathbf{A}^{q-1}\mathbf{S}$ (where, recall, $q \geq 1$) to see that

$$\mathbf{CW}^\dagger\mathbf{C}^T = \mathbf{A}^{1/2}\mathbf{P}_{\mathbf{A}^{q-1/2}\mathbf{S}}\mathbf{A}^{1/2}.$$

It follows that

$$\left\|\mathbf{A} - \mathbf{CW}^\dagger\mathbf{C}^T\right\|_2 = \left\|\mathbf{A}^{1/2}\left(\mathbf{I} - \mathbf{P}_{\left(\mathbf{A}^{1/2}\right)^{2q-1}\mathbf{S}}\right)\mathbf{A}^{1/2}\right\|_2^2. \tag{10}$$

Next, recall that $\mathbf{\Omega}_i = \mathbf{U}_i^T\mathbf{S}$ and that $\mathbf{A}^{1/2}$ has eigenvalue decomposition $\mathbf{A}^{1/2} = \mathbf{U}\mathbf{\Sigma}^{1/2}\mathbf{U}^T$, where

$$\mathbf{U} = \begin{pmatrix}\mathbf{U}_1 & \mathbf{U}_2\end{pmatrix} \text{ and } \mathbf{\Sigma}^{1/2} = \begin{pmatrix}\mathbf{\Sigma}_1^{1/2} & \\ & \mathbf{\Sigma}_2^{1/2}\end{pmatrix}.$$

It can be shown (see Halko et al., 2011, Theorems 9.1 and 9.2) that, because $\mathbf{\Omega}_1$ has full row rank,

$$\left\|\mathbf{A}^{1/2}\left(\mathbf{I} - \mathbf{P}_{\left(\mathbf{A}^{1/2}\right)^{2q-1}\mathbf{S}}\right)\mathbf{A}^{1/2}\right\|_2^2 \leq \left(\left\|\left(\mathbf{\Sigma}_2^{1/2}\right)^{2q-1}\right\|_2^2 + \left\|\left(\mathbf{\Sigma}_2^{1/2}\right)^{2q-1}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_2^2\right)^{1/(2q-1)}. \tag{11}$$

Equations (10) and (11) imply that

$$\begin{aligned}\left\|\mathbf{A} - \mathbf{CW}^\dagger\mathbf{C}^T\right\|_2 &\leq \left(\left\|\mathbf{\Sigma}_2^{q-1/2}\right\|_2^2 + \left\|\mathbf{\Sigma}_2^{q-1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_2^2\right)^{1/(2q-1)} \\ &\leq \|\mathbf{\Sigma}_2\|_2 + \left\|\mathbf{\Sigma}_2^{q-1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_2^{2/(2q-1)}\end{aligned}$$

The latter inequality follows from the fact that the $2q-1$ radical function is subadditive when $q \geq 1$ and the identity $\left\|\mathbf{\Sigma}_2^{q-1/2}\right\|_2^2 = \|\mathbf{\Sigma}_2\|_2^{2q-1}$. This establishes the stated bound. ■

Remark. The assumption that $\mathbf{\Omega}_1$ has full row rank is very non-trivial. It is, however, satisfied by our algorithms below. See Section 4.1.4 for more details on this point.

Remark. The proof of Theorem 2 proceeds in two steps. The first step relates low-rank approximation of an SPSD matrix $\mathbf{A}$ under the SPSD Sketching Model of Section 2.2 to column sketching (*e.g.*, sampling or projecting) from the square-root of $\mathbf{A}$. A weaker relation of this type was used by Drineas and Mahoney (2005), but the stronger form that we use here in Equation (10) was first proved in (Gittens, 2012). The second step is to use a deterministic structural result that holds for sampling/projecting from an arbitrary matrix. The structural bound of the form of Equation (11) was originally proven for $q = 1$ by Boutsidis et al. (2009), who applied it to the Column Subset Selection Problem. The bound was subsequently improved by Halko et al. (2011), who applied it to a random projection algorithm and extended it to apply when $q > 1$. Although the analyses of our next two results are more complicated, they follow the same high-level two-step approach.

4.1.2 Frobenius Norm Bounds

Next, we state and prove the following bound on the Frobenius norm of the residual error. The proof parallels that for the spectral norm bound, in that we divide it into two analogous parts, but the analysis is somewhat more complex.

The multiplicative eigengap $\gamma = \lambda_{k+1}(\mathbf{A})/\lambda_k(\mathbf{A})$ that appears in the statement of this theorem predicts the effect of using the power method when constructing sketches. Specifically, the additional errors of sketches constructed using $\mathbf{C} = \mathbf{A}^q\mathbf{S}$ are at least a factor of γ^{q-1} times smaller than those constructed using $\mathbf{C} = \mathbf{AS}$.

Theorem 3 *Let* $\mathbf{A}$ *be an* $n \times n$ *SPSD matrix with eigenvalue decomposition partitioned as in Equation* (1)*,* $\mathbf{S}$ *be a sketching matrix of size* $n \times \ell$*,* q *be a positive integer,* $\mathbf{\Omega}_1$ *and* $\mathbf{\Omega}_2$ *be as defined in Equation* (3)*, and define*

$$\gamma = \frac{\lambda_{k+1}(\mathbf{A})}{\lambda_k(\mathbf{A})}.$$

Then when $\mathbf{C} = \mathbf{A}^q\mathbf{S}$ *and* $\mathbf{W} = \mathbf{S}^T\mathbf{A}^{2q-1}\mathbf{S}$*, the corresponding low-rank SPSD approximation satisfies*

$$\left\|\mathbf{A} - \mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\right\|_\mathrm{F} \leq \|\mathbf{\Sigma}_2\|_\mathrm{F} + \gamma^{q-1}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_2 \cdot \left(\sqrt{2\,\mathrm{Tr}\,(\mathbf{\Sigma}_2)} + \gamma^{q-1}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_\mathrm{F}\right),$$

assuming $\mathbf{\Omega}_1$ *has full row rank.*

Proof Apply Lemma 1 with the sampling matrix $\mathbf{S}' = \mathbf{A}^{q-1}\mathbf{S}$ to see that

$$\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T = \mathbf{A}^{1/2}\mathbf{P}_{\mathbf{A}^{q-1/2}\mathbf{S}}\mathbf{A}^{1/2}.$$

It follows that

$$E := \left\|\mathbf{A} - \mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\right\|_\mathrm{F} = \left\|\mathbf{A}^{1/2}\left(\mathbf{I} - \mathbf{P}_{\mathbf{A}^{q-1/2}\mathbf{S}}\right)\mathbf{A}^{1/2}\right\|_\mathrm{F}.$$

To bound this quantity, we first use the unitary invariance of the Frobenius norm and the fact that

$$\mathbf{P}_{\mathbf{A}^{q-1/2}\mathbf{S}} = \mathbf{U}\mathbf{P}_{\mathbf{\Sigma}^{q-1/2}\mathbf{U}^T\mathbf{S}}\mathbf{U}^T$$

to obtain

$$E^2 = \left\|\mathbf{A}^{1/2}\left(\mathbf{I} - \mathbf{P}_{\mathbf{A}^{q-1/2}\mathbf{S}}\right)\mathbf{A}^{1/2}\right\|_\mathrm{F}^2 = \left\|\mathbf{\Sigma}^{1/2}\left(\mathbf{I} - \mathbf{P}_{\mathbf{\Sigma}^{q-1/2}\mathbf{U}^T\mathbf{S}}\right)\mathbf{\Sigma}^{1/2}\right\|_\mathrm{F}^2.$$

Then we take

$$\mathbf{Z} = \mathbf{\Sigma}^{q-1/2}\mathbf{U}^T\mathbf{S}\mathbf{\Omega}_1^\dagger\mathbf{\Sigma}_1^{-(q-1/2)} = \begin{pmatrix}\mathbf{I}\\ \mathbf{F}\end{pmatrix}, \tag{12}$$

where $\mathbf{I} \in \mathbb{R}^{k\times k}$ and $\mathbf{F} \in \mathbb{R}^{n-k\times k}$ is given by $\mathbf{F} = \mathbf{\Sigma}_2^{q-1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\mathbf{\Sigma}_1^{-(q-1/2)}$. The latter equality in Equation (12) holds because of our assumption that $\mathbf{\Omega}_1$ has full row rank. Since the range of $\mathbf{Z}$ is contained in the range of $\mathbf{\Sigma}^{q-1/2}\mathbf{U}^T\mathbf{S}$,

$$E^2 \leq \left\|\mathbf{\Sigma}^{1/2}(\mathbf{I} - \mathbf{P}_\mathbf{Z})\mathbf{\Sigma}^{1/2}\right\|_\mathrm{F}^2.$$

By construction, $\mathbf{Z}$ has full column rank, thus $\mathbf{Z}(\mathbf{Z}^T\mathbf{Z})^{-1/2}$ is an orthonormal basis for the span of $\mathbf{Z}$, and

$$\begin{aligned}\mathbf{I} - \mathbf{P}_\mathbf{Z} &= \mathbf{I} - \mathbf{Z}(\mathbf{Z}^T\mathbf{Z})^{-1}\mathbf{Z}^T = \mathbf{I} - \begin{pmatrix}\mathbf{I}\\ \mathbf{F}\end{pmatrix}(\mathbf{I} + \mathbf{F}^T\mathbf{F})^{-1}\begin{pmatrix}\mathbf{I} & \mathbf{F}^T\end{pmatrix}\\ &= \begin{pmatrix}\mathbf{I} - (\mathbf{I} + \mathbf{F}^T\mathbf{F})^{-1} & -(\mathbf{I} + \mathbf{F}^T\mathbf{F})^{-1}\mathbf{F}^T\\ -\mathbf{F}(\mathbf{I} + \mathbf{F}^T\mathbf{F})^{-1} & \mathbf{I} - \mathbf{F}(\mathbf{I} + \mathbf{F}^T\mathbf{F})^{-1}\mathbf{F}^T\end{pmatrix}.\end{aligned} \tag{13}$$

This implies that

$$\begin{aligned}E^2 &\leq \left\|\mathbf{\Sigma}^{1/2}\begin{pmatrix}\mathbf{I} - (\mathbf{I} + \mathbf{F}^T\mathbf{F})^{-1} & -(\mathbf{I} + \mathbf{F}^T\mathbf{F})^{-1}\mathbf{F}^T\\ -\mathbf{F}(\mathbf{I} + \mathbf{F}^T\mathbf{F})^{-1} & \mathbf{I} - \mathbf{F}(\mathbf{I} + \mathbf{F}^T\mathbf{F})^{-1}\mathbf{F}^T\end{pmatrix}\mathbf{\Sigma}^{1/2}\right\|_\mathrm{F}^2\\ &= \left\|\mathbf{\Sigma}_1^{1/2}\left(\mathbf{I} - (\mathbf{I} + \mathbf{F}^T\mathbf{F})^{-1}\right)\mathbf{\Sigma}_1^{1/2}\right\|_\mathrm{F}^2 + 2\left\|\mathbf{\Sigma}_1^{1/2}(\mathbf{I} + \mathbf{F}^T\mathbf{F})^{-1}\mathbf{F}^T\mathbf{\Sigma}_2^{1/2}\right\|_\mathrm{F}^2\\ &\quad + \left\|\mathbf{\Sigma}_2^{1/2}\left(\mathbf{I} - \mathbf{F}(\mathbf{I} + \mathbf{F}^T\mathbf{F})^{-1}\mathbf{F}^T\right)\mathbf{\Sigma}_2^{1/2}\right\|_\mathrm{F}^2\\ &:= T_1 + T_2 + T_3.\end{aligned} \tag{14}$$

Next, we provide bounds for T_1, T_2, and T_3. Using the fact that $\mathbf{0} \preceq \mathbf{I} - \mathbf{F}(\mathbf{I} + \mathbf{F}^T\mathbf{F})^{-1}\mathbf{F}^T \preceq \mathbf{I}$, we can bound T_3 with

$$T_3 \leq \|\mathbf{\Sigma}_2\|_\mathrm{F}^2.$$

Likewise, the fact that $\mathbf{I} - (\mathbf{I} + \mathbf{F}^T\mathbf{F})^{-1} \preceq \mathbf{F}^T\mathbf{F}$ (easily seen with an SVD) implies that we can bound T_1 as

$$\begin{aligned}T_1 &\leq \left\|\mathbf{\Sigma}_1^{1/2}\mathbf{F}^T\mathbf{F}\mathbf{\Sigma}_1^{1/2}\right\|_\mathrm{F}^2 \leq \left\|\mathbf{F}\mathbf{\Sigma}_1^{1/2}\right\|_2^2\left\|\mathbf{F}\mathbf{\Sigma}_1^{1/2}\right\|_\mathrm{F}^2\\ &= \left\|\mathbf{\Sigma}_2^{q-1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\mathbf{\Sigma}_1^{-(q-1)}\right\|_2^2\left\|\mathbf{\Sigma}_2^{q-1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\mathbf{\Sigma}_1^{-(q-1)}\right\|_\mathrm{F}^2\\ &\leq \left\|\mathbf{\Sigma}_2^{q-1}\right\|_2^4\left\|\mathbf{\Sigma}_1^{-(q-1)}\right\|_2^4\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_2^2\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_\mathrm{F}^2\\ &= \left(\|\mathbf{\Sigma}_2\|_2\left\|\mathbf{\Sigma}_1^{-1}\right\|_2\right)^{4(q-1)}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_2^2\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_\mathrm{F}^2\\ &= \left(\frac{\lambda_{k+1}(\mathbf{A})}{\lambda_k(\mathbf{A})}\right)^{4(q-1)}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_2^2\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_\mathrm{F}^2.\end{aligned}$$

We proceed to bound T_2 by using the estimate

$$T_2 \leq 2\left\|\mathbf{\Sigma}_1^{1/2}(\mathbf{I} + \mathbf{F}^T\mathbf{F})^{-1}\mathbf{F}^T\right\|_2^2\left\|\mathbf{\Sigma}_2^{1/2}\right\|_\mathrm{F}^2. \tag{15}$$

To develop the term involving a spectral norm, observe that for any SPSD matrix $\mathbf{M}$ with eigenvalue decomposition $\mathbf{M} = \mathbf{V}\mathbf{D}\mathbf{V}^T$,

$$\begin{aligned}(\mathbf{I} + \mathbf{M})^{-1}\mathbf{M}(\mathbf{I} + \mathbf{M})^{-1} &= (\mathbf{V}\mathbf{V}^T + \mathbf{V}\mathbf{D}\mathbf{V}^T)^{-1}\mathbf{V}\mathbf{D}\mathbf{V}^T(\mathbf{V}\mathbf{V}^T + \mathbf{V}\mathbf{D}\mathbf{V}^T)^{-1}\\ &= \mathbf{V}(\mathbf{I} + \mathbf{D})^{-1}\mathbf{D}(\mathbf{I} + \mathbf{D})^{-1}\mathbf{V}^T\\ &\preceq \mathbf{V}\mathbf{D}\mathbf{V}^T = \mathbf{M}.\end{aligned}$$

It follows that

$$\begin{aligned}\left\|\mathbf{\Sigma}_1^{1/2}(\mathbf{I}+\mathbf{F}^T\mathbf{F})^{-1}\mathbf{F}^T\right\|_2^2 &= \left\|\mathbf{\Sigma}_1^{1/2}(\mathbf{I}+\mathbf{F}^T\mathbf{F})^{-1}\mathbf{F}^T\mathbf{F}(\mathbf{I}+\mathbf{F}^T\mathbf{F})^{-1}\mathbf{\Sigma}_1^{1/2}\right\|_2 \\ &\leq \left\|\mathbf{\Sigma}_1^{1/2}\mathbf{F}^T\mathbf{F}\mathbf{\Sigma}_1^{1/2}\right\|_2 = \left\|\mathbf{F}\mathbf{\Sigma}_1^{1/2}\right\|_2^2 \\ &= \left\|\mathbf{\Sigma}_2^{q-1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\mathbf{\Sigma}_1^{-(q-1)}\right\|_2^2 \\ &\leq \left\|\mathbf{\Sigma}_2^{q-1}\right\|_2^2\left\|\mathbf{\Sigma}_1^{-(q-1)}\right\|_2^2\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_2^2 \\ &= \left(\frac{\lambda_{k+1}(\mathbf{A})}{\lambda_k(\mathbf{A})}\right)^{2(q-1)}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_2^2.\end{aligned}$$

Using this estimate in Equation (15), we conclude that

$$T_2 \leq 2\left(\frac{\lambda_{k+1}(\mathbf{A})}{\lambda_k(\mathbf{A})}\right)^{2(q-1)}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_2^2\left\|\mathbf{\Sigma}_2^{1/2}\right\|_{\mathrm{F}}^2.$$

Combining our estimates for T_1, T_2, and T_3 with Equation (14) gives

$$\begin{aligned}E^2 = \left\|\mathbf{A}^{1/2}\left(\mathbf{I}-\mathbf{P}_{\mathbf{A}^{q-1/2}\mathbf{S}}\right)\mathbf{A}^{1/2}\right\|_{\mathrm{F}}^2 &\leq \|\mathbf{\Sigma}_2\|_{\mathrm{F}}^2 \\ + \left(\frac{\lambda_{k+1}(\mathbf{A})}{\lambda_k(\mathbf{A})}\right)^{2(q-1)}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_2^2 &\cdot\left(2\left\|\mathbf{\Sigma}_2^{1/2}\right\|_{\mathrm{F}}^2 + \left(\frac{\lambda_{k+1}(\mathbf{A})}{\lambda_k(\mathbf{A})}\right)^{2(q-1)}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_{\mathrm{F}}^2\right).\end{aligned}$$

The claimed bound follows by identifying γ and applying the subadditivity of the square-root function:

$$E \leq \|\mathbf{\Sigma}_2\|_{\mathrm{F}} + \gamma^{q-1}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_2\cdot\left(\sqrt{2\operatorname{Tr}(\mathbf{\Sigma}_2)} + \gamma^{q-1}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_{\mathrm{F}}\right).$$

■

Remark. The quality of approximation guarantee provided by Theorem 3 depends on the quantities $\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_2$ and $\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_{\mathrm{F}}$; these quantities reflect the extent to which the sketching matrix is aligned with the eigenspaces of $\mathbf{A}$. The dependence on γ captures the facts that the power method is effective only when there is spectral decay, and that larger gaps between the k and $k+1$ eigenvalues lead to smaller errors when the power method is used.

Remark. To obtain a greater understanding of the additional error term in Theorem 3, assume that $\mathbf{S}$ is a particularly effective sketching matrix, so that $\left\|\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_2 = \mathrm{O}(1)$. Then

$$\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_2 = \mathrm{O}\left(\|\mathbf{\Sigma}_2\|_2^{1/2}\right) \quad \text{and} \quad \sqrt{2\operatorname{Tr}(\mathbf{\Sigma}_2)} + \left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_{\mathrm{F}} = \mathrm{O}\left(\|\mathbf{\Sigma}_2\|_\star^{1/2}\right),$$

and the theorem guarantees that the additional error is on the order of $\sqrt{\|\mathbf{\Sigma}_2\|_2\|\mathbf{\Sigma}_2\|_\star}$. This is an upper bound on the optimal Frobenius error:

$$\|\mathbf{\Sigma}_2\|_{\mathrm{F}} \leq \sqrt{\|\mathbf{\Sigma}_2\|_2\|\mathbf{\Sigma}_2\|_\star}.$$

We see, in particular, that if the residual spectrum is flat, i.e. $\lambda_{k+1}(\mathbf{A}) = \cdots = \lambda_n(\mathbf{A})$, then equality holds and the additional error is on the scale of the optimal error.

4.1.3 Trace Norm Bounds

Finally, we state and prove the following bound on the trace norm of the residual error. The proof method is analogous to that for the spectral and Frobenius norm bounds.

As in the case of the Frobenius norm error, we see that the multiplicative eigengap $\gamma = \lambda_{k+1}(\mathbf{A})/\lambda_k(\mathbf{A})$ predicts the effect of using the power method when constructing sketches.

Theorem 4 *Let $\mathbf{A}$ be an $n\times n$ SPSD matrix with eigenvalue decomposition partitioned as in Equation (1), $\mathbf{S}$ be a sketching matrix of size $n\times\ell$, q be a positive integer, $\mathbf{\Omega}_1$ and $\mathbf{\Omega}_2$ be as defined in Equation (3), and define*

$$\gamma = \frac{\lambda_{k+1}(\mathbf{A})}{\lambda_k(\mathbf{A})}.$$

Then when $\mathbf{C} = \mathbf{A}^q\mathbf{S}$ and $\mathbf{W} = \mathbf{S}^T\mathbf{A}^{2q-1}\mathbf{S}$, the corresponding low-rank SPSD approximation satisfies

$$\left\|\mathbf{A}-\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\right\|_\star \leq \operatorname{Tr}(\mathbf{\Sigma}_2) + \gamma^{2(q-1)}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_{\mathrm{F}}^2,$$

assuming $\mathbf{\Omega}_1$ has full row rank.

Proof Since $\mathbf{A}-\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T = \mathbf{A}^{1/2}(\mathbf{I}-\mathbf{P}_{\mathbf{A}^{q-1/2}\mathbf{S}})\mathbf{A}^{1/2} \succeq \mathbf{0}$, its trace norm simplifies to its trace. Thus

$$\begin{aligned}\left\|\mathbf{A}-\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\right\|_\star &= \operatorname{Tr}\left(\mathbf{A}-\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\right) = \operatorname{Tr}\left(\mathbf{\Sigma}^{1/2}\left(\mathbf{I}-\mathbf{P}_{\mathbf{\Sigma}^{q-1/2}\mathbf{S}}\right)\mathbf{\Sigma}^{1/2}\right) \\ &\leq \operatorname{Tr}\left(\mathbf{\Sigma}^{1/2}(\mathbf{I}-\mathbf{P}_{\mathbf{Z}})\mathbf{\Sigma}^{1/2}\right),\end{aligned}$$

where $\mathbf{Z} = \begin{pmatrix}\mathbf{I}\\ \mathbf{F}\end{pmatrix}$ is defined in Equation (12). The expression for $\mathbf{I}-\mathbf{P}_{\mathbf{Z}}$ given in Equation (13) implies that

$$\begin{aligned}&\operatorname{Tr}\left(\mathbf{\Sigma}^{1/2}(\mathbf{I}-\mathbf{P}_{\mathbf{Z}})\mathbf{\Sigma}^{1/2}\right) \\ &\qquad = \operatorname{Tr}\left(\mathbf{\Sigma}_1^{1/2}(\mathbf{I}-(\mathbf{I}+\mathbf{F}^T\mathbf{F})^{-1})\mathbf{\Sigma}_1^{1/2}\right) + \operatorname{Tr}\left(\mathbf{\Sigma}_2^{1/2}(\mathbf{I}-\mathbf{F}(\mathbf{I}+\mathbf{F}^T\mathbf{F})^{-1}\mathbf{F}^T)\mathbf{\Sigma}_2^{1/2}\right).\end{aligned}$$

Recall the estimate $\mathbf{I}-(\mathbf{I}+\mathbf{F}^T\mathbf{F})^{-1} \preceq \mathbf{F}^T\mathbf{F}$ and the basic estimate $\mathbf{I}-\mathbf{F}(\mathbf{I}+\mathbf{F}^T\mathbf{F})^{-1}\mathbf{F}^T \preceq \mathbf{I}$. Together these imply that

$$\begin{aligned}\operatorname{Tr}\left(\mathbf{\Sigma}^{1/2}(\mathbf{I}-\mathbf{P}_{\mathbf{Z}})\mathbf{\Sigma}^{1/2}\right) &\leq \operatorname{Tr}\left(\mathbf{\Sigma}_1^{1/2}\mathbf{F}^T\mathbf{F}\mathbf{\Sigma}_1^{1/2}\right) + \operatorname{Tr}(\mathbf{\Sigma}_2) \\ &= \operatorname{Tr}(\mathbf{\Sigma}_2) + \left\|\mathbf{\Sigma}_2^{q-1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\mathbf{\Sigma}_1^{-(q-1)}\right\|_{\mathrm{F}}^2 \\ &\leq \operatorname{Tr}(\mathbf{\Sigma}_2) + \left\|\mathbf{\Sigma}_2^{q-1}\right\|_2^2\left\|\mathbf{\Sigma}_1^{-(q-1)}\right\|_2^2\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_{\mathrm{F}}^2 \\ &= \operatorname{Tr}(\mathbf{\Sigma}_2) + \gamma^{2(q-1)}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_{\mathrm{F}}^2.\end{aligned}$$

The first equality follows from substituting the definition of $\mathbf{F}$ and identifying the squared Frobenius norm. The last equality follows from identifying γ. We have established the claimed bound.

■

Remark. Since the identity $\|\mathbf{X}\|_{\mathrm{F}}^2 = \left\|\mathbf{X}\mathbf{X}^T\right\|_\star$ holds for any matrix $\mathbf{X}$, the squared Frobenius norm term present in the deterministic error bound for the trace norm error is on the scale of $\|\mathbf{\Sigma}_2\|_\star$ when $\left\|\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_2$ is O(1).

4.1.4 Additional Remarks on Our Deterministic Structural Results

Before applying these deterministic structural results in particular randomized algorithmic settings, we pause to make several additional remarks about these three theorems.

First, for some randomized sampling schemes, it may be difficult to obtain a sharp bound on $\left\|\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_\xi$ for $\xi = 2, F$. In these situations, the bounds on the excess error supplied by Theorems 2, 3, and 4 may be quite pessimistic. On the other hand, since $\mathbf{A} - \mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T = \mathbf{A}^{1/2}(\mathbf{I} - \mathbf{P}_{\left(\mathbf{A}^{1/2}\right)^{2q-1}\mathbf{S}})\mathbf{A}^{1/2}$, it follows that $\mathbf{0} \preceq \mathbf{A} - \mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T \preceq \mathbf{A}$. This implies that the errors of *any* approximation generated used the SPSD Sketching Model, deterministic or randomized, satisfy at least the crude bound $\left\|\mathbf{A} - \mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\right\|_\xi \leq \|\mathbf{A}\|_\xi$.

Second, we emphasize that these theorems are deterministic structural results that bound the additional error (beyond that of the optimal rank-k approximation) of low-rank approximations which follow our SPSD sketching model. That is, there is no randomness in their statement or analysis. In particular, these bounds hold for deterministic as well as randomized sketching matrices $\mathbf{S}$. In the latter case, the randomness enters only through $\mathbf{S}$, and one needs to show that the condition that $\mathbf{\Omega}_1$ has full row rank is satisfied with high probability; conditioned on this, the quality of the bound is determined by terms that depend on how the sketching matrix interacts with the subspace structure of the matrix $\mathbf{A}$.

In particular, we remind the reader that (although it is beyond the scope of this paper to explore this point in detail) these deterministic structural results could be used to check, in an *a posteriori* manner, the quality of a sketching method for which one cannot establish an *a priori* bound.

Third, we also emphasize that the assumption that $\mathbf{\Omega}_1$ has full row rank (equivalently, that $\tan(\mathbf{S}, \mathbf{U}_1) < \infty$) is very non-trivial; and that it is false, in worst-case at least and for non-trivial parameter values, for common sketching methods such as uniform sampling. To see that some version of leverage-based sampling is needed to ensure this condition, recall that $\mathbf{U}_1^T\mathbf{U}_1 = \mathbf{I}$ and thus that $\mathbf{\Omega}_1\mathbf{\Omega}_1^T = \mathbf{U}_1^T\mathbf{S}\mathbf{S}^T\mathbf{U}_1$ can be viewed as approximating $\mathbf{I}$ with a small number of rank-1 components of $\mathbf{U}_1^T\mathbf{U}_1$. The condition that $\mathbf{\Omega}_1$ has full row rank is equivalent to $\left\|\mathbf{U}_1^T\mathbf{U}_1 - \mathbf{U}_1^T\mathbf{S}\mathbf{S}^T\mathbf{U}_1\right\|_2 < 1$. Work on approximating the product of matrices by random sampling shows that to obtain non-trivial bounds one must sample with respect to the norm of the rank-1 components (Drineas et al., 2006), which here (since we are approximating the product of two orthogonal matrices) equal the statistical leverage scores. From this perspective, random projections satisfy this condition since (informally) they rotate to a random basis where the leverage scores of the rotated matrix are approximately uniform and thus where uniform sampling is appropriate (Drineas et al., 2010; Mahoney, 2011).

Finally, as observed recently in Bach (2013), methods that use knowledge of a matrix square root Φ (*i.e.*, a Φ such that $\mathbf{A} = \Phi\Phi^T$) typically lead to $\Omega(n^2)$ complexity. An important feature of our approach is that we only use the matrix square root implicitly—that is, inside the analysis, and not in the statement of the algorithm—and thus we do *not* incur any such cost.

4.2 Stochastic Error Bounds for Low-rank SPSD Approximation

In this section, we apply the three theorems from Section 4.1 to bound the reconstruction errors for several random sampling and random projection methods that conform to our SPSD Sketching Model. In particular, we consider two variants of random sampling and two variants of random projections: sampling columns according to an importance sampling distribution that depends on the statistical leverage scores (in Section 4.2.1); randomly projecting by using subsampled randomized Fourier transformations (in Section 4.2.2); randomly projecting by uniformly sampling from Gaussian mixtures of the columns (in Section 4.2.3); and, finally, sampling columns uniformly at random (in Section 4.2.4).

The results are presented for the general case of SPSD sketches constructed using the power method, i.e., sketches constructed using $\mathbf{C} = \mathbf{A}^q\mathbf{S}$ for a positive integer q. The additive errors of these sketches decrease proportionally to the number of iterations q, where the constant of proportionality is given by the multiplicative eigengap $\gamma = \lambda_{k+1}(\mathbf{A})/\lambda_k(\mathbf{A})$. Accordingly, the bounds involve the terms γ^{q-1} and $\gamma^{2(q-1)}$. The bounds simplify considerably when $q = 1$ (*i.e.*, when there are no additional iterations) or $\gamma = 1$ (*i.e.*, when there is no eigengap). In either of these cases, the terms γ^{q-1} and $\gamma^{2(q-1)}$ all become the constant 1.

Before establishing these results, we pause here to provide a brief review of running time issues, some of which were addressed empirically in Section 3. The computational bottleneck for random sampling algorithms (except for uniform sampling that we address in Section 4.2.4, which is trivial to implement) is often the exact or approximate computation of the importance sampling distribution with respect to which one samples; and the computational bottleneck for random projection methods is often the implementation of the random projection. For example, if the sketching matrix $\mathbf{S}$ is a random projection constructed as an $n \times \ell$ matrix of i.i.d. Gaussian random variables, as we use in Section 4.2.3, then the running time of dense data in RAM is not substantially faster than computing $\mathbf{U}_1$, while the running time can be much faster for certain sparse matrices or for computation in parallel or distributed environments. Alternately, if the sketching matrix $\mathbf{S}$ is a Fourier-based projection, as we use in Section 4.2.2, then the running time for data stored in RAM is typically $O(n^2 \ln k)$, as opposed to the $O(n^2 k)$ time that would be needed to compute $\mathbf{U}_1$. These running times depend sensitively on the size of the data and the model of data access; see Mahoney (2011); Halko et al. (2011) for detailed discussions of these issues.

In particular, for random sampling algorithms that use a leverage-based importance sampling distribution, as we use in Section 4.2.1, it is often said that the running time is no faster than that of computing $\mathbf{U}_1$. (This $O(n^2 k)$ running time claim is simply the running time of the naïve algorithm that computes $\mathbf{U}_1$ "exactly," *e.g.*, with a variant of the QR decomposition, and then reads off the Euclidean norms of the rows.) However, the randomized algorithm of Drineas et al. (2012) that computes relative-error approximations to *all* of the statistical leverage in a time that is qualitatively faster—in worst-case theory

and, by using existing high-quality randomized numerical code (Avron et al., 2010; Meng et al., 2014; Halko et al., 2011), in practice—gets around this bottleneck, as was shown in Section 3. The computational bottleneck for the algorithms of Drineas et al. (2012) is that of applying a random projection, and thus the running time for leverage-based Nyström extension is that of applying a ("fast" Fourier-based or "slow" Gaussian-based, as appropriate) random projection to $\mathbf{A}$ (Drineas et al., 2012). See Section 3 or (Avron et al., 2010; Meng et al., 2014; Halko et al., 2011) for additional details.

4.2.1 Sampling with Leverage-based Importance Sampling Probabilities

Here, the columns of $\mathbf{A}$ are sampled with replacement according to a nonuniform probability distribution determined by the (exact or approximate) statistical leverage scores of $\mathbf{A}$ relative to the best rank-k approximation to $\mathbf{A}$, which in turn depend on nonuniformity properties of the top k-dimensional eigenspace of $\mathbf{A}$. To add flexibility (*e.g.*, in case the scores are computed only approximately with the fast algorithm of Drineas et al. (2012)), we formulate the following lemma in terms of any probability distribution that is β-close to the leverage score distribution. In particular, consider any probability distribution satisfying

$$p_j \geq \frac{\beta}{k} \left\|(\mathbf{U}_1)_j\right\|_2^2 \quad \text{and} \quad \sum_{j=1}^n p_j = 1,$$

where $\beta \in (0,1]$. Given these (β-approximate) leverage-based probabilities, the sketching matrix is $\mathbf{S} = \mathbf{RD}$ where $\mathbf{R} \in \mathbb{R}^{n\times\ell}$ is a column selection matrix that samples columns of $\mathbf{A}$ from the given distribution—*i.e.*, $\mathbf{R}_{ij} = 1$ iff the ith column of $\mathbf{A}$ is the jth column selected—and $\mathbf{D}$ is a diagonal rescaling matrix satisfying $\mathbf{D}_{jj} = \frac{1}{\sqrt{\ell p_i}}$ iff $\mathbf{R}_{ij} = 1$. For this case, we can prove the following.

Lemma 5 *Let $\mathbf{A}$ be an $n \times n$ SPSD matrix, q be a positive integer, and $\mathbf{S}$ be a sampling matrix of size $n \times \ell$ corresponding to a leverage-based probability distribution derived from the top k-dimensional eigenspace of $\mathbf{A}$, satisfying*

$$p_j \geq \frac{\beta}{k} \left\|(\mathbf{U}_1)_j\right\|_2^2 \quad \textit{and} \quad \sum_{j=1}^n p_j = 1$$

for some $\beta \in (0,1]$. Fix a failure probability $\delta \in (0,1]$ and approximation factor $\epsilon \in (0,1]$, and let

$$\gamma = \frac{\lambda_{k+1}(\mathbf{A})}{\lambda_k(\mathbf{A})}.$$

If $\ell \geq 3200(\beta\epsilon^2)^{-1}k\ln(4k/(\beta\delta))$, then, when $\mathbf{C} = \mathbf{A}^q\mathbf{S}$ and $\mathbf{W} = \mathbf{S}^T\mathbf{A}^{2q-1}\mathbf{S}$, the corresponding low-rank SPSD approximation satisfies

$$\left\|\mathbf{A} - \mathbf{CW}^\dagger\mathbf{C}^T\right\|_2 \leq \|\mathbf{A} - \mathbf{A}_k\|_2 + \left(\epsilon^2 \left\|(\mathbf{A} - \mathbf{A}_k)^{2q-1}\right\|_\star\right)^{1/(2q-1)}, \tag{16}$$

$$\left\|\mathbf{A} - \mathbf{CW}^\dagger\mathbf{C}^T\right\|_{\mathrm{F}} \leq \|\mathbf{A} - \mathbf{A}_k\|_{\mathrm{F}} + \left(\sqrt{2}\epsilon\gamma^{q-1} + \epsilon^2\gamma^{2(q-1)}\right)\|\mathbf{A} - \mathbf{A}_k\|_\star, \textit{ and} \tag{17}$$

$$\left\|\mathbf{A} - \mathbf{CW}^\dagger\mathbf{C}^T\right\|_\star \leq (1 + \gamma^{2(q-1)}\epsilon^2)\|\mathbf{A} - \mathbf{A}_k\|_\star, \tag{18}$$

simultaneously with probability at least $1 - 6\delta - 0.6$.

Proof In (Mackey et al., 2011a, proof of Proposition 22) it is shown that if ℓ satisfies the given bound and the samples are drawn from an approximate subspace probability distribution, then for any SPSD diagonal matrix $\mathbf{D}$,

$$\left\|\mathbf{D}\boldsymbol{\Omega}_2\boldsymbol{\Omega}_1^\dagger\right\|_{\mathrm{F}} \leq \epsilon\|\mathbf{D}\|_{\mathrm{F}}$$

with probability at least $1 - 2\delta - 0.2$. Thus, the estimates

$$\left\|\boldsymbol{\Sigma}_2^{1/2}\boldsymbol{\Omega}_2\boldsymbol{\Omega}_1^\dagger\right\|_{\mathrm{F}} \leq \epsilon\left\|\boldsymbol{\Sigma}_2^{1/2}\right\|_{\mathrm{F}} = \epsilon\sqrt{\mathrm{Tr}\left(\boldsymbol{\Sigma}_2\right)} = \epsilon\sqrt{\|\mathbf{A} - \mathbf{A}_k\|_\star},$$

and

$$\begin{aligned}
\left(\left\|\boldsymbol{\Sigma}_2^{q-1/2}\boldsymbol{\Omega}_2\boldsymbol{\Omega}_1^\dagger\right\|_2\right)^{2/(2q-1)} &\leq \left(\left\|\boldsymbol{\Sigma}_2^{p-1/2}\boldsymbol{\Omega}_2\boldsymbol{\Omega}_1^\dagger\right\|_{\mathrm{F}}\right)^{2/(2q-1)} \\
&\leq \left(\epsilon^2\left\|\boldsymbol{\Sigma}_2^{q-1/2}\right\|_{\mathrm{F}}^2\right)^{1/(2q-1)} \\
&= \left(\epsilon^2\,\mathrm{Tr}\left(\boldsymbol{\Sigma}_2^{2q-1}\right)\right)^{1/(2q-1)} \\
&= \left(\epsilon^2\left\|(\mathbf{A} - \mathbf{A}_k)^{2q-1}\right\|_\star\right)^{1/(2q-1)}
\end{aligned}$$

each hold, individually, with probability at least $1 - 2\delta - 0.2$. In particular, taking $q = 1$, we see that

$$\left\|\boldsymbol{\Sigma}_2^{1/2}\boldsymbol{\Omega}_2\boldsymbol{\Omega}_1^\dagger\right\|_2 \leq \epsilon\sqrt{\|\mathbf{A} - \mathbf{A}_k\|_\star}$$

with the same probability.

These three estimates used in Theorems 2, 3, and 4 yield the bounds given in the statement of the theorem. ■

Remark. The additive scale factors for the spectral and Frobenius norm bounds are much improved relative to the prior results of Drineas and Mahoney (2005). At root, this is since the leverage score importance sampling probabilities highlight structural properties of the data (*e.g.*, how to satisfy the condition in Theorems 2, 3, and 4 that $\boldsymbol{\Omega}_1$ has full row rank) in a more refined way than the importance sampling probabilities of Drineas and Mahoney (2005).

Remark. These improvements come at additional computational expense, but we remind the reader that leverage-based sampling probabilities of the form used by Lemma 5 can be computed faster than the time needed to compute the basis $\mathbf{U}_1$ (Drineas et al., 2012). The computational bottleneck of the algorithm of Drineas et al. (2012) is the time required to perform a random projection on the input matrix.

Remark. Not surprisingly, constant factors such as 3200 (as well as other similarly large factors below) and a failure probability bounded away from zero are artifacts of the analysis; the empirical behavior of this sampling method is much better. This has been observed previously (Drineas et al., 2008; Mahoney and Drineas, 2009).

4.2.2 Random Projections with Subsampled Randomized Fourier Transforms

Here, the columns of $\mathbf{A}$ are randomly mixed using a unitary matrix before the columns are sampled. In particular, $\mathbf{S} = \sqrt{\frac{n}{\ell}}\mathbf{DTR}$, where $\mathbf{D}$ is a diagonal matrix of Rademacher random variables, $\mathbf{T}$ is a highly incoherent unitary matrix, and $\mathbf{R}$ restricts to ℓ columns. For concreteness, and because it has an associated fast transform, we consider the case where $\mathbf{T}$ is the normalized Fourier transform of size $n \times n$. For this case, we can prove the following.

Lemma 6 *Let $\mathbf{A}$ be an $n \times n$ SPSD matrix, q be a positive integer, and $\mathbf{S} = \sqrt{\frac{n}{\ell}}\mathbf{DFR}$ be a sampling matrix of size $n \times \ell$, where $\mathbf{D}$ is a diagonal matrix of Rademacher random variables, $\mathbf{F}$ is a normalized Fourier matrix of size $n \times n$, and $\mathbf{R}$ restricts to ℓ columns. Fix a failure probability $\delta \in (0,1)$, approximation factor $\epsilon \in (0,1)$, and assume that $k \geq 4$. Define*

$$\gamma = \frac{\lambda_{k+1}(\mathbf{A})}{\lambda_k(\mathbf{A})}.$$

If $\ell \geq 24\epsilon^{-1}[\sqrt{k} + \sqrt{8\ln(8n/\delta)}]^2 \ln(8k/\delta)$, then, when $\mathbf{C} = \mathbf{A}^q\mathbf{S}$ and $\mathbf{W} = \mathbf{S}^T\mathbf{A}^{2q-1}\mathbf{S}$, the corresponding low-rank SPSD approximation satisfies

$$\begin{aligned}
\left\|\mathbf{A} - \mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\right\|_2 &\leq \left[1 + \left(\frac{1}{1-\sqrt{\epsilon}} \cdot \left(5 + \frac{16\ln(n/\delta)^2}{\ell}\right)\right)^{1/(2q-1)}\right] \cdot \|\mathbf{A} - \mathbf{A}_k\|_2 \\
&\quad + \left(\frac{2\ln(n/\delta)}{(1-\sqrt{\epsilon})\ell}\right)^{1/(2q-1)} \left\|(\mathbf{A} - \mathbf{A}_k)^{2q-1}\right\|_\star^{1/(2q-1)}, \qquad (19) \\
\left\|\mathbf{A} - \mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\right\|_\mathrm{F} &\leq \|\mathbf{A} - \mathbf{A}_k\|_\mathrm{F} + \left(7\gamma^{q-1}\sqrt{\epsilon} + 22\gamma^{2q-2}\epsilon\right)\|\mathbf{A} - \mathbf{A}_k\|_\star, \text{ and} \\
\left\|\mathbf{A} - \mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\right\|_\star &\leq (1 + 22\epsilon\gamma^{2(q-1)})\|\mathbf{A} - \mathbf{A}_k\|_\star
\end{aligned}$$

simultaneously with probability at least $1 - 2\delta$.

Proof Let $\mathbf{M} = \mathbf{\Sigma}_2^{q-1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger$ denote the matrix referenced in Theorems 2 and 4. In (Boutsidis and Gittens, 2013, proof of Theorem 4), it is shown that for the stated choice of $\mathbf{S}$ and number of samples ℓ,

$$\begin{aligned}
\|\mathbf{M}\|_2^2 &\leq \frac{1}{1-\sqrt{\epsilon}} \cdot \left(5\|\mathbf{\Sigma}_2\|_2^{2q-1} + \frac{\ln(n/\delta)}{\ell}\left(\left\|\mathbf{\Sigma}_2^{q-1/2}\right\|_\mathrm{F} + \sqrt{8\ln(n/\delta)}\left\|\mathbf{\Sigma}_2^{q-1/2}\right\|_2\right)^2\right) \\
&= \frac{1}{1-\sqrt{\epsilon}} \cdot \left(5\|\mathbf{\Sigma}\|_2^{2q-1} + \frac{\ln(n/\delta)}{\ell}\left(\left\|\mathbf{\Sigma}_2^{2q-1}\right\|_\star^{1/2} + \sqrt{8\ln(n/\delta)}\|\mathbf{\Sigma}_2\|_2^{q-1/2}\right)^2\right) \\
&\leq \frac{1}{1-\sqrt{\epsilon}} \cdot \left(\left(5 + \frac{16\ln(n/\delta)^2}{\ell}\right)\|\mathbf{\Sigma}_2\|_2^{2q-1} + \frac{2\ln(n/\delta)}{\ell}\left\|\mathbf{\Sigma}_2^{2q-1}\right\|_\star\right)
\end{aligned}$$

and

$$\|\mathbf{M}\|_\mathrm{F} \leq \sqrt{22\epsilon}\left\|\mathbf{\Sigma}_2^{1/2}\right\|_\mathrm{F} = \sqrt{22\epsilon\|\mathbf{\Sigma}_2\|_\star}$$

each hold, individually, with probability at least $1 - \delta$. These estimates used in Theorems 2 and 4 yield the stated bounds for the spectral and trace norm errors.

The Frobenius norm bound follows from the same estimates and a simplification of the bound stated in Theorem 3:

$$\begin{aligned}
\left\|\mathbf{A} - \mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\right\|_\mathrm{F} &\leq \|\mathbf{\Sigma}_2\|_\mathrm{F} + \gamma^{q-1}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_2\left(\sqrt{2\operatorname{Tr}(\mathbf{\Sigma}_2)} + \gamma^{q-1}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_\mathrm{F}\right) \\
&\leq \|\mathbf{\Sigma}_2\|_\mathrm{F} + \gamma^{q-1}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_\mathrm{F}\sqrt{2\operatorname{Tr}(\mathbf{\Sigma}_2)} + \gamma^{2(q-1)}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_\mathrm{F}^2 \\
&\leq \|\mathbf{\Sigma}_2\|_\mathrm{F} + \left(\gamma^{q-1}\sqrt{44\epsilon} + 22\gamma^{2q-2}\epsilon\right)\|\mathbf{\Sigma}_2\|_\star.
\end{aligned}$$

We note that a direct application of Theorem 3 gives a potentially tighter, but more unwieldy, bound. ■

Remark. Suppressing the dependence on δ and ϵ, the spectral norm bound ensures that when $q = 1$, $k = \Omega(\ln n)$ and $\ell = \Omega(k\ln k)$, then

$$\left\|\mathbf{A} - \mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\right\|_2 = \mathrm{O}\left(\frac{\ln n}{\ln k}\|\mathbf{A} - \mathbf{A}_k\|_2 + \frac{1}{\ln k}\|\mathbf{A} - \mathbf{A}_k\|_\star\right).$$

This should be compared to the guarantee established in Lemma 7 below for Gaussian-based SPSD sketches constructed using the same number of measurements:

$$\left\|\mathbf{A} - \mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\right\|_2 = \mathrm{O}\left(\|\mathbf{A} - \mathbf{A}_k\|_2 + \frac{1}{k\ln k}\|\mathbf{A} - \mathbf{A}_k\|_\star\right).$$

Lemma 6 guarantees that errors on this order can be achieved if one increases the number of samples by a logarithm factor in the dimension: specifically, such a bound is achieved when $k = \Omega(\ln n)$ and $\ell = \Omega(k\ln k\ln n)$. The difference between the number of samples necessary for Fourier-based sketches and Gaussian-based sketches is reflective of the differing natures of the random projections: the geometry of any k-dimensional subspace is preserved under projection onto the span of $\ell = \mathrm{O}(k)$ Gaussian random vectors (Halko et al., 2011), but the sharpest analysis available suggests that to preserve the geometry of such a subspace under projection onto the span of ℓ SRFT vectors, ℓ must satisfy $\ell = \Omega(\max\{k, \ln n\}\ln k)$ (Tropp, 2011). We note, however, that in practice the Fourier-based and Gaussian-based SPSD sketches have similar reconstruction errors.

Remark. The structure of the Frobenius and trace norm bounds for the Fourier-based projection are identical to the structure of the corresponding bounds from Lemma 5 for leverage-based sampling (and the bounds could be made identical with appropriate choice of parameters). This is not surprising since (informally) Fourier-based (and other) random projections rotate to a random basis where the leverage scores are approximately uniform and thus where uniform sampling is appropriate (Mahoney, 2011). The disparity of the spectral norm bounds suggests that leverage-based SPSD sketches should be expected to be more accurate in the spectral norm than Fourier-based sketches; the empirical results of Section 3.4 support this interpretation. The running times of the Fourier-based and the leverage-based algorithms are the same, to leading order, if the algorithm of Drineas et al. (2012) (which uses the same transform $\mathbf{S} = \sqrt{\frac{n}{\ell}}\mathbf{DTR}$) is used to approximate the leverage scores.

4.2.3 Random Projections with i.i.d. Gaussian Random Matrices

Here, the columns of $\mathbf{A}$ are randomly mixed using Gaussian random variables before sampling. Thus, the entries of the sampling matrix $\mathbf{S} \in \mathbb{R}^{n\times\ell}$ are i.i.d. standard Gaussian random variables.

Lemma 7 *Let $\mathbf{A}$ be an $n \times n$ SPSD matrix, q be a positive integer, $\mathbf{S} \in \mathbb{R}^{n\times\ell}$ be a matrix of i.i.d standard Gaussians, and define*

$$\gamma = \frac{\lambda_{k+1}(\mathbf{A})}{\lambda_k(\mathbf{A})}.$$

If $\ell \geq 2\epsilon^{-2}k\ln k$ where $\epsilon \in (0,1)$ and $k > 4$, then, when $\mathbf{C} = \mathbf{A}^q\mathbf{S}$ and $\mathbf{W} = \mathbf{S}^T\mathbf{A}^{2q-1}\mathbf{S}$, the corresponding low-rank SPSD approximation satisfies

$$\begin{aligned}
\left\|\mathbf{A}-\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\right\|_2 &\leq \left(1+\left(89\frac{\epsilon^2}{\ln k}+874\frac{\epsilon^2}{k}\right)^{1/(2q-1)}\right)\|\mathbf{A}-\mathbf{A}_k\|_2 \\
&\quad+\left(219\frac{\epsilon^2}{k\ln k}\right)^{1/(2q-1)}\cdot\|\mathbf{A}-\mathbf{A}_k\|_\star, \\
\left\|\mathbf{A}-\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\right\|_{\mathrm{F}} &\leq \|\mathbf{A}-\mathbf{A}_k\|_{\mathrm{F}}+\left[\gamma^{q-1}\epsilon\left(\frac{42}{\sqrt{k}}+\frac{14}{\sqrt{\ln k}}\right)\right. \\
&\quad\left.+\gamma^{2q-2}\epsilon^2\left(\frac{45}{\ln k}+\frac{140}{\sqrt{k\ln k}}+\frac{219}{k\sqrt{\ln k}}\right)\right]\sqrt{\|\mathbf{A}-\mathbf{A}_k\|_2\,\|\mathbf{A}-\mathbf{A}_k\|_\star} \\
&\quad+\left(21\gamma^{q-1}\frac{\epsilon}{\sqrt{k\ln k}}+70\gamma^{2q-2}\frac{\epsilon^2}{\sqrt{k}\ln k}\right)\|\mathbf{A}-\mathbf{A}_k\|_\star \\
&\quad+\gamma^{2q-2}\epsilon^2\left(\frac{140}{\sqrt{k\ln k}}+\frac{437}{k}\right)\|\mathbf{A}-\mathbf{A}_k\|_2, \text{ and} \\
\left\|\mathbf{A}-\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\right\|_\star &\leq \left(1+45\frac{\gamma^{2q-2}\epsilon^2}{\ln k}\right)\|\mathbf{A}-\mathbf{A}_k\|_\star+437\frac{\gamma^{2q-2}\epsilon^2}{k}\|\mathbf{A}-\mathbf{A}_k\|_2
\end{aligned}$$

simultaneously with probability at least $1-2k^{-1}-4k^{-k/\epsilon^2}$.

Remark. The way we have parameterized these bounds for Gaussian-based projections makes explicit the dependence on various parameters, but hides the structural simplicity of these bounds. In particular, note that the Frobenius norm approximation error is upper bounded by a term that depends on the Frobenius norm error of the optimal low-rank approximant and a term that depends on the trace norm error of the optimal low-rank approximant; and that, similarly, the trace norm approximation error is upper bounded by a multiplicative factor that can be set to $1+\epsilon$ with an appropriate choice of parameters.

Proof As before, this result is established by bounding the quantities involved in Theorems 2, 3, and 4. The following deviation bounds, established in (Halko et al., 2011, Section 10), are useful in that regard: if $\mathbf{D}$ is a diagonal matrix, $\ell = k+p$ with $p > 4$ and $u, t \geq 1$,

then with our choice of $\mathbf{S}$,

$$\begin{aligned}
\mathbb{P}\left\{\left\|\mathbf{D}\boldsymbol{\Omega}_2\boldsymbol{\Omega}_1^\dagger\right\|_2 > \|\mathbf{D}\|_2\left(\sqrt{\frac{3k}{p+1}}\cdot t+\frac{\mathrm{e}\sqrt{\ell}}{p+1}\cdot tu\right)+\|\mathbf{D}\|_{\mathrm{F}}\frac{\mathrm{e}\sqrt{\ell}}{p+1}\cdot t\right\} &\leq 2t^{-p}+\mathrm{e}^{-u^2/2}, \text{ and} \\
\mathbb{P}\left\{\left\|\mathbf{D}\boldsymbol{\Omega}_2\boldsymbol{\Omega}_1^\dagger\right\|_{\mathrm{F}} > \|\mathbf{D}\|_{\mathrm{F}}\sqrt{\frac{3k}{p+1}}\cdot t+\|\mathbf{D}\|_2\frac{\mathrm{e}\sqrt{\ell}}{p+1}\cdot tu\right\} &\leq 2t^{-p}+\mathrm{e}^{-u^2/2}.
\end{aligned} \tag{20}$$

Write $\ell = k+p$. Since $\ell \geq 2\epsilon^{-2}k\ln k$, we have that $p \geq \epsilon^{-2}k\ln k$. Accordingly, the following estimates hold:

$$\begin{aligned}
\sqrt{\frac{3k}{p+1}} &\leq \sqrt{\frac{3k}{p}} \leq \sqrt{\frac{3}{\ln k}}\epsilon \\
\frac{\sqrt{\ell}}{p+1} &\leq \frac{\sqrt{k+p}}{p} \leq \sqrt{\frac{\epsilon^4}{k\ln^2 k}+\frac{\epsilon^2}{k\ln k}} < \sqrt{\frac{2}{k\ln k}}\epsilon.
\end{aligned}$$

Use these estimates and take $t = \mathrm{e}$ and $u = \sqrt{2\ln k}$ in (20) to obtain that

$$\begin{aligned}
\left\|\boldsymbol{\Sigma}_2^{q-1/2}\boldsymbol{\Omega}_2\boldsymbol{\Omega}_1^\dagger\right\|_2^2 &\leq \left[\epsilon\left(\mathrm{e}\sqrt{\frac{3}{\ln k}}+2\mathrm{e}^2\sqrt{\frac{1}{k}}\right)\cdot\left\|\boldsymbol{\Sigma}_2^{q-1/2}\right\|_2+\epsilon\mathrm{e}^2\sqrt{\frac{2}{k\ln k}}\cdot\left\|\boldsymbol{\Sigma}_2^{q-1/2}\right\|_{\mathrm{F}}\right]^2 \\
&\leq 2\epsilon^2\left(\mathrm{e}\sqrt{\frac{3}{\ln k}}+2\mathrm{e}^2\sqrt{\frac{1}{k}}\right)^2\cdot\|\boldsymbol{\Sigma}_2\|_2^{2q-1}+\frac{4\epsilon^2\mathrm{e}^4}{k\ln k}\cdot\left\|\boldsymbol{\Sigma}_2^{q-1/2}\right\|_{\mathrm{F}}^2 \\
&\leq \left(\frac{12\mathrm{e}^2}{\ln k}+\frac{16\mathrm{e}^4}{k}\right)\epsilon^2\cdot\|\boldsymbol{\Sigma}_2\|_2^{2q-1}+\frac{4\epsilon^2\mathrm{e}^4}{k\ln k}\cdot\left\|\boldsymbol{\Sigma}_2^{2q-1}\right\|_\star
\end{aligned}$$

with probability at least $1-k^{-1}-2k^{-k/\epsilon^2}$ and

$$\begin{aligned}
\left\|\boldsymbol{\Sigma}_2^{1/2}\boldsymbol{\Omega}_2\boldsymbol{\Omega}_1^\dagger\right\|_{\mathrm{F}} &\leq \sqrt{\frac{3}{\ln k}}\epsilon\mathrm{e}\cdot\left\|\boldsymbol{\Sigma}_2^{1/2}\right\|_{\mathrm{F}}+\frac{2\mathrm{e}^2}{\sqrt{k}}\epsilon\cdot\left\|\boldsymbol{\Sigma}_2^{1/2}\right\|_2 \\
&= \epsilon\mathrm{e}\sqrt{\frac{3}{\ln k}\|\boldsymbol{\Sigma}_2\|_\star}+\frac{2\mathrm{e}^2}{\sqrt{k}}\epsilon\cdot\|\boldsymbol{\Sigma}_2\|_2^{1/2}
\end{aligned}$$

with the same probability. Likewise,

$$\begin{aligned}
\left\|\boldsymbol{\Sigma}_2^{1/2}\boldsymbol{\Omega}_2\boldsymbol{\Omega}_1^\dagger\right\|_{\mathrm{F}}^2 &\leq \left(\epsilon\mathrm{e}\sqrt{\frac{3}{\ln k}\|\boldsymbol{\Sigma}_2\|_\star}+\frac{2\mathrm{e}^2}{\sqrt{k}}\epsilon\cdot\|\boldsymbol{\Sigma}_2\|_2^{1/2}\right)^2 \\
&\leq \frac{6}{\ln k}\epsilon^2\mathrm{e}^2\cdot\|\boldsymbol{\Sigma}_2\|_\star+\frac{8\mathrm{e}^4}{k}\epsilon^2\cdot\|\boldsymbol{\Sigma}_2\|_2
\end{aligned}$$

with the same probability.

These estimates used in Theorems 2 and 4 yield the stated spectral and trace norm bounds. To obtain the corresponding Frobenius norm bound, define the quantities

$$\begin{aligned}
G_1 &= \left(\frac{12\mathrm{e}^2}{\ln k}+\frac{16\mathrm{e}^4}{k}\right)\epsilon^2 & G_3 &= 3\mathrm{e}^2\frac{\epsilon^2}{\ln k} \\
G_2 &= 4\mathrm{e}^4\frac{\epsilon^2}{k\ln k} & G_4 &= 4\mathrm{e}^4\frac{\epsilon^2}{k}
\end{aligned}$$

By Theorem 3 and our estimates for $\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_2$ and $\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_\mathrm{F}$,

$$\begin{aligned}\left\|\mathbf{A}-\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\right\|_\mathrm{F} &\leq \|\mathbf{\Sigma}_2\|_\mathrm{F}+\gamma^{q-1}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_2\cdot\left(\sqrt{2\operatorname{Tr}(\mathbf{\Sigma}_2)}+\gamma^{q-1}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_\mathrm{F}\right)\\ &\leq \|\mathbf{\Sigma}_2\|_\mathrm{F}+\gamma^{q-1}(G_1\|\mathbf{\Sigma}_2\|_2+G_2\|\mathbf{\Sigma}_2\|_\star)^{1/2}\times\\ &\quad\left(\sqrt{2\operatorname{Tr}(\mathbf{\Sigma}_2)}+\gamma^{q-1}\sqrt{G_3\|\mathbf{\Sigma}_2\|_\star}+\gamma^{q-1}\sqrt{G_4\|\mathbf{\Sigma}_2\|_2}\right)\\ &\leq \|\mathbf{\Sigma}_2\|_\mathrm{F}+\left(\gamma^{q-1}\sqrt{2G_1}+\gamma^{2q-2}(\sqrt{G_1G_3}+\sqrt{G_2G_4})\right)\cdot\sqrt{\|\mathbf{\Sigma}_2\|_2\|\mathbf{\Sigma}_2\|_\star}\\ &\quad+\left(\gamma^{q-1}\sqrt{2G_2}+\gamma^{2q-2}\sqrt{G_2G_3}\right)\cdot\|\mathbf{\Sigma}_2\|_\star\\ &\quad+\gamma^{2q-2}\sqrt{G_1G_4}\,\|\mathbf{\Sigma}_2\|_2.\end{aligned}\tag{21}$$

The following estimates hold for the coefficients in this inequality:

$$\begin{aligned}\sqrt{2G_1}&\leq\left(\frac{42}{\sqrt{k}}+\frac{14}{\sqrt{\ln k}}\right)\epsilon & \sqrt{G_1G_3}&\leq\left(\frac{45}{\ln k}+\frac{140}{\sqrt{k\ln k}}\right)\epsilon^2\\ \sqrt{G_2G_4}&\leq\frac{219}{k\sqrt{\ln k}}\epsilon^2 & \sqrt{2G_2}&\leq 21\frac{\epsilon}{\sqrt{k\ln k}}\\ \sqrt{G_2G_3}&\leq 70\frac{\epsilon^2}{\sqrt{k}\ln k} & \sqrt{G_1G_4}&\leq\left(\frac{140}{\sqrt{k\ln k}}+\frac{437}{k}\right)\epsilon^2.\end{aligned}$$

The Frobenius norm bound follows from using these estimates in Equation (21) and grouping terms appropriately:

$$\begin{aligned}\left\|\mathbf{A}-\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\right\|_\mathrm{F} &\leq \|\mathbf{\Sigma}_2\|_\mathrm{F}+\left[\gamma^{q-1}\epsilon\left(\frac{42}{\sqrt{k}}+\frac{14}{\sqrt{\ln k}}\right)\right.\\ &\qquad\left.+\gamma^{2q-2}\epsilon^2\left(\frac{45}{\ln k}+\frac{140}{\sqrt{k\ln k}}+\frac{219}{k\sqrt{\ln k}}\right)\right]\sqrt{\|\mathbf{\Sigma}_2\|_2\|\mathbf{\Sigma}_2\|_\star}\\ &\quad+\left(21\gamma^{q-1}\frac{\epsilon}{\sqrt{k\ln k}}+70\gamma^{2q-2}\frac{\epsilon^2}{\sqrt{k}\ln k}\right)\cdot\|\mathbf{\Sigma}_2\|_\star\\ &\quad+\gamma^{2q-2}\epsilon^2\left(\frac{140}{\sqrt{k\ln k}}+\frac{437}{k}\right)\|\mathbf{\Sigma}_2\|_2.\end{aligned}$$

■

4.2.4 Sampling Columns Uniformly at Random

Here, the columns of $\mathbf{A}$ are sampled uniformly at random (with or without replacement). Such uniformly-at-random column sampling only makes sense when the leverage scores of the top k-dimensional invariant subspace of the matrix are sufficiently uniform that no column is significantly more informative than the others. For this case, we can prove the following.

Lemma 8 *Let $\mathbf{A}$ be an $n\times n$ SPSD matrix, q be a positive integer, and $\mathbf{S}$ be a sampling matrix of size $n\times\ell$ corresponding to sampling the columns of $\mathbf{A}$ uniformly at random (with*

or without replacement). Let μ denote the coherence of the top k-dimensional eigenspace of $\mathbf{A}$ and fix a failure probability $\delta\in(0,1)$ and accuracy factor $\epsilon\in(0,1)$. Define

$$\gamma=\frac{\lambda_{k+1}(\mathbf{A})}{\lambda_k(\mathbf{A})}.$$

If $\ell\geq 2\mu\epsilon^{-2}k\ln(k/\delta)$, then, when $\mathbf{C}=\mathbf{A}^q\mathbf{S}$ and $\mathbf{W}=\mathbf{S}^T\mathbf{A}^{2q-1}\mathbf{S}$, the corresponding low-rank SPSD approximation satisfies

$$\begin{aligned}&\left\|\mathbf{A}-\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\right\|_2\leq\left(1+\left(\frac{n}{(1-\epsilon)\ell}\right)^{1/(2q-1)}\right)\|\mathbf{A}-\mathbf{A}_k\|_2,\\ &\left\|\mathbf{A}-\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\right\|_\mathrm{F}\leq\|\mathbf{A}-\mathbf{A}_k\|_\mathrm{F}+\left(\gamma^{q-1}\frac{\sqrt{2}}{\delta\sqrt{1-\epsilon}}+\frac{\gamma^{2q-2}}{(1-\epsilon)\delta^2}\right)\|\mathbf{A}-\mathbf{A}_k\|_\star,\ \textit{and}\\ &\left\|\mathbf{A}-\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\right\|_\star\leq\left(1+\frac{\gamma^{2q-2}}{\delta^2(1-\epsilon)}\right)\|\mathbf{A}-\mathbf{A}_k\|_\star,\end{aligned}$$

simultaneously with probability at least $1-3\delta$.

Proof In (Gittens, 2012), it is shown that

$$\left\|\mathbf{\Omega}_1^\dagger\right\|_2^2\leq\frac{n}{(1-\epsilon)\ell}$$

with probability at least $1-\delta$ when ℓ satisfies the stated bound. Observe that $\|\mathbf{\Omega}_2\|_2\leq\|\mathbf{U}_2\|_2\|\mathbf{S}\|_2\leq 1$, so that

$$\left\|\mathbf{\Sigma}_2^{q-1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_2^2\leq\left\|\mathbf{\Sigma}_2^{q-1/2}\right\|_2^2\left\|\mathbf{\Omega}_1^\dagger\right\|_2^2\leq\|\mathbf{\Sigma}_2\|_2^{2q-1}\frac{n}{(1-\epsilon)\ell}$$

with probability at least $1-\delta$. Also,

$$\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_\mathrm{F}\leq\sqrt{\frac{n}{(1-\epsilon)\ell}}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\right\|_\mathrm{F}\tag{22}$$

with at least the same probability. Observe that since $\mathbf{S}$ selects ℓ columns uniformly at random,

$$\mathbb{E}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\right\|_\mathrm{F}^2=\mathbb{E}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{U}_2^T\mathbf{S}\right\|_\mathrm{F}^2=\sum_{i=1}^{\ell}\mathbb{E}\|\mathbf{x}_i\|^2,$$

where the summands $\mathbf{x}_i$ are distributed uniformly at random over the columns of $\mathbf{\Sigma}_2^{1/2}\mathbf{U}_2^T$. Regardless of whether $\mathbf{S}$ selects the columns with replacement or without replacement, the summands all have the same expectation:

$$\mathbb{E}\|\mathbf{x}_i\|^2=\frac{1}{n}\sum_{j=1}^{n}\|(\mathbf{\Sigma}_2^{1/2}\mathbf{U}_2^T)^j)\|^2=\frac{1}{n}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{U}_2^T\right\|_\mathrm{F}^2=\frac{1}{n}\left\|\mathbf{\Sigma}_2^{1/2}\right\|_\mathrm{F}^2=\frac{1}{n}\|\mathbf{\Sigma}_2\|_\star.$$

Consequently,

$$\mathbb{E}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\right\|_\mathrm{F}^2=\frac{\ell}{n}\|\mathbf{\Sigma}_2\|_\star,$$

so by Jensen's inequality

$$\mathbb{E}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\right\|_{\mathrm{F}} \leq \left(\mathbb{E}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\right\|_{\mathrm{F}}^2\right)^{1/2} = \sqrt{\frac{\ell}{n}\left\|\mathbf{\Sigma}_2\right\|_\star}.$$

Now applying Markov's inequality to (22), we see that

$$\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_{\mathrm{F}} \leq \frac{1}{\delta}\sqrt{\frac{1}{(1-\epsilon)}\left\|\mathbf{\Sigma}_2\right\|_\star}$$

with probability at least $1-2\delta$. Thus, we also know that

$$\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_{\mathrm{F}}^2 \leq \frac{1}{(1-\epsilon)\delta^2}\left\|\mathbf{\Sigma}_2\right\|_\star,$$

also with probability at least $1-2\delta$. These estimates used in Theorems 2 and 4 yield the stated spectral and trace norm bounds.

To obtain the Frobenius norm bound, observe that Theorem 3 implies

$$\begin{aligned}\left\|\mathbf{A}-\mathbf{C}\mathbf{W}^\dagger\mathbf{C}^T\right\|_{\mathrm{F}} &\leq \left\|\mathbf{\Sigma}_2\right\|_{\mathrm{F}} + \gamma^{p-1}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_2\left(\sqrt{2\operatorname{Tr}(\mathbf{\Sigma}_2)}+\gamma^{p-1}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_{\mathrm{F}}\right)\\ &\leq \left\|\mathbf{\Sigma}_2\right\|_{\mathrm{F}} + +\gamma^{p-1}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_{\mathrm{F}}\left(\sqrt{2\operatorname{Tr}(\mathbf{\Sigma}_2)}+\gamma^{p-1}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_{\mathrm{F}}\right)\\ &\leq \left\|\mathbf{\Sigma}_2\right\|_{\mathrm{F}} + \gamma^{2p-2}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_{\mathrm{F}}^2 + \gamma^{p-1}\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_{\mathrm{F}}\sqrt{2\operatorname{Tr}(\mathbf{\Sigma}_2)}.\end{aligned}$$

Now substitute our estimate for $\left\|\mathbf{\Sigma}_2^{1/2}\mathbf{\Omega}_2\mathbf{\Omega}_1^\dagger\right\|_{\mathrm{F}}^2$ to obtain the stated Frobenius norm bound. ■

Remark. As with previous bounds for uniform sampling, (*e.g.*, Kumar et al., 2012; Gittens, 2012), these results for uniform sampling are much weaker than our bounds from the previous subsections, since the sampling complexity depends on the coherence of the input matrix. When the matrix has small coherence, however, these bounds are similar to the bounds derived from the leverage-based sampling probabilities. Recall that, by the algorithm of Drineas et al. (2012), the coherence of an arbitrary input matrix can be computed in roughly the time it takes to perform a random projection on the input matrix.

5. Discussion and Conclusion

We have presented a unified approach to a large class of low-rank approximations of Laplacian and kernel matrices that arise in machine learning and data analysis applications. In doing so, we have provided qualitatively-improved worst-case theory and clarified the performance of these algorithms in practical settings. Our theoretical and empirical results suggest several obvious directions for future work.

In general, our empirical evaluation demonstrates that obtaining moderately high-quality low-rank approximations, as measured by minimizing the reconstruction error, depends in complicated ways on the spectral decay, the leverage score structure, the eigenvalue gaps in

relevant parts of the spectrum, etc. (Ironically, our empirical evaluation also demonstrates that *all* the sketches considered are reasonably-effective at approximating both sparse and dense, and both low-rank and high-rank matrices which arise in practice. That is, with only roughly $\mathrm{O}(k)$ measurements, the spectral, Frobenius, and trace approximation errors stay within a small multiplicative factor of around 3 of the optimal rank-k approximation errors. The reason for this is that matrices for which uniform sampling is least appropriate tend to be those which are least well-approximated by low-rank matrices, meaning that the residual error is much larger.) Thus, *e.g.*, depending on whether one is interested in ℓ being slightly larger or much larger than k, leverage-based sampling or a random projection might be most appropriate; and, more generally, an ensemble-based method that draws complementary strengths from each of these methods might be best.

In addition, we should note that, in situations where one is concerned with the quality of approximation of the actual eigenspaces, one desires both a small spectral norm error (because by the Davis–Kahan $\sin\Theta$ theorem and similar perturbation results, this would imply that the range space of the sketch effectively captures the top k-dimensional eigenspace of $\mathbf{A}$) as well as to use as few samples as possible (because one prefers to approximate the top k-dimension eigenspace of $\mathbf{A}$ with as close to a k-dimensional subspace as possible). Our results suggest that the leverage score probabilities supply the best sampling scheme for balancing these two competing objectives.

More generally, although our empirical evaluation consists of *random* sampling and *random* projection algorithms, our theoretical analysis clearly decouples the randomness in the algorithm from the structural heterogenities in the Euclidean vector space that are responsible for the poor performance of uniform sampling algorithms. Thus, if those structural conditions can be satisfied with a deterministic algorithm, an iterative algorithm, or any other method, then one can certify (after running the algorithm) that good approximation guarantees hold for particular input matrices in less time than is required for general matrices. Moreover, this structural decomposition suggests greedy heuristics—*e.g.*, greedily keep some number of columns according to approximate statistical leverage scores and "residualize." In our experience, a procedure of this form often performs quite well in practice, although theoretical guarantees tend to be much weaker; and thus we expect that, when coupled with our results, such procedures will perform quite well in practice in many medium-scale and large-scale machine learning applications.

Abstract

Algorithms for inferring the structure of Bayesian networks from data have become an increasingly popular method for uncovering the direct and indirect influences among variables in complex systems. A Bayesian approach to structure learning uses posterior probabilities to quantify the strength with which the data and prior knowledge jointly support each possible graph feature. Existing Markov Chain Monte Carlo (MCMC) algorithms for estimating these posterior probabilities are slow in mixing and convergence, especially for large networks. We present a novel Markov blanket resampling (MBR) scheme that intermittently reconstructs the Markov blanket of nodes, thus allowing the sampler to more effectively traverse low-probability regions between local maxima. As we can derive the complementary forward and backward directions of the MBR proposal distribution, the Metropolis-Hastings algorithm can be used to account for any asymmetries in these proposals. Experiments across a range of network sizes show that the MBR scheme outperforms other state-of-the-art algorithms, both in terms of learning performance and convergence rate. In particular, MBR achieves better learning performance than the other algorithms when the number of observations is relatively small and faster convergence when the number of variables in the network is large.

Keywords: probabilistic graphical models, directed acyclic graph, Bayesian inference, Markov chain Monte Carlo

1. Introduction

A Bayesian network (BN) is a compact graphical representation of a multivariate joint probability distribution of variables. A BN is represented in the form of a directed acyclic graph (DAG), with nodes representing variables and directed edges representing probabilistic dependencies. An important feature of a BN is that each variable represented by a node is understood to be conditionally independent of the set of all its predecessors in the DAG, given the states of its parents (Neapolitan, 2004). In other words, the absence of a directly connecting edge between any two nodes implies that the two corresponding variables are independent given the states of the variables represented by intermediate nodes along a directed path. Thus, direct dependence between variables can be graphically distinguished from simple correlation mediated by other variables.

Algorithms have been developed to attempt to uncover the BN structures consistent with data from complex systems, with the goal of better understanding the direct and indirect mechanisms of action (Daly et al., 2011). This is particularly the case in systems biology, where diverse data on genes, gene expression, environmental exposure, and disease might be used to reveal the mechanistic links between genotype and phenotype (Su et al., 2013). Early attempts to learn BN structures from data focused on identifying the single best-fitting model. However, when the amount of data is relatively small compared to the number of variables, there are likely to be many different structures that fit the available data nearly equally well. The single best-fitting model is often an arbitrary result of the particular states of the variables that happen to have been observed. Further, presentation of this single best model provides no indication of the relative confidence one can have in its particular structural features (i.e., presence or absence of edges).

A Bayesian approach to structure learning allows for a quantification of the strength with which the data and any available prior knowledge jointly support each possible graph structure, in the form of posterior probabilities. Unfortunately, the number of possible DAGs grows super-exponentially with the number of variables being represented, making a full comparison of Bayesian posterior probabilities associated with alternative structures intractable. The Markov Chain Monte Carlo (MCMC) method as applied to graphical structures provides a numerical solution to this problem. In the original version of this algorithm, proposed by Madigan and York (1995), each transition in the Markov Chain consists of essentially a single edge change to the current graph. While this performs relatively well in small domains with 5-15 variables, it is rather slow in mixing and convergence with a larger number of variables. As the size of the structural search space grows, the chain is prone to getting trapped in local high probability regions separated by regions of lower probability regions. As a result, the samples obtained may not be representative of the true posterior distribution.

Friedman and Koller (2003) proposed a variation on the MCMC algorithm that explores the space of topological node orders rather than exact structures. The space of node orders is much smaller than the space of structures and is also likely to be smoother, allowing for better mixing. Thus, order MCMC is generally observed to converge more reliably to the same posterior probability estimates. More recently, Niinimki et al. (2012)introduced an algorithm based on partial, rather than linear, orders to create a still smaller and smoother posterior sampling space. Given a sample of (linear or partial) node orders, it is then straightforward to obtain a sample of graphs consistent with each order. However, as graphs can be consistent with more than one order, the effective prior probability over graphs involves marginalization over orders. This order-modular prior means that it is difficult to explicitly specify priors over graphs (Grzegorczyk and Husmeier, 2008) and that commonly-used order priors, such as the uniform, introduce bias by generating misrepresentative graph priors. Several variants of the order MCMC algorithm have been developed to address this prior bias (Koivisto and Sood, 2004; Eaton and Murphy, 2007; Ellis and Wong, 2008; Niinimki and Koivisto, 2013). Unfortunately, these approaches all incur substantial computational costs, making them impractical for learning the structure of networks with more than about 20 nodes. Recently Masegosa and Moral (2013) proposed a skeleton-based

approach, in which samples are restricted in the DAG space constrained by a given BN skeleton. This method scales to larger networks but performs poorly for small sample sizes.

In the present paper, we seek to improve the poor convergence of the structure MCMC algorithm without substantially increasing the computational costs. One way to do this is to introduce transitions that take larger steps in the structural search space, thus allowing the sampler to more effectively traverse low-probability regions when moving between local maxima and ridges (Koller and Friedman, 2009). With this intent, Grzegorczyk and Husmeier (2008) propose a new edge reversal move which selects an edge from the current MCMC iteration, reverses the direction of this edge, and then resamples new parents for the two nodes at either end of this edge. The idea is to implement a substantial modification to the current DAG that is customized to the new direction of the edge being reversed. The experimental results of Grzegorczyk and Husmeier (2008) indicate that this approach is an improvement over traditional structure MCMC with regard to convergence and mixing and is as computationally efficient as order MCMC.

We see an opportunity to take the approach of Grzegorczyk and Husmeier (2008) a step further by intermittently resampling the Markov blanket of randomly selected nodes. The Markov blanket of a node contains its parents, children, and the other parents of its children. These nodes comprise a module of local relations that shield a node from the rest of the network. These local relations are sometimes too sturdy to modify through small changes, causing the Markov Chain to linger in a region of the structural space for an unnecessarily long time. Our premise is that, by reconstructing the Markov blanket of a node, our search could more readily escape from local maxima, thus substantially improving the mixing of the Markov chain. For ease of comparison, we employ the same notation as Grzegorczyk and Husmeier (2008) and report similar diagnostic results.

2. BN Structure Learning Using MCMC

There are many ways to learn a BN from data. Since the size of search space of BNs is super exponential in the number of variables, it is impractical to do an exhaustive search. Many approaches therefore employ a score-based heuristic search algorithm, which starts with a random or seeded DAG and then proceeds by adding, reversing or deleting one edge at a time to obtain new DAGs. For each DAG, a score is calculated that indicates how well the DAG fits the data. The Bayesian approach to inference specifies that the consistency of a graph with data D is calculated as:

$$P(G \mid D) = \frac{P(D \mid G) \cdot P(G)}{\sum_{G^* \in \Omega} P(D \mid G^*) \cdot P(G^*)}, \tag{1}$$

where $P(G|D)$ is the posterior probability of a particular graph, $P(D|G)$ is the likelihood of the data given that graph and P(G) is the prior probability over the space of all possible graphs ($G \in \Omega$). Given the independence assumptions employed by a BN, and a noninformative graph prior (Grzegorczyk and Husmeier, 2008), the Bayesian score of a DAG, $P(G|D)$, can be factored into a product of local scores for each node X_n given its parents π_n as:

$$P(G \mid D) = \frac{1}{Z_N} \prod_{n=1}^{N} exp(\Psi[(X_n, \pi_n \mid D]), \tag{2}$$

where Z_N is a normalization term, N is the number of nodes, and $\Psi[X_n, \pi_n D]$ are the local scores defined by the probability model chosen for the likelihood $P(D|G)$. The multinomial distribution with a Dirichlet prior is often adopted, as it leads to a closed form expression for the local scores (Cooper and Herskovits, 1992).

The structure MCMC algorithm of Madigan and York (1995) seeks to generate a set of samples of possible structures with relative frequencies that correspond to the Bayesian posterior distribution. These samples can then be used, for example, to estimate the posterior probabilities of particular features of interest (marginalizing over the various structures). Implementations of the structure MCMC algorithm typically employ a Metropolis-Hastings sampler (Giudici and Castelo, 2003). At each step of the Markov chain, a candidate graph $G^{'}$ is proposed that will replace the current graph G with a probability equal to $\mu = min\{1, R(G^{'} \mid G)\}$ where

$$R(G^{'} \mid G) = \frac{P(G^{'} \mid D)}{P(G \mid D)} \cdot \frac{Q(G \mid G^{'})}{Q(G^{'} \mid G)}. \tag{3}$$

$Q(G^{'} \mid G)$ is the proposal probability for a move from G to $G^{'}$ and $Q(G|G')$ is the probability of a reverse move from $G^{'}$ to G. The ratio of these probabilities is referred to as the Hastings factor and serves to correct for any asymmetries that might be present in the proposal moves.

In the conventional structure MCMC algorithm, each step represents a move to a neighboring DAG, which is different in one edge from the current DAG. When Q is a uniform probability over the current structure's neighbors, the Hastings factor is equal to the ratio of number of neighbors for the reverse and forward moves, and the Markov chain is guaranteed to have a stationary distribution equal to the posterior distribution $P(G \mid D)$. Unfortunately, the space of DAGs is super exponential in the number of variables and the posterior landscape is characterized by ridges (representing equally well fitting graphs) separated by valleys. This makes it difficult for the chain to explore the space, making it slow to mix.

Grzegorczyk and Husmeier's (2008) 'new edge reversal'(REV) move replaces the simple single edge addition, removal, or reversal of Madigan and York's algorithm with a more substantial structural change. First, an edge in the current graph G is selected at random for reversal. The nodes at either end of this edge are then orphaned by removing all incoming edges. Next, a new parent set is sampled for each of these edges which contains the reversal of the originally selected edge and does not introduce any directed cycles to the graph. This then becomes the proposed graph $G^{'}$. Grzegorczyk and Husmeier specify the acceptance probability of the REV move, including the appropriate Hastings factor, thus guaranteeing convergence to the correct posterior distribution under ergodicity. As ergodicity is not assured, they intersperse their REV move with traditional structure MCMC moves in their final algorithm

3. Markov Blanket Resampling

Given the success of REV at improving mixing and convergence without added significant computational burden, we believe that there may be value to introducing more extreme steps into the structure MCMC algorithm. In particular, the traditional sampler may rarely leave regions of the structure space that have a similar posterior probability score. Graphs belonging to the same equivalence class, for example, comprise equiprobable ridges.

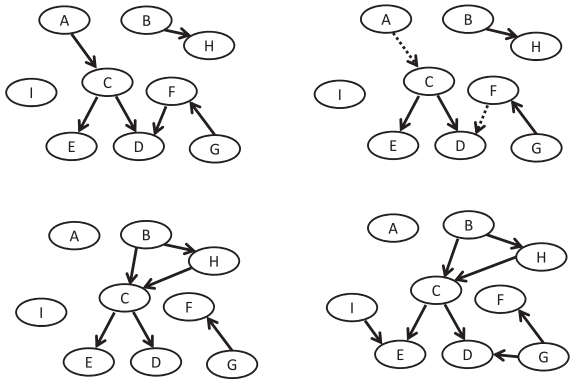

Figure 1: Illustration of the Markov Blanket Resampling (MBR) move. In this example, node C is selected as the target node (top left). Its Markov blanket includes nodes A, D, E, and F. First, all edges pointing to itself and to its children from other nodes are removed (top right). New nodes are next randomly selected as its new parents, in this case nodes B and H (bottom left). Finally, new additional parents are selected for its children, in this case G for D and I for E (bottom right).

Single edge reversals only lead to a new equivalence class when they involve a V-structure. REV improves on this by orphaning two nodes as an intermediate step, but in most cases the chain can easily revert to the same equivalence class within an iteration or two. Thus, even with REV, low probability valleys between ridges may not be readily traversed. As the Markov blanket of a node represents all the variables that can directly influence the state of that node, its entire reconstruction represents the most substantial change that can be made with respect to any single node. Thus, we believe that intermittent resampling of the Markov blanket could further improve the mixing and convergence of a Markov chain.

3.1 Overview

The idea of our Markov Blanket Resampling (MBR) move is shown in Figure 1. We start with the current DAG (upper left). First, a node is selected at random (node C, in this example). All edges pointing into this node are deleted, as well as edges pointing into its children from nodes other than itself (upper right, dotted edges), thus disconnecting much of the node's Markov blanket. New parents for this target node are then sampled disallowing any of its previous parents (bottom left), as are new additional parents, without any restrictions, for all the target node's children (bottom right), both under the condition of not creating any cycles.

3.2 Mathematical Details

Step 1: A node X_i is selected from a DAG, G, according to a uniform distribution over all nodes N in G. Orphaning this node and removing edges pointing into its children from nodes other than X_i creates a new DAG, G_0. (If X_i has no children, then only Step 2 is implemented and the products involving X_j in eq. (9) are set equal to 1.)
Step 2: A new parent set $\pi_i^{'}$ is selected for X_i, disallowing its previous parents π_i, to obtain new DAG, $G_0^{X_i \leftarrow \pi_i^{'}}$. Mathematically, therefore, $\pi_i^{'}$ conforms to the following distribution:

$$\Gamma(\pi_i^{'} \mid G_0, \pi_i) = \frac{exp(\Psi[X_i, \pi_i^{'} \mid D]) \cdot H(G_0^{X_i \leftarrow \pi_i^{'}}) \cdot I(\pi_i^{'}, \pi_i)}{Z^*(X_i \mid G_0, \pi_i)}, \tag{4}$$

where $H(G) = 0$ if the graph G contains a directed cycle and 1 otherwise, $I(\pi_i^{'}, \pi) = 0$ if $\pi \cap \pi_i^{'} \neq \phi$ and 1 otherwise, and $Z^*(X_i|G_0)$ represents the sum of local scores over all allowable parent sets π of X_i

$$Z^*(X_i \mid G_0, \pi_i) := \sum_{\substack{\pi: H(G_0^{X_i \leftarrow \pi}) = 1 \\ \pi_i \cap \pi_i^{'} \neq \phi}} exp(\Psi[X_i, \pi \mid D]). \tag{5}$$

This yields graph G_1.
Step 3: New parent sets $\pi^{'j}_i$ are sampled for each of X_i's children $X_i^j \in \gamma_i = \{X_i^1, ..., X_i^J\}$ that include node X_i and conform to the following distribution:

$$\Gamma(\pi_i^{'} \mid G_j) = \frac{exp(\Psi[X_i^j, \pi^{'j}_i \mid D]) \cdot H(G_j^{X_i^j \leftarrow \pi^{'j}_i}) \cdot J(\pi^{'j}_i, X_i)}{Z(X_i^j \mid G_j, X_i)}, \tag{6}$$

where G_j is the graph that exists prior to sampling new parents for node X_i^j, $J(\pi^{'j}_i, X_i) = 1$ if $X_i \in \pi^{'j}_i$ and 0 otherwise, and $Z(X_i^j|G_j, X_i)$ represents the sum of local scores over all allowable parent sets of X_i^j which contain X_i:

$$Z(X_i^j \mid G_j, X_i) := \sum_{\substack{\pi: H(G_j^{X_i^j \leftarrow \pi}) = 1 \\ X_i \in \pi}} exp(\Psi[X_i^j, \pi \mid D]). \tag{7}$$

It is important to note that sampling of new parent sets for each X_i^j occurs in a specified order that is randomized for each MBR move (see Appendix), so that if another child of X_i (i.e., a 'sibling' of X_i^j) becomes a parent of X_i^j in graph G_{j+1}, then X_i^j is not an allowable parent of that sibling when its new parents are subsequently sampled. This can be considered as a special case of disallowing directed cycles when sampling new parent sets for each X_i^j.

Thus, after these three steps, the DAG $G^{'}$ has been proposed by the MBR move, with overall proposal probability $Q(G^{'} \mid G)$ given by:

$$Q(G^{'} \mid G) = \frac{1}{N} \cdot \frac{exp(\Psi[X_i, \pi_i^{'} \mid D]) \cdot H(G_0^{X_i \leftarrow \pi_i^{'}}) \cdot I(\pi_i^{'}, \pi_i)}{Z^*(X_i \mid G_0, \pi_i)} \cdot \prod_{j=1}^{J} \frac{exp(\Psi[X_i^j, \pi^{'j}_i \mid D]) \cdot H(G_j^{X_i^j \leftarrow \pi^{'j}_i}) \cdot J(\pi^{'j}_i, Xi)}{Z(X_i^j \mid G_j, X_i)}. \tag{8}$$

To compute the acceptance probability of the Metropolis-Hastings algorithm, the probability of performing the complementary reverse move from G' to G, $Q(G \mid G')$, must be articulated. This involves another MBR move for node X_i in which the node is first orphaned and all edges pointing into its children from nodes other than itself are removed to yield DAG, $G_0^{'}$. In step 2, the original parent set π of X_i is selected resulting in graph $G_1^{'}$, while in step 3 the original parent sets of each of X_i's children are selected in graphs $G_j^{'}$ (accounting for node order) thus getting back to the original DAG G.

The numerators of the proposal distributions are cancelled out by the corresponding terms of the posterior ratio (Grzegorczyk and Husmeier 2008), as are all local scores corresponding to unaffected nodes. Therefore, the critical term in the acceptance probability can be written simply as:

$$R(G^{'} \mid G) = \frac{P(G^{'} \mid D)}{P(G \mid D)} \cdot \frac{Q(G \mid G^{'})}{Q(G^{'} \mid G)} = \frac{Z^*(X_i \mid G_0, \pi_i)}{Z^*(X_i \mid G_0^{'}, \pi_i^{'})} \cdot \frac{\prod_{j=1}^{J} Z(X_i^j \mid G_j, X_i)}{\prod_{j=1}^{J} Z(X_i^j \mid G_j^{'}, X_i)}. \tag{9}$$

An outline of the MBR algorithm is given in the Appendix.

3.3 Implementation Details

As with the order MCMC of Friedman and Koller (2003) and REV-enhanced structure MCMC of Grzegorczyk and Husmeier (2008), computational efficiency can be obtained when implementing the MBR algorithm by pre-computing and storing the scores associated with all potential parent sets of each node. Further efficiency can be gained for large networks by only considering as potential parents of each node those which have the highest local scores when considered as sole parents. However, as this is an approximate technique, we do not employ it in the examples presented here. We do, however, employ a fan-in restriction in which a maximum of three parents are allowed for any one node. When we sample for new parents for a node, we test all combinations of at most three. This approximation is used in most applications to reduce computational complexity and improve convergence.

To preserve acyclicity when sampling new parent sets for a node, we can simply eliminate invalid parent sets from the list of potential parent sets. In other words, if a parent set contains a node that is a descendant of the target node or its children, this parent set is removed from the current list of candidate parent sets. This method can also be used to define the scores used in computing the function Z^*. Finally, as the DAGs resulting from the first steps of both the forward and reverse MBR moves, G_0 and $G_0^{'}$, are the same, the identification of descendants only has to occur once during each MBR iteration.

In our applications we implement the MBR move probabilistically in the MCMC algorithm, with a fixed probability of p_m=1/15. The traditional structure move consisting of

the addition, deletion or reversal of a single edge is thus performed with probability p_s=1 p_m. These are the same probabilities as suggested by Grzegorczyk and Husmeier (2008) for their REV move. We experimented with different probabilities but found that 1/15 yields desirable results in terms of prediction quality and convergence rate. More frequent implementations lead to a decline in efficiency in sampling the highest probability regions as the chain seems to jump too often to low probability regions in the structure space, while a lower frequency reduces the mixing of the chain in efficiency incurred by using MBR. Since both the REV and MBR moves scores are pre-computed, MBR does not incur extra running time relative to REV, a fact we confirmed by through time trials using our selected data sets.

4. Experimental Testing

In this section, we test a version of the structure MCMC sampler enhanced by our MBR move against the standard structure sampler and one enhanced by the REV move of Grzegorczyk and Husmeier (2008). We find that the MBR-structure sampler performs better than the other two in terms of reliable convergence and learning performance, especially for relatively small sample sizes. We also find that it converges much faster for large and very large networks. These conclusions are drawn using data simulated from four models, all with more than 30 nodes: ALARM, a BN designed for patient monitoring consisting of 37 nodes and 46 edges (Beinlich et al., 1989); Hailfinder, a BN with 56 nodes and 66 edges developed to forecast severe weather (Abramson et al., 1996) HEPAR II, a BN built for diagnosis of liver disorders consisting of 70 nodes and 123 edges (Onisko, 2003), and GENS2, a tool for simulating genetic epidemiological datasets containing 100 exposure, gene, and disease variables (Pinelli et al., 2012). The ALARM data were used by Grzegorczyk and Husmeier (2008) to demonstrate that the REV-structure sampler performed much better than the standard MCMC sampler and equally well as the order sampler of Friedman and Koller (2003). We employ the other three datasets to compare performance for even larger networks.

Our algorithms were implemented in Matlab on a 128 GB machine with an Intel Xeon 2.00GHz processor. For the ALARM network with a simulated data set of m=1,000, precomputation of scores required 1017.6 sec, and implementation of 10,000 MCMC iterations required 382.6 sec for the standard structure algorithm, 401.5 sec for REV, and 407.3 sec for MBR. Given the 1/15 frequency of implementation, these times imply that the REV and MBR moves require approximately twice as much computation time as the conventional structure moves. This is consistent with the fact that the average number of children per node being considered in each iteration of MBR for ALARM was found to be 1.60.

4.1 Convergence Reliability

To compare the reliability of convergence of the three structure samplers, we generated two MCMC runs using datasets of various sizes (m=50, 100, 250, 500, 1000) simulated from ALARM: one initialized with an empty DAG and another initialized with a DAG identified as highest scoring through an independent run of the MCMC algorithm. We then compared the estimates of the posterior probabilities of the directed edges obtained from the two runs

using scatter plots. Points lying along the 1:1 line imply that the two runs agree, indicating reliable convergence.

We used the same run settings as Grzegorczyk and Husmeier (2008): for the standard structure sampler the burn-in was set to 500,000 iterations and 1000 DAGs were then collected by storing every 1000th iteration. For both the REV and MBR moves, the burn-in length was set to 312,500 and 1000 DAGS were collected by storing every 625th iteration. This difference was employed to ensure approximately equal computational costs across the three samplers, under the conservative assumption that the computational costs of the REV and MBR moves are 10-times greater than those of standard structure iterations and that the probability of these moves in any iteration was 1/15 (Grzegorczyk and Husmeier, 2008).

Scatter plots of the posterior probabilities of directed edges estimated from the two independent runs show that the MBR and REV structure samplers converge approximately equally reliably, even for small sample sizes (Figure 2). There is a high correspondence between the posterior probability estimates for the differently initialized runs. Under the traditional structure sampler, however, the posterior probabilities of some edge features depend on the initialization as indicated by off-diagonal points, even for very large samples, implying that this algorithm tends to get stuck at local maxima. Differences across algorithms also imply imperfect convergence.

4.2 Convergence Rate

Having established that, when added to the traditional MCMC structure sampler, the MBR move improves convergence reliability to the same degree as the REV move, we next compared the convergence rate for networks over a range of sizes: ALARM (37 nodes), HEPAR II (70 nodes), GENS2 (100 nodes). From each network, we generated sets of 1000 simulated observations and applied each of the MCMC algorithms described in the previous section, starting with an empty DAG. Trace plots reveal the speed and reliability of convergence.

For all three networks, the MBR-enhanced algorithm improves the convergence rate substantially over the REV-enhanced version (Figure 3). The highest scoring structures are found in approximately half the number of iterations of REV and in one tenth the number of the traditional structure sampler. In fact, it appears that both the REV and the traditional sampler may be getting stuck at local maxima for the largest networks, while the MBR sampler quickly converges.

4.3 Learning Performance

When the true graph network underlying a dataset is known, we can evaluate the performance of a structure learning algorithm using the concept of AUROC values. If we take the directed edges that have an estimated posterior probability greater than some threshold ϵ to be positive assertions of the existence of that feature, then a comparison against the true network will yield the number of true positive (TP), false positive (FP) and false negative (FN) assertions corresponding to that value of ϵ. The corresponding sensitivity, or true positive rate, TPR=TP/(TP+FN) and the complement of the specificity, or false positive rate, FPR=FP/(TN+FP) can then be calculated, and a plot of these two metrics for varying values of ϵ yields the Receiver Operator Characteristic (ROC) curve. Integrating the ROC

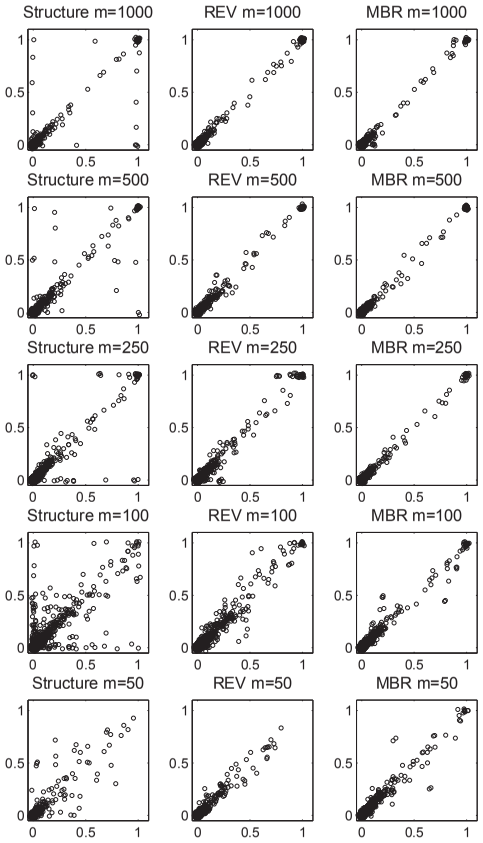

Figure 2: Scatter plots of posterior probability estimates for directed edges in the ALARM network, inferred from simulated datasets of various sizes. In each plot, the x-axis represents the posterior probabilities estimated from an MCMC run initialized with an empty DAG, and the y-axis represents the probability estimates obtained from an MCMC initialized with a high scoring DAG found from an independent run of the MCMC algorithm. When points lie along the diagonal, the two runs have results that agree, indicating reliable convergence. Values clustering near 0 and 1 for larger sample sizes indicate a reduction in inference uncertainty. Left column: traditional structure sampler; center column: REV-enhanced sampler; right column: MBR-enhanced sampler.

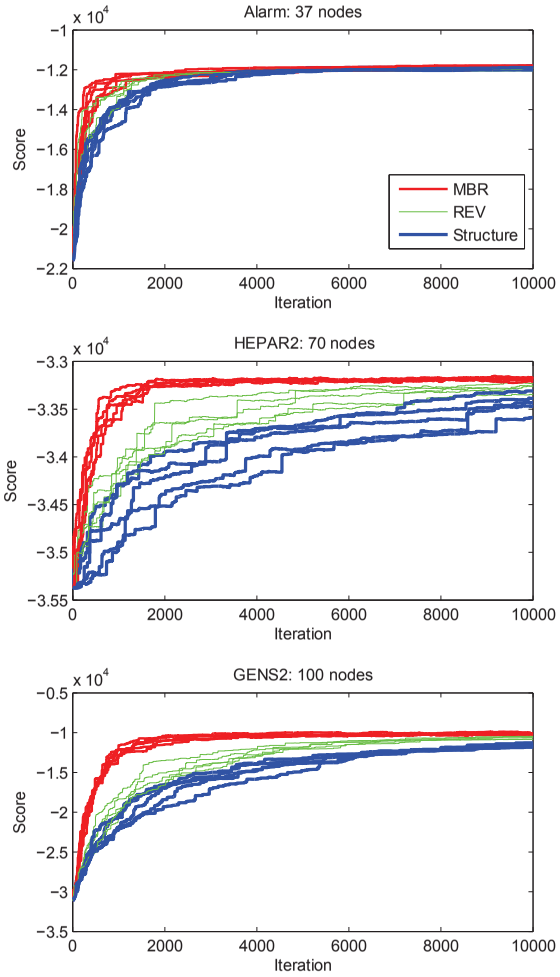

Figure 3: Trace plots of the first 10,000 iterations of five MCMC runs from each algorithm (MBR, REV, Structure) on data sets simulated from networks ranging in size. All runs involved 1000 simulated observations.

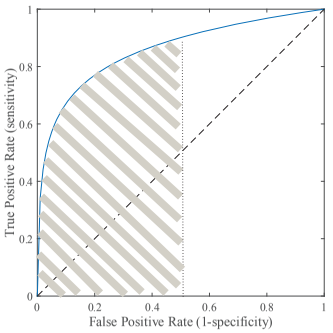

Figure 4: Hypothetical ROC curve. The hatched area represents the $AUROC_{0.5}$ corresponding to an upper limit of ϵ=0.5.

curve from 0 to an upper value of FPR=ϵ then gives the Area under the Receiver Operator Characteristic ($AUROC_\epsilon$) curve as a summary of learning performance, with high values indicating better performance (Figure 4). $AUROC_\epsilon$ values corresponding to low levels of the upper limit are of particular interest, as we are generally concerned with limiting the false positive rate.

For the ALARM network, we calculated $AUROC_\epsilon$ values for graphs learned from datasets of size m = 50, 100, 250, 500, and 1000 observations using each of the three MCMC algorithms and each of the two initializations, as described above. $AUROC_\epsilon$ values were calculated for ϵ = 1.0, 0.1, 0.05, and 0.01. Plots of these values (Figure 5) show that, as expected, learning performance tends to increase with the number of observations. The three algorithms perform nearly comparably at sample sizes of m=250 and greater, with the structure MCMC being somewhat less consistent between initializations, supporting the results shown in Fig. 2. At smaller sample sizes and lower values of ϵ, the traditional structure sampler performs poorly, the REV-enhanced version performs somewhat better, and the MBR-enhanced version performs the best of the three algorithms. Additionally, performance differs very little between the two independent initializations.

To assess learning performance on a different and somewhat larger network, we made comparable calculations with Hailfinder, using simulated datasets of size m = 500, 750, 1000, 1250, and 1500 observations (Figure 6). The traditional structure MCMC again shows increased learning performance with increasing number of observations. Yet, while the REV and MBR-enhanced versions show comparable performance with large datasets, they both yield even better performance with small datasets, as measured by $AUROC_1$, $AUROC_{0.01}$, and $AUROC_{0.05}$ values. This occurs because the Hailfinder network was originally constructed based, in part, on expert judgment. Therefore, the original network is not necessarily the best scoring one. For small sample sizes, the algorithms each find networks that fit the data better (i.e., more concisely) than the original network. Others working with similar-sized networks employing expert judgment or hidden nodes have found similar

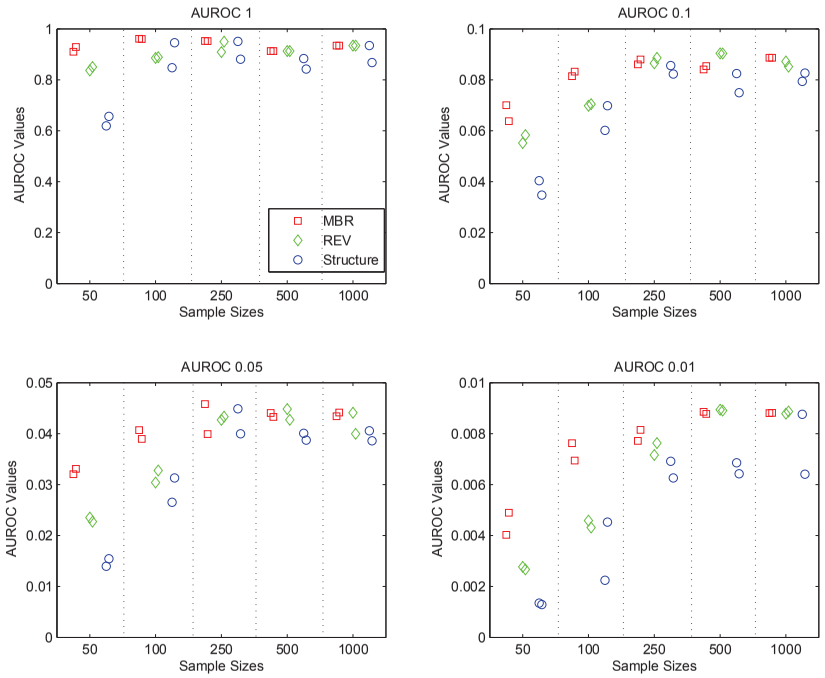

Figure 5: Learning performance of the three MCMC samplers as applied to simulated data from the ALARM network. Each panel shows $AUROC_\epsilon$ values corresponding to a different upper limit on the inverse specificity ($\epsilon = 1, 0.1, 0.05, 0.01$). Within each panel, results are shown for each sampler with a different symbol, as applied to varying numbers of simulated observations (m = 50, 100, 250, 500, 1000) across the x-axis. For each sampler, there are two values, corresponding to runs initialized with an empty DAG (slightly left) and a high scoring DAG found from an independent run of the MCMC algorithm (slightly right).

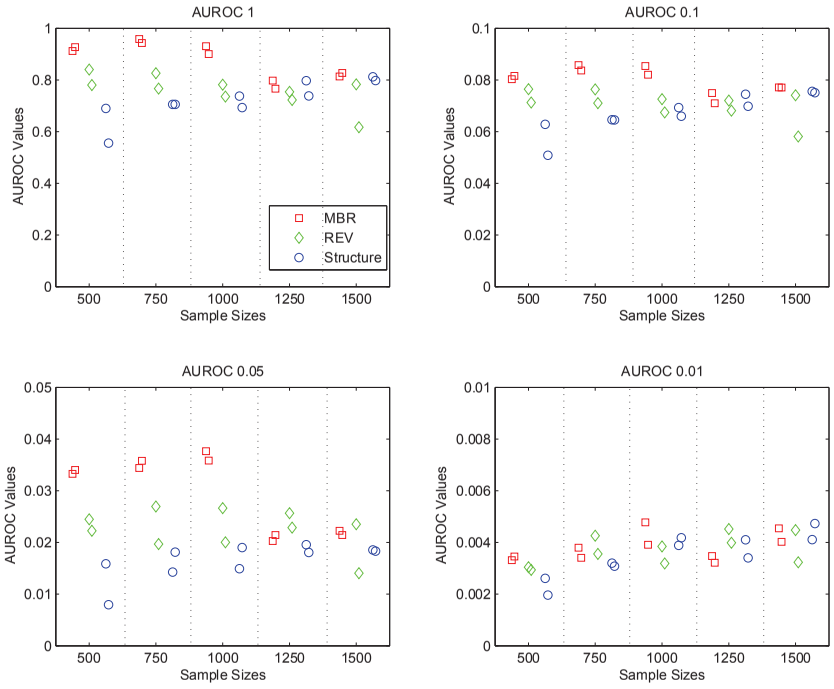

Figure 6: Learning performance of the three MCMC samplers as applied to simulated data from the Hailfinder network. Each panel shows $AUROC_\epsilon$ values corresponding to a different upper limit on the inverse specificity ($\epsilon = 1, 0.1, 0.05, 0.01$). Within each panel, results are shown for each sampler with a different symbol, as applied to varying numbers of simulated observations (m = 50, 100, 250, 500, 1000) across the x-axis. For each sampler, there are two values, corresponding to runs initialized with an empty DAG (slightly left) and a high scoring DAG found from an independent run of the MCMC algorithm (slightly right).

behavior (Masegosa and Moral, 2013). The MBR version appears to perform somewhat better than the REV version at the smallest sample sizes with the possible exception of $\epsilon = 0.01$.

To rigorously compare the learning performance of the three algorithms, we employed a statistical hypothesis testing procedure. First, we produced 10 independent data samples from the Alarm network and generated 10 corresponding MCMC runs for each algorithm starting with an empty structure. $AUROC_\epsilon$ values were calculated from these 10 runs for each algorithm. We then performed paired-sample t-tests in Matlab with null hypothesis that the differences in $AUROC_\epsilon$ values between each pair of algorithms have mean equal to zero (assuming a normal distribution with unknown variance), with a two-sided alternative hypothesis. A paired test was used because we were able to calculate $AUROC_\epsilon$ values for all three algorithms using the same random data sample. Our hypothesis test was implemented for a data sample size of 100.

Results (Figure 7) show that MBR gives consistently greater $AUROC_\epsilon$ values across all four values of and that the within algorithm variance is relatively small compared to the between-algorithm variance, suggesting that the differences are statistically significant. Indeed, results shown in Table 1 indicate that our MBR algorithm statistically outperforms the other two algorithms for the Alarm data of 100 observations. Q-Q plots (not shown) confirm the approximate normality of the $AUROC_\epsilon$ value differences.

5. Conclusions

We have presented a novel MCMC sampling scheme to improve the mixing and convergence of the traditional MCMC algorithm used for probabilistically inferring the structure of BNs from observational data. The idea is to occasionally introduce major moves in the structural search space, thus allowing the sampler to more effectively traverse low-probability regions between local maxima and ridges. Our moves are more extreme than the new edge reversal (REV) move of Grzegorczyk and Husmeier (2008) in that we propose resampling much of the Markov blanket of nodes. As the Markov blanket contains all the variables that can directly influence the state of a node, its resampling represents a substantial change. Yet, as we can derive the complementary forward and backward moves of MBR, the Metropolis-Hastings algorithm can be used to account for any asymmetries that might be present in these proposal moves.

Our experiments across a range of network sizes show that the Markov Blanket Resampling (MBR) scheme outperforms the state-of-the-art new edge reversal (REV) scheme of Grzegorczyk and Husmeier (2008), both in terms of learning performance and convergence rate. In particular, MBR achieves better learning performance than the other algorithms when the number of observations is relatively small and faster convergence when the number

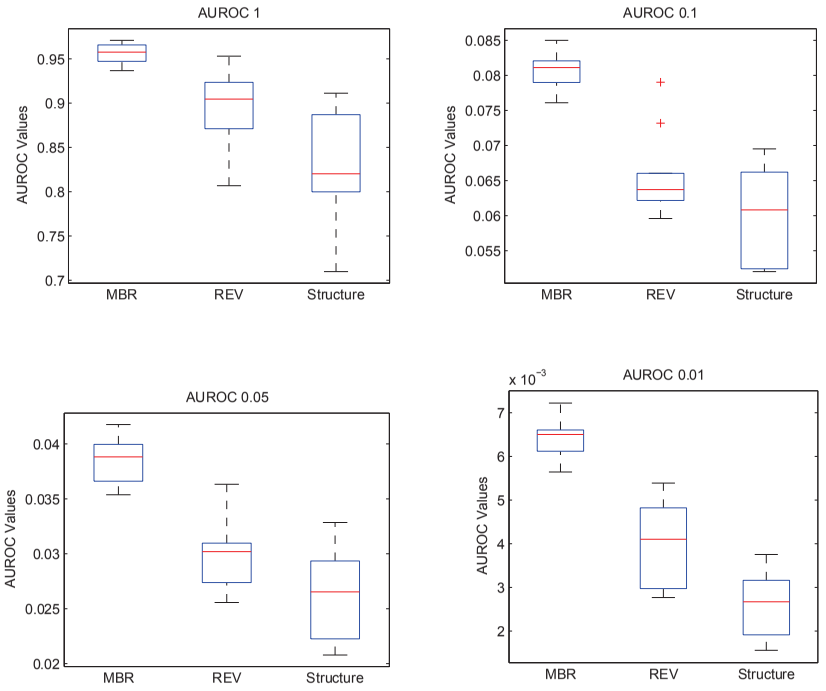

Figure 7: Boxplots of the $AUROC_\epsilon$ values from the three MCMC algorithms as applied to 10 independent sets of simulated data of sample size 100 from the Alarm network. Each panel shows values of $AUROC_\epsilon$ corresponding to a different upper limit on the inverse specificity ($\epsilon = 1, 0.1, 0.05, 0.01$). Boxes indicate the middle 50% (interquartile range, IQR) of the $AUROC_\epsilon$ values for each algorithm, central lines indicate median values, vertical whiskers extend out to the furthest value within 1.5*IQR of the boxes, and crosses indicate outlying values.

of variables in the network is large. As many problems in systems biology are characterized by a large number of variables and a relative paucity of observations (e.g. genome wide association studies), we believe our MBR algorithm will be especially useful in this field. Further, there typically exists prior knowledge (on gene-gene and gene-disease interactions for example) and this prior knowledge can be readily used to improve the performance of the structure-based MCMC algorithms (Imoto et al., 2004; Gao and Wang, 2011; Su et al., 2014), including our MBR scheme. This is not necessarily the case for other algorithms developed to address poor mixing and convergence, such as the order sampler of Friedman and Koller (2003), as discussed in the introduction. Thus, we believe a promising avenue of further research will be to improve methods for constructing informative structure priors from published data, experimental results, and expert opinion.

Appendix A. Markov Blanket Resampling (MBR) Algorithm

For all domain variables $\{X_1, ..., X_N\}$, pre-compute and store lists of scores of all valid parent sets. We constrain the maximum number of parents a node can have to three in all our tests.

Given the current DAG, perform an MBR move with probability p_m, otherwise perform a traditional single-edge move. If an MBR move is to be performed, then proceed as follows:

- Randomly select a node X_i in current graph G, with probability N^{-1}.
- Store the current parent set π_i of node X_i.
- Delete all edges pointing into X_i and into its children X_i^j with the exception of X_i itself, thus obtaining G_0.
- Find and store the set $D(X_i|G_0)$ of all of X_i's descendant nodes in the current graph G_0.
- In the list of pre-computed scores of possible parent sets of node X_i, mark those that contain a node from the set $D(X_i|G_0)$. Also mark those that contain its parents $_i$ in G_0.
- Sample a new parent set $\pi_i^{'}$ from the unmarked parents sets of X_i according to equation (4). Store the sum of all unmarked scores as the value of $Z^*(X_i|G_0, \pi_i)$.
- Add the new parent set $\pi_i^{'}$ to G_0 to obtain DAG G_1.
- For j from 1 to J (with J being the number of X_i's children), in a specified order that is randomized for each MBR move:

  - Find and store the set $D(X_i^j|G_j)$ of all of X_i^j's descendant nodes in the current graph G_j.
  - In the list of pre-computed scores of possible parent sets of node X_i^j, mark those that contain a node from the set $D(X_i^j|G_j)$. Also mark those that do not contain X_i.
  - Sample a new parent set $\pi_i^{'j}$ from the unmarked parents sets of X_i^j according to equation (6).
  - Add the new parent set $\pi_i^{'j}$ to G_j to obtain G_{j+1}
- The final graph is the DAG $G^{'}$ being proposed by the MBR move.
- To compute the terms of the complementary inverse move required for calculating the acceptance probability, proceed as follows:
  - Calculate the joint probability of again selecting X_i as N^{-1}.
  - Store the current parent set π_i of node X_i in G'.
  - Delete all edges in G' pointing into X_i and into its children X_j with the exception of X_i itself, thus obtaining $G_0^{'}$.
  - In the list of pre-computed scores of possible parent sets of X_i, mark those that contain a node in $D(X_i|G_0)$ (which is equivalent to $D(X_i|G_0^{'})$, but has already been computed). Also mark those that contain its parents $\pi^{'}\_i$ in $G^{'}$. Store the sum of the unmarked scores as the value of $Z^*(X_i|G_0^{'}, \pi_i^{'})$.
  - Adding the original parent set π_i to $G_0^{'}$ yields DAG $G_1^{'}$ (which is equivalent to G_1).
  - For j from 1 to J:
    - Find and store the set $D(X_i^j|G_j^{'})$ of all of X_i^j's descendant nodes in the current graph $G_j^{'}$.
    - In the list of pre-computed scores of possible parent sets of node X_i^j, mark those that contain a node from the set $D(X_i^j|G_j^{'})$. Also mark those that do not contain X_i.
    - Store the sum of the unmarked scores as $Z(X_i^j|G_j^{'}, X_i)$.
    - Adding the original parent set π_i^j to $G_j^{'}$ yields G'_{j+1}.
- Calculate the overall acceptance probability of the move from G to $G^{'}$ according to equation (9) using the stored values.
- If the move is accepted replace the current DAG G with $G^{'}$, otherwise keep the current DAG.

Abstract

Numerous learning problems that contain exploration, such as experiment design, multi-arm bandits, online routing, search result aggregation and many more, have been studied extensively in isolation. In this paper we consider a generic and efficiently computable method for action space exploration based on convex geometry.

We define a novel geometric notion of an exploration mechanism with low variance called volumetric spanners, and give efficient algorithms to construct such spanners. We describe applications of this mechanism to the problem of optimal experiment design and the general framework for decision making under uncertainty of bandit linear optimization. For the latter we give efficient and near-optimal regret algorithm over general convex sets. Previously such results were known only for specific convex sets, or under special conditions such as the existence of an efficient self-concordant barrier for the underlying set. [1]

Keywords: barycentric spanner, volumetric spanner, linear bandits, hard margin linear regression

1. Introduction

A fundamental challenge in machine learning is environment exploration. A prominent example is the famed multi-armed bandit (MAB) problem, in which a decision maker iteratively chooses an action from a set of available actions and receives a payoff, without observing the payoff of all other actions she could have taken. The MAB problem displays an exploration-exploitation tradeoff, in which the decision maker trades exploring the action space vs. exploiting the knowledge already obtained to pick the best arm. The exploration challenge arises in structured bandit problems such as online routing and rank aggregation: how to choose the most informative path in a graph, or the most informative ranking?

Another example in which environment exploration is crucial is experiment design, and more generally the setting of active learning. In this setting it is important to correctly identify the most informative experiments/queries so as to efficiently construct a solution.

1. This paper is the full version of a merger of two extended abstracts (Hazan et al., 2014) and (Karnin and Hazan, 2014).

Exploration is hardly summarized by picking an action uniformly at random. Indeed, sophisticated techniques from various areas of optimization, statistics and convex geometry have been applied to designing ever better exploration algorithms. To mention a few: (Awerbuch and Kleinberg, 2008) devise the notion of *barycentric spanners*, and use this construction to give the first low-regret algorithms for complex decision problems such as online routing. (Abernethy et al., 2012) use self-concordant barriers to build an efficient exploration strategy for convex sets in Euclidean space. (Bubeck et al., 2012) apply tools from convex geometry, namely the John ellipsoid to construct optimal-regret algorithms for bandit linear optimization, albeit not always efficiently.

In this paper we consider a generic approach to exploration, and quantify what efficient exploration with *low variance* requires in general. Given a set in Euclidean space, a low-variance exploration basis is a subset with the following property: given noisy estimates of a linear function over the basis, one can construct an estimate for the linear function over the entire set without increasing the variance of the estimates.

By definition, such low variance exploration bases are immediately applicable to noisy linear regression: given a low-variance exploration basis, it suffices to learn the function values only over the basis in order to interpolate the value of the underlying linear regressor over the entire decision set. This fact can be used for active learning as well as for the exploration component of a bandit linear optimization algorithm.

Henceforth we define a novel construction for a low variance exploration basis called **volumetric spanners** and give efficient algorithms to construct them. We further investigate the convex geometry implications of our construction, and define the notion of a **minimal volumetric ellipsoid** of a convex body. We give structural theorems on the existence and properties of these ellipsoids, as well as constructive algorithms to compute them in several cases.

We complement our findings with two applications to machine learning. The first application is to the problem of experiment design, in which we give an efficient algorithm for hard-margin active linear regression with optimal bounds. Next, we advance a well-studied open problem that has exploration as its core difficulty: an efficient and near-optimal regret algorithm for bandit linear optimization (BLO). We expect that volumetric spanners and volumetric ellipsoids can be useful elsewhere in experiment design and active learning.

1.1 Informal statement of results

Experiment design: In the statistical field called *optimal design of experiments*, or just *optimal design* (Atkinson and Donev, 1992; Wu, 1978) , a statistician is faced with the task of choosing experiments to perform from a given pool, with the goal of producing the optimal result within the budget constraint.

Formally, consider a pool of possible experiments denoted $x_1, ..., x_n \in \mathbb{R}^d$. The goal of the designer is to choose a distribution over the pool of experiments, such that experiments chosen according to this distribution produce a hypothesis $\hat{\mathbf{w}}$ that is as close as possible to the true linear function behind the data. The distance between the hypothesis and true linear function can be measured in different ways, each corresponding to a different *optimality criteria*. The common property of the criteria is that they all minimize the variance of the hypothesis. Since the variance is not a scalar but a $d \times d$ matrix, the different

criteria differ by the fact that each one minimizes a different function $\Phi : \mathcal{R}^{d\times d} \to \mathcal{R}$ over the covariance matrix. Common criteria are the A-, D-, and E-optimality criteria. D-optimality, minimizes the determinant of the covariance matrix, and thus minimizes the volume of the confidence region. In A-optimality the trace of the covariance matrix, i.e., the total variance of the parameter estimates, is minimized. E-optimality minimizes the maximum eigenvalue of the covariance matrix, and thus minimizes the size of the major axis of the confidence region.

The above criteria do not directly characterize the quality of predictions on test data. A common criterion that directly takes the test data into account is that of G-optimality. Here the goal is to minimize the maximum variance of the predicted values. In other words, by denoting $\mathrm{Var}_S(x_i)$ the variance of the prediction of x_i after querying the points of S, the goal in G-optimality is to minimize $\max_i \mathrm{Var}_S(x_i)$. G-optimality and D-optimality are closely related in the sense that an exact solution to one is the solution to the other, see for example (Spruill and Studden, 1979).

In this paper we solve a problem closely related to the G-optimality criteria. Given a pool of data points $\mathcal{K} \in \mathcal{R}^d$, say representing a pool of patients, we aim to solve an active regression problem finding w.h.p a regressor minimizing the *worst-case error*, while minimizing the number of (noisy) queries to the regressor. The formal definition of the problem is given in Section 6. This problem differs from classic linear regression results as there, the *mean square error* is bounded. The difference between the described problem and solving the optimal design problem with the G-optimality criteria is two-fold. First, we do not aim to minimize the variance but to obtain a high probability bound. Second, in optimal design the quality of the distribution is measured when the budget tends to infinity. Specifically, notice that for a distribution over the possible experiments, rather than a deterministic subset of them, the corresponding covariance matrix is random. The discussed minimizations are done over the expected covariance matrix, where the expectation is taken over the subset of chosen experiments. When the budget tends to infinity the actual covariance matrix is close w.h.p to its expected counterpart. We call this the *infinite budget setting*. Ours is a finite budget setting where one does not aim to provide a distribution over the possible experiments but a deterministic subset of them of a fixed size.

For the finite budget setting various relaxations have been considered in the statistical literature, usually without an approximation guarantee. Our method differs from previous works of this spirit by: First, we do not impose a hard-budget constraint of experiments, but rather bound the number of experiments as a function of the desired approximation guarantee. Second, we obtain a computationally efficient algorithm with provable optimality results. Finally, as an added bonus our solution has the property of choosing very few data points to explore, potentially much less than the budget. A motivating example for this property is the medical experiment design. Here a data point is a human subject and it is more realistic to have few volunteers being thoroughly tested on as opposed to performing few tests over many volunteers. Our setting is arguably more natural for the medical-patient-experiment motivating example; in general there are numerous examples where the budget of experiments is not fixed but rather the tolerable error. Of equal importance is the fact that our setting allows to derive efficient algorithms with rigorous theoretical guarantees.

A related and recently popular model is called random design (Hsu et al., 2012; Audibert and Catoni, 2010; Györfi et al., 2006; Audibert and Catoni, 2011). In this setting the designer is given a set of measurements $\{x_i, y_i | i \in [n]\}$ for $x_i \in \mathbb{R}^d$ drawn from an unknown distribution $\mathcal{D}$. The goal is to predict as well as the best linear predictor measured according to the mean square error, i.e., minimize

$$\mathop{\mathbf{E}}_{(x,y)\in\mathcal{D}} \left[(x^\top w - y)^2 - (x^\top w^* - y)^2 \right]$$

where w^* is the optimal linear regressor. Various other performance metrics have been considered in the referenced papers, i.e., measuring the norm of the regressor vs. the optimal regressor in a norm proportional to the covariance matrix. However, in this setting an expected error is the criterion vs. our criterion of worst-case, or a high confidence bound on the error[2], which is more suitable for some experiment design settings.

Active learning: The most well-studied setting in active learning is pool-based active learning (McCallum and Nigam, 1998), in which the learner has access to a pool of examples, and can iteratively query labels of particular examples of her choice. Compared to passive learning, in which labelled examples are drawn from a fixed unknown distribution, known active learning algorithms can attain a certain generalization error guarantee albeit observing exponentially fewer labelled examples, e.g., (Cohn et al., 1994; Dasgupta et al., 2009; Hanneke, 2007; Balcan et al., 2009), under certain assumptions such as special hypothesis classes, realizability or large-margin. Active learning with noise is a much less studied topic: (Balcan et al., 2009) give an exponential improvement over passive learning of linear threshold functions, but under the condition that the noise is smaller than the desired accuracy. Real valued active learning with a soft-margin criteria was addressed in (Ganti and Gray, 2012). The reader is referred to (Dasgupta and Langford, 2009) for a more detailed survey of active learning literature.

Bandit Linear Optimization Bandit linear optimization (BLO) is a fundamental problem in decision making under uncertainty that efficiently captures structured action sets. The canonical example is that of online routing in graphs: a decision maker iteratively chooses a path in a given graph from source to destination, the adversary chooses lengths of the edges of the graph, and the decision maker receives as feedback the length of the path she chose but no other information (Awerbuch and Kleinberg, 2008). Her goal over many iterations is to attain an average travel time as short as that of the best fixed shortest path in the graph.

This decision problem is readily modeled in the "experts" framework, albeit with efficiency issues: the number of possible paths is potentially exponential in the graph representation. The BLO framework gives an efficient model for capturing such structured decision problems: iteratively a decision maker chooses a point in a convex set and receives as a payoff an adversarially chosen linear cost function. In the particular case of online routing, the decision set is taken to be the s-t-flow polytope, which captures the convex hull of all source-destination shortest paths in a given graph, and has a succinct representation

2. Our results though stated as a worst case error can be generalized to a high probability solution in the random design scenario.

with polynomially many constraints and low dimensionality. The linear cost function corresponds to a weight function on the graphs edges, where the length of a path is defined as the sum of weights of its edges.

The BLO framework captures many other structured problems efficiently, e.g., learning permutations, rankings and other examples (Abernethy et al., 2012). As such, it has been the focus of much research in the past few years. The reader is referred to the recent survey of (Bubeck and Cesa-Bianchi, 2012a) for more details on algorithmic results for BLO. Let us remark that certain online bandit problems do not immediately fall into the convex BLO model that we address, such as combinatorial bandits studied in (Cesa-Bianchi and Lugosi, 2012).

In this paper we contribute to the large literature on the BLO model by giving the first polynomial-time and near optimal-regret algorithm for BLO over general convex decision sets; see Section 7 for a formal statement. Previously efficient algorithms, with non-optimal-regret, were known over convex sets that admit an efficient self-concordant barrier (Abernethy et al., 2012), and optimal-regret algorithms were known over general sets (Bubeck et al., 2012) but these algorithms were not computationally efficient. Our result, based on volumetric spanners, is able to attain the best of both worlds.

1.2 Volumetric Ellipsoids and Spanners

We now describe the main convex geometric concepts we introduce and use for low variance exploration. To do so we first review some basic notions from convex geometry.

Let $\mathbb{R}^d$ be the d-dimensional vector space over the reals. Given a set of vectors $S = \{v_1, \ldots, v_t\} \subset \mathbb{R}^d$, we denote by $\mathcal{E}(S)$ the ellipsoid defined by S:

$$\mathcal{E}(S) = \left\{ \sum_{i \in S} \alpha_i v_i \ : \ \sum_i \alpha_i^2 \leq 1 \right\}.$$

By abuse of notation, we also say that $\mathcal{E}(S)$ is *supported* on the set S.

Ellipsoids play an important role in convex geometry and specific ellipsoids associated with a convex body have been used in previous works in machine learning for designing good exploration bases for convex sets $\mathcal{K} \subseteq \mathbb{R}^d$. For example, the notion of *barycentric spanners* which were introduced in the seminal work of Awerbuch and Kleinberg (Awerbuch and Kleinberg, 2008) corresponds to looking at the ellipsoid of maximum volume supported by exactly d points from [3] $\mathcal{K}$. Barycentric Spanners have since been used as an exploration basis in several works: Online bandit linear optimization (Dani et al., 2007), A high probability counterpart of online bandit linear optimization (Bartlett et al., 2008), repeated decision making of approximable functions (Kakade et al., 2009) and a stochastic version of bandit linear optimization (Dani et al., 2008). Another example is the work of Bubeck et al. (Bubeck et al., 2012) which looks at the minimum volume enclosing ellipsoid (MVEE) also known as the John ellipsoid (see Section 2 for more background on this fundamental object from convex geometry).

As will be clear soon, our definition of a *minimal volumetric ellipsoid* enjoys the best properties of the examples above enabling us to get more efficient algorithms. Similar to

3. While the definition of (Awerbuch and Kleinberg, 2008) is not phrased as such, their analysis shows the existence of barycentric spanners by looking at the maximum volume ellipsoid.

barycentric spanners, it is supported by a small (linear) set of points of $\mathcal{K}$. Simultaneously and unlike the barycentric counterpart, the volumetric ellipsoid contains the body $\mathcal{K}$, a property shared with the John ellipsoid.

Definition 1 (Volumetric Ellipsoids) *Let $\mathcal{K} \subseteq \mathbb{R}^d$ be a set in Euclidean space. For $S \subseteq \mathcal{K}$, we say that $\mathcal{E}(S)$ is a* volumetric ellipsoid *for $\mathcal{K}$ if it contains $\mathcal{K}$. We say that $\mathcal{E}(S)$ is a* minimal volumetric ellipsoid *if it is a containing ellipsoid defined by a set of minimal cardinality*

$$S \in \arg\min_{S' \in \mathcal{S}(\mathcal{K})} |S'|, \qquad \mathcal{S}(\mathcal{K}) = \left\{ S' \mid S' \subseteq \mathcal{K} \subseteq \mathcal{E}(S') \right\}$$

We say that $|S|$ is the order *of the minimal volumetric ellipsoid or of* [4] *$\mathcal{K}$ denoted* $\mathbf{order}(\mathcal{K})$.

We discuss various geometric properties of volumetric ellipsoids later. For now, we focus on their utility in designing efficient exploration bases. To make this concrete and to simplify some terminology later on (and also to draw an analogy to barycentric spanners), we introduce the notion of *volumetric spanners*. Informally, these correspond to sets S that span all points in a given set with coefficients having Euclidean norm at most one. Formally:

Definition 2 *Let $\mathcal{K} \subseteq \mathbb{R}^d$ and let $S \subseteq \mathcal{K}$. We say that S is a* volumetric spanner *for $\mathcal{K}$ if $\mathcal{K} \subseteq \mathcal{E}(S)$.*

Clearly, a set $\mathcal{K}$ has a volumetric spanner of cardinality t if and only if $\mathbf{order}(\mathcal{K}) \leq t$.

Our goal in this work is to bound the order of arbitrary sets. A priori, it is not even clear if there is a universal bound (depending only on the dimension and not on the set) on the order S for compact sets $\mathcal{K}$. However, barycentric spanners and the John ellipsoid show that the order of any compact set in $\mathcal{R}^d$ is at most $O(d^2)$. Our main structural result in convex geometry gives a nearly optimal linear bound on the order of all sets.

Theorem 3 (Main) *Any compact set $\mathcal{K} \subseteq \mathbb{R}^d$ admits a volumetric ellipsoid of order at most $12d$. Further, if $\mathcal{K} = \{v_1, \ldots, v_n\}$ is a discrete set, then a volumetric ellipsoid for $\mathcal{K}$ of order at most $12d$ can be constructed in $\mathrm{poly}(n, d)$ time.*

This structural result is achieved by sparsifying (via the methods given in Batson et al. 2012) the John contact points of $\mathcal{K}$. We emphasize the last part of the above theorem giving an algorithm for finding volumetric spanners of small size; this could be useful in using our structural results for algorithmic purposes. We also give a different algorithmic construction for the discrete case (a set of n vectors) in Section 5. While being sub-optimal by logarithmic factors (gives an ellipsoid of order $O(d(\log d)(\log n))$ this alternate construction has the advantage of being simpler and more efficient to compute.

4. We note that our definition allows for multi-sets, meaning that S may contain the same vector more than once.

1.3 Approximate Volumetric Spanners

Theorem 3 shows the existence of good volumetric spanners and also gives an efficient algorithm for finding such a spanner in the discrete case, i.e., when $\mathcal{K}$ is finite and given explicitly. However, the existence proof uses the John ellipsoid in a fundamental way and it is not known how to compute (even approximately) the John ellipsoid efficiently for the case of general convex bodies. For such computationally difficult cases, we introduce a natural relaxation of volumetric ellipsoids which can be computed efficiently for a bigger class of bodies and is similarly useful. The relaxation comes from requiring that the ellipsoid of small support contain all but an ε fraction of the points in $\mathcal{K}$ (under some distribution). In addition, we also require that the measure of points decays exponentially fast w.r.t their $\mathcal{E}(S)$-norm (see precise definition in next section); this property gives us tighter control on the set of points not contained in the ellipsoid. When discussing a measure over the points of a body the most natural one is the uniform distribution over the body. However, it makes sense to consider other measures as well and our approximation results in fact hold for a wide class of distributions.

Definition 4 *Let $S \subseteq \mathcal{R}^d$ be a set of vectors and let V be the matrix whose columns are the vectors of S. We define the semi-norm*

$$\|x\|_{\mathcal{E}(S)} = \sqrt{x^\top (VV^\top)^{-1} x}\ ,$$

where $(VV^\top)^{-1}$ is the Moore-Penrose pseudo-inverse of $VV^\top$. Let $\mathcal{K}$ be a convex set in $\mathcal{R}^d$, p a distribution over it, and let $\varepsilon > 0$. A (p,ε)-exp-volumetric spanner *of $\mathcal{K}$ is a set $S \subseteq \mathcal{K}$ such that for any $\theta > 1$*

$$\Pr_{x\sim p}[\|x\|_{\mathcal{E}(S)} \geq \theta] \leq \varepsilon^{-\theta}.$$

To understand the intuition behind the above definition, notice that for any point x in $\mathcal{E}(S)$ we have $\|x\|_{\mathcal{E}(S)} \leq 1$. Hence, if S is such that $\mathcal{K} \subseteq \mathcal{E}(S)$ we have that S is a *(p,ε)-exp-volumetric spanner* of $\mathcal{K}$ for $\varepsilon = 0$ and any p. It follows that the above provides an approximate volumetric spanner; in what follows we show that this particular type of approximation can be computed efficeintly for log-concave p and is sufficient in certain cases.

Theorem 5 *Let $\mathcal{K}$ be a convex set in $\mathcal{R}^d$ and p a log-concave distribution over it. By sampling $O(d+\log^2(1/\varepsilon))$ i.i.d. points from p one obtains, w.p. at least $1-\exp\left(-\sqrt{\max\{\log(1/\varepsilon), d\}}\right)$, a (p,ε)-exp-volumetric spanner for $\mathcal{K}$.*

1.4 Structure of the paper

In the next section we list the preliminaries and known results from measure concentration, convex geometry and online learning that we need. In Section 3 we show the existence of small size volumetric spanners. In Sections 4 and 5 we give efficient constructions of volumetric spanners for continuous and discrete sets, respectively. We describe the application to experiment design in Section 6. We then proceed to describe the application of our geometric results to bandit linear optimization in Section 7.

2. Preliminaries

We now describe several preliminary results we need from convex geometry and linear algebra. We start with some notation:

- A matrix $A \in \mathbb{R}^{d\times d}$ is positive semi-definite (PSD) when for all $x \in \mathcal{R}^d$ it holds that $x^\top Ax \geq 0$. Alternatively, when all of its eigenvalues are non-negative. We say that $A \succeq B$ if $A - B$ is PSD.
- Given an ellipsoid $\mathcal{E}(S) = \{\sum_i \alpha_i v_i : \sum_i \alpha_i^2 \leq 1\}$, we shall use the notation $\|x\|_{\mathcal{E}(S)} \triangleq \sqrt{x^\top (VV^\top)^{-1} x}$ to denote the (Minkowski) semi-norm defined by the ellipsoid, where V is the matrix with the vectors v_i's as columns. Notice that $\mathcal{E}(S)$ is symmetric and convex hence it defines a norm.
- Throughout, we denote by I_d the $d \times d$ identity matrix.

We next describe properties of the John ellipsoid which plays an important role in our proofs.

2.1 The Fritz John Ellipsoid

Let $\mathcal{K} \subseteq \mathbb{R}^n$ be an arbitrary convex body. Then, the **John ellipsoid** of $\mathcal{K}$ is the minimum volume ellipsoid containing $\mathcal{K}$. This ellipsoid is unique and its properties have been the subject of important study in convex geometry since the seminal work of John (John, 1948) (see Ball 1997 and Henk 2012 for historic information).

Suppose that we have linearly transformed $\mathcal{K}$ such that its minimum volume enclosing ellipsoid (MVEE) is the unit sphere; in convex geometric terms, $\mathcal{K}$ is in *John's position*. The celebrated decomposition theorem by (John, 1948) gives a characterization of when a body is in John's position and will play an important role in our constructions (the version here is from Ball 1997).

Below we consider only symmetric convex sets, i.e., sets that admit the following property: if $x \in \mathcal{K}$ then also $-x \in \mathcal{K}$. The sets encountered in machine learning applications are most always symmetric, since estimating a linear function on a point x is equivalent to estimating it on its polar $-x$, and negating the outcome.

Theorem 6 (Ball 1997) *Let $\mathcal{K} \in \mathcal{R}^d$ be a symmetric set such that its MVEE is the unit sphere. Then there exist $m \leq d(d+1)/2 - 1$* contact points *of $\mathcal{K}$ and the sphere $u_1, \ldots, u_m$ and non-negative weights $c_1, \ldots, c_m$ such that $\sum_i c_i u_i = 0$ and $\sum c_i u_i u_i^T = I_d$.*

The contact points of a convex body have been extensively studied in convex geometry and they also make for an appealing exploration basis in our context. Indeed, (Bubeck et al., 2012) use these contact points to attain an optimal-regret algorithm for BLO. Unfortunately we know of no efficient algorithm to compute, or even approximate, the John ellipsoid for a general convex set, thus the results by (Bubeck et al., 2012) do not yield efficient algorithms for BLO.

For our construction of volumetric spanners we need to compute the MVEE of a discrete symmetric set, which can be done efficiently. We make use of the following (folklore) result:

Theorem 7 (folklore, see e.g., Khachiyan 1996; Damla Ahipasaoglu et al. 2008) *Let $\mathcal{K} \subseteq \mathcal{R}^d$ be a set of n points. It is possible to compute an ε-approximate MVEE for $\mathcal{K}$ (an enclosing ellipsoid of volume at most $(1+\varepsilon)$ that of the MVEE) that is also supported on a subset of $\mathcal{K}$ in time $O(n^{3.5}\log\frac{1}{\varepsilon})$.*

The run-time above is attainable via the ellipsoid method or path-following interior point methods (see references in theorem statement). An approximation algorithm rather than an exact one is necessary in a real-valued computation model, and the logarithmic dependence on the approximation guarantee is as good as one can hope for in general.

The above theorem allows us to efficiently compute a linear transformation such that the MVEE of $\mathcal{K}$ is essentially the unit sphere. We can then use linear programming to compute an approximate decomposition like in John's theorem as follows.

Theorem 8 *Let $\{x_1,\ldots,x_n\} = \mathcal{K} \subseteq \mathcal{R}^d$ be a set of n points and assume that:*

1. *$\mathcal{K}$ is symmetric.*
2. *The John Ellipsoid of $\mathcal{K}$ is the unit sphere.*

Then it is possible, in $O((\sqrt{n}+d)n^3)$ time, to compute non-negative weights $c_1,\ldots,c_n$ such that (1) $\sum_i c_i x_i = 0$ and (2) $\sum_{i=1}^n c_i x_i x_i^\top = I_d$.

Proof

Denote the MVEE of $\mathcal{K}$ by $\mathcal{E}$ and let V be its corresponding $d\times d$ matrix, meaning V is such that $\|y\|_{\mathcal{E}}^2 = y^\top V^{-1} y \le 1$ for all $y\in\mathcal{K}$. By our assumptions $I_d = V$.

As $\mathcal{K}$ is symmetric and its MVEE is the unit ball, according to Theorem 6, there exist $m \le d(d+1)/2-1$ contact points $u_1,\ldots,u_m$ of $\mathcal{K}$ with the unit ball and a vector $c'\in\mathcal{R}^m$ such that $c'\ge 0$, $\sum c'_i = d$ and $\sum c'_i u_i u_i^T = I_d$. It follows that the following LP has a feasible solution: Find $c\in\mathcal{R}^n$ such that $c\ge 0$, $\sum c_i \le d$ and $\sum c_i u_i u_i^T = I_d$. The described LP has $O(n+d^2)$ constraints and n variables. It can thus be solved in time $O(d+\sqrt{n})n^3)$ via interior point methods. ■

We next state the results from probability theory that we need.

2.2 Distributions and Measure Concentration

For a set $\mathcal{K}$, let $x\sim\mathcal{K}$ denote a uniformly random vector from $\mathcal{K}$.

Definition 9 *A distribution over $\mathcal{R}^d$ is log-concave if its probability distribution function (pdf) p is such that for all $x,y\in\mathcal{R}^d$ and $\lambda\in[0,1]$,*

$$p(\lambda x + (1-\lambda)y) \ge p(x)^\lambda p(y)^{1-\lambda}$$

Two log-concave distributions of interest to us are (1) the uniform distribution over a convex body and (2) a distribution over a convex body where $p(x)\propto\exp(L^\top x)$, where L is some vector in $\mathcal{R}^d$. The following result shows that given oracle access to the pdf of a log-concave distribution we can sample from it efficiently. An oracle to a pdf accepts as input a point $x\in\mathcal{R}^d$ and returns the value $p(x)$.

Lemma 10 (Lovász and Vempala 2007, Theorems 2.1 and 2.2) *Let p be a log-concave distribution over $\mathbb{R}^d$ and let $\delta>0$. Then, given oracle access to p, i.e., and oracle computing its pdf for any point in $\mathbb{R}^d$, there is an algorithm which approximately samples from p such that:*

1. *The total variation distance between the produced distribution and the distribution defined by p is no more than δ. That is, the difference between the probabilities of any event in the produced and actual distribution is bounded by δ.*
2. *The algorithm requires a pre-processing time of $\tilde{O}(d^5)$.*
3. *After pre-processing, each sample can be produced in time $\tilde{O}(d^4/\delta^4)$, or amortized time of $\tilde{O}(d^3/\delta^4)$ if more than d samples are needed.*

Definition 11 (Isotropic position) *A random variable x is said to be in isotropic position*
(or isotropic) if

$$\mathbf{E}[x] = 0, \qquad \mathbf{E}[xx^\top] = I_d.$$

A set $\mathcal{K}\subseteq\mathbb{R}^d$ is said to be in isotropic position if $x\sim\mathcal{K}$ is isotropic. Similarly, a distribution p is isotropic if $x\sim p$ is isotropic.

Henceforth we use several results regarding the concentration of log-concave isotropic random vectors. In these results we use the matrix operator norm (i.e., spectral norm) defined as $\|A\| = \sup_{x\neq 0}\frac{\|Ax\|}{\|x\|}$. We use slight modification where the center of the distribution is not necessarily in the origin. For completeness we present the proof of the modified theorems in Appendix A

Theorem 12 (Theorem 4.1 in Adamczak et al. 2010) *Let p be a log-concave distribution over $\mathcal{R}^d$ in isotropic position. There is a constant C such that for all $t,\delta>0$, the following holds for $n = \frac{Ct^4 d\log^2(t/\delta)}{\delta^2}$. For independent random vectors $x_1,\ldots,x_n\sim p$, with probability at least $1-\exp(-t\sqrt{d})$,*

$$\left\|\frac{1}{n}\sum_{i=1}^n x_i x_i^\top - I_d\right\| \le \delta.$$

Corollary 13 *Let p be a log-concave distribution over $\mathcal{R}^d$ and $x\sim p$. Assume that x is such that $\mathbf{E}[xx^T] = I_d$. Then, there is a constant C such that for all $t\ge 1,\delta>0$, the following holds for $n = \frac{Ct^4 d\log^2(t/\delta)}{\delta^2}$. For independent random vectors $x_1,\ldots,x_n\sim p$, with probability at least $1-\exp(-t\sqrt{d})$,*

$$\left\|\frac{1}{n}\sum_{i=1}^n x_i x_i^\top - I_d\right\| \le \delta.$$

Theorem 14 (Theorem 1.1 in Guédon and Milman 2011) *There exist constants c,C such that the following holds. Let p be a log-concave distribution over $\mathcal{R}^d$ in isotropic position and let $x\sim p$. Then, for all $\theta\ge 0$,*

$$Pr\left[\left|\|x\| - \sqrt{d}\right| > \theta\sqrt{d}\right] \le C\exp(-c\sqrt{d}\cdot\min(\theta^3,\theta)).$$

Corollary 15 *Let p be a log-concave distribution over $\mathcal{R}^n$ and let $x \sim p$. Assume that $\mathbf{E}[xx^T] = I_d$. Then for some universal C, c it holds for any $\theta \geq 3$ that*

$$\Pr\left[\|x\| > \theta\sqrt{d}\right] \leq C\exp\left(-c\theta\sqrt{d}\right)$$

The following theorem provides a concentration bound for random vectors originating from an arbitrary distribution.

Theorem 16 (Rudelson 1999) *Let X be a vector-valued random variable over $\mathbb{R}^d$ with $\mathbf{E}[XX^\top] = \Sigma$ and $\|\Sigma^{-1/2}X\|^2 \leq R$. Then, for independent samples $X_1, \ldots, X_M$ from X, and $M \geq CR\log(R/\varepsilon)/\epsilon^2$ the following holds with probability at least $1/2$:*

$$\left\|\frac{1}{M}\sum_{i=1}^{M} X_i X_i^\top - \Sigma\right\| \leq \epsilon\|\Sigma\|.$$

Finally, we also make use of barycentric spanners in our application to BLO and we briefly describe them next.

2.3 Barycentric Spanners

Definition 17 (Awerbuch and Kleinberg 2008) *A barycentric spanner of $\mathcal{K} \subseteq \mathcal{R}^d$ is a set of d points $S = \{u_1, \ldots, u_d\} \subseteq \mathcal{K}$ such that any point in $\mathcal{K}$ may be expressed as a linear combination of the elements of S using coefficients in $[-1, 1]$. For $C > 1$, S is a C-approximate barycentric spanner of $\mathcal{K}$ if any point in $\mathcal{K}$ may be expressed as a linear combination of the elements of S using coefficients in $[-C, C]$*

In (Awerbuch and Kleinberg, 2008) it is shown that any compact set has a barycentric spanner. Moreover, they show that given an oracle with the ability to solve linear optimization problems over $\mathcal{K}$, an approximate barycentric spanner can be efficiently obtained. In the following sections we will use this constructive result.

Theorem 18 (Proposition 2.5 in Awerbuch and Kleinberg 2008) *Let $\mathcal{K}$ be a compact set in $\mathcal{R}^d$ that is not contained in any proper linear subspace. Given an oracle for optimizing linear functions over $\mathcal{K}$, for any $C > 1$, it is possible to compute a C-approximate barycentric spanner for $\mathcal{K}$, using $O(d^2 \log_C(d))$ calls to the optimization oracle.*

3. Existence of Volumetric Ellipsoids and Spanners

In this section we show the existence of low order volumetric ellipsoids proving our main structural result, Theorem 3. Before we do so, we first state a few simple properties of volumetric ellipsoids (recall the Definition of **order** from Definition 1):

- The definition of **order** is linear invariant: for any invertible linear transformation $T : \mathbb{R}^d \to \mathbb{R}^d$ and $K \subseteq \mathbb{R}^d$, $\mathbf{order}(\mathcal{K}) = \mathbf{order}(T\mathcal{K})$.

  Proof Let $S \subseteq \mathcal{K}$ be such that $\mathcal{K} \subseteq \mathcal{E}(S)$. Then, clearly $T\mathcal{K} \subseteq \mathcal{E}(TS)$. Thus, $\mathbf{order}(T\mathcal{K}) \leq \mathbf{order}(\mathcal{K})$. The same argument applied to T^{-1} and $T\mathcal{K}$ shows that

Figure 1: In $\mathbb{R}^2$ the order of the volumetric ellipsoid of the equilateral triangle centered at the origin is at least 3. If the vertices are $[0, 1], [-\frac{\sqrt{3}}{2}, -\frac{1}{2}], [\frac{\sqrt{3}}{2}, -\frac{1}{2}]$, then the eigenpoles of the ellipsoid of the bottom two vertices are $[0, \frac{2}{3}], [2, 0]$. The second figure shows one possibility for a volumetric ellipsoid by adding $\frac{3}{4}$ of the first vertex to the previous ellipsoid. This shows the ellipsoid to be non-unique, as it can be rotated three ways.

  $\mathbf{order}(\mathcal{K}) \leq \mathbf{order}(T\mathcal{K})$. ■

- The minimal volumetric ellipsoid is not unique in general; see example in Figure 1. Further, it is in general different from the John ellipsoid.

- For non-degenerate bodies $\mathcal{K}$, their order is naturally lower bounded by d, and there are examples in which it is strictly larger than d (e.g., Figure 1).

In the proof Theorem 3 we require a modification of a result by (Batson et al., 2012) providing a method to sparsity a distribution over vectors while approximately maintaining its covariance matrix. We show that this technique can be applied over the distribution derived from John's decomposition of $\mathcal{K}$ in order to obtain a small set from which we construct a volumetric spanner. We begin by presenting the result given in (Batson et al., 2012), then its modification, and then proceed to the proof of Theorem 3.

Theorem 19 (Theorem 3.1 of Batson et al. 2012) *Let $v_1, \ldots, v_m$ be vectors in $\mathcal{R}^d$ and let $c > 1$. Assume that $\sum_i v_i v_i^\top = I_d$. There exist scalars $s_i \geq 0$ for $i \in [m]$ with $|\{i | s_i > 0\}| \leq cd$ such that*

$$I_d \preceq \sum_i s_i v_i v_i^\top \preceq \frac{c + 1 + 2\sqrt{c}}{c + 1 - 2\sqrt{c}} I_d$$

Furthermore, these scalars can be found in time $O(cd^3m)$.

Lemma 20 *Let $u_1, \ldots, u_m$ be unit vectors and let $p \in \Delta(m)$ be a distribution over $[m]$ such that $d\sum_{i=1}^m p_i u_i u_i^\top = I_d$. Then, there exists a (possibly multi) set $S \subseteq \{u_1, \ldots, u_m\}$ such that $\sum_{v \in S} vv^\top \succeq I_d$ and $|S| \leq 12d$. Moreover, such a set can be computed in time $O(md^3)$.*

Proof Let $v_i = \sqrt{p_i}u_i$. We fix c as some constant whose value will be determined later. Clearly for these vectors v_i it holds that $d\sum_i v_i v_i^\top = I_d$. It follows from the above theorem that there exist some scalars $s_i \geq 0$ for which at most cd are non-zeros and

$$I_d \preceq d\sum_i s_i v_i v_i^\top \preceq \frac{c+1+2\sqrt{c}}{c+1-2\sqrt{c}} I_d \tag{1}$$

Our set S will be composed by taking each u_i $\lceil ds_i p_i \rceil$ many times. Plugging in equation (1) shows that indeed

$$\sum_{w\in S} ww^\top \succeq I_d$$

and it remains to bound the size of S i.e., $\sum \lceil ds_i p_i \rceil$. By taking the trace of the expression and dividing by d we get that

$$\sum_i s_i \text{Trace}(v_i v_i^\top) \preceq \frac{c+1+2\sqrt{c}}{c+1-2\sqrt{c}}$$

Plugging in the expressions for v_i along with u_i being unit vectors (hence $\text{Trace}(u_i u_i^\top) = 1$) lead to

$$\sum_i s_i p_i \preceq \frac{c+1+2\sqrt{c}}{c+1-2\sqrt{c}}$$

It follows that

$$\sum \lceil ds_i p_i \rceil \leq d\frac{c+1+2\sqrt{c}}{c+1-2\sqrt{c}} + |\{i|s_i \geq 0\}| \leq d\left(c + \frac{c+1+2\sqrt{c}}{c+1-2\sqrt{c}}\right)$$

By optimizing c we get $\sum \lceil ds_i p_i \rceil \leq 12d$, and the lemma is proved. ■

Proof of Theorem 3 Let $\mathcal{K} \subseteq \mathbb{R}^d$ be a compact set. Without loss of generality assume that $\mathcal{K}$ is symmetric and contains the origin; we can do so as in the following we only look at outer products of the form $vv^\top$ for vectors $v \in \mathcal{K}$. Further, as $\textbf{order}(\mathcal{K})$ is invariant under linear transformations, we can compute, as detailed in Theorem 7 the MVEE[5] of $\mathcal{K}$ and transform the space into one where this ellipsoid is the Euclidean unit sphere. That is, move $\mathcal{K}$ into John's position, at $\text{poly}(n, d)$ time.

According to Theorem 8 it is then possible to compute a distribution p over $\mathcal{K}$ with

$$d\sum_{x\in\mathcal{K}} p_x xx^\top = I_d$$

Lemma 20 provides a way to compute a (multi-)set S of size at most $12d$ with

$$\sum_{v\in S} vv^\top \succeq I_d$$

5. Notice that the Theorem provides an approximation of $1+\varepsilon$ of the MVEE where the running time scales as $\log(1/\varepsilon)$. In what follows it is easy to see that the precision of all equalities is affected up to a multiplicative factor of $1 \pm \varepsilon$ by this issue. This eventually translates into a set of size $12(1+\varepsilon)d$ rather than $12d$. We omit these technical details for a more readable proof.

Since $\mathcal{K}$ is contained in the unit ball we get that S is a volumetric spanner for $\mathcal{K}$ as required. The total running time required to find s includes the computation of the transformation into John's position, John's decomposition, and its sparsification. The running time amounts to $O(n^{3.5} + dn^3 + nd^3)$. ■

4. Approximate Volumetric Spanners

In this section we provide a construction for (p, ε)-exp-volumetric spanner (as in Definition 4), proving Theorem 5. We start by providing a more technical definition of a spanner. Note that unlike previous definitions, the following is not impervious to linear operators and will only be used to aid our construction.

Definition 21 *A β-relative-spanner is a discrete subset $S \subseteq \mathcal{K}$ such that for all $x \in \mathcal{K}$, $\|x\|^2_{\mathcal{E}(S)} \leq \beta\|x\|^2$.*

A first step is a spectral characterization of relative spanners:

Lemma 22 *Let $S = \{v_1, ..., v_T\} \subseteq \mathcal{K}$ span $\mathcal{K}$ and be such that*

$$W = \sum_{i=1}^T v_i v_i^\top \succeq \frac{1}{\beta} I_d$$

Then S is a β-relative-spanner.

Proof Let $V \in \mathbb{R}^{d\times T}$ be a matrix whose columns are the vectors of S. As $VV^\top = W \succeq \frac{1}{\beta} I_d$ we have that

$$\beta I_d \succeq (VV^\top)^{-1}$$

It follows that

$$\|x\|_{\mathcal{E}(S)} = x^\top (VV^\top)^{-1} x \leq \beta\|x\|^2$$

as required. ■

Proof [Proof of Theorem 5] We analyze the algorithm of sampling i.i.d points according to p, previously defined within Theorem 5, assuming the vectors are sampled exactly according to the log-concave distribution. The result involving an approximate sample, which is necessary for implementing the algorithm in the general case, is an immediate application of Lemma 10 and Corollary 13.

Our analysis of the algorithm is for $T = C(d + \log^2(1/\varepsilon))$ samples, where C is some sufficiently large constant. Assume first that $\mathbf{E}_{x\sim p}[xx^\top] = I_d$. Let $W = \sum_{i=1}^T u_i u_i^\top$. Then, for $C > 0$ large enough, by Corollary 13, $\|\frac{1}{T}W - I_d\| \leq 1/2$ w.p. at least $1 - \exp(-\sqrt{d})$. Therefore, S spans $\mathbb{R}^d$ and

$$\frac{1}{T}W \succeq I_d - \frac{1}{2}I_d = \frac{1}{2}I_d$$

Thus according to Lemma 22, S is a $(2/T)$-relative spanner. Consider the case where $\Sigma = \mathbf{E}_{x\sim p}[xx^\top]$ is not necessarily the identity. By the above analysis we get that

$$\Sigma^{-1/2}S = \{\Sigma^{-1/2}u_1, \ldots, \Sigma^{-1/2}u_T\}$$

form a $(2/T)$-relative spanner for $\Sigma^{-1/2}\mathcal{K}$. This is since the r.v defined as $\Sigma^{-1/2}x$ where $x \sim p$ is log-concave. The latter along with Corollary 15 implies that for any $\theta \geq 1$,

$$\Pr_{x\sim p}\left[\|\Sigma^{-1/2}x\| \geq 3\theta\sqrt{d}\right] \leq c_1 \exp\left(-c_2\theta\sqrt{d}\right) \tag{2}$$

for some universal constants $c_1, c_2 > 0$. It follows that for our set S and any $\theta \geq 1$,

$$\begin{aligned}
\Pr_{x\sim p}\left[\|x\|_{\mathcal{E}(S)} > \theta\right] &= \Pr_{x\sim p}\left[\|\Sigma^{-1/2}x\|_{\mathcal{E}(\Sigma^{-1/2}S)} > \theta\right] && \|x\|_{\mathcal{E}(S)} = \\
&&& \|\Sigma^{-1/2}x\|_{\mathcal{E}(\Sigma^{-1/2}S)} \\
&\leq \Pr_{x\sim p}\left[\|\Sigma^{-1/2}x\| > \theta\sqrt{T/2}\right] && \Sigma^{-1/2}S \text{ is a} \\
&&& 2/T\text{-relative-spanner} \\
&= \Pr_{x\sim p}\left[\|\Sigma^{-1/2}x\| > 3\theta\sqrt{\tfrac{dC}{18}}\cdot\sqrt{1+\tfrac{\log^2(1/\varepsilon)}{d}}\right] && T = C(d+\log^2(1/\varepsilon)) \\
&\leq c_1\exp\left(-c_2\theta\sqrt{d}\sqrt{\tfrac{C}{18}}\cdot\sqrt{1+\tfrac{\log^2(1/\varepsilon)}{d}}\right) && \text{Equation (2), } C \geq 18 \\
&\leq \exp\left(-\theta\sqrt{d+\log^2(1/\varepsilon)}\right) && C \text{ sufficiently large} \\
&\leq \varepsilon^{-\theta}
\end{aligned}$$

■

In our application of volumetric spanners to BLO, we also need the following relaxation of volumetric spanners where we allow ourselves the flexibility to scale the ellipsoid:

Definition 23 *A ρ-ratio-volumetric spanner S of $\mathcal{K}$ is a subset $S \subseteq \mathcal{K}$ such that for all $x \in \mathcal{K}$, $\|x\|_{\mathcal{E}(S)} \leq \rho$.*

One example for such an approximate spanner with $\rho = \sqrt{d}$ is a barycentric spanner (Definition 17). In fact, it is easy to see that a C-approximate barycentric spanner is a $C\sqrt{d}$-ratio-volumetric spanner . The following is immediate from Theorem 18.

Corollary 24 *Let $\mathcal{K}$ be a compact set in $\mathcal{R}^d$ that is not contained in any proper linear subspace. Given an oracle for optimizing linear functions over $\mathcal{K}$, for any $C > 1$, it is possible to compute a $C\sqrt{d}$-ratio-volumetric spanner S of $\mathcal{K}$ of cardinality $|S| = d$, using $O(d^2\log_C(d))$ calls to the optimization oracle.*

5. Fast Volumetric Spanners for Discrete Sets

In this section we describe a different algorithm that constructs volumetric spanners for discrete sets. The order of the spanners we construct here is suboptimal (in particular, there is a dependence on the size of the set $\mathcal{K}$ which we didn't have before). However, the algorithm is particularly simple and efficient to implement (takes time linear in the size of the set).

Algorithm 1 Fast Volumetric Spanner construction

1: Input $\mathcal{K} = \{x_1, ..., x_n\} \subseteq \mathbb{R}^d$, $C \in \mathbb{R}$.
2: Set $T = \emptyset$
3: **while** $|K| > Cd\log d$ **do**
4: Compute $\Sigma = \sum_i x_i x_i^\top$ and let $u_i = \Sigma^{-1/2}x_i$, $p_i = 1/2n + \|u_i\|^2/2d$.
5: Set $S \leftarrow \emptyset$.
6: **for** $i = 1, ..., Cd\log d$ **do**
7: sample with replacement from $[n]$ according to $p_1, \ldots, p_n$: $S \leftarrow S \cup \{i\}$ w.p. p_i
8: **end for**
9: **if** $|\{i\ ,\ \|x_i\|_{\mathcal{E}(S)} \leq 1\}| < \frac{n}{2}$ **then**
10: Set $S \leftarrow \emptyset$ and GOTO step (6).
11: **end if**
12: Set $T \leftarrow T \cup S$
13: Set the remainder as $\mathcal{K} \leftarrow \{x_i \text{ s.t. } \|x_i\|_{\mathcal{E}(S)} > 1\}$
14: **end while**
15: **return** $T \leftarrow T \cup \mathcal{K}$

Theorem 25 *Given a set of vectors $\mathcal{K} = \{x_1, \ldots, x_n\} \in \mathbb{R}^d$, Algorithm 1 outputs a volumetric spanner of size $O((d\log d)(\log n))$ and has an expected running time of $O(nd^2)$.*

Proof Consider a single iteration of the algorithm with input $v_1, \ldots, v_n \in \mathbb{R}^d$. We claim that the random set S obtained in Step 7 satisfies the following condition with constant probability:

$$\Pr_{x\in\mathcal{K}}\left[\|x\|_{\mathcal{E}(S)} \leq 1\right] \geq 1/2 \tag{3}$$

Suppose the above statement is true. Then, the lemma follows easily as it implies that for the next iteration there are fewer than $n/2$ vectors. Hence, after $(\log n)$ recursive calls we will have a volumetric spanner. The total size of the set will be $O((d\log d)(\log n))$. To see the time complexity, consider a single run of the algorithm. The most computationally intensive steps are computing Σ and $\Sigma^{-1/2}$ which take time $O(nd^2)$ and $O(d^3)$ respectively. We also need to compute $(\sum_{v\in S} vv^\top)^{-1}$ (to compute the $\mathcal{E}(S)$ norm) which takes time $O(d^3\log d)$, and compute the $\mathcal{E}(S)$ norm of all the vectors which requires $O(nd^2)$. As $n = \Omega(d\log(d))$, it follows that a single iteration runs of a total expected time of $O(nd^2)$. Since the size of n is split in half between iterations, the claim follows.

We now prove that Equation 3 holds with constant probability

$$x_j^\top\left(\sum_{v\in S} vv^\top\right)^{-1} x_j = u_j^\top\left(\sum_{v\in S'} vv^\top\right)^{-1} u_j. \tag{4}$$

where $S' = \{\Sigma^{-1/2}v | v \in S\}$ is the (linearly) shifted version of S. Therefore, it suffices to show that with sufficiently high probability, the right hand side of the above equation is bounded by 1 for at least $n/2$ indices $j \in [n]$.

Note that $p_i = 1/2n + \|u_i\|^2/2d$ form a probability distribution: $\sum_i p_i = 1/2 + (\sum_i \|u_i\|^2)/2d = 1$. Let $X \in \mathbb{R}^d$ be a random variable with $X = u_i/\sqrt{p_i}$ with probability p_i for $i \in [n]$. Then, $\mathbf{E}[XX^\top] = I_d$. Further, for any $i \in [n]$

$$\|u_i\|^2/p_i \leq 2d.$$

Therefore, by Theorem 16, if we take $M = Cd(\log d)$ samples $X_1, \ldots, X_M$ for C sufficiently large, then with probability of at least $1/2$, it holds that

$$\sum_{i=1}^{M} X_i X_i^\top \succeq (M/2) I_d.$$

Let $T \subseteq [n]$ be the multiset corresponding to the indices of the sampled vectors $X_1, \ldots, X_M$. The above inequality implies that

$$\sum_{i \in T} \frac{1}{p_i} u_i u_i^\top \succeq (M/2) I_d.$$

Now,

$$\sum_{v \in S'} vv^\top \succeq (\min_i p_i) \sum_{v \in S'} \frac{1}{p_i} vv^\top \succeq (\min_i p_i)(M/2) I_d \succeq (M/4n) I_d.$$

Therefore,

$$\begin{aligned}
\sum_{i=1}^{n} u_i^\top \left(\sum_{v \in S'} vv^\top \right)^{-1} u_i &= \sum_{i=1}^{n} \mathrm{Tr}\left(\left(\sum_{v \in S'} vv^\top \right)^{-1} \left(u_i u_i^\top \right) \right) \\
&= \mathrm{Tr}\left(\left(\sum_{v \in S'} vv^\top \right)^{-1} \left(\sum_{i=1}^{n} u_i u_i^\top \right) \right) \\
&= \mathrm{Tr}\left(\left(\sum_{v \in S'} vv^\top \right)^{-1} \right) \\
&\leq \frac{4nd}{M} \leq \frac{4n}{C \log d} \leq \frac{n}{2 \log d},
\end{aligned}$$

for C sufficiently large. Therefore, by Markov's inequality and Equation 4, it follows that Equation 3 holds with high probability. The theorem now follows. ■

6. Experiment design using volumetric spanners

The active linear regression (ALR) problem is formally defined as follows. The input is a pool of n data points $\mathcal{K} = \{x_1, \ldots, x_n\} \subseteq \mathcal{R}^d$, a tolerable error $\varepsilon > 0$ and a confidence

parameter δ. A *query* to a point x returns an unbiased noisy estimate of $\langle w^*, x \rangle$ for some unknown vector $w^* \in \mathcal{R}^d$, with variance bounded by 1. Our objective is to actively choose points to query, and based on these queries, obtain a vector $w \in \mathcal{R}^d$ that with probability at least $1 - \delta$ has a *max-error* of

$$\max_{x \in \mathcal{K}} |\langle w^*, x \rangle - \langle w, x \rangle| < \varepsilon$$

We aim to minimize the *query complexity* of the solution, which is the mean number of queries required by the process. To avoid tedious definitions and details we assume that

1. all of the data points $\{x_i\}$ and w^* are bounded in the Euclidean unit sphere
2. the noise is bounded in absolute value by one with probability one.

Our results can be extended to remove the first assumption, simply by allowing an additional parameter which is the radius of the minimal enclosing Euclidian ball.

It is also possible to remove the second assumption, although this requires more robust estimators, e.g., the median-of-means estimator[6].

6.1 A lower bound for passive linear regression

In this section we provide an example for a set $\mathcal{K}$ where the passive learning algorithm must use $\Omega(\frac{n}{\varepsilon^2})$ observations to obtain a regressor w with additive error of at most ε on all of the data points. We start by formally defining the passive setup. Here, a query returns a random point x chosen uniformly from the set $\mathcal{K}$ and an unbiased noisy measurement of $\langle w^*, x \rangle$, with variance of at most 1. As before we assume that all points, including w^* are contained in the ℓ_2 unit sphere.

The set $\mathcal{K}$ in our example is defined in the following manner. Let $Y \subseteq \mathcal{R}^d$ be an arbitrary set of size $n - 1$ such that for all $x \in Y$, $\langle x, e_1 \rangle = 0$. Let $\mathcal{K} = Y \cup \{e_1\}$. Here, e_1 is the first vector in the standard basis for $\mathcal{R}^d$.

Theorem 26 *Any algorithm in the passive setting achieving an additive error of at most ε in all of the data points of $\mathcal{K}$ whose success probability is $1 - \delta$ requires $\Omega(\log(1/\delta)n/\varepsilon^2)$ queries.*

The theorem is an immediate corollary of the following lemma.

Lemma 27 *For $\mathcal{K}$ defined above, any policy distinguishing between the case where $\langle w^*, e_1 \rangle = -\varepsilon$ and $\langle w^*, e_1 \rangle = \varepsilon$ with probability larger than $1 - \delta$ must use $\Omega(n \log(1/\delta)/\varepsilon^2)$ queries.*

Proof We begin by mentioning that a query of a point x where $\langle x, e_1 \rangle = 0$ provides no information to the sign of $\langle w^*, e_1 \rangle$, hence does not help distinguish between the two hypotheses. The following lemma provides a lower bound to the number of queries at point e_1 required to estimate the $\langle w^*, e_1 \rangle$ up to a sufficiently small additive error and with sufficient confidence. It is a folklore lemma in statistics and appears e.g., in (Mannor and Tsitsiklis, 2004) in a much more general form.

6. The median-of-means estimator is defined as follows: Given m queries to a single dimensional distribution, the estimator of its mean is not taken to be the average of the queries; the m queries are instead split into $\log(1/\delta)$ equal sized buckets, each bucket has its average computed and the estimator is the median of these averages.

Lemma 28 (Theorem 1 of Mannor and Tsitsiklis 2004) *Let $\mathcal{D}$ be a distribution over $[-1,1]$. Let $\varepsilon > 0$ be such that for $X \sim \mathcal{D}$, $|\mathbf{E}[X]| \geq \varepsilon$. Let T be the expected number of queries required by any algorithm that queries i.i.d copies of $X \sim \mathcal{D}$ until being able to distinguish, with probability at least $1-\delta$ between the cases $\mathbf{E}[X] \leq -\varepsilon$ and $\mathbf{E}[X] \geq \varepsilon$. Then for universal constants $\varepsilon_0 > 0$, $\delta_0 > 0$, c_1, c_2 it holds that if $\varepsilon < \varepsilon_0$ and $\delta < \delta_0$ then $T \geq \frac{c_1 \log(c_2/\delta)}{\varepsilon^2}$.*

It follows that the expected number of queries needed in order to distinguish between the two hypotheses with probability $\geq 1-\delta$ is at least $\frac{c_1 n \log(c_2/\delta)}{\varepsilon^2}$, as the probability of observing a query to the inner product with e_1 is $1/n$. ■

6.2 Our ALR solution

In this section prove the following.

Theorem 29 *There exists an algorithm to the ALR problem with success probability of at least*
$1-\delta$ and with the following properties:

1. *The algorithm requires a preprocessing stage for building a volumetric spanner over $\mathcal{K}$*
2. *It's running time (after preprocessing) is $\tilde{O}\left(\frac{nd\log(1/\delta)}{\varepsilon^2}\right)$*
3. *It's query complexity is at most $O\left(\frac{d\log(n)\log(1/\delta)}{\varepsilon^2}\right)$.*

The intuition behind the algorithm is the following. We begin with a preprocessing stage of computing a volumetric spanner S for the set of points $\mathcal{K}$. Given this spanner we can implement a procedure that outputs, for all of the points of $\mathcal{K}$ simultaneously, an unbiased estimator of $\langle w^*, x\rangle$ with variance of at most $|S|$. To demonstrate the usefulness of this estimator, consider averaging $|S|\log(n/\delta)/\varepsilon^2$ i.i.d outputs of S. Standard concentration bound show that w.p at least $1-\delta$ the estimates of all points in $\mathcal{K}$ are correct up to an additive error of ε. Rather than computing a noisy output for w^* on the points and recovering a hypothesis w from that we use a technique by (Clarkson et al., 2012) that given an oracle for a function over a set of data points constructs a hypothesis w using a small number of queries to the oracle.

6.2.1 Constructing a low variance estimator

The main component of our method is a black box providing a noisy estimate of $\langle x, w^*\rangle$ to all of the data point of $\mathcal{K}$ simultaneously. The intuition behind the algorithm we describe next, is that given sufficiently many queries to the noisy estimator, a union bound argument can ensure an accurate estimate in all of the data points simultaneously.

We begin with the description of this black box providing the estimates. The main tool used for this 'all-point-estimator' is a volumetric spanner for the set $\mathcal{K}$. Algorithm 2 provides the formal description of how a volumetric spanner can be used to obtain these estimates.

The following lemma provides the analysis of Algorithm 2.

Algorithm 2 Sample($\mathcal{K}$)

1: Input: set $\mathcal{K} = \{x_1, ..., x_n\}$, Volumetric spanner for $\mathcal{K}$ denoted S, and measurement oracle that given x returns an unbiased estimator $\widehat{\langle x, w^*\rangle}$ with variance at most one for some fixed w^*.
2: Choose a point $v_j \in S$ uniformly at random, query its inner product $\hat{\ell} = \widehat{\langle v_j, w^*\rangle}$
3: let V be the $d \times |S|$ matrix whose columns are the elements of S, and let $V^\dagger \in \mathcal{R}^{|S|\times d}$ be its Moore-Penrose pseudo inverse.
4: For $x \in \mathcal{K}$, let $\alpha_x = V^\dagger x$ and let $\hat{\ell}_x \leftarrow (\alpha_x)_j \hat{\ell} \cdot |S|$
5: **return** estimates $\{\hat{\ell}_x\}_{x\in\mathcal{K}}$

Lemma 30 *Algorithm 2 queries a single point from $\mathcal{K}$. Its estimates have the properties of (1) being unbiased and (2) have a variance of at most $12d$. More formally, we have*

$$\forall x \in \mathcal{K}\ .\ \mathbf{E}[\hat{\ell}_x] = \langle x, w^*\rangle\ ,\ \mathbf{Var}(\hat{\ell}_x) \leq |S| \leq 12d$$

Proof

$$\begin{aligned}\mathbf{E}\left[\hat{\ell}_x\right] &= \textstyle\sum_{j\in S} \Pr[v_j] \cdot (\alpha_x)_j \,\mathbf{E}\,\widehat{\langle v_j, w^*\rangle} \cdot |S| \\ &= \textstyle\sum_{j\in S} (\alpha_x)_j \,\mathbf{E}\,\widehat{\langle v_j, w^*\rangle} \\ &= (V^\dagger x)^T V^T w^* = \langle x, w^*\rangle\end{aligned}$$

For the variance, recall that $x \in \mathcal{K}$ and S is a volumetric spanner of $\mathcal{K}$ indicates that $\|\alpha_x\|_2 \leq 1$:

$$\begin{aligned}\mathbf{E}[\hat{\ell}_x^2] &= \textstyle\sum_{j\in S} \Pr[v_j] \cdot (\alpha_x)_j^2 \,\mathbf{E}\left[\widehat{\langle v_j, w^*\rangle}^2\right] \cdot |S|^2 \\ &\leq |S| \textstyle\sum_{j\in S} (\alpha_x)_j^2 \leq |S|\end{aligned}$$

By Theorem 3 we can efficiently construct volumetric spanners of size $|S| = 12d$. ■

6.2.2 Algorithm and its analysis

In this section we present an algorithm for the ALR problem, following the primal-dual paradigm as in (Clarkson et al., 2012), and specifically their meta algorithm 3. This latter meta-algorithm can be used to solve any convex constrained feasibility problem, of which our ALR problem is a special case. The idea is to apply a low regret algorithm to a distribution over the constraints. The distribution over the constraints is changed according to a multiplicative update rule. The specific meta-algorithm we apply uses random estimates of the constraints that enable faster running time. We proceed to spell out the details.

To avoid extraneous notions we will assume henceforth w.l.o.g that $\mathcal{K}$ is symmetric meaning that $x \in \mathcal{K}$ iff $-x \in \mathcal{K}$. This is without loss of generality since an unbiased estimator for $\langle -x, w^*\rangle$ is obtained by negating the estimator for $\langle x, w^*\rangle$.

We write the ALR problem as the following mathematical program:

$$\min_{\|w\|\leq 1} g(w) \quad s.t. \qquad g(w) = \max_{x\in\mathcal{K}} c_x(w) \tag{5}$$
$$c_x(w) = \langle x, w\rangle - \langle x, w^*\rangle$$

Note that by definition $g(w^*) = 0$, which is the optimal solution to the problem as $\mathcal{K}$ is symmetric. In addition, an ε approximate solution to the ALR instance, assuming $\|w^*\| \leq 1$, corresponds to a vector $\hat{w}$ with $g(\hat{w}) \leq \varepsilon$.

Algorithm 3 Primal-Dual Algorithm for ALR

Input: T
Let $w_1 \leftarrow 0$, $q_0 \leftarrow \mathbf{1}_n$, $\eta \leftarrow \frac{1}{100}\sqrt{\frac{\log(n)}{T}}$.
for $t = 1$ to T **do**
  Query **Sample**($\mathcal{K}$) $12d$ times to obtain unit-variance zero-mean estimators $\tilde{a}_t(i)$ for all constraints c_i's:

$$\tilde{a}_t(i) \stackrel{\text{def}}{=} \langle x_i, w_t\rangle - \widehat{\langle x_i, w^*\rangle}$$

  where $\widehat{\langle x_i, w^*\rangle}$ is the estimate of $\langle x_i, w^*\rangle$ given by **Sample**($\mathcal{K}$).
  for $i \in [n]$ **do**
    $a_t(i) \leftarrow \text{clip}(\tilde{a}_t(i), 1/\eta)$, where

$$\text{clip}(\alpha, \beta) = \begin{cases} \min\{\alpha, |\beta|\} & \alpha \geq 0 \\ \max\{-\alpha, -|\beta|\} & \alpha < 0 \end{cases}$$

    $q_t(i) \leftarrow q_{t-1}(i)(1 - \eta a_t(i) + \eta^2 a_t(i)^2)$
  end for
  Choose $i_t \in [n]$ at random with $\Pr[i_t = i] \propto q_t(i)$
  $w_t \leftarrow w_{t-1} - \frac{1}{\sqrt{t}}\nabla_w c_{i_t}$, where $\nabla_w c_{i_t} = x_{i_t}$
end for
return $\bar{w} = \frac{1}{T}\sum_t w_t$

The following theorem bounds the performance of Algorithm 3. It immediately follows from Lemma 4.1 in (Clarkson et al., 2012).

Theorem 31 *Algorithm 3 runs in time $\tilde{O}(\frac{dn}{\varepsilon^2})$ and requires $O(\frac{d\log n}{\varepsilon^2})$ queries to the procedure* **Sample**($\mathcal{K}$)*. It returns, with probability of at least $\frac{1}{2}$, a vector w such that $\max_{x\in\mathcal{K}}\langle w - w^*, x\rangle \leq \varepsilon$.*

Proof

Notice that Algorithm 3 is an instantiation of Alg 3 from (Clarkson et al., 2012) applied to mathematical Program 5 with the following arguments:

1. The primal decision set $\{\|w\| \leq 1\}$ and (linear) cost functions $c_x(w)$, admits an iterative low regret algorithm, namely online gradient descent, with expected regret $\mathbf{E}[R(T)] \leq 2\sqrt{T}$. This follows since the norms of x, w (for all $x \in \mathcal{K}$) are bounded by one. See e.g., Theorem 1 by (Zinkevich, 2003).

   The expression $T_\epsilon(LRA)$ (here LRA stands for Low Regret Algorithm, and not the Active Linear Regression problem we are addressing) refers to the number T such that the average regret of online gradient descent is at most ϵ, in our case, this is $\frac{4}{\epsilon^2}$.

2. Meta-algorithm 3 in (Clarkson et al., 2012) assumes an oracle to a procedure **Sample**($\mathcal{K}$) that returns a vector of length $|\mathcal{K}|$ whose entries are unbiased estimators of $\langle x, w^*\rangle$, for all $x \in \mathcal{K}$ whose variance is upper bounded by 1. Recall that such a procedure, with variance $12d$ rather than 1, was given in Section 6.2.1. By averaging $12d$ such samples we obtain unit-variance estimates.

Thus, Lemma 4.1 (Clarkson et al., 2012) implies that the algorithm returns w.p. $\frac{1}{2}$ an ϵ-approximate solution in number of iterations bounded by

$$\max\{T_\epsilon(LRA), \frac{\log n}{\epsilon^2}\} \leq \frac{\log n}{\epsilon^2}$$

Each iteration involves elementary operations that can be implemented in time $\tilde{O}(nd)$ and $O(d)$ queries to **Sample**.

■

6.2.3 Validation and high probability algorithm

Algorithm 3 provides a method to obtain an approximated solution to the ALR problem with probability $1/2$. We now describe a method to amplify the success probability to $1-\delta$. The idea is to use a validation procedure and repeat the algorithm multiple times. It is easy to see that with a validation process, repeating Algorithm 3 for $O(\log(1/\delta))$ many times will increase the probability of success to $1 - \delta$.

We now describe a validation procedure that is in itself random, in the sense that it may err but its error probability is manageable. Algorithm 4 is given as input a hypothesis w and a ALR problem. It verifies, w.h.p., that w is an ε-approximate solution to the ALR problem accurate.

Algorithm 4 Verification

Input: Volumetric spanner S, parameters $\varepsilon, \delta > 0$, hypothesis $w \in \mathcal{R}^d$.
run **Sample**($\mathcal{K}$) $T = 2\ln(2n/\delta)|S|/\varepsilon^2$ times and obtain for each data point in $\mathcal{K}$, T i.i.d samples of $\langle w^*, x\rangle$
for each $x \in \mathcal{K}$ let $\tilde{f}(x)$ be the average of the above T samples.
declare w as accurate iff for all x, $|\langle w, x\rangle - \tilde{f}(x)| < 2\varepsilon$

Lemma 32 *Algorithm 4 has the following properties:*

- *It requires $O(\log(n/\delta)|S|/\varepsilon^2)$ queries to the oracle* **Sample**($\mathcal{K}$)

- *If the worst-case error of w is bounded by ε then w.p. at least $1-\delta$ it will be declared as accurate*
- *If the worst-case error of w is larger than 3ε then w.p. at least $1-\delta$ it will be declared as inaccurate.*

Proof We recall that the process **Sample**($\mathcal{K}$) returns unbiased estimates of $\langle w^*, x\rangle$ for all of the data points where the estimates are bounded in absolute value by $|S|$. Fix some point $x \in \mathcal{K}$. Chernoff's inequality dictates that

$$\Pr\left[\left|\langle w^*, x\rangle - \tilde{f}(x)\right| > \varepsilon\right] \leq 2\exp\left(-\frac{\varepsilon^2}{2|S|}\cdot\frac{2\ln(2n/\delta)|S|}{\varepsilon^2}\right) = \delta/n$$

Hence, w.p at least $1-\delta$ it holds for all $x \in \mathcal{K}$ simultaneously that $\left|\langle w^*, x\rangle - \tilde{f}(x)\right| < \varepsilon$. The claim immediately follows by using the triangle inequality in order to bound $\left|\langle w, x\rangle - \tilde{f}(x)\right|$. ■

Corollary 33 *There exists an algorithm that runs in time $\tilde{O}\left(\frac{dn\log\frac{1}{\delta}}{\varepsilon^2}\right)$ and returns, with probability of at least $1-\delta$, a vector w such that $\max_{x\in\mathcal{K}}\langle w - w^*, x\rangle \leq \varepsilon$.*

Proof Given the parameter δ, we run $\log(1/2\delta)$ independent copies of Algorithm 3 with parameter $\varepsilon' = \varepsilon/3$. Each such copy will produce a hypothesis w. We check for each such hypothesis w whether it is $\varepsilon' = \varepsilon/3$ accurate using Algorithm 4, with success probability $1-\delta/2\log(1/2\delta)$. With probability $1/2\delta$, all of the occurrences of the validation procedures will not err. Also, with probability at least $1-2\delta$ at least one hypothesis will be sufficiently accurate. Hence, by union bound we have with probability at least $1-\delta$ that at least one hypothesis will be declared accurate and any of the hypotheses declared accurate will be at least $3\varepsilon' = \varepsilon$ accurate. This concludes the quality of the output of the algorithm. The running time analysis is trivial. ■

7. Bandit Linear Optimization

Recall the problem of Bandit Linear Optimization (BLO): iteratively at each time sequence t, the environment chooses a loss vector L_t that is not revealed to the player. The player chooses a vector $x_t \in \mathcal{K}$ where $\mathcal{K} \subseteq \mathbb{R}^d$ is convex, and once she commits to her choice, the loss $\ell_t = x_t^\top L_t$ is revealed. The objective is to minimize the loss and specifically, the regret, defined as the strategy's loss minus the loss of the best fixed strategy of choosing some $x^* \in \mathcal{K}$ for all t. We henceforth assume that the loss vectors L_t's are chosen from the polar of $\mathcal{K}$, meaning from $\{L : |L^\top x| \leq 1\ \forall x \in \mathcal{K}\}$. In particular this means that the losses are bounded in absolute value, although a different choice of assumption (i.e., ℓ_∞ bound on the losses) can yield different regret bounds, see discussion in (Audibert et al., 2011).

The problem of BLO is a natural generalization of the classical Multi-Armed Bandit problem and extremely useful for efficiently modeling decision making under partial feedback for structured problems. As such the research literature is rich with algorithms and insights

into this fundamental problem (see surveys Bubeck and Cesa-Bianchi 2012b and Hazan 2014). In this section we focus on the first efficient and optimal-regret algorithm, and thus immediately jump to Algorithm 5. We make the following assumptions over the decision set $\mathcal{K}$:

1. The set $\mathcal{K}$ is equipped with a membership oracle. This implies via the results by (Lovász and Vempala, 2007) (Lemma 10) that there exists an efficient algorithm for sampling from a given log-concave distribution over $\mathcal{K}$. Via the discussion in previous sections, this also implies that we can construct approximate (both types of approximations, see Definitions 23 and 4) volumetric spanners efficiently over $\mathcal{K}$.
2. The losses are bounded in absolute values by 1. That is, the loss functions are always chosen (by an oblivious adversary) from a convex set $\mathcal{Z}$ such that $\mathcal{K}$ is contained in its polar, i.e., $\forall L \in \mathcal{Z}, x \in \mathcal{K}$, $|L^\top x| \leq 1$. This implies that the set $\mathcal{K}$ admits for any $\varepsilon > 0$ an ε-net, w.r.t the norm defined by $\mathcal{Z}$, whose size we denote by $|K|_\varepsilon \leq (\varepsilon/2)^{-d}$.

For Algorithm 5 we prove the optimal regret of Theorem 34.

Remark: notice that to obtain a (p,ε)-exp-volumetric spanner for a log-concave distribution p over a body $\mathcal{K}$ we simply choose sufficiently many i.i.d samples from p. Since in Algorithm 5 p_t is always log-concave, it follows that S'_t consists of i.i.d samples from p_t, meaning that if we would not have required S''_t, the exploration and exploration strategies would be the same! Since we still require the set S''_t, there exists a need for a separate exploration strategy. Interestingly, the $2\sqrt{d}$-ratio-volumetric spanner is obtained by taking a barycentric spanner, which is the exploration strategy given in (Dani et al., 2007).

Algorithm 5 GeometricHedge with Volumetric Spanners Exploration

$\mathcal{K}$, parameters γ, η, horizon T.
$p_1(x)$ uniform distribution over $\mathcal{K}$.
for $t = 1$ to T **do**
  Let S'_t be a $(p_t, \exp(-(4\sqrt{d} + \log(2T))))$-exp-volumetric spanner of $\mathcal{K}$.
  Let S''_t be a $2\sqrt{d}$-ratio-volumetric spanner of $\mathcal{K}$
  Set S_t as the union of S'_t, S''_t.
  $\hat{p}_t(x) = (1-\gamma)p_t(x) + \frac{\gamma}{|S_t|}1_{x\in S_t}$
  sample x_t according to $\hat{p}_t$ (via the tools described in Lemma 10)
  observe loss $\ell_t \triangleq L_t^\top x_t$
  Let $C_t \triangleq \mathbf{E}_{x\sim\hat{p}_t}[xx^\top]$
  $\hat{L}_t \triangleq \ell_t C_t^{-1} x_t$
  $p_{t+1}(x) \propto p_t(x)e^{-\eta\hat{L}_t^\top x}$
end for

Theorem 34 *Under the assumptions stated above, and let $s = \max_t |S_t|$, $\eta = \sqrt{\frac{\log|\mathcal{K}|_{1/T}}{dT}}$ and let $\gamma = s\sqrt{\frac{\log(|\mathcal{K}|_{1/T})}{dT}}$. Algorithm 5 given parameters γ, η suffers a regret bounded by*

$$O\left((s+d)\sqrt{\frac{T\log|\mathcal{K}|_{1/T}}{d}}\right)$$

We note that while the size $\log(|\mathcal{K}|_{1/T})$ can be bounded by $d\log(T)$, in certain scenarios such as s-t paths in graphs it is possible to obtain sharper upper bounds that immediately imply better regret via Theorem 34.

Corollary 35 *There exist an efficient algorithm for BLO for any convex set $\mathcal{K}$ with regret of*

$$O\left(\sqrt{dT\log|\mathcal{K}|_{1/T}}\right) = O\left(d\sqrt{T\log(T)}\right)$$

Proof The spanner in Step 4 of the algorithm does not have to be explicitly constructed. According to Theorem 5, to obtain such as spanner it suffices to sample sufficiently many points from the distribution p_t, hence this portion of the exploration strategy is identical to the exploitation strategy.

According to Corollary 24, a $2\sqrt{d}$-ratio-volumetric spanner of size d can be efficiently constructed, given a linear optimization oracle which in turn can be efficiently implemented by the membership oracle for $\mathcal{K}$. Hence, it follows that for the purpose of the analysis, $s = d$ and the bound follows. ■

To prove the theorem we follow the general methodology used in analyzing the performance of the geometric hedge algorithm. The major deviation from standard technique is the following sub-exponential tail bound, which we use to replace the the standard absolute bound for $|\hat{L}_t x|$. After giving its proof and a few auxiliary lemmas, we give the proof of the main theorem.

Lemma 36 *Let $x \sim p_t$, $x_t \sim \hat{p}_t$ and let $\hat{L}_t$ be defined according to x_t. It holds, for any $\theta > 1$ that*

$$\Pr\left[|\hat{L}_t^\top x| > \frac{\theta s}{\gamma}\right] \le \exp(-2\theta)/T$$

Proof

$$\begin{aligned}
\Pr\left[|\hat{L}_t^\top x| > \frac{\theta s}{\gamma}\right] &\le \Pr\left[\|x\|_{\mathcal{E}(S_t)} \cdot \|x_t\|_{\mathcal{E}(S_t)} \ge \theta\right] && \text{Lemma 37}\\
&\le \Pr\left[\|x\|_{\mathcal{E}(S_t)} \ge \sqrt{\theta} \ \bigvee \ \|x_t\|_{\mathcal{E}(S_t)} \ge \sqrt{\theta}\right]\\
&\le \Pr\left[\|x\|_{\mathcal{E}(S_t)} \ge \sqrt{\theta}\right] + \Pr\left[\|x_t\|_{\mathcal{E}(S_t)} \ge \sqrt{\theta}\right]\\
&\le 2\Pr\left[\|x\|_{\mathcal{E}(S_t)} \ge \sqrt{\theta}\right]
\end{aligned}$$

To justify the last inequality notice that $x \sim p_t$ and $x_t \sim \hat{p}_t$ where $\hat{p}_t$ is a convex sum of p_t and a distribution q_t for which $\Pr_{y\sim q_t}\left[\|y\|_{\mathcal{E}(S_t)} \ge \sqrt{\theta} > 1\right] = 0$. Before we continue recall that we can assume that $\sqrt{\theta} \le 2\sqrt{d}$, since S_t'' is a $2\sqrt{d}$-ratio-volumetric spanner .

$$\begin{aligned}
\Pr\left[|\hat{L}_t^\top x| > \frac{\theta s}{\gamma}\right] &\le 2\Pr\left[\|x\|_{\mathcal{E}(S_t)} \ge \sqrt{\theta}\right]\\
&\le 2\exp(-\sqrt{\theta}(4\sqrt{d} + \log 2T)) && \text{property of exp-volumetric spanner}\\
&\le \tfrac{1}{T}\exp(-2\sqrt{\theta\cdot 4d})\\
&\le \tfrac{1}{T}\exp(-2\theta) && \text{since } \theta \le 4d
\end{aligned}$$

■

Lemma 37 *For all $x \in \mathcal{K}$ it holds that $|\hat{L}_t^\top x| \le \frac{|S_t|\|x\|_{\mathcal{E}(S_t)}\|x_t\|_{\mathcal{E}(S_t)}}{\gamma}$.*

Proof Let $x \in \mathcal{K}$. Denote by V_t the matrix whose columns are the elements of S_t and recall that $\|y\|^2_{\mathcal{E}(S_t)} = y^\top(V_tV_t^\top)^{-1}y$. Since $C_t \triangleq \mathbf{E}_{x\sim\hat{p}_t}[xx^\top]$, it holds that

$$C_t \succeq \frac{\gamma}{|S_t|}\sum_{v\in S_t} vv^\top = \frac{\gamma}{|S_t|}V_tV_t^\top$$

since both matrices are full rank, it holds that

$$C_t^{-1} \preceq \frac{|S_t|}{\gamma}(V_tV_t^\top)^{-1}$$

Notice that due to the Cauchy-Schwartz inequality,

$$|x^\top\hat{L}_t| = |\ell_t|\cdot|x^\top C_t^{-1}x_t| \le |\ell_t|\cdot\|x^\top C_t^{-1/2}\|\cdot\|C_t^{-1/2}x_t\|$$

The matrix $C_t^{-1/2}$ is defined as C_t is positive definite. Now,

$$\|x^\top C_t^{-1/2}\|^2 = x^\top C_t^{-1}x \le x^\top\frac{|S_t|}{\gamma}(V_tV_t^\top)^{-1}x = \frac{|S_t|}{\gamma}\|x\|^2_{\mathcal{E}(S_t)}$$

Since the analog can be said for $\|C_t^{-1/2}x_t\|$ (as $x_t \in \mathcal{K}$), it follows that

$$|x^\top\hat{L}_t| \le |\ell_t|\frac{|S_t|\|x\|_{\mathcal{E}(S_t)}\|x_t\|_{\mathcal{E}(S_t)}}{\gamma} \le \frac{|S_t|\|x\|_{\mathcal{E}(S_t)}\|x_t\|_{\mathcal{E}(S_t)}}{\gamma}$$

The last inequality is since we assume the rewards are in $[-1, 1]$. ■

Implementation for general convex bodies. In the case where the set $\mathcal{K}$ is a general convex body, the analysis must include the fact that we can only approximately sample a log-concave distribution over $\mathcal{K}$. As the main focus of our work is to prove a polynomial solution we present only a simple analysis yielding a running time polynomial in the dimension d and horizon T. It is likely that a more thorough analysis can substantially reduce the running time.

Corollary 38 *In the general case where an approximate sampling is required, Algorithm 5 can be implemented with a running time of $\tilde{O}(d^5 + d^3T^6)$ per iteration.*

Proof

Fix an error parameter δ, and let us run Algorithm 5 with the approximate samplers p'_t guaranteed by Theorem 10. Then, in each use of the sampler we are replacing the true distribution we should be using p_t, with a distribution p'_t such that statistical distance between p_t, p'_t is at most δ. Let us now analyze the error incurred by this approximation by bounding

the loss from the first round onwards. Suppose the algorithm ran with the approximate sampler in the first round but the exact sampler in each round afterwards. Then, as the statistical distance between the distributions is at most δ and the loss in each round is bounded by 1 and there are T rounds, the net difference in expected regret between using p_1 and p'_1 will be at most $\delta \cdot T$. Similarly, if we ran the algorithm with $p'_1, \ldots, p'_{i-1}, p'_i, p_{i+1}, \cdots, p_T$ as opposed to[7] $p'_1, \ldots, p'_{i-1}, p_i, p_{i+1}, \cdots, p_T$ (we are changing the i'th distribution from exact to approximate), the net difference in expected regret would be at most $\delta \cdot T$. Therefore, the total additional loss we may incur for using the approximate oracles is at most $T \cdot (\delta T) = \delta T^2$. Thus, if we take $\delta = \Delta/T^2$, where Δ is the regret bound from Theorem 34, we get a regret bound of 2Δ. The required value of δ is bounded by $T^{-1.5}$. Applying Theorem 10 leads to a running time of $\tilde{O}(d^5 + d^3 T^6)$ per iteration. ■

7.1 Proof of Theorem 34

We continue the analysis of the Geometric Hedge algorithm similarly to (Dani et al., 2007; Bubeck et al., 2012), under certain assumptions over the exploration strategy. For convenience we will assume that the set of possible arms $\mathcal{K}$ is finite. This assumption holds w.l.o.g since if $\mathcal{K}$ is infinite, a $\sqrt{1/T}$-net of it can be considered as described earlier (this will have no effect on the computational complexity of our algorithm, but a mere technical convenience in the proof below).

Before proving the theorem we will require three technical lemmas. In the first we show that $\hat{L}_t$ is an unbiased estimator of L_t. In the second, we bound a proxy of its variance. In the third, we bound a proxy of the expected value of its exponent.

Lemma 39 *In each t, $\hat{L}_t$ is an unbiased estimator of L_t*

Proof

$$\hat{L}_t = \ell_t C_t^{-1} x_t = (L_t^\top x_t) C_t^{-1} x_t = C_t^{-1}(x_t x_t^\top) L_t$$

Hence,

$$\mathop{\mathbf{E}}_{x_t \sim p_t}[\hat{L}_t] = C_t^{-1} \mathop{\mathbf{E}}_{x_t \sim p_t}[x_t x_t^\top] L_t = C_t^{-1} C_t L_t = L_t$$

■

Lemma 40 *Let $t \in [T]$, $x \sim p_t$ and $x_t \sim \hat{p}_t$. It holds that $\mathbf{E}[(\hat{L}_t^\top x)^2] \le d/(1-\gamma) \le 2d$*

Proof For convenience, denote by q_t the uniform distribution over S_t - the exploration strategy at round t. First notice that for any $x \in \mathcal{K}$,

$$\begin{aligned}\mathop{\mathbf{E}}_{x_t \sim \hat{p}_t}[(\hat{L}_t^\top x)^2] &= x^\top \mathbf{E}_{x_t \sim \hat{p}_t}[\hat{L}_t \hat{L}_t^\top] x = x^\top \mathbf{E}_{x_t \sim \hat{p}_t}[\ell_t^2 C_t^{-1} x_t x_t^\top C_t^{-1}] x \\ &= \ell_t^2 x^\top C_t^{-1} \mathbf{E}_{x_t \sim \hat{p}_t}[x_t x_t^\top] C_t^{-1} x = \ell_t^2 x^\top C_t^{-1} x \\ &\le x^\top C_t^{-1} x \end{aligned} \tag{6}$$

7. Here, p_j's are interpreted as the distribution given by the algorithm based on the distribution from previous round and p'_j is the approximate oracle for this distribution p_j.

Next,

$$\mathop{\mathbf{E}}_{x \sim \hat{p}_t}[x^\top C_t^{-1} x] = \mathop{\mathbf{E}}_{x \sim \hat{p}_t}[C_t^{-1} \bullet x x^\top] = C_t^{-1} \bullet \mathop{\mathbf{E}}_{x \sim \hat{p}_t}[x x^\top] = C_t^{-1} \bullet C_t = \mathbf{Tr}(I_d) = d$$

Where we used linearity of expectation and denote $A \bullet B = \mathbf{Tr}(AB)$. Since C_t^{-1} is positive semi definite,

$$(1-\gamma) \mathop{\mathbf{E}}_{x \sim p_t}[x^\top C_t^{-1} x] \le (1-\gamma) \mathop{\mathbf{E}}_{x \sim p_t}[x^\top C_t^{-1} x] + \gamma \mathop{\mathbf{E}}_{x \sim q_t}[x^\top C_t^{-1} x] = \mathop{\mathbf{E}}_{x \sim \hat{p}_t}[x^\top C_t^{-1} x] = d \tag{7}$$

The lemma follows from combining Equations 6 and 7. ■

Lemma 41 *Denote by $\mathbf{1}_\phi$ the random variable taking a value of 1 if event ϕ occurred and 0 otherwise. Let $t \in [T]$, $x_t \sim \hat{p}_t$ and $x \sim p_t$. For $\hat{L}_t$ defined by x_t it holds that*

$$\mathbf{E}\left[\exp(-\eta \hat{L}_t^\top x) \mathbf{1}_{-\eta \hat{L}_t^\top x > 1}\right] \le \frac{2}{T}$$

Proof Let f, F be the pdf and cdf of the random variable $Y = -\eta \hat{L}_t^\top x$ correspondingly. From Lemma 36 and the fact that $1/\eta = s/\gamma$ ($s = \max_t |S_t|$) we have that for any $\theta \ge 1$,

$$1 - F(\theta) \le \frac{1}{T} e^{-2\theta}$$

and we'd like to prove that under this condition,

$$\mathbf{E}[e^Y \mathbf{1}_{Y>1}] = \int_{\theta=1}^{\infty} e^\theta f(\theta) d\theta \le \frac{2}{T}$$

which follows from the definition of the cdf and pdf:

$$\begin{aligned}\mathbf{E}[e^Y \mathbf{1}_{Y>1}] &= \textstyle\int_{\theta=1}^{\infty} e^\theta f(\theta) d\theta \\ &= \textstyle\sum_{k=1}^{\infty} \int_{\theta=k}^{k+1} e^\theta f(\theta) d\theta \\ &\le \textstyle\sum_{k=1}^{\infty} e^{k+1} \int_{\theta=k}^{k+1} f(\theta) d\theta \\ &\le \textstyle\sum_{k=1}^{\infty} e^{k+1} (F(k+1) - F(k)) \\ &\le \textstyle\sum_{k=1}^{\infty} e^{k+1} (1 - F(k)) \\ &\le \textstyle\sum_{k=1}^{\infty} e^{k+1} \cdot \frac{1}{T} e^{-2k} && \text{Lemma 36} \\ &= \textstyle\frac{e}{T} \sum_{k=1}^{\infty} e^{-k} = \frac{e}{T} \cdot \frac{e^{-1}}{1-e^{-1}} \le \frac{2}{T}\end{aligned}$$

■

Proof [Proof of Theorem 34] For convenience we define within this proof for $x \in \mathcal{K}$, $\hat{\ell}_{1:t-1}(x) \triangleq \sum_{i=1}^{t-1} \hat{L}_i^\top x$ and let $\hat{\ell}_t(x) \triangleq \hat{L}_t^\top x$. Let $W_t = \sum_{x \in \mathcal{K}} \exp(-\eta \hat{\ell}_{1:t-1}(x))$. For all

$t \in [T]$:

$$\begin{aligned}
\mathbf{E}\left[\frac{W_{t+1}}{W_t}\right] &= \mathbf{E}\left[\sum_{x\in\mathcal{K}} \frac{\exp(-\eta\hat{\ell}_{1:t-1}(x))\exp(-\eta\hat{\ell}_t(x))}{W_t}\right] \\
&= \mathbf{E}_{x_t\sim\hat{p}_t}\left[\sum_{x\in\mathcal{K}} p_t(x)\exp(-\eta\hat{\ell}_t(x))\right] \\
&= \mathbf{E}_{x_t\sim\hat{p}_t, x\sim p_t}[\exp(-\eta\hat{\ell}_t(x))] \leq \\
&\leq 1 - \eta\,\mathbf{E}[\hat{L}_t^\top x] + \eta^2\,\mathbf{E}[(\hat{L}_t^\top x)^2] + \mathbf{E}\left[\exp(-\eta\hat{L}_t^\top x)\mathbf{1}_{-\eta\hat{L}_t^\top x>1}\right]
\end{aligned}$$

using the inequality $\exp(y) \leq 1 + y + y^2 + \exp(y)\cdot\mathbf{1}_{y>1}$

$$\leq 1 - \eta\,\mathbf{E}[\hat{L}_t^\top x] + \eta^2\,\mathbf{E}[(\hat{L}_t^\top x)^2] + \tfrac{2}{T} \qquad \text{Lemma 41}$$

Since $\hat{L}_t$ is an unbiased estimator of L_t (Lemma 39) and according to Lemma 40, $\mathbf{E}[(\hat{L}_t^\top x)^2] \leq 2d$, we get:

$$\mathbf{E}\left[\frac{W_{t+1}}{W_t}\right] \leq 1 - \eta L_t^\top \mathop{\mathbf{E}}_{x\sim p_t}[x] + 2\eta^2 d + \frac{2}{T} \tag{8}$$

We now use Jensen's inequality:

$$\begin{aligned}
\mathbf{E}[\log(W_T)] - \mathbf{E}[\log(W_1)] &= \mathbf{E}[\log(W_T/W_1)] \\
&= \textstyle\sum_{t=1}^{T-1} \mathbf{E}[\log(W_{t+1}/W_t)] \\
&\leq \textstyle\sum_{t=1}^{T-1} \log(\mathbf{E}[W_{t+1}/W_t]) && \text{Jensen} \\
&\leq \textstyle\sum_{t=1}^{T-1} \log\left(1 - \eta L_t^\top \mathbf{E}_{x\sim p_t}[x] + 2\eta^2 d + \frac{2}{T}\right) && (8) \\
&\leq \textstyle\sum_{t=1}^{T-1} -\eta L_t^\top \mathbf{E}_{x\sim p_t}[x] + 2\eta^2 d + \frac{2}{T} && \ln(1+y) \leq y \\
& && \text{for all } y > -1 \\
&\leq 2 + 2\eta^2 T d - \eta \textstyle\sum_t \mathbf{E}_{x\sim p_t}[L_t^\top x]
\end{aligned}$$

Now, since $\log(W_1) = \log(|\mathcal{K}|)$ and $W_T \geq \exp(-\eta\hat{\ell}_{1:T}(x^*))$ for any $x^* \in \mathcal{K}$, by shifting sides of the above it holds for any $x^* \in \mathcal{K}$ that

$$\sum_t \mathop{\mathbf{E}}_{x\sim p_t}[L_t^\top x] - \sum_t L_t^\top x^* \leq \sum_t \mathop{\mathbf{E}}_{x\sim p_t}[L_t^\top x] + \mathbf{E}[\log W_T] \leq \frac{\log(|\mathcal{K}|)+2}{\eta} + 2\eta T d$$

Finally, by noticing that

$$\sum_t \mathop{\mathbf{E}}_{x\sim \hat{p}_t}[L_t^\top x] - \sum_t \mathop{\mathbf{E}}_{x\sim p_t}[L_t^\top x] \leq \gamma T$$

we obtain a bound of

$$\mathbf{E}[\text{Regret}] = \mathbf{E}[\sum_t L_t^\top x_t] - \sum_t L_t^\top x^* = \sum_t \mathop{\mathbf{E}}_{x\sim\hat{p}_t}[L_t^\top x] - \text{Loss}(x^*) \leq \frac{\log(|\mathcal{K}|)+2}{\eta} + 2\eta T d + \gamma T$$

on the expected regret. By plugging in the values of η, γ we get the bound of

$$O\left((s+d)\sqrt{\frac{T\log(|\mathcal{K}|)}{d}}\right)$$

as required. ■

8. Conclusion and Open Question

We have described a geometric mechanism for exploration in machine learning problems and its application to experiment design as well as bandit linear optimization.

The following question in high-dimensional geometry remains open: what is the worst-case order of a given set in $\mathbb{R}^d$ (cardinality of its minimal volumetric ellipsoid, as per Definition 1)? A gap remains between our lower bound of $d+1$ and upper bound of $12d$.

Acknowledgments

We would like to thank Raghu Meka for helpful discussions in areas related to high dimensional geometry that were key to the results of this paper.

Appendix A. Concentration bounds for non centered isotropic log concave distributions

We begin by proving an auxiliary lemma used in the proof of Corollary 13.

Lemma 42 *Let $\delta > 0$, $t \geq 1$, let d be a positive integer and let $n = \frac{Ct^4 d\log^2(t/\delta)}{\delta^2}$ for some sufficiently large universal constant C. Let $y_1, \ldots, y_n$ be i.i.d d-dimensional vectors from an isotropic log-concave distribution. Then*

$$\Pr\left[\left\|\frac{1}{n}\sum y_i\right\| > \delta\right] \leq \exp(-t\sqrt{d})$$

Proof For convenience let $S_n = \frac{1}{\sqrt{n}}\sum_{i=1}^n y_i$. Since the y's are independent, S_n is also log-concave distributed. Notice that $\mathbf{E}[S_n] = 0$ and $\mathbf{E}[S_n S_n^T] = \frac{1}{n}\sum \mathbf{E}[y_i y_i^T] = I_d$ hence S_n is isotropic. Now,

$$\begin{aligned}
\Pr\left[\left\|\frac{1}{n}\sum y_i\right\| > \delta\right] &= \Pr\left[\|S_n\| > \sqrt{n}\delta\right] \\
&= \Pr\left[\|S_n\| > \sqrt{d}\cdot\sqrt{Ct^4\log^2(t/\delta)}\right] \\
&\leq \Pr\left[\|S_n\| > \sqrt{d} + \sqrt{d}\cdot\tfrac{1}{2}t\sqrt{C}\right]
\end{aligned}$$

The last inequality holds for $t \geq 1$ and $C \geq 4$. It now follows from Theorem 14 that

$$\Pr\left[\left\|\frac{1}{n}\sum y_i\right\| > \delta\right] \leq c_1 \exp(-c_2 t\sqrt{Cd})$$

where c_1, c_2 are some universal constants. Since $t\sqrt{d} \geq 1$, setting $C \geq (\frac{1+\log(c_1)}{c_2})^2$ proves the claim. ■

Proof [Proof of Corollary 13] Let $a = \mathbf{E}[x]$ and let $\tilde{a} = \frac{1}{n}\sum x_i$. Notice that

$$\mathbf{E}[(x-a)(x-a)^T] = \mathbf{E}[xx^T] - \mathbf{E}[x]a^T - a\,\mathbf{E}[x] + aa^T = I_d - aa^T$$

is a PSD matrix hence $\|a\| \leq 1$. Consider the following equality.

$$\frac{1}{n}\sum_{i=1}^{n}(x_i-a)(x_i-a)^\top = \frac{1}{n}\sum_{i=1}^{n} x_i x_i^\top - a\tilde{a}^\top - \tilde{a}a^\top + aa^\top$$

According to Lemma 42, w.p. at least $1-\exp(-t\sqrt{d})$,

$$\|\tilde{a} - a\| \leq \delta$$

in which case, since $\|a\| \leq 1$ and according to the triangle inequality,

$$\left\|\frac{1}{n}\sum_{i=1}^{n} x_i x_i^\top - I_d\right\| \leq \left\|\frac{1}{n}\sum_{i=1}^{n}(x_i-a)(x_i-a)^\top - (I_d - aa^\top)\right\| + 2\delta$$

According to Theorem 12, w.p. at least $1-\exp(-t\sqrt{d})$

$$\left\|\frac{1}{n}\sum_{i=1}^{n}(x_i-a)(x_i-a)^\top - (I_d - aa^\top)\right\| \leq \delta$$

and the corollary follows. ■

Proof [Proof of Corollary 15] Let $\mathbf{E}[x] = a$. Consider the r.v $y = x - a$. It holds that $\mathbf{E}[y] = 0$ and $\mathbf{E}[yy^T] = I_d - aa^T$. Notice that we can derive that

$$\|a\| \leq 1 \tag{9}$$

As $\mathbf{E}[yy^T]$ is a PSD matrix. Also, it is easy to verify that y is log-concave distributed. We now consider the r.v[8] $z = (I_d - aa^t)^{-1/2}y$. It is easy to verify that the distribution of z is also log-concave and isotropic. It follows, from Theorem 14 that for any $\theta \geq 2$

$$\Pr\left[\|z\| > \theta\sqrt{d}\right] \leq \Pr\left[\|z\| - \sqrt{d} > \frac{1}{2}\theta\sqrt{d}\right] \leq C'\exp(-c\theta\sqrt{d})$$

By using Equation 9 we get that for $\theta > 3$

$$\Pr\left[\|x\| > \theta\sqrt{d}\right] \leq \Pr\left[\|y\| > \theta\sqrt{d} - 1\right] \leq \Pr\left[\|z\| > (\theta - 1/\sqrt{d})\sqrt{d}\right] \leq C'\exp(c' - c'\theta\sqrt{d}).$$

The last inequality holds since $\theta - 1/\sqrt{d} \geq 2$. ■

8. if $I_d - aa^T$ is not of full rank then y is in fact supported in an affine subspace of rank $d-1$ and we can continue the analysis there.

Abstract

We consider the problem of improving the efficiency of randomized Fourier feature maps to accelerate training and testing speed of kernel methods on large data sets. These approximate feature maps arise as Monte Carlo approximations to integral representations of shift-invariant kernel functions (e.g., Gaussian kernel). In this paper, we propose to use *Quasi-Monte Carlo* (QMC) approximations instead, where the relevant integrands are evaluated on a low-discrepancy sequence of points as opposed to random point sets as in the Monte Carlo approach. We derive a new discrepancy measure called *box discrepancy* based on theoretical characterizations of the integration error with respect to a given sequence. We then propose to learn QMC sequences adapted to our setting based on explicit box discrepancy minimization. Our theoretical analyses are complemented with empirical results that demonstrate the effectiveness of classical and adaptive QMC techniques for this problem.

1. Introduction

Kernel methods (Schölkopf and Smola, 2002; Wahba, 1990; Cucker and Smale, 2001) offer a comprehensive suite of mathematically well-founded non-parametric modeling techniques for a wide range of problems in machine learning. These include nonlinear classification, regression, clustering, semi-supervised learning (Belkin et al., 2006), time-series analysis (Parzen, 1970), sequence modeling (Song et al., 2010), dynamical systems (Boots et al., 2013), hypothesis testing (Harchaoui et al., 2013), causal modeling (Zhang et al., 2011) and many more.

∗. A short version of this paper has been presented in ICML 2014.
†. Equal contributors

The central object of kernel methods is a kernel function $k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ defined on an input domain $\mathcal{X} \subset \mathbb{R}^d$ [1]. The kernel k is (non-uniquely) associated with an embedding of the input space into a high-dimensional Hilbert space $\mathcal{H}$ (with inner product $\langle \cdot, \cdot \rangle_{\mathcal{H}}$) via a feature map, $\Psi : \mathcal{X} \to \mathcal{H}$, such that

$$k(\mathbf{x}, \mathbf{z}) = \langle \Psi(\mathbf{x}), \Psi(\mathbf{z}) \rangle_{\mathcal{H}} .$$

Standard regularized linear statistical models in $\mathcal{H}$ then provide non-linear inference with respect to the original input representation. The algorithmic basis of such constructions are classical Representer Theorems (Wahba, 1990; Schölkopf and Smola, 2002) that guarantee finite-dimensional solutions of associated optimization problems, even if $\mathcal{H}$ is infinite-dimensional.

However, there is a steep price of these elegant generalizations in terms of scalability. Consider, for example, least squares regression given n data points $\{(\mathbf{x}_i, y_i)\}_{i=1}^n$ and assume that $n \gg d$. The complexity of linear regression training using standard least squares solvers is $O(nd^2)$, with $O(nd)$ memory requirements, and $O(d)$ prediction speed on a test point. Its kernel-based nonlinear counterpart, however, requires solving a linear system involving the Gram matrix of the kernel function (defined by $\mathbf{K}_{ij} = k(\mathbf{x}_i, \mathbf{x}_j)$). In general, this incurs $O(n^3 + n^2 d)$ complexity for training, $O(n^2)$ memory requirements, and $O(nd)$ prediction time for a single test point – none of which are particularly appealing in "big data" settings. Similar conclusions apply to other algorithms such as Kernel PCA.

This is rather unfortunate, since non-parametric models, such as the ones produced by kernel methods, are particularly appealing in a big data settings as they can adapt to the full complexity of the underlying domain, as uncovered by increasing data set sizes. It is well-known that imposing strong structural constraints upfront for the purpose of allowing an efficient solution (in the above example: a linear hypothesis space) often limits, both theoretically and empirically, the potential to deliver value on large amounts of data. Thus, as big data becomes pervasive across a number of application domains, it has become necessary to be able to develop highly scalable algorithms for kernel methods.

Recent years have seen intensive research on improving the scalability of kernel methods; we review some recent progress in the next section. In this paper, we revisit one of the most successful techniques, namely the randomized construction of a family of low-dimensional approximate feature maps proposed by Rahimi and Recht (2008). These randomized feature maps, $\hat{\Psi} : \mathcal{X} \to \mathbb{C}^s$, provide low-distortion approximations for (complex-valued) kernel functions $k : \mathcal{X} \times \mathcal{X} \to \mathbb{C}$:

$$k(\mathbf{x}, \mathbf{z}) \approx \langle \hat{\Psi}(\mathbf{x}), \hat{\Psi}(\mathbf{z}) \rangle_{\mathbb{C}^s} \tag{1}$$

where $\mathbb{C}^s$ denotes the space of s-dimensional complex numbers with the inner product, $\langle \alpha, \beta \rangle_{\mathbb{C}^s} = \sum_{i=1}^s \alpha_i \beta_i^*$, with z^* denoting the conjugate of the complex number z (though Rahimi and Recht (2008) also define real-valued feature maps for real-valued kernels, our technical exposition is simplified by adopting the generality of complex-valued features). The mapping $\hat{\Psi}(\cdot)$ is now applied to each of the data points, to obtain a randomized feature representation of the data. We then apply a simple linear method to these random features. That is, if our data is $\{(\mathbf{x}_i, y_i)\}_{i=1}^n$ we learn on $\{(\mathbf{z}_i, y_i)\}_{i=1}^n$ where $\mathbf{z}_i = \hat{\Psi}(\mathbf{x}_i)$. As long as s is sufficiently smaller than n, this leads to more scalable solutions, e.g., for regression we get back to $O(ns^2)$ training and $O(sd)$ prediction time, with $O(ns)$ memory requirements. This technique is immensely successful, and has been used in

1. In fact, $\mathcal{X}$ can be a rather general set. However, in this paper it is restricted to being a subset of $\mathbb{R}^d$.

recent years to obtain state-of-the-art accuracies for some classical data sets (Huang et al., 2014; Dai et al., 2014; Sindhwani and Avron, 2014; Lu et al., 2014).

The starting point of Rahimi and Recht (2008) is a celebrated result that characterizes the class of positive definite functions:

Definition 1 *A function $g : \mathbb{R}^d \mapsto \mathbb{C}$ is a* positive definite function *if for any set of m points, $\mathbf{x}_1 \dots \mathbf{x}_m \in \mathbb{R}^d$, the $m \times m$ matrix $\mathbf{A}$ defined by $\mathbf{A}_{ij} = g(\mathbf{x}_i - \mathbf{x}_j)$ is positive semi-definite.*

Theorem 2 (Bochner (1933)) *A complex-valued function $g : \mathbb{R}^d \mapsto \mathbb{C}$ is positive definite if and only if it is the Fourier Transform of a finite non-negative Borel measure μ on $\mathbb{R}^d$, i.e.,*

$$g(\mathbf{x}) = \hat{\mu}(\mathbf{x}) = \int_{\mathbb{R}^d} e^{-i\mathbf{x}^T\mathbf{w}} d\mu(\mathbf{w}), \quad \forall \mathbf{x} \in \mathbb{R}^d \ .$$

Without loss of generality, we assume henceforth that $\mu(\cdot)$ is a probability measure with associated probability density function $p(\cdot)$.

A kernel function $k : \mathbb{R}^d \times \mathbb{R}^d \mapsto \mathbb{C}$ on $\mathbb{R}^d$ is called *shift-invariant* if $k(\mathbf{x}, \mathbf{z}) = g(\mathbf{x} - \mathbf{z})$, for some positive definite function $g : \mathbb{R}^d \mapsto \mathbb{C}$. Bochner's theorem implies that a scaled shift-invariant kernel can therefore be put into one-to-one correspondence with a density $p(\cdot)$ such that,

$$k(\mathbf{x}, \mathbf{z}) = g(\mathbf{x} - \mathbf{z}) = \int_{\mathbb{R}^d} e^{-i(\mathbf{x}-\mathbf{z})^T\mathbf{w}} p(\mathbf{w}) d\mathbf{w} \ . \tag{2}$$

For the most notable member of the shift-invariant family of kernels – the Gaussian kernel:

$$k(\mathbf{x}, \mathbf{z}) = e^{-\frac{\|\mathbf{x}-\mathbf{z}\|_2^2}{2\sigma^2}},$$

the associated density is again Gaussian $\mathcal{N}(0, \sigma^{-2}\mathbf{I}_d)$.

The integral representation of the kernel (2) may be approximated as follows:

$$\begin{aligned} k(\mathbf{x}, \mathbf{z}) &= \int_{\mathbb{R}^d} e^{-i(\mathbf{x}-\mathbf{z})^T\mathbf{w}} p(\mathbf{w}) d\mathbf{w} \\ &\approx \frac{1}{s} \sum_{j=1}^{s} e^{-i(\mathbf{x}-\mathbf{z})^T\mathbf{w}_s} \\ &= \langle \hat{\Psi}_S(\mathbf{x}), \hat{\Psi}_S(\mathbf{z}) \rangle_{\mathbb{C}^s} \ , \end{aligned}$$

through the feature map,

$$\hat{\Psi}_S(\mathbf{x}) = \frac{1}{\sqrt{s}} \left[e^{-i\mathbf{x}^T\mathbf{w}_1} \dots e^{-i\mathbf{x}^T\mathbf{w}_s} \right] \in \mathbb{C}^s \ . \tag{3}$$

The subscript S denotes dependence of the feature map on the sequence $S = \{\mathbf{w}_1, \dots, \mathbf{w}_s\}$.

The goal of this work is to improve the convergence behavior of this approximation, so that a smaller s can be used to get the same quality of approximation to the kernel function. This is motivated by recent work that showed that in order to obtain state-of-the-art accuracy on some important data sets, a very large number of random features is needed (Huang et al., 2014; Sindhwani and Avron, 2014).

Our point of departure from the work of Rahimi and Recht (2008) is the simple observation that when $\mathbf{w}_1, \dots, \mathbf{w}_s$ are are drawn from the distribution defined by the density function $p(\cdot)$, the approximation in (3) may be viewed as a standard *Monte Carlo* (MC) approximation to the integral representation of the kernel. Instead of using plain MC approximation, we propose to use the low-discrepancy properties of *Quasi-Monte Carlo* (QMC) sequences to reduce the integration error in approximations of the form (3). A self-contained overview of Quasi-Monte Carlo techniques for high-dimensional integration problems is provided in Section 2. In Section 3, we describe how QMC techniques apply to our setting.

We then proceed to apply an average case theoretical analysis of the integration error for any given sequence S (Section 4). This bound motivates an optimization problem over the sequence S whose minimizer provides *adaptive QMC* sequences fine tuned to our kernels (Section 5).

Finally, empirical results (Section 6) clearly demonstrate the superiority of QMC techniques over the MC feature maps (Rahimi and Recht, 2008), the correctness of our theoretical analysis and the potential value of adaptive QMC techniques for large-scale kernel methods.

2. Preliminaries

In this section we give the notation that will be used throughout the paper, a summary of related work and an overview of the Quasi-Monte Carlo method.

2.1 Notation

We use i both for subscript and for denoting $\sqrt{-1}$, relying on the context to distinguish between the two. We use $y, z, \dots$ to denote scalars. We use $\mathbf{w}, \mathbf{t}, \mathbf{x} \dots$ to denote vectors, and use w_i to denote the i-th coordinate of vectors $\mathbf{w}$. Furthermore, in a sequence of vectors, we use $\mathbf{w}_i$ to denote the i-th element of the sequence and use w_{ij} to denote the j-th coordinate of vector $\mathbf{w}_i$. Given $\mathbf{x}_1, \dots, \mathbf{x}_n$, the Gram matrix is defined as $\mathbf{K} \in \mathbb{R}^{n \times n}$ where $\mathbf{K}_{ij} = k(\mathbf{x}_i, \mathbf{x}_j)$ for $i, j = 1, \dots, n$. We denote the error function by $\mathrm{erf}(\cdot)$, i.e., $\mathrm{erf}(z) = \int_0^z e^{-z^2} dz$ for $z \in \mathbb{C}$; see Weideman (1994) and Mori (1983) for more details.

In "*MC sequence*" we mean points drawn randomly either from the unit cube or certain distribution that will be clear from the text. For "*QMC sequence*" we mean a deterministic sequence designed to reduce the integration error. Typically, it will be a low-discrepancy sequence on the unit cube.

It is also useful to recall the definition of Reproducing Kernel Hilbert Space (RKHS).

Definition 3 (Reproducing Kernel Hilbert Space (Berlinet and Thomas-Agnan, 2004)) *A* reproducing kernel Hilbert space (RKHS) *is a Hilbert Space $\mathcal{H} : \mathcal{X} \to \mathbb{C}$ that possesses a reproducing kernel, i.e., a function $h : \mathcal{X} \times \mathcal{X} \to \mathbb{C}$ for which the following hold for all $\mathbf{x} \in \mathcal{X}$ and $f \in \mathcal{H}$:*

- $h(\mathbf{x}, \cdot) \in \mathcal{H}$
- $\langle f, h(\mathbf{x}, \cdot) \rangle_{\mathcal{H}} = f(\mathbf{x})$ *(*Reproducing Property*)*

Equivalently, RKHSs are Hilbert spaces with bounded, continuous evaluation functionals. Informally, they are Hilbert spaces with the nice property that if two functions $f, g \in \mathcal{H}$ are close in the sense of the distance derived from the norm in $\mathcal{H}$ (i.e., $\|f - g\|_{\mathcal{H}}$ is small), then their values $f(\mathbf{x}), g(\mathbf{x})$ are also close for all $\mathbf{x} \in \mathcal{X}$; in other words, the norm controls the pointwise behavior of functions in $\mathcal{H}$ (Berlinet and Thomas-Agnan, 2004).

2.2 Related Work

In this section we discuss related work on scalable kernel methods. Relevant work on QMC methods is discussed in the next subsection.

Scalability has long been identified as a key challenge associated with deploying kernel methods in practice. One dominant line of work constructs low-rank approximations of the Gram matrix, either using data-oblivious randomized feature maps to approximate the kernel function, or using sampling techniques such as the classical Nyström method (Williams and Seeger, 2001). In its vanilla version, the latter approach - Nyström method - samples points from the data set, computes the columns of the Gram matrix that corresponds to the sampled data points, and uses this partial computation of the Gram matrix to construct an approximation to the entire Gram matrix. More elaborate techniques exist, both randomized and deterministic; see Gittens and Mahoney (2013) for a thorough treatment.

More relevant to our work is the randomized feature mapping approach. Pioneered by the seminal paper of Rahimi and Recht (2008), the core idea is to construct, for a given kernel on a data domain $\mathcal{X}$, a transformation $\hat{\Psi} : \mathcal{X} \to \mathbb{C}^s$ such that $k(\mathbf{x}, \mathbf{z}) \approx \langle \hat{\Psi}(\mathbf{x}), \hat{\Psi}(\mathbf{z}) \rangle_{\mathbb{C}^s}$. Invoking Bochner's theorem, a classical result in harmonic analysis, Rahimi and Recht show how to construct a randomized feature map for shift-invariant kernels, i.e., kernels that can be written $k(\mathbf{x}, \mathbf{z}) = g(\mathbf{x} - \mathbf{y})$ for some positive definite function $g(\cdot)$.

Subsequently, there has been considerable effort given to extending this technique to other classes of kernels. Li et al. (2010) use Bochner's theorem to provide random features to the wider class of group-invariant kernels. Maji and Berg (2009) suggested random features for the intersection kernel $k(\mathbf{x}, \mathbf{z}) = \sum_{i=1}^{d} \min(x_i, z_i)$. Vedaldi and Zisserman (2012) developed feature maps for γ-homogeneous kernels. Sreekanth et al. (2010) developed feature maps for generalized RBF kernels $k(\mathbf{x}, \mathbf{z}) = g(D(\mathbf{x}, \mathbf{z})^2)$ where $g(\cdot)$ is a positive definite function, and $D(\cdot, \cdot)$ is a distance metric. Kar and Karnick (2012) suggested feature maps for dot-product kernels. The feature maps are based on the Maclaurin expansion, which is guaranteed to be non-negative due to a classical result of Schoenberg (1942). Pham and Pagh (2013) suggested feature maps for the polynomial kernels. Their construction leverages known techniques from sketching theory. It can also be shown that their feature map is an *oblivious subspace embedding*, and this observation provides stronger theoretical guarantees than point-wise error bounds prevalent in the feature map literature (Avron et al., 2014). By invoking a variant of Bochner's theorem that replaces the Fourier transform with the Laplace transform, Yang et al. (2014) obtained randomized feature maps for semigroup kernels on histograms. We note that while the original feature maps suggested by Rahimi and Recht were randomized, some of the aforementioned maps are deterministic.

Our work is more in-line with recent efforts on scaling up the random features, so that learning and prediction can be done faster. Le et al. (2013) return to the original construction of Rahimi and Recht (2008), and devise a clever distribution of random samples $\mathbf{w}_1, \mathbf{w}_2, \ldots, \mathbf{w}_s$ that is structured so that the generation of random features can be done much faster. They showed that only a very limited concession in term of convergence rate is made. Hamid et al. (2014), working on the polynomial kernel, suggest first generating a very large amount of random features, and then applying them a low-distortion embedding based the Fast Johnson-Lindenstruass Transform, so the make the final size of the mapped vector rather small. In contrast, our work tries to design $\mathbf{w}_1, \ldots, \mathbf{w}_s$ so that less features will be necessary to get the same quality of kernel approximation.

Several other scalable approaches for large-scale kernel methods have been suggested over the years, starting from approaches such as chunking and decomposition methods proposed in the early days of SVM optimization literature. Raykar and Duraiswami (2007) use an improved fast Gauss transform for large scale Gaussian Process regression. There are also approaches that are more specific to the objective function at hand, e.g., Keerthi et al. (2006) builds a kernel expansion greedily to optimize the SVM objective function. Another well known approach is the Core Vector Machines (Tsang et al., 2005) which draws on approximation algorithms from computational geometry to scale up a class of kernel methods that can be reformulated in terms of the minimum enclosing ball problem.

For a broader discussion of these methods, and others, see Bottou et al. (2007).

2.3 Quasi-Monte Carlo Techniques: an Overview

In this section we provide a self-contained overview of Quasi-Monte Carlo (QMC) techniques. For brevity, we restrict our discussion to background that is necessary for understanding subsequent sections. We refer the interested reader to the excellent reviews by Caflisch (1998) and Dick et al. (2013), and the recent book Leobacher and Pillichschammer (2014) for a much more detailed exposition.

Consider the task of computing an approximation of the following integral

$$I_d[f] = \int_{[0,1]^d} f(\mathbf{x}) d\mathbf{x} \,. \tag{4}$$

One can observe that if $\mathbf{x}$ is a random vector uniformly distributed over $[0,1]^d$ then $I_d[f] = \mathbb{E}[f(\mathbf{x})]$. An empirical approximation to the expected value can be computed by drawing a random point set $S = \{\mathbf{w}_1, \ldots, \mathbf{w}_s\}$ independently from $[0,1]^d$, and computing:

$$I_S[f] = \frac{1}{s} \sum_{\mathbf{w} \in S} f(\mathbf{w}) \,.$$

This is the Monte Carlo (MC) method.

Define the integration error with respect to the point set S as,

$$\epsilon_S[f] = |I_d(f) - I_S(f)| \,.$$

When S is drawn randomly, the Central Limit Theorem asserts that if $s = |S|$ is large enough then $\epsilon_S[f] \approx \sigma[f] s^{-1/2} \boldsymbol{\nu}$ where $\boldsymbol{\nu}$ is a standard normal random variable, and $\sigma[f]$ is the square-root of the variance of f; that is,

$$\sigma^2[f] = \int_{[0,1]^d} (f(\mathbf{x}) - I_d(f))^2 \, d\mathbf{x} \,.$$

In other words, the root mean square error of the Monte Carlo method is,

$$\left(\mathbb{E}_S\left[\epsilon_S[f]^2\right]\right)^{1/2} \approx \sigma[f] s^{-1/2}. \tag{5}$$

Therefore, the Monte Carlo method converges at a rate of $O(s^{-1/2})$.

The aim of QMC methods is to improve the convergence rate by using a deterministic *low-discrepancy sequence* to construct S, instead of randomly sampling points. The underlying intuition

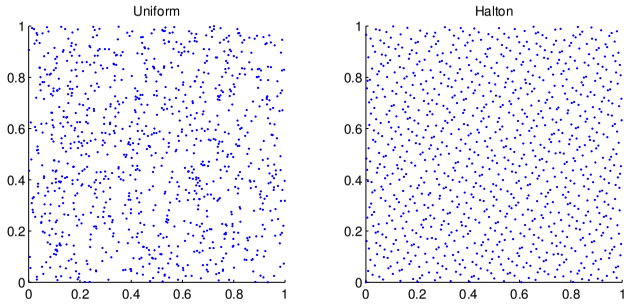

Figure 1: Comparison of MC and QMC sequences.

is illustrated in Figure 1, where we plot a set of 1000 two-dimensional random points (left graph), and a set of 1000 two-dimensional points from a quasi-random sequence (Halton sequence; right graph). In the random sequence we see that there is an undesired clustering of points, and as a consequence empty spaces. Clusters add little to the approximation of the integral in those regions, while in the empty spaces the integrand is not sampled. This lack of uniformity is due to the fact that Monte Carlo samples are independent of each other. By carefully designing a sequence of correlated points to avoid such clustering effects, QMC attempts to avoid this phenomena, and thus provide faster convergence to the integral.

The theoretical apparatus for designing such sequences are inequalities of the form

$$\epsilon_S(f) \leq D(S)V(f) \,,$$

in which $V(f)$ is a measure of the variation or difficulty of integrating $f(\cdot)$ and $D(S)$ is a sequence-dependent term that typically measures the *discrepancy*, or degree of deviation from uniformity, of the sequence S. For example, the expected Monte Carlo integration error decouples into a variance term, and $s^{-1/2}$ as in (5).

A prototypical inequality of this sort is the following remarkable and classical result:

Theorem 4 (Koksma-Hlawka inequality) *For any function f with bounded variation, and sequence $S = \{\mathbf{w}_1, \ldots, \mathbf{w}_s\}$, the integration error is bounded above as follows,*

$$\epsilon_S[f] \leq D^\star(S)V_{HK}[f] \,,$$

where V_{HK} is the Hardy-Krause variation of f *(see Niederreiter (1992)), which is defined in terms of the following partial derivatives,*

$$V_{HK}[f] = \sum_{I \subset [d], I \neq \emptyset} \int_{[0,1]^{|I|}} \left| \frac{\partial f}{\partial \mathbf{u}_I}\Big|_{u_j=1, j \notin I} \right| d\mathbf{u}_I \,, \tag{6}$$

and $D^\star$ is the star discrepancy *defined by*

$$D^\star(S) = \sup_{\mathbf{x} \in [0,1]^d} |\mathrm{disr}_S(\mathbf{x})| \,,$$

where disr_S *is the* local discrepancy function

$$\mathrm{disr}_S(\mathbf{x}) = \mathrm{Vol}(J_\mathbf{x}) - \frac{|\{i \,:\, \mathbf{w}_i \in J_\mathbf{x}\}|}{s}$$

with $J_\mathbf{x} = [0, x_1) \times [0, x_2) \times \cdots \times [0, x_d)$ *with* $\mathrm{Vol}(J_\mathbf{x}) = \prod_{j=1}^d x_j$.

Given $\mathbf{x}$, the second term in $\mathrm{disr}_S(\mathbf{x})$ is an estimate of the volume of $J_\mathbf{x}$, which will be accurate if the points in S are uniform enough. $D^\star(S)$ measures the maximum difference between the actual volume of the subregion $J_\mathbf{x}$ and its estimate for all $\mathbf{x}$ in $[0, 1]^d$.

An infinite sequence $\mathbf{w}_1, \mathbf{w}_2, \ldots$ is defined to be a *low-discrepancy sequence* if, as a function of s, $D^\star(\{\mathbf{w}_1, \ldots, \mathbf{w}_s\}) = O((\log s)^d/s)$. Several constructions are know to be low-discrepancy sequences. One notable example is the *Halton sequences*, which are defined as follows. Let $p_1, \ldots, p_d$ be the first d prime numbers. The Halton sequence $\mathbf{w}_1, \mathbf{w}_2, \ldots$ of dimension d is defined by

$$\mathbf{w}_i = (\phi_{p_1}(i), \ldots, \phi_{p_d}(i))$$

where for integers $i \geq 0$ and $b \geq 2$ we have

$$\phi_b(i) = \sum_{a=1}^{\infty} i_a b^{-a}$$

in which $i_0, i_1, \cdots \in \{0, 1, \ldots, b-1\}$ is given by the unique decomposition

$$i = \sum_{a=1}^{\infty} i_a b^{a-1} \,.$$

It is outside the scope of this paper to describe all these constructions in detail. However we mention that in addition to the Halton sequences, other notable members are *Sobol' sequences*, *Faure sequences*, *Niederreiter sequences*, and more (see Dick et al. (2013), Section 2). We also mention that it is conjectured that the $O((\log s)^d/s)$ rate for star discrepancy decay is optimal.

The classical QMC theory, which is based on the Koksma-Hlawka inequality and low discrepancy sequences, thus achieves a convergence rate of $O((\log s)^d/s)$. While this is asymptotically superior to $O(s^{-1/2})$ for a fixed d, it requires s to be exponential in d for the improvement to manifest. As such, in the past QMC methods were dismissed as unsuitable for very high-dimensional integration.

However, several authors noticed that QMC methods perform better than MC even for very high-dimensional integration (Sloan and Wozniakowski, 1998; Dick et al., 2013).[2] Contemporary QMC literature explains and expands on these empirical observations, by leveraging the structure of the space in which the integrand function lives, to derive more refined bounds and discrepancy measures, even when classical measures of variation such as (6) are unbounded. This literature has evolved along at least two directions: one, where worst-case analysis is provided under the assumption that the integrands live in a Reproducing Kernel Hilbert Space (RKHS) of sufficiently smooth and well-behaved functions (see Dick et al. (2013), Section 3) and second, where the analysis is done in terms of *average-case* error, under an assumed probability distribution over the integrands, instead of worst-case error (Wozniakowski, 1991; Traub and Wozniakowski, 1994). We refrain from more details, as these are essentially the paths that the analysis in Section 4 follows for our specific setting.

Algorithm 1 Quasi-Random Fourier Features

Input: Shift-invariant kernel k, size s.

Output: Feature map $\hat{\Psi}(\mathbf{x}) : \mathbb{R}^d \mapsto \mathbb{C}^s$.

1: Find p, the inverse Fourier transform of k.
2: Generate a low discrepancy sequence $\mathbf{t}_1, \ldots, \mathbf{t}_s$.
3: Transform the sequence: $\mathbf{w}_i = \Phi^{-1}(\mathbf{t}_i)$ by (7).
4: Set $\hat{\Psi}(\mathbf{x}) = \sqrt{\frac{1}{s}}\left[e^{-i\mathbf{x}^T\mathbf{w}_1}, \ldots, e^{-i\mathbf{x}^T\mathbf{w}_s}\right]$.

3. QMC Feature Maps: Our Algorithm

We assume that the density function in (2) can be written as $p(\mathbf{x}) = \prod_{j=1}^d p_j(x_j)$, where $p_j(\cdot)$ is a univariate density function. The density functions associated to many shift-invariant kernels, e.g., Gaussian, Laplacian and Cauchy, admits such a form.

The QMC method is generally applicable to integrals over a unit cube. So typically integrals of the form (2) are handled by first generating a low discrepancy sequence $\mathbf{t}_1, \ldots, \mathbf{t}_s \in [0,1]^d$, and transforming it into a sequence $\mathbf{w}_1, \ldots, \mathbf{w}_s$ in $\mathbb{R}^d$, instead of drawing the elements of the sequence from $p(\cdot)$ as in the MC method.

To convert (2) to an integral over the unit cube, a simple change of variables suffices. For $\mathbf{t} \in \mathbb{R}^d$, define

$$\Phi^{-1}(\mathbf{t}) = \left(\Phi_1^{-1}(t_1), \ldots, \Phi_d^{-1}(t_d)\right) \in \mathbb{R}^d\,, \tag{7}$$

where $\Phi_j(\cdot)$ is the cumulative distribution function (CDF) of $p_j(\cdot)$, for $j = 1, \ldots, d$. By setting $\mathbf{w} = \Phi^{-1}(\mathbf{t})$, then (2) can be equivalently written as

$$\int_{\mathbb{R}^d} e^{-i(\mathbf{x}-\mathbf{z})^T\mathbf{w}} p(\mathbf{w}) d\mathbf{w} = \int_{[0,1]^d} e^{-i(\mathbf{x}-\mathbf{z})^T\Phi^{-1}(\mathbf{t})} d\mathbf{t}\,.$$

Thus, a low discrepancy sequence $\mathbf{t}_1, \ldots, \mathbf{t}_s \in [0,1]^d$ can be transformed using $\mathbf{w}_i = \Phi^{-1}(\mathbf{t}_i)$, which is then plugged into (3) to yield the QMC feature map. This simple procedure is summarized in Algorithm 1. QMC feature maps are analyzed in the next section.

4. Theoretical Analysis and Average Case Error Bounds

The proofs for assertions made in this section and the next can be found in the Appendix.

The goal of this section is to develop a framework for analyzing the approximation quality of the QMC feature maps described in the previous section (Algorithm 1). We need to develop such a framework since the classical Koksma-Hlawka inequality cannot be applied to our setting, as the following proposition shows:

Proposition 5 *For any $p(\mathbf{x}) = \prod_{j=1}^d p_j(x_j)$, where $p_j(\cdot)$ is a univariate density function, let*

$$\Phi^{-1}(\mathbf{t}) = \left(\Phi_1^{-1}(t_1), \ldots, \Phi_d^{-1}(t_d)\right)\,.$$

For a fixed $\mathbf{u} \in \mathbb{R}^d$, consider $f_{\mathbf{u}}(\mathbf{t}) = e^{-i\mathbf{u}^T\Phi^{-1}(\mathbf{t})}$, $\mathbf{t} \in [0,1]^d$. The Hardy-Krause variation of $f_{\mathbf{u}}(\cdot)$ is unbounded. That is, one of the integrals in the sum (6) *is unbounded.*

Our framework is based on a new discrepancy measure, *box discrepancy*, that characterizes integration error for the set of integrals defined with respect to the underlying data domain. Throughout this section we use the convention that $S = \{\mathbf{w}_1, \ldots, \mathbf{w}_s\}$, and the notation $\bar{\mathcal{X}} = \{\mathbf{x} - \mathbf{z} \mid \mathbf{x}, \mathbf{z} \in \mathcal{X}\}$.

Given a probability density function $p(\cdot)$ and S, we define the integration error $\epsilon_{S,p}[f]$ of a function $f(\cdot)$ with respect to $p(\cdot)$ and the s samples as,

$$\epsilon_{S,p}[f] = \left| \int_{\mathbb{R}^d} f(\mathbf{x}) p(\mathbf{x}) d\mathbf{x} - \frac{1}{s}\sum_{i=1}^s f(\mathbf{w}_i) \right|\,.$$

We are interested in characterizing the behavior of $\epsilon_{S,p}[f]$ on $f \in \mathcal{F}_{\bar{\mathcal{X}}}$ where

$$\mathcal{F}_{\bar{\mathcal{X}}} = \left\{ f_{\mathbf{u}}(\mathbf{x}) = e^{-i\mathbf{u}^T\mathbf{x}},\ \mathbf{u} \in \bar{\mathcal{X}} \right\}\,.$$

As is common in modern QMC analysis (Leobacher and Pillichshammer, 2014; Dick et al., 2013), our analysis is based on setting up a Reproducing Kernel Hilbert Space of "nice" functions that is related to integrands that we are interested in, and using properties of the RKHS to derive bounds on the integration error. In particular, the integration error of integrands in an RKHS can be bounded using the following proposition.

Proposition 6 (Integration Error in an RKHS) *Let $\mathcal{H}$ be an RKHS with kernel $h(\cdot,\cdot)$. Assume that $\kappa = \sup_{\mathbf{x}\in\mathbb{R}^d} h(\mathbf{x},\mathbf{x}) < \infty$. Then, for all $f \in \mathcal{H}$ we have,*

$$\epsilon_{S,p}[f] \le \|f\|_{\mathcal{H}} D_{h,p}(S)\,, \tag{8}$$

where

$$\begin{aligned} D_{h,p}(S)^2 &= \left\| \int_{\mathbb{R}^d} h(\omega,\cdot)p(\omega)d\omega - \frac{1}{s}\sum_{l=1}^s h(\mathbf{w}_l,\cdot) \right\|_{\mathcal{H}}^2 \\ &= \int_{\mathbb{R}^d}\int_{\mathbb{R}^d} h(\omega,\phi)p(\omega)p(\phi)d\omega d\phi - \frac{2}{s}\sum_{l=1}^s \int_{\mathbb{R}^d} h(\mathbf{w}_l,\omega)p(\omega)d\omega \\ &\quad + \frac{1}{s^2}\sum_{l=1}^s\sum_{j=1}^s h(\mathbf{w}_l,\mathbf{w}_j)\,. \end{aligned} \tag{9}$$

Remark 7 *In the theory of RKHS embeddings of probability distributions (Smola et al., 2007; Sriperumbudur et al., 2010), the function*

$$\mu_{h,p}(\mathbf{x}) = \int_{\mathbb{R}^d} h(\omega,\mathbf{x})p(\omega)d\omega$$

is known as the kernel mean *embedding of $p(\cdot)$. The function*

$$\hat{\mu}_{h,p,S}(\mathbf{x}) = \frac{1}{s}\sum_{l=1}^s h(\mathbf{w}_l,\mathbf{x})$$

is then the empirical mean map.

The RKHS we use is as follows. For a vector $\mathbf{b} \in \mathbb{R}^d$, let us define $\square\mathbf{b} = \{\mathbf{u} \in \mathbb{R}^d \mid |u_j| \leq b_j\}$. Let

$$\mathcal{F}_{\square\mathbf{b}} = \left\{ f_{\mathbf{u}}(\mathbf{x}) = e^{-i\mathbf{u}^T\mathbf{x}},\ \mathbf{u} \in \square\mathbf{b} \right\} ,$$

and consider the space of functions that admit an integral representation over $\mathcal{F}_{\square\mathbf{b}}$ of the form

$$f(\mathbf{x}) = \int_{\mathbf{u}\in\square\mathbf{b}} \hat{f}(\mathbf{u}) e^{-i\mathbf{u}^T\mathbf{x}} d\mathbf{u} \text{ where } \hat{f}(\mathbf{u}) \in L_2(\square\mathbf{b}) . \tag{10}$$

This space is associated with bandlimited functions, i.e., functions with compactly-supported inverse Fourier transforms, which are of fundamental importance in the Shannon-Nyquist sampling theory. Under a natural choice of inner product, these spaces are called *Paley-Wiener spaces* and they constitute an RKHS (Berlinet and Thomas-Agnan, 2004; Yao, 1967; Peloso, 2011).

Proposition 8 (Kernel of Paley-Wiener RKHS) *By $PW_{\mathbf{b}}$, denote the space of functions which admit the representation in* (10)*, with the inner product $\langle f, g\rangle_{PW_{\mathbf{b}}} = (2\pi)^{2d}\langle \hat{f}, \hat{g}\rangle_{L_2(\square\mathbf{b})}$. $PW_{\mathbf{b}}$ is an RKHS with kernel function,*

$$\operatorname{sinc}_{\mathbf{b}}(\mathbf{u}, \mathbf{v}) = \pi^{-d} \prod_{j=1}^{d} \frac{\sin\left(b_j(u_j - v_j)\right)}{u_j - v_j} .$$

For notational convenience, in the above we define $\sin(b\cdot 0)/0$ to be b. Furthermore, $\langle f, g\rangle_{PW_{\mathbf{b}}} = \langle f, g\rangle_{L_2(\square\mathbf{b})}$.

If $b_j = \sup_{\mathbf{u}\in\bar{\mathcal{X}}} |u_j|$ then $\bar{\mathcal{X}} \subset \square\mathbf{b}$, so $F_{\bar{\mathcal{X}}} \subset F_{\square\mathbf{b}}$. Since we wish to bound the integration error on functions in $F_{\bar{\mathcal{X}}}$, it suffices to bound the integration error on $\mathcal{F}_{\square\mathbf{b}}$. Unfortunately, while $\mathcal{F}_{\square\mathbf{b}}$ defines $PW_{\mathbf{b}}$, the functions in it, being not square integrable, are *not* members of $PW_{\mathbf{b}}$, so analyzing the integration error in $PW_{\mathbf{b}}$ do not directly apply to them. However, damped approximations of $f_{\mathbf{u}}(\cdot)$ of the form $\tilde{f}_{\mathbf{u}}(\mathbf{x}) = e^{-i\mathbf{u}^T\mathbf{x}} \operatorname{sinc}(T\mathbf{x})$ are members of $PW_{\mathbf{b}}$ with $\|\tilde{f}\|_{PW_{\mathbf{b}}} = \frac{1}{\sqrt{T}}$. Hence, we expect the analysis of the integration error in $PW_{\mathbf{b}}$ to provide provide a discrepancy measure for integrating functions in $\mathcal{F}_{\square\mathbf{b}}$.

For $PW_{\mathbf{b}}$ the discrepancy measure $D_{h,S}$ in Proposition 6 can be written explicitly.

Theorem 9 (Discrepancy in $PW_{\mathbf{b}}$) *Suppose that $p(\cdot)$ is a probability density function, and that we can write $p(\mathbf{x}) = \prod_{j=1}^{d} p_j(x_j)$ where each $p_j(\cdot)$ is a univariate probability density function as well. Let $\varphi_j(\cdot)$ be the characteristic function associated with $p_j(\cdot)$. Then,*

$$\begin{aligned} D_{\operatorname{sinc}_{\mathbf{b}},p}(S)^2 \;=\; & \pi^{-d} \prod_{j=1}^{d} \int_{-b_j}^{b_j} |\varphi_j(\beta)|^2 d\beta - \\ & \frac{2(2\pi)^{-d}}{s} \sum_{l=1}^{s} \prod_{j=1}^{d} \int_{-b_j}^{b_j} \varphi_j(\beta) e^{iw_{lj}\beta} d\beta + \\ & \frac{1}{s^2} \sum_{l=1}^{s}\sum_{j=1}^{s} \operatorname{sinc}_{\mathbf{b}}(\mathbf{w}_l, \mathbf{w}_j) . \end{aligned} \tag{11}$$

This naturally leads to the definition of the *box discrepancy*, analogous to the star discrepancy described in Theorem 4.

Definition 10 (Box Discrepancy) *The box discrepancy of a sequence S with respect to $p(\cdot)$ is defined as,*

$$D_p^{\square\mathbf{b}}(S) = D_{\operatorname{sinc}_{\mathbf{b}},p}(S) .$$

For notational convenience, we generally omit the $\mathbf{b}$ from $D_p^{\square\mathbf{b}}(S)$ as long as it is clear from the context.

The worse-case integration error bound for Paley-Wiener spaces is stated in the following as a corollary of Proposition 6. As explained earlier, this result not yet apply to functions in $\mathcal{F}_{\square\mathbf{b}}$ because these functions are not part of $PW_{\mathbf{b}}$. Nevertheless, we state it here for completeness.

Corollary 11 (Integration Error in $PW_{\mathbf{b}}$) *For $f \in PW_{\mathbf{b}}$ we have*

$$\epsilon_{S,p}[f] \leq \|f\|_{PW_{\mathbf{b}}} D_p^{\square}(S) .$$

Our main result shows that the expected square error of an integrand drawn from a uniform distribution over $\mathcal{F}_{\square\mathbf{b}}$ is proportional to the square discrepancy measure $D_p^{\square}(S)$. This result is in the spirit of similar average case analysis in the QMC literature (Wozniakowski, 1991; Traub and Wozniakowski, 1994).

Theorem 12 (Average Case Error) *Let $\mathcal{U}(\mathcal{F}_{\square\mathbf{b}})$ denote the uniform distribution on $\mathcal{F}_{\square\mathbf{b}}$. That is, $f \sim \mathcal{U}(\mathcal{F}_{\square\mathbf{b}})$ denotes $f = f_{\mathbf{u}}$ where $f_{\mathbf{u}}(\mathbf{x}) = e^{-i\mathbf{u}^T\mathbf{x}}$ and $\mathbf{u}$ is randomly drawn from a uniform distribution on $\square\mathbf{b}$. We have,*

$$\mathbb{E}_{f\sim\mathcal{U}(\mathcal{F}_{\square\mathbf{b}})}\left[\epsilon_{S,p}[f]^2\right] = \frac{\pi^d}{\prod_{j=1}^{d} b_j} D_p^{\square}(S)^2 .$$

We now give an explicit formula for $D_p^{\square}(S)$ for the case that $p(\cdot)$ is the density function of the multivariate Gaussian distribution with zero mean and independent components. This is an important special case since this is the density function that is relevant for the Gaussian kernel.

Corollary 13 (Discrepancy for Gaussian Distribution) *Let $p(\cdot)$ be the d-dimensional multivariate Gaussian density function with zero mean and covariance matrix equal to $\operatorname{diag}(\sigma_1^{-2}, \ldots, \sigma_d^{-2})$. We have,*

$$\begin{aligned} D_p^{\square}(S)^2 \;=\; & \frac{1}{s^2} \sum_{l=1}^{s}\sum_{j=1}^{s} \operatorname{sinc}_{\mathbf{b}}(\mathbf{w}_l, \mathbf{w}_j) - \\ & \frac{2}{s} \sum_{l=1}^{s} \prod_{j=1}^{d} c_{lj} \operatorname{Re}\left(\operatorname{erf}\left(\frac{b_j}{\sigma_j\sqrt{2}} - i\frac{\sigma_j w_{lj}}{\sqrt{2}} \right) \right) + \\ & + \prod_{j=1}^{d} \frac{\sigma_j}{2\sqrt{\pi}} \operatorname{erf}\left(\frac{b_j}{\sigma_j}\right) , \end{aligned} \tag{12}$$

where

$$c_{lj} = \left(\frac{\sigma_j}{\sqrt{2\pi}}\right) e^{-\frac{\sigma_j^2 w_{lj}^2}{2}} .$$

Intuitively, the box discrepancy of the Gaussian kernel can be interpreted as follows. The function $\mathrm{sinc}(x) = \sin(x)/x$ achieves its maximum at $x = 0$ and minimizes at discrete values of x decaying to 0 as $|x|$ goes to ∞. Hence the first term in (12) tends to be minimized when the pairwise distance between $\mathbf{w}_j$ are sufficiently separated. Due to the shape of cumulative distribution function of Gaussian distribution, the values of $\mathbf{t}_j = \Phi(\mathbf{w}_j)$ $(j = 1, \ldots, s)$ are driven to be close to the boundary of the unit cube. As for second term, the original expression is - $\frac{2}{s}\sum_{l=1}^{s}\int_{\mathbb{R}^d} h(\mathbf{w}_l, \omega)p(\omega)d\omega$. This term encourages the sequence $\{\mathbf{w}_l\}$ to mimic samples from $p(\omega)$. Since $p(\omega)$ concentrates its mass around $\omega = 0$, the $\mathbf{w}_j$ also concentrates around 0 to maximize the integral and therefore the values of $\mathbf{t}_j = \Phi(\mathbf{w}_j)$ $(j = 1, \ldots, s)$ are driven closer to the center of the unit cube. Sequences with low box discrepancy therefore optimize a tradeoff between these competing terms.

Two other shift-invariant kernel that have been mentioned in the machine learning literature is the Laplacian kernel (Rahimi and Recht, 2008) and Matern kernel (Le et al., 2013). The distribution associated with the Laplacian kernel can be written as a product $p(\mathbf{x}) = \prod_{j=1}^{d} p_j(x_j)$, where $p_j(\cdot)$ is density associated with the Cauchy distribution. The characteristic function is simple ($\phi_j(\beta) = e^{-|\beta|/\sigma_j}$) so analytic formulas like (12) can be derived. The distribution associated with the Matern kernel, on the other hand, is the multivariate t-distribution, which cannot be written as a product $p(\mathbf{x}) = \prod_{j=1}^{d} p_j(x_j)$, so the presented theory does not apply to it.

Discrepancy of Monte-Carlo Sequences.

We now derive an expression for the expected discrepancy of Monte-Carlo sequences, and show that it decays as $O(s^{-1/2})$. This is useful since via an averaging argument we are guaranteed that there exists sets for which the discrepancy behaves $O(s^{-1/2})$.

Corollary 14 *Suppose $\mathbf{t}_1, \ldots, \mathbf{t}_s$ are chosen uniformly from $[0,1]^d$. Let $\mathbf{w}_i = \Phi^{-1}(\mathbf{t}_i)$, for $i = 1, \ldots, s$. Assume that $\kappa = \sup_{\mathbf{x}\in\mathbb{R}^d} h(\mathbf{x}, \mathbf{x}) < \infty$. Then*

$$\mathbb{E}\left[D_{h,p}(S)^2\right] = \frac{1}{s}\int_{\mathbb{R}^d} h(\omega,\omega)p(\omega)d\omega - \frac{1}{s}\int_{\mathbb{R}^d}\int_{\mathbb{R}^d} h(\omega,\phi)p(\omega)p(\phi)d\omega d\phi\ .$$

Again, we can derive specific formulas for the Gaussian density. The following is straightforward from Corollary 14. We omit the proof.

Corollary 15 *Let $p(\cdot)$ be the d-dimensional multivariate Gaussian density function with zero mean and covariance matrix equal to $\mathrm{diag}(\sigma_1^{-2}, \ldots, \sigma_d^{-2})$. Suppose $\mathbf{t}_1, \ldots, \mathbf{t}_s$ are chosen uniformly from $[0,1]^d$. Let $\mathbf{w}_i = \Phi^{-1}(\mathbf{t}_i)$, for $i = 1, \ldots, s$. Then,*

$$\mathbb{E}\left[D_p^{\square}(S)^2\right] = \frac{1}{s}\left(\pi^{-d}\prod_{j=1}^{d} b_j - \prod_{j=1}^{d}\frac{\sigma_j}{2\sqrt{\pi}}\,\mathrm{erf}\left(\frac{b_j}{\sigma_j}\right)\right). \tag{13}$$

5. Learning Adaptive QMC Sequences

For simplicity, in this section we assume that $p(\cdot)$ is the density function of Gaussian distribution with zero mean. We also omit the subscript p from $D_p^{\square}$. Similar analysis and equations can be derived for other density functions.

Error characterization via discrepancy measures like (12) is typically used in the QMC literature to prescribe sequences whose discrepancy behaves favorably. It is clear that for the box discrepancy,

a meticulous design is needed for a high quality sequence and we leave this to future work. Instead, in this work, we use the fact that unlike the star discrepancy (4), the box discrepancy is a smooth function of the sequence with a closed-form formula. This allows us to both evaluate various candidate sequences, and select the one with the lowest discrepancy, as well as to *adaptively learn* a QMC sequence that is specialized for our problem setting via numerical optimization. The basis is the following proposition, which gives an expression for the gradient of $D^{\square}(S)$.

Proposition 16 (Gradient of Box Discrepancy) *Define the following scalar functions and variables,*

$$\begin{aligned}
\mathrm{sinc}'(z) &= \frac{\cos(z)}{z} - \frac{\sin(z)}{z^2},\quad \mathrm{sinc}'_b(z) = \frac{b}{\pi}\mathrm{sinc}'(bz)\,;\\
c_j &= \left(\frac{\sigma_j}{\sqrt{2\pi}}\right), j = 1, \ldots, d\,;\\
g_j(x) &= c_j e^{-\frac{\sigma_j^2}{2}x^2}\,\mathrm{Re}\left(\mathrm{erf}\left[\frac{b_j}{\sigma_j\sqrt{2}} - i\frac{\sigma_j x}{\sqrt{2}}\right]\right)\,;\\
g'_j(x) &= -\sigma_j^2 x g_j(x) + \sqrt{\frac{2}{\pi}}c_j\sigma_j e^{-\frac{b_j^2}{2\sigma_j^2}}\sin(b_j x)\,.
\end{aligned}$$

In the above ,we define $\mathrm{sinc}'(0)$ to be 0. Then, the elements of the gradient vector of $D^{\square}$ are given by,

$$\begin{aligned}
\frac{\partial D^{\square}}{\partial w_{lj}} &= \frac{2}{s^2}\sum_{\substack{m=1\\ m\neq l}}^{s}\left(b_j\,\mathrm{sinc}'_{b_j}(w_{lj}, w_{mj})\prod_{q\neq j}\mathrm{sinc}_{b_q}(w_{lq}, w_{mq})\right) -\\
&\quad \frac{2}{s}g'_j(w_{lj})\left(\prod_{q\neq j} g_q(w_{lq})\right)\,.
\end{aligned} \tag{14}$$

We explore two possible approaches for finding sequences based on optimizing the box discrepancy, namely *global optimization* and *greedy optimization*. The latter is closely connected to *herding* algorithms (Welling, 2009).

5.1 Global Adaptive Sequences

The task is posed in terms minimization of the box discrepancy function (12) over the space of sequences of s vectors in $\mathbb{R}^d$:

$$S^* = \arg\min_{S=(\mathbf{w}_1\ldots\mathbf{w}_s)\in\mathbb{R}^{ds}} D^{\square}(S)\,.$$

The gradient can be plugged into any first order numerical solver for non-convex optimization. We use non-linear conjugate gradient in our experiments (Section 6.2).

The above learning mechanism can be extended in various directions. For example, QMC sequences for n-point rank-one Lattice Rules (Dick et al., 2013) are integral fractions of a lattice defined by a single generating vector $\mathbf{v}$. This generating vector may be learnt via local minimization of the box discrepancy.

5.2 Greedy Adaptive Sequences

Starting with $S_0 = \emptyset$, for $t \geq 1$, let $S_t = \{\mathbf{w}_1, \ldots, \mathbf{w}_t\}$. At step $t+1$, we solve the following optimization problem,

$$\mathbf{w}_{t+1} = \arg\min_{\mathbf{w}\in\mathbb{R}^d} D^{\square}(S_t \cup \{\mathbf{w}\}) \,. \tag{15}$$

Set $S_{t+1} = S_t \cup \{w_{t+1}\}$ and repeat the above procedure. The gradient of the above objective is also given in (14). Again, we use non-linear conjugate gradient in our experiments (Section 6.2).

The greedy adaptive procedure is closely related to the herding algorithm, recently presented by Welling (2009). Applying the herding algorithm to $PW_{\mathbf{b}}$ and $p(\cdot)$, and using our notation, the points $\mathbf{w}_1, \mathbf{w}_2, \ldots$ are generated using the following iteration

$$\begin{aligned} \mathbf{w}_{t+1} &\in \arg\max_{\mathbf{w}\in\mathbb{R}^d} \langle \mathbf{z}_t(\cdot), h(\mathbf{w},\cdot)\rangle_{PW_{\mathbf{b}}} \\ \mathbf{z}_{t+1}(\mathbf{x}) &\equiv \mathbf{z}_t(\mathbf{x}) + \mu_{h,p}(x) - h(\mathbf{w},\mathbf{x}) \,. \end{aligned}$$

In the above, $\mathbf{z}_0, \mathbf{z}_1, \ldots$ is a series of functions in $PW_{\mathbf{b}}$. The literature is not specific on the initial value of $\mathbf{z}_0$, with both $\mathbf{z}_0 = 0$ and $\mathbf{z}_0 = \mu_{h,p}$ suggested. Either way, it is always the case that $\mathbf{z}_t = \mathbf{z}_0 + t(\mu_{h,p} - \hat{\mu}_{h,p,S_t})$ where $S_t = \{\mathbf{w}_1, \ldots, \mathbf{w}_t\}$.

Chen et al. (2010) showed that under some additional assumptions, the herding algorithm, when applied to a RKHS $\mathcal{H}$, greedily minimizes $\|\mu_{h,p} - \hat{\mu}_{h,p,S_t}\|^2_{\mathcal{H}}$, which, recall, is equal to $D_{h,p}(S_t)$. Thus, under certain assumptions, herding and (15) are equivalent. Chen et al. (2010) also showed that under certain restrictions on the RKHS, herding will reduce the discrepancy in a ratio of $O(1/t)$. However, it is unclear whether those restrictions hold for $PW_{\mathbf{b}}$ and $p(\cdot)$. Indeed, Bach et al. (2012) recently shown that these restrictions never hold for infinite-dimensional RKHS, as long as the domain is compact. This result does not immediately apply to our case since $\mathbb{R}^d$ is not compact.

5.3 Weighted Sequences

Classically, Monte-Carlo and Quasi-Monte Carlo approximations of integrals are unweighted, or more precisely, have a uniform weights. However, it is quite plausible to weight the approximations, i.e. approximate $I_d[f] = \int_{[0,1]^d} f(\mathbf{x})d\mathbf{x}$ using

$$I_{S,\Xi}[f] = \sum_{i=1}^{n} \xi_i f(\mathbf{w}_i) \,, \tag{16}$$

where $\Xi = \{\xi_1, \ldots, \xi_s\} \subset \mathbb{R}$ is a set of weights. This lead to the feature map

$$\hat{\Psi}_S(\mathbf{x}) = \left[\sqrt{\xi_1}e^{-i\mathbf{x}^T\mathbf{w}_1} \ldots \sqrt{\xi_s}e^{-i\mathbf{x}^T\mathbf{w}_s}\right] \,.$$

This construction requires $\xi_i \geq 0$ for $i = 1, \ldots, s$, although we note that (16) itself does not preclude negative weights. We do not require the weights to be normalized, that is it is possible that $\sum_{i=1}^{s} \xi_i \neq 1$.

One can easily generalize the result of the previous section to derive the following discrepancy measure that takes into consideration the weights

$$\begin{aligned} D_p^{\square\mathbf{b}}(S,\Xi)^2 &= \pi^{-d}\prod_{j=1}^{d}\int_{-b_j}^{b_j} |\varphi_j(\beta)|^2 d\beta - \\ &\quad 2(2\pi)^{-d}\sum_{l=1}^{s}\xi_l\prod_{j=1}^{d}\int_{-b_j}^{b_j}\varphi_j(\beta)e^{iw_{lj}\beta}d\beta + \\ &\quad \sum_{l=1}^{s}\sum_{j=1}^{s}\xi_l\xi_j \operatorname{sinc}_{\mathbf{b}}(\mathbf{w}_l,\mathbf{w}_j) \,. \end{aligned}$$

Using this discrepancy measure, global adaptive and greedy adaptive sequences of points and weights can be found.

However, we note that if we fix the points, then optimizing just the weights is a simple convex optimization problem. The box discrepancy can be written as

$$D_p^{\square\mathbf{b}}(S,\Xi)^2 = \pi^{-d}\prod_{j=1}^{d}\int_{-b_j}^{b_j}|\varphi_j(\beta)|^2 d\beta - 2\mathbf{v}^T\xi + \xi^T\mathbf{H}\xi \,,$$

where $\xi \in \mathbb{R}^s$ has entry i equal to ξ_i, $\mathbf{v} \in \mathbb{R}^s$ and $\mathbf{H} \in \mathbb{R}^{s\times s}$ are defined by

$$\mathbf{H}_{ij} = \operatorname{sinc}_{\mathbf{b}}(\mathbf{w}_l,\mathbf{w}_j)$$

$$\mathbf{v}_i = (2\pi)^{-d}\prod_{j=1}^{d}\int_{-b_j}^{b_j}\varphi_j(\beta)e^{iw_{lj}\beta}d\beta \,.$$

The ξ that minimizes $D_p^{\square\mathbf{b}}(S,\Xi)^2$ is equal to $\mathbf{H}^{-1}\mathbf{v}$, but there is no guarantee that $\xi_i \geq 0$ for all i. We need to explicitly impose these conditions. Thus, the optimal weights can be found by solving the following convex optimization problem

$$\Xi^* = \arg\min_{\xi\in\mathbb{R}^s} \xi^T\mathbf{H}\xi - 2\mathbf{v}^T\xi \quad \text{s.t. } \xi \geq 0 \,. \tag{17}$$

Selecting the weights in such a way is closely connected to the so-called *Bayesian Monte Carlo* (BMC) method, originally suggested by Ghahramani and Rasmussen (2003). In BMC, a Bayesian approach is utilized in which the function is a assumed to be random with a prior that is a Gaussian Process. Combining with the observations, a posterior is obtained, which naturally leads to the selection of weights. Huszár and Duvenaud (2012) subsequently pointed out the connection between this approach and the herding algorithm discussed earlier.

We remark that as long as all the weights are positive, the hypothesis space of functions induced by the feature map (that is, $\{g_{\mathbf{w}}(\mathbf{x}) = \hat{\Psi}_S^T(\mathbf{x})\mathbf{w},\ \mathbf{w} \in \mathbb{R}^s\}$) will not change in terms of the set of functions in it. However, the norms will be affected (that is, the norm of a function in that set also depends on the weights), which in turn affects the regularization.

6. Experiments

In this section we report experiments with both classical QMC sequences and adaptive sequences learnt from box discrepancy minimization.

6.1 Experiments With Classical QMC Sequences

We examine the behavior of classical low-discrepancy sequences when compared to random Fourier features (i.e., MC). We consider four sequences: Halton, Sobol', Lattice Rules, and Digital Nets. For Halton and Sobol', we use the implementation available in MATLAB.[3] For Lattice Rules and Digital Nets, we use publicly available implementations.[4] For all four low-discrepancy sequences, we use scrambling and shifting techniques recommended in the QMC literature (see Dick et al. (2013) for details). For Sobol', Lattice Rules and Digital Nets, scrambling introduces randomization and hence variance. For Halton sequence, scrambling is deterministic, and there is no variance. The generation of these sequences is extremely fast, and quite negligible when compared to the time for any reasonable downstream use. For example, for `census` data set with size 18,000 by 119, if we choose the number of random features $s = 2000$, the running time for performing kernel ridge regression model is more than 2 minutes, while the time of generating the QMC sequences is only around 0.2 seconds (Digital Nets sequence takes longer, but not much longer) and that of MC sequence is around 0.01 seconds. Therefore, we do not report running times as these are essentially the same across methods.

In all experiments, we work with a Gaussian kernel. For learning, we use regularized least square classification on the feature mapped data set, which can be thought of as a form of approximate kernel ridge regression. For each data set, we performed 5-fold cross-validation when using random Fourier features (MC sequence) to set the bandwidth σ, and then used the same σ for all other sequences.

6.1.1 QUALITY OF KERNEL APPROXIMATION

In our setting, the most natural and fundamental metric for comparison is the quality of approximation of the Gram matrix. We examine how close $\tilde{\mathbf{K}}$ (defined by $\tilde{\mathbf{K}}_{ij} = \tilde{k}(\mathbf{x}_i, \mathbf{x}_j)$ where $\tilde{k}(\cdot,\cdot) = \langle \hat{\Psi}_S(\cdot), \hat{\Psi}_S(\cdot) \rangle$ is the kernel approximation) is to the Gram matrix $\mathbf{K}$ of the exact kernel.

We examine four data sets: `cpu` (6554 examples, 21 dimensions), `census` (a subset chosen randomly with 5,000 examples, 119 dimensions), `USPST` (1,506 examples, 250 dimensions after PCA) and `MNIST` (a subset chosen randomly with 5,000 examples, 250 dimensions after PCA). The reason we do subsampling on large data sets is to be able to compute the full exact Gram matrix for comparison purposes. The reason we use dimensionality reduction on `MNIST` is that the maximum dimension supported by the Lattice Rules implementation we use is 250.

To measure the quality of approximation we use both $\|\mathbf{K} - \tilde{\mathbf{K}}\|_2 / \|\mathbf{K}\|_2$ and $\|\mathbf{K} - \tilde{\mathbf{K}}\|_F / \|\mathbf{K}\|_F$. The plots are shown in Figure 2.

We can clearly see that except Sobol' sequences classical low-discrepancy sequences consistently produce better approximations to the Gram matrix than the approximations produced using MC sequences. Among the four classical QMC sequences, the Digital Nets, Lattice Rules and Halton sequences yield much lower error. Similar results were observed for other data sets (not reported here). Although using scrambled variants of QMC sequences may incur some variance, the variance is quite small compared to that of the MC random features.

Scrambled (whether deterministic or randomized) QMC sequences tend to yield higher accuracies than non-scambled QMC sequences. In Figure 3, we show the ratio between the relative errors

3. http://www.mathworks.com/help/stats/quasi-random-numbers.html
4. http://people.cs.kuleuven.be/ dirk.nuyens/qmc-generators/

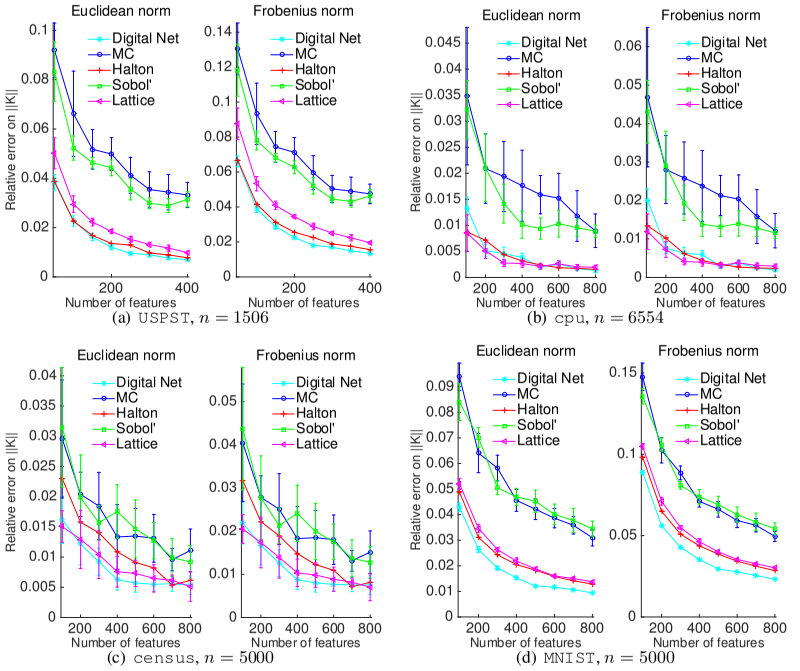

Figure 2: Relative error on approximating the Gram matrix measured in Euclidean norm and Frobenius norm, i.e., $\|\mathbf{K} - \tilde{\mathbf{K}}\|_2 / \|\mathbf{K}\|_2$ and $\|\mathbf{K} - \tilde{\mathbf{K}}\|_F / \|\mathbf{K}\|_F$, for various s. For each kind of random feature and s, 10 independent trials are executed, and the mean and standard deviation are plotted.

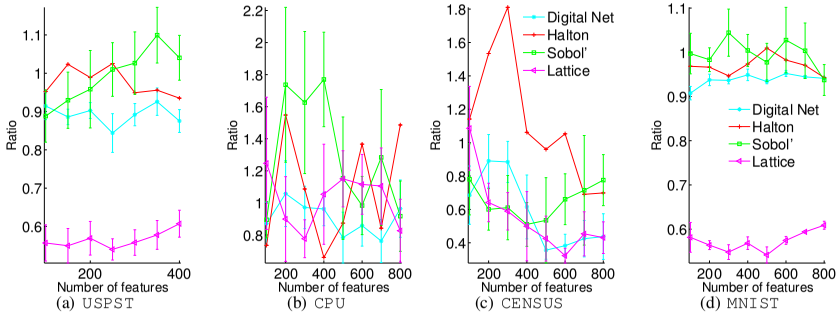
achieved by using both scrambled and non-scrambled QMC sequences. As can be seen, scrambled QMC sequences provide more accurate approximations in most cases as the ratio value tends to be less than one. In particular, scrambled Lattice sequence outperforms the non-scrambled one across all the cases for larger values of s. Therefore, in the rest of the experiments we use scrambled sequences.

6.1.2 GENERALIZATION ERROR

We consider two regression data sets, `cpu` and `census`, and use (approximate) kernel ridge regression to build a regression model. The ridge parameter is set by the optimal value we obtain via 5-fold cross-validation on the training set by using the MC sequence. Table 1 summarizes the results.



(a) USPST (b) CPU (c) CENSUS (d) MNIST

Figure 3: Ratio between relative errors on approximating the Gram matrix using both the scrambled and non-scambled version of the same QMC sequence for various s. The lower the ratio value is, the more accurate the scrambled QMC approximation is. For each kind of QMC sequences and s, 10 independent trails are executed, and the mean and standard deviation are plotted.

		(0)	(0.0084)	(0.0129)	(0.0100)	(0.0113)

Table 1: Regression error, i.e., $\|\hat{\mathbf{y}} - \mathbf{y}\|_2/\|\mathbf{y}\|_2$ where $\hat{\mathbf{y}}$ is the predicted value and $\mathbf{y}$ is the ground truth. For each kind of random feature and s, 10 independent trials are executed, and the mean and standard deviation are listed.

As we see, for cpu, all the sequences behave similarly, with the Halton sequence yielding the lowest test error. For census, the advantage of using Halton sequence is significant (almost 20% reduction in generalization error) followed by Digital Nets and Sobol'. In addition, MC sequence tends to generate higher variance across all the sampling size. Overall, QMC sequences, especially Halton, outperform MC sequences on these data sets.

When performed on classification data sets by using the same learning model, with a moderate range of s, e.g., less than 2000, the QMC sequences do not yield accuracy improvements over the MC sequence with the same consistency as in the regression case. The connection between kernel approximation and the performance in downstream applications is outside the scope of the current paper. Worth mentioning in this regard, is the recent work by Bach (2013), which analyses the connection between Nyström approximations of the Gram matrix, and the regression error, and the work of El Alaoui and Mahoney (2014) on kernel methods with statistical guarantees.

6.1.3 BEHAVIOR OF BOX DISCREPANCY

Next, we examine if $D^{\square}$ is predictive of the quality of approximation. We compute the normalized square box discrepancy values (i.e., $\pi^d(\prod_{j=1}^d b_j)^{-1}D^{\square}(S)^2$) as well as Gram matrix approximation error for the different sequences with different sample sizes s. The expected normalized square box discrepancy values for MC are computed using (13).

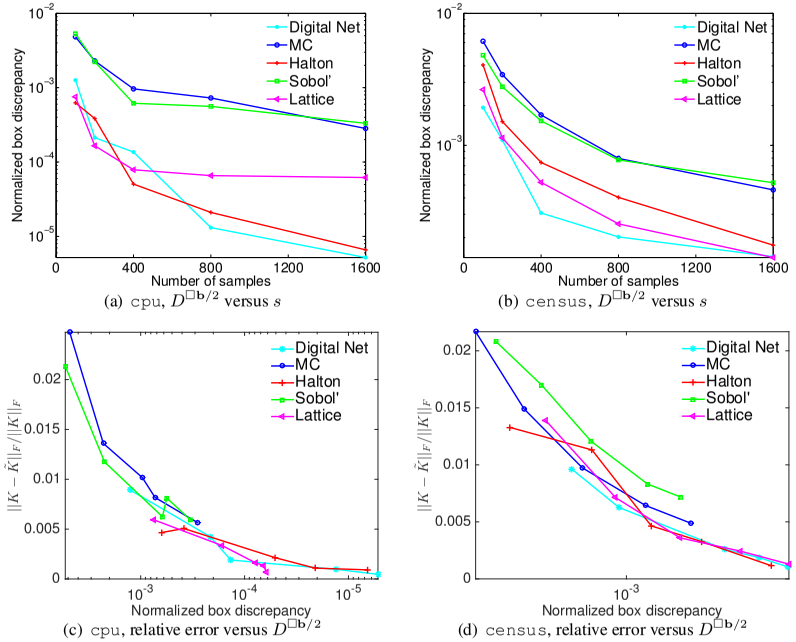
Our experiments revealed that using the full $\square\mathbf{b}$ does not yield box discrepancy values that are very useful. Either the values were not predictive of the kernel approximation, or they tended to stay constant. Recall, that while the bounding box $\square\mathbf{b}$ is set based on observed ranges of feature values in the data set, the actual distribution of points $\tilde{\mathcal{X}}$ encountered inside that box might be far from uniform. This lead us to consider the discrepancy measure when measured on the central part of the bounding box (i.e., $\square\mathbf{b}/2$ instead of $\square\mathbf{b}$), which is equal to the integration error averaged over that part of the bounding box. Presumably, points from $\tilde{\mathcal{X}}$ concentrate in that region, and they may be more relevant for downstream predictive task.

The results are shown in Figure 4. In the top graphs we can see, as expected, increasing number of features in the sequence leads to a lower box discrepancy value. In the bottom graphs, which compare $\|\mathbf{K} - \tilde{\mathbf{K}}\|_F/\|\mathbf{K}\|_F$ to $D^{\square\mathbf{b}/2}$, we can see a strong correlation between the quality of approximation and the discrepancy value.

6.2 Experiments With Adaptive QMC Sequences

The goal of this subsection is to provide a proof-of-concept for learning adaptive QMC sequences, using the three schemes described in Section 5. We demonstrate that QMC sequences can be improved to produce better approximation to the Gram matrix, and that can sometimes lead to improved generalization error.

Note that the running time of learning the adaptive sequences is less relevant in our experimental setting for the following reasons. Given the values of s, d, $\mathbf{b}$ and σ the optimization of a sequence needs only to be done once. There is some flexibility in these parameters: d can be adjusted by adding zero features or by doing PCA on the input; one can use longer or shorter sequences; and the data can be forced to a fit a particular bounding box using (possibly non-equal) scaling of the features (this, in turn, affects the choice of the σ) . Since designing adaptive QMC sequences is data-independent with applicability to a variety of downstream applications of kernel methods, it is quite conceivable to generate many point sets in advance and to use them for many learning tasks.



(a) cpu, $D^{\square \mathbf{b}/2}$ versus s (b) census, $D^{\square \mathbf{b}/2}$ versus s

(c) cpu, relative error versus $D^{\square \mathbf{b}/2}$ (d) census, relative error versus $D^{\square \mathbf{b}/2}$

Figure 4: Discrepancy values ($D^{\square \mathbf{b}/2}$) for the different sequences on cpu and census. We measure the discrepancy on the central part of the bounding box (we use $\square \mathbf{b}/2$ instead of $\square \mathbf{b}$ as the domain in the box discrepancy).

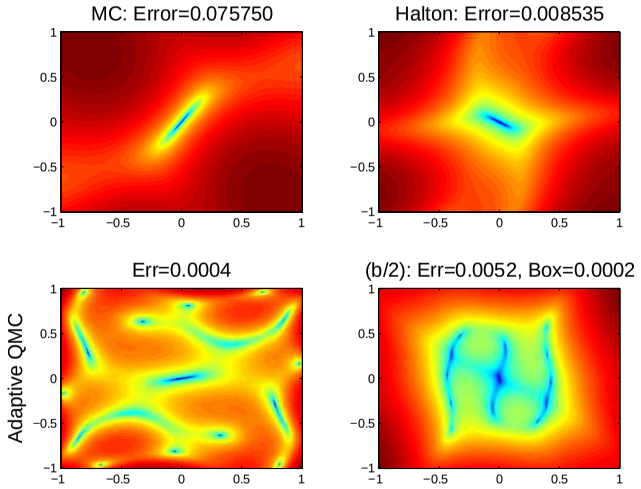


Figure 5: Integration error.

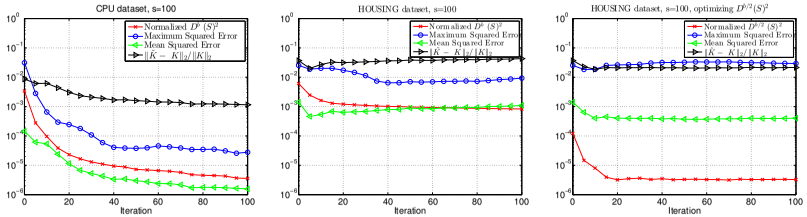
Furthermore, the total size of the sequences ($s \times d$) is independent of the number of examples n, which is the dominant term in large scale learning settings.

We name the three sequences as *Global Adaptive*, *Greedy Adaptive* and *Weighted* respectively. For *Global Adaptive*, the Halton sequence is used as the initial setting of the optimization variables S. For *Greedy Adaptive*, when optimizing for $\mathbf{w}_t$, the t-th point in the Halton sequence is used as the initial point. In both cases, we use non-linear conjugate gradient to perform numerical optimization. For *Weighted*, the initial features are generated using the Halton sequence and we optimize for the weights. We used CVX (Grant and Boyd, 2014, 2008) to compute the sequence (solve (17)).

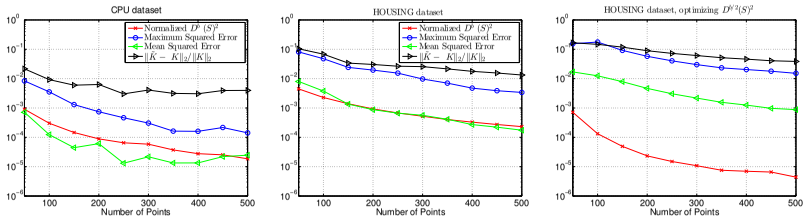
6.2.1 INTEGRAL APPROXIMATION

We begin by examining the integration error over the unit square by using three different sequences, namely, MC, Halton and global adaptive QMC sequences. The integral is of the form $\int_{[0,1]^2} e^{-i\mathbf{u}^T\mathbf{t}} d\mathbf{t}$ where $\mathbf{u}$ spans the unit square. The error is plotted in Figure 5. We see that MC sequences concentrate most of the error reduction near the origin. The Halton sequence gives significant improvement expanding the region of low integration error. Global adaptive QMC sequences give another order of magnitude improvement in integration error which is now diffused over the entire unit square; the estimation of such sequences is "aware" of the full integration region. In fact, by controlling the box size (see plot labeled b/2), adaptive sequences can be made to focus in a specified sub-box which can help with generalization if the actual data distribution is better represented by this sub-box.



(a) **(b)** **(c)**

Figure 6: Examining the behavior of learning *Global Adaptive* sequences. Various metrics on the Gram matrix approximation are plotted.



(a) **(b)** **(c)**

Figure 7: Examining the behavior of learning *Greedy Adaptive* sequences. Various metrics on the Gram matrix approximation are plotted.

6.2.2 QUALITY OF KERNEL APPROXIMATION

In Figure 6 and Figure 7 we examine how various metrics (discrepancy, maximum squared error, mean squared error, norm of the error) on the Gram matrix approximation evolve during the optimization process for both adaptive sequences. Since learning the adaptive sequences on data set with low dimensional features is more affordable, the experiment is performed on two such data sets, namely, `cpu` and `housing`.

For *Global Adaptive*, we fixed $s = 100$ and examine how the performance evolves as the number of iterations grows. In Figure 6 (a) we examine the behavior on `cpu`. We see that all metrics go down as the iteration progresses. This supports our hypothesis that by optimizing the box discrepancy we can improve the approximation of the Gram matrix. Figure 6 (b), which examines the same metrics on the scaled version of the `housing` data set, has some interesting behaviors. Initially all metrics go down, but eventually all the metrics except the box-discrepancy start to go up; the box-discrepancy continues to go down. One plausible explanation is that the integrands are not uniformly distributed in the bounding box, and that by optimizing the expectation over the entire box we start to overfit it, thereby increasing the error in those regions of the box where integrands actually concentrate. One possible way to handle this is to optimize closer to the center of the box

(e.g., on $\square\mathbf{b}/2$), under the assumption that integrands concentrate there. In Figure 6 (c) we try this on the `housing` data set. We see that now the mean error and the norm error are much improved, which supports the interpretation above. But the maximum error eventually goes up. This is quite reasonable as the outer parts of the bounding box are harder to approximate, so the maximum error is likely to originate from there. Subsequently, we stop the adaptive learning of the QMC sequences early, to avoid the actual error from going up due to averaging.

For *Greedy Adaptive*, we examine its behavior as the number of points increases. In Figure 7 (a) and (b), as expected, as the number of points in the sequence increases, the box discrepancy goes down. This is also translated to non-monotonic decrease in the other metrics of Gram matrix approximation. However, unlike the global case, we see in Figure 7 (c), when the points are generated by optimizing on a smaller box $\square\mathbf{b}/2$, the resulting metrics become higher for a fixed number of points. Although the *Greedy Adaptive* sequence can be computed faster than the adaptive sequence, potentially it might need a large number of points to achieve certain low magnitude of discrepancy. Hence, as shown in the plots, when the number of points is below 500, the quality of the optimization is not good enough to provide a good approximation the Gram matrix. For example, one can check when the number of points is 100, the discrepancy value of the *Greedy Adaptive* sequence is higher than that of the *Global Adaptive* sequence with more than 10 iterations.

Table 2: Discrepancy values, measured on the full bounding box and its central part, i.e., $D^{\square\mathbf{b}}$ and $D^{\square\mathbf{b}/4}$.

Table 2 also shows the discrepancy values of various sequences on `cpu` and `census`. Using adaptive sequences improves the discrepancy values by orders-of-magnitude. We note that a significant reduction in terms of discrepancy values can be achieved using only weights, sometimes yielding discrepancy values that are better than the hard-to-compute global or greedy sequences.

6.2.3 GENERALIZATION ERROR

We use the three algorithms for learning adaptive sequences as described in the previous subsections, and use them for doing approximate kernel ridge regression. The ridge parameter is set by the value which is near-optimal for both sequences in 5-fold cross-validation on the training set. Table 3 summarizes the results.

For both `cpu` and `census`, at least one of the adaptive sequences sequences can yield lower test error for each sampling size (since the test error is already low, around 3% or 5%, such improvement in accuracy is not trivial). For `cpu`, greedy approach seems to give slightly better results. When $s = 500$ or even larger (not reported here), the performance of the sequences are very close. For

	s	HALTON	GLOBAL$_{\mathbf{b}}$	GLOBAL$_{\mathbf{b}/4}$	GREEDY$_{\mathbf{b}}$	GREEDY$_{\mathbf{b}/4}$	WEIGHTED$_{\mathbf{b}}$	WEIGHTED$_{\mathbf{b}/4}$
CPU	100	0.0304	0.0315	**0.0296**	0.0307	**0.0296**	0.0366	0.0305
	300	0.0303	0.0278	0.0293	0.0274	**0.0269**	0.0290	0.0302
	500	0.0348	0.0347	0.0348	0.0328	**0.0291**	0.0342	0.0347
CENSUS	400	0.0529	0.1034	0.0997	0.0598	0.0655	**0.0512**	0.0926
	800	0.0545	0.0702	0.0581	0.0522	0.0501	**0.0476**	0.0487
	1200	0.0553	0.0639	**0.0481**	0.0525	0.0498	0.0496	0.0501
	1800	0.0498	0.0568	**0.0476**	0.0685	0.0548	0.0498	0.0491
	2200	0.0519	**0.0487**	0.0515	0.0694	0.0504	0.0529	0.0499

Table 3: Regression error, i.e., $\|\hat{\mathbf{y}} - \mathbf{y}\|_2/\|\mathbf{y}\|_2$ where $\hat{\mathbf{y}}$ is the predicted value and $\mathbf{y}$ is the ground truth.

census, the weighted sequence yields the lowest generalization error when $s = 400, 800$. Afterwards we can see global adaptive sequence outperforms the rest of the sequences, even though it has better discrepancy values. In some cases, adaptive sequences sometimes produce errors that are bigger than the unoptimized sequences.

In most cases, the adaptive sequence on the central part of the bounding box outperforms the adaptive sequence on the entire box. This is likely due to the non-uniformity phenomena discussed earlier.

7. Conclusion and Future Work

Recent work on applying kernel methods to very large data sets, has shown their ability to achieve state-of-the-art accuracies that sometimes match those attained by Deep Neural Networks (DNN) (Huang et al., 2014). Key to these results is the ability to apply kernel method to such data sets. The random features approach, originally due to Rahimi and Recht (2008), as emerged as a key technology for scaling up kernel methods (Sindhwani and Avron, 2014).

Close examination of those empirical results reveals that to achieve state-of-the-art accuracies, a very large number of random features was needed. For example, on TIMIT, a classical speech recognition data set, over 200,000 random features were used in order to match DNN performance (Huang et al., 2014). It is clear that improving the efficiency of random features can have a significant impact on our ability to scale up kernel methods, and potentially get even higher accuracies.

This paper is the first to exploit high-dimensional approximate integration techniques from the QMC literature in this context, with promising empirical results backed by rigorous theoretical analyses. Avenues for future work include incorporating stronger data-dependence in the estimation of adaptive sequences and analyzing how resulting Gram matrix approximations translate into downstream performance improvements for a variety of large-scale learning tasks.

Acknowledgements

The authors would like to thank Josef Dick for useful pointers to literature about improvement of the QMC sequences; Ha Quang Minh for several discussions on Paley-Wiener spaces and RKHS theory; the anonymous ICML reviewers for pointing out the connection to herding and other helpful comments; the anonymous JMLR reviewers for suggesting weighted sequences and other helpful

comments. This research was supported by the XDATA program of the Defense Advanced Research Projects Agency (DARPA), administered through Air Force Research Laboratory contract FA8750-12-C-0323. This work was done while H. Avron and V. Sindhwani were research staff members and J. Yang was a summer intern at IBM Research.

Appendix A. Technical Details

In this section we give detailed proofs of the assertions made in Section 4 and 5.

A.1 Proof of Proposition 5

Recall, for any $\mathbf{t} \in \mathbb{R}^d$, for $\Phi^{-1}(\mathbf{t})$, we mean $\left(\Phi_1^{-1}(t_1), \ldots, \Phi_d^{-1}(t_d)\right) \in \mathbb{R}^d$, where $\Phi_j(\cdot)$ is the CDF of $p_j(\cdot)$.

From $f_{\mathbf{u}}(\mathbf{t}) = e^{-i\mathbf{u}^T\Phi^{-1}(\mathbf{t})}$, for any $j = 1, \ldots, d$, we have

$$\frac{\partial f(\mathbf{t})}{\partial \mathbf{t}_j} = (-i)\frac{u_j}{p_j(\Phi_j^{-1}(t_j))}e^{-i\mathbf{u}^T\Phi_j^{-1}(\mathbf{t})} .$$

Thus,

$$\frac{\partial^d f(\mathbf{t})}{\partial t_1 \cdots \partial t_d} = \prod_{j=1}^{d}\left((-i)\frac{u_j}{p_j(\Phi_j^{-1}(t_j))}\right)e^{-i\mathbf{u}^T\Phi_j^{-1}(\mathbf{t})} .$$

In (6), when $I = [d]$,

$$\begin{aligned}
\int_{[0,1]^{|I|}}\left|\frac{\partial f}{\partial \mathbf{u}_I}\right|d\mathbf{t}_I &= \int_{[0,1]^d}\left|\frac{\partial^d f(\mathbf{t})}{\partial t_1 \cdots \partial t_d}\right|dt_1 \cdots dt_d \\
&= \int_{[0,1]^d}\left|\prod_{j=1}^{d}\left((-i)\frac{u_j}{p_j(\Phi_j^{-1}(t_j))}\right)e^{-i\mathbf{u}^T\Phi_j^{-1}(\mathbf{t})}\right|dt_1 \cdots dt_d \\
&= \int_{[0,1]^d}\prod_{j=1}^{d}\left|\frac{u_j}{p_j(\Phi_j^{-1}(t_j))}\right|dt_1 \cdots dt_d \\
&= \prod_{j=1}^{d}\left(\int_{[0,1]}\left|\frac{u_j}{p_j(\Phi_j^{-1}(t_j))}\right|dt_j\right) . \qquad (18)
\end{aligned}$$

With a change of variable, $\Phi_j(t_j) = v_j$, for $j = 1, \ldots, d$, (18) becomes

$$\prod_{j=1}^{d}\left(\int_{[0,1]}\left|\left(\frac{u_j}{p_j(\Phi_j^{-1}(t_j))}\right)\right|dt_j\right) = \prod_{j=1}^{d}\left(\int_{\mathbb{R}}|u_j|dv_j\right) = \infty .$$

As this is a term in (6), we know that $V_{HK}[f_{\mathbf{u}}(\mathbf{t})]$ is unbounded. ■

A.2 Proof of Proposition 6

We need the following lemmas, across which we share some notation.

Lemma 17 *Assuming that $\kappa = \sup_{\mathbf{x}\in\mathbb{R}^d} h(\mathbf{x},\mathbf{x}) < \infty$, if $f \in \mathcal{H}$, where $\mathcal{H}$ is an RKHS with kernel $h(\cdot,\cdot)$, the integral $\int_{\mathbb{R}^d} f(\mathbf{x})p(\mathbf{x})d\mathbf{x}$ is finite.*

Proof For notational convenience, we note that

$$\int_{\mathbb{R}^d} f(\mathbf{x})p(\mathbf{x})d\mathbf{x} = \mathbb{E}\left[f(X)\right],$$

where $\mathbb{E}[\cdot]$ denotes expectation and X is a random variable distributed according to the probability density $p(\cdot)$ on $\mathbb{R}^d$.

Now consider a linear functional T that maps f to $\mathbb{E}[f(X)]$, i.e.,

$$T[f] = \mathbb{E}\left[f(X)\right]. \tag{19}$$

The linear functional T is a bounded linear functional on the RKHS $\mathcal{H}$. To see this:

$$\begin{aligned}
|\mathbb{E}\left[f(X)\right]| &\leq \mathbb{E}\left[|f(X)|\right] \quad \text{(Jensen's Inequality)}\\
&= \mathbb{E}\left[|\langle f, h(X,\cdot)\rangle_{\mathcal{H}}|\right] \quad \text{(Reproducing Property)}\\
&\leq \|f\|_{\mathcal{H}}\mathbb{E}\left[\|h(X,\cdot)\|_{\mathcal{H}}\right] \quad \text{(Cauchy-Schwartz)}\\
&\leq \|f\|_{\mathcal{H}}\mathbb{E}\left[\sqrt{h(X,X)}\right] = \|f\|_{\mathcal{H}}\sqrt{\kappa} < \infty .
\end{aligned}$$

This shows that the integral $\int_{\mathbb{R}^d} f(\mathbf{x})p(\mathbf{x})d\mathbf{x}$ exists. ■

Lemma 18 *The mean $\mu_{h,p}(\mathbf{u}) = \int_{\mathbb{R}^d} h(\mathbf{u},\mathbf{x})p(\mathbf{x})d\mathbf{x}$ is in $\mathcal{H}$. In addition, for any $f \in \mathcal{H}$,*

$$\mathbb{E}\left[f(X)\right] = \int_{\mathbb{R}^d} f(\mathbf{x})p(\mathbf{x})d\mathbf{x} = \langle f, \mu_{h,p}\rangle_{\mathcal{H}} . \tag{20}$$

Proof From the Riesz Representation Theorem, every bounded linear functional on $\mathcal{H}$ admits an inner product representation. Therefore, for T defined in (19), there exists $\mu_{h,p} \in \mathcal{H}$ such that,

$$T[f] = \mathbb{E}\left[f(X)\right] = \langle f, \mu_{h,p}\rangle_{\mathcal{H}} .$$

Therefore we have, $\langle f, \mu_{h,p}\rangle_{\mathcal{H}} = \int f(\mathbf{x})p(\mathbf{x})d\mathbf{x}$ for all $f \in \mathcal{H}$. For any $\mathbf{z}$, choosing $f(\cdot) = h(\mathbf{z},\cdot)$, where $h(\cdot,\cdot)$ is the kernel associated with $\mathcal{H}$, and invoking the reproducing property we see that,

$$\mu_{h,p}(\mathbf{z}) = \langle h(\mathbf{z},\cdot), \mu_{h,p}\rangle_{\mathcal{H}} = \int_{\mathbb{R}^d} h(\mathbf{z},\mathbf{x})p(\mathbf{x})d\mathbf{x} .$$

■

The proof of Proposition 6 follows from the existence Lemmas above, and the following steps.

$$\begin{aligned}
\epsilon_{S,p}[f] &= \left|\int_{\mathbb{R}^d} f(\mathbf{x})p(\mathbf{x})d\mathbf{x} - \frac{1}{s}\sum_{l=1}^{s} f(\mathbf{w}_l)\right|\\
&= \left|\langle f, \mu_{h,p}\rangle_{\mathcal{H}} - \frac{1}{s}\sum_{l=1}^{s}\langle f, h(\mathbf{w}_l,\cdot)\rangle_{\mathcal{H}}\right|\\
&= \left|\langle f, \mu_{h,p} - \frac{1}{s}\sum_{l=1}^{s} h(\mathbf{w}_l,\cdot)\rangle_{\mathcal{H}}\right|\\
&\leq \|f\|_{\mathcal{H}}\left\|\mu_{h,p} - \frac{1}{s}\sum_{l=1}^{s} h(\mathbf{w}_l,\cdot)\right\|_{\mathcal{H}} = \|f\|_{\mathcal{H}} D_{h,p}(S) ,
\end{aligned}$$

where $D_{h,p}(S)$ is given as follows,

$$\begin{aligned}
D_{h,p}(S)^2 &= \left\|\mu_{h,p} - \frac{1}{s}\sum_{l=1}^{s} h(\mathbf{w}_l,\cdot)\right\|_{\mathcal{H}}^2\\
&= \langle\mu_{h,p},\mu_{h,p}\rangle_{\mathcal{H}} - \frac{2}{s}\sum_{l=1}^{s}\langle\mu_{h,p}, h(\mathbf{w}_l,\cdot)\rangle_{\mathcal{H}} + \frac{1}{s^2}\sum_{l=1}^{s}\sum_{j=1}^{s}\langle h(\mathbf{w}_l,\cdot), h(\mathbf{w}_j,\cdot)\rangle_{\mathcal{H}}\\
&= \mathbb{E}\left[\mu_{h,p}(X)\right] - \frac{2}{s}\sum_{l=1}^{s}\mathbb{E}\left[h(\mathbf{w}_l,\cdot)\right] + \frac{1}{s^2}\sum_{l=1}^{s}\sum_{j=1}^{s} h(\mathbf{w}_l,\mathbf{w}_j)\\
&= \int_{\mathbb{R}^d}\int_{\mathbb{R}^d} h(\omega,\phi)p(\omega)p(\phi)d\omega d\phi - \frac{2}{s}\sum_{l=1}^{s}\int_{\mathbb{R}^d} h(\mathbf{w}_l,\omega)p(\omega)d\omega\\
&\quad + \frac{1}{s^2}\sum_{l=1}^{s}\sum_{j=1}^{s} h(\mathbf{w}_l,\mathbf{w}_j) .
\end{aligned}$$

■

A.3 Proof of Theorem 9

We apply (9) to the particular case of $h = \mathrm{sinc}_{\mathbf{b}}$. We have

$$\begin{aligned}
\int_{\mathbb{R}^d}\int_{\mathbb{R}^d} h(\omega,\phi)p(\omega)p(\phi)d\omega d\phi &= \pi^{-d}\int_{\mathbb{R}^d}\int_{\mathbb{R}^d}\prod_{j=1}^{d}\frac{\sin(b_j(\omega_j-\phi_j))}{\omega_j-\phi_j}p_j(\omega_j)p_j(\phi_j)d\omega d\phi\\
&= \pi^{-d}\prod_{j=1}^{d}\int_{\mathbb{R}}\int_{\mathbb{R}}\frac{\sin(b_j(\omega_j-\phi_j))}{\omega_j-\phi_j}p_j(\omega_j)p_j(\phi_j)d\omega_j d\phi_j ,
\end{aligned}$$

and

$$\begin{aligned}
\sum_{l=1}^{s}\int_{\mathbb{R}^d} h(w_l,\omega)p(\omega)d\omega &= \pi^{-d}\sum_{l=1}^{s}\int_{\mathbb{R}^d}\prod_{j=1}^{d}\frac{\sin(b_j(w_{lj}-\omega_j))}{w_{lj}-\omega_j}p_j(\omega_j)d\omega\\
&= \pi^{-d}\sum_{l=1}^{s}\prod_{j=1}^{d}\int_{\mathbb{R}^d}\frac{\sin(b_j(w_{lj}-\omega_j))}{w_{lj}-\omega_j}p_j(\omega_j)d\omega_j .
\end{aligned}$$

So we can consider each coordinate on its own.

Fix j. We have

$$\begin{aligned}\int_{\mathbb{R}} \frac{\sin(b_j x)}{x} p_j(x)dx &= \int_{\mathbb{R}}\int_0^{b_j} \cos(\beta x)p_j(x)d\beta dx \\ &= \frac{1}{2}\int_{-b_j}^{b_j}\int_{\mathbb{R}} e^{i\beta x}p(x)dxd\beta \\ &= \frac{1}{2}\int_{-b_j}^{b_j}\varphi_j(\beta)d\beta\ .\end{aligned}$$

The interchange in the second line is allowed since the $p_j(x)$ makes the function integrable (with respect to x).

Now fix $w \in \mathbb{R}$ as well. Let $h_j(x,y) = \sin(b_j(x-y))/\pi(x-y)$. We have

$$\begin{aligned}\int_{\mathbb{R}} h_j(\omega, w)p_j(\omega)d\omega &= \pi^{-1}\int_{\mathbb{R}} \frac{\sin(b_j(\omega-w))}{\omega-w}p_j(\omega)d\omega \\ &= \pi^{-1}\int_{\mathbb{R}} \frac{\sin(b_j x)}{x}p_j(x+w)dx \\ &= (2\pi)^{-1}\int_{-b_j}^{b_j}\varphi_j(\beta)e^{iw\beta}d\beta\ ,\end{aligned}$$

where the last equality follows from first noticing that the characteristic function associated with the density function $x \mapsto p_j(x+w)$ is $\beta \mapsto \varphi(\beta)e^{iw\beta}$, and then applying the previous inequality.

We also have,

$$\begin{aligned}\int_{\mathbb{R}}\int_{\mathbb{R}} \frac{\sin(b_j(x-y))}{x-y}p_j(x)p_j(y)dxdy &= \int_{\mathbb{R}}\int_{\mathbb{R}}\int_0^{b_j}\cos(\beta(x-y))p_j(x)p_j(y)d\beta dxdy \\ &= \frac{1}{2}\int_{\mathbb{R}}\int_{\mathbb{R}}\int_{-b_j}^{b_j} e^{i\beta(x-y)}p_j(x)p_j(y)d\beta dxdy \\ &= \frac{1}{2}\int_{-b_j}^{b_j}\int_{\mathbb{R}}\int_{\mathbb{R}} e^{i\beta(x-y)}p_j(x)p_j(y)dxdyd\beta \\ &= \frac{1}{2}\int_{-b_j}^{b_j}\left(\int_{\mathbb{R}} e^{i\beta x}p_j(x)dx\right)\left(\int_{\mathbb{R}} e^{-i\beta y}p_j(y)dy\right)d\beta \\ &= \frac{1}{2}\int_{-b_j}^{b_j}\varphi_j(\beta)\varphi_j(\beta)^* d\beta \\ &= \frac{1}{2}\int_{-b_j}^{b_j}|\varphi_j(\beta)|^2 d\beta\ .\end{aligned}$$

The interchange at the third line is allowed because of $p_j(x)p_j(y)$. In the last line we use the fact that the $\varphi_j(\cdot)$ is Hermitian. ■

A.4 Proof of Theorem 12

Let $b > 0$ be a scalar, and let $u \in [-b, b]$ and $z \in \mathbb{R}$. We have,

$$\begin{aligned}\int_{-\infty}^{\infty} e^{-iux}\frac{\sin(b(x-z))}{\pi(x-z)}dx &= e^{-iuz}\int_{-\infty}^{\infty} e^{-i2\pi\frac{u}{2b}y}\frac{\sin(\pi y)}{\pi y}dy \\ &= e^{-iuz}\,\mathrm{rect}(u/2b) \\ &= e^{-iuz}\ .\end{aligned}$$

In the above, rect is the function that is 1 on $[-1/2, 1/2]$ and zero elsewhere.

The last equality implies that for every $\mathbf{u} \in \square\mathbf{b}$ and every $\mathbf{x} \in \mathbb{R}^d$ we have

$$f_{\mathbf{u}}(\mathbf{x}) = \int_{\mathbb{R}^d} f_{\mathbf{u}}(\mathbf{y})\,\mathrm{sinc}_{\mathbf{b}}(\mathbf{y},\mathbf{x})d\mathbf{y}\ .$$

We now have for every $\mathbf{u} \in \square\mathbf{b}$,

$$\begin{aligned}\epsilon_{S,p}[f_{\mathbf{u}}] &= \left|\int_{\mathbb{R}^d} f_{\mathbf{u}}(\mathbf{x})p(\mathbf{x})d\mathbf{x} - \frac{1}{s}\sum_{i=1}^{s} f(\mathbf{w}_i)\right| \\ &= \left|\int_{\mathbb{R}^d}\int_{\mathbb{R}^d} f_{\mathbf{u}}(\mathbf{y})\,\mathrm{sinc}_{\mathbf{b}}(\mathbf{y},\mathbf{x})d\mathbf{y}p(\mathbf{x})d\mathbf{x} - \frac{1}{s}\sum_{i=1}^{s}\int_{\mathbb{R}^d} f_{\mathbf{u}}(\mathbf{y})\,\mathrm{sinc}_{\mathbf{b}}(\mathbf{y},\mathbf{w}_i)d\mathbf{y}\right| \\ &= \left|\int_{\mathbb{R}^d} f_{\mathbf{u}}(\mathbf{y})\left[\int_{\mathbb{R}^d}\mathrm{sinc}_{\mathbf{b}}(\mathbf{y},\mathbf{x})p(\mathbf{x})d\mathbf{x} - \frac{1}{s}\sum_{i=1}^{s}\mathrm{sinc}_{\mathbf{b}}(\mathbf{y},\mathbf{w}_i)\right]d\mathbf{y}\right|\ .\end{aligned}$$

Let us denote

$$r_S(\mathbf{y}) = \int_{\mathbb{R}^d}\mathrm{sinc}_{\mathbf{b}}(\mathbf{y},\mathbf{x})p(\mathbf{x})d\mathbf{x} - \frac{1}{s}\sum_{i=1}^{s}\mathrm{sinc}_{\mathbf{b}}(\mathbf{y},\mathbf{w}_i)\ .$$

So,

$$\epsilon_{S,p}[f_{\mathbf{u}}] = \left|\int_{\mathbb{R}^d} f_{\mathbf{u}}(\mathbf{y})r_S(\mathbf{y})d\mathbf{y}\right|\ .$$

The function $r_S(\cdot)$ is square-integrable, so it has a Fourier transform $\hat{r}_S(\cdot)$. The above formula is exactly the value of $\hat{r}_S(\mathbf{u})$. That is,

$$\epsilon_{S,p}[f_{\mathbf{u}}] = |\hat{r}_S(\mathbf{u})|\ .$$

Now,

$$\begin{aligned}
\mathbb{E}_{f\sim\mathcal{U}(\mathcal{F}_{\square\mathbf{b}})}\left[\epsilon_{S,p}[f]^2\right] &= \mathbb{E}_{\mathbf{u}\sim\mathcal{U}(\square\mathbf{b})}\left[\epsilon_{S,p}[f_{\mathbf{u}}]^2\right] \\
&= \int_{\mathbf{u}\in\square\mathbf{b}} |\hat{r}_S(\mathbf{u})|^2 \left(\prod_{j=1}^d 2b_j\right)^{-1} d\mathbf{u} \\
&= \left(\prod_{j=1}^d 2b_j\right)^{-1} \|\hat{r}_S\|_{L2}^2 \\
&= \frac{(2\pi)^d}{\prod_{j=1}^d 2b_j} \|r_S\|_{PW_{\mathbf{b}}}^2 \\
&= \frac{\pi^d}{\prod_{j=1}^d b_j} D_p^{\square}(S)^2 \,.
\end{aligned}$$

The equality before the last follows from Plancherel formula and the equality of the norm in $PW_{\mathbf{b}}$ to the $L2$-norm. The last equality follows from the fact that r_S is exactly the expression used in the proof of Proposition 6 to derive $D_p^{\square}$. ■

A.5 Proof of Corollary 13

In this case, $p(\mathbf{x}) = \prod_{j=1}^d p_j(x_j)$ where $p_j(\cdot)$ is the density function of $\mathcal{N}(0, 1/\sigma_j)$. The characteristic function associated with $p_j(\cdot)$ is $\varphi_j(\beta) = e^{-\frac{\beta^2}{2\sigma_j^2}}$. We apply (11) directly.

For the first term, since

$$\begin{aligned}
\int_0^{b_j} |\varphi_j(\beta)|^2 d\beta &= \int_0^{b_j} e^{-\frac{\beta^2}{\sigma_j^2}} d\beta \\
&= \sigma_j \int_0^{b_j/\sigma_j} e^{-y^2} dy \\
&= \frac{\sigma_j\sqrt{\pi}}{2} \operatorname{erf}\left(\frac{b_j}{\sigma_j}\right) ,
\end{aligned}$$

we have

$$\pi^{-d} \prod_{j=1}^d \int_0^{b_j} |\varphi_j(\beta)|^2 d\beta = \prod_{j=1}^d \frac{\sigma_j}{2\sqrt{\pi}} \operatorname{erf}\left(\frac{b_j}{\sigma_j}\right) . \tag{21}$$

For the second term, since

$$\begin{aligned}
\int_{-b_j}^{b_j} \varphi_j(\beta) e^{iw_{lj}\beta} d\beta &= \int_{-b_j}^{b_j} e^{-\frac{\beta^2}{2\sigma^2} + iw_{lj}\beta} d\beta \\
&= e^{-\frac{\sigma_j w_{lj}}{2}} \int_{-b_j}^{b_j} e^{-\left(\frac{\beta}{\sqrt{2}\sigma_j} - i\frac{\sigma_j w_{lj}}{\sqrt{2}}\right)^2} d\beta \\
&= \sqrt{2}\sigma_j e^{-\frac{\sigma_j^2 w_{lj}^2}{2}} \int_{-\frac{b_j}{\sqrt{2}\sigma_j}}^{\frac{b_j}{\sqrt{2}\sigma_j}} e^{-\left(y - i\frac{\sigma_j w_{lj}}{\sqrt{2}}\right)^2} dy \\
&= \sqrt{2}\sigma_j e^{-\frac{\sigma_j^2 w_{lj}^2}{2}} \int_{-\frac{b_j}{\sqrt{2}\sigma_j} - i\frac{\sigma_j w_{lj}}{\sqrt{2}}}^{\frac{b_j}{\sqrt{2}\sigma_j} - i\frac{\sigma_j w_{lj}}{\sqrt{2}}} e^{-z^2} dz \\
&= \frac{\sqrt{\pi}\sigma_j}{\sqrt{2}} e^{-\frac{\sigma_j^2 w_{lj}^2}{2}} \left(\operatorname{erf}\left(-\frac{b_j}{\sqrt{2}\sigma_j} - i\frac{\sigma_j w_{lj}}{\sqrt{2}}\right) - \operatorname{erf}\left(\frac{b_j}{\sqrt{2}\sigma_j} - i\frac{\sigma_j w_{lj}}{\sqrt{2}}\right)\right) \\
&= \sqrt{2\pi}\sigma_j e^{-\frac{\sigma_j^2 w_{lj}^2}{2}} \operatorname{Re}\left(\operatorname{erf}\left(-\frac{b_j}{\sqrt{2}\sigma_j} - i\frac{\sigma_j w_{lj}}{\sqrt{2}}\right)\right) ,
\end{aligned}$$

we have

$$\frac{2}{s}(2\pi)^{-d} \sum_{l=1}^s \prod_{j=1}^d \int_{-b_j}^{b_j} \varphi_j(\beta) e^{i\mathbf{w}_{lj}\beta} d\beta = \frac{2}{s} \sum_{l=1}^s \prod_{j=1}^d \frac{\sigma_j}{\sqrt{2\pi}} e^{-\frac{\sigma_j^2 w_{lj}^2}{2}} \operatorname{Re}\left(\operatorname{erf}\left(-\frac{b_j}{\sqrt{2}\sigma_j} - i\frac{\sigma_j w_{lj}}{\sqrt{2}}\right)\right) . \tag{22}$$

Combining (21), (22) and (11), (12) follows. ■

A.6 Proof of Corollary 14

The proof is similar to the proof of Theorem 3.6 of Dick et al. (2013). Notice that since $\sup_{\mathbf{x}\in\mathbb{R}^d} h(\mathbf{x},\mathbf{x}) < \infty$, we have $\int_{\mathbb{R}^d} h(\mathbf{x},\mathbf{x})p(\mathbf{x})d\mathbf{x} < \infty$. From Lemma 18 we know that $\int_{\mathbb{R}^d} h(\cdot,\mathbf{y})p(\mathbf{y})d\mathbf{y} \in \mathcal{H}$, hence from Lemma 17, we have $\int_{\mathbb{R}^d}\int_{\mathbb{R}^d} h(\mathbf{x},\mathbf{y})p(\mathbf{x})p(\mathbf{y})d\mathbf{x}d\mathbf{y} < \infty$.

By (9), we have

$$\begin{aligned}
D_{h,p}(S)^2 &= \int_{\mathbb{R}^d}\int_{\mathbb{R}^d} h(\omega,\phi)p(\omega)p(\phi)d\omega d\phi \\
&\quad -\frac{2}{s}\sum_{l=1}^s \int_{\mathbb{R}^d} h(\mathbf{w}_l,\omega)p(\omega)d\omega \\
&\quad +\frac{1}{s^2}\sum_{l=1}^s h(\mathbf{w}_l,\mathbf{w}_l) + \frac{1}{s^2}\sum_{l,j=1,l\neq j}^s h(\mathbf{w}_l,\mathbf{w}_j) \,.
\end{aligned}$$

Then,

$$\begin{aligned}
\mathbb{E}\left[D_{h,p}(S)^2\right] = \int_{[0,1]^d}\cdots\int_{[0,1]^d} \Bigg(&\int_{\mathbb{R}^d}\int_{\mathbb{R}^d} h(\omega,\phi)p(\omega)p(\phi)d\omega d\phi - \frac{2}{s}\sum_{l=1}^s \int_{\mathbb{R}^d} h(\Phi^{-1}(\mathbf{t}_l),\omega)p(\omega)d\omega \\
&+\frac{1}{s^2}\sum_{l=1}^s h(\Phi^{-1}(\mathbf{t}_l),\Phi^{-1}(\mathbf{t}_l)) + \frac{1}{s^2}\sum_{l,j=1,l\neq j}^s h(\Phi^{-1}(\mathbf{t}_l),\Phi^{-1}(\mathbf{t}_j))\Bigg) d\mathbf{t}_1\cdots d\mathbf{t}_s \,.
\end{aligned}$$

Obviously, the first is a constant which is independent to $\mathbf{t}_1, \ldots, \mathbf{t}_s$. Since all the terms are finite, we can interchange the integral and the sum among rest terms. In the second term, for each l, the only dependence on $\mathbf{t}_1, \ldots, \mathbf{t}_s$ is $\mathbf{t}_l$, hence all the other $\mathbf{t}_j$ can be integrated out. That is,

$$\begin{aligned}\int_{[0,1]^d} \cdots \int_{[0,1]^d} \int_{\mathbb{R}^d} h(\Phi^{-1}(\mathbf{t}_l), \omega) p(\omega) d\omega d\mathbf{t}_1 \cdots d\mathbf{t}_s &= \int_{[0,1]^d} \int_{\mathbb{R}^d} h(\Phi^{-1}(\mathbf{t}_l), \omega) p(\omega) d\omega d\mathbf{t}_l \\ &= \int_{\mathbb{R}^d} \int_{\mathbb{R}^d} h(\phi, \omega) p(\phi) p(\omega) d\phi d\omega.\end{aligned}$$

Above, the last equality comes from a change of variable, i.e., $\mathbf{t}_l = (\Phi_1(\phi_1), \ldots, \Phi_d(\phi_d))$.

Similar operations can be done for the third and fourth term. Combining all of these, we have the following,

$$\begin{aligned}\mathbb{E}\left[D_{h,p}(S)^2\right] &= \int_{\mathbb{R}^d} \int_{\mathbb{R}^d} h(\omega, \phi) p(\omega) p(\phi) d\omega d\phi - 2 \int_{\mathbb{R}^d} \int_{\mathbb{R}^d} h(\omega, \phi) p(\omega) p(\phi) d\omega d\phi \\ &\quad + \frac{1}{s} \int_{\mathbb{R}^d} h(\omega, \omega) p(\omega) d\omega + \frac{s-1}{s} \int_{\mathbb{R}^d} \int_{\mathbb{R}^d} h(\omega, \phi) p(\omega) p(\phi) d\omega d\phi \\ &= \frac{1}{s} \int_{\mathbb{R}^d} h(\omega, \omega) p(\omega) d\omega - \frac{1}{s} \int_{\mathbb{R}^d} \int_{\mathbb{R}^d} h(\omega, \phi) p(\omega) p(\phi) d\omega d\phi \,.\end{aligned}$$

■

A.7 Proof of Proposition 16

Before we compute the derivative, we prove two auxiliary lemmas.

Lemma 19 *Let $\mathbf{x} \in \mathbb{R}^d$ be a variable and $\mathbf{z} \in \mathbb{R}^d$ be fixed vector. Then,*

$$\frac{\partial \operatorname{sinc}_{\mathbf{b}}(\mathbf{x}, \mathbf{z})}{\partial x_j} = b_j \operatorname{sinc}'_{b_j}(x_j, z_j) \prod_{q \neq j} \operatorname{sinc}_{b_q}(x_q, z_q) \,. \tag{23}$$

We omit the proof as it is a simple computation that follows from the definition of $\operatorname{sinc}_{\mathbf{b}}$.

Lemma 20 *The derivative of the scalar function $f(x) = \operatorname{Re}\left[e^{-ax^2} \operatorname{erf}(c + idx)\right]$, for real scalars a, c, d is given by,*

$$\frac{\partial f}{\partial x} = -2axe^{-ax^2} \operatorname{Re}\left[\operatorname{erf}(c + idx)\right] + \frac{2d}{\sqrt{\pi}} e^{-ax^2} e^{d^2x^2 - c^2} \sin(2cdx) \,.$$

Proof Since

$$\begin{aligned}f(x) &= \frac{1}{2}\left(e^{-ax^2} \operatorname{erf}(c + idx) + \left(e^{-ax^2} \operatorname{erf}(c + idx)\right)^*\right) \\ &= \frac{1}{2}\left(e^{-ax^2} \operatorname{erf}(c + idx) + e^{-ax^2} \operatorname{erf}(c - idx)\right) \,,\end{aligned} \tag{24}$$

it suffices to compute the the derivative $g(x) = e^{-ax^2} \operatorname{erf}(c + idx)$.

Let $k(x) = \operatorname{erf}(c + idx)$. We have

$$g'(x) = -2axe^{-ax^2} k(x) + e^{-ax^2} k'(x) \,. \tag{25}$$

Since

$$\begin{aligned}k(x) &= \operatorname{erf}(c + idx) \\ &= \frac{2}{\sqrt{\pi}} \int_0^{c+idx} e^{-z^2} dz \\ &= \frac{2}{\sqrt{\pi}} \left(\int_0^c e^{-z^2} dz + \int_c^{c+idx} e^{-z^2} dz\right) \\ &= \frac{2}{\sqrt{\pi}} \left(\int_0^c e^{-y^2} dy + (id) \int_0^x e^{-(c+idt)^2} dt\right) \,,\end{aligned} \tag{26}$$

we have

$$k'(x) = \frac{2}{\sqrt{\pi}} e^{-(c+idx)^2} = \frac{2d}{\sqrt{\pi}} e^{d^2x^2 - c^2} (\sin(2cdx) + i\cos(2cdx)) \,. \tag{27}$$

We now have

$$\begin{aligned}f'(x) &= \frac{1}{2}\left(g'(x) + (g^*(x))'\right) \\ &= \frac{1}{2}\left(g'(x) + (g'(x))^*\right) \\ &= \frac{1}{2}\left(-2axe^{-ax^2}(k(x) + k^*(x)) + e^{-ax^2}(k'(x) + (k'(x))^*)\right) \\ &= \frac{1}{2}\left(-4axe^{-ax^2} \operatorname{Re}\left[\operatorname{erf}(c + idx)\right] + e^{-ax^2} \frac{4d}{\sqrt{\pi}} e^{d^2x^2 - c^2} \sin(2cdx)\right) \\ &= -2axe^{-ax^2} \operatorname{Re}\left[\operatorname{erf}(c + idx)\right] + \frac{2d}{\sqrt{\pi}} e^{-ax^2} e^{d^2x^2 - c^2} \sin(2cdx) \,.\end{aligned} \tag{28}$$

■

Proof [Proof of Proposition 16] For the first term in (12), that is $\frac{1}{s^2} \sum_{m=1}^{s} \sum_{r=1}^{s} \operatorname{sinc}_{\mathbf{b}}(\mathbf{w}_m, \mathbf{w}_r)$, to compute the partial derivative of w_{lj}, we only have to consider when at least m or r is equal to l. If $m = j = l$, by definition, the corresponding term in the summation is one. Hence, we only have to consider the case when $m \neq r$. By symmetry, it is equivalent to compute the partial derivative of the following function $\frac{2}{s^2} \sum_{m=1, m\neq l}^{s} \operatorname{sinc}_{\mathbf{b}}(\mathbf{w}_l, \mathbf{w}_m)$. Applying Lemma 19, we get the first term in (14).

Next, for the last term in (12), we only have consider the term associated with one in the summation and the term associated with j in the product. Since $\left(\frac{\sigma_j}{\sqrt{2\pi}}\right) e^{-\frac{\sigma_j^2 w_{lj}^2}{2}} \operatorname{Re}\left(\operatorname{erf}\left(\frac{b_j}{\sigma_j\sqrt{2}} - i\frac{\sigma_j w_{lj}}{\sqrt{2}}\right)\right)$ satisfies the formulation in Lemma 20, we can simply apply Lemma 20 and get its derivative with respect to w_{lj}.

Equation (14) follows by combining these terms. ■
